This model is recognized as a special case of (I), the constraint matrix  $[F, G]$  being formed by the transpose of the node-arc incidence matrix of  $N$  with an additional row involving variable  $y_1$  only (with associated coefficient  $-1$ ).  $F$  is reduced in this case to a single column (the column corresponding to node  $n$  in the transpose of the incidence matrix of  $N$ ). The RHS vector  $b$  is the vector with coefficients equal to the opposite of the task durations (more specifically, the RHS coefficient for the constraint corresponding to arc  $(i, j) \in U$  is equal to  $-d_i$ ). Note that we do not state explicitly the nonnegativity conditions on  $y$ , since they are implied by the precedence constraints and nonnegativity of the  $d_i$  coefficients.

Thus, the problem is cast in a form very similar to that of (I), the only difference being that the nonnegativity conditions on  $y$  and  $z$  are dropped. The consequence of this for the analysis in Sect. “Two-Stage Robust (LP) Decision Model” is just that we have to consider the polyhedral cone  $C' = \{u/u^T G = 0 \text{ and } u \geq$

$0\}$  instead of the polyhedral cone:  $C = \{u/u^T G \geq 0 \text{ and } u \geq 0\}$ .

Owing to the special structure of the  $G$  matrix arising in the PERT scheduling problem, we have the following result.

**Proposition 1** *The extreme rays of the polyhedral cone  $C'$  are in 1-1 correspondence with the characteristic vectors of the various paths between node 1 and node  $n$  in  $N$ .*

*Proof:* By observing that  $G^T$  is the node-arc incidence matrix of the graph  $N$  without the row associated with node  $n$  but with an extra column with coefficient  $-1$  in the first row and all other coefficients 0, we realize that  $u$  satisfying  $G^T u = 0$  and  $u \geq 0$  corresponds to a non-negative flow between node 1 and node  $n$  in  $N$  with value equal to  $u_{1,1}$ , the component of  $u$  corresponding to the extra column with coefficient  $-1$  in the first row and all other coefficients 0. Therefore the extreme rays of the cone  $C'$  correspond to the incidence vectors of the various paths connecting node 1 to node  $n$  in  $N$ .  $\square$

Let us denote  $P = \{\pi^1, \pi^2, \dots, \pi^K\}$  the set of all paths between 1 and  $n$  in  $N$ ,  $u^1, u^2, \dots, u^K$  the corresponding characteristic vectors and the condition  $(u^k)^T(b - Fy) \geq 0$  specializes to  $-\sum_{i \in \pi^k} d_i + y_n \geq 0$  (this is because, in that case

$$(u^k)^T b = -\sum_{i \in \pi^k} d_i \text{ and } (u^k)^T Fy = -y_n).$$

So the condition for feasibility is that for each path  $\pi^k$ ,  $y_n \geq \sum_{i \in \pi^k} d_i$ . In view of this, the robust PERT scheduling problem can be reformulated as

$$\begin{aligned} &\max && -y_n \\ &\text{subject to} && \\ &&& y_n \geq \sum_{i \in \pi^k} d_i, \forall \pi^k \in P, \forall d \in D, \end{aligned}$$

where we recall that  $D$  denotes the uncertainty set for the task durations.

This problem therefore reduces to determining the path  $\pi^k$  maximizing, over the set  $P$  of all possible paths in  $N$ , the objective function

$$\max_{d \in D} \left\{ \sum_{i \in \pi^k} d_i \right\}.$$

In other words we want to solve

$$\max_{\pi \in P} \max_{d \in D} \left\{ \sum_{i \in \pi} d_i \right\} \text{ (RPS),}$$

where RPS stands for robust PERT scheduling problem.

Now, if we want to go further into the analysis of (RPS), we have to specify how the uncertainty set  $D$  is defined. Of course there are many possible ways for this; we content ourselves below with examining two among the most natural possible definitions, and show that, for each of them, the above robust optimization problem (RPS) can be efficiently solved.

**Case 1:**  $D$  is a scaled ball with respect to the  $L_\infty$  norm.

The first easy special case is when, for each task  $i$ , the duration  $d_i$  can take any value in a given real interval  $[d_i^-, d_i^+]$  with  $0 \leq d_i^- \leq d_i^+$ . In this case  $D$  is the Cartesian product  $[d_1^-, d_1^+] \times [d_2^-, d_2^+] \times \dots \times [d_n^-, d_n^+]$ , which may be viewed as a scaled ball with respect to the  $L_\infty$  norm (using component-wise scaling to have all intervals of equal width). It is easily seen that an optimal robust solution for problem (RPS) can be obtained in this case by looking at a longest path (critical path) in  $N$  when each of the tasks  $i$  is assigned the longest possible duration  $d_i^+$ .

As an illustration of the above, consider the following example with  $n = 7$  tasks, where the graph of precedence constraints has the following arcs: (1, 2), (1, 3), (2, 3), (2, 5), (2, 6), (3, 4), (3, 7), (4, 5), (5, 7) and (6, 7). Thus, task 2 cannot be started before completion of task 1, etc. Also note that the tasks are numbered according to a topological ordering of the graph, since there is no arc  $(i, j)$  with  $i > j$ . The associated intervals  $[d_i^-, d_i^+]$  for the durations of the tasks are given in Table 1:

**Robust Linear Programming with Right-Hand-Side Uncertainty, Duality and Applications, Table 1**  
Associated intervals  $[d_i^-, d_i^+]$  for the durations of the tasks

Task 1	Task 2	Task 3	Task 4	Task 5	Task 6
[2, 4]	[4, 8]	[3, 6]	[4, 8]	[4, 8]	[8, 16]

Task 7 is not shown in the table because it is a dummy task (of duration 0, without uncertainty) representing the end of the schedule. It is easy to see that in this example, the optimal solution to the (RPS) problem has duration 34 and corresponds to the critical path (1, 2, 3, 4, 5, 7). Indeed 34 is the earliest achievable termination date if we require that the schedule remains feasible for any possible choice of the task durations in the Cartesian product  $[d_1^-, d_1^+] \times [d_2^-, d_2^+] \times \dots \times$

$[d_6^-, d_6^+]$ . This corresponds to the situation where the duration of each task  $i$  is  $d_i^+$ .

**Case 2:**  $D$  is a scaled Hamming ball of bounded radius  $\Gamma$ .

Here again we assume that, for each task  $i$ , the duration  $d_i$  can take any value in a given real interval  $[d_i, d_i + \Delta_i]$  with  $d_i \geq 0$ .  $d_i$  is called the nominal value of the duration for task  $i$ ,  $d_i + \Delta_i$  being the possible extreme (or worst-case) value for the task duration. As is actually the case in many practical applications, it is unlikely that all tasks simultaneously take on worst-case values. To take this observation into account, we will impose an upper bound  $\Gamma$  on the number of task durations which are allowed to take on a worst-case value, given that all task durations which do not take on a worst-case value are assumed to have a value equal to their nominal value. More formally, if we associate with each task  $i$  a 0-1 integer variable  $u_i$ , the uncertainty set  $D$  corresponding to this definition is

$$D = \{ \theta = (\theta_i)_{i=1, \dots, n}, \theta_i = d_i + \Delta_i u_i \quad (i = 1, \dots, n) \text{ such that} \\ \sum_{i=1}^n u_i \leq \Gamma, u_i \in \{0, 1\}, \forall i \}.$$

As can be seen from the above definition, in the special case where all  $\Delta_i$  are equal to 1,  $D$  is recognized as the Hamming ball of radius  $\Gamma$  centered at  $d = (d_i), i = 1, \dots, n$  (in other words,  $\theta - d$  can be any 0-1 vector with at most  $\Gamma$  components equal to 1). When the  $\Delta_i$ 's take on arbitrary positive values, the Hamming ball structure is still present after applying scaling to each component  $i$  with respect to the corresponding  $\Delta_i$  value.

We note here that, in spite of the fact that the definition above is close in spirit to the concept of uncertainty suggested by Bertsimas and Sim [3,4], our model is fairly different from the one studied by those authors, since they restricted themselves to rowwise uncertainty, whereas in our robust PERT scheduling problem, we have uncertainty on the RHS only (a special case of columnwise uncertainty). For more detailed discussion of this issue, see Sect. "Differences with Bertsimas and Sim's Approach".

We now show that, with the above definition of the uncertainty set  $D$ , problem (RPS) can be efficiently solved via a dynamic programming recursion. To that

aim, we will consider the problem with parameter  $\Gamma$  as only one representative of the class of problems (RPS[ $i, k$ ]) for  $i$  running from 1 to  $n$  (the number of tasks) and  $k$  running from 0 to  $\Gamma$ . More precisely, assuming that the tasks are numbered according to a topological ordering of the circuitless graph  $N$ , (RPS[ $i, k$ ]) consists of the robust PERT scheduling sub-problem corresponding to the subset of tasks  $1, 2, \dots, i$ , the durations of at most  $k$  of which are allowed to take on their worst-case values. The case  $k = 0$  (no deviation allowed) corresponds to the usual PERT scheduling problem in terms of the nominal values for the task durations. We denote  $v^*[i, k]$  the optimal objective function value for problem (RPS[ $i, k$ ]), and for any task  $i$ , we denote  $\text{Pred}[i]$  the set of tasks  $j$  such that  $(j, i)$  is an arc of  $N$  (the set of direct predecessors of node  $i$ ). Bellman's optimality principle then leads to the following dynamic programming recursion:

$$\forall i \in [1, n], \forall k = 0, 1, \dots, \Gamma :$$

$$v^*[i, k] = \max_{j \in \text{Pred}[i]} \max\{v^*[j, k] + d_j; v^*[j, k - 1] + d_j + \Delta_j\}. \quad (3)$$

The optimal value of the robust PERT scheduling problem we are interested in is then  $v^*[n, \Gamma]$ . The rationale behind (3) can easily be explained as follows. Consider the set of all paths from 1 to  $j \in \text{Pred}[i]$ . The duration of arc  $(j, i)$  has nominal value  $d_j$  and worst-case value  $d_j + \Delta_j$ . The maximum duration of a path from 1 to  $i$  through  $j$  with at most  $k$  tasks allowed to deviate from their nominal values can be obtained: either by allowing for at most  $k$  deviations on the subset of tasks  $\{1, 2, \dots, j\}$  and taking the nominal duration for arc  $(j, i)$  or by allowing at most  $k - 1$  deviations on the subset of tasks  $\{1, 2, \dots, j\}$  and taking the worst-case duration for arc  $(j, i)$ . Thus, the optimal value for node  $i$  via node  $j$  is the maximum value among these two alternatives, and the optimal value for node  $i$  is the maximum taken on the set of all direct predecessors of  $i$ . Obviously, solving the recursion (3) is achieved in polynomial time  $O(m \times n)$ , where  $m$  is the number of arcs and  $n$  the number of nodes of the PERT network; more precisely the complexity is  $O(m \times \Gamma)$ , where  $\Gamma$ , the parameter defining the uncertainty set, is at most  $n$ , the number of tasks (but is often significantly smaller than  $n$  in practical applications).

**Robust Linear Programming with Right-Hand-Side Uncertainty, Duality and Applications, Table 2**

	$i = 2$	$i = 3$	$i = 4$	$i = 5$	$i = 6$	$i = 7$
$k = 0$	2	6	9	13	6	17
$k = 1$	4	10	13	17	10	22
$k = 2$	4	12	16	21	12	26
$k = 3$	4	12	18	24	12	29

Let us illustrate the above for the same seven-task example as the one considered to illustrate Case 1. We thus consider the same intervals for the task durations, the lower bound of each interval representing the nominal task duration, and the upper bound representing the worst-case duration. For  $\Gamma = 3$ , application of the recursion (3) leads to the  $v^*[i, k]$  values shown in Table 2.

For instance the value  $v^*[4, 2] = 16$  corresponds to the path (1, 2, 3, 4) with three arcs of nominal durations 2, 4 and 3, respectively. If, in this path, two arcs out of three are allowed to take on their worst-case durations, the worst case (maximum) is obtained when task 2 has duration 8 and task 3 has duration 6 (task 1 keeping its nominal duration 2), the resulting length of the path being  $8 + 6 + 2 = 16$ . Let us also illustrate how the recursion (3) works for computing, e.g.,  $v^*[7, 2]$  and  $v^*[7, 3]$ . We have

$$v^*[7, 2] = \max\{v^*[3, 2] + 3; v^*[3, 1] + 6;$$

$$v^*[5, 2] + 4; v^*[5, 1] + 8;$$

$$v^*[6, 2] + 8; v^*[6, 1] + 16\}$$

$$= \max\{15, 16, 25, 25, 20, 26\} = 26.$$

The maximum above is obtained for  $j = 6$  and the corresponding optimal path is (1, 2, 6, 7).

Similarly we have

$$v^*[7, 3] = \max\{v^*[3, 3] + 3; v^*[3, 2] + 6;$$

$$v^*[5, 3] + 4; v^*[5, 2] + 8;$$

$$v^*[6, 3] + 8; v^*[6, 2] + 16\}$$

$$= \max\{15, 18, 28, 29, 20, 28\} = 29.$$

The maximum above is obtained for  $j = 5$  and the corresponding optimal path is (1, 2, 3, 4, 5, 7). It is thus seen that, depending on the choice of the control parameter  $\Gamma$ , various optimal paths are obtained which, of course, may differ from the optimal solution to the

nonrobust PERT scheduling problem (considering only the nominal values for the task durations). Also, observe that the value  $v^*[7, 3] = 29$  corresponds to a less conservative robust solution than the one obtained in Case 1.

### Differences with Bertsimas and Sim's Approach

We now turn to show that, in spite of the similarity in the definition of the uncertainty sets, the robust version of the PERT scheduling problem investigated here is essentially different from the model proposed by Bertsimas and Sim [3] for the robust version of the shortest-path problem. From an abstract point of view, the difference basically stems from the fact that, in our case, we are faced with a LP problem with uncertainty on the RHS, whereas Bertsimas and Sim addressed a LP problem with uncertainty on the cost coefficients. However, to further understand the source of this difference, we show below which difficulties would arise if we wanted to apply the Bertsimas–Sim approach to the robust longest (critical) path problem on a directed circuitless graph  $G$ .

Following these authors, the robust shortest  $s$ - $t$  path problem in  $G$  with uncertainty parameter  $\Gamma$  (assuming  $\Gamma \in \mathbb{N}$ ) is formulated as

$$(\text{RSP}) \min_{x \in X} \left\{ \sum_{(i,j) \in U} c_{i,j} x_{i,j} + \max_{S \subseteq U, |S| \leq \Gamma} \sum_{(i,j) \in S} \Delta_{i,j} x_{i,j} \right\},$$

where  $X$  denotes the set of incidence vectors of all  $s$ - $t$  paths in  $G$ ,  $c_{i,j}$  denotes the nominal cost of arc  $(i,j)$  and  $c_{i,j} + \Delta_{i,j}$  is the worst-case cost of arc  $(i,j)$ . After transformation of (RSP) using the duality theorem to convert the second term in the braces into a minimization, the problem is reformulated as a standard LP, the solution of which reduces to  $m + 1$  applications of a standard shortest-path algorithm. Observe that one of the reasons for all the above to work so nicely is that the second term in the braces, as a function of  $x$ , is convex in  $x$ , since it is the pointwise maximum of a finite number of linear functions.

The above approach is still valid if, instead of looking for an optimum robust minimum cost path, we are looking for an optimum robust maximum benefit path:  $c_{i,j} > 0$  being interpreted as a reward associated with the use of arc  $(i,j)$ , the effect of uncertainty being to reduce the nominal reward  $c_{i,j}$  by the amount  $\Delta_{i,j}$ . The

problem would then take the form

$$\max_{x \in X} \left\{ \sum_{(i,j) \in U} c_{i,j} x_{i,j} - \max_{S \subseteq U, |S| \leq \Gamma} \sum_{(i,j) \in S} \Delta_{i,j} x_{i,j} \right\},$$

which is essentially analogous to the above robust minimum cost path, up to a change in the signs of the coefficients in the objective (still assuming, of course, that the graph  $G$  under consideration is circuitless). In particular, we note that the function to be maximized is concave, so we still have a convex optimization problem.

By contrast, the robust PERT scheduling problem addressed in the present paper is formulated as

$$\max_{x \in X} \left\{ \sum_{(i,j) \in U} c_{i,j} x_{i,j} + \max_{S \subseteq U, |S| \leq \Gamma} \sum_{(i,j) \in S} \Delta_{i,j} x_{i,j} \right\},$$

with  $c_{i,j} > 0$  and  $\Delta_{i,j} > 0$ .

It is then readily observed that this problem consists in maximizing a convex function of  $x$  on  $\{0, 1\}^m$ , and it is well known that this cannot be simply reduced to ordinary LP as is the case for Bertsimas and Sim's approach. Thus, robust PERT scheduling may be viewed as a typical illustration of the big differences between models featuring rowwise uncertainty and models featuring columnwise uncertainty in robust LP.

### Conclusions

In this chapter, various robust LP problems have been investigated, and the question of whether LP duality can still be used to help solve such problems has been addressed and answered negatively. Among the problems considered, robust LP problems with uncertainty on the RHS only have been recognized as an interesting subclass of problems, for which the solution techniques should not confine themselves to the classical approach proposed by Soyster [10]. In this respect we have been led to propose a new class of robust LP models referred to here as 'two-stage robust decision models' which can be expected to lead to less 'conservative' optimal robust solutions than those usually obtained from Soyster's model. In order to show the practical usefulness of this two-stage model, a specialization to robust PERT scheduling was discussed, leading, under two natural ways of defining the uncertainty set with respect to

the task durations, to efficient solution methods. Also some fundamental differences between our approach to robust PERT scheduling and the one proposed by Bertsimas and Sim [3] in the context of the robust shortest-path problem were pointed out. We think that many other possible applications of this two-stage robust modeling approach deserve further investigations, for instance in dynamic inventory management, optimal resource allocation problems and telecommunication problems.

Optimization

The analyst who attempts to build a mathematical model for a real-world system is often faced with the problem of uncertain, noisy, incomplete or erroneous data. This is true for several application domains. In business applications noisy data are prevalent. Returns of financial instruments, demand for a firm's products, the cost of fuel, and consumption of power and other resources are examples of model data that are known with some probabilistic distribution at best. In social sciences data are often incomplete – for example, partial census surveys are carried out periodically in lieu of a complete census of the population. In the physical sciences and engineering data are usually subject to measurement errors, as in models of image restoration from remote sensing experiments. For some applications not much is lost by assuming that the value of the uncertain data is known and then developing a deterministic mathematical programming model. Worst case or mean values can be used in this respect because they provide reasonable approximations when either the level of uncertainty is low, or when the uncertain parameters have a minor impact on the system we want to model. For many applications, however, uncertainty plays a key role in the performance of the real-world system: worst-case analysis often leads to conservative and potentially expensive solutions, and solving the *mean value problem*, i. e., a problem where all random variables are replaced by their mean values, can even lead to nonsensical solutions since the mean of a random variable might not be a value that can be realized in practice.

A general approach to dealing with uncertainty is to assign to the unknown parameters a probability distribution, which should then be incorporated into an appropriate mathematical programming model. Early models for dealing with data uncertainty were in the

form of sensitivity analysis of the mean value model. Later developments formulated stochastic linear programming models whereby the data uncertainty was incorporated in the estimation of the expected value of the objective function. This chapter addresses the problem of planning under uncertainty using robust optimization models.

### Robust Optimization Models

Robust optimization formulations are applicable to optimization models that have two distinct components: a *structural component* that is fixed and free of any noise in its input data; and a *control component* that is subject to noisy input data. In some cases the robust optimization model is identical to a two-stage stochastic program with recourse. But it also allows additional flexibility in dealing with noise. In order to define the model we introduce two sets of variables:

- $x \in \mathbf{R}^{n_0}$  denotes the vector of decision variables that depend only on the noise-free structural constraints. These are the *design variables* whose values are independent of realizations of the noisy parameters.
- $y \in \mathbf{R}^{n_1}$  denotes the vector of *control variables* that can be adjusted once the uncertain parameters are observed. Their optimal values depend both on the realization of uncertain parameters, and on the optimal values of the design variables.

The optimization model we are interested in has the following structure:

$$\min \langle c, x \rangle + \langle d, y \rangle \quad (1)$$

such that

$$Ax = b, \quad (2)$$

$$Bx + Cy = e, \quad (3)$$

$$x \in \mathbb{R}_+^{n_0}, \quad (4)$$

$$y \in \mathbb{R}_+^{n_1}, \quad (5)$$

where  $b, c, d, e$  are given vectors,  $A, B, C$  are given matrices and  $\langle \cdot, \cdot \rangle$  is the inner product of its arguments. Equation (2) denotes the *structural constraints* that are free of noise. Equation (3) denotes the *control constraints*. The coefficients of these constraints, i. e., the elements

of  $B, C$  and  $e$  are subject to noise. The cost vector  $d$  is also subject to noise, while  $A, b$  and  $c$  are not.

To define the robust optimization problem we introduce an index set  $\Omega := \{1, \dots, N\}$ . With each index  $s \in \Omega$  we associate the scenario set  $\{d(s), B(s), C(s), e(s)\}$  of realizations of the control coefficients. Reference to an index  $s$  implies reference to the scenario set associated with this index. The probability of the  $s$ th scenario is  $p_s$ , and  $\sum_{s \in \Omega} p_s = 1$ . Now the following question is posed: What are the desirable characteristics of a solution to problem (1)–(5) when the coefficients of the constraints (3) take values from some given set of scenarios? The solution is considered robust with respect to optimality if it remains ‘close’ to optimal for any realization of the scenario index  $s \in \Omega$ . The problem is then termed *solution robust*. The solution is robust with respect to feasibility if it remains ‘almost’ feasible for any realization of  $s$ . The problem is then termed *model robust*. The concepts of ‘close’ and ‘almost’ are precisely defined later through the choice of appropriate norms.

It is unlikely that a solution to the mathematical program will remain both feasible and optimal for all realizations of  $s$ . If the system being modeled has substantial built-in redundancies, then it might be possible to find solutions that remain both feasible and optimal. Otherwise a model is needed that permits a trade-off between solution and model robustness. Robust optimization models formalize a way to measure this trade-off.

First let us introduce a set  $\{y^1, \dots, y^N\}$  of control variables for each scenario  $s \in \Omega$ , and another set  $\{z^1, \dots, z^N\}$  of *feasibility error vectors* that measure the infeasibility of the control constraints under each scenario.

The real-valued objective function  $\xi(x, y) = \langle c, x \rangle + \langle d, y \rangle$  is a random variable taking the value  $\xi_s(x, y^s) := \langle c, x \rangle + \langle d(s), y^s \rangle$  with probability  $p_s$ . Hence, there is no longer a simple single choice for an aggregate objective function. The expected value

$$\sigma(\cdot) := \sum_{s \in \Omega} p_s \xi_s(\cdot) \quad (6)$$

is precisely the objective function used in stochastic programming formulations. Another choice is to employ worst-case analysis and minimize the maximal value. The objective function is then defined by

$$\sigma(\cdot) := \max_{s \in \Omega} \xi_s(\cdot).$$

The robust optimization formulation also allows the introduction of higher moments of the distribution of  $\xi$  ( $\cdot$ ) in the optimization model. Indeed, the introduction of higher moments is one of the features of robust optimization that distinguishes it from the stochastic programming model. For example, we could use a nonlinear utility function that embodies a trade-off between mean value and variability in this mean value. If  $\mathcal{U}(\xi_s)$  denotes the utility of  $\xi_s$ , then the function

$$\sigma(\cdot) := \sum_{s \in \Omega} p_s \mathcal{U}(\xi_s(\cdot))$$

captures the risk preference of the user. A popular choice of utility functions, typically used in portfolio management applications, is the logarithmic function  $\mathcal{U}(\xi_s) = \log \xi_s$ . The general robust optimization model includes a term  $\sigma(x, y^1, \dots, y^N)$  in the objective function to denote the dependence of the function value on the scenario index  $s$ . This term controls solution robustness, and can take different forms depending on the application. The examples mentioned above are some popular choices.

The robust optimization model introduces a second term in the objective function to control model robustness. This term is a feasibility penalty function, denoted by  $\rho(z^1, \dots, z^N)$ , and it is used to penalize violations of the control constraints under some of the scenarios. The introduction of this penalty function also distinguishes the robust optimization model from the stochastic programming approach for dealing with noisy data. In particular, the model recognizes that it may not always be possible to arrive at a feasible solution to a problem under all scenarios. Infeasibilities will inevitably arise, and they will be dealt with outside the optimization model. The robust optimization model generates solutions that present the modeler with the fewest infeasibilities to be dealt with outside the model.

The specific choice of penalty function is problem dependent, and it also has implications for the choice of a solution algorithm. Two suitable *penalty functions* are the following:

- $\rho(z^1, \dots, z^N) := \sum_{s \in \Omega} p_s \|z^s\|^2$ . This quadratic penalty function (i. e., a weighted  $\ell_2$ -norm) is applicable to equality control constraints where both positive and negative violations of the constraints are equally undesirable. The resulting quadratic programming problem is twice continuously differen-

table, and can be solved using standard quadratic programming algorithms, although it is typically large scale.

- $\rho(z^1, \dots, z^N) := \sum_{s \in \Omega} p_s \max(0, \max_j z_j^s)$ , where  $z_j^s$  is the  $j$ th element of vector  $z^s$ . This penalty function is applicable to inequality control constraints when only positive violations are of interest (negative values of some  $z_j$  indicate slack in the inequality constraints). With this choice of penalty function, however, the resulting mathematical program is nondifferentiable.

The robust optimization model takes a multicriteria objective form. A goal programming weight parameter  $\lambda$  is used to derive a spectrum of answers that trade off solution for model robustness. The general formulation of the robust optimization model is stated as follows:

$$\begin{cases} \min & \sigma(x, y^1, \dots, y^N) + \lambda \rho(z^1, \dots, z^N) \\ \text{s.t.} & Ax = b, \\ & B(s)x + C(s)y^s + z^s = e(s), \quad \forall s \in \Omega, \\ & x \in \mathbb{R}_+^{n_0}, \\ & y^s \in \mathbb{R}_+^{n_1}, \quad \forall s \in \Omega, \\ & z^s \in \mathbb{R}_+^m, \quad \forall s \in \Omega. \end{cases}$$

### Comparisons of Robust Optimization with Sensitivity Analysis and Stochastic Linear Programming

We compare here the alternative approaches for dealing with uncertainty. In particular, we contrast robust optimization (RO), stochastic linear programming (SLP) and sensitivity analysis (SA). We will see that RO enjoys several advantages, but it is not without its shortcomings.

Sensitivity analysis is a reactive approach to controlling uncertainty. It just measures the sensitivity of a solution – typically of the solution to the mean value problem – to changes in the input data. It provides no mechanism by which this sensitivity can be controlled.

Stochastic linear programming and robust optimization are constructive approaches for controlling uncertainty in the values of model parameters. In this respect they are both superior to SA. With stochastic linear programming models the decision maker is afforded the flexibility of recourse variables. These correspond to the control variables of RO and provide the mechanism with which the model recommendations

can be adjusted to account for the realizations of random data.

The SLP model, however, optimizes only the first moment of the distribution of the objective value  $\xi(\cdot)$ . It ignores higher moments of the distribution, and the decision maker's preferences towards risk. These aspects are particularly important for asymmetric distributions, and for risk averse decision makers. Furthermore, aiming at expected value optimization implicitly assumes an active management style whereby the control (i. e., recourse) variables are easily adjusted as scenarios unfold. Large changes in the objective values  $\xi_s$  may be observed across different scenarios, but their expected value will be minimal. The RO model minimizes higher moments as well, e. g., the variance of the distribution of  $\xi(\cdot)$ . Hence, it assumes a more passive management style. Since the value of  $\xi_s$  will not differ substantially among different scenarios, little or no adjustment of the control variables will be needed. In this respect RO can be viewed as a SLP whereby the recourse decisions are implicitly restricted.

This distinction between RO and SLP is important, and defines their domain of applicability. Applied to personnel planning, for example, a SLP solution will design a workforce that can be adjusted (by hirings or layoffs) to meet demand at the least expected cost. The important consideration of maintaining stability of employment can not be captured. The RO model, on the other hand, will design a workforce that will need few adjustments in order to cope with demand for all scenarios. However, the cost of the RO solution will be higher than the cost of the SLP solution.

Another important distinction of RO from SLP is the handling of the constraints. Stochastic linear programming models aim at finding the design variables  $x$  such that for each realized scenario  $s$  a control variable setting  $y^s$  is possible that satisfies the control constraints. For systems with some redundancy such a solution might always be possible. The SLP literature even allows for the notion of *relatively complete recourse*, whereby a feasible solution  $y^s$  exists for all scenarios, and for any value of  $x$  that satisfies the design constraints. What happens in cases where no feasible pair  $(x, y^s)$  is possible for every scenario? The SLP model is declared infeasible. RO explicitly accounts for this possibility. In engineering applications (e. g., image restoration) such situations inevitably arise due to mea-

surement errors. Multiple measurements of the same quantity may be inconsistent with each other. Hence, even if the underlying physical system has a solution (in this case an image does exist!) it will not satisfy all the measurements. The RO model, through the use of error terms  $\{z^s\}$  and the infeasibility penalty function  $\rho(\cdot)$ , will find a solution that violates the constraints by the least amount. This approach is receiving increasing attention in the operations research literature.

While RO has some distinct advantages over SA and SLP, it is not without limitations. First, RO models are *parametric programs* and we have no mechanism for specifying a priori a 'correct' choice of the parameter  $\lambda$ . Of course, this problem is prevalent in multicriteria programming optimization. Second, the scenarios in  $\Omega$  are just one possible set of realizations of the problem data. RO does not provide a means by which the scenarios can be specified. This problem is prevalent in SLP models as well. Substantial progress has been made in recent years in integrating variance reduction methods, such as importance sampling, into stochastic linear programming, and these techniques also apply to RO.

Despite these potential shortcomings, we emphasize that working only with expected values (as in the linear programming formulations) is fundamentally limited for problems with noisy data. Even going a step further – that is, working with expected values and *hedging* against small changes in these values – is also inappropriate. In this respect, RO provides a significantly improved modeling framework.

Robust optimization integrates the methods of multi-objective programming with stochastic programming. It also extends SLP with the introduction of higher moments of the objective value, and with the notion of model robustness. Both RO and SLP provide constructive mechanisms for dealing with uncertain data.

## Notes

The material in this article is drawn from [1, Chap. 13], where additional material and extensive discussion of the literature can be found.

The robust optimization model was suggested in [7], which also discussed example applications of robust optimization to the classic diet problem, and problems in finance, engineering design and capacity plan-

ning. J.K. Sengupta [10] had discussed earlier the robustness of stochastic linear programming solutions. Another approach for enforcing robustness in stochastic programs by means of restricted recourse models was introduced in [11].

The terminology of ‘structural’ and ‘control’ variables is borrowed from the flexibility analysis of manufacturing systems; see [9].

Applications of robust optimization are discussed in [5] (for environmental planning), [2] (for image reconstruction from projections), [8] (for capacity planning), [12] (for matrix balancing), [6] (for capacity expansion for power generation firms), [4] (for capacity expansion planning in manufacturing). A robust optimization approach to capacity planning for a multiproduct, multi-facility production firm was suggested in [3], and applied to plan car manufacturing facilities for the General Motors Company.

### Introduction

The research area of production scheduling has received considerable attention from both academia and the chemical processing industries over the past decade. Most of the work in the literature assumes that all data are deterministic - that is, they are of constant, known values. However, in reality, uncertainty is prevalent in

many scheduling problems due to lack of accurate process models and variability of process and environmental data. Thus, an emerging area of research aims at developing methods to address the problem of scheduling under uncertainty, in order to create reliable schedules which remain feasible in the presence of parameter uncertainty.

The issue of robustness in scheduling under uncertainty has received relatively little attention, in spite of its importance and the fact that there has been a substantial amount of work to address the problem of design and operation of batch plants under uncertainty. Most of the existing work has followed the scenario-based framework, in which the uncertainty is modeled through the use of a number of scenarios, using either discrete probability distributions or the discretization of continuous probability distribution functions, and the expectation of a certain performance criterion, such as the expected profit which is optimized with respect to the scheduling decision variables. The scenario-based approaches provide a straightforward way to implicitly incorporate uncertainty. However, they inevitably enlarge the size of the problem significantly as the number of scenarios increases exponentially with the number of uncertain parameters. This main drawback limits the application of these approaches to solve practical problems with a large number of uncertain parameters. An alternative approach for scheduling under uncertainty is reactive scheduling. It is carried out to adjust a schedule, which is usually obtained a priori in a deterministic manner, upon realization of the uncertain parameters or occurrence of unexpected events. Due to the “online” nature of reactive scheduling, it is required to generate updated schedules in a timely manner and often, heuristic approaches are developed for schedule modifications.

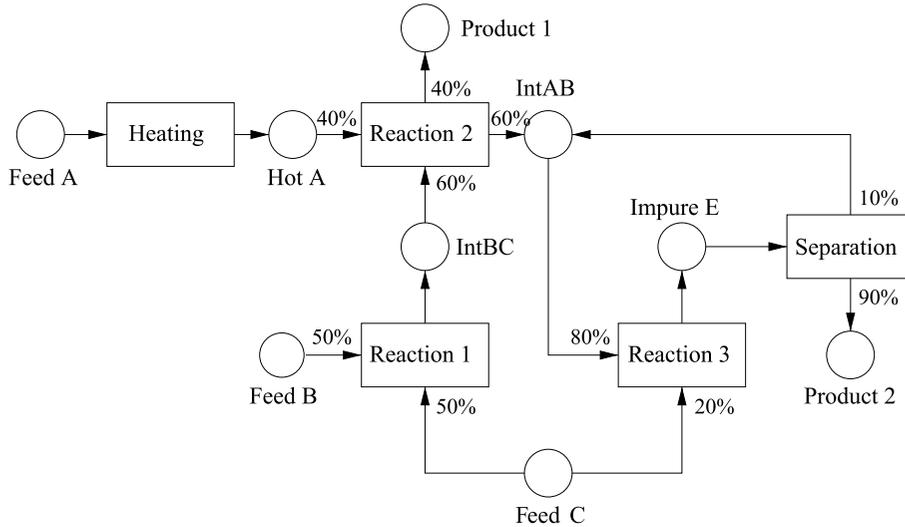

In this chapter, we propose a novel robust optimization approach to address the problem of scheduling under uncertainty. The underlying framework is based on a robust optimization methodology first introduced for Linear Programming (LP) problems by Ben-Tal and Nemirovski [1] and extended in this work for Mixed-Integer Linear Programming (MILP) problems. The approach produces “robust” solutions which are, in a sense, immune against uncertainties in both the coefficients and right-hand-side parameters of the inequality constraints. The approach can be applied to address

the problem of production scheduling with uncertain processing times, market demands, and/or prices of products and raw materials. We consider uncertainty in scheduling problems which can be characterized as bounded or bounded and symmetric as well as uncertainty described by a known probability distribution function, such as a uniform or normal distribution. Additional work on the robust optimization of short-term scheduling problems can be found in Lin et al. [2] and Janak et al. [3].

### A Motivating Example

Consider the following example process that was first presented by Kondili et al. [4] and has been widely studied in the literature. Two different products can be produced from three feeds according to the State-Task Network as shown in Fig. 1. Five processing tasks are considered including *Heating*, *Reaction 1*, *Reaction 2*, *Reaction 3*, and *Separation*. Four units are available and four intermediate materials are processed in-between tasks. The initial stock level for all intermediates and products is assumed to be zero. Each task has a unit-specific, variable processing time. The relevant data are shown in Table 1. The objective is to maximize the profit from the sale of products manufactured in a time horizon of 12 hours.

The continuous-time formulation proposed by Floudas and coworkers [5,6,7,8] is used to solve this simple scheduling problem. The “nominal” solution is shown in Fig. 2, which features intensive utilization of the two reactors and an objective function value (profit) of 3638.75. However, this solution can become completely infeasible when there is uncertainty in the processing times of the tasks. That is, when a task requires a longer processing time than its nominal value, it may not be able to finish processing within the time interval assigned in the nominal schedule. In this example, even a very small perturbation may make the schedule infeasible, especially for the two reactors, and can have a substantial effect on the scheduling decisions. For instance, if the processing time of each task is increased by simply 10% of its nominal value, then the nominal schedule will become infeasible and the optimal schedule with the slightly increased processing times will be significantly different from the nominal schedule, as shown in Fig. 3. In the *Heater* and the *Separator*, the number

Product 2	Unlimited	0.0	10.0

of tasks as well as processing amounts change, while in *Reactor 1* and *Reactor 2*, even the task sequences are different. Furthermore, the profit is reduced to 3264.69.

It is clear that solving a scheduling problem at the nominal values of the uncertain data is not enough. To obtain reliable and efficient schedules, systematic and effective approaches which take into account uncer-

tainty are required. In the rest of this chapter, we propose a new robust optimization framework to generate schedules that are reliable in the presence of uncertainty arising from various sources.

**Formulation**

Consider the following generic Mixed-Integer Linear Programming (MILP) problem

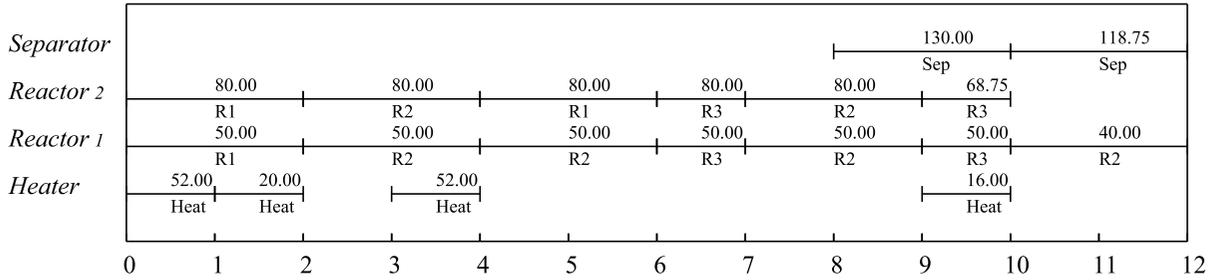

$$\begin{aligned}
 & \text{Min/Max } c^T x + d^T y \\
 & \text{s.t. } Ex + Fy = e \\
 & \quad Ax + By \leq p \\
 & \quad \underline{x} \leq x \leq \bar{x} \quad y = 0, 1.
 \end{aligned}
 \tag{1}$$

Assume that the uncertainty arises from both the coefficients and the right-hand-side parameters of the inequality constraints, namely,  $a_{lm}$ ,  $b_{lk}$  and  $p_l$ . We are then concerned about the feasibility of the following inequality:

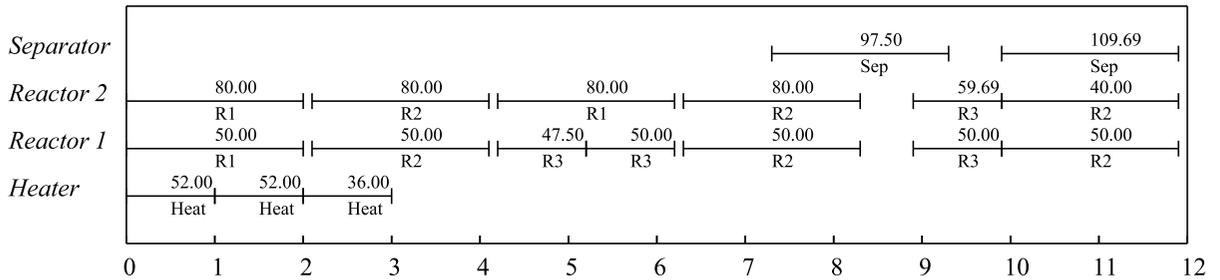

$$\sum_m \tilde{a}_{lm} x_m + \sum_k \tilde{b}_{lk} y_k \leq \tilde{p}_l,
 \tag{2}$$

where  $a_{lm}$ ,  $b_{lk}$ , and  $p_l$  are the nominal values of the uncertain parameters and  $\tilde{a}_{lm}$ ,  $\tilde{b}_{lk}$ , and  $\tilde{p}_l$  are the “true” values of the uncertain parameters.

As shown in the previous section with the motivating example on scheduling, the optimal solution of an

**Robust Optimization: Mixed-Integer Linear Programs, Figure 2**  
 Optimal solution with nominal processing times (profit = 3638.75)

**Robust Optimization: Mixed-Integer Linear Programs, Figure 3**  
 Optimal solution with processing times increased by 10% (profit = 3264.69)

MILP problem may become infeasible – that is, one or more constraints are violated substantially – if the nominal data is slightly perturbed. Our objective here is to develop a robust optimization methodology to generate “reliable” solutions to the MILP problem, which are immune against uncertainty. This robust optimization methodology was first introduced for Linear Programming (LP) problems with uncertain linear coefficients by Ben-Tal and Nemirovski [1] and is extended in this work to MILP problems under uncertainty. We consider several different types of uncertainty including: (i) bounded uncertainty, (ii) bounded and symmetric uncertainty, and (iii) uncertainty described by a known distribution such as a uniform or normal distribution.

**Bounded Uncertainty**

Suppose that the uncertain data range in the following intervals:

$$|\tilde{a}_{lm} - a_{lm}| \leq \epsilon |a_{lm}|, \quad |\tilde{b}_{lk} - b_{lk}| \leq \epsilon |b_{lk}|, \\ |\tilde{p}_l - p_l| \leq \epsilon |p_l|, \quad (3)$$

where  $\tilde{a}_{lm}$ ,  $\tilde{b}_{lk}$  and  $\tilde{p}_l$  are the “true” values,  $a_{lm}$ ,  $b_{lk}$  and  $p_l$  are the nominal values, and  $\epsilon > 0$  is a given (relative) uncertainty level.

We call a solution  $(x,y)$  robust if it satisfies the following conditions: (i)  $(x,y)$  is feasible for the nominal problem, and (ii) whatever are the true values of the coefficients and right-hand-side parameters within the corresponding intervals,  $(x,y)$  must satisfy the  $l$ th inequality constraint with an error of at most  $\delta \cdot \max[1, |p_l|]$ , where  $\delta$  is a given infeasibility tolerance.

**Theorem 1** Given an infeasibility tolerance,  $(\delta)$ , to generate robust solutions, the following so-called  $(\epsilon, \delta)$ -Interval Robust Counterpart (IRC $[\epsilon, \delta]$ ) of the original uncertain MILP problem can be derived.

$$\text{Min/Max}_{x, y, u} c^T x + d^T y \\ \text{s.t. } Ex + Fy = e \\ Ax + By \leq p \\ \sum_m a_{lm} x_m + \epsilon \sum_{m \in M_l} |a_{lm}| u_m + \sum_k b_{lk} y_k \\ + \epsilon \sum_{k \in K_l} |b_{lk}| y_k \\ \leq p_l - \epsilon |p_l| + \delta \cdot \max[1, |p_l|], \quad \forall l$$

$$\begin{aligned}
 & -u_m \leq x_m \leq u_m, \quad \forall m \\
 & \underline{x} \leq x \leq \bar{x} \\
 & y_k = 0, 1, \quad \forall k
 \end{aligned} \tag{4}$$

where  $M_l$  and  $K_l$  are the set of indices of the  $x$  and  $y$  variables, respectively, with uncertain coefficients in the  $l$ th inequality constraint.

*Proof 1* We want to find a robust solution  $(x,y)$  which satisfies condition (i) and condition (ii), that is:

$$\begin{aligned}
 \forall l, \quad & \forall (\tilde{a}_{lm}: |\tilde{a}_{lm} - a_{lm}| \leq \epsilon |a_{lm}|, \tilde{b}_{lk}: \\
 & |\tilde{b}_{lk} - b_{lk}| \leq \epsilon |b_{lk}|, \text{ and } \tilde{p}_l: |\tilde{p}_l - p_l| \leq \epsilon |p_l|): \\
 & \sum_{m \notin M_l} a_{lm} x_m + \sum_{m \in M_l} \tilde{a}_{lm} x_m \\
 & + \sum_{k \notin K_l} b_{lk} y_k + \sum_{k \in K_l} \tilde{b}_{lk} y_k \\
 & \leq \tilde{p}_l + \delta \cdot \max[1, |p_l|].
 \end{aligned} \tag{5}$$

Using the worst-case values of the uncertain parameters, or those that make the inequality constraint the most difficult to satisfy,

$$\begin{aligned}
 \tilde{a}_{lm} x_m & \leq a_{lm} x_m + \epsilon |a_{lm}| |x_m|, \\
 \tilde{b}_{lk} y_k & \leq b_{lk} y_k + \epsilon |b_{lk}| y_k, \\
 \text{and } \tilde{p}_l & \geq p_l - \epsilon |p_l|
 \end{aligned} \tag{6}$$

and substituting into Eq. (5) and rearranging terms, it is clear that a solution  $(x,y)$  is robust if and only if it is a feasible solution of the following optimization problem.

$$\begin{aligned}
 & \text{Min/Max}_{x,y} \quad c^T x + d^T y \\
 & \text{s.t. } Ex + Fy = e \\
 & Ax + By \leq p \\
 & \sum_m a_{lm} x_m + \epsilon \sum_{m \in M_l} |a_{lm}| |x_m| \\
 & \quad + \sum_k b_{lk} y_k + \epsilon \sum_{k \in K_l} |b_{lk}| y_k \\
 & \leq p_l - \epsilon |p_l| + \delta \cdot \max[1, |p_l|], \quad \forall l \\
 & \underline{x} \leq x \leq \bar{x} \\
 & y_k = 0, 1, \quad \forall k.
 \end{aligned} \tag{7}$$

The above problem is equivalent to problem (4) where the absolute value operator is represented with a set

of auxiliary variables  $(u_m)$  and a set of additional constraints.  $\square$

For each inequality constraint that involves uncertain coefficients and/or right-hand-side parameters, an additional constraint is introduced to incorporate the uncertainty and maintain the relationships among the relevant binary and continuous variables under the uncertainty level and the given infeasibility tolerance. Essentially, this constraint considers the worst-case values of the uncertain parameters which make the inequality the most difficult to maintain. At the same time, a certain degree of relaxation is introduced to allow tolerable violations of the constraint. Note that mathematical model (4) remains an MILP model. Compared to the original deterministic MILP problem, the robust counterpart has a set of auxiliary variables  $(u_m)$  and a set of additional constraints relating the variables  $x_m$  and  $u_m$ .

### Uncertainty with Known Probability Distribution

Assume that for the inequality constraint  $l$ , the true values of the uncertain parameters are obtained from their nominal values by the random perturbations

$$\begin{aligned}
 \tilde{a}_{lm} & = (1 + \epsilon \xi_{lm}) a_{lm} \\
 \tilde{b}_{lk} & = (1 + \epsilon \xi_{lk}) b_{lk} \\
 \tilde{p}_l & = (1 + \epsilon \xi_l) p_l
 \end{aligned} \tag{8}$$

where  $\xi_{lm}$ ,  $\xi_{lk}$  and  $\xi_l$  are independent random variables and  $\epsilon > 0$  is a given (relative) uncertainty level.

In this situation, we call a solution  $(x,y)$  robust if it satisfies the following: (i)  $(x,y)$  is feasible for the nominal problem, and (ii) for every inequality  $l$ , the probability of violation of the uncertain inequality is at most  $\kappa$ , or

$$\Pr \left\{ \sum_m \tilde{a}_{lm} x_m + \sum_k \tilde{b}_{lk} y_k > \tilde{p}_l + \delta \cdot \max[1, |p_l|] \right\} \leq \kappa \tag{9}$$

where  $\delta > 0$  is a given feasibility tolerance and  $\kappa > 0$  is a given reliability level. Thus,  $\kappa$  represents the probability of violation of constraint  $l$  where  $\kappa = 0\%$  indicates that there is no chance of constraint violation, yielding the most conservative solution.

If the probability distributions of the random variables  $\xi_{lm}$ ,  $\xi_{lk}$  and  $\xi_l$  in the uncertain parameters are

known, it is possible to obtain a more accurate estimation of the probability measures involved. The MILP from (1) can be rewritten as an uncertain MILP as follows

$$\begin{aligned} & \text{Min}_{x, y} \quad c^T x + d^T y \\ & \text{s.t.} \quad Ex + Fy = e \\ & \quad \quad \text{Max}_{\xi \in Z} [\tilde{A}x + \tilde{B}y - \tilde{p} \leq \delta \cdot \max[1, |p_l|]] \\ & \quad \quad \underline{x} \leq x \leq \bar{x} \\ & \quad \quad y = 0, 1 \\ & \quad \quad \xi \equiv [A, B, p] \in Z \end{aligned} \quad (10)$$

where the data set  $\xi \equiv [A, B, p]$  varies in a given uncertainty set  $Z$ ,  $\tilde{A}$ ,  $\tilde{B}$ , and  $\tilde{p}$  represent the “true” values of the uncertain coefficients, and  $\delta \geq 0$  is an infeasibility tolerance introduced to allow a certain amount of infeasibility into the inequality constraint. The inequality can be written in expanded form as

$$\text{Max}_{\xi \in Z} \left[ \sum_m \tilde{a}_{lm} x_m + \sum_k \tilde{b}_{lk} y_k - \tilde{p}_l \leq \delta \cdot \max[1, |p_l|] \right] \quad (11)$$

for every constraint  $l$  where  $\tilde{a}_{lm}$ ,  $\tilde{b}_{lk}$ , and  $\tilde{p}_l$  are again the true values of the uncertain coefficients. Using the expressions for the true values of the uncertain coefficients given in constraint (8), the uncertain inequality in (11) can be rewritten as follows

$$\begin{aligned} & \text{Max}_{\xi \in Z} \left[ \sum_m (1 + \epsilon \xi_{lm}) a_{lm} x_m + \sum_k (1 + \epsilon \xi_{lk}) b_{lk} y_k \right. \\ & \quad \left. - (1 + \epsilon \xi_l) p_l \leq \delta \cdot \max[1, |p_l|] \right]. \end{aligned} \quad (12)$$

Rearranging terms, we get

$$\begin{aligned} & \text{Max}_{\xi \in Z} \left[ \sum_m a_{lm} x_m + \sum_k b_{lk} y_k - p_l + \epsilon \right. \\ & \quad \left( \sum_{m \in M_l} \xi_{lm} a_{lm} x_m + \sum_{k \in K_l} \xi_{lk} b_{lk} y_k - \xi_l p_l \right) \\ & \quad \left. \leq \delta \cdot \max[1, |p_l|] \right] \end{aligned} \quad (13)$$

where  $M_l$  and  $K_l$  define the sets of uncertain parameters  $a_{lm}$  and  $b_{lk}$ , respectively, for constraint  $l$ . Then,

a solution  $(x, y)$  to the original uncertain MILP given in Eq. (10) which satisfies this constraint is called “reliable” because it takes into account the maximum amount of uncertainty  $\xi \in Z$  and allows an amount of infeasibility  $\delta$ . Now, to transform the constraint into a deterministic form, we instead consider the following formulation

$$\begin{aligned} & Pr \left\{ \sum_m a_{lm} x_m + \sum_k b_{lk} y_k - p_l + \epsilon \right. \\ & \quad \left( \sum_{m \in M_l} \xi_{lm} a_{lm} x_m + \sum_{k \in K_l} \xi_{lk} b_{lk} y_k - \xi_l p_l \right) \\ & \quad \left. > \delta \cdot \max[1, |p_l|] \right\} \leq \kappa. \end{aligned} \quad (14)$$

This constraint enforces that the probability of violation of the uncertain inequality is at most  $\kappa$ , where  $\delta \geq 0$  is a given feasibility tolerance (i. e., amount of error allowed in the feasibility of constraint  $l$ ) and  $\kappa \geq 0$  is a given reliability level (i. e., the probability of violation of constraint  $l$  where  $\kappa = 0$  indicates that there is no chance of constraint violation). Thus, if we know a probability distribution function for the sum of the random variables,

$$\xi = \sum_{m \in M_l} \xi_{lm} a_{lm} x_m + \sum_{k \in K_l} \xi_{lk} b_{lk} y_k - \xi_l p_l \quad (15)$$

we can use this information in the probabilistic constraint (14) to write a deterministic form for the uncertain constraint which is “almost reliable”, depending on the value of  $\kappa$ . This is done using the definition of a probability distribution function and the following relationship

$$F_\xi(\lambda) = Pr\{\xi \leq \lambda\} = 1 - Pr\{\xi > \lambda\} = 1 - \kappa \quad (16)$$

to replace the stochastic elements in constraint (13), generating a deterministic constraint that is “almost reliable” for the given uncertainty level,  $\epsilon$ , infeasibility tolerance,  $\delta$ , and reliability level,  $\kappa$ . The final form of the deterministic constraint (or robust counterpart problem) is simply determined using the inverse distribution function (quantile) of the random variable  $\xi$

$$F_\xi^{-1}(1 - \kappa) = f(\lambda, |a_{lm}|x_m, |b_{lk}|y_k, |p_l|). \quad (17)$$

Thus, the additional constraints in the Robust Counterpart (RC) problem can be written as

$$\sum_m a_{lm}x_m + \sum_k b_{lk}y_k + \epsilon f(\lambda, |a_{lm}|x_m, |b_{lk}|y_k, |p_l|) \leq p_l + \delta \cdot \max[1, |p_l|], \quad \forall l \tag{18}$$

where  $\epsilon$  is a given uncertainty level,  $\delta$  is a given infeasibility tolerance, and  $\lambda$  is determined from  $\kappa$  using constraint (16) and the probability distribution function for  $\xi$ .

**Uncertainty with Normal Probability Distribution**

Suppose that the distributions of the random variables  $\xi_{lm}$ ,  $\xi_{lk}$  and  $\xi_l$  in (8) are all standardized normal distributions with zero as the mean and one as the standard deviation. Then, the distribution of  $\xi$  defined in (15) is also a normal distribution, with zero as the mean and  $\sqrt{\sum_{m \in M_l} a_{lm}^2 x_m^2 + \sum_{k \in K_l} b_{lk}^2 y_k + p_l^2}$  as the standard deviation.

**Theorem 2** Given an uncertainty level ( $\epsilon$ ), an infeasibility tolerance ( $\delta$ ), and a reliability level ( $\kappa$ ), to generate robust solutions, the following ( $\epsilon, \delta, \kappa$ )-Robust Counterpart (RC[ $\epsilon, \delta, \kappa$ ]) of the original uncertain MILP problem can be derived.

$$\begin{aligned} & \text{Min/Max}_{x,y} \quad c^T x + d^T y \\ & \text{s.t.} \quad Ex + Fy = e \\ & \quad \quad Ax + By \leq p \\ & \quad \quad \sum_m a_{lm}x_m + \sum_k b_{lk}y_k + \epsilon \lambda \\ & \quad \quad \sqrt{\sum_{m \in M_l} a_{lm}^2 x_m^2 + \sum_{k \in K_l} b_{lk}^2 y_k + p_l^2} \\ & \quad \quad \leq p_l + \delta \cdot \max[1, |p_l|], \quad \forall l \\ & \quad \quad \underline{x} \leq x \leq \bar{x} \\ & \quad \quad y_k = 0, 1, \quad \forall k \end{aligned} \tag{19}$$

where  $\lambda = F_n^{-1}(1 - \kappa)$  and  $F_n^{-1}$  is the inverse distribution function of a random variable with standardized normal distribution. Thus,  $\lambda$  and  $\kappa$  are related as follows

$$\begin{aligned} \kappa &= 1 - F_n(\lambda) \\ \kappa &= 1 - \text{Pr}\{\xi \leq \lambda\} \\ \kappa &= 1 - \int_{-\infty}^{\lambda} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{x^2}{2}\right) dx \end{aligned}$$

where  $\xi$  is a random variable with standardized normal distribution.

*Proof 2* Let  $(x, y)$  satisfy the following

$$\sum_m a_{lm}x_m + \sum_k b_{lk}y_k + \epsilon \lambda \sqrt{\sum_{m \in M_l} a_{lm}^2 x_m^2 + \sum_{k \in K_l} b_{lk}^2 y_k + p_l^2} \leq p_l + \delta \cdot \max[1, |p_l|] \tag{20}$$

where  $\lambda = F_n^{-1}(1 - \kappa)$  and  $F_n^{-1}$  is the inverse distribution function of a random variable with standardized normal distribution. Then

$$\begin{aligned} & \text{Pr}\left\{ \sum_m \tilde{a}_{lm}x_m + \sum_k \tilde{b}_{lk}y_k > \tilde{p}_l + \delta \cdot \max[1, |p_l|] \right\} \\ &= \text{Pr}\left\{ \sum_m a_{lm}x_m + \epsilon \sum_{m \in M_l} \xi_{lm}|a_{lm}|x_m \right. \\ & \quad \left. + \sum_k b_{lk}y_k + \epsilon \sum_{k \in K_l} \xi_{lk}|b_{lk}|y_k \right. \\ & \quad \left. > p_l + \epsilon \xi_l |p_l| + \delta \cdot \max[1, |p_l|] \right\} \\ &\leq \text{Pr}\left\{ \left( \sum_{m \in M_l} \xi_{lm}|a_{lm}|x_m \right. \right. \\ & \quad \left. \left. + \sum_{k \in K_l} \xi_{lk}|b_{lk}|y_k - \xi_l |p_l| \right) / \right. \\ & \quad \left. \sqrt{\sum_{m \in M_l} a_{lm}^2 x_m^2 + \sum_{k \in K_l} b_{lk}^2 y_k + p_l^2} > \lambda \right\} \\ &= 1 - \text{Pr}\left\{ \left( \sum_{m \in M_l} \xi_{lm}|a_{lm}|x_m \right. \right. \\ & \quad \left. \left. + \sum_{k \in K_l} \xi_{lk}|b_{lk}|y_k - \xi_l |p_l| \right) / \right. \\ & \quad \left. \sqrt{\sum_{m \in M_l} a_{lm}^2 x_m^2 + \sum_{k \in K_l} b_{lk}^2 y_k + p_l^2} \leq \lambda \right\} \\ &= 1 - F_n(\lambda) = 1 - (1 - \kappa) = \kappa. \quad \square \end{aligned}$$

Note that

$$\frac{\sum_{m \in M_l} \xi_{lm}|a_{lm}|x_m + \sum_{k \in K_l} \xi_{lk}|b_{lk}|y_k - \xi_l |p_l|}{\sqrt{\sum_{m \in M_l} a_{lm}^2 x_m^2 + \sum_{k \in K_l} b_{lk}^2 y_k + p_l^2}}$$

is also a ran-

dom variable with standardized normal distribution. This formulation results in a convex MINLP problem, but can still be solved efficiently using a mixed-integer nonlinear solver (e. g., DICOPT [9], MINOPT [10]).

In the discussion above, for simplicity, we have assumed that there is a single common uncertainty level ( $\epsilon$ ), infeasibility tolerance ( $\delta$ ), and reliability level ( $\kappa$ ) in each MILP or convex MINLP problem with uncertain parameters. However, the proposed robust optimization techniques can easily be extended to account for the more general case in which the uncertainty level varies from one parameter to another and the infeasibility tolerance and reliability level are dependent on the constraint of interest. Furthermore, note that for each type of uncertainty addressed, one additional constraint is introduced for each inequality constraint with uncertain parameter(s) and auxiliary variables are added if needed. Because the transformation is carried out at the level of constraints, in principle, the various robust optimization techniques presented can be applied to a single MILP or convex MINLP problem involving different types of uncertainties. More specifically, for each inequality constraint, as long as all of its uncertain parameters are of the same type, an additional constraint that corresponds to the uncertainty type can be introduced to obtain the deterministic robust counterpart problem. It should be pointed out that the aforementioned robust optimization methodology circumvents any need for explicit or implicit discretization or sampling of the uncertain data, avoiding an undesirable increase in the size of the problem. Thus, the proposed methodology is potentially capable of handling problems with a large number of uncertain parameters.

## Applications

The robust optimization methodology proposed in the previous section can be applied to address the problem of scheduling under uncertainty. In this work, we employ the continuous-time formulation presented by Floudas and coworkers [5,6,7,8], which leads to MILP models, to develop new robust scheduling approaches for the following three classes of uncertainties: (i) uncertainty in processing times/rates of tasks, (ii) uncertainty in market demands for products, and (iii) uncertainty in market prices of products and raw materials.

## Uncertainty in Processing Times

The parameters of processing times/rates of tasks participate in the duration constraint and appear as linear coefficients of the binary variable (i. e.,  $\alpha_{ij}$ ) and the continuous variable (i. e.,  $\beta_{ij}$ ) as follows:

$$T^f(i, j, n) - T^s(i, j, n) = \alpha_{ij} \cdot wv(i, n) + \beta_{ij} \cdot B(i, j, n), \quad (21)$$

where  $wv(i, n)$  is a binary variable indicating whether or not task ( $i$ ) starts at event point ( $n$ ),  $B(i, j, n)$  is a continuous variable determining the batch-size of the task, and  $T^s(i, j, n)$  and  $T^f(i, j, n)$  are continuous variables representing the starting and finishing time of the task, respectively. Note that this is an equality constraint. Thus, in order to apply the robust optimization techniques proposed in the previous section for inequality constraints with uncertain parameters, the duration constraint is relaxed to an inequality constraint

$$T^f(i, j, n) - T^s(i, j, n) \geq \alpha_{ij} \cdot wv(i, n) + \beta_{ij} \cdot B(i, j, n). \quad (22)$$

Consequently, the variable  $T^f(i, j, n)$  represents the lower bound on the finishing time of the task, instead of the exact finishing time as determined by the original duration constraint. Using this modified duration constraint, the various robust optimization techniques can be readily applied to consider uncertainty in the parameters  $\alpha_{ij}$  and  $\beta_{ij}$ .

For example, consider a task with parameters  $\alpha_{ij}$  and  $\beta_{ij}$  exhibiting bounded uncertainty in the following ranges

$$\alpha_{ij}^L \leq \alpha_{ij} \leq \alpha_{ij}^U, \quad \beta_{ij}^L \leq \beta_{ij} \leq \beta_{ij}^U. \quad (23)$$

According to Theorem 1, to obtain the deterministic robust counterpart problem, the following constraint is added to the original scheduling model

$$T^f(i, j, n) - T^s(i, j, n) \geq \alpha_{ij}^U \cdot wv(i, n) + \beta_{ij}^U \cdot B(i, j, n) - \delta. \quad (24)$$

Note that no auxiliary variables need to be introduced because the variable  $B(i, j, n)$  (batch-size of the task) is non-negative by definition.

Alternatively, consider a batch task with fixed processing time represented by parameter  $\alpha_{ij}$ . Then, the

true value of the processing time can be represented in terms of the nominal processing time as follows:

$$\tilde{\alpha}_{ij} = (1 + \epsilon \xi_{\alpha_{ij}}) \alpha_{ij}, \tag{25}$$

where  $\xi_{\alpha_{ij}}$  is a random variable with known distribution.

For the case where the uncertainty is characterized by a standardized normal distribution, then, according to Theorem 2, to obtain the deterministic robust counterpart problem, the following constraint is added to the original scheduling model:

$$T^s(i, j, n) - T^f(i, j, n) + [1 + \epsilon \lambda] \alpha_{ij} \cdot wv(i, n) \leq \delta, \tag{26}$$

where  $\lambda = F^{-1}(1 - \kappa)$  and  $F_n^{-1}$  is the inverse distribution function of a random variable with a standardized normal distribution.

**Uncertainty in Product Demands**

The product demands (i. e.,  $dem_s$ ) appear as the right-hand-side parameters in the demand constraints

$$STF(s) \geq dem_s, \quad \forall s \in S^p \tag{27}$$

where  $STF(s)$  is a continuous variable representing the amount of state ( $s$ ) accumulated at the end of the time horizon and  $S^p$  is the set of final products.

The robust optimization techniques can be directly applied to these inequality constraints with uncertain parameters. For example, in the case of bounded uncertainty,

$$dem_s^L \leq \tilde{dem}_s \leq dem_s^U, \tag{28}$$

and according to Theorem 1, the constraint to be added to the original scheduling model to derive the deterministic robust counterpart problem is as follows:

$$STF(s) \geq dem_s^U - \delta. \tag{29}$$

Alternatively, for case of uncertainty with a known distribution, if we consider an uncertain product demand represented by parameter  $dem_s$ , then the true value of the product demand can be represented in terms of the nominal product demand as follows:

$$\tilde{dem}_s = (1 + \epsilon \xi_s) dem_s, \tag{30}$$

where  $\xi_s$  is a random variable with known distribution.

For the case of normal uncertainty, according to Theorem 2, the constraint to be added to the original scheduling model to derive the deterministic robust counterpart problem is

$$STF(s) \geq dem_s(1 + \epsilon \lambda - \delta) \tag{31}$$

where  $\lambda = F_n^{-1}(1 - \kappa)$  and  $F_n^{-1}$  is the inverse distribution function of a random variable with standardized normal distribution.

**Uncertainty in Market Prices**

The market prices (i. e.,  $price_s$ ) participate in the objective function for the calculation of the overall profit:

$$\begin{aligned} \text{Maximize Profit} &= \sum_{s \in S^p} price_s \cdot STF(s) \\ &\quad - \sum_{s \in S^r} price_s \cdot STO(s), \end{aligned} \tag{32}$$

where  $S^p$  and  $S^r$  are the sets of final products and raw materials, respectively, and  $STO(s)$  and  $STF(s)$  are continuous variables representing the initial amount of state ( $s$ ) at the beginning and the final amount of state ( $s$ ) at the end, respectively. The objective function can be expressed in an equivalent way as follows:

$$\begin{aligned} \text{Maximize Profit} \\ \text{s.t. Profit} &\leq \sum_{s \in S^p} price_s \cdot STF(s) \\ &\quad - \sum_{s \in S^r} price_s \cdot STO(s). \end{aligned} \tag{33}$$

Now the uncertain parameters  $price_s$  appear as linear coefficients multiplying the continuous variables  $STF(s)$  and  $STO(s)$  in an inequality constraint and the robust optimization techniques can be readily applied.

For example, if the uncertainty is normally distributed,

$$\tilde{price}_s = (1 + \epsilon \xi_s) price_s \tag{34}$$

where  $\xi_s$  is a standardized normal random variable, then according to Theorem 2 the deterministic robust counterpart problem can be obtained by introducing the following constraint to the original scheduling

model:

$$\begin{aligned} \text{Profit} \leq & \sum_{s \in SP} \text{price}_s \cdot STF(s) - \sum_{s \in Sr} \text{price}_s \cdot STO(s) \\ & - \epsilon \lambda \sqrt{\sum_{s \in SP} \text{price}_s^2 \cdot STF(s)^2 + \sum_{s \in Sr} \text{price}_s^2 \cdot STO(s)^2} \\ & + \delta, \end{aligned} \tag{35}$$

where  $\lambda = F^{-1}(1 - \kappa)$  and  $F_n^{-1}$  is the inverse distribution function of a random variable with standardized normal distribution.

**Cases**

In this section, the robust optimization formulation is applied to two example problems. Both the examples are implemented with GAMS [11] on a 3.20 GHz Linux workstation. The MILP problems are solved using CPLEX 8.1 while the MINLP problems are solved using DICOPT [9].

**Case 1: Bounded Uncertainty in the Processing Times**

Let us revisit the motivating example in Sect. “A Motivating Example”. Assume that the uncertainty of the processing times is bounded and the (relative) uncertainty level ( $\epsilon$ ) is 15%, that is,

$$0.85\alpha \leq \tilde{\alpha} \leq 1.15\alpha \tag{36}$$

and the infeasibility tolerance level ( $\delta$ ) is 10%.

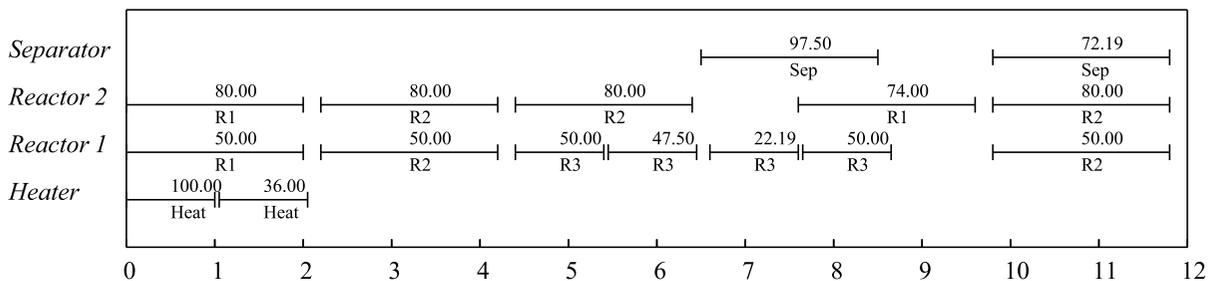

By solving the IRC[ $\epsilon, \delta$ ] problem, a “robust” schedule is obtained, as shown in Fig. 4, which takes into account uncertainty in the processing times. The nom-

**Robust Optimization: Mixed-Integer Linear Programs, Table 2**  
Model and solution statistics of case 1

	Nominal solution	Robust solution
Profit	3638.75	2887.19
CPU time (s)	2.68	114.47
Binary Variables	96	96
Continuous Variables	378	378
Constraints	553	713

inal schedule can be seen in Fig. 2 in Sect. “A Motivating Example”. Compared to the nominal solution which is obtained at the nominal values of the processing times, the robust solution exhibits very different scheduling strategies, including both task-unit assignments and task timings. Even the sequences of tasks in the two reactors in Fig. 4 deviates significantly from those in the nominal solution in Fig. 2. The robust solution ensures that the robust schedule obtained is feasible with the specified uncertainty level and infeasibility tolerance. However, the resulting profit is reduced, from 3638.75 to 2887.19, which reflects the effect of uncertainty on overall production. A comparison of the model and solution statistics for the nominal and robust solutions can be found in Table 2.

Figure 5 summarizes the results of the IRC problem with three different levels of uncertainty. It is shown that with a given infeasibility tolerance, the maximal profit that can be achieved decreases as the uncertainty level increases, which indicates more “conservative” scheduling decisions because of the existence of uncertainty. On the other hand, at a given uncertainty level, the profit increases as the infeasibility tolerance is increased, which means more “aggressive” schedul-

 Profit vs. infeasibility tolerance at different uncertainty levels for case 1

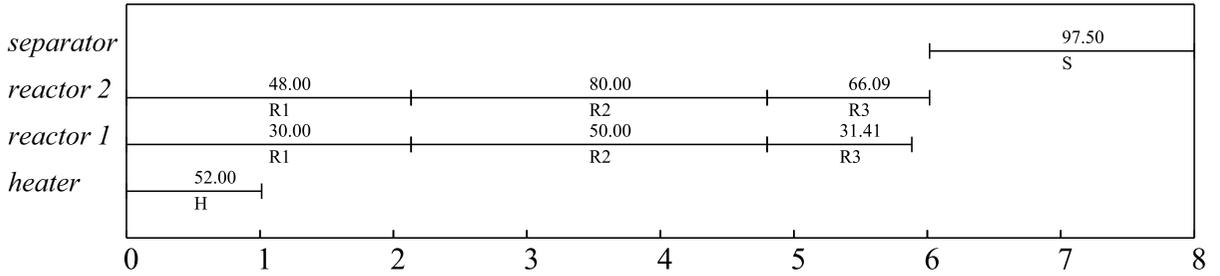

ing arrangements can be incorporated if violations of related timing constraints can be tolerated to a larger extent. These results are consistent with intuition and other approaches, however, with the robust optimization approach, the effects of uncertainty and the trade-offs between conflicting objectives are quantified rigorously and efficiently. It should be noted that at a given uncertainty level, the objective value of profit as well as the corresponding schedule change dramatically at discrete points as the infeasibility tolerance increases. This behavior is caused by special characteristics of the example problem, including the fixed time horizon and the fixed processing times of tasks.

**Case 2: Uncertainty with a Normal Distribution in the Market Prices**

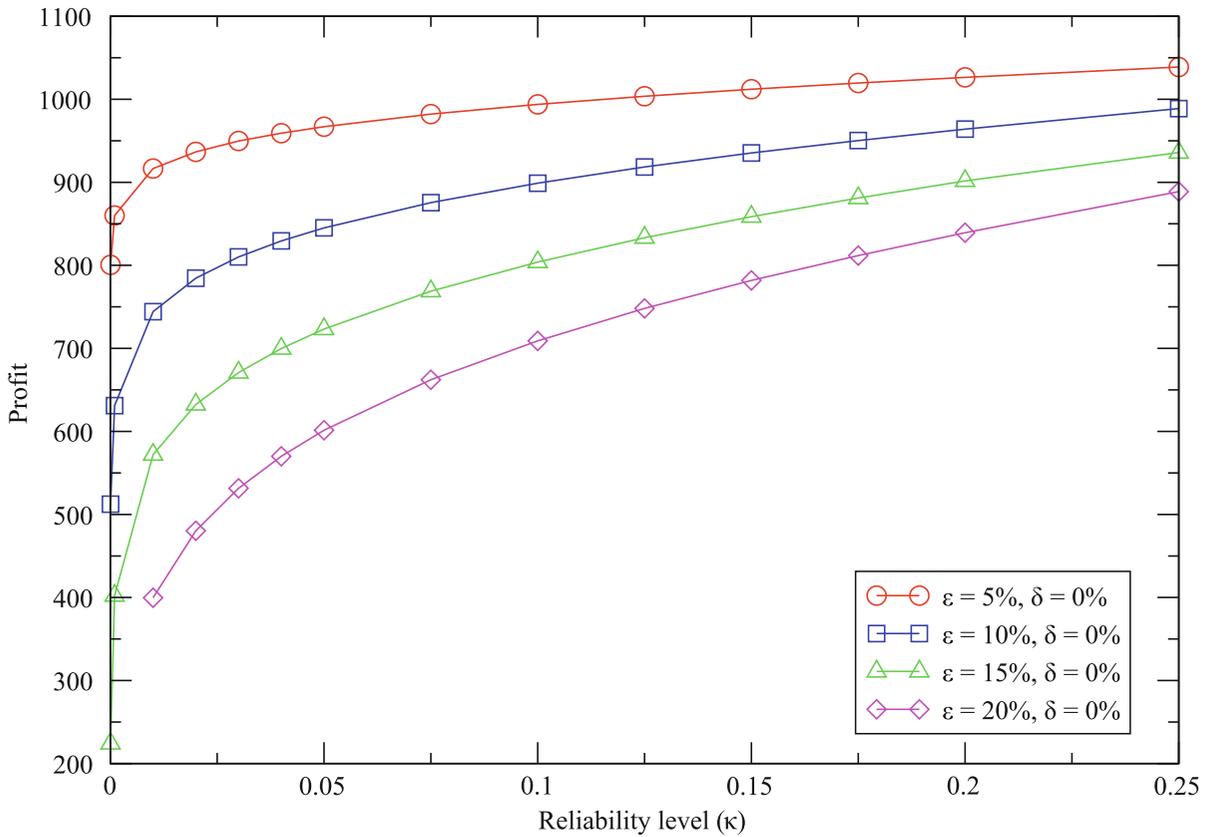

In this example, we consider uncertainty with a normal distribution in the market prices for the same process and processing time data given in Case 1. The objective function is the maximization of profit in a time horizon of 8 hours. The uncertainty level ( $\epsilon$ ) is 5%, the infeasibility tolerance ( $\delta$ ) is 5%, and the reliability level ( $\kappa$ ) is 5%. The nominal schedule is shown in Fig. 6 with a profit of 1088.75. The robust schedule is obtained by solving the robust counterpart problem, as shown in Fig. 7, and the corresponding profit is 966.97. By

**Robust Optimization: Mixed-Integer Linear Programs, Figure 8**  
 Profit vs. reliability level at different uncertainty and infeasibility levels for case 2

executing this schedule, the profit is guaranteed to be least 966.97 with a probability of 95% in the presence of the 5% uncertainty in the prices of the products and raw materials. A comparison of the model and solution statistics for the nominal and robust solutions can be found in Table 3.

Figure 8 summarizes the results of the RC problem at several different levels of uncertainty and an infeasibility tolerance of 0% at increasing values of the reliability level. It is shown that at a given reliability level, the maximal profit that can be achieved decreases as the uncertainty level increases, which indicates more con-

**Robust Optimization: Mixed-Integer Linear Programs, Table 3**  
Model and solution statistics for case 2

	Nominal solution	Robust solution
Profit	1088.75	966.97

Binary Variables	60	60
Continuous Variables	280	280
Constraints	334	334

servative scheduling decisions because of the existence of uncertainty. Also, at a given uncertainty level and infeasibility tolerance, the profit increases as the reliability level increases, meaning that as the probability of violation of the uncertain constraint, or  $\kappa$ , increases, then  $\lambda$  decreases and according to Eq. (35), the profit takes on a larger value.

## Conclusions

In this chapter, we propose a new approach to address the scheduling under uncertainty problem based on a robust optimization methodology, which when applied to MILP problems, produces “robust” solutions that are, in a sense, immune against uncertainties in both the coefficients in the objective function, the left-hand-side parameters and the right-hand-side parameters of the inequality constraints. A unique feature of the proposed approach is that it can address many uncertain parameters. The approach can be applied to address the problem of production scheduling with uncertain processing times, market demands, and/or prices of products and raw materials. Our computational results show that this approach provides an effective way to address scheduling problems under uncertainty, producing reliable schedules and generating helpful insights on the tradeoffs between conflicting objectives.

## Keywords

Gradient-free minimization; Rosenbrock method; Line search methods; Pattern search; Gram–Schmidt orthogonalization

The Rosenbrock method is in its basic form a *gradient-free minimization algorithm*. It was introduced by H.H. Rosenbrock [2], and avoids the use of *line searches*. It is based on *orthogonal search directions* with alternating minimizations between these and using *pattern search* at the end of each orthogonal direction search cycle. The algorithm is given below. The minimization problem considered is:

$$\min_{\mathbf{x}} f(\mathbf{x}).$$

### 1. Initialization

Set the search directions to be the coordinate directions,  $\mathbf{d}^{(1)}, \dots, \mathbf{d}^{(n)}$ , where the  $\mathbf{d}^{(i)}$  are vectors of zeros, except for a 1 in the  $i$ th position. Select a scalar value  $\epsilon > 0$  to be used as the termination tolerance, an expansion factor  $\beta_1 > 1$  and a contraction factor  $\beta_2$  such that  $-1 < \beta_2 < 0$ . Set the initial stepsizes  $\delta_i^{(0)}$ ,  $i = 1, \dots, n$ , along each of the above defined search directions. Select an initial point  $\mathbf{x}^{(0)}$  and initialize by setting  $\mathbf{z}^{(1)} = \mathbf{x}^{(0)}$ . Set the pattern iteration counter  $k = 0$  and the direction search counter  $i = 1$ . Initialize the stepsizes along each direction to  $\delta_i = \delta_i^{(0)}$ .

### 2. Main Iteration Step (direction Search)

```

2.1 Forward search
IF  $f(\mathbf{z}^{(i)} + \delta_i \mathbf{d}^{(i)}) < f(\mathbf{z}^{(i)})$ 
THEN
    forward search step  $i$  is successful;
    set  $\mathbf{z}^{(i+1)} = \mathbf{z}^{(i)} + \delta_i \mathbf{d}^{(i)}$ ;
    set  $\delta_i \leftarrow \beta_1 \delta_i$ .
ELSE (if  $f(\mathbf{z}^{(i)} + \delta_i \mathbf{d}^{(i)}) \geq f(\mathbf{z}^{(i)})$ )
    forward search step is unsuccessful;
    set  $\mathbf{z}^{(i+1)} = \mathbf{z}^{(i)}$ ;
    set  $\delta_i \leftarrow \beta_2 \delta_i$ .
END IF;
IF  $i < n$ ,
    increment search counter  $i \leftarrow i + 1$ ;
    go to step 2.1.
ELSE (if  $i = n$ ) go to step 2.2.
END IF;
```

```

2.2 IF  $f(\mathbf{z}^{(n+1)}) < f(\mathbf{z}^{(1)})$ 
    (at least one improvement achieved in 2.1);
    set  $\mathbf{z}^{(1)} = \mathbf{z}^{(n+1)}$ ,  $i = 1$ ;
    go to step 2.1.
ELSE (if  $f(\mathbf{z}^{(n+1)}) = f(\mathbf{z}^{(1)})$ )
    (no improvement achieved in 2.1);
    IF  $f(\mathbf{z}^{(n+1)}) < f(\mathbf{x}^{(k)})$ 
        (one improvement in iteration  $k$ );
        go to step 3.
    ELSE (if  $f(\mathbf{z}^{(n+1)}) = f(\mathbf{x}^{(k)})$ )
        (no improvement in iteration  $k$ );
        IF  $|\delta_i| \leq \epsilon$  for all  $i$ ,
            THEN  $\mathbf{x}^{(k)}$  is an estimate of the optimal
            solution;
            STOP.
        ELSE
            set  $\mathbf{z}^{(1)} = \mathbf{z}^{(n+1)}$ ;
            set  $i = 1$ , go to step 2.1.
        END IF;
    END IF;
END IF;
```

### 3. Pattern Search and New Search Direction Set Generation

```

3.1 Set  $\mathbf{x}^{(k+1)} = \mathbf{z}^{(n+1)}$ .
    IF  $\|\mathbf{x}^{(k+1)} - \mathbf{x}^{(k)}\| < \epsilon$ ,
        THEN  $\mathbf{x}^{(k+1)}$  is an estimate of the optimal so-
        lution; STOP.
    ELSE solve the linear system
         $[\mathbf{d}^{(1)}, \dots, \mathbf{d}^{(n)}] \cdot [\lambda_1, \dots, \lambda_n]^T = \mathbf{x}^{(k+1)} -$ 
         $\mathbf{x}^{(k)}$  for  $\lambda_i$ ;
        go to step 3.2
3.2 Orthonormalization of new search direc-
    tions (Gram–Schmidt procedure)
    a set  $\mathbf{a}^{(i)} = \mathbf{d}^{(i)}$  if  $\lambda_i = 0$ ;
    set  $\mathbf{a}^{(i)} = \sum_{j=1}^n \lambda_j \mathbf{d}^{(j)}$  if  $\lambda_i \neq 0$ .
    b set  $\mathbf{b}^{(1)} = \mathbf{a}^{(1)}$ ;
    set  $\mathbf{b}^{(i)} = \mathbf{a}^{(i)} - \sum_{j=1}^{i-1} \left( (\mathbf{a}^{(i)})^T \widehat{\mathbf{d}}^{(j)} \right) \widehat{\mathbf{d}}^{(j)}$ ,  $i \geq 2$ ,
    where  $\widehat{\mathbf{d}}^{(i)} = \mathbf{b}^{(i)} / \|\mathbf{b}^{(i)}\|$ ;
    denote these new directions  $\widehat{\mathbf{d}}^{(i)}$  as  $\mathbf{d}^{(i)}$ .
3.3 Reset the stepsizes  $\delta_i = \delta_i^{(0)}$ , for  $i = 1, \dots, n$ .
    set the initial point  $\mathbf{z}^{(1)} = \mathbf{x}^{(k+1)}$ ;
    increment the main cycle counter  $k \leftarrow k + 1$ ;
    set  $i = 1$ ;
    Go to step 1.
```

The procedure as described in the algorithm above can be seen to be taking discrete steps along each of the  $n$  directions. Success in each of these is followed by an expansion of the stepsize, while a failure is marked by a reduction of the stepsize, changing direction using  $\beta_2$  which is negative, to be taken in the next cycle. Upon a single success of the cycle of  $n$  searches a new set of search directions is generated by the orthogonalization procedure (Gram–Schmidt). Continued failures in the search directions will result in stepsize shrinking and triggering of the termination criterion (within  $\epsilon$  tolerance) eventually.

It is possible to derive a continuous minimization procedure along each of the search directions, by replacing the discrete step search with a line search procedure. Such a scheme can be found for example in [1], where it is also demonstrated that under differentiability assumptions on the objective function  $f$  it is possible to show that Rosenbrock's method converges to a stationary point of  $f$  (minimum under convexity assumptions).

Nonlinear programming; Rosen gradient projection method; Global convergence

The *gradient projection* method proposed by J.B. Rosen in 1960 [82,83] is one of earliest methods in the history of mathematical programming for solving constrained optimization problems. The importance of this method in the literature also stems from the fact that many more efficient algorithms, in linear and nonlinear programming, developed later (e. g. by D. Goldfarb [42], by B.H. Murtagh and R.W.H. Sargent [63] and by N.K. Karmarkar [53]) incorporated the basic ideas propounded by Rosen.

The *global convergence* of Rosen's method was a long-standing open problem. Since Rosen's method is included in many textbooks, the convergence problem became quite well-known. In fact, almost all books (such as [3,4,57,67]) that have a chapter or a section to introduce Rosen's method recognize the problem on the global convergence of Rosen's method. Through efforts of 26 years, the proof was finally found [35,36,47].

The study on the global convergence of Rosen's method had a great impact on the development of a general theory of global convergence in nonlinear programming. In fact, many new techniques [28,29] were discovered to reach the final solution. It is desirable to solve other open problems with them.

One of big remaining open problems about global convergence in nonlinear programming is *Powell's conjecture* that the *DFP method* (*Davidon–Fletcher–Powell*) for unconstrained optimization is globally convergent. Progress has been made slowly [69,70,71].

This article will review the story about Rosen's method and survey the results in theory of global con-

vergence and the development about Powell's conjecture.

### Rosen's Method

Consider *linearly constrained optimization problems* in the following form:

$$\begin{cases} \max & f(\mathbf{x}) \\ \text{s.t.} & \mathbf{a}_j^\top \mathbf{x} \geq b_j, \quad j = 1, \dots, m, \end{cases} \quad (1)$$

where  $\mathbf{x} \in \mathbf{R}^n$ ;  $\mathbf{R}^n$  is the  $n$ -dimensional Euclidean space whose points are represented as column vectors. A point is called a *feasible point* if it satisfies the constraints. The set of all feasible points is called the *feasible region*. Without special mentioning, we always assume that the function  $f$  is continuously differentiable in a convex set containing the feasible region. The function  $f$  is always referred to be an *objective function*. For simplicity of notations, we denote  $\mathbf{g}(\mathbf{x}) = \nabla f(\mathbf{x})$ , and especially  $\mathbf{g}_k = \mathbf{g}(\mathbf{x}_k)$  and  $\mathbf{g}^* = \mathbf{g}(\mathbf{x}^*)$ .

A nonzero vector  $\mathbf{d}$  is called a *feasible direction* at a feasible point  $\mathbf{x}$  if there exists  $\bar{\lambda} > 0$  such that for any  $\lambda \in [0, \bar{\lambda}]$ ,  $\mathbf{x} + \lambda \mathbf{d}$  is feasible.

A constraint is called an *active constraint* at a feasible point  $\mathbf{x}$  if its equality sign holds at the point. The set of indices of active constraints is called the *active set*, denoted by  $J(\mathbf{x})$ , i. e.

$$J(\mathbf{x}) = \{j: \mathbf{a}_j^\top \mathbf{x} = b_j\}.$$

In particular, we denote

$$J_k = J(\mathbf{x}_k) \quad \text{and} \quad J^* = J(\mathbf{x}^*).$$

For simplicity, we also denote  $M = \{1, \dots, m\}$ . Note that  $J \subset J'$  will stand for  $J \subseteq J'$  and  $J \neq J'$ . For a singleton  $\{h\}$ , we write  $J \setminus h$  and  $J \cup h$  instead of  $J \setminus \{h\}$  and  $J \cup \{h\}$ , respectively.

For the feasible region in the considered problem (1), a direction  $\mathbf{d}$  is *feasible* at a feasible point  $\mathbf{x}$  if and only if  $\mathbf{a}_j^\top \mathbf{d} = 0$  for  $j \in J(\mathbf{x})$ . In fact, if  $\mathbf{d}$  is a feasible direction at point  $\mathbf{x}$ , then there exists a number  $\lambda > 0$  such that  $\mathbf{x} + \lambda \mathbf{d}$  is a feasible point. Thus,  $\mathbf{a}_j^\top (\mathbf{x} + \lambda \mathbf{d}) \geq b_j$  for  $j \in M$ . Since  $\mathbf{a}_j^\top \mathbf{x} = b_j$  for  $j \in J(\mathbf{x})$ , we have  $\lambda \mathbf{a}_j^\top \mathbf{d} \geq 0$  for  $j \in J(\mathbf{x})$ . Therefore,  $\mathbf{a}_j^\top \mathbf{d} \geq 0$  for  $j \in J(\mathbf{x})$ .

Conversely, suppose  $\mathbf{a}_j^\top \mathbf{d} \geq 0$  for  $j \in J(\mathbf{x})$ . Set

$$\bar{\lambda} = \begin{cases} \min \left\{ \frac{b_j - \mathbf{a}_j^\top \mathbf{x}}{\mathbf{a}_j^\top \mathbf{d}} : \mathbf{a}_j^\top \mathbf{d} < 0 \right\} & \text{if } \exists j: \\ & \mathbf{a}_j^\top \mathbf{d} < 0, \\ 1 & \text{otherwise.} \end{cases}$$

Clearly,  $\bar{\lambda} > 0$  and for  $\lambda \in [0, \bar{\lambda}]$ ,  $\mathbf{x} + \lambda \mathbf{d}$  is feasible.

Now, define

$$D^1(\mathbf{x}) = \{\mathbf{d}: \mathbf{a}_j^\top \mathbf{d} = 0 \text{ for } j \in J(\mathbf{x})\}.$$

Then  $D^1(\mathbf{x})$  is exactly the set of all feasible direction at point  $\mathbf{x}$ .

A feasible point  $\mathbf{x}^*$  is said to be a *local maximum* of problem (1) if there exists a neighborhood of the point  $\mathbf{x}^*$  such that for any feasible point  $\mathbf{x}$  in the neighborhood,  $f(\mathbf{x}) \leq f(\mathbf{x}^*)$ .

A nonzero vector  $\mathbf{d}$  is called an *ascendant direction* at a feasible point  $\mathbf{x}$  if  $\mathbf{g}(\mathbf{x})^\top \mathbf{d} > 0$ . Clearly, if  $\mathbf{d}$  is a *feasible ascendant direction* at  $\mathbf{x}$ , then we can find a feasible point  $\mathbf{x}'$  along the direction  $\mathbf{d}$  such that  $f(\mathbf{x}') > f(\mathbf{x})$ . Therefore,  $\mathbf{x}$  is a local maximum only if there does not exist a feasible ascendant direction at  $\mathbf{x}$ . That is, a feasible point  $\mathbf{x}$  is a local maximum only if

$$D^1(\mathbf{x}) \cap D^2(\mathbf{x}) = \emptyset,$$

where

$$D^2(\mathbf{x}) = \{\mathbf{d}: \mathbf{g}^\top \mathbf{d} > 0\}.$$

The following Theorem states a necessary and sufficient condition for  $D^1(\mathbf{x}) \cap D^2(\mathbf{x}) = \emptyset$ .

**Theorem 1** *Let  $\mathbf{x}$  be a feasible point. Then  $D^1(\mathbf{x}) \cap D^2(\mathbf{x}) = \emptyset$  if and only if there exist  $u_j, j \in J(\mathbf{x})$ , such that*

$$\mathbf{g}(\mathbf{x}) = \sum_{j \in J(\mathbf{x})} u_j \mathbf{a}_j \quad (2)$$

and

$$u_j \leq 0 \text{ for } j \in J(\mathbf{x}). \quad (3)$$

A feasible point  $\mathbf{x}$  is called a *Kuhn-Tucker point* if there exist  $u_j, j \in J(\mathbf{x})$ , satisfying (2) and (3). Clearly, for a linearly constrained optimization problem, every local maximum is a Kuhn-Tucker point. However, a Kuhn-Tucker point may not be a local maximum.

A feasible point  $\mathbf{x}$  is *regular* if all active constraints at  $\mathbf{x}$  are linearly independent, i. e.  $\mathbf{a}_j$  for  $j \in J(\mathbf{x})$  are linearly dependent. The problem (1) is *nondegenerate* if its constraints satisfy the following *regularity condition*: Every feasible point is regular.

Suppose the problem (1) is nondegenerate. At each feasible point  $\mathbf{x}$ , the subspace  $D_j = \{\mathbf{d} : \mathbf{a}_j^\top \mathbf{d} = 0, j \in J\}$  where  $J = J(\mathbf{x})$  is the tangent plane at the point. The *orthogonal projection operator* on  $D_j$  is denoted by  $P_j$ . It is not hard to find out that

$$P_j = I - A_j(A_j^\top A_j)^{-1}A_j^\top,$$

where  $A_j$  denotes the matrix consisting of column vectors  $\mathbf{a}_j, j \in J$ . An important property of gradient projection is as follows.

**Theorem 2** Let  $0 < c \leq +\infty$ . For  $J = J(\mathbf{x})$ , define

$$\mathbf{d} = \begin{cases} P_j \mathbf{g} & \text{if } \|P_j \mathbf{g}\| > c \cdot u_h, \\ P_{J \setminus h} \mathbf{g} & \text{otherwise,} \end{cases}$$

where  $u_h = \max_{j \in J} u_j$ . Then  $\mathbf{d} = \mathbf{0}$  if and only if  $\mathbf{x}$  is a Kuhn-Tucker point. Furthermore, if  $\mathbf{d} \neq \mathbf{0}$ , then  $\mathbf{d}$  is an ascendant feasible direction.

Theorem 2 suggests the algorithm Rosen's method below.

The global convergence of Rosen's method relies on a parameter chosen at each iteration. To avoid the zigzag phenomena, Rosen chose the parameter to be a positive number with an upper bound. He also gave a convergence proof in his paper. However, it did not take very long for someone to point out that there is a serious mistake in the proof. Since then, substantial efforts have been made on the problem. Maybe, it is due to a natural expectation for seeking simplicity. Most books incorrectly state Rosen's method by setting the parameter to be zero which is exactly what Rosen tried to avoid. See [30] for a counterexample to the method described in those books. It was indicated in [35] that this counterexample also works for the case in which the parameter varies and converges to zero as the computation runs from the first iteration to the infinity. It follows that Rosen's restriction on the parameter is not sufficient for the convergence.

Initially, choose a feasible point  $\mathbf{x}_1$ . At each iteration  $k = 1, 2, \dots$ , the algorithm carries out the following steps.

- 1 Choose a positive number  $c_k$ . Compute a search direction by the following formula:

$$\mathbf{d}_k = \begin{cases} P_{J_k} \mathbf{g}_k & \text{if } \|P_{J_k} \mathbf{g}_k\| > c_k u_{kh_k}, \\ P_{J_k \setminus h_k} & \text{otherwise,} \end{cases}$$

where

$$(u_{kj}, j \in J_k)^\top = (A_{J_k}^\top A_{J_k})^{-1} A_{J_k}^\top \mathbf{g}^k$$

and

$$u_{kh_k} = \max\{u_{kj} : j \in J \setminus M'\}.$$

- 2 If  $\mathbf{d}_k \neq \mathbf{0}$ , then stop;  $\mathbf{x}_k$  is a Kuhn-Tucker point.

If  $\mathbf{d}_k \neq \mathbf{0}$ , then compute

$$m = \min\left\{\frac{b_j - \mathbf{a}_j^\top \mathbf{x}_k}{\mathbf{a}_j^\top \mathbf{d}_k} : \mathbf{a}_j^\top \mathbf{d}_k < 0\right\},$$

$$\bar{\lambda}_k = \begin{cases} 1 & \text{if } \mathbf{a}_j^\top \mathbf{d}_k \geq 0 \text{ for all } j \notin J_k, \\ m & \text{otherwise,} \end{cases}$$

and find a new point  $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda_k \mathbf{d}_k$ , ( $0 < \lambda_k \leq \bar{\lambda}_k$ ) by a line search procedure.

**Rosen's method**

The first convergent version was found by E. Polak [66]. Compared with the original one, Polak's version is too complicated. First of all, he used the  $\epsilon$ -active set strategy. Secondly, the version contains a special procedure, which involves computing the gradient projection several times. Polak proved the convergence of his version under a condition, named by  $\epsilon$ -hypothesis. X.-S. Zhang [96] showed that  $\epsilon$ -hypothesis is equivalent to

the regularity condition. Zhang's work motivated from a Yue–Han theorem [92].

M. Yue and J. Han utilized Polak's procedure to study the reduced gradient method. The reduced gradient method was first proposed by P. Wolfe [87]. An important step in the reduced gradient method is to compute a reduced basis. There are several ways for finding a reduced basis [33,85,86,92,93]. It has been known to be quite efficient in practice. Wolfe's original version of reduced gradient method is not globally convergent. A counterexample has been given by Wolfe [90] himself. Several convergent versions [57,85,86,92,93] appeared later. Among them, Wang [85] derived his version from the *Levitin–Polyak's method* [56]. Levitin–Polyak's method is a gradient projection method different from Rosen's method. In each iteration, they chose the search direction to be the projection of gradient on the feasible region. In general, we cannot find a closed form formula for such a projection. However, theoretically, the method can be put in very a general setting [1,46,52,60].

Yue and Han [92] also obtained a new property of a linearly constrained set in the format of the standard form of linear programming. These types of properties are very useful for the application of  $\epsilon$ -active set strategy. See [32] for a generalization. D.-Z. Du [22] also found a simpler convergent version for Rosen's method by deleting Polak's special procedure.

Although several convergent versions have been found, one still wanted to know what would happen when the parameter is also bounded below by a positive number. In fact, all the above convergent versions use some ideas different from Rosen's one for anti-zigzagging. Thus, it was still open whether Rosen's original idea that keeps the parameter away from zero and infinity works or not. (Allowing the parameter to approach zero as the iteration varies was considered as an oversight in [82].)

Zhang [97] made the first breakthrough in this direction; he showed that if the parameter  $c_k$  equals a positive constant at every iteration, then Rosen's method is convergent in the three-dimensional space. Soon later, Du and Zhang [35] established a more general result that if the parameter  $c_k$  is chosen to be a positive constant with a specific upper bound, then Rosen's method is convergent in the  $n$ -dimensional space. This is the first solution for the convergence problem. In the same

paper, Du and Zhang also conjecture that the upper bound on the constant can be deleted, that is, as long as the parameter does not vary as the iteration varies, it can be chosen to be any positive number. This conjecture was settled through several efforts including [26,47], and [36]. Finally, [34] showed a convergence theorem with a more general rule for selecting the parameter.

The global convergence of Rosen's method also depends on the choice of line search. In [36] it is assumed that the line search is normal, including exact line search, Curry test, Goldstein test, Wolfe test, and Armijo rule [2].

**Theorem 3** *Consider Rosen's method with a normal line search procedure. Let  $\alpha$  and  $\beta$  be two positive numbers with  $\alpha \leq \beta$ . Suppose in Rosen's method the parameters  $c_k$  are chosen to satisfy  $\alpha \leq c_k \leq \beta$ . Then the method either stops at a Kuhn–Tucker point or generates an infinite sequence whose cluster points are all Kuhn–Tucker points.*

If the line search is not normal, X.-D. Hu [48] showed that the global convergence of Rosen's method may fail. But, with Hu's counterexample, the method in [22] still has the global convergence property. If the steplength in the line search is uniformly bounded, the choice of parameter can be further relaxed [29], which gives an improvement of Ritter's result [80].

**Theorem 4** *Consider Rosen's method with a normal line search procedure of uniformly bounded steplength. Let  $\alpha$  and  $\beta$  be two positive numbers and  $\ell$  and  $\ell'$  two positive integers. Suppose in Rosen's method the parameters  $c_k$  are chosen to satisfy*

- a)  $c_k \geq \alpha$  whenever  $J_k = \dots = J_{k-\ell}$ ; and
- b)  $c_k \leq \beta$  whenever  $J_k \neq \dots \neq J_{k-\ell'}$  and  $|J_k| = \dots = |J_{k-\ell'}|$ .

*Then the method either stops at a Kuhn–Tucker point or generates an infinite sequence whose cluster points are all Kuhn–Tucker points.*

Finally, we would like to mention that [45] gives a method to deal with this degenerative case. This method uses the lexicographic simplex procedure to deal with degenerate line constraints. It is worth mentioning that Bland's rule [5] can also be used here instead of the lexicographic simplex procedure.

### Global Convergence

The significance of the solution for the global convergence problem of Rosen’s method is not only on a single algorithm. In fact, the solution is obtained based on discovery of new techniques and new developments of global convergence theory in nonlinear programming.

To give a unified convergence theorem, W.I. Zangwill [94,95] introduced a point-to-set mapping; each iteration that finds a new point from the current point is viewed as taking an element from the image set of the point-to-set mapping. He showed an abstract convergence theorem under the closeness of the mapping.

Let  $X$  and  $Y$  be two topological spaces. Denote by  $\mathcal{P}(X)$  the collection of all subsets of  $X$ . A mapping from  $X$  to  $\mathcal{P}(Y)$  is usually called a *point-to-set mapping*. A point-to-set mapping  $A: X \rightarrow \mathcal{P}(Y)$  is said to be *closed* at a point  $\mathbf{x}$  if

$$\begin{cases} \mathbf{x}_k \rightarrow \mathbf{x} \\ \mathbf{y}_k \rightarrow \mathbf{y} \\ \mathbf{y}_k \in A(\mathbf{x}_k) \end{cases} \rightarrow \mathbf{y} \in A(\mathbf{x}). \quad (4)$$

A point-to-set mapping is *closed* if it is closed at every point in its definition domain.

Consider the following abstract algorithm.

Let  $\Gamma$  be a subset of a topological space  $X$ . Let  $A$  be a point-to-set mapping from  $X \setminus \Gamma$  to  $\mathcal{P}(X)$ .

0 Choose an initial point  $\mathbf{x}_1$ .

$k$  If  $\mathbf{x}_k \in \Gamma$ , then stop. Otherwise, choose  $\mathbf{x}_{k+1} \in A(\mathbf{x}_k)$ .

#### Zangwill’s algorithm

**Theorem 5 (Zangwill’s theorem)** Let  $f$  be a continuous function on a topological space  $X$  and  $\Gamma$  a subset of  $X$ . Let  $A$  be a closed point-to-set mapping from  $X \setminus \Gamma$  to  $\mathcal{P}(X)$  such that

- a) the closure of  $\cup_{k=1}^{\infty} A(\mathbf{x}_k)$  is compact for every convergent sequence of points  $\mathbf{x}_1, \mathbf{x}_2, \dots$  in  $X \setminus \Gamma$ ; and
- b) for every  $\mathbf{x} \in X \setminus \Gamma$  and  $\mathbf{y} \in A(\mathbf{x})$ ,  $f(\mathbf{y}) > f(\mathbf{x})$ .

Then Zangwill’s algorithm either stops at a point in  $\Gamma$  or generates an infinite sequence whose cluster points are all in  $\Gamma$ .

However, for a constrained optimization problem, the closeness is lost when the line search procedure is stopped by a constraint. Du [23] proved a result to tell when an algorithm has the global convergence provable by Zangwill’s theorem. G.P. McCormick [58] suggested to search along a broken line, that is, if the search is stopped by reaching a new constraint then do not stop there and, keeping the constraint active, find a new direction to continue the search. K. Ritter [78,79,80] decomposed the broken line search into several line searches and applied it to a family of feasible direction method including the gradient projection method. Since the discovery of Zangwill’s theorem, many abstract convergence results based on the point-to-set mapping have been established. See [50,51,61,62] for some of them. Some necessary or sufficient conditions for global convergence, such as Bazaraa–Shetty’s condition [4] and Wolfe’s work [88,89,90], also appeared. However, none of them is powerful enough to show the convergence of Rosen’s gradient projection method.

As the open problem on Rosen’s method is resolved, a number of new techniques [28,29] for studying the global convergence of ‘nonclosed’ algorithms have been discovered. These techniques have now been known as *slope lemmas*.

**Lemma 6 (first slope lemma)** Let  $\{\mathbf{x}_k\}$  be a sequence of feasible points such that  $f(\mathbf{x}_k) < f(\mathbf{x}_{k+1})$  for  $k = 1, 2, \dots$ . Let  $\mathbf{x}^*$  be a cluster point of the sequence such that for any subsequence  $\{\mathbf{x}_k\}_{k \in K}$  converging to  $\mathbf{x}^*$ ,  $\mathbf{x}_{k+1} - \mathbf{x}_k \rightarrow \mathbf{0}$  as  $k \rightarrow \infty$ ,  $k \in K$ . If  $\{\mathbf{x}_k\}$  does not converge to  $\mathbf{x}^*$ , then there exists a subsequence  $\{\mathbf{x}_k\}_{k \in K}$  such that  $\mathbf{x}_k \rightarrow \mathbf{x}^*$  as  $k \rightarrow \infty$ ,  $k \in K$ , and

$$\lim_{k \rightarrow \infty, k \in K} \frac{\mathbf{g}_k^\top (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} = 0. \quad (5)$$

**Lemma 7 (second slope lemma)** Let  $\{\mathbf{x}_k\}$  be a sequence of feasible points, in a linearly constrained region, convergent to  $\mathbf{x}^*$ . Suppose  $f(\mathbf{x}_k) < f(\mathbf{x}_{k+1})$  for all  $k$ . Then there exists a subsequence  $\{\mathbf{x}_k\}_{k \in K}$  such that for every  $J$  with  $J = J_k$  for infinitely many  $k$ ,

$$0 \leq \lim_{k \rightarrow \infty, k \in K} \frac{\mathbf{g}_k^\top (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} \leq \|P_J \mathbf{g}(\mathbf{x}^*)\|.$$

**Lemma 8 (third slope lemma)** Let  $\{\mathbf{x}_k\}$  be a sequence of feasible points such that for all  $k$ ,  $f(\mathbf{x}_k) <$

$f(\mathbf{x}_{k+1})$ . Let  $\mathbf{x}^*$  be a cluster point of the sequence. Suppose that for any subsequence  $\{\mathbf{x}_k\}_{k \in K}$  converging to  $\mathbf{x}^*$ ,  $\lim_{k \rightarrow \infty, k \in K} (\mathbf{x}_{k+1} - \mathbf{x}_k) = \mathbf{0}$ . If there exists a positive number  $\mu$  such that for all  $k$ ,

$$\frac{\mathbf{g}_k^\top (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} \geq \mu \max\{\|P_{J_k} \mathbf{g}_k\|, \|P_{J_{k+1}} \mathbf{g}_k\|\},$$

then the following two statements are equivalent:

a) there exists a subsequence  $\{\mathbf{x}_k\}_{k \in K}$  converging to  $\mathbf{x}^*$  such that

$$\lim_{k \rightarrow \infty, k \in K} \frac{\mathbf{g}_k^\top (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} = 0. \quad (6)$$

b) For every subsequence  $\{\mathbf{x}_k\}_{k \in K}$  converging to  $\mathbf{x}^*$ , (6) holds.

The first and the second slope lemmas have intuitive background as follows.

When you passed by a mountain, you may have noticed that the road somehow looks like a snake in s-shape. Why was the road built in such a way? The answer is easy, increase the length to decrease the slope. The longer its length is, the smaller its slope is. However, did you think that as its length approaches infinity its slope approaches zero? This is what the first slope lemma states.

Consider a path going up on a mountain. The average slope is the ratio of the height increment over the length of the projection of the path onto the level plane. Clearly, the average slope of any path cannot exceed the slope of the direct path connecting the two endpoints. This is what the second slope lemma states.

The power of the first slope lemma is surprising. It can show that a large class of feasible direction methods share a convergence property that if the generated sequence of points has a cluster point but does not converge to it, then every cluster point of the sequence is a Kuhn–Tucker point. It is interesting to point out that Wolfe [90] has showed by a counterexample that Zoutendijk's method [4,98] can generate a sequence of points converging to a point which is not a Fritz John point. However, with the first slope lemma, we can still show that it generates a sequence of points which do not converge to a point, then every cluster point of the sequence is a Fritz John point.

## Powell's Conjecture

Consider an unconstrained optimization problem as follows:

$$\max f(\mathbf{x}),$$

where  $f$  is continuously differentiable in  $\mathbf{R}^n$ .

The first *quasi-Newton method* was initially proposed by W.C. Davidon [16] in 1959, but his work was published nine years later [17]. The public attention on Davidon's work was largely due to the introduction of R. Fletcher and M.J.D. Powell [41] in 1963. This method is called the *DFP method* (Davidon–Fletcher–Powell).

Choose an initial point  $\mathbf{x}_1$  and an initial positive definite symmetric matrix  $H_1$ . Set  $k = 1$ .

- 1 Compute  $\mathbf{g}_k$ . If  $\mathbf{g}_k = \mathbf{0}$ , then stop; else, go to step 2;
- 2 If  $k > 1$ , then compute a positive definite symmetric matrix  $H_k$  with an updating formula

$$H_k = H_{k-1} - \frac{\boldsymbol{\sigma}_{k-1} \boldsymbol{\sigma}_{k-1}^\top}{\boldsymbol{\sigma}_{k-1}^\top \mathbf{y}_{k-1}} - \frac{H_{k-1} \mathbf{y}_{k-1} (H_{k-1} \mathbf{y}_{k-1})^\top}{\mathbf{y}_{k-1}^\top H_{k-1} \mathbf{y}_{k-1}},$$

where  $\mathbf{y}_{k-1} = \mathbf{g}_k - \mathbf{g}_{k-1}$  and  $\boldsymbol{\sigma}_{k-1} = \mathbf{x}_k - \mathbf{x}_{k-1}$ . Compute a search direction  $\mathbf{d}_k = H_k \mathbf{g}_k$ . Set  $\mathbf{x}_{k+1} = \mathbf{x}_k + \theta \mathbf{d}_k$  and  $k := k + 1$ , where  $\theta$  is chosen by a line search. Go to step 1.

## DFP method

Since then, many variations and generalizations of quasi-Newton methods [6,7,44,49,84,91] appeared in the literature. There are three issues on the convergence of quasi-Newton methods: quadratic termination, global convergence, and convergence rate. All quasi-Newton methods have quadratic termination under certain conditions [8,9]. However, the global convergence is a difficult problem for quasi-Newton methods. Powell [69] in 1971 established the first convergence theorem that if the objective function is twice continuously differentiable and uniformly concave, then the DFP method with exact line search generates a sequence convergent to a stationary point.

L.C.W. Dixon [20,21] at the same period found that all methods in *Broyden's family* with exact line search actually generate an identical sequence. This discovery extended Powell's result to all members in Broyden's family. It is interesting to point out that although Powell in 1971 obtained a convergence theorem, he did not believe that DFP method in general is globally convergent. Thus, he conjectured in 1971 that there exists a twice continuously differentiable objective function such that DFP method generates a sequence convergent to a point which is not a stationary point. However, one year later he changed his mind. In fact, after eighteen months he worked on his own conjecture, but he did not find such a counterexample. Instead, he [70] proved that his conjecture in 1971 is false for objective functions with two variables and that the uniform concavity in his convergence theorem can be replaced by concavity and an upper bound on the objective function.

**Theorem 9** *Let  $f$  be a twice continuously differentiable concave real function on  $\mathbf{R}^n$ . Suppose that the level set  $\{\mathbf{x}: f(\mathbf{x}) \geq f(\mathbf{x}_1)\}$  is bounded. Then the DFP method with exact line search and initial point  $\mathbf{x}_1$  either stops at the maximum or generates an infinite sequence whose function value converges to the maximum value of  $f(\mathbf{x})$ .*

Therefore, since 1972, the following is considered as the conjecture of Powell:

**Conjecture 10 (Powell's conjecture)** *Suppose the objective function is continuously differentiable. Then every cluster point of the sequence generated by DFP method with exact line search is a stationary point. D. Pu and W. Yu [77] made an important progress on Powell's conjecture. They showed the following.*

**Theorem 11** *Suppose DFP method generates an infinite sequence  $\{\mathbf{x}_k\}$  converging to  $\mathbf{x}^*$ . If the objective function  $f$  belongs to the class  $C^{1,1}$ , that is, there exists a constant  $L$  such that for every  $\mathbf{x}$  and  $\mathbf{y}$*

$$\|\mathbf{g}(\mathbf{x}) - \mathbf{g}(\mathbf{y})\| \leq L \|\mathbf{x} - \mathbf{y}\|,$$

then

$$\liminf_{k \rightarrow \infty} \|\mathbf{g}_k\| = 0.$$

Powell [72] also showed a global convergence theorem for BFGS method with inexact line search (Wolfe test)

for twice continuously differentiable and concave objective functions with an upper bound. Ritter [81] tried to generalize Powell's result to whole Broyden's family. However, the restriction on search step in line search restricts success of his result. R.H. Byrd, J. Nocedal, and Y. Yuan [12] successfully generalized Powell's result to all members in Broyden's family except DFP method. It is an very interesting open problem whether the DFP method with the Wolfe test has the same global convergence. With a modified Wolfe test and a suitably smooth objective function, Pu [76] showed that if a member in Broyden's family generates a convergent sequence, then the sequence converges to a stationary point.

For the convergence rate, Powell [69] showed that if the objective function is uniformly concave and its Hessian matrix satisfies the Lipschitz condition, then DFP method with exact line search is superlinearly convergent. This can be extended to all members in Broyden's family by Dixon's theorem. Similarly, Powell [72] also showed that if the objective function is uniformly concave and its Hessian matrix satisfies Lipschitz condition, then BFGS method with Wolfe test is superlinearly convergent. Byrd, Nocedal, and Yuan [12] generalized this result to Broyden's family except DFP method under the condition that the Hessian matrix is Hölder continuous. Pu [75] showed that with the modified Wolfe test, DFP method is one-step superlinearly convergent.

Combining Rosen's method with variable metric methods, Goldfarb [42] and Murtagh and Sargent [63] obtained two efficient algorithms. Powell [71] showed that these two algorithms are actually equivalent. The convergence of such algorithms is still an open problem. However, several convergent variations [55,59,79,80] have been established. The convergence of quasi-Newton methods for nonlinearly constrained optimization can be found in [15,65,73,74].

### Keywords

Optimization; Saddle point

The notion of a saddle point is a fundamental concept in many areas of science and economics. A classical instance is the famous saddle point theorem for a zero-sum matrix game due to J. von Neumann [2]. We shall here emphasize the utility of saddle points in the context of optimization.

### Saddle Points

Let us first recall some fundamental observations about saddle points and duality. Consider a function  $K(x, y): X \times Y \rightarrow \mathbf{R}$ , where  $X \subseteq \mathbf{R}^n$  and  $Y \subseteq \mathbf{R}^m$ . We say that  $(x_0, y_0) \in X \times Y$  is a *saddle point* of  $K$  on the sets  $X$  and  $Y$  if

$$K(x, y_0) \leq K(x_0, y_0) \leq K(x_0, y) \quad (1)$$

for all  $x \in X$  and  $y \in Y$ .

Consider next the following two programs:

$$z = \max_{x \in X} \inf_{y \in Y} K(x, y) \quad (2)$$

and

$$w = \min_{y \in Y} \sup_{x \in X} K(x, y). \quad (3)$$

Since one program is derived from the other via an interchange of the optimization directions they constitute a pair of so-called *dual programs*.

We say that  $x_0 \in X$  is an *optimal solution of the program (2)* if  $\inf_{y \in Y} K(x_0, y) = \max_{x \in X} \inf_{y \in Y} K(x, y)$ . Similarly,  $y_0 \in Y$  is an optimal solution of the program (3) if  $\min_{y \in Y} \sup_{x \in X} K(x, y) = \sup_{x \in X} K(x, y_0)$ . Observe that

$$\inf_{y \in Y} K(x_0, y) \leq K(x_0, y_0) \leq \sup_{x \in X} K(x, y_0) \quad (4)$$

for any  $(x_0, y_0) \in X \times Y$ . This implies that we always have so-called *weak duality*:  $z \leq w$ . We speak of *strong duality* when optimal solutions  $(x_0, y_0)$  exist for program (2) and (3), respectively, so that  $z = w$ . If so, the inequalities of (4) are turned into equations. In this case  $\sup_{x \in X} K(x, y_0)$  is obtained by  $x_0$ , so that the sup operator is naturally replaced by the max operator. Similarly for the inf operator and we obtain that

$$\min_{y \in Y} K(x_0, y) = K(x_0, y_0) = \max_{x \in X} K(x, y_0).$$

However, this expression is equivalent to the definition of a saddle point.

This leads us to the result that  $(x_0, y_0)$  is a saddle point if and only if  $x_0$  and  $y_0$  are optimal solutions of the programs (2) and (3), respectively, and with equal values, i. e.  $z = w$ .

## Mathematical Programming

We shall now study the particular situation where  $K(x, y)$  is the Lagrange function of a mathematical programming problem. Let  $f(x): \mathbf{R}^n \rightarrow \mathbf{R}$  and  $g(x): \mathbf{R}^n \rightarrow \mathbf{R}^m$ . Further let  $K(x, y) = f(x) - yg(x) + yb$ , where  $b \in \mathbf{R}^m$ , and  $Y = \mathbf{R}_+^m$ , the nonnegative orthant. In this setting program (2) becomes an ordinary mathematical programming problem stated in the following so-called *primal* form:

$$z_p = \begin{cases} \max & f(x) \\ \text{s.t.} & g(x) \leq b \\ & x \in X. \end{cases} \quad (5)$$

The *dual* form of (5) is derived from program (3):

$$\min_{y \in \mathbf{R}_+^m} \sup_{x \in X} f(x) - yg(x) + yb$$

or with  $u \in \mathbf{R}$  alternatively as

$$w_p = \begin{cases} \min & u + yb \\ \text{s.t.} & u + yg(x) \geq f(x), \quad \forall x \in X, \\ & u \in \mathbf{R}, \quad y \in \mathbf{R}_+^m. \end{cases} \quad (6)$$

Since the programs (5) and (6) are special cases of the dual programs (2) and (3), we get that optimal solutions  $x_0$  and  $y_0$  exist for (5) and (6), respectively, and with  $z_p = w_p$  if and only if  $(x_0, y_0)$  is a saddle point for  $K(x, y) = f(x) - yg(x) + yb$ .

The condition (1) for a saddle point  $(x_0, y_0)$  looks here as follows:

$$\begin{aligned} & f(x) - y_0g(x) + y_0b \\ & \leq f(x_0) - y_0g(x_0) + y_0b \\ & \leq f(x_0) - yg(x_0) + yb \end{aligned} \quad (7)$$

for all  $x \in X$  and  $y \in \mathbf{R}_+^m$ .

We shall show in this particular case that the condition for a saddle point can be restated in an alternative form as the so-called *optimality conditions*:

- i)  $x_0$  maximizes  $f(x) - y_0g(x)$  over  $X$ ;
- ii)  $y_0(g(x_0) - b) = 0$ ;
- iii)  $y_0 \geq 0$ ; and
- iv)  $g(x_0) \leq b$ .

So, assume that we have a saddle point  $(x_0, y_0)$  satisfying (7). Then condition i) is implied by the left inequality of (7). If  $g(x_0) \not\leq b$  then by an appropriate choice

of nonnegative elements  $y$  we can violate the right inequality of (7). This implies iv). Condition iii) is implied directly. Conditions iii) and iv) imply that  $y_0(g(x_0) - b) \leq 0$ . If this inequality is strict then  $y_0$  does not minimize over  $\mathbf{R}_+$  according to the right inequality of (7). This proves ii). Conversely, by similar arguments we can show that i)–iv) imply the saddle point condition (7).

We shall next study the mathematical programming problem (5) and provide conditions leading directly to the existence of a saddle point or equivalently to the satisfaction of the optimality conditions. In this context we shall study the perturbation function of the primal program (5) by varying the right-hand side of the constraints. Let  $d \in \mathbf{R}^m$ . The perturbation function  $\phi(d)$  is then defined as follows:

$$\phi(d) = \begin{cases} \max & f(x) \\ \text{s.t.} & g(x) \leq d \\ & x \in X. \end{cases}$$

Let  $D = \{d \in \mathbf{R}^m : \exists x \in X \text{ s.t. } g(x) \leq d\}$ . Consider next the following program:

$$\begin{cases} \min & u + yb \\ \text{s.t.} & u + yd \geq \phi(d), \quad \forall d \in D, \\ & u \in \mathbf{R}, \quad y \in \mathbf{R}_+^m. \end{cases} \quad (8)$$

We shall show that (8) is equivalent to the dual program (6). Assume  $(u, y)$  is a feasible solution of (8), i. e. it satisfies the constraints of (8). For  $x \in X$  and  $d = g(x)$  we then obtain that  $u + yg(x) = u + yd \geq \phi(d) = \phi(g(x)) \geq f(x)$ . Hence  $(u, y)$  is also feasible in (6). Conversely, assume that  $(u, y)$  is feasible in (6). If  $x \in X$  and  $g(x) \leq d$  we immediately get that  $f(x) \leq \phi(d)$  and moreover that  $u + yd \geq u + yg(x) \geq f(x)$ . Hence  $u + yd \geq \phi(d)$  implying that  $(u, y)$  is also feasible in (8). So with equal set of feasible solutions and with the same objective function the two programs are equivalent.

The dual program in the form of (8) has a nice geometric interpretation. For a given set of coefficients  $(u, y)$  the sum  $u + yd$  becomes an affine function in  $d \in \mathbf{R}^m$ . The objective of (8) is to select the coefficients in such a way that this function always is above the perturbation function, but with the lowest possible value at the point  $b$ . (This confirms the existence of weak duality for the dual programs (5) and (6)). For an optimal solution

of the primal programming problem (5) we thus additionally have strong duality if the affine function coincides with the perturbation function at the point  $b$ . In mathematical terms the perturbation function  $\phi$  satisfies the following condition:

$$\phi(d) \leq \phi(b) + y(d - b), \quad \forall d \in D, \quad (9)$$

and we say that the perturbation function is *superdifferentiable* at  $b$ .

Significant cases exist for this to occur. For example, if the perturbation function is finite and concave over the set  $D$  of feasible right-hand sides then it is superdifferentiable at points in the relative interior of  $D$ . Moreover, at the boundary the perturbation function is not superdifferentiable if and only if the perturbation function has a directional derivative of value  $+\infty$  at the selected point. This case rarely occurs, and if this does not happen the perturbation function is said to be *stable*.

These mainly geometrical observations can be treated more rigorously applying some classical results about conjugate functions and supporting hyperplanes in convex analysis, see [3].

### Convex Programming

In this last section we assume that  $X = \mathbf{R}_+^n$ ,  $f(x)$  is differentiable and concave and that the components of  $g(x)$  are convex and differentiable. These assumptions are indeed fulfilled in many applications. In this case the perturbation function is finite and concave on  $\mathbf{R}_+^m$ . We also assume that the perturbation function is stable. By the observations above we then get the following *fundamental property*: If an optimal solution  $x_0$  exists for the primal program (5), then a vector  $y_0$  exists such that  $(x_0, y_0)$  constitutes a saddle point (or equivalently that  $(x_0, y_0)$  satisfies the optimality conditions).

Moreover by the assumptions made on convexity and differentiability the optimality conditions can be restated into the famous *Karush–Kuhn–Tucker conditions* [1]:

- $(\nabla_x f(x_0) - y_0 \nabla_x g(x_0)) \geq 0$ ;
- $(\nabla_x f(x_0) - y_0 \nabla_x g(x_0))x_0 = 0$ ;
- $y_0(g(x_0) - b) = 0$ ;
- $g(x_0) \leq b$  and  $(x_0, y_0) \geq 0$ .

Therefore and subject to the assumptions made, the Karush–Kuhn–Tucker conditions provide necessary

and sufficient conditions for an optimal solution of the mathematical programming problem (5). This result has had a tremendous impact on the development of algorithms to solve mathematical programming problems. Moreover, if the perturbation function  $\phi(d)$  is also differentiable at  $b$  then it is approximated by the right-hand side of (9). This happens in many applications. Thus with numerically small deviations  $d - b$  the vector  $y_0$  measures the marginal effects on the optimal value of the objective function of (5). Due to this property  $y_0$  is often denoted as the vector of *shadow prices* and as such it plays a central role in the discussion and interpretation of results obtained by mathematical programs, in particular when modeled over problems in economics.

Constraint qualification; Optimality conditions;  
Duality; Stability; Parabolic curve approach

A *second order constraint qualification* (SOCQ) is a condition which is imposed on the analytical description of the constraint set of an optimization problem and which usually involves second order approximations of the data functions. Second order constraint qualifications are essential in order to establish second order optimality conditions, but they play also a certain role in the perturbation analysis for optimization problems. Roughly speaking, second order constraint qualifications establish a link between the geometry of the given set and certain kinds of second order approximations of the analytical data. Second order constraint qualifications are closely related to *first order constraint qualifications* (cf. ► [First Order Constraint Qualifications](#)), in particular, see that article for notions such as LICQ, MFCQ, Robinson CQ and others.

Historically, SOCQs were first introduced in studies of second order optimality conditions for smooth nonlinear programs, see, e. g., [11,12,19,20]. Given twice continuously differentiable functions  $g_i: \mathbf{R}^n \rightarrow \mathbf{R}$  ( $i = 0, \dots, r$ ), the smooth mathematical programming problem is

$$(P) \begin{cases} \min & g_0(x) \\ \text{s.t.} & g_i(x) \leq 0, \\ & i \in I := \{1, \dots, m\}, \\ & g_j(x) = 0, \\ & j \in J := \{m+1, \dots, r\}. \end{cases} \quad (1)$$

A (dual) second order necessary optimality condition of Fritz John type is the following one: If  $\bar{x}$  is a local minimizer of (P), then for every *critical direction*  $d$ , i. e., every  $d$  satisfying

$$\begin{cases} \langle Dg_i(\bar{x}), d \rangle \leq 0, & i \in I_{\bar{x}}^0, \\ \langle Dg_j(\bar{x}), d \rangle = 0, & j \in J, \end{cases}$$

where  $I_{\bar{x}} := \{i \in I: g_i(\bar{x}) = 0\}$  and  $I_{\bar{x}}^0 := I_{\bar{x}} \cup \{0\}$ , there exist multipliers  $u_i \geq 0$  for  $i \in I_{\bar{x}}^0$  and  $u_j \in \mathbf{R}$  for  $j \in J$ , not all zero, such that

$$\begin{cases} u_i \langle Dg_i(\bar{x}), d \rangle = 0, & i \in I_{\bar{x}}^0, \\ \sum_{k \in I_{\bar{x}}^0 \cup J} u_k Dg_k(\bar{x}) = 0, \\ \sum_{k \in I_{\bar{x}}^0 \cup J} u_k \langle d, D^2 g_k(\bar{x}) d \rangle \geq 0, \end{cases} \quad (2)$$

see [2,3,16,18]. A SOCQ comes into play if one asks when  $u_0$  can be chosen as 1 in order to have an objective-independent condition of Kuhn–Tucker type. Suppose  $d$  is a critical direction. Then under the above assumptions, the multiplier  $u_0$  in (2) can be chosen as 1 if there holds (see [2]) the

- *Ben-Tal SOCQ*:  $Dg_j(\bar{x})$ ,  $j \in J$  are linearly independent, and there exists some  $h \neq 0$  such that  $\langle h, Dg_i(\bar{x}) \rangle + \langle d, D^2 g_i(\bar{x}) d \rangle < 0$  for  $i \in I(\bar{x}, d)$ , and  $\langle h, Dg_j(\bar{x}) \rangle + \langle d, D^2 g_j(\bar{x}) d \rangle = 0$  for  $j \in J$ , where  $i \in I(\bar{x}, d)$  if and only if  $i \in I_{\bar{x}}$  and  $\langle Dg_i(\bar{x}), d \rangle = 0$ .

A similar SOCQ plays a role in infinite-dimensional settings [3]. If MFCQ holds at a local minimizer  $\bar{x}$  of (P), then the Ben-Tal SOCQ is fulfilled at  $\bar{x}$  for each critical direction  $d$  [2,3,25]. The Ben-Tal SOCQ does not guarantee that the same multiplier vector can be taken such that (2) is satisfied (with  $u_0 = 1$ ) for *each* critical direction. However, under LICQ this so-called strong necessary condition holds, see [2]. For other SOCQs implying the strong necessary condition, see [12]. Classical textbooks like [11,19] often apply the

- *McCormick SOCQ* at  $\bar{x} \in M$ : Any vector  $d$  satisfying  $\langle Dg_i(\bar{x}), d \rangle = 0$  for  $i \in I_{\bar{x}} \cup J$  is the tangent of an arc  $\alpha(\theta)$ , twice differentiable, along which  $g_i(\alpha(\theta)) \equiv 0$  for all  $i \in I_{\bar{x}} \cup J$ , where  $\theta \in [0, \varepsilon]$ ,  $\varepsilon > 0$ .  $M$  denotes the constraint set of (P).

If McCormick's SOCQ, together with a first order CQ, holds, then a strong necessary condition is fulfilled in a much weaker form, namely, only for critical directions  $d$  satisfying additionally  $\langle Dg_i(\bar{x}), d \rangle = 0$  for all  $i \in I_{\bar{x}}$ . Note that LICQ implies the McCormick SOSC [11], but the Kuhn–Tucker (first order) CQ does not imply the McCormick SOSC [11].

While strong necessary optimality conditions and the corresponding (restrictive) SOCQs rely on assumptions ensuring that active inequalities may be handled as equations, the approach which goes back to

A. Ben-Tal [2,3] is based on verification of optimality along curves that have a second order expansion, so-called *parabolic curves*. On the one hand, the concept of parabolic curves and related second order tangent sets requires only weak and ‘natural’ constraint qualifications, on the other hand, it leads to explicit second order optimality conditions involving second order terms of the original data.

This approach was continued in the remarkable paper [9] for problems of the type

$$(\widehat{P}) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & G(x) \in C \end{cases} \quad (3)$$

(with (smooth) *abstract constraints*), where  $G$  maps a Banach space  $X$  into a Banach space  $Y$ ,  $f$  maps  $X$  into  $\mathbf{R}$ ,  $f, G$  are twice continuously differentiable, and  $C$  is a nonempty closed convex subset of  $Y$ . The following discussion of the role of SOCQs in this context takes pattern from [5,6,9,21,24].

Assume  $X = \mathbf{R}^n$ . Define the *Lagrange function* by  $L(x, u) := f(x) + \langle u, G(x) \rangle$ . The *first order tangent set*  $T_C(\bar{x})$  to  $C$  at  $\bar{x}$  consists of all directions  $p$  satisfying  $\text{dist}(\bar{x} + tp, C) \sim o(t)$ , the *second order tangent set*  $T_C^2(\bar{x}, p)$  to  $C$  at  $\bar{x}$  in direction  $p$  consists of all directions  $q$  satisfying

$$\text{dist}\left(\bar{x} + tp + \frac{1}{2}t^2q, C\right) \sim o(t^2),$$

where  $\text{dist}(x, C)$  denotes the Euclidean point-to-set distance from  $x$  to  $C$ , and  $\varphi(t) \sim o(t^k)$  means the *Landau notation*, i.e.,  $\lim_{t \downarrow 0} \varphi(t)/t^k = 0$ . Now the direction  $h \in X$  is said to be *critical* at the feasible point  $\bar{x}$  if and only if  $DG(\bar{x})h \in T_C(G(\bar{x}))$  and  $\langle Df(\bar{x}), h \rangle \leq 0$ . Then one has [9]:

**Theorem 1** *Let  $\bar{x}$  be a local minimizer for  $f$  on the feasible set  $S$  defined by (3). If Robinson’s CQ holds at  $\bar{x}$ , then for all critical directions  $h$  at  $\bar{x}$ ,*

$$\sup_{u \in \Lambda(\bar{x})} \{ \langle h, D_{xx}^2 L(\bar{x}, u)h \rangle - \sigma(u, Q_h) \} \geq 0, \quad (4)$$

where  $\Lambda(\bar{x})$  is the set of Lagrange multipliers associated with  $\bar{x}$  for  $(\widehat{P})$ ,  $Q_h := T_C^2(G(\bar{x}), DG(\bar{x})h)$ , and  $\sigma(\cdot, Q)$  is the support function of  $Q$ ,  $u \mapsto \sigma(u, Q) = \sup_{q \in Q} \langle u, q \rangle$ .

In order to have a narrow gap between necessary and sufficient optimality conditions, the following directional SOCQ, introduced in [4,6], is very important:

- *Directional SOCQ*: The set  $C$  is said to be *second order regular* at  $y \in C$  in a direction  $p \in T_C(y)$  and with respect to a linear mapping  $M: X \rightarrow Y$ , if for any sequence  $y_n \in C$  of the form

$$y_n := y + t_n p + \frac{1}{2}t_n^2 q_n,$$

where  $t \downarrow 0$ ,  $q_n := Mw_n + a_n$ ,  $\{a_n\}$  converging in  $Y$ ,  $w_n \in X$ ,  $t_n w_n \rightarrow 0$ , one has  $\lim \text{dist}(q_n, T_C^2(y, p)) = 0$ . If  $C$  is second order regular at  $y$  with respect to all such  $p, M, X$  then  $C$  is called *second order regular* at  $y$ .

For example, the polyhedral convex cone  $C$  in the setting of a nonlinear program (1) is second order regular. Further, the cones of positive and negative semidefinite matrices are second order regular (which is used for deriving optimality conditions in semidefinite programming [23]). For several other settings of  $C$ , for example in semi-infinite programming and composite optimization, the directional SOCQ has been specified in [6], where also the following crucial result can be found (known as the *equivalence theorem*):

**Theorem 2** *If Robinson’s CQ holds at a feasible point  $\bar{x}$ , and if for every critical direction  $h$ , the set  $C$  is second order regular at  $G(\bar{x})$  in the direction  $DG(\bar{x})h$  and with respect to  $DG(\bar{x})(\cdot)$ , then the inequality (4) holds strictly (i.e., with  $> 0$ ) for nonzero critical directions  $h$  if and only if  $f$  satisfies, with some positive  $c$ , the quadratic growth condition  $f(x) \geq f(\bar{x}) + c \|x - \bar{x}\|^2$  for feasible  $x$  near  $\bar{x}$ .*

In this sense, there is no gap between second order necessary and sufficient conditions. Similar second order optimality characterizations under some directional second order regularity were derived in [21] for so-called parabolically regular (extended-valued) functions. Note that the latter concept is weaker than that of the directional SOCQ.

If the abstract constraint (3) reduces to the nonlinear programming form (1), then the term  $\sigma(u, Q_h)$  in (4), called ‘shifting term’ or ‘ $\sigma$ -term’, vanishes. Hence, the equivalence theorem reduces to a well-known fact for smooth nonlinear programs (see, e.g., [2,25]), since MFCQ and Robinson’s CQ coincide in this situation.

In contrast to this, for more general settings,  $\sigma(u, Q_h)$  is essential. Conditions which allow a concrete representation of the  $\sigma$ -term can be considered as SOCQs. For standard semi-infinite programs with compact in-

dex set  $I$  (i. e.,  $C$  is the cone of nonnegative continuous functions on  $I$ ), this has been done in [5,24]. Conditions which ensure the local reduction of a semi-infinite program to a standard nonlinear program ('reduction approach') also allow a concrete representation of  $\sigma(u, Q_h)$ , for standard semi-infinite programs see, e. g., [13,22], for generalized semi-infinite programs see, e. g., [14,17].

The directional SOCQ defined above (or some stronger versions, respectively), together with a first order directional CQ, have been essentially used (e. g., in [5,7,8]) in sensitivity and stability analysis of problem  $(\hat{P})$  under perturbations along certain directions: second order expansion of optimal values, first order expansion of optimal solutions, differential stability, Lipschitz stability, etc.

### Remarks

In this article, the focus was on smooth problems. Though the notion SOCQ is not often used in *nonsmooth* optimization, the study of higher-order tangent sets and their influence in optimality conditions of higher order could be considered as an analogy to SOCQs. For many material in this direction see, e. g., [1,21]. A special case between smooth and nonsmooth programs are so-called  $C^{1,1}$  optimization problem (i. e., problems of type (P), but the data are differentiable with locally Lipschitzian gradients). A SOCQ for this class of problems is a stronger variant of the Abadie CQ: the Bouligand (contingent) cone has to coincide with the linearization cone [15]. This SOSQ, together with some first order CQ, is again of interest in deriving necessary second order optimality conditions, see [10,15].

conditions; KKT conditions; First order and second order optimality conditions

The quest for *optimality conditions for nonlinear optimization problems* started a long time ago, however, until calculus was invented there was little progress. Calculus has enriched and accelerated this endeavor significantly.

In the following discussion  $x = (x_1, \dots, x_n)^T$  denotes the column vector of decision variables whose optimal values need to be determined. All functions are assumed to be continuous real valued functions of  $x$ . When discussing the first (second) order optimality conditions, we make the assumption that all functions are continuously differentiable (twice continuously differentiable).

For any real valued function  $f(x)$ , we denote the *gradient vector* of  $f(x)$  at  $\bar{x}$ ,  $(\partial f(\bar{x})/\partial x_1, \dots, \partial f(\bar{x})/\partial x_n)$ , written as a row vector, by  $\nabla_x f(\bar{x})$  and the  $n \times n$  *Hessian matrix* of  $f(x)$  at  $\bar{x}$ ,  $(\partial^2 f(\bar{x})/\partial x_i \partial x_j)$ , by  $\nabla_{xx}^2 f(\bar{x})$ .

We discuss the nonlinear optimization problem in terms of ‘minimization’ of the objective function. Instead, if an objective function  $F(x)$  is required to be ‘maximized’, this problem is equivalent to minimizing  $-F(x)$  subject to the same constraints. Because of this, we state all our results in terms of minimization problems.

Nonlinear optimization problems can be classified into three broad types, which are of the following forms:

- *Unconstrained minimization*

$$\begin{cases} \min & \theta(x) \\ \text{s.t.} & x \in \mathbb{R}^n. \end{cases} \quad (1)$$

- *Equality-constrained optimization*

$$\begin{cases} \min & \theta(x) \\ \text{s.t.} & g_i(x) = 0, \quad i = 1, \dots, m. \end{cases} \quad (2)$$

- *General constrained optimization*

$$\begin{cases} \min & \theta(x) \\ \text{s.t.} & g_i(x) \begin{cases} = 0, & i = 1, \dots, m, \\ \geq 0, & i = m + 1, \dots, m + p. \end{cases} \end{cases} \quad (3)$$

The general problem (3) is said to be a *convex programming problem* [2,3] if the objective function to

be minimized,  $\theta(x)$ , is *convex*; the equality-constraint functions  $g_i(x)$ ,  $i = 1, \dots, m$ , are *affine*; and the inequality ( $\geq$ ) constraint functions  $g_i(x)$ ,  $i = m + 1, \dots, m + p$  are *concave*; a *nonconvex programming problem* otherwise.

In linear programming, we only talk about an *optimum solution*, but in nonlinear optimization, we need to consider different types of optimum solutions. In minimization problems the feasible solution  $\bar{x}$  is said to be a:

- *local (or relative) minimum* if  $\theta(x) \geq \theta(\bar{x})$  for all feasible  $x$  satisfying  $\|x - \bar{x}\| \leq \epsilon$  for some positive  $\epsilon$ .
- *strong (or strict) local (or relative) minimum* if  $\theta(x) > \theta(\bar{x})$  for all feasible  $x \neq \bar{x}$  satisfying  $\|x - \bar{x}\| \leq \epsilon$  for some positive  $\epsilon$ .
- *global minimum* if  $\theta(x) \geq \theta(\bar{x})$  for all feasible  $x$ .
- *stationary point* if it satisfies one of the necessary conditions for a local minimum.

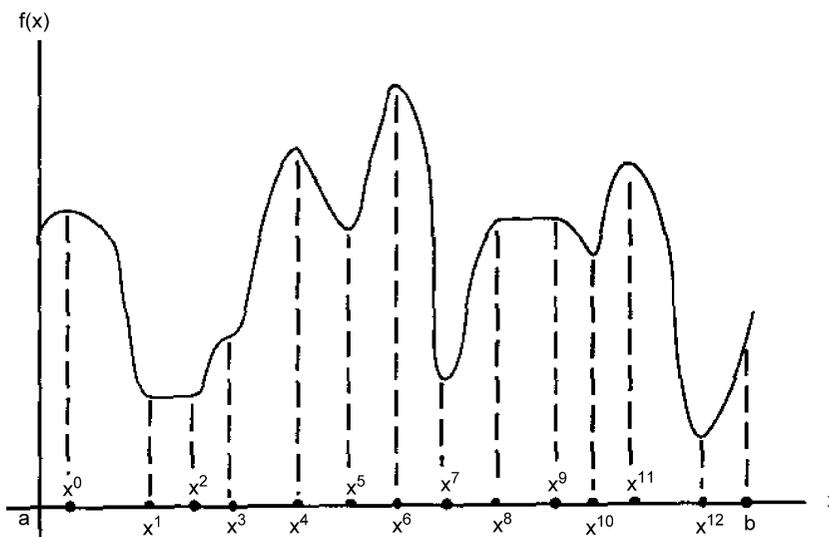

Corresponding concepts (weak or strong local maximum, global maximum) for maximization problems are defined analogously. We illustrate these concepts in Fig. 1 for the problem of minimizing the graphed function  $f(x)$  of a single variable  $x \in \mathbf{R}^1$  in the interval  $a \leq x \leq b$ . The points  $a, x^5, x^7, x^{10}, x^{12}$  are strong local minima;  $x^0, x^4, x^6, x^{11}, b$  are strong local maxima;  $x^{12}$  is the global minimum, and  $x^6$  is the global maximum.  $x^1, x^2$  are weak local minima; and  $x^8, x^9$  are weak local maxima.

$x^3$  is a stationary point even though it is neither a local maximum nor a local minimum. In each of the intervals  $x^1 \leq x \leq x^2$ , and  $x^8 \leq x \leq x^9$ ,  $f(x)$  is a constant; and every point in the interior of these intervals (i. e., points  $x$  satisfying  $x^1 < x < x^2$  or  $x^8 < x < x^9$ ) is both a weak local minimum and a weak local maximum.

In linear programming all local minima are global minima, hence we only talk about an ‘optimum solution’ there. As seen above, in nonlinear programming models these concepts could be different.

The original intent of the problem is of course to find a global minimum. Using existing algorithms, this is possible with reasonable efficiency only for convex programming problems (which includes linear programs and convex quadratic programs as special cases). As discussed in [3,4], for general nonconvex programming problems, even finding a local minimum is hard; existing efficient algorithms can at best guarantee convergence to a stationary point on such problems.

Unfortunately, there are no known useful conditions that can efficiently characterize a global minimum for the general nonlinear programming problem. We only know some necessary, and some sufficient conditions for a local minimum for this general problem. In convex programming problems however, every local minimum is a global minimum; so for this nice class of problems we have useful necessary and sufficient conditions for a global minimum.

Second Order Optimality Conditions for Nonlinear Optimization, Figure 1

**Optimality Conditions for the Unconstrained Minimization Problem (1)**

These were developed first for one-dimensional minimization problems in the 17th century as Newton was developing calculus, and very soon after extended to multidimensional minimization problems. These conditions are:

- *First order necessary conditions* for  $\bar{x}$  to be a local minimum:  $\nabla_x \theta(\bar{x}) = 0$ .
- *Second order necessary conditions* for  $\bar{x}$  to be a local minimum:  $\nabla_x \theta(\bar{x}) = 0$  and  $\nabla_{xx}^2(\theta(\bar{x}))$  is positive semidefinite (PSD).
- *Second order sufficient conditions* for  $\bar{x}$  to be a strict local minimum:  $\nabla_x \theta(\bar{x}) = 0$ , and  $\nabla_{xx}^2(\theta(\bar{x}))$  is positive definite (PD).
- *Necessary and sufficient conditions* for  $\bar{x}$  to be a global minimum if  $\theta(x)$  is convex:  $\nabla_x \theta(\bar{x}) = 0$ .

The computational effort needed to check whether a given square matrix is PSD or PD is  $O(n^3)$ . Hence, given  $\bar{x}$ , each of the above conditions can be checked efficiently.

When  $\theta(x)$  is nonconvex, there is a slight gap between the necessary and sufficient conditions for a local minimum when  $\nabla_x \theta(\bar{x}) = 0$  and  $\nabla_{xx}^2(\theta(\bar{x}))$  is PSD and not PD. In this case we are unable to conclude that either  $\bar{x}$  is a local minimum, or that it is not. To bridge this gap, more complicated conditions involving higher order derivatives are needed, but they are impractical, particularly when  $n$  is large.

**Optimality Conditions for the Equality Constrained Minimization Problem (2)**

Inspired by the study of problems in mechanics, these conditions, which form the foundation of nonlinear programming theory, were developed in the 18th and 19th centuries. Major results were obtained by L. Euler and J.L. Lagrange and were first published in a book written by Lagrange in 1788.

The necessary conditions are derived under a condition on the constraints in (2) known as a *constraint qualification (CQ)*. A well known CQ is known as the *regularity condition*.

The feasible solution  $\bar{x}$  for (2) is said to satisfy the regularity condition (and hence called a *regular point* for (2)) if  $\{\nabla_x g_1(\bar{x}), \dots, \nabla_x g_m(\bar{x})\}$  is linearly independent.

The optimality conditions for a feasible solution  $\bar{x}$  to be a local minimum for (2) are:

- *First order necessary conditions* for  $\bar{x}$  to be a local minimum for (2): If  $\bar{x}$  is a local minimum for (2), and either all the constraints are linear constraints, or  $\bar{x}$  is a regular feasible solution, there exists  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_m)$  such that

$$\nabla_x \theta(\bar{x}) = \sum_{i=1}^m \bar{\pi}_i \nabla_x g_i(\bar{x}).$$

The vector  $\bar{\pi}$  in the above condition is known as the *Lagrange multiplier vector*. The function  $L(x, \bar{\pi}) = \theta(x) - \sum_{i=1}^m \bar{\pi}_i g_i(x)$  is known as the *Lagrangian function* for (2) with Lagrange multiplier vector  $\bar{\pi}$ . The above necessary condition can also be written as  $\nabla_x L(\bar{x}, \bar{\pi}) = 0$ .

- *Second order necessary conditions* for  $\bar{x}$  to be a local minimum for (2): If  $\bar{x}$  is a local minimum for (2), and either all the constraints are linear constraints, or  $\bar{x}$  is a regular feasible solution, there exists  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_m)$  such that

$$\nabla_x \theta(\bar{x}) = \sum_{i=1}^m \bar{\pi}_i \nabla_x g_i(\bar{x})$$

and

$$y^T \nabla_{xx}^2(L(\bar{x}, \bar{\pi}))y \geq 0 \quad \text{for all } y \in T,$$

where  $T = \{y: \nabla_x g_i(\bar{x})y = 0 \text{ for all } i = 1, \dots, m\}$ .

- *Sufficient condition* for  $\bar{x}$  to be a strict local minimum for (2): If  $\bar{x}$  is a feasible solution for (2), and there exists a  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_m)$  such that

$$\nabla_x \theta(\bar{x}) = \sum_{i=1}^m \bar{\pi}_i \nabla_x g_i(\bar{x})$$

and

$$y^T \nabla_{xx}^2(L(\bar{x}, \bar{\pi}))y > 0 \quad \text{for all } 0 \neq y \in T,$$

where  $T$  is defined above, then  $\bar{x}$  is a strict local minimum for (2).

Given a regular feasible solution  $\bar{x}$ , the existence of a Lagrange multiplier vector  $\bar{\pi}$  which satisfies either of the necessary conditions given above together with  $\bar{x}$ , can be checked efficiently.

Here again, in nonconvex programs, there is a small gap between the necessary and sufficient optimality

conditions for a local minimum. If the second order necessary condition holds at  $\bar{x}$ , but not the sufficient condition, then using these conditions we are not able to guarantee that either  $\bar{x}$  is a local minimum, or that it is not.

**Optimality Conditions for the General Constrained Optimization Problem (3)**

Fundamental ideas about necessary optimality conditions for nonlinear optimization problems including some inequality constraints, have been investigated beginning with J.B.J. Fourier in 1798; and later by A. Cournot, M. Ostrogradsky, C.F. Gauss, J. Farkas, and G. Hamel among others. Rigorous development of these conditions in the form we know them today has been completed by W. Karush in 1939, and later in essentially the same form by H.W. Kuhn and A.W. Tucker in 1951.

Given a feasible solution  $\bar{x}$  for (3), the  $i$ th constraint in (3) is said to be *active* at  $\bar{x}$  if  $g_i(\bar{x}) = 0$ , *inactive* otherwise. Thus all equality constraints are active at every feasible solution, and an inequality constraint is active at a feasible solution if it holds as an equation there. We will denote the index set of active constraints at a feasible solution  $\bar{x}$ ,  $\{i: g_i(\bar{x}) = 0\}$  by  $B(\bar{x})$ .

Necessary optimality conditions are derived under a CQ. There are several CQ, some weaker than the others. The principal ones are:

- *Regularity condition:* The feasible solution  $\bar{x}$  satisfies this CQ and is therefore called a *regular point* for (3) if  $\{\nabla_x g_i(\bar{x}): i \in B(\bar{x})\}$  is linearly independent. This condition can be checked efficiently.
- *First order CQ:* The feasible solution  $\bar{x}$  for (3) satisfies this CQ if for each

$$y \in \left\{ y: \begin{array}{l} \nabla_x g_i(\bar{x})y = 0, \\ i = 1, \dots, m; \\ \nabla_x g_i(\bar{x})y \geq 0, \\ i \in \{m + 1, \dots, m + p\} \cap B(\bar{x}) \end{array} \right\},$$

$y$  is the tangent direction to a differentiable curve emanating from  $\bar{x}$  and lying in the feasible region. This condition is hard to check.

- *Second order CQ:* The feasible solution  $\bar{x}$  for (3) satisfies this CQ if for each  $y \in \{y: \nabla_x g_i(\bar{x})y = 0, i \in B(\bar{x})\}$ , there exists a twice differentiable curve emanating from  $\bar{x}$  and lying in the region  $\{x: g_i(x) = 0,$

$i \in B(\bar{x})\}$ , for which  $y$  is the tangent direction at  $\bar{x}$ . This condition is hard to check.

- *Mangasarian–Fromovitz CQ:* The feasible solution  $\bar{x}$  for (3) satisfies this CQ if the set

$$\left\{ d: \begin{array}{l} \nabla_x g_i(\bar{x})d = 0, \quad i = 1, \dots, m \\ \nabla_x g_i(\bar{x})d > 0, \\ \text{for } i \in \{m + 1, \dots, m + p\} \cap B(\bar{x}) \end{array} \right\}$$

is nonempty, and  $\{\nabla_x g_i(\bar{x}): i = 1, \dots, m\}$  is linearly independent. This condition can be checked efficiently.

The Lagrangian function for (3) with Lagrange multiplier vector  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_{m+p})$  is  $L(x, \bar{\pi}) = \theta(x) - \sum_{i=1}^{m+p} \bar{\pi}_i g_i(x)$ . The optimality conditions for a feasible solution  $\bar{x}$  to be a local minimum for (3) are:

- *First order necessary conditions* for  $\bar{x}$  to be a local minimum for (3): If  $\bar{x}$  is a local minimum for (3), and either all the constraints are linear constraints, or  $\bar{x}$  satisfies the regularity, or the 1st order, or the Mangasarian–Fromovitz CQs, there exists a Lagrange multiplier vector  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_{m+p})$  such that

$$\begin{aligned} \nabla_x \theta(\bar{x}) &= \sum_{i=1}^{m+p} \bar{\pi}_i \nabla_x g_i(\bar{x}), \\ \bar{\pi}_i &\geq 0 \quad \text{for } i \in \{m + 1, \dots, m + p\}, \\ \bar{\pi}_i g_i(\bar{x}) &= 0 \quad \text{for } i \in \{m + 1, \dots, m + p\}. \end{aligned}$$

In the literature, these conditions are commonly referred to as the *KKT conditions* (*Karush–Kuhn–Tucker conditions*). Given  $\bar{x}$ , checking for the existence of a Lagrange multiplier vector which together with  $\bar{x}$  satisfies these conditions can be posed as a linear programming problem and solved efficiently.

- *Second order necessary conditions* for  $\bar{x}$  to be a local minimum for (3): If  $\bar{x}$  is a local minimum for (3), and either all the constraints are linear constraints, or  $\bar{x}$  satisfies the regularity, or the 2nd order, or the Mangasarian–Fromovitz CQs, there exists a Lagrange multiplier vector  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_{m+p})$  such that

$$\begin{aligned} \nabla_x \theta(\bar{x}) &= \sum_{i=1}^{m+p} \bar{\pi}_i \nabla_x g_i(\bar{x}), \\ \bar{\pi}_i &\geq 0 \quad \text{for } i \in \{m + 1, \dots, m + p\}, \\ \bar{\pi}_i g_i(\bar{x}) &= 0 \quad \text{for } i \in \{m + 1, \dots, m + p\} \end{aligned}$$

and

$$y^T (\nabla_{xx}^2 L(\bar{x}, \bar{\pi})) y \geq 0 \quad \text{for all } y \in T_1,$$

where

$$T_1 = \{y : \nabla_x g_i(\bar{x}) y = 0, i \in B(\bar{x})\}.$$

Given  $\bar{x}$ , the existence of a Lagrange multiplier vector which together with  $\bar{x}$  satisfies these conditions can be checked efficiently using linear programming and PSD checking methods.

- *Sufficient conditions* for  $\bar{x}$  to be a strict local minimum for (3): If the feasible solution  $\bar{x}$  for (3) is such that there exists a Lagrange multiplier vector  $\bar{\pi} = (\bar{\pi}_1, \dots, \bar{\pi}_{m+p})$  which together with  $\bar{x}$  satisfies

$$\nabla_x \theta(\bar{x}) = \sum_{i=1}^{m+p} \bar{\pi}_i \nabla_x g_i(\bar{x}),$$

$$\bar{\pi}_i \geq 0 \quad \text{for } i \in \{m+1, \dots, m+p\},$$

$$\bar{\pi}_i g_i(\bar{x}) = 0 \quad \text{for } i \in \{m+1, \dots, m+p\}$$

and

$$y^T (\nabla_{xx}^2 L(\bar{x}, \bar{\pi})) y > 0 \quad \text{for all } y \in T_2,$$

where

$$T_2 = \{y : \nabla_x g_i(\bar{x}) y = 0$$

$$\text{for } i \in \{1, \dots, m\} \cup \{i : \bar{\pi}_i > 0\}$$

$$\cap \{m+1, \dots, m+p\} \cap B(\bar{x})\}$$

and

$$\nabla_x g_i(\bar{x}) y \geq 0 \quad \text{for all } i \text{ in the set}$$

$$\{i : \bar{\pi}_i = 0\} \cap \{m+1, \dots, m+p\} \cap B(\bar{x}).$$

If (3) is a nonconvex program, verifying whether the last condition among the sufficient optimality conditions holds is hard (K.G. Murty and S.N. Kabadi [4] have shown that the simple special case of this problem: checking whether  $x^T D x \geq 0$  for all  $x \geq 0$  is hard if  $D$  is not a PSD matrix).

A weaker sufficient condition for  $\bar{x}$  to be a strict local minimum for (3) is obtained by replacing  $T_2$  in the above condition by the set

$$T_3 = \{y : \nabla_x g_i(\bar{x}) y = 0$$

$$\text{for all } i \in \{1, \dots, m\} \cup \{i : \bar{\pi}_i > 0\}$$

$$\cap \{m+1, \dots, m+p\} \cap B(\bar{x})\}.$$

This weaker sufficient condition can be checked efficiently.

- *Necessary and sufficient conditions* for  $\bar{x}$  to be a global minimum of (3) if it is a convex program: If (3) is a convex program, then the first order necessary conditions stated above are necessary and sufficient for a given feasible solution to be a global minimum.

If (3) is a nonconvex program [2,3], the gap between the second order necessary conditions, and the sufficient conditions for a local minimum is small, but in case the problem under consideration falls in this gap, we are unable to confirm that either  $\bar{x}$  is or is not a local minimum using these conditions. ## Introduction

Gene expression microarray experiments have been celebrated as a revolution in biology, attracting significant interest because they allow for the analysis of the combined effects of numerous genetic and environmental components. This global approach will allow a fundamental shift from "... piece-by-piece to global analysis and from hypothesis driven research to discovery-based formulation and subsequent testing of hypotheses ..." [7,8,10,15,24,29,41]. One of the major challenges is to extract in a systematic and rigorous way the biologically relevant components from the array experiments in order to establish meaningful connections linking genetic information to cellular function. Because of the significant amount of experimental information that is generated (expression levels of thousands of genes), computer-assisted knowledge extraction is the only realistic alternative for managing such an information deluge. A number of excellent publications have focused on different aspects of gene expression experiments [1,2,3,6,15,20,25,32,35,36,38]. Novel computational approaches that exploit large warehouses of gene expression data have been identified as major enablers for realizing fully the potential of this technology [4]. A significant concern with microarray analyzes is the ability to assign a certain level of significance to smaller subsets of genes whose expression patterns could potentially indicate a more direct involvement in the biological process under study.

The identification of smaller sets of "informative genes" is a manifestation of a boarder problem in the machine learning community, namely the problem of "feature selection". Feature selection has received increased attention with the recent advances in functional genomics that resulted in the creation of high-di-

mensional feature sets. A number of recent publications [11,13,20,47] have devised various approaches for extracting critical, differentially expressed genes in a systematic manner. The advantage of multivariate methods is that they take into account collaborative effects of gene expression activities. Reducing the number of measured variables reduces the degrees of freedom, hence avoiding pointless over-fitting. Too few genes will not discriminate or predict; too many genes might introduce noise to the model rather than information. Therefore, the identification of informative genes is a significant component of an integrated, computer-assisted analysis of array experiments. In most cases the question of identifying differentially expressed genes is restated as a hypothesis-testing problem in which the null hypothesis of no association between expression levels and responses of interest is tested [15].

One of the reasons for performing gene selection, which will be the focus of this chapter, is in tissue classification. Samples from multiple cell types (for example different cancer types, cancerous and normal cells etc.) are comparatively analyzed using microarray gene expression measurements. The question therefore becomes how to identify which genes provide consistent signatures that distinctly characterize the different classes. The problem can be viewed as either a supervised classification problem in which the classes are already known, or as an unsupervised clustering problem in which we attempt to identify the classes contained within the data. In gene selection, the computational problem is equivalent to that of feature selection in multidimensional data sets. Identifying the minimum number of gene markers is however critical because this reduced set can provide information about the biology behind the experiment as well as define the basis for future therapeutic agents. Typical examples are discussed in [12,20,23,33].

The obvious way to simplify the complexity of the model (classifier) is to minimize the number of degrees of freedom used for building the model. Traditionally this problem is approached in a stepwise fashion as a feed-forward or backward feature selection process [30]. This approach is widely used in analyzing microarray data [20]. The problem however is that synergistic effects are not properly captured, and it is often difficult to come to a conclusion as to what the actual number of informative features is [27]. There-

fore, a search algorithm must explicitly account in the objective for the actual number of features used in the model. For linear discriminant models, concepts such as the Akaike and Bayesian Information Criteria (AIC, BIC) have been used, albeit in a stepwise fashion. In either case the objective (maximum likelihood estimation) is augmented to account for the number of features (variables) used in the model. Recently, researchers incorporated the number of features in their search objective [19]. Therefore, we treat the total number of features used in the model explicitly as one of our complexity criterion. The definition of model complexity is not an easy task. When the decision boundary is a hyper-plane, it is rather straightforward to require a minimum number of non-zero coefficients (AIC and BIC criteria discussed earlier). In nonlinear classifiers, or when the separations are defined as the intersection of multiple hyper-planes, it is not obvious how to decide which model is “simpler” as the notion of simplicity is ill defined.

In this article we will discuss two integer optimization formulations for selecting informative genes. The first formulation is based on a mixed integer linear formulation that while minimizing the classification error, attempts to simultaneously minimize the complexity of the classifier by controlling directly the number of features used. The second formulation expands the complexity quantification attempting to control both the number of features and the complexity of the classifier while maximizing its performance.

**Formulations**

**A Mixed Integer Formulation for Gene Selection**

A mixed-integer linear formulation was recently proposed [46]. Feature selection is always considered within the framework of a given analysis. This could be model development/fitting, classification, clustering etc. In other words we want to extract the minimum number of required independent variables necessary to perform a particular task. Therefore, an objective measuring the “goodness of fit” will be required. The parameters associated with the model naturally define a continuous optimization problem. The notion of selecting a subset of variables, out of a superset of possible alternatives, naturally lends itself to a combinatorial (integer) optimization problem. Therefore, depending

on the model used to describe the data the problem of feature selection will end up being a mixed integer (non) linear optimization problem. Furthermore, this problem is a multi-criteria optimization since one wishes to simultaneously minimize the model error and the number of features used. Let  $m$  denote the number of observations for a two-class problem such that  $k$  and  $l$  denote the number of samples in each class (for example number of benign and cancerous cells respectively). We also denote as  $I_1$  and  $I_2$  the indices of the corresponding samples and  $I = I_1 \cup I_2$  denotes the entire set of samples. Finally the set  $J$  denotes the set of all genes recorded in the observations and  $J' \subset J$  denotes the set of genes (features) that are required to develop an accurate model. The expression data is presented in the form  $x_{ij}$ ,  $i = 1, \dots, I$ ,  $j = 1, \dots, J$ . A linear classifier is constructed as:

$$\begin{cases} \beta_0 + \sum_{j \in J} \beta_j x_{ij} < 0, & i \in I_1 \\ \beta_0 + \sum_{j \in J} \beta_j x_{ij} > 0, & i \in I_2 \end{cases}$$

However, because the observations are not, in general, perfectly separable by a linear model a goal programming formulation can be proposed whose goal is to estimate the coefficients that minimize the deviations from the classifier model, Fig. 1.

In order to minimize the number of variables used in the classifier, thereby extracting the most relevant features for the specific linear model, binary variables need to be introduced to define whether a particular

$$\begin{aligned} \min : & \sum_{i \in I_1} d_i^1 + \sum_{i \in I_2} d_i^2 \\ \text{s.t.} & \\ & \beta_0 + \sum_{j \in J} \beta_j x_{ij} - d_i^1 + d_i^2 = -\sigma, i \in I_1 \\ & \beta_0 + \sum_{j \in J} \beta_j x_{ij} - d_i^1 + d_i^2 = \sigma, i \in I_2 \\ & \beta_j \in \mathbb{R} \\ & d_i^1, d_i^2 \in \mathbb{R}^+ \end{aligned}$$

**Selection of Maximally Informative Genes, Figure 1**  
**Optimization-based classification model**

$$\begin{aligned}
\min : & \sum_{i \in I_1} d_i^1 + \sum_{i \in I_2} d_i^2 \\
\text{s.t.} & \\
& \beta_0 + \sum_{j \in J} \beta_j x_{ij} - d_i^1 + d_i^2 = -\sigma, i \in I_1 \\
& \beta_0 + \sum_{j \in J} \beta_j x_{ij} - d_i^1 + d_i^2 = \sigma, i \in I_2 \\
& \sum_{j \in J} y_j \leq \epsilon \\
& \beta_j - M y_j \leq 0 \\
& -\beta_j - M y_j \leq 0 \\
& \beta_j \in \mathbb{R}, j \in J \\
& d_i^1, d_i^2 \in \mathbb{R}^+, i \in I \\
& y_j \in \{0, 1\}
\end{aligned}$$

**Selection of Maximally Informative Genes, Figure 2**  
Mixed integer formulation of the feature selection problem

variable is used in the model or not. Therefore:

$$y_j = \begin{cases} 1, & j \in J' \\ 0, & j \notin J' \end{cases}.$$

The number of “active” genes can therefore be constrained (that is introduced parametrically in the formulation in order to avoid the solution of a multi-criteria optimization problem). According to the  $\epsilon$ -constraint method one additional constraint of the form:  $\sum_{j \in J'} y_j \leq \epsilon$  is introduced. The complete MIP formulation is shown in Fig. 2.

### A Mixed Integer Formulation for Feature Selection and Classifier Complexity Minimization

An interesting idea was recently introduced [45] in the context of oblique multicategory classification trees, whereby the class assignment is modeled through the use of the concept of purity of a partition. Ideally, one wishes to construct a multivariate classifier in such a way that each “partition” is occupied by elements of a single class (orthogonal partitions). However, this formulation is faced with a number of complexities. First, it is highly non-linear, second it does not perform feature selection and finally it builds classifiers sequentially, in the sense of the one-against-all concept. However, the purity concept introduces a very intelligent

way of quantifying the ability of a classifier to partition the data. Furthermore, with proper modifications to be discussed shortly, it allows the quantification of the complexity of the classifier.

We will discuss the basic elements of recently proposed approach [53] which can be effectively generalized in the context of a mixed-integer optimization. This generalization will be used to develop a general framework of oblique multi-category trees to address the question of how to build simple, yet informative, classifiers that simultaneously perform informative feature selection. We assume that we are given the ensemble of gene expression data in the form of an  $f$ -dimensional vectors belonging to  $k$  distinct classes. The question is to identify how many, and which, of these  $f$  features are critical for the construction of a simplified, yet informative, classifier. An oblique multi-category classifier is defined by the intersection of a number of planes. We term these intersections “partitions”,  $\pi = 2^p$  where  $p$  is the number of planes. We define complexity as the number of occupied partitions that are required to properly classify the data.  $q_{n,\pi}$  is a binary variable indicating whether point “ $n$ ” belongs in a partition  $\pi$ . The total number of points of class  $k$  in partition  $\pi$  is termed  $\sigma_{k,\pi}$  whereas  $\nu_{k,\pi}$  denotes the fraction of points of class  $k$  in said partition. Finally,  $y_{k,\pi}$  is a binary variable which is 1 if that partition contains even a single point from class  $k$ , and 0 otherwise. The location of a point relative to a particular plane is defined according to the binary variable  $z_{n,p}$  which is 1 if the point is below the plane, and 0 otherwise. This variable is a critical one since it basically defines all the auxiliary variables in the formulation. Finally  $s_f$  is a binary variable indicating whether feature “ $f$ ” is used in the construction of the classifier. Give that  $p$  planes create  $2^p$  partitions, we wish to identify the partitions, and the corresponding spatial distribution of points in the reduced space defined by  $s_f$  which will create the “purest” possible partition. We model this by analyzing the product  $y_{k,\pi} \nu_{k',\pi}$ ,  $k \neq k'$ . In order to account for non-linearly classifiable problems we are basically looking for partitions that satisfy the set of constraints depicted in Fig. 3.

The modeling idea is that (i) the partition contains no point of class “ $k$ ” and the maximum numbers of “ $k$ ” (empty partition), (ii) the partition contains points of class “ $k$ ” and contains the minimum number of points

$$\begin{aligned}
 y_{k,\pi} \nu_{k',\pi} \leq E &\Rightarrow \begin{cases} y_{k,\pi} = 0 \wedge \nu_{k',\pi} \leq 1 \\ y_{k,\pi} = 1 \wedge \nu_{k',\pi} \leq E \\ y_{k,\pi} = 0 \wedge \nu_{k',\pi} \leq E \end{cases} \\
 &\text{or} \\
 y_{k',\pi} \nu_{k,\pi} \leq E &\Rightarrow \begin{cases} y_{k',\pi} = 0 \wedge \nu_{k,\pi} \leq 1 \\ y_{k',\pi} = 1 \wedge \nu_{k,\pi} \leq E \\ y_{k',\pi} = 0 \wedge \nu_{k,\pi} \leq E \end{cases}
 \end{aligned}$$

**Selection of Maximally Informative Genes, Figure 3**  
**Modeling occupied partitions**

of class “*k*”, and (iii) if no points of class “*k*” are present, then it may contain an arbitrary number of points of class “*k*”. Obviously, the point is to maximize the number of type (i) partitions while satisfying the “purity” requirements. The objective thus becomes to minimize the “slack” variable *E*. The novelty of our approach is that it allows the complete control of the complexity of the model by treating explicitly the number of features, and number of occupied partitions. The detailed formulation is summarized in Fig. 4.

The proposed formulation optimizes simultaneously for a number of design criteria:

- the feature selection;
- the construction of a multivariate, multi-class classifier; and
- the creation of multiple structurally alternative solutions via the introduction of integer cuts [5].

The overall framework remains linear and the solution is done parametrically for a given number of occupied partitions and number of features. This is a simple way for decoupling the objectives, however, more elaborate multi-objective schemes can, and will be, explored. We will discuss a number of computational studies to illustrate the method.

**Cases**

**Gene Selection and Complexity Minimization**

Our case study will focus on the model proposed in mainly because these results will demonstrate how to interpret computational results in their biological concept. This analysis demonstrated that there is indeed a string relationship between computational complexity, as modeled through the various optimization formulations, and biological relevance.

“Small Round Blue Cell Tumors” (SRBCT) is a descriptive category encompassing a large number of malignant tumors that tend to occur in childhood. They are united by their similar histo-pathological appearance. However, subtle clues may be present to distinguish between the tumors. For proper characterization, pathologists often employ immunohistochemistry, electron microscopy, and molecular analysis for chromosomal abnormalities. The SRBCTs of childhood include neuroblastoma (NB), rhabdomyosarcoma (RMS), non Hodgkin lymphoma (NHL), and the Ewing family of tumors (EWS). Currently no single biological or chemical test exists that can detect SRBCTs. A comprehensive study was presented in which a large number of genes were monitored. The data were reduced by SVD decomposition and the leading factors were used to train an Artificial Neural Network to build a predictive diagnostic device.

In order to analyzed this data set with the mixed integer formulation, Fig. 4 the raw data are first pre-processed used an extension of the signal-to-ratio approach introduced by [20]. The original method was extended for multiclass-class problems in order to assist in the elimination of irrelevant features. This step reduced the initial number of features to 500. Multiple cuts were generated for a multitude of features/plane combinations and we discuss representative results to illustrate the extracted information. The maximally informative model has 3 features and 2 planes (4 occupied partitions), Fig. 5. As a standard validation, it was verified that scrambling the data (systematic error) does significantly deteriorate the performance of the classifier which is a further validation that the underlying structure in the data in the result of a random process.

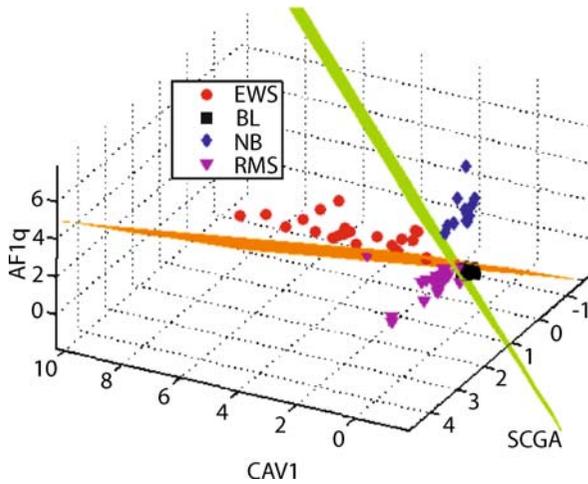

Through the aforementioned analysis several conserved key genes across multiple solutions were identified, all of which are integral in tumor progression. The first of these genes, caveolin-1 (CAV-1), has been documented, when its expression patterns are altered, to be a key component in the formation of a variety of tumors, such as prostate [50], bladder [37], esophageal, and mammary [26,51]. The effects of CAV-1 in tumorigenesis fall into three major categories: 1) deregulation of cell cycle control [49]; 2) metalloproteinase production [51]; and 3) induction of angiogenesis [44]. The second gene identified, neurofibromatosis 2 (NF2), has also been shown to be involved in cancer formation, in

neural based tumors such as schwannomas and meningiomas [17,31,40,52]. NF2 exerts its effect through its gene product, merlin, which is involved in the regulation of cell motility and cell proliferation. Recent studies have highlighted the involvement of merlin in tumor suppression through the inhibition of Rac signaling. In cases where the production of NF2 is diminished, RAC signaling becomes activated, and the tumor sup-

pression capabilities of NF2 are lost. The third major gene identified is a myeloid/lymphoid or mixed-lineage leukemia marker (AF1Q). While the literature on this gene is limited, it is known that this gene is necessary for neuronal differentiation [28]. Thus it may be possible that uncontrolled regulation of this gene may lead to neuronal-based tumors. The fourth gene, sarcoglycan, alpha (SGCA), is a component of the dystrophin-

**Selection of Maximally Informative Genes, Figure 5**  
**Optimal space decomposition for the SRBCT problem**

glycoprotein complex, and has been linked to the onset of mammary tumorigenesis [48]. Tumorigenesis is induced when mutations inhibit the production of SGCA. This leads to a subsequent loss of control over a variety of functions such as growth control, cell survival, cytoskeletal organization, basement membrane assembly, branching morphogenesis, polarity, and tumor suppression in epithelial cells. As mentioned previously in the case of CAV-1, when these key components of cellular function become aberrant, tumorigenesis ensues. The final gene identified through our analysis is the CD99 antigen (CD99), which has been determined to be a marker of lung carcinomas as well as mammary tumors. It is thought that CD99 might play an integral role in the aggregation of breast cancer cells, the initiating step of tumorigenesis. CD99 also assists in the invasive processes characteristic of metastatic tumors. Finally, the gene for receptor, IgG, alpha chain transporter (FCGRT, FCRN) was also selected. This gene, as well as a few others, has been detected through the use of cDNA microarrays, in studies involved in elucidating the underlying genomic profile of astrocytomas [22]. Specifically FCRN is known to mediate immune defense in response to the onset of pilocytic astrocytomas, possibly keeping the astrocytoma in a benign state. In addition, FCRN is known to be expressed by dendritic cells [54] and may serve as a basal mechanism of immune function.

## Conclusions

This summary presented a number of optimization-based formulation, with emphasis on mathematical programming, for addressing the problem of gene selection. Numerous issues can be raised for future research. In fact the advantage of a MP-based formalism is the tremendous flexibility it provides.

*Multi-objective optimization:* Interpretation of biological information needs to tackle multiple simultaneous objectives. In this short review we discussed simultaneous optimization of accuracy and size of classifier (number of features). In clustering applications the number of clusters is yet another level of complexity, hence an additional decision variable. Therefore, multicriteria trade-off curves (Pareto solutions) have to be developed for these high-dimensional mixed integer (non) linear optimization problems.

*Incorporation of biological constraints:* One of the advantages of using mathematical programming techniques is that constraints can be readily accounted for. Thus far microarray analyzes approaches treat the array data as raw unconstrained measurements. One of the targets of microarray analysis is to identify potential correlations among the data. However, prior biological knowledge is not taken into account mainly because most data mining methods cannot handle implicit or explicit constraints. Recently, the need to account for biological driven constraints when clustering expression profiles was demonstrated [42].

*Large-scale combinatorial optimization:* The development of scalable algorithms is a daunting task in optimization theory. With the recent developments in genomics we should be expecting routinely that the analysis of gene arrays composed of tens of thousands of probes (hence tens of thousands of binary variables in the MIP gene selection formulation). Recent works [14,18,39], discuss various mixed-integer reformulations to the classification problem. The recent work of Shioda et al. [43], identified opportunities for successful reformulations of various data mining tasks in the context of linear integer optimization. Busygin et al., present some more recent ideas for addressing the bi-clustering problem as a fractional 0-1 optimization problems [9]. Undoubtedly, integer optimization will play a prominent role in feature algorithmic developments as recent results demonstrate the complemen-

tarity of the different methodologies, suggesting that a unified approach may help to uncover complex genetic risk factors not currently discovered with a single method [34].

*Global optimization:* The development of general non-linear, non-convex separating boundaries naturally leads to requirements of solving large-scale combinatorial non-linear problems to global optimality. Recent advances in the theory and practice of deterministic global optimization are also expected to be critical enablers [16].

*Analyzing almost empty spaces:* The sparseness of the data set is a critical roadblock. Accurate models can be developed using convoluted optimization approaches. However, we would constantly lack appropriately populated datasets in order to achieve a reasonable balance between the thousands of independent variables (genes measured) and necessary measurements (tissue samples) for a robust identification. Information theoretic approaches accounting for complexity (Akaike and Bayesian Information Criteria) should be developed to strike a balance between the complexity and the accuracy of the model so as to avoid pointless over fitting of the sparsely populated datasets.

*Uncertainty considerations:* Noise and uncertainty in the data is a given. Therefore, data mining algorithms in general and mathematical programming formulations in particular have to account for the presence of noise. Issues from robustness and uncertainty propagation have to be incorporated. However, an interesting issue emerges: how do we distinguish between noise and an infrequent, albeit interesting observation? This in fact maybe a question with no answer especially if we consider the implications of sparsely populated data sets.

where  $x$  is a vector of continuous variables;  $A$  is a constant matrix;  $c$  and  $b$  are constant vectors and we assume that (1) does not contain redundant constraints (see [8] or [7] for a procedure for removing redundant constraints). The solution of (1) can be approached by primal or dual simplex methods, or their variants [4,8]; however, see [9] for interior point methods. Primal and dual simplex algorithms start from a primal or dual feasible solution, which is then solved to optimality by using primal or dual simplex pivot steps respectively. On the other hand, the selfdual parametric method, which is also called the criss-cross method, does not require a starting feasible solution and uses a combination of primal and dual simplex pivot steps. The criss-cross method is based upon introducing a parameter,  $\theta$ , into the model, (1), and then minimizing  $\theta$  by using primal or dual simplex pivot steps. If  $\theta$  decreases to zero the problem is primal or dual feasible and then the optimal solution is found by using primal or dual simplex method respectively, otherwise, the problem is infeasible.

In order to apply the selfdual parametric method, the parameter  $\theta$  is introduced and the problem in (1) is rewritten in the following form [4,8]:

$$\left\{ \begin{array}{l} \min_x \quad \sum_{j=1}^n (c'_j + \theta \widehat{c}_j) x_j \\ \text{s.t.} \quad x_i + \sum_{j=m+1}^n a'_{ij} x_j = b'_i + \theta \widehat{b}_i, \\ \quad \quad i = 1, \dots, m, \\ \quad \quad x_j \geq 0 \quad \text{for all } j \\ \quad \quad x \in \mathbb{R}^n, \end{array} \right. \quad (2)$$

where  $(x_1, \dots, x_m)$  is the vector of the selected basic variables;  $(0, \dots, 0, c'_{m+1}, \dots, c'_n)$  and  $(b'_1, \dots, b'_m)$  are the updated  $c$  and  $b$  vectors after pricing out the basic columns;  $\widehat{b}_i = 0$  if  $b'_i \geq 0$ ,  $\widehat{b}_i = 1$  otherwise; and,  $\widehat{c}_i = 0$ , if  $c'_i \geq 0$ ,  $\widehat{c}_i = 1$  otherwise. The basic idea of the selfdual parametric method is to minimize  $\theta$  by using primal or dual simplex pivot steps – the smallest value of  $\theta$  corresponding to an optimal tableau is called the *critical value*,  $\widetilde{\theta}$ . When  $b'_i, c'_j \geq 0$  then  $\widetilde{\theta} = 0$ , and the problem can be solved to an optimal solution by using primal or dual simplex method. Otherwise,  $\widetilde{\theta} > 0$  and

## Selfdual Parametric Method for Linear Programs

### Criss-cross Method

### Keywords

Linear programming; Primal and dual simplex algorithms

In this article we will describe the selfdual parametric method for solving linear programs (LPs) of the following form:

$$\left\{ \begin{array}{l} \min_x \quad c^\top x \\ \text{s.t.} \quad Ax = b, \quad x \geq 0, \quad x \in \mathbb{R}^n, \end{array} \right. \quad (1)$$

Selfdual Parametric Method for Linear Programs, Figure 1  
Criss-cross method

is given by

$$\max \left\{ \left\{ -\frac{b'_i}{\tilde{b}_i} : \text{with } i \text{ s.t. } b'_i < 0 \right\}, \left\{ -\frac{c'_j}{\tilde{c}_j} : \text{with } j \text{ s.t. } c'_j < 0 \right\} \right\}.$$

In such a case, i. e., when  $\tilde{\theta} > 0$ , if  $\tilde{\theta} = -(b'_i/\tilde{b}_i)$ , the  $i$ th row of the current tableau is defined as a *critical row* and if  $\tilde{\theta} = -(c'_j/\tilde{c}_j)$ , then the  $j$ th row of the current tableau is defined as a *critical column*. The criss-cross method identifies a critical column or a critical row and a primal or dual simplex step, respectively, is carried out. Either  $\tilde{\theta}$  decreases to zero in a finite number of steps or the problem is primal or dual infeasible. The basic idea of the algorithm is outlined in Fig. 1.

Other useful references on the subject are [1,2,3,5,10,11] and [6].

Semidefinite programming; Convex optimization; Linear matrix inequality; Interior point methods; Ellipsoidal approximation; Experiment design

A wide variety of nonlinear *convex optimization* problems can be expressed in terms of *linear matrix inequalities* (LMIs), i. e., convex constraints of the form

$$x_1 A_1 + \cdots + x_n A_n \preceq B$$

where  $x \in \mathbf{R}^n$  is the optimization variable,  $A_i = A_i^\top \in \mathbf{R}^{m \times m}$ ,  $B = B^\top \in \mathbf{R}^{m \times m}$  are given matrices, and the inequality sign denotes matrix inequality (i. e., the matrix  $B - \sum_i x_i A_i$  is positive semidefinite). Linear matrix inequalities arise in systems and control, combinatorial optimization, statistics, eigenvalue optimization, and several other fields.

The most widely studied problem of this type is the *semidefinite programming problem* (SDP), in which we minimize a linear function subject to an LMI constraint:

$$\begin{cases} \min & c^\top x \\ \text{s.t.} & x_1 A_1 + \cdots + x_n A_n \preceq B. \end{cases}$$

Semidefinite programming has received a great deal of attention recently, motivated by the discovery of new applications and by the development of new *interior point methods*. For surveys of the theory and applications of SDP, see [1,5,14,15,16,21]. SDPs are convex optimization problems, since the linear matrix inequality is a convex constraint, and the objective function is linear.

An interesting closely related problem is the problem of maximizing the determinant of a linear matrix function, subject to LMI constraints:

$$\begin{cases} \max & \det(C_0 + x_1 C_1 + \cdots + x_n C_n) \\ \text{s.t.} & C_0 + x_1 C_1 + \cdots + x_n C_n \succ 0 \\ & x_1 A_1 + \cdots + x_n A_n \preceq B \end{cases} \quad (1)$$

where  $C_i = C_i^\top \in \mathbf{R}^{p \times p}$ ,  $A_i = A_i^\top \in \mathbf{R}^{m \times m}$ , and  $B = B^\top \in \mathbf{R}^{m \times m}$  are given. Although the objective function is not concave, this problem can be easily transformed in a convex optimization problem. We can first note that the function  $f(X) = -(\det X)^{1/p}$  is convex on the set

of positive definite matrices in  $\mathbf{R}^{p \times p}$ , so problem (1) is equivalent to the convex minimization problem

$$\begin{cases} \min & -(\det C(x))^{1/p} \\ \text{s.t.} & C(x) \succ 0 \\ & x_1 A_1 + \cdots + x_n A_n \preceq B, \end{cases}$$

where  $C(x) = C_0 + x_1 C_1 + \cdots + x_n C_n$ . An alternative formulation is

$$\begin{cases} \min & \log \det C(x)^{-1} \\ \text{s.t.} & C(x) \succ 0 \\ & x_1 A_1 + \cdots + x_n A_n \preceq B. \end{cases}$$

This is a convex problem, since the function  $\log \det X^{-1}$  is convex on the set of positive definite matrices.

A unified form that includes both the SDP and the determinant maximization problem is

$$\begin{cases} \min & c^\top x + \log \det C(x)^{-1} \\ \text{s.t.} & C(x) \succ 0 \\ & x_1 A_1 + \cdots + x_n A_n \preceq B. \end{cases} \quad (2)$$

It is clear that this problem reduces to an SDP when  $C_0 = 1$  and  $C_i = 0$  for  $i > 0$ , and to a determinant maximization problem when  $c = 0$ . Moreover, as we will see below, there exist important applications where both terms arise.

Reference [22] gives a detailed discussion of problem (2), including an overview of applications and a description of an efficient interior point method. In this article, we illustrate the applications of (2) with a few examples from different areas. Following [22], we will refer to (2) as a *max-det problem*.

## Ellipsoidal Approximation

Our first class of examples are *ellipsoidal approximation* problems. We can distinguish two basic problems. The first is the problem of finding the *minimum-volume ellipsoid* around a given set  $C$ . The second problem is the problem of finding the *maximum-volume ellipsoid* contained in a given convex set  $C$ . Both can be formulated as convex (semi-infinite) programming problems.

To solve the first problem, it is convenient to parametrize the ellipsoid as the pre-image of a unit ball under an affine transformation, i. e., as

$$\mathcal{E} = \{v: \|Av + b\| \leq 1\}.$$

It can be assumed without loss of generality that  $A = A^T \succ 0$ , in which case the volume of  $\mathcal{E}$  is proportional to  $\det A^{-1}$ . The problem of computing the minimum-volume ellipsoid containing  $C$  can be written as

$$\begin{cases} \min & \log \det A^{-1} \\ \text{s.t.} & A = A^T \succ 0 \\ & \|Av + b\| \leq 1, \\ & \text{for all } v \in C, \end{cases} \quad (3)$$

where the variables are  $A$  and  $b$ . Note that both the objective function and the constraints are convex in  $A$  and  $b$ .

For the second problem, where we maximize the volume of ellipsoids enclosed in a convex set  $C$ , it is more convenient to represent the ellipsoid as the image of the unit ball under an affine transformation, i. e., as

$$\mathcal{E} = \{By + d : \|y\| \leq 1\}.$$

Again it can be assumed that  $B = B^T \succ 0$ . The volume is proportional to  $\det B$ , so we can find the maximum volume ellipsoid inside  $C$  by solving the convex optimization problem

$$\begin{cases} \max & \log \det B \\ \text{s.t.} & B = B^T \succ 0 \\ & By + d \in C, \\ & \forall y, \|y\| \leq 1 \end{cases} \quad (4)$$

in the variables  $B$  and  $d$ .

For general  $C$ , problems (4) and (3) are semi-infinite programming problems. They reduce to finite problems in certain cases, which we now review.

We first consider the problem of finding the minimum volume ellipsoid that contains given points  $x^1, \dots, x^K$  in  $\mathbf{R}^n$ , i. e.,

$$C = \{x^1, \dots, x^K\},$$

(or, equivalently, the convex hull of  $\{x^1, \dots, x^K\}$ ). This problem has applications in cluster analysis [4,18]), and robust statistics [19, §7]. Applying (3), we can write this problem as

$$\begin{cases} \min & \log \det A^{-1} \\ \text{s.t.} & \|Ax^i + b\| \leq 1, \quad i = 1, \dots, K, \\ & A = A^T \succ 0, \end{cases} \quad (5)$$

where the variables are  $A = A^T \in \mathbf{R}^{n \times n}$  and  $b \in \mathbf{R}^n$ . The norm constraints  $\|Ax^i + b\| \leq 1$ , which are convex quadratic inequalities in the variables  $A$  and  $b$ , can be expressed as LMIs

$$\begin{pmatrix} I & Ax^i + b \\ (Ax^i + b)^T & 1 \end{pmatrix} \succeq 0,$$

so (5) is a max-det problem in the variables  $A$  and  $b$ .

In a similar way, we can compute the maximum volume ellipsoid contained in a polytope described by a set of linear inequalities

$$C = \{x : a_i^T x \leq b_i, \quad i = 1, \dots, L\}.$$

To apply (4) we first work out the last constraint:

$$\begin{aligned} By + d \in C, \quad \forall \|y\| \leq 1 \\ \Rightarrow a_i^T (By + d) \leq b_i, \quad \forall \|y\| \leq 1 \\ \Rightarrow \max_{\|y\| \leq 1} a_i^T By + a_i^T d \leq b_i \\ \Rightarrow \|Ba_i\| + a_i^T d \leq b_i. \end{aligned}$$

This is a convex constraint in  $B$  and  $d$ , and equivalent to the LMI

$$\begin{pmatrix} (b_i - a_i^T d)I & Ba_i \\ a_i^T B & b_i - a_i^T d \end{pmatrix} \succeq 0.$$

We can therefore formulate (4) as a max-det problem in the variables  $B$  and  $d$ :

$$\begin{cases} \min & \log \det B^{-1} \\ \text{s.t.} & B \succ 0 \\ & \begin{pmatrix} (b_i - a_i^T d)I & Ba_i \\ (Ba_i)^T & b_i - a_i^T d \end{pmatrix} \succeq 0, \\ & i = 1, \dots, L. \end{cases}$$

These techniques extend to several interesting cases where  $C$  is not finite or polyhedral, but is defined as a combination (the sum, union, or intersection) of ellipsoids. In particular, it is possible to compute the optimal inner approximation of the intersection or the sum of ellipsoids, and the optimal outer approximation of the union or sum of ellipsoids, by solving a max-det problem. See [5] and [8] for details.

As an example, consider the problem of finding the minimum volume ellipsoid  $\mathcal{E}_0$  containing  $K$  given ellipsoids  $\mathcal{E}_1, \dots, \mathcal{E}_K$  described as

$$\mathcal{E}_i = \{x : x^T A_i x + 2b_i^T x + c_i \leq 0\}.$$

The solution can be found by solving the following max-det problem in the variables  $A_0 = A_0^\top$ ,  $b_0$ , and  $K$  scalar variables  $\tau_i$ :

$$\left\{ \begin{array}{l} \min \quad \log \det A_0^{-1} \\ \text{s.t.} \quad A_0 = A_0^\top \succ 0 \\ \tau_1 \geq 0, \dots, \tau_K \geq 0 \\ \begin{pmatrix} A_0 - \tau_i A_i & b_0 - \tau_i b_i & 0 \\ (b_0 - \tau_i b_i)^\top & -1 - \tau_i c_i & b_0^\top \\ 0 & b_0 & -A_0 \end{pmatrix} \preceq 0, \\ i = 1, \dots, K. \end{array} \right.$$

( $c_0$  is given by  $c_0 = b_0^\top A_0^{-1} b_0 - 1$ .) See [5, p. 43], for details.

### Experiment Design

The field of *experiment design* is another source of max-det problems. Suppose  $x \in \mathbf{R}^n$  is an unknown quantity that we want to estimate from a measurement  $y = Ax + w$  where  $w \sim \mathcal{N}(0, I)$  is measurement noise, and  $A \in \mathbf{R}^{N \times n}$  ( $N \geq n$ ) has full rank. The minimum variance estimator is given by  $\hat{x} = (A^\top A)^{-1} A^\top y$ , and has an error covariance  $E(x - \hat{x})(x - \hat{x})^\top = (A^\top A)^{-1}$ . Suppose that the rows of the matrix  $A$  can be chosen among  $M$  possible test vectors  $v^i \in \mathbf{R}^n$ . The goal of experiment design is to choose the rows of  $A$  so that the error covariance is ‘small’. We can write  $A^\top A = N \sum_{i=1}^M \lambda_i v_i v_i^\top$ , where  $\lambda_i$  is the fraction of measurements that use the test vector  $v^i$ . If  $N \gg M$  we can ignore the fact that the numbers  $\lambda_i$  are integer multiples of  $1/N$ , and treat them as continuous variables.

Several different criteria can be used to measure the size of the error covariance matrix (e. g., the maximum eigenvalue, the trace, or the determinant). A design in which the determinant  $\det(AA^\top)^{-1}$  is minimized is called *D-optimal*. This problem can be expressed as a max-det problem

$$\left\{ \begin{array}{l} \min \quad \log \det \left( \sum_{i=1}^M \lambda_i v^i (v^i)^\top \right)^{-1} \\ \text{s.t.} \quad \lambda_i \geq 0, \quad i = 1, \dots, M, \\ \sum_{i=1}^M \lambda_i = 1. \end{array} \right.$$

This formulation of *D-optimal* experiment design has the advantage that one can easily incorporate useful

convex constraints, e. g., linear inequalities on the numbers  $\lambda_i$ . A few interesting possibilities are mentioned in [22]. For surveys of experiment design, see [9,12,17].

### Estimation of Structured Covariance Matrices

Suppose we want to estimate the covariance matrix  $\Sigma \in \mathbf{R}^{p \times p}$  of a normal distribution  $\mathcal{N}(0, \Sigma)$  from  $M$  samples  $y^{(1)}, \dots, y^{(M)}$ . The *maximum likelihood estimate* for  $\Sigma$  is the positive definite matrix that maximizes  $\prod_{i=1}^M p(y^{(i)})$ , where

$$p(x) = ((2\pi)^p \det \Sigma)^{-\frac{1}{2}} \exp \left( -\frac{1}{2} x^\top \Sigma^{-1} x \right).$$

In other words,  $\Sigma$  can be found by solving

$$\left\{ \begin{array}{l} \min \quad \log \det \Sigma^{-1} - \frac{1}{M} \sum_{i=1}^M y^{(i)\top} \Sigma^{-1} y^{(i)} \\ \text{s.t.} \quad \Sigma = \Sigma^\top \succ 0, \end{array} \right. \quad (6)$$

which can be expressed as a max-det problem in the *inverse*  $R = \Sigma^{-1}$ :

$$\left\{ \begin{array}{l} \min \quad \text{Tr} SR + \log \det R^{-1} \\ \text{s.t.} \quad R \succ 0, \end{array} \right. \quad (7)$$

where

$$S = \frac{1}{M} \sum_{i=1}^M y^{(i)} y^{(i)\top}.$$

Without any additional constraints, this problem has a straightforward analytical solution:  $R = S^{-1}$  (provided  $S$  is nonsingular). The formulation as a max-det problem is useful when additional constraints are added. To give a simple illustration, bounds on the variances  $\Sigma_{ii}$  can be expressed as LMIs in  $R$

$$\Sigma_{ii} = e_i^\top R^{-1} e_i \leq \alpha \Rightarrow \begin{pmatrix} R & e_i \\ e_i^\top & \alpha \end{pmatrix} \succeq 0.$$

Adding constraints is also useful when the matrix  $S$  is singular (for example, because the number of samples is too small) and, as a consequence, the max-det problem (7) is unbounded below. In this case we can impose constraints (i. e., prior information) on  $\Sigma$ , for example lower and upper bounds on the diagonal elements of  $R$ . See also [2,3,6], [20, §6.13], and [10].

## Quasi-Newton Updates

In a quasi-Newton method for unconstrained minimization of a convex function  $f$  on  $\mathbf{R}^n$ , the Newton step  $-\nabla^2 f(x)^{-1} \nabla f(x)$  is replaced by  $-H^{-1} \nabla f(x)$ , where  $H = H^T > 0$  is an approximation of the Hessian matrix, based on prior information and previous gradient evaluations. At each iteration, as the algorithm moves from  $x$  to the next point  $x^+$ , a new approximation  $H^+$  is determined, based on the current  $H$ , and on the difference between the gradients at  $x^+$  and  $x$ . A good updating rule for  $H$  should satisfy several properties:  $H^+$  should be close to  $H$ , it should be easy to compute (or, more precisely, the search direction  $-H^{+^{-1}} \nabla f(x^+)$  should be easy to compute), and it should incorporate the new information obtained by evaluating the gradient  $\nabla f(x^+)$ . This last property is usually enforced by imposing the secant condition

$$H^+(x^+ - x) = \nabla f(x^+) - \nabla f(x). \quad (8)$$

R.H. Byrd and J. Nocedal [7] have proposed to measure the difference between  $H$  and  $H^+$  by using the *Kullback–Leibler divergence* (or *relative entropy*), given by

$$\frac{1}{2} (\text{Tr } H^{-1} H^+ - \log \det H^{-1} H^+ - n)$$

(see also [11]). The Kullback–Leibler divergence is non-negative for all positive definite  $H$  and  $H^+$ , and zero only if  $H^+ = H$ . The update  $H^+$  that satisfies the secant condition and minimizes the Kullback–Leibler divergence is the solution of the following optimization problem:

$$\begin{cases} \min & \text{Tr } H^{-1} H^+ - \log \det H^{-1} H^+ \\ \text{s.t.} & H^+ > 0 \\ & H^+(x^+ - x) = \nabla f(x^+) - \nabla f(x). \end{cases} \quad (9)$$

R. Fletcher [13] has shown that the solution is given by

$$H^+ = H - \frac{H s s^T H}{s^T H s} + \frac{g g^T}{s^T g}, \quad (10)$$

assuming that  $s^T g > 0$ , where  $s = x^+ - x$  and  $g = \nabla f(x^+) - \nabla f(x)$ . Formula (10) is well known in unconstrained optimization as the *BFGS quasi-Newton update* (*Broyden–Fletcher–Goldfarb–Shanno*).

Fletcher's observation opens the possibility of adding more complicated LMI constraints to (9), and

solving the resulting problem numerically. For example, we can impose a certain sparsity pattern on  $H^+$ , or we can relax the secant condition as

$$\|H^+(x^+ - x) - \nabla f(x^+) + \nabla f(x)\| \leq \epsilon,$$

where  $\epsilon$  is a given tolerance.

Updating  $H$  by numerically solving a convex optimization problem will obviously involve far more computation than the BFGS update. Thus, this formulation for *quasi-Newton updates* is only interesting when gradient evaluations are very expensive.

## Conclusion

The max-det problem (2) is an extension of the semidefinite programming problem, and includes a wide variety of convex optimization problems as special cases. Some of the applications we discussed have been studied extensively in the literature, and in some cases analytic solutions or efficient specialized algorithms have been developed. The practical importance of the general problem is that it can be handled efficiently using recently developed interior point methods. This allows us to solve interesting variations of problems for which no analytical solution or specialized method exist, and it opens the possibility of adding useful LMI constraints.

### Keywords

Semidefinite programming; Duality; Tangent cone; Nondegeneracy; Complementarity condition; Lagrange multipliers; Stability; Sensitivity analysis

In this article we discuss optimization problems of the form

$$\begin{cases} \min_{x \in \mathbb{R}^n} & f(x) \\ \text{s.t.} & G(x) \preceq 0, \end{cases} \quad (1)$$

where  $f(x)$  is a real valued function,  $G(x)$  is a mapping from  $\mathbb{R}^n$  into the space  $S^p$  of  $p \times p$  symmetric matrices, and the notation  $A \preceq 0$  (the notation  $A \succeq 0$ ) means that  $A$  is a negative (positive) semidefinite matrix. We refer to (1) as a *semidefinite programming problem*. The above semidefinite programming problem is said to be *linear* if the objective function  $f(x)$  is linear and the

mapping  $G(x)$  is affine, i. e. is of the form

$$\begin{cases} \min_{x \in \mathbb{R}^n} & c^\top x \\ \text{s.t.} & A_0 + \sum_{i=1}^n x_i A_i \preceq 0, \end{cases} \quad (2)$$

where  $c \in \mathbb{R}^n$  and  $A_0, \dots, A_n \in \mathcal{S}^p$  are given matrices.

Let us observe that the constraint  $G(x) \preceq 0$  can be written as  $G(x) \in \mathcal{S}_-^p$ , where

$$\mathcal{S}_-^p := \{Z \in \mathcal{S}^p : Z \preceq 0\}$$

denotes the set of  $p \times p$  negative semidefinite symmetric matrices. Note that the set  $\mathcal{S}_-^p$  forms a closed convex cone in the space  $\mathcal{S}^p$ , and that  $\mathcal{S}^p$  can be viewed as a linear (vector) space of dimension  $p(p+1)/2$ . We equip  $\mathcal{S}^p$  with the scalar (inner) product

$$A \bullet B := \text{trace}(AB) = \sum_{i,j=1}^p a_{ij}b_{ij},$$

between two matrices  $A = (a_{ij})$  and  $B = (b_{ij})$ .

With these observations at hand one can notice a certain similarity between problem (1) and *nonlinear programming* problems. In a nonlinear programming problem corresponding constraints can be written in the form  $G(x) \in \mathbf{R}^m$ , where  $G(x)$  is a mapping from  $\mathbf{R}^n$  into  $\mathbf{R}^m$  and  $\mathbf{R}^m$  is the negative orthant of the space  $\mathbf{R}^m$ . That is, in both cases the constraints can be formulated as convex cone inclusions. Let us note at this point that the *polar* (negative dual) of  $\mathcal{S}_-^p$  is given by the cone  $\mathcal{S}_+^p$  of positive semidefinite matrices.

## Duality

With problem (1) is associated the following *Lagrangian* function

$$L(x, \Omega) := f(x) + \Omega \bullet G(x)$$

of  $x \in \mathbf{R}^n$  and  $\Omega \in \mathcal{S}^p$ . Noting that, for a given  $x$ , the maximum of  $L(x, \Omega)$  with respect to  $\Omega \in \mathcal{S}_+^p$ , equals  $f(x)$  if  $G(x) \in \mathcal{S}_-^p$  and  $+\infty$  otherwise, we can write problem (1) in the form

$$\min_{x \in \mathbb{R}^n} \max_{\Omega \in \mathcal{S}_+^p} L(x, \Omega). \quad (3)$$

By interchanging the order in which the operators min and max are applied, we obtain

$$\max_{\Omega \in \mathcal{S}_+^p} \left\{ \phi(\Omega) := \min_{x \in \mathbb{R}^n} L(x, \Omega) \right\}. \quad (4)$$

We refer to the pair (1) and (4) as *primal* and *dual* problems, respectively. In particular, in case the primal problem is the *linear* semidefinite program (2), the dual problem takes the form

$$\begin{cases} \max_{\Omega \in \mathcal{S}_+^p} & \Omega \bullet A_0 \\ \text{s.t.} & c_i + \Omega \bullet A_i = 0, \\ & i = 1, \dots, n. \end{cases} \quad (5)$$

There is a long history in mathematical programming of considering dual problems. In semidefinite programming dual problems were studied in various forms, for example, in [1,9,12].

The optimal value of the primal problem is always greater than or equal to the optimal value of the dual problem. It is said that there is no *duality gap* between the primal and dual problems if their optimal values are equal. Note that in the semidefinite programming, the duality gap can happen even in the linear case. It is possible to give various regularity conditions, called constraint qualifications, ensuring the ‘no duality gap’ property. In the linear case, if  $\bar{x}$  and  $\bar{\Omega}$  are feasible points of the problems (2) and (5), respectively, then  $\bar{x}$  is an optimal solution of (2),  $\bar{\Omega}$  is an optimal solution of (5), and there is no duality gap between these problems if and only if the following complementarity condition

$$\bar{\Omega} \bullet G(\bar{x}) = 0 \quad (6)$$

holds, where  $G(\bar{x}) = A_0 + \sum_{i=1}^n \bar{x}_i A_i$ . This result can be extended to a certain class of convex semidefinite programming problems [10]. Note that since  $\bar{\Omega}$  is a feasible point of (5) and hence  $\bar{\Omega} \in \mathcal{S}_+^p$ , and  $\bar{x}$  is a feasible point of (2) and hence  $G(\bar{x}) \in \mathcal{S}_-^p$ , the complementarity condition (6) is equivalent to  $\bar{\Omega} G(\bar{x}) = \mathbf{O}$ , where  $\mathbf{O}$  denotes the zero  $p \times p$  matrix.

## First Order Optimality Conditions

Consider now a (possibly nonlinear) semidefinite programming problem in the form (1), and suppose that  $f(x)$  and  $G(x)$  are continuously differentiable. Let  $\bar{x}$  be a locally optimal solution of (1). With  $\bar{x}$  is associated the following system of first order optimality conditions:

$$\begin{cases} \nabla_x L(\bar{x}, \Omega) = 0, & \Omega \succeq 0, \\ \Omega \bullet G(\bar{x}) = 0. \end{cases} \quad (7)$$

In case the semidefinite program is linear, the first and second conditions in (7) ensure that  $\Omega$  is a feasible point of the dual problem (5), and the last condition corresponds to the complementarity condition (6). Therefore, in that case, if there exists a matrix  $\Omega \in \mathcal{S}^p$  satisfying conditions (7), then  $\Omega$  is an optimal solution of the corresponding dual problem. For general (possibly nonlinear) semidefinite programming problems, conditions (7) are obtained by linearization of  $f(x)$  and  $G(x)$  at the point  $\bar{x}$ .

It should be noted that existence of a matrix  $\Omega$  satisfying the first order optimality conditions (7), is not guaranteed even in the linear case. If such a matrix exists we refer to it as a *Lagrange multipliers* matrix. It is possible to show that the set of Lagrange multipliers matrices is non empty and bounded if and only if the following constraint qualification holds: there exists a vector  $h \in \mathbb{R}^n$  such that the matrix  $G(\bar{x}) + dG(\bar{x})h$  is negative definite (i. e. belongs to the interior of  $\mathcal{S}^p_-$ ), where

$$dG(\bar{x})h := \sum_{i=1}^n h_i \frac{\partial G(\bar{x})}{\partial x_i}$$

is the differential of  $G$  at  $\bar{x}$ .

The above constraint qualification can be viewed as an extension of the *Mangasarian–Fromovitz constraint qualification* [5], used in nonlinear programming. Note that in the linear case the partial-derivatives matrix  $\frac{\partial G(\bar{x})}{\partial x_i}$  equals  $A_i$ ,  $i = 1, \dots, n$ , and hence the above constraint qualification is equivalent to the Slater condition: there exists  $x^* \in \mathbb{R}^n$  such that the matrix  $G(x^*)$  is negative definite. This equivalence also holds for *convex* semidefinite programming problems. For a discussion of constraint qualifications in cone constrained problems see [6,7,8,13].

It is possible to formulate the above constraint qualification in another equivalent form. Recall that for a convex closed subset  $K$  of a finite-dimensional vector space and  $y \in K$ , the *tangent cone*  $T_K(y)$ , to  $K$  at  $y$ , is formed by vectors  $z$  such that the distance from  $y + tz$  to  $K$  is of order  $o(t)$ ,  $t \geq 0$ . The condition

$$dG(\bar{x})\mathbb{R}^n + T_{\mathcal{S}^p_-}(G(\bar{x})) = \mathcal{S}^p \quad (8)$$

is another equivalent form of the above constraint qualification. It is possible to show that the tangent cone to the set  $\mathcal{S}^p_-$ , at  $G(\bar{x})$ , can be written in the form

$$T_{\mathcal{S}^p_-}(G(\bar{x})) = \{Z \in \mathcal{S}^p : E^\top Z E \preceq 0\},$$

where  $E$  is a  $p \times (p - r)$  matrix of full column rank  $p - r$  such that  $G(\bar{x})E = \mathbf{0}$  and  $r$  is the rank of  $G(\bar{x})$ , e. g. [10]. (If  $r = p$ , i. e.  $G(\bar{x})$  is negative definite and hence belongs to the interior of  $\mathcal{S}^p_-$ , then  $T_{\mathcal{S}^p_-}(G(\bar{x}))$  coincides with the whole space  $\mathcal{S}^p$ .)

Consider now the set  $\mathcal{W}_r$  of  $p \times p$  symmetric matrices of rank  $r$ . This set forms a smooth manifold in the space  $\mathcal{S}^p$ , and the tangent space to  $\mathcal{W}_r$  at the point  $G(\bar{x})$  is given by

$$T_{\mathcal{W}_r}(G(\bar{x})) = \{Z \in \mathcal{S}^p : E^\top Z E = 0\}.$$

It follows from the above formulas that  $T_{\mathcal{W}_r}(G(\bar{x}))$  coincides with the *lineality* space of the cone  $T_{\mathcal{S}^p_-}(G(\bar{x}))$ , i. e. it is the largest linear subspace of  $T_{\mathcal{S}^p_-}(G(\bar{x}))$ . It is said that the point  $\bar{x}$  is *nondegenerate* ([2,10]) if the following condition holds

$$dG(\bar{x})\mathbb{R}^n + T_{\mathcal{W}_r}(G(\bar{x})) = \mathcal{S}^p. \quad (9)$$

The above condition (9) means that the mapping  $G$  intersects  $\mathcal{W}_r$  *transversally* at the point  $\bar{x}$ . It immediately follows from the corresponding result in differential geometry that nondegeneracy, in a certain sense, is a *generic* property (cf. [11]). It is clear that constraint qualification (8) implies (9). Therefore we have by the above discussion that if the point  $\bar{x}$  is nondegenerate, then there exists a Lagrange multipliers matrix  $\Omega$  satisfying conditions (7). In fact it is not difficult to show that if  $\bar{x}$  is nondegenerate, then such Lagrange multipliers matrix is *unique*.

Let us note now that it follows from the complementarity condition (6) that

$$\text{rank}(\bar{\Omega}) + \text{rank}(G(\bar{x})) \leq p.$$

It is said that the *strict complementarity* condition holds at  $\bar{x}$  if there is a Lagrange multipliers matrix  $\bar{\Omega}$  such that

$$\text{rank}(\bar{\Omega}) + \text{rank}(G(\bar{x})) = p.$$

It is possible to show that, in a certain sense, strict complementarity is also a generic property ([2]). Under the strict complementarity condition, nondegeneracy of  $\bar{x}$  is a necessary and sufficient condition for uniqueness of the corresponding Lagrange multipliers matrix.

## Second Order Optimality Conditions

In the convex (and, in particular, in the linear) case first order conditions (7) are also sufficient for a feasible point  $\bar{x}$  to be an optimal solution of the problem (1).

However, even in the convex case second order optimality conditions can be an important part of the analysis, e. g. second order conditions are intimately related to stability properties of the corresponding optimal solutions. From now on we assume that  $f(x)$  and  $G(x)$  are twice continuously differentiable.

Let  $\bar{x}$  be a *stationary* point of the problem (1), i. e.  $\bar{x}$  is feasible and there exists a Lagrange multipliers matrix  $\bar{\Omega}$  satisfying first order optimality conditions (7). With  $\bar{x}$  is associated the so-called *critical cone*

$$C(\bar{x}) := \left\{ h : \begin{array}{l} h^\top \nabla f(\bar{x}) = 0, \\ dG(\bar{x})h \in T_{S_{\bar{\Omega}}}(G(\bar{x})) \end{array} \right\}.$$

This critical cone represents those directions  $h \in \mathbf{R}^n$  for which first order conditions (7) do not provide an information about optimality of  $\bar{x}$ . Let us denote by  $\Lambda(\bar{x})$  the set of all Lagrange multipliers matrices  $\bar{\Omega}$  satisfying conditions (7), and suppose that the constraint qualification (8) holds. Recall that  $\Lambda(\bar{x})$  is non empty and bounded if and only if the constraint qualification (8) is satisfied. We can write now second order conditions for  $\bar{x}$  to be a locally optimal solution of the problem (1) as follows ([3,10]).

- Second order *necessary* conditions: for any critical direction  $h \in C(\bar{x})$  there exists a Lagrange multipliers matrix  $\bar{\Omega} \in \Lambda(\bar{x})$  such that

$$h^\top \nabla_{xx}^2 L(\bar{x}, \bar{\Omega})h + h^\top H(\bar{x}, \bar{\Omega})h \geq 0. \quad (10)$$

- Second order *sufficient* conditions: for any nonzero critical direction  $h \in C(\bar{x})$  there exists a Lagrange multipliers matrix  $\bar{\Omega} \in \Lambda(\bar{x})$  such that

$$h^\top \nabla_{xx}^2 L(\bar{x}, \bar{\Omega})h + h^\top H(\bar{x}, \bar{\Omega})h > 0. \quad (11)$$

Here  $\nabla_{xx}^2 L(\bar{x}, \bar{\Omega})$  stands for the Hessian matrix of second order partial derivatives and  $H(\bar{x}, \bar{\Omega})$  denotes the  $n \times n$  symmetric matrix whose  $ij$ -element is

$$[H(\bar{x}, \bar{\Omega})]_{ij} := -2 \operatorname{trace} \left( \bar{\Omega} G_i [G(\bar{x})]^\dagger G_j \right),$$

where  $G_i := \frac{\partial G(\bar{x})}{\partial x_i}$  and  $[G(\bar{x})]^\dagger$  denotes the Moore-Penrose pseudo-inverse of the matrix  $G(\bar{x})$ .

Note that there is no gap between the above second order necessary and sufficient conditions in the sense that the weak inequality sign in (10) is replaced by the strict inequality in (11). The additional term

$h^\top H(\bar{x}, \bar{\Omega})h$ , which appears in the above conditions, represents the *curvature* of the set  $S_{\bar{\Omega}}^p$ . The matrix  $H(\bar{x}, \bar{\Omega})$  is positive semidefinite, and therefore this ‘curvature term’ is always nonnegative.

In fact, the above second order sufficient conditions (11) are equivalent to the so-called *second order growth* condition: there exists a constant  $\alpha > 0$  such that for all feasible  $x$ , i. e. satisfying  $G(x) \in S_{\bar{\Omega}}^p$ , in a neighborhood of  $\bar{x}$  the inequality

$$f(x) \geq f(\bar{x}) + \alpha \|x - \bar{x}\|^2 \quad (12)$$

holds. If the semidefinite programming problem is linear, then all elements of the Hessian matrix  $\nabla_{xx}^2 L(\bar{x}, \bar{\Omega})$  are zeros, and hence the first term in (10) and (11) vanishes. Nevertheless, even in the linear case the second (curvature) term can be positive, and the second order growth condition (12) can hold.

If the point  $\bar{x}$  is nondegenerate, then there exists a unique Lagrange multipliers matrix  $\bar{\Omega}$ , and if, moreover, the strict complementarity condition holds, then the critical cone becomes a linear space and can be written as

$$C(\bar{x}) = \left\{ h : \sum_{i=1}^n h_i E^\top G_i E = 0 \right\}.$$

## Stability Analysis

Suppose now that the considered semidefinite programming problem is subject to perturbations. That is, consider the following family of optimization problems

$$\begin{cases} \min_{x \in \mathbf{R}^n} & f(x, u) \\ \text{s.t.} & G(x, u) \preceq 0, \end{cases} \quad (13)$$

depending on the parameter vector  $u \in \mathbf{R}^m$  guiding perturbations of the above problem. We assume that  $f(x, u)$  and  $G(x, u)$  are twice continuously differentiable and that for a given value  $u = u_0$  of the parameter vector, problem (13) coincides with the ‘unperturbed’ problem (1). For example, in the linear case we can view some of the matrices  $A_i$  as parameter vectors which are subject to perturbations.

Let us denote by  $S(u)$  the set of optimal solutions of the parametric problem (13). What can be said about continuity properties of  $S(u)$ , as a function of the pa-

parameter vector  $u$ ? Note that  $S(u)$  can have more than one element and can be empty. It is possible to construct examples where the optimal-solutions set  $S(u_0)$ , of the unperturbed problem, is non empty while  $S(u)$  is empty for arbitrary small changes in  $u$ . Of course such examples are pathological and unsuitable for numerical analysis since arbitrary small perturbations of the data may result in unsolvability of the considered problem.

It is possible to give various conditions ensuring continuity (upper semicontinuity) of  $S(u)$ . For example, in the convex (linear) case, if  $S(u_0) = \{\bar{x}\}$  is a singleton (i. e. the unperturbed problem has the unique optimal solution  $\bar{x}$ ) and the Slater condition holds, then any optimal solution  $\hat{x}(u) \in S(u)$ , of the parametric problem (13), converges to  $\bar{x}$  as  $u \rightarrow u_0$ . Yet even if  $\hat{x}(u)$  is continuous at  $u = u_0$ , the rate at which it changes can be much faster than the rate of change of  $u$ , i. e. small perturbations in  $u$  can bring large changes in the corresponding optimal solution. In that case the problem is said to be *ill-conditioned* and may be difficult for a numerical solution.

It is said that an optimal solution  $\bar{x}$ , of the unperturbed problem, is *stable* if for all  $u$  sufficiently close to  $u_0$  the optimal-solutions set  $S(u)$  is non empty and  $\hat{x}(u) \rightarrow \bar{x}$ , as  $u \rightarrow u_0$ , for any  $\hat{x}(u) \in S(u)$ . If, moreover, there is a positive constant  $\kappa$  such that

$$\|\hat{x}(u) - \bar{x}\| \leq \kappa \|u - u_0\|, \quad (14)$$

then  $\bar{x}$  is said to be *Lipschitz stable*.

It is not difficult to show that if the constraint mapping  $G(x, u) = G(x)$  does not depend on  $u$ , and hence the feasible set of (13) is fixed, then the second order growth condition (12) is a sufficient condition for a stable optimal solution  $\bar{x}$  to be Lipschitz stable. The general case is more subtle and, in order to ensure Lipschitz stability of  $\bar{x}$ , some additional conditions are required (see [4] for an extensive discussion of that type results).

Let us finally remark that if the point  $\bar{x}$  is nondegenerate and the strict complementarity condition holds, then the optimal solution  $\hat{x}(u)$  is a continuously differentiable function of the parameter vector ([10]). In that case one can approximately evaluate the constant  $\kappa$  in (14) by using the corresponding linear approximation (first order Taylor expansion) of  $\hat{x}(u)$  at  $u_0$ . It turns out that the rate of change of  $\hat{x}(u)$  is closely related to conditioning of the matrix  $\nabla_{xx}^2 L(\bar{x}, \bar{\Omega}) + H(\bar{x}, \bar{\Omega})$ , used

in the corresponding second order optimality conditions, restricted to the critical cone  $C(\bar{x})$  which is a linear space in that case.

## Introduction

Research on ad hoc wireless sensor networks has increased greatly in recent years [24]. Sensor networks usually consist of a large number of sensors which are deployed to collect data of interest. Such networks are versatile tools which provide a low-cost method of target tracking, as well as monitoring seismic activity, temperature, sound levels, and light [9]. Information gathered by the sensors is only useful if the positions of the sensors are known. However, it is often the case that the use of a GPS system is too costly or, consumes too much

power, or the network is being deployed in a location in which GPS is denied [21].

Recently, techniques have been developed which estimate the node locations based on a mixture of distance measurements and angle measurements between pairs of nodes in the network. This problem is referred to as the Sensor Network Localization Problem, (SNLP) and can be formally stated as follows: Given the true positions of some of the nodes and the pair-wise distances between some nodes, how can the positions of all of the nodes be estimated? [6,9,28].

## Organization

Throughout the article, we will investigate the SNLP. In the following section, we formally define the problem statement and in Sect. “Methods”, we review several solution techniques which appear throughout the literature. In Subsect. “Semidefinite Programming Model”, we describe a semidefinite programming (SDP) model for the problem. We then provide a general assessment of this approach and describe some implementation details. We highlight this method specifically because of its advantages over heuristic methods. Particularly, the SDP method is known to localize any network whenever a unique solution exists, and to do so in polynomial time. We provide some concluding remarks in Sect. “Conclusion” and indicate directions of future research. Finally, a list of cross references is provided in Sect. “See also”. We conclude this section with an introduction to some of the symbolology that will appear most prevalently throughout the article.

## Idiosyncrasies

Here we briefly introduce some of the symbols and notations we will employ throughout this paper. Define the trace of a symmetric matrix  $A$ , denoted  $\text{Trace}(A)$  as the sum of the diagonal entries. The standard trace inner product of two matrices  $A$  and  $B$  is given as  $\langle A, B \rangle = \text{Trace}(A^T B)$ . The 2-norm of a vector  $x$  is denoted as  $\|x\|$  and is defined to be  $\sqrt{\langle x, x \rangle}$ . A positive semidefinite matrix  $A$  will be denoted as  $A \succeq 0$ . Agree to let  $I_d$  and  $\mathbf{0}_d$  respectively represent the identity matrix and a vector containing all zeros, both with dimension  $d \in \mathbb{Z}$ . Finally, we will use *italics* for emphasis, *CALLIGRAPHY*

to refer to formulations, and Small Caps for problem names. Any other locally used terms and symbols will be defined in the sections in which they appear.

## Formulation

A wireless sensor network is typically made up of a number of densely distributed sensors that collect data. An instance of the SNLP consists of a set of  $m$  so-called *anchor* points whose positions are known a priori [9,12,22]. The object is to determine the location of  $n$  *sensor* points in the system based upon information obtained from the anchor sensors. Let the anchor points and the sensor points be respectively denoted as  $a_1, a_2, \dots, a_m \in \mathbb{R}^d$  and  $x_1, x_2, \dots, x_n \in \mathbb{R}^d$ . The Euclidean distances  $\bar{d}_{kj}$  between points  $a_k$  and  $x_j$  for some  $k, j$ , and  $d_{ij}$  between  $x_i$  and  $x_j$  for some  $i < j$  are also given. Let  $N_a = \{(k, j) : \bar{d}_{k,j} \text{ is specified}\}$  denote the sensor/sensor pairs and  $N_x = \{(i, j) : i < j, d_{ij} \text{ is specified}\}$  represent the sensor/anchor. Then the sensor network localization problem as defined in [9] is to find the localization (estimated position) of  $x_1, x_2, \dots, x_n \in \mathbb{R}^d$  such that:

$$\begin{aligned} \text{SNLP} : \quad & \|a_k - x_j\|^2 = \bar{d}_{kj}^2, \forall (k, j) \in N_a, \text{ and} \\ & \|x_i - x_j\|^2 = d_{ij}^2, \forall (i, j) \in N_x. \end{aligned} \quad (1)$$

From this seemingly simple formulation, many difficult questions arise. For a given instance of the SNLP, does this instance have a realization in the required dimension? If so, is the realization unique? We should note that these two seemingly related questions are quite different from a computational perspective. It has been shown that determining if an instance of the SNLP has a unique realization in  $\mathbb{R}^2$  can be determined efficiently under certain assumptions [20]. On the other hand, it remains  $\mathcal{NP}$ -complete [17] to compute a realization on the plane, even if the instance is *known* to have a unique realization [5]. This is the main problem of interest in this article.

## Methods

In this section, we review several solution methods which have been applied to the SNLP. Particularly in Subsect. “**Semidefinite Programming Model**”, we highlight the techniques of Ye et al. [1,8,9,28] and the ap-

plication of semidefinite programming methods for efficiently computing solutions to large-scale instances of the SNLP under a variety of circumstances.

## Review of Solution Approaches

Several techniques have been applied to the SNLP, all having some redeeming qualities [9,16,18]. Several techniques involve the use of distance or angle measurements between the anchor points in order to compute a localization [13,15,23,25,26,27]. Another common technique used by Bulusu et al. [11] and Howard et al. [19] is to employ a grid or a set of surveyed points whose locations are known. Then, the sensor localization is attempted using the relative distances between sensors and the set of *beacon* points [9].

The so-called “DV-Hop” technique of Niculescu and Nash [23] is an efficient method in dense topologies whereby the anchor nodes flood the network with their location information. This allows other points to *triangulate* their positions based on the information of the anchor nodes. This information is then passed along to other sensor nodes who use the combined locations to triangulate their positions. However, for widely dispersed and irregular topologies, the relative errors in the node estimation tends to be fairly substantial.

A similar technique proposed by Savarese et al. [25] uses a method similar to the “DV-Hop” algorithm described above to provide a rough estimate of the location information. These estimates are then improved by applying a least-squares triangulation using these estimates as well as a new collection of estimated positions [9].

The “iterative multilateration” technique of Savvides et al. [26] is another effective method especially when the number of anchor nodes is relatively high. This method calculates via triangulation the positions of those nodes that are adjacent to at least three anchor points. Then these new localized nodes become anchor points and the process continues. In the end every node in the network has become an anchor.

In [15], the so-called “multidimensional scaling” algorithm is proposed. The heuristic begins by making an initial estimate of the node positions based solely on the connectivity and basic distance and angle information of the *non-anchor* nodes. Then using a variant of singular value decomposition [29], a map is generated

of the relative locations of the nodes. Finally, these estimates are greatly improved and an absolute global map is produced by taking into account the locations of the anchor nodes and updating the estimates accordingly.

The work of Doherty et al. [13] involves a technique in which linear bounding hyperplanes are used to model the proximity constraints on the nodes which can communicate with each other as convex constraints [1,9]. However, these constraints are often too loose and provide solutions which are not helpful in terms of calculating the unique realization of the sensors.

As we see, the drawback with most sensor network localization techniques involving heuristics is that they do not always find a unique solution even when it exists, or require excessive computation time to do so [28]. A recently developed method introduced by So and Ye in [28] uses a semidefinite programming (SDP) model that guarantees the discovery of a unique solution when it exists. Furthermore, the solution can be computed in polynomial time. In the following subsection, we present the SDP model, discuss the motivation behind using this approach and analyze some properties of the model.

### Semidefinite Programming Model

A semidefinite program is a convex optimization problem where the objective function is linear and the constraint is defined by a linear matrix inequality. Given a vector  $c \in \mathbb{R}^m$ , and  $m + 1$  symmetric matrices  $F_0, F_1, \dots, F_m \in \mathbb{R}^{n \times n}$ , a semidefinite program can be written in the form:

$$\min_{x \in \mathbb{R}^m} \{c^T x | F(x) \succeq 0\},$$

where  $F(x) = F_0 + \sum_{i=1}^m x_i F_i$ , and  $F(x) \succeq 0$  implies that  $F(x)$  is positive semidefinite [14,30]. Hence, both the objective function and the constraint are convex, and therefore semidefinite programs are closely related to linear programs, and many algorithms for solving linear programming problems have generalizations that apply to semidefinite programs as well [30].

In [28], the authors note that (1) is a non-convex optimization problem, which is difficult to solve in general. They propose a SDP relaxation by converting the nonconvex quadratic distance constraints into linear constraints as follows. Specifically, let  $X =$

$[x_1, x_2, \dots, x_n]$  be the  $d \times n$  matrix which we are trying to determine. Let  $e_{ij} \in \mathbb{R}$  be the vector where the  $i$ th position is 1, the  $j$ th position is  $-1$ , and all other entries are zeros. Then for all  $(i, j) \in N_x$ , we have that:

$$\|x_i - x_j\|^2 = e_{ij}^T X^T X e_{ij}. \quad (2)$$

Furthermore, for all  $(k, j) \in N_a$  it follows that

$$\|a_k - x_j\|^2 = (a_k; e_j)^T [I_d; X]^T [I_d; X] (a_k; e_j), \quad (3)$$

where  $e_j$  is a vector of all zeros except for  $-1$  at entry  $j$ , and  $(a_k; e_j) \in \mathbb{R}^{d+n}$  is a vector consisting of  $a_k$  "on top of"  $e_j$  [9]. Using these definitions, we can reformulate the problem as follows.

$$\text{Find } X \in \mathbb{R}^{d \times n} \text{ and } Y \in \mathbb{R}^{n \times n} \quad (4)$$

such that

$$e_{ij}^T Y e_{ij} = d_{ij}^2, \forall (i, j) \in N_x, \quad (5)$$

$$(a_k; e_j)^T \begin{pmatrix} I_d & X \\ X^T & Y \end{pmatrix} (a_k; e_j) = \bar{d}_{kj}^2, \forall (k, j) \in N_a, \quad (6)$$

$$Y = X^T X. \quad (7)$$

The intuition behind the SDP formulation is to relax constraint (7) to  $Y \succeq X^T X$ ; thus implying that  $Y - X^T X$  is positive semidefinite. Boyd et al. [10] among others have shown that a positive semidefinite matrix  $Y - X^T X$  can be expressed as

$$Z = \begin{pmatrix} I_d & X \\ X^T & Y \end{pmatrix} \succeq 0. \quad (8)$$

Define  $Z_{1:d,1:d}$  to be the  $d \times d$  principle submatrix of  $Z$ . Then the SDP relaxation of the SNLP as given in [28], is to find  $Z \in \mathbb{R}^{(d+n) \times (d+n)}$  to:

$$SDP: \quad \text{maximize } 0 \quad (9)$$

subject to

$$Z_{1:d,1:d} = I_d, \quad (10)$$

$$\langle (\mathbf{0}; e_{ij})(\mathbf{0}; e_{ij})^T, Z \rangle = d_{ij}^2, \forall (i, j) \in N_x, \quad (11)$$

$$\langle (a_k; e_j)(a_k; e_j)^T, Z \rangle = \bar{d}_{kj}^2, \forall (k, j) \in N_a, \quad (12)$$

$$Z \succeq 0. \quad (13)$$

Notice that by definition, any feasible solution matrix  $Z$  must have at least rank  $d$  [9]. We can formulate the dual of the SDP relaxation as

*SDP-D* : minimize

$$\langle I_d, V \rangle + \sum_{(i,j) \in N_x} y_{ij} d_{ij}^2 + \sum_{(k,j) \in N_a} w_{kj} \bar{d}_{kj}^2 \quad (14)$$

subject to

$$\begin{pmatrix} V & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} + \sum_{(i,j) \in N_x} y_{ij} (\mathbf{0}; e_{ij})(\mathbf{0}; e_{ij})^T + \sum_{(k,j) \in N_a} w_{kj} (a_k; e_j)(a_k; e_j)^T \geq \mathbf{0}. \quad (15)$$

Notice that the dual formulation is always feasible. In particular having  $V = 0$ ,  $y_{ij} = 0$  for all  $(i, j) \in N_x$ , and  $w_{kj} = 0$  for all  $(k, j) \in N_a$  forms a feasible solution.

In [28], So and Ye postulate and prove several results regarding the above formulations. We will highlight the key theorems and provide a basic analysis. For detailed proofs and a more in-depth study, see [28].

The first result provides a class of instances for which the SDP relaxation is exact, i. e. for instances when the matrix  $Z$  has rank  $d$ . Suppose that formulation *SDP* is feasible. This implies that the distance measurements  $d_{ij}$  and  $\bar{d}_{kj}$  are exact for the positions  $\bar{X} = [\bar{x}_1, \dots, \bar{x}_n]$ . Then, we have the following result.

**Theorem 1** *Let  $\bar{Z}$  be a feasible solution for SDP and  $\bar{U}$  be an optimal slack matrix of SDP-D. Then by the duality theorem for semidefinite programming [4], it follows that:*

1.  $\langle \bar{Z}, \bar{U} \rangle = 0$ ;
2.  $\text{rank}(\bar{Z}) + \text{rank}(\bar{U}) \leq d + n$ ;
3.  $\text{rank}(\bar{Z}) \geq d$  and  $\text{rank}(\bar{U}) \leq n$ .

A immediate consequence of this theorem is that for optimal dual slack matrices  $\bar{U}$  such that  $\text{rank}(\bar{U}) = n$ , it follows that  $\text{rank}(\bar{Z}) = d$ . Therefore, formulation *SNLP* is equivalent to formulation *SDP* implying that the *SNLP* formulation can be solved optimally in polynomial time [28].

The next theorem establishes the existence of a large group of efficiently localizable graphs.

**Theorem 2** *Suppose that the network in question is connected. Then the following are equivalent:*

1. *Problem SNLP is uniquely localizable.*
2. *The max-rank solution matrix of SDP has rank  $d$ .*
3. *The solution matrix of SDP, represented by (8), satisfies  $Y = X^T X$ .*

This theorem has several significant implications. First, we have that as long as *SNLP* has a unique localization, then it can be computed in polynomial time by solving the corresponding semidefinite relaxation. The converse also holds. That is, if the solution matrix to the semidefinite relaxation  $X$  has rank  $d$ , then  $X$  is the unique localization for formulation *SNLP* [28]. Lastly, as we mentioned above we have the existence of a family of graphs for which the localization can be efficiently computed despite the underlying *NP*-completeness of the SNLP in general.

The seminal work of So and Ye [28] which we highlighted above provides a baseline to which many extensions can be made. To begin with, the results presented above are based on the assumption that the distance measurements are exact. The work of Biswas et al. in [9] provides extensions to handle inaccurate and incomplete measurements. This greatly improves the robustness of the SDP formulation, making the model more applicable to real-world scenarios in which inaccuracies are inevitable. Furthermore, in [1] the authors provide SDP formulations of the SNLP which incorporate angle information which can be used alone or in concert with distance information to calculate sensor realizations. This method is particularly useful when the sensors can detect multiple angles [1]. We see that many extensions are possible and that the by using semidefinite programming methods, a large class of sensor network localization problems are able to be solved more efficiently and effectively than by previous heuristic techniques.

## Conclusion

The focus of this article was the sensor network localization problem (SNLP), with particular attention given to a set of robust solution technique based on a semidefinite programming model. After an introduction to the problem, we highlighted several solution approaches which have been applied. Next, we presented an analyzed the SDP formulation of So and Ye [28]. The results proved for the SDP relaxation of the SNLP have provided a framework which can be extended to other

problems in distance geometry in which angle and distance information are mutual between pairs of points. Such problems include Euclidean ball packing and most recently 3-dimensional molecule conformation problems [7].

### Keywords

Optimal design; Linearly elastic systems; Semidefinite programming; Interior point methods

*Structural design* (SD) deals with optimal design of *linearly elastic mechanical constructions*. Mathematically, the SD problem is as follows. We are considering a mechanical construction  $S$  with finitely many degrees of

freedom  $M$ , so that virtual displacements of  $S$  are specified by vectors  $w \in \mathbf{R}^M$ . We are also given a set  $W \subset \mathbf{R}^M$  of *kinematically admissible displacements*. The energy of elastic deformation of  $S$  under a displacement  $w$  is a nonnegative quadratic form  $w^T B w / 2$  of the displacement.  $B$  is a symmetric positive semidefinite matrix characterizing  $S$ ; this matrix is assumed to depend linearly on the vector  $t$  of design parameters of the construction:  $B = B(t)$ .

The construction can be subject to an external *load*; mathematically, a load is a vector  $f \in \mathbf{R}^M$ . The equilibrium displacement  $W_f$  caused by the load minimizes the potential energy  $w^T B(t) w / 2 - f^T w$  over  $w \in W$ :

$$w_f \in \underset{w \in W}{\operatorname{Argmax}} \left[ f^T w - \frac{1}{2} w^T B(t) w \right]; \quad (1)$$

the corresponding optimal value

$$\operatorname{compl}(f; t) = \sup_{w \in W} \left[ f^T w - \frac{1}{2} w^T B(t) w \right] \quad (2)$$

— the *compliance* of  $S$  under load  $f$  — indicates how stiff is the construction w.r.t. the load (the less is the compliance, the better).

The SD problem in its general setting is:

- Given a set  $F \subset \mathbf{R}^M$  of tentative loads and a set  $T$  of admissible values of the design vector  $t$ , find  $t \in T$  which minimizes the worst-case, w.r.t. loads from  $F$ ,
- compliance:

$$(P_{ini}) \quad \begin{cases} \min & \operatorname{compl}_F(t) \\ & \equiv \sup_{f \in F} \operatorname{compl}(f; t) \\ \text{s.t.} & t \in T. \end{cases}$$

The outlined general setting has two particular cases of especial interest.

### Truss Design

A *truss* is a construction, like an electric mast or the Eifel Tower, comprised of thin *elastic bars* linked with each other at *nodes*. In the standard truss topology design problem the nodes form a given finite set in  $\mathbf{R}^d$  ( $d = 2$  for planar and  $d = 3$  for spatial trusses), and all pair connections of the nodes by bars are allowed. Virtual displacements of a node form a given linear subspace of  $\mathbf{R}^d$ , and the space  $\mathbf{R}^M$  of virtual displacements

of the truss is the direct product of these subspaces over all nodes. The set  $W$  of admissible displacements is cut off  $\mathbf{R}^M$  by a number of inequality constraints (typically linear) representing *obstacles* – restrictions on the displacements of the nodes coming from absolutely rigid partial supports.

The design variables of the truss are volumes  $t_\ell$  of all tentative bars, and the corresponding matrix  $B(t)$  is  $B(t) = \sum_{\ell=1}^N b_\ell b_\ell^\top t_\ell$ , where  $N$  is the number of tentative bars and the vectors  $b_\ell \in \mathbf{R}^M$  are readily given by the geometry of the nodal set. An external load – a collection of physical forces acting at the nodes of truss – can be identified with a vector  $f \in \mathbf{R}^M$ , and the equilibrium displacement and compliance of truss associated with load  $f$  are given by (1), (2), respectively.

The set  $T$  of feasible design vectors always is a subset of  $\mathbf{R}_+^N$  (bar volumes must be nonnegative) satisfying the *resource constraint*  $\sum_{\ell=1}^N t_\ell \leq v$  (upper bound on the weight of the truss); the description of  $T$  may include also some other, normally linear, constraints.

## Shape Design

A *shape* is a construction comprised of material continuously distributed in a given 2D or 3D domain  $\Omega$ , the mechanical properties of the material varying from point to point. Thus, a shape is a distributed mechanical system with infinitely many degrees of freedom. In order to get a computationally tractable model, a *finite element approximation* is applied. Specifically,

- the infinite-dimensional space of displacements of the actual construction (the space of vector fields on  $\Omega$ ) is approximated by its finite-dimensional subspace  $\mathbf{R}^M$ ;
- $\Omega$  is partitioned into  $N$  cells  $C_\ell$ ,  $\ell = 1, \dots, N$ , and the mechanical properties of the material are assumed to be constant within every cell.

With this approximation, the energy of elastic deformation of shape under displacement  $w$  is

$$E(w) = \frac{1}{2} \sum_{\ell=1}^N v_\ell^{-1} \text{Tr} \left( t_\ell \int_{C_\ell} e_P(w) e_P^\top(w) dP \right), \quad (3)$$

where  $\text{Tr}$  stands for the trace, and

- $v_\ell$  is the  $d$ -dimensional volume of  $C_\ell$ ;

- $e_P(w)$  is the *strain tensor* associated with displacement  $w$  at a point  $P \in \Omega$ ; the only property of this tensor important in our context is that  $e_P(w)$  is an  $L_\infty$  function of  $P$  taking values in the Euclidean space  $\mathbf{R}^D$  ( $D = d(d+1)/2$ ) linearly depending on  $w$ ;
- $v_\ell^{-1} t_\ell$  is the ‘rigidity tensor’ of the material specifying the mechanical properties of the material in cell  $C_\ell$ ; mathematically,  $t_\ell$  is a symmetric positive semidefinite  $D \times D$  matrix.

After finite element approximation, the set of kinematically admissible displacements becomes a subset  $W$  of  $\mathbf{R}^M$ , an external load acting at a shape can be identified with a vector  $f \in \mathbf{R}^M$ , the equilibrium displacement  $w_f$  of the shape minimizes the potential energy  $E(w) - f^\top w$ :

$$w_f \in \underset{w \in W}{\text{Argmax}} [f^\top w - E(w)], \quad (4)$$

and the rigidity properties of the shape w.r.t. the load are measured by the compliance

$$\text{compl}(t; f) = \sup_{w \in W} [f^\top w - E(w)]. \quad (5)$$

The set  $T$  of feasible design vectors is always a subset of the set  $(\mathbf{S}_+^D)^N$ ,  $\mathbf{S}_+^D$  being the cone of positive semidefinite  $D \times D$  matrices (the rigidity tensors must be positive semidefinite). Typical additional restrictions defining  $T$  are the ‘resource constraints’ imposed on the quantities  $\text{Tr}(t_\ell)$  (these quantities in a sense measure densities of the material in the cells). The most important case is the one of

$$T = \left\{ t = (t_1, \dots, t_N): \begin{array}{l} t_\ell \in \mathbf{S}^D, t_\ell \geq 0, \\ \underline{\rho}_\ell \leq \text{Tr}(t_\ell) \leq \bar{\rho}_\ell, \\ l = 1, \dots, N; \\ \sum_{\ell=1}^N \text{Tr}(t_\ell) \leq v \end{array} \right\}, \quad (6)$$

$$\left\{ \begin{array}{l} 0 \leq \underline{\rho}_\ell \leq \bar{\rho}_\ell < \infty, \quad l = 1, \dots, N; \\ \sum_{\ell=1}^N \underline{\rho}_\ell < v, \end{array} \right.$$

where  $\mathbf{S}^D$  is the space of symmetric  $D \times D$  matrices and the relation  $A \geq B$  for  $A, B \in \mathbf{S}^D$  means that  $A - B$  is symmetric positive semidefinite.

## ‘Standard Case’ of the SD Problem

The truss and the shape problems are covered by a single particular case of  $(P_{\text{ini}})$ , the one where the ‘design

variables'  $t_\ell$  are positive semidefinite symmetric matrices of certain row dimension  $D$ , the constraints defining  $T$  are restrictions on the vectors comprised of traces of these matrices, and

$$B(t) = \sum_{\ell=1}^N \sum_{s=1}^S b_{\ell s} t_\ell b_{\ell s}^\top, \tag{7}$$

where  $b_{\ell s}$  are given  $M \times D$  matrices.

Indeed, the truss problem clearly fits the indicated scheme (with  $D = S = 1, v_\ell = 1, l = 1, \dots, N$ ). In the case of the shape problem, there always exist  $S$  'quadrature grids'  $\{P_{\ell s} \in C_\ell\}_{s=1}^S$  and 'quadrature weights'  $\{\gamma_{\ell s}^2\}_{s=1}^S, \ell = 1, \dots, N$ , such that

$$\frac{1}{v_\ell} \int_{C_\ell} e_P(w) e_P^\top(w) dP = \sum_{s=1}^S \gamma_{\ell s}^2 e_{P_{\ell s}}(w) e_{P_{\ell s}}^\top(w)$$

identically in  $w \in \mathbf{R}^M$ . Specifying matrices  $b_{\ell s}$  according to

$$b_{\ell s}^\top w = \gamma_{\ell s} e_{P_{\ell s}}(w), \quad \forall w \in \mathbf{R}^M,$$

the energy (3) becomes  $\frac{w^\top B(t) w}{2}$  with  $B(t)$  given by (7), and relation (5) becomes (2).

**Standard Case**

The 'standard case' of the general SD problem is as follows:

- S.1 The space of the design vectors is the direct product of  $N$  of the spaces  $\mathbf{S}^D$  of symmetric  $D \times D$  matrices, so that the design vector is  $t = (t_1, \dots, t_N) : t_\ell \in \mathbf{S}^D, \ell = 1, \dots, N$ .
  - S.2 The set  $T$  of admissible designs is given by (6).
  - S.3 The mapping  $t \mapsto B(t)$  is given by (7), and the matrix  $\sum_{\ell=1}^N \sum_{s=1}^S b_{\ell s} b_{\ell s}^\top$  is positive definite;
  - S.4 The set  $W$  of kinematically admissible displacements is polyhedral:
- $$W = \{w \in \mathbf{R}^M : Pw \leq p\}, \quad p \in \mathbf{R}^q, \tag{8}$$

and the system of constraints  $Pw \leq p$  satisfies the Slater condition:  $\exists \bar{w} : P\bar{w} < p$ .

**The Set of Loads**

In the traditional literature on structural design (see [1,2,3,4,5,7] and references therein)  $F$  is either a singleton  $\{f\}$  ('single-load case'), or, more generally, a finite set:

$$F = \{f_1, \dots, f_k\}. \tag{9}$$

Recently, a *robust* setting of the problem was proposed and motivated [6], where  $F$  is an ellipsoid:

$$F = \left\{ f = Qu : u \in \mathbf{R}^k, u^\top u \leq 1 \right\}. \tag{10}$$

**Semidefinite Reformulation of  $P_{ini}$**

It turns out that the standard case of the multiload SD problem can be naturally posed as a *semidefinite program*; this is the case for the robust SD problem as well, provided that there are no obstacles ( $W = \mathbf{R}^M$ ). In fact, there are three semidefinite settings of the standard SD problem: the *primal*(P), the *dual*(D) and the *equivalent primal* ( $P^+$ ). The relations between these forms are as follows:

- is, basically, a straightforward semidefinite reformulation of ( $P_{ini}$ );
- (D) is obtained from the *Fenchel dual* of (P) by analytic elimination of part of variables,
- ( $P^+$ ) is obtained from the Fenchel dual of (D) by analytic elimination of part of variables.

The explicit semidefinite forms of the standard truss and shape design problems are as follows.

**Multiload Truss Design**

Here  $T, W, F$  are given by (6) (where  $D = 1$ ), (8) and (9), respectively.

$$(P) \begin{cases} \tau \rightarrow \min \\ \begin{pmatrix} 2[\tau - p^\top y_i] & y_i^\top P - f_i^\top \\ P^\top y_i - f_i & \sum_{\ell=1}^N b_\ell b_\ell^\top t_\ell \end{pmatrix} \succeq 0, \\ i = 1, \dots, k; \\ \underline{\rho}_\ell \leq t_\ell \leq \bar{\rho}, \\ \ell = 1, \dots, N; \\ \sum_{\ell=1}^N t_\ell \leq v; \\ y_i \geq 0, \quad i = 1, \dots, k, \end{cases}$$

$$[\tau, t_\ell \in \mathbb{R}, y_i \in \mathbb{R}^q],$$

$$(D) \left\{ \begin{array}{l} -2 \sum_{i=1}^k f_i^T w_i + \sum_{\ell=1}^N [\bar{\rho}_\ell \sigma_\ell^+ - \underline{\rho}_\ell \sigma_\ell^-] \\ \quad + v\gamma \rightarrow \min \\ \left( \begin{array}{ccc} \alpha_1 & \vdots & b_\ell^T w_1 \\ & \ddots & \vdots \\ & & \alpha_k & \vdots & b_\ell^T w_k \\ \dots & \dots & \dots & \dots & \dots \end{array} \right) \\ \left( b_\ell^T w_1 \quad \dots \quad b_\ell^T w_k \quad \vdots \quad \gamma + \sigma_\ell^+ - \sigma_\ell^- \right) \\ \geq 0, \quad \ell = 1, \dots, N; \\ \sigma_\ell^\pm \geq 0, \quad \ell = 1, \dots, N; \\ \gamma \geq 0; \\ Pw_i \leq \alpha_i p, \quad i = 1, \dots, k; \\ 2 \sum_{i=1}^k \alpha_i = 1 \end{array} \right.$$

$$[\alpha_i, \sigma_\ell^\pm, \gamma \in \mathbb{R}, w_i \in \mathbb{R}^M]$$

$$(P^+) \left\{ \begin{array}{l} \tau \rightarrow \min \\ \left( \begin{array}{ccc} 2[\tau - p^T y_i] & \vdots & q_1^i \quad \dots \quad q_N^i \\ \dots & \dots & \dots \\ & q_1^i & \vdots & t_1 \\ & \vdots & \vdots & \ddots \\ & q_N^i & \vdots & t_N \end{array} \right) \geq 0, \\ i = 1, \dots, k; \\ \underline{\rho}_\ell \leq t_\ell \leq \bar{\rho}_\ell, \\ \ell = 1, \dots, N; \\ \sum_{\ell=1}^N t_\ell \leq v; \\ y_i \geq 0, \quad i = 1, \dots, k; \\ \sum_{\ell=1}^N q_\ell^i b_\ell = f_i - P^T y_i, \\ i = 1, \dots, k, \end{array} \right.$$

$$[\tau, t_\ell, q_\ell^i \in \mathbb{R}, y_i \in \mathbb{R}^q].$$

The simplest truss design problem (single load, no obstacles, trivial bounds on bar volumes:  $\underline{\rho}_\ell = 0, \bar{\rho}_\ell = v$ ) can be reduced to a *linear programming program*. Indeed, in this case (P<sup>+</sup>) is the program

$$\left\{ \begin{array}{l} \frac{1}{2} \sum_{\ell} t_\ell^{-1} q_\ell^2 \rightarrow \min \\ t_\ell \geq 0, \\ \sum_{\ell} t_\ell \leq v, \\ \sum_{\ell} q_\ell b_\ell = f \end{array} \right.$$

$$[t_\ell, q_\ell \in \mathbb{R}, \quad \ell = 1, \dots, N].$$

Partial minimization w.r.t.  $t_\ell$  results in the program

$$\left\{ \begin{array}{l} \frac{1}{2v} \left( \sum_{\ell} |q_\ell| \right)^2 \rightarrow \min \\ \text{s.t.} \quad \sum_{\ell} q_\ell b_\ell = f, \end{array} \right.$$

which is, essentially, an LP program.

### Robust Obstacle-Free Truss Design

Here  $F$  is the ellipsoid (10),  $T$  is given by (6) with  $D = 1$ , and  $W = \mathbb{R}^M$ .

$$(P) \left\{ \begin{array}{l} \tau \rightarrow \min \\ \left( \begin{array}{cc} 2\tau I_k & Q^T \\ Q & \sum_{\ell=1}^N b_\ell b_\ell^T t_\ell \end{array} \right) \succeq 0; \\ \underline{\rho}_\ell \leq t_\ell \leq \bar{\rho}_\ell, \\ \ell = 1, \dots, N; \\ \sum_{\ell=1}^N t_\ell \leq v, \end{array} \right.$$

$$[\tau, t_\ell \in \mathbb{R}]$$

(from now on,  $I_k$  is the  $k \times k$  unit matrix),

$$(D) \begin{cases} -2 \operatorname{Tr}(Q^T w) + \sum_{\ell=1}^N [\bar{\rho}_\ell \sigma_\ell^+ - \underline{\rho}_\ell \sigma_\ell^-] + v\gamma \\ \rightarrow \min \\ \begin{pmatrix} \alpha & w^T b_\ell \\ b_\ell^T w & \gamma + \sigma_\ell^+ - \sigma_\ell^- \end{pmatrix} \succeq 0, \\ \ell = 1, \dots, N; \\ \sigma_\ell^\pm \geq 0, \quad \ell = 1, \dots, N; \\ \gamma \geq 0; \\ 2 \operatorname{Tr}(\alpha) = 1 \\ [\alpha \in \mathbf{S}^k, \sigma_\ell^\pm, \gamma \in \mathbb{R}, w \in \mathbb{R}^{M \times k}], \end{cases}$$

$$(P^+) \begin{cases} \tau \rightarrow \min \\ \begin{pmatrix} 2\tau I_k & \vdots & q_1^T & \cdots & q_N^T \\ \dots & \dots & \dots & \dots & \dots \\ q_1 & \vdots & t_1 & & \\ \vdots & \vdots & & \ddots & \\ q_N & \vdots & & & t_N \end{pmatrix} \succeq 0; \\ \underline{\rho}_\ell \leq t_\ell \leq \bar{\rho}_\ell, \\ \ell = 1, \dots, N; \\ \sum_{\ell=1}^N t_\ell \leq v; \\ \sum_{\ell=1}^N b_\ell q_\ell = Q \\ [\tau \in \mathbb{R}, t_\ell \in \mathbf{S}^D, q_\ell^T \in \mathbb{R}^k] \end{cases}$$

**Multiload Shape Design**

Here  $T, W, F$  are given by (6) (where  $D = 3$  for planar and  $D = 6$  for spatial shapes), (8), (9), respectively.

$$(P) \begin{cases} \tau \rightarrow \min \\ \begin{pmatrix} 2[\tau - p^T y_i] & y_i^T P - f_i^T \\ P^T y_i - f_i & \sum_{\ell=1}^N \sum_{s=1}^S b_{\ell s} t_\ell b_{\ell s}^T \end{pmatrix} \succeq 0, \\ i = 1, \dots, k; \\ t_\ell \geq 0, \quad \ell = 1, \dots, N; \\ \underline{\rho}_\ell \leq \operatorname{Tr}(t_\ell) \leq \bar{\rho}_\ell, \quad \ell = 1, \dots, N; \\ \sum_{\ell=1}^N \operatorname{Tr}(t_\ell) \leq v; \\ y_i \geq 0, \quad i = 1, \dots, k \\ [\tau \in \mathbb{R}, t_\ell \in \mathbf{S}^D, y_i \in \mathbb{R}^q] \end{cases}$$

$$(D) \begin{cases} -2 \sum_{i=1}^k f_i^T w_i + \sum_{\ell=1}^N [\bar{\rho}_\ell \sigma_\ell^+ - \underline{\rho}_\ell \sigma_\ell^-] + v\gamma \rightarrow \min \\ \begin{pmatrix} \alpha_1 I_S & & \vdots & B_\ell[w_1] \\ & \ddots & \vdots & \\ & & \alpha_k I_S & \vdots & B_\ell[w_k] \\ \dots & \dots & \dots & \dots & \dots \\ B_\ell^T[w_1] & \cdots & B_\ell^T[w_k] & \vdots & (\gamma + \sigma_\ell^+ - \sigma_\ell^-) I_D \end{pmatrix} \\ \succeq 0, \quad \ell = 1, \dots, N; \\ \sigma_\ell^\pm \geq 0, \quad \ell = 1, \dots, N; \\ \gamma \geq 0; \\ Pw_i \leq \alpha_i p, \quad i = 1, \dots, k; \\ 2 \sum_{i=1}^k \alpha_i = 1 \\ [\alpha_i, \sigma_\ell^\pm, \gamma \in \mathbb{R}, w_i \in \mathbb{R}^M], \end{cases}$$

where  $B_\ell[w] = \begin{pmatrix} w^T b_{\ell 1} \\ \vdots \\ w^T b_{\ell S} \end{pmatrix}$ ,

$$(P^+) \begin{cases} \tau \rightarrow \min \\ \begin{pmatrix} 2[\tau - p^T y_i] & \vdots & [q_1^i]^T & \cdots & [q_N^i]^T \\ \dots & \dots & \dots & \dots & \dots \\ q_1^i & \vdots & t_1 & & \\ \vdots & \vdots & & \ddots & \\ q_N^i & \vdots & & & t_N \end{pmatrix} \succeq 0, \\ i = 1, \dots, k; \\ \left[ q_\ell^i = \begin{pmatrix} q_{\ell 1}^i \\ \vdots \\ q_{\ell S}^i \end{pmatrix}, t_\ell = \begin{pmatrix} t_\ell & & \\ & \ddots & \\ & & t_\ell \end{pmatrix} \right] \\ \underline{\rho}_\ell \leq \operatorname{Tr}(t_\ell) \leq \bar{\rho}_\ell, \quad \ell = 1, \dots, N; \\ \sum_{\ell=1}^N \operatorname{Tr}(t_\ell) \leq v; \\ y_i \geq 0, \quad i = 1, \dots, k; \\ \sum_{\ell=1}^N \sum_{s=1}^S b_{\ell s} q_{\ell s}^i = f_i - P y_i^T, \quad i = 1, \dots, k; \\ [\tau \in \mathbb{R}, t_\ell \in \mathbf{S}^D, q_{\ell s}^i \in \mathbb{R}^D, y_i \in \mathbb{R}^q]. \end{cases}$$

**Robust Obstacle-Free Shape Design**

Here  $T$  is given by (6) (where  $D = 3$  for planar and  $D = 6$  for spatial shapes),  $F$  is the ellipsoid (10) and  $W = \mathbf{R}^M$ .

### Problem Statement and Early Numerical Solution Methods

Consider the linear semi-infinite programming problem LSIP, where ‘s.t.’ means ‘subject to’ throughout this paper:

$$\begin{cases} v_P = \max c^\top x \\ \text{s.t.} & f(x, t) \leq 0, \\ & t \in T, \quad d_* \leq x \leq d^*, \end{cases} \quad (1)$$

where

$$\begin{aligned} f(x, t) &= a^\top(t)x - b(t), \quad t \in T = [t_*, t^*], \\ x, c, d_*, d^* &\in \mathbb{R}^n; \\ a(\cdot) \in \mathbb{R}^n, \quad b(\cdot) &\in \mathbb{R}, \end{aligned}$$

are differentiable functions. Its *dual semi-infinite program* DLSIP is:

$$\begin{cases} v_D = \inf \int_T b(t) d\alpha(t) + \sum_{r=1}^n v_r^+ d_r^* + v_r^- d_{*r} \\ \text{s.t.} & \int_T a_r(t) d\alpha(t) + v_r^+ - v_r^- = c_r, \\ & r = 1, \dots, n, \end{cases}$$

where  $\alpha$  is a nonnegative *Riemann–Stieltjes measure* [13], and  $v_r^+, v_r \geq 0$ .

Examples in transportation theory and wavelet filter design are given, respectively, in [18,19]. In [4, Thm. 4] it is proved that  $v_P = v_D$ , but the infimum need not be attained. This equation is termed the *duality equality*.

*Example 1*

$$\max \left\{ -x_1: \begin{array}{l} -tx_1 - t^2x_2 \leq 0, \quad \forall t \in [0, 1], \\ -1 \leq x_i \leq 1, \quad i = 1, 2 \end{array} \right\}.$$

Here the common program value is 0 but it is not attained in the dual.

In the 1970s however algorithms were developed under more regularity.

**Definition 2** The linear system (1) satisfies the *Slater condition* if there exists  $\bar{x}, d_* \leq \bar{x} \leq d^*$ , for which it is satisfied strictly with  $\bar{x}$ .

With the Slater condition S.-Å. Gustafson [9] supplemented the necessary complementarity conditions (analogous to LP) with the now classical *matching of derivative conditions*, see also [11, (2.3)–(2.8)]. Rather than reviewing these we focus on recent extensions (appearing in Russian) of Gustafson's well known *three phase algorithm*, see [8,10]. [12, Fig. 28-1] presents the logic flow of semi-infinite programming algorithms appearing in 1973.

### The Support Problems Method Developed in Belarus

The support problems method was suggested in [6] and further developed and algorithmically implemented in [24]. It is based on the principle of eliminating the subsets of the index set ( $T$ ) where the constraints are violated. The first component consists of technical procedures for forming, solving, and analyzing sequences of LP problems having a small number of constraints which does not depend on a preassigned accuracy. The second component is a finishing procedure which roughly speaking employs a Newton procedure on a system of nonlinear necessary conditions (the matching of derivatives). However, the method is the most general available of the hybrid types [14] because it uses higher order derivatives.

We assume the set of feasible solutions of LSIP is nonempty, namely,

$$X = \left\{ x \in \mathbb{R}^n: \begin{array}{l} f(x, t) \leq 0, \quad \forall t \in T, \\ d_* \leq x \leq d^* \end{array} \right\}.$$

Define

$$\begin{aligned} J &= \{1, \dots, n\}, \\ f^{(s)}(x, t) &= \frac{\partial f(x, t)}{\partial t^s}, \\ a^{(s)}(t) &= \left( a_j^{(s)}(t) = \frac{d^s a_j(t)}{dt^s}, \quad j \in J \right), \\ N(q) &= \begin{cases} \emptyset & \text{if } q < 0, \\ \{0, \dots, q\} & \text{if } q \geq 0, \end{cases} \end{aligned}$$

and let  $p = p(x, t) \in \{0, 1, \dots\}$  be a positive integer satisfying

$$\begin{aligned} f^{(s)}(x, t) &= 0, \quad s \in N(p-1), \\ f^{(p)}(x, t) &\neq 0. \end{aligned} \quad (2)$$

From (2) it follows that

$$p = p(x, t) \in \begin{cases} \{0, 2, \dots\}, & f^{(p)}(x, t) < 0 \\ & \text{if } t \notin \{t^*, t_*\}, \\ \{0, 1, \dots\}, & f^{(p)}(x, t) < 0 \\ & \text{if } t = t_*, \\ \{0, 1, \dots\}, & f^{(p)}(x, t) < 0 \\ & \text{if } p \text{ is even} \\ & \text{and } t = t^*, \\ \{0, 1, \dots\}, & f^{(p)}(x, t) > 0 \\ & \text{if } p \text{ is odd} \\ & \text{and } t = t^*, \end{cases} \quad (3)$$

**Definition 3** The integer  $q = q(t)$  is called the *motionless degree* (see [20]) at the point  $t \in T$  in problem (1) if

$$f^{(s)}(x, t) = 0, \quad s \in N(q(t)), \quad \forall x \in X, \quad (4)$$

and there exists at least one feasible solution  $\hat{x} \in X$  such that

$$f^{(q(t)+1)}(\hat{x}, t) \begin{cases} < 0 & \text{if } t \neq t^* \text{ or} \\ & t = t^* \text{ and } p \text{ is even,} \\ > 0 & \text{if } t = t^* \text{ and } p \text{ is odd.} \end{cases} \quad (5)$$

It follows from Definition 3 that

$$q(t) \in \begin{cases} \{-1, 1, 3, 5, \dots, p^*(t) - 1\} & \text{if } t \in ]t_*, t^*[, \\ \{-1, 0, 1, 2, \dots, p^*(t) - 1\} & \text{if } t \in \{t_*; t^*\} \end{cases}$$

where  $p^*(t) = \max p(x, t), x \in X$ .

*Remark 4* If in problem (1) there exists at least one point  $t \in T$  so that  $q(t) \geq 0$ , then the Slater condition does not hold.

Following [20], let us describe the algorithm for constructing the function  $q(t)$ ,  $t \in T$ . Define

$$T(x) = \{t \in T: f(x, t) = 0\} = \{t_i: i \in I\},$$

$$I = I(x) = \{1, \dots, k = k(x)\}.$$

Set  $q_i^{(0)} = -1$ ,  $i \in I$ ;  $k = 0$ . Denote

$$I^{*(k)} = \left\{ i \in I: \begin{array}{l} t_i = t^*, \\ q_i^{(k)} + 1 \text{ an odd integer} \end{array} \right\},$$

$$I^{0(k)} = I \setminus I^{*(k)};$$

$$X_i^{(k)} = \left\{ z \in \mathbb{R}^k: \begin{array}{l} f^{(s)}(z, t_i) = 0, \\ s \in N(q_i^{(k)}), \\ f^{(q_i^{(k)}+1)}(z, t_i) \leq 0 \\ \text{if } i \in I^{0(k)}, \\ f^{(q_i^{(k)}+1)}(z, t_i) \geq 0 \\ \text{if } i \in I^{*(k)}, \\ d_* \leq z \leq d^* \end{array} \right\},$$

$$X^{(k)} = \bigcap_{i \in I} X_i^{(k)}.$$

For each  $j \in I$  let  $f_j^{(k)}(z) = f^{(q_i^{(k)}+1)}(z, t_j)$ , and let  $x^{(j)}$  be an optimal solution of the following LP problem:

$$x^{(j)} = \begin{cases} \operatorname{argmin}_{z \in X^{(k)}} f_j^{(k)}(z) & \text{if } j \in I^{0(k)}, \\ \operatorname{argmax}_{z \in X^{(k)}} f_j^{(k)}(z) & \text{if } j \in I^{*(k)}. \end{cases} \quad (6)$$

Since  $x \in X^{(k)}$ , it follows that an optimal solution of (6) always exists. Set  $I^{(k)} = \{j \in I: f_j^{(k)}(x^{(j)}) = 0\}$ . The following cases occur.

- $I^{(k)} \neq \emptyset$ . Set

$$q_j^{(k+1)} = \begin{cases} q_j^{(k)}, & j \in I \setminus I^{(k)}, \\ q_j^{(k)} + 2, & t_j \notin \{t_*, t^*\}, \\ q_j^{(k)} + 1, & t_j \in \{t_*, t^*\}; \end{cases}$$

- $I^{(k)} = \emptyset$ . Set

$$q(t) = \begin{cases} -1, & t \in T \setminus T(x) \\ q_j^{(k)}, & j \in I, t = t_j. \end{cases}$$

The function  $q(\cdot)$  so defined satisfies conditions (1)–(5), but the details must be left to [20].

Let  $x$  be the feasible solution of the problem (1). Define

$$T(x) = \{t \in T: f(x, t) = 0\} = \{t_i: i \in I\},$$

$$I = I(x) = \{1, \dots, \bar{k} = k(x)\},$$

$$p_i = p(x, t_i), \quad q_i = q(t_i), \quad i \in I,$$

$$I_0 = \{i \in I: q_i + 1 = p_i\}, I_* = I \setminus I_0,$$

$$I^* = \{i \in I: t_i = t^*, q_i + 1 \text{ odd}\}, I^0 = I \setminus I^*.$$

The following result is proved in [20].

**Theorem 5** *The feasible solution  $x \in X$  is the optimal solution of problem (1) if and only if the vector  $x$  is the optimal solution of the following LP problem:*

$$\begin{cases} \max & c^\top z \\ \text{s.t.} & d_* \leq z \leq d^*, \end{cases}$$

and

$$f^{(s)}(z, t_j) = 0, \quad s \in N(q_j), \quad j \in I, \quad (7)$$

$$f^{(q_j+1)}(z, t_j) \begin{cases} \leq 0 & \text{if } j \in I^0 \cap I_*, \\ \geq 0 & \text{if } j \in I^* \cap I_*. \end{cases} \quad (8)$$

## Extended Support Problems Method

We conclude the algorithmic part of the paper with a very general description of the extension to problems not having interior point (non-Slater problems).

- 1 Determine a feasible solution  $\hat{x}$  for problem (1).

In this step the LSIP problem with a floating number of variables is solved by the support problems method.

- 2 Determine motionless points  $t_j \in T(\hat{x})$  and the corresponding motionless degrees  $q_j$ ,  $j \in I(\hat{x})$ .

In this step one finds all points in the interval  $T$  for which  $f(\hat{x}, t) = 0$  and solves the sequence of the LP problems for defining the motionless degrees at these points.

- 3 Determine an optimal solution of (1).

In this step the constraints (7) – (8) are added to the constraints of the original problem (1). The resulting problem is solved by the support problems method.

## Extended support problems method

We turn now to very recent applications of SIP to finance, which employ semi-infinite programs having index sets,  $T$ , appearing in a partitioned form, corresponding to units of time. A basic structure for LSIP is an index set-partitioned form having the following structure:

$$(PLSIP) \begin{cases} \min & c^\top x \\ \text{s.t.} & b_*(t) \leq A(t)x \leq b^*(t), \\ & \forall t \in T^L, \\ & T^L = \bigcup_{i=1}^L T_i = [t_{i-1}, t_i], \\ & g_* \leq Gx \leq g^*, \\ & d_* \leq x \leq d^*, \end{cases} \quad (9)$$

where  $c, x, d^*, d_*$  are  $n$ -dimensional vectors,  $b_*(\cdot), b^*(\cdot)$  are  $m$ -dimensional functions,  $A(\cdot)$  an  $m \times n$  matrix function, and  $G$  an  $p \times n$  matrix, with  $g^*, g_*$   $p$ -dimensional vectors. We shall use the  $T^L$  notation throughout for various choices of the integer  $L$ . Typically,  $T_i$  is the  $i$ th day of an observational period.

**A SIP Approach for Estimating Uncertainty in Dynamical Systems**

Generally, the problem of estimation occurring in non-deterministic systems has been investigated by means of many stochastic models beginning with the papers of N. Wiener [28] and R.E. Kalman [16]. In the 1970s, nonstochastic observation models (‘minimax’, ‘guaranteed’) under uncertainty were developed in [5,21,22]. During the 1980s a new approach for optimization of linear dynamical systems under uncertainty was developed by R. Gabasov and F.M. Kirillova; see [7].

Our approach [17] to modeling uncertainty is in contrast to other qualitative approaches, for example, based on stochastic differential equations. In the latter case certain mathematical assumptions are made about the underlying stochastic processes which may be difficult to verify in real situations, for example, in the financial derivatives and assets markets. We demonstrate our approach by applying the following general *minimax observation problem*, stated with unknown parameters under nonstochastic uncertainty, to differential equations models for interest rates of shortest duration, termed the *spot interest rate*. The models we de-

velop are analogous to some of the stochastic differential equations models appearing in the literature.

**The Minimax Observation Problem Under Uncertainty with Perturbations**

Our main model is the well known linear dynamic system under nonstochastic uncertainty with perturbations, LDSU, over the time interval,  $\mathcal{T} = [0, T]$ :

$$\begin{aligned} \dot{x} &= Ax + Dw(t), \\ x(0) &= x_0 \in X_0, \\ X_0 &= \left\{ x \in \mathbb{R}^n : \begin{array}{l} d_* \leq x \leq d^*; \\ g_* \leq Gx \leq g^* \end{array} \right\}, \\ W(t) &= \left\{ w(t) \in \mathbb{R}^l : w_* \leq w(t) \leq w^* \right\}, \\ D &\in \mathbb{R}^{n \times l}, \quad w_*, w^* \in \mathbb{R}^l. \end{aligned} \quad (10)$$

The fundamental matrix  $F$  of (10) has the following properties:

$$\begin{aligned} \dot{F} &= AF, \quad F(0) = E, \\ F(t-s) &= F(t-p)F(p-s), \\ F(t+s) &= F(t)F(s), \\ F^{-1}(t) &= F(-t), \end{aligned}$$

yielding the form of a solution of (10) by the *Cauchy formula*:

$$x(t) = F(t)x_0 + \int_0^t F(t)F(-s)Du(s) ds. \quad (11)$$

We assume that the state  $x(t)$  of the system (10) is estimated from a sensor system of the form:

$$y(t) = h^\top x(t) + z(t), \quad \forall t \in \mathcal{T}, \quad (12)$$

which is a measurement system giving inexact information about current state of system (10), where  $z(t)$  is an unknown piecewise continuous measurement error function.

Let (10), (12) generate a signal  $y^*(t), t \in \mathcal{T}$  with some measurement error  $z^*(t), t \in \mathcal{T}$ . With our approach we seek  $\hat{x}(\cdot)$  by solving the following minimax observation problem:

$$\min_{(x, w(\cdot)) \in X_0 \times W(\cdot)} \max_{t \in \mathcal{T}} |z^*(t)|. \quad (13)$$

We obtain an equivalent infinite linear program from (13) by substituting (11) into (12) in order to obtain an

explicit expression for  $z^*(\cdot)$ :

$$z^*(t) = y^*(t) - h^T F(t)x_0 - h^T \int_0^t F(t)F(-s)Dw(s) ds.$$

Hence (13) is equivalent to:

$$\left\{ \begin{array}{l} \min \quad v \\ \text{s.t.} \quad y^*(t) \leq h^T F(t)x \\ \quad \quad + \int_0^t F(t)F(-s)Dw(s) ds + v, \\ \quad \quad h^T F(t)x + \int_0^t F(t)F(-s)Dw(s) ds \\ \quad \quad -v \leq y^*(t), \\ x \in X_0, \quad v \geq 0, \\ w_* \leq w(t) \leq w^*, \quad \forall t \in \mathcal{T}. \end{array} \right. \quad (14)$$

Our main application to state estimation is the following one. Suppose  $(x^0, w^0, v^0)$  is optimal for (14). Then

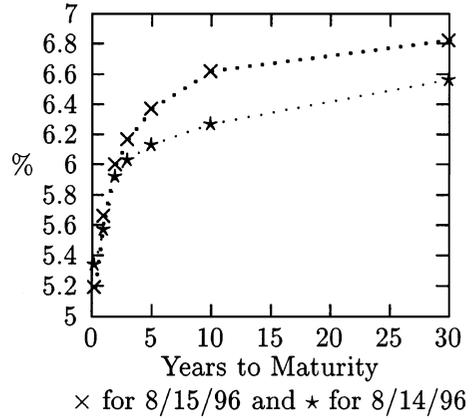

$$\hat{x}(t) = F(t)x^0 + \int_0^t F(t)F(-s)Dw^0(s) ds$$

is an estimate of the state  $x(t)$  of the system (10). This estimate gives the minimal possible maximum absolute value of the measurement error  $v^0$ . Special purpose algorithms for problems of this type have been developed in [24,25]. To implement this approach we must specify a class of impulse perturbations, and we illustrate one such prototype class next

**A Prototype: Analog of the Vasicek Model with Impulse Perturbations**

The financial markets setting shall be that of a default-free discount bond paying \$ 1 at maturity time  $T$ . At this point for convenience, we take the inception to be 0, while letting  $P(t, T)$  denote the price of this bond at time  $t, 0 \leq t \leq T$ . In actuality the bond may be a 91 day treasury bill issued at 10/1/97 ( $= t_0$ ) maturing on 12/31/97  $= t_0 + 91$ days. By definition,  $P(T, T) = 1$ . For  $t \leq T$ , the *yield to maturity*  $R(t, T)$  prevailing at time  $t$  is the internal rate of return at time  $t$  on a bond with maturity date  $T$ :

$$R(t, T) = -\frac{1}{T-t} \log P(t, T), \quad 0 \leq t \leq T. \quad (15)$$

Semi-infinite Programming and Applications in Finance, Figure 1  
US treasury yield curve: Constant maturities

The *interest rate yield curve* is the plot of  $R$  against the time to maturity, see [2,15,29]. For  $T \geq t$ , as a function of  $T, R(t, T)$  is usually called the *term structure of interest rates* at time  $t$ . Figure 1 is an illustration from recent data.

The instantaneous short rate or spot rate prevailing at time  $t, r(t)$ , (see, [26]) is defined as:

$$r(t) = \lim_{T \rightarrow t} R(t, T). \quad (16)$$

Hence,

$$P(t, T) = e^{-\int_t^T r(s) ds}. \quad (17)$$

The spot rate cannot be observed from real data, but it is the focus of various stochastic differential equations models. Our prototype LDSU model shall also be constructed around the spot rate,  $r$ . It follows from (15), (17) that

$$R(t, T) = \frac{1}{T-t} \int_t^T r(s) ds. \quad (18)$$

We illustrate the approach with the classical model of O. Vasicek [26], where the standard Brownian motion,  $Z$ , underlies the stochastic differential equation for the spot rate, and where  $\alpha, \beta$ , and  $\sigma$  are parameters, see [1,3,27]:

$$dr = (\alpha + \beta r) dt + \sigma dZ. \quad (19)$$

The parameters are employed to capture shifts and volatility of the spot rate, [3]. We hypothesize that the

spot rate is governed by the following linear dynamic system with unknown parameters and nonstochastic uncertainty. Let  $N$  be a positive integer,

$$\begin{aligned} \dot{r} &= \alpha + \beta r(t) + w(t), \\ \beta &\neq 0, \quad r(t_0) = r_0, \quad t \in T^N, \end{aligned} \quad (20)$$

where  $T^N$  is defined in (9),  $L = N$ . Assume that a priori information about the unknown parameters,  $\omega(\cdot)$ , of this LDEU takes the form:

$$\begin{aligned} \omega &= (r_0, \alpha, \beta, w_i, \quad i = 1, \dots, N), \\ \omega_* &= (r_*, \alpha_*, \beta_*, w_{*i}, \quad i = 1, \dots, N), \\ \omega^* &= (r^*, \alpha^*, \beta^*, w_i^*, \quad i = 1, \dots, N), \\ \Omega &= \{\omega \in \mathbb{R}^{N+3}: \omega_* \leq \omega \leq \omega^*\}, \\ w(t) &= w_i, \quad w_{*i} \leq w_i \leq w_i^*, \\ &\quad t \in T_i, \quad i = 1, \dots, N, \end{aligned} \quad (21)$$

where  $w(\cdot)$ , are *piecewise-constant perturbations*. Other choices of classes of perturbations appear in [17]. System (20)–(21) comprise our prototype of (10).

*Remark 6* We stress the dependence of the spot rate on the parameters in (21) by writing  $r(\cdot|\omega)$ . However, to emphasize the status of  $\omega$  as an independent variable we write  $r(t|\omega) = f(t, \omega)$ .

We address next how the general measurement system (12) specializes in our Vasicek-based prototype.

### Estimating the Spot Rate for Bonds with Constant Maturities

We define the period of observation to be  $T^M$ , for a positive integer,  $M$ , see (9). Let  $\tau$  be the current time-to-maturity (maturity term), so that with inception date  $t$  a  $\tau$ -maturity bond becomes due at date  $t + \tau$ .

Assume that we have observed values of the treasury yield curve giving a series of yields to maturity  $R_i^{(\tau)}$ ,  $i = 1, \dots, M$ , for some given maturity term  $\tau$  during  $M$  days of observation. The date  $t_M$  is the last day of the observation period, becoming the current date. Under this interpretation we build a piecewise constant form of the yield to maturity, for numerical stability reasons, and consistent with LDSU:

$$\begin{aligned} \widehat{R}(t, t + \tau) &= R_i^{(\tau)}, \\ t &\in T_i, \quad i = 1, \dots, M. \end{aligned} \quad (22)$$

The table below illustrates some observations of US treasury yield curve rates, for successive years.

Date	3-mo	6-mo	9-mo	1-yr	
01/03/94	3.16	← 1	3.39	3.67	4.66
.	.	.	.	.	.
01/18/96	5.11		5.02	5.01	
01/19/96	5.1		5.06	5.02	5.03

#### Observations of treasury yield curves.

Legend: ← 1 :  $R_i^{(\tau)} = R_{01/03/94}^{(3 \text{ mo})}$

**Definition 7** By the  $\Omega$ -based yield we mean the averaged integral

$$p(t, \omega|\tau) = \frac{1}{\tau} \int_t^{t+\tau} r(s|\omega) ds, \quad t \in T^M, \quad (23)$$

$\omega \in \Omega$ , the set of unknown parameters.

The *estimation error*,  $\varepsilon(t, \omega)$  is the difference,

$$\begin{aligned} p(t, \omega|\tau) - \widehat{R}(t, t + \tau), \\ t \in T^M, \quad \omega \in \Omega. \end{aligned} \quad (24)$$

Note that (24) corresponds to the measurement error function in (10). We compute the estimate  $\omega^0$  of unknown parameters  $\omega$  by minimizing over  $\omega \in \Omega$ , the maximum absolute value of the function of estimation errors  $\varepsilon(t, \omega)$  on the interval  $T^M$ . This leads to the following problem:

$$\min_{\omega \in \Omega} \max_{t \in T^M} |\varepsilon(t, \omega)|. \quad (25)$$

Problem (25) may be written as the following nonlinear semi-infinite programming NSIP problem, see [14]:

$$\begin{cases} \min & v_\tau \\ \text{s.t.} & p(t, \omega|\tau) - v_\tau \leq \widehat{R}(t, t + \tau), \\ & \widehat{R}(t, t + \tau) \leq p(t, \omega|\tau) + v_\tau, \\ & t \in T^M, \quad \omega \in \Omega, \quad v_\tau \geq 0. \end{cases} \quad (26)$$

We shall call problem (26) the  $\tau$ -programmed problem of spot rate estimation, but we must be more specific. We return to our basic model (20)–(21) and apply the Cauchy formula to find that the solution of the dif-

ferential equation (20) has the form

$$\begin{aligned}
 r(t|\omega) &= e^{\beta t} r_0 + \frac{\alpha}{\beta} (e^{\beta t} - 1) \\
 &+ \sum_{j=1}^{i-1} w_j \frac{e^{\beta t}}{\beta} (e^{-\beta t_{j-1}} - e^{-\beta t_j}) \\
 &+ w_i \frac{1}{\beta} (e^{\beta(t-t_{i-1})} - 1), \\
 t \in T_i, \quad i &= 1, \dots, N, \quad N = M + \tau.
 \end{aligned} \tag{27}$$

To derive the explicit form of problem (26) means that we must first specify the function

$$\begin{aligned}
 p(t, \omega|\tau) &= \frac{1}{\tau} \int_t^{t+\tau} r(s|\omega) ds, \\
 t \in T_i, \quad i &= 1, \dots, M.
 \end{aligned}$$

After a tedious series of integrations we obtain

$$\begin{aligned}
 p(t, \omega|\tau) &= \frac{e^{\beta(t+\tau)} - e^{\beta t}}{\tau\beta} r_0 \\
 &+ \left( \frac{e^{\beta(t+\tau)} - e^{\beta t}}{\tau\beta^2} - \frac{1}{\beta} \right) \alpha \\
 &+ \sum_{k=1}^{i+\tau} a_k^i(\beta, t|\tau) w_k,
 \end{aligned}$$

where  $a_k^i(\beta, t|\tau) =$

$$\begin{cases}
 \frac{e^{\beta(t-t_{k-1}+\tau)} - e^{\beta(t-t_k+\tau)} + e^{\beta(t-t_k)} - e^{\beta(t-t_{k-1})}}{\tau\beta^2}, & k < i, \\
 \frac{e^{\beta(t-t_{k-1}+\tau)} - e^{\beta(t-t_k+\tau)} - e^{\beta(t-t_{k-1})} + 1}{\tau\beta^2} - \frac{t_k - t}{\tau\beta}, & k = i, \\
 \frac{e^{\beta(t-t_{k-1}+\tau)} - e^{\beta(t-t_k+\tau)}}{\tau\beta^2} - \frac{t_k - t_{k-1}}{\tau\beta}, & i < k < i + \tau, \\
 \frac{e^{\beta(t-t_{k-1}+\tau)} - 1}{\tau\beta^2} - \frac{t - t_{k-1} + \tau}{\tau\beta}, & k = i + \tau.
 \end{cases} \tag{28}$$

From the above we obtain the following nonlinear semi-infinite programming problem

$$\begin{cases}
 \min & v_\tau \\
 \text{s.t.} & \frac{e^{\beta(t+\tau)} - e^{\beta t}}{\tau\beta} r_0 \\
 & + \left( \frac{e^{\beta(t+\tau)} - e^{\beta t}}{\tau\beta^2} - \frac{1}{\beta} \right) \alpha \\
 & + \sum_{k=1}^{i+\tau} a_k^i(\beta, t|\tau) w_k - v_\tau \\
 & \leq \hat{R}(t, t + \tau), \\
 & \hat{R}(t, t + \tau) \\
 & \leq \frac{e^{\beta(t+\tau)} - e^{\beta t}}{\tau\beta} r_0 \\
 & + \left( \frac{e^{\beta(t+\tau)} - e^{\beta t}}{\tau\beta^2} - \frac{1}{\beta} \right) \alpha \\
 & + \sum_{k=1}^{i+\tau} a_k^i(\beta, t|\tau) w_k + v_\tau,
 \end{cases} \tag{29}$$

where

$$\begin{aligned}
 t \in T_i, \quad i &= 1, \dots, M; \\
 \alpha_* \leq \alpha \leq \alpha^*, \quad \beta_* \leq \beta \leq \beta^*, \quad r_* \leq r_0 \leq r^*, \\
 v \geq 0, \quad w_* \leq w_i \leq w^*, \quad i &= 1, \dots, N.
 \end{aligned}$$

Let  $(\omega^0, v^{\tau 0})$  be the solution of problem (29), (26). Upon substituting  $\omega^0$  for  $\omega$  in (27) yields a formula that we term the  $\tau$ -estimate of the spot rate, i. e.,

$$r_\tau(t) = f(t, \omega^0), \quad t \in T^M. \tag{30}$$

It follows from (17) that the function

$$\begin{aligned}
 P(t, \hat{t}) &= e^{-\int_t^{\hat{t}} r_\tau(s) ds}, \\
 t \in [t_0, t_N], \quad \hat{t} &\in [t, t_N],
 \end{aligned} \tag{31}$$

will be an estimate of the price at time  $t$  of a discount bond maturing at time  $\hat{t}$ .

The function  $r_\tau(t) = f(t|\omega^0)$ , while an estimate in the interval  $[t_0, t_M]$ , becomes the forecast in the future interval (the time after the current time  $t_M$ ), namely, the forecast interval  $[t_M, t_N]$ , where  $N = M + \tau$ . If the function  $r(t, |\omega^0)$  is defined over  $t \in [t_N, t_{M^p}]$ , where  $M + \tau < M^p$ , then the predicted price of a discount bond maturing at time  $\hat{t}$  is given by:

$$\begin{aligned}
 \tilde{P}(t, \hat{t}) &= e^{-\int_t^{\hat{t}} r_\tau(s) ds}, \\
 t \in [t_N, t_{M^p}], \quad \hat{t} &\in [t, t_{M^p}],
 \end{aligned} \tag{32}$$

and the predicted yield is

$$\begin{aligned}\tilde{R}(t, \hat{t}) &= \frac{1}{\hat{t} - t} \int_t^{\hat{t}} r_\tau(\hat{t}) ds, \\ t &\in [t_N, t_{M^p}], \\ s &\in [t, t_{M^p}]\end{aligned}\quad (33)$$

at time  $t$  of discount bond maturing at date  $\hat{t}$ .

### A Nonarbitrage Condition for LDSU

Analogous to the stochastic case, we construct a portfolio with two bonds with differing maturities,  $T_1$  and  $T_2$ , selling one unit of the  $T_1$  maturity and buying  $\Delta$  of the  $T_2$  maturity. The value of the portfolio is (see [29, Sect. 17.5]),

$$\Pi(t) = P(t, T_1) - \Delta P(t, T_2). \quad (34)$$

Analogously, we differentiate  $\Pi(t)$  with respect to time,  $t$ , recognizing that all of our parameters are independent of time, (see also Remark 6. Hence we obtain

$$\frac{d\Pi(t)}{dt} = \Pi(t)f(t, \omega). \quad (35)$$

But (35) states that the return on the portfolio equals the risk-free rate, the spot rate, [29, p. 271]. But this required condition is not our complete measure of nonarbitrage because our approach depends on actual observations and real data. Let us be more precise.

If at time  $T_1$  \$1 is invested in the risk-free market (what the observations of actual data show) and grows to \$ $M$  at time  $T_2$ , then \$ $M$  must be compared with what the estimated spot rate returns over this period, where we assume  $f(s, \omega) \geq 0$  for all  $\omega$ , i. e.,

$$e^{\int_{T_1}^{T_2} f(s, \omega) ds}$$

If  $M > e^{\int_{T_1}^{T_2} f(s, \omega) ds}$ , we borrow \$1 at  $T_1$  at the spot rate and invest it in the risk-free market during the period  $[T_1, T_2]$ . At  $T_1$  we make a profit of  $M - e^{\int_{T_1}^{T_2} f(s, \omega) ds}$ . If  $M < e^{\int_{T_1}^{T_2} f(s, \omega) ds}$ , we borrow \$1 in the risk-free market (supported by observed data) and invest it at the spot rate over the period  $[T_1, T_2]$ . We make a profit of  $e^{\int_{T_1}^{T_2} f(s, \omega) ds} - M$ . This analysis motivates the following condition.

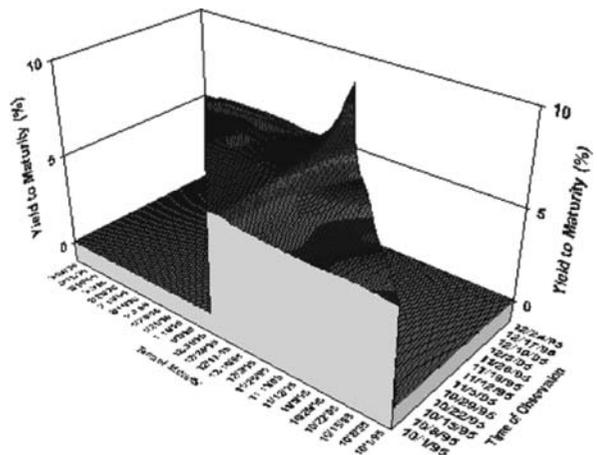

*Assumption 8* Let  $f(\cdot, \cdot)$  be a nonnegative function specified as in Remark 6. For any arbitrary  $T_1, T_2$ , and  $W$  satisfying  $T_1 < T_2, W > 0$ , there exists a  $\omega^* \in \Omega$  such that:

$$\int_{T_1}^{T_2} f(s, \omega^*) ds = W. \quad (36)$$

This is a necessary condition to guarantee existence of nonarbitrage in the broader sense of using real observational data for estimation by the rules and models we have introduced.

We conclude by presenting one of the figures obtained from a solution of problem (26), (29) with piecewise-constant perturbations for maturity term  $\tau = 91$  days over the last three months of 1995. Using the notation of (29) Fig. 2 is a three-dimensional plot of  $\tilde{R}(t, t + \tau) \equiv p(t, \omega^0 | \tau)$  having two boundaries both with slope 1 that have financial interpretations:

- the left-most boundary is  $\tilde{R}(t, t + 91 \text{ days}), 10/1/95 \leq t \leq 12/24/95$ , depicting the estimated yield curve over the observation period;
- the right-most boundary is  $\tilde{R}(t, t), 10/1/95 \leq t \leq 12/24/95$ , and depicts the unobservable estimated spot rate over the observation period.

Semi-infinite Programming and Applications in Finance, Figure 2

Estimate of the term structure of interest rates using the analog of the Vasicek model with piecewise-constant perturbations for observations of yield to maturity,  $\tau = 3$  mo, made during the observation period 1/8/1995 to 31/12/1995

It is interesting to note that in the stochastic case the market price of risk cannot be estimated uniquely in many cases. This result is demonstrated in [23].

Nonlinear semi-infinite programs; Computational equivalent; Index set; Nonnegative interpolatory operator

The class of general semi-infinite programming problems may be looked upon as a generalization of the class of optimization problems with finitely many variables and constraints since in a semi-infinite program, either the number of variables or the number of constraints (but not both at the same time) may be infinite. In the present paper we will mainly deal with semi-infinite programs with finitely many variables. The main theoretical as well as practical difficulty is that one needs to verify that a proposed optimal solution satisfies infinitely many inequality constraints. In addition, nonlinear problems may have many local minima and one needs to verify that a calculated optimum is indeed global. We will discuss the concept of *computational equivalence*, i. e. that for a fixed computer and software one may construct an optimization problem with finitely many variables and constraints which has the same computer representation as the semi-infinite program whose solution is sought. We will deal in detail with the class of linear problems and give some numerical examples, illustrating computational equivalence. We will consider one-sided approximation and approximation in the maximum norm. For the application of global optimization to linear semi-infinite programming and an illustration on the air quality control prob-

lem, see ► [Semi-infinite Programming: Methods for Linear Problems](#). The literature on semi-infinite programs and their applications to problems in science and engineering is extensive. For a general introduction to this field, see [8] [10] and [14]. Recent results are to be found, for instance, in [16].

### Nonlinear Semi-Infinite Programs

We will study the following class of problems:

**Definition 1** Let  $S$  be a fixed set,  $F: \mathbf{R}^n \rightarrow \mathbf{R}$  and  $G: \mathbf{R}^n \times S \rightarrow \mathbf{R}$  two fixed functions. Then the following task will be called a *semi-infinite program*:

$$\min F(y) \quad (1)$$

over all  $y \in \mathbf{R}^n$  subject to the constraint

$$G(y, s) \geq 0, \quad s \in S. \quad (2)$$

*Remark 2* The data of the semi-infinite program (1), (2) are hence the index set  $S$ , the real-valued functions  $F$  defined on  $\mathbf{R}^n$  and the real-valued function  $G$ , defined on  $\mathbf{R}^n \times S$ .

**Definition 3** Use the notation of Definition 1. Put

$$Y = \{y \in \mathbf{R}^n : G(y, s) \geq 0\}, \quad (3)$$

$$V = \inf_{y \in Y} F(y). \quad (4)$$

If  $Y$  is empty, then we define  $V = -\infty$ , i. e. the condition (2) is inconsistent.

We observe that (1) and (2) define a very general class of problems. If we restrict  $S$  to be finite, then we get nonlinear optimization problems with finitely many nonlinear constraints. If  $F$  and  $G$  are linear with respect to  $y$  then we get linear programs if  $S$  is finite, otherwise linear semi-infinite programs. If we require  $Y$ , the set of feasible solutions to be compact and  $F$  to be continuous on  $Y$ , then the existence of optimal solutions is guaranteed. We need to impose further assumptions in order to show that a proposed computational scheme is efficient. When a linear semi-infinite program is to be solved, a common approach is to discretize the problem, i. e. replace the index set  $S$  by a finite subset  $T$  and

then solve the linear program hereby arising numerically, which always can be done with a finite number of arithmetic operations. For nonlinear problems, the numerical solution of the discretized problem is still difficult, since it may have many local extrema and the verification that a calculated extremum is the global optimum sought is nontrivial. For this reason discretization has not been the main approach for the treatment of nonlinear semi-infinite programs. Instead one has sought binding constraints, worked with penalty methods and settled for calculation of a local optimum. See [3,4,6,7,13,14,15] and [16]. Quasirandom methods have also been used for estimating the global optimum. See, e. g., [5].

### Computationally Equivalent Semi-Infinite Programs

As known, a computer may only store a finite number of symbols. Symbol-manipulating languages like Maple and Mathematica may perform relatively complicated operations exactly by means of formula manipulations but their capacity is limited to a certain extent. This is illustrated by their treatment of operations on rational numbers which may be represented exactly as pairs of integers. However, if one would try to solve a linear systems of equations with rational coefficients exactly, then one would find that the available storage capacity is exceeded already for relatively small systems. We assume from now on that we have a language like Fortran which may manipulate integers exactly, provided that their magnitude is limited by a bound which is known but depends on the computer and the software used. Arithmetic operations on real numbers may be performed with high accuracy, but not exactly and bounds for the errors may be derived. Since the storage of the computer is limited the set  $\mathbf{R}$  of real numbers must be represented by a finite subset, the computer numbers. Therefore the set  $\mathbf{R}$  may be split into a finite number of subsets whose elements have identical representations in the computer. Two reals, which have the same computer representations are considered computationally equivalent, since it is not possible to distinguish between them by means of computational operations. As a consequence of this the index set  $S$  in (2) must be represented by a finite subset  $T$  of computer numbers. We introduce

**Definition 3** The program

$$\min F^*(y) \quad (5)$$

over all  $y \in \mathbf{R}^n$  subject to the constraint

$$G^*(y, s) \geq 0, \quad s \in S, \quad (6)$$

is said to be *computational equivalence* to the program (1), (2) if there is a compact set  $Y^* \subset \mathbf{R}^n$  which contains all the feasible solutions of both programs such that:

- $F^*(y)$  and  $F(y)$  are computationally equivalent on  $Y^*$ ;
- $G^*(y, s)$  and  $G(y, s)$  are computationally equivalent on  $Y^* \times S$ .

*Remark 5* The requirement that the set of feasible solutions should be compact may seem awkward, since a semi-infinite program may have an unbounded feasible set even if the set of optimal solutions is bounded. Therefore one considers regularized semi-infinite programs which have the constraint  $\|y\| \leq M$  where, the positive number  $M$  is chosen so large that this constraint is not binding for at least one optimal solution.

The next issue is to construct an optimization problem with finitely many constraints whose set of feasible solutions is computationally equivalent to that of (1), (2). We will outline the procedure for doing this which is presented in [1,11,12]. We next introduce

**Definition 6** Use the notations and definitions of (1) and (2). Let  $T \in S$  be a finite set with  $N$  points:

$$T = \{t_1, \dots, t_N\}.$$

Let further  $w_1, \dots, w_N$  be  $N$  continuous functions defined on  $S$  and having the properties:

$$\begin{cases} w_j(s) \geq 0, & s \in S, j = 1, \dots, N, \\ \sum_{j=1}^N w_j(s) = 1, & s \in S, \\ w_j(s_i) = \delta_{ij}, & i = 1, \dots, N, j = 1, \dots, N. \end{cases} \quad (7)$$

Let  $f$  be a continuous mapping defined on  $S$  and such that  $f(s)$  is either a real number or a vector in  $\mathbf{R}^n$ . We now define the nonnegative *interpolatory operator* based on  $T \in S$  by

$$(Lf)(s) = \sum_{j=1}^N w_j(s)f(t_j).$$

*Remark 7* We note that  $L$  is a linear operator having  $f$  as argument. Also note that  $(Lf)(s) = f(s)$  for all  $s \in T$ .

*Remark 8* In the case of linear semi-infinite programming one may prove that if we replace the functions defined on  $S$  with the outputs of the mapping  $L$  then this semi-infinite program has the same feasible set as the linear program obtained by replacing the index set  $S$  by the grid  $T$  used for defining  $L$ . See, e. g., [8] or [12].

*Example 9* We consider the simple linear semi-infinite program:

$$\min y_1 + \frac{y_2}{\pi},$$

subject to the constraints

$$y_1 + y_2 s \geq \sqrt{1+s}, \quad 0 \leq s \leq 1.$$

One finds directly that the optimal  $y_1, y_2$  are defined by the condition that the straight  $y_1 + y_2 s$  should be the tangent to the curve  $\sqrt{1+s}$  at the point  $s = 1/\pi$ . Assume that we use a computer with working relative accuracy  $1.0 \cdot 10^{-8}$ . We define here  $L$  as the result of equidistant linear interpolation with stepsize  $h$ . We notice that the functions  $a_1(s) = 1$  and  $a_2(s) = s$  are interpolated exactly and one may verify that the maximal relative interpolation error for  $\sqrt{1+s}$  is given by  $h^2/32$ . Therefore, if we take  $h = 5 \cdot 10^{-4}$ , the discretized linear program becomes computationally equivalent with the original one. In this case  $T$  has 2001 elements.

### Approximation in the Uniform Norm

We use the same definitions as in (1) and (2). Let  $f$  be a function which is continuous on  $S$ . We define its maximum norm:

$$\|f\| = \max_{s \in S} |f(s)|.$$

Next we consider the problem to determine

$$\min_{y \in \mathbb{R}^n} \max_{s \in S} |G(y, s)|.$$

An equivalent formulation of this task is given by the semi-infinite program:

$$\min y_0$$

subject to the constraints

$$G(y, s) + y_0 \geq 0, \quad -G(y, s) + y_0 \geq 0, \quad s \in S.$$

In this last problem, the variables are the real  $y_0$  and the vector  $y \in \mathbb{R}^n$ . At each point  $s \in S$  two inequality conditions are to be satisfied. To calculate the optimal value corresponding to a certain  $y$  one needs to perform a global optimization over  $S$ . We note that the problem is consistent. If we discretize the problem, replacing  $S$  by a finite subset  $T$  this may be interpreted as approximating over  $T$ .

If  $G$  can be written

$$G(y, s) = a(s)^\top y - b(s), \quad (8)$$

then we have a linear approximation problem and seek to approximate  $b$  by a linear combination of  $a_1, \dots, a_n$  which are real-valued functions on  $S$ . The corresponding discretized problem becomes a linear program which may be solved by means of the simplex algorithm. See, e. g., [8]. Due to the special structure of these problems the exchange algorithms by Remez, see [2] are applicable. If these latter algorithms are used for the original problem, one needs to perform a global optimization in each exchange step. The three-phase algorithm described in [8,9] and [10] may be adapted to the uniform approximation problem as well. The idea is to seek  $q$  points  $\{s_1, \dots, s_q\} \in S$  such that the absolute value of  $G(y, s)$  achieves its maximum  $y_0$ . One needs to keep track of the sign of the deviation and whether the extreme value is achieved at a boundary point of  $S$  or in the interior. The number of local extrema as well as their approximate positions may be obtained from a discretized version of the problem in the case of (8), i. e. the linear approximation problem. In the nonlinear case they are generally found by other means. See, e. g., papers in [13] and [16]. We illustrate this with an example.

*Example 10* Determine the straight line

$$y_1 + y_2 s$$

which approximates the function  $\exp s$  best in the maximum norm over the real interval  $[0, 1]$ . Thus we seek the solution to the problem

$$\min_{y_1, y_2} \max_{0 \leq s \leq 1} |e^s - y_1 - y_2 s|.$$

It is easy to verify, e. g., from a simple graph, that the maximum deviation in absolute value occurs at three points  $s_1, s_2, s_3$  and further, that  $s_1 = 0, s_3 = 1$ . Thus these

points are at the boundary of  $S$  and  $s_2$  is in the interior. Hence we get a condition on the derivative of the pointwise deviation considered as a function of  $s$  at  $s_2$ . Let  $y_0$  be the maximal absolute value of the deviation. Then we obtain the following nonlinear system of equations

$$\begin{cases} \exp(s_1) - y_1 - y_2 s_1 & = y_0, & i = 1, 3, \\ -\exp(s_2) + y_1 + y_2 s_2 & = y_0, \\ \exp(s_2) - y_2 & = 0, \\ s_1 = 0, & s_3 & = 1. \end{cases}$$

This system may be solved by means of Newton's method. Here it was easy to guess the form of the nonlinear system giving the optimal solution. The fact that the infinitely many constraints are satisfied, namely that the absolute value of the deviation at each point is less than or equal to  $y_0$  may be verified analytically. In a more general context, the nonlinear system giving the optimal solution may be constructed from a discretized version of the approximation problem. Still, the verification that the optimum approximation has been found may be nontrivial, even in the case of linear approximation problems. In this situation, quasirandom methods may be contemplated. Experiments with this approach will be reported elsewhere.

We have developed over the last twenty years an approach for the study of *optimal control* and *variational problems* based on the consideration of *measure spaces*; see [11,12] and the references there. In many ways this work has been inspired by the work of L.C. Young [19] which, starting in the period between the Wars, opened up a new vista for mathematics; concepts associated with distributions and chains, for instance, are descendants of his work, and so is our contribution.

### Integral Relationships

The applications of measure theory to optimization problems are based on the identification of linear functionals with a class of *Radon measures*, by *Riesz' theorem* [11]. We note that this theorem only applies if the underlying space is compact, this will cause trouble when considering unbounded sets of controls: the handling of infinities there will be done by means of *Loeb measures* in the setting of *nonstandard analysis*.

In order to use Riesz' theorem we need to rewrite the relationships associated with optimization problems in the form of linear functionals on appropriate function spaces. We show how to do this in two specific cases.

We consider first a *finite-dimensional control problem*, to be referred to as problem P1. Let  $x, u$  be vectors in Euclidean  $n$ -spaces  $\mathbf{R}^n$  and  $\mathbf{R}^m$  respectively,  $t$  a real variable,  $J := [t_0, t_f]$  with  $t_0 < t_f$ ,  $A$  a compact subset of  $\mathbf{R}^n$ ,  $x_0, x_f$  points in  $A$ , a bounded, closed subset  $U$  of  $\mathbf{R}^m$ . Further, let  $\Omega_1 := J \times A \times U$ , and  $g: \Omega_1 \rightarrow \mathbf{R}^n$  a continuous function. The *control function*  $t \in J \rightarrow u(t) \in U$  is Lebesgue-measurable, and the *trajectory function*  $t \in J \rightarrow x(t) \in A$  is the (absolutely continuous) solution of

$$\dot{x}(t) = g(t, x(t), u(t)), \quad t \in J^\circ, \quad (1)$$

the differential equation describing the system to be controlled. We assume that the class  $\mathcal{F}_1$  of all *admissible* trajectory-control pairs  $p := [x(\cdot), u(\cdot)]$  is nonempty,

and seek to minimize the functional  $I: \mathcal{F}_1 \rightarrow \mathbf{R}$

$$I(p) = \int_{t_0}^{t_f} f_{01}(t, x(t), u(t)) dt, \quad (2)$$

for  $p \in \mathcal{F}_1$ . Here  $f_{01}$  is a continuous function defined on  $\Omega_1$ .

We develop now some equalities that are satisfied by the admissible pairs. Let  $B$  be an open ball in  $\mathbf{R}^{m+1}$  containing  $J \times A$ ; we denote by  $C'(B)$  the space of all real-valued functions on  $B$  that are uniformly continuous on  $B$  together with their first derivatives. Let  $\phi \in C'(B)$ ; define

$$\widehat{\phi}(t, x, u) := \phi_x(t, x)u + \phi_t(t, x) \quad (3)$$

for all  $(t, x, u) \in \Omega_1$ . Of course,  $\widehat{\phi} \in C(\Omega_1)$ . If  $p = [x(\cdot), u(\cdot)]$  is an admissible pair,

$$\begin{aligned} \int_J \widehat{\phi}(t, x(t), u(t)) dt \\ = \phi(t_f, x_f) - \phi(t_0, x_0) := \Delta\phi, \quad (4) \end{aligned}$$

for all  $\phi \in C'(B)$ . There are two special cases which are of interest; in the first we put  $\psi(t, x) := x_j \psi(t)$ , with  $1 \leq j \leq n$ , and  $\psi \in \mathcal{D}(J^\circ)$ ; see [11]. Then, putting  $\psi_j(t, x, u) := x_j \psi'(t) + u_j \psi(t)$ , for  $1 \leq j \leq n$  and  $\psi \in \mathcal{D}(J^\circ)$ , the equality (4) becomes  $\int_J \psi_j(t, x(t), u(t)) dt = 0$ , since the (test) functions in  $\mathcal{D}(J^\circ)$  are zero at the boundary of  $J$ . The second case of interest happens when the function  $\phi$  is chosen as a differentiable function of the time  $t$  only,  $\psi(t, x, u) := \theta(t)$ ,  $(t, x, u) \in \Omega_1$ , then  $\widehat{\psi}(t, x, u) = \dot{\theta}(t)$ ,  $(t, x, u) \in \Omega_1$ . We introduce a subspace of  $C(\Omega_1)$ , to be denoted by  $C_a(\Omega_1)$ , consisting of those functions which depend only on the first variable  $t$ ; then the equalities (4) become:  $\int_J h(t, x(t), u) dt = a_h$ ,  $h \in C_a(\Omega_1)$ , with  $a_h$  the Lebesgue integral of  $h(\cdot, x, u)$  over  $J$ , independent of  $x$  and  $u$ . We will now choose for each of these spaces countable sets of functions whose linear combinations are dense in the corresponding spaces in the appropriate topologies. Thus we obtain countable sets of equalities.

For the space  $C'(\Omega_1)$  we shall choose  $\{\phi_i\}$ , a set of polynomials in  $(t, x_1, \dots, x_n)$ ; for  $\mathcal{D}(J^\circ)$ ,  $\{\chi_j\}$ , the sequence of functions of the type when the functions  $\psi$  are the sine and cosine functions

$$\sin\left(2\pi r \frac{t-t_0}{\Delta t}\right), \quad 1 - \cos\left(2\pi r \frac{t-t_0}{\Delta t}\right),$$

$r = 1, 2, \dots, j = 1, \dots, n$ , and for  $C_a(\Omega_1)$  the sequence  $\{h_k\}$ , a set of polynomials in  $t$ . Thus, finally, we obtain our set of integral equalities:

$$\begin{aligned} \int_J \widehat{\phi}_i(t, x(t), u(t)) dt &= \Delta\phi_i, & i = 1, 2, \dots, \\ \int_J \chi_j(t, x(t), u(t)) dt &= 0, & j = 1, 2, \dots, \\ \int_J h_k(t, x(t), u(t)) dt &= a_{h_k}, & k = 1, 2, \dots \end{aligned} \quad (5)$$

We will consider now an optimal control problem, to be denoted by P2, associated with a *nonlinear diffusion equation*. We follow the notation in [7] and [13]; see also [4], where we study a nonlinear wave equation. Take  $D$ , a bounded domain in  $\mathbf{R}^n$  with smooth boundary  $\partial D$ , and  $T$ , a positive real number, and define:  $Q_T := D \times (0, T)$ ;  $\Gamma_T := \partial D \times (0, T)$ ;  $D_0 := D \times \{0\}$ ;  $D_T := D \times \{T\}$ .

We also choose some functions:  $\overline{Q}_T \mathbb{R}$ ,  $k \in K$ ;  $f: \mathbb{R} \times \mathbb{R}^n \times \overline{Q}_T \rightarrow \mathbb{R}$ ,  $f \in C(\mathbb{R} \times \mathbb{R}^n \times \overline{Q}_T)$ .

Consider the nonlinear diffusion equation:

$$\begin{aligned} u_t(x, t) - \operatorname{div}(k(x, t)\nabla u(x, t)) \\ = f(u(x, t), \nabla u(x, t), x, t) \end{aligned} \quad (6)$$

for  $(x, t) \in Q_T$ , with the initial condition  $u(x, 0) = 0$ ,  $x \in D$ , and the *boundary condition*  $\nabla u \cdot n|_{\Gamma_T} = v$ ; here  $n$  is the outward normal, and the function  $(s, t) \in \Gamma_T \rightarrow v(s, t) \in V \subset \mathbf{R}$  is the *control function*, taking values in a *bounded* control set  $V$ .

A pair  $(u, v)$  of trajectory-function  $u$  and control-function  $v$  is said to be *admissible* if:

- i) The function  $(x, t) \rightarrow u(x, t)$  is a classical solution of (6), that is, it is in  $C^{2,1}(Q_T) \cap C(Q_T \cup \Gamma_T \cup \overline{D}_0)$  and satisfies (5).
- ii) The control function is continuous in  $\Gamma_T$ .
- iii) The terminal relationship  $u(\cdot, T) = g$  is satisfied;  $g$  is a given continuous function on  $D_T$ .

The set of admissible pairs for this problem will be denoted by  $\mathcal{F}_2$ , and assumed to be nonempty. Since the control set  $V$  is bounded, then there are *bounded* sets  $A \subset \mathbf{R}$  and  $B \subset \mathbf{R}^n$  so that  $u(x, t) \in A$ ,  $\nabla u(x, t) \in B$ , for all  $(x, t) \in \overline{Q}_T$ . Since there are many such sets  $A$  and  $B$ , we choose from those the *minimum sets*, that is, either the intersections  $\cap A$  and  $\cap B$  of all sets satisfying the relations above, or subsets of them. Thus, every point in our

set  $A$  (respectively,  $B$ ) will be a state (respectively, a gradient of a state) which can be reached by an admissible control inside the time interval  $[0, T]$ .

The optimization problem associated with this equation is as follows. Let  $f_{02}, f_1$  be nonnegative, Lipschitz-continuous real-valued functions on  $\mathbf{R}^{2n+2}, \mathbf{R}^{n+1}$  respectively. Then we wish to find a minimizing pair  $(u, v)$  of admissible trajectory  $u$  and control  $v$  for the functional

$$\begin{aligned} J(u, v) := \int_{Q_T} f_{02}(u(x, t), \nabla u(x, t), x, t) dx dt \\ + \int_{\Gamma_T} f_1(v(s, t), s, t) ds dt. \end{aligned} \quad (7)$$

We transform now this problem. Let  $\psi$  be in  $K$ . Then one can show [7] that the classical solution of (6), if it exists, satisfies the integral relation

$$\begin{aligned} \int_{Q_T} [u\psi_t - k\nabla u \nabla \psi + f\psi] dx dt \\ = - \int_{\Gamma_T} k\psi v ds dt + \int_{D_T} g\psi dx, \end{aligned} \quad (8)$$

for all  $\psi \in K$ . To these equalities we must add the equivalent of the last set of equations in (5). If a function  $\xi: A \times B \times Q_T \rightarrow \mathbf{R}$  depends only on  $(x, t)$ ,  $\int_{Q_T} \xi dx dt = a_\xi$ , the Lebesgue integral of  $\xi$  over  $Q_T$ . Also, if a function  $\zeta: V \times \Gamma_T \rightarrow \mathbf{R}$  depends only on  $(s, t)$ ,  $\int_{\Gamma_T} \zeta ds dt = b_\zeta$ , the Lebesgue integral of  $\zeta$  over  $\Gamma_T$ . By choosing countable dense sets as before,  $\{\psi_i\}, \{\xi_j\}, \{\zeta_k\}$ , we can obtain a countable set of equalities associated with problem P2:

$$\begin{aligned} \int_{Q_T} [u\psi_{it} - k\nabla u \nabla \psi_i + f\psi_i] dx dt \\ = - \int_{\Gamma_T} k\psi_i v ds dt + \int_{D_T} g\psi_i dx, \\ i = 1, 2, \dots, \\ \int_{Q_T} \xi_j dx dt = a_{\xi_j}, \quad j = 1, 2, \dots, \\ \int_{\Gamma_T} \zeta_k ds dt = b_{\zeta_k}, \quad k = 1, 2, \dots \end{aligned} \quad (9)$$

### Metamorphosis

We proceed to transform the control problems defined above; instead of minimizing over sets of admissible pairs trajectory-control, we find that it is possible to

minimize over a *measure space*, in the case of problem P1, and the product of two measure spaces, in that of problem P2. In general, the minimization of the functionals (2) over the set  $\mathcal{F}_1$  and (7) over the set  $\mathcal{F}_2$  are not possible: the infima are not attained; it is not possible, for instance, to write *necessary conditions* for these problems. We proceed then to transform them.

The advantages of the new formulations are:

- i) An automatic existence theory: there always are minimizers for our measure-theoretical problems;
- ii) The new problems are linear, and then one can use the whole paraphernalia of linear analysis;
- iii) Also, our minimization is *global*: the value reached, say, numerically is close to what one could reasonably call the global infimum of each problem.

The price to pay for these advantages is that the final state is reached only *asymptotically*: that is, as the number of (linear) constraints associated with the measure-theoretical problem tends to infinity.

Let us consider first problem P1. An admissible pair  $p := [x(\cdot), u(\cdot)]$  defines a linear, bounded, positive functional

$$p: F \rightarrow \int_J F(t, x(t), u(t)) dt \in \mathbb{R}$$

in the space  $C(\Omega_1)$  of continuous real-valued functions  $F$ , with  $\Omega_1 := J \times A \times U$ . By Riesz' theorem, the admissible pair  $p$  defines a *Radon measure*  $\mu$  on  $\Omega_1$  so that (2) becomes

$$I(\mu) = \mu(f_{01}), \tag{10}$$

while (5) becomes

$$\begin{aligned} \mu(\widehat{\phi}_i) &= \Delta\phi_i, & i &= 1, 2, \dots, \\ \mu(\chi_j) &= 0, & j &= 1, 2, \dots, \\ \mu(h_k) &= a_{h_k}, & k &= 1, 2, \dots, \end{aligned} \tag{11}$$

where we have written  $\mu(F) := \int_{\Omega_1} F d\mu$ . Note that we have not achieved anything new so far; the minimization of the functional (2) over (5) is exactly equivalent to that of the functional  $\mu(f_{01})$  over (11). We shall consider below the extension of our problem, the minimization of (10) over the set  $S_1$  of *all* measures  $\mu$  in  $\mathcal{M}^+(\Omega_1)$  satisfying (11).

In the case of Problem P2, we can proceed similarly. A solution of (6) defines a linear, bounded posi-

tive functional

$$u(\cdot, \cdot): F \rightarrow \int_{Q_T} F(u(x, t), \nabla u(x, t), x, t) dx dt$$

in the space  $C(\Omega_2)$  of continuous real-valued functions  $F$ , with  $\Omega_2 := A \times B \times Q_T$ . Also, a control  $v$  defines a linear, bounded, positive functional:

$$v(\cdot, \cdot): G \rightarrow \int_{\Gamma_T} G(v(s, t), s, t) ds dt$$

in the space  $C(\omega)$  of continuous functions  $G$ ,  $\omega := V \times \Gamma_T$ .

By Riesz's theorem, an admissible pair  $(u, v)$  defines two Radon measures  $\lambda$  and  $\nu$ , the first on  $\Omega_2$ , the second on  $\omega$ , so that (9) becomes:

$$\begin{aligned} \int_{\Omega_2} F_i d\lambda + \int_{\omega} G_i d\nu &= \int_{D_T} g\psi_i dx := \alpha_i, \\ i &= 1, 2, \dots, \end{aligned} \tag{12}$$

where

$$\begin{aligned} F_i(u, w, x, t) &:= u\psi_{ii}(x, t) \\ &\quad - \kappa(x, t)w\nabla\psi_i(x, t) + f(u, w, x, t)\psi_i(x, t), \\ G_i(v, s, t) &:= \psi_i(x|_{\partial D}, t)v. \end{aligned}$$

Thus, the minimization of the functional (7) over  $\mathcal{F}_2$  is equivalent to the minimization of

$$I(\lambda, \nu) = \lambda(f_{02}) + \nu(f_1), \tag{13}$$

where we have written as above  $\lambda(f)$  for  $\int_{\Omega_2} f d\lambda$ , and  $\nu(g)$  for  $\int_{\omega} g d\nu$ , over the set of measures  $(\lambda, \nu)$  corresponding to admissible pairs, which satisfy

$$\begin{aligned} \lambda(F_i) + \nu(G_i) &= \alpha_i, & i &= 1, 2, \dots, \\ \lambda(\xi_j) &= a_{\xi_j}, & j &= 1, 2, \dots, \\ \nu(\zeta_k) &= b_{\zeta_k}, & k &= 1, 2, \dots \end{aligned} \tag{14}$$

Again, we have not achieved anything new. As in the case of P1, we shall consider the extension of our problem, the minimization of (13) over the set  $S_2$  of *all pairs* of measures  $(\lambda, \nu)$  in  $\mathcal{M}^+(\Omega_2) \times \mathcal{M}^+(\omega)$  satisfying (14).

We have developed, therefore, two *infinite-dimensional linear programming* problems, the minimization of linear forms (10) or (13) over sets  $S_1$  and  $S_2$ , respectively, of positive Radon measures satisfying countably-infinite sets of linear equalities, (11) or (14). In the next section we consider the two main problems associated with their usefulness: do they have solutions; and how do the solutions help us solve our optimization problems.

**Existence and Structure**

We start by choosing finite, but variable, subsets of equalities from the sets (11) and (14); in this way we consider two *semi-infinite* linear programming problems, with finite number of equalities taking place in infinite-dimensional spaces. The first, to be denoted by  $LS1 = LS1(M_1, M_2, M_3)$  consists in minimizing the linear functional (10) over the subset  $S_1(M_1, M_2, M_3)$  of  $\mathcal{M}^+(\Omega_1)$  defined by the equalities

$$\begin{aligned} \mu(\widehat{\phi}_i) &= \Delta\phi_i, & i &= 1, \dots, M_1, \\ \mu(\chi_j) &= 0, & j &= 1, \dots, M_2, \\ \mu(h_k) &= a_{h_k}, & k &= 1, \dots, M_3; \end{aligned} \tag{15}$$

while the second, to be denoted by  $LS2 = LS2(N_1, N_2, N_3)$  consists in minimizing the linear functional (13) over the subset  $S_2(N_1, N_2, N_3)$  of  $\mathcal{M}^+(\Omega_2) \times \mathcal{M}^+(\omega)$  defined by

$$\begin{aligned} \lambda(F_i) + \nu(G_i) &= \alpha_i, & i &= 1, \dots, N_1, \\ \lambda(\xi_j) &= a_{\xi_j}, & j &= 1, \dots, N_2, \\ \nu(\zeta_k) &= b_{\zeta_k}, & k &= 1, \dots, N_3. \end{aligned} \tag{16}$$

We can prove that our minimization is global [11,12].

**Proposition 1**

i) As  $M_1, M_2, M_3 \rightarrow \infty$ ,

$$\begin{aligned} &\inf_{S_1(M_1, M_2, M_3)} \mu(f_{01}) \\ &\rightarrow \inf_{S_1} \mu(f_{01}) \leq \inf_{\mathcal{F}_1} I. \end{aligned} \tag{17}$$

ii) As  $N_1, N_2, N_3 \rightarrow \infty$ ,

$$\begin{aligned} &\inf_{S_2(N_1, N_2, N_3)} [\lambda(f_{02}) + \nu(f_1)] \\ &\rightarrow \inf_{S_2} [\lambda(f_{02}) + \nu(f_1)] \leq \inf_{\mathcal{F}_2} J. \end{aligned} \tag{18}$$

Thus, we can approach the *global infima* by taking a large enough number of equalities. The fact that the global infima can be strictly less than the classical one is discussed in [11].

There are two aspects of these *semi-infinite linear programming* problems which are of interest to us; their characteristics such as existence and characterization of solutions, and the relationship of these solutions to the original optimization problems. We examine first the linear programs themselves. The conclusions of the following proposition follow from weak\*-compactness of

the sets of measures, and *Rosenbloom’s theorem* [10]. We denote by  $\delta(z)$  the atomic measure with support  $\{z\}$ .

**Proposition 2**

- i) The linear programs  $LS1$  and  $LS2$  defined by (10)–(15) and (13)–(16) respectively have minimizers.
- ii) The solution of the program  $LS1$ , (10)–(15), has the form

$$\mu_{opt} = \sum_{i=1}^M \alpha_i \delta(t_i, x_i, u_i),$$

with  $\alpha_i \geq 0, M := M_1 + M_2 + M_3$ .

- iii) The solution of the program  $LS2$ , (13)–(16), has the form

$$\begin{aligned} &(\lambda_{opt}, \nu_{opt}) \\ &= \left( \sum_{i=1}^N \alpha_i \delta(u_i, w_i, x_i, t_i), \sum_{i=1}^N \beta_i \delta(v_i, s_i, t_i) \right), \end{aligned} \tag{19}$$

with  $\alpha_i, \beta_i \geq 0, N := N_1 + N_2 + N_3$ .

In part iii) of this Proposition we have identified  $(\lambda, \nu)$  with the product  $\mu \times \nu$ ; other possibilities exist [12].

We study now the other aspect of these solutions, how useful they are. How do we construct *suboptimal* pairs of trajectories and controls for our functionals, once we have solved the linear programming problems? We start with the problem  $LS1$ , (10)–(15), and shall proceed in several steps:

- 1) We proceed to obtain a solution  $\mu_{opt}$  of the form given above in ii).
- 2) We obtain a weak\*-approximation to this measure by a pair of piecewise constant functions  $(x, u)$ . The exact procedure for this construction, to be explained in detail below, involves the use of the support points of  $\mu_{opt}$  as well as the coefficients  $\alpha_i$ .
- 3) We use the function  $u$  as control in (1) with  $x(t_0) = x_0$  and obtain a trajectory  $x_R(\cdot)$ . The pair  $p_R := (x_R, u)$  can be shown to have the following properties:
  - a) By taking the numbers  $M_1, M_2, M_3$  sufficiently large, one can make  $I(p_R)$  as near as desired to  $\inf_S \mu(f_{01})$ .
  - b) The final state  $x_R(t_f)$  tends to  $x_f$  as  $M_1, M_2, M_3 \rightarrow \infty$ .
  - c) The constraint  $x_R(t_f) \in A$  tends to be satisfied in a similar manner.

In the case of problem *LS2*, (13)–(16), we proceed in a similar fashion.

- 1) Firstly we shall obtain optimal measures  $(\lambda_{\text{opt}}, \nu_{\text{opt}})$  for this problem.
- 2) We obtain then a weak\* approximation to  $(\lambda_{\text{opt}}, \nu_{\text{opt}})$  by a set of two piecewise-constant functions  $(u, \nu)$  by means of results involving weak\* -density.
- 3) The control function  $\nu$  obtained above is in  $L_2(\Gamma_T)$ , that is, for each  $t \in (0, T)$ ,  $\nu(\cdot, t) \in L_2(\partial D)$ , since it is piecewise constant and the set  $Q_T$  is bounded. It can serve then as boundary function for a (necessarily weak) solution of the system (6) to be denoted by  $u_\nu$ . This solution will be in  $H^1(Q_T)$ .
- 4) Borrowing the term from H. Rudolph [17], we shall call the pair  $(u_\nu, \nu)$  of trajectory and control functions *asymptotically admissible* if:
  - a) The control function  $\nu \in L_2(Q_T)$ , and  $\nu(s, t) \in V$ .
  - b) The trajectory  $u_\nu$  is the weak solution of (6) corresponding to the admissible control  $\nu \in L_2(Q_T)$ .
  - c) The trajectory function satisfies the appropriate constraints.
  - d) The final value  $u_\nu(\cdot, T)$  of the trajectory function tends in  $L_2(D_T)$  to the prescribed function  $g$  as  $N_1, N_2, N_3 \rightarrow \infty$ .
- 5) If the numbers  $N_1, N_2, N_3$  are sufficiently large, and the weak\*-approximation in step ii) above sufficiently good, then the value at the pair  $(u_\nu, \nu)$  of the functional  $J, J(u_\nu, \nu)$ , is close to the  $\inf_S J$ , and thus is a good suboptimal pair. Note that no use is made of the trajectory  $u$ , obtained in step ii) together with the control  $\nu$ .

We proceed in the next section to deal with approximation and examples.

### Approximations and Examples

The pattern should be clear; if one wants to obtain an estimate for a solution to problems such as P1 or P2, one should develop semi-infinite linear programming problems such as *LS1* or *LS2*, find out the corresponding solutions (the coefficients  $\alpha_i$  and the supports of the atomic measures as in Proposition 1) and then build suboptimal pairs. There are two main ways of estimating solutions of semi-infinite linear programming problems such as *LS1* or *LS2*.

The first consists in using functional analytical techniques in the space of measures; see [5,17]. *Rudolph's*

*method* has been used with great success to solve problems such as P1, in a large number of dimensions; see [18] for a most impressive application of Rudolph's method, as well as of our theory.

The second approach consists in approximating the infinite-dimensional problem by a finite-dimensional one, taking place in a Euclidean space of large dimension. We indicate first how to do this with respect to Problem P1. We note that in this problem the continuous functions  $h_k, k = 1, \dots, M_3$  have been replaced in practice by  $M_3$  *lower semicontinuous* pulse-like functions, also to be denoted by  $h_k$ ; the set  $J$  is divided into  $M_3$  equal segments, and the function  $h_k$  equals 1 in the  $k$ th of such segments, zero elsewhere. This is explained in detail in [11], and has been done because it brings better stability to the numerical processes.

A further concept must be introduced now [11]. Note that we have in *LS1* a *nonlinear* optimization problem, in which the unknowns are the coefficients  $\alpha_i$  and supports  $(t_i, x_i, u_i), i = 1, \dots, M$ . In order to find a linear approximation to this problem, we consider  $\widehat{\omega}$ , a countable dense subset of  $\Omega_1 := J \times A \times U$ . Taking  $\Upsilon \gg M$  elements from  $\omega$ , we can write (10)–(15) as follows. We write  $w_\ell := (t_\ell, x_\ell, u_\ell)$ , and wish to minimize

$$\sum_{\ell=1}^{\Upsilon} \alpha_\ell f_{01}(w_\ell) \quad (20)$$

on the set defined by the elements  $\alpha_\ell \geq 0, \ell = 1, \dots, \Upsilon$ , which satisfy, further,

$$\begin{cases} \sum_{\ell=1}^{\Upsilon} \alpha_\ell \widehat{\phi}_i(t_\ell, x_\ell, u_\ell) = \Delta \phi_i, & i = 1, \dots, M_1, \\ \sum_{\ell=1}^{\Upsilon} \alpha_\ell \chi_j(t_\ell, x_\ell, u_\ell) = 0, & j = 1, \dots, M_2, \\ \sum_{\ell=1}^{\Upsilon} \alpha_\ell h_k(t_\ell, x_\ell, u_\ell) = a_{h_k}, & k = 1, \dots, M_3. \end{cases} \quad (21)$$

Here, then, the supports  $w_\ell$  are fixed, in  $\widehat{\omega}$ ; the coefficients  $\alpha_\ell, \ell = 1, \dots, \Upsilon$ , are the only unknowns; this is an  $M \times \Upsilon$  (finite-dimensional) linear program. Of course as  $\Upsilon \rightarrow \infty$  the support of the optimal measure  $\mu_{\text{opt}}$  in Proposition 2 can be approximated closer and closer by that of  $\mu_{\text{opt}}^\Upsilon$ , the solution of (20)–(21). Note, further, that at most  $M$  of the unknown  $\alpha$ -s are nonzero; we shall assume that the problem has essential

regularity, and that exactly  $M$  of these  $\alpha$ -s are nonzero; see [11] for a discussion of this point. Once this *finite-dimensional linear program* is solved, suboptimal pairs can be constructed as explained above; the construction of the control function from the coefficients  $\alpha_\ell$  and supports  $u_\ell$  is as follows.

- 1) The time set  $J = [t_0, t_f]$  has been divided into  $M_3$  equal subdivisions  $J_k, k = 1, \dots, M_3$ , each of measure  $\Delta t/M_3$ , with  $\Delta t := t_f - t_0$ .
- 2) There is a total of  $M$  indices  $\ell$  associated with those values  $\alpha_\ell$  that are nonzero. To each of the subdivision  $J_k$  of  $J$  defined above are associated a number of these indices; if only one is so associated, then the value of  $\alpha_\ell$  equals  $\Delta t/M_3$ ; if more than one are associated, then the sum of the corresponding  $\alpha_\ell$ -s adds up to  $\Delta t/M_3$ .
- 3) Without loss of generality, let  $J_k$ , for  $1 \leq j \leq M_3$  be associated with two  $\alpha_\ell$ -s,  $\alpha_{\ell_1}$  and  $\alpha_{\ell_2}$ , as explained above, a typical situation; then we build the curve  $u(\cdot)$  on  $J_k$  by making  $u(t), t \in J_k$ , equal to  $u_{\ell_1}$  or  $u_{\ell_2}$  in each of the two partitions of  $J_k$  with lengths  $\alpha_{\ell_1}$  and  $\alpha_{\ell_2}$  respectively.

An example of this process will be given in the next section.

In the case of problem P2, a similar construction can be made. We have however chosen here Rudolph's method, for which an initial finite-dimensional estimate is necessary.

It is convenient to work in  $\mathcal{M}^+(\Omega_2 \times \omega)$ , identifying  $(\lambda, \nu) \rightarrow \lambda \times \nu$ ; see [13] for details. The system we have chosen is

$$\begin{aligned}
 & u_t(x, t) - \operatorname{div} \left( \frac{x^2}{1+t^2} \nabla u(x, t) \right) \\
 &= \frac{\|\nabla u(x, t)\|_E^2 + 1}{1+x^2+u(x, t)^2}, \tag{22} \\
 & u_x(0, t) = 0, \quad u_x(1, t) = \nu(t), \\
 & t \in (0, 1), \quad x \in (0, 1);
 \end{aligned}$$

that is,  $k(x, t) := x^2/(1+t^2), f(u, w, x, t) := \|w\|_E^2 + 1)/(1+x^2+u^2)$ . We have taken  $V = [-10, 10], g(x) = 0.075, x \in [0, 1]$ , and we wish to minimize:

$$J(u, \nu) = \int_{Q_T} \frac{u(x, t)^2 + \|\nabla u(x, t)\|_E^2}{1 + \sin^2(tu(t, x))} dt;$$

that is,  $f_{02}(u, w, x, t) := (u^2 + \|w\|_E^2)/(1+\sin^2(tu))$ , and  $f_1 \equiv 0$ . The boundary  $\partial D$  is composed of two points only,

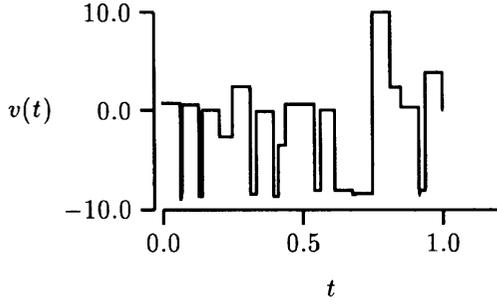

of which only one, the one at  $x = 1$ , plays an active role, the control being the heat flow at that point.

The functions  $\psi$  were chosen of the form  $\psi(x, t) = t^p \cos(\ell\pi x) + q(t)$ , or  $\psi(x, t) = t^p \sin(h\pi x) + q(t)$ ; the functions  $q$  are test functions introduced to improve the behavior at  $x = 1$  for the determination of an *initial solution*, as explained below. Ten such functions  $\psi$  were chosen, with values of  $p = 1, 2$  and  $\ell = 1, 2, 3, h = 1, 2$ . The 16 functions  $\xi$  were chosen by dividing the square  $[0, 1] \times [0, 1]$  into 16 equal squares, the functions  $\xi$  being the characteristic functions of the individual squares. Thus the total number of constraints  $m$  equals  $m = 1 + 10 + 16 = 27$ . The computational method consists of three steps:

- i) The most difficult problem encountered was that of finding an initial solution from which, in part ii) of the method, one can iterate towards the minimum. This was done here by means of a finite-dimensional linear program, obtained by *discretizing* all the variables of the problem. It was necessary to find an initial solution by first solving for some of the parameters, thus the need of the functions  $q$  introduced above, because the (rather rough) discretization tended to make the problem infeasible. Then a finite-dimensional *simplex program* was run, of rather small size, with 677 variables and, of course, 27 constraints. Only the first phase (the one that produces a feasible solution) was run. It is usual in these problems to use a discretized solution as an initial one; see [5,17, Chaps. 5, 6].
- ii) Then the *simplex algorithm* of Rudolph was run using the output of step i) as initial solution, and after 87 iterations it converged to a value of 0.202247; it had started with a value of 1.93919. This is a numerical estimation of the *global minimum*.
- iii) Once the optimization is performed, a nearly-optimal control  $\nu$  can be constructed; the method is shown in detail in [13], and follows the same general rules as the previous case. The graph of the resulting control is shown in Fig. 1.

**Unbounded Controls and Nonstandard Methods**

We consider in this last section a finite-dimensional control problem just like P1, but in which the control set  $U$  is unbounded. We shall use the same notation for P1 as above. The problem now is that since  $U$  is un-

**Semi-infinite Programming and Control Problems, Figure 1**  
 Graph of the nearly-optimal control  $v$ . Note that the control set is  $V = [-10, 10]$

bounded we may obtain ‘impulses’ as controls and thus discontinuous trajectories. We need to be able to handle infinities, a role for which nonstandard analysis is well suited. We start by extending the control space, and consider  $U$  a subset of  $\mathbb{R}^m$ , the  $m$ -dimensional space generated by the extended real line  $\overline{\mathbb{R}}$ . Nothing much has changed, but we can put a topology on  $\Omega := J \times A \times U$  which makes it compact [1]. We proceed now with our nonstandard construction; see [2,12,14]. We will work in a *nonstandard framework* given by a *superstructure*  $V(W)$ ,  $\mathbb{R} \subset W$ . The superstructure  $V(*V)$  is also an *enlargement*, and  $\mathcal{N}_1$ -saturated. We study integrals of the form

$$\int_J f(t, x(t), u(t)) dt, \tag{23}$$

with  $p \in \mathcal{F}_1$  and  $f \in C(\Omega')$ . Then,

$$\forall p \in \mathcal{F}_1: \int_J f(t, x(t), u(t)) dt \in \overline{\mathbb{R}}; \tag{24}$$

by transfer,

$$\forall p \in {}^* \mathcal{F}_1: {}^* \int_{{}^* J} {}^* f(t, x(t), u(t)) dt \in {}^* \overline{\mathbb{R}}. \tag{25}$$

Thus, the nonstandard version of P1 consists in minimizing

$${}^* I(p) := {}^* \int_{{}^* J} {}^* f_{01}(t, x(t), u(t)) dt \tag{26}$$

on the class  ${}^* \mathcal{F}_1$  of pairs satisfying

$${}^* \int_{{}^* J} {}^* f_i(t, x(t), u(t)) dt = b_i, \quad i = 1, \dots, M, \tag{27}$$

where the system (15) has been written in a compact form. Consider now the map suggested by (24). If  $p \in \mathcal{F}_1$  is fixed, the map

$$\begin{aligned} \nu_p: F &\rightarrow \int_J F(t, x(t), u(t)) dt \in \overline{\mathbb{R}}, \\ F &\in C(\Omega') \end{aligned} \tag{28}$$

is linear and positive. By Riesz’s theorem, there is a measure, to be denoted also by  $\nu_p$ , on the *Borel sets*  $\mathcal{B}$  of  $\Omega'$ , that represents this map; remember that  $\Omega'$  is compact. Then  $({}^* \Omega', {}^* \mathcal{B}, {}^* \nu)$  is a nonstandard measure space and then (see [9]):

**Lemma 3** *There is a measure space  $({}^* \Omega', \mathcal{A}, \mu_L^p)$  so that  $\mu_L^p$  is the Loeb measure associated with  $\nu_p$ ; then,*

$$\begin{aligned} {}^* \int_{{}^* J} F(t, x(t), u(t)) dt &= \mu_L^p(F) \\ &:= \int_{{}^* \Omega'} F d\mu_L^p, \quad F \in C({}^* \Omega'). \end{aligned} \tag{29}$$

The algebra  $\mathcal{A}$  is an extension of the algebra  ${}^* \mathcal{B}$ .

Thus, one can write the optimization problem as the problem of minimizing

$$J(\mu_L^p) := \mu_L^p(f_{01}), \tag{30}$$

over the set  $\mathcal{M}_M^L$  of measures of the form  $\mu_L^p$  defined by

$$\mu_L^p(f_i) = b_i, \quad i = 1, \dots, M. \tag{31}$$

**Proposition 4**

- i) *The infima associated with the problems (26)–(27) and (30)–(31) are equal.*
- ii) *For any positive infinitesimal  $s \in {}^* \overline{\mathbb{R}}$ , we can find a near-minimizer  $\mu_s \in \mathcal{M}_M^L$  for the functional  $J$  in (30) in the set  $\mathcal{M}_M^L$ , so that*

$$J(\mu_s) = \inf_{\mathcal{M}_M^L} J + s. \tag{32}$$

Let, then,  $s$  be a fixed positive infinitesimal in  ${}^* \overline{\mathbb{R}}$ , and  $\mu_s$  the corresponding near-minimizer for  $J$  on  $\mathcal{M}_M^L$ . We can proceed to map back this measure to the standard world, by means of the *standard part map*, see [2].

**Proposition 5** *There is a Baire measure  $\mu_{opt}$  on  $\Omega'$  so that:*

i) If  $S$  is a Baire set in  $\Omega'$ ,

$$\mu_{opt}(S) = \circ \mu_s(st_{\Omega'}^{-1}(S)),$$

where  $st_{\Omega'}^{-1}(S)$  is the union of the monads of the elements of  $S$ .

ii)

$$\mu_{opt}(f_{01}) := \int_{\Omega'} f_{01} d\mu_{opt} \leq \inf_{F_1} \int_J f_{01}(t, x(t), \dot{x}(t)) dt. \quad (33)$$

iii) The measure  $\mu_{opt}$  is a solution of the following optimization problem. Minimize

$$\mu(f_{01}) \quad (34)$$

over the set  $\mathcal{M}_M^+(\Omega')$  of positive Baire measures on  $\Omega'$  satisfying

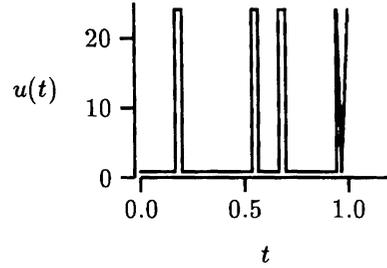

$$\mu(f_i) = b_i, \quad i = 1, \dots, M. \quad (35)$$

iv) The support of  $\mu_{opt}$  contains subsets of  $\Omega'$  in which at least one component of the variable  $u$  is either  $-\infty$  or  $\infty$ . The measure  $\mu_{opt}$  is defined by a Baire measure on  $J \times A \times V$ , with  $V$  the set of all finite elements of  $U$ , plus atomic measures on those subsets.

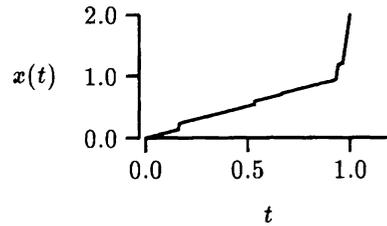

In problems of interest, in which the function  $f_{01}$  tends to infinity at infinity, and in which the infimum is finite, elements  $(t, x, u) \in \Omega'$  with one or more components of value  $\infty$  or  $-\infty$  do not really occur in the support of  $\mu_{opt}$ ; note that expressions such as  $\infty - \infty$  are not defined for the extended real line. Thus, if  $|f_{01}(t, x, z)| = \infty$  whenever a component of  $u$  is either  $\infty$  or  $-\infty$ , and that the minimum associated with the linear program is finite, such elements are not present in the support of  $\mu_{opt}$ .

We are now in a strong position to solve our original problem: the optimization problem P1 with unbounded  $U$  in the standard world. We proceed as in P1 in previous sections, solving for  $\mu_{opt}$ , approximating its support, building suboptimal pairs.

We have solved a simple problem, taken from [6], with  $n = 1$  and  $f_{01}(t, x, u) := (u^3 - 1)^{1/3}$ , and  $\dot{x} = u$ ; the other parameters are  $t_0 = 0, t_f = 1, x_0 = 0, x_f = 2$ . The numerical approximation was performed with the following parameters:  $Q = 24, M_1 = 2, M_2 = 8, M_3 = 30, M = 40, N = 27000$ . Each of the axis associated with the variables  $(t, x, u)$  was divided into 30 parts; the minimum obtained was 0.49587, which should be compared with

Semi-infinite Programming and Control Problems, Figure 2  
Graph of the control  $u$

Semi-infinite Programming and Control Problems, Figure 3  
Graph of the trajectory  $x$

the minimum for the problem obtained by semiclassical means in [6] of 0.413. The approximation problems for this kind of optimization problems are fierce; it is necessary to have a large value of  $Q$  as well as very fine mesh, thus very large linear programs. The graphs of the control  $u$  and the trajectory  $x$  can be seen in Fig. 2 and Fig. 3.

We should note that, even in this simple problem, we have achieved something not easily accomplished by the more traditional methods, which would have found it extremely hard to deal with the cube of a 'delta function'; they mostly deal in problems in which the control variable, our  $u$ , appears linearly.

The method employed here appears promising to deal with partial differential equations with solutions exhibiting shocks, such as those studied in [8]. See also [15,16].

We have also extended these methods to the design of optimal shapes associated with nonlinear differential equations [3].

Discretization of optimization problems

Consider the following optimization problem with respect to  $x \in \mathbf{R}^n$ , in which  $Y \subseteq \mathbf{R}^m$  is a nonempty com-

pact set and  $F \in C(\mathbf{R}^n)$  and  $g \in C(\mathbf{R}^n \times Y)$  are given functions:

$$P[Y] \quad \begin{cases} \min & f(x) \\ \text{s.t.} & g(x, y) \leq 0, \quad y \in Y. \end{cases}$$

If  $Y$  is an infinite set, this problem includes finitely many unknowns and infinitely many inequality constraints and, therefore, is said to be a *semi-infinite programming* (briefly: *SIP*) problem. The problem is denoted as *linear* if  $f$  and  $g(\cdot, y)$ ,  $y \in Y$ , are affine-linear, as *convex* if these functions are convex, and as *nonlinear* in all other cases.

Results which hold for  $P[Y]$  under the given general conditions similarly apply to problems with constraints  $g_j(x, y) \leq 0$ ,  $y \in Y^j$ , for  $j = 1, \dots, p$ , where  $Y^j \subseteq \mathbf{R}^{m_j}$  is nonempty and compact and  $g_j \in C(\mathbf{R}^n \times Y^j)$  (e. g. [43]). Note in this connection that an ordinary inequality constraint  $\tilde{g}_j(x) \leq 0$  can, for example, be expressed as  $g_j(x, y) \leq 0$ ,  $y \in \{1\}$ , for  $[g_j(x, y) := \tilde{y}\tilde{g}_j(x)$  and that an equality constraint  $h_j(x) = 0$  can be described by the two inequality constraints  $\pm h_j(x) \leq 0$ . Inclusion of equality constraints in this way, however, is not possible when the existence of a point is required at which all inequality constraints are strictly satisfied. A comprehensive survey of numerical methods for the solution of such SIP problems can be found in [43].

In the following discussion,  $\|\cdot\|$  is an arbitrary norm and  $\|\cdot\|_p$ ,  $1 \leq p \leq \infty$ , the  $l^p$ -norm in some space  $\mathbf{R}^s$ . The set  $\mathbf{N}_0$  equals  $\mathbf{N} \cup \{0\}$ , the number  $|A|$  means the cardinality of a set  $A$ , and

$$\text{dist}(D, Y) := \sup_{y \in Y} \inf_{z \in D} \|y - z\|_\infty$$

is the *density* of  $D \subseteq Y$  in  $Y$ . Moreover, for each  $D \subseteq Y$ , a problem  $P[D]$  is defined by

$$P[D] \quad \begin{cases} \min & f(x) \\ \text{s.t.} & g(x, y) \leq 0, \quad y \in D. \end{cases}$$

The *set of feasible points* of  $P[D]$  is denoted by

$$F(D) := \{x \in \mathbf{R}^n : g(x, y) \leq 0, \quad y \in D\}$$

and its *minimal value* by

$$\mu(D) := \inf_{x \in F(D)} f(x).$$

In case  $D \subseteq Y$  is a finite and  $Y$  an infinite set, problem  $P[D]$  is said to be a *discretized SIP problem*.

A point  $x^* \in F(D)$  is called a *global solution* of  $p[D]$  if  $f(x^*) = \mu(D)$  and a *local solution* if  $f(x^*) \leq f(x)$  is true for all  $x \in F(D) \cap U(x^*)$  with some open ball  $U(x^*)$  centered at  $x^*$ . Usually convergence of algorithms to a global solution of some problem  $p[D]$  can be guaranteed only for linear and convex problems. Therefore, if not specified, a ‘solution’ of  $p[D]$  for some  $D$  in the following is a point which can be obtained in practice as the limit point of some sequence generated by an algorithm. This may be a local or a global solution of the problem or, more generally, a point at which some first order optimality condition is satisfied.

One approach to the solution of a SIP problem  $p[Y]$  is to (approximately) solve  $p[Y_i]$  for  $i = 0, 1, \dots$ , where  $\{Y_i\}$  is a sequence of finite subsets (‘grids’) of  $Y$  with

$$\lim_{i \rightarrow \infty} \text{dist}(Y_i, Y) = 0.$$

A procedure of the latter type is denoted as a *discretization method*. The grid sequence  $\{Y_i\}$  needed for that is usually prescribed a priori where, typically, the grids are equidistant and have the property  $Y_{i+1} \supseteq Y_i$ ,  $i \in \mathbf{N}_0$ . Occasionally  $\{Y_i\}$  is also successively defined a posteriori (‘adaptively’) such that information obtained on the  $i$ th discretization level is utilized to define  $Y_{i+1}$ .

If  $x^{*i} \in F(Y_i)$  is a solution of  $p[Y_i]$ ,  $i \in \mathbf{N}_0$ , and accumulation points of  $\{x^{*i}\}$  solve  $p[Y]$ , then also accumulation points of each sequence  $\{\tilde{x}^i\}$  of approximate solutions  $\tilde{x}^i$  of  $p[Y_i]$  are solutions of  $p[Y]$  as long as  $\lim_{i \rightarrow \infty} (\tilde{x}^i - x^{*i}) = 0$ . Thus, it has to be guaranteed that accumulation points of  $\{x^{*i}\}$  solve  $p[Y]$  and that the algorithm used for the solution of  $p[Y_i]$  generates such point  $\tilde{x}^i$  end after finitely many iterations. Both is separately discussed below.

In practice, only a finite set of discretized problems  $p[Y_i]$ ,  $i = 0, \dots, I$ , can be solved for some  $I \in \mathbf{N}$ . Thus a discretization method describes a way to efficiently compute a solution of a (finely) discretized SIP problem  $p[Y_I]$ . Such solution serves as an approximate solution of the given SIP problem where its accuracy is usually determined by the density of  $Y_I$  in  $Y$ .

A clear advantage of discretization methods over other SIP methods is that they exclusively work with finite subsets of  $Y$ . In particular, for the finite program  $p[Y_i]$ , feasibility of a point  $x \in \mathbf{R}^n$  can be checked easily, other than for the SIP problem  $p[Y]$  itself. Therefore a discretization method is especially suited for SIP problems with a solution  $x^*$  at which  $g(x^*, \cdot)$  is (almost) constant on  $Y$  or on parts of  $Y$ . The latter occurs, for example, at SIP problems originating from complex Chebyshev approximation [41].

A drawback of discretization methods is that they require a huge number of function evaluations and that the numerical costs for solving the discretized problems and hence for gaining accuracy with respect to the SIP problem increase dramatically with decreasing grid densities. Therefore, in view of reasonable computing times, the maximal number of grid points and hence the accuracy obtainable by discretization methods are limited in practice. (Grids with at most 50,000 to 100,000 points for problems with less than 100 variables are typical.) Furthermore, a solution  $x^{*i} \in F(Y_i)$  of  $p[Y_i]$  is normally only an *outer approximation* of a solution of the SIP problem, and hence especially an approximate solution of  $p[Y]$  that is not feasible for  $p[Y]$ . Observe that, for  $Y_i \subseteq Y$ , a global solution  $x^{*i}$  of  $p[Y_i]$  which is feasible for  $p[Y]$  also solves  $p[Y]$  since

$$f(x^{*i}) = \inf_{x \in F(Y_i)} f(x) \leq \inf_{x \in F(Y)} f(x) \leq f(x^{*i}),$$

but that such equivalence of a SIP problem with a finite optimization problem is the exceptional case [43].

The solution reached by a discretization procedure, however, often suffices for practical purposes. If this is not the case, then, under certain conditions, the solution can be improved by a locally convergent *reduction based method* [43]. Such two-phase procedures currently represent the most promising methods at least for the solution of nonlinear SIP problems.

**Convergence of Solutions of Discretized SIP Problems**

A solution of a discretized SIP problem is not necessarily an approximate solution of the SIP problem (see [23,43] for counterexamples). Such approximation property is only given under suitable assumptions. For

that let  $\{Y_i\}$  be a sequence of finite subsets of  $Y$  satisfying

$$\lim_{i \rightarrow \infty} \text{dist}(Y_i, Y) = 0$$

and let

$$\Lambda(x^F, D) := F(D) \cap \{x \in \mathbf{R}^n : f(x) \leq f(x^F)\}$$

be a *level set* with respect to  $x^F \in F(Y)$  and  $D \subseteq Y$ .

Then, if  $Y_i \subseteq Y_{i+1} \subseteq Y$  for  $i \in \mathbf{N}_0$  and  $\Lambda(x^F, Y_0)$  is bounded for some  $x^F \in F(Y)$ , the following can be shown (see [42] for a more general form of this result): Problem  $p[Y_i]$ ,  $i \in \mathbf{N}_0$ , possesses a global solution  $x^{*i} \in \mathbf{R}^n$ ; moreover,  $\{x^{*i}\}$  has an accumulation point, each such point is a global solution of  $p[Y]$ , and  $\{\mu(Y_i)\}$  converges monotonically increasing to  $\mu(Y)$ .

Especially for convex problems, a bounded set  $\Lambda(x^F, Y_0)$  exists if and only if the SIP problem  $p[Y]$  has a nonempty bounded set of solutions [43]. Similar results were also proved for linear problems in [10,11,17], for convex problems in [46], and for nonlinear ones in [12]. Furthermore, for linear problems, the general possibility of discretization is studied in [4,5,6]. Some of the given theorems do not require the inclusion  $Y_i \subseteq Y_{i+1}$  for all  $i \in \mathbf{N}_0$ , but efficient use of the obtained solution of  $p[Y_i]$  as a starting vector for  $p[Y_{i+1}]$  normally suggests that  $Y_{i+1}$  contains  $Y_i$  or at least those points of  $Y_i$  which belong to constraints that are active this solution.

An extension of the above convergence result guarantees convergence of solutions  $x^{*i}$  of problems  $p[D_i]$ ,  $i \in \mathbf{N}_0$ , where  $D_0$  equals  $Y_0$ , the set  $D_{i+1}$  satisfies  $D_i \cup \{y^i\} \subseteq D_{i+1} \subseteq Y_{i+1}$ , and  $Y^i$  is a point with  $g(x^{*i}, y^i) = \max_{y \in Y_{i+1}} g(x^{*i}, y)$  [40,42,43]. A variant of this statement concerning also nonlinear problems is derived in [30, p. 464] where  $x^{*i}$  only needs to be a certain (approximate) stationary point of  $p[D_i]$ . Rules which allow to drop some of the constraints in  $p[D_i]$  were given in [7,26]. But, in this case, the size of  $|D_i|$  is not easily controlled and the choice of  $\{Y_i\}$  not obvious ( $|Y_i|$  should grow slowly if e. g.  $D_{i+1} := D_i \cup \{y^i\}$ ).

Another convergence theorem refers to nonlinear SIP problems and the practically relevant case that  $p[Y_i]$  is solved by a *sequential quadratic programming* (briefly: *SQP*) type method. For that let  $f \in C^3(\mathbf{R}^n)$  and  $g \in C^{3,0}(\mathbf{R}^n \times Y)$ , and define, for each  $x \in \mathbf{R}^n$ ,  $\rho > 0$ , and compact set  $D \subseteq Y$ , the *exact  $L_\infty$ -penalty function*

$$L_\infty(x, \rho, D) := f(x) + \rho \phi^+(x, D),$$

where

$$\phi^+(x, D) := \max_{y \in D} \max\{g(x, y), 0\}.$$

A *stationary*, respectively *critical*, point of  $L_\infty(\cdot, \rho, D)$  that is feasible for  $p[D]$  is a *Karush–Kuhn–Tucker point* (KKT point) of  $p[D]$ , and, conversely, a KKT point of  $p[D]$  is a stationary point of  $L_\infty(\cdot, \rho, D)$  if  $\rho$  is sufficiently large (see e. g. [2,9] for details in the finite case and use the definition of a KKT point of a SIP problem from e. g. [16,17], which also applies to finite problems).

Then, if, for all  $i \in \mathbf{N}_0$ , there exists a stationary point  $x^{*i}$  of  $L_\infty(\cdot, \rho_i, Y_i)$  for some  $\rho_i > 0$  and if  $\rho_i \leq \rho^*$  with some  $\rho^*$ , one has [43]: Each accumulation point  $x^*$  of  $\{x^{*i}\}$  is a stationary point of  $L_\infty(\cdot, \rho^*, Y)$ ; if  $\{x^{*ij}\}$  converges to  $x^*$  and  $\lim_{j \rightarrow \infty} \phi^+(x^{*ij}, Y_{ij}) = 0$ , then  $x^*$  also is a KKT point of  $p[Y]$ .

For example, the SQP type methods in [9] and [24] for the solution of a discretized SIP problem  $p[Y_i]$  (see below) converge to a stationary point  $x^{*i}$  of  $L_\infty(\cdot, \rho_i, Y_i)$  and a KKT point of  $p[Y_i]$ , respectively. The existence of an accumulation point of  $\{x^{*i}\}$  is especially guaranteed for the method in [9] if a certain level set for the exact  $L_\infty$ -penalty function is compact [9].

Only few rate of convergence results for a sequence of solutions of discretized SIP problems are known (cf. [30,41,43]). Note also in this regard that the numerical costs for solving discretized SIP problems normally tend to infinity with decreasing grid density. For a general theory on the discretization of SIP problems, the reader is referred to [29,30].

### Solution of Discretized SIP Problems

Except for small  $n$  and  $|Y_i|$ , it is not advisable to solve a discretized SIP problem  $p[Y_i]$  by an arbitrary method for finite programming, since such methods often require the solution of subproblems which have the same number of constraints as the problem itself and hence do not use to advantage that the constraints in a SIP problem originate from a continuous function. Moreover, if a finely discretized SIP problem  $p[Y_I]$  is to be solved (the objective of a discretization method), it is much more efficient to solve  $p[Y_I]$  via a sequence of problems  $p[Y_i]$ ,  $i = 0, \dots, I$ , with progressively refined grids  $Y_i$  rather than to approach  $p[Y_I]$  directly. (See e. g.

[9] for numerical examples showing this.) For the all-over efficiency of a discretization method it is, therefore, also important that the (approximate) solution  $\tilde{x}^i$  of  $p[Y_i]$  (and possibly additional information) can be exploited for the solution of  $p[Y_{i+1}]$ . Such point  $\tilde{x}^i$ , however, is usually infeasible for  $p[Y_{i+1}]$  if  $Y_{i+1} \neq Y_i$ . Therefore methods which start from a feasible point of  $p[Y_i]$  may turn out to be too costly within such scheme.

A variety of methods for the efficient solution of a discretized SIP problem  $p[Y_i]$  has been suggested. Concerning *linear SIP problems*, in particular the following algorithm has been specified and successfully applied (let  $i \in \mathbf{N}_0$  be fixed and choose  $k := 0$  if  $i = 0$ ):

- 0 Choose  $k \in \mathbf{N}_0$  and  $D_k \subseteq Y_i$  with  $n \leq |D_k| < \infty$ .
- 1 Find a solution  $x^k \in \mathbf{R}^n$  of  $P[D_k]$ .  
Let  $A_k := \{y \in D_k : g(x^k, y) = 0\}$ .
- 2 Find  $y^k \in Y_i$  such that  $g(x^k, y^k) = \max_{y \in Y_i} g(x^k, y)$ .
- 3 IF  $g(x^k, y^k) \leq 0$ , STOP!  
ELSE choose  $D_{k+1} \subseteq Y_i$  with  $D_{k+1} \supseteq A_k \cup \{y^k\}$ .
- 4 Set  $k := k + 1$  and go to Step 1.

If the stopping criterion of the algorithm is fulfilled, the algorithm can be continued with  $i := i + 1$ , beginning with Step 2 and the current index  $k$ . Especially, if  $\{Y_i\}$  is a sequence of grids such that  $Y_i \subseteq Y_{i+1} \subseteq Y$ , if  $D_0 := Y_0$  and if  $\Lambda(x^F, Y_0)$  is bounded for some  $x^F \in F(Y)$ , then each problem  $p[D_k]$  has a global solution.

It can be shown that this algorithm stops after finitely many iterations with a global solution  $x^k \in F(Y_i)$  of  $p[Y_i]$ , provided that  $\mu(D_{k+1}) = \mu(D_k)$  is true only for finitely many  $k \in \mathbf{N}$  in succession [40]. The latter is guaranteed, for example, if the solution of problem  $p[D_k]$  is unique [40], which is almost always the case on a computer. In practice, such solution should be computed via solution of the dual problem for  $p[D_k]$ , since, in that way,  $p[D_{k+1}]$  can be solved very efficiently and much computing time is saved (e. g. [43]). The stopping criterion in Step 3 may be exchanged for  $g(x^k, y^k) \leq \varepsilon_i$  where  $\{\varepsilon_i\}$  is a zero sequence of nonnegative numbers.

Discretization procedures of this type for linear SIP problems were proposed in [14,17,40] with certain sets

$$D_{k+1} \supseteq \left\{ y \in Y_i : g(x^k, y) \geq \vartheta_k \right\}$$

and different choices of  $\vartheta_k \leq 0$  (see also [15] for an extension to quadratic problems). The cardinality  $|D_{k+1}|$  of such set  $D_{k+1}$ , however, can become quite large so that, in practice, a proper subset of  $D_{k+1}$  may have to be selected by a cumbersome management. Another promising choice of  $D_{k+1}$ , which can be motivated by the success of the methods e. g. in [8,9,28], and [36], but which has not been tried yet, would be to only add some or all violating discrete local maximizers of  $g(x^k, \cdot)$  on  $Y_i$  to the set of active points  $A_k$ .

An extension of the algorithm for linear problems from [40] to *convex problems* was developed in [41,42] and applied to large filter design problems in [35] (see also [36] for computing times and a comparison with another method). As a *cutting plane method*, this latter method requires the knowledge of a compact set  $X \supseteq \Lambda(x^F, Y_0)$  for some  $x^F \in F(Y)$ , which is described by finitely many linear inequality constraints. Typically, in practice,  $X$  is given by box constraints  $\alpha_j \leq x_j \leq \beta_j$ ,  $j = 1, \dots, n$ , where it is known or assumed that  $p[Y]$  has a global solution which satisfies such bounds. A way to construct a bounded set  $X$  numerically without use of such a priori knowledge on the solution has been found for SIP problems which correspond to linear complex Chebyshev approximation problems [41].

An approach to finite convex programs in [13] combines an *interior point logarithmic barrier method* with a cutting plane technique, which allows to add and delete constraints and hence is capable of solving finely discretized convex SIP problems. In [20] this method has been modified and incorporated into a ‘dynamic’ heuristic discretization procedure for the solution of SIP problems. (See [43] for a comment on the numerical results in [20].) Further ideas concerning the solution of discretized convex SIP problems can be found in [21,22,23,47], and [48].

A number of methods is oriented towards the solution of *nonlinear discretized SIP problems*. In the 1970s, some authors had developed *combined methods of feasible directions* for nonlinear finite optimization problems, which can start from an arbitrary point in  $\mathbf{R}^n$  (e. g. [34]). For SIP problems, such methods have been

embedded into a discretization scheme, where convergence of certain obtainable (approximate) stationary points of  $p[Y_i]$  to a related stationary point, respectively KKT point, of  $p[Y]$  can be proven under relatively weak assumptions [8,28,33]. In particular, in [33], the subproblems occurring at solution of the discretized problem  $p[Y_i]$  contain one constraint for each member of the entire *set of  $\varepsilon$ -most active points*

$$Y_{i,\varepsilon}^+(x) := \left\{ y \in Y_i : g(x, y) \geq \phi^+(x, Y_i) - \varepsilon \right\},$$

for some  $\varepsilon \geq 0$ , while, in [8], the special structure of a discretized SIP problem is exploited and constraints are needed only for the usually much smaller set of *discrete ‘left’ local maximizers* in  $Y_{i,\varepsilon}^+(x)$ . The behavior of the algorithm could be improved by addition of further points to the latter set [28]. A numerical comparison of the method in [8] with other methods is found in [45].

Using first order information only, these algorithms for  $p[Y_i]$  normally have at best a linear rate of convergence. Indeed, the  $r$ -linear convergence of a modification of the method for finite problems from [34] could be shown [31], where, in this method, however, all constraints have to be respected for the construction of the quadratic subproblems. The method was incorporated into an adaptive discretization procedure such that, for certain convex problems, the entire sequence of iterates has the same  $r$ -linear rate of convergence as the inner method for the finite subproblems [32]. Another variant of the method from [34], using  $\varepsilon$ -most active constraints only, can be found in [30, p.279], but the convergence rate of this method does not seem to be known.

A combined discretization procedure and exact penalty function method using first order information was developed in [30, p. 479]. Another, normally at best linearly convergent method can be found in [18,19], where the subproblems contain constraints for all elements of the *set of  $\varepsilon$ -global points*

$$Y_{i,\varepsilon}(x) := \left\{ y \in Y_i : g(x, y) \geq \max_{y \in Y_i} g(x, y) - \varepsilon \right\}$$

at  $x$  with respect to  $Y_i$  for a certain  $\varepsilon \geq 0$ . (Note that  $Y_{i,\varepsilon}(x)$  equals  $Y_{i,\varepsilon}^+(x)$  for each point  $x \in \mathbf{R}^n$  outside or on the boundary of  $F(Y_i)$  and that especially  $Y_{i,0}(x)$

represents the set of *discrete global maximizers* of  $g(x, \cdot)$  on  $Y_i$ .) Consult, furthermore, [1] for an unconventional discretization procedure for problems with convex constraints, which generates feasible points with respect to  $p[Y]$ .

Some authors have developed *SQP type algorithms* for the solution of nonlinear finite optimization problems with large numbers of constraints, as they are given by discretized SIP problems. The purpose of such developments is to considerably reduce the size of the arising quadratic subproblems and the total number of gradient evaluations in comparison to standard SQP methods and to simultaneously preserve the good convergence properties of these methods (e. g. [3]). Methods of this form were given in [9,24] (with code contained in the software package CFSQP), [27,44] (without convergence proofs), and, for linearly constrained problems, in [39] (with code in [24]). A special feature of the algorithm in [24] is that the iterates remain feasible with respect to  $p[Y_i]$ . The peculiarity of the algorithm in [9] is that the quadratic subproblem at the  $k$ th iteration only needs to include constraints for the usually small set of *discrete  $\epsilon$ -global local maximizers*

$$Y_{i,\epsilon}^l(x^k) := \left\{ \tilde{y} \in Y_{i,\epsilon}(x^k) : g(x^k, \tilde{y}) \geq g(x^k, y), y \in U_i(\tilde{y}) \right\},$$

where  $U_i(\tilde{y})$  is a *discrete neighborhood* of  $\tilde{y}$  in  $Y_i$ , consisting of  $\tilde{y}$  and neighboring points of  $\tilde{y}$  in  $Y_i$  (see also [43]). As an example of such SQP type algorithms for the solution of a discretized SIP problem  $p[Y_i]$ , the algorithm from [9] is given below in a rudimentary form (again let  $i \in \mathbf{N}_0$  be fixed and choose  $k := 0$  if  $i = 0$ ).

Convergence of this algorithm to a stationary point of the exact  $L_\infty$ -penalty function, respectively a KKT point, of  $p[Y_i]$  is guaranteed under standard assumptions. If, in addition, the Maratos effect avoiding scheme from [25] is properly incorporated into the algorithm, then, under some additional assumptions usually required in this context, it also converges  $r$ -superlinearly. The final data obtained by the algorithm (with an adequate stopping criterion) can normally be completely employed to initialize the algorithm for  $p[Y_{i+1}]$ , in case a sequence of discretized SIP problems is solved.

0 Select  $\alpha \in (0, 1/2)$ ,  $\beta \in (0, 1)$ ,  $\epsilon > 0$ , and  $k \in \mathbf{N}_0$ .

Choose  $\rho_k > 0$ ,  $x^k \in \mathbf{R}^n$ , a symmetric positive definite matrix  $H_k \in \mathbf{R}^{n \times n}$ , and a subset  $D_k \subseteq Y_i$  with  $D_k \supseteq Y_{i,\epsilon}^l(x^k)$ .

1 Compute the unique solution  $(d^k, \xi_k) \in \mathbf{R}^n \times \mathbf{R}$  of the quadratic problem

$$\begin{cases} \min & \frac{1}{2} d^\top H_k d + \nabla f(x^k)^\top d + \rho_k \xi \\ \text{s.t.} & g(x^k, y) + \nabla_x g(x^k, y)^\top d \leq \xi, \\ & y \in D_k, \\ & \xi \geq 0, \end{cases}$$

and associated Lagrange multipliers  $(\lambda^k, \tilde{\lambda}_k) \in \mathbf{R}^{|D_k|} \times \mathbf{R}$ .

IF  $\|d^k\| = 0$ , STOP!

2 IF  $\xi_k = 0$  and  $\|\lambda^k\|_1 \geq \rho_k$ , set  $\rho_k := 1.5 \|\lambda^k\|_1$ .

3 Let  $\ell \in \mathbf{N}_0$  be the smallest number such that  $t_k := \beta^\ell$  satisfies

$$L_\infty(x^k, \rho_k, Y_i) - L_\infty(x^k + t_k d^k, \rho_k, Y_i) \geq \alpha t_k d^k{}^\top H_k d^k$$

Set  $x^{k+1} := x^k + t_k d^k$  and  $\rho_{k+1} := \rho_k$ .

4 Compute  $H_{k+1}$  by Powell's modification of the BFGS update ([37]) with respect to the Hessian of the Lagrangian

$$L_i(x, \lambda(Y_i)) := f(x) + \sum_{y \in Y_i} \lambda(y) g(x, y)$$

of  $P[Y_i]$ , where  $\lambda(Y_i) := (\lambda(y))_{y \in Y_i}$ , and choose a set  $D_{k+1} \subseteq Y_i$  with  $D_{k+1} \supseteq Y_{i,\epsilon}^l(x^{k+1})$ . Set  $k := k + 1$  and go to Step 1.

Applied to a discretized SIP problem, the algorithm of [9] improves another one from [2, Sect. 4.2] which, instead of  $Y_{i,\epsilon}^l(x^k)$ , employs the in this case usually much larger, upper set  $Y_{i,\epsilon}(x^k)$ . But, although the choice  $D_k := Y_{i,\epsilon}^l(x^k)$  is suitable in the above algorithm, addition of further points to  $D_k$  is advised to improve the all-over efficiency of the method. In this regard, the selection rules from [24] and [44] have turned out to be valuable.

The SQP algorithm in [9] can be similarly used also for the solution of the *locally reduced problem* in a second phase of a two-phase approach to the solution of

$p[Y]$  and has shown to yield excellent results in this way. At earlier two-phase approaches, always two different methods had been applied to the problems in both phases.

In addition to the mentioned methods, also *stochastic discretization procedures* have been developed which are capable of providing a *quasi-optimal solution* of a finely discretized SIP problem (e. g. [49]).

Primal (linear) semi-infinite program; Dual semi-infinite program; Global maximization problem; Pseudorandom; Curse of dimensionality; Air pollution; Source class; generalized Gauss quadrature rule

The class of linear semi-infinite programming problems may be looked upon as a generalization of the class of linear programs. In a semi-infinite program, either the number of variables or the number of constraints (but not both at the same time) may be infinite. In the present paper we will mainly deal with semi-infinite programs of the latter type. The main theoretical as well

as practical difficulty is that one needs to verify that a proposed optimal solution satisfies infinitely many linear inequality constraints. We will describe two applications which illustrate this, namely global optimization and an air quality control problem. In a companion paper in this volume we will describe how to solve semi-infinite programs numerically by means of systematic approximation with simpler problems. The literature on linear semi-infinite programs is vast. For a general introduction to this field, see [5,6] and [7]. Recent results are to be found for instance, in [11].

### Definition of Linear Semi-Infinite Programs

We now introduce, following [6]:

**Definition 1** Let  $S$  be a fixed set,  $a: S \rightarrow \mathbf{R}^n$ ,  $b: S \rightarrow \mathbf{R}$  two fixed functions,  $c \in \mathbf{R}^n$  a fixed vector. Then the following task will be called a *primal linear semi-infinite program*:

$$\min c^\top y, \quad (1)$$

over all  $y \in \mathbf{R}^n$  subject to the constraint

$$a(s)^\top y \geq b(s), \quad s \in S. \quad (2)$$

*Remark 2* The data of the semi-infinite program (1) and (2) are hence the index set  $S$ , the vector-valued function  $a$  and the real-valued function  $b$ , both defined on  $S$  as well as the fixed vector  $c \in \mathbf{R}^n$ .

**Definition 3** Use the notation of Definition 1. Put

$$Y = \{y \in \mathbf{R}^n: a(s)^\top y \geq b(s), s \in S\}, \quad (3)$$

$$V = \inf_{y \in Y} c^\top y. \quad (4)$$

If  $Y$  is empty, then we define  $V = -\infty$ , i. e. the condition (2) is inconsistent.  $Y$  is called the *set of feasible solutions* to (1), (2).

The following theorem on dual inequality holds:

**Theorem 4** Use the notations of Definition 1. Assume that there is a subset  $\{s_1, \dots, s_q\} \subset S$ , such that

$$\sum_{i=1}^q x_i a(s_i) = c, \quad x_i \geq 0, \quad i = 1, \dots, q. \quad (5)$$

Then the following inequality holds for all  $y$  satisfying (2):

$$c^\top y \geq \sum_{i=1}^q x_i b(s_i).$$

*Proof* Let (2) and (5) be satisfied. Then

$$a(s_i)^\top y \geq b(s_i), \quad i = 1, \dots, q.$$

Multiplying by  $x_i$  and summing over  $i$  we obtain

$$\sum_{i=1}^q x_i a(s_i)^\top y \geq \sum_{i=1}^q x_i b(s_i). \quad (6)$$

The result now follows from (5).

*Remark 5* The right-hand side of (6) gives a lower bound for the optimal value of the linear semi-infinite program defined by (1) and (2).

We next consider the task of finding the largest value of this lower bound:

**Definition 6** The *dual semi-infinite program* is defined by: Determine a finite subset  $\{s_1, \dots, s_q\} \subset S$  and real numbers  $x_1, \dots, x_q$  such that the expression

$$\sum_{i=1}^q x_i b(s_i) \quad (7)$$

is maximized, subject to the constraints

$$\sum_{i=1}^q x_i a(s_i) = c, \quad x_i \geq 0, \quad i = 1, \dots, q. \quad (8)$$

*Remark 7* If  $S$  is a finite set, then (1), (2) define a linear program and (7), (8) is equivalent to its dual.

The problems in Definitions 1 and 6 above admit several different geometric interpretations. Thus (8) means that the vector  $c$  shall be written as a nonnegative linear combination of the  $q$  vectors  $a(s_1), \dots, a(s_q)$ . The inequality (2) means that the real-valued function  $b$  is to be approximated from the above over  $S$  by a linear combination of the  $n$  functions  $a_1, \dots, a_n$ .

We note that the feasible subset  $Y$  defined by (3) is a convex subset of  $\mathbf{R}^n$ , if it is nonempty. For each fixed  $s \in S$  the relation

$$a(s)^\top y = b(s)$$

defines a supporting hyperplane to  $Y$ . Hence program (1), (2) is the task to minimize the linear form  $c^T y$  over  $Y$ . The latter problem may be formally rewritten as the equivalent task of minimizing

$$c^T y,$$

subject to the single constraint

$$g(y) \geq 0,$$

where

$$g(y) = \min_{s \in S} a(s)^T y - b(s).$$

Thus the evaluation of  $g(y)$  requires the solution of a global minimization problem, which may be nontrivial if  $S$  is infinite. Under fairly general assumptions the duality results of linear programming may be extended to semi-infinite programs. In particular, the programs (1), (2) and (7), (8) have optimal solutions and the same optimal value. See e. g. [5] and [6]. We state the following theorem on *complementary slackness*:

**Theorem 8** *Let  $y$  be an optimal solution of (1), (2) and let  $q, \{s_1, \dots, s_q\} \in S, x_1, \dots, x_q$  be an optimal solution of (7), (8). Put*

$$d(s) = a(s)^T y - b(s), \quad s \in S.$$

*If the two problems also have the same optimal value, the following relations hold:*

$$d(s) \geq 0, \quad s \in S, \quad (9)$$

$$\sum_{i=1}^q x_i a(s_i) = c, \quad (10)$$

$$x_i d(s_i) = 0, \quad i = 1, \dots, q, \quad (11)$$

*the function  $d$  achieves its global minimum at*

$$s_i, \quad i = 1, \dots, q. \quad (12)$$

The proof is given e. g. in [6].

**Remark 9** The relations (9)–(12) give necessary conditions for optimality. If the set  $S$  is finite, then (1), (2) and (7), (8) form a dual pair of linear programs and we recognize Theorem 8 in this case as the complementary slackness result in linear programming.

If  $S$  is infinite, then (10), (11) may be combined to a nonlinear system of equations with  $x_i, s_i, i = 1, \dots, q$ , and  $y$  as unknown variables. Further relations may be derived from (12) and included in the system which then has equally many scalar unknowns as it has equations. This requires that  $q$  is known and one must also require that the function  $d$  has continuous partial derivatives of the first order. In addition it must be known for each  $s_i$  whether this point is at the boundary or in the interior of  $S$ . These considerations are used in the three-phase algorithm. See e. g. [5,6] or [7], whose main ideas are as follows:

- 1 | Solve the problems (1), (2) and (7), (8) approximately by replacing  $S$  with a finite subset  $T$  to obtain a dual pair of linear programs.
- 2 | Determine  $q$  and approximate values for the variables  $x_i, s_i, i = 1, \dots, q$ , and  $y$  from the results of Phase 1. Decide for each  $s_i$  whether it is an interior or boundary point of  $S$ . Construct a nonlinear system of equations with respect to the variables sought.
- 3 | Solve the nonlinear system of equations by a suitable numerical scheme. Check the feasibility of the calculated solution, in particular that the infinitely many constraints in (2) are satisfied. In case of failure return to Phase 1 and redo the whole process with a finer grid.

## A Global Maximization Problem

We discuss now a very special instance of the problem (1), (2). The treatment of this test problem illustrates some fundamental properties of semi-infinite programs. Thus we put  $n = 1, a_1(s) = 1, c_1 = 1$  and consider the task

*Example 10*

$$\min y, \quad (13)$$

subject to the constraint

$$y \geq b(s), \quad s \in S. \quad (14)$$

In this example  $y$  is a real number. We note that (14) may define infinitely many constraints. The dual of the problem (13), (14) may be written

$$\max b(s), \quad s \in S. \quad (15)$$

By placing various assumptions on the function  $b$  and the set  $S$  one may illustrate the different properties a dual pair of semi-infinite programs may have. Thus if  $S$  is finite, then both programs achieve their optimal values in accordance with the theory of linear programs. If  $b$  is bounded on  $S$ , then the primal program (13), (14) has the optimal solution

$$y = \sup_{s \in S} b(s). \tag{16}$$

If in addition  $S$  is compact and  $b$  continuous, then the dual (15) also achieves its optimal value and we write

$$y = \max_{s \in S} b(s). \tag{17}$$

For a discussion of the various states of semi-infinite programs, see [5,6] and [7].

Example 10 may also be used to illustrate the properties of some suggested numerical schemes for linear semi-infinite programs. We note that (17) is useful for numerical work only if there is a way to determine all local maxima to  $b$  on  $S$ . If  $b$  has continuous partial derivatives of the first order, we may try to solve by numerical methods the equation

$$\nabla b(s) = 0. \tag{18}$$

In addition one would need to study the values of  $b$  at the boundary of  $S$ .

We discuss now the three-phase algorithm as described in [3,5,6,7,9,10]. When applied to the problem (13), (14) this scheme becomes:

1	<p>Let <math>T_\ell, \ell = 1, 2, \dots</math>, be a sequence of grids (subsets to <math>S</math>) such that each <math>T_\ell</math> contains finitely many points and</p> $\lim_{\ell \rightarrow \infty} \max_{s \in S} \min_{t \in T_\ell} \ s - t\  = 0. \tag{19}$ <p>Calculate an <math>s_\ell</math> which solves</p> $\max_{t \in T_\ell} b(t). \tag{20}$
2	Take $s_\ell$ as starting value.
3	To determine the local maxima of $b$ with some numerical scheme.

*Example 11* We consider the following special case of Example 10:

$$\min b(s) = \sin \frac{1}{s + 0.000001}, \quad s \in [0, 1].$$

In this case there are many local maxima and the grid would need to be very fine, if the three-phase method should locate them all. A direct analytic treatment would of course be easy, since the expression for  $b$  is simple but the example illustrates potential difficulties.

We note that if  $S$  has several dimensions, then the ‘curse of dimensionality’ sets in, making a systematic discretization approach inefficient, since it implies that  $b$  must be tabulated and this table must be large in order to describe  $b$ . In a practical situation there is no assurance that the optimal solution has been found, if this cannot be tested analytically. Since one has to accept the possibility that a nonoptimal value has been accepted one may consider pseudorandom generation of grids instead of the deterministic approaches described above and in the references given up to now. A major advantage of these approaches is that the computational complexity is not crucially dependent on the number of dimensions and statistical estimates for the uncertainty in the optimal value may be developed. For an introduction to global optimization methods based on random processes, see [12]. The author is working on methods for applying random schemes for the general semi-infinite program (1), (2).

### An Air Pollution Control Problem

The three-phase approach, described above may be directly applied to general linear semi-infinite programs. We illustrate with the air pollution control problem as described on [6, p. 17; 184]. Here the air quality control area is represented by the compact set  $A \subset \mathbb{R}^2$ . The annual mean concentration of a certain inert pollutant (e.g. sulphur dioxide, SO<sub>2</sub>) is represented by a real-valued function  $p$ , defined on  $A$ . There are many sources emitting pollution and each car, house or power plant may contribute to the pollution. The permissible level of pollution is defined by a given function  $v$ . If there is a point  $s \in A$  such that the standard  $v$  is exceeded, i.e. is such that

$$p(s) > v(s), \tag{21}$$

then the pollution concentration must be reduced. After reduction, the remaining pollution must satisfy the standard at each point  $s \in A$  and this fact implies that infinitely many inequality constraints must be met. We will assume that the sources of pollution may be split

into  $n + 1$  classes and that the sources in each class will be regulated in the same way. We further require that the superposition principle is valid, i. e. that the concentration contributions add up. Therefore we write

$$p(s) = \sum_{r=0}^n u_r(s), \quad s \in A, \quad (22)$$

where the concentration contribution from source-class  $r$  is given by the nonnegative function  $u_r$ . In particular,  $u_0$  represents the concentration contribution from background sources which cannot be regulated. Next,  $u_1$  may be the contribution from trucks, operating in  $A$ ,  $u_2$  from passenger cars,  $u_3$  from residential heating and so on. The implementation of an abatement policy implies that the contribution from class  $r$  is reduced by the fraction  $E_r$ , hence the remaining concentration contribution from this class is

$$(1 - E_r)u_r(s), \quad 0 \leq E_r \leq 1.$$

The reduction vector  $E \in \mathbf{R}^n$  must therefore satisfy the constraints

$$\begin{aligned} 0 \leq E_r \leq 1, \quad r = 1, \dots, n, \\ u_0(s) + \sum_{r=1}^n (1 - E_r)u_r(s) \leq v(s), \quad s \in A. \end{aligned}$$

The last relation may also be written

$$\sum_{r=1}^n E_r u_r(s) \geq p(s) - v(s), \quad s \in A,$$

which may be interpreted as the requirement that the total removed pollution should amount at least to the difference between the original pollution and the required standard  $v(s)$ .

Assume that the cost associated with the pollution abatement is given by the linear form  $K(E)$  where

$$K(E) = \sum_{r=1}^n c_r E_r.$$

The task to determine  $E$  such that the air quality standard  $v$  is satisfied at each  $s \in S$ , while the control cost is minimized is hence the solution to the problem: Determine

$$V = \min_{E \in \mathbf{R}^n} \sum_{r=1}^n c_r E_r, \quad (23)$$

subject to the constraints

$$\sum_{r=1}^n E_r u_r(s) \geq p(s) - v(s), \quad s \in A, \quad (24)$$

$$E_r \geq 0, \quad r = 1, \dots, n, \quad (25)$$

$$-E_r \geq -1, \quad r = 1, \dots, n. \quad (26)$$

Thus the equations (23)–(26) define a linear semi-infinite program of the type (1) and (2). We note that if there is a point  $s^* \in A$ , such that  $u_0(s^*) > v(s^*)$ , then the background pollution is above the standard and there is no control policy achieving the desired goal. Hence the program (23)–(26) is inconsistent. Otherwise we conclude the existence of an optimal policy if the functions  $u_r$ ,  $r = 0, \dots, n$  are continuous. For the purpose of numerical treatment we replace the area  $A$  by a finite grid  $T$  in (24) and solve the corresponding linear program. In so doing, we enforce the standard at the finite grid only and hence it may be violated somewhere between the gridpoints. However, convergence obtains if we consider a sequence of finer and finer grids as in (19). It is also possible to derive a nonlinear system and use the three-phase algorithm. It is of interest here that Theorem 8 implies that if an optimal control policy has been calculated, there is a subset of points where the standard is met exactly. It has been proposed to put air quality sampling stations at these points. For further details, see [6].

## Concluding Remarks

There are a large number of other applications of semi-infinite programming. One such is the approximation of functions in the maximum norm. Special algorithms have been developed for classes of such applications. For the approximation in the maximum norm, the algorithms of Remez (see [2]) are applicable. But we note also here that a global maximization needs to be carried out at each step of the algorithm. An one-sided approximation problem has been studied by [1]. The solutions of the dual of this problem are associated with quadrature rules of generalized Gauss type. However, the determination of abscissæ and weights of such rules, using only the parameters of the corresponding semi-infinite program, is notoriously ill-conditioned. For the so-called classical cases associated with the names of Legendre, Hermite and Jacobi, other analytic informa-

tion is used, for instance, the coefficients of the three-term recurrence relation formulas for corresponding orthogonal polynomials. See e.g. [4] and [8]. These methods give an alternative way of finding the solutions of certain special semi-infinite programs which may be used for testing the accuracy and efficiency of general methods for semi-infinite programs.

### Keywords

Semi-infinite optimization; Approximation; Numerical algorithms

The problem

$$\mathcal{P}(T) \begin{cases} \min & \{F(z) : z \in K\}, \\ K = & \{z \in \mathbf{R}^n : g(z, t) \leq 0, \forall t \in T\}, \end{cases} \quad (1)$$

is considered, where  $T$  is a compact subset of the space  $\mathbf{R}^m$ ,  $F$  and  $g(\cdot, t)$  are continuous functions from  $\mathbf{R}^n$  into  $\mathbf{R}$  and  $g(z, \cdot)$  is continuous on  $T$ . If the functions  $F$  and  $g(\cdot, t)$  are assumed to be convex, we deal with convex semi-infinite problems, and many important applications lead to linear semi-infinite problems, with linear functions  $F$  and  $g(\cdot, t)$ .

With some additional writing effort, the content of this article can be easily extended to the case that the set of feasible points is given as the intersection of finitely many sets

$$\{z \in \mathbf{R}^n : g_s(z, t) \leq 0, \quad \forall t \in T^s\}, \quad s \in S,$$

where, for each  $s \in S$ ,  $T^s$  is a compact subset of  $\mathbf{R}^{m_s}$  and  $g_s$  has the same properties as  $g$ .

The notion ‘semi-infinite programming problem’ is due to the property that the feasible set  $K$  belongs to a finite-dimensional space whereas  $T$  is an infinite set.

The references here are not primarily intended to give a complete documentation of the original papers and sources or to reflect the historical development of this field. Except for the case that reference is given to explicit statements or techniques, it was our aim to draw the reader's attention to the basic approaches.

Concerning theory and properties of semi-infinite programming, see the monographs [1,19,24], papers [12,18] and to the preceding volumes [6,33].

Transforming  $g(z, t) \leq 0, \forall t \in T$ , into  $\max_{t \in T} g(z, t) \leq 0$ , one could treat semi-infinite problems in the framework of nondifferentiable optimization. We do not adopt this approach here (see the review paper [27]).

The algorithms for semi-infinite problems generate usually a sequence of finitely constrained auxiliary optimization problems suitable for being solved by standard algorithms for finite optimization. We assume the latter to be available. We concentrate on the different ways these auxiliary problems may be generated and confine ourselves to some remarks on properties the finite optimization algorithms should favorably have. Roughly one can distinguish three classes of methods according to the way the auxiliary (finite) problems are generated: Exchange methods, including cutting plane methods (applicable only for convex problems), discretization methods and methods based on local reduction. Exchange and discretization methods are more recommendable for a 'first phase' of the solution process, whereas the reduction approach is recommendable for a final stage in order to provide a higher accuracy of the solution and a better rate of convergence.

In order to sketch briefly the respective ideas behind the exchange and discretization methods, we suppose that  $K$  is a compact set and introduce the finitely constrained auxiliary problems

$$\mathcal{P}(T_i) \quad \begin{cases} \min & \{F(z): z \in K_i\}, \\ K_i = & \{z \in Z_0: g(z, t) \leq 0, \forall t \in T_i\}, \end{cases} \quad (2)$$

with  $Z_0$  a convex compact set,  $Z_0 \supset K$ . Sometimes  $Z_0$  is artificially introduced in order to provide solvability of these problems. If  $K \neq \emptyset$ , the approximate problem (2) has a solution for every finite set  $T_i \subset T$ .

Omitting detailed assumptions on the problems and methods involved, we concentrate on the main ideas of the numerical approaches mentioned above.

## Exchange Methods

This notion refers to the fact that in step  $i$  the set  $K_{i+1}$  is obtained from  $K_i$  by addition of at least one new constraint and (in many algorithms) deletion of some of the constraints of  $K_i$ , i. e., an exchange of constraints takes place.

- Step  $i$ : Given  $T_i \subset T, |T_i| < \infty$ . Compute (approximately) a solution  $z^i$  of  $\mathcal{P}(T_i)$  and some (or all) local maxima  $t_1^i, \dots, t_{q_i}^i$  of the subproblem

$$\mathcal{Q}(z^i) \quad \max \{g(z^i, t): t \in T\}.$$

Stop if  $g(z^i, t_j^i) \leq 0, j = 1, \dots, q_i$ . Otherwise, choose  $T_{i+1}$  such that the following relations hold:

$$T_{i+1} \subset T_i \cup \{t_1^i, \dots, t_{q_i}^i\}, \\ \max_{t \in T_{i+1}} g(z^i, t) > 0.$$

Necessary for convergence is

$$\max_{j=1, \dots, q_i} g(z^i, t_j^i) = \max_{t \in T} g(z^i, t), \quad (3)$$

i. e. the global solution of the nonconvex optimization problem  $\mathcal{Q}(z^i)$  is required in each step (or at least in a subsequence of steps) which for  $\dim T \geq 2$  may be very costly. Under (3) convergence may be proved for instance in case that constraints are never deleted from  $T_i$  (cf. [18]).

In fact, exchange methods are similar to the classical REMES-algorithm for solving linear Chebyshev approximation problems. Special algorithms mainly differ in the choice of  $T_{i+1}$ . In the literature, cf., e. g., [14,23,30,40,41], there are different algorithms which have important additional features: The ability to add several constraints  $g(z, t^i) \leq 0$ , where  $t^i$  are some points with  $g(z^i, t^i) > 0$ , (or to add only the constraint which is maximally violated at  $z^i$ ) and to delete constraints in an efficient way in the case of a convex problem (1). In [23] a cutting plane algorithm for convex problems is suggested, which ensures a linear rate of convergence with respect to the values of the objective functional.

## Discretization Methods

Algorithms of this type compute a solution of problem (1) by solving a sequence of problems  $\mathcal{P}(T_i)$ , where  $T_i$  is an  $h_i$ -grid on  $T$ , i. e., a finite subset  $T_i \subset T$  such that  $\sup_{t \in T} \text{dist}(t, T_i) \leq h_i$ . In the  $i$ th step a fixed (usually,

uniform) grid  $T_i$  is considered, generated by  $h_i = \gamma_i h_{i-1}$ , with  $\gamma_i \in (0, 1)$  chosen a priori or defined by the solution procedure itself. In step  $i$  only subsets  $\bar{T}_i$  of  $T_i$  are used and in a number of algorithms one has ( $k_i \in \mathbf{N}$ ):

$$\gamma_i = \frac{1}{k_{i-1}} \quad \text{with} \quad k_{i-1} \geq 2$$

implying  $T_{i-1} \subset T_i \forall i$ .

- Step  $i$ : Given  $h_{i-1}$ , the last set  $\bar{T}_{i-1} \subset T_{i-1}$  and a solution  $z^{i-1}$  of problem  $\mathcal{P}(\bar{T}_{i-1})$ ;

i1) choose  $h_i = \gamma_i h_{i-1}$  and generate  $T_i$ ;

i2) select  $\bar{T}_i \subset T_i$ ;

i3) compute a solution  $\bar{z}$  of  $\mathcal{P}(\bar{T}_i)$ . If  $\bar{z}$  is feasible for  $\mathcal{P}(T_i)$  within a given accuracy, put  $z^i := \bar{z}$  (define also  $\gamma_{i+1}$  if the sequence  $\{\gamma_k\}$  is not a priori chosen) and continue with Step  $(i+1)$ . Otherwise repeat i2) for a new choice of  $\bar{T}_i$ , enlarging the old one.

With regard to efficiency, it is important to use as much information as possible from former grids in solving  $\mathcal{P}(\bar{T}_i)$ . Substantial differences among the algorithms of this type are in the choice of  $\bar{T}_i$ . Preferably  $\bar{T}_i$  should be chosen such that the solution of  $\mathcal{P}(\bar{T}_i)$  approximately solves also  $\mathcal{P}(T_i)$ . Most of the suggested algorithms select  $\bar{T}_i$  such that

$$\bar{T}_i \supset T_i^\alpha = \{t \in T_i : g(\bar{z}, t) \geq -\alpha\},$$

with  $\alpha > 0$  some chosen threshold and  $\bar{z}$  the foregoing inner iterate (cf. i3)).

The choice of  $\alpha$  is crucial (cf. [15,31,32]): A large value of  $\alpha$  leads to many constraints in  $\mathcal{P}(\bar{T}_i)$  and choosing  $\alpha$  too small one should expect a large number of steps i2), i3) for fixed  $T_i$ . Adaptive strategies for decreasing  $\alpha$  are used in [7] and [26].

In [39] special versions of the method of feasible directions coordinate the choice of the grid and the search direction in order to obtain feasible solutions of (1) in each step. In this and some other papers information about the last  $\bar{T}_{i-1}$  and  $z^{i-1}$  is used in choosing  $\gamma_i$  and the initial set  $\bar{T}_i$  at  $i$ th step. In [28] discretization processes are carried out such that, for a certain class of convex semi-infinite programming problems, the rate of convergence of the basic optimization algorithm used for solving the discretized problems is retained for the whole solution procedure. Hereby only

one step of the optimization algorithm is performed in each problem  $\mathcal{P}(\bar{T}_i)$  to define  $\bar{z}$  (see i3)).

## Reduction Methods

These methods use the fact that under appropriate assumptions the original (infinitely many) constraints

$$g(z, t) \leq 0, \quad \forall t \in T,$$

can be replaced by finitely many constraints which locally are sufficient to describe  $K$ . In the sequel, we assume that  $F \in C^2(\mathbf{R}^n)$ ,  $g \in C^2(\mathbf{R}^n \times T)$ . Let  $\bar{z} \in \mathbf{R}^n$  be a given point. Let  $\bar{t}_1, \dots, \bar{t}_{q(\bar{z})}$ , with  $q(\bar{z}) < \infty$ , be all the local solutions of

$$Q(\bar{z}) = \max \{g(\bar{z}, t) : t \in T\}.$$

Obviously,  $\bar{z} \in K$ , if and only if

$$g(\bar{z}, \bar{t}_j) \leq 0, \quad j = 1, \dots, q(\bar{z}).$$

Assume now that there exist a neighborhood  $\bar{U}$  of  $\bar{z}$  and twice continuously differentiable functions

$$t_j : \bar{U} \rightarrow T, \quad t_j(\bar{z}) = \bar{t}_j, \quad j = 1, \dots, q(\bar{z})$$

such that for all  $z \in \bar{U}$  the  $t_j(z)$  are all local solutions of  $Q(z)$ . Then, with

$$G_j(z) := g(z, t_j(z)), \quad j = 1, \dots, q(\bar{z}),$$

we have  $G_j \in C^2(\bar{U})$  and

$$K \cap \bar{U} = \{z \in \bar{U} : G_j(z) \leq 0, \quad j = 1, \dots, q(\bar{z})\},$$

i. e. in  $\bar{U}$  we may replace problem  $\mathcal{P}(T)$  by the finite problem

$$\mathcal{P}_{\bar{z}}(T) = \min \{F(z) : G_j(z) \leq 0, \quad j = 1, \dots, q(\bar{z})\}.$$

Sufficient for the existence of  $\bar{U}$  and  $t_j$  as above is that all solutions  $\bar{t}_j$  of  $Q(\bar{z})$  are nondegenerate (cf. [17,18] and also ► **Semi-infinite Programming: Second Order Optimality Conditions**). We note that this ‘reducibility in  $\bar{z}$ ’ is a generic property (see [20,44]), thus it holds ‘almost everywhere for almost all problems’.

Now, reduction methods generally can be described as follows:

- Step  $i$ : Given  $z^{i-1}$  (not necessarily feasible);
  - compute all local maxima  $t_1^{i-1}, \dots, t_{q_{i-1}}^{i-1}$  of problem  $\mathcal{Q}(z^{i-1})$ ;
  - apply some steps of an algorithm for finite problems to the reduced finite-dimensional problem  $\mathcal{P}_{z^{i-1}}(T)$ :

$$\min \{F(z): G_j(z) \leq 0, j = 1, \dots, q_{i-1}\},$$

where  $G_j(z) = g(z, t_j(z))$  and the functions  $t_j(\cdot)$  are defined in a neighborhood of  $z^{i-1}$ . Let  $z^{i,k_i}$  be the last iterate of the algorithm mentioned;

- set  $z^i = z^{i,k_i}$  and continue with Step( $i + 1$ ).

In order to apply second order methods usually second order derivatives are required and to guarantee superlinear convergence, additionally a strong second order optimality condition has to be satisfied. Conditions concerning problem (1) which provide locally superlinear convergence of some SQP-methods applied to problem  $\mathcal{P}_{z^{i-1}}(T)$  are given in [9] (see also ► **Semi-infinite Programming: Second Order Optimality Conditions**). These conditions ensure, in particular, twice continuous differentiability of the functions  $G_j$ . SQP-methods, using augmented Lagrangian functions and quasi-Newton update of their Hessians have been effective in this context (cf. [9,16,25,29,38,43]). Here, according to the results in [9], an inexact evaluation of the functions  $t_j(\cdot)$ , and hence, of the functions  $G_j$ , is admitted.

To give a more explicit version of the reduction approach, we specify the steps i2) and i3) from above, following [9].

Given  $z^{i,0} = z^{i-1}$ ,  $B_{i,0} = B_{i-1}$  ( $B_0$  is, in principle, an arbitrary symmetric positive definite  $n \times n$ -matrix). Then, for  $l = 1, \dots, k_i$ , with given  $z^{i,l-1}$ ,  $B_{i,l-1}$  do:

- compute a solution  $s^l$  and a vector of Lagrange multipliers  $\lambda^{i,l}$  of the quadratic programming problem

$$\begin{cases} \min & \{\nabla F(z^{i,l-1})^\top s + \frac{1}{2}s^\top B_{i,l-1}s\} \\ \text{s.t.} & G_j(z^{i,l-1}) + \nabla G_j(z^{i,l-1})^\top s \leq 0, \\ & j = 1, \dots, q_{i-1}; \end{cases}$$

- compute a steplength  $\alpha_l$  by a rule providing a decrease of function (4) below (see, for instance [3]);

- update

$$\begin{aligned} z^{i,l} &= z^{i,l-1} + \alpha_l s^l, \\ B_{i,l} &= B_{i,l-1} \\ &+ \frac{y^l (y^l)^\top}{(y^l)^\top s} - \frac{B_{i,l-1} s^l (B_{i,l-1} s^l)^\top}{(s^l)^\top B_{i,l-1} s^l}, \end{aligned}$$

(BFGS-formula), where

$$\begin{aligned} y^l &= \nabla_z \mathcal{L}^{i-1}(z^{i,l}, \lambda^{i,l}, c) \\ &- \nabla_z \mathcal{L}^{i-1}(z^{i,l-1}, \lambda^{i,l}, c), \\ \mathcal{L}^{i-1}(z, \lambda, c) &= F(z) + \sum_{j=1}^{q_{i-1}} \lambda_j G_j(z) + \frac{c}{2} \sum_{j=1}^{q_{i-1}} (G_j(z))^2 \end{aligned}$$

is the augmented Lagrangian of problem  $\mathcal{P}_{z^{i-1}}(T)$ , concerning the choice of  $c > 0$  see [18 Assumption 7.8];

- set  $B_i = B_{i,k_i}$ ,  $z^i = z^{i,k_i}$ ,  $i = i + 1$ .

Conditions ensuring a local  $q$ -superlinear convergence of the sequence  $\{(z^{i,l}, \lambda^{i,l})\}$  to a Kuhn–Tucker point of problem (1) are given in [9].

In the first instance SQP-methods are only locally convergent. Therefore, hybrid techniques combining robust globally convergent descent algorithms with SQP-methods have been developed (cf. [8,10,11]). Globalization techniques for SQP-methods were introduced in [13] using the exact penalty function

$$F(z) + d \sum_{j=1}^{q_i} \max[0, G_j(z)] \quad (4)$$

(with sufficient large  $d > 0$ ) to control the stepsize. In the papers [3,42] and [37] alternative penalty functions with the same goal have been introduced.

The idea to apply for semi-infinite programming a penalty technique coupled with a discretization seems to be promising. However, numerically this may be rather difficult: The condition number of the Hessians of the objective functions of the auxiliary problems depends essentially not only on the penalty parameter, but also on the common influence of almost active constraints. The number of these constraints usually increases with the number of discretization points. Therefore, the use of exact penalty functions or their smooth approximations has the advantage that it is possible

to work with a fixed penalty parameter. Exact penalty functions of integral type for semi-infinite programming have been proposed in [2]. In [4] and [5] exchange techniques are coupled with penalization of the auxiliary problems, which are finally solved by interior point methods. Interior point methods for solving smooth, convex semi-infinite programming are also suggested in [35,36] and [34]. This approach requires computations of integrals over  $T$  to obtain the components of the gradients and Hessians of some aggregated, logarithmic barrier functions. The solution is reached by following the so-called central path of the problem by a predictor-corrector method. In [21,22] proximal penalty approaches have been proposed, with a special deleting rule for the constraints based on the existence of upper bounds for the Lagrange multipliers of the regularized auxiliary problems uniform with respect to a sequence of discretizations.

### Keywords

Semi-infinite optimization; Second order necessary and sufficient optimality conditions; Reduced problem in semi-infinite programming

We are concerned with *semi-infinite optimization problems*

$$\text{SIP} \quad \begin{cases} \max & F(z) \\ \text{s.t.} & z \in Z \end{cases}$$

with feasible set

$$Z = \{z \in \mathbb{R}^n : g(z, t) \leq 0 \text{ for all } t \in B\},$$

and

$$B = \{t \in \mathbb{R}^m : h^j(t) \leq 0, j \in J\},$$

$J$  a finite index set,  $F \in C^2(\mathbf{R}^n, \mathbf{R})$ ,  $g \in C^2(\mathbf{R}^n \times \mathbf{R}^m, \mathbf{R})$ ,  $h^j \in C^2(\mathbf{R}^m, \mathbf{R})$ ,  $j \in J$ . We assume that  $B$  is compact.

Later on we consider *generalized semi-infinite problems* GSIP, where the index set  $B = B(z)$  depends on  $z$ , i. e.  $B = B(z) = \{t \in \mathbf{R}^m: h^j(z, t) \leq 0, j \in J\}$  with given  $h^j \in C^2(\mathbf{R}^n \times \mathbf{R}^m, \mathbf{R}), j \in J$ . In this case we assume that the range of the set-valued mapping  $B$  remains in a compact set  $B_0 \subset \mathbf{R}^m$ , i. e.  $B(z) \subset B_0$  for all  $z \in \mathbf{R}^n$ .

In the same way as in finite optimization, second order optimality conditions for SIP are an important tool for answering a number of theoretical and practical questions. First order optimality conditions may again be given by a system of nonlinear equations, the so-called Karush–Kuhn–Tucker equations. Then, strong sufficient second order conditions imply this system to be regular and this regularity allows to answer questions of stability of solutions, dependence of solutions on problem parameters but also superlinear convergence of some classes of numerical methods (cf. [3] and the references therein). We give the conditions in a form which is suitable for applications like these. We follow the ‘reduction approach’ as in [3] and [4].

In the sequel, the *parametric optimization problem*

$$\Theta(z) \begin{cases} \max_t & g(z, t) \\ \text{s.t.} & t \in B \end{cases}$$

will play an important role. For  $\bar{z} \in Z$  we define the *active index set*

$$E(\bar{z}) = \{\bar{t} \in B: g(\bar{z}, \bar{t}) = 0\}.$$

Obviously, any point  $\bar{t}$  in  $E(\bar{z})$  is a (global) maximum of  $\Theta(\bar{z})$ . Throughout we assume that  $E(\bar{z})$  is nonempty. (If  $E(\bar{z}) = \emptyset$ , then by the assumptions above, the point  $\bar{z}$  is an interior point of  $Z$  and the optimality conditions coincide with the optimality conditions in unconstrained optimization.)

The row vectors of partial derivatives of  $g$  with respect to  $z, t$  will be denoted by  $g_z, g_t$ . For a function  $v: \mathbf{R}^n \rightarrow \mathbf{R}$  we denote the directional derivative of  $v$  in  $\bar{z}$  in the direction  $\xi \in \mathbf{R}^n$  by  $Dv(\bar{z}; \xi)$ ,

$$Dv(\bar{z}; \xi) = \lim_{\tau \rightarrow 0+} \frac{v(\bar{z} + \tau\xi) - v(\bar{z})}{\tau}.$$

If the derivative  $v_z$  is itself directionally differentiable in the direction  $\xi$ , we put  $D^2v(\bar{z}; \xi) := Dv_z(\bar{z}; \xi)\xi$ .

For brevity, we do not consider vector-valued functions  $g$  or equality constraints in the definition of  $Z$  and  $B$ .

### The Parametric Problem $\Theta(\bar{z})$

In this section we prepare the ‘reduction approach’ for obtaining optimality conditions for SIP. We briefly outline a stability result (cf. [5]) for the parametric problem (applying to SIP and GSIP as well)

$$\Theta(z) \begin{cases} \max_t & g(z, t) \\ \text{s.t.} & t \in B(z), \end{cases}$$

$B(z) := \{t: h^j(z, t) \leq 0, j \in J\}$ . Let  $\bar{z}$  and a point  $\bar{t}$  which is feasible for  $\Theta(\bar{z})$  be given. We define the active index set of  $\Theta(\bar{z})$  as

$$J(\bar{z}, \bar{t}) = \{j \in J: h^j(\bar{z}, \bar{t}) = 0\}.$$

We say that the *linear independency constraint qualification* (LICQ) holds if the vectors

$$h_t^j(\bar{z}, \bar{t}), \quad j \in J(\bar{z}, \bar{t}),$$

are linearly independent. The (weaker) *Mangasarian–Fromovitz constraint qualification* (MFCQ) is said to hold in  $\bar{t}$  for  $\Theta(\bar{z})$ , if there exists a vector  $\bar{\eta} \in \mathbb{R}^m$  such that

$$h_t^j(\bar{z}, \bar{t})\bar{\eta} < 0, \quad j \in J(\bar{z}, \bar{t}).$$

Let a solution  $\bar{t}$  of  $\Theta(\bar{z})$  be given. If at  $\bar{t}$  the MFCQ is satisfied, then necessarily the Kuhn–Tucker condition is fulfilled, i. e. there exists a multiplier vector  $\bar{\gamma} \in \mathbb{R}^{|J(\bar{z}, \bar{t})|}$  such that

$$L_{t'}^{\bar{\gamma}}(\bar{z}, \bar{t}, \bar{\gamma}) = 0, \quad \bar{\gamma} \geq 0, \tag{1}$$

where  $L^{\bar{\gamma}}$  denotes the *Lagrange function* of  $\Theta(z)$  at  $(\bar{z}, \bar{t})$ ,

$$L^{\bar{\gamma}}(z, t, \gamma) = g(z, t) - \sum_{j \in J(\bar{z}, \bar{t})} \gamma_j h^j(z, t).$$

We say that *strict complementary slackness* (SCS) holds if the multiplier  $\bar{\gamma}$  in (1) satisfies

$$\bar{\gamma}_j > 0, \quad j \in J(\bar{z}, \bar{t}).$$

Let us introduce the following second order sufficient optimality condition for  $\Theta(\bar{z})$ :

**A<sub>red</sub>)** Let a solution  $\bar{t}$  of  $\Theta(\bar{z})$  be given. Assume that LICQ is satisfied. (Under LICQ there is a unique multiplier  $\bar{\gamma}$  such that (1) is fulfilled.) We assume

that the strong second order condition (SSOC) holds,

$$\eta^\top L_{tt}^{\bar{t}}(\bar{z}, \bar{t}, \bar{\gamma})\eta < 0 \quad \text{for all } \eta \in T(\bar{z}, \bar{t}) \setminus \{0\},$$

where  $T(\bar{z}, \bar{t})$  is the subspace  $T(\bar{z}, \bar{t}) = \{\eta \in \mathbb{R}^m : \bar{\gamma}_j h_t^j(\bar{z}, \bar{t})\eta = 0, j \in J(\bar{z}, \bar{t})\}$ .

**Theorem 1** *Let  $\bar{t}$  be a solution of  $\Theta(\bar{z})$  such that  $A_{\text{red}}$  is satisfied. Then there exist neighborhoods  $U(\bar{z})$  of  $\bar{z}$  and  $V(\bar{t})$  of  $\bar{t}$  and mappings  $t : U(\bar{z}) \rightarrow V(\bar{t}), \gamma : U(\bar{z}) \rightarrow \mathbb{R}^{|J(\bar{z}, \bar{t})|}$  such that:*

- $t(\bar{z}) = \bar{t}$ ,
- $\gamma(\bar{z}) = \bar{\gamma}$ ,
- and for all  $z \in U(\bar{z})$  the value  $t(z)$  is the unique local solution of  $\Theta(z)$  in  $V(\bar{t}) \cap B(z)$  with corresponding multiplier  $\gamma(z)$  such that LICQ and SSOC are satisfied.

The functions  $t, \gamma$  are Lipschitz continuous and directionally differentiable. The value function

$$G(z) := g(z, t(z)),$$

is continuously differentiable in  $U(\bar{z})$  and the derivative  $G_z$  is Lipschitz continuous and directionally differentiable with:

$$G_z(z) = g_z(z, t(z)) - \sum_{j \in J(\bar{z}, \bar{t})} \gamma_j(z) h_z^j(z, t(z)) \quad (2)$$

$$= L_z^{\bar{t}}(z, t(z), \gamma(z)),$$

$$D^2G(z; \xi) = \xi^\top L_{zz}^{\bar{t}}(z, t(z), \gamma(z))\xi - D^\top t(z; \xi) L_{tt}^{\bar{t}}(z, t(z), \gamma(z)) Dt(z; \xi) - 2 \sum_{j \in J(\bar{z}, \bar{t})} D\gamma_j(z; \xi) h_z^j(z, t(z))\xi. \quad (3)$$

The directional derivatives  $Dt(z; \xi)$  are given as the unique solutions of the quadratic program

$$P(\xi) \begin{cases} \max_{\eta} & F(\xi, \eta) \\ \text{s.t.} & h_z^j(z, t(z))\xi + h_t^j(z, t(z))\eta \\ & \begin{cases} = 0 & \text{if } \gamma_j(z) > 0 \\ \leq 0 & \text{if } \gamma_j(z) = 0 \end{cases} \\ & \text{for } j \in J(\bar{z}, \bar{t}), \end{cases}$$

where

$$F(\xi, \eta) := \frac{1}{2} \eta^\top L_{tt}^{\bar{t}}(z, t(z), \gamma(z))\eta + \eta^\top L_{zt}^{\bar{t}}(z, t(z), \gamma(z))\xi$$

The directional derivatives  $D\gamma(z; \xi)$  are given by the unique multipliers  $\beta(\xi)$  of  $P(\xi)$ ,  $D\gamma(z; \xi) = \beta(\xi)$ .

**Remark 2**

- a) For SIP, i. e. if the functions  $h^j$  do not depend on  $z$ , the derivatives of  $G$  and problem  $P(\xi)$  take the simpler form:

$$G_z(z) = g_z(z, t(z)),$$

$$D^2G(z; \xi) = \xi^\top g_{zz}(z, t(z))\xi$$

$$- D^\top t(z; \xi) L_{tt}^{\bar{t}}(z, t(z), \gamma(z)) Dt(z; \xi)$$

and

$$P(\xi) \begin{cases} \max_{\eta} & \frac{1}{2} \eta^\top L_{tt}^{\bar{t}}(z, t(z), \gamma(z))\eta \\ & + \eta^\top g_{zt}(z, t(z))\xi \\ \text{s.t.} & h_t^j(z, t(z))\eta \\ & \begin{cases} = 0 & \text{if } \gamma_j(z) > 0 \\ \leq 0 & \text{if } \gamma_j(z) = 0 \end{cases} \\ & j \in J(\bar{z}, \bar{t}). \end{cases}$$

- b) If in  $A_{\text{red}}$ , in addition to LICQ and SSOC, we assume SCS, then the functions  $t, \gamma$  are continuously differentiable and  $G$  is twice continuously differentiable. Consequently, in (3) we can write  $Dt(z; \xi) = t_z(z)\xi, D\gamma(z; \xi) = \gamma_z(z)\xi$ .

### The Reduced Problem

Let  $\bar{z}$  be feasible for SIP. By assuming that  $A_{\text{red}}$  is satisfied for all solutions  $\bar{t}$  of  $\Theta(\bar{z})$  (i. e. all  $\bar{t} \in E(\bar{z})$ ), by applying Theorem 1, the problem SIP can locally be reduced to an equivalent finite optimization problem.

**Theorem 3** *Let  $\bar{z} \in Z$  be given such that  $A_{\text{red}}$  is satisfied for all  $\bar{t} \in E(\bar{z})$ . Then the set  $E(\bar{z})$  is finite,  $E(\bar{z}) = \{\bar{t}^1, \dots, \bar{t}^r\}$ , and there is a neighborhood  $U(\bar{z})$  of  $\bar{z}$  such that with the functions*

$$G^\ell(z) := g(z, t^\ell(z)), \quad \ell = 1, \dots, r,$$

in Theorem 1 (corresponding to the solutions  $\bar{t}^\ell$  of  $\Theta(\bar{z})$ ) the following holds:  $z \in U(\bar{z})$  is a local maximizer of SIP if and only if  $z$  is a local maximizer of the so-called reduced problem

$$\text{SIP}_{\text{red}}(\bar{z}) \begin{cases} \max & F(z) \\ \text{s.t.} & z \in U(\bar{z}) \\ & G^\ell(z) \leq 0, \\ & \ell = 1, \dots, r. \end{cases}$$

By Theorem 1, the functions  $G^\ell$  are continuously differentiable in  $U(\bar{z})$  and  $G_z^\ell$  is Lipschitz continuous and directionally differentiable.

**Optimality Conditions for SIP**

We consider SIP and assume, that for  $\bar{z} \in Z$  the regularity conditions of Theorem 3 hold. Then, in a neighborhood  $U(\bar{z})$  of  $\bar{z}$ , the problem SIP is equivalent with the finite problem  $SIP_{red}(\bar{z})$ . Let  $L$  denote the (F. John type) Lagrangian of  $SIP_{red}(\bar{z})$ ,

$$L(z, \lambda) = \lambda_0 F(z) - \sum_{\ell=1}^r \lambda_\ell G^\ell(z),$$

with  $G^\ell(z) = g(z, t^\ell(z))$ , and  $K$  the cone of critical directions for  $SIP_{red}(\bar{z})$  in  $\bar{z}$ ,

$$K = \left\{ \xi \in \mathbb{R}^n : \begin{array}{l} F_z(\bar{z})\xi \geq 0, \\ G_z^\ell(\bar{z})\xi \leq 0, \end{array} \ell = 1, \dots, r \right\}.$$

The following dual optimality conditions hold.

**Theorem 4** Let  $\bar{z}$  be feasible for SIP such that the assumptions of Theorem 3 are satisfied. Then we have:

a) (Necessary conditions) Suppose,  $\bar{z}$  is a local maximizer of SIP. Then, for any  $\xi \in K$  there exist multipliers  $\bar{\lambda}_0(\xi), \dots, \bar{\lambda}_r(\xi) \geq 0$ , not all zero, such that (with the expressions for  $S_{SIP}(\xi), Q_{SIP}(\xi)$  below)

$$S_{SIP}(\xi) = 0 \quad \text{and} \quad Q_{SIP}(\xi) \leq 0.$$

The multipliers  $\bar{\lambda}_\ell(\xi)$  can be chosen 0 if  $g_z(\bar{z}, \bar{t}^\ell)\xi < 0$ , and  $\bar{\lambda}_0(\xi)$  can be chosen 0 if  $F_z(\bar{z})\xi > 0$ .

b) (Sufficient conditions) Suppose that for any  $\xi \in K \setminus \{0\}$  there exist multipliers  $\bar{\lambda}_0(\xi), \dots, \bar{\lambda}_r(\xi) \geq 0$  such that

$$S_{SIP}(\xi) = 0 \quad \text{and} \quad Q_{SIP}(\xi) < 0.$$

Then  $\bar{z}$  is a strict local maximizer of SIP.

The expressions for  $S_{SIP}(\xi), Q_{SIP}(\xi)$  are:

$$\begin{aligned} S_{SIP}(\xi) &= L_z(\bar{z}, \bar{\lambda}(\xi)) \\ &= \bar{\lambda}_0(\xi)F_z(\bar{z}) - \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi)g_z(\bar{z}, \bar{t}^\ell) \end{aligned} \quad (4)$$

$$\begin{aligned} Q_{SIP}(\xi) &= \xi^\top \left( \bar{\lambda}_0(\xi)F_{zz}(\bar{z}) - \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi)g_{zz}(\bar{z}, \bar{t}^\ell) \right) \xi \\ &+ \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi)D^\top t^\ell(\bar{z}; \xi)L_{tt}^{\bar{t}^\ell}(\bar{z}, \bar{t}^\ell, \bar{\gamma}^\ell)Dt^\ell(\bar{z}; \xi). \end{aligned} \quad (5)$$

The proof of Theorem 4 follows by applying F. John type optimality conditions of finite optimization to  $SIP_{red}(\bar{z})$  (conditions, modified to deal with functions whose derivatives are Lipschitz continuous and directionally differentiable cf. [4]). This leads to the following primal necessary conditions (under the assumptions of Theorem 4): Let  $\bar{z}$  be a local solution of SIP. Then, for any  $\xi \in K$  the following system has no solution  $d \in \mathbb{R}^n$ :

$$\begin{cases} g_z(\bar{z}, \bar{t}^\ell)d + \xi^\top g_{zz}(\bar{z}, \bar{t}^\ell)\xi \\ -D^\top t(\bar{z}; \xi)L_{tt}^{\bar{t}^\ell}(\bar{z}, \bar{t}^\ell, \bar{\gamma}^\ell)Dt(\bar{z}; \xi) < 0, \\ \bar{t}^\ell \in E(\bar{z}; \xi), \\ F_z(\bar{z})d + \xi^\top F_{zz}(\bar{z})\xi > 0, \\ \text{if } F_z(\bar{z})\xi = 0, \end{cases} \quad (6)$$

where  $E(\bar{z}, \xi) = \{\bar{t}^\ell \in E(\bar{z}) : g_z(\bar{z}, \bar{t}^\ell)\xi = 0\}$ . An appropriate theorem of the alternative implies Theorem 4a. Correspondingly, the sufficient condition in Theorem 4b is equivalent to the nonsolvability of the system (6) with strict signs replaced by the weak signs,  $E(\bar{z}; \xi)$  replaced by  $E(\bar{z})$  and ‘if  $F_z(\bar{z})\xi = 0$ ’ omitted.

In the following remark we discuss optimality conditions under stronger as well as conditions under weaker regularity assumptions.

**Remark 5** Let  $\bar{z}$  be feasible for SIP.

a) If in  $A_{red}$ , in addition to LICQ and SSOC we assume SCS, then (cf. Remark 2b) the functions  $G^\ell$  in the reduced problem  $SIP_{red}(\bar{z})$  are twice continuously differentiable and in Theorem 4 the term  $Q_{SIP}(\xi)$  can be replaced by

$$\begin{aligned} &\xi^\top \left( \bar{\lambda}_0(\xi)F_{zz}(\bar{z}) - \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi)g_{zz}(\bar{z}, \bar{t}^\ell) \right. \\ &\left. + \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi)t_z^\ell(\bar{z})^\top L_{tt}^{\bar{t}^\ell}(\bar{z}, \bar{t}^\ell, \bar{\gamma}^\ell)t_z^\ell(\bar{z}) \right) \xi. \end{aligned} \quad (7)$$

Such optimality conditions have been derived in [2]. The idea of the ‘reduction approach’ goes back to [12] where in addition, it is assumed that LICQ holds:  $g_z(\bar{z}, \bar{t}^\ell) (= G_z^\ell(\bar{z}))$ ,  $\ell = 1, \dots, r$ , are linearly independent. Then in the terms  $S$  and  $Q$  we have  $\bar{\lambda}_0 = 1$  (Kuhn-Tucker condition) and the multipliers  $\bar{\lambda}_1, \dots, \bar{\lambda}_r$  are unique (independently of  $\xi$ ), i. e. the matrix between parentheses in (7) is negative (semi)definite.

- b) In [3, Thm. 5.4] a sufficient optimality condition similar to Theorem 4b is proven which does not make use of a reduction assumption. It is based on the idea to replace in (5) the directional derivative  $Dt^\ell(\bar{z}; \xi)$  by a solution of the quadratic problem  $P^\ell(\xi)$  and assumes that condition LICQ holds at all points  $\bar{t} \in E(\bar{z})$ .
- c) In [7,8] H. Kawasaki has given necessary and sufficient optimality conditions under weaker regularity assumptions and without assuming differentiability of  $g$  with respect to  $t$ . The expressions

$$D^\top t^\ell(\bar{z}; \xi) L_{tt}^{\bar{t}^\ell}(\bar{z}, \bar{t}^\ell, \bar{\gamma}^\ell) D t^\ell(\bar{z}; \xi) \quad (8)$$

are replaced by terms  $2\varepsilon(\bar{t}^\ell, \xi)$  which describe a second order approximation of the feasible set  $Z$  at  $\bar{z}$  in the direction  $\xi$ . The necessary dual conditions (cf. [8, Thm. 3.1]) do not make regularity assumptions on  $\Theta(\bar{z})$ . A similar sufficient condition without a gap is obtained (apart from the strong sign in the second order condition) (cf. [8, Thm. 4.1]) under the assumption that  $B$  is convex and conditions on the behavior of certain functions such as  $g(\bar{z}, t)$  which, in particular, imply that the set  $E(\bar{z}; \xi)$  is finite. In [8] it is shown that for the special case  $B = [0, 1]$ , under the regularity conditions of Theorem 4, the term  $2\varepsilon(\bar{t}^\ell, \xi)$  coincides with (8). These terms (often called ‘shift terms’) reflect the ‘semi-infinite structure’ inasmuch as they describe the dependence of  $E(z)$  on  $z$ .

- d) In [1] the ‘shift terms’ are given in the form

$$\sigma(\lambda(\xi), \tau(\xi)) \quad (9)$$

where  $\lambda$  is a multiplier function (in the space of measures),  $\tau(\xi)$  describes a second order approximation of the feasible set and  $\sigma$  denotes the support function. There is a gap between the necessary and the sufficient conditions (cf. [1, Thms. 3.1; 3.2]) inasmuch as (apart from the strong sign) in the sufficient condition the term (9) is given with a set  $\tau(\xi)$  which can be strictly larger than the corresponding set in the necessary condition. However, under the following assumptions there is no gap:  $g(\cdot, t)$  is twice differentiable,  $g_{zz}$  is continuous on  $\mathbf{R}^n \times B$ ,  $g(\bar{z}, \cdot)$  is twice continuously differentiable,  $g_{z_i}(\bar{z}, \cdot)$  are continuously differentiable; the constraint qualification (CQ) is fulfilled: there exists  $\bar{\xi}$  such that

$g_z(\bar{z}, \bar{t}) \bar{\xi} < 0$ ,  $\bar{t} \in E(\bar{z})$ ;  $g(\bar{z}, t)$  satisfies a certain second order growth condition;  $B$  and  $E(\bar{z})$  are smooth (compact) manifolds.

### Optimality Conditions for GSIP

We briefly outline optimality conditions for GSIP. The statements of Theorems 3 and 4 remain true for the generalized problem with the only modification that due to the dependence of  $B$  (i.e.  $h^j$ ) on  $z$  the expressions for  $S(\xi)$  and  $Q(\xi)$  (cf. Theorem 4) contain extra terms (all terms in (2), (3)). Consequently, Theorem 4 holds for GSIP if the expressions for  $S_{\text{SIP}}(\xi)$  and  $Q_{\text{SIP}}(\xi)$  in (4) and (5) are replaced by:

$$\begin{aligned} S_{\text{GSIP}}(\xi) &= S_{\text{SIP}}(\xi) + \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi) \sum_{j \in J(\bar{z}, \bar{t}^\ell)} \bar{\gamma}_j^\ell h_z^j(\bar{z}, \bar{t}^\ell), \\ Q_{\text{GSIP}}(\xi) &= Q_{\text{SIP}}(\xi) + \sum_{\ell=1}^r \bar{\lambda}_\ell(\xi) \\ &\times \sum_{j \in J(\bar{z}, \bar{t}^\ell)} \left( \bar{\gamma}_j^\ell \xi^\top h_{zz}^j(\bar{z}, \bar{t}^\ell) \xi + 2D\gamma_j^\ell(\bar{z}; \xi) h_z^j(\bar{z}, \bar{t}^\ell) \xi \right). \end{aligned}$$

We give some information on other optimality conditions for GSIP.

*Remark 6* Under the additional assumption SCS  $A_{\text{red}}$ , as in the SIP case in Remark 5a, the formula for  $Q_{\text{GSIP}}(\xi)$  simplify. Corresponding optimality conditions are implicitly contained in [10] (see also [11]).

A second order sufficient condition not based on a reduction (as in Remark 5b) is to be found in [4, Thm. 5.1]. For first order necessary conditions under weak regularity assumptions, see [6] and [9]. In the first paper no regularity assumption on  $\Theta(\bar{z})$  is made, whereas the latter assumes that MFCQ is fulfilled for any  $\bar{t} \in E(\bar{z})$ .

### Duality of the Linear SIP Problem

Linear semi-infinite programming is a next level of extension of elementary finite linear programming where now finitely many variables occur in infinitely many linear inequalities. Some of the earliest papers were by A. Charnes, W.W. Cooper, and K.O. Kortanek, [3,4,5,6]. More recent surveys by S.-Å. Gustafson and R. Hettich were co-authored with Kortanek, see [8,11], and several symposium volumes on semi-infinite programming have appeared since the late 1970s, [7,10].

In this paper we begin with the primal program denoted by **Program I**. The analogy to a primal finite linear program is thus made apparent.

**Program I.** Let  $T$  be a nonempty set and  $u = (u_1, \dots, u_{n+1})$  be real-valued functions on  $T$  and  $b \in \mathbf{R}^n$ . Find  $v_I = \sup_{y \in \mathbf{R}^n} y^T b$  from among  $y \in \mathbf{R}^n$  such that  $y^T u(t) \leq u_{n+1}(t), \forall t \in T$ .

Clearly, if we choose a finite subset of  $\{t_1, \dots, t_k\}$  of  $T$ , then we obtain a finite LP approximation to Program I, namely,

**Program  $I_k$ .** Find  $v_{I_k} = \max_{y \in \mathbf{R}^n} y^T b$  subject to  $y \in \mathbf{R}^n$  and  $y^T u(t_i) \leq u_{n+1}(t_i), i = 1, k$ .

*Remark 1* Without sufficient regularity conditions, Program  $I_k$  may be a very bad approximation to Program I, and possibly useless. Here, we also use the typical Russian notation  $i = \overline{1, m}$  for  $i = 1, \dots, m$ .

Constructing the dual program to a finite LP is a pleasant task, and in this case yields the following,

**Program  $II_k$ .** Find  $v_{II_k} = \min \sum_{i=1}^k u_{n+1}(t_i) \lambda_i$  with  $\lambda_i \geq 0, i = \overline{1, k}$  such that  $\sum_{i=1}^k u(t_i) \lambda_i = b$ .

Now any finite LP approximation depends on a selection of a finite subset of the given *SIP index set*  $T$ , and of course there are infinitely many such choices. To attempt to recover the given infinite problem by this procedure requires that we at least allow the finite subsets of  $T$  to be freely chosen. This is formulated mathematically with *generalized finite sequences*, a particular *function space*, in the dual program. There are close connections between this construction and G.B. Dantzig’s concept of *generalized linear programming with variable coefficients*, and some of these were explored in a paper by Kortanek in the 1970s, [12].

**Program II.** Find  $v_{II} = \inf_{\lambda \in \text{supp } \lambda} u_{n+1}(t)\lambda(t)$  from among  $\lambda \in \mathbf{R}^{(S)}$ ,  $\lambda(\cdot) \geq 0$ , such that  $\sum_{t \in \text{supp } \lambda} u(t)\lambda(t) = b$ , where  $\lambda \in \mathbf{R}^{(S)}$  are generalized finite sequences, namely  $\text{supp } \lambda = \{t: \lambda(t) \neq 0\}$  is a finite set.

From a probabilist’s point of view Program II is equivalent to the following:

**Program IIB.** Find  $v_{IIB} = \inf \int_T u_{n+1} d\alpha$  where  $\alpha$  are nonnegative Borel measures on a Borel set  $T \subset \mathbf{R}^n$  subject to  $\int_T u_i d\alpha = b_i, i = \bar{1}, k$ , and where  $u_i$  are Borel integrable functions, see [9].

Using analogous algebraic manipulations as in finite linear programming, one can verify that if  $y$  and  $\lambda$  are feasible respectively for Programs I and II, then

$$y^\top b \leq \sum_{s \in \text{supp } \lambda} u_{n+1}(s)\lambda(s).$$

When both programs are feasible, it follows that

$$v_I \leq v_{II}. \tag{1}$$

Termed the *duality inequality*, (1) becomes an equality when certain regularity conditions hold. The most widespread sufficient condition is that the functions  $u(\cdot)$  are continuous on a compact set  $S$ , and the *Slater condition* holds, namely there exists  $\hat{y}$  such that  $\hat{y}^\top u(t) < u_{n+1}(t), \forall t \in S$ . This condition is also termed *superconsistency*, and it is defined for the dual Program II in a different way. As reviewed in [11, Thm. 6.11], a program is superconsistent if and only if its dual program has *bounded level sets*. Bounded level sets are necessary and sufficient to overcome the ‘danger’ noted below Program  $I_k$  about using any one finite linear program as an approximation to a linear semi-infinite program.

In general, without a constraint qualification a *duality gap*,  $v_I < v_{II}$  can occur.

*Example 2*

$$v_{II} \sup \{-y_1: -y_1 t - y_2 t^2 \leq -t, \forall t \in [0, 1]\}.$$

Here  $v_{II} = -1$ , but  $v_{II} = +\infty$  reflecting the inconsistency of the dual program.

During the 1970s affine perturbations of the  $b$ -vector were constructed of the form  $b + \epsilon v$ , where  $\epsilon > 0, v \in \mathbf{R}^n$  leading naturally to the following dual programs.

$$I_v^\epsilon \begin{cases} v_{I_v^\epsilon} = \sup y^\top (b + \epsilon v) \\ \text{s.t. } y^\top u(t) \leq u_{n+1}(t), \quad \forall t \in T \end{cases}$$

and

$$II_v^\epsilon \begin{cases} v_{II_v^\epsilon} = \inf_{\lambda \in \text{supp } \lambda} u_{n+1}(t)\lambda(t) \\ \text{from among } \lambda \in \mathbf{R}^{(S)}, \quad \lambda(\cdot) \geq 0, \\ \text{s.t. } \sum_{t \in \text{supp } \lambda} u(t)\lambda(t) = b + \epsilon v. \end{cases}$$

The idea was that  $II_v^\epsilon$  would suggest a Program  $II^*$  that would be in perfect duality with Program I. To accomplish this, certain properties were required of the vector  $v$  used in the perturbation.

**Definition 3** A vector  $v \in \mathbf{R}^n$  that satisfies the following property is termed a *descent vector* for Program I: given any  $\epsilon > 0$ , there exists a generalized finite sequence  $\lambda^\epsilon(\cdot)$  which is feasible for Program  $II_v^\epsilon$  such that in addition,

$$\sum_t u_{n+1}(t)\lambda^\epsilon(t) \leq v_I. \tag{2}$$

To see how a descent vector is used, let  $\delta > 0$  but otherwise arbitrary. Let  $y^{(\delta)}$  be  $I$ -feasible such that

$$v_I \geq b^\top y^{(\delta)} \geq v_I - \frac{\delta}{2}. \tag{3}$$

Let  $\epsilon < \delta/2 \|y^{(\delta)\top} v\|$ , where without loss of generality  $y^{(\delta)\top} v \neq 0$ . By Definition 3 there exists  $\lambda^\epsilon(\cdot)$  which is  $II_v^\epsilon$ -feasible. Hence by the duality inequality,

$$\sum_t u_{n+1}(t)\lambda^\epsilon(t) \geq y^{(\delta)\top} b + \epsilon y^{(\delta)\top} v. \tag{4}$$

Combining (2)–(4) yields

$$\begin{aligned} v_I &\geq \sum_t u_{n+1}(t) \lambda^\epsilon(t) \geq v_I - \frac{\delta}{2} - \frac{\delta}{2} \\ &= v_I - \delta. \end{aligned} \quad (5)$$

The interpretation of (5) is that we can obtain a solution of  $II_v^\epsilon$  with objective function value as close to  $v_I$  as desired. The *formal* perfect dual to Program  $I$  is the following one.

**Program  $II^*$ .** inf $w$  from  $w \in \mathbf{R}$ ,  $(v, v_{m+1}) \in \mathbf{R}^{m+1}$  which satisfy the following constraints: given any  $\epsilon > 0$ ,  $\exists \delta, 0 < \delta \leq \epsilon$  such that

$$\begin{aligned} \sum_{t \in \text{supp } \mu} u_i(t) \mu(t) &= c_i + \delta v_i, \quad i = \overline{1, m}, \\ \sum_{t \in \text{supp } \mu} u_0(t) \mu(t) - w &\leq \delta v_{m+1} \end{aligned}$$

has a solution  $\mu \in \mathbf{R}^{(B)}$ .

Rather than pursue duality theory in depth, we look to newly discovered relationships between of LSIP and semidefinite programming, SDP, see [14,15,18,19].

## Dual Semidefinite Programs

We begin with the following standard primal SDP program:

$$P \quad \begin{cases} \sup & c^\top x \\ \text{s.t.} & \sum_{i=1}^m x_i Q_i \preceq Q_0, \end{cases} \quad (6)$$

where  $Q_i, i = \overline{0, m}$ , are  $\bar{n} \times \bar{n}$  symmetric matrices.

*Remark 4* It is convenient to denote the value of a program  $(P)$  by  $v(P)$ , and the value of a particular feasible point/solution, say  $x$ , simply by  $v(x)$ .

$$D \quad \begin{cases} \inf & U \bullet Q_0 \\ \text{s.t.} & U \bullet Q_i = c_i, \quad i = \overline{1, m}, \\ & U \succeq 0. \end{cases} \quad (7)$$

For Programs  $P$  and  $D$ , we have the following weak duality lemma, also termed the *duality inequality*.

**Lemma 5** If  $U$  is  $D$ -feasible and  $x$  is  $P$ -feasible, then  $v(x) \leq v(U)$ .

Now let  $\mathcal{V}_j, j = \overline{1, \bar{n}}$ , be an orthonormal basis for the linear space  $\mathbf{S}^{\bar{n}}$  (of  $\bar{n} \times \bar{n}$  symmetric matrices,  $n = \frac{\bar{n}}{2} \times (\bar{n} + 1)$ ) with inner product  $U \bullet W \equiv \langle U, W \rangle = \text{trace } UW$ , where  $U, W \in \mathbf{S}^{\bar{n}}$ , and  $UW$  denotes ordinary, dimension compatible matrix multiplication.

Let

$$\begin{aligned} Q_0 &= \sum_{j=1}^n b_j \mathcal{V}_j \equiv b^\top \mathcal{V}, \\ Q_i &= \sum_{j=1}^n a_{ij} \mathcal{V}_j, \quad A = (a_{ij})_{m \times n}, \\ U &= \sum_{j=1}^n y_j \mathcal{V}_j \equiv y^\top \mathcal{V}. \end{aligned}$$

**Definition 6** The convex cone  $\mathbf{K} \subset \mathbf{R}^n$  is defined with respect to the given orthonormal basis by:

$$z = \{z_j\} \in \mathbf{K} \quad \text{if and only if} \quad z^\top \mathcal{V} \succeq 0.$$

The dual cone is conveniently expressed as  $\mathbf{K}^* = \{s \in \mathbf{R}^n: s^\top \mathbf{K} \subseteq \mathbf{R}_+, \mathbf{R}_+$  is the set of nonnegative reals. Here,  $\mathbf{K} = \mathbf{K}^*$ . We also use the terminology appearing in [16, Sec. 1.5.1] namely:

$$\begin{aligned} Q^* &: \mathbf{S}^{\bar{n}} \rightarrow \mathbb{R}^m, \\ Q^*(U) &= (U \bullet Q_i)_{i=\overline{1, m}}, \\ Q^\# &: \mathbf{S}^{\bar{n}} \rightarrow \mathbb{R}^{m+1}, \\ Q^\#(U) &= (Q_0 \bullet U, Q^*(U))^\top. \end{aligned}$$

## Perfect Duality from the View of Linear Semi-Infinite Programming

Program  $(P)$  is equivalent to the following LSIP:

$$\begin{cases} \sup & c^\top x \\ \text{s.t.} & \sum_{i=1}^m x_i u_i(t) \leq u_0(t), \quad \forall t \in \mathbf{B}, \end{cases} \quad (8)$$

$$\mathbf{B} \equiv \{t \in \mathbb{R}^{\bar{n}}: \|t\| = \|t\|_2 = 1\}$$

$$\text{where } u_i(t) = t^\top Q_i t, \quad i = \overline{0, m}.$$

As reviewed in [11 Sec. 6.4], we have the following perfect dual,  $D_G$ :

$$\begin{aligned} v(D_G) &= \inf w; \\ w &\in \mathbb{R} \\ \text{s.t. } (c, w)^\top &\in \text{cl}(M_{m+1}), \\ \text{where } M_{m+1} &= \text{co}(\{(u_1(t), \dots, u_m(t), u_0(t))^\top\}_{t \in \mathbf{B}}) \subset \mathbb{R}^{m+1}. \end{aligned} \tag{9}$$

Rather than considering arbitrary paths in  $M_{m+1}$  converging to  $(c, w)^\top$ , we need only consider movement along a *descent ray*, [13], associated with the minimization of Program  $D^*$ , which generates straight line paths, (9), namely:

$$D^* \begin{cases} \inf w; \\ w \in \mathbb{R} \text{ and } (v \ v_{m+1})^\top \in \mathbb{R}^{m+1} \end{cases}$$

which satisfy the condition:

$$\left\{ \begin{array}{l} \text{given } \epsilon > 0, \\ \exists \mu \in \mathbb{R}^{(\mathbf{B})}, \mu \geq 0, \\ \text{s.t. } \sum_{t \in \text{supp } \mu} u_i(t)\mu(t) = c_i + \epsilon v_i, \\ \quad i = \overline{1, m}, \\ \sum_{t \in \text{supp } \mu} u_0(t)\mu(t) - w \leq \epsilon v_{m+1}. \end{array} \right. \tag{10}$$

We need another program using descent vectors (for minimization) that is visibly close to the SDP structure:

$$D_{DV} \begin{cases} \inf (U + W) \bullet Q_0, \\ \text{where } U, W \in \mathbf{S}^{\overline{n}}, \quad U \succeq 0, \end{cases}$$

satisfying: given any  $\kappa > 0, \exists \epsilon_\kappa > 0$ :

$$\begin{aligned} \epsilon_\kappa > \delta > 0 &\Rightarrow \exists U_\delta : \\ Q_i \bullet (U_\delta + \delta W) &= c_i, \quad i = \overline{1, m} \end{aligned} \tag{11}$$

$$Q_0 \bullet (U_\delta + \delta W) - \kappa \leq Q_0 \bullet (U + W). \tag{12}$$

**Definition 7** We say that  $V$  is *feasible* for  $D_{DV}$  if there are  $U, W \in \mathbf{S}^{\overline{n}}$  with  $U \succeq 0$ , such that  $V = U + W$ , and the constraints of  $D_{DV}$  are satisfied.

Our first goal is to show that Programs  $D^*$  and  $D_{DV}$  are equivalent. We need two lemmas for this task.

**Lemma 8** If  $\mu \in \mathbf{R}^{(\mathbf{B})}, \mu \geq 0$ , then  $\exists a$  PSD  $U$  such that

$$\sum_t u_i(t)\mu(t) = Q_i \bullet U, \quad i = \overline{0, m}.$$

Conversely, if  $U$  is PSD, then  $\exists \mu \in \mathbf{R}^{(\mathbf{B})}, \mu \geq 0$ , such that

$$\sum_t u_i(t)\mu(t) = Q_i \bullet U, \quad i = \overline{0, m}.$$

*Proof* Let  $\text{supp } \mu(t) = \{t_1, \dots, t_p\}$  with  $t_j^\top = (t_{j1}, \dots, t_{j\overline{n}})$ . Then

$$u_i(t_j) = t_j^\top Q_i t_j = Q_i \bullet U_j, \tag{13}$$

where  $U_j = (t_{jk} t_{jl})_{k,l=\overline{1, \overline{n}}}$ .

Set  $U = \sum_{j=1}^p \mu(t_j) U_j$ . Since each  $U_j \succeq 0, j = \overline{1, p}$ , it follows that

$$\begin{aligned} U &\text{ is PSD, and} \\ Q_i \bullet U &= \sum_{t \in \text{supp } \mu} u_i(t)\mu(t), \quad i = \overline{0, m}. \end{aligned}$$

Conversely, if  $U$  is PSD, then there exists  $B \in \mathbf{S}^{\overline{n}}$  such that

$$B^\top = B^{-1} \text{ with } BXB^{-1} = U, \quad X \text{ diagonal.}$$

Therefore,

$$\begin{aligned} Q_i \bullet U &= Q_i \bullet BXB^{-1} = \text{tr}(Q_i BXB^{-1}) \\ &= \text{tr}(B^{-1} Q_i BX) = B^{-1} Q_i B \bullet X. \end{aligned}$$

Let

$$X = \text{diag}\{\lambda_1, \dots, \lambda_{\overline{n}}\}, \quad \lambda_j \geq 0, \quad j = \overline{1, \overline{n}}.$$

Then

$$Q_i \bullet U = \text{tr}(B^{-1} Q_i BX) = \sum_{j=1}^{\overline{n}} \theta_j^\top B^{-1} Q_i B \theta_j,$$

where  $\theta_j$  has  $\sqrt{\lambda_j}$  in its  $j$ th component, and zero elsewhere.

Let

$$t_j = \begin{cases} 0 & \text{if } \lambda_j = 0, \\ \frac{\theta_j^\top B^{-1}}{\|\theta_j^\top B^{-1}\|} & \text{if } \lambda_j \neq 0 \end{cases}$$

and

$$\mu(t) = \begin{cases} 0 & \text{if } t \notin \{t_1, \dots, t_{\overline{n}}\}, \\ \left\| \frac{\theta_j^\top B^{-1}}{\|\theta_j^\top B^{-1}\|} \right\|^2 & \text{if } t = t_j, \quad j = \overline{1, \overline{n}}. \end{cases}$$

Hence, we obtain,

$$Q_i \bullet U = B^{-1} Q_i B \bullet X = \sum_{t \in \text{supp } \mu} \mu(t) u_i(t).$$

For the next result we will need the following program:

$$D^{**} \begin{cases} \inf & w; \\ \text{where} & w \in \mathbb{R} \quad \text{and} \quad W \in \mathbf{S}^{\bar{n}} \quad \text{satisfy:} \end{cases}$$

given any  $\epsilon > 0$ ,  $\exists U_\epsilon \in \mathbf{S}^{\bar{n}}$ ,  $U_\epsilon \geq 0$ :

$$Q_i \bullet (U_\epsilon + \epsilon W) = c_i, \quad i = \overline{1, m}, \quad (14)$$

$$Q_0 \bullet (U_\epsilon + \epsilon W) \leq w. \quad (15)$$

**Lemma 9** Program  $D^*$  is equivalent to Program  $D^{**}$ .

*Proof* Let  $D^{**}$  be consistent with feasible point  $w \in \mathbb{R}$ ,  $W \in \mathbf{S}^{\bar{n}}$ . Simply use Lemma 8 and set

$$Q_i \bullet W = -v_i, \quad i = \overline{1, m},$$

$$Q_0 \bullet W = -v_{m+1}.$$

Hence, any feasible solution of  $D^{**}$  is feasible for  $D^*$ .

Suppose now  $(v, v_{m+1}, w)^\top$  is feasible for  $D^*$ . By Lemma 8, for any  $\epsilon > 0$ ,  $\exists U_\epsilon$  such that

$$Q_i \bullet U_\epsilon = c_i + \epsilon v_i, \quad i = \overline{1, m}, \quad (16)$$

$$Q_0 \bullet U_\epsilon - w \leq \epsilon v_{m+1}. \quad (17)$$

Therefore, for any  $\epsilon > 0$  the equation  $AY = c + \epsilon v$  has solutions and so does  $AY = -v$ , ( $A$  is the matrix defined above Definition 6), so  $\exists W \in \mathbf{S}^{\bar{n}}$  such that  $Q^*(W) = -v$ . We consider two cases.

1)  $Q_0 \in \text{linear span } \{Q_i\}_{i=1}^m$ .

Suppose  $Q_0 = \sum_{i=1}^m a_i Q_i$ . Then set  $w' = \sum_{i=1}^m a_i c_i$ . It follows from (17) that  $w' \leq w$  and  $(W, w')$  is feasible for  $D^{**}$ .

2)  $Q_0$  is linearly independent of  $\{Q_i\}_{i=1}^m$ .

For this case it follows that there exists  $Y_1, Y_2 \subset \mathbf{R}^n$  such that,

$$\begin{pmatrix} A \\ b^\top Y_1 \end{pmatrix} Y_1 = \begin{pmatrix} 0 \\ -v_{m+1} \end{pmatrix}$$

and

$$\begin{pmatrix} A \\ b^\top Y_1 \end{pmatrix} Y_2 = \begin{pmatrix} -v \\ 0 \end{pmatrix}.$$

Therefore,  $\exists W_i \in \mathbf{S}^{\bar{n}}$ ,  $i = 1, 2$ , such that

$$Q^*(W_1) = 0, \quad Q^*(W_2) = -v,$$

$$Q_0 \bullet W_1 = -v_{m+1}, \quad Q_0 \bullet W_2 = 0.$$

Hence,  $(W_1 + W_2, w)$  is feasible for  $D^{**}$ .

Since the objective functions are identical, namely  $w$ , it follows that  $D^*$  is equivalent to  $D^{**}$ .

**Theorem 10** Programs  $D^*$  and  $D_{DV}$  are equivalent.

*Proof* It suffices to show that  $D_{DV}$  and  $D^{**}$  are equivalent. We begin by supposing that  $D_{DV}$  is feasible with feasible solution  $V$ . This means  $\exists U \geq 0$ ,  $W \in \mathbf{S}^{\bar{n}}$  satisfying (11) and (12). Let  $w_n = Q_0 \bullet (U + W) + 1/n$ . Then  $(W, w_n)$  is feasible for  $D^{**}$  and  $v(D_{DV}) \geq v(D^{**})$ .

Conversely, suppose  $D^{**}$  is feasible with feasible solution,  $(W, w)$ . Then  $\exists U$  such that

$$Q_i \bullet (U + W) = c_i$$

$$Q_0 \bullet (U + W) \leq w, \quad i = \overline{1, m}.$$

1)  $Q_0 \in \text{linear span } \{Q_i\}_{i=1}^m$ .

In this case  $Q_0 \bullet (U + W)$  is determined by  $\{Q_i \bullet (U + W)\}_{i=1}^m$ . Therefore,  $U + W$  is feasible for  $D_{DV}$  and  $v(D_{DV}) \leq v(D^{**})$ .

2)  $Q_0$  is linearly independent of  $\{Q_i\}_{i=1}^m$ .

In this case there exists  $W_0 \in \mathbf{S}^{\bar{n}}$  satisfying

$$Q_i \bullet W_0 = 0, \quad Q_0 \bullet W_0 = 1.$$

Now, for any  $\kappa > 0$ ,  $\exists M > 0$ ,  $M\kappa = w - Q_0 \bullet (U + W)$ . Hence,

$$w = Q_0 \bullet (U + W + M\kappa W_0)$$

and

$$Q_i \bullet (U + W + M\kappa W_0) = c_i, \quad i = \overline{1, m}.$$

But for any  $\delta < 1/M$  ( $\equiv \epsilon$ ),  $\exists U_\delta \geq 0$   $U_\delta$  satisfies (14) and 15.

Hence,  $Q_i \bullet (U_\delta + \delta(W + M\kappa W_0)) = c_i$ ,  $i = \overline{1, m}$ , and

$$Q_0 \bullet (U_\delta + \delta(W + M\kappa W_0))$$

$$= Q_0 \bullet (U_\delta + \delta W) + \delta M\kappa \leq w + \delta M\kappa.$$

Therefore,

$$\begin{aligned} Q_0 \bullet (U_\delta + \delta(W + M\kappa W_0)) - \delta M\kappa \\ \leq Q_0 \bullet (U + (W + M\kappa W_0)). \end{aligned}$$

So

$$\begin{aligned} Q_0 \bullet (U_\delta + \delta(W + M\kappa W_0)) - \kappa \\ \leq Q_0 \bullet (U + (W + M\kappa W_0)). \end{aligned}$$

Therefore,  $(U + W + (w - Q_0 \bullet (U + W)) W_0)$  is a feasible solution for  $D_{DV}$  and it is easy to show that  $v(D_{DV}) = v(D^{**})$ . Hence, in conclusion we have obtained the following equivalence:

$$D_{DV} \Leftrightarrow D^{**} \Leftrightarrow D^*.$$

**Corollary 11** *Program  $P$  and Program  $D_{DV}$  are in perfect duality.*

### The SDP as a Conic Convex Program

Recently, M.V. Ramana [16], Zhi-Quan Luo, Jos.F. Sturm, and Shuzhong Zhang [15], and J.F. Strum [18] developed a perfect dual of the semidefinite program  $P$ , (6) involving only linear and positive definiteness constraints. The authors [15] state that their regularized program coincides with Ramana's *extended Lagrange-Slater dual* and that this fact was already recognized in [17]; see also [1,2]. In [14] we investigate these connections by using results for regularized conic convex programs. We develop some relationships between all the perfect duals including the one presented earlier in this paper,  $\Pi^*$ . We refer the interested reader to all of these papers, but here conclude by showing how to restate the SDP program  $P$  as a conic convex program.

Earlier the convex cone  $\mathbf{K}$  and the matrix  $A$  were introduced. Clearly, Program  $P$ , (6), is equivalent to:

$$\begin{cases} \sup & c^\top x \\ \text{s.t.} & b - A^\top x \in \mathbf{K}^* \quad (= \mathbf{K}) \end{cases} \quad (18)$$

with dual program,

$$\begin{cases} \inf & b^\top y \\ \text{s.t.} & Ay = c, \quad y \in \mathbf{K}. \end{cases} \quad (19)$$

Program  $P$  is equivalent to the following conic convex program:

$$P' \begin{cases} \inf & (0, c)^\top (s, t) \\ \text{s.t.} & (s, t) \in \mathbb{R}^{n+m}, \\ & (s, t) - (b, 0) = (A^\top x, x), \\ & \exists x \in \mathbb{R}^m \\ \text{and} & (s, t) \in \mathbf{K}^* \times \mathbb{R}^m = \mathbf{K} \times \mathbb{R}^m. \end{cases}$$

Program  $D$  is equivalent to:

$$D' \begin{cases} \inf & (b, 0)^\top (y, u) \\ \text{from among} & (y, u) \in \mathbb{R}^{n+m} \\ \text{s.t.} & (y, u) - (0, c) \in \ker[A \ I] \\ \text{and} & (y, u) \in \mathbf{K} \times \{0\}. \end{cases}$$

Program  $D'$  is a conic convex program which in the notation used in [15] becomes:

$$CP((0, c), (b, 0), \ker[A \ I], \mathbf{K} \times \{0\}).$$

In [15] a finite sequence of regularized programs is constructed having certain properties that lead to the construction of an SDP perfect dual.

### Keywords

Complementarity problem; Sensitivity analysis

Sensitivity analysis has been extensively developed for a variety of problems in mathematical programming and applied mathematics [2]. It is concerned, in general, with investigation of properties of solutions to problems with perturbed data. This type of analysis derives its importance from the fact that almost all problems in mathematical programming and applied mathematics are solved for a fixed, specified set of data. As a result, the computed solution may be considerably inaccurate or even infeasible if the data are subjected to changes.

*Nonlinear complementarity problems* were originally formulated in the context of mathematical programming and then shown to be a special case of variational inequality problems ([1,6]). *Linear complementarity problems* were introduced earlier as extensions of convex quadratic programming problems (and bimatrix games) [1]. Initial sensitivity analysis results were developed for linear complementarity problems by extending corresponding results from linear and quadratic programming [1]. In recent years it has been widely recognized that complementarity problems generalize many economic, game-theoretic and transportation *equilibrium problems* ([1,6,11]). These equilibrium

problems were modeled as finite-dimensional complementarity problems (and variational inequalities) and the issues of computational efficiency and sensitivity analysis became an important part of their analysis. The computation of equilibria results in predictions of the behavior of the underlying system. As a result, the sensitivity of the equilibrium solution to changes in model parameters and data needs to be analyzed by the modeler.

The (finite-dimensional) *parametric nonlinear complementarity problem* is defined as

$$\text{NCP}(\epsilon) \begin{cases} \text{find } x \\ \text{s.t. } x \geq 0, \\ F(x, \epsilon) \geq 0, \\ F(x, \epsilon)^\top x = 0, \end{cases}$$

where  $F$  is a mapping from  $\mathbf{R}^n \times \mathbf{R}^k$  to  $\mathbf{R}^n$  and  $\epsilon \in \mathbf{R}^k$  is the parameter vector. Observe that  $\text{NCP}(\epsilon)$  is equivalent to the parametric variational inequality  $\text{VI}(\epsilon)$  with mapping  $F$  and the fixed feasible set  $X(\epsilon) = K = \{x: x \geq 0\}$ . The *parametric linear complementarity problem* is defined as

$$\text{LCP}(M, q) \begin{cases} \text{find } x \\ \text{s.t. } x \geq 0, \\ Mx + q \geq 0, \\ (Mx + q)^\top x = 0, \end{cases}$$

where  $M$  is an  $n \times n$  matrix and  $q \in \mathbf{R}^n$  (both  $M$  and  $q$  are considered parameters here).

Let  $S$  be the solution point-to-set map for  $\text{NCP}(\epsilon)$  which assigns to each parameter  $\epsilon \in \mathbf{R}^k$  the set of solutions of  $\text{NCP}(\epsilon)$

$$S(\epsilon) = \{x \geq 0: F(x, \epsilon) \geq 0, F(x, \epsilon)^\top x = 0\}.$$

Similarly, let the solution point-to-set map for  $\text{LCP}(M, q)$  be defined as

$$S(M, q) = \{x \geq 0: Mx + q \geq 0, (Mx + q)^\top x = 0\}.$$

Sensitivity analysis of the parametric nonlinear complementarity problem  $\text{NCP}(\epsilon)$  is concerned with:

- The existence and (local) uniqueness of solutions of  $\text{NCP}(\epsilon)$ , that is, investigating whether the solution set  $S(\epsilon)$  is nonempty and a singleton.

- Continuity properties of the solution set map  $S$ , such as Lipschitz continuity, both for multivalued and single-valued  $S$ .
- Differentiability properties of the solution set map  $S$ , such as directional or Fréchet differentiability of a single-valued map  $S$  and differentiability in a generalized sense of a multivalued map  $S$ .

The fundamental sensitivity analysis results were obtained for the  $\text{NCP}(\epsilon)$  problem using the equivalent parametric *generalized equation* of the form ([12,13]):

$$\text{GE}_K(\epsilon) \begin{cases} \text{find } x \\ \text{s.t. } 0 \in F(x, \epsilon) + N_K(x), \end{cases}$$

where  $N_K(x)$  is the *normal cone* of the set  $K = \{x: x \geq 0\}$  at  $x$ .

S.M. Robinson [13] showed that under the assumptions that the mapping  $F$  is continuously differentiable and that the solution  $x^*$  of the unperturbed problem  $\text{NCP}(\epsilon^*)$  is a *regular solution*, the solution set  $S(\epsilon)$  of  $\text{NCP}(\epsilon)$  is (locally) nonempty and a singleton (that is,  $S(\epsilon) = \{x(\epsilon)\}$  for all  $\epsilon$  near  $\epsilon^*$ ). In addition, the solution  $x(\epsilon)$  is Lipschitz continuous in  $\epsilon$ . Under the same assumptions it was also shown later that  $x(\epsilon)$  is directionally differentiable at  $\epsilon^*$  [7] and, under further assumptions on  $K$ , that  $x(\epsilon)$  is Fréchet differentiable at  $\epsilon^*$  (see surveys in [6,8]). Sensitivity analysis results described up to now for the problem  $\text{NCP}(\epsilon)$  can be directly applied to the perturbed linear complementarity problem  $\text{LCP}(\epsilon)$  where we substitute  $M(\epsilon)$  and  $q(\epsilon)$  for the matrix  $M$  and the vector  $q$  in the formulation  $\text{LCP}(M, q)$ .

Further extensions of the sensitivity analysis results for  $\text{NCP}(\epsilon)$  were obtained for situations where the solution set map  $S(\epsilon)$  is multivalued. These include conditions for the existence, continuity and differentiability (in a generalized sense) of the point-to-set map  $S(\epsilon)$  ([4,9]).

Another approach to the study of perturbed solutions for nonlinear complementarity problems, called *stability analysis*, was proposed in [5]. In this approach, the mapping  $F$  itself is the problem parameter (instead of being dependent on a parameter  $\epsilon$ ) and results from degree theory are utilized to obtain conditions for existence and (generalized) continuity of the multivalued solution map  $S$  as a function of  $F$ . This approach was also applied to linear complementarity problems  $\text{LCP}(M, q)$  where  $(M, q)$  is the problem parameter and

conditions for stability are expressed in terms of properties of the matrix  $M$  [1]. Recent extensions of stability analysis for linear and nonlinear complementarity problems, using degree theory, can be found in [3,4].

Sensitivity analysis of nonlinear complementarity problems was applied to several equilibrium problems, including the general spatial price equilibrium model [14] and the *Cournot–Nash oligopolistic equilibrium model* [15]. Another class of problems to which sensitivity analysis results for complementarity problems may be applied are mathematical programs with equilibrium constraints which arise in game theory, bilevel programming, and network design problems [10]. These problems include constraints of the type  $x \in S(\epsilon)$  where, in certain cases,  $S(\epsilon)$  may be the solution set of a complementarity problem. Computational methods for solving these problems rely on the ability to calculate the (generalized) derivatives of the solution set map  $S(\epsilon)$ .

Variational inequalities; Sensitivity analysis

Sensitivity analysis has been extensively developed for a variety of problems in mathematical programming and applied mathematics [2]. It is concerned, in general, with investigation of properties of solutions to

problems with perturbed data. This type of analysis derives its importance from the fact that almost all problems in mathematical programming and applied mathematics are solved for a fixed, specified set of data. As a result, the computed solution may be considerably inaccurate or even infeasible if the data are subjected to changes.

Variational inequality problems were originally developed to model partial differential equations arising from applications in mechanics [5]. These problems were formulated in infinite-dimensional spaces and sensitivity analysis issues were not addressed. However, it has been widely recognized in recent years that variational inequalities are direct generalizations of many economic, game-theoretic and transportation equilibrium problems ([4,10]). These equilibrium problems were modeled as finite-dimensional variational inequalities and the issues of computational efficiency and sensitivity analysis became an important part of their analysis. The computation of equilibria results in predictions of the behavior of the underlying system. As a result, the sensitivity of the equilibrium solution to changes in model parameters and data needs to be analyzed by the modeler.

The (finite-dimensional) general *parametric variational inequality problem* is defined as

$$VI(\epsilon) \quad \left\{ \begin{array}{l} \text{find } x \in X(\epsilon) \\ \text{s.t. } F(x, \epsilon)^\top (y - x) \geq 0 \\ \text{for all } y \in X(\epsilon), \end{array} \right.$$

where  $F$  is a mapping from  $\mathbf{R}^n \times \mathbf{R}^k$  to  $\mathbf{R}^n$ ,  $X$  is a feasible point-to-set map from  $\mathbf{R}^k$  to  $\mathbf{R}^n$  (that is, it assigns to each point  $\epsilon$  the feasible set  $X(\epsilon)$  of  $VI(\epsilon)$ ), and  $\epsilon \in \mathbf{R}^k$  is the parameter vector. Let  $S$  be the solution point-to-set map which assigns to each parameter  $\epsilon \in \mathbf{R}^k$  the set of solutions

$$S(\epsilon) = \left\{ x \in X(\epsilon) : \begin{array}{l} F(x, \epsilon)^\top (y - x) \geq 0, \\ \forall y \in X(\epsilon) \end{array} \right\}.$$

Sensitivity analysis of the parametric variational inequality  $VI(\epsilon)$  problem is concerned with:

- The existence and (local) uniqueness of solutions of  $VI(\epsilon)$ , that is investigating whether the solution set  $S(\epsilon)$  is nonempty and a singleton.
- Continuity properties of the solution set map  $S$ , such as Lipschitz continuity, both for multivalued and single-valued  $S$ .

- Differentiability properties of the solution set map  $S$  such as directional or Fréchet differentiability of a single-valued map  $S$  and differentiability in a generalized sense of a multivalued map  $S$ .

The fundamental sensitivity analysis results were initially obtained for the special  $VI(\epsilon)$  problem, where  $X(\epsilon) = K$  is a fixed (closed and convex) set, using the equivalent parametric *generalized equation* of the form ([12,13]):

$$GE_K(\epsilon) \quad \left\{ \begin{array}{l} \text{find } x \\ \text{s.t. } 0 \in F(x, \epsilon) + N_K(x), \end{array} \right.$$

where  $N_K(x)$  is the *normal cone* of the set  $K$  at  $x$ .

S.M. Robinson [13] showed that under the assumptions that the mapping  $F$  is continuously differentiable and that the solution  $x^*$  of the unperturbed problem  $VI(\epsilon^*)$  is *regular*, the solution set  $S(\epsilon)$  is (locally) nonempty and a singleton (that is  $S(\epsilon) = \{x(\epsilon)\}$ ) for all  $\epsilon$  near  $\epsilon^*$ . In addition, the solution  $x(\epsilon)$  is Lipschitz continuous in  $\epsilon$ . Under an additional assumption that  $K$  is polyhedral, it was also shown later that  $x(\epsilon)$  is directionally differentiable at  $\epsilon^*$  and, under further assumptions on  $K$ , that  $x(\epsilon)$  is Fréchet differentiable at  $\epsilon^*$  (see the surveys in [4,7]).

Sensitivity analysis results were then extended to the more general  $VI(\epsilon)$  problem, where  $X(\epsilon) = \{x \in \mathbf{R}^n : g(x, \epsilon) \geq 0, h(x, \epsilon) = 0\}$  is defined using mappings  $g$  and  $h$ . For this problem, the equivalent parametric generalized equation is of the form ([7,7]):

$$GKKT_0(\epsilon) \quad \left\{ \begin{array}{l} \text{find } (x, u, w) \\ \text{s.t. } 0 \in T(x, u, w, \epsilon) \\ \quad + N_{\mathbf{R}^n \times \mathbf{R}_+^m \times \mathbf{R}^p}(x, u, w), \end{array} \right.$$

where

$$\begin{aligned} T(x, u, w, \epsilon)^\top &= [L_D(x, u, w, \epsilon)^\top, g(x, \epsilon)^\top, h(x, \epsilon)^\top] \end{aligned}$$

and  $L_D(x, u, w, \epsilon) = F(x, \epsilon) - \nabla_x g(x, \epsilon)^\top u + \nabla_x h(x, \epsilon)^\top w$ . The generalized equation  $GKKT_0(\epsilon)$  is equivalent to the system of *generalized Karush-Kuhn-Tucker conditions* similar to those in nonlinear programming [2].

By applying the results obtained for  $VI(\epsilon)$  with fixed  $K$  to  $GKKT_0(\epsilon)$ , Robinson [13] showed that under the assumptions that the mapping  $F$  is once- and the mappings  $g$  and  $h$  are twice-continuously differentiable and

that the solution  $(x^*, u^*, w^*)$  of the unperturbed problem  $\text{GKKT}_0(\epsilon^*)$  is regular, the solution set  $S(\epsilon)$  is (locally) nonempty and a singleton (that is  $S(\epsilon) = \{(x(\epsilon), u(\epsilon), w(\epsilon))\}$ ) for all  $\epsilon$  near  $\epsilon^*$ . In addition, the solution  $(x(\epsilon), u(\epsilon), w(\epsilon))$  is Lipschitz continuous in  $\epsilon$ . Under the same assumptions, it was also shown later that  $(x(\epsilon), u(\epsilon), w(\epsilon))$  is directionally differentiable at  $\epsilon^*$  [6] and, under an additional *strict complementarity slackness condition*, that  $(x(\epsilon), u(\epsilon), w(\epsilon))$  is Fréchet differentiable at  $\epsilon^*$  (see the surveys in [4,7]).

Further extensions of the sensitivity analysis results for  $\text{VI}(\epsilon)$  were obtained for situations where the solution set map  $S(\epsilon)$  is multivalued. These include conditions for the existence, continuity and differentiability (in a generalized sense) of the point-to-set map  $S(\epsilon)$  ([3,8,11]).

Sensitivity analysis of variational inequalities was applied to a variety of equilibrium problems. These applications include the traffic assignment or network equilibrium model ([10,11]), the general spatial economic equilibrium models ([1,10,14]), and the *spatial competition facility location models* including *spatial price equilibrium* and *Cournot–Nash oligopolistic equilibrium* [15]. Another class of problems to which sensitivity analysis results were extensively applied are mathematical programs with equilibrium constraints which arise in game theory, bilevel programming, and network design problems [9]. These problems include constraints of the type  $x \in S(\epsilon)$  where  $S(\epsilon)$  is the solution set of a variational inequality  $\text{VI}(\epsilon)$ . Computational methods for solving these problems rely on the ability to calculate the (generalized) derivatives of the solution set map  $S(\epsilon)$ .

Nonlinear programming; Linear programming;  
 Optimality conditions; Sensitivity analysis

We are interested in what happens to a solution of a problem when there are changes in the problem data. We shall use the term *sensitivity analysis* to refer to the calculation and study of any collection of measurements associated with any changes, infinitesimally small or finite. The measure of change may be explicit or implicit, qualitative or quantitative. For example, a qualitative characteristic may be the continuity of a change, while a quantitative one might be a numerical bound. An explicit measure is usually a closed form expression while an implicit one is inferred by a proof of existence of a property or quantity. Stable will mean ‘well-behaved’ or ‘well-conditioned’, in a given context. Traditionally, *well-conditioned* generally meant small solution changes from small data changes, but many subjective interpretations are possible and currently in use. The concept is relative to a given property, data value or data change. Stochastic changes and effects are certainly possible and frequently encountered in applications, but our focus is deterministic.

Some familiar examples will hopefully clarify the kinds of problems and conclusions that are of interest. Suppose  $Ax = b$ , where  $A$  is an  $n \times n$  matrix and  $x$  and  $b$  are in  $E^n$ ,  $n$ -dimensional Euclidean space. If  $A$  is nonsingular, then we know that  $x = A^{-1}b$ . Now, if  $A$  or  $b$  changes, we can track the change in  $x$  if we know  $A^{-1}$ . We have a closed form smooth stable explicit solution  $x(A; b)$  of  $x$  as a function of  $A$  and  $b$ . Of course, computationally, we may even here encounter serious difficulties, since  $A^{-1}$  or  $b$  may be difficult to evaluate. For example, suppose that  $A$  and  $b$  are functions of some parameter  $\epsilon \in E^q$ , which we denote by  $A(\epsilon)$  and  $b(\epsilon)$ . If  $A$  remains nonsingular and  $b$  remains defined for  $\epsilon \in T \subseteq E^q$ , then  $x(\epsilon) = A^{-1}(\epsilon)b(\epsilon)$  for  $\epsilon \in T$ . In this instance, at least we know the general form of the parametric solution, but even so a closed form expression  $x(\epsilon)$  of  $x$  as a function of  $\epsilon$  might be too difficult to obtain. Issues become more complicated, e. g., for what  $\epsilon$  is  $x$  continuous, differentiable, rational, bounded, etc.? Can we calculate  $x$  and its derivatives or bounds, relative to  $\epsilon$ , or at least make good estimates? If  $A$  is singular or  $b$  is not in the range of  $A$ , then  $x(\epsilon)$  may not exist or may be mul-

tivalued. Can we characterize the solution set  $S(\epsilon)$  for  $\epsilon \in T$ ?

This example suggests that we are thinking of a solution as a function of the problem data, though the function may be extremely complicated, multivalued and only implicitly defined. Our central objective is to characterize this functional relationship. Why? Because, inevitably, data are ‘soft’, subject to error or change, uncertain. It is usually desirable to approximate new solutions and the effects of data changes, once a solution has been calculated, without requiring the calculation of a solution for each new data value.

A closed form solution will generally not be available, except at an aggregate level for simple models such as that noted above. There are many such models in the sciences, in effect whenever we have a formula for a quantity as a closed form expression. The reader will know many examples (e.g., the quadratic formula for the solution of  $ax^2 + bx + c = 0$  where  $x, a, b, c \in E^1$ ,  $A = \pi r^2$ ,  $F = ma$ ,  $E = mc^2$ , etc.), but perhaps may not have focused on viewing these formulas as representations of solutions of parametric problems, in effect solutions in terms of problem data. This is our orientation here, albeit as noted, we will not usually have the luxury of a closed form solution at our disposal.

We are interested in a particular problem formulation that has many varied and important applications. The model is the nonlinear programming (NLP) problem that is defined as follows: Find a vector  $x$  that solves

$$(P) \quad \begin{cases} \min_x & f(x) \\ \text{s.t.} & g_i(x) \geq 0 \quad (i = 1, \dots, m), \\ & h_j(x) = 0 \quad (j = 1, \dots, p). \end{cases}$$

Since our focus is on the effect of data changes on  $x$ , we explicitly introduce a vector  $\epsilon$  that represents the data and study the problem of finding a solution  $x(\epsilon)$  of

$$P(\epsilon) \quad \begin{cases} \min_x & f(x, \epsilon) \\ \text{s.t.} & g_i(x, \epsilon) \geq 0 \quad (i = 1, \dots, m), \\ & h_j(x, \epsilon) = 0 \quad (j = 1, \dots, p). \end{cases}$$

We assume that  $x \in E^n$  (Euclidean  $n$ -space), though all the results we mention have extensions to more general spaces, and we assume  $\epsilon \in T$ , a subset of  $E^q$ . In this framework, when  $\epsilon$  is fixed, the parametric NLP  $P(\epsilon)$  becomes a standard NLP of the form (P). We are in-

terested in a solution  $x(\epsilon)$ , the ‘optimal value’  $f[x(\epsilon), \epsilon]$  and other quantities, when  $\epsilon$  changes.

Some simple examples may help to illustrate the problem. Suppose we have the linear program:

$$\begin{cases} \min_x & x \\ \text{s.t.} & x \geq \epsilon \\ & x \in E^1, \quad \epsilon \in E^1. \end{cases}$$

Then, the solution  $x(\epsilon) = \epsilon$  and the optimal value  $f[x(\epsilon), \epsilon] = x(\epsilon) = \epsilon$ , where  $\epsilon$  can be any number. This situation is rather ideal: the solution is defined and unique for every  $\epsilon$ , the solution and optimal value are infinitely differentiable, in this case linear in  $\epsilon$ . Everything is completely stable.

As another example of a very well-behaved problem, now an NLP in  $E^2$ , consider:

$$\begin{cases} \min_x & (x_1 - \epsilon_1^2)^2 + (x_2 - |\epsilon_2|)^2 \\ \text{s.t.} & x_1, x_2 \geq 0, \\ & x \in E^2, \quad \epsilon \in E^2. \end{cases}$$

It is easy to see that  $x(\epsilon) = [x_1(\epsilon), x_2(\epsilon)] = (\epsilon_1^2, |\epsilon_2|)$  and  $f[x(\epsilon), \epsilon] = 0$  for any  $\epsilon \in E^2$ . Here again, the solution  $x(\epsilon)$  is a well-defined unique continuous function for all  $\epsilon \in E^2$ . The component  $x_1(\epsilon)$  is infinitely differentiable, but now  $x_2(\epsilon)$  is not differentiable at  $\epsilon_2 = 0$ . The optimal value is perfectly stable, indeed constant. Again, we have  $x(\epsilon)$  and  $f[x(\epsilon), \epsilon]$  in closed form.

Unfortunately, things are not always so nice, even for very simple problems. Consider the linear program

$$LP(\epsilon) \quad \begin{cases} \min_x & \epsilon x \\ \text{s.t.} & x \geq 0, \\ & x \in E^1, \quad \epsilon \in E^1. \end{cases}$$

When  $\epsilon > 0$ , then  $x(\epsilon) = 0$  solves this problem and  $f[x(\epsilon), \epsilon] = 0$ . When  $\epsilon = 0$ , then  $f[x(\epsilon), \epsilon] = 0$  for any  $x \in E^1$ , hence  $LP(0)$  is solved for any  $x \geq 0$ , so the solution set  $S(\epsilon)$  by  $\epsilon = 0$  is given by  $S(0) = \{x \in E^1: x \geq 0\}$  and of course  $f[x(0), 0] = 0$ . When  $\epsilon < 0$ , things collapse, since the objective function  $f(x, \epsilon)$  is unbounded below in the feasible set  $R = \{x \in E^1: x \geq 0\}$ . Symbolically, we see that  $f(x, \epsilon) = \epsilon x \rightarrow -\infty$  as  $x \rightarrow +\infty$  when  $\epsilon < 0$ . Here, we say that the infimum (smallest value of  $f$ ) is ‘not attained’, nor is the solution (minimizing value of  $x$ ) attained. Summarizing, the solution is stable for  $\epsilon$

$> 0$ , unstable for  $\epsilon = 0$ , since the solution set  $S(0)$  can vanish in every small neighborhood of  $\epsilon = 0$ , and unsolvable for  $\epsilon < 0$ .

An equivalent example in  $E^2$  may give more perspective on the geometry of the problem. Consider

$$\begin{cases} \min_x & x_2 \\ \text{s.t.} & \epsilon x_1 \leq x_2, \quad x_1 \geq 0, x \in E^2, \quad \epsilon \in E^1. \end{cases}$$

The reader is encouraged to sketch the feasible region for  $\epsilon > 0$ ,  $\epsilon = 0$  and  $\epsilon < 0$ . Clearly, the smallest value of  $x_2$  for  $\epsilon > 0$  or  $\epsilon = 0$  is  $x_2 = 0$ , but for  $\epsilon < 0$ , the component  $x_2$  is not bounded below. The associated values of  $x_1$  are  $x_1 = 0$  for  $\epsilon > 0$  and any  $x_1 \geq 0$  for  $\epsilon = 0$  and  $x_1$  unbounded above as  $x_2 \rightarrow -\infty$  for  $\epsilon < 0$ . Collecting this information, we have the following: The solution  $x(\epsilon) = (0, 0)$  for  $\epsilon > 0$ ;  $x(\epsilon)$  is any  $x \in S(0) = \{x \in E^2: x_1 \geq 0, x_2 = 0\}$  for  $\epsilon = 0$ ; and the solution is not attained for  $\epsilon < 0$ . The optimal value  $f[x(\epsilon), \epsilon] = 0$  for  $\epsilon \geq 0$  and is not bounded below for  $\epsilon < 0$ . As before, the problem is stable for  $\epsilon > 0$ , but unstable for  $\epsilon = 0$  since the solution does not exist for some  $\epsilon$  in any neighborhood of  $\epsilon = 0$ , and unsolvable for  $\epsilon < 0$ .

What causes such erratic behavior and what guarantees such stability, for different parameter values? Can we identify conditions that imply some sort of stability or that warn of the presence of instability? Can changes in a solution be predicted within a specified error tolerance for problem data changes, without solving the problem again for each new perturbation? A resolution and understanding of such questions is the substance of sensitivity and stability analysis. Note that in our small examples, the problem functions taken individually are continuous and differentiable and extremely well behaved. Clearly, we need to capture the effect of parameter changes on their joint collective behavior, at least in a neighborhood of a solution.

Some of the important tools and concepts that have been especially useful in obtaining conditions and results for sensitivity calculations and stability characterizations are:

- i) optimality conditions,
- ii) constraint qualifications,
- iii) implicit function theorems,
- iv) directional derivatives,
- v) point-to-set maps and set and map convergence and continuity,

- vi) condition number,
- vii) convexity and convex analysis, and
- viii) duality.

The list is subjective and far from exhaustive. Some of these constructs will be utilized in the preliminary results we mention, but we cannot provide additional coverage in this brief presentation.

We next present a few basis results that illustrate the application of some of the mentioned mathematical tools and indicate typical assumptions and conclusions. Consider the important special realization of our general problem  $P(\epsilon)$  when the constraints  $g(x) \geq 0$  and  $h(x) = 0$  are not present, resulting in the so-called *unconstrained problem*

$$P_1(\epsilon) \begin{cases} \min_x & f(x, \epsilon) \\ \text{s.t.} & x \in E^n \quad (\epsilon \in E^q). \end{cases}$$

Assume that  $f$  is twice jointly continuously differentiable in  $(x, \epsilon)$ . Let  $\nabla_x f(x) = [\partial f(x)/\partial x_1, \dots, \partial f(x)/\partial x_n]$  denote the usual *gradient* of  $f$  at  $x$  and  $\nabla_x^2 f(x) = \nabla[\nabla f(x)^T]$  (with  $(i, j)$ th element given by  $\partial^2 f(x)/\partial x_i \partial x_j$ ) define the matrix called the *Hessian* of  $f$  at  $x$ . (Note that  $\nabla_x f$  is an  $n$ -dimensional row vector and  $\nabla_x^2 f$  is an  $n \times n$  matrix.) The following result is well known and the assumptions will be called the *second order sufficient conditions* at  $(x, \epsilon)$ , denoted by  $\text{SOSC}(x, \epsilon)$ . Let  $\epsilon = \bar{\epsilon}$ , a fixed quantity.

**Proposition 1** *If  $\nabla_x f(\bar{x}, \bar{\epsilon}) = 0$  and  $\nabla_x^2 f(\bar{x}, \bar{\epsilon})$  is positive definite, then  $\bar{x}$  is a strict and locally isolated minimizer of  $f(x, \bar{\epsilon})$ .*

This result is of intrinsic interest and is very important and well known. What is especially intriguing is that sensitivity results follow without additional assumptions.

**Proposition 2** *Assuming  $\text{SOSC}(\bar{x}, \bar{\epsilon})$  as before, for  $\epsilon$  near  $\bar{\epsilon}$  there exists a unique once continuously differentiable vector function  $x$  with value  $x(\epsilon)$  such that  $x(\bar{\epsilon}) = \bar{x}$  and  $\text{SOSC}(x(\epsilon), \epsilon)$  continues to hold and hence  $x(\epsilon)$  is a locally unique (i. e., isolated) local minimizer of  $f(x, \epsilon)$ . Furthermore, the optimal value  $f^*$  is twice continuously differentiable, where we define  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$ .*

This may be viewed as a stability result, essentially an existence theorem (following directly from a classical implicit function theorem) that guarantees that the assumptions made at  $(\bar{x}, \bar{\epsilon})$  will persist near  $(\bar{x}, \bar{\epsilon})$  at  $[x(\epsilon),$

$\epsilon]$ , hence also the conclusions. This suggests an intuitively appealing definition of an ideal form of stability, with respect to a given change in the data. We might define ‘assumption stability’ to be the persistence of initial conditions and assumptions in the sense indicated.

Interestingly, we can go even further and derive a sensitivity formula from our observations, again without any new assumptions.

**Proposition 3** *Assuming as in Proposition 1 and with  $x(\epsilon)$  as in Proposition 2, we obtain the following relations at  $[x(\epsilon), \epsilon]$  near  $(\bar{x}, \bar{\epsilon})$ :*

i) *Defining the optimal value  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$ , we conclude from the chain rule for differentiation that*

$$\begin{aligned}\nabla_{\epsilon} f^*(\epsilon) &= d/d\epsilon[f[x(\epsilon), \epsilon]] \\ &= \nabla_x f \cdot \nabla_{\epsilon} x + \nabla_{\epsilon} f = \nabla_{\epsilon} f(x, \epsilon)|_{x=x(\epsilon)}\end{aligned}$$

*since  $\nabla_x f[x(\epsilon), \epsilon] = 0$ , where  $F(y)|_{y=z}$  means to evaluate  $F$  at  $y = z$ . With this understanding, we write*

$$\nabla_{\epsilon} f^*(\epsilon) = \nabla_{\epsilon} f[x(\epsilon), \epsilon].$$

ii) *Differentiating the last result again by  $\epsilon$ , we find that*

$$\nabla_{\epsilon}^2 f^*(\epsilon) = \nabla_{x\epsilon}^2 f \nabla_{\epsilon} x + \nabla_{\epsilon\epsilon}^2 f|_{x=x(\epsilon)}.$$

iii) *Differentiating  $\nabla_x f[x(\epsilon), \epsilon] = 0$  by  $\epsilon$  yields*

$$\nabla_x^2 f \nabla_{\epsilon} x + \nabla_{\epsilon x}^2 f = 0$$

*from which we conclude that*

$$\nabla_{\epsilon} x(\epsilon) = -\nabla_x^2 f[x(\epsilon), \epsilon]^{-1} \nabla_{\epsilon x}^2 f[x(\epsilon), \epsilon].$$

*Here,  $\nabla_{\epsilon x}^2 f = \nabla_{\epsilon}(\nabla_x f^{\top})$ .*

Thus, without additional conditions other than the optimality conditions SOSC and the assumption of the presence of data in the form of a parameter vector and appropriate smoothness, we have a characterization of local optimality in Proposition 1, a parametric stability and existence theorem in Proposition 2, and sensitivity measurements in the form of parameter-derivative formulas, for both the optimal value and local minimizing point, in Proposition 3. Note that the derivatives are computable, once we have calculated a solution  $x(\epsilon)$  for a given  $\epsilon$ , hence in particular at  $\bar{\epsilon}$  where  $x(\bar{\epsilon}) = \bar{x}$ . These results are extremely important and useful and they also dramatize some important prin-

ciples, i. e., the persistence of assumptions as a key to stability, and the intimate connection between optimality conditions and stability and sensitivity analysis. Of course, the conclusions are local, but this is not surprising since the results are based on information at one point. As a postscript, we also note that SOSC is often invoked and generally needed for the optimal convergence and rate of convergence behavior of numerical algorithms, e. g., for the quadratic convergence rate of Newton’s method. Thus, we conclude that sensitivity and stability analysis, optimality conditions and characterizations and the convergence properties of computational algorithms are extremely closely related. Their underlying theory can undoubtedly be unified at a general level.

Applications of results such as those given are numerous. Perhaps most directly, we can estimate  $f^*(\epsilon)$  and  $x(\epsilon)$  for small changes in  $\epsilon$  by using a truncated Taylor’s series as follows:

- i)  $f^*(\epsilon) \approx f^*(\bar{\epsilon}) + \nabla_{\epsilon} f^*(\bar{\epsilon})(\epsilon - \bar{\epsilon}) + \frac{(\epsilon - \bar{\epsilon})^{\top} \nabla_{\epsilon}^2 f^*(\bar{\epsilon})(\epsilon - \bar{\epsilon})}{2}$   
where  $\nabla_{\epsilon} f^*$  and  $\nabla_{\epsilon}^2 f^*$  are as given above in i) and ii), and
- ii)  $x(\epsilon) \approx x(\bar{\epsilon}) + \nabla_{\epsilon} x(\bar{\epsilon})(\epsilon - \bar{\epsilon}) = \bar{x} - \nabla_x^2 f^{-1}(\bar{x}, \bar{\epsilon}) \nabla_{\epsilon x}^2 f(\bar{x}, \bar{\epsilon})(\epsilon - \bar{\epsilon})$ .

These estimates are available when a good approximation to  $\bar{x}$  has been obtained.

We conclude this brief expository article by indicating a number of other applications, extensions and references.

There is now an enormous body of literature devoted to sensitivity and stability results in mathematical programming, most of which have been published starting in the 1970s. The issues surrounding well-posedness and resulting definitions, e. g., solvability for small data perturbations, continuous solution changes for continuous data changes, and others are classical however and have been studied in mathematics and physics and other disciplines since early times. A rudimentary general theory has been known for some years. The recent burst of activity was undoubtedly stimulated by the tremendous advances in NLP in the 1960s and 1970s, largely resulting from the preceding emergence and computational demands of modern optimization applications in the sciences, engineering, economics, industry, and collectively what came to be known as *operations research*, the advent of modern computers,

and the development and success of linear programming (LP) methodology.

For LP, developed in the 1940s, there quickly followed what was called *post-optimality sensitivity analysis* that included parametric closed form expressions for solution changes with data changes and error bounds, this having been recently significantly extended. Existence theorems and closed form expressions have also been recently developed for optimal value and solution point parameter-derivatives and directional derivatives, as well as parametric bounds, for the general parametric nonlinear program (NLP) of the form  $P(\epsilon)$ , analogous to those given in this article for the unconstrained problem  $P_1(\epsilon)$ . Significant sensitivity and stability results have been obtained for many important and well known classes of problems, e. g., geometric programs, separable programs, semi-infinite and infinite programming, control theory, multi-objective optimization, integer programming and stochastic programming. The parametric perturbation theory has been significantly extended to more general models as well, e. g., variational inequalities and generalized equations. Results include many variations in optimality conditions, constraint qualifications, definitions of continuity and differentiability, generalized convexity and other mathematical notions and tools. A significant body of theory now also extends to nonsmooth (i. e., nondifferentiable) functions, and to perturbations that are more general than perturbation of a parameter, e. g., function and set perturbations.

Applications are abundant. They include solution and optimal value extrapolation for perturbed data, as already noted, model validation, scaling and regularization, decomposition algorithms, bilevel programming, optimization involving implicitly defined functions, duality relations, analysis of convergence properties of algorithms, the effect of data perturbations on algorithmic performance, approximation of sensitivity measurements from algorithmic information and much more. Computational implementations on actual practical real-world problems do exist but are still quite limited. Much remains to be done both in theory and practice, e. g., the provision of standard software for user-friendly sensitivity and stability calculations in major NLP solution computer programs, as available in LP (though user-friendliness may need more emphasis, even here). The theory is rich and every facet of opti-

mality characterization and algorithmic definition and performance is a fertile field for the study of the effect of data perturbations.

The significant contributions to this field are too numerous to mention and thus we shall not attempt to single out key contributors. Instead, we shall cite only [1,2,3], references with which the author has been personally involved, not to presume to monopolize personal credit but because they contain numerous references and state-of-the-art surveys and scholarly papers from many established and emerging leaders in the field. These books and journals and the tutorial and research articles and hundreds of references therein will hopefully quickly and surely lead the interested reader to the central core of the published results in this vital area.

## Keywords

Sensitivity analysis; Quadratic programming; Bounds

In this article, we describe a number of (for the most part) computable formulas and bounds that can be used to approximate sensitivity and stability measurements for nonlinear programming (NLP) involving a parameter. We draw freely from the definitions and results presented in ► [Sensitivity and stability in NLP](#) and ► [Sensitivity and stability in NLP: Continuity and differential stability](#). The reader is advised to read these before proceeding with the results we present here.

As noted in ► [Sensitivity and stability in NLP](#) and ► [Sensitivity and stability in NLP: Continuity and differential stability](#), the problem of interest is to find a solution  $x(\epsilon)$  of

$$P(\epsilon) \begin{cases} \min_x & f(x, \epsilon) \\ \text{s.t.} & g_i(x, \epsilon) \geq 0 \quad (i = 1, \dots, m), \\ & h_j(x, \epsilon) = 0 \quad (j = 1, \dots, p), \end{cases}$$

where  $x \in E^n$  and the parameter  $\epsilon \in T \subseteq E^q$ . We denote a local solution by  $x(\epsilon)$ , the local optimal value by  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$ , solution set by  $S(\epsilon)$ , and feasible region by  $R(\epsilon)$ .

Our focus is on general finite-dimensional deterministic NLP involving a parameter. The reader may know that there is a fairly fine-tuned sensitivity analysis methodology for linear programming (LP), often referred to as *post-optimality analysis*, including a *range-analysis* concerned with maximum tolerances on changes in the objective function coefficients within which a solution and basis does not change, and formulas for right-hand side and constraint coefficient matrix changes, bounds on changes, and the like. Recent work has sharpened the classical theory to allow for more simultaneous data changes and extend the parameter change tolerance idea. Likewise, sensitivity approximation results have been developed for quadratic programs, networks, separable programs, geometric programs, and many other mathematical programs having a special structure. In the direction of more generality, sensitivity and stability approximation results have been developed for semi-infinite programming, infinite programming, control theory, discrete programming, stochastic programming, and many other general programs, extending further to related generalizations such as variational inequalities, generalized equations, nonsmooth analysis, and more.

We consider here three types of sensitivity and stability measurements at a general level for smooth NLP involving a parameter:

- i) parameter-derivatives of a local solution  $x(\epsilon)$  and the local optimal value function  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$ ;
- ii) algorithmic approximations of solution parameter-derivatives using a classical and well known barrier function (interior point) algorithm; and
- iii) parameter-dependent solution bounds.

## Parameter Derivatives

In ► [Sensitivity and stability in NLP: Continuity and differential stability](#) we defined the *Karush-Kuhn-Tucker conditions* (KKT) at a feasible point  $x$  of  $P(\epsilon)$  to be the existence of  $u \geq 0$  and  $w$  such that (conditions  $\text{KKT}(x, u, w, \epsilon)$ ):

$$\begin{cases} \nabla_x L(x, u, w, \epsilon) = 0, \\ u_i g_i(x, \epsilon) = 0 & (i = 1, \dots, m), \\ h_j(x, \epsilon) = 0 & (j = 1, \dots, p), \end{cases}$$

where

$$L(x, u, w, \epsilon) = f(x, \epsilon) - \sum_{i=1}^m u_i g_i(x, \epsilon) + \sum_{j=1}^p w_j h_j(x, \epsilon)$$

is the Lagrangian and  $u, w$  are called the *Lagrange multipliers* associated with  $x$ . Definitions of SOSC, LI and SCS were also given in [► Sensitivity and stability in NLP: Continuity and differential stability](#), along with the following result, which we repeat here for convenience. For simplicity, assume that the functions defining  $P(\epsilon)$  are twice jointly continuously differentiable in  $(x, \epsilon)$  unless otherwise specified.

**Proposition 1** *Assume that KKT, SOSC, LI and SCS hold at a feasible point  $\bar{x}$  of  $P(\bar{\epsilon})$  with associated Lagrange multipliers  $(\bar{u}, \bar{w})$ , where  $\bar{\epsilon} \in \text{interior } T$ . Then, for  $\epsilon$  in a neighborhood of  $\bar{\epsilon}$  in  $T$  we have the following consequences:*

- i) *There exists a locally unique once continuously differentiable vector function  $y = (x, u, w)$  such that the assumptions continue to hold at  $y(\epsilon) = [x(\epsilon), u(\epsilon), w(\epsilon)]$ , where  $y(\bar{\epsilon}) = \bar{y} = (\bar{x}, \bar{u}, \bar{w})$ .*
- ii) *The point  $x(\epsilon)$  is an isolated local minimizer of problem  $P(\epsilon)$  with associated unique Lagrange multipliers  $[u(\epsilon), w(\epsilon)]$ ; and*
- iii) *The local optimal value function  $f^*$  is twice continuously differentiable in  $\epsilon$ .*

This Proposition follows from the fact that the  $(x, u, w)$ -Jacobian (i. e., the matrix of partial derivatives with respect to  $(x, u, w)$ ) of the KKT equation system given above is nonsingular at  $(\bar{x}, \bar{u}, \bar{w}, \bar{\epsilon})$ . Thus, a classical implicit function theorem is applicable and the results quickly follow, once it is shown that SOSC persists near  $\epsilon = \bar{\epsilon}$ .

*Remark 2* G.P. McCormick must be credited for initially identifying and applying the conditions, KKT, SOSC, LI and SCS, which imply the existence of the KKT  $\gamma$ -Jacobian inverse. He initiated the use of these assumptions to obtain extrapolation results for classical barrier function methods in terms of the algorithmic parameter. See [6, Chap. 5]. He also used these to obtain results similar to those in Proposition 1 but for a problem that has additive perturbations that may be nonlinear in  $x$  and linear in  $\epsilon$ , a special case of problem  $P(\epsilon)$ . See [6, Thm. 6]. The author showed that KKT,

SOSC, LI and SCS suffice for results for the general problem  $P(\epsilon)$  as given in Proposition 1, as well as for the results given in the rest of this article. These developments are pursued in detail in [2]. McCormick also stated a partial converse of Proposition 1 as follows: If KKT and a weakened form of SONC hold and the KKT  $\gamma$ -Jacobian has an inverse at  $(\bar{x}, \bar{u}, \bar{w})$  (for problem  $P(\epsilon)$  with  $\epsilon$  not involved, i. e.,  $\epsilon$  fixed), then SOSC must hold at  $(\bar{x}, \bar{u}, \bar{w})$ . This is [6, Cor. 7], where SONC (the second order necessary condition) here means the second order part of SOSC, weakened to  $z^\top \nabla_x^2 L z \geq 0$  for all  $z$  as in SOSC. We note that SCS and LI also follow from the assumptions of [6, Cor. 7]. We can show and here note that the following partial converse of Proposition 1 is true and equivalent to [6, Cor. 7] just cited: If  $\bar{x}$  is a local minimizer of problem  $P(\epsilon)$  (with  $\epsilon$  fixed) and KKT and the KKT  $\gamma$ -Jacobian inverse exist at  $(\bar{x}, \bar{u}, \bar{w})$ , then again all the assumptions of Proposition 1, i. e., KKT, SOSC, LI and SCS, must hold at  $(\bar{x}, \bar{u}, \bar{w})$ .

To obtain parameter derivatives of  $(x, u, w)$ , we simply note that KKT $(x, u, w, \epsilon)$  is locally identically satisfied at  $[x(\epsilon), u(\epsilon), w(\epsilon)]$  near  $\epsilon = \bar{\epsilon}$ , and hence these equations can be differentiated with respect to  $\epsilon$ . We have the following (conditions KKT $[x(\epsilon), u(\epsilon), w(\epsilon), \epsilon]$ ):

$$\begin{cases} \nabla_x L[x(\epsilon), u(\epsilon), w(\epsilon), \epsilon] = 0, \\ u_i(\epsilon) g_i[x(\epsilon), \epsilon] = 0 & (i = 1, \dots, m), \\ h_j[x(\epsilon), \epsilon] = 0 & (j = 1, \dots, p). \end{cases}$$

With  $F$  representing the vector function of equalities on the left, this has the form  $F[y(\epsilon), \epsilon] = 0$  where  $y = (x, u, w)$ . Since our assumptions imply that  $F$  is differentiable in  $\epsilon$ , we can use the chain rule for differentiation to conclude that  $dF/d\epsilon = \nabla_y F \nabla_\epsilon y + \nabla_\epsilon F = 0$ . Applying this calculation to the KKT equations we get the following:

$$M(\epsilon) \nabla_\epsilon y(\epsilon) + \tilde{N}(\epsilon) = 0,$$

where

$$M = \begin{pmatrix} \nabla_x^2 L & -\nabla g_1^\top & \cdots & -\nabla g_m^\top & \nabla h_1^\top & \cdots & \nabla h_p^\top \\ u_1 \nabla_x g_1 & g_1 & & 0 & & & \\ \vdots & & \cdots & 0 & & & 0 \\ u_m \nabla_x g_m & 0 & & g_m & & & \\ \nabla h_1 & & & & & & \\ \vdots & & & 0 & & & 0 \\ \nabla h_p & & & & & & \end{pmatrix}$$

is the Jacobian of the KKT equations with respect to  $y$  and

$$\tilde{N} = [\nabla_{\epsilon x}^2 L^\top, u_1 \nabla_{\epsilon} g_1^\top, \dots, u_m \nabla_{\epsilon} g_m^\top, \nabla_{\epsilon} h_1^\top, \dots, \nabla_{\epsilon} h_p^\top]^\top$$

is the Jacobian of the KKT with respect to  $\epsilon$ .

Since  $M$  is nonsingular, as noted, we obtain the result

$$\nabla_{\epsilon} y(\epsilon) = M(\epsilon)^{-1} N(\epsilon), \quad (1)$$

where we have introduced  $N = -\tilde{N}$ , for convenience. Thus, (1) provides a formula for the parameter derivatives of all components of  $(x, u, w)$  for  $\epsilon$  near  $\bar{\epsilon}$ . In particular, once we calculate the local solution  $\bar{x}$  with associated Lagrange multipliers  $(\bar{u}, \bar{w})$ , then we can compute

$$\nabla_{\epsilon} y(\bar{\epsilon}) = M(\bar{\epsilon})^{-1} N(\bar{\epsilon}), \quad (2)$$

where  $y(\bar{\epsilon}) = [x(\bar{\epsilon}), u(\bar{\epsilon}), w(\bar{\epsilon})] = (\bar{x}, \bar{u}, \bar{w}) = \bar{y}$  and of course  $\nabla_{\epsilon} y = [\nabla_{\epsilon} x^\top, \nabla_{\epsilon} u^\top, \nabla_{\epsilon} w^\top]^\top$ . It also follows that  $\nabla_{\epsilon} y$  is continuous near  $\bar{\epsilon}$ , so  $\nabla_{\epsilon} y(\epsilon) \rightarrow \nabla_{\epsilon} y(\bar{\epsilon})$  as  $\epsilon \rightarrow \bar{\epsilon}$ .

We can also calculate parameter derivatives of first and second order of the local optimal value function  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$ , again by repeated use of the chain rule. The results follow. Since the KKT imply that

- $f^*(\epsilon) = L[x(\epsilon), u(\epsilon), w(\epsilon), \epsilon]$ , then, since  $\nabla_{\epsilon} f^* = \nabla_y L \nabla_{\epsilon} y + \nabla_{\epsilon} L$  and since it can be shown that  $\nabla_y L \nabla_{\epsilon} y = 0$ , it follows that
- $\nabla_{\epsilon} f^*(\epsilon) = \nabla_{\epsilon} L(x, u, w, \epsilon)|_{(x, u, w) = [x(\epsilon), u(\epsilon), w(\epsilon)]}$ , and the derivative of this gives  $\nabla_{\epsilon}^2 f^*(\epsilon)$ , i. e.,
- $\nabla_{\epsilon}^2 f^*(\epsilon) = d/d\epsilon [\nabla_{\epsilon} L[x(\epsilon), u(\epsilon), w(\epsilon), \epsilon]]$ , where the vertical bar in b) denotes evaluation at the specified point.

As before, these expressions apply for all  $\epsilon$  near  $\bar{\epsilon}$ , they can be evaluated at  $\bar{\epsilon}$  once  $(\bar{x}, \bar{u}, \bar{w})$  is available, and they are continuous near  $\bar{\epsilon}$ .

We derive a formula for  $\nabla_{\epsilon}^2 f^*$  in explicit form in the next section, for the general problem  $P(\epsilon)$ .

Some special realizations of problem  $P(\epsilon)$  should be mentioned. They are intrinsically important and also result in considerably simplified formulas.

If problem  $P(\epsilon)$  is unconstrained, then the result (as stated in ► **Sensitivity and stability in NLP**) is that  $\nabla_{\epsilon} f^* = \nabla_{\epsilon} f[x(\epsilon), \epsilon]$ , with  $\nabla_{\epsilon} x = -\nabla_x^2 f^{-1} \nabla_{\epsilon x}^2 f$  and  $\nabla_{\epsilon}^2 f^* = \nabla_{\epsilon x}^2 f \nabla_{\epsilon} x + \nabla_{\epsilon}^2 f$ , which can be conveniently expressed

$$\nabla_{\epsilon}^2 f^* = [\nabla_{\epsilon} x^\top, I] \nabla_{(x, \epsilon)}^2 f [\nabla_{\epsilon} x^\top, I]^\top,$$

where

$$\nabla_{(x, \epsilon)}^2 f = \begin{pmatrix} \nabla_x^2 f & \nabla_{\epsilon x}^2 f \\ \nabla_{x\epsilon}^2 f & \nabla_{\epsilon}^2 f \end{pmatrix}.$$

If the constraints of problem  $P(\epsilon)$  are present but independent of  $\epsilon$ , then again  $\nabla_{\epsilon} f^* = \nabla_{\epsilon} f[x(\epsilon), \epsilon]$  and  $\nabla_{\epsilon}^2 f^* = \nabla_x \epsilon^2 f \nabla_{\epsilon} x + \nabla_{\epsilon}^2 f$ , but now  $\nabla_{\epsilon} x$  is obtained from (1) with  $N = [-\nabla_{\epsilon x}^2 f^\top, 0]^\top$ .

An extremely important case is the so-called *right-hand side problem*, an instance of problem  $P(\epsilon)$  with form

$$P_1(\epsilon) \begin{cases} \min_x & f(x) \\ \text{s.t.} & g_i(x) \geq \epsilon_i \quad (i = 1, \dots, m), \\ & h_j(x) = \epsilon_j + m \quad (j = 1, \dots, p). \end{cases}$$

This was mentioned also in ► **Sensitivity and stability in NLP: Continuity and differential stability**, in the context of the directional derivative  $D_z f^*$  of  $f^*$  which we found there to be  $D_z f^*(\epsilon) = [u(\epsilon), -w(\epsilon)]^\top z$ . Consistent with this result, we find for problem  $P_1(\epsilon)$ , under our current assumptions, that

$$\begin{aligned} \nabla_{\epsilon} f^*(\epsilon) &= [u(\epsilon), -w(\epsilon)]^\top; \\ \nabla_{\epsilon}^2 f^*(\epsilon) &= [\nabla_{\epsilon} u(\epsilon)^\top, -\nabla_{\epsilon} w(\epsilon)^\top]^\top. \end{aligned} \quad (3)$$

Thus, as noted in ► **Sensitivity and stability in NLP: Continuity and differential stability**, the rate of change of the optimal value with respect to a small change only in the  $k$ th constraint value is captured by the value of the associated optimal Lagrange multiplier. In applications, since the components of  $\epsilon$  may generally be viewed as ‘resource levels’, this establishes a direct connection between a given level and its imputed value (with regard to a marginal change in the optimal value), given by the associated optimal Lagrange multiplier. Thus, as noted before in ► **Sensitivity and stability in NLP: Continuity and differential stability**, optimal Lagrange multipliers are often called ‘shadow prices’.

The Lagrange multipliers are explicitly involved as variables in dual programs, and constitute all the dual variables for linear programming problems. A consid-

erable literature is devoted to duality and dual programs and their relationship. As noted, duality and sensitivity analysis results are closely connected. We do not pursue this here. See [2] or any standard NLP-LP textbook for an introduction.

### Applications of Sensitivity Analysis

There are numerous applications of sensitivity and stability results such as those briefly presented. One of the most immediate is verification of local stability and the determination of the relative importance of each parameter at a local solution, in accordance with its relative effect on the optimal value, solution point or Lagrange multipliers. This assessment is also relevant to model validation in determining if the relative effects noted are reasonable, whether changes are warranted, whether some parameters should be rescaled or calculated with more precision or others assumed constant and locally ignored for simplicity because of their little effect, etc.

Another immediate application is the estimation of a solution or optimal value for perturbed data. This was indicated in ► **Sensitivity and stability in NLP** for the unconstrained problem. For the general problem  $P(\epsilon)$ , under the assumptions of Proposition 1, an approximation of  $y(\epsilon)$  in a neighborhood of  $\bar{\epsilon}$  is given by the first order terms of a Taylor's series

$$y(\epsilon) \approx y(\bar{\epsilon}) + \nabla_{\epsilon} y(\bar{\epsilon})(\epsilon - \bar{\epsilon}).$$

Using the results of the previous section, particularly (2), this translates into

$$(x(\epsilon), u(\epsilon), w(\epsilon)) \approx (\bar{x}, \bar{u}, \bar{w}) + M(\bar{\epsilon})^{-1} N(\bar{\epsilon})(\epsilon - \bar{\epsilon}). \quad (4)$$

Similarly, we can obtain first- or second order estimates of the optimal value function, respectively as follows, near  $\epsilon = \bar{\epsilon}$ :

$$f^*(\epsilon) \approx f^*(\bar{\epsilon}) + \nabla_{\epsilon} f^*(\bar{\epsilon})(\epsilon - \bar{\epsilon}),$$

and

$$f^*(\epsilon) \approx f^*(\bar{\epsilon}) + \nabla_{\epsilon} f^*(\bar{\epsilon})(\epsilon - \bar{\epsilon}) + \frac{1}{2}(\epsilon - \bar{\epsilon})^{\top} \nabla_{\epsilon}^2 f^*(\bar{\epsilon})(\epsilon - \bar{\epsilon}). \quad (5)$$

These approximations provide computable estimates when a close approximation of  $((\bar{x}, \bar{u}, \bar{w}))$  is available,

where we can use the relationships indicated in the previous section for  $\nabla_{\epsilon} f^*$ ,  $\nabla_{\epsilon}^2 f^*$ , etc., under the various cases that can arise.

Numerous other applications are known and documented and the reader can undoubtedly think of several. We cannot pursue more developments here, but we do indicate some computational efficiencies and algorithmic approximation possibilities in the next section.

### Computational Efficiencies and Algorithmic Approximations

First, we show how the results of Proposition 1 can be exploited to greatly simplify the calculation of the parameter-derivatives, and also yield some new formulas. Then, we show how the solution point and optimal value parameter derivatives can be approximated by a solution algorithm as a solution is approached.

#### Computational Efficiencies

Above, we noted that the equations  $\text{KKT}[y(\epsilon), \epsilon]$ , i. e.

$$\begin{cases} \nabla_x L[x(\epsilon), u(\epsilon), w(\epsilon), \epsilon] = 0, \\ u_i(\epsilon) g_i[x(\epsilon), \epsilon] = 0 & (i = 1, \dots, m), \\ h_j[x(\epsilon), \epsilon] = 0 & (j = 1, \dots, p), \end{cases}$$

hold in a neighborhood of  $\bar{\epsilon}$ . Under the assumptions, all is changing continuously with  $\epsilon$ , locally, and indeed the system is once continuously differentiable. Having calculated  $(\bar{x}, \bar{u}, \bar{w})$  with  $\epsilon = \bar{\epsilon}$ , we have valuable additional information. We know which  $g_i$  and  $u_i$  are 0 or positive at  $(\bar{y}, \bar{\epsilon})$ , and we know this relative status of  $g_i$  and  $u_i$  will sustain near  $\epsilon = \bar{\epsilon}$  at  $y(\epsilon)$ . Thus, we can delete the nonbinding-constraint equations and we can divide out the positive  $u_i$ , without losing any information, locally. We proceed to do this and, for convenience, relabel the binding constraints  $\hat{g} = (g_1, \dots, g_r)^{\top}$ , and associated (all positive) Lagrange multipliers  $\hat{u} = (u_1, \dots, u_r)^{\top}$ , so that  $g_i > 0$  and  $u_i = 0$  for  $i = r + 1, \dots, m$  can be ignored and suppressed in the subsequent calculation. We redefine the Lagrangian accordingly to  $\hat{L} = f - \sum_{i=1}^r u_i g_i + \sum_{j=1}^p w_j h_j$  and relabel  $\nabla_{\epsilon} y$  as  $\nabla_{\epsilon} \hat{y}$ , to indicate the reduced derivative, so that  $\hat{y} = (x, \hat{u}, w)$ .

Given all these simplifications, the KKT system becomes  $\text{KKT}[\hat{y}(\epsilon), \epsilon]$ :

$$\begin{cases} \nabla_x \hat{L}[x(\epsilon), \hat{u}(\epsilon), w(\epsilon), \epsilon] = 0, \\ -g_i[x(\epsilon), \epsilon] = 0 & (i = 1, \dots, r), \\ h_j[x(\epsilon), \epsilon] = 0 & (j = 1, \dots, p), \end{cases}$$

where we have written  $-g_i$  rather than  $+g_i$  to obtain a symmetric  $(x, u, w)$ -Jacobian of this system and further computational advantage. Now, differentiating by  $\epsilon$  yields

$$\hat{M}(\epsilon) \nabla_\epsilon \hat{y}(\epsilon) - \hat{N}(\epsilon) = 0$$

and analogously as before in (1), we obtain

$$\nabla_\epsilon \hat{y}(\epsilon) = \hat{M}(\epsilon)^{-1} \hat{N}(\epsilon), \quad (6)$$

where the Jacobian of KKT with respect to  $(x, \hat{u}, w)$  is

$$\hat{M} = \begin{pmatrix} \nabla_x^2 \hat{L} & P^\top \\ P & 0 \end{pmatrix}$$

and the negative of the Jacobian with respect to  $\epsilon$  is

$$\hat{N} = [-\nabla_{\epsilon x}^2 \hat{L}^\top, \nabla_\epsilon g_1^\top, \dots, \nabla_\epsilon g_r^\top, \\ -\nabla_\epsilon h_1^\top, \dots, -\nabla_\epsilon h_p^\top]^\top$$

and

$$P^\top = [-\nabla_x g^\top, \nabla_x h^\top].$$

*Remark 3* We note that the above system  $\text{KKT}[\hat{y}(\epsilon), \epsilon]$  turns out to be  $\nabla_y \hat{L} = 0$  and we get  $\hat{M} = \nabla_y^2 \hat{L}$ , all evaluated at  $[\hat{y}(\epsilon), \epsilon]$ , where we recall that  $\hat{y} = (x, \hat{u}, w)$ . Also, note that  $\nabla_{\epsilon y}^2 \hat{L} = -\hat{N} = \nabla_{y\epsilon}^2 \hat{L}^\top$ .

Of course, all of the formulas presented in the first Section still hold, in terms of this new reduced structure, to provide all the relevant and nontrivial formulas for all the cases mentioned there. In addition, we are able to express all of the block components  $A_{11}, A_{12}, A_{21}, A_{22}$  of  $\hat{M}^{-1}$ , for all cases that can arise, in terms of the original problem derivatives, resulting in enormous computational savings. See [2, Chap. 4, Sect. 2]. Further economies are introduced in the special formulas that apply for the right-hand side perturbation problem  $P_1(\epsilon)$  and other particular instances of the general problem  $P(\epsilon)$ . The optimal value formulas also simplify

considerably and, for the general problem since  $f^* = \hat{L}$  and  $\nabla_\epsilon f^* = \nabla_\epsilon \hat{L}$ , we obtain the elegant result

$$\begin{aligned} \nabla_\epsilon^2 f^* &= \nabla_{y\epsilon}^2 \hat{L} \nabla_\epsilon \hat{y} + \nabla_\epsilon^2 \hat{L} \\ &= -\hat{N}^\top \nabla_\epsilon \hat{y} + \nabla_\epsilon^2 \hat{L} = -\hat{N}^\top \hat{M}^{-1} \hat{N} + \nabla_\epsilon^2 \hat{L} \end{aligned} \quad (7)$$

which can be expressed as

$$\begin{aligned} \nabla_\epsilon^2 f^* &= [\nabla_\epsilon \hat{y}^\top, I] \nabla_{(y,\epsilon)}^2 \hat{L} \begin{pmatrix} \nabla_\epsilon \hat{y} \\ I \end{pmatrix} \\ &= (\nabla_\epsilon \hat{y}^\top, I) \begin{pmatrix} \nabla_x^2 \hat{L} & \nabla_{\epsilon y}^2 \hat{L} \\ \nabla_{y\epsilon}^2 \hat{L} & \nabla_\epsilon^2 \hat{L} \end{pmatrix} \begin{pmatrix} \nabla_\epsilon \hat{y} \\ I \end{pmatrix} \\ &= (\nabla_\epsilon \hat{y}^\top, I) \begin{pmatrix} \hat{M} & -\hat{N} \\ -\hat{N}^\top & \nabla_\epsilon^2 \hat{L} \end{pmatrix} \begin{pmatrix} \nabla_\epsilon \hat{y} \\ I \end{pmatrix}. \end{aligned}$$

This expression and the first equation in (7) are new and were not given in [2]. It turns out that  $\nabla_\epsilon^2 f^*$  can be reduced to the simpler form (presented in [2]),

$$\begin{aligned} \nabla_\epsilon^2 f^* &= (\nabla_\epsilon x^\top, I) \nabla_{(x,\epsilon)}^2 \hat{L} \begin{pmatrix} \nabla_\epsilon x \\ I \end{pmatrix} \\ &= (\nabla_\epsilon x^\top, I) \begin{pmatrix} \nabla_x^2 \hat{L} & \nabla_{\epsilon x}^2 \hat{L} \\ \nabla_{x\epsilon}^2 \hat{L} & \nabla_\epsilon^2 \hat{L} \end{pmatrix} \begin{pmatrix} \nabla_\epsilon x \\ I \end{pmatrix}. \end{aligned} \quad (8)$$

*Remark 4* If the given problem  $P(\epsilon)$  is jointly convex in  $(x, \epsilon)$ , i. e.,  $f$  convex, all  $g_i$  concave, all  $h_j$  linear affine in  $(x, \epsilon)$  with  $T$  convex, then it is well known that  $f^*$  is convex. This fact becomes immediately evident from (8), since  $P(\epsilon)$  jointly convex implies that  $\hat{L}$  is jointly convex. But this implies that  $\nabla_{(x,\epsilon)}^2 \hat{L}$  is positive semidefinite, which means that  $\nabla_\epsilon^2 f^*$  is positive semidefinite, hence  $f^*$  must be convex. Of course, we need to assume that problem  $P(\epsilon)$  has a solution for each  $\epsilon \in T$  where the conclusion of Proposition 1iii) holds, to guarantee that (8) holds for each  $\epsilon \in T$ .

### Algorithmic Approximations

An intriguing possibility is the simultaneous approximation of sensitivity and stability analysis information, as a solution is being estimated by an algorithm in progress. We illustrate the feasibility of this idea with results that have been obtained by a classical combination barrier-exterior point algorithm, forerunner of a powerful class of interior-exterior point methods that are currently among the best methods available, both for LP and NLP.

The classical *logarithmic-quadratic barrier-penalty function* for problem  $P(\epsilon)$  is defined as

$$W(x, \epsilon, r) = f(x, \epsilon) - r \sum_{i=1}^m \log g_i(x, \epsilon) + \frac{1}{2r} \sum_{j=1}^p h_j^2(x, \epsilon). \quad (9)$$

A solution procedure based on  $W$  for solving problem  $P(\epsilon)$  for any fixed value of  $\epsilon$  is briefly described as follows: Select  $r_k > 0$  such that  $r_k \rightarrow 0$  as  $k \rightarrow +\infty$  and solve  $\min_x W(x, \epsilon, r_k)$  s.t.  $g_i(x, \epsilon) > 0$  (for all  $i$ ) to obtain  $x(\epsilon, r_k)$ , for  $k = 1, 2, \dots$ . Then, ideally,  $x(\epsilon, r_k) \rightarrow x(\epsilon)$ , a solution of  $P(\epsilon)$ , as  $k \rightarrow +\infty$ .

At a minimizer  $x(\epsilon, r)$  of  $W(x, \epsilon, r)$ , we must have  $\nabla_x W = 0$ . Since  $\nabla_x W = \nabla_x f - \sum_{i=1}^m (r/g_i) \nabla g_i + \sum_{j=1}^p (h_j/r) \nabla h_j$  and since the Lagrangian of problem  $P(\epsilon)$  is  $L = f - \sum_{i=1}^m u_i g_i + \sum_{j=1}^p w_j h_j$ , yielding  $\nabla_x L = \nabla_x f - \sum_{i=1}^m u_i \nabla_x g_i + \sum_{j=1}^p w_j \nabla h_j$ , then  $\nabla_x W = 0$  is equivalent to  $\nabla_x L = 0$  with  $r/g_i = u_i$  and  $h_j/r = w_j$ . Hence, combined with the results of Proposition 1, we have the following additional consequences.

**Proposition 5** *Under the assumptions of Proposition 1, for any  $(\epsilon, r)$  in a neighborhood of  $(\bar{\epsilon}, 0)$ , with  $r > 0$ , there exists a unique once continuously differentiable vector function  $y$  such that  $y(\epsilon, r) = [x(\epsilon, r), u(\epsilon, r), w(\epsilon, r)]$ , where the assumptions of Proposition 1 continue to hold, and such that conditions KKT $[y(\epsilon, r), \epsilon, r]$ :*

$$\begin{cases} \nabla_x L[x(\epsilon, r), u(\epsilon, r), w(\epsilon, r), \epsilon] = 0, \\ u_i(\epsilon, r) g_i[x(\epsilon, r), \epsilon] = r \quad (i = 1, \dots, m), \\ h_j[x(\epsilon, r), \epsilon] = r w_j \quad (j = 1, \dots, p), \end{cases}$$

with  $y(\bar{\epsilon}, 0) = (\bar{x}, \bar{u}, \bar{w})$ , and such that  $x(\epsilon, r)$  is a locally unique unconstrained local minimizer of  $W(x, \epsilon, r)$ , with all  $g_i[x(\epsilon, r), \epsilon] > 0$  and  $\nabla_x^2 W[x(\epsilon, r), \epsilon, r]$  positive definite.

Note that the resulting equations in Proposition 5, satisfied at  $y(\epsilon, r)$ , are a simple perturbation of the KKT equations exhibited above, and we have labeled them accordingly. This is a striking example of the close relationship between optimality conditions and algorithmic theory, and as we now indicate, sensitivity analysis as well.

Just as above, we can immediately differentiate equations KKT $[y(\epsilon, r), \epsilon, r]$  with respect to  $\epsilon$ , now to obtain the perturbed formula for the parameter derivative

$\nabla_\epsilon y(\epsilon)$  given in (1). The analogous reasoning applies and we obtain

$$\nabla_\epsilon y(\epsilon, r) = M(\epsilon, r)^{-1} N(\epsilon, r), \quad (10)$$

where  $M$  and  $-N$  are the Jacobians of the perturbed KKT system with respect to  $(x, u, w)$  and  $\epsilon$ , respectively.

The following results hold, for any  $\epsilon$  or  $\hat{\epsilon}$  sufficiently close to  $\bar{\epsilon}$  and for  $r > 0$  and small enough:

- i)  $y(\hat{\epsilon}, 0) = y(\bar{\epsilon})$ ,
- ii)  $\nabla_\epsilon y(\hat{\epsilon}, 0) = \nabla_\epsilon y(\bar{\epsilon})$ ,
- iii)  $y(\epsilon, r) \rightarrow y(\bar{\epsilon})$  as  $(\epsilon, r) \rightarrow (\bar{\epsilon}, 0)$ , and
- iv)  $\nabla_\epsilon y(\epsilon, r) \rightarrow \nabla_\epsilon y(\bar{\epsilon}) = M(\bar{\epsilon})^{-1} N(\bar{\epsilon})$  as  $(\epsilon, r) \rightarrow (\bar{\epsilon}, 0)$ .

Thus, in particular, we can take  $\hat{\epsilon} = \bar{\epsilon}$  and estimate  $y(\bar{\epsilon})$  and  $\nabla_\epsilon y(\bar{\epsilon})$  by  $y(\epsilon, r)$  and  $\nabla_\epsilon y(\epsilon, r)$ , for  $(\epsilon, r)$  near  $(\bar{\epsilon}, 0)$ .

These results lead immediately to optimal value approximations since we find that, for  $\epsilon$  near  $\bar{\epsilon}$  and  $r > 0$  small:

- i)  $W^*(\epsilon, r) \rightarrow f^*(\epsilon)$ ,
- ii)  $\nabla_\epsilon W^*(\epsilon, r) \rightarrow \nabla_\epsilon f^*(\epsilon)$ , and
- iii)  $\nabla_\epsilon^2 W^*(\epsilon, r) \rightarrow \nabla_\epsilon^2 f^*(\epsilon)$  as  $r \rightarrow 0$ , where  $W^*(\epsilon, r) = W[x(\epsilon, r), \epsilon, r]$ .

We also note that since  $\nabla_x W = 0$  and  $\nabla_x^2 W$  is positive definite near  $\nabla_x W = 0$ , we have that  $\nabla_x^2 W \nabla_{\epsilon x} + \nabla_{\epsilon x}^2 W = 0$ , yielding

$$\nabla_\epsilon x(\epsilon, r) = -\nabla_x^2 W^{-1} \nabla_{\epsilon x}^2 W, \quad (11)$$

an alternative calculation for  $\nabla_\epsilon x$ , leading immediately to simple formulas for  $\nabla_\epsilon u_i(\epsilon, r)$  and  $\nabla_\epsilon w_j(\epsilon, r)$ , through the relations  $u_i = r/g_i$  and  $w_j = h_j/r$ . These results provide a basis for approximating solution sensitivity information at an unconstrained minimizer of  $W$  by exploiting algorithmic properties and calculations. It is important to note that most of the information required to calculate the parameter derivatives will already be available from the usual implementations of an algorithm based on  $W$  that is used to find a solution of problem  $P(\epsilon)$ .

In the next section, we present a few basic results that provide upper bounds on a solution point change and upper and lower bounds on the change in the optimal value, when the problem data parameter is perturbed. Many extensions and variations are possible and many have been reported. Our objective here is to give an idea of the kind of bound information that can be calculated, once a solution has been determined.

## Bounds

### Linear Equations

In ► [Sensitivity and stability in NLP](#), our first example of an important and widely encountered mathematical model is a system of equations,

$$Ax = b, \quad (12)$$

where  $A$  is an  $n \times n$  real matrix and  $x$  and  $b$  are in  $E^n$ . We briefly discussed a number of issues that might arise in characterizing a solution  $x$  for changes in the data,  $A$  and  $b$ . As noted, we may think of a solution or set of solutions as a function of  $A$  and  $b$ , viewed as parameters, exploit the nonsingularity of  $A$  to actually obtain a closed form expression for  $x(A; b)$  and otherwise endeavor to track  $x$  as  $A$  and  $b$  vary, or at least establish existence and continuity and parameter-differentiability properties and the like. Another approach is the development of bounds on a solution change resulting from the data perturbations. Since the equations model is so important, and since many of the sensitivity results that we have presented here and in ► [Sensitivity and stability in NLP](#) and ► [Sensitivity and stability in NLP: Continuity and differential stability](#) and that have been presented elsewhere reduce the problem to equations (or their linearization) that follow from optimality conditions, the model is also quite relevant. Hence, we give a classical result that is both important and instructive in revealing what information is crucial in the calculation of bounds.

Let  $\|\cdot\|$  denote a vector norm or its corresponding matrix norm, as relevant in the following context. Perturbations in the data  $A$  and  $b$  are denoted by  $\delta A$  and  $\delta b$ , respectively.

**Proposition 6** *Suppose  $A^{-1}$  exists and  $x$  solves  $Ax = b$  while  $x + \delta x$  solves  $(A + \delta A)(x + \delta x) = b + \delta b$ . Suppose  $\alpha = \|A^{-1}\delta A\| < 1$ . Then, the corresponding change  $\delta x$  in the solution  $x$  satisfies the following inequality*

$$\frac{\|\delta x\|}{\|x\|} \leq \frac{c(A)}{1 - \alpha} \left( \frac{\|\delta A\|}{\|A\|} + \frac{\|\delta b\|}{\|b\|} \right), \quad (13)$$

where  $c(A) = \|A\| \|A^{-1}\|$  is the so-called condition number of  $A$ .

This result provides a bound for a generally small perturbation of  $A$  (since we require  $\alpha < 1$ ) on the relative change in  $x$  for relative changes in the data. For  $\|\delta A\|$

small enough,  $\alpha$  will be close to 0, and the crucial factor is the condition number: if  $c(A)$  is small enough, then small relative solution changes result from small relative data changes, but if  $c(A)$  is too large, then large solution changes may result from small data changes. The former and latter cases correspond to what is often termed to be ‘well-conditioned’ or ‘ill-conditioned’, respectively. (Generally the larger the value of  $c(A)$ , the more difficult it is to solve (12) with prescribed accuracy.) This bound is of intrinsic interest and should provide a useful perspective for the reader. Some of the bounds results that follow for various classes of parametric programs may be seen to be related to some variation of (13). In this context, note that the condition number  $c(A) = \lambda_{\max}/\lambda_{\min} \geq 1$ , where  $\lambda_{\max}$  and  $\lambda_{\min}$  are the positive square root of the maximum and minimum eigenvalues of  $A^T A$ , respectively, and we assume that  $\lambda_{\min} > 0$ . If  $A$  is a real positive definite symmetric matrix, then  $\lambda_{\min}$  and  $\lambda_{\max}$  are simply the minimum and maximum eigenvalues of  $A$ .

### Solution-Point Bounds for NLP

We begin with a bound on the perturbed solution of a *quadratic program* (QP), i.e., a mathematical programming problem having a quadratic objective function and linear constraints:

$$Q(K, k) \begin{cases} \min_{x \in E^n} & \frac{1}{2} x^T K x - k^T x \\ \text{s.t.} & Cx \leq c, \quad Dx = d. \end{cases}$$

**Proposition 7** *Assume that  $K$  is a real positive definite and symmetric matrix, with minimum eigenvalue  $\bar{\lambda}$ . Suppose the data  $K$  and  $k$  are perturbed to  $\widehat{K}$  and  $\widehat{k}$  and let  $\delta = \max\{\|\widehat{K} - K\|, \|\widehat{k} - k\|\}$ . Assume that  $\bar{x}$  solves  $Q(K, k)$  and  $\widehat{x}$  solves  $Q(\widehat{K}, \widehat{k})$ . Then, provided  $\delta < \bar{\lambda}$ , it follows that*

$$\|\widehat{x} - \bar{x}\| \leq \frac{\delta}{\bar{\lambda} - \delta} (1 + \|\bar{x}\|). \quad (14)$$

The following results apply to the general parametric problem  $P(\epsilon)$  introduced above, under various assumptions and conditions already used here and in ► [Sensitivity and stability in NLP: Continuity and differential stability](#) for continuity and derivative characterizations. See ► [Sensitivity and stability in NLP: Continuity and differential stability](#) for the involved definitions.

The next proposition invokes all the same assumptions as Proposition 1, except that we now assume that the functions of problem  $P(\epsilon)$  have twice differentiable partial derivatives in  $x$  that are jointly continuous in  $(x, \epsilon)$ , rather than assuming twice continuous partial derivatives jointly in  $(x, \epsilon)$  as was done for Proposition 1. With this understanding, we have the following result.

**Proposition 8** *If the conditions  $\text{KKT}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$ ,  $\text{SOSC}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$  and  $\text{LI}(\bar{x}, \epsilon)$  and  $\text{SCS}(\bar{x}, \epsilon)$  hold for  $\bar{x} \in R(\epsilon)$  at  $\epsilon = \bar{\epsilon} \in \text{interior } T$ , with the differentiability assumptions weakened as explained in the preceding paragraph, then there exists a locally unique continuous vector function  $y = (x, u, w)$  such that  $y(\bar{\epsilon}) = [x(\bar{\epsilon}), u(\bar{\epsilon}), w(\bar{\epsilon})] = (\bar{x}, \bar{u}, \bar{w}) = \bar{y}$  and such that these assumptions continue to hold at  $y(\epsilon) = [x(\epsilon), u(\epsilon), w(\epsilon)]$  in a neighborhood of  $\bar{\epsilon}$ . This implies that  $x(\epsilon)$  is an isolated local minimizer with associated unique Lagrange multipliers  $[u(\epsilon), w(\epsilon)]$ . Furthermore, for any  $\lambda \in (0, 1)$ , near  $[u(\epsilon), w(\epsilon)]$ , the following bound holds:*

$$\|y - y(\epsilon)\| \leq (1 - \lambda)^{-1} \|M(\bar{\epsilon})^{-1}\| \|F(y, \epsilon)\|, \quad (15)$$

where  $F = [\nabla_x L, u_1 g_1, \dots, u_m g_m, h_1, \dots, h_p]^T$  so that  $F(\bar{y}, \bar{\epsilon}) = 0$  represents the Karush–Kuhn–Tucker conditions and  $M = \nabla_y F$ , all as introduced in above.

The real-valued function  $\phi$  is said to be *Lipschitz continuous* on a set  $S$  contained in a normed space  $X$  if there exists a quantity  $\lambda > 0$  such that  $|\phi(x) - \phi(y)| \leq \lambda \|x - y\|$  for all  $x, y \in S$ .

In **► Sensitivity and stability in NLP: Continuity and differential stability** we gave the following result, summarized here for convenience.

**Proposition 9** *If the conditions  $\text{KKT}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$ ,  $\text{SSOSC}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$  and  $\text{LI}(\bar{x}, \epsilon)$  hold for a feasible  $\bar{x}$  at  $\epsilon = \bar{\epsilon} \in \text{interior } T$ , then near  $\bar{\epsilon}$  there exists  $y = (x, u, w)$  continuous and locally unique such that  $y(\bar{\epsilon}) = \bar{y}$  and such that the assumptions persist at  $y(\epsilon)$ ;  $x(\epsilon)$  is an isolated local minimizer with associated unique Lagrange multipliers  $[u(\epsilon), w(\epsilon)]$ ;  $x, u$  and  $w$  are locally Lipschitz and directionally differentiable; and  $f^*$  is once continuously differentiable and twice directionally differentiable. Therefore, in particular it follows that for  $\epsilon$  near  $\bar{\epsilon}$ , there exists  $\alpha, \beta, \gamma > 0$  such that*

- a)  $\|x(\epsilon) - \bar{x}\| \leq \alpha \|\epsilon - \bar{\epsilon}\|$ ;
- b)  $\|u(\epsilon) - \bar{u}\| \leq \beta \|\epsilon - \bar{\epsilon}\|$ ; and
- c)  $\|w(\epsilon) - \bar{w}\| \leq \gamma \|\epsilon - \bar{\epsilon}\|$ .

Thus, we have bounds on the local solution point and associated Lagrange multipliers that strongly regulate the local rate of change of these quantities, assuring that it is uniform and stable in the sense indicated and providing a sharper result than merely knowing continuity. However, the result is theoretical per se and does not give a prescription for calculating the Lipschitz constants,  $\alpha, \beta$ , and  $\gamma$ . Such issues are important and ongoing in obtaining *computable solution* bounds.

Many such Lipschitz continuity results have been obtained in this area, both for a local solution point and its associated Lagrange multipliers, as well as for the local and global optimal value function. To cite still another, under assumptions that we have encountered in **► Sensitivity and stability in NLP: Continuity and differential stability**, Proposition 10, we have the following (in addition to the several conclusions given in **► Sensitivity and stability in NLP: Continuity and differential stability**): If KKT, GSSOSC and MFCQ hold at  $(\bar{x}, u, w)$  for  $\epsilon = \bar{\epsilon}$ , then the local solution  $x$  is again locally unique and Lipschitz, although here the Lagrange multipliers associated with  $x$  are not unique in general.

Next, we present a simple general scheme for obtaining computable optimal value bounds for finite parameter perturbations, once a solution point is available. This will be briefly presented for the classes of problems of the form  $P(\epsilon)$  where the optimal value function  $f^*$  is convex on a convex parameter set  $T$ . Since a concave function is the negative of a convex function, the results also apply to  $f^*$  concave. The approach has even been extended to special classes of problems where  $f^*$  is neither convex nor concave. To avoid any pathological exceptions, we assume solution attainment and constraint regularity sufficient to imply the Karush–Kuhn–Tucker conditions at any subject local solution point, in the remainder of the article.

### Computable Optimal Value Bounds $f^*$ Convex

We shall first assume that  $f^*$  is convex and well-defined for all  $\epsilon \in T$ , a convex subset of  $E^q$ . Conditions implying the convexity of  $f^*$  for problem  $P(\epsilon)$  are well known. For example, in **► Sensitivity and stability in NLP: Continuity and differential stability** we noted the following result:

If  $P(\epsilon)$  is jointly convex in  $(x, \epsilon)$ , i. e., if  $f$  and the  $-g_i$  are jointly convex and the  $h_j$  are linear-affine in  $(x, \epsilon)$

for all  $i$  and  $j$  and any  $\epsilon \in T$  convex, then the optimal value  $f^*$  is convex on  $T$ . More general assumptions are known that imply the convexity of  $f^*$ . Suffice it to say that the class is large of problems  $P(\epsilon)$  for which  $f^*$  is convex. Many results involving convexity and concavity characterizations of  $f^*$  are given in [4] and [7].

We are assuming that  $f^*$  is convex on  $T$ , a convex nonempty set. Consider any  $\epsilon_1, \epsilon_2 \in T$ , with  $\epsilon_1 \neq \epsilon_2$  and denote by  $[\epsilon_1, \epsilon_2]$  the interval from  $\epsilon_1$  to  $\epsilon_2$ . We first show how to obtain bounds on  $f^*$  over  $[\epsilon_1, \epsilon_2]$ . Define  $\epsilon(\alpha) = \alpha\epsilon_2 + (1-\alpha)\epsilon_1$ , where  $0 \leq \alpha \leq 1$ . Note that for any  $\bar{\epsilon} \in [\epsilon_1, \epsilon_2]$ , there exists a unique  $\bar{\alpha}$  such that  $\bar{\epsilon} = \epsilon(\bar{\alpha})$ . Then, we obtain a unique global upper bound  $U(\alpha)$  on  $f^*$  over  $[\epsilon_1, \epsilon_2]$  from the following result that follows from the definition of a convex function:

$$f^*[\epsilon(\alpha)] \leq \alpha f^*(\epsilon_2) + (1-\alpha)f^*(\epsilon_1) \equiv U(\alpha). \quad (16)$$

Next, suppose that  $\nabla_{\epsilon} f^*(\epsilon_1)$  and  $\nabla_{\epsilon} f^*(\epsilon_2)$  exist. Then, again from the definition of convexity it is known that at any  $\hat{\epsilon} \in T$  where  $\nabla_{\epsilon} f^*(\hat{\epsilon})$  exists we have

$$f^*(\epsilon) \geq f^*(\hat{\epsilon}) + \nabla_{\epsilon} f^*(\hat{\epsilon})(\epsilon - \hat{\epsilon}), \quad \text{for any } \epsilon \in T. \quad (17)$$

For  $\hat{\epsilon} = \epsilon_1$ , or  $\hat{\epsilon} = \epsilon_2$ , we thus obtain two global lower bounds  $L_1^*(\epsilon)$  and  $L_2^*(\epsilon)$ . Thus,  $L^*(\epsilon) = \max\{L_1^*(\epsilon), L_2^*(\epsilon)\}$  gives a convex lower bound for any  $\epsilon \in T$ . We can apply this result to  $\epsilon = \epsilon(\alpha)$ , with  $\hat{\epsilon} = \epsilon_1$  and  $\hat{\epsilon} = \epsilon_2$  and denote the right-hand side of the inequality by  $L_1(\alpha)$  and  $L_2(\alpha)$ , respectively. Next, let  $L(\alpha) = \max\{L_1(\alpha), L_2(\alpha)\}$ . Then, it follows that

$$\begin{aligned} L(\alpha) &\leq f^*[\epsilon(\alpha)] \\ &\leq U(\alpha) \quad \text{for any } \alpha \in [0, 1]. \end{aligned} \quad (18)$$

This last inequality gives global upper and lower bounds on the optimal value  $f^*$  over the interval  $[\epsilon_1, \epsilon_2]$ . Note that  $U(\alpha)$  can be calculated when we have determined only the value of  $f^*$  at  $\epsilon_1$  and  $\epsilon_2$ . The lower bound  $L(\alpha)$  can be computed when we have also determined  $\nabla_{\epsilon} f^*$  at  $\epsilon_1$  and  $\epsilon_2$ . Thus, with  $f^*$  and  $\nabla_{\epsilon} f^*$  well-defined at  $\epsilon_1, \epsilon_2 \in T$ , these quantities associated with only two problems,  $P(\epsilon_1)$  and  $P(\epsilon_2)$ , respectively, are enough to provide parametric global upper and lower bounds over any interval  $[\epsilon_1, \epsilon_2]$ .

The bounds over  $[\epsilon_1, \epsilon_2]$  can be significantly improved in general each time  $f^*$  and  $\nabla_{\epsilon} f^*$  are determined for a new value of  $\epsilon$  in the interval. For example,

suppose we take  $\epsilon = \epsilon_3 \in (\epsilon_1, \epsilon_2)$ . Once we determine  $f^*$  and  $\nabla_{\epsilon} f^*$  at  $\epsilon_3$ , we can calculate new upper and lower bounds, as above, over  $[\epsilon_1, \epsilon_3]$  and  $[\epsilon_3, \epsilon_2]$ . Because of the convexity of  $f^*$ , the new bounds can only improve. In fact, continuing this way with new intermediate parameter values in  $[\epsilon_1, \epsilon_2]$ , it is theoretically possible to calculate upper and lower bounds to any prescribed degree of accuracy, since the bounds will converge ultimately from below and above to the graph of  $f^*$  over  $[\epsilon_1, \epsilon_2]$ .

Note that to calculate bounds over  $[\epsilon_1, \epsilon_2]$ , we need the convexity of  $f^*$  only over the interval  $[\epsilon_1, \epsilon_2]$ , not over the entire set  $T$ , allowing for significant additional generality, e. g., allowing us to drop the assumption of convexity of  $T$ . Furthermore, the process can be extended to provide bounds over more general subsets of  $T$ , as follows. Suppose we are interested in  $\epsilon_1, \dots, \epsilon_k \in T$  and suppose we can determine  $f^*$  and  $\nabla_{\epsilon} f^*$  at the  $\epsilon_i$ . Analogously as before, define  $\epsilon(\alpha) = \sum_{i=1}^k \alpha_i \epsilon_i$ , with  $\sum_{i=1}^k \alpha_i = 1$  and  $\alpha_i \geq 0$ . Then, an upper bound at any such  $\epsilon(\alpha)$  is obtained from Jensen's inequality,

$$f^*[\epsilon(\alpha)] \leq \sum_{i=1}^k \alpha_i f^*(\epsilon_i) \equiv U(\alpha), \quad (19)$$

where  $\alpha = (\alpha_1, \dots, \alpha_k)$ . Lower bounds  $L_i^*(\epsilon)$  on  $f^*$  over the entire set  $T$  are computable at each  $\epsilon_i$  using (17) with  $\hat{\epsilon} = \epsilon_i$  ( $i = 1, \dots, k$ ), yielding  $L^*(\epsilon) = \max\{L_1^*(\epsilon), \dots, L_k^*(\epsilon)\}$  as a piecewise-linear convex global lower bound on  $f^*$  over  $T$ . Adapting this to  $\epsilon = \epsilon(\alpha)$ , we replace  $\epsilon$  in the lower bound inequality (17) by  $\epsilon(\alpha)$  and the  $\hat{\epsilon}$  by  $\epsilon_i$  to get  $L_i(\alpha)$  ( $i = 1, \dots, k$ ), finally getting  $L(\alpha) = \max\{L_1(\alpha), \dots, L_k(\alpha)\}$ . We thus have

$$L(\alpha) \leq f^*[\epsilon(\alpha)] \leq U(\alpha) \quad (20)$$

for any  $\alpha = (\alpha_1, \dots, \alpha_k)$  such that  $\sum_{i=1}^k \alpha_i = 1$  and  $\alpha_i \geq 0$  ( $i = 1, \dots, k$ ).

*Remark 10* We note that, unlike before where  $\epsilon(\alpha) = \alpha\epsilon_2 + (1-\alpha)\epsilon_1$  and there is only one  $\alpha$  for a given  $\epsilon = \epsilon(\alpha) \in [\epsilon_1, \epsilon_2]$ , there now may be a set of values of  $\alpha$  such that  $\epsilon(\alpha) = \epsilon$ . Thus, for a given  $\epsilon$  such that  $\epsilon = \epsilon(\alpha)$ , the upper bound  $U(\alpha)$  may have a range of values. In this instance, we note that the best bound  $U^*(\epsilon)$  is the optimal value of:  $\min_{\alpha} U(\alpha)$  s.t.  $\sum_{i=1}^k \alpha_i \epsilon_i = \epsilon$ ,  $\sum_{i=1}^k \alpha_i = 1$ ,  $\alpha_i \geq 0$  ( $i = 1, \dots, k$ ), a linear program with parameter  $\epsilon$ . (The lower bound will have only one

value for any such  $\epsilon$ , as before.) The upper bound will be single-valued for  $\epsilon = \epsilon(\alpha)$ , if the set of  $\epsilon$  such that  $\epsilon = \epsilon(\alpha)$  is a *simplex* with vertices  $\epsilon_i$  in the subset of  $T$  that is spanned by the given  $\epsilon_i$ . Thus, an effective way to generate upper bounds over any subset  $S$  of  $T$  is to systematically cover  $S$  with contiguous simplexes, using points  $\epsilon_i$  of  $S$ . The upper and lower bounds over each simplex will be uniquely determined and loose bounds over a given simplex can be sharpened by selecting a new parameter vector  $\bar{\epsilon}$  in the given simplex, subdividing into newly determined contiguous simplexes with the new vertex  $\bar{\epsilon}$ , and proceeding as indicated above, to obtain upper and lower bounds over each simplex.

Next, we show how to obtain a simpler and sharper upper bound, if the constraint functions  $g_i$  and  $h_j$  are as prescribed when  $P(\epsilon)$  is a jointly convex program (i. e.,  $g_i$  jointly concave and  $h_j$  jointly linear-affine, for all  $i$  and  $j$ ).

### $g_i$ Jointly Concave, $h_j$ Jointly Linear Affine

With  $g_i$  and  $h_j$  as indicated, it turns out that if  $\hat{x}(\epsilon_1)$  is a feasible point of  $P(\epsilon_1)$  and  $\hat{x}(\epsilon_2)$  is a feasible point of  $P(\epsilon_2)$ , then  $\tilde{x}(\alpha) \equiv \alpha\hat{x}(\epsilon_2) + (1 - \alpha)\hat{x}(\epsilon_1)$  is a feasible point of  $P[\epsilon(\alpha)]$  for any  $\alpha \in [0, 1]$ , where  $\epsilon(\alpha) = \alpha\epsilon_2 + (1 - \alpha)\epsilon_1$ . This gives us a feasible point of  $P(\epsilon)$  for any  $\epsilon \in [\epsilon_1, \epsilon_2]$ . It also means that  $f^*[\epsilon(\alpha)] \leq f[\tilde{x}(\alpha), \epsilon(\alpha)] = \tilde{f}(\alpha)$ , i. e., the optimal value of problem  $P[\epsilon(\alpha)]$  is bounded above by the objective function evaluated at the feasible point  $\tilde{x}(\alpha)$ . This immediately provides an easily computable upper bound on  $f^*$  over  $[\epsilon_1, \epsilon_2]$  once  $\hat{x}(\epsilon_1)$  and  $\hat{x}(\epsilon_2)$  are available. There is no requirement here that  $f$  be convex. If  $\hat{x}(\epsilon_1)$  solves  $P(\epsilon_1)$  and  $\hat{x}(\epsilon_2)$  solves  $P(\epsilon_2)$ , then this upper bound is exact at  $\epsilon_1$  and  $\epsilon_2$ . (Note that  $f^*$  will generally be nonconvex if  $f$  is not convex.)

### $P(\epsilon)$ Jointly Convex

If problem  $P(\epsilon)$  is jointly convex, then we not only have the  $g_i$  jointly concave and the  $h_j$  jointly linear affine as before but now also have  $f$  jointly convex, hence  $f^*$  is convex and the upper bound has additional properties. In this case, it turns out that  $\nabla_{\epsilon}^2 f^*$  is also convex over  $[0, 1]$ . Furthermore, if  $x(\epsilon_1)$  solves  $P(\epsilon_1)$  and  $x(\epsilon_2)$  solves  $P(\epsilon_2)$ , and  $\bar{x}(\alpha) = \alpha x(\epsilon_2) + (1 - \alpha)x(\epsilon_1)$  then it follows that  $\bar{f}(\alpha) = f[\bar{x}(\alpha), \epsilon(\alpha)]$  gives a convex upper bound

on  $f^*$  over  $[\epsilon_1, \epsilon_2]$  that either agrees with or is lower and hence sharper than the linear upper bound  $U(\alpha)$  described earlier, i. e.,

$$f^*[\epsilon(\alpha)] \leq \bar{f}(\alpha) \leq U(\alpha) \quad \text{for all } \alpha \in [0, 1]. \quad (21)$$

As noted,  $\bar{f}(\alpha)$  is immediately computable once a solution is determined for  $P(\epsilon_1)$  and  $P(\epsilon_2)$ . Following the technique for improving  $U(\alpha)$ , this bound can be improved by solving  $P(\epsilon)$  for  $\epsilon_3 \in (\epsilon_1, \epsilon_2)$ , then proceeding as above for the sub-intervals  $[\epsilon_1, \epsilon_3]$  and  $[\epsilon_3, \epsilon_2]$ .

### $\tilde{f}$ and $\bar{f}$ for Subsets of $T$

The calculation of  $\tilde{f}$  and  $\bar{f}$  can be extended to bound  $f^*$  above over more general subsets of  $T$ , as well, proceeding somewhat analogously to the procedure given above for  $f^*$  convex that was indicated for  $U(\alpha)$ . We shall illustrate this for  $\bar{f}(\alpha)$ , and assume that  $P(\epsilon)$  is jointly convex. Given a set of values  $\{\epsilon_1, \dots, \epsilon_k\}$ , where  $\epsilon_i \in T$ , suppose we obtain solutions  $x(\epsilon_i)$  for  $P(\epsilon_i)$ ,  $i = 1, \dots, k$ . Then, as before we consider  $\epsilon(\alpha) = \sum_{i=1}^k \alpha_i \epsilon_i$ , with  $\sum_{i=1}^k \alpha_i = 1$  and  $\alpha_i \geq 0$  for all  $i$ . If we denote  $\bar{x}(\alpha) = \sum_{i=1}^k \alpha_i x(\epsilon_i)$ , then it follows that  $\bar{x}(\alpha)$  is a feasible point of  $P[\epsilon(\alpha)]$ , hence again

$$f^*[\epsilon(\alpha)] \leq f[\bar{x}(\alpha), \epsilon(\alpha)] \equiv \bar{f}(\alpha) \leq U(\alpha), \quad \text{for } \alpha = (\alpha_1, \dots, \alpha_k), \quad (22)$$

where here  $U(\alpha) = \sum_{i=1}^k \alpha_i f^*(\epsilon_i)$  as in (19) and  $\bar{f}$  is convex over  $\alpha$  and we thus have an upper bound on  $f^*(\epsilon)$  for any  $\epsilon \in T$  such that  $\epsilon = \epsilon(\alpha)$  for  $\alpha$  as prescribed. Similar remarks to those given previously apply regarding multiple values of  $\alpha$  corresponding to any given  $\epsilon = \sum_{i=1}^k \alpha_i \epsilon_i$ . Again, proceeding to cover  $T$  systematically with contiguous simplexes and calculating bounds over each simplex would eliminate this multiple-value problem and result in unique upper and lower bounds, and would appear to be a very effective and natural way to proceed.

*Remark 11* As for  $g_i$  jointly concave and  $h_j$  jointly linear affine, we can drop the convexity assumption on  $f$  and we can also simply assume that we have only a *feasible point*  $\hat{x}(\epsilon_i)$  of  $P(\epsilon_i)$  for  $i = 1, \dots, k$  (rather than a solution point  $x(\epsilon_i)$ ). Then, we still obtain an upper bound since we again have  $\tilde{x}(\alpha) \in R[\epsilon(\alpha)]$  and hence we again have  $\tilde{x}(\alpha) \in R[\epsilon(\alpha)]$ , where we now have  $\tilde{x}(\alpha) = \sum_{i=1}^k \alpha_i \hat{x}(\epsilon_i)$ .

We turn last to a calculation of a bound on the distance from a feasible point of  $P(\epsilon)$  to a solution of  $P(\epsilon)$ .

### Bounds on the Distance of a Feasible Point to a Solution Point

The first bound is for a given unperturbed problem.

**Proposition 12** *Suppose we are given problem  $P(\epsilon)$ , with feasible region  $R(\epsilon)$  convex in  $x$  with  $\epsilon$  fixed. Assume  $x(\epsilon)$  locally solves  $P(\epsilon)$ , assume that the feasible region is not a singleton, and assume that there exists a number  $m(\epsilon) > 0$  such that  $z^T \nabla_x^2 f(x, \epsilon) z \geq m(\epsilon) \|z\|^2$  for any  $x \in R(\epsilon)$  and any  $z \in E^n$  such that  $z$  is a feasible direction of  $R(\epsilon)$  from  $x(\epsilon)$ , i. e.,  $x(\epsilon) + \beta z \in R(\epsilon)$  for any  $\beta$  and some  $\bar{\beta}$  such that  $0 < \beta \leq \bar{\beta}$ . Then,  $x(\epsilon)$  is the unique global minimizer and the following bound holds:*

$$\|x - x(\epsilon)\| \leq \left( \frac{f(x, \epsilon) - f^*(\epsilon)}{\frac{m(\epsilon)}{2}} \right)^{\frac{1}{2}} \quad (23)$$

for any  $x \in R(\epsilon)$ .

*Remark 13* The conclusions of this Proposition hold in some neighborhood of  $x(\epsilon)$  if we assume that the uniform quadratic underestimation of  $z^T \nabla_x^2 f z$  holds only near  $x(\epsilon)$  (rather than for any  $x \in R(\epsilon)$ ). Hence, Propositions 14 and 15 also hold if the respective distances being bounded are sufficiently small.

Using the fact that  $\nabla_x f[x(\epsilon), \epsilon] z \geq 0$  must hold, the inequality (23) follows easily from a second order Taylor's series expansion of  $f$  around  $x(\epsilon)$ . This provides a bound on the distance from any given feasible point of problem  $P(\epsilon)$  to the solution  $x(\epsilon)$  of  $P(\epsilon)$ . This bound is of theoretical interest but may not be computable without  $x(\epsilon)$  because  $m$ ,  $z$ , and  $f^*$  depend on  $R(\epsilon)$  and  $x(\epsilon)$ . As for  $z$ , if we let  $z$  be any  $z \in E^n$ , then the largest suitable  $m$  will generally be smaller than with  $z$  restricted, but  $z$  will be free of dependency on  $x(\epsilon)$  and the results will apply if  $m > 0$ . Also, with  $z$  unrestricted, we note that the function  $f$  is strictly convex in  $R(\epsilon)$ . Nonetheless, even for  $z$  unrestricted, the largest suitable value of  $m$  is the optimal value (if positive) of a nonconvex program,  $\min_{(x, z)} z^T \nabla_x^2 f(x, \epsilon) z$  s.t.  $\|z\| = 1, x \in R(\epsilon)$ , which may be prohibitive except for special classes of problems. For example, if  $f$  is quadratic in  $x$  and  $\nabla_x^2 f$  is positive definite, then  $m$  may be taken to be the minimum eigenvalue of  $\nabla_x^2 f$ . We deal with  $f^*$  by using a computable upper bound in the sequel.

Next, we allow  $\epsilon$  to change and obtain a bound on the distance from a solution  $x[\epsilon(\alpha)]$  of  $P[\epsilon(\alpha)]$  to the computable feasible point  $\tilde{x}(\alpha)$ , as defined in Remark 11, using the bound (23).

**Proposition 14** *In addition to the assumptions of Proposition 12, suppose that for any  $\epsilon = \epsilon(\alpha)$ , the problem constraints  $g_i$  are jointly concave in  $(x, \epsilon)$  and the  $h_j$  jointly affine, and also suppose that problem  $P(\epsilon)$  has a feasible point  $\hat{x}(\epsilon)$  for  $\epsilon = \epsilon_i \in T$  convex, where  $i = 1, \dots, k$ . Then it follows that  $\tilde{x}(\alpha) \in R[\epsilon(\alpha)]$  and*

$$\|\tilde{x}(\alpha) - x[\epsilon(\alpha)]\| \leq \left( \frac{f[\tilde{x}(\alpha), \epsilon(\alpha)] - f^*[\epsilon(\alpha)]}{\frac{m[\epsilon(\alpha)]}{2}} \right)^{\frac{1}{2}} \quad (24)$$

for any  $\alpha = (\alpha_1, \dots, \alpha_k)$   $\sum_{i=1}^k \alpha_i = 1$  and  $\alpha_i \geq 0$  ( $i = 1, \dots, k$ ), where  $\tilde{x}(\alpha) = \sum_{i=1}^k \alpha_i \hat{x}(\epsilon_i)$ ,  $\epsilon(\alpha) = \sum_{i=1}^k \alpha_i \epsilon_i$ ,  $x[\epsilon(\alpha)]$  solves  $P[\epsilon(\alpha)]$  and  $f^*[\epsilon(\alpha)]$  is the optimal value of  $P[\epsilon(\alpha)]$ .

The upper bound (24) involves  $f^*[\epsilon(\alpha)]$  which would generally not be available unless  $x[\epsilon(\alpha)]$  were known. We want a computable upper bound not requiring  $x[\epsilon(\alpha)]$ , and such is available if the optimal value  $f^*$  of  $P(\epsilon)$  is convex over the set of  $\epsilon = \epsilon(\alpha)$ , using the results for  $f^*$  convex above. In particular, recall that  $f^*$  is convex if  $P(\epsilon)$  is jointly convex. We obtain the following result that gives computable bounds, once a suitable value for  $m$  has been determined.

**Proposition 15** *In addition to the assumptions of Proposition 14, assume that  $x(\epsilon_i)$  solves  $P(\epsilon_i)$  ( $i = 1, \dots, k$ ) and  $\bar{x}(\alpha) = \sum_{i=1}^k \alpha_i x(\epsilon_i)$ , suppose that we also have  $f$  jointly convex in the set of  $\epsilon = \epsilon(\alpha)$  (thus making  $P(\epsilon)$  jointly convex and hence  $f^*$  convex). Then, since  $f^*[\epsilon(\alpha)] \geq L(\alpha)$  from (20), we have from (24) that*

$$\|\bar{x}(\alpha) - x[\epsilon(\alpha)]\| \leq \left( \frac{f[\bar{x}(\alpha), \epsilon(\alpha)] - L(\alpha)}{\frac{m[\epsilon(\alpha)]}{2}} \right)^{\frac{1}{2}} \quad (25)$$

and therefore

$$\|\bar{x}(\alpha) - x[\epsilon(\alpha)]\| \leq \left( \frac{U(\alpha) - L(\alpha)}{\left[ \frac{m[\epsilon(\alpha)]}{2} \right]} \right)^{\frac{1}{2}} \quad (26)$$

for any  $\alpha = (\alpha_1, \dots, \alpha_k)$  such that  $\sum_{i=1}^k \alpha_i = 1$  and  $\alpha_i \geq 0$  ( $i = 1, \dots, k$ ), where  $U(\alpha)$  and  $L(\alpha)$  are given above and we have also used (22).

This provides computable bounds over any  $\epsilon = \epsilon(\alpha)$ , once the solutions  $x(\epsilon_i)$  ( $i = 1, \dots, k$ ) have been determined, provided  $m$  can be calculated or bounded below. There are results that are applicable to the calculation of such a number for important classes of problems. For a fixed  $(x, \epsilon)$ , the value  $m$  can be taken to be the minimum eigenvalue of  $\nabla_x^2 f$ . For  $f$  quadratic, this simplifies, as noted earlier. For this and other important computable cases, see [5].

Our last result gives bounds under the same conditions as Propositions 12, 14 and 15, but using a first order bounding condition on the objective function  $f$ , rather than the second order condition of Proposition 12. It is a simple consequence of the convexity of  $f$ .

**Proposition 16** *Assume as in Proposition 15, except that we now let  $\nabla f[x(\epsilon), \epsilon]z \geq m(\epsilon) \|z\|$  replace the condition that  $z^\top \nabla_x^2 f(x, \epsilon)z \geq m(\epsilon) \|z\|^2$ . Then, it follows that*

$$\|x - x(\epsilon)\| \leq \frac{f(x, \epsilon) - f^*(\epsilon)}{m(\epsilon)} \quad (27)$$

for any  $x \in R(\epsilon)$ . Now, adding the other assumptions of Proposition 15, we get the bounds

$$\begin{aligned} \|\bar{x}(\alpha) - x[\epsilon(\alpha)]\| &\leq \frac{f[\bar{x}(\alpha), \epsilon(\alpha)] - L(\alpha)}{m[\epsilon(\alpha)]} \\ &\leq \frac{U(\alpha) - L(\alpha)}{m[\epsilon(\alpha)]}. \end{aligned} \quad (28)$$

These bounds are mainly of theoretical interest because the verification of our condition involving  $m$  requires the solution  $x(\epsilon)$ . Our condition,  $\nabla_x f z \geq m \|z\|$  is a minimal growth condition on the directional derivative of  $f$  at a solution  $x(\epsilon)$  in any feasible direction. A suitable  $m$  would be the infimum at  $x(\epsilon)$  of  $\nabla_x f z$  for  $\|z\| = 1$  and  $z$  a feasible direction from  $x(\epsilon)$ , providing this is positive. This leads to the more relaxed problem (where  $x = x(\epsilon)$ ):  $\min_z \nabla f z$  s.t.  $\nabla g_i z \geq 0$  for all  $i$  such that  $g_i = 0$  and  $\nabla h_j z = 0$  for all  $j$  and  $\|z\| = 1$ . See the Remark below. This can be formulated as a linear program and precisely corresponds to the search direction problem required for well-known *methods of feasible directions*. Thus, we obtain another connection between optimality, algorithmic and sensitivity analysis calculations.

*Remark 17* With convexity, the condition  $\nabla f z > 0$  at a feasible point, for any feasible direction  $z$ , is sufficient

for unique global minimization at that point. This condition is frequently satisfied at a solution, e. g., it holds at the minimizer of a nondegenerate linear programming problem. We note further that  $\nabla f z \geq 0$  for any such  $z$  is a sufficient condition for a global minimum of a convex problem and is a necessary condition at a local minimizer of a general (i. e., not necessarily convex) differentiable programming problem. It should also be mentioned that at  $x = x(\epsilon)$ , the set of unit vectors  $z$ , such that  $\nabla g_i z \geq 0$  for all  $i$  such that  $g_i = 0$  and  $\nabla h_j z = 0$  for all  $j$ , is the same or larger than the set of unit vectors  $z$  that are feasible directions of  $R(\epsilon)$  from  $x(\epsilon)$ . Thus, the largest acceptable number  $m = \min_z \nabla f z$  at  $x(\epsilon)$  will be the same or smaller for the former set of  $z$  than for the latter set. However, the former set has the advantage of having a simple algebraic formulation and computability (as noted, it yields a linear programming problem). Thus, we can strengthen the quadratic growth condition in Propositions 12, 14 and 15, and the linear growth condition in Proposition 16, to the indicated set of  $z$ . All of these results will then be valid with respect to the newly resulting bounds. Finally, we should mention another appealing fact. With the set of  $z$  so chosen,  $\nabla f z > 0$  at  $x(\epsilon)$  implies that  $x(\epsilon)$  is a strict local minimizer for a general programming problem (i. e., without convexity).

Most of the material in this article and many references can be found in [2]. References [1] and [3] give state-of-the-art tutorials and numerous extensions in a modern setting, along with an extensive bibliography. The bounds result of Proposition 6 for the solution of a linear system of equations can be found in [8, Chap. 6, Sect. 6.4]. Other bounds results may be found in [2] and [5], and many other optimal value convexity and concavity results are given in [4] and [7].

In ► **Sensitivity and stability in NLP** we introduced the parametric nonlinear programming (NLP) problem, gave several examples, mentioned various important applications of sensitivity and stability results for parameter changes and indicated several tools and con-

cepts that have proved effective. We suggest that the reader peruse these preliminaries before reading this continuation of developments.

For convenience, we again state the problem of interest:

$$P(\epsilon) \begin{cases} \min & f(x, \epsilon) \\ \text{s.t.} & g_i(x, \epsilon) \geq 0 \quad (i = 1, \dots, m), \\ & h_j(x, \epsilon) = 0 \quad (j = 1, \dots, p), \end{cases}$$

where  $x \in E^n$  and the parameter (data)  $\epsilon \in T \subseteq E^q$ . We present some basic continuity and differentiability results of the parameter-dependent solution point  $x(\epsilon)$  and optimal value  $f^*(\epsilon)$  of problem  $P(\epsilon)$ . We focus on concrete results for specific classes of problems that are frequently encountered. More general results may be found in more detailed technical treatments elsewhere and a few publications will be noted for reference and further study. In particular, we do not include nonsmooth results or the notions of point-to-set maps, semicontinuity of maps and functions, generalized gradients, alternative definitions of continuity or differentiability, functional or set perturbations (e. g.,  $f$  to  $\tilde{f}$ ,  $g$  to  $\tilde{g}$ ,  $h$  to  $\tilde{h}$ ,  $x \in M$  to  $x \in \tilde{M}$ , etc.) and other very important mathematical concepts, models or instruments that lead to significant extensions and generalizations of the basic results we present. Our purpose here is to provide a quick and hopefully unencumbered introduction and simple exposition of significant rudimentary results.

The results we present require some well-known smoothness properties, optimality conditions and constraint regularity assumptions, called *constraint qualifications*. We briefly review these in the next section.

If  $f$  and  $-g_i$  are convex in  $x$  and  $h_j$  is linear-affine in  $x$ , for all  $i, j$  and any  $\epsilon \in T$ , the problem  $P(\epsilon)$  is said to be *convex* in  $x$ . If these function properties hold jointly in  $(x, \epsilon)$  and  $T$  is a convex set, then  $P(\epsilon)$  is said to be *jointly convex*. For simplicity, continuous differentiability and continuity are assumed.

### Optimality Conditions and Constraint Qualification

Associated with the problem  $P(\epsilon)$  are the *Lagrangian*

$$L(x, u, w, \epsilon) = f(x, \epsilon) - \sum_{i=1}^m u_i g_i(x, \epsilon) + \sum_{j=1}^p w_j h_j(x, \epsilon)$$

and the *optimal value function*

$$f^*(\epsilon) = \begin{cases} \inf_{x \in R(\epsilon)} f(x, \epsilon) & \text{if } R(\epsilon) \neq \emptyset, \\ +\infty & \text{if } R(\epsilon) = \emptyset, \end{cases}$$

where the *feasible region*

$$R(\epsilon) = \left\{ x \in E^n : \begin{array}{l} g_i(x, \epsilon) \geq 0 \quad (i = 1, \dots, m) \\ h_j(x, \epsilon) = 0 \quad (j = 1, \dots, p) \end{array} \right\}.$$

If a local solution  $x(\epsilon)$  is known to exist, then it is understood that the optimal value is the local optimal value  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$  for local results involving  $x(\epsilon)$ . The *solution set*  $S(\epsilon)$  of  $P(\epsilon)$  is defined as

$$S(\epsilon) = \{x \text{ is a local solution} : f(x, \epsilon) = f^*(\epsilon)\}.$$

The following concepts and definitions are needed.

a) The *directional derivative* of  $f^*$  at  $\bar{\epsilon}$  in direction  $z$  is

$$D_z f^*(\bar{\epsilon}) = \lim_{\alpha \rightarrow 0^+} \frac{f^*(\bar{\epsilon} + \alpha z) - f^*(\bar{\epsilon})}{\alpha}.$$

In the next conditions, assume that  $x$  is feasible and that  $\epsilon$  is fixed at some value in  $T$ . Differentiability is assumed as needed.

b) The *Karush–Kuhn–Tucker conditions* (known to be necessary under appropriate regularity conditions at a local solution  $x$  of a differentiable problem) are: there exist  $u \geq 0$  and  $w$  such that (condition KKT( $x, u, w, \epsilon$ ))

$$\begin{cases} \nabla_x L(x, u, w, \epsilon) = 0, \\ u_i g_i(x, \epsilon) = 0 & (i = 1, \dots, m), \\ h_j(x, \epsilon) = 0 & (j = 1, \dots, p), \end{cases}$$

where  $x \in R(\epsilon)$ ,  $u = (u_1, \dots, u_m)$  and  $w = (w_1, \dots, w_p)$  are called *Lagrange multipliers*,  $u \geq 0$  means  $u_i \geq 0$  ( $i = 1, \dots, m$ ), and  $\nabla_x$  denotes the  $n$ -component gradient (row vector) with respect to  $x$ .

The set of Lagrange multipliers  $(u, w)$  that satisfy KKT( $x, u, w, \epsilon$ ) is denoted by  $K(x, \epsilon)$ .

c) The *second order sufficient condition*, noted by SOSOC( $x, u, w, \epsilon$ ), is as follows: KKT( $x, u, w, \epsilon$ ) holds for some  $(u, w)$  at  $x \in R(\epsilon)$  and

$$z^\top \nabla_x^2 L(x, u, w, \epsilon) z > 0$$

for all  $z \neq 0, z \in Z$ , where

$$Z = \left\{ z \in E^n : \begin{array}{l} \nabla_x g_i(x, \epsilon) z \geq 0 \\ \text{for } i \text{ s.t.} \\ g_i(x, \epsilon) = 0; \\ \nabla_x g_i(x, \epsilon) z = 0 \\ \text{for } i \text{ s.t.} \\ g_i(x, \epsilon) = 0, u_i > 0; \\ \nabla_x h_j(x, \epsilon) z = 0 \\ (j = 1, \dots, p) \end{array} \right\}.$$

- d) The *general second order sufficient condition*, designated GSOSC( $x, u, w, \epsilon$ ), requires that SOSOC holds for all  $(u, w) \in K(x, \epsilon)$ .
- e) The *strong second order sufficient condition*, denoted by SSOSC( $x, u, w, \epsilon$ ), is the same as SOSOC( $x, u, w, \epsilon$ ) with one change: the restriction in the set  $Z$ , that  $\nabla_x g_i(x, \epsilon) z \geq 0$  for  $i$  such that  $g_i(x, \epsilon) = 0$ , is dropped.
- f) The *general strong second order sufficient condition*, designated GSSOSC( $x, u, w, \epsilon$ ), requires that SSOSC holds for all  $(u, w) \in K(x, \epsilon)$ .
- g) *strict complementary slackness* at a point  $x$ , noted by SCS( $x, \epsilon$ ), is said to hold if the associated KKT multipliers are such that  $u_i > 0$  for all binding  $g_i$  (i. e., all  $i$  such that  $g_i(x, \epsilon) = 0$ ). (This term derives from the fact that the condition  $u_i g_i = 0$  in the KKT equations is known as *complementary slackness*.)

There are many *constraint qualifications*. We shall give results involving the following three:

- i) The first is *linear independence* at a point  $x \in R(\epsilon)$  of the binding constraint gradients, designated by LI( $x, \epsilon$ ); i. e.,  $\nabla_x g_i(x, \epsilon)$  for  $i$  such that  $g_i(x, \epsilon) = 0$  and  $\nabla_x h_j(x, \epsilon)$  for  $j = 1, \dots, p$  are linearly independent.
- ii) The *Mangasarian–Fromovitz constraint qualification* holds at  $x \in R(\epsilon)$ , noted by MFCQ( $x, \epsilon$ ), if: a) there exists a vector  $z$  such that  $\nabla_x g_i(x, \epsilon) z > 0$  for all  $i$  such that  $g_i(x, \epsilon) = 0$  and  $\nabla_x h_j(x, \epsilon) z = 0$  for  $j = 1, \dots, p$ ; and b) the vectors  $\nabla_x h_j(x, \epsilon)$  ( $j = 1, \dots, p$ ) are linearly independent.
- iii) The *generalized Slater constraint qualification*, denoted by GS( $\epsilon$ ), holds for the convex problem  $P(\epsilon)$  if there exists a feasible point  $\bar{x}$  such that  $g_i(\bar{x}, \epsilon) > 0$  for all  $i$  and such that  $\nabla_x h_1(\bar{x}, \epsilon), \dots, \nabla_x h_p(\bar{x}, \epsilon)$  are linearly independent. For  $P(\epsilon)$  convex, MFCQ holding at each feasible point and GS are equivalent.

The following well known results can now be stated, for the standard nonparametric problem  $P(\epsilon)$ , i. e., with  $\epsilon$  fixed:

- a)  $\text{SOSC}(\bar{x}, u, w, \epsilon)$  implies that  $\bar{x}$  is a *strict local minimizer* (i. e., the unique global minimizer over the intersection of the feasible region and some neighborhood of  $\bar{x}$ );
- b)  $\text{GSOSC}(\bar{x}, u, w, \epsilon)$ ,  $u, w, \epsilon$  and  $\text{MFCQ}(\bar{x}, \epsilon)$  imply that  $\bar{x}$  is an *isolated local minimizer* (i. e., the unique local minimizer in the intersection of the feasible region and some neighborhood of  $\bar{x}$ );
- c) Although  $\text{GSSOSC}$  at  $\bar{x}$  implies  $\text{GSOSC}$  at  $\bar{x}$  and also implies  $\text{SSOSC}(\bar{x}, u, w, \epsilon)$ , which implies  $\text{SOSC}(\bar{x}, u, w, \epsilon)$ ,  $u, w, \epsilon$ , the condition  $\text{GSSOSC}$  alone does not imply that  $\bar{x}$  is an isolated local minimizer. A constraint qualification is needed, along with each second order condition, as in b) above and as in Propositions 8, 9 and 10 below. In fact, even the much stronger conditions,  $\text{KKT}(\bar{x}, u, w, \epsilon)$  and  $z^T \nabla_x^2 L(x, u, w, \epsilon)z > 0$  for all  $z \neq 0$  and any  $x$  and any  $(u, w) \in K(\bar{x}, \epsilon)$ , do not imply that  $\bar{x}$  is an isolated local minimizer. (See the counterexample by S.M. Robinson in [2, p. 71].)
- d) If  $x$  is a local minimizer and  $\text{LI}(\bar{x}, \epsilon)$  or  $\text{MFCQ}(\bar{x}, \epsilon)$  holds, then  $\text{KKT}(\bar{x}, u, w, \epsilon)$  holds. If  $\text{LI}(\bar{x}, \epsilon)$  holds, then the Lagrange multipliers  $(u, w)$  are unique.  $\text{MFCQ}(\bar{x}, \epsilon)$  holds if and only if the set of associated Lagrange multipliers satisfying  $\text{KKT}(\bar{x}, u, w, \epsilon)$  is nonempty, compact and convex. If  $\text{LI}(\bar{x}, \epsilon)$  holds, then  $\text{MFCQ}(\bar{x}, \epsilon)$  holds. Therefore, it follows from b) that  $\text{SOSC}(\bar{x}, u, w, \epsilon)$  and  $\text{LI}(\bar{x}, \epsilon)$  imply that  $\bar{x}$  is an isolated local minimizer.

*Remark 1* A stronger form of  $\text{MFCQ}$  is necessary and sufficient for a unique Lagrange multiplier, but will not be used here.

- e) If problem  $P(\epsilon)$  is convex, then any local solution is global and the solution set is convex, and if the  $\text{KKT}(\bar{x}, u, w, \epsilon)$  holds, then  $\bar{x}$  is a global solution. Also, if  $\text{GS}(\epsilon)$  holds, then so does  $\text{KKT}(x, u, w, \epsilon)$  at any local solution  $x$ .

With this brief perspective, we present several basic sensitivity and stability results that hold for problem  $P(\epsilon)$ . We avoid detail and focus only on certain key implications of the assumptions.

**Proposition 2** *For the once differentiable problem with nonempty uniformly compact feasible region  $R(\epsilon)$ , for  $\epsilon$*

*near  $\bar{\epsilon}$ , the optimal value function  $f^*$  is continuous at  $\bar{\epsilon}$  if  $\text{MFCQ}$  holds for some  $x \in S(\bar{\epsilon})$ .*

**Proposition 3** *The optimal value function  $f^*$  is convex on  $T$  if  $P(\epsilon)$  is jointly convex in  $(x, \epsilon)$  as defined. Assuming solution attainment, this further implies that  $f^*$  is continuous and directionally differentiable in the interior of  $T$ .*

**Proposition 4** *If  $R$  does not vary with  $\epsilon$  and  $f$  is concave in  $\epsilon$ , and  $T$  is convex, then  $f^*$  is concave on  $T$ . Again, assuming the solution is attained, this means  $f^*$  is continuous and directionally differentiable in the interior of  $T$ .*

**Proposition 5** *Suppose  $R(\epsilon) \neq \emptyset$  and compact and does not change with  $\epsilon$ , and assume  $f$  and  $\nabla_\epsilon f$  are continuous in  $(x, \epsilon)$ . Then, at any  $\epsilon \in T$ , it follows that  $S(\epsilon) \neq \emptyset$  and compact and the directional derivative  $D_z f^*$  exists for any direction  $z$  and is given by*

$$D_z f^*(\epsilon) = \min_x \nabla_\epsilon f(x, \epsilon)z \quad \text{s.t. } x \in S(\epsilon). \quad (1)$$

**Proposition 6** *Assume that the problem  $P(\epsilon)$  is convex in  $x$  for each  $\epsilon \in T$  convex and the problem functions are once continuously differentiable in  $(x, \epsilon)$ . Then, if  $\bar{\epsilon} \in \text{interior } T$  and the set of points satisfying  $\text{KKT}(x, u, w, \bar{\epsilon})$  is nonempty and bounded, or equivalently, if the solution set  $S(\epsilon) \neq \emptyset$  and bounded (hence compact) and the Slater constraint qualification  $\text{GS}(\epsilon)$  holds for  $P(\epsilon)$  with  $\epsilon = \bar{\epsilon} \in \text{interior } T$ , then in a neighborhood  $N(\bar{\epsilon})$  of  $\bar{\epsilon}$ ,  $\text{GS}(\epsilon)$  holds,  $S(\epsilon) \neq \emptyset$  (and  $S(\epsilon)$  is convex) for each  $\epsilon \in N(\bar{\epsilon})$  and  $S(\epsilon)$  is uniformly compact in  $N(\bar{\epsilon})$ . Furthermore,  $f^*$  is continuous and directionally differentiable in  $N(\bar{\epsilon})$  and in any direction  $z$  and*

$$D_z f^*(\epsilon) = \min_{x \in S(\epsilon)} \max_{(u, w) \in K(x, \epsilon)} \nabla_\epsilon L(x, u, w, \epsilon)z, \quad (2)$$

where  $K(x, \epsilon)$  is the set of  $(u, w)$  such that  $\text{KKT}(x, u, w, \epsilon)$  holds.

*Remark 7* As indicated, the assumption  $\text{GS}$  is equivalent to  $\text{MFCQ}$  or to assuming  $K(x, \epsilon) \neq \emptyset$  and bounded at a local solution. Dispensing with convexity but assuming  $\text{LI}(x, \epsilon)$  holds for each  $x \in S(\epsilon)$ , rather than  $\text{GS}(\epsilon)$ , we have for each  $K(x, \epsilon)$  a singleton set  $\{(u(x), w(x))\}$  and hence

$$D_z f^*(\epsilon) = \min_{x \in S(\epsilon)} \nabla_\epsilon L(x, u(x, \epsilon), w(x, \epsilon), \epsilon)z. \quad (3)$$

Suppose we assume that the functions defining  $P(\epsilon)$  are twice continuously differentiable in  $(x, \epsilon)$ . Then, we have the following second order results.

**Proposition 8** *If  $\text{KKT}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$ ,  $\text{SOSC}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$  and  $\text{LI}(\bar{x}, \epsilon)$  and  $\text{SCS}(\bar{x}, \epsilon)$  hold for  $\bar{x} \in R(\epsilon)$  at  $\epsilon = \bar{\epsilon} \in \text{interior } T$ , then there exists a locally unique and once continuously differentiable vector function  $(x, u, w)$  such that  $[x(\bar{\epsilon}), u(\bar{\epsilon}), w(\bar{\epsilon})] = (\bar{x}, \bar{u}, \bar{w})$  and such that these assumptions continue to hold at  $[x(\epsilon), u(\epsilon), w(\epsilon)]$  in a neighborhood  $N(\bar{\epsilon})$  of  $\bar{\epsilon}$ . This implies that  $x(\epsilon)$  is an isolated local minimizer with associated unique Lagrange multipliers  $[u(\epsilon), w(\epsilon)]$ . Furthermore,  $f^*$  is continuous and in fact twice continuously differentiable in  $N(\bar{\epsilon})$ , where  $f^*(\epsilon) = f[x(\epsilon), \epsilon]$ .*

**Proposition 9** *Suppose  $\text{KKT}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$  and  $\text{SSOSC}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$  and  $\text{LI}(\bar{x}, \epsilon)$  hold for  $\bar{x} \in R(\bar{\epsilon})$  and  $\bar{\epsilon} \in \text{interior } T$ . Then there exists  $(x, u, w)$  continuous and locally unique in  $N(\bar{\epsilon})$  such that  $[x(\bar{\epsilon}), u(\bar{\epsilon}), w(\bar{\epsilon})] = (\bar{x}, \bar{u}, \bar{w})$  and such that the assumptions persist at  $[x(\epsilon), u(\epsilon), w(\epsilon)]$  and as before,  $x(\epsilon)$  is an isolated local minimizer with associated unique Lagrange multipliers  $[u(\epsilon), w(\epsilon)]$ . Now, it turns out that for  $\epsilon \in N(\bar{\epsilon})$ ,  $x, u, w$  are Lipschitz and directionally differentiable, and  $f^*$  is continuous and once continuously differentiable and twice directionally differentiable.*

**Proposition 10** *If we again assume  $\text{KKT}(\bar{x}, \bar{u}, \bar{w}, \epsilon)$  and further strengthen the second order conditions to  $\text{GSSOSC}(\bar{x}, u, w, \epsilon)$  and now assume  $\text{MFCQ}(\bar{x}, \epsilon)$ , for  $\bar{x} \in R(\epsilon)$  and  $\epsilon = \bar{\epsilon} \in \text{interior } T$ , it follows that there exists a locally unique vector function  $x$  for  $\epsilon \in N(\bar{\epsilon})$  such that  $x(\bar{\epsilon}) = \bar{x}$  and once again the assumptions continue to persist at  $x$  and its associated nonempty compact convex set of Lagrange multipliers also exists as a result of  $\text{MFCQ}$  continuing to hold in  $N(\bar{\epsilon})$ . Again,  $x(\epsilon)$  is an isolated local minimizer, but now we can show only that  $x$  is continuous and  $f^*$  is once directionally differentiable. It follows that for  $\epsilon \in N(\bar{\epsilon})$ ,*

$$D_z f^*(\epsilon) = \max_{(u, w) \in K[x(\epsilon), \epsilon]} \nabla_{\epsilon} L[x(\epsilon), u, w, \epsilon] z. \quad (4)$$

Propositions 6–10 demonstrate what we have called *assumption stability* (i. e., persistence of initial assumptions). A unique local solution with the given properties continues to be locally unique and continuous and sometimes even differentiable, with continuous small

data changes, and satisfying characterizations follow. All of the results we have given are now very well known and have been finely tuned, most therefore invoking close to ‘minimal assumptions’. Weaker conditions will generally significantly change the conclusions. For example if  $\text{GSSOSC}$  is replaced by the weaker condition  $\text{GSOSC}$  in the assumptions given in Proposition 10, then the perturbed solution  $x(\epsilon)$  need no longer be locally unique, although the initial solution  $\bar{x} = x(\bar{\epsilon})$  is an isolated local minimizer. Assumption stability is lost, since  $\text{GSOSC}$  does not persist.

We offer a few observations concerning the rate of change of the optimal value  $f^*(\epsilon)$ , with data changes. See (2).  $D_z f^*$  is itself an optimal value, a contribution to which comes either from  $f$  or from the  $g_i$  and  $h_j$ , through the Lagrangian, its value generally depending on the problem solution set and the optimal set of Lagrange multipliers. Note that if the constraints are not dependent on the parameter  $\epsilon$ , then (2), (3) and (4) all collapse to formula (1):  $D_z f^*(\epsilon) = \min_{S(\epsilon)} \nabla_{\epsilon} f(x, \epsilon) z$ , formula (4) reducing to (1) without the min, as expected from Proposition 5. Note further that this formula does not depend on the Lagrange multipliers, but only on the behavior of  $f$  over the solution set. On the other hand, if  $f$  does not depend on  $\epsilon$ , the dependency is all on the constraints and multipliers. In particular, consider the so-called *right-hand side perturbation problem*

$$P_1(\epsilon) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & g_i(x) \geq \epsilon_i \quad (i = 1, \dots, m), \\ & h_j(x) = \epsilon_j + m \quad (j = 1, \dots, p). \end{cases}$$

Then, applying the results given in Propositions 6 and 10, assuming for simplicity that the local solution  $x(\epsilon)$  and its associated optimal Lagrange multipliers  $(u(\epsilon), w(\epsilon))$  are unique, and using formulas (2), (3) or (4), we find that

$$D_z f^*(\epsilon) = [u(\epsilon), -w(\epsilon)]^T z \quad (5)$$

Thus, the directional rate of change of  $f^*$  with respect to changes in the constraint values is captured entirely by the optimal Lagrange multipliers, e. g., at the local minimizer  $x(\epsilon)$  the rate of change of  $f^*(\epsilon)$  along a unit vector in the direction of  $\epsilon_i$ ,  $1 \leq i \leq m$ , is given by  $u_i(\epsilon)$ . This is an extremely important and well known result. In ap-

plications, it translates to the multipliers being *shadow prices* (i. e., imputed values) of resource levels.

Two simple examples may help to clarify some of these results. The interested reader should graph these problems to appreciate the geometry.

*Example 11* (Assume  $|\epsilon| \leq 1/2$ .)

$$P(\epsilon) \begin{cases} \min & \epsilon x_1 + x_2 \\ \text{s.t.} & x_1 \geq 0, \quad x_2 \geq 0, \\ & x_1 + x_2 \geq 1, \quad x_1^2 + x_2^2 \leq 4. \end{cases}$$

The solution is  $S(0) = \{x \in E^2 : 1 \leq x_1 \leq 2, x_2 = 0\}$ ,  $f^*(0) = 0$ ;  $S(\epsilon) = (1, 0)$  and  $f^*(\epsilon) = \epsilon$  for  $\epsilon > 0$ ; and  $S(\epsilon) = (2, 0)$  with  $f^*(\epsilon) = 2\epsilon$  for  $\epsilon < 0$ . It follows that  $D_z f^*(0) = \min_{S(0)} \nabla_{\epsilon} f[x(0), 0]z = \min_{S(0)} x_1 z = z$  if  $z > 0$  and  $2z$  if  $z < 0$ , which agrees with the values that follow by direct calculation of the closed form solution. We also note that the optimal value is concave, agreeing with results given previously, since  $f$  is concave in  $\epsilon$  and the feasible region  $R$  is fixed. (Note that the problem is convex in  $x$ , Slater's condition holds, and  $S(0)$  is bounded, so Propositions 4, 5 and 6 all apply.)

The next example is trivial, but illustrative.

*Example 12*

$$\begin{cases} \min & x_2 \\ \text{s.t.} & x_2 - x_1^2 \geq \epsilon. \end{cases}$$

The solution is  $x(\epsilon) = (0, \epsilon)$ , the optimal value  $f^*(\epsilon) = \epsilon$  and the optimal Lagrange multiplier is  $u(\epsilon) = 1$ , for any  $\epsilon$ . The problem is jointly convex and Slater's condition holds. The solution is unique, LI and SCS hold and in fact all the given second order conditions hold for this problem, so all the results we have given for these will hold. In particular, we see that  $D_z f^*(\epsilon) = u(\epsilon)z = z$ , as expected. Note that  $f^*$  is convex and differentiable and  $x(\epsilon)$  and  $u(\epsilon)$  are unique and differentiable, all as predicted by the theory.

There are many variations and extensions of the small sample of results that we have presented here. We have only been able to give the reader a flavor of this interesting and important subject.

Many references exist and many would have to be cited, if we were to give proper credit to all the many re-

searchers who have contributed, even to the handful of results presented. Rather than attempt this, we refer the reader to three references. These references contain numerous tutorials and hundreds of additional references and should provide a quicker introduction to the subject than initially attempting to study scholarly papers scattered in the literature.

## Keywords and Phrases

Mixed integer nonlinear programming; Extended cutting plane; Sequential cutting plane; Branch and bound

The SCP (Sequential Cutting Plane) algorithm [6,7,8] can be used for solving both NLP (Nonlinear Programming) and MINLP (Mixed Integer Nonlinear Programming) problems efficiently. For convex problems the algorithm finds global optimal solutions. For non-convex problems, global optimality cannot be guaranteed. Nevertheless, the algorithm can also be used on non-convex problems to find good approximations of the global optimal solution.

The SCP algorithm presented here uses a branch and bound strategy to solve MINLP problems where an NLP problem is solved in each integer node of the tree. The NLP problems are not solved to optimality, rather one iteration step is taken at each integer node of the tree and linearizations of the nonlinear constraints are added as cuts to the problem. The iteration step consists of performing an NLP iteration as described in [6,8], where the algorithm solves a sequence of linear programming problems. Note that in [7], the approach was different than the one used here. In [7], an NLP iteration was performed in each node of the branch and bound tree, which can be inefficient in difficult combinatorial problems where the branch and bound tree is large.

## Formulation

The SCP algorithm solves problems of the form

$$\begin{aligned} \min \quad & f(x, y), \\ \text{s.t.} \quad & g_j(x, y) \leq 0, j = 1, \dots, m, x \in X, y \in Y. \end{aligned} \quad (1)$$

The set  $X$  is a bounded, box-constrained set of the form  $X = \{x \in \mathbb{R}^{n_r} | x^{LB} \leq x \leq x^{UB}\}$  and the set  $Y$  is a finite bounded set  $Y = \{y \in \mathbb{Z}^{n_z} | y^{LB} \leq y \leq y^{UB}\}$ . The functions  $f$  and  $g$  are convex and continuously differentiable.

The performance of the algorithm on a difficult set of block optimization problems, see [2], is presented. The ECP (Extended Cutting Plane) algorithm [9,10] proved to be very efficient in [2] for solving these types of optimization problems. The SCP algorithm further

enhances the ideas from the Extended Cutting Plane algorithm in order to solve these difficult MINLP problems even more efficiently.

## Methods

The problem (1) is solved by the SCP algorithm by doing a normal branch and bound procedure on a relaxed version of (1). In each integer node of the tree, the integer variables are fixed. An NLP iteration is then performed on the NLP subproblem obtained by fixing the integer variables. If the iterate is optimal, the solution in the integer node is an upper bound on the optimal solution of the original problem (1) and can be used for dropping nodes from the tree. If not, linearizations of the nonlinear constraints are added in the current iterate as cuts to the relaxed version of (1) and the branching process is continued.

## Branch and Bound

The root node  $\bar{P}^1$  of the tree is constructed by relaxing (1) such that the integer requirements and the nonlinear constraints from the problem formulation are dropped. If some of the constraints  $g_j(x, y) \leq 0$ ,  $j = 1, \dots, m$ , are linear, they can be kept in the relaxed problem.

A branch and bound procedure, see [4], is then performed on this linear relaxation until an integer feasible node  $\bar{P}^k$  is obtained. In this node, the integer variables  $y^k$  are fixed and an NLP iteration is performed in order to solve the NLP subproblem

$$\begin{aligned} \min \quad & f(x, y^k), \\ \text{s.t.} \quad & g(x, y^k) \leq 0, x \in X. \end{aligned} \quad (2)$$

Note that the problem is not solved to optimality. Instead one NLP iteration is performed in order to get a good approximation of the optimal solution to the subproblem. Let  $x^k$  be the iterate obtained after the NLP iteration on (2).

The iterate  $(x^k, y^k)$  can be used to add linearizations of the violated and active nonlinear constraints in  $(x^k, y^k)$ ,

$$\begin{aligned} g_j(x^k, y^k) + \nabla g_j(x^k, y^k)^T (x - x^k, y - y^k) \leq 0, \\ j \in \{j : g_j(x^k, y^k) \geq 0\}, \end{aligned}$$

to the set of cuts  $\Omega_k$  in order to obtain a new set of cuts  $\Omega_{k+1}$ .

If  $x^k$  is the optimal solution to (2), then  $f(x^k, y^k)$  is an upper bound of the optimal solution to (1) and can be used to drop unexplored nodes from the branch and bound tree whenever the lower bounds of the nodes are greater than this upper bound.

### NLP Iteration

The NLP subproblem (2) is solved by performing an NLP iteration [6,8]. In an NLP iteration, a sequence of linear programming (LP) subiterations is performed. In each subiteration ( $i$ ) within the NLP iteration, an LP problem  $LP(x^{(i)})$  is generated in the current iterate  $(x^{(i)}, y^k)$ . The LP problem  $LP(x^{(i)})$  is of the form

$$\begin{aligned} \min \quad & \nabla f(x^{(i)}, y^k)^T d + Ct, \\ \text{s.t.} \quad & g_j(x^{(i)}, y^k) + \nabla g_j(x^{(i)}, y^k)^T d - t \leq 0, \\ & j = 1, \dots, m, \\ & (d^{(r)})^T H^{(i)} d = 0, r = 1, \dots, i-1, \quad i > 1, \\ & t \geq 0, \\ & x^{(i)} + d_x \in X, d_y = \mathbf{0}, \end{aligned}$$

where  $d = (d_x, d_y)$ , and  $d^{(r)}, r = 1, \dots, i-1$ , are the previously obtained search directions within the NLP iteration. Also,  $H^{(i)}$  is the current estimate of the Hessian of the Lagrangian

$$L(x, \lambda) = f(x, y^k) + \sum_{j=1}^m \lambda_j g_j(x, y^k).$$

The BFGS update formula was used in the implementation of the algorithm to approximate  $H^{(i)}$ .

The dual optimal solution to the LP problem  $LP(x^{(i)})$  provides a Lagrange multiplier estimate, which can be used when estimating the Hessian of the Lagrangian. Consequently, the Hessian approximation can be updated in each LP subiteration.

The solution to each LP problem  $LP(x^{(i)})$  provides a search direction  $d^{(i)} = (d_x^{(i)}, \mathbf{0})$ . A line search is performed in the obtained search direction minimizing a modified function based on the Lagrangian of (2),

$$\begin{aligned} \tilde{L}(x, \lambda) = f(x, y^k) + \sum_{j=1}^m \lambda_j g_j(x, y^k)^+ \\ + \rho \sum_{j=1}^m (g_j(x, y^k)^+)^2, \end{aligned}$$

where  $g_j(x, y^k)^+ = \max(g_j(x, y^k), 0)$  and  $\rho (> 0)$  is a penalty parameter.

The current iterate  $(x^{(i)}, y^k)$  is then updated using the solution  $\alpha^{(i)}$  of the line search such that  $x^{(i+1)} = x^{(i)} + \alpha^{(i)} d_x^{(i)}$ , where  $\alpha^{(i)}$  is the step length found in the line search.

A new LP problem is then constructed in the updated iterate  $(x^{(i+1)}, y^k)$ . The new LP problem is constructed in a similar way as the previous LP problem with equality constraints requiring the new search direction to be a conjugate direction to the previously obtained search directions with respect to the current estimate of the Hessian of the Lagrangian.

The linear equality constraints

$$(d^{(r)})^T H^{(i)} d = 0, \quad r = 1, \dots, i-1,$$

are cutting hyperplanes ensuring that  $d$  will be a conjugate direction to the old directions  $d^{(r)}$ .

**Initialize:** Do a number of NLP iterations on the continuous relaxation of (1) to obtain the initial iterate for the problem. Construct the relaxed node  $\bar{P}^1$  and insert it into the branch and bound tree as the top node and set the upper bound  $U = \infty$ . Add cutting planes for the initial iterate to the set of cutting planes  $\Omega_1$ . Let  $k = 1$ .

**While** (there are unexamined nodes in the tree) **do**

1. Do normal branching on the branch and bound tree including the cutting planes  $\Omega_k$  as linear cuts until integer solution  $(\tilde{x}^k, y^k)$  found.
2. Fix  $y^k$  and perform an NLP iteration on (2). Let the iterate after the NLP iteration be  $x^k$ .
3. **If** solution  $x^k$  optimal for (2) Then update upper bound  $U := \min\{U, f(x^k, y^k)\}$ .
4. **If** (2) is found to be infeasible Then let  $x^k$  be the last iterate from the NLP iteration.
5. Let  $\Omega_{k+1} = \Omega_k$ . Add cutting planes generated in  $(x^k, y^k)$  for the active and violated constraints and add them to  $\Omega_{k+1}$ . Let  $k := k+1$ .

**End While**

**Sequential Cutting Plane Algorithm, Algorithm 1**  
Pseudo-code for the SCP algorithm

The new LP problem is then solved, a new line search performed and the iterate updated again. The procedure is repeated until the LP problem becomes infeasible, a sufficient number of steps have been taken or the current solution to the LP problem is sufficiently close to zero.

Normally, the NLP iteration would then be repeated until an optimal point is found. However, in this version of the algorithm only one NLP iteration is performed in each integer node of the branch and bound tree in order to improve the performance of the algorithm.

Convergence properties of the NLP version of the SCP algorithm have been analyzed in earlier papers, see [6] and [8].

### Algorithm Pseudo-Code

The algorithm is summarized in Algorithm 1.

### Cases

The performance of the algorithm is illustrated on a set of difficult block optimization problems presented in [2]. The paper concerns optimizing the arrangement of a number of departments with unequal area requirements. It is possible to formulate the problems as mixed integer nonlinear programming problems, where the constraints are department and floor area requirements as well as department locational restrictions. The optimization target is to minimize the cost associated with the projected interactions between departments. In [2], the Extended Cutting Plane method was compared to a number of commercial algorithms and proved to be superior to the other solvers.

In Table 1 the results for the solvers in [2] are summarized in terms of the number of problems solved to optimality, number of problems for which a feasible solution was obtained and number of problems for which

no solution was obtained within 12 h of CPU time. More information about the solvers used can be found in [1].

The results are excellent for the  $\alpha$ -ECP algorithm on these test problems. It only failed to solve one problem to global optimality and obtained the best integer feasible solution for the problem it could not solve to global optimality.

In Fig. 1 the results of the new SCP algorithm are compared with the  $\alpha$ -ECP algorithm using a performance profile [3]. The results are also compared with a version where each integer node is solved to optimality by repeating the NLP iterations until an optimal solution to (2) is found. This version of the SCP algorithm is denoted SCP-NLP. Note that if you solve the integer nodes to optimality, the procedure is similar to the method described in [5]. CPLEX was used as the MILP solver and the NLP part of the algorithm was implemented in MATLAB. A maximum of 12 CPU h for each problem was used when solving the problems.

As can be seen from the results, the SCP algorithm performed very well on the test problems. In more than half of the cases it was the fastest solver. Considering that some of these problems can take several hours to solve, the performance improvement is significant.

In Fig. 2 the best-known solutions of the SCP and  $\alpha$ -ECP solvers, when running the solvers for a maximum of 60 CPU s, are compared with the best-known solutions for the other solvers in [2], when running these solvers for a maximum of 12 CPU h.

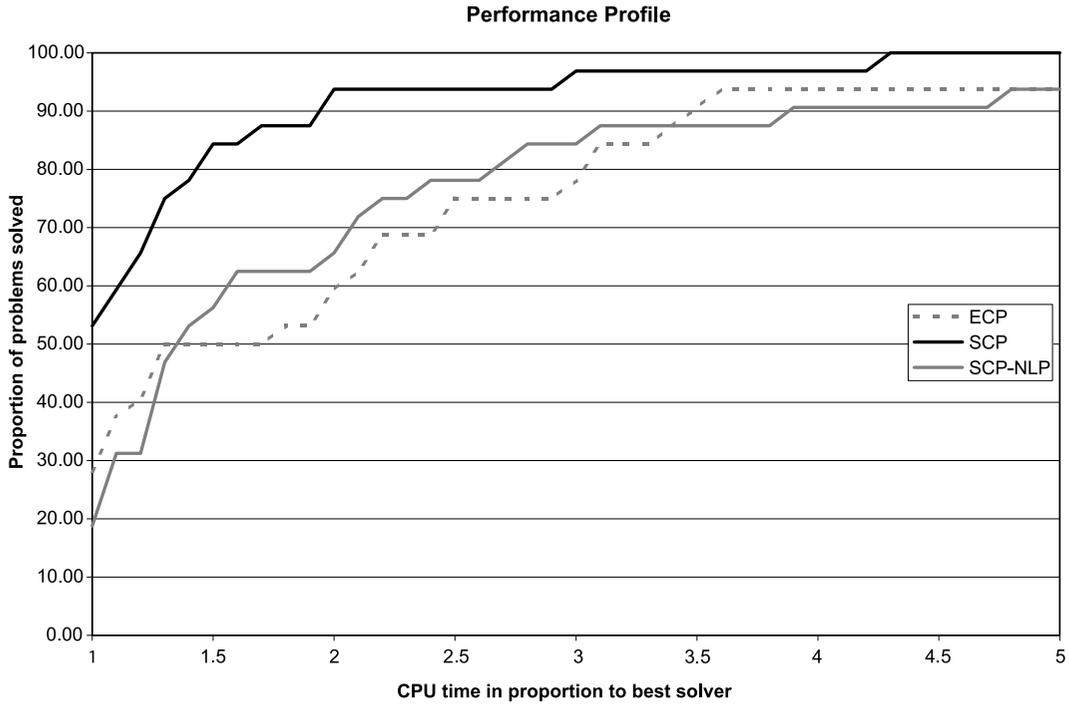

Note that both the SCP and  $\alpha$ -ECP solvers return very good solutions after 60 CPU s in comparison with the other solvers that were run for a maximum of 12 CPU h. In fact, the SCP algorithm reported the best-known solution in almost half of the cases. Thus, the SCP algorithm can also be used for efficiently finding good solution candidates, when the problems are too difficult to solve to the global optimum.

**Sequential Cutting Plane Algorithm, Table 1**  
Performance of the solvers on the block layout problem as reported in [2]

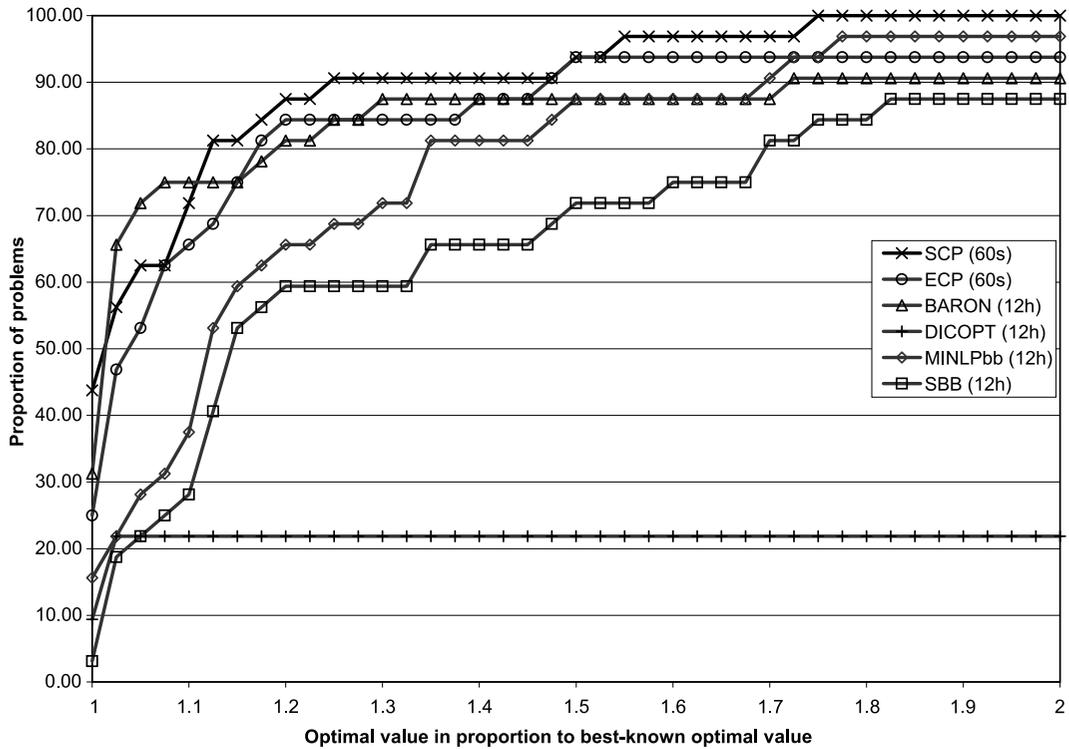

Solution	BARON	DICOPT	MINLPbb	SBB	$\alpha$ -ECP
Optimal	13	5	5	5	31
Feasible	16	2	27	23	1
No solution	3	25	0	4	0

### Conclusions

The Sequential Cutting Plane algorithm is well-suited for solving mixed integer nonlinear programming problems. The numerical results above for a set of challenging block layout problems support this claim. Another advantage is that the algorithm will efficiently find a good feasible solution to a problem, even when the

Sequential Cutting Plane Algorithm, Figure 1  
Performance profile comparing CPU times for solving the block layout problems

Sequential Cutting Plane Algorithm, Figure 2  
Performance profile comparing the optimal values of the solvers. Observe that 60 CPU seconds is used for SCP/ECP and 12 CPU hours for the other solvers

problem is not solved to optimality. Thus, difficult combinatorial optimization problems in real-world applications could be solved by combining the SCP algorithm with some non-deterministic approach such as an evolutionary algorithm.

Optimal control problem; Partial differential equations; Sequential quadratic programming; Interior point methods

For the purpose of this article, *distributed optimal control problems* are optimization problems which are posed in function space and in which one of the constraints is a partial differential equation. An example of such a problem is

$$\left\{ \begin{array}{l} \min \quad \frac{1}{2} \int_{\Omega} (y(x) - \widehat{y}(x))^2 dx + \frac{\omega}{2} \int_{\Gamma} u^2(x) dx \\ \text{s.t.} \quad -\Delta y(x) + y^3(x) - y(x) = 0 \quad \text{in } \Omega, \\ \quad \frac{\partial}{\partial n} y(x) = u(x) \quad \text{in } \Gamma, \\ \quad u_l(x) \leq u(x) \leq u_u(x) \quad \text{a.e. on } \Gamma, \\ \quad y_l(x) \leq y(x) \leq y_u(x) \quad \text{a.e. in } \Omega, \end{array} \right.$$

where  $\Omega$  is a bounded open domain in  $\mathbf{R}^2$ ,  $\Gamma$  is the boundary of  $\Omega$ ,  $\omega > 0$  is a given parameter, and the functions  $u_l$ ,  $u_u$ ,  $\widehat{y}$ ,  $y_l$ ,  $y_u$  are given. The functions  $y$  and  $u$  are called the *states* and *controls*, respectively. The partial differential equation including the boundary conditions is called the *state equation* or the *governing equation*.

Abstractly, a distributed optimal control problem may be written as

$$\min J(y, u), \quad (1)$$

such that

$$c(y, u) = 0, \quad (2)$$

$$u \in U_{\text{ad}}, \quad (3)$$

$$y \in Y_{\text{ad}}, \quad (4)$$

where  $Y$ ,  $C$  are Hilbert spaces,  $U$  is a Banach space,  $Y_{\text{ad}} \subset Y$ ,  $U_{\text{ad}} \subset U$  are closed convex sets, and  $J: Y \times U \rightarrow \mathbf{R}$ ,  $c: Y \times U \rightarrow C$  are twice Fréchet differentiable functions.

In the previous example,  $Y = H^1(\Omega)$ ,  $C = (H^1(\Omega))_*$ ,  $U = L^2(\Gamma)$ , and  $Y_{\text{ad}} = \{y \in H^1(\Omega): y_l \leq y \leq y_u \text{ a.e. in } \Omega\}$ ,  $U_{\text{ad}} = \{u \in L^2(\Gamma): u_l \leq u \leq u_u \text{ a.e. in } \Gamma\}$ . Several optimal control problems that fit into this framework are studied in [4,7,8,12]. This problem formulation also covers *optimal design problems* [5,9] and *parameter identification problems*.

After a discretization of the problem (1)–(4) using, e. g., finite elements, one often obtains a *nonlinear programming problem* of the form

$$\min J^h(y^h, u^h), \quad (5)$$

such that

$$c^h(y^h, u^h) = 0, \quad (6)$$

$$u_l^h \leq u^h \leq u_u^h, \quad (7)$$

$$y_l^h \leq y^h \leq y_u^h, \quad (8)$$

where  $y^h \in \mathbf{R}^{n_y}$ ,  $u^h \in \mathbf{R}^{n_u}$  and  $J^h: \mathbf{R}^{n_y+n_u} \rightarrow \mathbf{R}$ ,  $c^h: \mathbf{R}^{n_y+n_u} \rightarrow \mathbf{R}^{n_c}$  are twice differentiable functions. The number of discretized states  $n_y$  tends to be large. Depending on the type of control,  $n_u$  can be small (boundary control) or large (distributed control).

Sequential quadratic programming interior point (SQPIP) methods have been used to solve distributed optimal control problems. See, e. g., [2,3,5,7,9,10,11]. While the various SQPIP methods differ, they share some important design features. In each iteration a subproblem is solved that only involves a linearization of the state equation (2) or (6) and a quadratic approximation of the Lagrangian  $L^h(y^h, u^h, \lambda^h) = J^h(y^h, u^h) + \langle c^h(y^h, u^h), \lambda^h \rangle$ . All iterates stay strictly feasible with respect to the bounds, but the nonlinear state equation is only satisfied in the limit. SQPIP methods attempt to achieve feasibility and optimality at the same time. Such all-at-once approaches are usually more efficient than solution approaches that maintain feasibility of the nonlinear state equation at every iteration. For a general introduction to SQP methods and interior point methods for nonlinear programming problems see ► **Successive quadratic programming: Solution by active sets and interior point methods**; ► **Linear programming: Interior point methods**.

This article focuses on the application of SQPIP methods to distributed optimal control problems.

For such problems *affine scaling SQPIP methods* [3] and various versions of *primal-dual SQPIP methods* ([2,5,7,9,10,11]) have been used. Primal-dual interior point methods have been applied to the nonlinear problem (5)–(8) directly or as inequality constrained quadratic programming subproblem solvers. In all references above, SQPIP methods have been applied to *discretized optimal control problems* (5)–(8). While these applications have been successful, there are several open research issues. The development of SQPIP methods for large scale nonlinear programming problems is a very active research area. Additional research issues arise when SQPIP methods are applied to distributed optimal control problems. The latter research issues and achievements will be described in the following.

Distributed optimal control problems have a particular problem structure. It is derived from the underlying infinite-dimensional problem and from the division of optimization variables into states and controls. Since one is interested in the solution of the infinite-dimensional problem (1)–(4), one needs to consider sequences of discretized problems (5)–(8). While for a fixed discretization the nonlinear programming framework may be applicable, the underlying infinite-dimensional problem is important when sequences of successively refined discretizations are considered. It is important to understand the convergence behavior of the SQPIP algorithm in the infinite-dimensional setting, because this often dominates the convergence behavior of the algorithm for the discretized problem when the discretization is fine. Convergence results in [2,11] for SQPIP algorithms applied to elliptic optimal control problems show that in several cases the number of optimization iterations increases only slowly, if at all, when the discretization is refined. This indicates that there might be an underlying infinite-dimensional convergence theory. However, such a theory is not yet known for most interior point algorithms. Currently, the only analyses of interior point methods for infinite-dimensional problems are [6,13,14].

Most available SQPIP algorithms for nonlinear programming use sparse direct linear algebra to solve subproblems. This is not suitable for many distributed optimal control problems. Here, subproblems involve the solution of linearized partial differential equations,

which is best done using problem specific solvers, such as multigrid or domain decomposition techniques. How to adjust the accuracy of iterative subproblem solves within SQPIP methods to obtain an efficient, globally convergent algorithm is not yet completely understood. An analysis of the influence of inexact problem information on the convergence of SQPIP methods is also important because discretizations of distributed optimal control problems can lead to errors in the derivative information. For example, this may happen when derivative information for the discretized problem (5)–(8) is computed by discretizing the Fréchet-derivatives of the infinite-dimensional problem (1)–(4). In such cases error in derivative information often goes to zero as the discretization is refined. An understanding of the influence of inexact derivative information on the convergence of SQPIP methods is necessary for the development of efficient and robust algorithms, including the development of grid refinement strategies within the optimization.

When considering SQPIP methods for distributed optimal control problems it is useful to distinguish between problems with and without state constraints (4), (8). Problems (1)–(3) or (5)–(7) which include only control constraints are often easier to solve. For control constrained problems there exist more solution approaches, like projection methods, than for state constrained problems. If the controls  $u$  are in  $U = L^p$ ,  $p \in [1, \infty)$  or  $p = \infty$ , which is, e. g., the case in the example problem at the beginning of this article, then optimality conditions for the infinite-dimensional problem can be formulated in a form that is suitable for the development of interior point methods. In particular, under suitable assumptions it is possible to show that Lagrange multipliers corresponding to (3) are in  $L^\infty$ . See, e. g., [13,14]. Development of optimality conditions for distributed optimal control problems (1)–(4) with state constraints that are suitable for use in optimization algorithms is an active research area. Existing results are less general than the ones for control constrained problems. Moreover, the Lagrange multipliers corresponding to the state constraints (4), which are optimization variables in most SQPIP methods, are usually only measures that can not be represented by functions in  $L^p$ . See, e. g., the discussion and references in [10]. For the discretized problem (5)–(7) it is often possible to show that the partial Jacobian  $\partial/\partial y)c^h(y^h, u^h)$  is invertible for

all  $u_l^h \leq u^h \leq u_u^h, y^h \in \mathbf{R}^{n_y}$ . In this case the Jacobian

$$\begin{pmatrix} \frac{\partial}{\partial y}c^h(y^h, u^h) & \frac{\partial}{\partial u}c^h(y^h, u^h) \\ 0 & \pm I_{A(u^h)} \end{pmatrix}$$

of the active constraints (6), (7) has full row rank, i. e., it is appropriate to assume the *linear independence constraint qualification* for the problem (5)–(7). This assumption is made in many local convergence analyses for SQPIP methods for nonlinear programming. For the problem (5)–(8) with state constraints, this assumption is often too restrictive. For example, the linear independence constraint qualification will be violated if more than  $n_u + n_y$  control and state constraints (7), (8) are active ([1,15]). Finally, the quality of some preconditioners for the iterative solution of subproblems within SQPIP method is improved when control constraints (7) are present, but decreased if state constraints (8) are given (see, e. g., [1]).

SQPIP methods for distributed optimal control problems is a rapidly developing area. This class of optimization algorithms shows great promise, especially for problems with state constraints. The reader will find detailed discussions in the references and related information in ► [Successive quadratic programming: Solution by active sets and interior point methods](#); ► [Linear programming: Interior point methods](#) on SQP methods and interior point methods for nonlinear programming problems.

Gradient-free minimization; Sequential simplex method; Expansion operations; Contraction operation; Reflection operations; Nondifferentiable objective functions

The sequential simplex method is due to the original work of W. Spendley, G.R. Hext and F.R. Himsworth [2]. It was later developed further by J.A. Nelder and R. Mead [1]. An exposition of the ideas underlying the method and its operation are as follows.

The minimization problem considered is:

$$\min_{\mathbf{x}} f(\mathbf{x}).$$

First, a *simplex* is defined as the geometric object formed by a set of  $n + 1$  points in the case of  $n$  variables (dimensions). Equidistant points form a *regular simplex*. In two dimensions such an object is a triangle, in three dimensions it is a tetrahedron and so forth.

The basic idea of the *downhill simplex method* (for minimization of  $n$ -dimensional functions) rests on the ability to use the geometric object to move a vertex at a time in the direction of descending function values. To achieve this firstly one needs to define the initial layout of the vertices, and then apply general types of moves to modify the object. The basic moves are three, namely, *reflection*, *expansion*, and *contraction*. A suitable termination criterion is also needed. All these basic characteristics of the sequential simplex algorithm are outlined below.

### 1. Initial simplex construction

Generally, one can select any number of  $n + 1$  points to form the *initial simplex*, as long as each subset of  $n$  of them is capable of spanning the  $n$ -dimensional space, in other words there are precisely  $n$  linearly independent vectors in the set. A simple procedure is to select for example an initial vertex point  $\mathbf{x}^{(1)}$  and then arraying the remaining  $n$  points scaled in the coordinate directions:

$$\mathbf{x}^{(i)} = \mathbf{x}^{(1)} + \lambda_i \mathbf{e}^{(i-1)}, \quad i = 2, \dots, n + 1,$$

where  $\lambda_i$  is some set of constants which reflect the guess of the problem's characteristic scales in each of its variables. The vectors  $\mathbf{e}^{(i)}$  are the unit vectors along each coordinate.

Having constructed the initial simplex each of the vertices must be evaluated in terms of the objective function value, leading to the corresponding values  $f_1, \dots, f_{n+1}$ . Following this, we denote the corresponding index, function value and vertex vector for the lowest, highest and replacing new vertex by the triplets  $\{l, f_l, \mathbf{x}^{(l)}\}$ ,  $\{h, f_h, \mathbf{x}^{(h)}\}$ ,  $\{r, f_r, \mathbf{x}^{(r)}\}$ . It is also useful to define the *centroid of the simplex* (excluding the highest function value vertex) by:

$$\mathbf{x}^{(c)} = \frac{1}{n} \sum_{i=1, i \neq h}^{n+1} \mathbf{x}^{(i)}, \quad (1)$$

thus having a new triplet representing this centroid given by  $\{c, f_c, \mathbf{x}^{(c)}\}$ .

### 2. Reflection (main operation)

This corresponds to rejecting vertex  $h$ , with maximum function value among all other vertices, and replacing it by a reflected point  $r$  through the opposite face of the simplex. This is based on the expectation that such a new point will have a smaller value. The reflected point is constructed by:

$$\mathbf{x}^{(r)} = \mathbf{x}^{(c)} + \alpha_1 (\mathbf{x}^{(c)} - \mathbf{x}^{(h)}),$$

where  $\alpha_1 > 0$  is the *reflection coefficient*, determining how far the new point will be on the far side of the centroid vertex  $c$ . Clearly, the definition above results in  $\mathbf{x}^{(r)}$  to lie on the line joining the vectors  $\mathbf{x}^{(h)}$  and  $\mathbf{x}^{(c)}$ . The definition of the reflection coefficient is thus:

$$\alpha_1 = \frac{\|\mathbf{x}^{(r)} - \mathbf{x}^{(c)}\|_2}{\|\mathbf{x}^{(h)} - \mathbf{x}^{(c)}\|_2}.$$

If  $f_l \leq f_r \leq f_h$ , then the new vertex  $r$  is accepted, defining a new simplex. It is quite easy though for reflection-only based operation to get in a cyclic operation without improvement. This may happen if the simplex gets positioned in such a way that the reflected point gives the same function value as the original one (the highest) which it is replacing. One may be able to introduce rules, such as not allowing returns to be made to already visited locations, or by replacing the second highest value of the simplex by a new point.

If the function value is found to be  $f_r < f_l$  then the expansion operation is carried out in step 3. If, on the other hand, the expansion produces a point for which  $f_r$

$> f_l$  holds for all points in the simplex except the highest value one (point  $h$ ) then the contraction operation is carried out in step 4.

### 3. Expansion

If during the *reflection* process above, it is found that the new point is better than all others in the previous simplex, that is  $f_r < f_l$ , then the reflection is successful in producing a new candidate minimum point. In such a case it is expected that the direction along the centroid defined in (1) and the replaced point  $h$  is a *descent direction*. Hence, it is desirable to move further along this direction by expanding the simplex. The expansion is defined by a new index  $e$  point:

$$\mathbf{x}^{(e)} = \mathbf{x}^{(c)} + \alpha_2(\mathbf{x}^{(r)} - \mathbf{x}^{(c)}),$$

again having as a definition of the *expansion coefficient* the ratio:

$$\alpha_2 = \frac{\|\mathbf{x}^{(e)} - \mathbf{x}^{(c)}\|_2}{\|\mathbf{x}^{(r)} - \mathbf{x}^{(c)}\|_2},$$

which indicates how much further the original replacement step is taken in the expansion phase.

If the procedure satisfies  $f_e < f_l$  the point  $\mathbf{x}^{(h)}$  is replaced by the point  $\mathbf{x}^{(e)}$  and another reflection operation is restarted. If this does not improve the function value, that is  $f_e > f_l$  holds, then the replacement is such that the point  $\mathbf{x}^{(h)}$  is replaced by the point  $\mathbf{x}^{(r)}$  and another reflection process is started again (going back to step 2).

### 4. Contraction

If the *reflection* process has produced a point for which  $f_r > f_l$  holds for all points in the simplex except the highest value one (point  $h$ ), then the point  $\mathbf{x}^{(h)}$  is replaced by  $\mathbf{x}^{(r)}$ . But this will cause the new highest value point to be the one just introduced, hence it is necessary to contract the simplex by the following rule, where  $s$  indicates the new contracted point:

$$\mathbf{x}^{(s)} = \mathbf{x}^{(c)} + \alpha_3(\mathbf{x}^{(h)} - \mathbf{x}^{(c)}), \tag{2}$$

where the parameter  $\alpha_3$  is the *contraction coefficient*, such that  $0 \leq \alpha_3 \leq 1$ , and defines the ratio:

$$\alpha_3 = \frac{\|\mathbf{x}^{(s)} - \mathbf{x}^{(c)}\|_2}{\|\mathbf{x}^{(h)} - \mathbf{x}^{(c)}\|_2},$$

defining by how much the direction to the highest value vertex from the centroid is contracted.

If  $f_r > f_h$ , then the contraction operation in (2) is used, without of course replacing the original highest value point  $h$ .

If the point  $s$  is such that  $f_s < \min\{f_h, f_r\}$  then point  $\mathbf{x}^{(h)}$  is replaced by  $\mathbf{x}^{(s)}$  and reflection operations resume (going to step 2).

If the contraction has failed, yielding  $f_s \geq \min\{f_h, f_r\}$  then it is proposed to replace all points  $\mathbf{x}^{(i)}$  by moving closer to the lowest value point using  $(\mathbf{x}^{(i)} + \mathbf{x}^{(l)})/2$  and restarting reflection operations (going to step 2).

### 5. Termination criteria

Termination criteria are necessarily by the construction of the method going to have to be based on some ‘average’ value along all current vertices in the simplex. A suitable criterion, which may be tested each time the simplex has been modified by any of the above three operations, is the following:

$$\left( \frac{1}{n+1} \sum_{i=1}^{n+1} (f_i - f_0)^2 \right)^{1/2} \leq \epsilon,$$

where the value  $f_0$  may be set to be the centroid calculated in (1), or one that includes all present points, i. e. even the highest point excluded in the summation in (1).

The above criterion is a standard deviation measure of all simplex points, which should be less or equal to some  $\epsilon > 0$  specified tolerance on its value.

The various parameters  $\alpha_1, \alpha_2, \alpha_3$  appearing in the various operations of the algorithm are either fixed, or can be adapted using line search type operations to find the best values that will enhance the desired effect of the operation involved (steps 2–4).

The sequential simplex method requires only function values generally, and is a simple algorithmic procedure. Generally, it is not the best derivative-free methods, requiring several function evaluations for larger problems (in terms of number of variables). However, whenever a quick and easy search phase is required for an unconstrained optimization problem, without too many variables, this method may be quite useful. Another advantage is that the method does not require the objective function  $f(x)$  to be differentiable, hence it may be useful for such practical applications.

We consider the class of problems having the following structure:

$$\begin{cases} \min & cx \\ \text{s.t.} & Ax \geq e^T \\ & x_j = 0, 1 \quad \text{for } j = 1, \dots, n, \end{cases}$$

where  $A$  is a  $m \times n$  matrix of zeros and ones,  $e = (1, \dots, 1)$  is a vector of  $m$  ones and  $c$  is a vector of  $n$  (arbitrary) rational components. This *pure 0–1 linear programming problem* is called the *set covering problem*. When the inequalities are replaced by equations the problem is called the *set partitioning problem*, and when all of the  $\geq$  constraints are replaced by  $\leq$  constraints, the problem is called the *set packing problem*.

**Applicability of the Problem**

Many applications arise having the packing, partitioning and covering structure. Delivery and routing problems, scheduling problems and location problems often take on a set covering structure whereby one wishes to assure that every customer is served by some location, vehicle or person. Other applications include switching theory, the testing of VLSI circuits, and line balancing. Similarly, scheduling problems whereby one wishes to satisfy as much demand as possible, without creating conflicts often requires the set packing format. Finally, when every customer must be served by exactly one server, the problem takes on the set partitioning format. Commonly cited problems having this structure include the *crew-scheduling problem*, where every flight leg of an airline must be scheduled by exactly one cockpit crew; another is the *political districting problem*, whereby regions must be divided into voting districts such that every citizen is assigned to exactly one district. See the survey [4] which contains a bibliography on applications.

Recently (as of 2000), reformulating them as either set-covering problems or set-partitioning problems having an extraordinary number of variables has

solved a variety of difficult problems. Because, for even small instances of the problem, the problem size cannot be explicitly solved, techniques known as column-generation, which began with the seminal work [16] on the *cutting-stock problem*, are employed. An overview of such transformation methods can be found in [5]. For specific implementations to the *vehicle routing problem*, see [11], for the bandwidth packing problem, see [27], for the generalized assignment problem see [29] and for alternative column-generation strategies for solving the cutting-stock problems, see [5].

J. Bramel and D. Simchi-Levi [7] have shown that the set-partitioning formulation for the vehicle routing problem with time windows is a tight formulation, i. e. the relative gap between the fractional linear programming solution and the global integer solution is small. Similar results are obtained for the bin-packing problem [9] and for machine scheduling [8].

### Solution Approaches

Once the problem has been formulated as a set-covering, set-packing or set-partitioning problem, the search for an optimal (or near-optimal) solution to this NP-hard 0–1 linear programming problem remains. Most solution approaches start by considering the *linear programming relaxation* (LP relaxation) of the respective problem. If the matrix  $A$  is a perfect zero-one matrix, see [23], then the LP relaxation of both the set packing and the set partitioning problem have a zero-one optimal solution for all choices of the objective function. Likewise, if the matrix  $A$  is an ideal matrix, see [26], then the same holds true for the set covering and the set-partitioning problem. Problems arising in practice need not, however, have perfect or ideal matrices. Nevertheless, it has been observed in computational practice that as long as the problems to be solved are relatively small, linear programming (or linear programming coupled with branch and bound) is likely to provide integer solutions quickly. However, as the problem size increases, the nonintegrality of the linear programming solution increases dramatically as does the length and size of the branching tree. It is for these larger instances of the problem that approximation techniques, *reformulation* and exact procedures have been developed that exploit the underlying structure of the problem.

### Reformulation of the Linear Description of the Problem

The natural structure of packing, covering and partitioning approaches provides opportunities to automatically remove any unnecessary rows or columns, and to remove any variables that cannot exist in any optimal solution. Checks for inconsistencies among the constraints are also performed. Reformulation procedures for the set covering problem have been well known for a long time [15] but had not been implemented into a special-purpose code for solving very large scale problems until 1993 [19].

### Heuristics for the Set Partitioning and Covering Problems

Virtually every heuristic approach for solving general integer programming problems has been applied to the set-covering, packing and partitioning problems. The set covering and packing formulations naturally lend themselves to greedy starts (i. e. an approach that at every iteration myopically chooses the next best step without regard for its implications on future moves), see e. g. [14]. Interchange approaches have also been applied here; a swap of one or more columns is taken whenever such a swap improves the objective function value. Newer heuristic approaches such as genetic algorithms (cf. also ► [Genetic algorithms](#)), probabilistic search [13], simulated annealing (cf. also ► [Simulated annealing methods in protein folding](#)) [5], and neural networks (cf. also ► [Neural networks for combinatorial optimization](#)) [1] have each been tried. Unfortunately, there has not been a comparative testing across such methods to determine under what circumstances a specific method might perform best. J.E. Beasley [6] maintains an extensive test set of problem instances for these important problems.

In addition, one can embed heuristics within exact algorithms so that one iteratively tightens the upper bound at the same time that one is attempting to get a tight approximation to the lower bound for the problem. See [19] for a description of a linear-programming based heuristic for the set-partitioning problem with side constraints, and [2] for heuristics based on using Lagrangian relaxation (cf. also ► [Integer programming: Lagrangian relaxation](#)) embedded within branch and bound to solve the set covering problem.

## Exact Solution Approaches to the Set Covering, Packing and Partitioning Problems

Exact approaches to solving set partitioning, covering and packing problems require algorithms that generate both good lower and upper bounds on the true minimum value of the problem instance. One can use any of the heuristics mentioned above to obtain a good upper bound to these problems. One should note, however, that the set covering and packing problems are easier problems for heuristic search because for these problems, it is, in general, easy to find feasible solutions. The set-partitioning problem may create unique concerns for some of these algorithms specifically because each row must be covered exactly once.

In general, the lower bound on the optimal solution value is obtained by solving a relaxation of the optimization problem. That is, one solves another optimization problem whose set of feasible solutions properly contains all feasible solutions of the original problem and whose objective function value is less than or equal to the true objective function value for points feasible to the original problem. Thus, we replace the ‘true’ problem by one with a larger feasible region that is more easily solved. There are two standard relaxations for covering, packing and partitioning problems: Lagrangian relaxation (where the feasible set is usually required to maintain 0–1 feasibility, but many if not all of the constraints are moved to the objective function with a penalty term) and the linear programming relaxation (where only the integrality constraints are relaxed and the objective function remains the original function). For the set-covering problem, in [12] a Lagrangian formulation and *subgradient optimization* is used. In [3] various Lagrangian relaxations are tested, including some that incorporated cuts within the formulation and kept a disjoint set of the original linear constraints unrelaxed. In [2], dual and primal heuristics, recursive variable fixing and subgradient optimization are embedded within a *branch and bound* tree search.

An alternative approach to solving set partitioning, packing and set covering problems is *branch and cut*. This method begins by solving the linear programming relaxation to the problem and then tightening the formulation by adding new linear inequalities to the constraint set.

Specifically, it requires finding linear inequalities that are violated by a given relaxation but are satisfied by all feasible zero-one points. The most successful *cutting plane approaches* are based on *polyhedral theory*, that is they replace the constraint set of an integer programming problem by a convexification of the feasible zero-one points and extreme rays of the problem. Some of the polyhedral cuts useful for set-partitioning problems are clique inequalities, odd cycles, and the complements of odd cycles in the intersection graph associated with the matrix  $A$ . For a complete description of how such cuts are embedded into a tree search structure that also uses heuristics, and reformulation and variable fixing techniques, see [19].

For details on polyhedral structure see [10,22,24,25] and [28]. Currently, the polyhedral description of these problems is incomplete. As our understanding of the mathematical structure of the set partitioning, packing and covering polytopes improves, and with the continuing advancement in computer technology, it is likely that many difficult and important problems will be solved by being able to solve larger and larger set partitioning problems to proven optimality.

## The Future

The recent interest (as of 2000) in reformulating hard, important scheduling problems into set partitioning problems via column generation has reinvigorated research into both linear and integer programming solution techniques. The linear programming relaxations of these very large set partitioning problems yield highly degenerate problems for the primal simplex method to solve. This degeneracy resulted in the revisiting of both primal and dual steepest edge methods, see [17]. The fact that the *column generation approaches* require the solution to many set-partitioning problems requires that we better understand the structure of these problems. More research into polyhedral structure, time-staged network optimization (for the subproblem solutions), and careful attention to computer implementation details are likely to yield successes to problems (such as machine-shop scheduling) that up until now have not allowed exact solution approaches.

### Keywords

Set-valued analysis; Vector optimization

Nowadays (2000) *set-valued optimization* means set-valued analysis and its application to optimization, and it is an extension of continuous optimization to the set-valued case. In this research area one investigates optimization problems with constraints and/or an objective function described by set-valued maps, or investigations in set-valued analysis are applied to standard optimization problems. In the last decade there has been an increasing interest in set-valued optimization (e. g., see the special issue [7]).

General optimization problems with *set-valued constraints* or a *set-valued objective function* are closely related to problems in stochastic programming, fuzzy programming and optimal control. If the values of a given function vary in a specified region, this fact could be described using a membership function in the theory of fuzzy sets or using information on the distribution of the function values. In this general setting probability distributions or membership functions are not needed because only sets are considered.

Optimal control problems with differential inclusions belong to this class of set-valued optimization problems as well. Set-valued optimization seems to have the potential to become a bridge between different areas in optimization. And it is a substantial extension of standard optimization theory. Set-valued analysis is the most important tool for such an advancement in continuous optimization. And conversely, the development of set-valued analysis receives important impulses from optimization.

Set-valued optimization problems have been investigated by many authors for instance, there are papers on optimality conditions (e. g., [3,4,5,6,9,11,14,17,19,21,22]), duality theory (e. g., [8,20,23,24]) and related topics (e. g., [10,15,16,25]). For further developments see [7].

In the following let  $X$ ,  $Y$  and  $Z$  be real linear spaces, let  $Y$  and  $Z$  be partially ordered by convex cones  $C_Y \subset Y$  and  $C_Z \subset Z$ , respectively (then  $\leq_{C_Y}$  and  $\leq_{C_Z}$  denote the corresponding partial orderings), let  $\widehat{S}$  be a nonempty subset of  $X$ , and let  $F: \widehat{S} \rightarrow 2^Y$  and  $G: \widehat{S} \rightarrow 2^Z$  be set-valued maps. Throughout this article it is generally assumed that the domain of a set-valued map equals its effective domain, i. e. for every element of the domain the image is a nonempty set.

Under these assumptions one considers the *set-valued optimization problem*

$$(SVOP) \quad \begin{cases} \min & F(x) \\ \text{s.t.} & G(x) \cap (-C_Z) \neq \emptyset, \\ & x \in \widehat{S}. \end{cases}$$

For simplicity let

$$S := \{x \in \widehat{S}: G(x) \cap (-C_Z) \neq \emptyset\}$$

denote the feasible set of this problem which is assumed to be nonempty. If  $G$  is single-valued, the constraint in (SVOP) reduces to  $G(x) \in -C_Z$  or  $G(x) \leq_{C_Z} 0_Z$  generalizing equality and inequality constraints. If, in addition,  $F$  is single-valued, then the problem (SVOP) is a general vector optimization problem.

It is also possible to use a constraint of the form  $G(x) \subset -C_Z$ . But with a simple transformation (see [20]) this type of a constraint can be transformed to the type of the constraint in problem (SVOP). This transformation has the drawback that convexity and continuity properties of the map may be lost.

As a simple example for problem (SVOP) consider the case that the objective function of a standard optimization problem is not known explicitly. But one assumes that for every feasible  $x$  a lower bound  $f(x)$  and an upper bound  $g(x)$  are given. In this case one can replace the objective function by a set-valued map  $F$  with

$$F(x) := [f(x), g(x)] \quad \text{for all } x \in S.$$

In practice it turns out that set-valued optimization makes only sense for a set-valued map  $F$  whose lower

bound cannot be described by a function  $f$  (because the minimization of  $F$  is in a certain sense equivalent to the minimization of  $f$ ).

Now the actual minimality notion used in set-valued optimization is presented.

**Definition 1** A pair  $(\bar{x}, \bar{y})$  with  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$  is called a *minimizer* of problem (SVOP), if  $\bar{y}$  is a minimal element of the set  $F(S) := \cup_{x \in S} F(x)$ , i. e.

$$(\{\bar{y}\} - C_Y) \cap F(S) \subset \{\bar{y}\} + C_Y.$$

It is known from *vector optimization* that the so-called weak minimality notion is the appropriate concept for the formulation of necessary and sufficient optimality conditions. This fact also holds for the set-valued case.

**Definition 2** If in addition  $\text{int}(C_Y) \neq \emptyset$ , then a pair  $(\bar{x}, \bar{y})$  with  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$  is called a *weak minimizer* of problem (SVOP), if  $\bar{y}$  is a weakly minimal element of the set  $F(S)$ , i. e.

$$(\{\bar{y}\} - \text{int}(C_Y)) \cap F(S) = \emptyset.$$

In order to obtain optimality conditions generalizing the known classical conditions a suitable differentiability notion is now introduced.

**Definition 3 [14]** In addition, let  $X$  and  $Y$  be real normed spaces, and let a pair  $(\bar{x}, \bar{y})$  with  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$  be given. A single-valued map  $DF(\bar{x}, \bar{y}): X \rightarrow Y$  whose epigraph equals the contingent cone (e. g., see [13]) to the epigraph of  $F$  at  $(\bar{x}, \bar{y})$ , i. e.

$$\text{epi}(DF(\bar{x}, \bar{y})) = T(\text{epi}(F), (\bar{x}, \bar{y}))$$

is called *contingent epiderivative* of  $F$  at  $(\bar{x}, \bar{y})$ .

Here the *epigraph* of  $F$  is defined as

$$\begin{aligned} \text{epi}(F) \\ := \{(x, y) \in X \times Y : x \in S, y \in F(x) + C_Y\}. \end{aligned}$$

The contingent epiderivative is a possible generalization of the well-known directional derivative in the single-valued case. Under convexity assumptions the contingent epiderivative is a sublinear map. In set-valued optimization convex maps are introduced as follows.

**Definition 4** The set-valued map  $F: S \rightarrow 2^Y$  is called  $C_Y$ -convex, if for all  $x_1, x_2 \in S$  and  $\lambda \in [0, 1]$

$$\begin{aligned} \lambda F(x_1) + (1 - \lambda)F(x_2) \\ \subset F(\lambda x_1 + (1 - \lambda)x_2) + C_Y. \end{aligned}$$

Using the concept of the contingent epiderivative it is also possible to introduce subgradients of a set-valued map.

**Definition 5 [2]** Let the contingent epiderivative  $DF(\bar{x}, \bar{y})$  of  $F$  at  $(\bar{x}, \bar{y})$  exist with  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$ . A linear map  $L: X \rightarrow Y$  with

$$L(x) \leq_{C_Y} DF(\bar{x}, \bar{y})(x), \quad \text{for all } x \in X,$$

is called a *subgradient* of  $F$  at  $(\bar{x}, \bar{y})$ . The set  $\partial F(\bar{x}, \bar{y})$  of all subgradients  $L$  of  $F$  at  $(\bar{x}, \bar{y})$  is called *subdifferential* of  $F$  at  $(\bar{x}, \bar{y})$ .

**Theorem 6 [2]** In addition to the assumptions, let  $X$  and  $Y$  be real normed spaces, let  $S = X$ , let  $C_Y$  be pointed, let  $Y$  be order complete, let  $F$  be  $C_Y$ -convex, and let the contingent epiderivative  $DF(\bar{x}, \bar{y})$  of  $F$  at  $(\bar{x}, \bar{y})$  exist with  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$ . Then the subdifferential  $\partial F(\bar{x}, \bar{y})$  is nonempty.

Next, a complete characterization of weak minimizers in convex set-valued optimization is presented.

**Theorem 7 [14]** In addition to the assumptions, let  $X$  and  $Y$  be real normed spaces, let  $S$  be a convex set, let  $\text{int}(C_Y) \neq \emptyset$ , let  $F$  be  $C_Y$ -convex, and let the contingent epiderivative  $DF(\bar{x}, \bar{y})$  exist at  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$ . The pair  $(\bar{x}, \bar{y})$  is a weak minimizer of problem (SVOP) if and only if

$$DF(\bar{x}, \bar{y})(x - \bar{x}) \notin -\text{int}(C_Y) \quad \text{for all } x \in S.$$

A corresponding result can be shown for the constrained case where  $G$  describes an inequality constraint as in problem (SVOP). This optimality condition extends the *Lagrange multiplier rule* to the set-valued case.

**Theorem 8 [11]** In addition to the assumptions, let  $X$  and  $Y$  be real normed spaces, let  $\hat{S}$  be a convex set, let  $\text{int}(C_Y) \neq \emptyset$ , let  $F$  be  $C_Y$ -convex, let  $G$  be  $C_Z$ -convex, let  $\bar{x} \in S$  and  $\bar{y} \in F(\bar{x})$  be given, and let the contingent epiderivative of  $(F, G)$  at  $(\bar{x}, (\bar{y}, \bar{z}))$  exist for an arbitrary

$\bar{z} \in G(\bar{x}) \cap (-C_Z)$ . Moreover, let the regularity assumption

$$\{z: (y, z) \in D(F, G)(\bar{x}(\bar{y}, \bar{z}))(\text{cone}(S - \{\bar{x}\}))\} + \text{cone}(C_Z + \{\bar{z}\}) = Z$$

be satisfied ( $\text{cone}(\dots)$  denotes the cone generated by a set [13]). Then  $(\bar{x}, \bar{y})$  is a weak minimizer of the problem (SVOP) if and only if there are continuous linear functionals  $t \in C_{Y^*} \setminus \{0_{Y^*}\}$  and  $u \in C_{Z^*}$  with

$$t(y) + u(z) \geq 0$$

for all  $(y, z) = D(F, G)(\bar{x}(\bar{y}, \bar{z}))(x - \bar{x})$  with  $x \in \widehat{S}$ , and

$$u(\bar{z}) = 0.$$

General results on set-valued analysis can be found in [1]; while [12] and [18] present the theoretical background of vector optimization.

Shape optimization; Optimal shape design; Shape sensitivity analysis

Shape optimization is a part of the larger field called structural optimization (cf. ► **Structural optimization**; ► **Structural optimization: History**). Structural optimization can be characterized as an applied branch of the optimal control theory in which the control variable is related to the geometry of structures. It can be divided into 3 parts:

- i) *sizing optimization* (optimization of a typical size: a thickness optimization of beams, plates, etc.);
- ii) *shape optimization* (optimization of a shape of structures, keeping the topology of an initial design);
- iii) *topology optimization* (it makes possible to change the topology of an initial design).

An abstract formulation of a large class of optimal shape design problems reads as follows:

$$(P) \begin{cases} \text{Find } \Omega^* \in \mathcal{O} \\ \text{s.t. } I(\Omega^*, u(\Omega^*)) \leq I(\Omega, u(\Omega)), \\ \quad \forall \Omega \in \mathcal{O}. \end{cases}$$

Here  $\mathcal{O}$  is a family of *admissible domains*,  $u(\Omega)$  is a solution of a *state problem*  $(\mathcal{P}(\Omega))$ , describing the behavior of a structure, represented by a domain  $\Omega$  and  $I$  is a *cost functional*. The state problem is typically given by partial differential equations (PDEs) or by variational inequalities (VIs). The mathematical analysis of (P) includes:

- j) the study of existence of solutions to (P);
- jj) discretization of (P) and the convergence analysis;
- jjj) sensitivity analysis.

In order to guarantee the existence of solutions to (P) we make several assumptions (note that there is no uniqueness of the solution, in general). First we introduce the concept of a convergence in  $\mathcal{O}$ , i. e. if  $\{\Omega_n\}$ ,  $\Omega_n \in \mathcal{O}$ , is a sequence, we specify the meaning of saying: ‘ $\Omega_n$  tends  $\omega$ ’ to  $\Omega_n \xrightarrow{\mathcal{O}} \Omega$ . With any  $\Omega \in \mathcal{O}$ , a Hilbert space  $V(\Omega)$  of functions defined in  $\Omega$  will be associated (space of functions with finite energy). If  $\Omega_n \xrightarrow{\mathcal{O}} \Omega$  and  $y_n \in V(\Omega_n)$ ,  $y \in V(\Omega)$ , then one has to define the convergence ‘ $y_n \rightarrow y$ ’ (note that the domain of definition of functions varies). Finally, let  $u: \Omega \rightarrow u(\Omega) \in V(\Omega)$ ,  $\Omega$

$\in \mathcal{O}$  be a *state relation* (PDE, VI, etc.) with  $u(\Omega)$  being the solution of  $(\mathcal{P}(\Omega))$  and  $G = \{(\Omega, u(\Omega)): \Omega \in \mathcal{O}\}$  be its graph. We suppose that:

- 1)  $G$  is *compact* in the following sense: if  $\{\Omega_n\}$ ,  $\Omega_n \in \mathcal{O}$ , is an arbitrary sequence, then there exist a subsequence  $\{(\Omega_{n_k}, u(\Omega_{n_k}))\}$  and an element  $(\Omega, u(\Omega)) \in G$  such that

$$\Omega_{n_k} \xrightarrow{\mathcal{O}} \Omega, \quad u(\Omega_{n_k}) \rightarrow u(\Omega), \quad k \rightarrow \infty,$$

in the specified sense;

- 2)  $I$  is *lower semicontinuous*: if  $\{\Omega_n\}$ ,  $\{v_n\}$ , where  $\Omega_n \in \mathcal{O}$ ,  $v_n \in V(\Omega_n)$  are arbitrary sequences such that  $\Omega_n \xrightarrow{\mathcal{O}} \Omega$ , ‘ $v_n \rightarrow v$ ’ with  $\Omega \in \mathcal{O}$ ,  $v \in V(\Omega)$  then

$$\liminf_{n \rightarrow \infty} I(\Omega_n, v_n) \geq I(\Omega, v).$$

It holds (see [4]):

**Theorem 1** *Let 1)–2) be satisfied. Then (P) has a solution.*

**Example 2** Let  $\mathcal{O}$  be a family of bounded domains satisfying the *uniform cone property* (see [1]), let  $(\mathcal{P}(\Omega))$  be given by the Neumann problem

$$(\mathcal{P}(\Omega)) \begin{cases} -\Delta u + u(\Omega) = f & \text{in } \Omega \in \mathcal{O} \\ \frac{\partial u(\Omega)}{\partial \nu} = 0 & \text{on } \partial \Omega, \end{cases}$$

and  $I(\Omega, y) = \int_{\Omega} |y - z_d|^2 dx$ , where  $f, z_d \in L^2_{loc}(\mathbb{R}^m)$  are given functions. We set  $V(\Omega) \equiv H^1(\Omega)$ , i. e.  $V(\Omega)$  is the standard Sobolev space of functions defined in  $\Omega$ , whose derivatives up to the order one are square integrable in  $\Omega$ , i. e. elements of  $L^2(\Omega)$  (see [7]). The weak formulation of  $(\mathcal{P}(\Omega))$  is given by:

$$\begin{cases} \text{Find } u(\Omega) \in H^1(\Omega) \\ \text{s.t. } \int_{\Omega} (\text{grad } u(\Omega) \cdot \text{grad } \phi + u\phi) dx \\ \quad = \int_{\Omega} f\phi dx, \quad \forall \phi \in H^1(\Omega). \end{cases}$$

We define:

- $\Omega_n \xrightarrow{\mathcal{O}} \Omega$  if and only if  $\chi(\Omega_n) \rightarrow \chi(\Omega)$  in  $L^2(\mathbb{R}^m)$ ;
- ‘ $y_n \rightarrow y$ ’ if and only if  $\chi(\Omega_n) \rightarrow \chi(\Omega)$  (weakly) in  $L^2(\mathbb{R}^m)$ .

Here,  $\chi(\Omega)$  is the characteristic function of  $\Omega$ ,  $\widehat{\Omega}$  is a domain containing all  $\Omega \in \mathcal{O}$  and the symbol ‘ $\sim$ ’ stands for the *uniform extension* of functions from their domain of definition to  $\widehat{\Omega}$  (see [1]). One can verify 1)–

2) for the convergences introduced above (see [1,4,8]). Thus, the corresponding SO problem has a solution.

To define an *approximation* of (P) we replace  $\mathcal{O}$  by a system  $\{\mathcal{O}_h, h \rightarrow 0+\}$ . Any  $\mathcal{O}_h$  contains domains  $\Omega_h$  whose shapes are described by a finite number of parameters. This number depends on the discretization parameter  $h$  (the boundary of  $\Omega_h$  is piecewise linear, a spline function, etc.). In what follows we shall suppose that  $\mathcal{O}_h \subset \mathcal{O}$  for any  $h > 0$ . With any  $\Omega_h \in \mathcal{O}_h$ , a finite-dimensional space  $V_h(\Omega_h)$  will be associated (a finite element space, e.g.). The state problem  $(\mathcal{P}(\Omega))$  will be replaced by its suitable discretization  $(\mathcal{P}(\Omega_h))_h$  (by using the Ritz–Galerkin method, e.g.). Finally, the cost functional  $I$  may be approximated  $(I_h)$ , as well. The *approximation* of (P) reads as follows:

$$(P)_h \begin{cases} \text{Find } \Omega_h^* \in \mathcal{O}_h \\ \text{s.t. } I_h(\Omega_h^*, u_h(\Omega_h^*)) \leq I_h(\Omega_h, u_h(\Omega_h)), \\ \quad \forall \Omega_h \in \mathcal{O}_h. \end{cases}$$

Here,  $u_h(\Omega_h)$  is a solution of  $(\mathcal{P}(\Omega_h))_h$ . Problem (P)<sub>h</sub> expressed in the algebraic form leads to a *nonlinear mathematical programming problem*, in general.

To establish a relation between solutions to (P) and (P)<sub>h</sub>, when  $h \rightarrow 0+$ , the following assumptions are needed:

3) for any  $\Omega \in \mathcal{O}$  there exists a sequence  $\{\Omega_h\}$ ,  $\Omega_h \in \mathcal{O}_h$ , such that

$$\Omega_h \xrightarrow{\mathcal{O}} \Omega, \quad h \rightarrow 0+;$$

4) for every sequence  $\{(\Omega_h, u_h(\Omega_h))\}$ , where  $\Omega_h \in \mathcal{O}_h$  and  $u_h(\Omega_h)$  solves  $(\mathcal{P}(\Omega_h))_h$ , there exist its subsequence  $\{(\Omega_{h_k}, u_{h_k}(\Omega_{h_k}))\}$  and an element  $(\Omega, u(\Omega)) \in G$  such that

$$\Omega_{h_k} \xrightarrow{\mathcal{O}} \Omega,$$

$$'u_{h_k}(\Omega_{h_k}) \rightarrow u(\Omega)', \quad k \rightarrow \infty;$$

5) if  $\Omega_h \xrightarrow{\mathcal{O}} \Omega$  with  $\Omega_h \in \mathcal{O}_h$ ,  $\Omega \in \mathcal{O}$  and  $'u_h(\Omega_h) \rightarrow u(\Omega)$ , then

$$\lim_{h \rightarrow 0+} I_h(\Omega_h, u_h(\Omega_h)) = I(\Omega, u(\Omega)).$$

Then one can prove (see [4]):

**Theorem 3** *Let 3)–5) be satisfied and let for any  $h > 0$  there exists an optimal pair  $(\Omega_h^*, u_h(\Omega_h^*))$ . Then there*

*exists a subsequence  $\{(\Omega_{h_k}^*, u_{h_k}(\Omega_{h_k}^*))\}$  and an element  $(\Omega^*, u(\Omega^*)) \in G$  such that*

$$6) \quad \begin{cases} \Omega_{h_k}^* \xrightarrow{\mathcal{O}} \Omega^* \\ 'u_{h_k}(\Omega_{h_k}^*) \rightarrow u(\Omega^*)', \quad k \rightarrow \infty, \end{cases}$$

*and  $(\Omega^*, u(\Omega^*))$  is an optimal pair for (P). Moreover any such cluster point  $(\Omega^*, u(\Omega^*))$  of a sequence  $\{(\Omega_{h_k}^*, u_{h_k}(\Omega_{h_k}^*))\}$  in the sense of 6) is an optimal pair for (P).*

*Example 4* We describe the approximation of (P) from Example 2, considered in  $\mathbf{R}^2$ . For any  $h > 0$ , the family  $\mathcal{O}_h$  contains polygonal domains, being the piecewise linear approximations of  $\Omega \in \mathcal{O}$  and such that

$$\partial\Omega_h = \bigcup_{i=1}^{n(h)} \overline{A_i A_{i+1}}$$

( $A_{n(h)+1} \equiv A_1$ ) with the length  $|\overline{A_i A_{i+1}}| \leq h$  for any side. Let  $\{\mathcal{T}(h, \Omega_h)\}$ ,  $h \rightarrow 0+$  be a family of triangulations of  $\overline{\Omega_h}$  (see [2]) satisfying:

- 7) any  $\overline{A_i A_{i+1}}$  is the side of just one boundary triangle  $T \in \mathcal{T}(h, \Omega_h)$ ;
- 8) the number of nodes in  $\mathcal{T}(h, \Omega_h)$  is the same for any  $\Omega_h \in \mathcal{O}_h$  ( $h$  being fixed) and the nodes have still the same neighbors;
- 9) the position of internal nodes of  $\mathcal{T}(h, \Omega_h)$  continuously depends on variations of the boundary nodes  $A_i, i = 1, \dots, n(h)$ ;
- 10) the family  $\{\mathcal{T}(h, \Omega_h)\}$  satisfies the *uniform angle condition*:

$$\exists \theta_0 > 0 \quad \text{such that } \theta_T \geq \theta_0$$

holds for any triangle  $T \in \mathcal{T}(h, \Omega_h)$ , for any  $\Omega_h \in \mathcal{O}_h$  and any  $h > 0$ , where  $\theta_T$  is the minimal interior angle of  $T$ .

With any such  $\mathcal{T}(h, \Omega_h)$ , the space of all piecewise linear functions  $V_h(\Omega_h)$  will be associated (see [2]). Finally,  $(\mathcal{P}(\Omega))$  is replaced by:

$$(P(\Omega_h))_h \begin{cases} \text{Find } u_h(\Omega_h) \in V_h(\Omega_h) \\ \text{s.t. } \int_{\Omega_h} (\text{grad } u_h(\Omega_h) \cdot \text{grad } \phi_h \\ \quad + u_h(\Omega_h) \phi_h) \, dx \\ \quad = \int_{\Omega_h} f \phi_h \, dx, \\ \quad \forall \phi_h \in V_h(\Omega_h). \end{cases}$$

It can be shown (see [4]) that 3)–5) are satisfied, provided that 7)–10) hold. Thus (P) and (P)<sub>h</sub> are close on subsequences as follows from Theorem 3.

*Shape sensitivity analysis* is a specific field of SO, analyzing the differentiability of the solution of state problems with respect to shape variations. There are several concepts of the shape differential calculus: the *method of mappings* [6], the *material derivative approach* [9] and the *boundary variation technique* [8]. Higher order derivatives in SO and their application are studied in [3,5]. On the contrary, if the state problem is given by VI, then the differentiability of the mapping:  $\Omega \rightarrow u(\Omega)$  is weakened due to the fact that such mapping is only *Lipschitz continuous* (see [9]). Thus the resulting minimization problem is nonsmooth, in general. Such a type of problems can be realized or by using methods of *nonsmooth optimization* or by *regularizing* the state problem (see [4]). The use of global optimization methods in SO based on function evaluations only combined with the so-called *fictitious domain methods* is studied in [4].

### Introduction

Uncertainties in chemical plants appear for a variety of reasons. There are internal reasons, such as fluctuations of values of reaction constants and physical properties, and external reasons, such as quality and flow rates of feed streams. The need to account for uncertainty in various stages of plant operations has been identified as one of the most important problems in chemical plant design and operation [7,8,18].

There are two main problems associated with the consideration of uncertainty in decision making: the quantification of the feasibility and flexibility of a process design and the incorporation of uncertainty within a decision stage. The quantification of process feasibility is most commonly addressed by utilizing the feasibility function introduced by Swaney and Grossmann, which requires constraint satisfaction over a specified uncertainty space, whereas flexibility evaluation is associated with a quantitative measure of the feasible space. Halemane and Grossmann [10] proposed a feasibility measure for a given design based on the worst points for feasible operation, which can be mathematically formulated as a max-min-max optimization problem:

$$\chi(d) = \max_{\theta \in T} \min_z \max_{j \in J} f_j(d, z, \theta), \quad (1)$$

where  $T$  is the feasible space of  $\theta$  described as  $T = \{\theta | \theta^L \leq \theta \leq \theta^U\}$ , where  $\theta_L, \theta_U$  are lower and upper bounds, respectively.

The general formulation for quantifying flexibility, known as the *flexibility index problem*, can be defined as the determination of maximum deviation  $\Delta$  that a given design  $d$  can tolerate, such that every point  $\theta$  in the uncertain parameter space ( $T(\delta)$ ) is feasible [1]. A well-studied case is the hyperrectangle representation  $\delta$ ,  $T(\delta) = \{\theta | \theta^N - \delta \Delta \theta^- \leq \theta \leq \theta^N + \delta \Delta \theta^+\}$ , where  $\Delta \theta^+$  and  $\Delta \theta^-$  are the expected deviations of the uncertain parameters in the positive and negative directions and  $\delta$  the deviation along a specified direction. Other descriptions of  $T(\delta)$ , such as the parametric hyperellipsoid, have also been investigated [15].

The flexibility index can be determined from the formulation proposed by Swaney and Grossmann [18] as:

$$\begin{aligned} F &= \max \delta \\ \text{Subject to } \max_{\theta \in T(\delta)} \psi(\theta, d) &\leq 0 \\ \delta &\geq 0. \end{aligned} \quad (2)$$

One approach to determining the flexibility index is by vertex enumeration, in which the maximum displacement is computed along each vertex direction. This scheme is based on the assumption that the critical points ( $\theta^c$ ) lie at the vertices of  $T(\Delta^c)$ , which holds only under certain convexity conditions. Other existing approaches to quantifying flexibility involves deterministic measures such as the resilience index (RI) proposed by Saboo et al. [16] and stochastic measures such as design reliability proposed by Kubic and Stein [12] and the stochastic flexibility index proposed by Pistikopoulos and Mazzuchi [14] and Straub and Grossmann [17]. Recently Ierapetritou and coworkers [6] introduced a new approach to quantifying process feasibility based on the description of the feasible region by an approximation of the convex hull. Their approach results in an accurate representation of process feasibility.

However, the convex hull approach is limited in its application to only convex and 1-D quasiconvex feasible regions, and its performance deteriorates in the presence of nonconvex constraints. This shortcoming can be overcome by utilizing surface reconstruction

ideas to capture the accurate shape of the feasible region.

### Definition

The main problem definition for surface reconstruction is, given a set of range points, to reconstruct a manifold that closely approximates the surface of the original model. The range data are a set of discrete points in three-dimensional space that have been sampled from the physical environment or can be obtained using laser scanners that generate data points on the surface of an object. The problem naturally arises in a variety of practical situations such as range scanning an object from multiple view points, recovery of biological shapes from two-dimensional slices, interactive surface sketching, etc. Surface reconstruction has extensive applications in the areas of automatic mesh generation and geometric modeling, molecular structure, and protein folding analysis.

The problem of feasibility analysis is analogous to that of surface reconstruction since the main effort of feasibility analysis lies in identifying and accurately estimating the boundary of the feasible region. In previous approaches this boundary is approximated by linear inequalities, either by incorporating a hyperrectangle [18] or by describing an approximation of the convex hull [6] inside the feasible space. These methods can have satisfactory performance in case of convex, connected feasible regions but will be inaccurate for cases of nonconvex or disjoint feasible regions. On the other hand, the surface reconstruction scheme can successfully describe both nonconvex and disjoint regions defining the bounding surface by piecewise linear functions. The present work proposes a feasibility analysis scheme based on surface reconstruction ideas, in particular, the  $\alpha$ -shape methodology for surface reconstruction.

### $\alpha$ -Shape Approach

Various approaches are described in the literature for determining the shape of a pattern class from sampled points. Many of these approaches are concerned with efficient construction of convex hulls for a set of points in a plane. Jarvis [11] was one of the first to consider the problem of computing shape as a generalization of the convex hull of a planar point set.

A mathematically rigorous definition of shape was later introduced by Edelsbrunner et al. [3] as a natural generalization of the convex hulls, which is referred to as  $\alpha$  hull. The  $\alpha$  hull of a point set is based on the notion of generalized discs in a plane. The family of  $\alpha$  hulls includes the smallest enclosing circle, the set itself, and an essentially continuous set of enclosing regions in between these two extremes.

Edelsbrunner et al. [3] also define a combinatorial variant of the  $\alpha$  hull called the  $\alpha$  shape of a planar set, which can be viewed as the boundary of the  $\alpha$  hull with curved edges replaced by straight ones. Conceptually,  $\alpha$  shapes are a generalization of the convex hull of a point set  $\mathcal{S}$ , with  $\alpha$  varying from 0 to  $\infty$ . The  $\alpha$  shape of  $\mathcal{S}$  is a polytope that is neither necessarily convex nor connected. For  $\alpha = \infty$ , the  $\alpha$  shape is identical to the convex hull of  $\mathcal{S}$ . However, as  $\alpha$  decreases, the  $\alpha$  shape shrinks by gradually developing cavities. When  $\alpha$  becomes small enough, the polytope disappears and reduces to the data set itself.

To provide an intuitive notion of the concept, Edelsbrunner describes the space  $R^3$  to be filled with styrofoam and the point set  $\mathcal{S}$  to be made of more solid material, such as rock. Now if a spherical eraser with radius  $\alpha$  curves out the styrofoam at all positions where it does not enclose any of the sprinkled rocks (the point set  $\mathcal{S}$ ), the resulting object that formed will be called an  $\alpha$  hull. The surface of the object can be straightened by substituting straight edges for circular ones and triangles for spherical caps. The obtained object is the  $\alpha$  shape of  $\mathcal{S}$ . It is a polytope in a fairly general sense: it can be concave and even disconnected; it can contain two-dimensional patches of triangles and one-dimensional strings of edges, and its components can be as small as single points. The parameter  $\alpha$  controls the degree of details captured by the  $\alpha$  shape.

It is possible to generalize all the concepts involved in the construction of  $\alpha$  shape (i. e.,  $\alpha$  hulls,  $\alpha$  complexes, Delaunay triangulation, Voronoi diagrams) to a finite set of points  $\mathcal{S}$  in  $\mathcal{R}^d$  for arbitrary dimension  $d$ . This generalization, combined with an extension to weighted points, is developed in Edelsbrunner [2]. However, the implementation details of the problem becomes progressively more complex with increasing dimension, and the worst-case complexity of the problem grows exponentially.

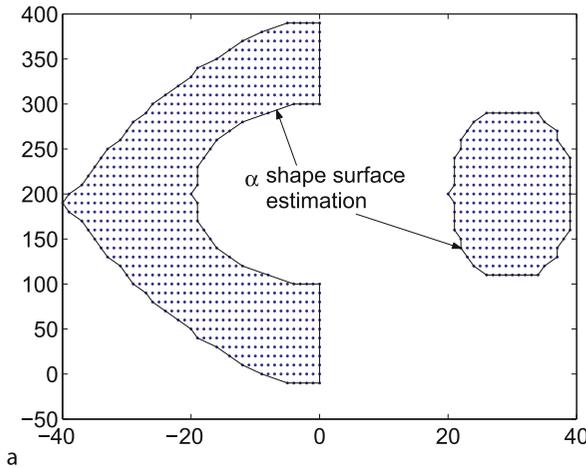

## Selection of $\alpha$

The computed  $\alpha$  shape of a given set of sample points explicitly depends on the chosen value of  $\alpha$ , which controls the level of detail of the constructed surface. Mandal et al. [13] present a systematic methodology for selecting the value of  $\alpha$  in  $R^2$ . They visualize the problem of obtaining the shape of  $\mathcal{S}$  as a set-estimation problem where an unknown set  $\mathcal{X} \in \mathcal{B}$  is to be estimated on the basis of a finite number of points  $X_1, X_2, \dots, X_n \in \mathcal{X}$ . As  $n$  increases,  $\mathcal{S}(n)$  will cover many parts of  $\mathcal{X}$ , and hence the value of  $\alpha$  for  $\mathcal{S}(n)$  should depend on the sample size ( $n$ ); thus  $\alpha$  is a function of  $n$ . Additionally  $\alpha$  should also be a function of the interpoint distance of the sampled  $n$  points of  $\mathcal{S}(n)$ . To account for the dependence on the interpoint distance, the authors have constructed the minimum spanning tree (MST) of the sampled data points. If  $l_n$  represents the sum of edge weights of the MST, where the edge weight is taken to be the Euclidean distance between the points, then the appropriate value of  $\alpha$  for the construction of  $\alpha$  shape is given by

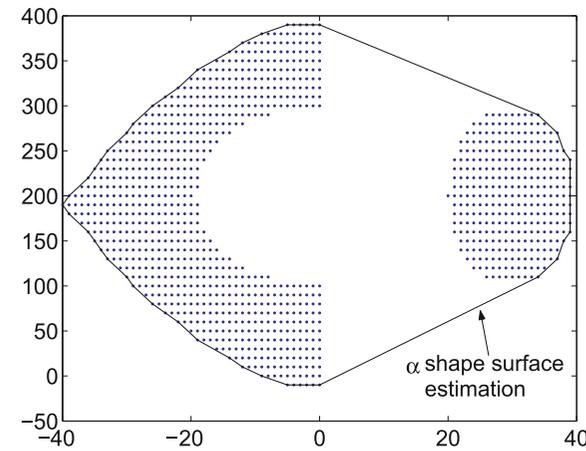

$$h_n = \sqrt{\frac{l_n}{n}}, \quad (3)$$

where  $n$  is the total number of sample points.

To illustrate the performance of  $\alpha$  shape in capturing the shape of an object, a disjoint, nonconvex object is chosen, as illustrated in Fig. (1). The sampled points represent a 2-D object, which is the input to the  $\alpha$ -shape construction code. The  $\alpha$  shape identifies from the input data set points that lie on the boundary of the object. These points are joined by a line to describe the surface of the object. The above figure also illustrates the dependence of the captured shape on the chosen value of  $\alpha$ . The  $\alpha$  value estimated by performing the MST operation is 120, at which value the  $\alpha$  shape was found to capture the nonconvex as well as the disjoint nature of the object. By further increasing the value of  $\alpha$  the performance of  $\alpha$  shape deteriorates, and at very high  $\alpha$  the  $\alpha$  shape forms a convex hull of the object (Fig. 1b). Hence the level of detail captured by the  $\alpha$  shape strongly depends on the chosen value of  $\alpha$ , and progressively decreasing the value of  $\alpha$  will capture the shape more accurately.

## Formulation

### Feasibility Analysis Using $\alpha$ Shape

The overall aim of feasibility analysis is the determination of the range of parameters over which a particular process is feasible. A formal definition of this problem is to obtain a mathematical description of the region in parameter space bounded by the process constraints. This region can be considered analogous to an object whose shape or surface can be estimated using the  $\alpha$ -shape technique. The input to any surface-reconstruction algorithm needs to be a set of points representing the object whose surface needs to be deter-

Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 2

Point-in-polygon test: an odd number of intersections means the point is inside; an even number of intersections means the point is outside

mined. The steps involved in determining the feasible region using the surface reconstruction ideas are as follows:

- Generate sample data points to adequately represent the feasible region under consideration.
- Construct the  $\alpha$  shape for the sampled data using the  $\alpha$  estimate obtained from the MST of the data set.
- Join the identified boundary points to obtain a polygonal representation of the feasible region.

Having defined the surface or shape of the feasible region, the next step involves determining whether a particular point belongs to the feasible region. Since the feasible region has been approximated by a polygon, a simple way to check if a point is inside the polygon is by using one of the point-in-polygon tests [9]. One method to determine whether a point is inside a region is the *Jordan Curve Theorem*, which states that a point is inside a polygon if, for any semi-infinite ray from this point, there is an odd number of intersections of the ray with the polygon's edges (Fig. 2). Conversely, a point is outside a polygon if the ray intersects the polygon's edges an even number of times or does not intersect at all. Following this, whenever a parameter needs to be checked for feasibility in a polygon estimated feasible region, a semi-infinite ray is drawn from the point in any direction, and the number of intersections is noted, which determines whether or not the point is feasible.

### Sampling Technique

The first step in the proposed approach is to have a good representation of the feasible region. Most of the com-

mon sampling techniques sample the parameter space based on the distribution of the uncertain parameter, which are considered to be uniform for the cases considered here for simplicity of presentation. Under this condition it leads to uniform sampling of the entire parameter space, irrespective of whether or not the sampled points are feasible. However, typically, the feasible region covers only a very restricted region of the entire parameter space. Hence sampling techniques covering the entire range of uncertain parameter prove to be inefficient, particularly when evaluation of the process constraints is an expensive operation. A new sampling technique is thus introduced here that takes advantage of the fact that typically a small section of the entire parameter space is feasible. The sampling problem is formulated as an optimization problem and is solved using a genetic algorithm (GA). The use of a GA as a solution procedure proves to be very efficient for this problem since the search scheme has the inherent property of concentrating around regions having good solutions, which is the feasible solution for the problem addressed here, thereby reducing expensive function evaluation.

The formulation of the sampling problem as an optimization problem is given by

$$\begin{aligned} & \max_{\theta} V_{feas} \\ & \text{subject to } (f_1)_{\theta} \leq 0 \\ & \quad (f_2)_{\theta} \leq 0 \\ & \quad \vdots \\ & \quad (f_n)_{\theta} \leq 0, \end{aligned} \tag{4}$$

where  $V_{feas}$  is the volume of the feasible region evaluated by constructing the  $\alpha$  shape using the sampled feasible points. The optimization variables are the parameter values  $\theta$ , which are sampled by the GA to optimize the objective, and  $f_1, f_2 \dots, f_n$  are the constraints of the feasibility problem evaluated at  $\theta$ . However, in this formulation there is no optimal value of the variable  $\theta$  that will maximize the volume, but we are interested in the entire sampled set of feasible  $\theta$  values, using which the volume is evaluated by constructing an  $\alpha$  shape over the entire set of feasible  $\theta$  values. Since the objective is to maximize the volume of the feasible space, whenever a chosen value of  $\theta$  satisfies the constraint functions, the volume is evaluated to update the

objective function. When the value is not feasible, there is no need to reevaluate the volume since it will not change, but the fitness function is penalized by assigning it a small value. Solving this problem using a GA reduces the required number of function evaluations by minimizing the unnecessary evaluation of infeasible parameter space.

**Cases**

The idea of using surface reconstruction for the estimation of a feasible region is illustrated by a few case studies.

The feasible region is defined by the following sets of convex and nonconvex constraints:

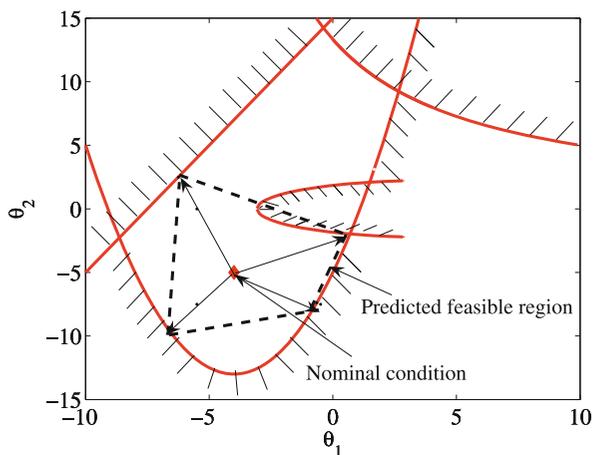

$$f_1 = \theta_2 - 2\theta_1 - 15 \leq 0, \tag{5}$$

$$f_2 = \frac{\theta_1^2}{2} + 4\theta_1 - 5 - \theta_2 \leq 0, \tag{6}$$

$$f_3 = \theta_2(6 + \theta_1) - 80 \leq 0, \tag{7}$$

$$f_4 = 10 - \frac{(\theta_1 - 4)^2}{5} - 2\theta_2^2 \leq 0. \tag{8}$$

Figure (3) illustrates the actual nature of the feasible region bounded by inequalities (5)–(8) and the convex hull approximation of the enclosed feasible region. The first step in the proposed scheme is to sample the feasi-

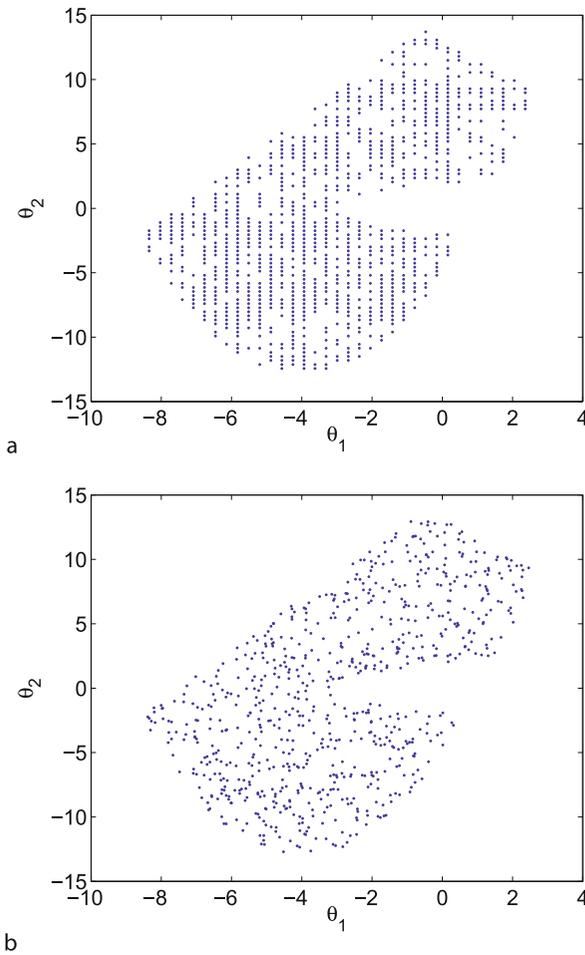

**Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 3**  
 Feasible region bounded by convex and nonconvex constraints and its estimation using convex hull

ble space efficiently. The optimization problem for sampling is given by

$$\begin{aligned} & \max_{\theta_1, \theta_2} V_{\text{feas}}, \\ & \theta_2 - 2\theta_1 - 15 \leq 0, \\ & \frac{\theta_1^2}{2} + 4\theta_1 - 5 - \theta_2 \leq 0, \\ & 10 - \frac{(\theta_1 - 4)^2}{5} - \frac{\theta_2^2}{0.5} \leq 0, \\ & \theta_2(6 + \theta_1) - 80 \leq 0. \end{aligned} \quad (9)$$

Both uncertain parameters are considered to vary within the range of  $(-20, 20)$ . In order to solve the

**Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 4**  
Sampling of feasible space using (a) genetic algorithm and (b) random sample

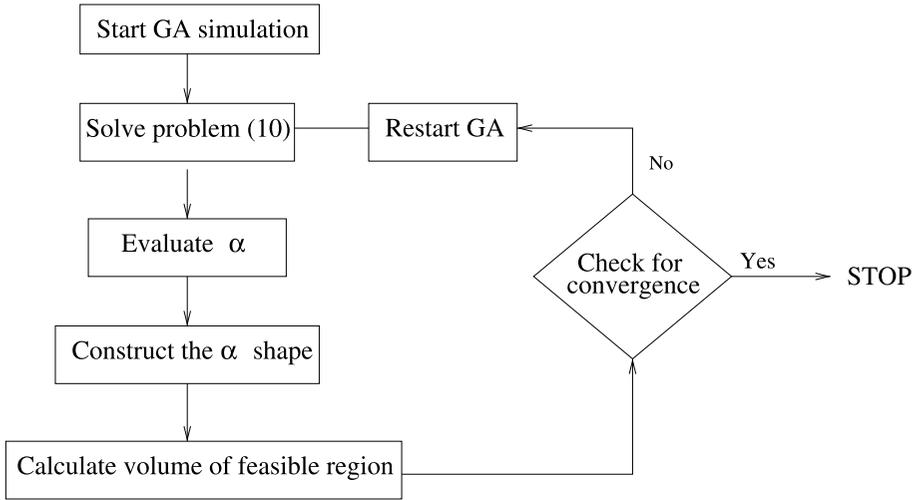

problem using a GA, the parameters  $\theta_1$  and  $\theta_2$  are encoded as bits, with 7 bits for each parameters, giving rise to a 14-bit chromosome. A population size of 20 is chosen for this problem following the guideline of Edwards et al. [4].

The working principle of a GA is based on generating multiple numbers of good solutions. Hence evaluating the volume for each of the feasible parameter values ( $\theta$ ) will reduce the efficiency of the procedure because of the repetition of the solution. To avoid this, a memory of the sampled parameter value is maintained and updated. For every generated chromosome in the population of the GA simulation, the stored parameter values are searched to check for uniqueness of the new solution. If a new solution is unique, then the constraints are evaluated; else it is updated from the memory. Chromosome evolution through 2000 generations requires a total of 40,000 function calls, of which only 3064 are unique and 938 are feasible points as illustrated in Fig. 4. The same problem was solved by drawing random samples in the range  $(-20, 20)$  for both uncertain parameters (Fig. 4b), where 9830 function calls were required to generate 950 feasible points. However, this procedure is particularly advantageous when the feasible region is a small portion of the entire parameter range. Otherwise its performance becomes comparable to random sampling over the entire parameter range.

In the above formulation, the volume of the feasible region,  $V_{\text{feas}}$ , is computed by generating an  $\alpha$  shape of the sampled points. An alternative formulation for generating the sampled data set is given by

$$\begin{aligned} & \max \sum \Theta_{\text{feas}}, \\ & \theta_2 - 2\theta_1 - 15 \leq 0, \\ & \frac{\theta_1^2}{2} + 4\theta_1 - 5 - \theta_2 \leq 0, \\ & 10 - \frac{(\theta_1 - 4)^2}{5} - \frac{\theta_2^2}{0.5} \leq 0, \\ & \theta_2(6 + \theta_1) - 80 \leq 0, \end{aligned} \quad (10)$$

where  $\Theta_{\text{feas}}$  represents a feasible sample point and the objective is to maximize the total number of sampled feasible points. This formulation is computationally less demanding since it does not require volume evaluation of the feasible region at every step. However, it suffers from the disadvantage of a lack of a convergence criterion. To overcome this problem, a hybrid of these two

Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 5  
 Modified algorithm for sampling of feasible region

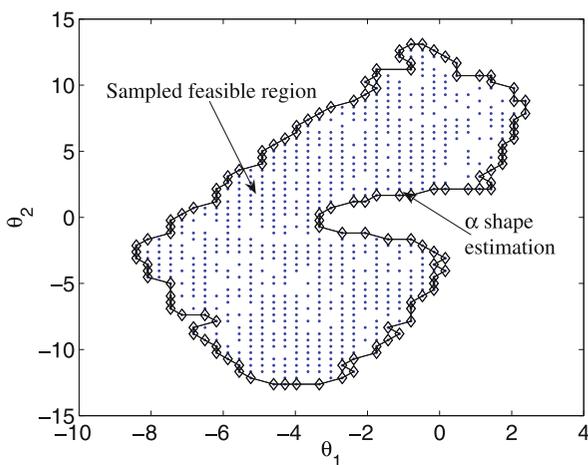

formulations (9) and (10) is used, where the main algorithm is evolved according to formulation (9), and the volume is evaluated only at intermediate points to check for convergence of the simulation. The overall procedure is illustrated in Fig. 5.

Once a good estimate of the feasible region is obtained by the sampling scheme, the surface-reconstruction algorithm is used to determine points forming the boundary of the feasible region, which are then joined

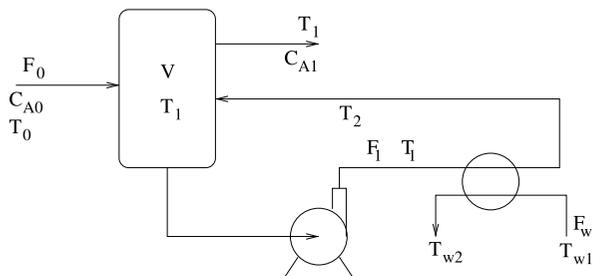

by a straight line as illustrated by Fig. 6. The value of  $\alpha$  plays a crucial role in determining the degree of detail captured by the  $\alpha$  shape. The  $\alpha$  value determined by the procedure outlined in Sect. “ $\alpha$ -Shape Approach” for the 938 sampled points is 25, which was found to capture the nonconvex nature of the object with adequate accuracy, as illustrated in Fig. 6.

**Process Operation Example**

This example represents the flow sheet shown in Fig. 7, consisting of a reactor and heat exchanger [5] where a first-order exothermic reaction  $A \rightarrow B$  is taking place. The existing design has a reactor volume ( $V$ ) of 4.6 m<sup>3</sup> and a heat exchanger area ( $A$ ) of 12 m<sup>2</sup>. Two uncertain parameters are considered, the feed flow rate  $F_0$

Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 6  
 Performance of  $\alpha$  shape in predicting feasible space using  $\alpha = 25$

Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 7  
 Reactor-cooler example

and the activation energy  $E/R$ . A mathematical model of this process is given by:

$$F_0(c_{A0} - c_{A1})/c_{A0} = V k_0 \exp(-E/RT) c_{A1}$$

$$(-\Delta H)F_0(c_{A0} - c_{A1})/c_{A0} = F_0 c_p (T_1 - T_0) + Q_{HE}$$

$$Q_{HE} = F_1 c_p (T_1 - T_2)$$

$$Q_{HE} = F_w c_{pw} (T_{w2} - T_{w1})$$

$$Q_{HE} = AU \Delta T_{ln}$$

$$\Delta T_{ln} = \frac{(T_1 - T_{w2}) - (T_2 - T_{w1})}{\ln(T_1 - T_{w2}) / (T_2 - T_{w1})}$$

$$V^d \geq V$$

$$(c_{A0} - c_{A1})/c_{A0} \geq 0.9$$

$$311 \leq T_1 \leq 389$$

$$T_1 - T_2 \geq 0.0$$

$$T_{w2} - T_{w1} \geq 0.0$$

$$T_1 - T_{w2} \geq 11.1$$

$$T_2 - T_{w1} \geq 11.1$$

$$T_0 = 333 \text{ K}, T_{w1} = 300 \text{ K},$$

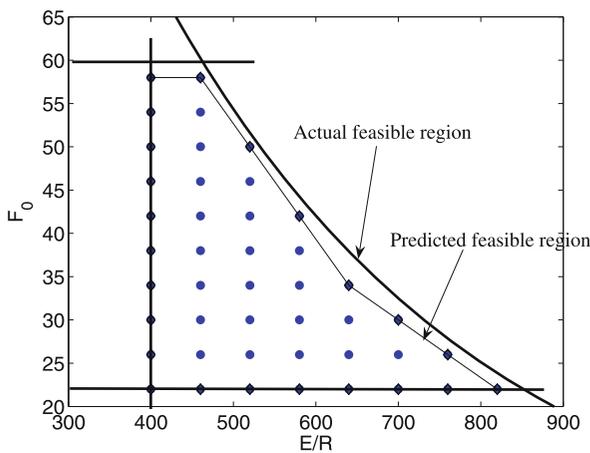

$$U = 1635 \text{ kJ}/(\text{m}^2 \text{ h K})$$

$$c_p = 167.4 \text{ kJ}/\text{kmol},$$

$$c_{A0} = 32.04 \text{ kmol}/\text{m}^3,$$

$$-\Delta H = 23260 \text{ kJ}/\text{kmol}. \quad (11)$$

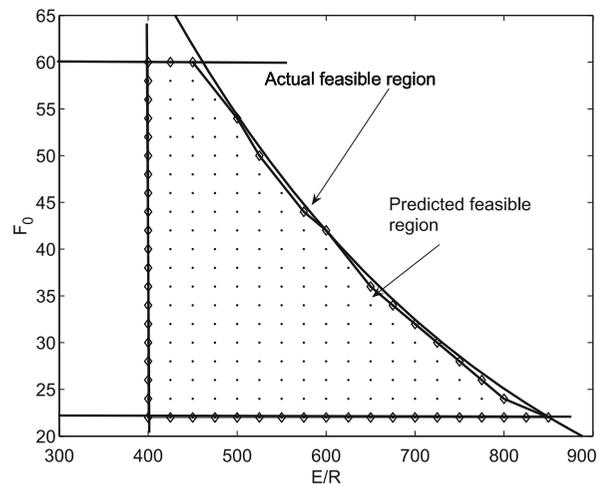

The range of uncertain parameters  $E/R$  and  $F_0$  over which the design remains feasible is illustrated in Fig. 8.

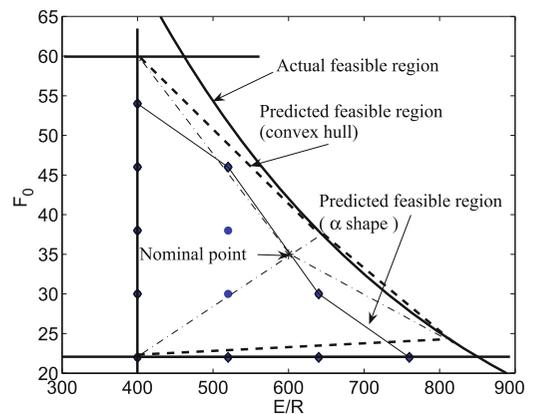

Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 8

Performance of  $\alpha$  shape in predicting the feasible space of reactor-cooler example

The aim is to have a description of the range of the parameters  $E/R$  and  $F_0$  over which the operation remains feasible. Following the proposed approach for feasibility analysis, the feasible space is first sampled by solving the problem at different values of the parameters, and a representation of the feasible region is obtained. In the next step, these sampled points are analyzed by  $\alpha$  shape to identify points lying on the boundary of the feasible region. These identified surface points are joined by straight lines to obtain a polygonal estimation of the feasible region. Figure 8 compares the actual feasible region with that of  $\alpha$ -shape estimation obtained with 400 sample points, which was found to perform with great accuracy. To understand the effect of

a

b

Shape Reconstruction Methods for Nonconvex Feasibility Analysis, Figure 9

Effect of sampling density on the performance of  $\alpha$  shape (a) 100 points (b) 25 points

sample density on the performance of the  $\alpha$ -shape procedure, the feasible region evaluation was performed with fewer sample points of 100 and 25, as illustrated in Fig. 9. The  $\alpha$ -shape prediction was found to underpredict the feasible region since the sampling density was inadequate in capturing the entire region. However, there was no overprediction of the nonconvex feasible region. Figure 9b also compares the performance of the convex hull with that of  $\alpha$  shape, where it is observed that even though the sampling density was very low,  $\alpha$  shape still captured the nonconvex nature of the feasible region. The convex hull is constructed by performing line searches toward the vertices of the uncertain space to locate points on the boundary of the feasible region. The convex hull covers a larger percentage of the feasible region compared to the  $\alpha$  shape for the case of sparse sampling, but it overpredicts the feasible region over the nonconvex constraint. The performance of  $\alpha$  shape is directly dependent on the information captured by the sampling of the feasible space. It is important to know, however, that in the absence of sufficient information the  $\alpha$  shape will be a poor predictor of the feasible space, but it will not lead to erroneous results.

## Conclusions

The problem of evaluating the feasible range of a process operation is addressed in this paper using surface-reconstruction ideas. The problem definition is to evaluate and quantify the uncertain parameter range over which a process retains its feasibility. In the present approach the feasible region is viewed as an object, with process constraints defining the boundary of the object. Surface-reconstruction ideas are used to define the shape of the object. The procedure starts by first sampling the feasible region to obtain a representation of the feasible space. An  $\alpha$  shape is then constructed of the sampled points, which identifies points forming the boundary of the object. These points are joined to have a polygonal representation of the feasible region. Finally, determination of whether a point is feasible or not can be done by a point-in-polygon check. Examples are presented to illustrate the performance of the proposed scheme in nonconvex and even disjoint problems.

The application of the proposed technique in higher dimensions becomes computationally challenging. One

way of dealing with this issue is by reducing the dimensionality of the problem. The ideas of principal component analysis [19] can be utilized to map the original uncertainty space to the reduced dimensional space of important eigen directions. The  $\alpha$ -shape ideas can then be applied in the reduced space and the feasibility information mapped back to the original uncertain space. These ideas are currently being explored by the authors.

### Introduction

The use of zeolites as molecular sieves, absorbents and catalysts has today been well established in a wide variety of processes. However, almost the totality of applications involves a very small number of nearly circular structures, like Linde type A, faujasite and ZSM-5. These structures are usually modified to meet the specific needs of each process. Modification techniques, such as ion exchange or coke deposition, usually result in a distribution of pore sizes and shapes, something that retards the ability of the molecular sieve to be highly selective. On the other hand, there is a great variety of natural and synthetic zeolites that has been developed, but no significant effort has been made to find potential catalysis and separation applications for them. There could very well be existing structures that

are highly selective in their unmodified state, or requiring a small amount of modification, just because their windows happen to be of the proper size and shape. Gounaris et al. [7,8] developed a mathematical framework, which is based on optimization, to address exactly this issue. The framework can identify shape selective zeolite structures and provide researchers with a rigorous way to determine the best candidate portals for the process of interest.

### Characterization of Molecular Footprints

For spherical molecules going through circular windows, such as the noble gases approaching a Linde type A window, the molecular shape and the rotational orientation are not important for penetration into a channel since every possible rotation results in the same projection. The Lennard-Jones length is often used as an order-of-magnitude estimation of the size of the molecule [11]. It is also the starting point for several attempts to compare these lengths with nominal zeolite window diameters so as to identify zeolite windows that are suitable for separating a set of molecules. For instance, zeolite 3A has a diameter that is between that of H<sub>2</sub> and O<sub>2</sub>; thus, it would be a good candidate for their separation. Since most molecules are not spherical, and most windows are not circular, we need more accurate methods to characterize molecules.

We start from a simple model of a molecule as atoms connected by bonds, obtained by a quantum mechanics or a molecular mechanics calculation. In the hard-sphere model, each atom is represented by a sphere of van der Waals radius, and the bond lengths and angles are considered fixed – equivalent to an inflexible molecule at absolute zero temperature.

When a molecule approaches the opening of a channel, various rotational orientations of the molecule give rise to different projections on the horizontal plane. From this ensemble of projections, the ones that are most favorable for penetration are usually the smallest, which we would call “footprints.” If the molecule is a spheroid with three different axes, then the molecule should be oriented so that the longest axis is perpendicular to the plane, and the footprint is the ellipse formed by the two smaller axes. If the molecule is a rectangular parallelepiped, then the footprint is the rectangle formed by the two smaller axes. This suggests the fol-

lowing useful quantitative measures of the size of a footprint involving no more than two parameters:

- The footprint is the projection that can be enclosed by the smallest possible circle, characterized by its radius  $\rho_0$ .
- The footprint is the projection that can be enclosed by the ellipse with the smallest possible area. This footprint is characterized by its major and minor radii, which are denoted, respectively, with  $\rho_1$  and  $\rho_2$ . Its eccentricity is defined as  $e = \sqrt{1 - \rho_2/\rho_1}$ .
- The footprint is the projection that can be enclosed by the rectangle with the smallest possible area. This footprint is characterized by its major and minor lengths, which are denoted respectively with  $\alpha_1$  and  $\alpha_2$ . The aspect ratio is defined as  $AR = \alpha_2/\alpha_1$ .
- The footprint is the projection that minimizes the sum of the distances of the projected atomic nuclei from a suitable center. This footprint can be characterized by a major diameter  $d_M$ , which is the largest distance between two points on the edge of the footprint, and a minor one  $d_m$ , which is the width in the direction perpendicular to the major diameter. For an exact definition and a detailed description of the calculation of these diameters, see Gounaris et al. [8].
- The footprint is the projection that minimizes the sum of the distances of all the projected atomic nuclei from each other. It can be quantified with the same parameters as in measure *d*.

The computations of these quantitative measures are formulated as nonlinear programming problems or as bilevel nonlinear programming problems, and are described in detail in Gounaris et al. [8]. See Gounaris et al. [7] for examples of footprints of popular molecules and for relevant illustrations.

### Definition of Strain and Calculation of Strain Index

When a guest molecule approaches a host portal, there are three possible outcomes: free passage, constrained passage, and no passage. When the molecular projection of the guest can be entirely contained within the portal, there is no hindrance and the passage is free. When some of the atomic nuclei in the projection fall outside the window, and no rotation and translation can prevent this, then there is no passage. However, if

all nuclei fall inside the portal but some atomic radii extend beyond this area, then there can be constrained passage in the sense that the atomic spheres have to be squeezed so as to fit in the portal.

We define the amount of distortion on a single atom as

$$\delta = \frac{r_s}{r_o} \quad (1)$$

where  $r_o$  is the original atomic radius and  $r_s$  is the squeezed atomic radius.

The total strain, *S*, for a guest to penetrate through a host portal is quantified as

$$S = S_G + S_H = \sum_i \left( \frac{1}{\delta_i^{12}} - \frac{1}{\delta_i^6} \right) + \sum_j \left( \frac{1}{\delta_j^{12}} - \frac{1}{\delta_j^6} \right) \quad (2)$$

where  $\delta_i$  and  $\delta_j$  are, respectively, the amounts of distortion on the *i*th guest (G) and *j*th host (H) atom. In practice, only the oxygen atoms in the zeolite window and the outer (often hydrogen) atoms of the molecule make significant contributions.

There is a strain associated with every projection of the guest molecule, but there is some optimal projection that exhibits the minimum possible strain, denoted as  $S^*$ . This optimal projection for one channel may be different from that for another channel with a different shape. For instance, a molecule in the shape of a cylinder can give a rectangular or a circular projection, depending on the requirement posed by the shape of the portal.

Since  $S^*$  values could span a wide range of orders of magnitude, the introduction of a logarithmic scale is necessary for a better representation. We define the “strain index” as

$$SI = \log(1 + S^*) \quad (3)$$

The strain index can serve as a measure of the total distortion required for penetration to take place. A host-guest pair exhibiting a strain index of zero would correspond to a free passage, while a strain index approaching infinity would correspond to no passage at all.

A rigorous algorithmic framework to calculate robustly the strain index of a given host-guest pair was developed by Gounaris et al. [7,8]. The optimization formulation that models the problem is described below. Let us first present the notation used.

**Indices:**

- $i = 1, 2, \dots, M$  Atoms in the guest molecule  
 $j = 1, 2, \dots, N$  Atoms in the host molecule  
 $k = 1, 2, \dots, K$  Constraints defining host interior

**Decision variables:**

- $\varphi, \vartheta, \psi$  Rotation angles  
 $xt, yt$  Translation of guest projection on the x-y plane  
 $\delta_i, \delta_j$  Required distortion of guest and host atoms

**Auxiliary variables:**

- $d_{ij}$  Distance of the  $i$ th guest atom projection from the  $j$ th host atom  
 $\begin{bmatrix} x_i \\ y_i \end{bmatrix}$  Position of the  $i$ th guest atom (after rotation and projection)

**Parameters:**

- $\begin{bmatrix} x_i^0 \\ y_i^0 \\ z_i^0 \end{bmatrix}$  Coordinates of the  $i$ th guest atom (random orientation)  
 $\begin{bmatrix} xh_j \\ yh_j \end{bmatrix}$  Position of  $j$ th host atom on x-y plane  
 $a_k, b_k, c_k$  Parameters defining the convex hull of the host  
 $r_i, r_j$  Effective atomic radius of guest and host atoms

The objective is to minimize the total strain,  $S$ , required for penetration:

$$\min_{\substack{\varphi, \theta, \psi \\ xt, yt \\ \delta_i, \delta_j}} S = \min_{\substack{\varphi, \theta, \psi \\ xt, yt \\ \delta_i, \delta_j}} \left\{ \sum_i \left( \frac{1}{\delta_i^{12}} - \frac{1}{\delta_i^6} \right) + \sum_j \left( \frac{1}{\delta_j^{12}} - \frac{1}{\delta_j^6} \right) \right\}. \quad (4)$$

For every guest atom, the position of its center should correspond to a valid rotation that resulted from the original conformation provided. According to the “x y z” convention for rotation matrices, the coordinates of the projected atom nuclei are given by

$$\begin{aligned} x_i &= \cos \theta \cdot \cos \varphi \cdot x_i^o + \cos \theta \cdot \sin \varphi \cdot y_i^o \\ &\quad - \sin \theta \cdot z_i^o + xt \quad \forall i \\ y_i &= (\sin \psi \cdot \sin \theta \cdot \cos \varphi - \cos \psi \cdot \sin \varphi) \cdot x_i^o \\ &\quad + (\sin \psi \cdot \sin \theta \cdot \sin \varphi + \cos \psi \cdot \cos \varphi) \cdot y_i^o \\ &\quad + \cos \theta \cdot \sin \psi \cdot z_i^o + yt \quad \forall i. \end{aligned} \quad (5)$$

The terms  $xt$  and  $yt$  allow for translation of the projection on the x-y plane, so as to obtain a better fit with respect to the host. Note that the host-guest conformations are provided independently, and there is no requirement that they use the same reference coordinate system.

For every pair of host-guest atoms, we impose the condition that their effective spheres cannot intersect with each other, therefore implying that they have to be squeezed to fit:

$$\begin{aligned} d_{ij} &\geq \delta_i \cdot r_i + \delta_j \cdot r_j \\ d_{ij}^2 &= (x_i - xh_j)^2 + (y_i - yh_j)^2 \quad \forall (i, j). \end{aligned} \quad (6)$$

In order to avoid obtaining (otherwise valid) solutions where the guest is completely outside the portal area, we have to include also a set of constraints that outer-approximates the portal. A set of linear constraints that serves the purpose is the one that describes the convex polygon whose vertices coincide with the atom centers of the host:

$$a_k \cdot x_i + b_k \cdot y_i \leq c_k \quad \forall (i, k). \quad (7)$$

The parameters  $a_k$ ,  $b_k$ , and  $c_k$  can be easily calculated from the host atom coordinates  $\begin{bmatrix} xh_j \\ yh_j \end{bmatrix}$ . Note that only those atoms that participate in the host’s convex outer approximation are used for this calculation; therefore,  $K$  does not necessarily have to equal  $N$ . This only happens in the case of convex portals.

Finally, the following bounds have to be applied to the decision variables of the problem:

$$-\pi < \varphi, \theta, \psi \leq +\pi \quad (8)$$

$$\begin{aligned} 0 &\leq \delta_i \leq 1 \quad \forall i \\ 0 &\leq \delta_j \leq 1 \quad \forall j. \end{aligned} \quad (9)$$

The bounds on the Euler angles are imposed so as not to obtain periodic solutions, while the bounds on the deltas relate to their definitions. Note that no bound is imposed on the translation variables  $xt$  and  $yt$ , which are allowed to vary freely.

The minimization of the objective function (4), subject to constraints (5)–(9), constitutes a nonlinear programming problem that involves continuous variables. The problem is nonconvex, with nonconvexities introduced both by the objective function (definition of total strain) and by the constraints (projected rotations

nitrogen and oxygen approaching the relatively large opening of faujasite, there is no selectivity and no separation. When none of the molecules pass, such as the case of oleic and linoleic acid approaching the channel of SAPO-56, there is also no selectivity and no separation. When some of the molecules have strain indices different from those of others, such as in the case of ethane and ethylene approaching ERS-7, then there is selectivity and potential for catalysis or separation. A higher strain index may reduce the diffusion rate or reduce the equilibrium adsorption, instead of completely denying passage, but it would nevertheless serve the separation scheme.

When a molecule is being squeezed to fit a host channel, some activation energy is required which would lead to a decrease of the equilibrium concentration in the channel according to the Boltzmann equation:

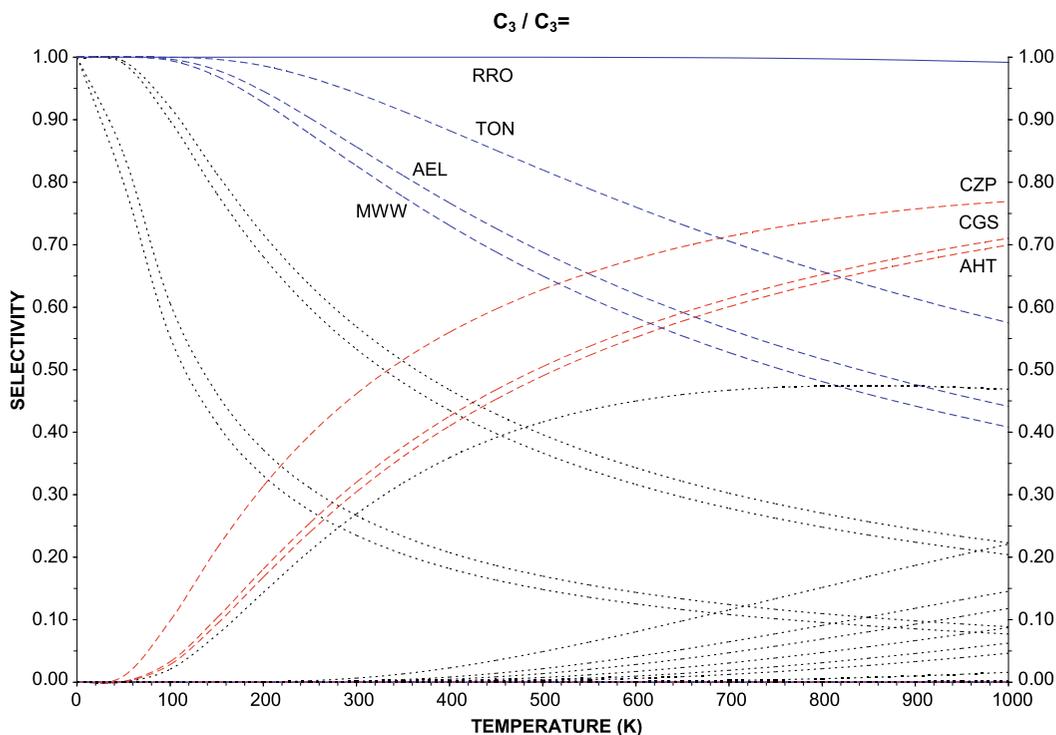

$$\frac{C}{C_0} = \exp\left(-\frac{E}{RT}\right) = \exp\left(-\frac{4\varepsilon S}{RT}\right), \quad (10)$$

where  $\varepsilon$  is some “hardness” coefficient. An averaged Lennard–Jones parameter may be used.

Let us define selectivity between two molecules A and B,  $\gamma_{AB}$ , as the difference between their reduced equilibrium concentrations:

$$\begin{aligned} \gamma_{AB} &= \left| \left(\frac{C}{C_0}\right)^A - \left(\frac{C}{C_0}\right)^B \right| \\ &= \left| \exp\left(-\frac{E^A}{RT}\right) - \exp\left(-\frac{E^B}{RT}\right) \right|. \end{aligned} \quad (11)$$

If the distortion energies required are similar, both molecules will penetrate the same relative amount, and therefore  $C^A/C^B \approx C_0^A/C_0^B$  and there is no selectivity ( $\gamma_{AB} \rightarrow 0$ ). On the other hand, if the energies are substantially different, the penetration levels will be different and high selectivity will be achieved ( $\gamma_{AB} \rightarrow 1$ ). In the case where  $E_A \rightarrow 0$ , selectivity is at a maximum at very low temperatures, but a rise in temperature can activate molecules B and selectivity will decline.

Shape Selective Zeolite Separation and Catalysis: Optimization Methods, Figure 2

Selectivity vs. temperature for the  $C_3/C_3=$  system. RRO RUB-41, TON Theta-1, AEL AIPO-11, MWW MCM-22, CZP chiral zincophosphate, CGS cobalt gallium phosphate-6, AHT AIPO-H2

An illustrative example of such calculations is presented in Fig. 2, where selectivity is plotted versus temperature for the system of propane/propylene. RUB-41 is identified as the most promising candidate for the separation of the two C<sub>3</sub> molecules. It maintains a very high selectivity along the whole range of temperatures considered. Theta-1, AlPO-11 and MCM-22 are also selective at ambient temperature, but their performance deteriorates at higher temperatures. All these structures correspond to the case where one of the two molecules (propylene) enjoys a free passage through the portal, while the second molecule (propane) has to experience some distortion. A different trend holds for chiral zincophosphate (CZP), cobalt gallium phosphate-6 and AlPO-H2, which seem to benefit from an increase in temperature. The potential of RUB-41 to be highly selective on the C<sub>3</sub> system can be explained by the high degree of similarity between propylene's projection and the actual shape of the portal, a similarity that resembles the analogy between a lock and a key.

## Biographical Summary

Naum Zuselevich Shor (1937–2006) is recognized as one of the paramount researchers in the field of optimization. He is well known for his significant contributions to many important areas of optimization, including nonlinear and stochastic programming, computational methods for nonsmooth optimization, discrete optimization problems, matrix optimization, dual quadratic bounds in multiextremal programming problems, and numerical algorithms for solving large-scale optimization problems.

## Biographical Details

A renowned Ukrainian mathematician, Shor was born on January 1, 1937. His childhood took place during the horrific years of World War II. In 1954, Shor entered the Mechanics and Mathematics Department of National Taras Shevchenko University in Kiev, Ukraine. Two years later in 1956, the young brilliant scientist Victor Mikhylovich Glushkov moved to Kiev and was

appointed director of a newly created Computing Center (formerly one of the laboratories at the Institute of Mathematics) of the National Academy of Sciences of Ukraine (NASU). Shor decided to focus his attention on differential algebra and began working on his diploma thesis under Glushkov's supervision.

In 1958, Shor graduated from Taras Shevchenko University and was invited by Glushkov to join the Computing Center, which 4 years later became the Institute of Cybernetics of NASU. There Shor became an active part of the research group guided by another talented mathematician, Vladimir Sergeevich Mikhalevich. First, Shor examined the problems of modeling and optimization of the reliability of computing devices, as well as application of noise power spectrum analysis to various problems in radiology. By 1960, the research team of Mikhalevich had evolved into the Department for Applied Problems with a focus on optimal planning and design. This transformation had completely shifted Shor's scientific interests toward the field of optimization, which emerged as a new area of mathematics in the 1940s. Working together on the optimal selection of design decisions, Shor and Mikhalevich constructed a numerical procedure for sequential analysis of variants. The proposed procedure represented a generalization of dynamic programming algorithms. It could easily be employed for solving various applied problems of optimal design and planning, including, but not limited to, gas supply systems, electrical networks, and transportation route systems. As a result, their ingenious numerical scheme received a high number of citations. Continuing his work in optimal design, Shor had also suggested a method for solving optimal design problems for lengthy objects and treelike structures. In addition, Shor was the first to apply the subgradient descent method to optimization of nonsmooth functions in 1962. Specifically, using the subgradient scheme, he devised an approach for solving large-scale dual network transportation problems by reduction to the maximization of a piecewise linear function. His approach later became well known as the generalized gradient descent method. In 1964, Shor defended his Ph.D. dissertation entitled "On the Structure of Algorithms for Numerical Solution of Problems of Optimal Planning and Design."

After earning his doctor of philosophy degree in 1964, Shor continued his work on application of his

generalized gradient descent method to various mathematical programming problems, including block programming and two-stage stochastic programming. In 1967, he also cowrote a book with Mikhalevich on the computational approaches to optimal selection of design decisions. Only 1 year after the book on optimal design had been published, Yuriy Ermoliev and Shor devised a modification of Shor's subgradient method for solving two-stage stochastic programming problems. This revolutionary approach was later advanced even further by the research team led by Ermoliev and became known as the direct quasi-gradient method for optimization under uncertainty.

Another pioneering approach in optimization, which was introduced by Shor in 1970, was based on the idea of space transformation known as dilation. Almost concurrently, Shor worked on two methods involving space dilation. The first technique is the method with space dilation in the direction of the subgradient, which is used for solving systems of nonlinear equations and inequalities. The second method, also known as the  $r$ -algorithm, utilizes the operation of space dilation in the direction of the difference between two consecutive subgradients. The  $r$ -algorithm has become one of the most efficient procedures for solving complex optimization problems. Nearly a decade of his research on the subgradient and subgradient-type methods with space transformation was finally summarized by Shor in his monograph *Minimization Methods for Non-Differentiable Functions and Applications*, which was first published in 1979, and just 6 years later was translated into English.

Remarkably, the famous ellipsoid method, which was independently formulated by A.S. Nemirovsky and D.B. Yudin in 1975, and which was used by L.G. Khachiyan in 1979 to prove that linear programming problems can be solved in polynomial time, is actually a special case of Shor's method with space dilation in the direction of the difference between two consecutive subgradients.

In the early 1980s, Shor became captivated with graph theory while working on the network optimization problems. Together with his Ph.D. student G.A. Donets, he was investigating the graph coloring problems. In particular, they formulated a hypothesis on the number of solutions for coloring of a plain graph. This hypothesis on plain graph colorings is ev-

idently supported by computational experiments. In 1982, their treatise on the algebraic approach to the problems of plain graph coloring was published.

In the second half of the 1980s, Shor collaborated with S.I. Stetsenko on quadratic extremal problems. Later he investigated dual estimates in multiextremal problems and produced a paper on this subject in 1992. The same year, Shor's joint paper with O.A. Berezovski, where they described new procedures for constructing optimal inscribed and circumscribed ellipsoids, also appeared in the press. The scope of his research was continuously expanding to other complex areas of optimization to include minimization of matrix functions (1995), generalized set partitioning problems (1996), polynomial optimization problems (1998), nonsmooth optimization in stochastic programming (1999), and Lagrangian bounds for multiextremal polynomial and discrete optimization problems (2002). Furthermore, in 1998, his extensive analysis of polynomial problems using methods of nondifferential optimization was published in a monograph. The book included a comprehensive review of techniques used in nondifferential optimization as well as their application to various problems, such as the problems of discrete optimization and graph optimization, polynomial problems, and optimal Lyapunov functions. Polynomial problems were given special consideration. Specifically, Shor discovered that in order for the dual quadratic bound of a polynomial to be equal to the global minimum of such a polynomial, it is necessary and sufficient that the difference between the polynomial and its global minimum could be represented as a sum of squares of real polynomials. This result illustrates the connection between the problems of nonconvex polynomial optimization and David Hilbert's 17th problem about representation of a definite rational function as a quotient of the sum of squares, which was posed by Hilbert in 1900 and solved by Emil Artin in 1927.

Until his death on February 25, 2006, Shor kept actively working on different intricate optimization problems. His dedication to research, immense knowledge, and unstoppable intellect were manifested in his undisputable achievements in the field of mathematical programming. During his long research career, Shor won numerous awards. Among the most prestigious are both the former USSR and Ukraine State Prizes in Science and Technology (1973, 1981, 1993, and 2000). In

addition, for his great contribution to computational methods for solving large-scale optimization problems, Shor was recently awarded the Glushkov Prize and the Mikhalevich Prize. In recognition of his lifelong scientific accomplishments, he was elected as an Associate Member of the National Academy of Sciences in Ukraine in 1990, and became a full Member of the Academy on December 4, 1997. During his life, Shor had over 180 research papers and nine books published and supervised Ph.D. dissertations of over 35 students who now continue his scientific work not only in Ukraine, but all over the world.

## Keywords

Combinatorial optimization; Auction technique;  
Network optimization; Shortest path problem

The shortest path tree problem is a classical and widely studied combinatorial problem ([1,23,24]). The scope of this article is to provide an extensive treatment of the major classical approaches. It then proceeds focusing on the auction algorithm and some of its recently developed variants. There is a discussion of the theoretical and practical performance of the treated methods comparing their effectiveness.

## Mathematical Model

The shortest path problem can be posed in more than one way:

- 1) to find the shortest path from a single source to a single destination;
- 2) to find the shortest path from each of several sources to each of several destinations;
- 3) to find the shortest path from one single source to all destinations.

Problems of type 3) are also called *shortest path tree problems* (SPT).

Before describing the single source-all destinations shortest path problem, we report in the following the needed notation and definitions.

Let  $G = (V, E, C)$  be a directed graph, where

- $V$  is a set of nodes, numbered  $1, \dots, n$ ;
- $E = \{(i, j) : i, j \in V\}$  is a set of  $m$  edges;
- $C: E \rightarrow \mathbf{R}$  is a function that assigns a length to any edge  $(i, j) \in E$ ;
- a *forward path*  $P = \{(i_1, i_2), \dots, (i_{k-1}, i_k)\}$  is a set of edges, whose length is the length of its edges.

In order to assure that the shortest path problem admits a solution, it must be assumed that:

- all cycles in the graph have nonnegative length;
- the graph is strongly connected.

The last assumption can be removed by defining the distance between not connected nodes equal to  $+\infty$ .

Let moreover  $s$  be the label of the source node; then the *single source shortest path tree problem* (SPT) can be formulated as

$$\begin{cases} \min & \sum_{(i,j) \in E} c(i,j)x(i,j) \\ \text{s.t.} & \sum_{(i,j) \in E} x(i,j) - \sum_{(h,i) \in E} x(h,i) = b_i \\ & b_i = -1, \quad i \neq s, \quad \text{and} \quad b_s = n - 1 \\ & x(i,j) \in \{0, 1\}, \quad \forall (i,j) \in E. \end{cases} \quad (1)$$

The dual problem (DSPT) is:

$$\begin{cases} \max & (n-1)\pi(s) - \sum_{j \neq s} \pi(j) \\ \text{s.t.} & \pi(i) - \pi(j) \leq c(i,j), \quad \forall (i,j) \in E, \end{cases} \quad (2)$$

where  $\pi(i)$  is the dual variable associated with the node  $i$ .

## A Generic Shortest Path Algorithm

Any shortest path algorithm for the single source-all destinations problem maintains and adjusts a vector  $\{\pi(1), \dots, \pi(n)\}$  of *distance labels* that can be scalars either  $\infty$  and that satisfy

**Proposition 1** Let  $\{\pi(1), \dots, \pi(n)\}$  be scalars satisfying

$$\pi(j) \leq \pi(i) + c(i,j), \quad \forall (i,j) \in E, \quad (3)$$

and let  $P$  be a path starting from a node  $i_1$  and ending at a node  $i_k$ . If

$$\pi(j) = \pi(i) + c(i,j), \quad \forall (i,j) \in P. \quad (4)$$

Then  $P$  is a shortest path from  $i_1$  to  $i_k$ .

The conditions (3) and (4) are also known as *complementary slackness conditions* (CSC) from the connection of the shortest path problem with the minimum cost flow problem. The generic shortest path algorithm starts with some vector of labels  $\{\pi(1), \dots, \pi(n)\}$  and successively selects edges  $(i,j)$  that violate (4). For each violating edge it sets

$$\pi(j) = \pi(i) + c(i,j)$$

and stops when CSC is satisfied by all edges. Intuitively, the labels  $\pi(i)$  can be view as the length of some path  $P_i$  from the source to the node  $i$ . Therefore, if  $\pi(j) > \pi(i) + c(i, j)$ , the path obtained by extending  $P_i$  by edge  $(i, j)$  is shorter than  $P_j$  whose length is  $\pi(j)$ . This can be iterated to find successively better paths from the source to various destinations.

The violating edges could be arbitrarily chosen, but a more efficient way is to establish an order of selecting nodes from a set  $L$ , called *candidate list*, and checking violation of the CSC for all of their outgoing edges.

Let the node labeled 1 be the source node; then the pseudocode of a prototype shortest path algorithm is as follows:

```

Set  $L = \{1\}$ ,  $\pi(1) = 0$ ,  $\pi(i) = \infty \forall i \neq 1$ .
WHILE  $L \neq \emptyset$ 
  select from  $L$  a node  $i$ ;
  FOR each outgoing edge  $(i, j)$ 
    IF  $\pi(j) > \pi(i) + c(i, j)$ 
      set  $\pi(j) = \pi(i) + c(i, j)$ 
      add  $j$  to  $L$  if  $j \notin L$ 
    ENDIF
  ENDFOR
ENDWHILE

```

Pseudocode of a prototype shortest path algorithm

## Implementations of the Generic Algorithm

In the literature there exist many implementations of the generic algorithm that differ in the criterion of selection of the next node to be removed from the set  $L$ . Traditionally, they are divided into two groups:

- 1) *Label setting methods*: the node  $i$  to be removed from  $L$  corresponds to the minimum label. If the input data are nonnegative, it can be shown that each node will enter  $L$  at most once and its label has permanent value the first time that node is extracted from  $L$ . At each iteration must be calculated the minimum label over  $L$  and many implementations of this approach differ in the procedure they use to obtain that minimum.
- 2) *Label correcting methods*: the choice of the node  $i$  requires less calculations, even if a node  $i$  can be involved more than once.

## Label Setting Methods

The first label setting algorithm is due to E.W. Dijkstra in 1959 [20]. In this method the next node to be removed from  $L$  is the node  $i$  such that  $i = \arg \min_{j \in L} \pi(j)$ . There are different versions of this algorithm depending on the particular data structure representing the set  $L$  and used to facilitate the removal and the addition of nodes, as well as finding the node with the minimum label and this choice is crucial for good practical and theoretical performance. The most famous and efficient Dijkstra-like algorithms are S-HEAP and S-DIAL.

```

Set  $L = \{1\}$ ,  $\pi(1) = 0$ ,  $\pi(i) = \infty \forall i \neq 1$ .
Set  $L(1) = 1$ ,  $L(\text{last}) = \text{nil}$ ,  $p_i = \text{nil} \forall i$ 
WHILE  $L \neq \emptyset$ 
   $i = L(1)$ ;
  replace  $L(1)$  by  $L(\text{last})$ 
  order heap  $L$ 
  FOR each outgoing edge  $(i, j)$ 
    IF  $\pi(j) > \pi(i) + c(i, j)$ 
      set  $\pi(j) = \pi(i) + c(i, j)$ 
      set  $p_j = i$ 
      IF  $j \notin L$ 
        insert  $j$  into  $L$  as  $L(\text{last})$ 
        order heap  $L$ 
      ENDIF
    ENDIF
  ENDFOR
ENDWHILE

```

Pseudocode of S-HEAP

## S-HEAP

The data structure chosen to represent the set  $L$  is a *binary heap*, i. e. a tree whose radix corresponds to the node having the minimum label and in which each node has label not greater than those of its children. By using this data structure, the removal of the node  $L(1)$  corresponding to the minimum label, the insertion of a new node in the last position  $L(\text{last})$  and the correction of the label of a node already inserted in  $L$  have complexity  $O(\log q) \leq O(\log n)$ , where  $q$  is the cardinality of  $L$  and  $n$  the number of nodes. At each iteration the radix of the heap  $L$  is removed and some labels of nodes belonging to  $L$  may decrease. Therefore, some nodes may have to be repositioned in  $L$ , while

some other nodes may enter in it for the first time in  $L$  and have to be put at the right position. Each of the just mentioned operations takes  $O(\log n)$  time. The total number of insertions is  $n$  as well as that of removals. Therefore, the number of operations needed to keep ordered the heap  $L$  is  $O((n+r)\log n)$ , where  $r$  is the total number of repositioning operations. To get an upper bound on  $r$ , it is enough to observe that there is at most one repositioning for each edge, because each edge is involved at most once. Thus,  $r \leq m$  and the total operation count needed to maintain  $L$  is  $O(m \log n)$ . Because this dominates the  $O(m)$  operation count to examine each edge, the worst-case running time of S-HEAP is  $O(m \log n)$ , even if experimental results ([9]) indicate that it grows approximately like  $O(m + n \log n)$ , because usually  $r$  is a small multiple of  $n$  and considerably less than  $m$ .

### S-DIAL

This algorithm, due to R.B. Dial in 1969 [19], assumes that all edge lengths are nonnegative.  $L$  is implemented as a direct-address table, a dynamic array having a number of elements equal to the maximum number of different label values. Since every finite label is equal to the length of some path with no cycles, the possible label values range in

$$[0, (n-1) \max_{(i,j) \in E} c(i,j)].$$

The entry  $i$  of  $L$ , also called a *bucket*, is a double-linked list containing each node whose label is  $i$ . The algorithm starts with the source node 1 in the bucket  $L(0)$  and all other buckets are empty. At the first iteration the algorithm puts each node  $(1, i)$  in the bucket  $L(c(1, i))$  and then proceeds to examine the bucket  $L(1)$ . If  $L(1)$  is nonempty, it repeats the process, removing from  $L$  each node with label 1 and moving other nodes to smaller numbered buckets, otherwise it proceeds checking bucket  $L(2)$  etc.

Checking the emptiness of a bucket and inserting or removing a node from a bucket require  $O(1)$  time; searching the minimum label node requires  $O(n \max_{(i,j) \in E} c(i,j))$ , while adjusting node labels and repositioning nodes between buckets require  $O(m)$ . Therefore, the running time of S-DIAL is pseudopolynomial and is given by  $O(m + n \max_{(i,j) \in E} c(i,j))$ .

```

Set  $L(0) = \{1\}$ ,  $\pi(1) = 0$ ,  $\pi(i) = \infty \forall i \neq 1$ .
Set  $z = 0$ ,  $p_i = \text{nil} \forall i$ .
WHILE  $L \neq \emptyset$ 
  move on  $L$  until  $L(z) \neq \emptyset$ ;
  set  $i$  equal to the first element of  $L(z)$ 
  remove  $i$  from  $L(z)$ 
  FOR each outgoing edge  $(i, j)$ 
    IF  $\pi(j) > \pi(i) + c(i, j)$ 
      IF  $j \in L$  THEN remove  $j$  from  $L(\pi(j))$

### Label Correcting Methods

The label correcting methods require less sophisticated calculations to select the next node to be removed from  $L$ , but as counterpart they may involve a node more than once. All these methods implement the set  $L$  as a queue and differ in the particular type of queue they use and in the choice of the position in the queue  $L$ , where new node labels are inserted. In this section we will treat two among the most famous label correcting methods: the Bellman–Ford method and the D’Esopo–Pape method.

### Bellman–Ford Method

The Bellman–Ford method is related to the method proposed by R. Bellman [3] and L.R. Ford [22]. It uses a FIFO strategy to maintain the queue  $L$ : a node is removed only from the top of the queue and is inserted at its bottom. This method proceeds in cycles of iterations: the first cycle consists of iterating on the source node 1, while in each subsequent cycle the nodes entered  $L$  during the previous cycle are removed from  $L$  in the same order that they were inserted.

The Bellman–Ford algorithm solves the SPT in the more general case in which the edge lengths can be negative and fails to terminate if and only if there exists a path starting from the source and containing a negative cycle. In the case where all cycles in the graph have

```

Set  $L = \{1\}$ ,  $\pi(1) = 0$ ,  $\pi(i) = \infty \forall i \neq 1$ .
Set  $p_i = \text{nil}$ ,  $\forall i$ .
WHILE  $L \neq \emptyset$ 
  set  $i = \text{top element of the queue } L$ 
  remove  $i$  from  $L$ 
  FOR each outgoing edge  $(i, j)$ 
    IF  $\pi(j) > \pi(i) + c(i, j)$ 
      set  $\pi(j) = \pi(i) + c(i, j)$ ,  $p_j = i$ 
      IF  $j \notin L$  THEN
        insert  $j$  into  $L$  at the bottom
      ENDIF
    ENDIF
  ENDFOR
ENDWHILE

```

### Pseudocode of the Bellman–Ford method

nonnegative length, the shortest distance of every node can be obtained after at most  $n - 1$  iteration cycles. Since in each iteration cycle each edge is involved at most once and each iteration cycle requires  $O(m)$  operations, the running time of this method is  $O(nm)$ .

### D’Esopo–Pape Method

Like the Bellman–Ford method this method can be used to detect the presence of a negative cycle and like the Bellman–Ford method, a node is always removed from the top of the queue  $L$ , but it is inserted at its bottom if it has never been in  $L$  before, otherwise it is put at the top. The choice of this inserting strategy comes observing that the removal and the updating of the label of a node  $i$  affect the labels of a subset  $N_i$  of neighbor nodes  $j$  with  $(i, j) \in E$ . Therefore, by placing the node at the top of the queue, the labels of nodes belonging to  $N_i$  will be updated as quickly as possible.

### Auction Algorithms

The *auction approach* was proposed by D. Bertsekas [4] (see also [5,6]) for solving the assignment problem. It was then generalized for the transportation problem, the minimum cost flow problem [10,11,12] and for the shortest path [7]. A complete survey of the auction algorithm can be found in [8, Chapt. 4].

To solve the problem SP, the standard forward auction algorithm follows a primal-dual approach and con-

sists of tree basic operations: *path extension*, *path contraction* and *dual price increase*.

```

Let  $i$  be the terminal node of  $P$ .
IF  $\pi(i) < \min_{(i,j) \in E} \{c(i, j) + \pi(j)\}$ 
  THEN go to Step 1;
  ELSE go to Step 2.
ENDIF
Step 1 (CONTRACT PATH)
  Set  $\pi(i) = \min_{(i,j) \in E} \{c(i, j) + \pi(j)\}$ .
  IF  $i \neq s$ 
    contract  $P$  and go to next iteration.
  ENDIF
Step 2 (EXTEND PATH)
  Extend  $P$  by node
   $j_i = \arg \min_{(i,j) \in E} \{c(i, j) + \pi(j)\}$ .

```

The algorithm starts with a pair  $(P, \pi)$  satisfying CSC, (at start  $P$  may consist only of  $s$  and  $\pi$  may be zero), then it proceeds in iterations, transforming  $(P, \pi)$  into another pair satisfying CSC, that is at each iteration a dual feasible solution and a primal (infeasible) solution are available for which complementary slackness holds. Therefore, while the algorithm maintains complementary slackness, it either constructs a new primal solution (not necessarily feasible) or a new dual feasible solution, until a primal feasible (and hence also optimal) is obtained. In more detail, at each iteration the candidate path  $P$  is either extended by adding a new node at the end of the path or contracted by deleting from  $P$  the last inserted node, said terminal node. At any iteration, if no extensions or contractions are possible, the value of the dual variable corresponding to the terminal node of  $P$  is raised. The algorithm terminates when the candidate path  $P$  is extended by the target node, in case of single source-single destination problem, or when each node has been involved at least once, in case of single source-all destinations problem.

Even if the auction algorithm is introduced for solving the single source-single destination problem, it can be easily adapted to solve the SPT problem. In fact, in this case it terminates when each node has been visited at least once by the algorithm.

### Graph Reduction in Auction Algorithms

The original version of the auction algorithm for the shortest path problem was modified by S. Pallottino and

M.G. Scutellá [27], who found out conditions under that it is possible to ‘prune’ the original graph. In more detail in [27], they showed that every time the standard forward auction algorithm reaches a node  $f$ , the optimality of the candidate path  $P$  enables to delete from the original graph all edges whose head is  $f$ , except the edge  $(k, f)$ , if  $k$  is its predecessor in  $P$ . The set  $V$  of the nodes becomes in that way partitioned in the set of the nodes never visited by the algorithm and those visited at least once and that have only one incoming edge. The algorithm they have developed has a strongly polynomial computational time equal to  $O(m^2)$ , where  $m$  is the number of edges in the graph, without requiring that the cycle lengths must be positive, without assumptions on the topology of the graph and whatever are the input data.

Strengthening the graph reduction idea using upper bounds to the node shortest distances, they developed [13] an auction algorithm, whose computational time is  $O(n \min\{m, n \log n\})$ , since it deletes arcs more effectively. The set  $V$  of the nodes becomes now partitioned in three sets: the set of the nodes never visited by the algorithm, the set of those visited at least once (said *tree nodes set*) and that of the nodes never visited, but connected through an edge to at least one tree node (said *border nodes set*). The upper bounds  $u_j, j \in V$ , to the node shortest distances that they use, behave exactly as the temporary labels that Dijkstra’s algorithm associates to each node of the graph (see e.g. [8,20,23,28]). In fact, such an upper bound  $u_i$  expresses exactly the shortest distance from the source to  $i$  and as soon as the *border node*  $i$  becomes *tree node*. Bertsekas, Pallottino and Scutellá use those upper bounds in order to ‘prune’ the original graph as much as possible. In fact the algorithm they developed in [13] deletes not only the incoming edges of the last visited node  $i$  as in [27], but also all the edges  $(i, j) \in E$  if  $u_i + c(i, j) \geq u_j$  or otherwise the edge  $(k, j) \in E$  for which  $k$  is a *tree node* other than  $i$ .

### Modified Version of the Standard Auction Algorithm

A modified auction algorithm (MA), due to [16], reaches a substantial computational time improvement over the standard algorithm. Its peculiar characteristic is that the CSC are not longer maintained verified during the algorithm iterations. It proceeds as the standard

algorithm, but it does not require that the dual feasibility has to be maintained throughout the algorithm; this allows to raise the dual prices higher than in the standard algorithm and, consequently, the number of path contractions becomes substantially reduced. More precisely, the dual variable associated with the terminal node  $i$  of the candidate path  $P$  is raised to the second minimum value in the set

$$\{-(c(k, i) - \pi(k) + \pi(i), (c(i, p) - \pi(i) + \pi(p)) : (i, p) \in E\}$$

where  $k$  is the node that immediately comes before  $i$  in  $P$ . The correctness and convergence of MA are showed true through the following theoretical results, whose proofs are in [16].

### Graph Collapsing In Auction Algorithms

All *graph collapsing auction algorithms* due to [15], are based on the following simple idea. When a node of the graph is visited for the first time by the auction algorithm, then the shortest path from the source to this node is found. Moreover, during the successive computations, any sub-paths extracted from an optimal path can be substituted by (collapsed to) a single arc of the same length. Suppose that at the end of the  $k$ th iteration of the auction algorithm the node  $i_l$  is visited for the first time. This means that  $i_l$  is the terminal node of the current candidate path  $P = \{s = i_0, \dots, i_l\}$ . The CSC are satisfied and for the arcs belonging to  $P$  it holds that

$$\pi(i_j) = \pi(i_{j+1}) + c(i_j, i_{j+1}).$$

Due of this property of the candidate path  $P$ , from the point of view of the algorithm, i. e. with respect to the sequence of nodes visited for the first time, it is equivalent to consider the original graph or a graph where a subpath is replaced by a single arc, whose length is equal to the length of the replaced subpath. The exact meaning of this equivalence has been clarified in [15]. Here the description of the topological transformations has been intentionally left vague, because there are several different methods to realize these transformations leading to different algorithms which can perform more or less efficiently. In the next section one of such approaches, which seem particularly fruitful, will be described in full details. Because it performs also the graph

Let  $s$  and  $d$  be the labels of the source and the target node respectively.  
 For each  $i \in E$  let  $\text{FS}(i)$  be its forward star and let  $P$  be the candidate path.  
 Let  $\text{pred}(i)$  be the node  $k$  such that  $(k, i) \in E \cap P$ .

*Step 0:* Set  $\text{pred}(i) = \text{oldpred}(i) = \text{NIL}$ ,  $\forall i \in V$ .  
 $P = \{s\}$ .  
 Choose  $\pi \in \mathbf{R}^{|V|}$  such that  $c_{lp} - \pi_l + \pi_p \geq 0$ ,  $\forall (l, p) \in E$ .

*Step 1:* Let  $i$  be the terminal node of the path  $P$ .  
 IF  $i = d$ , THEN stop, ELSE go to Step 2.

*Step 2:* Compute  $\text{FS}(i) := \{(i, p) \in E\}$ ,  $k = \text{pred}(i)$ .  
 IF  $i = s$   
 $\gamma_1 = \min_{(s,p) \in \text{FS}(s)} \{c_{sp} + p_i\}$   
 $p^* = \arg \min_{(s,p) \in \text{FS}(s)} \{c_{sp} + \pi_p\}$   
 IF  $\text{pred}(p^*) = \text{NIL}$   
   remove from  $E$  each arc  $(l, p^*)$ ,  $l \neq s$   
    $\text{oldpred}(p^*) = s$   
 $\text{pred}(p^*) = s$   
 IF  $|\text{FS}(s)| > 1$   
    $\pi(s) = \min_{(s,p) \in \text{FS}(s), p \neq p^*} \{c_{sp} + \pi_p\}$   
 ELSE  $\pi(s) = \gamma_1$   
 $i = p^*$  and go to Step 1.

ELSE // case  $i \neq s$  //  
 IF  $\text{FS}(i) = \emptyset$  // Construction due to  $\text{FS}(i) = \emptyset$  //  
   remove from  $E$  each arc  $(l, i)$   
    $i = \text{pred}(i)$  and go to Step 1.  
 ELSE // case  $\text{FS}(i) \neq \emptyset$  //  
 $k = \text{pred}(i)$ ,  $\text{in} = \pi(k) - c_{ki}$ ,  
 $\gamma_1 = \min_{(i,p) \in \text{FS}(i)} \{c_{ip} + \pi_p\}$   
 IF  $\text{in} < \gamma_1$  // Normal contraction //  
    $\pi(i) = \gamma_1$ ,  $i = k$  and go to Step 1.  
 ELSE  
 $p^* = \arg \min_{(i,p) \in \text{FS}(i)} \{c_{ip} + \pi_p\}$   
 $\gamma_2 = \min_{(i,p) \in \text{FS}(i), p \neq p^*} \{c_{ip} + \pi_p\}$   
 $\pi(i) = \gamma_2$   
 IF  $\text{in} > \gamma_2$  // Normal extension //  
   IF  $\text{pred}(p^*) = \text{NIL}$   
     remove from  $E$  each arc  $(l, p^*)$ ,  $l \neq i$   
      $\text{oldpred}(p^*) = i$   
      $\text{pred}(p^*) = i$   
   ELSE // Graph collapsing extension //  
     add the arc  $(k, p^*)$  to the set  $E$   
     set  $c_{kp^*} = c_{ki} + c_{ip^*}$   
     IF  $\text{pred}(p^*) = \text{NIL}$   
       remove from  $E$  each arc  $(l, p^*)$   
        $\text{oldpred}(p^*) = i$   
     ELSE  
       remove from  $E$  the arc  $(i, p^*)$   
        $\text{pred}(p^*) = k$   
      $i = p^*$  and go to Step 1.

‘pruning’ operation proposed in [27], it returns a solution under the same assumptions made in [27], that is without the requirement of positive cycle lengths, without assumptions on the topology of the graph and for any kind of input data.

The main idea of graph reduction seems to be similar to that introduced in [13], because the effectiveness of both belongs to the reduction of the number of iterations (nodes visiting), but the approaches are somewhat different. In fact, while their method uses several criteria to delete those edges that certainly will not belong to a shortest path before passing over them, the approach in [15] deletes edges belonging to shortest paths, replacing a chain of them with a single edge.

### Graph Collapsing Auction Algorithm

In this section is described an auction algorithm (GCA2), due to [15], that applies fruitfully the graph collapsing concept to the modified version of the auction algorithm (MA). Note that, because during the computation MA does not maintain verified the CSC along the current candidate path, it is no longer straightforward to implement the substitution of a piece of the path with only one arc. In GCA2 this substitution is realized during the extension step, only when the second minimum value computed during the price updating phase of MA results from the incoming arc on the current node, because only in this case the CSC are verified as equality.

Besides applying the graph collapsing concept to the modified auction algorithm, GCA2 uses the dual prices updating idea even when a graph collapsing occurs. In fact, in step 2 of GCA2, when a graph collapsing occurs, a certain amount of computational effort is achieved updating the price of the current node through  $\gamma_2$ , the third minimum value, which after the collapsing becomes the second minimum value. In [15] it is shown that the computational complexity of GCA2 is not worst than that of MA, which is no worse than that of the Pallottino’s algorithm [27].

### Virtual Source Concept Applied in Auction Algorithms

In [14] two algorithms were proposed having complexity  $O(n^2)$  and in which the computational effort is reduced fully exploiting the below described property of

```

Step 0: choose  $\pi \in \mathbf{R}^{|V|}$  such that
 $c(l, p) - \pi(l) + \pi(p) \geq 0, \forall (l, p) \in E.$ 
 $\text{pred}(i) = \text{NIL}$  and  $d(i) = +\infty$  for each  $i \in V$ 
sort FS( $s$ ) in nondecreasing order
 $w(s) = \pi(s) = \text{SELECT.MIN FS}(s)$ 
 $w(l) = \pi(l)$  for each  $l \in V, l \neq s$ 
 $E = E \setminus \{(l, s), (g, j_s) : l, g \in V\}$ 
 $Q = \{s\}, i = s$  and go to Step 1.
Step 1: IF  $|Q| = |V|$  OR  $w(q) = +\infty, \forall q \in Q,$ 
THEN stop.
IF  $\pi(i) = \text{SELECT.MIN FS}(i)$  go to Step 2
ELSE go to Step 3.
Step 2: Let  $j_i = \arg \min_{(i,p) \in \text{FS}(i)} \{c(i, p) + \pi(p)\}$ 
sort FS( $j_i$ ) in nondecreasing order
 $\text{pred}(j_i) = i, d(j_i) = w(i)$ 
 $\pi(j_i) = \text{SELECT.MIN FS}(j_i)$ 
 $w(j_i) = w(i) + \pi(j_i)$ 
 $E = E \setminus \{(l, j_i) : l \in V\}$ 
INSERT( $Q, j_i$ ) and go to Step 3.
Step 3: IF  $\pi(j) = +\infty, \forall j \in \text{FS}(i)$  OR  $\text{FS}(i) = \emptyset$ 
 $w(i) = \pi(i) = +\infty$ 
ELSE
 $\pi(i)^{\text{old}} = \pi(i)$ 
 $\pi(i) = \text{SELECT.MIN FS}(i)$ 
 $w(i) = w_k(i) + (\pi(i) - \pi(i)^{\text{old}}).$ 
UPDATE( $Q, i$ )
 $i = \text{SELECT.MIN}(Q)$  and go to Step 1.

```

### Pseudocode for VSA2

the auction algorithm: when it reaches for the first time a node, said current node, the shortest path from the source to current node is found. Hence, it is obvious that all the subtrees rooted at the current node can be computed applying the algorithm from a *virtual source* located on the current node itself, and that the complete shortest path tree can be assembled joining pieces of optimal subpaths so obtained.

In order to make well defined the joining operation, the algorithm associates a label to each virtual source. In this aspect it resembles Dijkstra’s algorithm [20], but the order on which new nodes are explored remains equal to that of the auction algorithm. The *virtual source algorithm* actually combines the good characteristics of both the approaches.

The first version of the virtual source algorithm (VSA1) evolves as the standard auction algorithm with

two differences. First of all the algorithm maintains a special list  $Q$  of those nodes that during the computation become virtual sources. Moreover, the contraction phase is modified: every time it becomes needed to perform a contraction on a node  $i$ , the algorithm updates the value of a parameter  $w(i)$ , called *weight* associated to  $i$ , which is inserted in  $Q$  if it does not belong to  $Q$  yet. The next terminal node is that corresponding to the actual minimum weight on  $Q$ . During the iterations of the algorithm the list  $Q$  is maintained sorted in nondecreasing order of weights. The crucial characteristic of VSA1 is the way in which the weights of the nodes are updated. At any iteration the weight associated to each node  $i$  expresses the shortest distance from the source to the node  $i$  itself added to the actual minimum value of the function  $c + \pi$  on the set of edges outgoing from  $i$ .

Even if VSA1 is interesting from a theoretical point of view, it can be easily furthermore improved to completely eliminate not only the contraction phases, as performed by VSA1, but also extension phases. The resulting algorithm, called VSA2, performs only insertions of nodes in  $Q$  and updating of  $Q$ . Since any extension of the auction algorithms is followed by a contraction and since VSA1 creates a virtual source during a contraction phase, the authors thought to anticipate the virtual source placement on a node as soon as that node is discovered by the algorithm. A relative pseudocode is given above.

### A New Virtual Source Algorithm

In the algorithm VSA2 described in the previous section both the contraction and the extension phases are completely eliminated. The computational time depends exclusively on how efficiently can be performed the dictionary operations of insertion and updating of the data structure chosen to represent  $Q$ , the set containing the virtual sources.

In order to improve the performance of VSA2, in which  $Q$  is implemented as a queue, in the new proposed algorithm the virtual sources weights are maintained in some sorted fashion, using the property that VSA2 assigns nondecreasing weights. The basic idea is similar to that realized by Dial, who chose a direct-address table as data structure. Nevertheless, given the bounds of the memory available on a typical computer, storing a direct-address table of size equal to the max-

imum length of a path is impractical, or even impossible, if the number of nodes and/or the maximum arc cost are large. In the new proposed algorithm, instead of using the virtual sources weights as an array index directly, the array index is computed from the weight. The data structure resulting is called hash table. Since it typically uses an array of size proportional to the number of elements actually stored, a hash table is more effective than the direct addressing technique, when, as in our case, the number of elements actually stored is small compared to the size of the direct-address table. In fact, while in a direct-address table a node having label  $k$  is directly stored in the slot  $k$ , with hashing the virtual source having weight  $k$  is stored in the slot  $g(k)$ , where if  $n$  is the number of nodes of the graph and  $l = (n - 1) \max_{(i,j) \in EC(i,j)}$

$$g: U = \{0, \dots, l\} \rightarrow \{0, \dots, m - 1\}$$

is a function that maps  $U$  into the slots  $V[0, \dots, m - 1]$ . The efficiency of an hash table depends on the choice of the hash function  $g$ . An hash function is 'good' if it is such that each element is almost equally likely to hash to any of the  $m$  slots. The most popular techniques for designing a good hash function are hashing by division, hashing by multiplication and universal hashing. In practice, heuristic techniques can be also used to create hash functions that are likely to perform well. For a detailed analysis of these techniques, see [18].

The hash function allocated in the new proposed algorithm has been designed following the division method, in which for creating hash functions a key  $k$  is mapped into one of  $m$  slots by taking the remainder of  $k$  divided by  $m$ . Formally, the general hash function is the following:

$$g(k) = k \bmod m.$$

In the new virtual source algorithm  $m$  has been chosen in order to process at most 10 elements for each unsuccessful search.

Even if this line of research is still being investigated, the hash function  $g$  above defined has already led to satisfactory results, as discussed in the next section dedicated to the computational results.

### Computational Results

Detailed results are reported in [15,21], and [14]. Here, we briefly describe the results obtained comparing two

classes of algorithms that seem to be the most competitive: the auction class, from that GCA algorithms descend, and the class of Dijkstra-like algorithms.

In [15,21], and [14] we have considered as representative of the first class the forward modified auction (MA) [16], that in some preliminary performed tests has been selected as the faster one over the all competitors in all the instances. For the second class we have chosen the forward S-HEAP and the forward S-DIAL of [24] because they are widely known state of the art algorithms and because all the implementations of Dijkstra's forward algorithm often behaves similarly [17].

The experiments were conducted on a Digital Alpha 4100 running Digital UNIX V4.0B. All the auction programs were written in C and compiled with gcc ver. 2.7.2, while for the S-HEAP and S-DIAL algorithms we used the Fortran implementation due to [25].

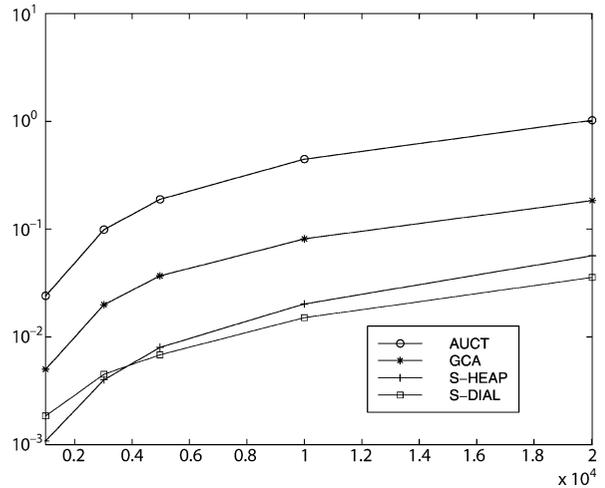

To cover most of the practically encountered instances different kinds of problems were studied; for any family of problems different sizes were considered and for any size we recorded running times employed by any algorithm averaged over ten different random generated instances.

The types of problems taken into account were: square and long grid networks, generated using the GRIDGEN code by Y. Lee and J.B. Orlin and networks generated using the NETGEN code [26] with different densities. For any of such networks we have solved the SPT problem.

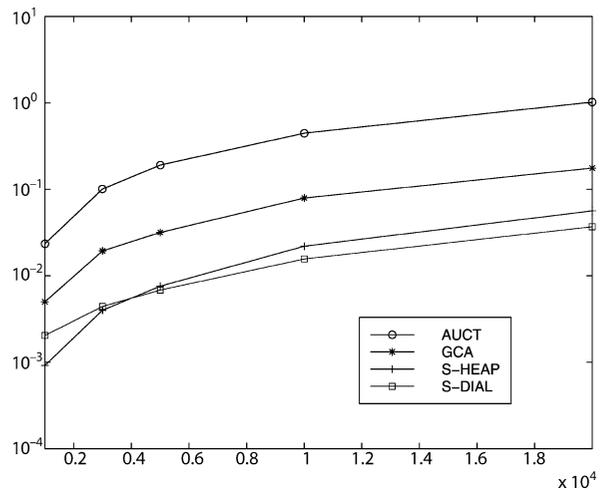

The following three groups of graphs are considered:

- 1) Square and long grid-like graphs, generated by using the GRIDGEN code, whose node number  $n$  varies from 1000 to 20000. The source is always placed at one end of the grids, so the diameter is large. All grids are planar and square with average degree for any node equal to 4. The length/height ratio is approximately 30.
- 2) General random networks generated by using the NETGEN code [26]. Even in this case  $n$  ranges from 1000 to 20000, using as arc number  $m$  both  $4n$  and  $10n$ .
- 3) Complete networks, whose nodes number  $n$  ranges from 100 to 500.

In all cases the arc lengths are randomly chosen in the range 0–10000; for any of them we solved the SPP from

Shortest Path Tree Algorithms, Figure 1  
Mean computational time on square grids

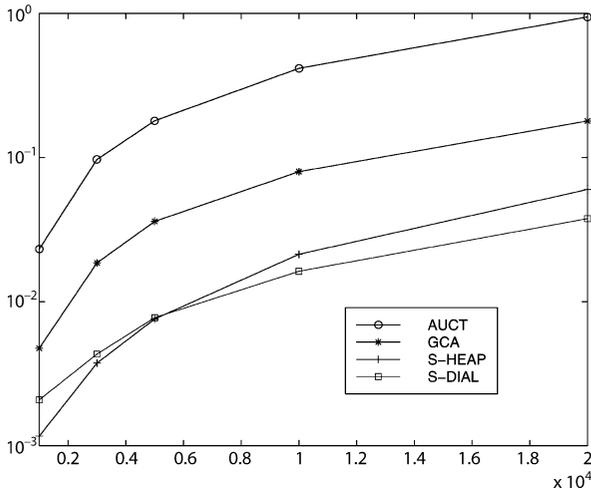

Shortest Path Tree Algorithms, Figure 2  
Mean computational time on elongated grids

the node labelled 1 by the network generator to all the other nodes. In all instances GCA2 has outperformed MA.

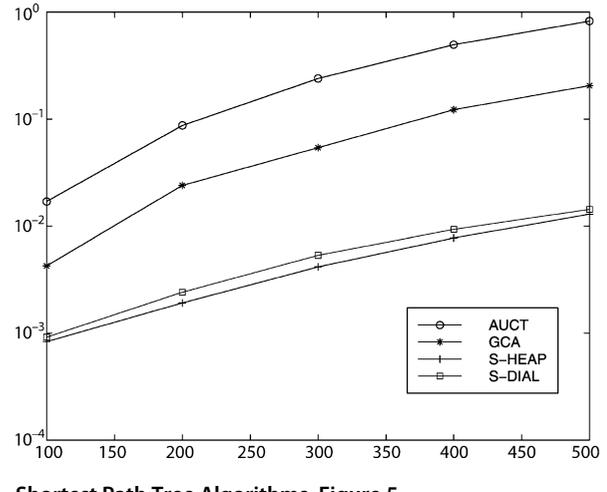

The figures show the mean computational time of the tested algorithms in seconds and in log. scale.

MA and GCA2 have analogous behavior, but in each instance GCA2 leads to a computational time saving at least of 50% over MA.

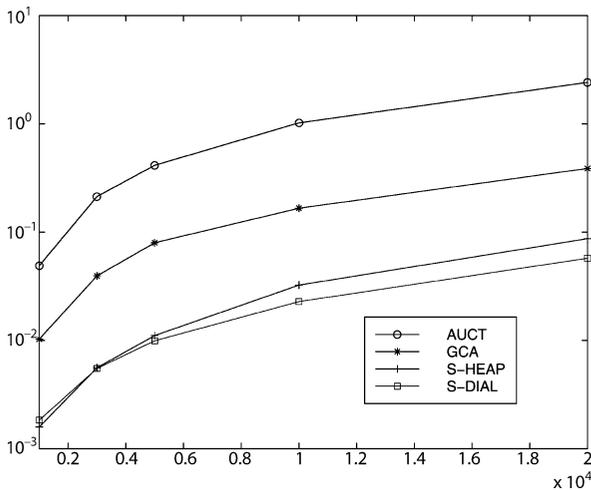

Recently (as of 1999), we have realized a new implementation of the algorithm VSA2 in which the set con-

taining the virtual sources is an hash table. Even if the worst-case complexity has been not improved, the new algorithm reduces in practice the computational time of VSA2. Even though the testing phase of this new algorithm is at the moment limited to general dense random graphs, analyzing the results obtained, it seems to be competitive with the Dijkstra-like algorithms.

## Conclusions

This article is a brief survey of the most popular algorithms and of some novel approaches for solving

shortest path problems. The new methods proposed are variations of the auction technique. They are based on topological transformations of the graph, operated during the iteration of the algorithms. The main idea is based on the property of any auction algorithm for the shortest path that if a node is included at a certain step in the candidate path, then the shortest path to this node is found. Different realizations of such approaches are described leading to different algorithms: graph collapsing algorithms and virtual sources algorithms. The graph collapsing algorithms presented are two. The former one is the straight application of the idea to the standard auction algorithm of Bertsekas improved in [27], while the latter applies the same concept to the modified auction of [16]. Strengthening the peculiar characteristics of the standard auction method, it has been developed the family of virtual source algorithms.

For all the algorithms an upper bound on the total number of required operations is found. An extensive set of numerical test has been carried out and looking the results it is possible to conclude that the algorithm GCA1 has only a theoretical relevance. GCA2, instead, has been revealed in all cases much more efficient. It seems to be one of the better algorithms for solving the shortest path problem and extends the applicability of the auction approach. GCA2 fills the performance gap between them and the better Dijkstra-like algorithms,

while the most recent virtual source algorithm seems to completely eliminate it.

### Introduction

In this chapter, we propose an enhanced state-task network (STN) mixed-integer linear programming (MILP) model for the short-term scheduling of multi-product and multipurpose batch plants with intermediate due dates. The proposed approach extends the continuous-time scheduling model which was originally developed by Floudas and coworkers [6,7,8,10]. This enhanced formulation is able to account for limited, renewable resources, various storage policies, including unlimited intermediate storage (UIS), finite intermediate storage (FIS), no intermediate storage (NIS),

and zero-wait (ZW) conditions, and incorporates several additional features, including variable batch sizes and processing times, batch mixing and splitting, and sequence-dependent changeover times. The enhanced formulation still utilizes a continuous-time representation employing a necessary number of event points of unknown location corresponding to the activation of a task. However, tasks are allowed to continue over several, consecutive event points, enabling resource and storage quantities to be correctly determined at each task activation. The full mathematical model and additional computational results can be found in [9].

There are several other models in the scheduling literature which are capable of accounting for resource constraints as well as mixed storage policies in short-term scheduling problems. Maravelias and Grossmann [11] developed a global event based continuous-time MILP model which utilizes the STN approach and addresses the general problem of batch scheduling, including resource constraints, variable batch sizes and processing times, various storage policies, batch mixing and splitting, and sequence-dependent changeover times. Their model utilizes the idea of task decoupling, eliminates binaries for unit assignment and the continuous variables for start times of tasks, proposes a new class of valid tightening inequalities, and was the first general STN-based model capable of handling resource considerations. However, owing to the continuous-time representation used, which is common for all units, their formulation always requires an extra event point for the end of the last task, generating larger and more complex models than the proposed formulation. In addition, Castro et al. [2] presented a general, continuous-time MILP model for scheduling of batch processes based on the resource-task network (RTN) representation. It uses a global event based representation of time and treats all types of resources in a unified way so that no special sequencing constraints are required. The authors claim that it is a simpler and less degenerate mathematical model than other RTN continuous-time formulations, such as the model of Schilling [13]. In later work, Castro et al. [3] extended their RTN formulation to consider continuous processing tasks, better constraints to handle ZW conditions for batch tasks, and tighter timing constraints. The authors also extended their formulation to deal with sequence-dependent cleaning tasks.

### Conceptual Model Enhancements: Splitting of the Tasks

As previously mentioned, the proposed formulation allows all tasks to continue over several consecutive event points. This change was implemented so that the amount of resource utilized by a task is correctly determined in relationship to all other tasks which utilize the same resource at all instances of time. For example, consider the production schedule and associated resource utilization given in Fig. 1 for a process which has two tasks that utilize the same resource. Both tasks (T1 and T2) have a processing time of 1 and utilize ten units of the resource with each batch. The schedule on the left, which is determined with the original scheduling model, does not recognize that task T1 is active when task T2 begins. At time 2 when task T2 starts, it does not see that task T1 is active and thus determines that only ten units of the resource are currently being used instead of 20. However, if you look at the images on the right, which were generated with the proposed formulation, task T1 is split over two consecutive event points. Thus, when task T2 starts at time 1, task T1 is active at that time point and the calculated resource utilization is correct.

Note that splitting of processing tasks in our continuous-time model is also necessary to account for several other features inherent in scheduling prob-

lems in addition to limited, renewable resources. For instance, in order to model FIS for a state that can be produced or consumed by more than one task, it may be necessary to allow the tasks to continue over more than one event point. If the tasks have different processing times or do not start and/or finish at the same time, then task splitting will have to be incorporated to ensure that storage limits are maintained. Also, for STNs that employ recycle loops, the intermediate state recycled in the loop is consumed by a task that occurs earlier in the STN than the task that produces the recycled state, creating a complicated time dependence between the two tasks that must be maintained in order to avoid violating material balances. If these related tasks have different processing times, it may be necessary to allow task splitting for the task(s) with longer processing times in order to determine the best possible solutions.

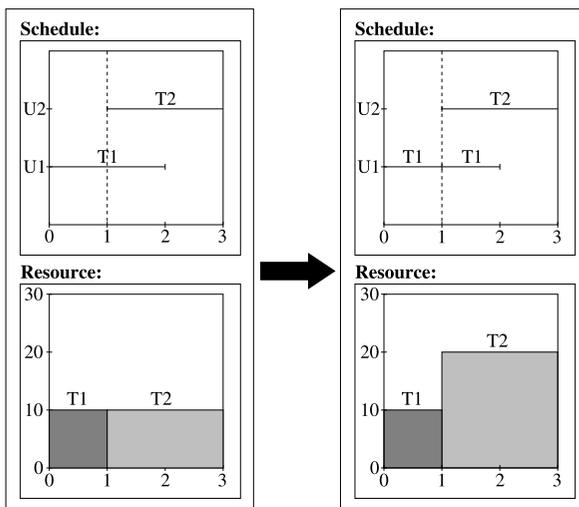

As a consequence of tasks extending over multiple event points, each processing task must have two sets of binary variables and one set of continuous variables associated with it. The binary variable  $ws(i, n)$  indicates that a task  $i$  starts at event point  $n$ , while the binary variable,  $wf(i, n)$  indicates that a task  $i$  ends at event point  $n$ . In addition, the continuous variable  $w(i, n)$  indicates that a task  $i$  is active at event point  $n$ , regardless of whether the task is starting, finishing, or just processing at that event point. In response to this change, the enhanced model has an expanded set of constraints in order to accurately keep track of the utilization of units as well as the timing and sequence of tasks that have been split. In addition, two new sets of tasks are introduced into the mathematical model. One set, ( $i^{st}$ ), represents the storage of intermediate states, while the other set, ( $u$ ), gives the utilization of a resource. New constraints are then introduced into the enhanced model in order to relate the timing and sequence of these new tasks with their associated processing tasks so that specified limits can be enforced.

### Formulation

The proposed formulation requires the following indices, sets, parameters, and variables:

#### Indices:

- $i$  processing tasks;
- $i^{st}$  storage tasks;
- $j$  units;

Short-Term Scheduling of Batch Processes with Resources,  
Figure 1  
Task splitting for resource utilization

$k$  orders;  
 $n$  event points representing the beginning of a task;  
 $s$  states;  
 $u$  utilities;

**Sets:**

$I$  processing tasks;  
 $I_s^{\text{st}}$  storage tasks for state  $s$ ;  
 $I_j$  tasks which can be performed in unit  $j$ ;  
 $I_k$  tasks which process order  $k$ ;  
 $I^{\text{ps}}$  tasks which are processing or storing;  
 $I_s^{\text{p}}$  tasks which produce state  $s$ ;  
 $I_s^{\text{c}}$  tasks which consume state  $s$ ;  
 $I_u$  tasks which consume utility  $u$ ;  
 $J$  units;  
 $J_i$  units which are suitable for performing task  $i$ ;  
 $K$  orders;  
 $K_i$  orders which are processed by task  $i$ ;  
 $K_s$  orders which produce state  $s$ ;  
 $N$  event points within the time horizon;  
 $S$  states;  
 $S_f$  states with finite intermediate storage;  
 $S_n$  states with no intermediate storage;  
 $S_p$  states which are final products;  
 $S_r$  states which are raw materials;  
 $S_z$  states with ZW constraint;  
 $U$  utilities;

**Parameters:**

$\alpha_{ij}$  constant term of processing time of task  $i$  in unit  $j$ ;  
 $\beta_{ij}$  variable term of processing time of task  $i$  in unit  $j$ ;  
 $\delta_{iu}$  variable term of consumption of utility  $u$  by task  $i$ ;  
 $\gamma_{iu}$  constant term of consumption of utility  $u$  by task  $i$ ;  
 $\rho_{is}$  proportion of state  $s$  produced that is consumed by task  $i$ ;  
 $am_k$  amount of order  $k$ ;  
 $av_u$  maximum availability of utility  $u$ ;  
 $cap_{ij}^{\text{max}}$  maximum capacity for task  $i$  in unit  $j$ ;  
 $cap_{ij}^{\text{min}}$  minimum capacity for task  $i$  in unit  $j$ ;  
 $cap_s^{\text{st}}$  capacity of storage for state  $s$ ;  
 $dem_s$  demand of state  $s$ ;  
 $due_k$  due date of order  $k$ ;  
 $H$  time horizon;  
 $price_s$  price of state  $s$ ;

$ST_s^0$  initial available amount of state  $s$ ;  
 $ST_s^{\text{max}}$  maximum amount of state  $s$ ;

**Continuous variables:**

$B(i, j, n)$  amount of material undertaking task  $i$  in unit  $j$  at event point  $n$ ;  
 $B^{\text{s}}(i, j, n)$  amount of material starting processing at event point  $n$ ;  
 $B^{\text{f}}(i, j, n)$  amount of material finishing processing at event point  $n$ ;  
 $BU(i, u, n)$  amount of utility  $u$  consumed by task  $i$  at event point  $n$ ;  
 $B_{\text{ut}}(u, n)$  remaining level of utility  $u$  at event point  $n$ ;  
 $B_{\text{st}}(i^{\text{st}}, n)$  amount of material stored by storage task  $i^{\text{st}}$  at event point  $n$ ;  
 $D(s, n)$  amount of state  $s$  delivered at event point  $n$ ;  
 $MS$  makespan;  
 $ST(s, n)$  amount of state  $s$  at event point  $n$ ;  
 $STF(s)$  final amount of state  $s$  at the end of the time horizon;  
 $STO(s)$  initial amount of state  $s$  at the beginning of the time horizon;  
 $T^{\text{s}}(i, j, n)$  time at which task  $i$  starts in unit  $j$  at event point  $n$ ;  
 $T^{\text{f}}(i, j, n)$  time at which task  $i$  finishes in unit  $j$  at event point  $n$ ;  
 $T_{\text{st}}^{\text{s}}(i^{\text{st}}, n)$  time at which storage task  $i^{\text{st}}$  starts at event point  $n$ ;  
 $T_{\text{st}}^{\text{f}}(i^{\text{st}}, n)$  time at which storage task  $i^{\text{st}}$  finishes at event point  $n$ ;  
 $T_{\text{ut}}^{\text{s}}(u, n)$  starting time of a change in utility  $u$  at event point  $n$ ;  
 $T_{\text{ut}}^{\text{f}}(u, n)$  finishing time of a change in utility  $u$  at event point  $n$ ;  
 $TT^{\text{s}}(j, n)$  starting time of the active task in unit  $j$  at event point  $n$ ;  
 $TT^{\text{f}}(j, n)$  finishing time of the active task in unit  $j$  at event point  $n$ ;  
 $w(i, n)$  indicates if task  $i$  is activated at event point  $n$ ;

**Binary variables:**

$ws(i, n)$  assigns the beginning of task  $i$  at event point  $n$ ;  
 $wf(i, n)$  assigns the ending of task  $i$  at event point  $n$ ;  
 $y(k, i, n)$  assigns the delivery of order  $k$  through task  $i$  at event point  $n$ .

On the basis of this notation, the mathematical model for the short-term scheduling of batch plants with mixed storage policy and resource constraints involves the following constraints.

### Allocation Constraints

$$\sum_{i \in I_j} w(i, n) \leq 1, \quad \forall j \in J, \quad n \in N \quad (1)$$

$$w(i, n) = \sum_{n' \leq n} ws(i, n') - \sum_{n' < n} wf(i, n'), \quad \forall i \in I, n \in N \quad (2)$$

$$\sum_{n \in N} ws(i, n) = \sum_{n \in N} wf(i, n), \quad \forall i \in I \quad (3)$$

$$ws(i, n) \leq 1 - \sum_{n' < n} ws(i, n') + \sum_{n' < n} wf(i, n'), \quad \forall i \in I, n \in N \quad (4)$$

$$wf(i, n) \leq \sum_{n' \leq n} ws(i, n') - \sum_{n' < n} wf(i, n'), \quad \forall i \in I, n \in N \quad (5)$$

These constraints express the requirement that for each unit  $j$  and at each event point  $n$ , only one of the tasks that can be performed in this unit (i.e.,  $i \in I_j$ ) should take place. Constraints (2) relate the continuous variable  $w(i, n)$  to the binary variables  $ws(i, n)$  and  $wf(i, n)$  so that  $w(i, n)$  will take on a value of 1 if task  $i$  is activated at event point  $n$ . Constraints (3) require that each processing task  $i$  must both start and finish during the time horizon. Constraints (4) require that processing task  $i$  cannot start at event point  $n$  if it has started at an earlier event point  $n'$  and has not finished by event point  $n$ . Constraints (5) require that processing task  $i$  cannot finish at event point  $n$  unless it has started at an earlier event point  $n'$  and has not finished by event point  $n$ .

### Capacity Constraints

$$cap_{ij}^{\min} \cdot w(i, n) \leq B(i, j, n) \leq cap_{ij}^{\max} \cdot w(i, n), \quad \forall i \in I, j \in J_i, n \in N \quad (6)$$

$$B_{st}(i^{st}, n) \leq cap_s^{st}, \quad \forall i^{st} \in I_s^{st}, n \in N \quad (7)$$

These first set of constraints express the requirement for the batch size of a processing task  $i$  at a unit  $j$ ,

$B(i, j, n)$ , to be greater than the minimum amount of material,  $cap_{ij}^{\min}$ , and less than the maximum amount of material,  $cap_{ij}^{\max}$ , that can be processed by task  $i$  in unit  $j$ . Constraints (7) represent the maximum available storage capacity for each storage task  $i^{st}$  at each event point  $n$ .

### Batch-Size Matching Constraints: Processing Tasks

$$B(i, j, n) \leq B(i, j, n-1) + cap_{ij}^{\max} [1 - w(i, n-1) + wf(i, n-1)], \quad \forall i \in I, j \in J_i, n \in N, n > 1 \quad (8)$$

$$B(i, j, n) \geq B(i, j, n-1) - cap_{ij}^{\max} [1 - w(i, n-1) + wf(i, n-1)], \quad \forall i \in I, j \in J_i, n \in N, n > 1 \quad (9)$$

$$B^s(i, j, n) \leq B(i, j, n), \quad \forall i \in I, j \in J_i, n \in N \quad (10)$$

$$B^s(i, j, n) \leq cap_{ij}^{\max} \cdot ws(i, n), \quad \forall i \in I, j \in J_i, n \in N \quad (11)$$

$$B^s(i, j, n) \geq B(i, j, n) - cap_{ij}^{\max} [1 - ws(i, n)], \quad \forall i \in I, j \in J_i, n \in N \quad (12)$$

$$B^f(i, j, n) \leq B(i, j, n), \quad \forall i \in I, j \in J_i, n \in N \quad (13)$$

$$B^f(i, j, n) \leq cap_{ij}^{\max} \cdot wf(i, n), \quad \forall i \in I, j \in J_i, n \in N \quad (14)$$

$$B^f(i, j, n) \geq B(i, j, n) - cap_{ij}^{\max} [1 - wf(i, n)], \quad \forall i \in I, j \in J_i, n \in N \quad (15)$$

Constraints (8) and (9) represent the relationship between the batch size of task  $i$  in unit  $j$  at two consecutive event points  $n-1$  and  $n$ . These constraints are required because tasks can extend over several event points and the batch sizes at these consecutive event points must be consistent. Constraints (10)–(12) relate the variables  $B(i, j, n)$  and  $B^s(i, j, n)$ , where  $B^s(i, j, n)$  is the amount of material that is starting to be processed at event point  $n$ . Similar to the previous set of constraints, constraints (13)–(15) relate the variables

$B(i, j, n)$  and  $B^f(i, j, n)$ , where  $B^f(i, j, n)$  is amount of material that is finishing being processed at event point  $n$ .

### Batch-Size Matching Constraints: Utility Tasks

$$BU(i, u, n) = \gamma_{iu}w(i, n) + \eta_{iu}B(i, j, n), \quad \forall u \in U, \\ i \in I_u, \quad j \in J_i, \quad n \in N \quad (16)$$

$$\sum_{i \in I_u} BU(i, u, n) + B_{ut}(u, n) \\ = \sum_{i \in I_u} BU(i, u, n-1) + B_{ut}(u, n-1), \\ \forall u \in U, \quad n \in N, \quad n > 1 \quad (17)$$

$$\sum_{i \in I_u} BU(i, u, n) + B_{ut}(u, n) = av_u, \\ \forall u \in U, \quad n \in N, \quad n = 1 \quad (18)$$

where  $\gamma_{iu}$  and  $\eta_{iu}$  are the constant and variable terms of the amount of utility  $u$  consumed by task  $i$  in unit  $j$  at event point  $n$ ,  $BU(i, u, n)$  is the amount of utility  $u$  consumed by task  $i$  at event point  $n$ , and  $B_{ut}(u, n)$  is the amount of utility  $u$  available at event point  $n$ . Constraints (16) represent the amount of utility required by the unit to process  $B(i, j, n)$  of material while performing task  $i$ . Constraints (17) express the mass balance on the utilities, requiring that the amount of utility at event point  $n$  is equal to the amount of utility at event point  $n-1$ . Constraints (18) express the requirement that the amount of utility  $u$  at the first event point, including the amount available,  $B_{ut}(u, n)$ , and the amount consumed,  $\sum_{i \in I_u} BU(i, u, n)$ , must be equal to the original amount of utility  $u$  available,  $av_u$ .

### Material Balances

$$ST(s, n) = ST(s, n-1) - D(s, n) \\ + \sum_{i \in I_s^p} \rho_{is} \sum_{j \in J_i} B^f(i, j, n-1) \\ + \sum_{i \in I_s^c} \rho_{is} \sum_{j \in J_i} B^s(i, j, n) \\ + \sum_{i^{st} \in I_s^{st}} B_{st}(i^{st}, n-1) - \sum_{i^{st} \in I_s^{st}} B_{st}(i^{st}, n), \\ \forall s \in S, \quad n \in N, \quad n > 1 \quad (19)$$

$$ST(s, n) = STO(s) + \sum_{i \in I_s^c} \rho_{is} \sum_{j \in J_i} B^s(i, j, n) \\ - \sum_{i^{st} \in I_s^{st}} B_{st}(i^{st}, n), \quad \forall s \in S, \quad n \in N, \quad n = 1 \quad (20)$$

$$STF(s) = ST(s, n) - D(s, n) + \sum_{i \in I_s^p} \rho_{is} \sum_{j \in J_i} B^f(i, j, n) \\ + \sum_{i^{st} \in I_s^{st}} B_{st}(i^{st}, n), \quad \forall s \in S, \quad n \in N, \quad n = N \quad (21)$$

According to constraints (19), the amount of material of state  $s$  at event point  $n$  is equal to that at event point  $n-1$  increased by any amounts produced or stored at event point  $n-1$ , decreased by any amounts consumed or stored at event point  $n$ , and decreased by the amount required by the market at event point  $n$ ,  $D(s, n)$ . Constraints (20) and (21) represent the material balance on state  $s$  at the first and last event points, respectively. The amount of state ( $s$ ) at the first event point is equal to the initial amount,  $STO(s)$ , decreased by any amounts consumed or stored at the first event point. The total amount of state  $s$  at the end of last event point,  $STF(s)$ , is equal to the amount at the beginning of the last event point,  $ST(s, n)$ , increased by any amounts produced or stored at the last event point and decreased by the amount required by the market at the last event point.

### Duration Constraints

$$T^f(i, j, n) \geq T^s(i, j, n), \quad \forall i \in I, \quad j \in J_i, \quad n \in N \quad (22)$$

$$T^f(i, j, n) \leq T^s(i, j, n) + H \cdot w(i, n), \\ \forall i \in I, \quad j \in J_i, \quad n \in N \quad (23)$$

$$T^s(i, j, n) \leq T^f(i, j, n-1) + H[1 - w(i, n-1) \\ + wf(i, n-1)], \\ \forall i \in I, \quad j \in J_i, \quad n \in N, \quad n > 1 \quad (24)$$

$$T^f(i, j, n') - T^s(i, j, n) \geq \alpha_{ij}ws(i, n) + \beta_{ij}B^s(i, j, n) \\ - H[1 - ws(i, n)] \\ - H[1 - wf(i, n')] \\ - H[\sum_{n \leq n'' < n'} wf(i, n'')], \\ \forall i \in I, \quad j \in J_i, \quad n \in N, \quad n' \in N, \quad n \leq n' \quad (25)$$

$$\begin{aligned}
T^f(i, j, n') - T^s(i, j, n) &\leq \alpha_{ij}ws(i, n) + \beta_{ij}B^s(i, j, n) \\
&\quad + H[1 - ws(i, n)] \\
&\quad + H[1 - wf(i, n')] \\
&\quad + H\left[\sum_{n \leq n'' < n'} wf(i, n'')\right], \\
\forall i \notin I^{ps}, j \in J_i, n \in N, n' \in N, n \leq n'. & \quad (26)
\end{aligned}$$

The first set of constraints represent the relationship between the starting and finishing times of task  $i$  in unit  $j$  at event point  $n$ . Because tasks can extend over multiple event points, the finishing time is not assigned from the start time, but must be greater or equal to the start time. Constraints (23) also represent the relationship between the starting and finishing times of task  $i$  in unit  $j$  at event point  $n$ . If task  $i$  does not take place at event point  $n$ , then along with constraints (22), the finishing time is set equal to the starting time. Constraints (24) relate the starting time of task  $i$  in unit  $j$  at event point  $n$  to the finishing time of the same task in the same unit at the previous event point,  $n - 1$ . These constraints are relaxed unless task  $i$  is active and does not finish processing at event point  $n - 1$ . In this case, task  $i$  must extend to the following event point,  $n$ , so that this constraint,  $T^s(i, j, n) \leq T^f(i, j, n - 1)$ , along with the sequencing constraints (29),  $T^s(i, j, n) \geq T^f(i, j, n - 1)$ , results in the two times being equal. Constraints (25) and (26) relate the starting time of task  $i$  in unit  $j$  at event point  $n$  with its finishing time at a later event point  $n'$ .

$$T_{st}^f(i^{st}, n) \geq T_{st}^s(i^{st}, n), \quad \forall i^{st} \in I_s^{st}, n \in N \quad (27)$$

$$T_{ut}^f(u, n) \geq T_{ut}^s(u, n), \quad \forall u \in U, n \in N. \quad (28)$$

The first set of constraints relate the starting and finishing times of a storage task  $i^{st}$  so that the finishing time must always be greater than or equal to the start time. The second set of constraints relate the starting and finishing times of changes in the amount of utility  $u$  so that the finish time must always be greater than or equal to the start time.

### Sequence Constraints: Processing Tasks

$$\begin{aligned}
T^s(i, j, n) &\geq T^f(i, j, n - 1), \\
\forall i \in I, j \in J_i, n \in N, n > 1 & \quad (29)
\end{aligned}$$

$$\begin{aligned}
T^s(i, j, n) &\geq T^f(i', j, n - 1) - H[1 - w(i', n - 1)], \\
\forall j \in J, i \in I_j, i' \in I_j, i \neq i', n \in N, n > 1 & \quad (30)
\end{aligned}$$

$$\begin{aligned}
T^s(i, j, n) &\geq T^f(i', j', n - 1) - H[1 - wf(i', n - 1)], \\
\forall s \in S, i \in I_s^c, i' \in I_s^p, \\
j \in J_i, j' \in J_{i'}, j \neq j', n \in N, n > 1 & \quad (31)
\end{aligned}$$

$$\begin{aligned}
T^s(i, j, n) &\leq T^f(i', j', n - 1) + H[2 - wf(i', n - 1) - ws(i, n)], \\
\forall s \in S^z, S^f, S^n, i \in I_s^c, i' \in I_s^p, \\
j \in J_i, j' \in J_{i'}, j \neq j', n \in N, n > 1. & \quad (32)
\end{aligned}$$

The sequence constraints in (29) state that task  $i$  starting at event point  $n$  should start after the end of the same task performed at the same unit  $j$  which has finished at the previous event point,  $n - 1$ . The constraints in (30) are written for tasks  $i$  and  $i'$  that are performed in the same unit  $j$  at event points  $n$  and  $n - 1$ , respectively. If both tasks take place in the same unit, they should be at most consecutive. Constraints (31) relate tasks  $i$  and  $i'$  which are performed in different units  $j$  and  $j'$  but take place consecutively according to the production recipe. Constraints (32) are written for different tasks  $i$  and  $i'$  that take place consecutively with the “zero-wait” (ZW) condition owing to storage restrictions on the intermediate material. Combined with constraints 31, these constraints enforce that task  $i$  in unit  $j$  at event point  $n$  starts immediately after the end of task  $i'$  in unit  $j'$  at event point  $n - 1$  if both tasks are activated.

### Sequence Constraints: Storage Tasks

$$\begin{aligned}
T^s(i, j, n) &\geq T_{st}^f(i^{st}, n - 1), \\
\forall s \in S, i \in I_s^c, j \in J_i, i^{st} \in I_s^{st}, \\
n \in N, n > 1 & \quad (33)
\end{aligned}$$

$$\begin{aligned}
T^s(i, j, n) &\leq T_{st}^f(i^{st}, n - 1) + H[1 - ws(i, n)], \\
\forall s \in S^f, i \in I_s^c, j \in J_i, i^{st} \in I_s^{st}, \\
n \in N, n > 1 & \quad (34)
\end{aligned}$$

$$\begin{aligned} T_{st}^s(i^{st}, n) &\geq T^f(i', j', n-1) - H[1 - wf(i', n-1)], \\ \forall s \in S, \quad i' \in I_s^p, \quad j' \in J_{i'}, \quad i^{st} \in I_s^{st}, \\ n \in N, \quad n > 1 \end{aligned} \quad (35)$$

$$\begin{aligned} T_{st}^s(i^{st}, n) &\leq T^f(i', j', n-1) + H[1 - wf(i', n-1)], \\ \forall s \in S^f, \quad i' \in I_s^p, \quad j' \in J_{i'}, \quad i^{st} \in I_s^{st}, \\ n \in N, \quad n > 1 \end{aligned} \quad (36)$$

$$T_{st}^s(i^{st}, n) = T_{st}^f(i^{st}, n-1), \quad \forall i^{st} \in I_s^{st}, \quad n \in N, \quad n > 1 \quad (37)$$

The first two sets of constraints relate the starting time of a processing task  $i$  at an event point  $n$  to the finishing time of a storage task  $i^{st}$  at the previous event point,  $n-1$ . Note that (34) is only written for states  $s$  with FIS. Thus, if task  $i$  starts at event point  $n$  and consumes a state  $s$  that requires FIS, then we have  $T^s(i, j, n) = T_{st}^f(i^{st}, n-1)$  for all storage tasks  $i^{st}$  for state  $s$ . Constraints (35) and (36) relate the starting time of a storage task  $i^{st}$  at an event point  $n$  to the processing task  $i'$  at the previous event point,  $n-1$ . Similar to constraints (33) and (34), these constraints enforce the timing for a processing task that produces a FIS state and a storage task which stores the same FIS state. Constraints (37) relate the starting and finishing time of a storage task  $i^{st}$  at two consecutive event points. They ensure that, along with constraints (33)–(36), the timing for storage of FIS states will be enforced so that storage limitations are not violated.

### Sequence Constraints: Utility-Related Tasks

$$\begin{aligned} T^f(i, j, n-1) \\ \geq T_{ut}^s(u, n) - H[1 - w(i, n-1) + wf(i, n-1)], \\ \forall u \in U, \quad i \in I_u, \quad j \in J_i, \quad n \in N, \quad n > 1 \end{aligned} \quad (38)$$

$$\begin{aligned} T^f(i, j, n-1) &\leq T_{ut}^s(u, n) + H[1 - w(i, n-1)], \\ \forall u \in U, \quad i \in I_u, \quad j \in J_i, \quad n \in N, \quad n > 1 \end{aligned} \quad (39)$$

$$\begin{aligned} T_{ut}^s(u, n) &\geq T^s(i, j, n) - H[1 - w(i, n)], \\ \forall u \in U, \quad i \in I_u, \quad j \in J_i, \quad n \in N \end{aligned} \quad (40)$$

$$\begin{aligned} T_{ut}^s(u, n) &\leq T^s(i, j, n) + H[1 - w(i, n)], \\ \forall u \in U, \quad i \in I_u, \quad j \in J_i, \quad n \in N \end{aligned} \quad (41)$$

$$T_{ut}^s(u, n) = T_{ut}^f(u, n-1), \quad \forall u \in U, \quad n \in N, \quad n > 1 \quad (42)$$

The first two sets of constraints relate the finishing time of a processing task  $i$  which utilizes utility  $u$  at an event point  $n-1$  to the starting time of the usage of utility  $u$  at the next event point. Constraints (40) and (41) relate the starting time of the usage of utility  $u$  at event point  $n$  to the processing task  $i$  which utilizes utility  $u$  at the current event point. Constraints (42) relate the starting and the finishing time of the usage of utility  $u$  at two consecutive event points. They ensure that, along with constraints (38)–(41), the timing for the changes in the utility level will be consistent and the amounts of utilities used can be monitored exactly and specified limits enforced.

### Order Satisfaction Constraints

The order satisfaction constraints provided here are written for problems involving network-represented processes. Note that these constraints can easily be modified for the case of sequential process problems. This is done by relating orders to units in the same manner as orders are related to tasks below.

$$\sum_{i \in I_k} \sum_{n \in N} y(k, i, n) = 1, \quad \forall k \in K \quad (43)$$

$$wf(i, n) = \sum_{k \in K_i} y(k, i, n), \quad \forall i \in I, \quad n \in N \quad (44)$$

$$\begin{aligned} D(s, n) &= \sum_{k \in K_s} \sum_{i \in I_k} am_k \cdot y(k, i, n), \\ \forall s \in S^p, \quad n \in N \end{aligned} \quad (45)$$

$$\begin{aligned} T^f(i, j, n) &\leq due_k + H[2 - y(k, i, n) - wf(i, n)], \\ \forall s \in S, \quad k \in K_s, \quad i \in I_k, \quad j \in J_i, \quad n \in N \end{aligned} \quad (46)$$

$$\begin{aligned} T^f(i, j, n) &\geq due_k - H[2 - y(k, i, n) - wf(i, n)], \\ \forall s \in S, \quad k \in K_s, \quad i \in I_k, \quad j \in J_i, \quad n \in N \end{aligned} \quad (47)$$

The first set of constraints ensure each order  $k$  is met exactly once; thus, each order is processed by only one

task  $i$  and is delivered at exactly one event point  $n$ . Constraints (44) relate the delivery of an order  $k$  through task  $i$  to the activation of task  $i$  at event point  $n$ . Constraints (45) relate the amount of state  $s$  delivered at event point  $n$ ,  $D(s, n)$ , to the amount of that state due through order  $k$ . Thus, if state  $s$  has two orders associated with it,  $k_1$  and  $k_2$ , of amounts  $am_{k_1}$  and  $am_{k_2}$ , respectively, and orders  $k_1$  and  $k_2$  are both delivered at event point  $n$ , then the delivery of state  $s$  at event point  $n$  is represented as  $D(s, n) = am_{k_1} + am_{k_2}$  and the amount of the state delivered will be equal to the amount ordered. Constraints (46) and (47) relate the time that order  $k$  is due to the actual time that order  $k$  is delivered.

### Bound Constraints

$$\begin{aligned}
 T^f(i, j, n) &\leq H, \quad \forall i \in I, \quad j \in J_i, \quad n \in N \\
 T^s(i, j, n) &\leq H, \quad \forall i \in I, \quad j \in J_i, \quad n \in N \\
 T_{ut}^f(u, n) &\leq H, \quad \forall u \in U, \quad n \in N \\
 T_{ut}^s(u, n) &\leq H, \quad \forall u \in U, \quad n \in N \\
 T_{ut}^s(u, n) &= 0, \quad \forall u \in U, \quad n \in N, \quad n = 1 \\
 STO(s) &= 0, \quad \forall s \notin S^r \\
 STO(s) &\leq ST_s^0, \quad \forall s \in S^r \\
 ST(s, n) &= 0, \quad \forall s \in S^z, S^f, S^n \quad n \in N \\
 ST(s, n) &\leq ST_s^{\max}, \quad \forall s \in S, \quad n \in N \\
 D(s, n) &= 0, \quad \forall s \notin S^p, \quad n \in N \\
 0 &\leq w(i, n) \leq 1, \quad \forall i \in I, \quad n \in N
 \end{aligned} \tag{48}$$

These constraints represent bounds on several of the continuous variables. The starting and finishing times of processing tasks and changes in utility level must all be within the time horizon. The start time for the changes in utilities at the first event point is set to zero. The initial amounts of all non-raw-material states are set to zero, the intermediate amounts of all ZW, NIS, and FIS states are set to zero, and the amounts of all nonproduct deliveries are set to zero. Also, the continuous variable representing the activation of task  $i$  in unit  $j$  at event point  $n$ ,  $w(i, n)$ , must fall between zero and one.

### Objective Function

There are several different objective functions that can be employed with a general short-term scheduling

problem. Three of the most common types are reviewed below.

#### Maximization of sales

$$\max \sum_{s \in S^p} price_s \cdot \left[ \sum_{n \in N} D(s, n) + STF(s) \right] \tag{50}$$

The objective function represents the maximization of the value of the final products.

#### Minimization of makespan

$$\text{Min } MS \tag{50}$$

$$s.t. \quad MS \geq T^f(i, j, n), \quad \forall i \in I, \quad j \in J_i, \quad n \in N \tag{51}$$

$$STF(s) = dem_s, \quad \forall s \in S^p, \tag{52}$$

where MS is the makespan. The objective function represents the minimization of the makespan of the process for a fixed demand for each state  $s$ ,  $dem_s$ , contained in the set of final products,  $S^p$ .

#### Minimization of order earliness

$$\text{Min} \sum_{k \in K} due_k - \left[ \sum_{i \in I_k} \sum_{j \in J_i} \sum_{n \in N} T^f(i, j, n) \cdot y(k, i, n) \right] \tag{52}$$

The objective function represents the minimization of the total earliness of all orders where the bilinear term, which is a product of a continuous and a binary variable, can be replaced with a continuous variable and supporting constraints using a Glover transformation [4,5].

## Methods

### Number of Event Points

In this formulation, the number of event points is determined using the same approach as proposed in [6]. First, the problem is solved with a small number of event points to obtain a solution. Then, the number of event points is increased by one and the problem is resolved to obtain a better solution. This is repeated until an additional increase in the number of event points does not result in any improvement in the objective function.

### Tightening Constraints

Following the tightening constraints suggested by Maravelias and Grossmann [11], similar constraints are introduced to tighten the relaxed solution of the proposed enhanced formulation. Specifically, constraints (54) tighten the formulation by enforcing the condition that the summation of the processing times of the tasks assigned to a specific unit  $j$  should be less than or equal to the time horizon.

$$\sum_{i \in I_j} \sum_{n \in N} \alpha_{ij} ws(i, n) + \beta_{ij} B^s(i, j, n) \leq H, \quad \forall j \in J \quad (54)$$

Furthermore, this condition is also enforced for each unit  $j$  at each event point  $n$  as follows:

$$\begin{aligned} \sum_{i \in I_j} \sum_{n' \geq n} \alpha_{ij} ws(i, n') + \beta_{ij} B^s(i, j, n') \\ \leq H - TT^s(j, n), \quad \forall j \in J, \quad n \in N \end{aligned} \quad (55)$$

$$\begin{aligned} \sum_{i \in I_j} \sum_{n' < n} \alpha_{ij} ws(i, n') + \beta_{ij} B^s(i, j, n') \\ \leq TT^f(j, n-1) + H[1 - \sum_{i \in I_j} wf(i, n-1)], \\ \forall j \in J, \quad n \in N, \quad n > 1, \end{aligned} \quad (56)$$

where  $TT^s(j, n)$  and  $TT^f(j, n)$  are the starting time and the finishing time, respectively, of the task active in unit  $j$  at event point  $n$ . They are defined as follows:

$$\begin{aligned} TT^s(j, n) &\leq T^s(i, j, n) + H[1 - ws(i, n)], \\ &\quad \forall j \in J, \quad i \in I_j, \quad n \in N \end{aligned} \quad (57)$$

$$\begin{aligned} TT^s(j, n) &\geq T^s(i, j, n) - H[1 - ws(i, n)], \\ &\quad \forall j \in J, \quad i \in I_j, \quad n \in N \end{aligned}$$

$$\begin{aligned} TT^f(j, n) &\leq T^f(i, j, n) + H[1 - wf(i, n)], \\ &\quad \forall j \in J, \quad i \in I_j, \quad n \in N \end{aligned} \quad (58)$$

$$\begin{aligned} TT^f(j, n) &\geq T^f(i, j, n) - H[1 - wf(i, n)], \\ &\quad \forall j \in J, \quad i \in I_j, \quad n \in N \end{aligned}$$

Thus, constraints (55) enforce the condition that the summation of the processing times of all tasks starting in unit  $j$  at event points  $n$  or greater must be less than or equal to the amount of time remaining. Likewise, constraints (56) enforce the condition that the summation of the processing times of all tasks finishing in unit  $j$

before event point  $n$  must be less than or equal to the amount of time that has passed up to the beginning of event point  $n$ . Note that constraints (56) are only active if a task finishes at the previous event point,  $n-1$ , otherwise,  $TT^f(j, n)$  will not have an exact value and the constraint is relaxed.

The addition of constraints (54)–(58) leads to relaxed solutions with smaller sums of processing times, or smaller durations. This then leads to fewer activated binary variables,  $ws(i, n)$  and  $wf(i, n)$ . Moreover, the continuous variables including the batch sizes ( $B^s(i, j, n)$ ,  $B^f(i, j, n)$ ,  $B(i, j, n)$ ) and the amounts of states ( $ST(s, n)$ ,  $STF(s)$ ) are all bounded by the binary variables. Finally, because these continuous variables appear in the objective function, the addition of these constraints results in tighter relaxations.

### Sequential Processes

Single-stage and multistage sequential processes are batch- or order-oriented and thus do not need to include tasks or states or any of the constraints involving states. The model described in the previous section can be applied to sequential processes with a few modifications. For instance, there are no defined tasks, states, batch sizes, or material amounts and all material balances and capacity constraints are unnecessary. Thus, the basic constraints (1)–(5), (22)–(26), (29)–(32), and part of (48) all apply. The order satisfaction constraints (43)–(47) need to be modified as previously detailed. If storage constraints are to be considered, then constraints (27) and (33)–(37) need to be included and if resource constraints are to be considered, then constraints (28) and (38)–(42) should also be included. Furthermore, all of the binary and continuous variables and their participating constraints should be modified similarly to the order satisfaction constraints to reflect a dependence on orders associated with units instead of tasks associated with units.

### Cases

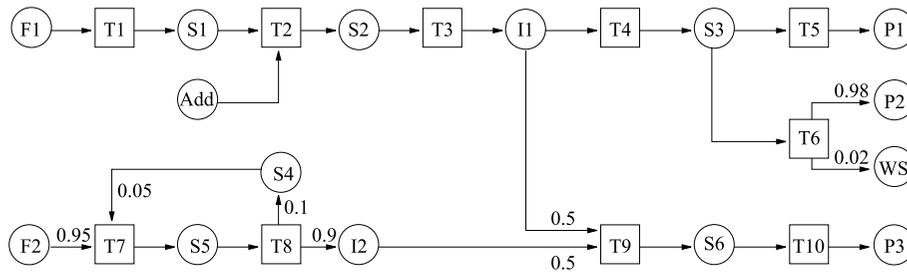

In this section, two example problems are presented to demonstrate the effectiveness of the proposed approach. Both general network-represented and sequential processes are considered. Comparisons with previously published approaches are also provided. All examples are implemented with GAMS 2.5 [1] and are

solved using CPLEX 8.1 with a 3.00 GHz Linux workstation. The default GAMS/CPLEX options are used in all runs with the exception that the CPLEX option for feasibility is activated and a relative optimality tolerance equal to 0.01% was used as the termination criterion.

**Case 1: Resource Constraints, Mixed Storage Policies, Variable Batch Sizes, and Processing Times**

The second case also comes from Maravelias and Grossmann [11] and involves the STN given in Fig. 2. This example includes resource constraints, mixed storage policies, and utility requirements. The plant consists of six units involving ten processing tasks and fourteen states. Un-

limited intermediate storage (UIS) is available for raw materials F1 and F2, intermediates I1 and I2, and final products P1–P3 and WS. Finite intermediate storage (FIS) is available for states S3 and S4, while no intermediate storage (NIS) is available for states S2 and S6 and a ZW policy applies for states S1 and S5. There are three different renewable utilities: cooling water (CW), low-pressure steam (LPS), and high-pressure steam (HPS). Tasks T2, T7, T9, and T10 require CW; tasks T1, T3, T5, and T8 require LPS; and tasks T4 and T6 require HPS. The maximum availabilities of CW, LPS, and HPS are 25, 40, and 20 kg/min, respectively. The corresponding data for the example can be found in Tables 1 and 2. The objective function is the maximization of sales and time horizons of 12 and 14 h are considered.

Short-Term Scheduling of Batch Processes with Resources, Figure 3

Schedule for case 1 with a time horizon of 12 h. HPS high-pressure steam, LPS low-pressure steam, CW cooling water

For a time horizon of 12 h, the optimal sales are \$13,000 and eight event points are required. The production schedule and resource utilization levels can be seen in Fig. 3. The problem involves 3318 constraints, 110 binary variables, and 1077 continuous variables. Its optimal solution was found in 222 nodes and 1.71 s. For a time horizon of 14 h, the optimal sales are \$16,350 and eight event points are required. The production schedule and resource utilization levels can be seen in Fig. 4. The problem involves 3354 constraints, 109 binary variables, and 1077 continuous variables. Its optimal solution was found in 2869 nodes and 15.65 s. Note that in both cases, the limiting resource is CW, as can be seen from the resource utilization levels. In both schedules, tasks T2 and T7 occurring at the same time requires the maximum amount of CW available.

Case 1 was also solved with the model  $M^*$  of Maravelias and Grossmann [11] to compare the two formulations. Although this example was solved in their original paper, we have re-solved it here in order to compare the models using the same computational tools. The model and solution statistics using both models can be seen in Table 3. For the time horizon of 12 h using nine time points, the model involved 2396 constraints, 180 binary variables, and 1408 continuous variables. The same optimal solution of \$13,000 was found in 23,235 nodes and 64.92 s. For the time horizon of 14 h using ten time points, the model involved 2663 constraints, 200 binary variables, and 1564 continuous variables. The same optimal solution of \$16,350 was found in 22,625 nodes and 112.66 s. Note that the reported number of nodes and CPU seconds for both time hori-

Short-Term Scheduling of Batch Processes with Resources, Figure 4  
Schedule for case 1 with a time horizon of 14 h

zons using our application of model  $M^*$  are different from those found by Maravelias and Grossmann [11]. For a time horizon of 12 h, they reported 2107 nodes, while our application of model  $M^*$  took 23,235 nodes. For a time horizon of 14 h, they reported 60,070 nodes, while our application of model  $M^*$  took 22,625 nodes. In addition, for both time horizons, model  $M^*$  of Maravelias and Grossmann [11] takes at least one more time point and thus involves more binary and continuous variables. Also, the time horizon of 12 h took over 100 times more nodes to solve, while the time horizon of 14 h took over 10 times more nodes to solve. This indicates that when a larger number of time points are considered in a problem, the proposed model performs better computationally than the model of Maravelias and Grossmann [11], even when the objective is the maximization of sales.

### Case 2: Sequential Process with Order-Dependent Processing Times

The second case is taken from Pinto and Grossmann [12] and involves a sequential process containing one stage with four parallel extruders of unequal capacity and with processing times depending on the order being processed. A total of 12 orders are due at specific times over a 30-day period. The corresponding processing rate and due date data for the example can be found in Table 4. The objective of the problem is to meet all orders while minimizing earliness, as seen in constraint (53).

The optimal processing schedule is given in Fig. 5 with an objective function value of 1.026. The problem was modeled with the formulation of Ierapetritou and Floudas [6] using only the allocation, duration, and

same task in the same unit and different task in the same unit sequencing constraints along with the order satisfaction constraints outlined in (43)–(47) and the objective given in constraint (53).

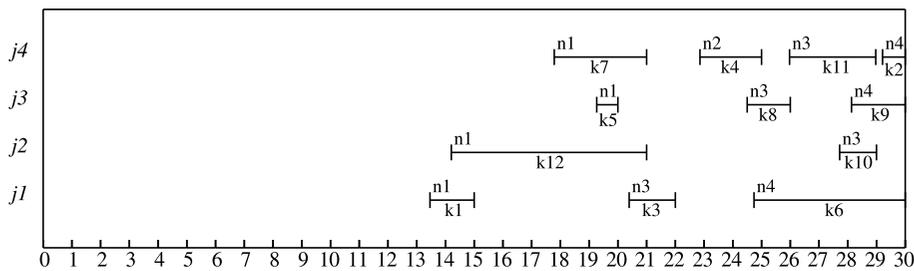

Suppose now that, owing to limited manpower, there is a hard constraint on the number of extruders which can operate at the same time. We will consider the case where three extruders may operate simultaneously (type 1) and the case where only two extruders may operate simultaneously (type 2). For both cases, we employ the model outlined in Sect. “Sequential Processes”, again using the order satisfaction constraints and the objective function to minimize the earliness of the orders. For type 1 with three extruders, the optimal objective function value is 1.895 and the production schedule can be seen in Fig. 6. For type 2, the op-

timal objective function value is 7.909 and the production schedule can be seen in Fig. 7. Model and solution statistics for all three cases can be seen in Table 5.

It can be seen from Table 5 that consideration of resource constraints in the form of limited manpower increases the computational complexity of the problem. Resource considerations require a more complicated model involving more variables and constraints. For instance, resource considerations require an event point for every time the resource level changes, or in this case, for each order. However, a problem without resources only requires as many event points as the maximum number of sequential tasks. For this example, the simpler problem without resource considerations only requires four event points, while the more com-

Schedule for case 2 with two extruders (type 2)

plicated problem with resource constraints requires 12 event points, resulting in many more binary variables and thus a much more complex problem.

In order to test the effectiveness of the proposed formulation when used with sequential processes, we performed a computational comparison for this example with the model of Pinto and Grossmann [12]. Al-

though this example was solved in their original paper, the objective function used was the maximization of starting times instead of the minimization of tardiness. So, we re-solved our model using the maximization of the starting times as the objective. Pinto and Grossmann [12] reported optimal objectives of 269.10, 268.24, and 264.98 for the three cases of no resources, resources limited to three extruders, and resources limited to two extruders. Our optimal objective function values with the same objective were 269.10, 268.82, and 265.74, respectively. Thus, the proposed model found improved schedules with a better objective function value for the case where resources are limited to three extruders and the case where resources are limited to two extruders. This is not unexpected, however, owing to the fact that the model used in [12] employs the concept of time slots and all slot-based formulations restrict the time representations and hence they can result, by definition, in suboptimal solutions. Note that the model and solution statistics found in Table 5 for this problem using an objective function of minimization of order earliness are comparable to the model and solution statistics determined using an objective of maximization of start times. We do not make a com-

parison with the model and solution statistics presented in [12] because the authors did not report the integrality gaps or other optimality criterion used; thus, a direct comparison would not be meaningful.

## Conclusions

In this chapter, an enhanced continuous-time formulation was presented for the short-term scheduling of multipurpose batch plants with intermediate due dates. The proposed formulation incorporates several features, including various storage policies (UIS, FIS, NIS, ZW), resource constraints, variable batch sizes and processing times, batch mixing and splitting, and sequence-dependent changeover times. The key features of the proposed formulation include a continuous-time representation utilizing a necessary number of event points of unknown location corresponding to the activation of a task. Also, tasks are allowed to continue over several event points, enabling resource quantities to be correctly determined at the beginning of each resource utilization. Four examples were presented to illustrate the effectiveness of the proposed formulation. The computational results were compared with those in the literature and it was shown that the proposed formulation is significantly faster than other general resource-constrained models, especially for problems requiring many time points.

## Introduction

The scheduling problem of multiproduct and multipurpose continuous plants has received relatively little attention in the literature despite its practical importance in the chemical process industries that produce a variety of products using both batch and continuous production modes. Scheduling of a continuous plant typically involves handling continuous production, management of transitions, and accommodating inventory constraints, while meeting demands for final products with specified due dates. The problem deals with sequencing of products on each unit, quantitative determination of production amounts, optimal start and finish times of production, and storage tasks. One of the key differences between scheduling of batch processes and scheduling continuous processes is in handling the processing times. In batch plants, the processing times are typically fixed and known a priori, and the production amount depends on the capacity of the batch unit. In continuous plants, the processing times are a function of unit-dependent processing rates, final product demand, and storage limitations. Additionally, in continuous plants, the production amount is available continuously while it is being produced, unlike in batch plants, where the amount is available only after the end time for the batch that is being processed. Owing to these differences, the problem of scheduling of continuous plants has drawn separate attention.

Floudas and Lin [3,4] presented extensive reviews comparing various discrete-time-based and continuous-time-based formulations. During the last two decades, numerous formulations have been proposed in the literature based on continuous-time representation, owing to their established advantages over discrete-time representations. On the basis of the time representation used, the different continuous-time models proposed in the literature can be broadly classified into three distinct categories: slot-based, global event-based, and unit-specific event-based formulations for both network-represented and sequential processes. In the slot-based models, the time horizon is represented in terms of ordered blocks of unknown, variable lengths, or time slots. In addition, alternative methods have been developed which define continuous variables directly to represent the timings of tasks without the use of time slots. These methods can be clas-

sified into two different representations of time, global event-based models and unit-specific event-based models. Global event-based models use a set of events that are common across all units, and the event points are defined for either the beginning or the end (or both) of each task in each unit. On the other hand, unit-specific event-based models define events on a unit basis, allowing tasks corresponding to the same event point but in different units to take place at different times. For sequential processes, other alternative approaches based on precedence relationships have also been used. A detailed comparison of various continuous-time models for short-term scheduling of batch plants was performed recently by Shaik et al. [28]. They concluded that, owing to the heterogeneous locations of the event points used, the unit-specific event-based models always require fewer event points and exhibit favorable computational performance compared with both slot-based and global event-based models.

There are two types of demand patterns for scheduling of continuous processes that have been addressed in the literature: cyclic and short-term. In cyclic scheduling, a cyclic mode is assumed and the product demands are specified in terms of constant demand rates at the end of a specified time horizon, while short-term scheduling deals with a general problem where the product demands have different sets of due dates. Sahinidis and Grossmann [25] proposed a slot-based mixed-integer nonlinear programming (MINLP) model for cyclic scheduling of single-stage continuous parallel production lines that do not share any common resources. Pinto and Grossmann [24] modeled cyclic scheduling for sequential operation of a multistage, multiproduct continuous plant based on a slot-based continuous-time representation, leading to an MINLP model with explicit inventory breakpoints for representing intermediate storage. Munawar et al. [23] extended the slot-based cyclic scheduling formulation of Pinto and Grossmann [24] to hybrid flowsheets consisting of serial and parallel configurations of processing and storage units. They proposed a modified definition of the time slot to account for feed losses during product transitions. Zhang and Sargent [30,31] proposed a global event-based MINLP model using a resource-task network (RTN) for the optimal operation of a mixed-production facility consisting of batch and continuous processes. Schilling and Pantelides [26]

also used the RTN framework for their slot-based continuous-time formulation for short-term scheduling of batch and continuous processes and proposed a special branch and bound solution that branches both on discrete and on continuous variables. Karimi and McDonald [15,19] developed two slot-based models for production planning and short-term scheduling, which differ in the pre-assignment of slots to the time periods for a single-stage multiproduct facility consisting of parallel semicontinuous processors. Floudas and coworkers [7,8,9,10,11,12,13,14,16,17,18] developed unit-specific event-based models for a variety of problems involving design, synthesis, short-term scheduling, medium-term scheduling, reactive scheduling, and scheduling under uncertainty. Ierapetritou and Floudas [7,8] proposed a novel short-term scheduling model for batch and continuous processes using a state-task-network (STN) framework deploying a unit-specific event-based continuous-time representation. They used an approximation of the storage-task timings for handling different storage requirements in their model for continuous processes [8]. Mockus and Reklaitis [21,22] proposed a global event-based MINLP model for short-term scheduling of batch and continuous processes in which both the start and the end times of tasks occur at events that are common across all units. Their formulation can handle resource constraints such as limited availability of utilities and manpower. Giannelos and Georgiadis [5,6] proposed a unit-specific event-based formulation for short-term scheduling of batch and continuous processes using a STN representation. Their model is similar to that of Ierapetritou and Floudas [7,8], but they relaxed the task durations using buffer times and implicitly eliminated the various big-M constraints of Ierapetritou and Floudas [7,8]. In their models [5,6], the authors introduced special duration and sequencing constraints to ensure feasibility of material balances. The start and end times of the tasks producing/consuming the same state were, respectively, enforced to be the same. While this feature is essential for continuous processes when bypassing of storage is allowed (the reasons are discussed later in this chapter), for all other cases, it will be very restrictive and may lead to suboptimal solutions. Giannelos and Georgiadis [6] enforced these restrictions in their model for short-term scheduling of batch plants as well, leading to subop-

timal solutions as recently observed by Sundaramoorthy and Karimi [29] and Shaik et al. [28]. Mendez and Cerda [20] proposed a production-campaign-based algorithmic approach for short-term scheduling of continuous processes, leading to compact models for the case when storage bypassing is allowed, with the assumptions that only one state is produced by each task and no initial inventories exist for intermediate states. Castro et al. [1] developed a global event-based formulation for short-term scheduling of batch and continuous processes using a RTN representation, where changeovers are treated as additional batch tasks. Most of the above mentioned models [1,5,8,20] can handle different storage requirements such as unlimited, finite, flexible, dedicated, and no intermediate storage policies. However, for an industrial case study of consumer goods manufacturing involving making, storage, and packing tasks, Ierapetritou and Floudas [8] solved the cases of unlimited and finite intermediate storage and reported approximate suboptimal solutions. Mendez and Cerda [20] and Giannelos and Georgiadis [5] also reported suboptimal solutions for the case of finite intermediate storage with no maximum demand limits. Castro et al. [1,2] could not find the global optimal solution for the no-intermediate-storage case even at higher event points and large computational times. They classified the problem as intractable and used a decomposition strategy [2] to improve the computational performance.

Recently, Shaik and Floudas [27] proposed an improved model for short-term scheduling of continuous processes using the unit-specific event-based continuous-time representation. They modified and extended the formulation of Ierapetritou and Floudas [8] and presented improved sequencing constraints to rigorously address the different storage requirements. Their formulation is based on the STN representation, resulting in a mixed-integer linear programming model that accurately accounts for various storage requirements such as dedicated, finite, unlimited, and no intermediate storage policies. The formulation allows for unit-dependent variable processing rates, sequence-dependent changeovers, and with/without the option of bypassing of storage. The Shaik and Floudas model is presented in Sect. “**Formulation**” for the cases with and without storage bypassing. In Sect. “**Computational Case Study**,” different variants of an industrial case

study from fast moving consumer goods manufacturing is presented to demonstrate the capability of the model.

### Formulation

The Shaik and Floudas model for short-term scheduling of continuous plants is described below for several instances of different storage requirements, which include (a) unlimited intermediate storage, (b) dedicated finite intermediate storage, (c) no intermediate storage, and (d) flexible finite intermediate storage. Both the with and the without bypassing of storage requirements options are discussed. Initially, the first case, when storage bypassing is allowed, is discussed, and then, the second case, without bypassing of storage, is discussed in Sect. “**Dedicated and Flexible Finite Intermediate Storage Without Storage Bypassing.**”

#### Unlimited Intermediate Storage

Initially, consider the simple case of unlimited intermediate storage. For this case, there is no need to model the storage tasks explicitly, and hence the model is described only using the continuous processing tasks  $i_p$ . There is no difference in the model due to whether bypassing of storage is allowed or not, because of the availability of unlimited intermediate storage. The mathematical model consists of the following allocation constraints, capacity constraints, material balances for raw materials and intermediates, demand, duration, and sequencing constraints:

##### Allocation Constraints.

$$\sum_{i \in I_j} w(i, n) \leq 1 \quad \forall j \in J, n \in N \quad (1)$$

In each unit, only one task or no task takes place at any event as represented by constraint (1).

##### Capacity Constraints for Processing Tasks.

$$\begin{aligned} R_{i_p}^{\min}(T^f(i_p, n) - T^s(i_p, n)) &\leq b(i_p, n) \\ &\leq R_{i_p}^{\max}(T^f(i_p, n) - T^s(i_p, n)), \quad \forall i_p \in I_p, n \in N \end{aligned} \quad (2)$$

$$b(i_p, n) = R_{i_p}(T^f(i_p, n) - T^s(i_p, n)) \quad \forall i_p \in I_p, n \in N \quad (3)$$

The amount of material processed by a continuous processing task is constrained by lower and upper bounds in (2), which are a function of the duration of the corresponding task  $i_p$ , which is represented by the difference between the end time and the start time of the task at event  $n$ ,  $(T^f(i_p, n) - T^s(i_p, n))$ , and the minimum and the maximum processing rate of the task  $i_p$ . For the case of constant processing rates, the amount of production is related as described by constraint (3).

##### Material Balances. (A) Raw Materials.

$$ST_0(s, n) + \sum_{i_p \in I_s} \rho_{s i_p}^c b(i_p, n) = 0 \quad \forall s \in S^R, n \in N \quad (4)$$

In constraint (4), the amount of raw material, as and when required from the external resources, is related to the amounts consumed at the corresponding event  $n$ . On the other hand, if the entire raw material requirement is supplied at the beginning of the scheduling horizon, then constraint (4) is modified as follows:

$$\begin{aligned} ST(s, n) &= ST(s, n-1) + \sum_{i_p \in I_s} \rho_{s i_p}^c b(i_p, n) \\ &\forall s \in S^R, n \in N, n > 1, \end{aligned} \quad (5)$$

$$\begin{aligned} ST(s, n) &= ST_0(s) + \sum_{i_p \in I_s} \rho_{s i_p}^c b(i_p, n) \\ &\forall s \in S^R, n = 1. \end{aligned} \quad (6)$$

The total initial amount required from external resources,  $ST_0(s)$ , calculated in (6), is either partly consumed at the first event  $n = 1$  or remains in the storage, which is consumed during the subsequent events as described in (5).

##### (B) Intermediates.

$$\begin{aligned} ST(s, n) &= ST(s, n-1) + \sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) \\ &+ \sum_{i_p \in I_s} \rho_{s i_p}^c b(i_p, n) \quad \forall s \in S^{\text{IN}}, n \in N, n > 1 \end{aligned} \quad (7)$$

$$\begin{aligned} ST(s, n) &= ST_0(s) + \sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) \\ &+ \sum_{i_p \in I_s} \rho_{s i_p}^c b(i_p, n) \quad \forall s \in S^{\text{IN}}, n = 1 \end{aligned} \quad (8)$$

Similarly, for the intermediate state  $s$ , the material balance is written in constraints (7) and (8).  $ST(s, n)$

defines the excess amount of state  $s$  at event  $n$ . In constraint (7), the first term on the right-hand side signifies the amount of state  $s$  stored at the previous event ( $n - 1$ ) in the storage; the second term represents the amount of state  $s$  produced by the upstream processing task at event  $n$ . This total amount is either consumed in the downstream processing task indicated by the third term or remains in the storage at event  $n$  as shown on the left-hand side. At the first event, the initial amount of available intermediates is taken into account in (8). These constraints are based on the condition that an intermediate material is allowed to go directly to the production task bypassing the storage, because only the excess amount,  $ST(s, n)$ , is stored. The other case, where storage bypassing is not allowed, irrespective of whether the amount produced by the upstream processing unit is in excess of the amount consumed by the downstream processing, is discussed in Sect. “**Dedicated and Flexible Finite Intermediate Storage Without Storage Bypassing.**”

#### Demand Constraints.

$$D_s^{\min} \leq \sum_{n \in N} \sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) \leq D_s^{\max} \quad \forall s \in S^p \quad (9)$$

The material balance for the final product state  $s$  is given in constraint (9), where the total production of state  $s$  is limited between the specified lower and upper bounds on the demands of the final product.

#### Duration Constraints for Processing Tasks.

$$T^f(i_p, n) - T^s(i_p, n) \leq Hw(i_p, n) \quad \forall i_p \in I_p, n \in N \quad (10)$$

The duration constraint for processing tasks is given in (10), which states that the duration is zero if the corresponding processing task is not active, otherwise the constraint is relaxed.

#### Sequencing Constraints. (A) Same Task in the Same Unit.

$$T^s(i, n+1) \geq T^f(i, n) \quad \forall i \in I, n \in N, n \neq N \quad (11)$$

Constraint (11) states that the start time of a task at the next event should be greater than the finish time of the same task at the current event.

**(B) Different Tasks in the Same Unit.** For two different tasks taking place in the same unit, the different possible changeover requirements are (i) no setup

time required, (ii) changeover time is required but is independent of the sequence in which the two consecutive tasks take place, and (iii) sequence-dependent changeovers.

For the first case of no changeover times, the two constraints for the same task in the same unit and different tasks in the same unit can be combined into one equation as shown in (12):

$$T^s(i, n+1) \geq T^f(i', n) \quad \forall j \in J, i \in I_j, i' \in I_j, n \in N, n \neq N. \quad (12)$$

For the second case of sequence-independent changeovers, the constraint for different tasks in the same unit requires modification as shown in (13), where  $\tau_j$  is the changeover time in unit  $j$ :

$$T^s(i, n+1) \geq T^f(i', n) + \tau_j w(i', n) \quad \forall j \in J, i, i' \in I_j, i \neq i', n \in N, n \neq N. \quad (13)$$

For the third case of sequence-dependent changeovers, the constraint for different tasks in the same unit is generalized as follows:

$$T^s(i, n) \geq T^f(i', n') + t_{i' i}^c w(i, n) - H(1 - w(i', n')) - H \sum_{i''} \sum_{n' < n'' < n} w(i'', n'') \quad \forall j \in J, i, i' \in I_j, i \neq i', n, n' \in N, n > n'. \quad (14)$$

Note that in constraints (12)–(14), only the last constraint (14), has big-M terms, unlike in the previous formulations of Ierapetritou and Floudas [7,8]. This feature is observed to result in better linear programming relaxed solutions which often improve the computational performance.

**(C) Different Tasks in Different Units for Processing Tasks.** The start and finish times of different processing tasks  $i'_p$  and  $i_p$ , which produce or consume the same state  $s$ , need to be aligned, and we have the following two alternative ways of writing these constraints, (15) and (16) or (15A) and (16A):

$$T^s(i_p, n) \geq T^s(i'_p, n) - H(1 - w(i'_p, n)) \quad \forall s \in S^{IN}, i_p \in I_s, i'_p \in I_s, i_p \neq i'_p, \rho_{s i'_p}^p > 0, \rho_{s i_p}^c < 0, n \in N, \quad (15)$$

$$\begin{aligned}
T^f(i_p, n) &\geq T^f(i'_p, n) - H(1 - w(i'_p, n)) \\
\forall s \in S^{\text{IN}}, i_p \in I_s, i'_p \in I_s, i_p \neq i'_p, \rho_{si'_p}^p > 0, \\
\rho_{si_p}^c < 0, n \in N, \quad (16)
\end{aligned}$$

$$\begin{aligned}
T^s(i_p, n) &\geq T^s(i'_p, n) - H(2 - w(i'_p, n) \\
&- w(i_p, n)) \quad \forall s \in S^{\text{IN}}, i_p \in I_s, i'_p \in I_s, \\
i_p \neq i'_p, \rho_{si'_p}^p > 0, \rho_{si_p}^c < 0, n \in N, \quad (15A)
\end{aligned}$$

$$\begin{aligned}
T^f(i_p, n) &\geq T^f(i'_p, n) - H(2 - w(i'_p, n) \\
&- w(i_p, n)) \quad \forall s \in S^{\text{IN}}, i_p \in I_s, i'_p \in I_s, \\
i_p \neq i'_p, \rho_{si'_p}^p > 0, \rho_{si_p}^c < 0, n \in N. \quad (16A)
\end{aligned}$$

In these constraints the start and end times of the downstream (consuming) processing tasks are enforced to be later than the corresponding times of the upstream (producing) processing tasks that process the same state  $s$ . Constraints (15) and (16) enforce the condition that the start and end times of the consuming tasks need to be always aligned to those of the corresponding producing tasks whenever the producing task is active; (15A) and (16A) state that the start and end times of the corresponding processing tasks need to be aligned conditionally, when both tasks are active.

Constraints (15) and (16) are required when we use the variable  $ST(s, n)$  in the material balance constraint (7), for instance, when we do not consider storage as a separate task for the unlimited intermediate storage case (or for the dedicated finite intermediate storage case discussed later). Otherwise, if we do not have  $ST(s, n)$  (for instance, for the no intermediate storage case discussed later) or if we consider storage as a separate task and use the variable  $B(i_{st}, n)$  instead of  $ST(s, n)$  in the material balance (for instance, for the dedicated and flexible finite intermediate storage cases discussed later), then we need constraints (15A) and (16A). The reason for this is that when we do not consider storage as a separate task and use the variable  $ST(s, n)$  in the material balance constraint (7), there is an implicit assumption that when the downstream consuming task starts at event  $n$ , the amount stored in  $ST(s, n - 1)$  would be available for consumption, which may not always be valid (because of the heterogeneous locations of events used), unless the con-

suming tasks are always aligned to the producing tasks whenever the producing tasks are active, as described in the sequencing constraints (15) and (16). It should be noted that the fact that the model of Ierapetritou and Floudas [8] for continuous processes results in the reported approximate solutions [1,5,20] is due to lack of the second constraint, (16) or (16A), relating the end times of the producing and consuming tasks.

**Extra Tightening Constraint.** The following tightening constraint gives a better linear programming relaxation:

$$\sum_{n \in N} \sum_{i \in I_j} (T^f(i, n) - T^s(i, n)) \leq H - \tau_j^{\min} \quad \forall j \in J. \quad (17)$$

It states that the sum of the durations of all tasks suitable in unit  $j$  is limited by the available time in the horizon ( $H - \tau_j^{\min}$ ), where  $\tau_j^{\min}$  is a lower bound on the total cleanup time required in unit  $j$ .

### Dedicated Finite Intermediate Storage with Storage Bypassing Allowed

Next, consider the case where a dedicated finite intermediate storage is available for each intermediate state  $s$ . For this case as well, there is no need to model the storage tasks explicitly, because the storage tasks are anyway dedicated in nature. We are only interested in constraining the finite nature of the intermediate storage. Hence, the model is described here only using the continuous processing tasks  $i_p$ , and the other case when storage is considered as a separate task is discussed in Sect. “Flexible Finite Intermediate Storage with Storage Bypassing Allowed.” All the above constraints for the case of unlimited storage remain the same except for the constraints for different tasks in different units for processing tasks. Here, since we do not consider storage as a separate task, we use constraints (15) and (16). Additional constraints would be required depending on whether storage bypassing is allowed or not. Initially, we consider the case when storage bypassing is allowed and then discuss the other case in Sect. “Dedicated and Flexible Finite Intermediate Storage Without Storage Bypassing”.

**Storage Bypassing Allowed.** When an intermediate material is allowed to go directly to the production task

bypassing a finite intermediate storage or if there is no intermediate storage available, then to ensure the feasibility of the inventory capacity balance, the start and finish times of processing tasks  $i'_p$  and  $i_p$ , which produce and consume the same state  $s$ , respectively, need to be the *same* if both tasks are active at the same event point as shown in the following constraints:

$$\begin{aligned} T^s(i_p, n) &\leq T^s(i'_p, n) + H(2 - w(i'_p, n) \\ &\quad - w(i_p, n)) \quad \forall s \in S^{\text{FIS}}, i_p \in I_s, i'_p \in I_s, \\ &\quad i_p \neq i'_p, \rho_{s i'_p}^p > 0, \rho_{s i_p}^c < 0, n \in N, \end{aligned} \quad (18)$$

$$\begin{aligned} T^f(i_p, n) &\leq T^f(i'_p, n) + H(2 - w(i'_p, n) \\ &\quad - w(i_p, n)) \quad \forall s \in S^{\text{FIS}}, i_p \in I_s, i'_p \in I_s, \\ &\quad i_p \neq i'_p, \rho_{s i'_p}^p > 0, \rho_{s i_p}^c < 0, n \in N. \end{aligned} \quad (19)$$

So, from constraints (15), (16), (18), and (19), both the start and the end times of the producing and the consuming tasks of the same state  $s$  would be the same, if both tasks are active at event  $n$ . If either of the tasks is not active, then constraints (18) and (19) are relaxed and are trivially satisfied. This zero-wait condition is required to ensure the feasibility of the inventory capacity balance as illustrated in Shaik and Floudas [27], because of the unit-specific nature of the continuous-time representation used. The formulation of Ierapetritou and Floudas [8] did not take this into account. In the formulation of Giannelos and Georgiadis [6], this condition was enforced even for batch plants as well, which is unrealistic, and hence their formulation led to sub-optimal solutions as observed by Sundaramoorthy and Karimi [29] and Shaik et al. [28].

Now, to constrain the finite nature of the intermediate storage available, the following bounds are added for the states that have the finite storage requirements:

$$ST(s, n) \leq ST_s^{\text{max}} \quad \forall s \in S^{\text{FIS}}, n \in N. \quad (20)$$

### No Intermediate Storage

For the case when no intermediate storage is available, the excess amount of state  $s$ ,  $ST(s, n)$ , is driven to zero at each event  $n$  or simply this variable is eliminated. Then, the material balance constraints (7) and

(8) reduce to the following, meaning that the amount of state  $s$  produced at an event has to be consumed at the same event:

$$\sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) + \sum_{i_p \in I_s} \rho_{s i_p}^c b(i_p, n) = 0 \quad \forall s \in S^{\text{IN}}, n \in N. \quad (21)$$

The condition of enforcing the same start and end times of the producing and consuming tasks of the same state  $s$ , described in constraints (15A), (16A), (18), and (19) is again applicable because no intermediate storage is available. Here we use (17) and (18) because in the material balance constraint (21), there is no assumption that the consuming task will receive material from the storage at the previous event, and hence there is no need to enforce the alignment unconditionally.

### Flexible Finite Intermediate Storage with Storage Bypassing Allowed

This is a general case where finite intermediate storage is available and for each material state several suitable storage options exist. A material state can be stored in all or a limited number of storage units and vice versa. To handle this general case we need to introduce separate tasks for the storage activity, because the storage cannot have more than one state at any time and we need to accommodate additional constraints for relating the timing of storage tasks ( $i_{st}$ ) to that of the processing tasks ( $i_p$ ). The nature of these constraints would be different depending on whether storage bypassing is allowed or not. Initially, we consider the case when storage bypassing is allowed and then discuss the other case in Sect. “Dedicated and Flexible Finite Intermediate Storage Without Storage Bypassing.” For the dedicated finite intermediate storage case, in contrast to the model discussed in Sect. “Dedicated Finite Intermediate Storage with Storage Bypassing Allowed,” if we alternatively chose to consider storage as a separate task, then the following same model would be applicable.

The additional constraints in the mathematical model are described below for the case of flexible finite intermediate storage when storage bypassing is allowed. The allocation constraint in (1) remains the same except that now it is written over all units (both processing and storage).

### Allocation Constraints for Storage Tasks.

$$w(i_{st}, n + 1) \geq w(i_{st}, n) + z(i_{st}, n) - 1 \quad \forall i_{st} \in I_{st}, n \in N \quad (22)$$

Constraint (22) states that if a storage task is active and it stores a nonzero amount at event  $n$ , then the same storage task should be active at the next event  $n + 1$  as well. Additionally, this constraint also avoids unnecessary tank-to-tank transfer of material because the same storage task would be active at the next event as well.

### Capacity Constraints for Storage Tasks

$$b(i_{st}, n) \leq V_{i_{st}}^{\max} w(i_{st}, n) \quad \forall i_{st} \in I_{st}, n \in N \quad (23)$$

$$b(i_{st}, n) \leq V_{i_{st}}^{\max} z(i_{st}, n) \quad \forall i_{st} \in I_{st}, n \in N \quad (24)$$

The capacity constraints for processing tasks remain the same as in (2) or (3), while for storage tasks the amount of material that can be stored is limited by the available capacity of the corresponding storage unit as shown in constraint (23). Constraint (24) is the same as (25), but uses a different binary variable  $z(i_{st}, n)$  to confine only those instances when  $b(i_{st}, n) \neq 0$ , which is realized through the penalty term on the number of binary variables in the objective function described in (45).

**Material Balances** Constraint (4), for calculating the amount of raw material as and when required from the external resources, remains the same. For the other case when the entire raw material requirement is supplied at the beginning of the scheduling horizon, constraints (5) and (6) are modified as follows:

$$\sum_{i_{st} \in I_{st}} \rho_{s i_{st}}^p b(i_{st}, n - 1) + \sum_{i \in I_s} \rho_{s i}^c b(i, n) = 0 \quad \forall s \in S^R, n \in N, n > 1, \quad (25)$$

$$ST_0(s) + \sum_{n=1} \sum_{i \in I_s} \rho_{s i}^c b(i, n) = 0 \quad \forall s \in S^R, \quad (26)$$

where the set  $I_s$  consists of both processing and storage tasks. The variable  $ST(s, n)$  is eliminated here because separate storage tasks are defined explicitly. Similarly, the material balances in (7) and (8) for the intermedi-

ates are modified as given below:

$$\sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) + \sum_{i_{st} \in I_s} \rho_{s i_{st}}^p b(i_{st}, n - 1) + \sum_{i \in I_s} \rho_{s i}^c b(i, n) = 0 \quad \forall s \in S^{\text{FIS}}, n \in N, n > 1, \quad (27)$$

$$\sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) + ST_0(s) + \sum_{i \in I_s} \rho_{s i}^c b(i, n) = 0 \quad \forall s \in S^{\text{FIS}}, n = 1, \quad (28)$$

where the set  $I_s$  consists of both processing and storage tasks. These constraints are based on the same condition that an intermediate material is allowed to go directly to the production task bypassing the storage. The demand constraint in (9) remains the same.

### Duration Constraints for Storage Tasks

$$T^f(i_{st}, n) \geq T^s(i_{st}, n) \quad \forall i_{st} \in I_{st}, n \in N \quad (29)$$

The duration constraint given in (10) remains the same for processing tasks, while for the storage tasks the finish times have to be later than the start times as shown in (29).

The sequencing constraints, (11)–(14), (15A), (16A), (18), (19) for the same task in the same unit, different tasks in the same unit, and different tasks in different units for the processing tasks remain the same. Here, because storage is considered as a separate task we use constraints (15A) and (16A). The sequencing constraints for storage tasks are defined below.

**Sequencing Constraints. Different Tasks in Different Units for Storage Tasks** The start time of a storage task that stores the intermediate state  $s$  should be same as the start time of the processing task that either produces or consumes state  $s$  as follows:

$$T^s(i_{st}, n) \geq T^s(i_p, n) - H(2 - w(i_{st}, n) - w(i_p, n)) \quad \forall s \in S^{\text{IN}}, i_{st} \in I_s, i_p \in I_s, n \in N, \quad (30)$$

$$T^s(i_{st}, n) \leq T^s(i_p, n) + H(2 - w(i_{st}, n) - w(i_p, n)) \quad \forall s \in S^{\text{IN}}, i_{st} \in I_s, i_p \in I_s, n \in N. \quad (31)$$

If the corresponding processing task that either produces or consumes state  $s$  is not active ( $w(i_p, n) = 0$ ), and there is a nonzero amount in the storage ( $z(i_{st}, n) = 1$ ), then the start time of the storage task should be equal to the finish time of the same task at the previous event and is realized through constraints (32) and (11).

$$\begin{aligned} T^s(i_{st}, n) &\leq T^f(i_{st}, n-1) + H(1 - z(i_{st}, n) + w(i_p, n)) \\ \forall s \in S^{IN}, i_{st} \in I_s, i_p \in I_s, n \in N, n > 1 \end{aligned} \quad (32)$$

The finish time of the storage task for storing state  $s$  should be greater than the finish times of both the producing and the consuming tasks of state  $s$  as follows:

$$\begin{aligned} T^f(i_{st}, n) &\geq T^f(i_p, n) - H(2 - w(i_{st}, n) - w(i_p, n)) \\ \forall s \in S^{IN}, i_{st} \in I_s, i_p \in I_s, n \in N. \end{aligned} \quad (33)$$

Additionally, if the amount stored in the storage is zero ( $z(i_{st}, n) = 0$ ), then the finish time of the storage task should be same as the finish time of the corresponding consuming processing task and is realized from constraints (33) and (34).

$$\begin{aligned} T^f(i_{st}, n) &\leq T^f(i_p, n) + H(2 - w(i_{st}, n) - w(i_p, n)) + Hz(i_{st}, n) \\ \forall s \in S^{IN}, i_{st} \in I_s, i_p \in I_s, \rho_{s i_p}^c < 0, n \in N \end{aligned} \quad (34)$$

However, if the amount stored in the storage is nonzero ( $z(i_{st}, n) = 1$ ), then it should remain in the storage until the start time of the processing task at the next event. So, the finish time of the storage task should be same as the start time of the next processing task and is realized from constraints (35) and (36):

$$\begin{aligned} T^f(i_{st}, n) &\geq T^s(i_p, n+1) - H(2 - w(i_{st}, n) \\ &- w(i_p, n+1)) - H(1 - z(i_{st}, n)), \\ \forall s \in S^{IN}, i_{st} \in I_s, i_p \in I_s, n \in N, n \neq N, \end{aligned} \quad (35)$$

$$\begin{aligned} T^f(i_{st}, n) &\leq T^s(i_p, n+1) + H(2 - w(i_{st}, n) \\ &- w(i_p, n+1)) + H(1 - z(i_{st}, n)), \\ \forall s \in S^{IN}, i_{st} \in I_s, i_p \in I_s, n \in N, n \neq N. \end{aligned} \quad (36)$$

The tightening constraint given in (17) is again applicable.

### Dedicated and Flexible Finite Intermediate Storage Without Storage Bypassing

The nature of constraints is different when storage bypassing is not allowed for the cases where production must go through finite storage (dedicated or flexible) before consumption in the downstream units. This is a general case and we do not need to enforce the same start and end times for producing or consuming tasks of the same state, because the material always goes through storage.

### Dedicated Finite Intermediate Storage Case Without Bypassing of Storage

Here again, we have the option of considering storage as a separate task or not. In this section, we describe the model without considering storage as a separate task, and the other case when storage is considered as a separate task is discussed in the next section along with the flexible finite intermediate storage case.

When we do not consider storage as a separate task, the model comprises all the constraints, (1)–(14), (15), (16), and (17), discussed in Sect. “Unlimited Intermediate Storage.” Additionally we need constraint (20) and the following material balance constraints for the intermediate states.

### Material Balance for Intermediates

$$\begin{aligned} ST(s, n-1) + \sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) &\leq ST_s^{\max} \\ \forall s \in S^{FIS}, n \in N, n > 1 \end{aligned} \quad (37)$$

$$\begin{aligned} ST_0(s) + \sum_{i_p \in I_s} \rho_{s i_p}^p b(i_p, n) &\leq ST_s^{\max} \\ \forall s \in S^{FIS}, n \in N, n = 1 \end{aligned} \quad (38)$$

In constraints (37) and (38), the total amount received into the dedicated storage at each event is constrained to be within the maximum capacity limits.

### Flexible Finite Intermediate Storage Case Without Bypassing of Storage

For the dedicated finite intermediate storage case as well, in contrast to the model discussed in the previous section, if we alternatively chose to consider storage as a separate task, then the following same model would be applicable for both

the dedicated and the flexible finite storage cases. Constraints (1), (2), (4), (9)–(11), (14), (16A), (17), (22)–(24), (27)–(29), and (32)–(36), discussed in the previous sections, are required. Constraint (15A) is not required as it is implicitly enforced, because consuming tasks are aligned with storage tasks, which in turn are aligned with the producing tasks. Additionally, we need the following allocation, material balance, and sequencing constraints.

### Allocation Constraints

$$\sum_{i_{st} \in \rho_{s_{ist}}^c} w(i_{st}, n) \geq w(i_p, n) \quad \forall s \in S^{FIS}, i_p \in \rho_{s_{ip}}^p, n \in N \quad (39)$$

Constraint (39) states that whenever a producing task of state  $s$  is active then one or more of suitable storage tasks also need to be active for all intermediate states that have the finite storage requirement.

**Material Balance for Intermediates** Here, because the storage tasks are modeled explicitly, constraints (37) and (38) are modified as follows:

$$\sum_{i_{st} \in I_s} \rho_{s_{ist}}^p b(i_{st}, n-1) + \sum_{i_p \in I_s} \rho_{s_{ip}}^p b(i_p, n) \leq \sum_{i_{st} \in I_s} V_{i_{si}}^{\max} w(i_{st}, n) \quad \forall s \in S^{FIS}, n \in N, n > 1, \quad (40)$$

$$ST_0(s) + \sum_{i_p \in I_s} \rho_{s_{ip}}^p b(i_p, n) \leq \sum_{i_{st} \in I_s} V_{i_{si}}^{\max} w(i_{st}, n) \quad \forall s \in S^{FIS}, n = 1. \quad (41)$$

### Sequencing Constraints. Different Tasks in Different Units

$$T^s(i_{st}, n) \geq T^s(i_p, n) - H(2 - w(i_{st}, n) - w(i_p, n)) \quad \forall s \in S^{IN}, i_{st} \in I_s, i_p \in \rho_{s_{ip}}^p, n \in N \quad (42)$$

$$T^s(i_{st}, n) \leq T^s(i_p, n) + H(2 - w(i_{st}, n) - w(i_p, n)) \quad \forall s \in S^{IN}, i_{st} \in I_s, i_p \in \rho_{s_{ip}}^p, n \in N \quad (43)$$

$$T^s(i_p, n) \geq T^s(i_{st}, n) - H(2 - w(i_{st}, n) - w(i_p, n)) \quad \forall s \in S^{IN}, i_{st} \in I_s, i_p \in \rho_{s_{ip}}^c, n \in N \quad (44)$$

Constraints (42) and (43) impose the requirement that the start time of the storage task is the same as the start time of the corresponding processing task that produces the intermediate state, if both the storage task and the producing task are active. Constraint (44) states that the start time of the processing task that consumes the intermediate state should be later than the start time of the corresponding storage task if both tasks are active.

### Objective: Maximization of Profit

$$C_1 \sum_{s \in S^P} \sum_{n \in N} price_s \sum_{i \in I_s} \rho_{s_i}^p b(i, n) - C_2 \sum_{i \in I} \sum_{n \in N} w(i, n) - C_3 \sum_{i_{st} \in I_{st}} \sum_{n \in N} z(i_{st}, n) \quad (45)$$

The objective is maximization of profit due to sales from the production of final products, and additionally there are penalties for the total number of binary variables as shown in (45), where  $C_i$  is the corresponding cost coefficient.

**Objective: Minimization of Makespan** For the objective of minimization of the makespan (MS) the following constraints need to be added:

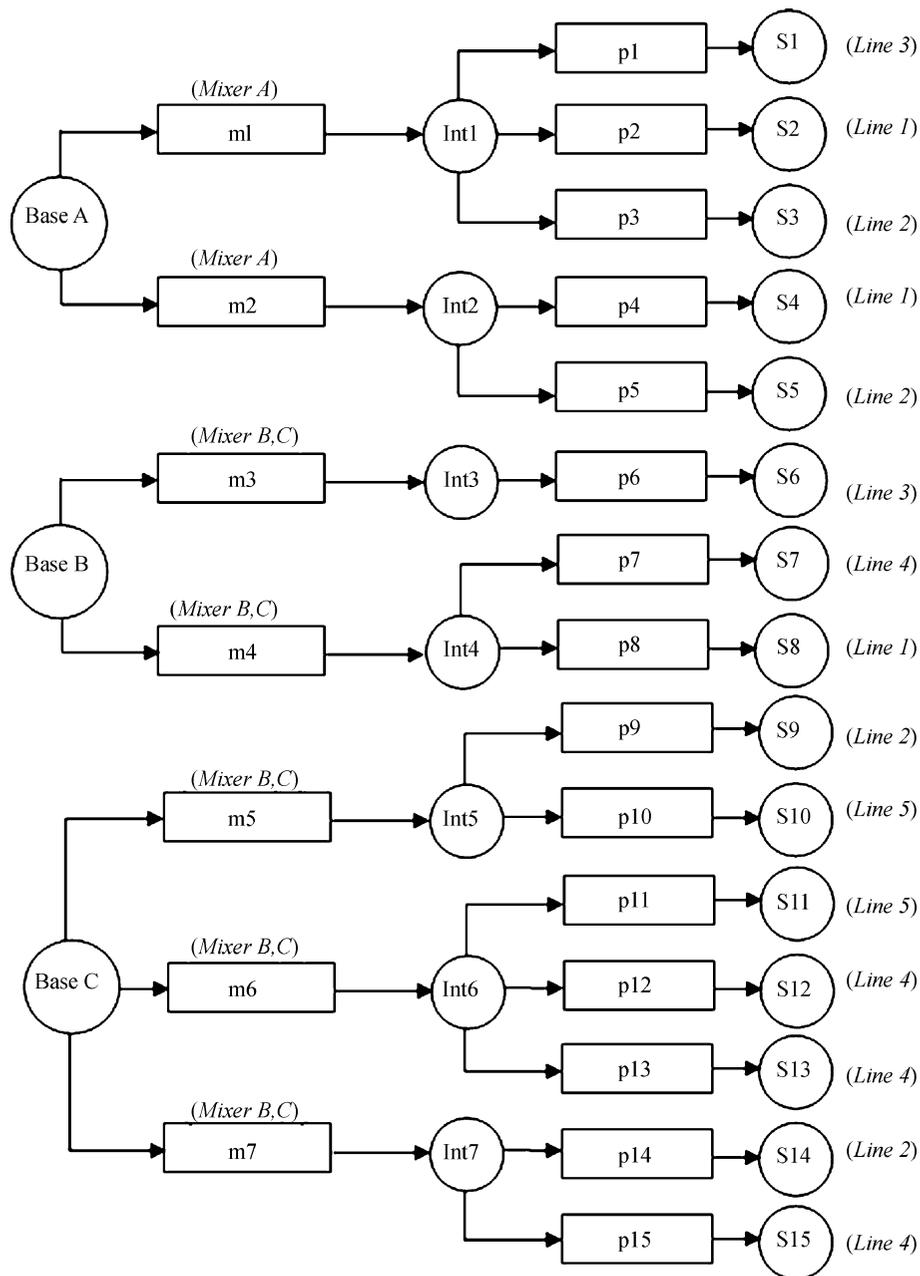

$$\text{Minimize MS and } T^f(i, n) \leq MS \quad \forall i \in I, n \in N. \quad (46)$$

The tightening constraint in (17) is modified as follows:

$$\sum_{n \in N} \sum_{i \in I_j} (T^f(i, n) - T^s(i, n)) \leq MS - \tau_j^{\min} \quad \forall j \in J. \quad (47)$$

### Computational Case Study

An industrial case study of a fast moving consumer goods manufacturing plant that has been extensively studied by several authors [1,2,5,8,20,27] is considered. The plant follows a common production sequence: mixing, storage, and packing. The mixing stage has

**Short-Term Scheduling of Continuous Processes, Figure 1**  
State-task-network representation of the plant

three parallel mixers (mixers A, B, and C) operating in a continuous mode that produce seven intermediates (Int1–Int7) using three different base stocks (bases A, B, and C) available as required. These intermediates may be stored in three storage tanks (tanks A, B, and C) or directly packed in five continuous packing lines (lines

1–5), thus producing 15 final products (S1–S15). The STN representation of the plant is shown in Fig. 1 along with the unit suitability for each task.

The base stocks are available in unlimited initial amounts. For each task suitable on multiple units, a separate task is considered. For instance, two making tasks

(m31 and m32) are considered for producing “Int3” using mixers B and C, respectively. The 15 final products are produced using 15 packing tasks (p1–p15). The problem data such as production rates, task-unit suitability, and cleanup times used in the literature [5,27] are given in Tables 1 and 2. The state-specific data such as minimum demand specifications and prices for the final products, and storage limitations are shown in Table 3. A time horizon of 120 h is considered.

The case study with finite intermediate storage is considered. We compare the results from the literature [1,2,5,8,20], except for the model of Giannelos and Georgiadis [5], for which the comparison is based on our implementation of their model. All the computations in this work were performed using a 3.2 GHz Pen-

**Finite Intermediate Storage.** Consider the case of flexible finite intermediate storage for all the intermediates. Three storage tanks (tanks A, B, and C) are available each with a maximum capacity of 60 ton, and any intermediate can be stored in any of the three tanks. Since there are seven intermediates, 21 additional storage tasks need to be considered. Unlike in the Shaik and Floudas model, the start and end times of storage tasks are not precisely calculated in the model of Giannelos and Georgiadis [5]; rather it seems that they determine and/or adjust these timings during postprocessing. In our implementation of their model, we used the following equation to calculate the start times of all active

storage tasks during postprocessing:

$$T_{it}^s = \tau_{it} - \theta_{st}, \quad \forall s \in S^{fis}, i \in I_s^{st}, t \in T. \quad (48)$$

Then, in order to avoid the unnecessary activation of storage tasks in our implementation of their model, we used the following objective function, which is similar to (45) of the Shaik and Floudas model:

$$C_1 \sum_{s \in S^p} \text{price}_s ST(s, t_n) - C_2 \sum_{i \in I} \sum_{t \in T} x(i, t) - C_3 \sum_{s \in S^{fis}} \sum_{t \in T} y(s, t). \quad (49)$$

The model statistics are reported in Table 4. For the objective function of maximization of profit in (45) with  $C_1 = 10$  and  $C_2 = C_3 = 1$ , the Shaik and Floudas model requires four events, and the objective function is found to be 26910.181 in 465.61 CPU s with an integrality gap of 0.12%, which corresponds to a profit of 2695.32. The Gantt chart for the Shaik and Floudas model is depicted in Fig. 2.

This case is regarded as one of the hardest instances to solve in the literature. The Shaik and Floudas model finds the global optimum solution and requires consideration of only four events compared with the global event-based model of Castro et al. [1], which re-

ported ten events for this case as shown in Table 4. The campaign-based algorithmic model of Mendez and Cerda [20], although it is very compact in terms of the fewest problem statistics, could not find the global optimal solution for this case (the best solution reported corresponds to a profit of 2670.28). The formulation of Giannelos and Georgiadis [5] also reported a suboptimal solution corresponding to a profit of 2689.48 using four events. On the basis of our implementation of their model, an improved objective value of 2692.06 was found within a maximum CPU time of 60000 s and an integrality gap of 0.12%. However, in the Gantt chart it was observed that the end times of some storage tasks are not precisely calculated as discussed in Shaik and Floudas [27].

## Conclusions

In this study, the formulation of Shaik and Floudas [27], an improved model for short-term scheduling of continuous processes based on a STN representation using a unit-specific event-based continuous-time formulation, was presented. The model of Ierapetritou and Floudas [8] for continuous processes was modified and extended to precisely account for different storage requirements, such as dedicated, flexible, unlimited, and no intermediate storage policies. The efficacy of their formulation was demonstrated for an industrial case study from a fast moving consumer goods manufacturing process reported in the literature.

## Nomenclature

### Indices

- $i$  tasks
- $i_p$  processing tasks
- $i_{st}$  storage tasks
- $j$  units
- $n$  events indicating beginning of a task
- $s$  states

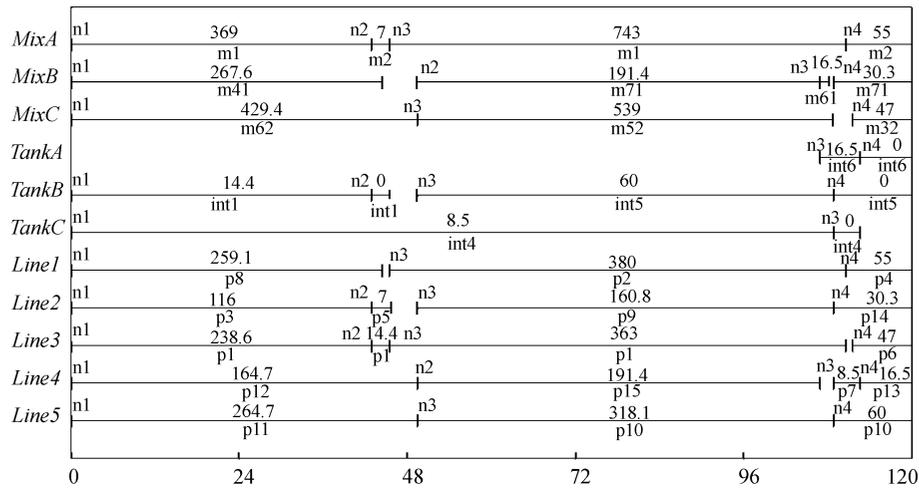

### Sets

- $I$  tasks
- $I_p$  processing tasks
- $I_{st}$  storage tasks
- $I_j$  tasks which can be performed in unit  $j$
- $I_s$  tasks which process state  $s$  and either produce or consume

$R_i^{\min}$  minimum processing rate of task  $i$ , ton/h  
 $R_i^{\max}$  maximum processing rate of task  $i$ , ton/h  
 $R_i$  processing rate of task  $i$  if it is constant, ton/h  
 $V_{ist}^{\max}$  maximum storage capacity for storage task  $i_{st}$ , ton  
 $H$  time horizon, h  
 $price_s$  price of state  $s$   
 $D_s^{\min}$  lower bound on demand for state  $s$ , ton  
 $D_s^{\max}$  upper bound on demand for state  $s$ , ton  
 $\tau_j$  sequence independent cleanup time required in unit  $j$ , h  
 $t_{ii'}^{cl}$  sequence dependent cleanup time required between tasks  $i$  and  $i'$ , h  
 $\tau_j^{\min}$  minimum total cleanup time required for unit  $j$ , h

$\rho_{si}^p, \rho_{si}^c$  proportion of state  $s$  produced, consumed from tasks  $i$ , respectively,  $\rho_{si}^p \geq 0, \rho_{si}^c \leq 0$

#### Variables

$w(i, n)$  binary variable for assignment of task  $i$  at the beginning of event  $n$   
 $z(i_{st}, n)$  binary variable to determine if storage task  $i_{st}$  stores a nonzero amount at event  $n$   
 $b(i, n)$  amount of material undertaking task  $i$  at event  $n$ , ton  
 $ST_0(s, n)$  amount of state  $s \in S^R$  that is required from external resources at event  $n$ , ton  
 $ST(s, n)$  excess amount of state  $s$  that needs to be stored at event  $n$ , ton  
 $T^s(i, n)$  time at which task  $i$  starts at event  $n$ , h  
 $T^f(i, n)$  time at which task  $i$  ends at event  $n$ , h

## Introduction

The research area of batch and continuous process scheduling has received great attention from both academia and industry in the past two decades. Floudas and Lin [2,3] presented extensive reviews comparing various discrete- and continuous-time-based formulations. During the last two decades, numerous formulations have been proposed in the literature based on continuous-time representation, due to their established advantages over discrete-time representations. On the basis of the time representation used, the different continuous-time models proposed in the literature can be broadly classified into three distinct categories: slot-based, global event-based, and unit-specific event-based formulations. In the slot-based models, the time horizon is represented in terms of ordered blocks of unknown, variable lengths, or time slots. Global event-based models use a set of events that are common across all units, and the event points are defined for either the beginning or end (or both) of each task in each unit. On the other hand, unit-specific event-based models define events on a unit basis, allowing tasks corresponding to the same event point but in different units to take place

at different times. For sequential processes, other alternative approaches based on precedence relationships have also been used.

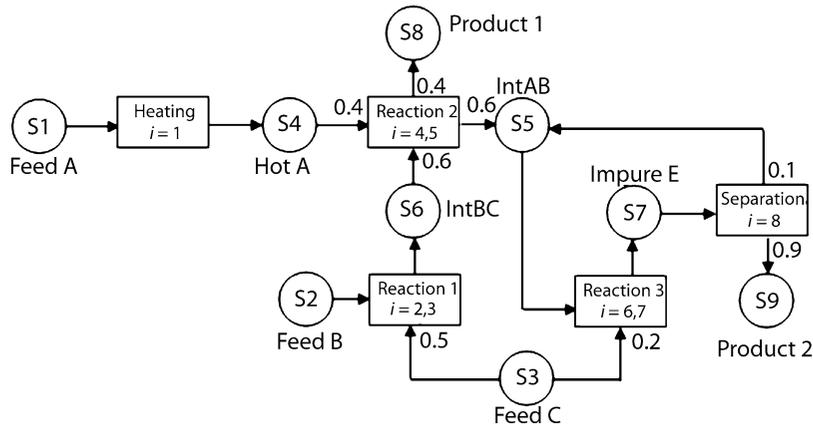

## Motivation

A detailed comparison of various continuous-time models for short-term scheduling of batch plants was performed recently by Shaik et al. [8] They concluded that, due to heterogeneous locations of event points used, the unit-specific event-based models always require less event points and exhibit favorable computational performance compared to both slot-based and global event-based models. For problems that do not have resource considerations such as utility constraints, it was found [8] that the modified model of Ierapetritou and Floudas [4] as presented in Shaik et al. [8], outperforms the other models both in terms of least problem size and fast computational performance. Similarly, for problems with resource constraints the enhanced model of Janak et al. [5,6] was found [5,6,8] to perform well.

However, for an additional instance of the following example involving a recycle stream shown in Fig. 1, it is observed that the model of Ierapetritou and Floudas [4] yields a suboptimal solution as discussed below.

*Example 1* Consider the second example discussed in Shaik et al. [8], in which two different products are produced through five processing stages: heating, reactions 1, 2, and 3, and separation, as shown in the STN representation of the plant flow sheet in Fig. 1. Since each of the reaction tasks can take place in two different reactors, each reaction is represented by two separate tasks. The processing time of task  $i$  on unit  $j$  is assumed to be a linear function,  $\alpha_i + \beta_i B$ , of its batch size,  $B$ . The relevant data [8] of the constant ( $\alpha_i$ ) and variable ( $\beta_i$ ) coefficients for processing times of different tasks ( $i$ ), the suitable units ( $j$ ), and their minimum ( $B_i^{\min}$ ) and maximum ( $B_i^{\max}$ ) batch sizes are shown in Table 1. The initial stock level for all intermediates is assumed to be zero and unlimited storage capacity is assumed for all states. The prices of products 1 and 2 are \$10/mu.

For the objective of maximization of profit and a time horizon ( $H$ ) of 10 h, this example is solved using the unit-specific event-based model of Ierapetritou and Floudas [4] (I&F), the global event-based models of Castro et al. [1](CBMN), and Maravelias and Gross-

	( <i>i</i> = 7) Reactor2	0.667	0.008325	–	80
Separation	( <i>i</i> = 8) Separator	1.3342	0.00666	–	200

mann [7] (M&G), and using the slot-based model of Sundaramoorthy and Karimi [10] (S&K). All the resulting mixed-integer linear programming (MILP) models are solved in GAMS distribution 21.1 using CPLEX 8.1.0 on the same computer (3 GHz Pentium 4 with 2 GB RAM) as in Shaik et al. [8] Table 2 provides a comparative study of these models in terms of the problem statistics such as the number of binary and continuous variables, number of constraints, CPU time taken to solve to the specified integrality gap, the number of nodes taken to reach the optimal solution, the objective function at the relaxed node, and so forth. It should be noted that for the S&K model,  $n$  event points are shown to represent  $n-1$  slots for a valid comparison with the other global-event and unit-specific event-based models. In the CBMN model, there is an additional parameter ( $\Delta t$ ) that defines a limit on the maximum number of events over which a task can occur.

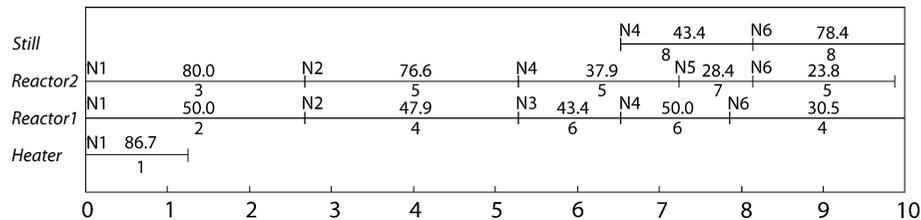

For this case, the slot-based and global event-based models require at least eight event points and are able to find the global optimal solution of 1962.7, compared to the unit-specific event-based I&F model, which gives a suboptimal solution of 1943.2 with six events and with higher events as well. When this case is solved using the enhanced unit-specific event-based model of Janak et al. [5,6], (JLF) it found the global optimal solution of 1962.7 using six events, as shown in Table 2. The Gantt chart for the JLF model is shown in Fig. 2.

The reason for this exception can be attributed to the fact that the I&F model does not allow a task to continue over several events, while the JLF model is an enhanced version of the I&F model that allows tasks to take place over multiple event points in order to accurately account for the resource considerations such as utility requirements. Although, there are no resource

<sup>a</sup> Suboptimal solution

**Short-Term Scheduling, Resource Constrained: Unified Modeling Frameworks, Figure 2**  
**Gantt chart for example 1 using the JLF model**

constraints in this example, it can be observed from the Gantt chart of Fig. 2 for the JLF model, that this schedule will not be feasible for the I&F model. According to the constraint for different tasks in different units of the I&F model, for state 's5', the consuming task ( $i = 7$ ) at event 'N5' should start after the end time of the producing task ( $i = 8$ ) at event 'N4', which is clearly not the case in the global optimal solution of Fig. 2. This constraint becomes relaxed in the JLF model because the producing task does not end at event 'N4', but it continues over the next event and ends at event 'N5' in the global optimal solution. The models of S&K, M&G, and CBMN allow tasks to take place over multiple events, and hence, are able to find the global optimal solution. Moreover, in these models the events/slots are globally aligned, and hence, they do not require the above-mentioned sequencing constraint for different tasks in different units, which is generally required for the unit-specific event-based models.

This example demonstrates that, although, there are no resource constraints, in some cases, it is a requirement for the unit-specific event-based models as well to allow tasks to take place over multiple events in order to find the global optimal solution. To understand such cases, let us examine the constraint for different tasks in different units that is used in the I&F model. It states that the consuming task at the current event should start after the end time of producing task at the previous event that processes the same state, which need not be true if there is sufficient material for the consuming task to start production, which happens to be the case in the particular instance of Fig. 2. The amount of state 's5' produced by the recycle stream ( $i = 8$ ) at event 'N4' is not necessary for starting the consuming task ( $i = 7$ ) at event 'N5'. So, this constraint needs to be relaxed depending on whether there is sufficient amount for the consuming task to start production or not, which is implicitly realized by allowing the tasks to take place over multiple events.

If we focus on the computational performance of the JLF model in Table 2, it has poor LP relaxation, and requires large number of constraints, nonzeros, and CPU time, compared to the other competitive models of S&K and CBMN. Because, the JLF model was originally developed to handle the more general case of problems with resource constraints, it can be observed that it does not reduce well, in terms of problem statistics, to the case of no resources. With this motivation, Shaik and Floudas [9], proposed a unified modeling approach using unit-specific event-based continuous-time representation, which (i) can handle problems with resource constraints by allowing tasks to take place over multiple events, (ii) efficiently reduces to the case of no resources, and (iii) is applicable for batch as well as continuous processes with mixed storage policies. The unified model of Shaik and Floudas [9] (S&F) for short-term scheduling of batch plants is described in the next section. In Sect. “Computational Case Studies”, we consider examples of problems with and without resources and compare the performance of the S&F model with other models.

### Formulation

The nomenclature used in the S&F formulation is given in the Nomenclature section. The three index binary variable  $w(i,n,n')$  defines the assignment of task  $i$  that starts at event  $n$  and ends at event  $n'$  ( $n' \geq n$ ). To exercise control on the maximum number of events over which a task is allowed to continue, a parameter,  $\Delta n$ , is defined such that  $n \leq n' \leq n + \Delta n$ ,  $\Delta n = 0, 1, \dots$ . So, the task  $i$  that starts at event  $n$  may end either at the same event point  $n$  ( $\Delta n = 0$ ), which would be similar to I&F model, or it may end at a later event  $n + \Delta n$  ( $\Delta n = 1, \dots$ ), which would be similar to the model of Janak et al. [5,6] In the model of Castro et al. [1](CBMN) also such parameter ( $\Delta t$ ) was defined. However, unlike in the S&F model [9], in all the slot-based and global event-based models [1,7,10], a task that starts at an event cannot end at the same event, thus by definition, the unit-specific event-based models [5,6,9] would require at least one event less compared to the slot-based and global event-based models.

The mathematical model has the following allocation, capacity, material balance, duration, sequencing, and utility related constraints.

### Allocation Constraints

$$\sum_{i \in I_j} \sum_{n' \in N, n \leq n' \leq n + \Delta n} w(i, n, n') \leq 1 \quad \forall j \in J, n \in N \quad (1)$$

$$\sum_{i \in I_j} \sum_{n \in N, n \leq n' \leq n + \Delta n} w(i, n, n') \leq 1 \quad \forall j \in J, n' \in N, \Delta n > 0 \quad (2)$$

$$\sum_{i' \in I_j, i' \neq i} \sum_{n' \in N, n \leq n' \leq n + \Delta n} w(i', n', n) \leq 1 - \sum_{n' \in N, n \leq n' \leq n + \Delta n} w(i, n, n') \quad \forall i \in I_j, j \in J, n \in N, \Delta n > 0 \quad (3)$$

$$\sum_{n' \in N, n \leq n' \leq n + \Delta n} w(i, n, n') \leq 1 - \sum_{n' \in N, n' < n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} \sum_{j \in J_i} \sum_{i' \in I_j} w(i', n', n'') + \sum_{n'' \in N, n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} \sum_{j \in J_i} \sum_{i' \in I_j} w(i', n'', n') \quad \forall i \in I, n \in N, n > 1, \Delta n > 0 \quad (4)$$

$$\sum_{n' \in N, n' \leq n \leq n' + \Delta n} w(i, n', n) \leq \sum_{n' \in N, n' \leq n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') - \sum_{n'' \in N, n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \quad \forall i \in I, n \in N, \Delta n > 0 \quad (5)$$

Constraint (1) enforces that at the most one task can start at each event and constraint (2) states that at the most one task can end at each event. Constraint (3) states that if a task starts at an event, a different task cannot end at the same event, because only the task that starts at an event can end at the same event. Constraint (4) states that a new task can start only if the total number of tasks that started earlier matches the total number of tasks ending. Constraint (5) states that a task cannot end unless it started earlier. Note that constraints (2)–(5) are applicable only if  $\Delta n > 0$ .

### Capacity Constraints

$$B_i^{\min} w(i, n, n') \leq b(i, n, n') \leq B_i^{\max} w(i, n, n') \quad (6)$$

$$\forall i \in I, n, n' \in N, n \leq n' \leq n + \Delta n$$

For each task, constraint (6) enforces the minimum and maximum batch size.

### Material Balances

$$ST(s, n) = ST(s, n - 1) + \sum_{i \in I_s^p} \sum_{n' \in N, n' \leq n-1 \leq n'+\Delta n} b(i, n', n-1) + \sum_{i \in I_s^c} \sum_{n' \in N, n \leq n' \leq n+\Delta n} b(i, n, n') \quad (7)$$

$$\forall s \in S, n \in N, n > 1$$

$$ST(s, n) = ST_0(s) + \sum_{i \in I_s^c} \sum_{n' \in N, n \leq n' \leq n+\Delta n} b(i, n, n') \quad (8)$$

$$\forall s \in S, n = 1$$

In the material balance (7), the amount of a state at the previous event is adjusted by the amount of the state produced by the tasks that are ending at the previous event and by the amount of the state being consumed by the tasks that are starting at the current event. In (8), the initial available amount of the state is taken into account.

### Duration Constraints

$$T^f(i, n) = T^s(i, n) + \alpha_i w(i, n, n) + \beta_i b(i, n, n) \quad (9)$$

$$\forall i \in I, n \in N, \Delta n = 0$$

$$T^f(i, n) \geq T^s(i, n) \quad \forall i \in I, n \in N, \Delta n > 0 \quad (10)$$

$$T^f(i, n') \geq T^s(i, n) + \alpha_i w(i, n, n') + \beta_i b(i, n, n') - M(1 - w(i, n, n')) \quad (11)$$

$$\forall i \in I, n, n' \in N, n \leq n' \leq n + \Delta n, \Delta n > 0$$

$$T^f(i, n') \leq T^s(i, n) + \alpha_i w(i, n, n') + \beta_i b(i, n, n') + M(1 - w(i, n, n')) \quad (12)$$

$$\forall i \in I, n, n' \in N, n \leq n' \leq n + \Delta n, \Delta n > 0$$

If  $\Delta n = 0$ , then the finish time of a task that started at the same event is calculated from (9). Otherwise, if  $\Delta n > 0$ , then the finish time of a task that started at an earlier event is calculated from (10)–(12). Note that, because of the usage of three-index binary and continuous variables, the duration constraints in the S&F model are simpler and have fewer big-M terms compared to the duration constraints in the model of Janak et al. [5,6], and hence it is observed to result in improved LP relaxations. Janak et al. [5,6] used several additional tightening constraints and bilinear variables to improve the LP relaxation, which are not necessary in the S&F formulation.

### Sequencing Constraints

#### Same Task in the Same Unit

$$T^s(i, n + 1) \geq T^f(i, n) \quad (13)$$

$$\forall i \in I, n \in N, n < N$$

$$T^s(i, n + 1) \leq T^f(i, n) + M \left[ 1 - \left( \sum_{n'' \in N, n' \leq n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') - \sum_{n'' \in N} \sum_{n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \right) \right] \quad (14)$$

$$+ M \sum_{n' \in N, n' \leq n \leq n' + \Delta n} w(i, n', n)$$

$$\forall i \in I, n \in N, n < N, \Delta n > 0$$

If  $\Delta n = 0$ , then the constraint for same task in the same unit is given in (13). Otherwise, if  $\Delta n > 0$ , then the constraint for same task in the same unit is given by (13) and (14), where the zero wait condition of (14) is additionally applied when the task is active at event  $n$  but not ending at event  $n$ .

#### Different Tasks in the Same Unit

$$T^s(i, n + 1) \geq T^f(i', n) \quad (15)$$

$$\forall i, i' \in I_j, i \neq i', j \in J, n \in N, n < N$$

### Different Tasks in Different Units

$$\begin{aligned}
 T^s(i, n+1) &\geq T^f(i', n) \\
 &- M \left( 1 - \sum_{n' \in N, n' \leq n \leq n' + \Delta n} w(i', n', n) \right) \\
 &\forall s \in S, i \in I_s^c, i' \in I_s^p, i \in I_j, i' \in I_{j'}, \\
 &i \neq i', j, j' \in J, j \neq j', n \in N, n < N
 \end{aligned} \tag{16}$$

For different tasks that produce or consume the same state, the start time of the consuming task at the next event is enforced to be later than the finish time of the producing task at the current event, provided the producing task is finishing at the current event.

### Tightening Constraint

$$\sum_{i \in I_j} \sum_{n \in N} \sum_{n' \in N, n \leq n' \leq n + \Delta n} (\alpha_i w(i, n, n') + \beta_j b(i, n, n')) \leq H \quad \forall j \in J \tag{17}$$

The sum of the durations of all tasks suitable in each unit should be within the time horizon.

### Utility Related Constraints

$$\begin{aligned}
 &\sum_{i \in I_u} \left[ \gamma_{iu} \left( \sum_{n' \in N, n' \leq n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') \right. \right. \\
 &\quad \left. \left. - \sum_{n'' \in N} \sum_{n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \right) \right] \\
 &+ \sum_{i \in I_u} \left[ \delta_{iu} \left( \sum_{n' \in N, n' \leq n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} b(i, n', n'') \right. \right. \\
 &\quad \left. \left. - \sum_{n'' \in N} \sum_{n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} b(i, n'', n') \right) \right] \\
 &\leq U_u^{\max} \quad \forall u \in U, n \in N
 \end{aligned} \tag{18}$$

The consumption of each utility at an event by all suitable active tasks is limited to the maximum availability in (18).

### Sequencing of Utility Related Tasks

$$T_{\text{ut}}^s(u, n+1) \geq T_{\text{ut}}^s(u, n) \quad \forall u \in U, n \in N, n < N \tag{19}$$

Constraint (19) is similar to the constraint for same task in the same unit for each utility.

$$\begin{aligned}
 T_{\text{ut}}^s(u, n) &\geq T^s(i, n) \\
 &- M \left[ 1 - \left( \sum_{n' \in N, n' \leq n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') \right. \right. \\
 &\quad \left. \left. - \sum_{n'' \in N} \sum_{n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \right) \right] \\
 &\forall u \in U, i \in I_u, n \in N
 \end{aligned} \tag{20}$$

$$\begin{aligned}
 T_{\text{ut}}^s(u, n) &\leq T^s(i, n) \\
 &+ M \left[ 1 - \left( \sum_{n' \in N, n' \leq n} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') \right. \right. \\
 &\quad \left. \left. - \sum_{n'' \in N} \sum_{n' \in N, n' < n, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \right) \right] \\
 &\forall u \in U, i \in I_u, n \in N
 \end{aligned} \tag{21}$$

In constraints (20) and (21), at each event, the start times of all suitable tasks that consume a utility are enforced to be equal, and are assigned to  $T_{\text{ut}}^s(u, n)$ , if the task is active.

$$\begin{aligned}
 T^f(i, n-1) &\geq T_{\text{ut}}^s(u, n) \\
 &- M \left[ 1 - \left( \sum_{n' \in N, n' \leq n-1} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') \right. \right. \\
 &\quad \left. \left. - \sum_{n'' \in N} \sum_{n' \in N, n' < n-1, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \right) \right] \\
 &- M \sum_{n' \in N, n' \leq n-1 \leq n' + \Delta n} w(i, n', n-1) \\
 &\forall u \in U, i \in I_u, n \in N, n > 1
 \end{aligned} \tag{22}$$

$$\begin{aligned}
& T^f(i, n-1) \leq T_{\text{ut}}^s(u, n) \\
& + M \left[ 1 - \left( \sum_{n' \in N, n'' \leq n-1} \sum_{n'' \in N, n' \leq n'' \leq n' + \Delta n} w(i, n', n'') \right. \right. \\
& \left. \left. - \sum_{n'' \in N, n' \in N, n' < n-1, n'' \leq n' \leq n'' + \Delta n} w(i, n'', n') \right) \right] \\
& \forall u \in U, i \in I_u, n \in N, n > 1
\end{aligned} \tag{23}$$

In constraints (22) and (23), the end times of all suitable tasks that consume a utility at previous event are enforced to be before  $T_{\text{ut}}^s(u, n)$ , if the task is active. If any of these tasks are finishing at the previous event, then the end times are enforced to be equal to  $T_{\text{ut}}^s(u, n)$ . Note that, unlike in the model of Janak et al. [5,6], the end time of utility consumption  $T_{\text{ut}}^f(u, n)$  is not part of the model here, but is accurately calculated as a parameter after solving the model.

### Bounds on Variables

$$\begin{aligned}
& T^s(i, n) \leq H; T^f(i, n) \leq H; T_{\text{ut}}^s(u, n) \leq H; \\
& b(i, n, n') \leq B_i^{\text{max}}; ST(s, n) \leq ST_s^{\text{max}}; \\
& ST_0(s) \leq ST_s^0
\end{aligned} \tag{24}$$

$$w(i, n, n') = 0, b(i, n, n') = 0 \quad \forall n' < n \tag{25}$$

$$T_{\text{ut}}^s(u, n) = 0, \quad \forall n = 1 \tag{26}$$

$$ST_0(s) = 0, \forall s \notin S^R \tag{27}$$

In (24), general bounds are added to different continuous variables. The non-permissible cases of the three-index binary and continuous variables are eliminated in (25). In (26),  $T_{\text{ut}}^s(u, n)$  at the first event should be assigned to the reference start time of the horizon, which is assigned to zero for simplicity. In (27), the initial amounts of all states, except the raw materials, should be assigned to their appropriate values, which are assigned to zero for simplicity. Depending on the STN of actual process considered, additionally it is possible to identify tasks that cannot occur at certain events and the corresponding binary and continuous variables can be eliminated.

## Objective Function

### Maximization of Profit

$$\begin{aligned}
& \text{Max Profit} = \\
& \sum_{s \in S^f} \sum_{n=N} \left( ST(s, n) + \sum_{i \in I_s^p} \sum_{n' \in N, n' \leq n \leq n' + \Delta n} b(i, n', n) \right)
\end{aligned} \tag{28}$$

For the objective of maximization of profit, the total amount of the final products produced by the last event is considered in (28). In all the constraints involving big-M terms, the value of  $M$  can be assigned to the time horizon,  $H$ .

### Minimization of Makespan (MS)

$$\text{Min MS} \tag{29}$$

$$\begin{aligned}
& ST(s, N) + \sum_{n=N} \sum_{i \in I_s^p} \sum_{n' \in N, n' \leq n \leq n' + \Delta n} b(i, n', n) \geq D_s \\
& \forall s \in S^f
\end{aligned} \tag{30}$$

$$T^f(i, N) \leq MS \quad \forall i \in I \tag{31}$$

For the objective of minimization of makespan,  $MS$ , the demand constraints for the final products are given in (30). The makespan should be the upper bound on the end time of each task at the last event. The parameter  $H$ , in the tightening constraint of (17) needs to be replaced by  $MS$ .

## Computational Case Studies

*Example 1* Consider the same example discussed earlier. There are no resource considerations, hence, constraints 18–33 will disappear. For the objective of maximization of profit, Shaik et al. [8] presented the comparative study for two different time horizons ( $H = 8$  h and  $H = 12$  h) for this example. In this study, we will consider two more instances of this example ( $H = 10$  h and  $H = 16$  h) and evaluate the performance of the unified S&F model. The model statistics for the objective of maximization of profit are given in Table 3.

Similar to the CBMN model, for each instance, at each event, the S&F model is solved using increasing values of  $\Delta n = 0, 1, \dots$

<sup>a</sup> Suboptimal solution; Relative Gap: 1.59%<sup>b</sup>, 3.16%<sup>c</sup>, 5.12%<sup>d</sup>, 28.16%<sup>e</sup>, 2.58%<sup>f</sup>, 5.46%<sup>g</sup>, 7.72%<sup>h</sup>

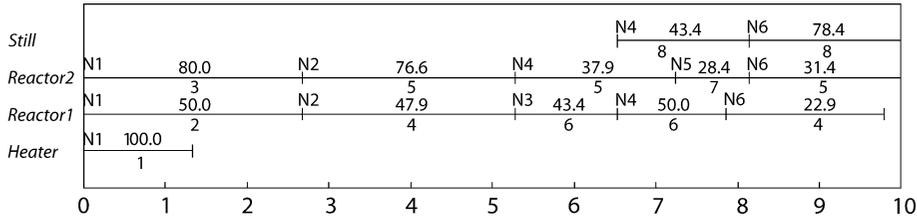

For the first instance, (example 1a), for  $H = 8$  h, it can be observed that the unified model (S&F) performs equally well compared to the I&F model. The S&F model requires less number of nodes and gives better RMIP values compared to the I&F model. The S&F model requires the same number of binary variables as that of I&F model. For the second instance of this example, (example 1b), for  $H = 10$  h, as already discussed in the motivation section, the I&F model fails to find the global optimal solution even at higher events. This can be confirmed by solving the S&F model for  $\Delta n = 0$ , which also gives the same suboptimal solution, because when  $\Delta n = 0$  (similar to  $\Delta t = 1$  for the CBMN model), the tasks are not allowed to take place over multiple events. For  $\Delta n = 0$ , the S&F model gives better RMIP values compared to I&F model. For  $\Delta n = 1$ , using six events the S&F model is able to find the global optimal solution in 14.4 CPU s. The CBMN model requires a value of  $\Delta t = 3$  to find the global optimal solution. Compared to the JLF model from Table 2, there is almost 50% reduction in the RMIP value, in the number of constraints, and nonzeros for the S&F model. The number of binary and continuous variables are also fewer, apart from the exceptional computational performance of the S&F model. The schedule obtained by the S&F model is similar to the JLF model as shown in Fig. 3.

For the third instance (example 1c), for  $H = 12$  h, it can be observed that the unified model (S&F) at  $\Delta n = 0$ ,

performs slightly faster compared to the I&F model. The S&F model requires less number of nodes and gives better RMIP values compared to the I&F model. Among the slot-based/global event-based models that require at least 11 events, only the M&G model is able to find the global optimal solution in the specified CPU time. The unit-specific event-based models require only 7 events to find the global optimal solution with exceptional computational performance. Similar conclusions hold true for the fourth instance (example 1d), for  $H = 16$  h. The unified model (S&F) at  $\Delta n = 0$ , performs faster compared to the I&F model. The S&F model requires less number of nodes and gives better RMIP values compared to the I&F model. The slot-based/global event-based models require 10 events, while the unit-specific event-based models require only 8 events to find the global optimal solution with faster computational performance. When we consider an additional event, the S&F model again outperforms all the other models as seen in Table 3.

For the objective of minimization of makespan the computational results are given in Table 4. For models involving big-M constraints a value of  $M = 50$  h is used, similar to Shaik et al. [8]. The S&F model gives better RMIP values compared to the I&F model.

Among the slot-based/global event-based models that require 10 events, the CBMN model takes a total CPU time of 106.6 s. As discussed in Shaik et al. [8] since the CBMN model gives a suboptimal solution at

<sup>a</sup> Suboptimal solution

$\Delta t = 1$ , we consider the total time for both  $\Delta t = 1$  and  $\Delta t = 2$ . Similarly, for the S&F model as well we need to add the total CPU time while comparing with other models. The unit-specific event-based models require 9 events to find the global optimal solution. Here, the I&F model solves faster compared to the unified S&F model. For problems involving no resource considerations, the

S&F model was found [9] to perform either equally well or better than the I&F model.

*Example 2* Now, consider an example with resource considerations and mixed storage policies. The STN for this example is shown in Fig. 4, and the corresponding data [5,7,8] is given in Table 5 and 6.

<sup>a</sup>  $B^{\min}/B^{\max}$  in kg,  $\alpha$  in h,  $\beta$  in h/kg,  $\gamma$  in kg/min, and  $\delta$  in kg/min per kg of batch

There are two types of reactors available for the process (types I and II), with two reactors of type I (R1 and R2) and one reactor of type II (R3) with four reactions suitable in them. Reactions T1 and T2 require a type I reactor, whereas reactions T3 and T4 require a type II reactor. Additionally, reactions T1 and T3 are endothermic, where the required heat is provided by steam (HS) available in limited amounts. Reactions T2 and T4 are exothermic, and the required cooling water (CW) is also available in limited amounts. Each reactor allows variable batch sizes, where the minimum batch size is half the capacity of the reactor. The processing times and the utility requirements include a fixed time and a variable term that is proportional to the batch size. The processing times are set so that the minimum batch size is processed in 60% of the time needed for the maximum batch size. For the raw materials and final products, unlimited storage is available, while for the intermediates, finite storage is available. Two different cases of this example studied in the literature [5,7,8] are considered that differ in the resource availability. In the first case (example 2a), we assume that the availability of both HS and CW is 40 kg/min, and in the second case (example 2b), it is 30 kg/min.

Also, two different objective functions, maximization of profit and minimization of makespan, are considered. A comparative study of different continuous-time models for this example was already provided in Janak et al. [5,6] (JLF) and Shaik et al. [8], where additional bounding constraints were added to improve the computational performance of the JLF model. In this study, in order to investigate the effect of using the three-index binary and continuous variables, we compare the performance of the unified S&F model with the JLF model without the addition of any additional bounding constraints.

**Maximization of Profit.** For the objective of maximization of profit and a time horizon of 8 h, the optimal solution is \$5904.0 in the first case (example 2a) and \$5227.778 in the second case (example 2b). The computational results in terms of the model statistics and the CPU times are reported in Table 7 for the models of JLF and S&F.

**Minimization of Makespan** For the objective of minimization of makespan, the optimal solution is 8.5 h in the first case (example 2a) and 9.025 h in the second case (example 2b). The computational results in terms of the model statistics and the CPU times are

Example 2a									
JLF	6	6.31	2838	11927.3	5904.0	48	273	1254	4483
SF( $\Delta n = 1$ )	6	2.03	2140	10713.8	5904.0	42	169	679	2135
Example 2b									
JLF	5	0.31	52	7147.1	5227.8	36	220	984	3198
SF( $\Delta n = 1$ )	5	0.07	49	6240	5227.8	30	136	540	1607

**Short-Term Scheduling, Resource Constrained: Unified Modeling Frameworks, Table 8**  
**Model statistics and computational results for example 2 under minimization of makespan**

Model	Events	CPU Time (s)	Nodes	RMILP (h)	MILP (h)	Binary variables	Continuous variables	Constraints	Nonzeros
Example 2a									
JLF	7	10.95	2365	2.44	8.5	60	326	1545	5999
SF( $\Delta n = 1$ )	7	6.03	4612	5.08	8.5	54	202	825	2677
Example 2b									
JLF	6	1.63	166	3.00	9.025	48	273	1263	4519
SF( $\Delta n = 0$ )	6	0.22	103	5.08	9.025	24	151	404	1072

reported in Table 8. For constraints involving big-M terms, a common value of  $M = 10$  is used.

For both the objective functions, the unified S&F model has better RMIP values and faster computational performance compared to the JLF model. Also there is a drastic reduction in the problem statistics especially the number of continuous variables, constraints and nonzeros in all the instances considered.

## Conclusions

When there are resource considerations such as utility requirements, the unit-specific event-based models need to consider the formulations such as Janak et al. [5,6], that allow tasks to take place over multiple events. In this study, it is demonstrated that for short-term scheduling problem of batch plants involving no resource considerations as well, we need to allow tasks to take place over multiple events in order to ensure achieving the global optimal solution. In such cases, the model of Ierapetritou and Floudas [4] yields suboptimal solutions, while the model of Janak et al. [5,6] which was originally developed for solving problems with resource constraints, does not reduce well to the case of no resources in terms of problem statistics. Hence, a unified modeling approach is discussed based on the unit-specific event-based continuous-time formulation of Shaik and Floudas [9] where they consider three-index binary and continuous variables. Their model is applicable to both problems of with and without resources in a unified way. The Shaik and Floudas [9] model is found to perform either equally well or better than the I&F model for problems involving no resource considerations, and is found to perform better than the JLF model for problems with resource constraints.

## Nomenclature

### Indices

$i, i'$	tasks
$j, j'$	units
$n, n', n''$	events
$s$	states
$u$	utilities

### Sets

$I$	tasks
$I_j$	tasks which can be performed in unit $j$
$I_s$	tasks which process state $s$ and either produce or consume
$I_s^P$	tasks which produce state $s$
$I_s^C$	tasks which consume state $s$
$I_u$	tasks which consume utility $u$
$J$	units
$J_i$	units which are suitable for performing task $i$
$N$	event points within the time horizon
$S$	states
$S^R$	states that are raw materials
$S^{IN}$	states that are intermediates
$S^P$	states that are final products
$U$	utilities

### Parameters

$B_i^{\min}$	minimum capacity (batch size) of task $i$
$B_i^{\max}$	maximum capacity (batch size) of task $i$
$ST_s^o$	initial amount of state $s$ available
$ST_s^{\max}$	maximum amount of state $s$
$\alpha_i$	coefficient of constant term of processing time of task $i$

$\beta_i$	coefficient of variable term of processing time of task $i$
$\gamma_{iu}$	coefficient of constant term of consumption of utility $u$ by task $i$
$\delta_{iu}$	coefficient of variable term of consumption of utility $u$ by task $i$
$\rho_{is}$	proportion of state $s$ produced ( $\rho_{is} \geq 0$ ), consumed ( $\rho_{is} \leq 0$ ) by task $i$
$H$	time horizon, $h$
$price_s$	price of state $s$
$D_s$	demand for state $s$ ,
$\Delta n$	limit on the maximum number of events over which a task is allowed to continue
$U_u^{\max}$	maximum availability of utility $u$
$M$	large positive number in big-M constraints

### Binary Variables

$w(i, n, n')$  binary variable for assignment of task  $i$  that starts at event  $n$  and ends at event  $n'$

### Positive Variables

$b(i, n, n')$  amount of material undertaking task  $i$  that starts at event  $n$  and ends at event  $n'$

$ST_0(s)$  initial amount of state  $s \in S^R$  that is required from external resources

$ST(s, n)$  excess amount of state  $s$  that needs to be stored at event  $n$

$T^s(i, n)$  time at which task  $i$  starts at event  $n$

$T^f(i, n)$  time at which task  $i$  ends at event  $n$

$T_{\text{ut}}^s(u, n)$  start time at which there is a change in the consumption of utility  $u$  at event  $n$

$T_f(i, j, n)$  = finishing time of task  $i$  in unit  $j$  at event point  $n$

## Introduction

There has been a significant amount of work devoted to the area of short-term scheduling, which involves the determination of the order in which tasks use units and various resources and the detailed timing of the execution of all tasks so as to achieve the desired performance. The problem data are usually assumed to be deterministic in the studies. However, in real plants, parameters like raw material availability, processing times, and market requirements vary with respect to time and are often subject to unexpected deviations. Therefore, the consideration of uncertainty in the scheduling problem becomes of great importance in order to preserve plant feasibility and viability during operations.

Although there are a large number of papers that address uncertainty in process design, much less attention has been devoted to the issue of uncertainty in process planning and scheduling, mainly owing to the increased complexity of the deterministic problem. Among the work that has appeared in the literature

is that of Shah and Pantelides [18] that addressed the problem of the design of multipurpose batch plants considering different schedules for different sets of production requirements using a scenario-based approach [6] and an approximate solution strategy. Pistikopoulos and Ierapetritou [14] presented a two-stage stochastic programming formulation for the problem of batch plant design and operations under uncertainty. The multiperiod planning and scheduling of multiproduct plants under demand uncertainty was addressed by Petkov and Maranas [13]. The stochastic elements in their proposed model are expressed with equivalent deterministic forms, resulting in a convex mixed-integer nonlinear programming (MINLP) problem. Schmidt and Grossmann [16] considered the optimal scheduling of new product testing tasks and reformulated the initial nonlinear, nonconvex disjunctive model as a mixed-integer linear programming (MILP) problem using different sets of simplifying assumptions that give rise to different models. The uncertainties in planning and scheduling problems are generally described through probabilistic models. During the last decade, fuzzy set theory has been applied to scheduling optimization using heuristic search techniques [8,10]. Recently, Balasubramanian and Grossmann [2] developed MILP models for flowshop scheduling and new product development processing scheduling, based on a fuzzy representation of uncertainty. Daniels and Carrillo [4] addressed the problem of  $\beta$ -robust scheduling in single-stage production facilities with uncertain processing times. Vin and Ierapetritou [20] proposed a multiperiod programming model to improve the schedule performance of batch plants under demand uncertainty. Acevedo and Pistikopoulos [1] addressed linear process engineering problems under uncertainty using a branch and bound algorithm, based on solution of multiparametric linear programs at each node of the tree, and the evaluation of the uncertain parameter space for which a node must be considered.

However, most of the existing approaches can handle only a certain type of uncertain parameters, mostly uncertainty in product demands, and more importantly, the additional complexity makes them infeasible for realistic applications. In this work, a novel framework is proposed for uncertainty analysis of scheduling problems based on the ideas of sensitivity analysis of the

corresponding MILP problem which is addressed using a branch and bound solution method.

## Methods

### Deterministic Scheduling Formulation

In this work, the mathematical model used for batch plant scheduling follows the main idea of the continuous time formulation proposed by Ierapetritou and Floudas [9]. The model involves the following constraints:

$$\text{Minimize } H \text{ or maximize } \sum_s \sum_n \text{price}(s)d(s, n), \quad (1)$$

$$\text{subject to } \sum_{i \in I_j} wv(i, j, n) \leq 1, \quad (2)$$

$$\begin{aligned} st(s, n) = & st(s, n - 1) - d(s, n), \\ & + \sum_{i \in I_j} \rho^p(s, i) \sum_{j \in I_i} b(i, j, n - 1) \\ & + \sum_{i \in I_j} \rho^c(s, i) \sum_{j \in I_i} b(i, j, n), \end{aligned} \quad (3)$$

$$st(s, n) \leq stmax(s), \quad (4)$$

$$\begin{aligned} Vmin(i, j)wv(i, j, n) \\ \leq b(i, j, n) \leq Vmax(i, j)wv(i, j, n), \end{aligned} \quad (5)$$

$$\sum_n d(s, n) \geq r(s), \quad (6)$$

$$\begin{aligned} Tf(i, j, n) = & Ts(i, j, n) + \alpha(i, j)wv(i, j, n) \\ & + \beta(i, j)b(i, j, n), \end{aligned} \quad (7)$$

$$Ts(i, j, n + 1) \geq Tf(i, j, n) - U(1 - wv(i, j, n)), \quad (8)$$

$$Ts(i, j, n) \geq Tf(i', j, n) - U(1 - wv(i', j, n)), \quad (9)$$

$$Ts(i, j, n) \geq Tf(i', j', n) - U(1 - wv(i', j', n)), \quad (10)$$

$$Ts(i, j, n + 1) \geq Ts(i, j, n), \quad (11)$$

$$Tf(i, j, n + 1) \geq Tf(i, j, n), \quad (12)$$

$$Tf(i, j, n) \leq H, \quad (13)$$

$$Ts(i, j, n) \leq H, \quad (14)$$

where  $U$  denotes an upper bound of the makespan, for the cases where the objective is the minimization of the

makespan. For the cases where maximization of profit is considered,  $U = H$  in constraints (8)–(10). In general, the objective function is to minimize the makespan as shown in (1) or to maximize the total profit. Allocation constraint (2) states that only one of the tasks can be performed in each unit at an event point  $n$ . Constraint (3) represents the material balance for each material at each event point  $n$  being equal to that at event point  $n - 1$ , adjusted by any amounts produced and consumed between event points  $n - 1$  and  $n$ , and delivered to the market at event point  $n$ . The storage and capacity limitations of the production units are expressed by constraints (4) and (5). Constraint (6) is written to satisfy the demands of the final products. Constraints (7)–(14) represent time limitations due to task duration and sequence requirements in the same or different production units.

Although there are a large number of papers that deal with uncertainty issues concerning process design and production planning, as reported in “**Introduction**,” the issue of uncertainty is not well studied for scheduling problems, mainly owing to the high complexity of the deterministic case.

### MILP Sensitivity Analysis

The formulation presented in “**Deterministic Scheduling Formulation**” corresponds to the MILP problem where the binary variables ( $wv(i, j, n)$ ) denote the assignment of tasks  $i$  to units  $j$  at event point  $n$ , respectively, throughout the time horizon. Therefore, the effects of operation parameters on the plant performance can be investigated through the sensitivity analysis of the MILP model of the deterministic scheduling problem.

Although sensitivity analysis theory is well developed in linear programming, efforts are still being made in order to handle the integer programming case, mainly owing to lack of optimality criteria for the integer optimization problems. Schrage and Wolsey [17] examined the effect of a small perturbation on the right-hand side or objective function coefficients in an integer program by collecting dual information at each node of the branch and bound tree while solving the original integer program and using a recursive scheme to obtain an upper bound on the objective function. Their results were extended to nonlinear integer programming

problems by Skorin-Kapov and Granot [19]. Pertsinidis et al. [12] developed a sensitivity analysis algorithm for parametric MILP programs, which also provides the results of the MILP master problem for the MINLP case, while an algorithm that provides a sequence of improving parametric lower and upper bounds is employed for parametric nonlinear integer programming subproblems. An algebraic geometry algorithm for solving integer programming problems was presented by Bertsimas et al. [3] Their method provides a natural generalization of the Farkas lemma for integer programming and leads to a method of performing sensitivity analysis.

A method of sensitivity analysis for MILP was presented by Dawande and Hooker [5], based on the idea of inference duality. It reveals that any perturbation that satisfies a certain system of linear inequalities will reduce the optimal value no more than a prespecified amount. The inference-based sensitivity analysis consists of two parts: dual analysis that determines how much the problem can be perturbed while keeping the objective function value in a certain range, while primal analysis gives an upper bound on how much the objective function value will increase if the problem is perturbed by a certain amount. The dual solution is obtained by using inference methods to generate constraints at every node that is violated by the branching cuts. The dual solution can be viewed as a proof of optimality and can be utilized to determine under what parameter perturbations the dual solution still provides a valid proof. More specifically the main results of the inference-based sensitivity analysis are summarized below.

For the general mixed-integer problem

$$\begin{aligned} & \text{Minimize } z = cx \\ & \text{subject to } Ax \geq a, 0 \leq x \leq h, \\ & \quad x_j \text{ integer, } j = 1, \dots, k. \end{aligned} \quad (15)$$

Assuming a perturbation of all problem parameters such that

$$\begin{aligned} & \text{Minimize } z = (c + \Delta c)x \\ & \text{subject to } (A + \Delta A)x \geq a + \Delta a, 0 \leq x \leq h, \\ & \quad x_j \text{ integer, } j = 1, \dots, k. \end{aligned} \quad (16)$$

If there exist  $s_1^p, \dots, s_n^p$  that satisfy the following set of inequalities, the constraint  $z \geq z^* - \Delta z$  remains

valid: for the perturbations  $\Delta A$  and  $\Delta a$  in the parameters involved in the left-hand side and the right-hand side of the constraints

$$\begin{aligned} \lambda_i^p \sum_{j=1}^n A_{ij} u_j^p + \sum_{j=1}^n s_j^p (\bar{u}_j^p - u_j^p) - \lambda_i^p \Delta a_i &\leq r_p, \\ s_j^p &\geq \lambda_i^p \Delta A_{ij}, \quad s_j^p \geq -q_j^p, \quad j = 1, \dots, n, \quad (17) \\ r_p &= - \sum_{j=1}^n q_j^p \bar{u}_j^p + \lambda^p a - z_p + \Delta z_p; \end{aligned}$$

for a perturbation  $\Delta c$  of the coefficients of the objective function

$$\begin{aligned} \sum_{j=1}^n \Delta c_j u_j^p - s_j^p (\bar{u}_j^p - u_j^p) &\geq -r_p, \\ s_j^p &\geq -\Delta c_j, \quad s_j^p \geq -q_j^p, \quad j = 1, \dots, \end{aligned} \quad (18)$$

where  $q_j^p = \lambda_i^p A_{ij} - \lambda_0^p c_j$ ;  $p$  corresponds to the leaf node where the dual variable of the objective function ( $\lambda_0^p$ ) equals 1, whereas  $u_j^p$  and  $\bar{u}_j^p$  denote the lower and the upper bound of  $x_j$  at node  $p$ , respectively;  $z_p$  is the objective value at node  $p$ ; and  $\Delta z_p = z^* - z_p$ . Leaf nodes are the nodes at which the branch and bound procedure terminates based on standard fathoming criteria [7]. Thus, with use of constraints (17) and (18) in the scheduling problem, the range of parameters where the objective remains within certain limits can be identified and used to evaluate alternative schedules at the branch and bound tree. Moreover, the importance of different constraints and parameters is obtained and can be utilized to improve future plant operability.

### Robustness Metric

In order to improve the schedule flexibility prior to its execution, it is important to measure the performance of a deterministic schedule under changing conditions due to uncertainty.

Standard deviation (SD) is one of the most commonly used metrics to evaluate the robustness of a schedule. To evaluate the SD, the deterministic model with a fixed sequence of tasks ( $wv(i, j, n)$ ) is solved for different realizations of uncertain parameters that define the set of scenarios  $k$  which results in different makespans  $H_k$ . The SD is then defined as

$$SD_{\text{avg}} = \sqrt{\sum_k \frac{(H_k - H_{\text{avg}})^2}{(p_{\text{tot}} - 1)}}, \quad H_{\text{avg}} = \frac{\sum_k H_k}{p_{\text{tot}}}, \quad (19)$$

where  $H_{\text{avg}}$  is the average makespan over all the scenarios, and  $(p_{\text{tot}})$  denotes the total number of scenarios. A detailed discussion of different robustness metrics can be found in Samsatli et al. [15]. Vin and Ierapetritou [20] proposed a robustness metric taking into consideration the infeasible scenarios. In the case of infeasibility, the problem is solved to meet the maximum demand possible by incorporating slack variables in the demand constraints. Then the inventories of all raw materials and intermediates at the end of the schedule are used as the initial conditions in a new problem with the same schedule to satisfy the unmet demand. The makespan under infeasibility ( $H_{\text{corr}}$ ) is determined as the sum of those two makespans. Their proposed robustness metric is defined as

$$SD_{\text{corr}} = \sqrt{\sum_k \frac{(H_{\text{act}} - H_{\text{avg}})^2}{(p_{\text{tot}} - 1)}}, \quad (20)$$

where  $H_{\text{act}} = H_k$ , if scenario  $k$  is feasible and  $H_{\text{act}} = H_{\text{corr}}$ , if scenario  $k$  is infeasible.

### Proposed Uncertainty Analysis Approach

The basic idea of the proposed approach is to utilize the information obtained from the sensitivity analysis of the deterministic solution to determine (1) the importance of different parameters and constraints and (2) the range of parameters where the optimal solution remains unchanged. The main steps of the proposed approach are shown in Fig. 1. More specifically, there are two parts in the proposed analysis. In the first part, important information about the effect of different parameters is extracted following the sensitivity analysis step, whereas in the second part alternative schedules are determined and evaluated for different uncertainty ranges.

First, the deterministic scheduling is solved at the nominal values using a branch and bound solution approach, and the dual multipliers  $\lambda^p$  are collected at each leaf node  $p$ . Then the inference-based sensitivity analysis as described in the previous section is performed for all the important scheduling parameters, including demands, prices, processing times and capacities. Note that only the dual information of the nodes that correspond to nonzero dual variables is required. Using

the results of this analysis, one can answer a number of very interesting questions regarding the robustness of the plant to parameter changes.

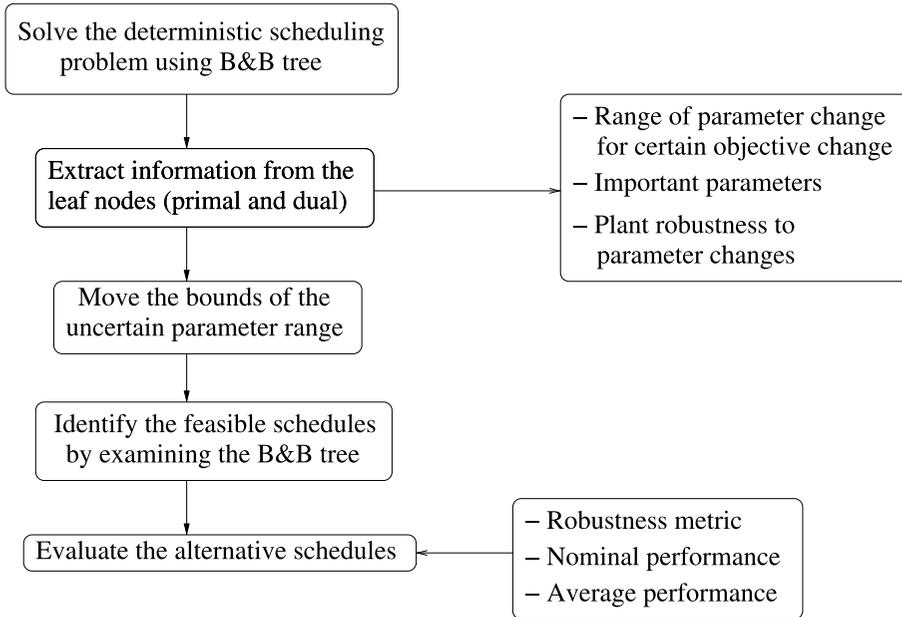

In particular:

- How does the capacity of the units affect the production objective?
- What is the range of product demand that can be covered and how much would the profit be affected by such changes?
- What is the effect of a price change on the objective value?
- What is the significance of the constraints involved in the model? Are there any redundant sets of constraints?

The first question can be answered by imposing the same perturbation on capacity constraint (5) for the different units involved in the production of specific products and determining the change in the objective function ( $\Delta z$ ). The unit with the largest effect on the objective value is also the most critical one for the production of this product and thus a change in its capacity will result in the largest production change. Similarly, the rest of the questions can be answered by analyzing perturbations at the appropriate constraints together with the effects on the objective function. The results for two examples are given in the next section.

In the second part of the analysis, the sensitivity information is used to define the range of uncertain parameters where the schedule is optimal and to identify alternative schedules at different uncertainty ranges. The set of constraints (17) and (18) are used to determine the range of uncertain parameters for certain changes in the objective function. The branch and bound procedure is then continued on the nodes with the objective value within the predicted limits to identify new optimal solutions. The alternative schedules are evaluated using the robustness metric ( $SD_{\text{corr}}$ ) as defined in “Robustness Metric,” the average and the nominal schedule performance in terms of the objective function.

Since the entire analysis is based on a single branch and bound tree among a large number of possible branch and bound trees that can be used to solve the MILP, it provides conservative sensitivity ranges. Theoretically, the exact sensitivity ranges can be obtained by investigating an exponential number of branch and bound trees. However, using the above analysis, one can

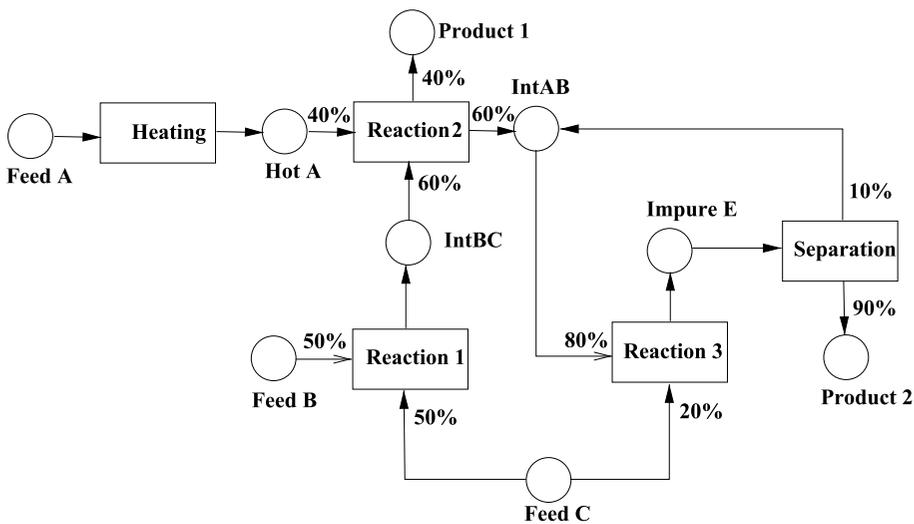

Short-Term Scheduling Under Uncertainty: Sensitivity Analysis, Figure 1  
Flow chart of proposed approach. *B&B* branch and bound

extract useful information regarding the approximate range of the parameter change for a certain objective change and the robustness of the plant to parameter changes, and one can also determine the importance of different parameters as illustrated in the next section.

**Case**

The case study [9] considers two different products produced through five processing stages: heating, reactions 1, 2 and 3, and separation of product 2 from impure E as

Short-Term Scheduling Under Uncertainty: Sensitivity Analysis, Figure 2  
State-task network representation for the case

illustrated in the state-task network (STN) representation in Fig. 2. For the first part of the analysis, the problem is solved with the objective of maximizing the profit within the time horizon of 12 h. After the sensitivity analysis has been performed, the following information is obtained. It is found that the most critical task of the production line is reaction 2. By decreasing the processing capacity of reaction 2 in reactor 1 or reactor 2 by 11 units, the profit will be reduced by 5%, whereas very small change or no change at all is observed in the objective function with a processing capacity change for reaction 1 or reaction 3 in both reactors. The objective value is also not sensitive to the change of other parameters, for example, the processing capacity of separation in the separator can drop by up to 120 units without the profit decreasing. Another important modeling issue that can be addressed is the question of constraint redundancy. Here the importance of storage constraints is investigated and it is found that these constraints are redundant since they are not active in any of the solution branch and bound nodes. More interestingly, the duration constraints are also found to be redundant, which means that the maximum processing capacities are already reached with the current processing times, so the profit cannot be improved even with zero processing times assuming a fixed number of event points. For the second part of the analysis, the demand of product 2 is considered to be the uncertain parameter varying within the range [20, 80] and the objective function is modified to minimize the makespan. A branch and bound tree is constructed at nominal point  $r'(p_2') = 50$  and the dual information is stored at each node.

Applying the inference duality sensitivity analysis, one obtains the following expression regarding the range of demand change following a specific objective change ( $\Delta H$ ):  $-0.0297\Delta d \leq \Delta H$ , which means that if the demand is increased by  $\Delta d$ , the new makespan becomes at most  $H_{\text{nom}} + 0.0297\Delta d$ . When  $r'(p_2')$  is in-

creased from 50 to 80, schedule 1 becomes infeasible. Then, we solve the linear programming problem at each leaf node with the demand of 80 and check the leaf nodes with the objective value below 7.89 that is obtained using this inequality in the branch and bound tree. The new optimal solution is found to be schedule 2 and schedule 3 is one feasible solution, as illustrated in Table 2. The schedules are then evaluated with respect to the mean and nominal makespan and the SD within the demand range [20, 80] and the val-

### Short-Term Scheduling Under Uncertainty: Sensitivity Analysis, Table 2

#### Values of binary variables of optimal schedules

(Task, unit)	$n_0$	$n_1$	$n_2$	$n_3$
(Heating, heater)	1	0	0	0
(Reaction 1, reactor 1)	0	0	0	0
(Reaction 1, reactor 2)	1	1	0	0
(Reaction 2, reactor 1)	0	1	0	1
(Reaction 2, reactor 2)	0	0	0	0
(Reaction 3, reactor 1)	0	0	1	0
(Reaction 3, reactor 2)	0	0	1	0
(Separation, still)	0	0	0	1
(schedule 1)				

(Task, unit)	$n_0$	$n_1$	$n_2$	$n_3$
(Heating, heater)	1	1	0	0
(Reaction 1, reactor 1)	1	0	0	0
(Reaction 1, reactor 2)	1	0	0	0
(Reaction 2, reactor 1)	0	1	0	1
(Reaction 2, reactor 2)	0	1	0	0
(Reaction 3, reactor 1)	0	0	1	0
(Reaction 3, reactor 2)	0	0	1	0
(Separation, still)	0	0	0	1
(schedule 2)				

(Task, unit)	$n_0$	$n_1$	$n_2$	$n_3$
(Heating, heater)	1	0	0	0
(Reaction 1, reactor 1)	1	0	0	0
(Reaction 1, reactor 2)	1	0	0	0
(Reaction 2, reactor 1)	0	1	0	0
(Reaction 2, reactor 2)	0	1	0	0
(Reaction 3, reactor 1)	0	0	1	0
(Reaction 3, reactor 2)	0	0	1	0
(Separation, still)	0	0	0	1
(schedule 3)				

### Short-Term Scheduling Under Uncertainty: Sensitivity Analysis, Table 1

#### Comparison of alternative schedules for the case

	Schedule 1	Schedule 2	Schedule 3
$H_{\text{nom}}(h)$	7.00	7.14	7.40
$H_{\text{avg}}(h)$	8.15	7.24	7.40
$SD_{\text{corr}}$	2.63	0.29	0.27

ues are shown in Table 1. Compared with schedule 2, schedule 3 has a larger mean makespan but a lower SD, which means higher robustness; therefore, depending on the decision-maker's attitude towards risk and the expected growth in demand, one can choose schedule 3 over schedule 2, whereas schedule 1 remains a valid alternative if the demand is expected to remain constant.

Note that the proposed uncertainty analysis does not substantially increase the problem complexity. That is due to the fact that the required information is already obtained from the solution of the deterministic problem.

## Conclusions

An integrated framework was developed in the work reported here to handle uncertainty in short-term scheduling based on the idea of inference-based sensitivity analysis for the MILP problem and the utilization of a branch and bound solution method. The proposed method leads to the determination of the importance of different parameters and constraints on the objective function and the generation and evaluation of a set of alternative schedules given the variability of the uncertain parameters. The main advantage of the proposed method is that no substantial complexity is added compared with the solution of the deterministic case since the only additional information required is the dual information at the leaf nodes of the branch and bound tree. One illustrative example was presented to highlight the information extracted by the proposed approach and the complexity involved.

Higher-order statistics; nonGaussian signal processing; Nonlinear signal processing

Signal processing methodologies based on *higher-order statistics* or spectra (HOS) of order greater than two have become important signal processing tools in a variety of application areas: digital communications, system identification and spectral analysis, source separation and array processing, time delay estimation, image and speech processing and biomedical applications among others, [3,4,9]. The increased popularity of HOS in signal processing applications can be attributed to many attractive properties they possess: preservation of *nonminimum phase* information, ability to detect/identify nonlinear behavior, robustness to Gaussian and other forms of noise, etc. It is well known that when a signal is Gaussian there is no benefit in considering the HOS of this signal since all the statistical information is conveyed by its first and second order statistics (SOS). However, for nonGaussian signals the SOS do not provide a complete description and a lot of important information can be extracted from their HOS, [8,9,11].

The  $n$ -order moment and cumulant sequences of an  $n$ -order stationary random process  $\{y(i)\}$ ,  $i = 1, 2, \dots$  are defined as, [9]:

$$\begin{aligned} M_{y,n}(\lambda_1, \dots, \lambda_{n-1}) &= E\{y_1 \cdots y_n\}, \\ C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) &= \sum (-1)^{p-1} (p-1)! E \left\{ \prod_{i \in I_1} y_i \right\} \cdots E \left\{ \prod_{i \in I_p} y_i \right\}, \end{aligned} \quad (1)$$

where,  $y_1 = y(i)$ ,  $y_2 = y(i + \lambda_1)$ ,  $\dots$ ,  $y_n = y(i + \lambda_{n-1})$ , the summation covers all partitions  $(I_1, \dots, I_p)$ ,  $p = 1, \dots, n$ , of the set  $\{1, \dots, n\}$ ,  $\lambda_k = 0, \pm 1, \pm 2, \dots$ , and  $E\{\cdot\}$  denotes

statistical expectation. The second, third and fourth order cumulants of zero-mean processes are utilized often in practice and take the form

$$C_{y,2}(\lambda) = M_{y,2}(\lambda), \quad (2)$$

$$C_{y,3}(\lambda_1, \lambda_2) = M_{y,3}(\lambda_1, \lambda_2), \quad (3)$$

$$\begin{aligned} C_{y,4}(\lambda_1, \lambda_2, \lambda_3) &= M_{y,4}(\lambda_1, \lambda_2, \lambda_3) \\ &\quad - M_{y,2}(\lambda_1)M_{y,2}(\lambda_2 - \lambda_3) \\ &\quad - M_{y,2}(\lambda_2)M_{y,2}(\lambda_3 - \lambda_1) \\ &\quad - M_{y,2}(\lambda_3)M_{y,2}(\lambda_1 - \lambda_2). \end{aligned} \quad (4)$$

The  $\gamma_{y,2} = C_{y,2}(0)$  is the *variance*, the  $\gamma_{y,3} = C_{y,3}(0, 0)$  is the *skewness*, and the  $\gamma_{y,4} = C_{y,4}(0, 0, 0)$  is the *kurtosis* of  $\{y(i)\}$ . For a complex process the definitions in (1) may include conjugation in one or more terms in the products.

The  $n$ -order *polyspectrum* (*higher-order spectrum*) of  $\{y(i)\}$  is defined as the  $(n-1)$ -dimensional discrete Fourier transform of  $C_{y,n}(\lambda_1, \dots, \lambda_{n-1})$ , that is

$$\begin{aligned} S_{y,n}(e^{j\omega_1}, \dots, e^{j\omega_{n-1}}) &= \sum_{\lambda_1, \dots, \lambda_{n-1} = -\infty}^{\infty} C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) \prod_{l=1}^{n-1} e^{-j\omega_l \lambda_l}, \end{aligned} \quad (5)$$

$|\omega_l| \leq \pi$ ,  $l = 1, \dots, n-1$ ,  $|\sum_{l=1}^{n-1} \omega_l| \leq \pi$ . For  $n = 2, 3, 4$  we obtain the power spectrum, the bispectrum and the trispectrum, respectively.

Cumulants are utilized as measures of ‘Gaussianity’ and statistical independence because they satisfy the following two important properties:

1) Given that the set of random variables  $\{y(i), y(i + \lambda_1), \dots, y(i + \lambda_{n-1})\}$  is divided into any number of mutually independent subsets, then,  $C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) = 0$ . Therefore, if a random process  $\{y(i)\}$  is independent identically distributed, then

$$\begin{aligned} C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) &= \gamma_{y,n} \delta(\lambda_1) \cdots \delta(\lambda_{n-1}), \end{aligned}$$

where  $\delta(\lambda) = 0$ ,  $\lambda \neq 0$ , is the delta function. Also, given that  $\{x(i)\}$ ,  $\{z(i)\}$ ,  $i = 1, 2, \dots$  are two independent processes and  $y(i) = x(i) + z(i)$ , then

$$\begin{aligned} C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) &= C_{x,n}(\lambda_1, \dots, \lambda_{n-1}) + C_{z,n}(\lambda_1, \dots, \lambda_{n-1}). \end{aligned} \quad (6)$$

2) If the set of random variables  $\{y(i), y(i + \lambda_1), \dots, y(i + \lambda_{n-1})\}$  are jointly Gaussian, then  $C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) = 0$ , for  $n \geq 3$ .

These properties do not hold for moments. For this reason cumulants are often more attractive than moments in applications of HOS, [7,9].

Often in practice we want to calculate the higher-order cumulants of the process

$$y(k) = s(k) + w(k),$$

where the  $s(k)$  may be either deterministic signal or a random process and the  $w(k)$  is a zero-mean stationary Gaussian noise process independent from  $s(k)$ . In practice, the estimation of HOS is based on time averaging. To overcome problems of nonstationarity of  $y(k)$  in the case where  $s(k)$  is a deterministic energy signal, it is necessary to assume multiple realizations  $y_j(k), j = 1, \dots, J, k = 1, \dots, K$ , of sufficient length and estimate the  $n$ -order moment as follows:

$$\begin{aligned} \widehat{M}_{y,n}(\lambda_1, \dots, \lambda_{n-1}) \\ = G \sum_{j=1}^J \sum_{k=1}^K y_j(k) y_j(k + \lambda_1) \cdots y_j(k + \lambda_{n-1}) \end{aligned} \quad (7)$$

for  $\lambda_l = 0, \pm 1, \dots, \pm L$ , and  $G = 1/J$ , [9,10]. If  $s(k)$  is random and locally stationary or a deterministic power signal, then (7) applies by segmenting the  $y(k)$  into  $J$  possibly overlapping segments (considered as multiple realizations) with  $G = 1/JK$ . The sample estimate  $\widehat{C}_{y,n}(\lambda_1, \dots, \lambda_{n-1})$  is obtained by substituting moment estimates in the definitions of cumulants.

To gain insight into the utilization of HOS let us consider the following examples.

*Example 1* Let  $x(k) = \sum_n C_n e^{(j\omega_n k + \phi_n)}$  where,  $\phi_n$  are independent identically distributed random variables uniformly distributed in the interval  $[-\pi, \pi]$ . This is a harmonic stationary process. Let  $y(k)$  and  $z(k)$  be the responses of a linear and a nonlinear system, respectively, both driven by  $x(k)$ . Then,

$$\begin{aligned} y(k) &= \sum_n A_n e^{(j\omega_n k + \theta_n)}, \\ z(k) &= \sum_n B_n e^{(j\omega_n k + \psi_n)} \\ &+ \sum_{m,l} B_m B_l e^{[j(\omega_m + \omega_l)k + \psi_m + \psi_l]} + \sum_{m,l,i} \dots \end{aligned}$$

It can be shown that [3,9]:

$$C_{y,3}(\lambda_1, \lambda_2) = 0, \quad C_{z,3}(\lambda_1, \lambda_2) \neq 0.$$

In general, the polyspectra of a system output can be utilized in various ways in detecting as well as characterizing various types of nonlinearities in the system, e. g., detecting quadratic and cubic phase coupling in harmonic processes and identifying nonlinear *Volterra filters* driven by Gaussian processes among others, [9].

*Example 2* Consider now a linear filtering problem where the linear time invariant (LTI) system with impulse response  $\{f(k)\}$  is driven by a stationary random sequence  $\{x(k)\}_{k=1,2,\dots}$ . Assuming that the system is stable, the following expression can be written for the  $n$ -order cumulant of the system output  $\{y(k)\}$ , [2,7]:

$$\begin{aligned} C_{y,n}(\lambda_1, \dots, \lambda_{n-1}) &= C_{x,n}(\lambda_1, \dots, \lambda_{n-1}) \\ * \left[ \sum_{k=-\infty}^{\infty} f(k) f(k + \lambda_1) \cdots f(k + \lambda_{n-1}) \right], \end{aligned} \quad (8)$$

where  $*$  denotes  $(n - 1)$ -dimensional linear convolution. In the special case where  $\{x(k)\}$  is independent identically distributed, zero-mean, non-Gaussian,  $\{f(k), k = 0, \dots, q\}$ , is finite length and  $\{w(k)\}$  is additive stationary zero-mean Gaussian noise statistically independent from  $\{x(k)\}$ , the following relations hold for the diagonal cumulants ( $\lambda_i = \lambda$  for all  $i$ ):

$$\begin{aligned} y(k) &= \sum_{n=0}^q f(n) \cdot x(k - n) + w(k), \\ C_{y,2}(\lambda) &= \gamma_{x,2} \cdot \sum_{k=0}^q f(k) f(k + \lambda) + C_{w,2}(\lambda), \\ C_{y,n}(\lambda, \dots, \lambda) &= \gamma_{x,n} \cdot \sum_{k=0}^q f(k) f^{n-1}(k + \lambda), \\ \lambda &= -q, \dots, 0, \dots, q, \quad n \geq 3. \end{aligned}$$

The  $C_{y,2}(\lambda)$  is corrupted by noise. On the other hand, the  $C_{y,n}(\lambda, \dots, \lambda), n \geq 3$ , are noise free and proportional to the corresponding order correlation of the channel coefficients. Note that the second order cumulants (power spectrum) above do not preserve the true phase character of  $f(k)$  unless the system is *minimum phase* (that is, all  $q$  zeros of its  $Z$ -transform are inside the unit circle). Thus, from  $C_{y,2}(\lambda)$  alone only an equivalent

minimum phase system (within all-pass phase ambiguities) can be recovered. On the other hand, cumulants of order greater than two (polyspectra) preserve the true phase character of the system and thus are able to identify the system correctly up to a sign and possibly a constant linear phase term. This property, is the reason behind the wide utilization of HOS for blind system identification and deconvolution in seismic signal processing, dispersive communications channels, speech processing and other applications, [4,8].

To have a glance of optimization procedures that involve HOS, consider the recovery of the coefficients  $f(k)$ , in the linear filtering problem. The nonlinear-least squares approach proposes the minimization of the nonlinear function

$$\sum_{\lambda=-q}^q \left[ \widehat{C}_{y,n}(\lambda, \dots, \lambda) - \gamma_{x,n} \sum_{k=0}^q f(k) f^{(n-1)}(k + \lambda) \right]^2 \quad (9)$$

with respect to the unknown parameters  $\{\gamma_{x,n}, f(k): k = 0, \dots, q\}$ , [2,6].  $\widehat{C}_{y,n}(\lambda, \dots, \lambda)$  is the estimated diagonal cumulant from data samples. In practice the unknown order  $q$  must be estimated by means of model order selection criteria.

Minimization of (9) is a difficult problem which requires tedious searching programming techniques and proper initialization to avoid local equilibria. Thus, it is customary to seek solutions based on linear relations, [2,9,12]. Usually, a linear relation between the unknown parameters of the system model and the higher-order cumulants of the observed process is established. The solution is obtained by forming and solving an overdetermined linear system of equations. A variety of such algorithms have been proposed in the literature based on various system models.

Alternatively, we may consider the following deconvolution scenario, [1,3,4]:

$$\widetilde{x}(n) = u(n) * y(n) = [u(n) * f(n)] * x(n),$$

where  $u(n)$  is an appropriate filter so that  $\widetilde{x}(n) = A \cdot x(n - D)$  where  $D$  is a constant delay and  $A$  a constant phase term. Since the effect of linear filtering (i. e., convolution with  $f(n)$ ) increases the Gaussianity of a random process (central limit theorem), then, inverse filtering (i. e., deconvolution with  $u(n)$ ) must decrease the

Gaussianity of the process. Based on this idea, deconvolution can rely on maximizing or minimizing an appropriate measure of Gaussianity such as the kurtosis,  $\gamma_{\widetilde{x},4}$ , of  $\widetilde{x}(n)$  with respect to the inverse filter coefficients. Actually, a variety of algorithms have been derived for deconvolution based on the constrained maximization of the objective function (for  $m \neq r, m, r \geq 2$ ), [1]:

$$\frac{|\gamma_{\widetilde{x},m}|^r}{|\gamma_{\widetilde{x},r}|^m}.$$

To date the utilization of HOS in applications has been hampered by: i) the high computational complexity and the requirement for long data records in obtaining reliable estimates of HOS, and ii) the hard assumptions made regarding the stationarity and ergodicity of the available data. The emergence of faster digital hardware and the introduction of efficient HOS estimators will facilitate the wider utilization of HOS, [5,9]. A detailed coverage of signal processing algorithms and applications with HOS can be found in [9]. A recent extensive biography of HOS containing over 1700 entries has been compiled in [11].

## Simple Recourse Problem

SHANE DYE

University Canterbury, Christchurch, New Zealand

MSC2000: 90C06, 90C08, 90C15

### Article Outline

[Keywords](#)

[See also](#)

[References](#)

### Keywords

Stochastic programming; Recourse; Newsboy problem

A simple recourse problem is a stochastic linear program with recourse (cf. [► Stochastic linear programs with recourse and arbitrary multivariate distributions](#)) for which the recourse action simply involves calculating linear penalties based on the surplus and shortfalls of scarce resources. In general all second stage parameters may be random.

The general simple recourse problem may be formulated as follows:

$$\min \{cx + E_{\xi}[Q(x, \xi)]: Ax = b, x \geq 0\}, \quad (1)$$

where

$$Q(x, \xi) = \begin{cases} \inf & q^+(\xi)y^+ + q^-(\xi)y^- \\ \text{s.t.} & y^+ - y^- = h(\xi) - T(\xi)x, \\ & y^+, y^- \geq 0. \end{cases} \quad (2)$$

Here  $A \in \mathbf{R}^{m \times n}$ ,  $b \in \mathbf{R}^m$ , and  $c \in \mathbf{R}^n$  are given matrices. The uncertain parameters are  $h: \mathbf{R}^r \rightarrow \mathbf{R}^k$ ,  $q^+: \mathbf{R}^r \rightarrow \mathbf{R}^k$ ,  $q^-: \mathbf{R}^r \rightarrow \mathbf{R}^k$ , and  $T: \mathbf{R}^r \rightarrow \mathbf{R}^{k \times n}$  where  $\xi$  is a random

variable defined on the probability space  $(\mathcal{E}, F, \mu)$  with  $\mathcal{E} \subset \mathbf{R}^r$  the support of the measure  $\mu$ . In the general case the probability distribution of  $\xi$  is continuous or has a very large number of realizations, which makes directly solving the deterministic equivalent very difficult.

One well-known example of a simple recourse problem is the *newsboy problem*. In this problem a newsboy must decide how many newspapers to order for sale the next day with only probabilistic information about the next day's demand. Unsold newspapers will be sold back to the supplier at a reduced rate and additional demand must be supplied to the customers but at a higher cost to the newsboy.

Three efficient methods have been developed for the case where only the right-hand side parameters are random. These methods are: the *primal method* (see [► Simple recourse problem: Primal method](#)); the *dual method* (see [► Simple recourse problem: Dual method](#)); and a method using the dualplex algorithm [1]. A good reference for the primal and dual methods for simple recourse problems is [2].

## Simple Recourse Problem: Dual Method

SHANE DYE

University Canterbury, Christchurch, New Zealand

MSC2000: 90-08, 90C05, 90C06, 90C08, 90C15

### Article Outline

[Keywords](#)

[See also](#)

[References](#)

## Keywords

Stochastic programming; Recourse

The dual method for solving simple recourse problems (cf. ► [Simple recourse problem](#)), devised by A. Prékopa [1], is based on the dual simplex algorithm. As with the *primal method* (see ► [Simple recourse problem: Primal method](#)), this method only allows for uncertainty in the right-hand side parameters, and a finite, discrete probability distribution, while the stochastic dependence or independence of the random variables is not important.

This simple recourse problem may be formulated as follows:

$$\min \{cx + E_{\xi}[Q(x, \xi)]: Ax = b, x \geq 0\}, \quad (1)$$

where

$$Q(x, \xi) = \begin{cases} \inf & q^+ y^+ + q^- y^- \\ \text{s.t.} & y^+ - y^- = \xi - Tx, \\ & y^+, y^- \geq 0. \end{cases} \quad (2)$$

Here  $A \in \mathbf{R}^{m \times n}$ ,  $b \in \mathbf{R}^m$ ,  $c \in \mathbf{R}^n$ ,  $q^+ \in \mathbf{R}^r$ ,  $q^- \in \mathbf{R}^r$ ,  $q = q^+ - q^- > 0$ , and  $T \in \mathbf{R}^{r \times n}$  are given matrices.  $\xi$  is a random variable defined on the probability space  $(\mathcal{E}, F, \mu)$  with  $\mathcal{E} \subset \mathbf{R}^r$  the support of the measure  $\mu$ .

Using linear programming duality,  $E_{\xi}[Q(x, \xi)]$  may be rewritten as

$$\sum_{i=1}^r \left( q_i^+ (E_{\xi}[\xi_i] - T_i x) + q \int_{-\infty}^{T_i x} F_i(z) dz \right). \quad (3)$$

The objective function of (1) is then a piecewise-linear, convex function with breakpoints derived from the elements of  $\mathcal{E}$ .

Let  $\xi_{i,1}, \dots, \xi_{i,k_i}$  be the possible values of  $\xi_i$  in increasing order, with  $p_{i,1}, \dots, p_{i,k_i}$  the corresponding probabilities. Introduce  $\xi_{i,0} < \xi_{i,1}$  and  $\xi_{i,k_i+1} > \xi_{i,k_i}$  for  $i = 1, \dots, r$  with the property that  $\xi_{i,0} < T_i x < \xi_{i,k_i+1}$  for all  $x$  feasible for (1) and put  $p_{i,0} = p_{i,k_i+1} = 0$ . The stochastic linear program (1) is reformulated as an equivalent (deterministic) linear program. The following notation is used:

$$f_{ij} = -q_i^+ + q(p_{i1}\xi_{i1} + \dots + p_{i,j-1}\xi_{i,j-1}),$$

for  $j = 1, \dots, k_i + 1$ ,  $i = 1, \dots, r$ , representing the function values at the breakpoints.

$$\begin{cases} \min & cx + f\lambda \\ \text{s.t.} & Ax = b, \\ & T_i x - \sum_{j=0}^{k_i+1} \xi_{ij} \lambda_{ij} = 0, \quad i = 1, \dots, r, \\ & \sum_{j=0}^{k_i+1} \lambda_{ij} = 1, \quad i = 1, \dots, r, \\ & x \geq 0, \quad \lambda \geq 0. \end{cases} \quad (4)$$

This linear program may be efficiently solved using the dual simplex method. All dual feasible bases have the following form. For some  $s$ ,  $1 \leq s \leq r$ , there are  $m + s$  basic  $x$  variables,  $r - s$  of the  $i$  in  $\{1, \dots, r\}$  have basic variable pairs of the form  $(\lambda_{i,j_i}, \lambda_{i,j_i+1})$  and the remaining  $s$  of these  $i$  have only one basic  $\lambda_{ij_i}$  variable.

The algorithm corresponds to finding an initial dual feasible basis then using the dual simplex method. Only columns corresponding to variables which might enter the basis need to be calculated at each step. This amounts to all nonbasic  $x$  variables and at most two  $\lambda_{ij}$  for each  $i \in \{1, \dots, r\}$  (the two immediately surrounding the basic  $\lambda_{ij}$  variables for each  $i$ ).

## Keywords

Stochastic programming; Recourse; Working basis

The primal method for solving simple recourse problems (cf. also ▶ [Simple recourse problem](#)), devised by R.J-B. Wets [3], is based on the concept of a *working basis* introduced by G.B. Dantzig [1]. The primal method only allows for uncertainty in the right-hand side parameters, however stochastic dependence or independence of these parameters is not important to the method. A good reference for this algorithm is [2].

This simple recourse problem may be formulated as follows:

$$\min \{cx + E_{\xi}[Q(x, \xi)]: Ax = b, x \geq 0\}, \quad (1)$$

where

$$Q(x, \xi) = \begin{cases} \inf & q^+ y^+ + q^- y^- \\ \text{s.t.} & y^+ - y^- = \xi - Tx, \\ & y^+, y^- \geq 0. \end{cases} \quad (2)$$

Here  $A \in \mathbf{R}^{m \times n}$ ,  $b \in \mathbf{R}^m$ ,  $c \in \mathbf{R}^n$ ,  $q^+ \in \mathbf{R}^r$ ,  $q^- \in \mathbf{R}^r$ ,  $q = q^+ - q^- > 0$ , and  $T \in \mathbf{R}^{r \times n}$  are given matrices.  $\xi$  is a random variable defined on the probability space  $(\mathcal{E}, F, \mu)$  with  $\mathcal{E} \subset \mathbf{R}^r$  the support of the measure  $\mu$ .

The method given here assumes  $\xi$  is a discrete random variable with finitely many realizations (i. e.,  $\mathcal{E}$  is finite). For continuous distributions the method may be efficiently used on successively finer approximating distributions and error bounds calculated for each approximation.

Using linear programming duality,  $E_{\xi}[Q(x, \xi)]$  may be rewritten as

$$\sum_{i=1}^r \left( q_i^+ (E_{\xi}[\xi_i] - T_i x) + q \int_{-\infty}^{T_i x} F_i(z) dz \right). \quad (3)$$

The objective function of (1) is then a piecewise-linear, convex function with breakpoints derived from the elements of  $\mathcal{E}$ .

Let  $\xi_{i,1}, \dots, \xi_{i,k_i}$  be the possible values of  $\xi_i$  in increasing order, with  $p_{i,1}, \dots, p_{i,k_i}$  the corresponding probabilities. Introduce  $\xi_{i,0} < \xi_{i,1}$  and  $\xi_{i,k_i+1} > \xi_{i,k_i}$  for  $i = 1, \dots, r$  with the property that  $\xi_{i,0} < T_i x < \xi_{i,k_i+1}$  for all  $x$  feasible for (1) and put  $p_{i,0} = p_{i,k_i+1} = 0$ . The stochastic linear program (1) is reformulated as an

equivalent (deterministic) linear program. The following notation is used:

$$h_{ij} = \xi_{i,j} - \xi_{i,j-1},$$

for  $j = 1, \dots, k_i + 1, i = 1, \dots, r$ , representing the lengths of the intervals of the piecewise linear function, and

$$g_{ij} = -q_i^+ + q(p_{i0} + \dots + p_{i,j-1}),$$

for  $j = 1, \dots, k_i + 1, i = 1, \dots, r$ , representing the gradients between breakpoints.

$$\left\{ \begin{array}{l} \min \quad cx + gv \\ \text{s.t.} \quad Ax = b, \\ \quad \quad \quad \sum_{j=1}^{k_i+1} v_{ij} = \xi_{i,0} \quad i = 1, \dots, r, \\ \quad \quad \quad v + s = h, \\ \quad \quad \quad x \geq 0, \quad 0 \leq v, s \leq h. \end{array} \right. \quad (4)$$

This linear program may be solved using the simplex method only considering bases with the property that for each  $i = 1, \dots, r$  there is  $\ell_i$  such that  $v_{i1}, \dots, v_{i\ell_i}, s_{i,\ell_i+1}, \dots, s_{i,k_i+1}$  are basic,  $s_{i1}, \dots, s_{i,\ell_i-1}, v_{i,\ell_i+1}, \dots, v_{i,k_i+1}$  are nonbasic, and  $s_{i\ell_i}$  may or may not be basic. To reduce the amount of computation involved only so-called *key variables* need to be recorded as being basic. These are and basic  $x_j$  and basic  $v_{i\ell}$  for which  $s_{i\ell}$  is also basic. There are always  $m+r$  key variables and the *working basis*,  $W$ , is given by the first  $m+r$  rows of the columns corresponding to the key variables in the (full) basis.

The algorithm corresponds to finding an initial working basis, then using the (upper bounded) simplex method with only the working basis inverse stored. For this, all reduced costs may be calculated with little extra effort beyond that required for a linear program with as many variables and only  $m+r$  constraints. The choice of the pivot column is constrained by the requirement of maintaining a basis with the required property. The calculation of the pivot row and the pivot step are essentially the same as for the upper bounded simplex method.

Carathéodory theorem; Column generation; Convex combinations; Convex hull; Dantzig–Wolfe decomposition; Dimension; Extreme point; first order Taylor series expansion; Frank–Wolfe algorithm; Globally optimal; Inner linearization; Restriction; Linear program; Master problem; Node-arc incidence matrix; Nonlinear dynamic network flow problem; Nonlinear multicommodity flow problems; Nonlinear programming; Nonlinear program; Nonlinear single commodity network flow problem; Polyhedron; Polyhedral set; Positive definite matrix; Pseudoconvexity; P-simplex; Rank; regularized Frank–Wolfe algorithm; Regularized subproblem; Restricted simplicial decomposition; Shortest path problem; Simplex algorithm; Simplicial decomposition; Subproblem; Superlinear convergent rate; Traffic assignment problem; Side constraints

*Simplicial decomposition* (SD) can be viewed either as a generalization of the Frank–Wolfe algorithm [6] (cf. ► [Frank–Wolfe algorithm](#)) or an extension of Dantzig–Wolfe decomposition [5] to *nonlinear programs*. The term ‘simplicial decomposition’ is due to B. von Hohenbalken [22], but the essential idea is generally known as

*column generation* and has been called *inner linearization/restriction* by A.M. Geoffrion [7].

In general, SD addresses the following problem

$$\min_{x \in S} f(x), \quad (1)$$

where  $f(x)$  is *pseudoconvex*. The set  $S$  is typically a nonempty and bounded *polyhedron*, i. e.,  $S = \{x \in \mathbf{R}^n: Ax \leq b, x \geq 0\}$ ,  $A$  is a  $m \times n$  matrix, and  $b \in \mathbf{R}^m$ . With  $S$  being bounded and *polyhedral*, problem (1) can be restated as

$$\begin{cases} \min & f\left(\sum_{i=1}^n \lambda_i Y^i\right) \\ \text{s.t.} & \sum_{i=1}^n \lambda_i = 1, \\ & \lambda_i \geq 0, \quad \forall i = 1, \dots, n, \end{cases} \quad (2)$$

where  $n$  is the number of extreme points of  $S$ , each of which is represented as  $Y^i$ . In words, problem (2) finds a *convex combination of the extreme points*,  $Y^i$ , that minimizes  $f(x)$ . For real-world problems, the number of extreme points is generally large and it is impractical to generate all of them a priori. Instead, SD generates extreme points one at a time as follows.

```

0 | Select  $x^1 \in S$  and set  $k = 1$ .
1 | Let  $Y^k = \operatorname{argmin}_{y \in S} \nabla f(x^k)^\top y$ .
   | IF  $\nabla f(x^k)^\top (Y^k - x^k) \geq 0$ ,
   | THEN stop and  $x^k$  is an optimal solution.
   | ELSE, go to Step 2.
2 | Let

```

$$\lambda^k = \begin{cases} \operatorname{arg\,min}_{\lambda} & f(\lambda_0 Z^k + \sum_{i \in I^k} \lambda_i Y^i) \\ \text{s.t.} & \lambda_0 + \sum_{i \in I^k} \lambda_i = 1, \\ & \lambda_i \geq 0, \quad \forall i \in I^k \cup \{0\}, \end{cases}$$

where  $I^k \subseteq \{1, \dots, k\}$ , and  $Z^k = 0$  or  $x^j$  for some  $j \in \{1, \dots, k\}$ .

Set  $x^{k+1} = \lambda_0^k Z^k + \sum_{i \in I^k} \lambda_i^k Y^i$  and  $k = k + 1$ .

Return to Step 1.

### Simplicial decomposition technique

Since  $S$  is polyhedral, the problem in Step 1 is a *linear program*, generally called the *subproblem*. When solved by the simplex algorithm, its solution,  $Y^k$ , is guaranteed to be an extreme point. In the event that  $x^k$  satisfies the stopping criterion, the following sequence of inequalities demonstrates that  $x^k$  must be globally optimal:

$$\begin{aligned} \forall x \in S: f(x) &\geq f(x^k) + \nabla f(x^k)^\top (x - x^k) \\ &\geq f(x^k) + \nabla f(x^k)^\top (Y^k - x^k) \geq f(x^k). \end{aligned}$$

The three inequalities follow from the pseudoconvexity of  $f(x)$ , the fact that  $Y^k$  solves the subproblem, and the stopping criterion, respectively.

The problem in Step 2, or the *master problem*, is structurally the same as problem (2) and finds a convex combination of  $Z^k$  and extreme points in  $I^k$  that minimizes  $f(x)$ . This convex combination produces a new point,  $x^{k+1}$ , with a better objective value. To justify, consider the *first order Taylor series expansion* of  $f(x)$ , i. e.,

$$\begin{aligned} &f(x^k + \lambda(Y^k - x^k)) \\ &= f(x^k) + \lambda \nabla f(x^k)^\top (Y^k - x^k) \\ &\quad + \lambda \left\| Y^k - x^k \right\| \alpha(x^k; \lambda(Y^k - x^k)), \end{aligned}$$

where  $\lim_{\lambda \rightarrow 0} \alpha(x^k; \lambda(Y^k - x^k)) = 0$ . When Step 2 is executed,  $\nabla f(x^k)^\top (Y^k - x^k) < 0$  and the above expansion implies that there exists a sufficiently small  $\hat{\lambda} \in (0, 1)$  such that  $f(x^k + \hat{\lambda}(Y^k - x^k)) < f(x^k)$ . When  $Z^k$  and  $I^k$  are properly defined (see below),  $x^k + \hat{\lambda}(Y^k - x^k)$  lies in the convex hull of  $Z^k$  and  $Y^i$ , for all  $i \in I^k$ . Since  $\lambda^k$  solves the master problem, the following must hold:

$$\begin{aligned} f(x^{k+1}) &= f(\lambda_0^k Z^k + \sum_{i \in I^k} \lambda_i^k Y^i) \\ &\leq f(x^k + \hat{\lambda}(Y^k - x^k)) < f(x^k). \end{aligned}$$

So, the objective value decreases after each iteration.

Note that  $Z^k$  is not necessarily an extreme point of  $S$ . However,  $Z^k$  and the (index) set  $I^k$  provide some flexibility and determine the number of iterations to achieve an optimal solution. For example, if  $I^k = \{k\}$  and  $Z^k = x^k$  in Step 2, then SD reduces to the Frank–Wolfe algorithm, which converges in the limit to an optimal solution.

When  $I^0 = \emptyset$ ,

$$I^k = \left\{ i: i \in I^{k-1} \text{ and } \lambda_i^{k-1} > 0 \right\} \cup \{k\},$$

and  $Z^k = 0$ , the resulting algorithm is essentially the same as those in [11,22] and [23], and converges after a finite number of iterations. For this choice of  $Z^k$  and  $I^k$ , SD drops or discards extreme points with zero weight,  $\lambda_i^{k-1} = 0$ , to reduce the size of the master problem and, perhaps, to release computational resources for other uses as well. To obtain finite convergence, note that the number of possible index sets,  $I^k$ , is finite since there are only a finite number of extreme points for  $S$ . For each  $I^k$  generated by the algorithm, there is an associated minimum objective value,  $f(x^{k+1})$ , that is always decreasing for  $k \geq 1$ . This implies that the algorithm generates a sequence of distinct  $I^k$ . Since the number of possible  $I^k$  is finite, the sequence cannot be infinite, i. e., the algorithm must terminate finitely.

For the above choice of  $Z^k$  and  $I^k$ , the *Carathéodory theorem* (see, e.g., [2]) guarantees that the cardinality of  $I^k$  is at most  $\text{rank}(A) + 1$ . Thus, allocating computational resources for storing  $\text{rank}(A) + 1$  extreme points is sufficient to ensure finite convergence. However,  $\text{rank}(A) + 1$  is large for large scale problems and allocating such a large amount of resources may be impractical. As an alternative, D.W. Hearn, S. Lawphongpanich, and J.A. Ventura [10] proposed the following extreme point dropping scheme to restrict the cardinality of  $I^k$  to at most  $r$ , where  $r \geq 1$ .

1	When $k = 1$ , $I^1 = \{1\}$ and $Z^1 = x^1$ .
2	For $k > 1$ , let $\beta$ denote the cardinality of the set $\{i: i \in I^{k-1} \text{ and } \lambda_i^{k-1} > 0\}$ .
2a	IF $\beta < r$ , THEN set $I^k = \{i: i \in I^{k-1} \text{ and } \lambda_i^{k-1} > 0\} \cup \{k\}$ $Z^k = Z^{k-1}$ .
2b	IF $\beta = r$ , THEN set $I^k = \{i: i \in I^{k-1}, i \neq i^\#, \text{ and } \lambda_i^{k-1} > 0\} \cup \{k\}$ $Z^k = x^k$ , where $i^\# = \text{argmin}_i \{\lambda_i^{k-1} : \lambda_i^{k-1} > 0\}$ .

**An extreme point dropping scheme**

In Step 2, extreme points with zero weight, i. e.,  $\lambda_i^{k-1} = 0$ , are dropped from the master problem in iteration  $k$ . When the number of remaining (or positively

weighted) extreme points is less than  $r$ , the new extreme point,  $Y^k$ , is added to the master problem (see step 2a). Otherwise, the new extreme point replaces one of remaining extreme points with the smallest weight (see step 2b) to keep the cardinality of  $I^k$  at  $r$ . The choices for  $Z^k$  in steps 2a and 2b ensure that  $Z^k$  and the extreme points in  $I^k$  always form a  $p$ -simplex (see [20]), a fact essential for proving finite convergence. With the above extreme point dropping scheme, the resulting SD, known as the *restricted simplicial decomposition* (RSD), converges finitely when problem (1) has a unique solution,  $x^*$ , and  $r \geq \dim(\Phi) + 1$ , where  $\Phi = \{Y^i: \nabla f(x^*)^\top(Y^i - x^*) = 0, i = 1, \dots, n\}$ . (See [9].) When  $r < \dim(\Phi) + 1$ , RSD can be shown to converge in the limit to  $x^*$  using standard arguments in nonlinear programming (see, e. g., [9] and [15]).

In practice, a more successful application of SD is in solving *large nonlinear multicommodity flow problems* (see, e. g., [1]) of the form:

$$\begin{cases} \min_x & f\left(\sum_{c=1}^C x(c)\right) \\ \text{s.t.} & Ax(c) = b(c), \quad \forall c, \\ & x(c) \geq 0, \quad \forall c, \end{cases} \quad (3)$$

where  $A$  is a node-arc incidence matrix of a network with  $m$  nodes and  $n$  arcs,  $b(c) \in \mathbf{R}^m$  is a supply/demand vector for each commodity  $c$ ,  $x(c) \in \mathbf{R}^n$  is a flow vector for commodity  $c$ , and  $f(x)$  is a pseudoconvex travel cost function. In Step 1 of SD, the subproblem for problem (3) decomposes into  $C$  problems (one for each commodity  $c$ ) of the following form:

$$y^*(c) = \begin{cases} \operatorname{argmin}_y & \nabla f\left(\sum_{c'=1}^C x^k(c')\right)^\top y \\ \text{s.t.} & Ay = b(c), \\ & y \geq 0. \end{cases} \quad (4)$$

Problem (4) is a *shortest path problem* and can be solved efficiently with specialized network algorithms (see, e. g., [1]). J.D. Murchland [18] first discussed SD as a method for solving problem (3) that is generally known as the *traffic assignment problem* in transportation science. D.G. Cantor and M. Gerla [4] (see also [8]) implemented SD for solving problem (3) to route messages in computer communication networks. Later, the

results in [9] and [10] renewed the interest in SD by demonstrating empirically that RSD efficiently solves large traffic assignment problems. In [10], the master problem is solved by a method with at least a superlinear convergent rate, e. g., [3] and [17], and  $r$  is relatively small.

When applied to nonlinear single commodity (e. g., [10] and [17]) or *dynamic network flow problems* (e. g., [19]), SD may not be as efficient as other methods. For these problems, the dimension of  $\Phi$  tends to be large and each extreme point in  $\Phi$  contributes little as part of the convex combination that forms  $x^*$ .

In the literature, there are several extensions and modifications to SD, restricted or otherwise. First, it is claimed in [11] that SD also applies to problems in which  $S$  is convex, but not necessarily polyhedral. For example,  $S = \{x \in \mathbf{R}^n: g_i(x) \leq 0, i = 1, \dots, m\}$ , where  $g_i(x)$  is convex on  $\mathbf{R}^n$ . In this case, a straightforward application of SD (see [11]) would yield a subproblem with nonlinear constraints, a problem as complex as the original. Later, Ventura and Hearn [21] proposed a modification for RSD in which the subproblem is a linear program instead.

Second, when applied to problem (3), the representation of the extreme points can effect the convergence rate of SD. In particular, the extreme point,  $Y^k$ , can be represented either as  $Y^k = \sum_{c=1}^C y^k(c)$ , an aggregate form, or  $(Y^k)^\top = (y^k(1)^\top, \dots, y^k(C)^\top)$ , a disaggregate form. The latter renders the master problem larger and more complex as shown below:

$$\begin{cases} \min & f\left(\sum_{c=1}^C \left[ \lambda_0(c)z^k(c) + \sum_{i \in I^k} \lambda_i(c)y^k(c) \right]\right) \\ \text{s.t.} & \lambda_0(c) + \sum_{i \in I^k} \lambda_i(c) = 1, \quad \forall c, \\ & \lambda_i(c) \geq 0, \quad \forall c \text{ and } i \in I^k \cup \{0\}. \end{cases}$$

Despite the increased in problem complexity, T. Larson and M. Patriksson [12] demonstrated empirically that SD with disaggregate extreme points converges faster on several real-world traffic assignment problems.

Third, A. Migdalas [16] introduced an extension to the Frank-Wolfe algorithm called the *regularized Frank-Wolfe algorithm* in which the subproblem has a nonlinear term in the objective function to control the distance between  $Y^k$  and  $x^k$ . For example, one version

of the regularized subproblem is

$$Y^k = \underset{y \in S}{\operatorname{argmin}} \left\{ \nabla f(x^k)^\top y + \frac{1}{2}(y - x^k)^\top D^k (y - x^k) \right\},$$

where  $D^k$  is a positive definite matrix. In [13], Larsson, Patriksson, and C. Rydergren solved the above subproblem approximately by performing several iterations of the Frank–Wolfe algorithm and showed empirically that the regularized subproblem can improve the convergence of SD.

Finally, C.H. Wu and Ventura [24] and Lawphongpanich [14] extended SD to solve problems with side constraints, i. e.,  $S = \{x \in \mathbf{R}^n: Ax \leq b, Dx \leq d, x \geq 0\}$ , where  $A$  and  $b$  are as defined for problem (1),  $D$  is a  $q \times n$  matrix, and  $d \in \mathbf{R}^q$ . Here,  $A$  may have a special structure that can be exploited computationally, and  $D$ , representing the side constraints, does not.

Inner approximation; Representation theorem; Carathéodory's theorem; Simplex; Linearization; Pseudoconvex function; Decomposition/coordination; Column generation; Restricted master problem; Dantzig–Wolfe decomposition; Pricing-out; Column dropping; Optimal face; Frank–Wolfe; Disaggregated representation; Variational inequalities; Merit function; Nondifferentiable convex program

Simplicial decomposition (SD) is a class of methods for solving continuous problems in mathematical programming with convex feasible sets. There are two main characteristics of the methods in this class:

- i) an approximation of the original problem is constructed and solved, wherein the original feasible set is replaced by a polyhedral subset thereof, that is, an *inner approximation* of it which is spanned by a finite set of feasible solutions; and
- ii) this inner approximation is improved (that is, enlarged) by generating a vector (or, column) in the feasible set through the solution of another approximation of the original problem wherein the original cost function is approximated (often by a linear function).

As such, the class of SD methods may be placed within the framework of *column generation* methods. Another characteristic of an SD method however is that the sequence of solutions to the inner approximated problems tends to a solution to the original problem in such a way that the cost function (or, some merit function) strictly monotonically approaches its optimal value. Therefore, the class of SD methods also falls within the

framework of iterative descent (or, ascent) algorithms for continuous mathematical programs.

We consider, for the most part, the solution of the differentiable optimization problem

$$\begin{cases} \min & f(x), \\ \text{s.t.} & x \in X, \end{cases} \quad (1)$$

where  $f: X \rightarrow \mathbf{R}$  is *pseudoconvex* on  $X$  (that is, for any  $x, y \in X$ ,  $\nabla f(x)^\top(y - x) \geq 0$  implies  $f(x) \leq f(y)$ ), and where  $X := \{x \in \mathbf{R}^n: Ax = b; x \geq 0^n\}$  is a nonempty polyhedral set.

The derivation of the method rests on two classical results on the representation of convex sets and of points in such sets. The first result is the *representation theorem* (e. g., [2,18]), which states that:

- i) the set of extreme points  $p^i$ ,  $i \in \mathcal{P}$ , of the polyhedral set  $X$  is nonempty and finite;
- ii) the set of extreme directions  $d^i$ ,  $i \in \mathcal{D}$ , is empty if and only if  $X$  is bounded, and if  $X$  is not bounded, then it is nonempty and finite; finally, and most importantly,
- iii) a vector  $x \in \mathbf{R}^n$  belongs to  $X$  if and only if it can be represented as a convex combination of the extreme points plus a nonnegative linear combination of the extreme directions, that is, for some vectors  $\lambda$  and  $\mu$ ,

$$x = \sum_{i \in \mathcal{P}} \lambda_i p^i + \sum_{i \in \mathcal{D}} \mu_i d^i, \quad (2a)$$

$$\sum_{i \in \mathcal{P}} \lambda_i = 1, \quad (2b)$$

$$\lambda_i \geq 0, \quad i \in \mathcal{P}, \quad (2c)$$

$$\mu_i \geq 0, \quad i \in \mathcal{D}. \quad (2d)$$

Thus, in principle, the polyhedral set  $X$  can be given an inner representation in terms of extreme points and directions, and the problem (1) can be cast in the variables  $\lambda_i$  and  $\mu_i$  instead of in  $x$ . The advantage of making this problem transformation is that the inner representation of  $X$  is much simpler than its original, outer, representation in terms of linear equalities and inequalities; disregarding the definitional constraints (2a), the set described by (2) is the Cartesian product of a *simplex* and the nonnegative orthant, an optimization over which often can be made with little more effort than for an unconstrained problem (e. g., [3,4]). Furthermore,

the inner representation may also be useful for interpreting the result of an optimization, since the extreme points and directions may have further significance; in applications to network flows, for example, the representation theorem states that a link flow  $x \in X$ , where the polyhedral set  $X$  describes the flow conservation and nonnegativity constraints for the network flow, can equivalently be represented by (or, decomposed into) the sum of flows on routes and in cycles (e. g., [1, Thm. 3.5]). The latter also explains the origin of the term *simplicial decomposition*: the variable transformation decomposes a feasible solution into the sum of variables that (in the bounded case) forms a simplex.

The disadvantage of the transformation is that since the number of extreme points and directions of a polyhedral set grows exponentially with its dimension, the transformation introduces an impractically large number of variables. The practical use of simplicial decomposition then hinges on the second basic result in the representation of convex sets, *Carathéodory's theorem* (e. g., [26, Thm. 17.1]). This result states that a point  $x$  in the convex hull of any subset  $X$  of  $\mathbf{R}^n$  can be represented as a convex combination of at most as many elements of  $X$  as its dimension,  $\dim X$  (which is defined as the dimension of its affine hull), plus one. (This number is not larger than  $n + 1$ .) Although Carathéodory's theorem is not stated in terms of extreme points and directions, its natural application in the context of simplicial decomposition is that, in the case of a bounded polyhedral set, for example, any feasible point can be described as the convex combination of extreme points of the set, the total number of which need never exceed the dimension of the polyhedron plus one. (This result obviously refines the representation theorem.)

The classical form of the simplicial decomposition method was first described by B. von Hohenbalken [31] (see however the end of this article for some earlier references to similar algorithms) for the problem (1). The algorithm alternates between the solution of two problems. Given known subsets  $\widehat{\mathcal{P}}$  and  $\widehat{\mathcal{D}}$  of  $\mathcal{P}$  and  $\mathcal{D}$ , respectively,  $f$  is minimized over the inner approximation of  $X$  which is defined when these subsets replace  $\mathcal{P}$  and  $\mathcal{D}$  in (2), in terms of the variables  $\widehat{\lambda}_i$ ,  $i \in \widehat{\mathcal{P}}$ , and  $\widehat{\mu}_i$ ,  $i \in \widehat{\mathcal{D}}$ . (We will denote this problem the *restricted master problem* (RMP); it is also sometimes referred to as the *coordination step*.) Notice that we use the notation  $\widehat{\lambda}$  and  $\widehat{\mu}$  to distinguish the vectors in the RMP from the

(longer) vectors  $\lambda$  and  $\mu$  in the *complete master problem* which is equivalent to (1) and is defined by the system (2). Further denoting by  $\widehat{\Lambda}$  the set of vectors  $(\widehat{\lambda}, \widehat{\mu})$  satisfying the restriction of the system (2b)–(2c) to the known subsets  $\widehat{\mathcal{P}}$  and  $\widehat{\mathcal{D}}$  and utilizing (2a) to substitute  $x$  for  $(\widehat{\lambda}, \widehat{\mu})$  (we write  $x = x(\widehat{\lambda}, \widehat{\mu})$ ), the RMP may then be formulated as

$$\begin{cases} \min & f(x(\widehat{\lambda}, \widehat{\mu})), \\ \text{s.t.} & (\widehat{\lambda}, \widehat{\mu}) \in \widehat{\Lambda}. \end{cases} \quad (3)$$

Alternately, a profitable extreme point or direction of  $X$  is generated through the solution of an approximation of (1), in which  $f$  is replaced by its first order, linear, approximation,  $y \mapsto f(x) + \nabla f(x)^\top(y - x)$ , defined at the solution,  $x$ , to the RMP (3), that is, by the problem

$$\begin{cases} \min & \nabla f(x)^\top y, \\ \text{s.t.} & y \in X; \end{cases} \quad (4)$$

this approximate problem is a linear programming problem, which in general is much easier to solve than the original one. (This is called the *column generation subproblem*, and corresponds to the *decomposition step* in some descriptions of column generation methods.) If the solution to this problem lies within the current inner approximation, then the conclusion is that the current solution,  $x$ , is optimal in (1), since, then,  $\nabla f(x)^\top(y - x) \geq 0$  must hold for all  $y \in X$ . Otherwise,  $\widehat{\mathcal{P}}$  or  $\widehat{\mathcal{D}}$  is augmented by a new element, the resulting inner approximation is improved (that is, enlarged), and the solution to the new RMP has a strictly lower objective value than the previous one; the latter result follows since the strict inequality  $\nabla f(x)^\top d < 0$  holds (that is,  $d$  defines a direction of descent with respect to  $f$  at  $x$ ), where  $d$  denotes either the direction  $d := y - x$  towards the new extreme point  $y$  or an extreme direction. The iteration is then repeated with the solution of a new column generation subproblem defined at the solution to the RMP. In the method of [31], Carathéodory's theorem is utilized in the validation of a *column dropping rule*, according to which any extreme point or direction whose weight in the expression of the solution  $x$  to the RMP is zero is removed; thanks to the finiteness of  $\mathcal{P}$  and  $\mathcal{D}$  and the strictly decreasing values of  $f$ , the convergence of the SD algorithm in the number of RMP is finite.

In the case of a convex function  $f$ , a finite termination criterion is automatically supplied, on the one hand by the upper bound on the optimal objective value of (1) that is defined by the solution to the RMP, and on the other hand by the lower bound that is supplied by the solution to the column generation subproblem; in fact, letting  $x$  be an arbitrary feasible solution to (1), and  $x^*$  be any optimal solution to (1), we obtain from the optimality of  $x^*$  and by the convexity of  $f$  that

$$\begin{aligned} f(x) &\geq f(x^*) \\ &\geq f(x) + \nabla f(x)^\top (x^* - x) \\ &\geq f(x) + \min_{y \in X} \{ \nabla f(x)^\top (y - x) \}; \end{aligned} \tag{5}$$

note that the problem defined in (5) is precisely the column generation subproblem (4) defined at  $x$ . A finite termination criterion for the solution of the RMP can be defined by the analogous lower bound. In this case, due to the simple form of the constraints defined by (2b)–(2d), the lower bound is available directly from the value of the gradient of  $f$  with respect to  $(\hat{\lambda}, \hat{\mu})$  at  $x = x(\hat{\lambda}, \hat{\mu})$ . Indeed, the lower bound is either (analogously to (5)) given by the current objective value plus

$$\begin{aligned} &\min_{i \in \hat{\mathcal{P}}} \left\{ \frac{\partial f(x(\hat{\lambda}, \hat{\mu}))}{\partial \hat{\lambda}_i} \right\} \\ &- \nabla_{\hat{\lambda}} f(x(\hat{\lambda}, \hat{\mu}))^\top \hat{\lambda} - \nabla_{\hat{\mu}} f(x(\hat{\lambda}, \hat{\mu}))^\top \hat{\mu} \end{aligned}$$

or it is minus infinity (if  $\nabla f(x)^\top d^i < 0$  holds for some  $i \in \hat{\mathcal{D}}$ ).

Assume now that the function  $f$  is *strictly pseudo-convex* (that is, for any  $x, y \in X$  with  $x \neq y$ ,  $\nabla f(x)^\top (y - x) \geq 0$  implies that  $f(x) < f(y)$  holds), so that the optimal solution  $x^*$  is unique, and for simplicity we also assume that  $X$  is bounded. For such problems, an improvement over the original scheme was devised in [10,11]. The basis for the improvement is the observation that a particular feasible solution, such as the optimal one, can be represented as the convex combination of an often much smaller number of extreme points than  $\dim X + 1$ , as implied by Carathéodory’s theorem; in fact, the highest number of extreme points needed to describe the optimal solution  $x^*$  is  $\dim F^* + 1$ , where  $F^*$  is the *optimal face* of  $X$ , that is, the face of  $X$  of the smallest dimension which contains  $x^*$ . (In the present context, this set may be described by

$$F^* = \{ y \in X : \nabla f(x^*)^\top (y - x^*) = 0 \},$$

a set which is spanned by the extreme points of  $X$  that solve the linear approximation (4) to (1) defined at the optimal solution.) Based on this observation, they devise a modification of the original scheme, in which the number of extreme points retained is kept below a positive integer,  $r$ ; when this number of extreme points has been reached, any new extreme point generated replaces the column in  $\hat{\mathcal{P}}$  that received the least weight in the solution to the RMP. In order to ensure the convergence of the algorithm, the optimal solution  $x$  to the RMP must also be retained as an individual column (however not counted among the  $r$  columns). They show that the modified algorithm is finitely convergent in the number of RMP, provided that  $r \geq \dim F^* + 1$ . Referred to as restricted simplicial decomposition (RSD), the scheme is shown below, for the case of a bounded set  $X$ .

PROCEDURE RSD( $r$ )

- (Init):  $x^0 \in X, p^x := x^0, \hat{\mathcal{P}} = \emptyset, t := 0.$
- (Sub): Solve (4) defined at  $x^t \Rightarrow p^{i^t}, i^t \in \mathcal{P}.$
- (Augment):  $i_t \in \hat{\mathcal{P}} \Rightarrow x^t$  is optimal.
  - $|\hat{\mathcal{P}}| = r \Rightarrow$  replace an element of  $\hat{\mathcal{P}}$  by  $i_t.$
  - $|\hat{\mathcal{P}}| < r \Rightarrow \hat{\mathcal{P}} := \hat{\mathcal{P}} \cup \{i_t\}.$
- (Master):  $x^{t+1}$  minimizes  $f$  over the convex hull of  $p^x$  and  $p^i, i \in \hat{\mathcal{P}}.$
- (Update): Let  $p^x := x^{t+1}, t := t + 1.$
- Go to the Subproblem.

END

The value of  $r$  is crucial to the performance of the algorithm. If  $r \geq \dim F^* + 1$ , then since the number of RMP is finite, the local rate of convergence is governed by the local convergence rate of the method chosen for the solution of the RMP; thus, a superlinear or quadratic convergence rate may be attained if a (projected) Newton method is used ([11]). If  $r < \dim F^* + 1$ , however, then the algorithm is only asymptotically convergent, and the rate of convergence is the same as that of the *Frank–Wolfe algorithm* (or, *conditional gradient method*; which is actually obtained as a special case of RSD when  $r := 1$ ), that is, the convergence rate is sub-linear. Since the threshold value for finite convergence cannot be estimated from the original data and thus is unknown a priori, the proper value of  $r$  must in general be based on computational experience.

In column generation methods for linear programs, such as *Dantzig–Wolfe decomposition* ([16]), the columns are generated through the *pricing* operation of the *simplex method* in linear programming, which utilizes an estimate of the dual optimal solution. Its extension to nonlinear programming, *nonlinear Dantzig–Wolfe decomposition* (e.g., [18]), also utilizes the pricing operation in the construction of the column generation subproblem, which in both cases is equivalent to the result of performing a Lagrangian relaxation of the original problem using the current estimate of the vector of Lagrange multipliers; while the column generation subproblem is nonlinear in the latter algorithm, the RMP are in both cases linear programs. In contrast, the class of SD algorithms are column generation methods where the columns are generated through the solution of the primal, linearized problem (4), and which thus does not utilize dual information. However, it is established in [14] that Dantzig–Wolfe decomposition is in fact a special case of simplicial decomposition, when the latter is applied to a primal–dual (saddle point) reformulation of the linear program. Also for linearly constrained nonlinear programs of the form (1), simplicial decomposition may be based on the *pricing-out* of a subset of the linear constraints. Identifying a subset of the constraints defining  $X$  as complicating, these may be priced-out (that is, Lagrangian relaxed) in the column generation subproblem, and instead included in the master problem, just as in Dantzig–Wolfe decomposition for linear and nonlinear programming problems. Such methods have been devised in [20,28]. It should be noted, however, that just as in the original (primal) SD method, the column generation subproblems in these methods are based on the linearization of the original objective function, and are therefore linear programs, and their RMP are nonlinear; this is precisely the opposite to the case of nonlinear Dantzig–Wolfe decomposition.

The RSD algorithm has been successfully applied to large scale, structured nonlinear optimization problems, in particular mathematical programming models of various nonlinear network flow problems, where the column generation subproblem reduces to efficiently solvable linear network flow problems (e.g., [11,15,23]).

Other special structures in the feasible set  $X$  may also be taken into account efficiently in the construc-

tion of an SD method. For example, assume that the set  $X$  is a Cartesian product of polyhedral sets  $X_k$  in smaller dimensions  $\mathbf{R}^{n_k}$ , with  $k \in \mathcal{K}$  and  $\sum_{k \in \mathcal{K}} n_k = n$ . (In network flow problems,  $k$  could denote a commodity of goods to be transported or a pair of origin and destination in an urban transportation network.) Noting that the linear column generation subproblem decomposes into  $|\mathcal{K}|$  independent linear column generation problems, it is possible to store extreme points and directions of the individual (smaller-dimensional) sets  $X_k$  rather than extreme points and directions of  $X$ . The RMP of such a *disaggregate simplicial decomposition* (DSD) method ([15]) would then have variables of the form  $\lambda_{ik}$ ,  $i \in \mathcal{P}_k$ ,  $k \in \mathcal{K}$ , and likewise for  $\mu_{ik}$ , and  $|\mathcal{K}|$  convexity constraints (2b) instead of only one as in the SD method. The total number of extreme points and directions is much less in the disaggregated representation ( $\sum_{k \in \mathcal{K}} \{\mathcal{P}_k + \mathcal{D}_k\}$  in the disaggregated case, and  $\prod_{k \in \mathcal{K}} \{\mathcal{P}_k + \mathcal{D}_k\}$  in the aggregated case; [24]). On the other hand, according to Carathéodory’s theorem, the total number of columns needed to express an optimal solution is in this case bounded above by  $\sum_{k \in \mathcal{K}} (\dim F_k^* + 1)$ , which may be a much higher number than  $\dim F^* + 1$ . This result notwithstanding, it has been observed in applications of Dantzig–Wolfe decomposition to linear multicommodity network flow problems ([13]) that a disaggregated representation of the solution (in this case, as commodity route flows instead of as aggregated link flows) speeds up the convergence of the method. The same conclusion has been drawn from applications to nonlinear multicommodity network flow problems ([15]) of the DSD algorithm.

Experience with the RSD method has shown that it makes rapid progress initially, quickly reaching a near-optimal solution, especially when relatively large values of  $r$  are used and when second order methods are used for the solution of the RMP, but that it slows down close to an optimal solution. It is also relatively less efficient for larger values of  $\dim F^*$ .

The explanation for this behavior is to be found in the construction of the column generation subproblem, which utilizes first order approximations of  $f$ . The column generation subproblem of RSD is the same as that of the Frank–Wolfe (FW) method mentioned earlier, the quality of whose search directions are known to deteriorate rapidly. The reason is that as the sequence  $\{x^t\}$

tends to an optimal solution, the sequence  $\{\nabla f(x^t)^\top d^t\}$  of directional derivatives of the search directions  $d^t := y^t - x^t$  tends to zero whereas  $\{d^t\}$  does not; thus, the search directions rapidly tend to become orthogonal to the gradient of  $f$ , and the result of the deteriorating descent property is a decreasing step length in the line search of this algorithm.

We then make the observation that the RSD method is similar to FW, since the same descent direction-generating subproblem is used, and that the only difference between FW and RSD lies in the updating phase, the latter algorithm using a multidimensional search (when  $r \geq 2$ ) rather than a one-dimensional search, which one may interpret as a device for reducing the zig-zagging effect inherent in the FW algorithm. It is a natural conclusion from this discussion that better approximations of  $f$  could be exploited in the column generation phase of SD methods, since then the columns generated would be of better quality, thus leading to larger improvements in the inner approximations of the feasible set. (The counterpart in line search methods for (1) is that improved approximations of  $f$  in a direction-finding subproblem yield better search directions.)

An extension of the RSD algorithm was made by T. Larsson, M. Patriksson and C. Rydgergren [16] based on this observation. The motivation behind the *nonlinear simplicial decomposition* (NSD) method is that by generating columns based on better approximations of the objective function, the sensitivity of the method to the dimension of the optimal face will be reduced, fewer columns will be needed to describe an optimal solution, resulting in fewer iterations, and enabling a smaller value of the parameter  $r$  to be chosen.

The NSD method is obtained from the RSD method by replacing the linear column generation subproblem (4) with

$$\min_{y \in X} \{\nabla f(x^t)^\top y + \varphi(y, x^t)\}, \quad (6)$$

where  $\varphi: X \times X \rightarrow \mathbf{R}$  is a continuous function of the form  $\varphi(y, x)$ , convex and continuously differentiable with respect to  $y$  for all  $x \in X$ , and with the property that  $\nabla_y \varphi(x, x) = 0^n$  for all  $x \in X$ . Among the possible choices for  $\varphi$  we mention the following, where  $\text{diag}$  denotes the diagonal part of the matrix and where  $\gamma_t > 0$ :

$\varphi(y, x^t)$	Subproblem
0	Frank-Wolfe
$\frac{1}{2} y^\top \nabla^2 f(x^t) y$	Newton
$\frac{1}{2} y^\top [\text{diag} \nabla^2 f(x^t)] y$	Diag. Newton
$\frac{1}{2\gamma_t} y^\top y$	Projection

Even though the finite convergence property will be lost (because nonextremal points will be generated), one may expect a more rapid convergence of the NSD method than the RSD method, both in terms of the number of iterations needed to reach a given solution accuracy and in terms of the required solution time, provided however that the nonlinear column generation subproblems can be efficiently solved, at least approximately. In numerical experiments performed on large scale nonlinear network flow problems, such conclusions were indeed made. It was particularly observed that the NSD method is relatively much less sensitive to the value of  $\dim F^*$  than is RSD, which permits the use of a much smaller value of  $r$  in the NSD method.

Convergence results for SD methods allow for both the column generation subproblem and the RMP to be solved inexactly, thus facilitating its practical use. In [11], convergence is established for the RSD method, wherein the RMP is solved using one iteration of Newton's method only. Further developments along these lines are found in [8,14] for a general class of SD methods and in [25, Chap. 9] for the NSD method. The convergence results established in the latter reference not only validate inexact computations but also quite arbitrary rules both for defining and for dropping columns.

SD algorithms have been extended to handle nonlinear constraints as well. In [30], the column generation subproblem is made linear by approximating the nonlinear constraint functions by piecewise linear functions, reminiscent to the Topkis–Veinott scheme ([29]). The NSD method of [16,25] applies to general convex sets  $X$  directly. A combination of sequential quadratic programming (SQP) and NSD is devised in [25, Chap. 9]. There, in the column generation subproblem one replaces the nonlinear constraints with linear approximations, and dual information about these constraints is included in the objective function. SD methods for nonlinearly constrained problems are believed to be efficient, if the nonlinearity is mild, as

concluded from the computational results of [30]; however, few applications of SD methods to nonlinearly constrained problems have been reported.

The class of SD methods has furthermore been extended to the solution of the general *variational inequality problem* (VIP) of finding  $x^* \in X$  such that

$$F(x^*)^\top(x - x^*) \geq 0, \quad \forall x \in X, \quad (7)$$

where  $F: X \rightarrow \mathbf{R}^n$  is a continuous and monotone mapping. If the mapping  $F$  satisfies  $F \equiv \nabla f$ , that is, it is the gradient of  $f$ , then the VIP defines the first order optimality conditions for  $x^*$  in (1), and the SD method for the VIP becomes that for (1). If this is not the case, then  $F$  replaces  $\nabla f$  in the column generation subproblem (4), and the RMP is defined as the restriction of the variational inequality problem (7) to the currently known inner approximation of  $X$ . Further, in this case there is no objective function (or, *merit function*) immediately available for monitoring the convergence of the SD method. Column dropping rules in SD methods for the VIP must however be based on the improvement of the method in terms of some merit function, without which the method may cycle. (This is evidenced by the nonconvergence of the FW method applied to the VIP; see [9].) S. Lawphongpanich and D.W. Hearn [19] utilize the *primal gap function*,

$$\psi(x) := \max_{y \in X} F(x)^\top(x - y),$$

which is zero at solutions to VIP and positive elsewhere in  $X$ , to guide the dropping of columns. A related merit function is used in [27]. The NSD and NSD/SQP methods are extended to VIP in [25, Chap. 9], there using the merit function

$$\psi(x) := \max_{y \in X} \{F(x)^\top(x - y) - \varphi(y, x)\}.$$

In contrast to the case of the problem (1), the sequence of solutions to the RMP in SD methods applied to (7) does not necessarily yield a monotonically decreasing sequence of values of any merit function for the VIP unless very restrictive assumptions are made on the original data, whence the theoretical properties of SD methods for VIP are less strong; for example, a consequence of the property just mentioned is that the finite convergence result for the RSD method cannot be transferred to the VIP. The solution methods that have been considered for the RMP for the VIP are generalizations of

those used for the RMP of (1); the most popular ones are projection algorithms, due to a large degree to the simple form of the constraints of the RMP; see, e.g., [22] for numerical investigations of different algorithmic approaches to the RMP.

Larsson, Patriksson and A.-B. Strömberg [17] develop an SD scheme for *nondifferentiable convex optimization*. There, the gradient  $\nabla f(x)$  is replaced by the set of subgradients, the *subdifferential*,  $\partial f(x)$ , defined by

$$\partial f(x) = \left\{ \xi_f \in \mathbf{R}^n : \begin{array}{l} f(y) \geq f(x) + \xi_f^\top(y - x), \\ \forall y \in \mathbf{R}^n \end{array} \right\}.$$

It is shown that the utilization of an arbitrary subgradient  $\xi_f \in \partial f(x)$  in place of the gradient in the column generation subproblem may lead to the termination of the algorithm at a nonoptimal solution, since not all subgradients define descent directions. A modification of the SD scheme is therefore made, wherein the subgradients evaluated in the course of solving the RMP are averaged with weights proportional to the step lengths used in the solution method for RMP; this vector of averaged (or, ergodic) subgradients is then shown to yield an improved inner approximation. An alternative, and probably computationally much more efficient, means to define a linear column generation subproblem with the properties required is through the generation of (approximately) shortest  $\varepsilon$ -subgradients.

The first simplicial decomposition type methods evolved from the experience of the poor convergence of the FW method (e.g., [5,12,21]). The perhaps first thorough theoretical investigation of SD methods is due to C.A. Holloway [12]. Its close relationships to column generation methods however make it difficult to trace its earliest history; for example, already the first urban transportation planning studies in the 1950s applied heuristics resembling the DSD algorithm (see [24] for an overview of the history of such methods). A related class of methods also exist for least-distance and other problems in quadratic programming (e.g., [7]).

Further surveys on simplicial decomposition methods, their history and their relationships to column generation, are found in [15,24,25].

Simplicial algorithms; Integer programming; Knapsack problem; Horn formulas

Simplicial *path following methods* are relatively new in the area of integer programming (cf. ► **Integer programming**). They are based on a *triangulation* of Euclidean space and a *pivoting algorithm* which, for a restrictive class of problems, terminates with an integral solution or shows that no such solution exists. The path constructed consists of a sequence of neighboring *simplices*, the vertices of which are integral lattice points.

Simplicial methods originated in *fixed point theory*, where they are used to approximate fixed points of continuous mappings [7,18].

In the area of continuous mathematics they have been applied successfully in disciplines such as game theory [19], the approximation of roots of systems of complex polynomials [8,13], economics and econometrics [20] and they have provided a useful machinery to prove a variety of intersection lemmas [10,16].

Returning to discrete problems again, the essentials of the method consist of the following ingredients:

- triangulations
- labelings
- pivoting
- termination- and noncycling arguments.

The simplicial algorithms developed so far yield a conclusive answer to the feasibility problem: ‘Does a given bounded set in Euclidean space contain a lattice point?’ for a restrictive class of sets, the so called *max-*

*closed sets*. In fact, for this class, they provide a polynomial time algorithm (for polyhedral cases) which generalizes earlier work of A. Pnueli [17], F. Glover [11], R. Chandrasekaran [1] and R.W. Cottle and A.F. Veinott [3].

In the sequel we shall pay attention to the notions quoted above. Also, some intriguing complexity issues which arise when studying *unimodular max-closed form transformations* are discussed briefly. Finally, we discuss the use of simplicial methods outside this tractable class of max-closed sets, namely to locate regions of specific interest, and their possible incorporation into *branching algorithms*.

## Triangulations

A *triangulation of Euclidean space* is a set of simplices which union covers the space and moreover satisfies the condition that any two simplices from this set intersect in a member of this set.

For our purposes we need a triangulation which uses *all* lattice points as zero-dimensional elements and triangulates the unit-cube together with all its integral translates. There are various ways to triangulate space in such a manner. An extensive study on triangulations and simplicial methods is [4].

## Labelings

The labelings form the most crucial part of the simplicial methods. It is through the labeling device that the original problem is translated to a format where the arguments of the pivoting algorithms adapt to. There are two cases to consider, integer labeling and vector labeling.

## Integer Labeling

This part needs some introductory notations and conventions. Given  $a \in \mathbb{R}^n$  the following cones play a crucial role:

$$P(a) = \{x \in \mathbb{R}^n : x_i \geq a_i \text{ for } i = 1, \dots, n\},$$

$$P_k(a) = \{x \in \mathbb{R}^n : x \in P(a) \text{ and } x_k = a_k\},$$

$$N(a) = \{x \in \mathbb{R}^n : x_i \leq a_i \text{ for } i = 1, \dots, n\},$$

$$N_k(a) = \{x \in \mathbb{R}^n : x \in N(a) \text{ and } x_k = a_k\}.$$

Now suppose a set  $S \subset \mathbf{R}^n$  is given. A point  $a \in \mathbf{R}^n$  carries label  $k$  if (following [15])

$$S \cap N_k(a) = \emptyset.$$

According to the above, a point may carry more labels (in which case the smallest such is chosen, for example) or it may carry no label at all. Drawing some pictures, one sees that a labeling device as above partitions Euclidean space into  $n$  regions, except for points in  $S$  itself and except for some part which is located near the so called Pareto boundary of  $S$ . The latter part might vanish if  $S$  has a specific shape, which shall be precisely the case for the max-closed sets that will be discussed later on.

Of course, it is understood in this context that the set  $S$  is accessible to questions whether some point carries label  $k$ . In case  $S$  is polyhedral, linear programming answers these questions. If  $S$  is convex, one needs convex programming to do so. In all cases of interest we assume that membership questions related to  $S$  are relatively easy as long they are *not* specified to lattice points of  $S$ , that is, as long as they deal with  $S$  as a continuous set!

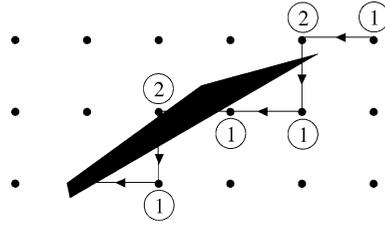

In [5,6] it is shown that if  $S$  is a simplex (*knapsack problem*) one can even avoid the use of linear programs in establishing labels. An explicit device is available in that case.

**Vector Labeling**

Relative to a set  $S \subset \mathbf{R}^n$  we can associate to any point  $a \in \mathbf{R}^n$  the vector which starts at  $a$  and ends at a point of  $S$  nearest to  $a$ . Here  $S$  is assumed to be closed, and preferably convex, in which case this vector is unique. The reader may notice that now all points carry a label! This labeling device was introduced in [15] where it is shown that it can be used to obtain similar results as provided by integer labeling rules but, moreover, enables a pivoting algorithm to continue where it would terminate in the former case due to the lack of labels!

**Pivoting**

We shall explain the pivoting structure only in the case where integer labelings are used. See [15] for the more complicated process involving vectors. Also, we restrict

**Simplicial Pivoting Algorithms for Integer Programming, Figure 1**  
Pnueli’s algorithm

ourselves here to full-dimensional pivots, which lead from a  $n + 1$ -dimensional simplex of the triangulation to a neighboring one. Although *varying dimension pivoting algorithms* [6] are essential in speeding up performance, they involve rather technical details and go beyond the scope of this overview.

Before going into simplicial pivoting we discuss *Pnueli’s algorithm* [17] first. Because of introductory purposes we will present a strongly modified form of it.

A set  $S \subset \mathbf{R}^n$  is specified, together with a lattice point  $u$ , being an *upper bound* for  $S$ ; this means that  $S \subset N(u)$ . A *lower bound* for  $S$  is any lattice point  $\ell$  for which  $N(\ell) \cap S = \emptyset$ . Clearly, if  $S$  is bounded, it has both upper and lower bounds in the above cone-like sense. In the sequel  $e_k$  denotes the  $k$ th unit vector. Now the modified form of Pnueli’s algorithm (see Fig. 1 for a two-dimensional example) consists of the following iterative procedure:

```

1 | let  $x_0 = u$ 
2 | if  $x_j$  has label  $k$  let  $x_{j+1} = x_j - e_k$ .
    
```

It is not at all that hard to see that, *as long as the algorithm runs*, we have all integral lattice points of  $S$  contained in  $N(x_j)$ . This means that the algorithm terminates in three possible states:

- 1) The iterate  $x_j$  is recognized as a lower bound.  $S$  is proven to contain no integral solutions.
- 2) The iterate  $x_j$  has no label. If this is because  $x_j \in S$  we have located a solution.
- 3) The iterate  $x_j$  has no label and, unfortunately,  $x_j \notin S$ .

**Start** A simplex of the triangulation is located with the following property: all labels from  $1, \dots, n$  are present as labels of the  $n+1$  vertices of the simplex involved. Such a simplex can easily be found near an upper bound of  $S$  (as is done in Fig. 2). In the case of an arbitrary starting, varying dimension algorithm [6] such a simplex shows up during the execution of the algorithm itself!

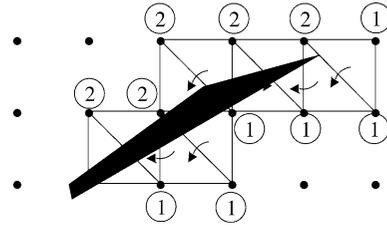

**Pivot** If a simplex carrying all labels is found, two vertices of this simplex must carry the *same* label. These two vertices define two neighboring simplices of the triangulation: those two full dimensional simplices which intersect the given one in one of the two facets opposed to the two vertices involved. Now one of those simplices is supposed to represent the previous state of the algorithm. The next state is defined as the other simplex. Thus a new lattice point is found, its label is calculated, and when it has one, a new simplex is found carrying all labels, one of which occurs twice at a vertex.

As shall become clear later, 3) cannot happen whenever  $S$  is max-closed. Pnueli's algorithm in the above form is extremely simple and it runs (as long as it runs) in polynomial time if  $S$  is polyhedral: it uses at most

$$n \sum_{i=1}^n (u_i - \ell_i)$$

linear programs to travel from an upper bound  $u$  to a lower bound  $\ell$ . A disadvantage however is that it cannot start at an arbitrary point, in the neighborhood of which an integral solution is expected for some reason whatsoever (this remark will turn out to be even more relevant when we will deal with the unimodular transformations later). Simplicial algorithms are much more flexible with respect to starting conditions and this is precisely the reason why they deserve attention as a substitute for Pnueli's algorithm.

We now turn to the pivoting structure (see Fig. 2) (Comparing Fig. 1 and Fig. 2, one might prefer Pnueli's algorithm above the simplicial one; however, note the latter can start everywhere.)

**Simplicial Pivoting Algorithms for Integer Programming, Figure 2**

### A simplicial algorithm

The above construction of a path of neighboring simplices forms the basic idea of each simplicial algorithm. Again we emphasize that in arbitrary starting, variable dimension algorithms the construction is considerably more complicated. However sophisticated a simplicial algorithm may be, the ultimate goal is to create a sequence of almost solutions, thereby carefully avoiding *cycling*.

### Termination and Noncycling Arguments

An elegant feature of simplicial algorithms is that, if special care is taken in the construction of the sequence of simplices, cycling is impossible. Moreover, they are designed in such a way that they cannot tend to infinity without passing an upper or lower bound of the set  $S$ . This means that, as long as the algorithm runs, it creates new candidate solutions on every iteration. Using these arguments one can prove that

1) The algorithm reaches a recognizable lattice point (which can be an upper bound or a lower bound, depending on the starting position and the state of the algorithm) in which case  $S$  is proven not to contain any lattice point. The argument is similar but slightly more involved than in Case 1 to Pnueli's algorithm and was first used in [5]:

If  $\nu$  is a lattice point of  $S$  the set  $P_k(\nu)$  clearly does not contain points carrying label  $k$ . Therefore the algorithm cannot pass this set! In order to pass it, it would have needed *all* labels there to be present. As a consequence, the algorithm cannot pass from  $P(\nu)$  to a lower bound or vice versa, without hitting  $\nu$  or another solution. Hence it cannot run between an upper bound and a lower bound without hitting a solution when there is one.

- 2) The algorithm encounters a point carrying no label. If  $S$  is max-closed (see below) this must be a solution.

**Max-Closed Sets**

Following [15] a set  $S$  is called *max-closed* if it satisfies

$$x, y \in S \Rightarrow \max(x, y) \in S$$

where

$$\max(x, y) = (\max(x_1, y_1), \dots, \max(x_n, y_n)).$$

As one may verify, the following generalities are easily established:

- 1) Translations map max-closed sets to such sets.
- 2) Intersections of max-closed sets are max-closed.
- 3) Inequalities of the form  $x_i \leq \alpha_i$  and  $x_i \geq \beta_i$  define max-closed sets.
- 4) An inequality of the form

$$c_1x_1 + \dots + c_nx_n \leq c$$

defines a max-closed set whenever *at most one* of the  $c_i$  is positive. Special features around these kinds of inequalities in integer programming were already investigated in [1,11,12,17]. Of special interest are the inequalities of this type on two variables: They arise as integer programming reformulations of the *simultaneous Diophantine approximation problem* [14].

- 5) If  $f$  is a monotone increasing function in each of its variables, the set  $\{(x, z): f(x) \geq z\}$  is max-closed.
- 6) Max-closed sets need not be polyhedral, nor need they be convex. They need not even be connected!
- 7) A function  $g$  is called *max-closed* whenever it satisfies

$$g(\max(x, y)) \leq \max(g(x), g(y)).$$

Such functions define max-closed sets by the inequalities  $g(x) \leq \gamma$ .

- 8) A bounded max-closed set contains a *unique* coordinatewise maximum point, that is, a  $u$  with  $S \subset N(u)$ .

Based on the above properties it is seen that the following algorithm solves the integer feasibility program whenever  $S$  is defined by inequalities of the type mentioned in 4):

- 1  $\left| \max_{x \in S} \sum x_i.$
- 2  $\left| \text{If } x \text{ solves Step 1 let } u = \lfloor x \rfloor, \text{ the lattice point obtained by rounding the } x_i \text{ downwards.}$
- 3  $\left| \text{Let } S := S \cap N(u) \text{ and repeat.}$

The algorithm sketched above can be found in more or less comparable form in [1,11,17]. It only uses

$$\sum_{i=1}^n (u_i - \ell_i)$$

linear programs but it is subjected to the *recognition problem*: ‘Is a given set  $S$  definable by inequalities of the form mentioned in 4)? Or, more generally, is  $S$  max-closed?’

Our modified form presented earlier requires more linear programs to run, but it provides a correct answer whenever it has run without halting between an upper and lower bound, without having checked  $S$  first on max-closedness. In other words: it avoids the recognition problem.

Max-closed sets have an important analogue in the area of computational logic. There, so called *Horn formulas*, constituting the basics of data-base-reasoning, play an important algorithmic role. The reader familiar with Horn formulas shall certainly recognize property 4) above. Also, Pnueli’s algorithm in the form presented above recalls the *single-lookahead-unit-resolution* procedure. See [2,9,21]. V. Chandru and J.N. Hooker, using results of Chandrasekaran established this interesting link.

Resuming the results so far: Pnueli’s algorithm, or a simplicial substitute of it, conclusively answers the question whether a max-closed set  $S$  contains a lattice point. This is because of the following theorem.

**Theorem 1** *If  $S$  is max-closed, the only points carrying no label are the points of  $S$  itself.*

We emphasize that max-closedness is a sufficient condition for the above algorithms to run in a conclusive manner. But for these algorithms to run it is not a necessary one: they might even occasionally run conclusively (that is, never encountering a non labeled point which is not a solution) whenever  $S$  is not max-closed.

### Unimodular Max-Closed Form Transformations

Bounded linear integer programming should have turned out to be an easy job in case polyhedral sets would have been automatically max-closed. Unfortunately, this is not the case. An important result, however, is that simplices can be brought into max-closed form through a unimodular transformation [17]. This transformation can be found in a polynomial number of arithmetical operations. This is the more intriguing since the problem of finding a lattice point in a simplex (knapsack problem) is *NP*-complete. The breakdown of this transformation approach is that after transforming a simplex into max-closed form the number

$$\sum_{i=1}^n (u_i - l_i)$$

might grow exponentially with the dimension. For this reason, an arbitrary starting algorithm certainly is to be favored over one which has to start at an upper bound, at least in cases where solutions exist.

Transforming arbitrary polyhedral sets (unimodularly) into max-closed form is not possible. Therefore, simplicial methods clearly are *incomplete methods* when they are applied to arbitrary sets. They return no answer in case a point is encountered which carries no label and is not a solution, before they have entered the upper or lower bound area. As indicated earlier, vector labeling avoids this situation and simplicial methods using this kind of labeling keep running until either a solution is encountered or a specific region of interest is reached: a so called *twinplex* [15].

A twinplex consists of a simplex of the triangulated region which is very specific in the sense that the  $n + 1$  associated distance vectors point in all possible directions. To be precise, these  $n + 1$  vectors  $a_1, \dots, a_{n+1}$  satisfy

$$\sum_{i=1}^{n+1} \lambda_i a_i = 0$$

for a nontrivial  $\lambda \geq 0$ . Moreover, these vectors  $a_1, \dots, a_{n+1}$  determine  $n+1$  valid inequalities, each of which is violated by at least one of the vertices of the simplex involved. Intuitively, a twinplex is located where the set  $S$  is locally the fattest. Based on this intuition it is suggested in [15] to cut  $S$  at this place in two or more components, thereby creating a branching algorithm where

simplicial methods are incorporated. The various components are transformed then in a manner which make them more likely to be max-closed. Thus a branching tree is designed where tighter max-closed relaxations of the problem are solved with increasing depth.

Yet another possibility, when meeting a nonsolution point  $a$  without (integer) label is to go into a *recursion*: If  $S \cap N_k(a) \neq \phi$ , decrease dimension and find out whether  $S \cap N_k(a)$  contains a lattice point. If not,  $a$  can be assigned label  $k$  after all and the simplicial search continues again in full dimension. In this approach it is suggested to select an index  $k$  for the recursion which has a large effect on the non max-closedness of the problem. For example, if  $S$  is polyhedral, one selects an index  $k$  which appears most often with a nonnegative coefficient. Exploiting twinplexes and incorporating simplicial algorithms in branch and bound search trees is still an area under investigation. In the *satisfiability* area, however, branching algorithms which tend to create Horn-like subproblems with increasing depth have been studied with success.

Optimization; Approximation algorithms

For  $NP$ -hard optimization problems, the use of exact algorithms for the evaluation of the optimal solution is computationally intensive requiring an effort that increases exponentially with the size of the problem. In practice, exact algorithms are used for solv-

ing only moderately sized problem instances. This results in the development of heuristic optimization techniques which provide good quality solutions in a reasonable amount of computational time. One such popular technique is simulated annealing (SA) which has been widely applied in both discrete and continuous optimization problems ([1,4]). SA is a *stochastic search method* modeled according to the physical annealing process which is found in the field of thermodynamics. *Annealing* refers to the process of a thermal system initially melting at high temperature and then cooling slowly by lowering the temperature until it reaches a stable state (*ground state*), in which the system has its lowest energy. S. Kirkpatrick, C.D. Gelatt and M.P. Vecchi [7] initially proposed an effective connection between simulated annealing and combinatorial optimization (cf. ► **Evolutionary algorithms in combinatorial optimization**), based on the original work in [9].

The main advantage of the SA algorithm is its ability to escape from local optima by using a mechanism which allows deterioration in the objective function value (OFV). That is, in the optimization process SA accepts not only better than previous solutions, but also worse quality solutions controlled probabilistically through the temperature parameter  $T$ . More particularly, in the first stages of SA where  $T$  is relatively high, the search of the solution space is widely ‘explored’ so that different solution directions are identified, and often ‘bad’ solutions are accepted with high probability. During the course of the algorithm the temperature  $T$  decreases in order to steadily reduce the probability  $P$  of accepting solutions that lead to worse objective function values. With the allowance of controlled ‘uphill’ movements one can avoid the entrapment to local optima and, eventually, higher quality solutions can be obtained.

There are many factors that have a strong impact on the performance of the SA algorithm:

- The *initial temperature*  $T_1$ . A high value of  $T_1$  means that the probability  $P$  of accepting inferior solutions is also high, leading to a diversified search in the first iterations of the algorithm. With low values of the initial temperature the search becomes more localized.
- The *thermal equilibrium*. This is the condition in which further improvement in the solution cannot be expected with high probability.
- The *annealing schedule*, which determines in what point of the algorithm and by how much the temperature  $T$  is to be reduced.

Now consider a minimization process. Let  $\Delta E$  denote the change of the OFV between the current state and the state under consideration that occurs as  $T$  decreases. This change corresponds to the change in the energy level in the analogy with physical annealing. Then the probability  $P$  of accepting a worse quality solution is equal to  $e^{-\Delta E/(k_B T)}$ , where  $k_B$  is the *Boltzmann constant*. Simulated annealing is presented below in pseudocode:

```

PROCEDURE simulated annealing()
  InputInstance();
  Generate randomly an initial solution;
  initialize  $T$ ;
  DO  $T > 0$ 
    DO thermal equilibrium not reached →
      Generate a neighbor state randomly;
      evaluate  $\Delta E$ ;
      update current state
      IF  $\Delta E < 0$  with new state;
      IF  $\Delta E \geq 0$  with new state with probability  $e^{-\Delta E/(k_B T)}$ ;
    OD;
  Decrease  $T$  using annealing schedule;
  OD;
  RETURN (solution with the lowest energy)
END simulated annealing;

```

#### A pseudocode for simulated annealing procedure

The following example (the *quadratic assignment problem*, QAP) illustrates the basic principles of SA in combinatorial optimization. The QAP is defined as follows.

Given a set  $N = \{1, \dots, n\}$  and two  $(n \times n)$  matrices  $F = (f_{ij})$  and  $D = (d_{ki})$ , find a permutation  $p$  of the set  $N$  that minimizes the following function:

$$\sum_{i=1}^n \sum_{j=1}^n f_{ij} d_{p(i)p(j)}.$$

In the context of location theory one uses the QAP formulation to model the problem of allocating  $n$  facilities to  $n$  locations with the objective to minimize the cost

associated not only with the distance between locations but also with the flow.  $F$  and  $D$  correspond to the flow and distance matrices respectively [11].

Let  $T_i$  represent the temperature at stage  $i$  of the procedure and  $T_1 > \dots > T_f$  represent the annealing schedule. Then the application of SA to the QAP ([2,12]) can be described with the following steps:

- Start with a feasible solution (permutation). Make an exchange between two randomly selected permutation elements (2-exchange). Evaluate the consequent change  $\Delta E$ .
- While  $\Delta E < 0$  repeat the above step. If  $\Delta E \geq 0$  then randomly select a variable  $x$  from a *uniform distribution*  $U(0, 1)$ . Accept the pair exchange if  $x < P(\Delta E) = e^{-\frac{\Delta E}{T_i}}$ , and repeat the process.
- The system remains at stage  $i$  until a fixed number of pair exchanges (equilibrium) has taken place before going to the next stage.
- The procedure stops when all the temperatures in the annealing schedule have been used, i. e. when  $i > f$ .

Simulated annealing has been used to solve a wide variety of combinatorial optimization problems, such as graph partitioning and graph coloring ([5,6]), VLSI design [7], quadratic assignment problems [2], image processing [3] and many others. In addition, implementations of SA in parallel environments have recently appeared, with applications in cell placement problems, traveling salesman problems, quadratic assignment problems, and others [10]. General references on simulated annealing can be found in [1] and in [8].

Molecular optimization; Protein folding

Proteins are essential molecules for the functioning of biological systems. They are linear polymers, with the monomeric units drawn from a set of 20 amino-acids. The number of amino-acids in a protein ranges from tens to thousands. In their biologically active state, *proteins* assume, out of the immense number of possible configurations, a unique state, the so-called native state. How the protein chain folds into this native state is the essence of the *protein folding* problem. Leaving aside the actual kinetics of the folding process, of great interest and pragmatic value is even the prediction, by any means, of the three-dimensional structure from the knowledge of only the sequence of amino-acids and the potential of interaction between the atoms in the amino-acids.

If one adopts as a working hypothesis that the native state is that which minimizes the protein's potential energy, then the above prediction now reduces, given a potential energy as a function of the positions of the atoms in the protein, to an *optimization* problem. This has been a view which has been advocated by H.A. Scheraga as the *ab initio* solution of the protein structure prediction problem [7].

How can one estimate the potential energy, which will serve as the objective function in the optimization procedure? Commonly used *empirical potentials* for proteins [5] usually have the form

$$\begin{aligned}
 U(\mathbf{r}^N) &= \sum_{\text{pairs}} \frac{1}{2} k_b (b - b_0)^2 + \sum_{\text{bond angles}} \frac{1}{2} k_\theta (\theta - \theta_0)^2 \\
 &+ \sum_{\text{dihedral angles}} k_\phi [1 + \cos(n\phi - \delta)] \\
 &+ \sum_{\text{nonbonded pairs } i,j} 4\epsilon_{ij} \left[ \left( \frac{\sigma_{ij}}{r} \right)^{12} - \left( \frac{\sigma_{ij}}{r} \right)^6 \right] \\
 &+ \sum_{\text{nonbonded pairs } i,j} \frac{q_i q_j}{\epsilon r}.
 \end{aligned}$$

The potential energy  $U(\mathbf{r}^N)$  of a protein with  $N$  atoms having a certain configuration  $\mathbf{r}^N$  in the  $3N$ -dimensional configuration space is modeled by harmonic bond terms with force constant  $k_b$  and bond length  $b$ , bond angle terms with force constant  $k_\theta$ , dihedral angle terms with force constant  $k_\phi$ , multiplicity  $n$  and phase  $\delta$ , van der Waals terms of the Lennard-Jones type with parameters  $\sigma_{ij}$  and  $\epsilon_{ij}$ , and Coulombic terms, with  $q_i$  the

charges and  $\epsilon$  the dielectric constant. The exact value of the parameters will depend on the identity of the participating atoms.

Several related physical problems have been shown to suffer from *NP-hardness*, i. e., to find their optimal solution, a search algorithm requires a simulation time which scales with the size of the system faster than any polynomial function. Among them are the ground state determination of atomic clusters [24] or various spin glass models [4]; demonstrations that the protein folding problem is *NP-hard* have also been given [13].

Since the problem is *NP-hard*, *heuristic algorithms* must be sought for its solution. From the variety of approaches developed (for a review see [20]), we focus on the method of *simulated annealing* [9] as applied to proteins. It has an obvious and physically interpretable application. Once a cooling schedule is chosen, representative configurations of the allowed micro-states are generated by methods either of the *molecular dynamics* (MD) or *Monte-Carlo* (MC) type [6]. For proteins, simulated annealing is traditionally built on an MD approach where the dynamics of the system is simulated by integrating the Newtonian equations of motion and the temperature is controlled through some form of coupling to a heat-bath. If the MC approach is used, after having drawn a new configuration, it is accepted or rejected according to an updating probability of, for example, the Metropolis type [12]

$$p = \min [1, \exp(-\beta \Delta V)], \quad (1)$$

where  $\beta = 1/kT$  and  $\Delta V$  is the change in potential energy. This acceptance probability has the desirable features that

- i) it obeys detailed balance; and
- ii) it reduces to a steepest descent minimizer at low temperature (where only moves which decrease the potential energy are accepted).

In addition to the standard Metropolis Monte-Carlo protocol, several other smarter MC algorithms have been designed, based on atomic moves biased by the forces acting upon the atoms in the molecule [16,18].

Substantial improvements to the method of simulated annealing can be obtained by propagating not just one phase point through configuration space, but a whole distribution of points. In the method titled *Gaussian density annealing* [11], the probability den-

sity is approximated by a single Gaussian distribution which is a product of the individual distributions for each atom. This Gaussian distribution is propagated as the temperature decreases according to the Bloch equation, and the dependence of the first two moments of the distribution (i.e., measures of its center position and of its width) is followed as a function of the inverse temperature.

With  $\mathbf{r}$  the  $d$ -dimensional vector of Gaussian random variables, the multivariate probability density function in the spherically symmetric case has the form

$$\rho(\mathbf{r}, \beta) = (2\pi\sigma^2)^{-\frac{d}{2}} e^{-\frac{(\mathbf{r}-\mathbf{r}_0)^2}{4\sigma^2}},$$

where the center of the packet is at  $\mathbf{r}_0$ , and the second moment is  $M_2 = d\sigma^2$ . For many degrees of freedom, the many body density distribution can be approximated as a product of single body density distributions, each with its own center and variance.

The differential equations describing the evolution explicitly in the inverse temperature, obtained from the reduced Bloch equation, are found to be

$$\frac{d\mathbf{r}_0}{d\beta} = -\frac{1}{d}M_2\nabla_{\mathbf{r}_0}\langle U \rangle, \tag{2}$$

$$\frac{dM_2}{d\beta} = -\frac{1}{d^2}M_2^2\nabla_{\mathbf{r}_0}^2\langle U \rangle, \tag{3}$$

where  $\langle U \rangle$  is the potential energy averaged by weighting with the Gaussian probability density. Note that the center  $\mathbf{r}_0$  moves in a steepest descent on the effective potential  $\langle U \rangle$  while the width of the distribution adjusts to the curvature of the effective potential.

A variant of the Gaussian density annealing has been applied by C. Tsou and C.L. Brooks [23], for the study of optimization of water clusters. The popular diffusion equation method of Scheraga and coworkers [10] exists as a special case of the Gaussian density annealing method when all Gaussian packets are characterized by the same variance.

Of particular interest and promise are two related methods. The first is the elegant packet annealing method of D. Shalloway and coworkers [15] of which the Gaussian density annealing method can be shown to be a special case. The second is the locally enhanced sampling (LES) method of R. Elber and coworkers [17]. The LES method has been applied to complex systems such as solvated peptides with excellent results. It

has the additional advantage that it is relatively simple to implement. These and other related methods have recently been reviewed [20].

The *potential smoothing algorithms* based on a Gaussian smoothing transform of the potential energy surface are quite effective for a large number of systems. For a complicated biomolecular potential energy surface it is possible to carry out the smoothing transformation approximately by fitting the nonbonded potential functions to Gaussians or exponentials. However, there is computational overhead associated with computing these transformed functions. It has recently been shown that it is possible to derive all the benefits of the Gaussian smoothing transform while carrying out no explicit transform of the potential energy function. The method substitutes a ‘top hat’ (impulse) function for the Gaussian in the smoothing transform. In one dimension the result is that the force on the smoothed potential is simply the difference in the potential energy evaluated at each side of the top hat divided by twice the top hat’s width – that is, a finite difference formula for the force. Since the width of the smoothing function is not always small, this exact force derived for the smoothed potential can be thought of as a ‘bad derivative’. Most significantly, it is possible to use this method to smooth the Boltzmann probability distribution function. This approach is similar in spirit to the packet annealing algorithm of Shalloway and coworkers, which involves a Gaussian smoothing of the Boltzmann distribution [15]. However, the *method of bad derivatives* requires no explicit integral transform. The method was applied to isolate low lying energy minima for a small peptide with excellent results demonstrating the superiority of the method to standard Gaussian smoothing algorithms [3].

Other recent improvements of the simulated annealing method include the use of the *Tsallis probability distributions* [19]. In the Tsallis formalism, a generalized statistics is built from the generalized entropy

$$S_q = k \frac{1 - \sum p_i^q}{q - 1}, \tag{4}$$

where  $q$  is a real number and  $S_q$  tends to the information entropy

$$S = -k \sum p_i \ln p_i \tag{5}$$

when  $q \rightarrow 1$ . By means of maximizing the Tsallis entropy with the constraints

$$\sum p_i = 1 \quad \text{and} \quad \sum p_i^q \epsilon_i = \text{const},$$

where  $\epsilon_i$  is the energy spectrum, the generalized probability distribution is found to be

$$p_i = \frac{[1 - (1 - q)\beta\epsilon_i]}{Z_q}, \quad (6)$$

where  $Z_q$  is the generalized partition function. This distribution goes to the Gibbs–Boltzmann distribution when  $q$  tends to 1. But for  $q \neq 1$ , the probability distributions have power-law tails, and are thus broader than the Gibbs–Boltzmann distributions. This delocalization of the distribution is the essential feature that allows more ample exploration of the configuration space and faster cooling schedules.

A typical implementation of a generalized simulated annealing algorithm has been proposed by I. Andricioaei and J. Straub [2] (for a variety of MD and MC based sampling algorithms of the Tsallis class, see [21]) and has the following structure:

- 1) generate trial moves by the method of choice;
- 2) accept trial moves with probability

$$p = \min \left[ 1, \left( \frac{1 - (1 - q(T))\beta E_{\text{new}}}{1 - (1 - q(T))\beta E_{\text{old}}} \right)^{\frac{q(T)}{1 - q(T)}} \right] \quad (7)$$

that obeys detailed balance;

- 3) reduce the temperature and reduce  $q$  such that  $\lim_{T \rightarrow 0} q(T) = 1$  and go to 1).

At constant temperature, the sampling converges towards the Tsallis equilibrium probability distribution in (6). As temperature decreases, the parameter  $q$  is varied as a monotonically decreasing function of temperature. The steepest descent behavior is imposed by starting with a convenient value of  $q$  at the initial temperature and by having  $q$  tend towards 1 as the temperature decreases during the annealing schedule. Since  $q \rightarrow 1$  at low  $T$ , the desirable reduction to a steepest descent at low temperature is preserved.

Interestingly enough, it was shown [1], that when the maximum entropy formalism is applied to the entropy postulated by Tsallis (4) one is able to recover the more general *Levy probability distributions* (corresponding to fractal random walk, the dimension of

which is determined by  $q$ ), which a variational entropic formalism based on the Boltzmann entropy is unable to do. At initial values of  $q(T) > 1$ , a Markov chain generated at the initial temperatures would converge towards a Levy distribution. For example, in the particular case of  $q = 2$  and a harmonic potential, the Levy distribution is a Cauchy–Lorentz distribution which is the same distribution used for trial moves in the fast simulated annealing method of H. Szu and R. Hartley [22].

Of importance is to study how does the simulated annealing time depend on the features of the potential energy surface of the proteins. One can derive a simple scaling relation for the optimal cooling schedule in a simulated annealing optimization protocol. The relevant energy scales of  $U(\mathbf{r}^N)$  are  $\Delta U$ , the difference in energy between the ground and first excited state minima, and  $U^\ddagger$ , the highest barrier on the potential surface accessed from the global energy minimum. The final temperature reached in a simulated annealing run must be small enough so that at equilibrium the mole fraction in the global energy minimum basin is significant.

The time that the trajectory must spend at the lowest temperature to ensure that the equilibrium distribution is sampled is at least  $\tau_{\text{min}}$ , the time required to surmount the largest barrier separating the global energy minimum from other thermodynamically important states, which can be shown to go as

$$\tau_{\text{min}} \sim \left( \frac{U^\ddagger}{\Delta U} \right)^{\frac{q}{q-1}}.$$

In the limit  $q \rightarrow 1$  of Gibbs–Boltzmann statistics, one finds that

$$\tau_{\text{min}} \sim e^{\frac{U^\ddagger}{\Delta U}}.$$

The time for classical simulated annealing increases exponentially as a function of the ratio of the energy scales  $U^\ddagger/\Delta U$ . However, for  $q > 1$  the situation is qualitatively different. As a result of the weak temperature dependence in the barrier crossing times, the time for simulated annealing increases only weakly as a power law [21]. Given the large separation in energy scales on the potential energy surface of proteins, and the large value of  $U^\ddagger/\Delta U$ , the generalized simulated annealing is expected to be well suited for problems of global optimization as one encounters in protein folding.

The algorithm based on the generalized Tsallis probability distribution has been recently adopted and employed for proteins by U.H.E. Hansmann and Y. Okamoto [8]; see [14] for a review of other generalized ensembles as applied to the protein folding problem.

### Introduction

In applied work, there is often no a priori unique functional form and parametrization for models of empirical processes, nor are there generally accepted ones. For many empirical processes the functional form and the parameters of the system are not known and must be estimated from the data and the optimal control derived [10].

The model of a phenomenon must consider suitable functional forms for the merit function and for the constraints, and determine suitable parameters for these and suitable inputs of the control variables to obtain a specified set of output variables which will render the merit function a minimum (maximum), possibly global. Since the estimation problem is usually posed as an unconstrained optimization problem and determining the optimal control is an optimization problem, two optimization problems must be solved.

Except for simple model categories, interactions occur between the estimation space, where the values of the variables are determined, and the control space, where the optimal control is derived [7], so there is a variational aspect with regard to the optimal control to be analyzed. To avoid severe suboptimization all the unknowns must be determined at the same time, by solving a single more general optimization problem.

To achieve an efficient control of an empirical process, a mathematical programming problem must be solved simultaneously in the estimation and control spaces, to determine a sufficiently accurate estimate of the functional, form and the parameters and the least-cost solution of the optimal control problem.

Statistical conditions have been studied [19], and empirical aspects of the approach have been considered [2,3].

### Definitions

To control phenomena of any type [10], including problems of pathological conditions [3], a set of decisions regarding what are the best actions for their control, so as to render optimal the merit function, are considered. Three approaches can be indicated by which the problem could be specified and solved:

1. Ad hoc methods may be used, such as calibration, simulation, experience or intuition, which are limited and may lead to wrong formulations of the problem.
2. The classic three-stage approach: determine the model to implement, estimate the parameters of the form adopted and then solve the quantified optimization problem.
3. Solve the estimation and the optimization problem simultaneously [19].

Whatever the approach, it must be ensured that the estimation of the functional forms and the parameters satisfies the following statistical properties to ensure that the estimates are the best, correct and consistent ones that can be formulated. Statistical estimation methods are important, because, when implemented correctly, with regard to an accurately specified functional form, they will provide estimates of parameters that have the following properties [1,15]:

1. The parameter estimates are unbiased:
  - As the size of the data set grows larger, the estimated parameters tend to their true values.
2. The parameter estimates are consistent, which then will satisfy the following conditions:
  - The estimated parameters are asymptotically unbiased.
  - The variance of the parameter estimate must tend to zero as the data set tends to infinity.
3. The parameter estimates are asymptotically efficient:
  - The estimated parameters are consistent.
  - The estimated parameters have smaller asymptotic variance compared with any other consistent estimator.
4. The residuals have minimum variance, which is ensured by:
  - The variance of the residuals must be a minimum.
  - The residuals must be homoscedastic.
  - The residuals must not be serially correlated.
5. The residuals are unbiased (have zero mean).
6. The residuals have a noninformative distribution (usually, a Gaussian distribution).
  - If the distribution of the residuals is informative, the extra information could somehow be obtained, reducing the variance of the residuals, their bias, etc. with the result that better estimates are obtained.

Through a correct implementation of statistical estimation techniques the estimates are as close as possible to their true values, all the information that is available is applied and the uncertainty surrounding the estimates and the data fit is reduced to the maximum extent possible. Thus, the estimates of the parameters, which satisfy all these conditions, are the “best” possible in a “technical sense” [1].

### Definition and Properties of the Traditional Estimation Approach

The estimation and optimization of an empirical model by the traditional three-stage statistical method [20] considers:

- A functional form is posited and an error structure for the residuals is assumed.
- Under these hypotheses a data set is used to determine the values of the parameters, by solving an unconstrained optimization problem and then the estimates determined are checked to verify that they satisfy the properties indicated above [13,1]. If this is so, it is possible to proceed to the next stage, otherwise a new functional form must be specified and a new unconstrained optimization problem must be solved.
- An optimization problem is solved in the space of the control variables, to determine the optimal policy.

With regard to empirical processes, which require the estimation of nonlinear models, there may be many alternative models to represent the behavior of a phenomenon [4]. Therefore the efficacy of the control policy to be adopted will depend on which of the alternative models is chosen and how the parameter values and the functional form are selected [12]. This leads to a number of problems in applications:

- For nonlinear and dynamic estimation problems, the likelihood function to be maximized is usually not concave, so there are many local maxima, each leading to a different set of estimation coefficients. Determining the global maximum of the function may not be helpful.
- Certain statistical properties must be satisfied to ensure a statistically correct estimate. Such conditions may hold at some local maxima, but not at others. There is no assurance that the global maximum, even if unique, will satisfy these conditions; thus, all local maxima must be verified.
- Since there may be many alternative models, the model chosen may not have a different optimal control policy, or the optimization may not yield the best policy for the possible parametrization, while other candidate models could satisfy both criteria.

For estimation problems linear in the parameters, the whole process is simplified. In general, however, the

stages of such a procedure are interrelated and so enumerative solution techniques over all stationary points must be adopted, providing serious limitations to this approach.

### The Simultaneous Estimation and Optimization Approach

It would appear more plausible, to avoid suboptimization and to balance the eventual imprecision, to solve both problems simultaneously, imposing the statistical conditions that must be satisfied as constraints [19].

Let the data set of a phenomenon consist of sufficient measurements  $(y_n, x_n, u_n)$  over  $(n = 1, 2, \dots, N)$  periods, where it is assumed, that  $y_n \in R^p$  is a  $p$ -dimensional vector to be explained, while  $x_n \in R^r$  is an  $r$ -dimensional vector of explanatory or state variables of the dynamic process and  $u_n$  is a  $q$ -dimensional vector of control variables and a horizon  $\mathcal{T}$  is indicated, over which the merit function must be optimized and the control variables must be determined. Thus, the whole period considered is composed of a historical period  $\{1, 2, \dots, N\}$  and a future period for which policy must be determined, given by  $\{N + 1, N + 2, \dots, \mathcal{T}\}$ . Further, let  $w_i \in R^r$  and  $v_i \in R^p$  be random variables to be determined with mean zero and finite variance.

It is desired to determine functional forms  $\varphi: R^{r+q} \rightarrow R^r$  and  $\eta: R^{r+1} \rightarrow R^p$  and a set of suitable coefficients  $\Theta \in R^m$  such that

$$\text{Min } J = \sum_{i=N+1}^{\mathcal{T}} c(x_i, u_i, y_i), \quad (1)$$

$$x_{i+1} = \varphi(x_i, u_i, y_i, w_i; \theta_1) \quad i = 1, 2, \dots, \mathcal{T}, \quad (2)$$

$$y_{i+1} = \eta(x_i, u_i, v_i; \theta_2) \quad i = 1, 2, \dots, \mathcal{T}. \quad (3)$$

Equation (1) is the objective function for the model and (2) and (3) are the state space formulation of the problem, while a similar representation may be adopted for the input-output formulation, [14]. To ensure that all the statistical properties that the given estimates of the residuals must fulfill are satisfied at every iteration, instead of solving an unconstrained maximum-likelihood or least-squares problem [13], the required statistical properties of the estimates are set up as constraints, together with the specification of the model of the phenomenon and this global optimization problem is solved for all the undetermined variables.

### Formulation

A phenomenon can be represented by a model which will capture all the prescribed input-output relations, at a preset level of precision. Suppose that it is desired to determine an optimal control for the system (1)–(3) over a given period  $i = N + 1, \dots, \mathcal{T} - 1$  based on a historical period  $i = 1, 2, \dots, N$  for which a suitable data set is given.

To achieve this, a set of constraints must be added to enforce that the parameter values that will be estimated have the required properties.

The unknowns to be determined are the input and output variables considered and the parameters of the functional form specified in the current iteration, indicated as  $\Theta = \{\theta_1, \theta_2\} \subset R^m$ . Note that  $m$  may be much larger than  $2r + q + p + 1$ , the number of variables present in each system, since the system is nonlinear.

The mathematical program is formulated with respect to the residual variables, but it is immediate that for a given functional form the unknown parameters will be specified and thus the unknowns of the problem will also be defined and available. Hence, the mathematical program is fully specified for each functional form to be considered, as the residual terms can be stated so:

$$w_i = \hat{x}_{i+1} - \varphi_h(\hat{x}_i, \hat{u}_i, \hat{y}_i; \theta_1) \quad i = 1, 2, \dots, N, \\ h \in \mathcal{H} \quad (4)$$

$$v_i = \hat{y}_{i+1} - \eta_k(x_i, u_i, v_i; \theta_2) \quad i = 1, 2, \dots, N, \\ k \in \mathcal{K} \quad (5)$$

where  $\hat{\cdot}$ , as usual indicates the historical values of a variable and thus suitable values of  $\theta_1, \theta_2$  must be determined by the mathematical program, such that all the constraints expressed in terms of  $w_i, v_i \forall i$  are specified and  $\mathcal{H}, \mathcal{K}$  are suitable function spaces.

The mathematical programming problem, in the notation defined above in “Definitions,” to be solved for each functional form in the given sets, with a suitable optimization routine, is the following:

$$\text{Min } J = \sum_{i=N+1}^{\mathcal{T}} c(x_i, u_i, y_i), \quad (6)$$

$$x_{i+1} = \varphi(x_i, u_i, y_i, w_i; \theta_1), \quad (7)$$

$$y_{i+1} = \eta(x_i, u_i, v_i; \theta_2),$$

$$\frac{1}{N} \sum_{i=1}^N w_i = 0,$$

$$\frac{1}{N} \sum_{i=1}^N v_i = 0,$$

$$\frac{1}{N} \sum_{i=1}^N w_i^2 \leq k_w,$$

$$\frac{1}{N} \sum_{i=1}^N v_i^2 \leq k_v,$$

$$-\epsilon_0 \leq \frac{1}{N} \sum_{i=1}^N v_i w_i \leq \epsilon_0,$$

$$-\epsilon_1 \leq \frac{1}{N} \sum_{i=1}^N w_i w_{i-1} \leq \epsilon_1,$$

$$-\epsilon_2 \leq \frac{1}{N} \sum_{i=1}^N v_i v_{i-1} \leq \epsilon_2,$$

$$-\epsilon_3 \leq \frac{1}{N} \sum_{i=1}^N v_i w_{i-1} \leq \epsilon_3,$$

$$-\epsilon_4 \leq \frac{1}{N} \sum_{i=1}^N w_i v_{i-1} \leq \epsilon_4,$$

.....

$$-\epsilon_{2s} \leq \frac{1}{N} \sum_{i=1}^N v_{i-s} w_{i-s} \leq \epsilon_{2s},$$

$$-\epsilon_{2s+1} \leq \frac{1}{N} \sum_{i=1}^N w_i w_{i-s} \leq \epsilon_{2s+1},$$

$$-\epsilon_{2s+2} \leq \frac{1}{N} \sum_{i=1}^N v_i v_{i-s} \leq \epsilon_{2s+2},$$

$$-\epsilon_{2s+3} \leq \frac{1}{N} \sum_{i=1}^N v_i w_{i-s} \leq \epsilon_{2s+3},$$

$$-\epsilon_{2s+4} \leq \frac{1}{N} \sum_{i=1}^N w_i v_{i-s} \leq \epsilon_{2s+4},$$

$$\frac{1}{2} g_w^T \Psi (\Psi^T \Psi)^{-1} \Psi^T g_w - \frac{N}{2} \leq \chi_{1-\alpha; p-1}^2,$$

$$\frac{1}{2} g_v^T \Psi (\Psi^T \Psi)^{-1} \Psi^T g_v - \frac{N}{2} \leq \chi_{1-\alpha; p-1}^2,$$

$$-\epsilon_{2r+1} \leq \frac{1}{N} \sum_{i=1}^N w_i^{2r+1} \leq \epsilon_{2r+1} r = 3, 4, \dots,$$

$$\frac{1}{N} \sum_{i=1}^N w_i^{2r} \leq \frac{2r!}{r!2^r} \sigma_w^{2r} r = 3, 4, \dots,$$

$$-\epsilon_{2r+1} \leq \frac{1}{N} \sum_{i=1}^N v_i^{2r+1} \leq \epsilon_{2r+1} r = 3, 4, \dots,$$

$$\frac{1}{N} \sum_{i=1}^N v_i^{2r} \leq \frac{2r!}{r!2^r} \sigma_v^{2r} r = 3, 4, \dots,$$

$$x_i \in X, y_i \in Y, u_i \in U, w_i \in W, v_i \in V.$$

The abstract model of the dynamical system Eqs. (1)–(3) given by the system of Eqs. (7) and (8) is to be optimized with regard to a given merit function Eq. (6) subject to the means of the residuals that should be zero Eqs. (19), (10), and the sum of squares of the residuals should be less than critical values  $k_w, k_v$  Eqs. (11), (12), which can be decreased by dichotomous search at every iteration, until the problem does not yield a feasible solution.

The least values obtained for these parameters, while retaining a feasible solution to the whole problem, are equivalent to a minimization of the statistical estimation error and of a maximization of the maximum likelihood, under appropriate distributional assumptions concerning the residuals.

Further, all the serial correlations between the residual must not be significantly different from zero, as enforced by constraints Eqs. (13)–(23).

To ensure that these conditions hold throughout the possible variation of the independent variables, the residuals must be homoscedastic and thus satisfy Eqs. (23) and (24).

The homoscedasticity condition on the residuals is obtained by regressing the original variables of the problem, indicated by the data matrix  $\Psi$ , on the normalized square of the residuals, which are indicated, respectively, by  $g_w, g_v$ . This leads to a set of nonlinear equations in the squared residuals to be determined. The  $\chi^2$  test is applied at a confidence level of  $(1 - \alpha)$  with  $m - 1$  degrees of freedom and a significance level of  $\alpha$  [6].

Constraints Eqs. (25)–(28) are sample moments of the probability distribution function of the residuals which are made to assume given values in terms of the variance  $\sigma^2$  and its higher powers. These constraints enforce the residuals to have a noninformative distribution, here a Gaussian.

This constrained minimization problem Eqs. (6)–(29) will dominate the solutions obtainable by the traditional three-phase procedure, since whenever the latter has a solution, the new procedure will also have a solution.

**Theorem 1** *Let the given optimal control problem as described in Eqs. (1)–(3) have a unique solution and let all the statistical conditions indicated above hold, so that the solution of the maximum-likelihood estimate of the unconstrained problem is well defined. Then, the solution of optimal control problem Eqs. (1)–(3) will be equal to the solution of the constrained optimization problem Eqs. (6)–(29).*

## Methods and Applications

Nonlinear optimization routines which use line search methods may cause difficulties, since some of the constraints may be highly nonlinear, so trust region methods may be better.

A specialized technique based on complementarity theory is used to actually solve this problem.

Consider the following optimization problem which represents in summary form the problem Eqs. (6)–(29).

$$\text{Min } Z = f(w) \quad f: R^n \rightarrow R, \quad (30)$$

$$g(w) \geq 0 \quad g: R^n \rightarrow R^p, \quad (31)$$

$$h(w) = 0 \quad h: R^n \rightarrow R^q. \quad (32)$$

The proposed algorithm consists in defining a quadratic approximation to the objective function, a linear approximation to the constraints and determining a critical point of the approximation by solving a linear complementarity problem, as given in [18].

Expanding the functions in a Taylor series, at the given iteration point  $w^k$ , one may eliminate the equality constraints simply by converting them into  $p + 1$  inequality constraints. Thus,

$$h(w) = h(w^k) + \nabla h(w^k)(w - w^k) \geq 0, \quad (33)$$

$$-e_q^T h(w) = -e_q^T (h(w^k) + \nabla h(w^k)(w - w^k)) \geq 0. \quad (34)$$

Unconstrained variables must be transformed into nonnegative variables for the linear complementarity

problem (LCP) algorithm. So let

$$\zeta = \text{Inf}\{w_i \mid w_i \in \{g(w) \geq 0, h(w) = 0\}\} \quad (35)$$

where  $\zeta$  is a suitable lower bound to the unrestricted variables, which will be expressed as

$$x_i = w_i - \zeta \geq 0. \quad (36)$$

Should there be no lower bound specifiable for a variable, then as it is well known, the variable can be represented as the difference of two nonnegative variables.

A set of trust region constraints can be imposed on the problem as a system of linear inequalities centered around the iteration point, to limit the change in the possible solution. Note that such a set of inequalities has properties quite different from those of the usual trust region constraint imposed in nonlinear optimization [8]:

$$Dx + d \geq 0 \quad (37)$$

where  $D \in R^{n \times n}$  is a suitable matrix which may be changed at every iteration and  $d \in R^n$  a suitable vector. These can be included in the inequalities.

The resulting quadratic problem is easily transformed into a linear complementarity problem, which can be solved by linear programming routines [18]. A new solution point will always exist whenever the trust region is included in the problem, and will lie either inside the trust region or on a trust region constraint.

Whenever this point occurs inside the trust region, it is an approximate stationary point. If the solution point occurs on a trust region constraint and the solution is feasible while a reduction in the objective function has occurred, the solution point is taken as the new starting point and a new iteration is started. Otherwise, if the new point is infeasible, the trust region is reduced. Finally, if there has been an increase in the objective function, the trust region is enlarged and the iteration is repeated, with suitable safeguards to provoke a reduction in the objective function.

If the objective function is bounded for all values of the variables which satisfy the constraints, then a local minimum point will be found. Thus, the convergence of the algorithm can be proved without difficulty by standard techniques [19].

**Models**

The data sets of empirical processes of phenomena may be of various types, such as dynamic, cross-sectional or both cross-sectional and dynamic, but the model is suitable and accurate for all types of models, replacing the dynamic model indicated in Eqs. (2) and (3) by an appropriate model of the phenomenon, suitable for the data available and the purposes of the application.

In Table 1 three well-known examples are indicated and their salient estimation characteristics are presented. The model for naphthalene arose in an investigation of the oxidation of naphthalene to phthalic anhydride [5,11]. The model fitted was a full quadratic cross-sectional model. As can be seen, the results for the two estimations are identical and all the statistical conditions are satisfied, so confirming Theorem 1.

The model for the tire composition studies the effect of three process variables. The data are very scanty, but the full quadratic model applied indicated that the model as a whole was significant, although the coefficients of the squared terms and the cross-product terms under the null hypothesis are not significant. Heteroscedasticity is found to be significant, by the appropriate test. Our algorithm indicates that lagged variables should be included and the estimates of such a model result have a very low residual.

The model specified for the Constant Elasticity of Substitution (CES) function in economics is a function which is nonlinear in the parameters although it can be

almost linearized by a logarithm transformation. Log transformations gave good results for traditional routines, while no transformations were required with this algorithm, which is a definite advantage.

Further computational experiments are given in Table 2 for some important chemical processes and similar results are reported. For example, in the chlorides experiment it is indicated that more variables are required by defining suitable cross products and lagged terms of the original set of variables.

In Table 3 a time series implementation is presented with a number of variants. The experiment is very well known and the original data were analyzed [9] and a polynomial model was fitted. A dynamic model with an exponential term was subsequently fitted [16,17] and autocorrelated terms were added to the series, in the third instance. Traditional techniques provide limited results, whereas this algorithm solves the problem well.

**Cases**

While in the previous section the application of various models was presented and the results were shown in all cases to be good, here we shall consider dynamic models with exogenous and endogenous variables and examine their performance.

Two general instances will be considered: financial prediction models and optimal control in drilling for oil.

**Financial Prediction**

A number of chronological series of quotations on various stock exchanges were gathered and it was attempted to make predictions one period ahead for the series. The series considered are:

1. The Standard and Poor 500 common stock index (SPX).
2. The Dow Jones Euro Stock Index, consisting of 50 stocks expressed in euros (SX5E).
3. The Nikkei 225 stock average (NKY).
4. US Government bonds 10-year index (USGG10YR).
5. The 10-year fixed US dollar fixed swap rate (USSWAP10).
6. German government bonds 10-year index (GDBR10).
7. Deutsche mark–euro exchange rate (DM-EUR).
8. Gold spot price (GOLDS).
9. Chicago Board Options Exchange: Volatility Index (VIX).
10. Reuters Jeffries CRB Futures Price Index (CRY).

The results of fitting suitable dynamical models to this data, available for over 12 years, are given in Table 4.

Notice how the estimation system (here there is no concurrent optimization system) through the specification of the constraints which impose the statistical properties on the estimates results in very precise predictions one period ahead.

**Simultaneous Estimation and Optimization of Nonlinear Problems, Table 4**

Results have also been obtained for predictions two periods ahead and up to five periods ahead with comparable results. Thus, this algorithm is extremely robust.

### Optimal Control in Drilling of Oil

Determining optimal control policies for petroleum drilling is a very interesting problem, since through the mudlogging data bases which are compiled for every well, the underlying empirical process can be studied in detail.

In Table 5 the actual time series of the drilling process is compared with the best predictions obtained from an endogenous model for each process. The best model indicated a differing number of endogenous variables, but for all 16 processes the model with five lags was the most accurate.

The determination of optimal control policies in processes for the extraction of oil from underground sources requires that they be formulated as formal procedures. In each process during 1 week, the original mudlogging data set was resampled every 30 elementary periods, which were of 5 s, so the fundamental period considered was 150 s.

The period over which to determine the optimal controls was chosen to be 192 periods, or 8 h, while the historical period was relatively long. The results are shown in Table 6, in which the optimal increment determined on the basis of this algorithm with a closed-loop policy is compared with what actually happened.

In Table 6 the six instances determining optimal controls are indicated and each entry is concerned with the drilling experience of the given well for that week with regard to the given period. From the active perforation intervals an initial period was selected randomly and the optimal control was defined for the next 192 periods (8 h). The average predicted increment over the actual increment was more than 30%.

### Conclusions

Simultaneous estimation and optimization provides very robust and versatile algorithms for nonlinear estimation and optimization of all types of empirical data sets. Here a more complex unique optimization problem was used instead of a succession of optimization problems, the first being unconstrained and the second being a constrained decision or allocation optimization problem.

This approach always imposes the satisfaction of the required statistical properties, so as to ensure that at every iteration a statistically correct solution is determined for that functional form. By iterating on the functional forms and on the specification of the problem, one will always obtain better solutions, until a lower bound is reached.

The lower bound indicates the pure noise of the empirical process, but as can be seen it is usually much lower than the noise components determined by traditional methods.

**Simultaneous Estimation and Optimization of Nonlinear Problems, Table 6**

Optimal predicted versus actual increment for six oil wells over 192 periods (8 h)

Well and week	Optimal increment	Real increment	Difference (%)
FT02D 9	114.0	73.3	35.70
FT02D 16	116.7	83.8	28.19
FT02D 23	73.7	13.45	81.75
GX01 3	94.8	72.2	23.84
GX01 11	57.9	18.8	67.53
BE01 1	181.4	160.25	11.66

Thus, the simultaneous estimation and optimization algorithm for nonlinear and dynamic problems is an extremely powerful instrument.

Minimum circle; Minimum sphere; Sylvester's problem

In 1857 the British mathematician J.J. Sylvester, in a one sentence article [28], posed the problem:

It is required to find the *least circle* which shall contain a given set of points in the plane.

From then until the 1960s, the problem attracted the occasional interest of mathematicians who proposed algorithms [1,5,21], applications [21,29] and related theory [17,26], both for the problem in the plane and for the *minimum sphere problem* in higher dimensions. The references, especially [1,14,26], cover the history in more detail.

Starting in 1971, the problem attracted greater interest in the context of location theory because finding the center of the circle of minimum radius is equivalent to locating a central facility for which the maximum distance to any service point is minimized [8,9,11,12,16,23]. The problem was also introduced in the 1970s computer science literature as one of the closest point problems of computational geometry [27]. This article provides an optimization formulation, characterization of the solution, one of the primary algorithms for the problem in the plane and references to extensions.

A minimax statement of the minimum sphere problem in  $\mathbf{R}^n$  is:

$$\min_{x \in \mathbf{R}^n} \max_{i=1, \dots, m} \|x - a_i\|,$$

where there are  $m$  given points  $a_i \in \mathbf{R}^n$  and  $\|\cdot\|$  denotes the Euclidean norm. Converting this to a constrained optimization problem with differentiable functions is accomplished by squaring the norm term and introducing a new variable  $s$  for the squared radius of the minimum sphere:

$$\begin{cases} \min_{(s,x)} & s \\ \text{s.t.} & \|x - a_i\|^2 \leq s, \quad i = 1, \dots, m, \\ & (s, x) \in \mathbf{R}^{n+1}. \end{cases}$$

In this form the problem is a convex program for which the *Karush–Kuhn–Tucker conditions* [20] are both necessary and sufficient. Applying these conditions shows that there exist nonnegative multipliers  $u_i$ ,  $i = 1, \dots, m$  such that

$$\begin{aligned} \sum_{i=1}^m u_i a_i &= x^*, \\ \sum_{i=1}^m u_i &= 1, \\ u_i (s^* - \|x - a_i\|^2) &= 0, \quad i = 1, \dots, m, \\ u_i &\geq 0, \quad i = 1, \dots, m. \end{aligned}$$

Thus  $x^*$ , the center of the minimum sphere with radius  $\sqrt{s^*}$ , is a convex combination of points on its boundary since, for points within the sphere, the associated  $u_i$  must be zero. Further, by *Carathéodory's theorem* (cf. ► **Carathéodory theorem**), at most  $n + 1$  of the given points are required for this convex combination. In the plane, therefore, the minimum circle is defined by either

- two points of maximum separation, or
  - three of the points which form a nonobtuse triangle.
- This characterization of the solution is also evident from geometrical arguments.

Given this characterization, a finite procedure could be devised in which all circles defined by two or three points are constructed. In this procedure, three points would be discarded if they formed an obtuse triangle. From the circles constructed, the smallest covering circle would be chosen. However, this total enumerative approach would not be effective for large values of  $m$  – the number of two and three point combinations grows rapidly with the number of points. If, for example,  $m = 100$ , over 160,000 combinations would be considered.

Below is an outline of a more efficient method due to J. Elzinga and D.W. Hearn [8]:

0. Choose any two of the given points and go to Step 1.
1. Let these two points define the diameter of a circle.  
IF this circle covers all points THEN STOP  
ELSE find an outside point and go to Step 2 with these three points.
2. Solve the minimum circle problem for these three points.  
IF the minimum circle is defined by two points THEN go to Step 1.  
IF three points define it THEN go to Step 3.
3. IF the circle defined by three points covers all points THEN STOP  
ELSE find an outside point (e.g., the farthest one) and go to Step 4.
4. Solve the minimum circle problem for these four points.  
IF it is defined by two points THEN go to Step 1.  
IF defined by three points THEN go to Step 3.

#### Elzinga–Hearn algorithm

This outline omits many details of how the different steps are executed and efficiencies such as reducing the given set of  $m$  points to their *convex hull*. See [2,8,14] for a discussion of those details and [15] for a computer code. In computational testing on random data, the most effective versions compute the solution of a problem with 100 points in fewer than 10 iterations [14]. Empirically, the computational effort goes up linearly with the number of points, however, an example given in [6] requires  $O(m^2)$  time. In theory, there are methods of lower complexity, e. g., methods based on construction of *Voronoi diagrams* [25,27] and the  $O(m)$  method of N. Megiddo [22], but effective implementations of these methods have not been developed. E. Welzl [30] gives a random method of *expected* complexity  $O(m)$  and reports on the implementation of an effective heuristic variation.

The *Elzinga–Hearn algorithm* can be classified as a *dual* procedure [14] – only the final circle covers all points and is therefore feasible. Primal methods, in particular, the first algorithm, due to G. Chrystal [5] and, independently, to B. Peirce [29] also exist, and the most efficient implementations are competitive with that of Elzinga and Hearn. In [14] these implementations are described and a classification scheme is given which shows the equivalence of a number of other proposed algorithms.

In the location theory context positive weights indicating relative importance may be associated with the given service points [11,14]. Then the problem is one of minimizing the *maximum weighted distance* and it loses its covering circle interpretation [14]. The algorithm given above has been extended to this weighted problem in [13,14].

By a change of variables of the form  $s = v + x^T x$ , the above constrained problem becomes

$$\begin{cases} \min_{(v,x)} & v + x^T x \\ \text{s.t.} & v + 2a_i^T x - a_i^T a_i \geq 0, \\ & i = 1, \dots, m, \\ & (v, x) \in \mathbb{R}^{n+1}, \end{cases}$$

which is recognized to be a *convex quadratic program* [9,19,23]. Thus there are many general purpose algorithms which can solve the minimum sphere problem. A pivoting method reminiscent of the revised simplex

method for linear programming, and with storage requirements that depend only on  $n$ , is given in [9].

Extensions of the basic problem include covering a convex polyhedron defined by algebraic inequalities [10,18] and *minimax location on a sphere* or hemisphere using great circle distances [7,24]. See also the  $O(m \log m)$  method of G. Xue and S. Sun [31].

- c) pump in chemical operations;
- d) well in an oil field development.

A generalization of this problem involves the *multifacility location-allocation* problem, [5]. A mathematical formulation of the single-facility problem is as follows:  $m$  existing facilities are located at known distinct points  $P_1, \dots, P_m$ , a new facility is to be located at a point  $X$ , costs of 'transportation' nature are incurred and are directly proportional to an appropriately defined distance between the new facility and the existing ones. Let  $d(X, P_i)$  represent the distance between points  $X$  and  $P_i$  and let  $w_i$  represent the cost of transportation between the new facility and existing facility  $i$  at  $P_i$ . Then the total 'transportation' cost between the new facility and the existing facilities is given by:

$$f(X) = \sum_{i=1}^m w_i d(X, P_i),$$

where terms  $w_i$  are referred to as 'weights'. The single facility location problem is to determine the location of a new facility, say  $X^*$ , that minimizes  $f(X)$ . In many applications the cost per unit distance is a constant thus the minimization problem often reduces to a determination of the location that minimizes distance. The  $l_p$  norm is a popular distance measure in facility location theory. If the coordinates for the new facility are  $x_1, x_2$ , so that  $X = (x_1, x_2)$ , and for the existing facility  $i$  the coordinates are  $a_i, b_i$ , so that  $P_i = (a_i, b_i)$ , the  $l_p$  norm is as follows:

$$l_p = ((x_1 - a_i)^p + (x_2 - b_i)^p)^{\frac{1}{p}}, \quad p \geq 1.$$

Typically in the literature it is assumed that  $p = 1$  or  $2$ , for which we obtain the rectangular and Euclidean norms, respectively. Examples of facility location problems where Euclidean distance applies are the network location problems as well as the pipeline design problems. Examples of facility location problems where *rectilinear distance* applies are machine location problems where transportation occurs along a set of aisles arranged in a rectangular pattern as well as the well location problem in an oil field where the no flow boundaries are located in the midpoint between the extraction wells, [6].

## Single Facility Location: Multi-objective Euclidean Distance Location

Facility location; Optimization

The problem of *single facility location* can be stated as follows: Determine the location of a single new facility with respect to a number of existing facilities that minimizes an appropriate defined total cost function which is chosen to be proportional to distance. Typical examples are the location of a new:

- a) machine in a manufacturing facility;
- b) warehouse relative to production;

## Mathematical Model

The Euclidean distance location problem can be stated mathematically as:

$$\min f(X) = \sum_{i=1}^m w_i((x_1 - a_i)^2 + (x_2 - b_i)^2)^{\frac{1}{2}}. \quad (1)$$

It is variously referred to as the *Steiner-Weber problem* or the *general Fermat problem*. The first important property of the problem is that since  $w_i l_2(X, a_i)$  is a convex function of  $X$  and the sum of convex functions is a convex function as well, it follows that  $f(X)$  is a convex function. This means that local minima are global optima of problem (1), [8]. With this information we are assured that the following *extremal equations* for  $f(X)$  can produce only global optima of problem (1):

$$\frac{\partial f(X)}{\partial x_k} = \sum_{i=1}^m \frac{w_i((x_k - a_i)k)}{l_2(X, a_i)} = 0, \quad k = 1, 2. \quad (2)$$

One difficulty that the above equation has is that the derivatives are undefined if  $l_2(X, a_i) = 0$ . Therefore, if the optimal location for the new facility coincides with that of an existing facility, equation (2) cannot be used to check optimality. However, each existing facility can be easily checked for optimality by utilizing the following property, [8]:  $f(X)$  is minimized at the  $r$ th existing facility location  $(a_{r1}, a_{r2})$ , if and only if

$$CR_r^2 = \left( \sum_{i=1, \neq r}^m \frac{w_i(a_{r1} - a_{i1})}{l_2(a_r, a_i)} \right)^2 + \left( \sum_{i=1, \neq r}^m \frac{w_i(a_{r2} - a_{i2})}{l_2(a_r, a_i)} \right)^2 \leq w_r. \quad (3)$$

## Solution Approach

An iterative procedure has been proposed for the solution of problem (1) which is known as *Weiszfeld procedure*. This iterative procedure is based on the following equation, which can be obtained from (2) so as to get  $x_k$ :

$$x_k = \frac{\sum_{i=1}^m \frac{w_i a_{i1}}{l_2(X, a_i)}}{\sum_{i=1}^m \frac{w_i}{l_2(X, a_i)}}, \quad k = 1, 2. \quad (4)$$

Note that  $x_k$  is also involved in the right-hand side of (4) so that an iterative scheme should be employed to

solve (4). The following form holds at iteration  $l + 1$ :

$$x_k^{l+1} = \frac{\sum_{i=1}^m \frac{w_i a_{i1}}{l_2(X^l, a_i)}}{\sum_{i=1}^m \frac{w_i}{l_2(X^l, a_i)}}, \quad k = 1, 2. \quad (5)$$

A good initial point comes from the solution of the *squared Euclidean problem*, that is the same as the Euclidean location problem except that each distance  $l_2(X, a_i)$  is squared. The solution to this problem was found to be the *center of gravity location* given by:

$$x_k^0 = \frac{\sum_{i=1}^m w_i a_{i1}}{\sum_{i=1}^m w_i}, \quad k = 1, 2. \quad (6)$$

The iterative procedure is guaranteed to converge to the optimum location. Discussion about the convergence is given in [7].

## Duality

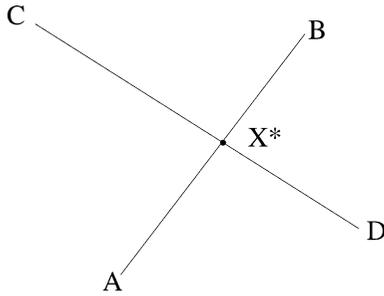

A strict convex approximation function to eliminate the problem of discontinuities of the derivatives of  $f(X)$  is the following:

$$\min f(X) = \sum_{i=1}^m w_i((x_1 - a_i)^2 + (x_2 - b_i)^2 + \epsilon^2)^{\frac{1}{2}}. \quad (7)$$

Based on this problem one can derive, [8], the dual limit as  $\epsilon \rightarrow 0$ :

$$\left\{ \begin{array}{l} \max_{U, Z} D(U) = - \sum_{i=1}^m (a_{i1} u_i + a_{i2} v_i) \\ \text{s.t.} \quad \sum_{i=1}^m u_i = 0, \\ \quad \quad \sum_{i=1}^m v_i = 0, \\ \quad \quad u_i^2 + v_i^2 \leq w_i, \quad i = 1, \dots, m. \end{array} \right. \quad (8)$$

The inequality constraints can be equivalently posed as  $u_i^2 + v_i^2 \leq w_i$  to produce a differentiable problem that can be solved using standard nonlinear programming algorithm. The optimal *Lagrange multipliers* of problem (5) solve the original problem (1), [8]. It is of interest to notice the geometric interpretation of optimal facility location. Figure 1 gives the case of four existing facilities at points  $A, B, C$  and  $D$ . For the case of equal weights suppose that the four points can be arranged in pairs  $(A, B)$  and  $(C, D)$  so that the straight

**Single Facility Location: Multi-objective Euclidean Distance Location, Figure 1**

**Graphical solution for the Euclidean distance problem**

lines  $AB$  and  $CD$  intersect. The intersection point  $X^*$  is the optimum location for the new facility. However, if a point, for example  $D$ , lies within the triangle  $ABC$ , then the optimal location of new facility coincides with the location  $D$ .

### Discrete Location Problem

In the *discrete location problem*, [4], the new facility is to be located and a single choice must be made from among a finite number of sites, say  $n$ . The mathematical model for this *assignment problem* is the following:

$$\left\{ \begin{array}{l} \min \quad f(x) = \sum_{i=1}^n \sum_{j=1}^n c_{ij} x_{ij} \\ \text{s.t.} \quad \sum_{i=1}^n x_{ij} = 1, \quad j = 1, \dots, n, \\ \sum_{j=1}^n x_{ij} = 1, \quad i = 1, \dots, n, \\ x_{ij} = 0 \text{ or } 1, \quad \forall i, j. \end{array} \right. \quad (9)$$

As an example of the use of the *assignment model* in a context similar to continuous location problem, suppose that there are  $p$  existing facilities and  $d_{kj}$  represents the Euclidean distance between existing facility  $k$  and site  $j$  and that  $w_{ik}$  represents a total cost per unit distance incurred in transporting items between a new facility  $i$  and existing facility  $k$ . Then, for a given assignment,  $w_{ik} \sum_{j=1}^n d_{kj} x_{ij}$  represents the total cost incurred transporting items between new facility  $j$  and existing facility  $k$ . The total cost of transportation of all items is

then given by:

$$\sum_{i=1}^n \sum_{k=1}^p w_{ik} \sum_{j=1}^n d_{kj} x_{ij} = \sum_{j=1}^n c_{ij} x_{ij}, \quad (10)$$

where  $c_{ij} = \sum_{k=1}^p w_{ik} d_{kj}$ . With the above transformation the location problem can then be solved as an assignment problem, [4].

### Objectives

In the previous sections the objective considered for the location problem was the most commonly used minimization of cost that can be translated to minimization of distance since the cost has been considered directly proportional to distance. However, there are many other objectives used in the literature concerning the location problem. A complete review could be found in [3]. One can distinguish three different objective categories:

- the *push objectives*,
- the *pull objectives* and
- the *balancing objectives*.

The pull objectives are based on the assumption that the facility to be located is desirable and so the distance from the 'customers' has to be minimized. In this category belong the objectives mentioned before as well as objectives of profit maximization where there is a price associated with each demand cite. In the push objectives the facility is undesirable as for example a dangerous facility due to leak possibility, and so is located to maximize the distance from the 'customer' cites. The balancing objectives try to minimize the weighted (balance) distance between the new facility and the customers. If we consider the distribution of all facility-customer distances for any given solution, push and pull objectives optimize some function of the mean i. e., the first central moment of this distribution. In contrast most balancing objectives target on minimizing the variability of the distribution of distances i. e., the second moment. A number of criteria exist to evaluate the selection of the balancing objectives, [9]. Among them are the *scale invariance criterion*, according to which the optimal facility location remains the same irrespective of the type of measure applied to the problem; the *principle of transfers*, that states that the distri-

bution will become suboptimal if a facility from above the average distance is transferred to the facility that is below the average. Other criteria include *analytical tractability*, *normalization of measures*, *appropriateness*, *sensitivity* and *Pareto optimality*. For the latter one considers a single facility location problem where the three points are almost collinear. The distances to the three points are equal if the points lie on the circumference of a circle with its center at the facility. However, the closer the points are to the line the larger the radius of a circle is. Customers in all three locations will benefit from getting the facility closer to them until it reaches the central point. The above case is an example where the equality objective alone is not meaningful. Based on the problems associated with balancing objectives a number of authors, [1], have considered the trade-offs between equality and efficiency in the objective function. Concluding the facility location problem is usually multi-objective in nature. Location under any of the aforementioned objectives satisfies but a single objective. Specialized solution approaches can be used to guide the optimization when more than one objective is considered, [2].

### Keywords

Facility location; Optimization

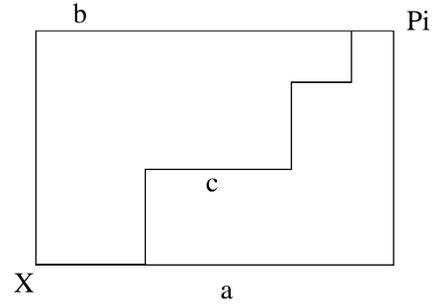

The problem of *single facility location* can be stated as follows: Determine the location of a single new facility with respect to a number of existing facilities that minimizes an appropriate defined total cost function which is chosen to be proportional to distance. A mathematical formulation of the single facility problem is as follows:  $m$  existing facilities are located at known distinct points  $P_1, \dots, P_m$ , a new facility is to be located at a point  $X$ , costs of ‘transportation’ nature are incurred that are directly proportional to an appropriately defined distance between the new facility and the existing ones. Let  $d(X, P_i)$  represent the distance between points  $X$  and  $P_i$  and  $w_i$  represent the cost of transportation between the new facility and existing facility  $i$  at  $P_i$ , then the total ‘transportation’ cost between the new facility and the existing facilities is given by:

$$f(X) = \sum_{i=1}^m w_i d(X, P_i),$$

where the terms  $w_i$  are referred to as ‘weights’. The single facility location problems is to determine the location of a new facility, say  $X^*$ , that minimizes  $f(X)$ . In many applications the cost per unit distance is a constant thus the minimization problem often reduces to a determination of the location that minimizes distance. The appropriate determined distance can be a straight line (i. e. *Euclidean distance*), [7], or a rectilinear distance. Examples of facility location problems where Euclidean distance applies are the network location problems as well as the pipeline design problems. If the coordinates for the new facility are  $x, y$  so that  $X = (x, y)$  and the coordinates for the existing facility  $i$  are  $a_i, b_i$  so that  $P_i = (a_i, b_i)$ , the rectilinear distance between  $X$  and  $P_i$  is defined as:

$$d(X, P_i) = |x - a_i| + |y - b_i|.$$

Examples of facility location problems where *rectilinear distance* applies are machine location problems where transportation occurs along a set of aisles arranged in a rectangular pattern as well as the well location problem in an oil field where the no flow boundaries are located in the midpoint between the extraction wells. A distinct difference between the rectilinear and Euclidean distance is illustrated in Fig. 1, which illustrates that there are several different paths between  $X$  and  $P_i$  for which the rectilinear distance is the same. The num-

**Single Facility Location: Multi-objective Rectilinear Distance Location, Figure 1**

Different rectilinear paths between  $X$  and  $P_i$

ber of such paths is, of course, infinite. This is not the case with Euclidean distance where the path is unique.

### Mathematical Model

The rectilinear distance location problem can be stated mathematically as:

$$\min f(x, y) = \sum_{i=1}^m w_i (|x - a_i| + |y - b_i|), \quad (1)$$

which is equivalently stated as:

$$\min_x \sum_{i=1}^m w_i (|x - a_i|) + \min_y \sum_{i=1}^m w_i (|y - b_i|),$$

where each quantity can be treated as separate optimization problem [4]:

$$\min_x \sum_{i=1}^m w_i (|x - a_i|),$$

$$\min_y \sum_{i=1}^m w_i (|y - b_i|).$$

Some properties if the optimum solution are:

- The  $x$ -coordinate of the new facility will be the same as the  $x$ -coordinate of some existing facility. Similarly, the  $y$ -coordinate of the new facility will coincide with the  $y$ -coordinate of some existing facility. It is not necessary however, that both coordinates be for the same existing facility.
- The optimum  $x$ -coordinate ( $y$ -coordinate) location for the new facility is a *median location*.

A different way to addressing the same problem is proposed in [10], where the problem is formulated as a linear programming model. Let us consider the absolute distance between the new and the existing facility  $i$ . This is given by:

$$\begin{aligned} d_{i1} &= a_i - x && \text{if } x \leq a_i, \\ d_{i2} &= x - a_i && \text{if } x \geq a_i, \\ d_{i1}, d_{i2} &\geq 0, && i = 1, \dots, m. \end{aligned}$$

Using these expressions:

$$\begin{aligned} x + d_{i1} - d_{i2} &= a_i, \\ d_{i1} \times d_{i2} &= 0, \\ d_{i1}, d_{i2} &\geq 0, && i = 1, \dots, m, \end{aligned}$$

and the location problem (1) become a linear programming problem:

$$\begin{cases} \min & \sum_{i=1}^m w_i(d_{i1} + d_{i2}) \\ \text{s.t.} & x + d_{i1} - d_{i2} = a_i, \\ & d_{i1}, d_{i2} \geq 0, \quad i = 1, \dots, m. \end{cases} \quad (2)$$

Note that the condition  $d_{i1} \times d_{i2} = 0$ , which is not included in the above formulation, is always satisfied at the optimal solution of problem (2). For example, let the current values of  $d_{i1}, d_{i2}$  be given by  $d'_{i1}, d'_{i2}$ , where  $d'_{i1} > d'_{i2}$  and  $d'_{i2} \neq 0$ . Then a solution which reduces the value of the objective function is given by  $d_{i1} = d'_{i1} - d'_{i2}$  and  $d_{i2} = 0$ . Problem (2) represents a linear programming problem with  $2m + 1$  variables and  $m$  nontrivial constraints. The dual of problem (2) is:

$$\min \sum_{i=1}^m a_i s_i - s_{m+1} \sum_{i=1}^m a_i.$$

By defining a new variable  $z_i = s_i - s_{m+1} + \max_i[w_i]$ ,  $i = 1, \dots, m$ , the dual becomes:

$$\begin{cases} \min & \sum_{i=1}^m (z_i - \max_i[w_i]) a_i \\ \text{s.t.} & \sum_{i=1}^m (z_i - \max_i[w_i]) \geq 0, \\ & \max_i[w_i] - w_i \leq z_i \leq w_i + \max_i[w_i], \\ & i = 1, \dots, m. \end{cases} \quad (3)$$

Problem (3) has all its constraints but one of the bounded-variable type and can therefore solved efficiently by linear programming techniques.

See [8], for a proof that the function  $W_k(x_k) = \sum_{i=1}^m w_i |x_k - a_{jk}|$ , where  $k = 1, 2$  for the two-dimensional problems, is a convex function and for the following optimality conditions: at some  $t^*$ ,

$$\sum_{i=1}^{t-1} w_i^k - \sum_{i=t}^{n_k} w_i^k < 0, \quad (4)$$

$$\sum_{i=1}^t w_i^k - \sum_{i=t+1}^{n_k} w_i^k \geq 0 \quad (5)$$

are satisfied. If condition (5) is met as a strict inequality, then  $x_k^* = a_{t^*k}$ . If condition (5) is met as an equality, then  $x_k^* \in [a_{t^*k}, a_{t^*+1k}]$ . Based on the above conditions, [8] propose an iterative procedure to determine  $t^*$ .

### Uncertainty

Uncertainty may appear in the destinations, which are also called *regional demand*, and the weights. Regional demand is modeled by a continuous spatial distribution of one or more destinations. The location objective then corresponds to minimizing the expected value of the distance of the facility to the random destinations. The analytical evaluation of the integral type of the objective is only possible in the simple cases of rectangular or circular regions that however lead to objectives that are not easy to optimize, [1]. Let us consider the single facility location problem with rectangular distances. Let each of the  $m$  existing facilities have random coordinates  $(Y_{j1}, Y_{j2})$ , described by bivariate normal probability density function  $f(y_{j1}, y_{j2})$ . We want to find a facility location  $(x_1^*, x_2^*)$  that minimizes the expected sum of weighted rectangular distances. The total expected cost is:

$$EW(X) = E_Y \left( \sum_{j=1}^m w_j d(X, Y_j) \right), \quad (6)$$

where  $Y_j = (Y_{j1}, Y_{j2})$  and  $Y = (Y_{11}, Y_{12}, \dots, Y_{n1}, Y_{n2})$ . It follows that:

$$\begin{aligned} EW(X) &= \sum_{j=1}^m w_j E_Y d(X, Y_j) \\ &= \sum_{j=1}^m w_j E_{Y_j} |x_1 - Y_{j1}| + \sum_{j=1}^m w_j E_{Y_j} |x_2 - Y_{j2}| \end{aligned}$$

$$\begin{aligned} &= \sum_{j=1}^m w_j E_{Y_{j1}} |x_1 - Y_{j1}| + \sum_{j=1}^m w_j E_{Y_{j2}} |x_2 - Y_{j2}| \\ &= EW_1(x_1) + EW_1(x_2), \end{aligned}$$

which means that the location problem becomes:

$$\min_X EW(X) = \min_{x_1} EW_1(x_1) + \min_{x_2} EW_1(x_2). \quad (7)$$

Using the density function  $f$  we can evaluate each one of these terms:

$$EW_1(x_1) = \sum_{j=1}^m w_j \int_{-\infty}^{\infty} |x_1 - y_{j1}| f(y_{j1}) dy_{j1} \quad (8)$$

Let  $Y_{j1}$  have mean  $\mu_{j1}$  and standard deviation  $\sigma_{j1}$ . Then:

$$f(y_{j1}) = \frac{1}{(2\pi)\sigma_{j1}} \exp\left(-\frac{1}{2} \left(\frac{y_{j1} - \mu_{j1}}{\sigma_{j1}}\right)^2\right). \quad (9)$$

As the derivative of  $EW_1(x_1)$  is easily evaluated as follows:

$$EW_1'(x_1) = \sum_{j=1}^m w_j \left(1 - 2P_r\left(z \geq \frac{x_1 - \mu_{j1}}{\sigma_{j1}}\right)\right), \quad (10)$$

we may use a method such as interval bisection to find  $x_1^*$ .

Another approach to overcome the regional demand is to replace each region by a representative point, a centroid, and solve the resulting classical location problem, [2]. Although this approach is relative simple it raises questions regarding the involved aggregation error due to the arbitrary way of selecting the used centroids. In case of uncertainty in the weights the most typical question is to determine all the points which may be optimal for any choice of weights. Assuming a distribution to be known for each one of them H.C.L.W. Williams [11] derived the probability for each one of the destinations of being optimal. Also the degree of nonoptimality of a given site is an important information that can be extracted from the uncertainty analysis. This type of information is important when considering a possible relocation decision of a facility, [5].

### Constraints

Many practical applications need methods able to handle feasible regions of any shape even disconnected

ones. See [6], for a special method for location problems with  $l_p$ -distance within a finite union of convex polygons; this method was subsequently extended in [9] to general objectives and arbitrary polygonal shaped feasible regions.

### Dynamic Location

Let us assume that a facility is expected to serve over  $r$  periods of time during which may be repeatedly relocated. The problem of *dynamic facility location* is to find the single facility location but for each of the  $r$  periods. Let the weights  $w_{jk}$  be the present value of the cost per unit distance between the new facility and existing facility  $j$  in period  $k$ , and let  $c_k$  be the present value of the cost. The objective is then to find a series of locations  $X_k = (x_{1k}, x_{2k})$ ,  $k = 1, \dots, r$ , that minimize the present value of the location plan. The dynamic location problem to be considered is [8]:

$$\min \sum_{k=1}^r \sum_{j=1}^m w_{jk} d(X_k, a_j) + \sum_{k=2}^r c_k z_k, \quad (11)$$

where  $z_k = 1$  if  $X_k \neq X_{k-1}$  is allowed and  $z_k = 0$  otherwise. The variables  $z_k$  serve as indicators if the facility is permitted to move from where it was the previous period.

### Objectives

The problem of facility location is usually a multi-objective problem since more than one objectives have to be optimized simultaneously. The models described above result in the location solution where only the objective of minimizing a distance function is being considered. However, a number of alternative objectives have been considered in the literature that can be classified in the *pull objectives*, *push objectives* and *balancing objectives*, [7]. The first category involve the constraints that minimize the distance to the new facility assuming that it is a desirable unit whereas, the push objectives maximize the corresponding distances assuming the location of undesirable unit. The balancing objectives try to weight the distances from the new facility to the existing ones. An alternative to the objective of minimizing the distance is the *maxmin objective*, [8], that has

the following form:

$$\begin{cases} \max & f(x) \\ \text{s.t.} & f(x) = \min w_j l_1(X, a_j), \quad j = 1, \dots, m. \end{cases}$$

In order to incorporate more than one objective in the facility location problem, *multi-objective optimization* techniques should be applied, [3]. The basic idea of these techniques is the systematic generation of the *Pareto optimal solution* set that involves the points in which one objective can be improved only at the expense of other objectives.

### Introduction

Optimization problems for a finite-dimensional decision variable under infinitely many inequality constraints are called *semi-infinite* (see [8,19] for reviews).

For smoothing methods one considers them in the form

$$\text{SIP: } \min_{x \in \mathbb{R}^n} f(x) \text{ subject to } g(x, y) \geq 0 \text{ for all } y \in Y,$$

with the objective function  $f \in C^2(\mathbb{R}^n, \mathbb{R})$ , the constraint function  $g \in C^2(\mathbb{R}^n \times \mathbb{R}^m, \mathbb{R})$ , and a nonempty and compact index set  $Y \subset \mathbb{R}^m$ . Moreover,  $Y$  is assumed to be described by finitely many inequality constraints,

$$Y = \{y \in \mathbb{R}^m \mid v(y) \geq 0\},$$

with  $v \in C^2(\mathbb{R}^m, \mathbb{R}^s)$  and  $s \in \mathbb{N}$ . The feasible set of SIP is denoted by

$$M = \{x \in \mathbb{R}^n \mid g(x, y) \geq 0 \text{ for all } y \in Y\}.$$

A basic problem in semi-infinite optimization is to check whether a point  $x \in \mathbb{R}^n$  is feasible, since this involves the verification of infinitely many inequality constraints.

The semi-infinite constraint in SIP is equivalent to

$$G(x) := \min_{y \in Y} g(x, y) \geq 0,$$

which means that the feasible set  $M$  is the upper level set of the, in general, nonsmooth function  $G$ . Smoothing methods try to replace  $G$  by a smooth function, but to keep important properties of the original problem under this modification. More explicitly, one wishes that *under weak assumptions* a nonempty and compact feasible set  $M$  can be approximated arbitrarily well by a level set of a *single smooth function* with certain *regularity properties*. Moreover, there should be a *correspondence between Karush–Kuhn–Tucker points* of the original and of the smoothed problem, along with their *Morse indices*.

### Smoothing Approaches Motivated by Nonlinear Programming

A smoothing procedure for *finite* optimization problems is given in [12]. There the main idea is to use the logarithmic barrier approach to approximate finitely many inequality constraints  $g_i(x) \geq 0$ ,  $i \in I$ ,  $|I| < \infty$ , by one smooth and nondegenerate constraint  $\sum_{i \in I} \ln(g_i(x)) \geq \ln(\varepsilon)$  for  $\varepsilon > 0$ . A similar approach is taken in [5] to smooth finite maximum functions.

However, obvious generalizations of this approach to semi-infinite programming are not successful.

In fact, there are two standard arguments which connect SIP to finite optimization problems. First, a sufficiently fine discretization of the index set leads to an arbitrarily accurate outer approximation of  $M$  by finitely many inequality constraints which could, in a next step, be smoothed by the logarithmic barrier approach. Unfortunately, the so-called second-order shift terms of semi-infinite programs are ignored by the discretized problem, so correspondences of Morse indices cannot even be established between the original and the discretized problem, let alone the smoothed discretized problem.

Second, assuming the so-called reduction ansatz at some point  $\bar{x} \in M$ , the feasible set can locally be described by finitely many smooth inequality constraints. The logarithmic barrier approach for this locally reduced SIP is used in [10]. While Morse indices are modeled well in this approach, the assumption of the reduction ansatz in the whole feasible set is not generic [16].

Another obvious generalization of the approach from finite programming is to directly use the barrier term  $\int_Y \ln(g(x, y)) \, dy$  for SIP. For infinite quadratic programming problems a related interior point approach is presented in [18]. For nonlinear SIP, however, this logarithmic barrier term is neither self-concordant nor does it necessarily enforce interior points, as an example from [10] shows. The main problem is that in some situations even the singularity of the logarithm is smoothed by the integral, and boundary points can become feasible for the approximation (note that  $\int \ln(y) = y \ln(y) - y$  can be continuously extended to  $y = 0$  with value 0).

### Smoothing Approaches for Semi-Infinite Programs

An approximation of the feasible set in semi-infinite optimization by a quadratic distance function is presented in [6]. While smoothness of the approximating problem is shown, it is inherently degenerate, so no results on Morse indices can be expected from this approach.

A smoothing method for semi-infinite programs adhering to *all* the above criteria is given in [14,15]. There the function  $G$  is smoothed by mollification, as is explained in the remainder of this contribution.

**Definitions**

The auxiliary function  $G$  is the optimal value function of the so-called *lower level problem*:

$$Q(x) := \min_{y \in \mathbb{R}^m} g(x, y) \text{ subject to } v(y) \geq 0.$$

Points  $x$  from the topological boundary  $\partial M$  of  $M$  satisfy  $G(x) = 0$ , and the corresponding globally minimal points of  $Q(x)$  are denoted by

$$Y_0(x) = \{y \in Y \mid g(x, y) = 0\}.$$

The set  $Y_0(x)$  is also called the *active index set* of  $x$  for SIP.

**The Extended Mangasarian–Fromovitz Constraint Qualification**

A nice topological structure of  $M$  at its boundary points can be guaranteed under constraint qualifications. Since  $G$  is directionally differentiable [1], according to [21] the natural extension of the well-known and basic Mangasarian–Fromovitz constraint qualification [17] at a zero  $\bar{x}$  of  $G$  is

$$\{d \in \mathbb{R}^n \mid G'(\bar{x}, d) > 0\} \neq \emptyset.$$

With the formula for the directional derivative from [1], one obtains the following explicit condition which is well known for semi-infinite programs [9,16].

**Definition 1** At  $\bar{x} \in M$  the *extended Mangasarian–Fromovitz constraint qualification (EMFCQ)* is said to hold if there exists some vector  $d \in \mathbb{R}^n$  with

$$D_x g(\bar{x}, y)d > 0 \text{ for all } y \in Y_0(\bar{x}).$$

Here  $D_x g$  denotes the row vector of partial derivatives of  $g$  with respect to  $x$ . In [16] it is shown that EMFCQ holds generically in semi-infinite programming and is, thus, a weak assumption.

**The Reduction Ansatz and Nondegenerate KKT Points**

For theoretical as well as numerical purposes it is of crucial importance to keep track of the elements of the active index set  $Y_0(x)$  for varying  $x$ . Recall that each  $y \in Y_0(x)$  is a global minimizer of  $Q(x)$ . The *reduction ansatz* [7,22] is said to hold at  $\bar{x} \in M$  if all

global minimizers of  $Q(\bar{x})$  are *nondegenerate* in the sense of Jongen et al. [11]. Since nondegenerate minimizers are isolated, and  $Y$  is a compact set, the closed set  $Y_0(\bar{x})$  can only contain finitely many points, say,  $Y_0(\bar{x}) = \{\bar{y}^1, \dots, \bar{y}^p\}$  with  $p \in \mathbb{N}$ . By a result from [3] the local variation of these points with  $x$  can be described by the implicit function theorem.

In fact, for  $x$  locally around  $\bar{x}$  there exist continuously differentiable functions  $y^i(x)$ ,  $1 \leq i \leq p$ , with  $y^i(\bar{x}) = \bar{y}^i$  such that  $y^i(x)$  is the locally unique local minimizer of  $Q(x)$  around  $\bar{y}^i$ . It turns out that the functions  $G_i(x) := g(x, y^i(x))$  are even  $C^2$  in a neighborhood of  $\bar{x}$ .

A major consequence of the reduction ansatz is the so-called reduction lemma: if the reduction ansatz holds at  $\bar{x}$ , then for all  $x$  from a neighborhood  $U$  of  $\bar{x}$  we have

$$G(x) = \min_{1 \leq i \leq p} G_i(x).$$

This means that  $M$  can locally be described by finitely many  $C^2$  constraints, that is, SIP is locally equivalent to the smooth finite optimization problem:

$$\text{SIP}_{\text{red}}: \min_{x \in \mathbb{R}^n} f(x) \text{ subject to } G_i(x) \geq 0, \quad i = 1, \dots, p.$$

Examples show that the reduction ansatz cannot be expected to hold everywhere in the feasible set of a generic semi-infinite program [16]. As nondegeneracy in the sense of Jongen et al. is a local property, one can, however, define a nondegenerate KKT point of the SIP via the locally reduced problem  $\text{SIP}_{\text{red}}$ . Let

$$L(x, \lambda) = f(x) - \sum_{i=1}^p \lambda_i G_i(x)$$

denote the Lagrangian of  $\text{SIP}_{\text{red}}$  with multiplier vector  $\lambda \in \mathbb{R}^p$ .

**Definition 2** A point  $\bar{x} \in M$  is called a *nondegenerate Karush–Kuhn–Tucker point of SIP* if the reduction ansatz holds at  $\bar{x}$  and if  $\bar{x}$  is a nondegenerate Karush–Kuhn–Tucker point of  $\text{SIP}_{\text{red}}$ , that is, the following three conditions hold:

1. The linear independence constraint qualification holds at  $\bar{x}$ , and there exists a (unique) multiplier vector  $\bar{\lambda} \geq 0$  with  $D_x L(\bar{x}, \bar{\lambda}) = 0$ .

2. The multipliers satisfy  $\bar{\lambda}_i > 0, i = 1, \dots, p$ .
3. The matrix  $D_x^2 L(\bar{x}, \bar{\lambda})|_{T_{\bar{x}} M_{\text{red}}}$ , that is, the Hessian of the Lagrangian, restricted to the tangent space to  $M_{\text{red}}$  at  $\bar{x}$ , is nonsingular.

The number of negative eigenvalues of the matrix in condition 3 is called the *Morse index* of  $\bar{x}$ .

For generic SIP all Karush–Kuhn–Tucker points are nondegenerate [20,24]. In this sense, nondegeneracy of KKT points for SIP is a weak assumption.

**Mollifiers**

With the Euclidean norm  $\|\cdot\|_2$  on  $\mathbb{R}^n$  the *standard mollifier* [2] is the  $C^\infty$  function:

$$\eta(x) = \begin{cases} C \exp\left(\frac{1}{\|x\|_2^2 - 1}\right), & \|x\|_2 < 1, \\ 0, & \|x\|_2 \geq 1, \end{cases}$$

where  $C > 0$  is chosen such that  $\int_{\mathbb{R}^n} \eta(x) dx = 1$ . For  $\varepsilon > 0$  put

$$\eta_\varepsilon(x) = \frac{1}{\varepsilon^n} \eta\left(\frac{x}{\varepsilon}\right).$$

The function  $\eta_\varepsilon$  is also  $C^\infty$ , it satisfies  $\int_{\mathbb{R}^n} \eta_\varepsilon(x) dx = 1$ , and its support is the closed ball  $B(0, \varepsilon)$  with  $B(0, \varepsilon) = \{x \in \mathbb{R}^n \mid \|x\|_2 < \varepsilon\}$ .

**Definition 3** For  $\varepsilon > 0$  the  $\varepsilon$ -mollification of a locally integrable function  $F: \mathbb{R}^n \rightarrow \mathbb{R}$  is the convolution  $F^\varepsilon = \eta_\varepsilon * F$  on  $\mathbb{R}^n$ , that is,

$$F^\varepsilon(x) = \int_{\mathbb{R}^n} \eta_\varepsilon(x-z)F(z) dz = \int_{B(0,\varepsilon)} \eta_\varepsilon(z)F(x-z) dz$$

for all  $x \in \mathbb{R}^n$ .

**Theorem 1 ([2])**

1. For all  $\varepsilon > 0$ , the  $\varepsilon$ -mollification  $F^\varepsilon$  is in  $C^\infty(\mathbb{R}^n, \mathbb{R})$ .
2. If  $F$  is continuous on  $\mathbb{R}^n$ , then  $F^\varepsilon$  converges to  $F$  uniformly on compact sets for  $\varepsilon \rightarrow 0$ .

**Formulation**

To formulate the smoothing method, the following three weak assumptions are made in [14,15].

**Assumption 1** The feasible set  $M$  of SIP is nonempty and compact.

**Assumption 2** The EMFCQ holds everywhere in  $M$ .

**Assumption 3** All KKT points of SIP are nondegenerate.

The smoothing approach is based on the mollification of the optimal value function  $G$ :

$$G^\varepsilon = \eta_\varepsilon * G = \eta_\varepsilon * \min_{y \in Y} g(\cdot, y).$$

In view of Theorem 1, the function  $G^\varepsilon$  is  $C^\infty$  for each  $\varepsilon > 0$ , and  $G^\varepsilon$  converges to  $G$  uniformly on compact sets for  $\varepsilon \rightarrow 0$ .

Intuitively, for sufficiently small  $\varepsilon > 0$  the set

$$M^\varepsilon = \{x \in \mathbb{R}^n \mid G^\varepsilon(x) \geq 0\}$$

and the smooth finite optimization problem

$$\text{SIP}^\varepsilon: \min_{x \in \mathbb{R}^n} f(x) \text{ subject to } G^\varepsilon(x) \geq 0$$

should be strongly related to  $M$  and SIP, respectively. This statement is made precise in the following theorems.

**Theorem 2 ([14])**  $M^\varepsilon$  converges to  $M$  in the Hausdorff distance for  $\varepsilon \rightarrow 0$ .

**Theorem 3 ([14])** For all sufficiently small  $\varepsilon > 0$ , EMFCQ holds everywhere in the set  $M^\varepsilon$ .

**Theorem 4 ([14])** For all sufficiently small  $\varepsilon > 0$ , the set  $M^\varepsilon$  is homeomorphic with  $M$ .

**Theorem 5 ([14,15])**

1. The set  $\text{KKT}(f, M)$  of Karush–Kuhn–Tucker points of SIP is finite.
2. For each  $\bar{x} \in \text{KKT}(f, M)$  let  $U(\bar{x})$  be some neighborhood of  $\bar{x}$ . Then outside the sets  $U(\bar{x}), \bar{x} \in \text{KKT}(f, M)$ , the problem  $\text{SIP}^\varepsilon$  has no KKT points for sufficiently small  $\varepsilon > 0$ .
3. The neighborhoods  $U(\bar{x}), \bar{x} \in \text{KKT}(f, M)$ , from part 2 can be chosen such that each  $U(\bar{x})$  contains exactly one KKT point  $x^\varepsilon$  of  $\text{SIP}^\varepsilon$  for sufficiently small  $\varepsilon > 0$ . Moreover,  $x^\varepsilon$  is nondegenerate, and the Morse index of  $\bar{x}$  in SIP and the Morse index of  $x^\varepsilon$  in  $\text{SIP}^\varepsilon$  coincide.

**Conclusions**

As an application of smoothing by mollifiers, Jongen and Stein [14] showed an important topological property of semi-infinite optimization problems. In fact, assume that at any  $x \in M$  one can define ascent and

descent directions for  $f$ . Then these define ascent and descent flows for  $f$ , respectively. For compact  $M$  suppose that all local minima and maxima of  $f$  on  $M$  are isolated critical points. Starting in a neighborhood of a local minimum one follows the ascent flow and might reach a local maximum. From there one steps downwards via the descent flow and might reach a local minimum. Perhaps the latter minimum is different from the former one, and the previous procedure is repeated. In this way one obtains a kind of “bang-bang” path in  $M$  which connects certain local minima and local maxima. The main question that arises is whether one can reach all local minima via such a bang-bang strategy or, equivalently, if a certain “min–max digraph” is strongly connected [12]. Of course,  $M$  has to be assumed to be connected, since only local information is used.

Even for finitely many constraints, in general the answer to the latter question is negative. A two-dimensional counterexample was given in [23], and the general mechanism which generates obstructions is presented in [4]. On the other hand, a special global adaptation of the metric, constructed in [12], gives a positive result. Moreover, Jongen and Stein [13] presented an automatic adaptation of the metric based on local information which generically gives a positive result.

Smoothing by mollifiers allows one to derive a similar result for SIP. In fact, for generic Riemannian metrics and sufficiently small  $\varepsilon > 0$  the corresponding min–max digraph of  $\text{SIP}^\varepsilon$  is strongly connected [14]. In view of Theorem 5 the corresponding KKT points (especially the local minima and maxima) of  $\text{SIP}^\varepsilon$  are arbitrarily close to those of the unperturbed SIP. This shows that SIP can be approximated arbitrarily well by a smooth finite  $\text{SIP}^\varepsilon$  with strongly connected min–max digraph.

### Keywords

Smooth nonlinear optimization; Nonconvex optimization; Lagrange multiplier rule; Optimality conditions; Geodesic convexity

Smooth *optimization problems* can be considered in the form of

$$\begin{cases} \min & f(\mathbf{x}) \\ \text{s.t.} & h_j(\mathbf{x}) = 0, \quad j = 1, \dots, n - k, \\ & g_i(\mathbf{x}) \leq 0, \quad i = 1, \dots, m, \\ & \mathbf{x} \in \mathbb{R}^n, \end{cases} \quad (1)$$

where  $k > 0$ ,  $\mathbf{R}^n$  is the  $n$ -dimensional Euclidean space,  $f, h_j, j = 1, \dots, n - k, g_i, i = 1, \dots, m$ , are at least twice continuously differentiable real valued functions and the aim is to find a solution point and/or the optimal value of the objective function  $f$ . Note that the underlying space can be more general than the Euclidean one,

e. g., Hilbert space. A smooth optimization problem (1) is *nonlinear* if the objective function  $f$  or at least one *constraint* function is nonlinear. Problem (1) is *nonconvex* if at least one function from  $f, g_i, i = 1, \dots, m$ , is not convex or at least one function from  $h_j, j = 1, \dots, n - k$ , is not affine. An important class of problems (1) is that of the *unconstrained optimization problems*, where the constraints  $g_i$  and  $h_j$ , for all  $i, j$  are not present or where every point in the domain of  $f$  is *feasible*, i. e., satisfies the constraints. If the number of constraints is infinite, then (1) result in *semi-infinite optimization problems*, and if the variables are restricted to a subset of the integers, then *integer optimization problems* are obtained. Since minimization and maximization are mathematically equivalent, without loss of generality, maximization should be replaced with minimization in (1). The practical applications of *nonlinear optimization* are incredibly vast, and moreover, smooth nonlinear optimization has very good properties with respect to structural investigations and *computational performances*.

Problem (1) can be considered a representation of models providing tools to describe real-life constraints of different types. For theoretical investigations, other representations could be helpful. Let  $\mathbf{h}$  denote the map from  $\mathbf{R}^n$  into  $\mathbf{R}^{n-k}$  of components  $h_j, j = 1, \dots, n - k$ ; furthermore, assume that the following *regularity condition* holds: 0 is a *regular value* of  $\mathbf{h}$ , i. e., the Jacobian matrix  $J\mathbf{h}(\mathbf{x}) \in \mathcal{L}(\mathbf{R}^n, \mathbf{R}^{n-k})$  of  $\mathbf{h}$  at  $\mathbf{x}$  is of full rank  $(n - k)$  for all  $\mathbf{x} \in M = \{\mathbf{x} \in \mathbf{R}^n: h_j(\mathbf{x}) = 0, j = 1, \dots, n - k\}$ . Under this assumption, the *feasible set*

$$A = \{\mathbf{x} \in M: g_i(\mathbf{x}) \leq 0, i = 1, \dots, m\} \quad (2)$$

is a subset of the  $k$ -dimensional submanifold  $M$  of class  $C^2$  in  $\mathbf{R}^n$  which can be endowed with a *Riemannian metric* (e. g., the one induced by the Euclidean structure of  $\mathbf{R}^n$ ). Assume, furthermore, that  $A$  is connected. In order to better see the structure of problem (1), we reformulate it into the following form:

$$\begin{cases} \min & f(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in A \subseteq M \subseteq \mathcal{M}, \end{cases} \quad (3)$$

where  $M$  is a  $k$ -dimensional *Riemannian manifold* and  $\mathcal{M}$  is the  $n$ -dimensional differentiable manifold  $\mathbf{R}^n$  endowed with the Riemannian metric  $G_1(\mathbf{x}) = I, \mathbf{x} \in \mathbf{R}^n$ , which induces the Riemannian metric of  $M$  defined as the restriction of the  $n \times n$  identity matrix to all the tangent spaces of  $M$ . The speciality of problem (1) is that

the representation of the manifold  $M$  is not a *curvilinear coordinate system* in the sense of differential geometry and the essential condition  $M \subseteq \mathcal{M}$  holds, which motivates the investigation of the common curvilinear coordinate representations of  $\mathcal{M}$  and  $M$  from the point of view of nonlinear optimization.

A *local minimizer* of problem (1) or (3) is a feasible point  $\mathbf{x}^* \in A$  such that  $f(\mathbf{x}^*) \leq f(\mathbf{x})$  for all  $\mathbf{x}$  in a feasible neighborhood of  $\mathbf{x}^*$ . If  $f(\mathbf{x}^*) \leq f(\mathbf{x})$  for all feasible  $\mathbf{x}$ , then  $\mathbf{x}^*$  is called a *global optimizer*. If  $\mathbf{x}^*$  is a local optimizer and  $f(\mathbf{x}^*) < f(\mathbf{x})$  for all  $\mathbf{x} \neq \mathbf{x}^*$  in a feasible neighborhood of  $\mathbf{x}^*$ , then  $\mathbf{x}^*$  is called a *strict local optimizer*. If  $\mathbf{x}^*$  is the only local minimizer in some feasible neighborhood of  $\mathbf{x}^*$ , it is called an *isolated local minimizer*.

A fundamental result due to K. Weierstrass is the fact that a feasible global minimizer of a continuous function  $f$  exists in a nonempty and compact feasible region  $A$ . If  $f$  is once continuously differentiable and  $\mathbf{x}^*$  is a local unconstrained minimizer, then the gradient  $\nabla f(\mathbf{x}^*) = 0$ . If  $f$  is twice continuously differentiable and  $\mathbf{x}^*$  is a local unconstrained minimizer, then  $\nabla f(\mathbf{x}^*) = 0$  and the Hessian matrix  $Hf(\mathbf{x}^*)$  is positive semidefinite. If  $\nabla f(\mathbf{x}^*) = 0$  and  $Hf(\mathbf{x}^*)$  is positive definite, then  $\mathbf{x}^*$  is an isolated (hence, also strict) local minimizer.

In the case of a finite number of equalities, the local optimality conditions are deduced by the *Lagrange multiplier rule*, [9,10]. This classical rule was independently extended to constraints including a finite number of equalities and inequalities in [2,3,6,7,8]. A transparent description of the smooth local optimality conditions can be found, e. g., in [1,4,5,11]. By improving these rules [13], global optimality conditions can be obtained which are formulated as follows.

Let  $\mathbf{x}^* \in A$  be a given point,  $I(\mathbf{x}^*)$  denote the index set of the *active inequality constraints* at  $\mathbf{x}^*$ ,  $|I(\mathbf{x}^*)|$  the number of active constraints, and  $\mathbf{g}_{I(\mathbf{x}^*)}: \mathbf{R}^n \rightarrow \mathbf{R}^{|I(\mathbf{x}^*)|}$  the mapping of the active constraints at  $\mathbf{x}^*$ . (An inequality constraint is active at  $\mathbf{x}^*$  if equality holds.)

Let us introduce:

- $M_{\mathbf{x}^*}$  as the set

$$\left\{ (\mathbf{x}, \mathbf{z}) \in \mathbb{R}^{n+|I(\mathbf{x}^*)|} : \begin{array}{l} h_j(\mathbf{x}) = 0, \\ j = 1, \dots, n-k, \\ g_i(\mathbf{x}) + \frac{1}{2}z_i^2 = 0, \\ i \in I(\mathbf{x}^*) \end{array} \right\}, \quad (4)$$

- the set  $TM_{\mathbf{x}^*}$ :

$$\left\{ (\mathbf{v}_1, \mathbf{v}_2) \in \mathbb{R}^{n+|I(\mathbf{x}^*)|} : \begin{array}{l} \nabla h_j(\mathbf{x})\mathbf{v}_1 = 0, \\ j = 1, \dots, n-k, \\ \nabla g_i(\mathbf{x})\mathbf{v}_1 + z_i\mathbf{v}_2 = 0, \\ i \in I(\mathbf{x}^*), \\ (\mathbf{x}, \mathbf{z}) \in M_{\mathbf{x}^*} \end{array} \right\}, \quad (5)$$

- a regularity condition

$$\begin{aligned} r([\mathbf{J}h(\mathbf{x}), 0]^\top, [\mathbf{J}g_{I(\mathbf{x}^*)}(\mathbf{x}), D_z]^\top) \\ = n - k + |I(\mathbf{x}^*)|, \\ (\mathbf{x}, \mathbf{z}) \in M_{\mathbf{x}^*}, \end{aligned} \quad (6)$$

where  $\mathbf{J}h$  and  $\mathbf{J}g_{I(\mathbf{x}^*)}$  are the Jacobian matrices of the mappings  $\mathbf{h}: \mathbf{R}^n \rightarrow \mathbf{R}^{n-k}$  and  $\mathbf{g}_{I(\mathbf{x}^*)}: \mathbf{R}^n \rightarrow \mathbf{R}^{|I(\mathbf{x}^*)|}$ , respectively, and  $D_z = \text{diag}(z_1, \dots, z_{|I(\mathbf{x}^*)|})$  the diagonal matrix with the components of the vector  $\mathbf{z}$ .

Here, problems satisfying (6), i. e., regular problems, are considered for which the inequality  $n \geq k$  holds. It is well-known that there cannot exist Lagrange multipliers for a local minimum in an irregular problem. Instead of (1) or (3), let us consider the problem

$$\min_{(\mathbf{x}, \mathbf{z}) \in M_{\mathbf{x}^*}} f(\mathbf{x}). \quad (7)$$

As a point  $\mathbf{x}^* \in A$  is a local optimal solution of problem (1) if and only if  $(\mathbf{x}^*, 0) \in M_{\mathbf{x}^*}$  is a local optimal solution of (7), and since the orthogonal projection of  $M_{\mathbf{x}^*}$  to  $\mathbf{R}^n$  with respect to the Euclidean metric contains  $A$ , a point  $\mathbf{x}^* \in A$  is a global optimal solution of problem (1) if  $(\mathbf{x}^*, 0) \in M_{\mathbf{x}^*}$  is a global optimal solution of (7), we deal with this latter problem only.

Let the *Lagrangian function* associated with  $f$  and  $M_{\mathbf{x}^*}$  be defined as

$$\begin{aligned} L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) \\ = f(\mathbf{x}) - \sum_{j=1}^{n-k} \mu_j(\mathbf{x})h_j(\mathbf{x}) \\ - \sum_{i \in I(\mathbf{x}^*)} \lambda_i(\mathbf{x}, \mathbf{z}) \left( g_i(\mathbf{x}) + \frac{1}{2}z_i^2 \right), \\ (\mathbf{x}, \mathbf{z}) \in M_{\mathbf{x}^*}, \\ \mu: \mathbf{R}^n \rightarrow \mathbf{R}^{n-k}, \\ \lambda: \mathbf{R}^{n+|I(\mathbf{x}^*)|} \rightarrow \mathbf{R}^{|I(\mathbf{x}^*)|}, \end{aligned} \quad (8)$$

where

$$\begin{aligned}\mu(\mathbf{x})^\top &= \nabla f(\mathbf{x})\mathbf{J}\mathbf{h}^\top(\mathbf{x})[\mathbf{J}\mathbf{h}(\mathbf{x})\mathbf{J}\mathbf{h}(\mathbf{x})^\top]^{-1}, \\ \lambda(\mathbf{x}, \mathbf{z})^\top &= \nabla f(\mathbf{x})\mathbf{J}\mathbf{g}_{I(\mathbf{x}^*)}^\top(\mathbf{x}) \\ &\times [\mathbf{J}\mathbf{g}_{I(\mathbf{x}^*)}(\mathbf{x}), D_z][\mathbf{J}\mathbf{g}_{I(\mathbf{x}^*)}(\mathbf{x}), D_z]^\top]^{-1}.\end{aligned}$$

Let the *geodesic gradient vector* and the *geodesic Hessian matrix* of the Lagrange function (8) be defined as

$$\begin{aligned}\nabla_{\mathbf{x}}^g L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) \\ &= \nabla f(\mathbf{x}) - \sum_{j=1}^{n-k} \mu_j(\mathbf{x})\nabla h_j(\mathbf{x}) \\ &- \sum_{i \in I(\mathbf{x}^*)} \lambda_i(\mathbf{x}, \mathbf{z})\nabla g_i(\mathbf{x}), \\ (\mathbf{x}, \mathbf{z}) &\in M_{\mathbf{x}^*}, \\ \nabla_{\mathbf{z}}^g L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) \\ &= - \sum_{i \in I(\mathbf{x}^*)} \lambda_i(\mathbf{x}, \mathbf{z})z_i\mathbf{e}_i^\top, \\ (\mathbf{x}, \mathbf{z}) &\in M_{\mathbf{x}^*},\end{aligned}$$

where  $\mathbf{e}_i, i = 1, \dots, |I(\mathbf{x}^*)|$ , are the unit vectors,

$$\begin{aligned}H_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) \\ &= \begin{pmatrix} Hf(\mathbf{x}) - \sum_{j=1}^{n-k} \mu_j(\mathbf{x})Hh_j(\mathbf{x}) & & & \\ - \sum_{i \in I(\mathbf{x}^*)} \lambda_i(\mathbf{x}, \mathbf{z})Hg_i(\mathbf{x}) & & 0 & \\ & & 0 & \\ & & & -D_\lambda \end{pmatrix} \Big|_{TM_{\mathbf{x}^*}}, \quad (9) \\ (\mathbf{x}, \mathbf{z}) &\in M_{\mathbf{x}^*},\end{aligned}$$

where the symbol  $|_{TM_{\mathbf{x}^*}}$  denotes the restriction to the tangent spaces of  $M_{\mathbf{x}^*}$  and  $D_\lambda$  is the diagonal matrix with components  $\lambda_i(\mathbf{x}, \mathbf{z}), i = 1, \dots, |I(\mathbf{x}^*)|$ , at  $(\mathbf{x}, \mathbf{z})$ .

Now, the global Lagrange multiplier rule is formulated for the case of equality and inequality constraints. First, a definition of *geodesic convex sets* is recalled where the geodesic is used in the classical meaning. If  $M$  is a Riemannian manifold, then a set  $A \subseteq M$  is geodesic convex if any two points of  $A$  are joined by a geodesic belonging to  $A$ , moreover, a singleton is geodesic convex. It is emphasized that every Riemannian metric generates a geodesic convexity notion. In optimization theory related to the Lagrange multiplier rule, the induced Riemannian metric seems to be the most important.

**Theorem 1 (Global Lagrange multiplier rule)** *If the point  $(\mathbf{x}^*, 0) \in M_{\mathbf{x}^*}$  is a (strict) local or global minimum of problem (7), then*

$$\begin{aligned}\nabla_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}^*, 0, \mu(\mathbf{x}^*), \lambda(\mathbf{x}^*, 0)) &= 0, \\ (\mathbf{v}_1, \mathbf{v}_2)^\top H_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}^*, 0, \mu(\mathbf{x}^*), \lambda(\mathbf{x}^*, 0)) \\ &\times (\mathbf{v}_1, \mathbf{v}_2) \geq (>) 0, \\ (\mathbf{v}_1, \mathbf{v}_2) &\in TM_{\mathbf{x}^*}(\mathbf{x}^*, 0), \\ ((\mathbf{v}_1, \mathbf{v}_2) &\neq 0).\end{aligned}$$

*If  $\widehat{A} \subseteq M_{\mathbf{x}^*}$  is an open geodesic convex set with respect to the induced Riemannian metric and*

$$\begin{aligned}\nabla_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}^*, 0, \mu(\mathbf{x}^*), \lambda(\mathbf{x}^*, 0)) &= 0, \\ (\mathbf{v}_1, \mathbf{v}_2)^\top H_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) \\ &\times (\mathbf{v}_1, \mathbf{v}_2) \geq (>) 0, \\ (\mathbf{v}_1, \mathbf{v}_2) &\in TM_{\mathbf{x}^*}(\mathbf{x}, \mathbf{z}), \\ ((\mathbf{v}_1, \mathbf{v}_2) &\neq 0), \\ (\mathbf{x}, \mathbf{z}) &\in M_{\mathbf{x}^*},\end{aligned} \quad (10)$$

*then the point  $(\mathbf{x}^*, 0)$  is a (strict) global minimum of the function  $f$  on  $\widehat{A}$ . Moreover,*

$$\nabla_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) = Df(\mathbf{x}, \mathbf{z}), \quad (11)$$

$$(\mathbf{x}, \mathbf{z}) \in M_{\mathbf{x}^*},$$

$$H_{(\mathbf{x}, \mathbf{z})}^g L(\mathbf{x}, \mathbf{z}, \mu(\mathbf{x}), \lambda(\mathbf{x}, \mathbf{z})) = D^2f(\mathbf{x}, \mathbf{z}), \quad (12)$$

$$(\mathbf{x}, \mathbf{z}) \in M_{\mathbf{x}^*},$$

*where  $Df$  and  $D^2f$  are the first and second covariant derivatives of the function  $f$  with respect to the induced Riemannian metric of the manifold  $M_{\mathbf{x}^*}$ , respectively.*

Because of the linear independence of the active gradients, the first order optimality condition is equivalent to the classical one, and in the case of equality constrained problems, the second order optimality conditions coincide with the classical ones at the stationary points as well, moreover, a geodesic convex feasible neighborhood always exists around a stationary point in a Riemannian manifold, so this latter condition does not mean a new restriction. If inequality constraints are present, then from (5) and (9), the classical optimality conditions and the nonpositivity of the Lagrange multipliers at the stationary points can be deduced. In this approach, neither Farkas' lemma in the necessary part

nor strict complementarity assumption ( $\lambda_i(\mathbf{x}^*, 0) > 0$ ,  $i \in I(\mathbf{x}^*)$ ) in the sufficiency part are used; they are replaced by the regularity condition and the smoothness of the functions.

By the global Lagrange multiplier rule, the necessary and sufficient optimality conditions are given by the same tensor formulae based on the first and second covariant derivatives, only the domains are different where the second order formula holds. The second order conditions (10) define a class of functions on geodesic convex sets with respect to the induced Riemannian metric, the *geodesic convex functions* with respect to the same metric, introduced in optimization theory in [12]. It is recalled that if  $M$  is a Riemannian manifold and  $A \subseteq M$  a geodesic convex set, then a function  $f: A \rightarrow \mathbf{R}$  is geodesic (strictly) convex if its restrictions to all geodesic arcs belonging to  $A$  are (strictly) convex in the arc length parameter. From the point of view of geometry, the existence of a constrained minimum is equivalent to the existence of a geodesic convex function with respect to the induced Riemannian metric. It follows that the Lagrange method can be considered the transformation of a constrained problem in  $\mathbf{R}^n$  into an unconstrained problem on the constraint submanifold with the induced Riemannian metric in  $\mathbf{R}^n$ . In the case of a Euclidean space, the geodesic convexity coincides with the classical one. The application of the Riemannian geometry highlighted the geometric background of smooth optimization and provides it with strong mathematical tools to study structural properties (e. g., geodesic convexity) and to deepen the theory of algorithms (e. g., *variable metric methods*).

## Problem Formulation and Basic Facts

Let  $X$  be a nonempty convex set in the real  $n$ -dimensional space  $\mathbb{R}^n$ , and let  $G: X \rightarrow \Pi(\mathbb{R}^n)$  be a multivalued mapping. Here and below  $\Pi(A)$  denotes the family of all nonempty subsets of a set  $A$ . Then one can define the multivalued or *generalized variational inequality (GVI) problem*, which is to find an element  $x^* \in X$  such that

$$\exists g^* \in G(x^*), \langle g^*, y - x^* \rangle \geq 0 \quad \forall y \in X. \quad (1)$$

If the cost mapping  $G$  is single-valued, GVI (1) reduces to the following usual *variational inequality (VI) problem*: Find an element  $x^* \in X$  such that

$$\langle G(x^*), y - x^* \rangle \geq 0 \quad \forall y \in X, \quad (2)$$

where  $G: \mathbb{R}^n \rightarrow \mathbb{R}^n$  is a given mapping.

VIs are now regarded as very useful and powerful tools for investigation and solution of various equilibrium-type problems arising in economics, engineering, operations research and mathematical physics. Many such applied problems involve multivalued mappings with rather weak continuity properties. The article is devoted to the construction of solution methods

for VIs with multivalued cost mappings. These problems involve in particular multivalued inclusions, complementarity and fixed-point problems, nonsmooth optimization and game problems, and mixed VIs (MVIs). Problem (1) was originally considered by Browder [5].

It is well known that the multivaluedness creates certain difficulties for providing convergence of many iterative methods, which are applied successfully to single-valued problems. This fact leads to the necessity of construction of new solution methods. In this article, we outline briefly the current situation and describe some new advances in this field.

First we consider some existence results for GVI (1) which are based on certain continuity-type properties of multivalued mappings; see, e. g., [11,16,17].

**Definition 1** A multivalued mapping  $Q: \mathbb{R}^n \rightarrow \Pi(\mathbb{R}^n)$  is said to be a  $K$  (Kakutani) mapping on  $X$  if it is upper semicontinuous on  $X$  and has nonempty, convex, and compact values.

**Proposition 1** Let  $G: X \rightarrow \Pi(\mathbb{R}^n)$  be a  $K$ -mapping. Suppose at least one of the following assumptions holds:

- (a) The set  $X$  is bounded;
- (b) there exists a nonempty bounded subset  $Y$  of  $X$  such that for every  $x \in X \setminus Y$  there is  $y \in Y$  with

$$\langle g, x - y \rangle \geq 0 \quad \forall g \in G(x).$$

Then GVI (1) has a solution.

The solution of GVI (1) is closely related to that of the corresponding *dual (or Minty) GVI (DGVI) problem*, which is to find a point  $\tilde{x} \in X$  such that

$$\forall x \in X \text{ and } \forall g \in G(x): \langle g, x - \tilde{x} \rangle \geq 0. \quad (3)$$

We denote by  $X^*$  (respectively, by  $X^d$ ) the solution set of problem (1) (respectively, problem (3)). Recall certain monotonicity-type properties for multivalued mappings.

**Definition 2** Let  $Q: \mathbb{R}^n \rightarrow \Pi(\mathbb{R}^n)$  be a multivalued mapping. The mapping  $Q$  is said to be

- (a) *strongly monotone* on  $X$  with constant  $\tau > 0$  if for each pair of points  $x, y \in X$  and for all  $q' \in Q(x)$ ,  $q'' \in Q(y)$ , we have

$$\langle q' - q'', x - y \rangle \geq \tau \|x - y\|^2;$$

(b) *strictly monotone* on  $X$  if for all distinct  $x, y \in X$  and for all  $q' \in Q(x), q'' \in Q(y)$ , we have

$$\langle q' - q'', x - y \rangle > 0;$$

(c) *monotone* on  $X$  if for each pair of points  $x, y \in X$  and for all  $q' \in Q(x), q'' \in Q(y)$ , we have

$$\langle q' - q'', x - y \rangle \geq 0;$$

(d) *pseudomonotone* on  $X$  if for each pair of points  $x, y \in X$  and for all  $q' \in Q(x), q'' \in Q(y)$ , we have

$$\langle q'', x - y \rangle \geq 0 \text{ implies } \langle q', x - y \rangle \geq 0.$$

From the definitions we have the following implications:

$$(a) \implies (b) \implies (c) \implies (d).$$

The reverse assertions are not true in general.

Now we give an extension of the Minty lemma for the multivalued case.

**Proposition 2**

- (i) *The set  $X^d$  is convex and closed.*
- (ii) *If  $G$  is a  $K$ -mapping, then  $X^d \subseteq X^*$ .*
- (iii) *If  $G$  is pseudomonotone, then  $X^* \subseteq X^d$ .*

We also recall some conditions under which GVI (1) has a unique solution.

**Proposition 3**

- (i) *If  $G$  is strictly monotone, then GVI (1) has at most one solution.*
- (ii) *If  $G$  is a strongly monotone  $K$ -mapping, then GVI (1) has a unique solution.*

Of course, there exist various modifications and extensions of the above results; see, e. g., [3,16] for more details.

**Projection Methods for GVIs**

We observe that the existence and uniqueness results for multivalued problems are very similar to those for single-valued VIs, but this is not the case for solution methods in general. That is, the substantiation of convergence and derivation of rates of convergence for iterative methods applied to multivalued problems meet certain difficulties in comparison with those in the single-valued case. This reduces essentially the number of

approaches to the creation of efficient solution methods. To illustrate this assertion, we first outline the behavior of projection-type methods.

Unless otherwise stated, throughout the article we suppose that

(C1)  *$X$  is a nonempty, convex and closed subset of the real  $n$ -dimensional space  $\mathbb{R}^n$ ,  $G: X \rightarrow \Pi(\mathbb{R}^n)$  is a  $K$ -mapping.*

**Projection Method**

Let us consider the standard *projection method*

$$x^{k+1} := \pi_X[x^k - \lambda_k g^k], \quad g^k \in G(x^k), \quad \lambda_k > 0, \quad (4)$$

where  $\pi_X(\cdot)$  denotes the projection mapping onto  $X$ . Usually, during the computation process we can find at least one element from  $G(x^k)$  at the current point  $x^k$ , but the whole set  $G(x^k)$  is not determined explicitly. The problem is to find a suitable rule for choosing the step size  $\lambda_k > 0$ , which provides convergence under mild assumptions and a good rate of convergence. We recall that in the single-valued case, where (C1) means that  $G$  is continuous, the above method is rewritten as follows

$$x^{k+1} := \pi_X[x^k - \lambda_k G(x^k)], \quad \lambda_k > 0, \quad (5)$$

and its convergence requires either integrability, or strengthened monotonicity (co-coercivity, strong monotonicity) and Lipschitz continuity assumptions. That is, if  $G$  is of the form  $G = \nabla f$ , where  $f$  is a given function, the step size  $\lambda_k$  can be chosen in conformity with the known exact or inexact (Armijo-type) rules. Then method (5) generates a sequence whose limit points are solutions of VI (2) with  $G = \nabla f$ ; moreover, it attains a linear rate of convergence if  $G$  is strongly monotone and Lipschitz continuous. The superlinear rate of convergence can be obtained within the conjugate gradient approach. However, this is not the case if  $G$  is not integrable. In fact, the same method (5) does not provide convergence even in the nonintegrable monotone case, for instance, when  $G(x) = Ax + b$  with  $A$  being skew-symmetric, regardless of the step-size choice. Therefore, we have to utilize different step-size rules and impose certain additional assumptions, such as co-coercivity.

**Definition 3** A mapping  $Q: \mathbb{R}^n \rightarrow \mathbb{R}^n$  is said to be co-coercive with constant  $\mu > 0$  on  $X$ , if for each pair

of points  $x, y \in X$ , we have

$$\langle Q(x) - Q(y), x - y \rangle \geq \mu \|Q(x) - Q(y)\|^2.$$

In fact, if  $G$  is co-coercive and VI (2) is solvable, then method (5) with the fixed step size  $\lambda_k = \lambda \in (0, 2\mu)$  generates a sequence  $\{x^k\}$  which converges to a solution of VI (2); see [15]. At the same time, the co-coercivity of  $G$  again implies the single-valuedness and even Lipschitz continuity of  $G$ .

Nevertheless, method (4) becomes convergent if we utilize the *divergent series step-size rule*

$$\lambda_k = \frac{\alpha_k}{\|g^k\|}, \quad \alpha_k > 0, \quad \sum_{k=0}^{\infty} \alpha_k = \infty, \quad \sum_{k=0}^{\infty} \alpha_k^2 < \infty, \quad (6)$$

and replace monotonicity of  $G$  with the *acute angle condition*:

(C2') GVI (1) is solvable, and for every  $x^* \in X^*$ , it holds that

$$\forall x \in X \setminus X^*, \quad \forall g \in G(x), \quad \langle g, x - x^* \rangle > 0; \quad (7)$$

see [15]. This property has clear geometric sense: the angle between  $-G(x)$  and  $x^* - x$  has to be acute at each nonoptimal point  $x$ . For instance, (7) holds if  $G$  is strictly monotone.

However, rule (6) leads to very slow convergence and prevents the method from attaining a linear rate of convergence. For this reason, we have to apply other approaches

- to utilize more efficient step-size rules,
- to attain more rapid convergence,
- to weaken sufficient conditions for convergence.

### Basic Solution Methods for GVIs

So, we intend to describe some other solution methods for GVI (1). First of all, in addition to (C1) we will utilize the following weakened condition

(C2) GVI (1) is solvable, and for every  $x^* \in X^*$ , it holds that

$$\forall x \in X, \quad \forall g \in G(x), \quad \langle g, x - x^* \rangle \geq 0 \quad (8)$$

(cf. (3) and (7)) or the somewhat more restrictive, but simplified version

(C3) GVI (1) is solvable, and  $G$  is monotone.

Clearly, we have the following implications

$$(C2') \implies (C2) \quad \text{and} \quad (C3) \implies (C2)$$

but the reverse assertions are not true.

Owing to Proposition 2, we see that (C2) is equivalent to

$$X^* = X^d \neq \emptyset$$

for GVI (1) if (C1) is fulfilled. Also note that (8) may in principle be called the *nonobtuse angle condition*; see [26] for more details.

We divide the basic solution methods into the following families:

- **Averaging methods;**
- **Center-type methods;**
- **Combined relaxation methods;**
- **Proximal point methods;**
- **Regularization methods.**

In the next sections, we describe properties of these general approaches to enhance the convergence properties of methods (4) and (6).

### Averaging and Regularization Type Methods

We now consider the methods which utilize modifications of the initial problems or some other kind of convergence.

#### Averaging Method

The idea of the *averaging method* consists in replacing the usual convergence of  $\{x^k\}$  with an ergodic convergence. It utilizes the same divergent series step-size rule (6). In fact, the sequence

$$z^k = \sum_{i=0}^k \alpha_i x^i / \sum_{i=0}^k \alpha_i, \quad (9)$$

enjoys stronger convergence properties than  $\{x^k\}$ . This idea leads to the so-called *averaging method*, which is due to Bruck [8].

**Method (AVR).** Choose a point  $x^0 \in X$  and a positive sequence  $\{\alpha_k\}$ . Set  $z^0 := x^0, \beta_0 := \alpha_0$ . At the  $k$ th iteration,  $k = 0, 1, \dots$ , set

$$\begin{aligned} \beta_{k+1} &:= \beta_k + \alpha_{k+1}, \quad \tau_{k+1} = \alpha_{k+1} / \beta_{k+1}; \\ x^{k+1} &:= \pi_X(x^k + \alpha_k g^k), \quad g^k \in G(x^k); \\ z^{k+1} &:= \tau_{k+1} x^{k+1} + (1 - \tau_{k+1}) z^k. \end{aligned}$$

From the description it follows that the sequence  $\{z^k\}$  generated by (AVR) satisfies (9).

**Theorem 1** *Suppose that (C1) and (C3) hold and that sequences  $\{x^k\}$  and  $\{z^k\}$  are constructed by (AVR) and that the sequence  $\{\alpha_k\}$  satisfies the following conditions:*

$$\sum_{k=0}^{\infty} \alpha_k = \infty, \quad \sum_{k=0}^{\infty} (\alpha_k \|g^k\|)^2 < \infty.$$

*Then there exist limit points of  $\{z^k\}$  and all these points belong to  $X^*$ .*

The rate of convergence of the averaging method was investigated by several authors. It was shown by Nemirovskii [40] that  $\|z^k - x^*\| = O(1/\sqrt{k})$ , where  $x^* \in X^*$ .

**Regularization Methods**

The idea of the earliest and most popular regularization method consists in replacing the initial GVI (1) with a sequence of the following auxiliary problems: Find a point  $x^\varepsilon \in X$  such that

$$\exists g^\varepsilon \in G(x^\varepsilon), \langle g^\varepsilon + \varepsilon x^\varepsilon, x - x^\varepsilon \rangle \geq 0 \quad \forall x \in X, \quad (10)$$

where  $\varepsilon > 0$  is a regularization parameter. It was first proposed by Tikhonov [46] and was adjusted to VIs by Browder [7]. Suppose that (C1) and (C3) hold. Then  $G$  is monotone,  $G + \varepsilon I$  is strongly monotone and, by Proposition 3, (10) has a unique solution, which can be found by one of the versions of the above projection method within a given accuracy. The basic approximation property of the exact regularization method is formulated as follows:

**Theorem 2** *Suppose that (C1) and (C3) are fulfilled and that the sequence  $\{x^{\varepsilon_k}\}$  is obtained from (10) with  $\{\varepsilon_k\} \searrow 0$ . Then the following assertions are true:*

- (i) *each auxiliary GVI (10) has a unique solution;*
- (ii) *the sequence  $\{x^{\varepsilon_k}\}$  converges to the solution  $x_n^*$  of (1) nearest to the origin.*

We also can replace (C3) with (C2) and obtain similar convergence properties despite the fact that the cost mapping in (10) is not monotone. We present a strengthened version of the result from [34].

**Theorem 3** *Suppose that (C1) and (C2) are fulfilled and that the sequence  $\{x^{\varepsilon_k}\}$  is obtained from (10) with  $\{\varepsilon_k\} \searrow 0$ . Then the following assertions are true:*

- (i) *each auxiliary GVI (10) has a solution;*
- (ii)  *$\{x^{\varepsilon_k}\}$  converges to the solution  $x_n^*$  of (1) nearest to origin.*

Moreover, we can obtain convergence results for (RM) under even weaker conditions which are utilized for providing existence results for GVIs; see [33]. Namely, let us consider the following coercivity condition (see e. g. [3]):

**(C2'')** *There exists a number  $r > 0$  such that for any point  $x \in X \setminus X_r$  there is a point  $y \in X$ ,  $\|y\| < \|x\|$  such that  $\langle g, y - x \rangle \leq 0, \forall g \in G(x)$ , where*

$$X_r = \{x \in X \mid \|x\| \leq r\}.$$

The basic approximation properties of the regularization method are then formulated as follows:

**Theorem 4** *Suppose conditions (C1) and (C2'') are fulfilled. Then:*

- (i) *GVI (1) has a solution;*
- (ii) *GVI (10) has a solution for each  $\varepsilon > 0$ ;*
- (iii) *Each sequence  $\{x^{\varepsilon_k}\}$  of solutions of GVI (10) has limit points and if  $\{\varepsilon_k\} \searrow 0$  all these limit points are solutions of GVI (1).*

The regularization approach allows various modifications. One of them was proposed by Bakushinskii and Polyak [2] and is called the *iterative regularization method*. The idea of this approach consists in simultaneous changes of the regularization parameters and the step sizes of an approximation method, i. e., it is intermediate between the above averaging and regularization methods, and has similar convergence properties.

**Proximal Point Method**

The idea of the *proximal point method*, which was suggested by Martinet [39], also consists in replacing the initial GVI (1) with a sequence of auxiliary problems. The essential features of the proximal point method are that the regularization parameter may in principle be fixed and that the perturbed mapping depends on the previous iteration point. We first recall the convergence result for the exact version of the proximal point method applied to monotone problems.

**Theorem 5** *Suppose that (C1) and (C3) are fulfilled and that a sequence  $\{x^k\}$  is generated in conformity with*

the rules

$$\begin{aligned} \exists g^k \in G(x^k), \langle g^k + \theta^{-1}(x^k - x^{k-1}), y - x^k \rangle \geq 0 \\ \forall y \in Y, \end{aligned} \quad (11)$$

where  $\theta > 0$  is a regularization parameter. Then the following assertions are true:

- (i) each auxiliary GVI (11) has a unique solution;
- (ii) the sequence  $\{x^k\}$  converges to a solution of GVI (1).

In fact, since (C1) and (C3) hold, the cost mapping in (11) is strongly monotone and, by Proposition 3, (11) has a unique solution. However, we can replace (C3) with (C2) and obtain similar convergence properties; see e. g., [1,4,12,28]. We now give such a strengthened result for the proximal point method.

**Theorem 6** Suppose that (C1) and (C2) are fulfilled and that a sequence  $\{x^k\}$  is generated in conformity with the rules in (11) with  $\theta > 0$ . Then the following assertions are true:

- (i) each auxiliary GVI (11) has a solution;
- (ii) the sequence  $\{x^k\}$  converges to a solution of GVI (1).

Observe that the cost mapping in (11) need not be strongly monotone but (11) is still solvable. Under the additional Lipschitz continuity type condition on  $G$  we can choose  $\theta$  large enough for the cost mapping in (11) to be strongly monotone, thus providing the uniqueness of a solution as well.

The exact proximal point method attains linear and even superlinear convergence rates as was shown by Rockafellar [44]. At the same time, the total rates of convergence of both the proximal point method and the regularization method, involving expenses for approximate solutions of auxiliary problems, need further investigations.

**Direct Iterative Methods for GVIs**

We now present iterative methods for solving GVI (1) without any explicit monotonicity assumptions.

**Center-Type Methods**

The best known of the center-type methods is the famous ellipsoid method, which was proposed first by Yudin and Nemirovskii [47] and by Shor [45] for convex programming and afterwards adjusted for saddle

point problems and VIs [40]. In this method, each iterate  $x^k$  is associated with an ellipsoid  $U_k$  centered at  $x^k$  and containing at least one solution point. After finding a half-space  $H^+_k$  containing this solution point, the next ellipsoid  $U_{k+1}$  is precisely the smallest ellipsoid containing the set  $U_k \cap H^+_k$ . Set

$$P(z) = \begin{cases} G(z) & \text{if } z \in X, \\ \{p \in \mathbb{R}^n \mid \langle p, y - z \rangle \leq 0 \ \forall y \in X\} & \text{if } z \notin X. \end{cases}$$

**Method (EM).** Choose a point  $x^0 \in \mathbb{R}^n$ , a number  $\lambda > 0$  such that  $\|x^0 - x^*\| \leq \lambda$  for some  $x^* \in X^*$  and set  $A_0 := \lambda^2 I$ . At the  $k$ th iteration,  $k = 0, 1, \dots$ , choose  $p^k \in P(x^k)$  and set

$$\begin{aligned} x^{k+1} &:= x^k - \frac{1}{n+1} \frac{A_k p^k}{\sqrt{(p^k)^T A_k p^k}}, \\ A_{k+1} &:= \frac{n^2}{n^2-1} \left( A_k - \frac{2}{n+1} \frac{A_k p^k (A_k p^k)^T}{(p^k)^T A_k p^k} \right), \end{aligned}$$

and  $k := k + 1$ .

If the basic assumptions (C1) and (C2) are fulfilled, the process is well-defined. Namely, then

$$U_k = \{x \in \mathbb{R}^n \mid \langle A_k^{-1}(x - x^k), x - x^k \rangle \leq 1\}$$

and

$$H^+_k = \{x \in \mathbb{R}^n \mid \langle p^k, x - x^k \rangle \leq 0\}.$$

The implementation of (EM) is similar to that of variable metric methods. It is well known that the volumes of  $U_k$  will also tend to zero at a linear rate, which depends on the dimensionality of the problem. These properties yield the convergence of the sequence  $\{x^k\}$  to a solution.

The idea of various proximal-level methods is rather close to that of the center methods [14,18,36]. In fact, the methods are based on sequential updating of a polyhedral approximation of a nonsmooth merit function for GVI and computing the prox-center of the corresponding level sets. These methods possess similar convergence properties.

**Combined Relaxation Methods**

The idea of *combined relaxation methods* consists in defining the next iterate  $x^{k+1}$  as the projection of the

current iterate  $x^k$  onto a hyperplane  $H_k$  which separates strictly  $x^k$  and the solution set and is computed by an auxiliary procedure. This approach to solve VIs was proposed first by Konnov [19], where it was also noticed that the parameters of the hyperplane  $H_k$  can be found with the help of an iteration of any relaxation method. Afterwards, combined relaxation methods were developed in several directions. In [20], a combined relaxation method for GVI of form (1) was proposed and linear convergence rates were established. All these methods ensure convergence to a solution of GVI under assumption (C2) or (C3). Within the general combined relaxation framework, different rules for determining the separating hyperplane and auxiliary procedures were presented; see [26] and references therein.

**Combined Relaxation Method for GVIs** We now consider a combined relaxation method for solving GVI (1) with explicit usage of constraints [20,22]. In addition to the basic assumptions (C1) and (C2), we suppose that

- $X$  is defined by

$$X = \{x \in \mathbb{R}^n \mid h(x) \leq 0\},$$

where  $h: \mathbb{R}^n \rightarrow \mathbb{R}$  is a convex and subdifferentiable function;

- the Slater condition is satisfied, i.e., there exists a point  $\bar{x}$  such that  $h(\bar{x}) < 0$ .

Let us define the mapping  $Q: \mathbb{R}^n \rightarrow \Pi(\mathbb{R}^n)$  by

$$Q(x) = \begin{cases} G(x) & \text{if } h(x) \leq 0, \\ \partial h(x) & \text{if } h(x) > 0. \end{cases}$$

**Definition 4** A mapping  $P: \mathbb{R}^n \rightarrow \mathbb{R}^n$  is said to be a pseudo-projection onto  $X$ , if for every  $y \in \mathbb{R}^n$  it holds that

$$P(y) \in X \text{ and } \|P(y) - x\| \leq \|y - x\| \quad \forall x \in X.$$

We denote by  $\mathcal{F}$  the class of all pseudo-projection mappings onto  $X$ . Clearly,  $\pi_X \in \mathcal{F}$ . That is, the pseudo-projection is weaker but it can be implemented in the case where  $h$  is essentially nonlinear; see [26] for more details.

**Method (CRM).** Step 0 (initialization): Choose a point  $x^0 \in X$ , bounded positive sequences  $\{\varepsilon_l\}$  and

$\{\eta_l\}$ , and a sequence of mappings  $\{P_k\}$ , where  $P_k \in \mathcal{F}$ . Also, choose numbers  $\theta \in (0, 1)$ , and  $\gamma \in (0, 2)$ . Set  $k := 0, l := 1$ .

Step 1 (auxiliary procedure):

Step 1.1: Choose  $q^0$  from  $Q(x^k)$ , set  $i := 0, p^i := q^i, w^{k,0} := x^k$ .

Step 1.2: If  $\|p^i\| \leq \eta_l$ , set  $x^{k+1} := x^k, k := k + 1, l := l + 1$  and go to step 1. (null step)

Step 1.3: Set  $w^{k,i+1} := w^{k,0} - \varepsilon_l p^i / \|p^i\|$ , choose  $q^{i+1} \in Q(w^{k,i+1})$ . If  $\langle q^{i+1}, p^i \rangle > \theta \|p^i\|^2$ , then set  $y^k := w^{k,i+1}, g^k := q^{i+1}$ , and go to step 2. (descent step)

Step 1.4: Set  $p^{i+1} := \text{Nr conv}\{p^i, q^{i+1}\}, i := i + 1$  and go to step 1.2.

Step 2 (Main iteration): Set  $\omega_k := \langle g^k, x^k - y^k \rangle$ ,

$$x^{k+1} := P_k[x^k - \gamma(\omega_k / \|g^k\|^2)g^k],$$

$k := k + 1$  and go to step 1.

Here NrS denotes the element of  $S$  nearest to the origin. We will call one increase of the index  $i$  an inner step, so that the number of inner steps gives the number of computations of elements from  $Q(\cdot)$  at the corresponding points.

**Theorem 7** Let a sequence  $\{x^k\}$  be generated by (CRM) and let  $\{\varepsilon_l\}$  and  $\{\eta_l\}$  satisfy the following relations:

$$\{\varepsilon_l\} \searrow 0, \{\eta_l\} \searrow 0. \tag{12}$$

Then:

- (i) The number of inner steps at each iteration is finite.
- (ii) It holds that

$$\lim_{k \rightarrow \infty} x^k = x^* \in X^*.$$

Given a starting point  $x^0$  and a number  $\delta > 0$ , we define the complexity of the method, denoted by  $N(\delta)$ , as the total number of inner steps  $t$  which ensures finding a point  $\bar{x} \in X$  such that

$$\|\bar{x} - x^*\| / \|x^0 - x^*\| \leq \delta.$$

Therefore, since the computational expense per inner step can be evaluated for each problem under examination, this estimate in fact gives the total amount of work. We thus proceed to obtain an upper bound for  $N(\delta)$ .

**Theorem 8 (Konnov [26], Theorem 2.3.3)** Suppose  $G$  is monotone and there exists  $x^* \in X^*$  such that

$$\begin{aligned} &\text{for every } x \in X \text{ and for every } g \in G(x), \\ &\langle g, x - x^* \rangle \geq \mu \|x - x^*\|, \end{aligned}$$

for some  $\mu > 0$ . Let a sequence  $\{x^k\}$  be generated by (CRM) where

$$\varepsilon_l = \nu^l \varepsilon', \eta_l = \eta', l = 0, 1, \dots; \quad \nu \in (0, 1).$$

Then, there exist some constants  $\bar{\varepsilon} > 0$  and  $\bar{\eta} > 0$  such that

$$N(\delta) \leq B_1 \nu^{-2} (\ln(B_0/\delta) / \ln \nu^{-1} + 1),$$

where  $0 < B_0, B_1 < \infty$ , whenever  $0 < \varepsilon' \leq \bar{\varepsilon}$  and  $0 < \eta' \leq \bar{\eta}$ ,  $B_0$  and  $B_1$  being independent of  $\nu$ .

The assertion of Theorem 8 remains valid without the additional monotonicity assumption on  $G$  if  $X = \mathbb{R}^n$ . Thus, (CRM) attains a logarithmic complexity estimate, which corresponds to a linear rate of convergence with respect to inner steps. We can give a similar upper bound for  $N(\delta)$  in the single-valued case.

**Theorem 9 (Konnov [26], Theorem 2.3.4)** Suppose that  $X = \mathbb{R}^n$  and that  $G$  is strongly monotone and Lipschitz continuous. Let a sequence  $\{x^k\}$  be generated by (CRM), where

$$\varepsilon_l = \nu^l \varepsilon', \eta_l = \nu^l \eta', l = 0, 1, \dots; \varepsilon' > 0, \eta' > 0; \quad \nu \in (0, 1).$$

Then,

$$N(\delta) \leq B_1 \nu^{-6} (\ln(B_0/\delta) / \ln \nu^{-1} + 1),$$

where  $0 < B_0, B_1 < \infty$ ,  $B_0$  and  $B_1$  being independent of  $\nu$ .

**Combined Relaxation Method for Multivalued Inclusions** To solve GVI (1), we can also apply (CRM) for finding stationary points of the mapping  $P$  defined as follows:

$$P(x) = \begin{cases} G(x) & \text{if } h(x) < 0, \\ \text{conv}\{G(x) \cup \partial h(x)\} & \text{if } h(x) = 0, \\ \partial h(x) & \text{if } h(x) > 0. \end{cases} \quad (13)$$

Such a method need not include (pseudo)projections and is based on the following observations [21,26].

We note  $P$  in (13) is a  $K$ -mapping. Next, GVI (1) is equivalent to the multivalued inclusion

$$0 \in P(x^*). \quad (14)$$

We denote by  $S^*$  the solution set of problem (14). In order to apply (CRM) to this problem we have to show that its dual problem is solvable. Namely, let us consider the problem of finding a point  $x^*$  of  $\mathbb{R}^n$  such that

$$\forall x \in \mathbb{R}^n, \forall p \in P(u), \langle p, x - x^* \rangle \geq 0,$$

which can be viewed as the dual problem of (14). We denote by  $S^d$  the solution set of this problem.

**Theorem 10 (Konnov [26], Theorem 2.3.1 and Proposition 2.4.1)** It holds that

- (i)  $X^* = S^*$ ,
- (ii)  $X^d = S^d$ .

Therefore, we can apply (CRM) by replacing  $G, X$ , and  $P_k$  by  $P, \mathbb{R}^n$ , and  $I$ , respectively, to the multivalued inclusion (14) under the same blanket assumptions. We call this modification (CRMIS).

**Theorem 11** Let a sequence  $\{x^k\}$  be generated by (CRMIS) and let  $\{\varepsilon_l\}$  and  $\{\eta_l\}$  satisfy (15). Then:

- (i) The number of inner steps at each iteration is finite.
- (ii) It holds that

$$\lim_{k \rightarrow \infty} x^k = x^* \in S^* = X^*.$$

### Iterative Methods for Generalized Complementarity Problems

It is well known that taking into account additional peculiarities of the problem under examination could yield more efficient solution methods in comparison with those in the general case. We intend to describe several recent results for certain classes of multivalued VIs.

Let us consider problem (1) where the feasible set  $X$  coincides with the nonnegative orthant  $\mathbb{R}_+^n = \{x \in \mathbb{R}^n \mid x_i \geq 0 \forall i = 1, \dots, n\}$ . Then it can be rewritten in the equivalent *generalized complementarity problem* (GCP) format:

$$x^* \geq 0, \exists g^* \in G(x^*), g^* \geq 0, \langle g^*, x^* \rangle = 0. \quad (15)$$

Owing to the special form of the constraint sets of these problems, their existence and uniqueness results of solutions can be based upon rather weak order monotonicity properties instead of the previous norm monotonicity ones [9,10,17]. We recall several order monotonicity properties of single-valued mappings.

**Definition 5** A mapping  $F: X \rightarrow \mathbb{R}^n$  is said to be

- (a) a  $P_0$ -mapping, if for each pair of points  $x', x'' \in X$  there exists an index  $i$  such that  $x'_i \neq x''_i$  and

$$(x'_i - x''_i)(F_i(x') - F_i(x'')) \geq 0;$$

- (b) a  $P$ -mapping, if for each pair of points  $x', x'' \in X$  such that  $x' \neq x''$  it holds that

$$\max_{1 \leq i \leq n} (x'_i - x''_i) [F_i(x') - F_i(x'')] > 0;$$

- (c) a  $Z$ -mapping if for each pair of points  $x', x'' \in X$  such that  $x' \geq x''$  it holds that  $F_k(x') \leq F_k(x'')$  for each index  $k$  with  $x'_k = x''_k$ .

Clearly, each monotone (respectively, strictly monotone) mapping is a  $P_0$ -mapping (respectively,  $P$ -mapping).

One of the most useful and fruitful concepts is that of the  $Z$ -mapping (or off-diagonal antitone mapping). However, the creation of efficient solution methods and even the generalization of this concept for multivalued mappings meet considerable difficulties.

Following [29] and [32], we consider some kinds of multivalued  $Z$ -mappings and discuss their properties. For rather a general class of GCPs of form (15), we suggest an extension of the Jacobi algorithm and obtain its convergence to a solution, thus presenting an existence result.

**Properties of Multivalued  $Z$ -Mappings**

We present streamlined extensions of the above concepts for the multivalued case.

**Definition 6** A multivalued mapping  $G: X \rightarrow \Pi(\mathbb{R}^n)$  is said to be

- (a) a  $P_0$ -mapping, if for each pair of points  $x', x'' \in X$ , and for each pair of vectors  $g' \in G(x')$ ,  $g'' \in G(x'')$  there exists an index  $i$  such that  $x'_i \neq x''_i$  and

$$(x'_i - x''_i)(g'_i - g''_i) \geq 0;$$

- (b) a  $P$ -mapping, if for each pair of points  $x', x'' \in X$  such that  $x' \neq x''$  and for each pair of vectors  $g' \in G(x')$ ,  $g'' \in G(x'')$  there exists an index  $i$  such that

$$(x'_i - x''_i)(g'_i - g''_i) > 0;$$

- (c) a  $Z$ -mapping if for each pair of points  $x', x'' \in X$  such that  $x' \geq x''$ ,  $x' \neq x''$  it holds that  $g'_k \leq g''_k$  for all  $g' \in G(x')$ ,  $g'' \in G(x'')$  and for each index  $k$  such that  $x'_k = x''_k$ .

Note that the additional condition  $x' \neq x''$  cannot be dropped in Definition 6c since otherwise the  $Z$ -mapping becomes single-valued. Hence, the above concept of the  $Z$ -mapping may appear too restrictive.

**Definition 7** A mapping  $G: \mathbb{R}^n \rightarrow \Pi(\mathbb{R}^n)$  is said to be

- (a) *diagonal* if  $G(x) = \prod_{i=1}^n G_i(x_i)$ ;

- (b) *quasi-diagonal* if  $G(x) = \prod_{i=1}^n G_i(x)$ .

Clearly, (a)  $\implies$  (b). Moreover, each single-valued mapping is quasi-diagonal. Next, observe that each diagonal single-valued mapping is  $Z$ , but this is not the case if it is multivalued; hence, various compositions of multivalued diagonal and  $Z$ -mappings may not possess the  $Z$  property as well.

We now present modified order monotonicity concepts of multivalued  $Z$ -mappings which enable us to remove these difficulties.

**Definition 8** A mapping  $G: X \rightarrow \Pi(\mathbb{R}^n)$  is said to be an *upper* (a *lower*)  $Z$ -mapping if for each pair of points  $x', x'' \in D$  such that  $x' \geq x''$  and for each  $g' \in G(x')$  there exists  $g'' \in G(x'')$  (respectively, for each  $g'' \in G(x'')$  there exists  $g' \in G(x')$ ) such that  $g'_k \leq g''_k$  for every index  $k$  such that  $x'_k = x''_k$ .

Obviously, these concepts extend the similar one from Definition 6 and the condition  $x' \neq x''$  is now unnecessary. They are also additive. Moreover, each diagonal mapping is both an upper and a lower  $Z$ -mapping.

**Extended Jacobi Algorithm for Multivalued Mixed Complementarity Problems**

Let us consider GCP (15), where  $G: X \rightarrow \Pi(\mathbb{R}^n)$  is of the form

$$G(x) = \sum_{s=1}^l F^{(s)} \circ H^{(s)}(x), \tag{16}$$

where  $F^{(s)}: \mathbb{R}^n \rightarrow \Pi(\mathbb{R}^n)$  is a quasi-diagonal, an upper  $Z$ - and a  $K$ -mapping on some rectangle containing  $H^{(s)}(X)$ ,  $H^{(s)}: X \rightarrow \Pi(\mathbb{R}^n)$  is a diagonal monotone

*K*-mapping for each  $s = 1, \dots, l$ . Let us introduce the auxiliary set for GCP (15) and (16) as follows:

$$\mathbb{Q} = \{x \geq 0 \mid \exists g \in G(x), g \geq 0\} .$$

Given a vector  $x \in \mathbb{R}^n$  and a number  $y_i$ , we set

$$(x_{-i}, y_i) = (x_1, \dots, x_{i-1}, y_i, x_{i+1}, \dots, x_n) .$$

**Algorithm (Jacobi).** Choose a point  $\tilde{x} \in \mathbb{Q}$  and, beginning from the point  $x^0 = \tilde{x}$ , construct a sequence  $\{x^k\}$  in conformity with the following rules.

At the  $k$ th iteration,  $k = 0, 1, \dots$ , we have a point  $x^k \in \mathbb{Q}$  such that  $x^k \leq x^0$  and that there exists  $g^k \in \sum_{s=1}^l F_i^{(s)}(h_i^{(s),k})$  for some  $h_i^{(s),k} \in H_i^{(s)}(x^k)$ ,  $s = 1, \dots, l$ , such that  $g^k \geq 0$ .

For each separate index  $i = 1, \dots, n$ , we determine numbers  $x_i^{k+1}, p_i^{(1)}, \dots, p_i^{(l)}$  such that

$$0 \leq x_i^{k+1} \leq x_i^k, \exists \tilde{g}_i^k \in \sum_{s=1}^l F_i^{(s)}(h_{-i}^{(s),k}, p_i^{(s)}), \tilde{g}_i^k \geq 0, \\ x_i^{k+1} \tilde{g}_i^k = 0, \quad (17)$$

$$p_i^{(s)} \in H_i^{(s)}(x_i^{k+1}), p_i^{(s)} \leq h_i^{(s),k} \text{ for } s = 1, \dots, l, \quad (18)$$

with the help of the bisection procedure below. Afterwards, set  $h_i^{(s),k+1} = p_i^{(s)}$  for  $s = 1, \dots, l$  and go to the  $(k + 1)$ th iteration.

**Procedure (Bisection).** It is applied when the indices  $k$  and  $i$  are fixed and consists of the following sequence of steps.

*Step 1:* If  $g_i^k = 0$  or  $x_i^k = 0$ , set  $x_i^{k+1} = x_i^k, \tilde{g}_i^k = g_i^k, p_i^{(s)} = h_i^{(s),k}$  for  $s = 1, \dots, l$  and stop. Otherwise go to step 2.

*Step 2:* Choose  $p_i^{(s)} \in H_i^{(s)}(0)$  for  $s = 1, \dots, l$  and compute an element  $\tilde{g}_i^k \in \sum_{s=1}^l F_i^{(s)}(h_{-i}^{(s),k}, p_i^{(s)})$ . If  $\tilde{g}_i^k \geq 0$ , then set  $x_i^{k+1} = 0$  and stop. Otherwise set  $x_i' = 0, x_i'' = x_i^k$  and  $\alpha_i^{(s)} = p_i^{(s)}, \beta_i^{(s)} = h_i^{(s),k}$  for  $s = 1, \dots, l$ .

*Step 3:* Generate a sequence of inscribed segments  $[x_i', x_i'']$  contracting to a point  $z_i$  by choosing  $y_i = \frac{1}{2}(x_i' + x_i'')$ , computing  $\tilde{\beta}_i^{(s)} \in H_i^{(s)}(y_i)$  for  $s = 1, \dots, l$  and  $\tilde{g}_i = \sum_{s=1}^l F_i^{(s)}(h_{-i}^{(s),k}, \tilde{\beta}_i^{(s)})$ , and setting  $x_i'' = y_i, \beta_i^{(s)} = \tilde{\beta}_i^{(s)}$  for  $s = 1, \dots, l$  if  $\tilde{g}_i \geq 0$  and  $x_i' = y_i, \alpha_i^{(s)} = \tilde{\beta}_i^{(s)}$  for  $s = 1, \dots, l$  if  $\tilde{g}_i < 0$ .

*Step 4:* Set  $x_i^{k+1} = z_i$  and compute numbers  $p_i^{(s)} \in H_i^{(s)}(z_i)$  for  $s = 1, \dots, l$  such that conditions (17) and (18) are satisfied.

We present a convergence result for the Jacobi algorithm.

**Theorem 12** Suppose that the set  $\mathbb{Q}$  is nonempty. Then the Jacobi algorithm with the bisection procedure is well defined and generates a sequence  $\{x^k\}$  converging to a solution  $x^*$  of GCP (15) and (16) such that  $0 \leq x^* \leq \tilde{x}$ .

Clearly, the corresponding modification of the Gauss-Seidel algorithm will possess similar convergence properties. Note that the above theorem in fact contains also the existence result.

**Corollary 1** If the set  $\mathbb{Q}$  is nonempty, then GCP (15) and (16) has a solution.

It was also shown in [32] that the auxiliary set  $\mathbb{Q}$  is a meet semisublattice, i.e., for each pair of points  $x, y \in \mathbb{Q}$  it contains their minimal point (meet)  $z = \min\{x, y\}$  with  $z_i = \min\{x_i, y_i\}$  for  $i = 1, \dots, n$ ; if (16) is replaced by

$$G(x) = F \circ H(x) + V(x),$$

$V: X \rightarrow \Pi(\mathbb{R}^n)$  is a quasi-diagonal, an upper  $Z$ - and a  $K$ -mapping,  $H: X \rightarrow \Pi(\mathbb{R}^n)$  is a diagonal monotone  $K$ -mapping, and  $F: \mathbb{R}^n \rightarrow \Pi(\mathbb{R}^n)$  is a quasi-diagonal, an upper  $Z$ - and a  $K$ -mapping on a rectangle containing  $H(X)$ . Hence, the set  $\mathbb{Q}$  has the least element  $\min \mathbb{Q}$  which is a solution of the GCP.

The above Jacobi algorithm can be extended to a more general class of problems. In fact, we can consider problem (1) where the feasible set  $X$  is defined as follows:

$$X = \{x \in \mathbb{R}^n \mid -\infty < a_i \leq x_i \leq b_i \leq +\infty \\ i = 1, \dots, n\} .$$

It is called the *generalized mixed complementarity problem* (GMCP) and can be also equivalently rewritten as follows: Find a point  $x^* \in X$  such that

$$\exists g^* \in G(x^*), \quad g_i^* \begin{cases} \geq 0 & \text{if } x_i^* = a_i, \\ = 0 & \text{if } x_i^* \in (a_i, b_i), \\ \leq 0 & \text{if } x_i^* = b_i, \end{cases} \quad (19) \\ \text{for } i = 1, \dots, n .$$

Then we should define the auxiliary set for the GMCP as follows

$$\mathbb{Q} = \{x \in X \mid \exists g \in G(x), x_i < b_i \Rightarrow g_i \geq 0 \quad \forall i = 1, \dots, n\},$$

and all the above results remain true.

We can enhance the assertions of the theorems from Sects. “Regularization Methods” and “Proximal Point Method” for the regularization-type methods applied to GCP (15) or to GMCP (19) with order monotonicity ( $P_0$ ) properties. In fact, if  $G$  is  $P_0$ , then the auxiliary mappings in (10) and (11) are  $P$  and the corresponding auxiliary problems will have a unique solution, thus strengthening assertions (i) of Theorem 3, (ii) of Theorem 4, and (i) of Theorem 6 [1,30,34].

**Iterative Methods for MVIs**

Let  $Q: \mathbb{R}^n \rightarrow \mathbb{R}^n$  be a continuous single-valued mapping and  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  be a convex, proper and lower semicontinuous function. The MVI problem is the problem of finding a point  $x^* \in X$  such that

$$\langle Q(x^*), x - x^* \rangle + f(x) - f(x^*) \geq 0 \quad \forall x \in X. \quad (20)$$

In this section, we denote by  $X^*$  the solution set of problem (20). Problem (20) was originally considered by Lescarret [37] and Browder [6] and was studied by many authors owing to its various applications. In the case  $f \equiv 0$ , it corresponds to the usual VI (2). If  $f$  is subdifferentiable, MVI (20) becomes equivalent to the problem of finding  $x^* \in X$  such that

$$\exists h^* \in \partial f(x^*), \quad \langle Q(x^*) + h^*, x - x^* \rangle \geq 0 \quad \forall x \in X, \quad (21)$$

i. e., to GVI (1) with  $G = Q + \partial f$ , where  $\partial f$  denotes the subdifferential mapping of  $f$ . Also, GVI (21) is a particular case of the problem: Find  $x^* \in X$  such that

$$\exists h^* \in H(x^*), \quad \langle Q(x^*) + h^*, x - x^* \rangle \geq 0 \quad \forall x \in X, \quad (22)$$

where  $H: X \rightarrow \Pi(\mathbb{R}^n)$  is a monotone multivalued mapping. In turn, GVI (22) is a particular case of GVI (1) with  $G = Q + H$ .

In order to construct an efficient solution method for multivalued GVI (22) (or (21)) we can utilize the so-called splitting approach as a basis. In fact, if the mapping  $H$  in GVI (22) (respectively,  $\partial f$  in GVI (21)) is invertible rather easily, then one can apply the forward-backward splitting method which is due to Lions and Mercier [38] and consists in constructing a sequence  $\{x^k\}$  as follows:  $x^{k+1} \in X$  such that

$$\begin{aligned} \exists h^{k+1} \in H(x^{k+1}), \quad \langle Q(x^k) + \theta^{-1}(x^{k+1} - x^k) \\ + h^{k+1}, y - x^{k+1} \rangle \geq 0 \quad \forall y \in X, \quad (23) \end{aligned}$$

where  $\theta > 0$ , i. e., each iteration is explicit with respect to  $Q$  and implicit with respect to  $H$ . Method (23) is clearly simpler than the general proximal point method with respect to  $Q + H$ , but it requires strengthened monotonicity (co-coercivity) assumptions on  $Q$  for convergence [13]. The combined averaging and splitting method (see [41]) allows for establishing convergence if  $Q$  is only monotone, but it also utilizes the divergent series step-size rule.

**Descent Methods for MVIs**

In order to enhance the step-size rule we can utilize the descent approach with respect to some artificial merit (or otherwise, gap) function, which enables one to convert the MVI problem into an optimization problem.

**Gap Function Approach for MVIs** The simplest regularized gap function can be defined as follows:

$$\varphi_\alpha(x) = \max_{y \in X} \Phi_\alpha(x, y),$$

where

$$\begin{aligned} \Phi_\alpha(x, y) = \langle G(x), x - y \rangle - 0.5\alpha\|x - y\|^2 \\ + f(x) - f(y), \quad \alpha > 0. \end{aligned}$$

The function  $\Phi_\alpha(x, \cdot)$  is strongly concave; hence, there exists the unique element  $y_\alpha(x) \in X$  such that  $\Phi_\alpha(x, y_\alpha(x)) = \varphi_\alpha(x)$ . Observe that the computation of  $y_\alpha(x)$  is equivalent to an iteration of the forward-backward splitting method applied to MVI (20).

From the definition we have that the following properties are equivalent:

- (a)  $\varphi_\alpha(x) = 0$ ,  
 (b)  $x = y_\alpha(x)$ ,  
 (c)  $x$  is a solution of problem (20).

i. e.,  $\phi_\alpha$  is a gap function for MVI (20) and MVI (20) is equivalent to the optimization problem

$$\min_{x \in X} \rightarrow \varphi_\alpha(x). \quad (24)$$

Despite the fact that  $\phi_\alpha$  is nondifferentiable and non-convex, we can describe descent methods with respect to  $\phi_\alpha$  without computation of its derivatives. Such a descent method with exact linesearch was proposed by Patriksson [42]. Moreover, it generates a sequence which converges to a unique solution of MVI (20) if the mapping  $Q$  is strongly monotone. At the same time, inexact linesearch procedures are more suitable for implementation. For this reason we describe a descent method with an inexact Armijo-type linesearch procedure.

**Method (DIG).** Choose a point  $x^0 \in X$  and numbers  $\alpha > 0$ ,  $\beta \in (0, 1)$ , and  $\gamma \in (0, 1)$ .

At the  $k$ th iteration,  $k = 0, 1, \dots$ , we have a point  $x^k \in X$ , compute  $y_\alpha(x^k)$  and set  $d^k := y_\alpha(x^k) - x^k$ . If  $d^k = 0$ , stop. Otherwise, we find  $m$  as the smallest non-negative integer such that

$$\varphi_\alpha(x^k + \gamma^m d^k) \leq \varphi_\alpha(x^k) - \beta \gamma^m \|d^k\|^2,$$

set  $\lambda_k := \gamma^m$ ,  $x^{k+1} := x^k + \lambda_k d^k$  and go to the next iteration.

**Theorem 13** *If the mapping  $Q$  is continuously differentiable and strongly monotone with constant  $\tau$ , and  $\beta < \tau$ , (DIG) generates a sequence  $\{x^k\}$  which converges to a unique solution of MVI (20).*

**D-Gap Function Approach for MVIs** For the usual VI (2), Peng [43] introduced the so-called  $D$ -gap function, which allows one to convert it into an unconstrained optimization problem. Following this approach, Konnov [23] proposed the  $D$ -gap function for MVI (20) and showed that, unlike the usual gap functions, it becomes differentiable if the mapping  $Q$  is so, regardless of the properties of the function  $f$ . Hence, we can apply the rapidly convergent algorithms in order to find a solution of the initial MVI.

The  $D$ -gap function is defined as follows:

$$\psi_{\alpha\beta}(x) = \varphi_\alpha(x) - \varphi_\beta(x),$$

where  $0 < \alpha < \beta$ . It follows that MVI (20) is equivalent to the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} \rightarrow \psi_{\alpha\beta}(x).$$

Next, if  $Q$  is continuously differentiable, so is  $\psi_{\alpha\beta}$  and

$$\begin{aligned} \nabla \psi_{\alpha\beta}(x) &= \nabla Q(x)[y_\beta(x) - y_\alpha(x)] \\ &\quad + \beta(x - y_\beta(x)) - \alpha(x - y_\alpha(x)). \end{aligned}$$

If  $\nabla Q(x)$  is positive definite on  $\mathbb{R}^n$ , then MVI (20) is equivalent to the equation

$$\nabla \psi_{\alpha\beta}(x) = 0.$$

Utilizing the above properties, we can describe a descent method with respect to  $\psi_{\alpha\beta}$  without computation of its derivatives.

**Method (DIDG).** Choose a point  $x^0 \in \mathbb{R}^n$  and numbers  $\beta > \alpha > 0$ ,  $\mu > 0$ ,  $\gamma \in (0, 1)$ ,  $\theta > 0$ .

At the  $k$ th iteration,  $k = 0, 1, \dots$ , we have a point  $x^k$ , compute  $y_\alpha(x^k)$  and  $y_\beta(x^k)$ , set

$$\begin{aligned} r(x^k) &:= y_\alpha(x^k) - y_\beta(x^k), \\ s(x^k) &:= \alpha(x^k - y_\alpha(x^k)) - \beta(x^k - y_\beta(x^k)) \end{aligned}$$

and  $d^k := r(x^k) + \mu s(x^k)$ . If  $d^k = 0$ , stop. Otherwise, we compute  $m$  as the smallest nonnegative integer such that

$$\begin{aligned} \psi_{\alpha\beta}(x^k + \gamma^m d^k) \\ \leq \psi_{\alpha\beta}(x^k) - \gamma^m \theta (\|r(x^k)\| + \mu \|s(x^k)\|)^2 \end{aligned}$$

set  $\lambda_k := \gamma^m$ ,  $x^{k+1} := x^k + \lambda_k d^k$  and go to the next iteration.

If the mapping  $Q$  is strongly monotone, (DIDG) also generates a sequence  $\{x^k\}$  which converges to a unique solution of MVI (20).

In [25], this approach was extended for MVI (20) with order monotonicity ( $P$ ) properties. In the case when the mapping  $Q$  is only monotone (or  $P_0$ ), but not strongly monotone, the above descent methods can be combined with either regularization or proximal point methods, such that their auxiliary subproblems are solved approximately.

### Combined Relaxation Methods for MVIs

We describe a combined relaxation method for solving monotone MVI (20) which utilizes a similar iteration of

the forward-backward splitting method as an auxiliary procedure [24,26]. In this subsection we suppose that  $X$  is a nonempty, closed and convex subset of the space  $\mathbb{R}^n$ ,  $Q: \mathbb{R}^n \rightarrow \mathbb{R}^n$  is a continuous monotone mapping and  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  is a convex and subdifferentiable function. For the sake of clarity, we describe a simplified version of the method.

**Method (CRS).** *Step 0 (initialization):* Choose a point  $x^0 \in \mathbb{R}^n$  and a sequence of  $n \times n$  symmetric matrices  $\{A_k\}$  such that

$$\tau' \|p\|^2 \leq \langle A_k p, p \rangle \leq \tau'' \|p\|^2 \quad \forall p \in \mathbb{R}^n, \quad 0 < \tau' \leq \tau'' < \infty. \quad (25)$$

Choose numbers  $\alpha \in (0, 1)$ ,  $\beta \in (0, 1)$ , and  $\gamma \in (0, 2)$ . Set  $k := 0$ .

*Step 1 (auxiliary procedure):*

*Step 1.1:* Determine  $m$  as the smallest nonnegative integer such that

$$\begin{aligned} & \langle Q(x^k) - Q(z^{k,m}), x^k - z^{k,m} \rangle \\ & \leq (1 - \alpha)\beta^{-m} \langle A_k(z^{k,m} - x^k), z^{k,m} - x^k \rangle, \end{aligned}$$

where  $z^{k,m}$  is a solution of the auxiliary problem: Find  $z^{k,m} \in X$  such that

$$\begin{aligned} & \langle Q(x^k) + \beta^{-m} A_k(z^{k,m} - x^k), x - z^{k,m} \rangle \\ & + f(x) - f(z^{k,m}) \geq 0 \quad \forall x \in X. \quad (26) \end{aligned}$$

*Step 1.2:* Set  $\theta_k := \beta^m$ ,  $y^k := z^{k,m}$ . If  $x^k = y^k$ , stop. Otherwise set

$$\begin{aligned} g^k & := Q(y^k) - Q(x^k) - \theta_k^{-1} A_k(y^k - x^k), \\ \omega_k & := \langle g^k, x^k - y^k \rangle. \end{aligned}$$

*Step 2 (main iteration):* Set

$$x^{k+1} := x^k - \gamma \omega_k g^k / \|g^k\|^2,$$

$k := k + 1$  and go to step 1.

Obviously, there exist a number of rules for choosing the sequence  $\{A_k\}$  satisfying condition (25). The simplest is  $A_k \equiv I$ , which yields the usual forward-backward splitting iteration.

**Theorem 14** *Let a sequence  $\{x^k\}$  be constructed by (CRS). If the method terminates at the  $k$ th iteration, then  $x^k \in X^*$ . Otherwise, if  $\{x^k\}$  is infinite, then*

$$\lim_{k \rightarrow \infty} x^k = x^* \in X^*.$$

Note that problem (20) has a unique solution if  $Q$  is strongly monotone. Then (CRS) converges at least linearly.

**Theorem 15** *Suppose that  $Q$  is strongly monotone. If (CRS) generates an infinite sequence  $\{x^k\}$ , then  $\{x^k\}$  converges to a solution of problem (20) at a linear rate.*

This approach admits various extensions and modifications. For instance, we can adjust the previous combined relaxation method to problem (20) with the function  $f$  having the form

$$f(x) = \max_{i=1, \dots, m} f_i(x), \quad (27)$$

where  $f_i: \mathbb{R}^n \rightarrow \mathbb{R}$ ,  $i = 1, \dots, m$  are continuously differentiable convex functions [27]. In this method, the function  $f$  in (26) is replaced by its lower approximation:

$$\tau_k(x) = \max_{i=1, \dots, m} \left\{ f_i(x^k) + \langle f'_i(x^k), x - x^k \rangle \right\}.$$

Hence, if the feasible set  $X$  is defined by affine functions, then the auxiliary problem is equivalent to a convex quadratic programming problem and can be solved exactly by one of the finite algorithms. At the same time, the modified method possesses the same convergence properties.

The combined relaxation methods described above based on the auxiliary splitting iterations can be applied to nonmonotone multivalued GVIs of form (22) and to nonmonotone mixed-equilibrium problems; see [24,31,35] for more details.

Bundle methods

*Hemivariational inequalities* are generalizations of variational inequalities. They are used to model mathematically problems from mechanics, engineering and economics whenever nonconvex energy functionals are present. Typical applications, e.g. in mechanics are contact problems of elastic bodies in which nonmonotone friction laws or adhesive contact laws are involved or delamination of adhesively connected plates. The basic hemivariational inequality is of the following form:

Find  $u \in K$  ( $K$  is a convex subset of a Hilbert space  $X$ ) such that

$$a(u, v - u) + \int_{\Omega} j^{\circ}(u; v - u) dx \geq \langle F, v - u \rangle, \quad \forall v \in K, \quad (1)$$

where  $a: X \times X \rightarrow \mathbf{R}$  is a bilinear form,  $\Omega$  a subset of  $\mathbf{R}^N$ ,  $j^{\circ}(\cdot; \cdot)$  the Clarke generalized directional derivative of the locally Lipschitz function  $j: \mathbf{R}^M \rightarrow \mathbf{R}$  defined in [3] by

$$j^{\circ}(\xi; \eta) = \limsup_{\substack{\xi' \rightarrow \xi, \\ t \downarrow 0}} \frac{j(\xi' + t\eta) - j(\xi')}{t},$$

$\langle \cdot, \cdot \rangle$  the duality pairing between  $X$  and  $X^*$  ( $X^*$  is the dual space of  $X$ ) and  $F \in X^*$ . If the function  $j$  is convex then the hemivariational inequality (1) is reduced to the classical variational inequality: Find  $u \in K$  such that

$$a(u, v - u) + \int_{\Omega} j(v) dx - \int_{\Omega} j(u) dx \geq \langle F, v - u \rangle, \quad \forall v \in K.$$

The concept of the hemivariational inequality was introduced by P.D. Panagiotopoulos. The mathematical theory and the applications are studied in [14,15].

### Discrete Problem

For the discretization of the hemivariational inequalities it is used the finite element technique [2]. By means of it the following fully discrete problem is formulated: Find  $u \in K$  such that

$$u^{\top} A(v - u) + \sum_{i \in I} c_i j^{\circ}(u_i; v_i - u_i) \geq F^{\top}(v - u), \quad \forall v \in K, \quad (2)$$

where  $A$  is the stiffness matrix,  $F$  the load vector,  $c_i$  the coefficients of the appropriate numerical integration formula,  $K$  a convex subset of the finite element space  $X_h \subset X$ ,  $h$  the discretization parameter connected to the mesh size of the triangulation of  $X_h$  and  $I$  the set of the components of  $u$  for which the function  $j$  has an effect. The following stability and convergence result has been proved for the above approximation scheme [9,10]:

**Theorem 1** *The problems (2) are solvable for every  $h$ . Further, their solutions converge in subsequences to the solutions of the continuous problem (1).*

Due to the nonconvex character of the function  $j$  the solutions of the continuous problem (1) and the discrete problems (2) are not in general unique. This also explains that in the above result the convergence is guaranteed only for subsequences and it has not been proved any convergence rate estimate.

**Numerical Realization**

Because of the nonsmoothness and the nonconvexity of  $j$  the numerical realization of (2) is a challenging problem. There are different approaches for that (see, e.g. [15]). The most obvious one is to regularize the nonsmoothness and use methods for smooth problems. The other possibility is to approximate (2) by a convex, possibly nonsmooth, problem and apply numerical methods for the classical variational inequalities. Both approaches are typically iterative methods: in the former one the problem is solved with many regularization parameters and in the latter one the convex approximation is updated in every iteration step. In order to solve (2) directly in its original form one can use *nonsmooth nonconvex optimization* methods.

Next it is explained in detail how the discrete hemivariational inequality (2) can be transformed to a nonsmooth optimization problem. The following concepts from nonsmooth analysis are needed [3]:

- Suppose that  $f: \mathbf{R}^M \rightarrow \mathbf{R}$  is locally Lipschitz continuous. Then  $\xi^*$  is called a *stationary point* of  $f$  on  $K$  if

$$0 \in \partial f(\xi^*) + N_K(\xi^*),$$

where  $N_K(\xi)$  is the *normal cone* of  $K$  at  $\xi$ , defined by

$$N_K(\xi) = \text{cl} \left\{ \bigcup_{\lambda \geq 0} \lambda \partial d_K(\xi) \right\},$$

$d_K$  the distance function of  $K$ , and  $\partial f(\xi)$  is the *Clarke subdifferential*, defined by

$$\begin{aligned} \partial f(\xi) &= \{ \eta \in \mathbf{R}^M : f^\circ(\xi; \zeta) \geq \eta^\top \zeta, \quad \forall \zeta \in \mathbf{R}^M \}. \end{aligned}$$

- The function  $f: \mathbf{R}^M \rightarrow \mathbf{R}$  is said to be *upper semismooth* if for any  $\xi \in \mathbf{R}^M, \zeta \in \mathbf{R}^M$  and sequences  $\{\eta_i\} \subset \mathbf{R}^M$  and  $\{t_i\} \subset (0, \infty)$  satisfying  $\eta_i \in \partial f(\xi + t_i \zeta)$  and  $t_i \downarrow 0$ , one has

$$\limsup_{i \rightarrow \infty} \eta_i^\top \zeta \geq \liminf_{i \rightarrow \infty} \frac{f(\xi + t_i \zeta) - f(\xi)}{t_i}.$$

In the sequel it is assumed that the stiffness matrix  $A$  is symmetric. Then the following discrete energy function can be defined:

$$f(u) = \frac{1}{2} u^\top A u + \sum_{i \in I} c_i j(u_i) - F^\top u.$$

And, consequently, the following optimization problem

$$\min_{u \in K} f(u) \tag{3}$$

is formulated.

The main question is now what is the relation between the optimization problem (3) and the inequality problem (2). Under reasonable assumptions, which are generally satisfied for real applications, the subdifferential of  $f$  is equal to

$$\partial f(u) = A u + \sum_{i \in I} c_i \partial j(u_i) - F.$$

Then from the definition of the subdifferential and the upper semismoothness it follows the result (see the proofs in [2,3]):

**Theorem 2** *Every stationary point of  $f$  on  $K$  is a solution of the discrete hemivariational inequality (2). Moreover, the functional  $f$  is upper semismooth.*

This result gives the theoretical basis and the motivation for the use of nonsmooth optimization methods for the numerical solution of hemivariational inequalities. In what follows optimization methods are introduced for nonsmooth nonconvex functionals which are convergent under the condition that the functional is upper semismooth. Furthermore, some observations are presented of the numerical tests being performed in [11,12].

**Nonsmooth Optimization Methods**

The methods for solving the nonsmooth optimization problem (3) can be divided into two main classes: *subgradient methods* and *bundle methods*. The basic idea behind the subgradient methods is to generalize the smooth methods by replacing the gradient by an arbitrary subgradient (see [17]). Due to this simple structure they are widely used, but suffer from some theoretical and numerical drawbacks.

Bundle methods have their origin in cutting planes and can be stated, at the moment, the most efficient

and promising methods in nonsmooth optimization (see [13]). The aim is to produce a sequence  $\{u_k\}_{k=1}^\infty \subset \mathbf{R}^N$  converging to a local minimum of (3) being also a substationary point of  $f$  on  $K$ . Suppose that in addition to the current iteration point  $u_k$  there exist some trial points  $y_j \in \mathbf{R}^N$  (from past iterations) and subgradients  $g_j \in \partial f(y_j)$  for  $j \in J_k$ , where the index set  $J_k$  is a nonempty subset of  $\{1, \dots, k\}$ .

The idea behind the bundle methods is to approximate the objective function below by a piecewise linear function, in other words,  $f$  is replaced by so called *cutting plane model*

$$\widehat{f}_k(u) = \max_{j \in J_k} \{f(y_j) + g_j^\top(u - y_j)\}, \quad (4)$$

which equivalently can be written in the form

$$\widehat{f}_k(u) = \max_{j \in J_k} \{f(u_k) + g_j^\top(u - u_k) - \alpha_j^k\},$$

with the *linearization error*

$$\alpha_j^k = f(u_k) - f(y_j) - g_j^\top(u_k - y_j). \quad (5)$$

If  $f$  is convex, then  $\widehat{f}_k(u) \leq f(u)$  for all  $u \in \mathbf{R}^N$  and  $\alpha_j^k \geq 0$  for all  $j \in J_k$ . In other words, the cutting plane model  $\widehat{f}_k$  is an under estimate for  $f$  and the nonnegative linearization error  $\alpha_j^k$  measures how good an approximation the model is to the original problem. In the non-convex case these facts are not valid anymore and thus the linearization error (5) is replaced by so called *subgradient locality measure* (cf. [5])

$$\beta_j^k = \max \left\{ \left| \alpha_j^k \right|, \gamma |u_k - y_j|^2 \right\}, \quad (6)$$

where  $\gamma \geq 0$  ( $\gamma = 0$  if  $f$  is convex). Then obviously  $\min_{u \in K} \widehat{f}_k(u) \leq f(u_k)$  and  $\beta_j^k \geq 0$  for all  $j \in J_k$ . The search direction is then calculated by

$$d_k = \arg \min_{u_k + d \in K} \left\{ \widehat{f}_k(u_k + d) + \frac{1}{2} d^\top M_k d \right\}. \quad (7)$$

The role of the stabilizing term  $\frac{1}{2} d^\top M_k d$  is to guarantee the existence of the solution  $d_k$  and keep the approximation local enough. The  $n \times n$  matrix  $M_k$  is intended to accumulate some second order information about the curvature of  $f$  around  $u_k$ .

The different bundle methods deviate mostly in the choice of  $M_k$ . Roughly speaking, the following methods can be distinguish.

- *Cutting plane method* [4] with  $M_k \equiv 0$ .
- *Conjugate subgradient method* [18] with  $M_k \equiv I$  and  $\beta_j^k \equiv 0$ .
- $\varepsilon$ -*steepest descent* [7] and *generalized cutting plane method* [5] with  $M_k \equiv I$ .
- *Bundle trust region* [16] and *proximal bundle method* [6] with  $M_k = \lambda_k I$ .
- *Variable metric bundle method* [1] with  $M_k$  as a full matrix.

Although the more advanced bundle methods try to accumulate the second order information, they are based on first order (sub)gradient information and thus have to be considered as first order methods. The ‘real’ second order method, called *bundle-Newton method*, was derived in [8]. Instead of piecewise linear cutting plane model (4) a quadratic model was introduced in the form

$$\widetilde{f}_k(u) = \max_{j \in J_k} \left\{ f(y_j) + g_j^\top(u - y_j) + \frac{1}{2} \varrho_j(u - y_j)^\top M_j(u - y_j) \right\},$$

where  $M_j \approx \nabla^2 f(y_j)$ . The search direction finding problem (7) is then replaced by the problem

$$d_k = \arg \min_{u_k + d \in K} \{ \widetilde{f}_k(u_k + d) \}. \quad (8)$$

Next the problem of determining the stepsize into search direction  $d_k$  is considered. Assume that  $m_L \in (0, 1/2)$ ,  $m_R \in (m_L, 1)$  and  $\bar{t} \in (0, 1]$  are some fixed line search parameters. First search for the largest number  $t_L^k \in [0, 1]$  such that  $t_L^k \geq \bar{t}$  and

$$f(u_k + t_L^k d_k) \leq f(u_k) + m_L t_L^k v_k, \quad (9)$$

where  $v_k$  is the predicted amount of descent

$$v_k = \widehat{f}_k(u_k + d_k) - f(u_k) < 0.$$

If such a parameter exists take a *long serious step*

$$u_{k+1} = u_k + t_L^k d_k \quad \text{and} \quad y_{k+1} = u_{k+1}.$$

Otherwise, if (9) holds but  $0 < t_L^k < \bar{t}$  then take a *short serious step*

$$u_{k+1} = u_k + t_L^k d_k \quad \text{and} \quad y_{k+1} = u_k + t_R^k d_k$$

and if  $t_L^k = 0$  take a *null step*

$$u_{k+1} = u_k \quad \text{and} \quad y_{k+1} = u_k + t_R^k d_k,$$

where  $t_R^k > t_L^k$  is such that

$$-\beta_{k+1}^{k+1} + g_{k+1}^\top d_k \geq m_R v_k. \quad (10)$$

In short serious steps and null steps there exists discontinuity in the gradient of  $f$ . Then the requirement (10) ensures that  $u_k$  and  $y_{k+1}$  lie on the opposite sides of this discontinuity and the new subgradient  $g_{k+1} \in \partial f(y_{k+1})$  will force a remarkable modification of the next search direction finding problem. The iteration is terminated if  $|v_k|$  is small enough.

The pseudocode of general bundle method is the following:

```

PROCEDURE bundle method()
InputInstance();
Generate an initial solution  $u_k$ ;
Initialize the bundle  $J_k$  and  $v_k$ ;
Set  $k = 1$ ;
DO  $|v_k| \geq \varepsilon$ 
    Generate the search direction  $d_k$ ;
    Find stepsizes  $t_L^k$  and  $t_R^k$ ;
    Update  $u_k$  and  $J_k$ ;
    Set  $k = k + 1$ ;
    Evaluate  $f(u_k)$  and  $g_k \in \partial f(u_k)$ ;
OD;
RETURN (final solution  $u_k$ )
END bundle method;

```

## Numerical Experience

The numerical tests in [12] indicate the applicability of bundle methods for hemivariational inequalities. Especially the second order bundle-Newton method based on the piecewise quadratic model works very reliable and efficiently way. This is natural, since the optimization problem arising from hemivariational inequalities has a dominated quadratic part. The most promising feature of bundle-Newton method discovered was the independence of the iteration number and function evaluations from the dimension of the problem even in the large scale case.

### Keywords

Semidefinite programming; Sparse matrix;  
Primal-dual; Potential function; Potential reduction

The standard semidefinite program has the form:

$$(\text{SDP}) \quad \begin{cases} \min & C \bullet X \\ \text{s.t.} & A_i \bullet X = b_i, \\ & i = 1, \dots, m, \\ & X \succeq 0, \end{cases}$$

where the given matrices  $A_i \in \mathbf{R}^{n \times n}$  and  $C \in \mathbf{R}^{n \times n}$  are symmetric,  $b \in \mathbf{R}^m$ , and unknown  $X \in \mathbf{R}^{n \times n}$  is also symmetric. Furthermore,  $C \bullet X = \text{tr } C^T X = \sum_{jk} C_{jk} X_{jk}$ , and  $X \succeq 0$  means that  $X$  is positive semidefinite. In most applications,  $A_i = a_i a_i^T$ ,  $a_i \in \mathbf{R}^n$ , is a *rank-one matrix* and  $C$  is sparse.

The dual of (SDP) can be written as:

$$(\text{DSDP}) \quad \begin{cases} \max & b^T y \\ \text{s.t.} & \sum_{i=1}^m y_i A_i + S = C, \\ & S \succeq 0, \end{cases}$$

where  $y_i$ ,  $i = 1, \dots, m$  are scalar variables.

This pair of semidefinite programs can be solved in ‘polynomial time’. There are actually several polynomial algorithms. One is the *primal-scaling algorithm* ([1,13,16,17]), which is the analogue of the primal potential reduction algorithm for linear programming. This algorithm uses  $X$  to generate the next iterate direction. Another is the *dual-scaling algorithm*

([2,9,16,17]), which is the analogue of the dual-scaling algorithm for linear programming. The dual-scaling algorithm uses only  $S$  to generate the iterate direction. The third is the primal-dual scaling algorithm, which uses both  $X$  and  $S$  to generate iterate directions, including Alizadeh-Haeberly-Overton, Helmberg-Rendl-Vanderbei-Wolkowicz/Kojima-Shida-Hara/Monteiro, Nesterov-Todd, Gu, and Toh directions, as well as directions called the MTW and Half directions (see [6,15], and references therein). All these algorithm possess  $O(\sqrt{n} \log(\frac{1}{\epsilon}))$  iteration complexity to yield duality gap accuracy  $\epsilon$ .

Although they are ‘polynomially’ solvable, semidefinite programs with dimension  $n$  above 1000 have been extremely hard to solve in practice, due to the density of matrices involved in computation. Thus, exploiting the structure and sparsity characteristic of large scale semidefinite programs becomes critical to the efficient computation of their solution.

Many large scale semidefinite programs, such as the relaxations of combinatorial and quadratic optimization problems, have features which make the dual-scaling algorithm the most suitable choice:

- 1) For large scale problems,  $S$  tends to be very *sparse* and *structured* since it is the linear combination of  $C$  and the  $A_i$ s. This sparsity allows considerable savings in both memory and computation time. On the other hand,  $X$ , the primal matrix, may be much less sparse and its structure not known beforehand. Thus, primal or primal-dual algorithms cannot fully exploit the sparseness and structure of the data.
- 2) Many problems under consideration require less accuracy than some other applications. Therefore, the superlinear convergence, exhibited by the primal-dual algorithm, may not be utilized in our applications. The *dual-scaling* linear programming algorithm has been shown to perform equally well when only a lower precision answer is required.
- 3) In most combinatorial applications, we need only a lower bound for the optimal objective value of (SDP). Solving (DSDP) alone would be sufficient to provide such a lower bound. Moreover, in most applications an interior-feasible point is available to start with. Thus, we may not need to generate and store  $X$  at all.
- 4) Even if an optimal primal solution is necessary, the dual-scaling algorithm can generate a sparsely struc-

tured optimal  $X$  at the termination of the algorithm.

The dual-scaling algorithm, which is an extension of the linear programming algorithm, is to reduce the Tanabe-Todd-Ye *primal-dual potential function*

$$\Psi(X, S) = \rho \ln(X \bullet S) - \ln \det X - \ln \det S,$$

where  $\rho \geq n + \sqrt{n}$ , by a constant at each iteration. Since

$$n \ln(X \bullet S) - \ln \det X - \ln \det S \geq n \ln n,$$

the reduction of the potential leads the duality gap,  $X \bullet S$ , converging 0.

Let

$$\mathcal{A}(X) = \begin{pmatrix} A_1 \bullet X \\ \vdots \\ A_l \bullet X \end{pmatrix} \quad \text{and} \quad \mathcal{A}^\top(y) = \sum_{i=1}^m y_i A_i,$$

and let  $\bar{z} = C \bullet X$  for some feasible  $X$ . Consider the dual potential function

$$\psi(y, \bar{z}) = \rho \ln(\bar{z} - b^\top y) - \ln \det S.$$

Note the relation between the two potential functions:

$$\Psi(X, S) = \psi(y, \bar{z}) - \ln \det X.$$

The *gradient* of  $\psi$  with respect to  $y$  is:

$$\nabla \psi(y, \bar{z}) = -\frac{\rho}{\bar{z} - b^\top y} b + \mathcal{A}(S^{-1})$$

Each step in the dual-scaling algorithm minimizes the linearized *dual potential function* subject to an *ellipsoidal constraint* that keeps  $S \succ 0$  and the quadratic error term small. More precisely, beginning with a strictly feasible dual point  $(y^k, S^k)$  and a  $\bar{z}^k$ , each iteration solves the problem:

$$\begin{cases} \min & \nabla \psi^\top(y^k, \bar{z}^k)(y - y^k) \\ \text{s.t.} & \|(S^k)^{-.5} (\mathcal{A}^\top(y - y^k)) (S^k)^{-.5}\| \leq \alpha, \end{cases} \quad (1)$$

where  $\alpha$  is a constant in  $(0, 1)$ . Here, all matrix norms used here will be the Frobenius norm.

Define

$$\tilde{m}(i, j) = \text{tr}(S^k)^{-1} A_i (S^k)^{-1} A_j$$

and the positive definite matrix

$$M^k = \begin{pmatrix} \tilde{m}(1, 1) & \cdots & \tilde{m}(1, m) \\ \vdots & \ddots & \vdots \\ \tilde{m}(m, 1) & \cdots & \tilde{m}(m, m) \end{pmatrix}. \quad (2)$$

In particular, if  $A_i = a_i a_i^\top$  is a rank-one matrix, where  $a_i \in \mathbf{R}^n$ , for  $i = 1, \dots, n$ , then

$$M^k = \begin{pmatrix} (a_1^\top (S^k)^{-1} a_1)^2 & \cdots & (a_1^\top (S^k)^{-1} a_m)^2 \\ \vdots & \ddots & \vdots \\ (a_m^\top (S^k)^{-1} a_1)^2 & \cdots & (a_m^\top (S^k)^{-1} a_m)^2 \end{pmatrix}.$$

The minimal solution,  $y^{k+1}$ , of (1) is given by

$$y^{k+1} - y^k = \frac{\alpha}{\sqrt{\nabla \psi^\top(y^k, \bar{z}^k) M^{-1} \nabla \psi(y^k, \bar{z}^k)}} d(\bar{z}^k)_y$$

where

$$d(\bar{z}^k)_y = -(M^k)^{-1} \nabla \psi(y^k, \bar{z}^k). \quad (3)$$

Let

$$\begin{aligned} P(\bar{z}^k) &= (S^k)^{-0.5} \mathcal{A}^\top \left( (M^k)^{-1} \nabla \psi(y^k, \bar{z}^k) \right) (S^k)^{-0.5} \\ &= (S^k)^{-0.5} \mathcal{A}^\top \left( -d(\bar{z}^k)_y \right) (S^k)^{-0.5}. \end{aligned}$$

Then

$$\begin{aligned} \nabla \psi^\top(y^k, \bar{z}^k) d(\bar{z}^k)_y &= -\|P(\bar{z}^k)\|^2, \\ \nabla \psi^\top(y^k, \bar{z}^k) (y^{k+1} - y^k) &= -\alpha \|P(\bar{z}^k)\|, \end{aligned}$$

and the reduction in the potential function satisfies the inequality

$$\psi(y^{k+1}, \bar{z}^k) - \psi(y^k, \bar{z}^k) \leq -\alpha \|P(\bar{z}^k)\| + \frac{\alpha^2}{2(1-\alpha)}.$$

Focusing on the expression of  $P(\bar{z}^k)$ , it can be rewritten as

$$P(\bar{z}^k) = -\frac{\rho}{\bar{z}^k - b^\top y^k} (S^k)^{-0.5} X(\bar{z}^k) (S^k)^{-0.5} + I$$

with

$$\begin{aligned} X(\bar{z}^k) &= \frac{\bar{z}^k - b^\top y^k}{\rho} (S^k)^{-1} \left( \mathcal{A}^\top(d(\bar{z}^k)_y) + S^k \right) (S^k)^{-1}. \end{aligned} \quad (4)$$

Note that  $\mathcal{A}(X(\bar{z}^k)) = b$ , and  $X(\bar{z}^k)$  is a primal feasible solution if and only if  $X(\bar{z}^k) \succeq 0$ . Furthermore, from the multiplicative structure of (4),  $X(\bar{z}^k) \succeq 0$  if and only if

$$\mathcal{A}^\top(d(\bar{z}^k)_y) + S^k \succeq 0,$$

which is a sparse matrix in many applications. Also note that

$$\begin{aligned} C \bullet X(\bar{z}^k) &= S^k \bullet X(\bar{z}^k) + b^\top y^k \\ &= \frac{\bar{z}^k - b^\top y^k}{\rho} \\ &\quad \cdot \left( \mathcal{A}^\top(d(\bar{z}^k)_y) \bullet (S^k)^{-1} + n \right) + b^\top y^k, \end{aligned}$$

which can be efficiently computed.

One can show that, when  $\|P(\bar{z}^k)\|$  is small, then  $(X(\bar{z}^k), y^k, S^k)$  is in the neighborhood of the *central path* and  $C \bullet X(\bar{z}^k) < \bar{z}^k$ . Thus, we can decrease  $\bar{z}^k$  to  $C \bullet X(\bar{z}^k)$ . Moreover,  $\Psi(X(\bar{z}^k), S^k)$  is reduced from  $\Psi(X^k, S^k)$  by a constant.

The theoretical algorithm can be stated as follows.

```

Given  $\mathcal{A}(X^0) = b$ ,  $X^0 \succ 0$ ,  $\bar{z}^0 = C \bullet X^0$ ,  $S^0 = C - \mathcal{A}^\top y^0 \succ 0$ , and  $k := 0$ .
do the following:
WHILE  $\bar{z}^k - b^\top y^k \geq \epsilon$  DO
1  Compute the matrix  $M^k$  of (2).
2  Solve (3) for the dual step direction  $d(\bar{z}^k)_y$ .
3  IF  $\bar{z}^k > C \bullet X(\bar{z}^k)$  AND  $\mathcal{A}^\top(d(\bar{z}^k)_y) + S^k \succeq 0$ ,
   THEN  $X^{k+1} = X(\bar{z}^k)$  and  $\bar{z}^{k+1} = C \bullet X^{k+1}$ 
   ELSE  $X^{k+1} = X^k$  and  $\bar{z}^{k+1} = \bar{z}^k$ 
   ENDIF
4  Let  $y^{k+1} = y^k + \frac{\alpha}{\|P(\bar{z}^{k+1})\|} d(\bar{z}^{k+1})_y$  and  $S^{k+1} = C - \mathcal{A}^\top(y^{k+1})$ .
5  Set  $k := k + 1$  and return to Step 1.

```

#### Dual algorithm

The algorithm occasionally updates the primal solution  $X$  and its objective value, but it does not need  $X$  in computation. We can derive the following potential reduction theorem:

**Theorem 1**

$$\Psi(X^{k+1}, S^{k+1}) \leq \Psi(X^k, S^k) - \delta$$

where  $\delta > 1/20$  for a suitable  $\alpha$ .

This theorem leads to

**Corollary 2** Let  $\rho \geq n + \sqrt{n}$ . Then, the algorithm terminates in at most  $O((\rho - n) \log(X^0 \bullet S^0/\epsilon))$  iterations.

To accelerate the convergence of the algorithm, one may increase the value of  $\rho$  in practice and consider a bigger stepsize  $\alpha$ , see [4]. The stopping criterion is often

$$\frac{\bar{z}^k - b^\top y^k}{1 + |b^\top y^k|} \leq \epsilon,$$

that is, when the *relative duality gap* is less than prescribed accuracy  $\epsilon$ .

The *dual-scaling* algorithm, described above, has been implemented for solving semidefinite programs, arisen from maximum-cut and ‘box’-constrained quadratic optimization, with dimension up to 10000. The computational results are promising.

Perfectly competitive; Partial equilibrium; Spatial markets; Quantity model; Price model; Variational inequality formulations

Spatial price equilibrium modeling and computation are concerned with the prediction of commodity trade flow patterns between spatially separated supply and demand markets as well as the market commodity prices. The distinctive character of spatial price problems lies in the recognition of transportation costs associated with shipping the commodities between producing and consuming locations or regions. Such models are perfectly competitive partial equilibrium models; *perfectly competitive* in the sense that it is assumed that there are many producers and consumers with no individual being able to affect the market prices and *partial* (as opposed to general) in the sense that only a subset of the commodities in the economy is assumed to be modeled.

In particular, in the *spatial price equilibrium problem*, one seeks to compute the commodity supply prices, demand prices, and trade flows satisfying the equilibrium condition that the demand price is equal to the supply price plus the cost of transportation, if there is trade between the pair of supply and demand markets; if the demand price is less than the supply price plus the transportation cost, then there will be no trade. Spatial price equilibrium problems arise

in agricultural markets, energy markets, and financial markets and such models provide the basis for inter-regional and international trade modeling (see, e.g., [14,16,19,20,21,30]).

The first reference in the literature to such problems was by A. Cournot [2] in 1838, who considered two spatially separated markets. S. Enke [8], more than a century later, used an analogy between spatial price equilibrium and electronic circuits to give the first computational approach, albeit analogue, to such problems, in the case of linear and separable supply and demand functions.

P.A. Samuelson [28] subsequently initiated the rigorous treatment of such problems by establishing that the solution to the spatial price equilibrium problem, as posed by Enke, could be obtained by solving an optimization problem in which the objective function, although artificial, had the interpretation of a net social pay-off function. The spatial price equilibrium, in this case, coincided with the Kuhn-Tucker conditions of the appropriately constructed optimization problem. Samuelson also related Enke's specification to a standard problem in linear programming, the Hitchcock-Koopmans transportation problem and noted that the spatial price equilibrium problem was more general in the sense that the supplies and demands were not known a priori. Finally, Samuelson also identified the network structure of such problems.

T. Takayama and G.C. Judge [29,30] further expanded on the work of Samuelson [28] and showed that the prices and commodity flows satisfying the spatial price equilibrium conditions could be determined by solving a quadratic programming problem in the case of linear supply and demand price functions for which the Jacobians were symmetric and not necessarily diagonal. This theoretical advance enabled not only the qualitative study of equilibrium patterns, but also opened up the possibility for the development of effective computational procedures, based on convex programming, as well as, the exploitation of the network structure (see [5,12,15]).

As noted in Takayama and Judge [30], who developed a variety of spatial price equilibrium models, distinct model formulations are needed, in particular, both quantity and price formulations, depending upon the availability and format of the data. In a *quantity* formulation it is assumed that the supply price functions

and demand price functions are given (and these are a function, respectively, the quantities produced and consumed) whereas in a *price* formulation it is assumed that the supply and demand functions are given and these are a function, respectively, of the supply and demand prices. Moreover, Takayama and Judge [30] realized that a pure optimization framework was not sufficient to handle, for example, multicommodity spatial price equilibrium problems in which the Jacobians of the supply and demand price functions were no longer symmetric.

Towards that end, new formulations were proposed for the spatial price equilibrium problem under more general settings, including fixed point, complementarity, and variational inequality formulations. J.G. MacKinnon [18] gave a fixed point formulation which was then used by H.W. Kuhn and MacKinnon [17] for computational purposes. R. Asmuth, B.C. Eaves, and E.L. Peterson [1] considered the linear asymmetric spatial price equilibrium problem formulated as a linear complementarity problem and proposed Lemke's algorithm for the computation of the spatial price equilibrium. J.S. Pang and P.L. Lee [27] developed special-purpose algorithms based on the complementarity formulation of the problem. M. Florian and M. Los [10] and S.C. Dafermos and A. Nagurney [4] addressed the variational inequality formulations of general spatial price equilibrium models with the latter authors providing sensitivity analysis results. The interrelationships between variational inequality, complementarity, and extremal formulations of spatial price equilibrium problems are given in [11].

Dafermos and Nagurney [5] established the equivalence of the spatial price equilibrium problem with the traffic network equilibrium problem. This identification stimulated further research in network equilibria (cf. [9,21], and the references therein) and in algorithm development for such problems. Computational testing of different algorithms for spatial price equilibrium problems can be found in [11] and [20]. Spatial price equilibrium models have also been used for policy analysis (see, e. g., [16,23,26], and the references therein).

Since spatial price equilibrium problems can be large scale in practice parallel computational approaches have been implemented to solve such problems (cf. [13,22,23]). Recently, general dynamic spatial price equilibrium models have been developed (cf.

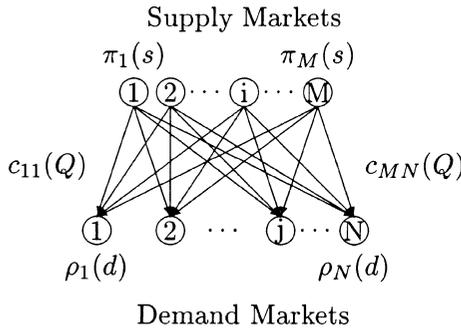

[24,25]), based on the connection between solutions to variational inequality problems and the stationary points of projected dynamical systems (cf. [7]), and solved using parallel computers.

For definiteness, we first present the quantity model and then the price model and provide the variational inequality formulations of the governing equilibrium conditions. We then present a dynamic quantity model. For additional background, including qualitative and computational results, see [21] and [25].

### The Quantity Model

Consider the spatial price equilibrium problem in quantity variables with  $M$  supply markets and  $N$  demand markets involved in the production and consumption of a homogeneous commodity under perfect competition. Denote a typical supply market by  $i$  and a typical demand market by  $j$ . Let  $s_i$  denote the supply and  $\pi_i$  the supply price of the commodity at supply market  $i$ . Let  $d_j$  denote the demand and  $\rho_j$  the demand price at demand market  $j$ . Group the supplies and supply prices, respectively, into a column vector  $s \in \mathbf{R}^M$  and a row vector  $\pi \in \mathbf{R}^M$ . Similarly, group the demands and demand prices, respectively, into a column vector  $d \in \mathbf{R}^N$  and a row vector  $\rho \in \mathbf{R}^N$ . Let  $Q_{ij}$  denote the nonnegative commodity shipment between the supply and demand market pair  $(i, j)$ , and let  $c_{ij}$  denote the unit transaction cost associated with trading the commodity between  $(i, j)$ . The unit transaction costs are assumed to include the unit costs of transportation from supply markets to demand markets, and, depending upon the application, may also include a tax/tariff, duty, or subsidy incorporated into these costs. Group the commodity shipments into a column vector  $Q \in \mathbf{R}^{MN}$  and the transaction costs into a row vector  $c \in \mathbf{R}^{MN}$ . The *network structure of the problem* is depicted in Fig. 1.

Assume that the supply price at any supply market may, in general, depend upon the supply of the commodity at every supply market, that is,  $\pi = \pi(s)$ , where  $\pi$  is a known smooth function. Similarly, the demand price at any demand market may depend upon, in general, the demand of the commodity at every demand market, that is,  $\rho = \rho(d)$ , where  $\rho$  is a known smooth function. The unit transaction cost between a pair of supply and demand markets may depend upon the shipments of the commodity between every pair of

**Spatial Price Equilibrium, Figure 1**  
**Network structure of spatial market problem**

markets, that is,  $c = c(Q)$ , where  $c$  is a known smooth function.

The supplies, demands, and shipments of the commodity, in turn, must satisfy the following feasibility conditions, which are also referred to as the *conservation of flow equations*:

$$s_i = \sum_{j=1}^N Q_{ij}, \quad i = 1, \dots, M,$$

$$d_j = \sum_{i=1}^M Q_{ij}, \quad j = 1, \dots, N,$$

$$Q_{ij} \geq 0, \quad i = 1, \dots, M; j = 1, \dots, N.$$

In other words, the supply at each supply market is equal to the commodity shipments out of that supply market to all the demand markets. Similarly, the demand at each demand market is equal to the commodity shipments from all the supply markets into that demand market.

**Definition 1 (spatial price equilibrium)** Following [28] and [30], the supply, demand, and commodity shipment pattern  $(s^*, Q^*, d^*)$  constitutes a spatial price equilibrium, if it is feasible, and for all pairs of supply and demand markets  $(i, j)$ , it satisfies the conditions:

$$\pi_i(s^*) + c_{ij}(Q^*) \begin{cases} = \rho_j(d^*), & \text{if } Q_{ij}^* > 0 \\ \geq \rho_j(d^*), & \text{if } Q_{ij}^* = 0. \end{cases}$$

Hence, if the commodity shipment between a pair of supply and demand markets is positive at equilibrium, then the demand price at the demand market must be equal to the supply price at the originating supply market plus the unit transaction cost. If the commodity

shipment is zero in equilibrium, then the supply price plus the unit transaction cost can exceed the demand price.

The spatial price equilibrium can be formulated as a variational inequality problem (cf. [3,10], and [21] for proofs). Precisely, we have

**Theorem 2 (variational inequality formulation)** A commodity supply, shipment, and demand pattern  $(s^*, Q^*, d^*) \in K$  is a spatial price equilibrium if and only if it satisfies the following variational inequality problem:

$$\langle \pi(s^*), s - s^* \rangle + \langle c(Q^*), Q - Q^* \rangle + \langle -\rho(d^*), d - d^* \rangle \geq 0, \quad \forall (s, Q, d) \in K,$$

where

$$K \equiv \{(s, Q, d) : \text{feasibility conditions hold}\}$$

and  $\langle \cdot, \cdot \rangle$  denotes the inner product.

**Example 3** For illustrative purposes, we now present a small example. Consider the spatial price equilibrium problem consisting of two supply markets and two demand markets. Assume that the functions are as follows:

$$\begin{aligned} \pi_1(s) &= 5s_1 + s_2 + 1, \\ \pi_2(s) &= 4s_2 + s_1 + 2, \\ c_{11}(Q) &= 2Q_{11} + Q_{12} + 3, \\ c_{12}(Q) &= Q_{12} + 5, \\ c_{21}(Q) &= 3Q_{21} + Q_{22} + 5, \\ c_{22}(Q) &= 3Q_{22} + 2Q_{21} + 9, \\ \rho_1(d) &= -2d_1 - d_2 + 21, \\ \rho_2(d) &= -5d_2 - 3d_1 + 29. \end{aligned}$$

It is easy to verify that the spatial price equilibrium pattern is given by:

$$\begin{aligned} s_1^* &= 2, & s_2^* &= 1, \\ Q_{11}^* &= 1, & Q_{12}^* &= 1, & Q_{21}^* &= 1, & Q_{22}^* &= 0, \\ d_1^* &= 2, & d_2^* &= 1. \end{aligned}$$

In one of the simplest models, in which the Jacobians of the supply price functions,  $[\partial\pi/\partial s]$ , the transportation (or transaction) cost functions,  $[\partial c/\partial Q]$ , and minus the demand price functions,  $-[\partial\rho/\partial d]$  are di-

agonal and positive definite, then the spatial price equilibrium pattern coincides with the Kuhn-Tucker conditions of the strictly convex optimization problem:

$$\min_{Q \in \mathbb{R}_+^{MN}} \left[ \sum_{i=1}^M \int_0^{\sum_{j=1}^N Q_{ij}} \pi_i(x) dx - \sum_{i=1}^M \sum_{j=1}^N \int_0^{Q_{ij}} c_{ij}(y) dy - \sum_{j=1}^N \int_0^{\sum_{i=1}^M Q_{ij}} \rho_j(z) dz \right].$$

**The Price Model**

We now describe briefly the price model. The notation is as for the quantity model except now we consider the situation where the supplies at the supply markets, denoted by the row vector  $s$  may, in general, depend upon the column vector of supply prices  $\pi$ , that is,  $s = s(\pi)$ . Similarly, assume that the demands at the demand markets, denoted by the row vector  $d$ , may, in general, depend upon the column vector of demand prices  $\rho$ , that is,  $d = d(\rho)$ . The transaction/transportation costs are of the same form as in the quantity model.

The spatial equilibrium conditions now take the following form: For all pairs of supply and demand markets  $(i, j), i = 1, \dots, M; j = 1, \dots, N$ :

$$\pi_i^* + c_{ij}(Q^*) \begin{cases} = \rho_j^* & \text{if } Q_{ij}^* > 0, \\ \geq \rho_j^* & \text{if } Q_{ij}^* = 0, \end{cases}$$

where

$$s_i(\pi^*) \begin{cases} = \sum_{j=1}^N Q_{ij}^* & \text{if } \pi_i^* > 0, \\ \geq \sum_{j=1}^N Q_{ij}^* & \text{if } \pi_i^* = 0, \end{cases}$$

and

$$d_j(\rho^*) \begin{cases} = \sum_{i=1}^M Q_{ij}^* & \text{if } \rho_j^* > 0, \\ \leq \sum_{i=1}^M Q_{ij}^* & \text{if } \rho_j^* = 0. \end{cases}$$

The first equilibrium condition is as in the quantity model with the exception that the prices are now variables. The other two conditions allow for the possibility that if the equilibrium prices are zero, then one may have excess supply and/or excess demand at the respec-

tive market(s). If the prices are positive, then the markets will clear.

The variational inequality formulation of the equilibrium conditions governing the price model is now given (for a proof, see [21]).

**Theorem 4 (variational inequality formulation)** *The vector  $x^* \equiv (Q^*, \pi^*, \rho^*) \in \mathbb{R}_+^{MN+M+N}$  is an equilibrium shipment and price vector if and only if it satisfies the variational inequality:*

$$\langle F(x^*), x - x^* \rangle \geq 0, \quad \forall x \in \mathbb{R}_+^{MN+M+N},$$

where  $F: K \rightarrow \mathbb{R}^{MN+M+N}$  is the row vector:  $F(x) \equiv (T(x), S(x), D(x))$ , where  $T: \mathbb{R}_+^{MN+M+N} \rightarrow \mathbb{R}^{MN}$ ,  $S: \mathbb{R}_+^{MN+M} \rightarrow \mathbb{R}^M$ , and  $D: \mathbb{R}_+^{MN+N} \rightarrow \mathbb{R}^N$  are defined by:

$$\begin{aligned} T_{ij} &= \pi_i + c_{ij}(Q) - \rho_j, \\ S_i &= s_i(\pi) - \sum_{j=1}^N Q_{ij}, \\ D_j &= \sum_{i=1}^M Q_{ij} - d_j(\rho). \end{aligned}$$

**A Dynamic Model**

We now present the projected dynamical system model of the latter spatial price problem. For additional background, qualitative properties, as well as computational results, see [25] and the references therein. In view of variational inequality governing the price model, we may write the dynamical system as:

$$\begin{pmatrix} \dot{Q} \\ \dot{\pi} \\ \dot{\rho} \end{pmatrix} = \Pi_{\mathbb{R}_+^{MN+M+N}} \left( \begin{pmatrix} Q \\ \pi \\ \rho \end{pmatrix}, \begin{pmatrix} -T(Q, \pi, \rho) \\ -S(Q, \pi) \\ -D(Q, \rho) \end{pmatrix} \right),$$

where assuming that the feasible set  $K$  is a convex polyhedron (as is the case here), and given  $x \in K$  and  $v \in \mathbb{R}^n$ , we define the projection of the vector  $v$  at  $x$  (with respect to  $K$ ) by

$$P_K(x, v) = \lim_{\delta \rightarrow 0} \frac{P_K(x + \delta v) - x}{\delta},$$

where  $P_K$  is defined as:

$$P_K(x) = \arg \min_{z \in K} \|x - z\|,$$

and  $\|\cdot\|$  denotes the Euclidean norm.

More explicitly, if the demand price at a demand market exceeds the supply price plus the unit transaction cost associated with shipping the commodity between a pair of supply and demand markets, then the commodity shipment between this pair of markets will increase. On the other hand, if the supply price plus unit transaction cost exceeds the demand price, then the commodity shipment between the pair of supply and demand markets will decrease. If the supply at a supply market exceeds (is exceeded by) the commodity shipments out of the market, then the supply price will decrease (increase). In contrast, if the demand at a demand market exceeds (is exceeded by) the commodity shipments into the market, then the demand price will increase (decrease).

However, if at the boundary the vector field  $-F$  points 'out' of the feasible set, the right-hand side of the ordinary differential equation becomes the projection of  $F$  onto the boundary. In other words, if the commodity shipments, and/or the supply prices, and/or the demand prices are driven to be negative, then the projection ensures that the commodity shipments and the prices will be nonnegative, by setting the values equal to zero. The solution to the projected dynamical system then evolves along a 'section' of the boundary of the feasible set. At a later time, the solution may re-enter the interior of the constraint set, or it may enter a lower-dimensional part of its boundary, with, ultimately, the spatial price equilibrium conditions being reached at a stationary point, that is, when  $\dot{x} = 0$ .

### Introduction

Cauchy's steepest descent algorithm [22] is the most ancient method for multidimensional unconstrained minimization. Given  $f$ , a real smooth function defined on  $\mathbb{R}^n$ , the idea is to iterate according to:

$$x_{k+1} = x_k - \alpha_k \nabla f(x_k), \quad (1)$$

with the expectancy that the sequence  $\{x_k\}$  would approximate a minimizer of  $f$ . The greedy choice of the steplength  $\alpha_k$  is

$$f(x_k - \alpha_k \nabla f(x_k)) = \min_{\alpha \geq 0} f(x_k - \alpha \nabla f(x_k)). \quad (2)$$

The poor practical behavior of (1)–(2) has been known for many years. If the level sets of  $f$  resemble long valleys, the sequence  $\{x_k\}$  displays a typical zig-zagging trajectory and the speed of convergence is very slow. In the simplest case, in which  $f$  is a strictly convex quadratic, the method converges to the solution with a Q-linear rate of convergence whose factor tends to 1 when the condition number of the Hessian tends to infinity.

Nevertheless, the structure of the iteration (1) is very attractive, especially when one deals with large-scale (many variables) problems. Each iteration only needs the computation of the gradient  $\nabla f(x_k)$  and the number of algebraic operations is linear in terms of  $n$ . As a consequence, a simple paper by Barzilai and Borwein published in 1988 [4] attracted some justified attention. Barzilai and Borwein discovered that, for some choices of  $\alpha_k$ , Cauchy's method converges superlinearly to the solution, if  $f : \mathbb{R}^2 \rightarrow \mathbb{R}$  is a convex quadratic. Some members of the optimization community began to believe that the existence of an efficient method for large-scale minimization based only on gradient directions could be possible.

In 1993, Raydan [60] proved the convergence of the Barzilai–Borwein method for arbitrary strictly convex quadratics. He showed that the method was far more efficient than the steepest descent algorithm (1)–(2) although it was not competitive with the Conjugate Gradient method of Hestenes and Stiefel [49] for quadratic

problems. The possibility of obtaining superlinear convergence for arbitrary  $n$  was discarded by Fletcher's work [40] (see also [60]) and a bizarre behavior of the method seemed to discourage the application to general (not necessarily quadratic) unconstrained minimization: the sequence of functional values  $f(x_k)$  did not decrease monotonically and, sometimes, monotonicity was severely violated.

However, starting with the work by Grippo, Lampariello and Lucidi [47], nonmonotone strategies for function minimization began to become popular. These strategies made it possible to define globally convergent algorithms without monotone decrease requirements. The philosophy behind nonmonotone strategies is that, many times, the first choice of a trial point by a minimization algorithm hides a lot of wisdom about the problem structure and that such knowledge can be destroyed by the decrease imposition. For example, if one applies Newton's method to a problem in which several components of the gradient are linear, these components vanish at the first trial point of each iteration, but the objective function value does not necessarily decrease at this trial point.

Therefore, the conditions were given for the implementation of the Barzilai–Borwein method for general unconstrained minimization with the help of a nonmonotone strategy. Raydan [61] defined this method in 1997 using the GLL strategy [47]. He proved global convergence and exhibited numerical experiments that showed that, perhaps surprisingly, the method was more efficient than classical conjugate gradient methods for minimizing general functions. These nice comparative numerical results were possible because, albeit the Conjugate Gradient method of Hestenes and Stiefel continued to be the rule of choice for solving many convex quadratic problems, its efficiency was hardly inherited by generalizations for minimizing general functions. Therefore, there existed a wide space for variations of the Barzilai–Borwein idea.

The Spectral Projected Gradient (SPG) method [16, 17, 18] was born from the marriage of the Barzilai–Borwein (spectral) nonmonotone ideas with classical projected gradient strategies [7, 46, 53]. This method is applicable to convex constrained problems in which the projection on the feasible set is easy to compute. Since its appearance, the method has been intensively used in applications [3, 6, 10, 14, 15, 19, 20, 24, 26,

35, 42, 50, 59, 63, 64, 65, 69]. Moreover, it has been the object of several spectral-parameter modifications, alternative nonmonotone strategies have been suggested, convergence and stability properties have been elucidated and it has been combined with other algorithms for different optimization problems.

## Method

### The Secant Connection

Quasi-Newton secant methods for unconstrained optimization [36, 37] obey the recursive formula

$$x_{k+1} = x_k + \alpha_k B_k^{-1} \nabla f(x_k). \quad (3)$$

The sequence of matrices  $\{B_k\}$  satisfy the *secant equation*

$$B_{k+1} s_k = y_k, \quad (4)$$

where  $s_k = x_{k+1} - x_k$  and  $y_k = \nabla f(x_{k+1}) - \nabla f(x_k)$ . By (4), it can be shown that, at the *trial point*  $x_k - B_k^{-1} \nabla f(x_k)$ , the affine approximation of  $\nabla f(x)$  that interpolates the gradient at  $x_k$  and  $x_{k-1}$  vanishes for all  $k \geq 1$ .

Now assume that we want a matrix  $B_{k+1}$  with a very simple structure that satisfies (4). More precisely, we wish

$$B_{k+1} = \sigma_{k+1} I,$$

with  $\sigma_{k+1} \in \mathbb{R}$ . (4) becomes:

$$\sigma_{k+1} s_k = y_k.$$

In general, this equation cannot be solved. However, accepting the least-squares solution that minimizes  $\|\sigma s_k - y_k\|_2^2$ , we obtain:

$$\sigma_{k+1} = \frac{s_k^T y_k}{s_k^T s_k}. \quad (5)$$

This formula defines the most popular Barzilai–Borwein method [61]. Namely, the method for unconstrained minimization is of the form (3), where, at each iteration,

$$d_k = -\frac{1}{\sigma_k} \nabla f(x_k)$$

and formula (5) is used to generate the coefficients  $\sigma_k$  provided that they are bounded away from zero and

that they are not very large. In other words, the method uses safeguards  $0 < \sigma_{\min} < \sigma_{\max} < \infty$  and defines, at each iteration:

$$\sigma_{k+1} = \min \left\{ \sigma_{\max}, \max \left\{ \sigma_{\min}, \frac{s_k^T y_k}{s_k^T s_k} \right\} \right\} .$$

By the Mean-Value Theorem of Integral Calculus, one has:

$$y_k = \left( \int_0^1 \nabla^2 f(x_k + ts_k) dt \right) s_k .$$

Therefore, formula (5) defines a Rayleigh quotient relative to the average Hessian matrix  $(\int_0^1 \nabla^2 f(x_k + ts_k) dt) s_k$ . This coefficient is between the minimum and the maximum eigenvalue of the average Hessian, which motivates the denomination of Spectral Method [16].

Writing the secant equation as  $Hy_k = s_k$ , which is also standard in the Quasi-Newton tradition, we arrive to a different spectral coefficient:  $\frac{y_k^T y_k}{s_k^T y_k}$ . Curiously, both this dual and the primal coefficient had been used for many years in practical quasi-Newton methods to define the initial matrices  $B_0$  [58].

**The Line Search**

The Spectral Projected Gradient method (SPG) aims to minimize  $f$  on a closed and convex set  $\Omega$ . The method, as well as its unconstrained counterpart [61] has the form

$$x_{k+1} = x_k + \alpha_k d_k . \tag{6}$$

The search direction  $d_k$  has been defined in [16] as

$$d_k = P(x_k - \frac{1}{\sigma_k} \nabla f(x_k)) - x_k ,$$

where  $P$  denotes the Euclidean projection on  $\Omega$ . A related method with approximate projections has been defined in [18]. The direction  $d_k$  is a descent direction, which means that, if  $d_k \neq 0$ , one has that  $f(x_k + \alpha d_k) \ll f(x_k)$  for  $\alpha$  small enough. This means that, in principle, one could define convergent methods imposing sufficient decrease at every iteration. However, this leads to disastrous practical results. For this reason, the spectral methods employ a nonmonotone line search that does not impose functional decrease at every iteration. In [16,17,18] the GLL [47] search is

used. This line search depends on an integer parameter  $M \geq 1$  and imposes a functional decrease every  $M$  iterations (if  $M = 1$  then GLL line search reduces to a monotone line search).

The line search is based on a safeguarded quadratic interpolation and aims to satisfy an Armijo-type criterion with a sufficient decrease parameter  $\gamma \in (0, 1)$ . The safeguarding procedure acts when the minimum of the one-dimensional quadratic lies outside  $[\tau_1, \tau_2\alpha]$ , and not when it lies outside  $[\tau_1\alpha, \tau_2\alpha]$  as usually implemented. This means that, when interpolation tends to reject 90% (for  $\sigma_1 = 0.1$ ) of the original search interval  $[0, 1]$ , we judge that its prediction is not reliable and we prefer the more conservative bisection. The complete line search procedure is described below.

**Algorithm 3.1: Line Search**

Compute  $f_{\max} = \max\{f(x_{k-j}) | 0 \leq j \leq \min\{k, M - 1\}\}$ ,  $x_+ \leftarrow x_k + d_k$ ,  $\delta \leftarrow \langle \nabla f(x_k), d_k \rangle$  and set  $\alpha \leftarrow 1$ .

**Step 1.** Test nonmonotone Armijo-like criterion

If  $f(x_+) \leq f_{\max} + \gamma\alpha\delta$  then set  $\alpha_k \leftarrow \alpha$  and stop.

**Step 2.** Compute a safeguarded new trial steplength

Compute  $\alpha_{tmp} \leftarrow -\frac{1}{2}\alpha^2\delta / (f(x_+) - f(x_k) - \alpha\delta)$ .

If  $\alpha_{tmp} \geq \sigma_1$  and  $\alpha_{tmp} \leq \sigma_2\alpha$  then set  $\alpha \leftarrow \alpha_{tmp}$ . Otherwise, set  $\alpha \leftarrow \alpha/2$ .

**Step 3.** Compute  $x_+ \leftarrow x_k + \alpha d_k$  and go to Step 1.

**Remark.** In the case of rejection of the first trial point, the next ones are computed along the same direction. As a consequence, the projection operation is performed only once per iteration.

**General Form and Convergence**

The Spectral Projected Gradient method SPG aims to solve the problem

$$\text{Minimize } f(x) \text{ subject to } x \in \Omega , \tag{7}$$

where  $f$  admits continuous first derivatives and  $\Omega \subset \mathbb{R}^n$  is closed and convex.

We say that a point  $x \in \Omega$  is stationary if

$$\nabla f(x)^T d \geq 0$$

for all  $d \in \mathbb{R}^n$  such that  $x + d \in \Omega$ .

In [18], SPG method has been presented as a member of a wider family of “Inexact Variable Metric” methods for solving (7). Let  $\mathbb{B}$  be the set of  $n \times n$  positive definite matrices such that  $\|B\| \leq L$  and  $\|B^{-1}\| \leq L$ . Therefore,  $\mathbb{B}$  is a compact set of  $\mathbb{R}^{n \times n}$ . In the spectral gradient approach, the matrices will be of the form  $\sigma I$ , with  $\sigma \in [\sigma_{\min}, \sigma_{\max}]$ .

#### Algorithm 4.1: Inexact Variable Metric Method

Assume  $\eta \in (0, 1]$ ,  $\gamma \in (0, 1)$ ,  $0 < \tau_1 < \tau_2 < 1$ ,  $M \geq 1$  an integer number. Let  $x_0 \in \Omega$  be an arbitrary initial point. We denote  $g_k = \nabla f(x_k)$  for all  $k = 0, 1, 2, \dots$ . Given  $x_k \in \Omega$ ,  $B_k \in \mathbb{B}$ , the steps of the  $k$ th iteration of the algorithm are:

##### Step 1. Compute the search direction

Consider the subproblem

$$\text{Minimize } Q_k(d) \quad \text{subject to } x_k + d \in \Omega, \quad (8)$$

where

$$Q_k(d) = \frac{1}{2} d^T B_k d + g_k^T d.$$

Let  $\bar{d}_k$  be the minimizer of (8). (This minimizer exists and is unique by the strict convexity of the subproblem (8), but does not need to be computed.)

Let  $d_k$  be such that  $x_k + d_k \in \Omega$  and

$$Q_k(d_k) \leq \eta Q_k(\bar{d}_k).$$

If  $d_k = 0$ , stop the execution of the algorithm declaring that  $x_k$  is a stationary point.

##### Step 2. Compute the steplength

Compute  $f_{\max} = \max\{f(x_{k-j}) \mid 0 \leq j \leq \min\{k, M-1\}\}$ ,  $\delta \leftarrow \langle g_k, d_k \rangle$  and set  $\alpha \leftarrow 1$ .

If

$$f(x_k + \alpha d_k) \leq f_{\max} + \gamma \alpha \delta, \quad (9)$$

set  $\alpha_k = \alpha$ ,  $x_{k+1} = x_k + \alpha_k d_k$  and finish the iteration. Otherwise, choose  $\alpha_{\text{new}} \in [\tau_1 \alpha, \tau_2 \alpha]$ , set  $\alpha \leftarrow \alpha_{\text{new}}$  and repeat test (9).

**Remarks.** (a) Algorithm 3.1 is a particular case of Step 2 of Algorithm 4.1. (b) In the definition of Algorithm 4.1 the possibility  $\eta = 1$  corresponds to the case in which the subproblem (8) is solved exactly.

The main theoretical results [18] are stated below. Firstly, it is shown that an iteration necessarily finishes and then it is shown that every limit point of a sequence generated by the algorithm is stationary.

**Theorem 4.1.** *The algorithm is well defined.*

**Theorem 4.2.** *Assume that the level set  $\{x \in \Omega \mid f(x) \leq f(x_0)\}$  is bounded. Then, either the algorithm stops at some stationary point  $x_k$ , or every limit point of the generated sequence is stationary.*

#### Numerical Example

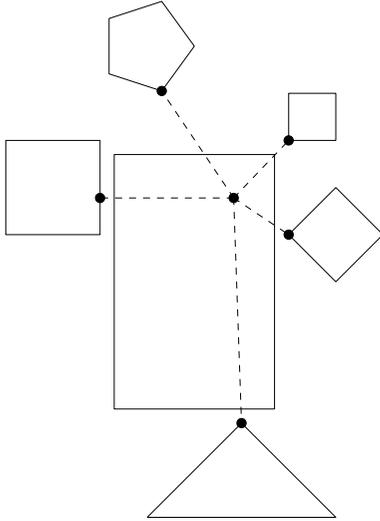

In [17] a family of *location* problems was introduced. Given a set of  $npol$  disjoint polygons in  $\mathbb{R}^2$  we wish to find the point  $y$  that minimizes the sum of the distances to those polygons. Therefore, the problem is

$$\begin{aligned} \min_{z^i, y} \sum_{i=1}^{npol} \|z^i - y\|_2 \\ \text{subject to } z^i \in P_i, \quad i = 1, \dots, npol. \end{aligned}$$

Let us write  $x = (z_1^1, z_2^1, \dots, z_1^{npol}, z_2^{npol}, y_1, y_2)$ . We observe that the problem has  $2 \times (npol + 1)$  variables. The number of (linear inequality) constraints is  $\sum_{i=1}^{npol} v_i$ , where  $v_i$  is the number of vertices of the polygon  $P_i$ . Each constraint defines a half-plane in  $\mathbb{R}^2$ . Figure 1 shows the solution of a small five-polygons problem.

For projecting  $x$  onto the feasible set observe that we only need to project each  $z^i$  separately onto the corresponding polygon  $P_i$ . In the projection subroutine we consider the half-planes that define the polygon. If  $z^i$  belongs to all these half-planes, then  $z^i$  is the projection onto  $P_i$ . Otherwise, we consider the set of half-planes to which  $z^i$  does not belong. We project  $z^i$  onto these half-planes and we discard the projected points that do not belong to  $P_i$ . Let  $A_i$  be the (finite) set of nondiscarded half-plane projections and let  $V_i$  be the set of vertices of  $P_i$ . Then, the projection of  $z^i$  onto  $P_i$  is the point of  $A_i \cup V_i$  that is closest to  $z^i$ . The projection subroutine are included in the test driver for SPG method [17].

Varying  $npol$  and choosing randomly the localization of the polygons and the number of vertices of each one, several test problems were generated and solved by the SPG method in [17]. The biggest prob-

**Spectral Projected Gradient Methods, Figure 1**  
Five-polygons problem

lem had 48,126 polygons, 96,254 variables and 578,648 constraints. Using the origin as initial approximation, it was solved by the SPG method in 17 iterations, using 19 function evaluations and 12.97 s of CPU time on a Sun SparcStation 20 with the following main characteristics: 128 Mbytes of RAM, 70 MHz, 204.7 mips, 44.4 Mflops. (Codes were in Fortran 77 and the compiler option adopted was “-O”.)

### Further Developments

Developments on spectral gradient and spectral projected gradient ideas include:

1. Application and implementation of the spectral methods to particular optimization problems: Linear inequality constraints were considered in [1]. In [38] the SPG method was used to solve Augmented Lagrangian subproblems. The spectral gradient method solves the subproblems originated by the application of an exponential penalty method to linearly constrained optimization in [56].
2. Preconditioning: The necessity of preconditioning for very ill-conditioned problems has been recognized in several works [5,23,45,54,57].
3. Extensions: The spectral residual direction was defined in [51] to introduce a new method that aims to solve nonlinear systems of equations using only the vector of residues. See, also, [48,52,70]. The

SPG method has been extended for solving non-differentiable convex constrained problems [25].

4. Association with other methods: The SPG method has been used in the context of active-set methods for box-constrained optimization in [2,13,12]. Namely, SPG iterations are used in these methods for abandoning faces whereas Newtonian iterations are employed inside the faces of the feasible region. The opposite idea was used in [44], where spectral directions were used inside the faces and a different orthogonal strategy was employed to modify the set of current active constraints (see also [9]). Spectral ideas were also used in association with conjugate gradients in [11]. Combinations of the spectral gradient method with other descent directions were suggested in [21,28].
5. Nonmonotone alternative rules: Dai and Fletcher [30] observed that, in some cases, even the descent GLL strategy was very conservative and, so, more chance should be given to the pure spectral method ( $\alpha_k = 1$  for all  $k$ ). However, they showed that, for quadratic minimization with box constraints, the pure method is not convergent. Therefore, alternative tolerant nonmonotone rules were suggested. Dai and Zhang [31] noted that the behavior of spectral methods heavily depend on the choice of the parameter  $M$  of the GLL search and proposed an adaptive nonmonotone search independent of  $M$ . Over and under relaxations of the spectral step were studied by Raydan and Svaiter [62].
6. Alternative choices of the spectral parameter: In [43] it was observed that the convergence theory of the spectral gradient method for quadratics remains valid when one uses Rayleigh coefficients originated in retarded iterations (see also [55]). In [32], for unconstrained optimization problems, the same stepsize is reused for  $m$  consecutive iterations (CBB method). This cyclic method is locally linearly convergent to a local minimizer with positive definite Hessian. Numerical evidence indicates that when  $m > n/2 \geq 3$ , where  $n$  is the problem dimension, CBB is locally superlinearly convergent. In the special case  $m = 3, n = 2$ , the convergence rate is, in general, no better than linear [32]. In [34] the stepsize in the spectral gradient method was interpreted from the point of view of interpolation and two competitive modified spectral-like

gradient methods were defined. Yuan [68] defined a new stepsize for unconstrained optimization that seems to possess spectral gradient properties preserving monotonicity.

7. Asymptotic behavior analysis: A careful consideration of the asymptotic practical and theoretical behavior of the Barzilai–Borwein method may be found in [41]. Dai and Fletcher [29] showed interesting transition properties of the spectral gradient method for quadratic functions as depending on the number of variables. Dai and Liao [33] proved the  $R$ -linear convergence of the spectral gradient method for general functions and, as a consequence, established that the spectral stepsize is always accepted by the non-monotone line search when the iterate is close to the solution. The convergence of the inexact SPG method was established in [66,67] under different assumptions than the ones used in [18]. Assuming Lipschitz-continuity of the objective functions, these authors eliminated the bounded-level-set assumption of [18].

### Keywords

LCP; Splitting method; SOR method

Splitting methods were originally proposed as a generalization of the classical SOR method for solving a system of linear equations [8,25], and in the late 1970s they were extended to the linear complementarity problem (LCP; cf. ► [Linear complementarity problem](#)) [1,2, Chap. 5], [10,13,18]. These methods are iterative and are best suited for problems in which exploitation of sparsity is important, such as large sparse linear programs and the discretization of certain elliptic boundary value problems with obstacle.

To describe the splitting methods, we formulate the LCP (with bound constraints) as the problem of finding an  $x = (x_1, \dots, x_n) \in \mathbf{R}^n$  solving the following system of nonlinear equations:

$$x = \max [l, \min [u, x - (Mx + q)]] \tag{1}$$

where  $M = [m_{ij}]_{i,j=1,\dots,n} \in \mathbf{R}^{n \times n}$ ,  $q = (q_1, \dots, q_n) \in \mathbf{R}^n$  and the lower bound  $l = (l_1, \dots, l_n)$  and upper bound  $u = (u_1, \dots, u_n)$  are given. (Here max and min are understood to be taken componentwise and we allow  $l_i = -\infty$  or  $u_i = \infty$  for some  $i$ . The case of  $l_i = 0$  and  $u_i = \infty$  for all  $i$  corresponds to the standard LCP.) In the splitting methods, we express

$$M = B + C$$

for some  $B \in \mathbf{R}^{n \times n}$  and  $C \in \mathbf{R}^{n \times n}$ ; then, starting with any  $x \in \mathbf{R}^n$ , we iteratively update  $x$  by solving the following equation for  $x'$ :

$$x' = \max [l, \min [u, x' - (Bx' + Cx + q)]] \tag{2}$$

and then replacing  $x$  with  $x'$ . Thus, at each iteration, we effectively replace  $M$  and  $q$  in the original problem by, respectively,  $B$  and  $Cx + q$  which we then solve to obtain the new iterate.

A key to the performance of the splitting methods lies in the choice of the matrix  $B$ . We should choose  $B$  to be a good approximation of  $M$  so that the methods have rapid convergence and, at the same time, such that  $x'$  is easy to compute at each iteration (e. g.,  $B$  is diagonal or upper/lower triangular). The best known choice, corresponding to the SOR method of C. Hildreth [3,7], is

$$B = \frac{1}{\omega} D + L, \tag{3}$$

where  $D$  and  $L$  denote, respectively, the diagonal and the strictly lower-triangular part of  $M$  and  $\omega \in (0, 2)$  is a relaxation parameter (see [2, p. 397], [13]). For this choice of  $B$  and assuming  $M$  has positive diagonal entries, the components of  $x'$  can be computed using  $n$ -step backsolve:

$$x'_i = \max \left[ l_i, \min \left[ u_i, x_i - \frac{\omega}{m_{ii}} \times \left( \sum_{j<i} m_{ij} x'_j + \sum_{j \geq i} m_{ij} x_j + q_i \right) \right] \right], \tag{4}$$

$i = 1, \dots, n.$

In the case where  $l_i = -\infty$  and  $u_i = \infty$  for all  $i$ , the above iteration reduces to the classical SOR method for solving the system of linear equations  $Mx + q = 0$ . More generally, we can choose  $B$  to be block-lower/upper-triangular, e. g.,

$$B = \begin{pmatrix} B_{11} & & & \\ B_{21} & B_{22} & & \\ \vdots & \vdots & \ddots & \\ B_{p1} & B_{p2} & \cdots & B_{pp} \end{pmatrix}$$

for some  $1 < p \leq n$ , with the diagonal and triangular blocks possibly coming from  $M$ . Then, each block of components of  $x'$  can be computed recursively by solving an LCP of dimension equal to the block size. Other choices of  $B$  are discussed in [2, Chap. 5], [13] and below. Computation with the (block) SOR method on solving sparse linear programs and LCP with symmetric positive definite  $M$  is investigated in [1,4,14,16].

An original application of the SOR method is to the solution of convex quadratic programs of the form

$$\begin{cases} \min & \frac{1}{2}y^\top y \\ \text{s.t.} & Ay \leq b, \end{cases}$$

where  $A \in \mathbf{R}^{n \times m}$  and  $b \in \mathbf{R}^n$  are given, with  $A$  having nonzero rows. (Here,  $\top$  denotes the transpose.) Specifically, by attaching nonnegative Lagrange multipliers (cf. also ► **Lagrangian multipliers methods for convex programming**)  $x = (x_1, \dots, x_n)$  to the constraints  $Ay \leq b$ , we obtain the following dual problem in  $x$ :

$$\begin{aligned} \max_{x \geq 0} \left\{ \min_y \left\{ \frac{1}{2}y^\top y + x^\top (Ay - b) \right\} \right\} \\ = \max_{x \geq 0} \left\{ -\frac{1}{2}x^\top AA^\top x - x^\top b \right\} \end{aligned}$$

whose optimal solution, related to the optimal solution of the original problem by  $y + A^\top x = 0$  [7], solves the LCP (1) with  $M = AA^\top$ ,  $q = b$  and  $l_i = 0$ ,  $u_i = \infty$  for all  $i$  [7, p. 4]. In this case,  $M$  is symmetric positive semidefinite with positive diagonal entries and  $x'$  computed in the SOR method is alternatively given by the formula:

$$\begin{aligned} \Delta_i &= \max \left[ -x_i, \frac{\omega}{A_i A_i^\top} (A_i y^i - b_i) \right], \\ x'_i &= x_i + \Delta_i, \\ y^{i+1} &= y^i - A_i^\top \Delta_i, \quad i = 1, \dots, n, \end{aligned}$$

where  $y^1 = -A^\top x$  and  $A_i$  denotes the  $i$ th row of  $A$ . The above iteration is reminiscent of the *Agmon–Motzkin–Fourier relaxation method* for solving the inequalities  $Ay \leq b$  and, in fact, differs from the latter only in that the term  $-x_i$ , rather than zero, appears inside the max.

Convergence of the splitting methods, despite their relatively long history, was more fully analyzed only in the last ten years. In particular, if  $M$  is symmetric (not necessarily positive semidefinite) and the function

$$f(x) = \frac{1}{2}x^\top Mx + q^\top x \tag{4}$$

is bounded below on the box  $l \leq x \leq u$ , then it is known that  $x$  generated by the splitting method (2) converges to a solution of the LCP at a linear rate (in the root sense [17]), provided that  $(B, C)$  is a *regular Q-splitting* in the sense that

$$B - C \text{ is positive definite and for every } x \text{ there exists a solution } x' \text{ to (2)}$$

[12, Thm. 3.2]. (Earlier results of this kind that further assumed  $M$  is positive semidefinite or nondegenerate can be found in [2 Chap. 5], [5,11,19,20] and references therein.) For the SOR method, corresponding to  $B$  given by (3) with  $\omega \in (0, 2)$ , it can be verified that  $(B, C)$  is a regular Q-splitting provided  $M$  has positive diagonal entries. The proof of the above convergence result uses two key facts about the LCP, namely, that  $f(x)$  assumes only a finite number of values on the solution set and that the distance to the solution set from any point  $x$  near the solution set is in the order of the ‘residual’ at  $x$ , defined to be the difference in the two sides of (1). In addition, the function  $f(x)$  can be used in a line-search strategy to accelerate convergence of the splitting methods [2, Sec. 5.5].

If  $M$  is not symmetric but positive semidefinite, it is known that  $x$  generated by the splitting method (2) converges to a solution of the LCP at a linear rate (in the root sense), provided that

$$B - M \text{ is symmetric positive definite}$$

[2, Thm. 5.6.1], [24, Cor. 5.3]. One choice of  $B$  that satisfies the above assumption is

$$B = M + \widehat{D} - L - L^\top,$$

where  $L$  denotes the strictly lower-triangular part of  $M$

and  $\widehat{D}$  is any  $n \times n$  diagonal matrix such that  $\widehat{D} - L - L^T$  is positive definite. This choice of  $B$  is upper-triangular and hence the corresponding  $x'$  can be computed in the order of  $n^2$  arithmetic operations using  $n$ -step back-solve [22, Sec. 6], [24]. Computationally, the asymmetry of  $M$  makes it difficult to incorporate line-search strategies since no ‘natural’ merit function analogous to (4) is known. As a result, on problems where  $M$  is highly asymmetric, such as the LCP formulation of linear programs, the convergence of the splitting methods can be slow. Thus, accelerating convergence of the splitting methods on asymmetric problems remains a challenge. In this direction, we point out related methods based on projection or operator splitting (see [6,21] and references therein). These methods are applicable to the case where  $M$  is positive semidefinite (not necessarily symmetric) and the major part of their iterations also involves solving a matrix-splitting equation of the form (2), except the solution  $x'$  must undergo additional transformations to yield the new iterate  $x$ . These methods, which may be viewed as a hybrid form of the splitting methods, admit some forms of line search and show good promise in computation.

In summary, building on the early work of Hildreth and H.B. Keller and others, splitting methods have been well developed in the last twenty years to solve the LCP (1) when the matrix  $M$  is either symmetric or positive semidefinite. Computationally, these methods are best suited when  $M$  is symmetric, possibly having some sparsity structure (e. g.,  $M = AA^T$  with  $A$  sparse), and the function (4) is used in a line-search strategy to accelerate convergence. Extensions of these methods to problems where the box  $l \leq x \leq u$  is replaced by a general polyhedral set, including as special cases the *extended linear/quadratic programming problem* of R.T. Rockafellar and R.J-B. Wets and the quadratic program formulation of the LCP with *row sufficient matrix*, have also been studied [2, Sec. 5.5], [6,12,22,23]. Inexact computation of  $x'$  is discussed in [2, Sec. 5.7], [9,12,15]. Acceleration of the methods in the case where  $M$  is not symmetric remains an open issue. In fact, if  $M$  is not symmetric nor positive semidefinite, convergence of the splitting methods is known only for the case where  $M$  is an *H-matrix* with positive diagonal entries and  $B$  is likewise, with the comparison matrix of  $B$  having a contractive property [2, p. 418], [18,19]. Thus, even if  $M$  is a *P-matrix*, it is not known whether the

splitting methods converge for some practical choice of  $B$ .

Optimization with noises; Hybrid algorithm;  
Robustness

SSC algorithms are a class of local minimization algorithms developed within the framework of supervisor and searcher cooperation (SSC). One of the distinct characteristics of this class of algorithms is that they are both efficient and robust, and therefore suitable for minimization problems with strong noises. Some of these algorithms have been studied in [5] and [6].

Most of the existing fast minimization algorithms are not suitable for noisy minimization problems. One of the main reasons seems that the effectiveness of the line search procedures, which are usually incorporated into these algorithms, are rather sensitive to the accuracy of function or gradient value evaluations. One may increase the accuracy of these evaluations by, for example, using an averaging process to diminish the effects of stochastic noises. However this will normally increase the computational work required.

Most of the existing robust minimization algorithms, such as the stochastic approximation (SA) method, the N-M simplex method, the genetic algorithms, the Hooke–Jeeves method, do not use the classical line search, see [7] and [2]. Consequently they have been widely employed to tackle noisy optimization problems. Unfortunately, these algorithms are, in general, very slow and inefficient even for the noise free case. The stochastic approximation method, for example, is very robust. Its global convergence has been established under various assumptions for the noise. However, even for deterministic problems without noises, SA has been known to be very slow in comparison with efficient gradient algorithms like the conjugate gradient (CG) method and the GBB algorithm (see [8]). This is mainly due to the use of pre-assigned stepsizes in the search for optimizers.

The SSC framework provides an effective mechanism to address the above issues. The essential idea adopted in SSC algorithms is to combine the desirable characteristics of two algorithms: a supervisor algorithm (SR) and a searcher (or search engine) algorithm (SE). The former is used to ensure global convergence and to enhance robustness, while the latter is employed to increase the efficiency of the solution searching work. The SSC framework can be viewed as a systematic way of exploring possible combinations of some existing minimization algorithms. The resulting algorithms are a class of piecewise or hybrid algorithms.

Assume that we wish to minimize an objective function  $f(x)$  on  $\mathbf{R}^n$ . Assume, for given  $x_0, \dots, x_l$ , that we have an iterative algorithm, called *search engine* (SE):

$$x_{k+1} = x_k - se_k(x_k, \dots, x_{k-l}, k, f),$$

$$k = l, l + 1, \dots$$

This particular form of  $se_k$  may depend on  $k$  and the values (or estimates) of  $\{f(x_{k-i})\}_{i=0}^l, \{\nabla f(x_{k-i})\}_{i=0}^l, \{H(x_{k-i})\}_{i=0}^l$ , etc, where  $H(x)$  is the Hessian matrix of  $f$  at the point  $x$ . Suppose that this algorithm is convergent to a local minimizer of  $f$  provided the starting points are close enough to the minimizer.

Assume that we also have a *supervisor algorithm* (SR): Given  $x_0, \dots, x_l$

$$x_{k+1} = x_k - sr_k(x_k, \dots, x_{k-l}, k, f),$$

$$k = l, l + 1, \dots$$

In general, an SR is slow but robust, while an SE is fast but only convergent locally. For the two algorithms to work together efficiently, a principle is needed to regulate their relationship. In [5] the following framework was introduced, based on the idea of cooperation between the supervisor and the searcher (SSC): the supervisor acts only if it believes that the performance of the search engine is not satisfactory while the search engine does most of the solution searching work.

There are many different ways of designing new algorithms in this framework. In [5] the following simple implementation has been proposed: Assume  $f \geq 0$ . Given  $x_0, \dots, x_l$ , define  $(k = l, l + 1, \dots)$  the following (SSC) algorithm:

$$x_{k+1} = \begin{cases} x_k - sr_k & \text{if } T_k f(x_k - sr_k) \\ & \leq f(x_k - se_k), \\ x_k - se_k & \text{otherwise,} \end{cases}$$

where  $\{T_k\}$  is a given sequence of nonnegative real numbers.

Note that as far as minimization is concerned, one can always assume that  $f \geq 0$  by adding a positive constant to the original function. Alternatively, one can use the following SSC algorithm for the general case:

$$x_{k+1} = \begin{cases} x_k - sr_k & \text{if } T_k^{\text{sign}(f(x_k - sr_k))} \\ & \times f(x_k - sr_k) \\ & \leq f(x_k - se_k), \\ x_k - se_k & \text{otherwise.} \end{cases}$$

where  $\{T_k\}$  is a given sequence of nonnegative real numbers.

Other forms of implementation or extensions have also been studied in [5,6]. For example, the following nonmonotone version of SSC algorithm was proposed in [6] (NOMSSC algorithm): For a fixed positive integer  $m > 0$  and a real number  $\delta > 0$ , define  $x_k$  as follows:

$$x_{k+1} = \begin{cases} x_k - se_k & \text{if } f(x_k - se_k) \leq \max_{0 \leq j \leq m(k)} \\ & \{f(x_{k-j})\} - \epsilon_k |g_k|^2 \\ & \text{or if } f(x_k - se_k) \\ & \leq T_k f(x_k - sr_k), \\ x_k - sr_k & \text{otherwise,} \end{cases}$$

where  $g_k = \nabla f(x_k)$ ,  $m(k) = \min(k, m)$  and  $\{\epsilon_k\}$  is a given sequence of nonnegative real numbers such that  $\epsilon_k \geq \delta$  ( $k = 0, 1, \dots$ ).

It was found that in some cases the nonmonotone version performs better than the simpler original version (see [5]).

In principle, any globally convergent iterative algorithm, e. g. CG, BFGS, etc., could be used as a supervisor. In general, one wishes that supervisors should have simpler structures to increase robustness. Two classes of supervisors have been examined in [6].

The first class uses pre-assigned steplengths as in SA. Let  $\{t_k\}(k = 0, 1, \dots)$  be such that

- i)  $t_k > 0$ ;
- ii)  $\sum_{k=0}^{\infty} t_k = +\infty$ .

Let  $x_k \in \mathbf{R}^n$  ( $k = 0, 1, \dots$ ) and let  $g_k = \nabla f(x_k)$ . Let  $l \geq 0$  and let  $\{d_k(x_k, \dots, x_{k-l}, f)\}$  be a sequence of  $\mathbf{R}^n$  vectors so that there exist  $c, C > 0$  such that the following assumptions hold:

$$(D) \quad d_k^\top g_k \geq c |g_k|^2; |d_k| \leq C |g_k|, \quad k = 0, 1, \dots$$

One of the most frequently used forms of  $d_k$  in this paper is  $d_k = g_k$ , though there are other possible choices as well.

The first class of supervisors have the following form: for given  $x_0, \dots, x_l$ ,

$$x_{k+1} = x_k - t_k d_k, \quad k = l, l + 1, \dots$$

When  $d_k = g_k$ , it is the SA algorithm.

The second class of supervisors have the following form: for given  $x_0, \dots, x_l$ ,

$$x_{k+1} = x_k - t_k d_k, \quad k = l, l + 1, \dots$$

where  $\{t_k\}, \{d_k\}$  are chosen so that there exists an  $\alpha > 0$ , independent of  $k$ , such that

$$f(x_k - t_k d_k) - f(x_k) \leq -\alpha \frac{(d_k^T \nabla f(x_k))^2}{|d_k|^2},$$

and

$$\sum_l^\infty \cos^2(\theta_k) = +\infty,$$

where

$$\cos(\theta_k) = \frac{(g_k, d_k)}{|g_k| |d_k|}, \quad k = l, l + 1, \dots$$

For instance, let  $d_k = g_k$  and let  $\{t_k$  be generated using the Wolfe line search procedure. Then the above assumptions hold. Clearly other line search methods can also be considered in the same way.

Again, in principle, any locally convergent iterative algorithm could be used as a search engine. Some possible examples, which have been already investigated, are as follows:

1) *Newton search engine*: Given  $x_0$ ,

$$x_{k+1} = x_k - se_k, \quad k = 0, 1, \dots,$$

where  $se_k = H_k^{-1}g_k$ , and  $H_k$  and  $g_k$  are the Hessian matrix and gradient of  $f$  at the point  $x_k$ . If  $H_k$  is not invertible, then the SSC switches to SR.

2) *Quasi-Newton search engine*: Given  $x_0$ ,

$$x_{k+1} = x_k - se_k, \quad k = 0, 1, \dots,$$

where  $se_k = B_k g_k$  and  $B_k$  is given by a quasi-Newton recursive formula (see [4] and [3] for the details). It has been found that a straightforward use of this class of search engines may lead to poor performance of the resulting algorithms.

3) *BB search engine*: Given  $x_0$ ,

$$x_{k+1} = x_k - se_k, \quad k = 0, 1, \dots,$$

where  $se_k = \alpha_k g_k$ , where  $\alpha_0 = 1$  and for  $k \geq 1$

$$\alpha_k = \frac{|y_k|^2}{y_k^T s_k},$$

where

$$y_k = x_k - x_{k-1},$$

$$s_k = \nabla f(x_k) - \nabla f(x_{k-1}).$$

This steplength  $\alpha_k$  was first proposed in [1], where the BB algorithm was introduced. This search engine has been studied in detail in [5].

Three SSC algorithms have been studied and tested in [6]: SSC-SABB, SSC-SANEWTON, and SSC-SABFGS, which use SA as the supervisor, and, BB, Newton's, and BFGS as the search engines, respectively. For example the SSC-SABB algorithm is as follows:

Let  $x \in \mathbb{R}^n$  be given and  $\alpha_0 = 1$ .

Let  $T_k \geq 0, k = 0, 1, \dots$ , be given, and assume that  $f \geq 0$ .

Then (the SSC-SABB algorithm):

$$x_{k+1} = x_k - \begin{cases} t_k g_k & \text{if } T_k f(x_k - t_k g_k) \leq f(x_k - \alpha_k g_k), \\ \alpha_k g_k & \text{otherwise,} \end{cases}$$

where, for  $k \geq 1$ ,

$$\alpha_k = \frac{|y_k|^2}{y_k^T s_k},$$

with

$$y_k = x_k - x_{k-1},$$

$$s_k = \nabla f(x_k) - \nabla f(x_{k-1}).$$

These algorithms were found to be efficient and very robust. For instance, SSC-SABB was able to solve difficult stochastic optimization problems efficiently, while for the noise free case, it was comparable with some fastest gradient algorithms like CG and GBB (see [5]). In [6], it was also reported that SSC-SANEWTON and SSC-SABFGS can solve difficult optimization problems, using rough approximations of the gradient and the Hessian, while they are very fast when the errors are small. In these experiments,  $t_k = \min(0.01, \frac{1}{\sqrt{k}})$  and  $T_k = \min(0.01, 1/k)$  are tested, while connection  $T_k$  is fixed as a constant  $T > 0$ . For example, one may take  $T = 3$  or  $T = 5$  when there is little noise in an optimization problem, and one has to let  $T = 1$  if the noise is strong.

In the noise free case the following global convergence result has been established in [6] for SSC algorithms.

Let  $f$  be twice continuously differentiable and bounded below. Assume that  $\nabla f$  is Lipschitz with a global Lipschitz constant. Let  $\{x_k\}$  be generated by the

SSC algorithm. Assume that  $\prod_0^\infty \max(T_k, 1) < \infty$ . If the supervisor belongs to the first class, then there is an  $\epsilon(f) > 0$  such that  $\{\sum_i^k t_k |\nabla f(x_k)|^2\}$  is convergent as  $k \rightarrow \infty$  for any sequence  $\{t_k\}$  such that there is a  $N > 0$  satisfying that  $t_k \leq \epsilon(f)$  after  $k \geq N$ . If the supervisor belongs to the second class, then  $\{\sum_i^k \cos^2(\theta_k) |\nabla f(x_k)|^2\}$  is convergent as  $k \rightarrow \infty$ .

It should be noted that the above convergence is independent of the search engines used. The result can be further extended. For instance, SSC-SABB has been shown to be globally convergent when only finite  $T_k = 1$  and the rest  $T_k = T > 1$ . It was also shown that the speed of SSC-SABB is R-linear.

In general, the SSC algorithms are at least as fast as their SE provided  $T_k > T > 1$  after  $k$  large enough. Therefore, the global convergence of SSC algorithms is ensured by the SR, while their speed is largely decided by the SE. More details can be found in [6].

The above basic SCC algorithms have been extended for different applications, like training of feed-forward neural networks (FNNs). For example, the following extended version of the SSC algorithms, which forces the search engine to run  $m$  iteration before attempting switching, is proposed. Let  $x_0 \in \mathbf{R}^n$  be given. Let  $T_k \geq 0$  be given for  $k = 0, 1, \dots$ , and let  $m > 0$ . Assume that  $f \geq 0$  and that we have  $x_k$ . Then define

$$\begin{aligned} x_{k+m}^1 &= x_k - sr_k, \\ x_{k+m}^2 &= y_{k+m}, \end{aligned}$$

where  $y_{k+m}$  is defined by  $y_k = x_k$ ,

$$y_{k+l+1} = y_{k+l} - se_{k+l}, \quad l = 0, \dots, m - 1.$$

Then define

$$x_{k+1} = \begin{cases} x_{k+m}^1 & \text{if } T_k f(x_{k+m}^1) \\ & \leq f(x_{k+m}^2). \\ x_{k+m}^2 & \text{otherwise.} \end{cases}$$

The purpose of the above extension is to create a ‘memory’ effect which may be important for the efficient performance of some search engines.

It seems that the supervisor-searcher cooperation framework offers a promising way for combining characteristics of existing algorithms. It seems that the new algorithms can retain the desirable properties of their

‘parents’. Consequently these algorithms are both efficient and robust. This makes them suitable for both deterministic and stochastic minimization problems. This unique feature is largely due to the fact that the algorithms use neither line search nor pre-assigned step-sizes *all* the time. Finally, the additional computational work required is also very light.

Stochastic optimization; Nonsmooth optimization; Global optimization; Robustness

SSC algorithms are a class of local minimization algorithms developed within the framework of supervisor and searcher cooperation, see ► **SSC minimization algorithms** for definitions. Some of the algorithms are both efficient and robust, and therefore suitable for minimization problems with strong noise. Further studies of SSC algorithms can be found in [4,5], and [7].

Nonsmooth optimization problems, where the objective functions may not be differentiable, are frequently met in many important applications. There exist some minimization algorithms, which are applicable to certain types of nonsmooth optimization problems, such as the subgradient method, the conjugate subgradient method, and the cutting plane method (see, [3,8], and [9]). However, more research is still much needed to develop fast minimization algorithms for nonsmooth optimization problems.

Some of the SSC algorithms have been extended to nonsmooth optimization problems, see [6]. It is clear that the SSC framework described in ► **SSC minimization algorithms** can be used to design minimization algorithms for nonoptimization problems, though it is not straightforward to select suitable supervisors and searchers. In [6], the SSC-SABB (see ► **SSC minimization algorithms**) algorithm was extended to nonsmooth optimization: the supervisor was replaced by the subgradient method, while the BB search engine was still used. This gives the *SSC-SBB algorithm*, described below.

Assume that we wish to minimise an objective function  $f(x)$  on  $\mathbf{R}^n$ . Assume that  $f \geq 0$  is Lipschitz. Let  $t_k \geq 0$  ( $k = 0, 1, \dots$ ) be such that  $\sum_0^\infty t_k = \infty$  and  $\sum_0^\infty t_k^2 < \infty$ . Define  $\partial f(x)$ , the *general gradient* at  $x$ , as in [9]:

$$\partial f(x) = \text{conv}(V_f(x)),$$

with

$$V_f(x) = \left\{ v \in \mathbf{R}^n : \begin{array}{l} v = \lim_{x_i \rightarrow x} \nabla f(x_i), \\ \text{where } \nabla f(x_i) \text{ exists} \end{array} \right\},$$

where  $\text{conv}(V_f(x))$  represents the close convex hull of  $V_f(x)$ . Since every Lipschitz function on  $\mathbf{R}^n$  is differentiable almost everywhere, the above general gradient is well-defined. The *SSC-SBB algorithm* is then defined as follows: For given  $x_0$  and  $T_k > 0$  ( $k = 0, 1, \dots$ ), define

$$x_{k+1} = \begin{cases} y_{k+1} = x_k - t_k \xi_k & \text{if } T_k f(y_{k+1}) \\ & \leq f(z_{k+1}), \\ z_{k+1} = x_k - \alpha_k \xi_k & \text{otherwise,} \end{cases}$$

where  $\xi_k \in V_f(x_k)$ ,  $\alpha_0 = 1$ , and for  $k \geq 1$

$$\alpha_k = \frac{|y_k|^2}{y_k^t s_k},$$

where

$$y_k = x_k - x_{k-1}, \quad s_k = \xi_k - \xi_{k-1}.$$

Note that in the above definition,  $\xi_k$  is taken from  $V_f(x_k)$ , instead of  $\partial f(x_k)$  as in the subgradient method. In general, this causes no extra computational work. For instance, for the most common case where  $f(x) = \max_{1 \leq i \leq J} f_i(x)$ , where  $f_i$  ( $i = 1, \dots, J$ ) is smooth, one can simply use  $\xi_k = \nabla f_j(x_k)$ , where  $j$  is such that  $f_j(x_k) = \max_{1 \leq i \leq J} f_i(x_k)$ . In fact, it is also possible to simply require  $\xi_k \in \partial f(x_k)$  with  $|\xi_k| = 1$  in the above definition, as in the subgradient method. Then the formula of  $\alpha_k$  has to be modified because of the normalization of  $\xi_k$ .

Some global convergence results have been established in [6] for the *SSC-SBB algorithm*. The following is just an example. Assume that

- $f$  is continuous and strictly convex;
- $x^*$  is the global minimizer of  $f$  such that  $f(x^*) = \min_{x \in \mathbf{R}^n} f(x) > 0$ ; and
- there exist constants  $c, m > 0$  such that for all  $x \in \mathbf{R}^n$

$$c|x - x^*| \leq f(x) - f(x^*) \leq m|x - x^*|.$$

Assume that  $\{\beta_k\}$  is a sequence of real numbers. Let  $x_0$  be given and let  $T_k = T > 0$  ( $k = 0, 1, \dots$ ). Let  $\{x_k\}$  be defined by ( $k = 1, 2, \dots$ )

$$x_{k+1} = \begin{cases} y_{k+1} = x_k - t_k \xi_k & \text{if } T f(y_{k+1}) \\ & \leq f(z_{k+1}), \\ z_{k+1} = x_k - \beta_k \xi_k & \text{otherwise,} \end{cases}$$

where  $\xi_k \in \partial f(x_k)$  with  $|\xi_k| = 1$ , and  $t_k \geq 0$  such that  $\sum_0^\infty t_k = \infty$ , and  $\sum_0^\infty t_k^2 < \infty$ . Then  $\lim_{k \rightarrow \infty} |x_k - x^*| = 0$  if  $T \leq c/m$ . If we further have  $U = \sup_{x,y} (f(x) - f(y)) < \infty$ , then for any  $0 < T < 1$  there exists a  $C_T > 0$  such that  $\lim_{k \rightarrow 0} |x_k - x^*| = 0$ , where  $x_k$  is generated from the above SSC-SBB algorithm for any shifted objective function  $f_C = f + C$ , where  $C \geq C_T$ .

The above result basically says that if  $0 < T < 1$ , then by adding a suitable positive number  $C$  to the objective function  $f$  (this does not change the minimizer of  $f$ ), the SSC-SBB algorithm will converge. It does not, however, give any estimate for the constant  $C$ . In [6], convergence was observed for all  $C > 0$ . More general convergence results have also been established in [6], where some of the above conditions have been further relaxed.

Numerical experiments indicated that the SSC-SBB is quite fast when  $\{x_k\}$  are far away from a minimizer. It then slows down when the approximations are near the minimizer, if it happens that the objective function is not differentiable at that point. The main reason seems that the BB search engine is frequently redundant in the computation when  $x_k$  is near a nonsmooth minimizer. This problem is yet to be solved. Nevertheless, in some cases, a considerable improvement on the overall speed over the subgradient method has been observed in [6].

It has been found that some SSC algorithms seem quite suitable for stochastic optimization:

$$\begin{cases} \min & f(x), \\ \text{with} & f(x) = F(x) + \epsilon, \end{cases}$$

where  $F$  is the smooth underlying exact mathematical model, and  $\epsilon$  is stochastic noise, which may depend on  $x$ . Of course, here we really mean to find a minimizer of  $F$ . Among the algorithms, a stochastic version of SSC-SABB has been much studied and tested, see, [4] and [7].

Assume that we have some estimators for  $F(x)$  and  $\nabla F(x)$ . Whenever we refer to  $f(x)$  and  $\nabla f(x)$ , we mean the estimators of the value or the gradient of  $F$  at the point  $x$ . When  $\epsilon = 0$ , all the estimators are assumed to be identical to the exact values.

Then the stochastic version of SSC-SABB is as follows: Let  $x_0 \in \mathbf{R}^n$  be given and  $\alpha_0 = 1$ . For  $k = 0, 1, \dots$ , let  $T_k \geq 0$  be given. Define the *stochastic SSC-SABB algorithm*

*algorithm*

$$x_{k+1} = \begin{cases} x_k - t_k g_k & \text{if } T_k f(x_k - t_k g_k) \\ & \leq f(x_k - \alpha_k g_k), \\ x_k - \alpha_k g_k & \text{otherwise,} \end{cases}$$

where  $g_k = \nabla f(x_k)$ , and for  $k \geq 1$ ,

$$\alpha_k = \frac{|y_k|^2}{y_k^t s_k},$$

with

$$y_k = x_k - x_{k-1}, \quad s_k = \nabla f(x_k) - \nabla f(x_{k-1}).$$

Actually it has the exactly same form as the deterministic version of SSC-SABB (see ► **SSC minimization algorithms**) but with a different interpretation for  $f$  and  $\nabla f$ . More importantly, the parameters have to be selected differently. For example, it has been found in [4] that if one takes  $t_k = \min(c, \frac{1}{\sqrt{k}})$  or  $t_k = \min(c, 1/k)$ , then the constant  $c$  may be very much problem dependent to ensure a fast convergence. It was reported in [4] and [7] that  $T_k \equiv 1$  was always a safe choice for the stochastic problems studied there. One may use any estimator for  $F$  or  $\nabla F$  in the above algorithm. In [4] and [7], the linear or quadratic approximation for  $F$ , and the second order central difference estimator for  $\nabla F$  have been tested.

Performance of the algorithm was found to be promising. A considerable improvement over the stochastic approximation algorithm (SA) was observed in [4] and [7]. It was found to be able to solve some hard stochastic optimization problems efficiently. This improvement seems due to its unique adaptive (switching) feature in calculating its steplengths – they are neither pre-assigned nor determined by line search.

However, this unique feature leads to a major difficulty in establishing convergence for the algorithm (indeed for this class of algorithms) in the stochastic case. In the literature, most existing convergence results for the SA type of algorithms are established on the assumption that the size of the steplengths tends to zero. For instance, in the case of the stochastic approximation algorithm, the steplength at the  $k$ th iteration is just  $t_k$ , which goes to zero as  $k \rightarrow \infty$ . However this assumption is certainly not true for the stochastic version of SSC-SABB, since at the  $k$ th iteration, the

steplength is either  $t_k$  or  $\alpha_k$ . In fact, it was observed that the steplengths in the stochastic version of SSC-SABB often jumped, and this actually speeded up the algorithm.

Some convergence results were established for this algorithm in [2], based on the observation that the shifted minimization problem:  $\min_{R^n}(f + C)$  has weaker noise relative to the value of  $F + C$ , if  $C$  is larger. One of the convergence results will be very briefly described below. For ease of exposition, we will only state the result for the one-dimensional case.

Assume that  $\{\xi_k\}_{\{k \geq 1\}}$ ,  $\{\eta_k\}_{\{k \geq 1\}}$ ,  $\{\zeta_k\}_{\{k \geq 1\}}$ , and  $\{\chi_k\}_{\{k \geq 1\}}$  are independent random sequences defined on the probability space  $(\Omega, P, \mathcal{F})$  with bounded variances. For  $n = 1, 2, \dots$ , define the sub- $\sigma$ -algebra  $\mathcal{F}_n$  by

$$\mathcal{F}_n = \sigma(\{\xi_k\}_{\{k \leq n\}}, \{\eta_k\}_{\{k \leq n\}}, \{\zeta_k\}_{\{k \leq n\}}, \{\chi_k\}_{\{k \leq n\}}).$$

Assume that  $\chi_k \sim N(0, \gamma(k))$  and  $\zeta_k \sim N(0, \theta(k))$  for  $\gamma(k) > 0$  and  $\theta(k) > 0$ , respectively. Assume that the function  $F \in C^2(\mathbf{R})$  with bounded second derivatives. Let  $\{t_k\}$  be defined as before. Let  $\{\beta_k\}$  be a sequence of positive numbers, and let  $T > 0$ . Then for a given starting point  $X_0 = x_0$ , define the random process ( $k = 1, 2, \dots$ )

$$X_{k+1} = Y_{k+1}$$

if

$$\begin{aligned} T[F(X_k - t_k(\nabla F(X_k) + \xi_{k+1})) + \zeta_{k+1}] \\ \leq [F(X_k - \beta_k(\nabla F(X_k) + \eta_{k+1})) + \chi_{k+1}], \end{aligned}$$

and otherwise by

$$X_{k+1} = Z_{k+1},$$

where

$$\begin{cases} Y_{k+1} = X_k - t_k(\nabla F(X_k) + \xi_{k+1}), \\ Z_{k+1} = X_k - \beta_k(\nabla F(X_k) + \eta_{k+1}). \end{cases}$$

Suppose that  $\{\xi_k, \mathcal{F}_k\}$  is a sequence of martingale differences. Then it was shown in [2] that for any given  $T < 1$ , one has that

$$\lim_{k \rightarrow \infty} F(X_k)$$

exists almost surely, and

$$P(\liminf_{k \rightarrow \infty} \text{dis}(X_k, \Omega) = 0) = 1,$$

provided  $C$  is large enough and

$$\gamma(k) + \theta(k) \leq \frac{[(1 - T)C]^2}{10 \log(k + 1)},$$

where

$$\Omega = \{x: \nabla F(x) = 0\}.$$

Convergence has also been established when all the noises are bounded, see [2]. It should be noted that the above convergence is independent of the selection of the sequence  $\{\beta_k\}$ . However, the speed of the algorithm will very much depend on the selection. The assumptions of the results are in fact quite weak, and can be met easily, e. g. by averaging two or three samples of  $\chi_k$  and  $\zeta_k$ , or by taking a larger value of  $C$ . For instance, in [4],  $C$  was fixed to be 250 when  $F \geq 0$ .

### Keywords

Cutting plane algorithm; Stochastic programming

Decomposition methods for stochastic linear programming problems often use cutting planes to develop piecewise linear approximations of the objective function. This article provides a summary of techniques that can be used to stabilize these algorithms. By providing a unified treatment of deterministic as well as stochastic cutting plane algorithms, this article provides a common ground for both classes of methods.

### Introduction

Stochastic programming problems often give rise to highly structured optimization problems that are solved

using decomposition techniques. Many of these methods rely on cutting plane algorithms that generate successive approximations of the objective function. By and large, these algorithms generate deterministic approximations (e.g. [1,14]). More recently, new randomized versions of cutting plane methods have also been studied ([6] and [10]). The approximations used by such algorithms (deterministic or stochastic) are piecewise linear functions, which have the potential to provide arbitrarily close approximations, especially near an optimum solution. However, these basic methods suffer from the following drawback: cutting planes are derived in each iteration, and proofs of convergence are often based on retaining all cuts generated during the course of the algorithm. Since the cuts often result in dense linear inequalities, the unfettered proliferation of cuts leads to scarcity of computer memory. On the other hand, deleting cutting planes indiscriminately leads to instability in the approximations, and consequently in the solutions as well. This article is devoted to the discussion of algorithmic methods to curtail the size of the approximations without a degradation in the convergence properties of the algorithm.

Cutting plane algorithms for the solution of stochastic linear programming (SLP) problems may use one of a class of alternative representations of the SLP objective function. There is a great deal of flexibility in the manner in which cutting plane algorithms are designed. For stochastic programming problems, each iteration may generate anywhere from 1 to  $S$  cutting planes, where  $S$  is the number of possible outcomes associated with the random events of interest. Our discussion of stabilization methods will focus on two basic tools: incumbent solutions and regularization ([12,13] and [7]). These tools are then used within deterministic as well as stochastic cutting plane algorithms to provide well defined schemes for the deletion of cutting planes that do not compromise the integrity of the algorithm. For problems with  $n$  decision variables, deterministic algorithms that generate  $q$  cuts ( $1 \leq q \leq S$ ) can be shown to be convergent using a maximum of  $n + 2q$  deterministic cuts. In case of a stochastic cutting plane algorithm that uses  $q$  cuts per iteration, convergence results can be obtained by using a maximum of  $n + 3q$  cuts. We conclude this article with an illustration of these stabilization techniques.

### Alternative Methods for Approximating The Recourse Function

A two-stage stochastic linear program (SLP) may be stated as

$$(SLP) \quad \begin{cases} \min & c^\top x + E[h(x, \tilde{\omega})] \\ \text{s.t.} & x \in X, \end{cases}$$

where  $\tilde{\omega}$  is a random variable and

$$h(x, \omega) = \begin{cases} \min & g^\top y \\ \text{s.t.} & Wy = r(\omega) - T(\omega)x, \\ & y \geq 0, \end{cases}$$

and  $X \subseteq \mathbf{R}^n$  is a convex polyhedral set. Note that  $h$  is a value function of a linear program. For the sake of simplicity in this presentation, we assume that for all  $x \in X$ ,  $h(x, \tilde{\omega}) < \infty$  with probability one.

Most deterministic methods for SP work with the entire sample space of scenarios. For these methods it is therefore customary to assume that the random variable  $\tilde{\omega}$  is discrete, so that the possible outcomes may be numbered  $\{\omega_s\}_{s=1}^S$ . In such cases, the expectation in the objective function may be written as

$$E[h(x, \tilde{\omega})] = \sum_{s=1}^S h(x, \omega_s) p_s.$$

where  $p_s = P\{\tilde{\omega} = \omega_s\}$ , the probability of scenario  $s$ .

The structure of the SLP problem is well suited for Benders' decomposition which, in the SLP literature, goes under the name of the *L-shaped method* ([14]). At each iteration of the *L-shaped method* one constructs a supporting hyperplane of the recourse function  $E[h(x, \tilde{\omega})]$ . This hyperplane is then added to the collection of previously generated hyperplanes, and the method proceeds in this manner until a stopping rule is satisfied. The sequence of hyperplanes are called 'cuts' and they provide a piecewise linear lower bounding envelope of  $E[h(x, \tilde{\omega})]$ . Some variants of this method develop cutting plane approximations of the value functions  $\{h(x, \omega_s)\}_{s=1}^S$  so that  $S$  cuts are generated at a time (see [2,13]). These types of cutting plane algorithms are often called *multicut methods* since each iteration requires the development of as many cuts as there are scenarios in  $S$ . Since these multicut methods use sums of piecewise linear approximations, rather than one aggregated approximation (as in the *L-shaped method*),

they provide better lower bounds than the *L-shaped method*, although there is no similar guarantee regarding the quality of the upper bounds derived.

### Two Basic Tools: Incumbent Solutions and Regularization

Consider optimization problems of the form  $\min\{f(x):x \in X\}$ , where  $f:\mathbf{R}^n \rightarrow \mathbf{R}$  is convex and  $X \subseteq \mathbf{R}^n$  is a convex set. At each iteration, we assume that a point  $x^k$  is given, and we generate a lower bounding linearization  $\alpha_k + \beta_k^\top x$ , where the cut coefficients  $\beta_k \in \partial f(x^k)$  and  $\alpha_k = f(x^k) - \beta_k^\top x^k$ . (Since we are dealing with convex functions, the Clarke subdifferential, [3], will suffice for the purposes of this exposition.) The collection of all previously generated cuts define a piecewise linear lower bounding function, denoted  $f_k(x)$ , and is represented as

$$f_k(x) = \max_{t \in J_k} \alpha_t + \beta_t^\top x, \quad (1)$$

where  $J_k$  is an index set,  $\alpha_t \in \mathbf{R}$ ,  $\beta_t \in \mathbf{R}^n$  were generated in iteration  $t$ .

For the case of SLP, the cut coefficients are obtained by recognizing that as long as  $h(x^t, \omega)$  is finite, LP duality implies that

$$h(x, \omega) = \begin{cases} \max & [r(\omega) - T(\omega)x^t]^\top \pi \\ \text{s.t.} & W^\top \pi \leq g. \end{cases}$$

Letting  $\pi^t(\omega)$  denote an optimal dual solution, a subgradient of  $h$  is

$$-T(\omega)^\top \pi^t(\omega) \in \partial h(x^t, \omega).$$

Hence the cut coefficients for the SLP problem are defined as

$$\begin{aligned} \beta_t &= c - E[T(\tilde{\omega})^\top \pi^t(\tilde{\omega})], \\ \alpha_t &= E[r(\tilde{\omega})^\top \pi^t(\tilde{\omega})]. \end{aligned} \quad (2)$$

A more detailed explanation of this cut is provided in **► Stochastic linear programming: Decomposition and cutting planes**. It is worth noting at this point that one of the major handicaps associated with deterministic cutting plane algorithms for SLP arises from the calculations necessary in (2), which involves multidimensional integration. For problems involving a large number of outcomes, this operation becomes computationally burdensome, and one must then resort to sampling

based methods such as those discussed in the next section.

The iterates obtained by cutting plane methods may be generated as

$$x^{k+1} \in \operatorname{argmin} \{f_k(x) : x \in X\}. \tag{3}$$

We will designate these points as ‘candidate’ solutions. Since  $f_k$  has the form shown in (1), it can be written as a linear programming problem. In the language of Benders’ decomposition ([1]), this problem is called a *master problem* (program).

There are several criticisms that may be leveled against cutting plane methods. For example, in the earliest versions of these methods (including [11]) the index set  $J_k$  was defined as  $\{1, \dots, k\}$ ; consequently, the size of the LP and its data structures would grow indefinitely. In order to curtail the growth of the LP size, one may resort to dropping some of the inequalities. As one might expect, it is important to derive mathematically justifiable cut dropping rules, for otherwise, the sequence generated by (3) may not converge to an optimal solution. In this article we will summarize *stabilization* schemes that guarantee convergence, while ensuring that there is a fixed upper limit on the size of the master program. Another criticism is that the sequence  $\{f(x^k)\}$  is not a decreasing sequence. As a result, it is advisable to monitor decreases in  $f(x^k)$  and record points that suggest significant improvements. Such iterates will be designated as ‘incumbent’ solutions, so that the sequence of incumbent solutions is a subsequence of the sequence of candidate solutions.

We now proceed to a discussion of regularization, in which the piecewise linear approximation in (1) is augmented with a strictly convex casting function [15] or an auxiliary function [4]. The most commonly used casting function is a quadratic proximal term (see [12,13]). In iteration  $k$ , let  $\bar{x}^k$  denote the incumbent solution. The regularized master program is defined as

$$x^{k+1} \in \operatorname{argmin} \left\{ f_k(x) + \frac{\sigma}{2} \|x - \bar{x}^k\|^2 : x \in X \right\},$$

where  $\sigma > 0$  is a parameter that may be chosen during the course of the algorithm. Note that if we define

$$\rho_k(x; \sigma) = f_k(x) + \frac{\sigma}{2} \|x - \bar{x}^k\|^2$$

then

$$\partial \rho_k(\bar{x}^k; \sigma) = \partial f_k(\bar{x}^k).$$

Hence, if 0 belongs to the set  $\partial \rho_k(\bar{x}^k; \sigma)$ , then  $0 \in \partial f_k(\bar{x}^k)$ . Moreover, if  $\partial f_k(\bar{x}^k) \subseteq \partial f(\bar{x}^k)$ , then  $0 \in \partial \rho_k(\bar{x}^k; \sigma)$  implies  $0 \in \partial f(\bar{x}^k)$ , the first order optimality condition at  $\bar{x}^k$ .

### Regularization of Deterministic Cutting Plane Methods

In the following we shall work with the understanding that  $X$  is a convex polyhedral set represented in the form  $\{x: Ax \leq b\}$ . For the remainder of the development, it will be convenient to rewrite the approximation in terms of the displacement,  $d$ , from the incumbent solution,  $\bar{x}^k$ . Let  $x \leftarrow \bar{x}^k + d$ . In order to write the cuts as a function of  $d$ , we define  $\bar{f}_t^k = \alpha_t + \beta_t^\top \bar{x}^k$  that is,  $\bar{f}_t^k$  denotes the value of the cut  $\alpha_t + \beta_t^\top x$  at the incumbent point  $\bar{x}^k$ . Hence the approximation in terms of the direction vector  $d$  may be written as

$$v_k(d) = f_k(\bar{x}^k + d) = \max_{t \in J_k} \{ \bar{f}_t^k + \beta_t^\top d \}. \tag{4}$$

The *primal master problem* (direction finding problem) can now be written as

$$(\text{PRM}^k) \quad v_k = \begin{cases} \min & v + \frac{\sigma}{2} \|d\|^2 \\ \text{s.t.} & v - \beta_t^\top d \geq \bar{f}_t^k, \quad \forall t \in J_k, \\ & \bar{x}^k + d \in X. \end{cases}$$

Since this section is devoted to a deterministic algorithm, we work with the assumption that

$$v_k(0) = f_k(\bar{x}^k) = f(\bar{x}^k). \tag{5}$$

We now state a prototypical regularized deterministic cutting plane algorithm.

This algorithm has several important properties. First note from (4) and (5), and the definition of  $d^k$  (a solution to  $\text{PMK}^k$ ) that

$$\begin{aligned} v_k(d^k) &= f_k(\bar{x}^k + d^k) \\ &\leq f_k(\bar{x}^k) - \frac{\sigma}{2} \|d^k\|^2 = f(\bar{x}^k) - \frac{\sigma}{2} \|d^k\|^2. \end{aligned} \tag{6}$$

Hence  $\Delta_k \geq 0$ , with strict inequality if  $d^k \neq 0$ . Consequently, the sequence of incumbents defined in Step 2 yields a descending sequence of objective values. Furthermore, the stopping rule is based on the observation that if  $\Delta_{k+1} \leq \epsilon$ , then  $\sigma \|d\|^2/2 \leq \epsilon$ . Thus with an appropriate choice of  $\epsilon$ , the stopping rule tests whether the direction  $d^k$  has a sufficiently small norm.

- 0 (Initialize)
- 0a (Problem parameters) A convex function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  and a convex polyhedral set  $X = \{x: Ax \leq b\}$  are given. For SLP problems,  $f(x) = c^\top x + \mathbf{E}[h(x, \bar{\omega})]$ .
- 0b (Algorithm parameters)  $\sigma > 0$ ,  $\gamma \in (0, 1)$  and  $\epsilon > 0$  are given.
- 0c  $x^1 \in X$  is given,  $k \leftarrow 0$ ,  $J_0 \leftarrow \emptyset$ ,  $\bar{x}^0 \leftarrow x^1$ ,  $\Delta k = \infty$ .
- 1 (Define/Update the piecewise linear approximation)  
 $k \leftarrow k + 1$ . Evaluate  $\beta_k \in \partial f(x^k)$  and  $\alpha_k = f(x^k) - \beta_k^\top x^k$ . (For SLP these quantities are calculated as in (2).)  $J_k = \{t \in J_{k-1} : \theta_t^{k-1} > 0\} \cup \{k\}$ .
- 2 (Update the incumbent)  
 IF  $f(x^k) \leq f(\bar{x}^{k-1}) - \gamma \Delta_k$ . THEN  $\bar{x}^k = x^k$ .  
 ELSE  $\bar{x}^k = \bar{x}^{k-1}$ .
- 3 (Solve the regularized master)  
 Let  $x^{k+1} = \bar{x}^k + d^k$ , where  $d^k$  denotes an optimal solution to (PRM<sup>k</sup>). Similarly let  $\theta_t^k$  denote the optimal Lagrange multipliers associated with the cuts indexed by  $t \in J_k$ .
- 4 (Stopping rule)  
 Let  $\Delta_{k+1} = f(\bar{x}^k) - v_k(d^k)$ .  
 IF  $\Delta_{k+1} \leq \epsilon$ , THEN stop ELSE repeat from Step 1.

### A regularized deterministic cutting plane algorithm

In Step 4,  $\Delta_{k+1}$  is defined using the objective function approximation,  $v_k(d^k)$ . Thus, the decision to update the incumbent is based on how well  $\Delta_{k+1}$  predicts the actual change in the objective value. For higher values of  $\gamma$  an incumbent change is accepted only when the prediction is accurate, whereas smaller values of  $\gamma$  yield a less stringent criterion.

The analysis of this algorithm relies heavily on a dual statement of the regularized master (PRM<sup>k</sup>). In fact, [12] states the algorithm in terms of the dual to the master problem specified above. To write the dual, let  $F_k$  denote the vector of scalars  $\{\bar{f}_t^k\}_{t \in J_k}$ , and similarly, let  $B_k$  denote a matrix whose rows are given by the cut coefficients  $\{\beta_t^\top\}_{t \in J_k}$ . Furthermore, let  $b_k$  denote the vector  $A\bar{x}^k - b$ . Then the dual to (PRM<sup>k</sup>) is

$$(\text{DRM}^k) \quad \begin{cases} \max & F_k^\top \theta + b_k^\top \lambda - \frac{1}{2\sigma} \|B_k^\top \theta + A^\top \lambda\|^2 \\ \text{s.t.} & \mathbf{1}^\top \theta = 1, \quad \theta \geq 0, \quad \lambda \geq 0. \end{cases}$$

One of the important relationships between the primal and dual optimal solutions for the pair (PRM<sup>k</sup>) and (DRM<sup>k</sup>) is

$$d = -\frac{1}{\sigma} (B_k^\top \theta + A^\top \lambda). \quad (7)$$

Finally, we note that the total number of cutting planes retained in Step 1 cannot exceed  $n + 2$ . To see this, note that since  $\sigma > 0$ , the primal and dual master problems are strictly convex programs, and consequently both have unique optimal solutions. Suppose now that  $d^k$  and  $(\theta^k, \lambda^k)$  are the optimal solutions for the primal-dual pair. Clearly these solutions must satisfy (7) which in combination with the convexity constraint in (DRM<sup>k</sup>), yields  $n + 1$  linear equations involving the dual variables  $(\theta, \lambda)$ . Note that  $(\theta^k, \lambda^k)$  (the optimal dual solution) must be an extreme point of the resulting polyhedron; for if not, then  $(\theta^k, \lambda^k)$  can be written as a convex combination of two other points with the same dual objective value. The latter, of course, contradicts the uniqueness of the dual optimum. Hence  $(\theta^k, \lambda^k)$  must be an extreme point of the polyhedron determined by (7) and the dual feasibility restrictions. Since there are at most  $n + 1$  equations, it follows that there can be at most  $n + 1$  components of  $\theta^k$  which can be positive. Thus by including the new cut, we conclude that the cardinality of  $J_k$  cannot exceed  $n + 2$ .

We should mention that similar benefits can also be realized in multicut methods. For instance, if we use the sum of  $q$  piecewise linear approximations as in above, then one needs to carry at most  $n + q$  cuts from one iteration to the next. By accounting for the  $q$  cuts generated in each iteration of a multicut method, it follows that the size of the master problem can be restricted to at most  $n + 2q$ . In applying this class of methods to SLP problems, the regularized decomposition algorithm [13] uses  $q = S$ , the total number of outcomes. Hence the resulting master problem requires  $n + 2S$  cuts.

### A Regularized Stochastic Decomposition Algorithm

In contrast to the previous sections, this one is dedicated to SLP problems. For this class of problems, the calculation of multidimensional integrals in (2) creates a computational bottleneck for deterministic algorithms. In order to overcome this bottleneck, the

Stochastic Decomposition (SD) algorithm combines sampling within a cutting plane algorithm. In this section we discuss a regularized version of stochastic decomposition (SD).

It is clear that the primary change in going from the deterministic method of the previous section to the stochastic method is the inclusion of sampling. Referring to the algorithmic statement of the previous section, we augment the statement of step 1 with the inclusion of a sampled outcome (generated independently of previous observations). Further differences between SD and other cutting plane algorithms arise from the manner in which the approximations are generated/updated (Step 1) as well as the rule for accepting an incumbent (Step 2). The process for creating the cutting plane coefficients is presented in ► **Stochastic linear programming: Decomposition and cutting planes**, we do not reproduce those details here; instead, we summarize the changes to step 1 as follows:

1 | (Define/Update the piecewise linear approximation)  
 $k \leftarrow k + 1$ . Generate  $\omega^k$ , an outcome of  $\tilde{\omega}$ . Evaluate cut coefficients  $(\alpha_k^k, \beta_k^k)$  for a new cut, and update coefficients of previously generated cuts. Denote the updated cuts by  $(\alpha_t^k, \beta_t^k)$ . Update  $J_k$ .

Next we motivate the reason for updating  $J_k$  in a manner that is slightly different that that used in a deterministic algorithm. We also argue the need to update the incumbent (in Step 2) with a slightly different, though analogous rule.

Unlike the regularized deterministic algorithm which uses at most  $n + 2$  cuts in the master problem, convergence results for the regularized SD method requires  $n + 3$  cuts in the master program. This is because of the inherent inaccuracy of the objective function estimates used in a sampling algorithm. Recall that Step 2 of the deterministic method uses objective function values  $f(x^k)$  and  $f(\bar{x}^{k-1})$  to decide whether the incumbent needs to be updated. In a sample based algorithm these quantities cannot be calculated, and the choice of an incumbent is necessarily based on sampled information.

In order to prove asymptotic results regarding the sequence of incumbent solutions, one needs to have

asymptotic accuracy of a subgradient and the function value at an accumulation point of the incumbent sequence. One way to accomplish this is to require that the cut associated with an incumbent becomes asymptotically accurate (with probability one). This property may be attained algorithmically by periodically updating the cut associated with the incumbent solution. To clarify the process, suppose that at iteration  $k$ , we know that the most recent iteration at which the incumbent cut was generated (or updated) was  $\bar{i}_k < k$ . Furthermore, let us suppose that we intend to update the incumbent cut every  $\tau$  iterations ( $\infty > \tau \geq 1$ ). Then, at an iteration in which  $k = \bar{i}_k + \tau$ , the incumbent cut is updated to reflect the impact of outcomes as well as the dual vertices that may have been generated since iteration  $\bar{i}_k$ . These updates then guarantee that the sample size used for the incumbent cut grows indefinitely as required by the law of large numbers.

As suggested by the above discussion, the rule for cut retention ought to maintain a cut associated with the incumbent solution. At iteration  $k$ , let  $t_k$  denote the index associated with a cut generated at the incumbent solution. Then the rule used for cut retention is the following:

$$J_k = \left\{ t \in J_{k-1} : \theta_t^{k-1} > 0 \right\} \cup \{k, t_k\}.$$

Hence the maximum number of cuts used in the regularized master for SD is  $n + 3$ . With these changes included in the definition of the approximation  $f_k$ , we now provide the rule used for updating incumbents in Step 2.

2 | (Update the incumbent)  
 IF  $k = 1$ , THEN put  $\Delta_k = \infty$ ,  
 ELSE  $\Delta_k = f_{k-1}(\bar{x}^{k-1}) - v_{k-1}(d^{k-1})$ .  
 IF  $f_k(x^k) \leq f_k(\bar{x}^{k-1}) - \gamma\Delta_k$ ,  
 THEN  $\bar{x}^k = x^k$ , ELSE  $\bar{x}^k = \bar{x}^{k-1}$ .

Finally, there is one additional issue that arises whenever one uses sampled information. In some cases, as in SD, sampling is incorporated within the decomposition algorithm. In other cases, sampling is undertaken prior to using the optimization algorithm. Nevertheless, since each case uses sampled data, one should explore the possibility of error. We refer the reader to two articles in this area. The first of these ([5]) is based

on designing stopping rules that work with ‘in-sample’ information, and is tailored for the SD algorithm. Another approach, using ‘out-of-sample’ scenarios is provided in [8].

## Conclusions

We conclude this article with two examples taken from [9]. The illustrative application for these examples deals with an electricity reserve planning problem that finds an optimal trade-off between the cost of reserve capacity and the cost of unmet demand [9]. In Fig. 1, we illustrate two trajectories: the solid line is the trajectory of incumbent solutions and the dotted line is the set of candidate solutions. In order to isolate the impact of using an incumbent solution from the impact of the quadratic term, we used only the LP master in generating Fig. 1. It is clear that the solid line of incumbent solutions provides a far more stable trajectory.

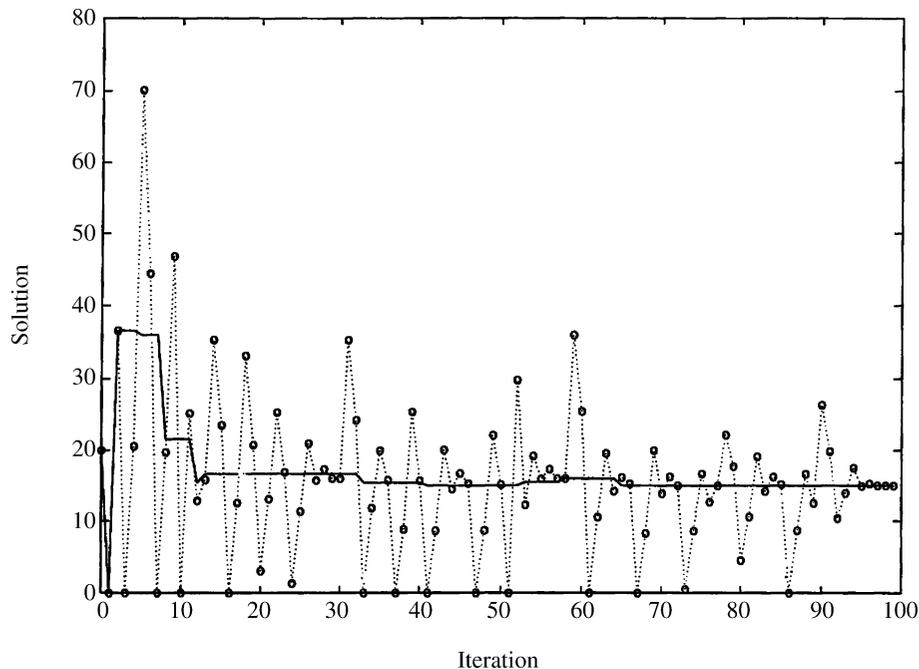

Next we discuss the impact of the quadratic term with reference to the same reserve planning example. In order to isolate the impact of the quadratic term, we examine the candidate sequences from two implementations: one in which the weight on the quadratic term

is very small ( $\sigma = 10^{-8}$ ) and another in which  $\sigma = 1$ . The candidate solutions from the former implementation are depicted by dotted lines in Fig. 2, whereas, the candidates from the latter implementation are shown by the solid line. Once again, the solid line, representing the impact of regularization, exhibits a more stable trajectory than the trajectory associated with the dotted line.

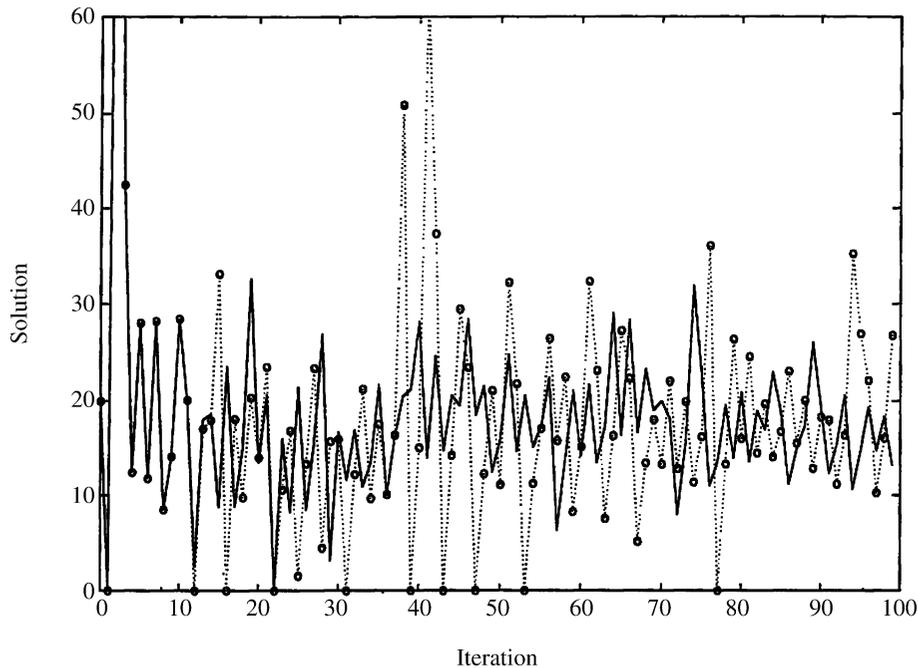

Before we close the article, we should mention one acceleration technique that often helps speed-up regularized algorithms in practice. The idea is to change the magnitude of  $\sigma$  dynamically:  $\sigma$  is reduced when the incumbent changes and  $\|x^{k+1} - \bar{x}^k\|$  increases; on the other hand,  $\sigma$  is increased when the incumbent does not change. This allows the algorithm to take smaller steps (higher  $\sigma$ ) when the approximation seems to be poor, whereas, the steps are allowed to more ‘daring’ (lower  $\sigma$ ) when progress is rapid.

## Abstract

In this article, we provide an overview on how the maximum weighted stable set problem can be solved exactly with Branch & Cut techniques. In addition, we provide selected references to other exact methods. We start with a brief introduction of the stable set problem and a few basic definitions but assuming that the reader is already familiar with the basic concepts. The main stress of this article lies in the review of polyhedral results for the stable set polytope in Sect. “[Stable Set Polytope](#)” and the discussion of separation procedures, Sect. “[Separation](#)”. An efficient Branch & Cut algorithm needs, in addition to strong separation routines, also a good branching strategy. This is discussed in Sect. “[Branching](#)”. At the end, some implementation aspects are considered.

## Introduction

Let  $G = (V, E)$  be an undirected graph consisting of a nonempty finite set  $V$ , the node set; and a finite set  $E$ , the edge set, of unordered pairs of distinct elements of  $V$ . A stable set of graph  $G$  is defined as a set of nodes  $S$  with the property that the nodes of  $S$  are pairwise non adjacent; two nodes are called adjacent if there is an edge in  $E$  connecting them. In the literature, stable set is also called independent set, vertex packing, co-clique or anticlique. If each node  $v_i$  of a graph  $G$  is assigned a weight  $c_i$ , then the graph is called

weighted. In this case, the maximum weighted stable set problem looks for a stable set  $S$  which maximizes the sum of the weights corresponding to the nodes in  $S$ ,  $\sum_{v_i \in S} c_i$ . In the case when  $G$  is not weighted, or all  $c_i = 1$ , we are interested in a stable set with the maximum number of nodes, which is called maximum cardinality stable set. The size of a maximum cardinality stable set is called the stability number of graph  $G$  and is denoted by  $\alpha(G)$ . Throughout this article, references to the maximum stable set problem, or just stable set problem, consider the weighted case unless otherwise noted.

Following from its definition, the stable set problem has many applications in various fields, [15]. Especially when “conflict(s)” between some objects occur, it is an indicator that the stable set problem is applicable. Next to the Traveling Salesman Problem, it is one of the most important combinatorial optimization problems. It is well known that it is  $\mathcal{NP}$ -hard to determine a maximum stable set in an arbitrary graph, [37]. This holds true for the cardinality case. Furthermore, it is also hard to approximate the stable set number: It can be shown that for any fixed  $\varepsilon > 0$  there is no polynomial time algorithm for approximating the stability number within a factor of  $|V|^\varepsilon$ , under the assumption that  $\mathcal{P} \neq \mathcal{NP}$ , [3,36].

Let us briefly and informally introduce some polyhedral terminologies. In our case it is sufficient to define a polyhedron as the solution set of a system of linear inequalities. If the solution set is bounded, it is called a polytope. Graphically speaking, a polytope in  $\mathbb{R}^n$  is of full-dimension if it contains an  $n$ -dimensional sphere completely; in 2-dimensions it is therefore forbidden that the polytope is empty, one point or a line segment. A linear inequality  $\beta^\top x \leq b_0$  is valid with respect to a polyhedron  $P$ , if  $P$  is a subset of  $\{x \mid \beta^\top x \leq b_0\}$ . We call a set  $F \subseteq P$  a facet of  $P$  if there is a valid inequality  $\beta^\top x \leq b_0$  for  $P$  such that  $F = \{x \in P \mid \beta^\top x = b_0\}$ , and the inequality is not dominated by any other valid inequality. This inequality is called a facet-defining inequality for  $P$ . In the case when  $v$  is a point in the polyhedron  $P$  and  $F = \{v\}$ , we call  $v$  a vertex of polyhedron  $P$ . Now, let  $P$  be a polytope and  $x^*$  be a given point. The task to decide if this point lies in  $P$  or if not to find a valid inequality  $\beta^\top x \leq b_0$  for  $P$  which is violated by  $x^*$ , is called the separation problem for polytope  $P$ . The convex hull

of points  $y_1, \dots, y_n \in \mathbb{R}^d$  is the set of points  $x$  satisfying  $x = \sum_{i=1}^n \lambda_i y_i$  with  $\sum_{i=1}^n \lambda_i = 1$  and  $\lambda_i \geq 0 \forall i$ . It is denoted by  $\text{conv}\{y_1, \dots, y_n\}$ . More details can be found for instance in [20,42,82].

We introduce now, in addition to the ones above, several graph theoretic definitions and notations needed throughout this article. A node  $v$  is incident to an edge  $e$ , if  $e = uv$ . The two nodes incident to an edge are its endnodes. A node is isolated if it has no neighbor in the graph, which means that it is not an endnode of any edge of the graph. The neighborhood of a node  $v$  is the collection of all its neighbors and is abbreviated with  $\Gamma(v)$ . If a graph has no isolated nodes, it is called connected. A graph is said to be complete if it contains an edge connecting each pair of its nodes. A clique is the node set of a complete subgraph. If a clique has three nodes it is also called a triangle. The cardinality of a graph  $G$  is abbreviated by  $|G|$  and denotes the number of nodes in the graph. The complement graph  $\bar{G}$  of the graph  $G$  has the same node set as  $G$  and contains an edge between two nodes, iff no edge is contained in  $G$ . We call a graph  $G$  bipartite if its node set  $V$  can be partitioned into two disjoint sets  $V_1, V_2$  with  $V = V_1 \cup V_2$  such that neither two nodes of set  $V_1$  nor two nodes of set  $V_2$  are neighbors. We call  $H = (W, F)$  a subgraph of  $G$ , and write  $H \subseteq G$ , when  $W \subseteq V$  and  $F \subseteq E$  is the set of edges of graph  $G$  with both endnodes in  $W$ . Two graphs  $G = (V, E)$  and  $H = (W, F)$  are called isomorphic, if there is a bijection  $\phi: V \rightarrow W$  such that  $uv \in E \Leftrightarrow \phi(u)\phi(v) \in F$ . A matching is a collection of pairwise disjoint edges. If in a matching  $M$  every node of  $G$  is incident with exactly one edge  $M$ , then it is a perfect matching. More about graph theory can be found in [33,78].

We do not describe the Branch & Cut algorithm in general here, as we assume the reader is familiar with its basic ideas. For more information we refer to [40, 46,61,79].

Before we discuss some aspects of a Branch & Cut algorithm to solve the maximum stable set problem, we provide a list of some other exact solution methods. Clearly, this list does not claim to be complete. A more detailed list of exact methods can be found in [15,22]. In this context, we want to point out that the stable set problem is equivalent to the maximum clique problem in the complement graph. Hence, each method solving the maximum clique problem can also

be used to solve the stable set problem. For polynomial time algorithms for some special classes of graphs, see [2,6,8,14,17,32,48,54,55,59,63] and Sect. “**Stable Set Polytope**”. Algorithms finding all maximum stable sets in a graph are considered in [19,29,44,49,73]. In the literature, many variants of Branch & Bound algorithms have been discussed, [4,12,35,51,60,65,71,76,80]. Other methods using, for instance, continuous formulations, column generation or constraint programming can be found in [5,16,18,21,25,53,64,68,75,77].

Benchmark instances are provided by the second DIMACS Challenge, [34], from 1992/1993 and by the BHOS library from 2000, [13]. Note that some of these stable set instances are still unsolved. A test case generator was introduced by Hasselberg et al. [45].

## Method

Let us now formulate the maximum stable set problem as a linear program. Therefore, one choice could be to introduce variables  $x_i$  for each node  $v_i \in V$ , which have value one, if node  $v_i$  is in a stable set, say  $S$ , and otherwise zero. Such a vector is called an incidence vector. Obviously, for each edge, only one endnode can be in a stable set and hence, we get the so called edge-inequalities

$$x_i + x_j \leq 1 \quad \forall ij \in E. \quad (1)$$

It is easy to see, that if vector  $x$  has a positive integer domain (or more precisely, binary domain), each vector satisfying inequalities (1) induces a stable set and vice versa. Hence, if  $c$  denotes the (positive) weight vector of the nodes, one gets the following integer program

$$\begin{aligned} \max_x \quad & c^\top x \\ \text{s.t.} \quad & x_i + x_j \leq 1 \quad \forall ij \in E \\ & x \in \{0, 1\}^{|V|}, \end{aligned} \quad (2)$$

which solves the maximum weighted stable set problem. We recognize, that this formulation has only  $|E|$  constraints and  $|V|$  variables. So the formulation is quite compact. Unfortunately, the binary constraints on  $x$  make it hard to solve this linear program. We will discuss some relaxations of this problem in the next section which is mainly based on [9,39,42,58,70].

## Stable Set Polytope

The stable set polytope of graph  $G = (V, E)$  is defined as the convex hull of the incidence vectors of all stable sets in  $G$ . It is denoted by

$$P_{\text{STAB}}(G) := \text{conv}\{\chi^S \mid S \subseteq V \text{ stable set}\},$$

where  $\chi^S$  is the incidence vector of set  $S$ . From the integer program formulation (2) we see that  $P_{\text{STAB}}(G)$  is a polyhedron. As it is bounded by the  $|V|$ -dimensional unit cube, it is indeed a polytope. The definition of a stable set implies that the unit vectors are always stable sets. Trivially, the zero vector is a stable set, the empty set, therefore, the stable set polytope is full-dimensional. This implies that all facets of  $P_{\text{STAB}}(G)$  are inequalities, and hence, we do not have to consider equalities, [58,67].

Let us now discuss some relaxations of the integer program formulation (2) which will also give us relaxations of the stable set polytope. The obvious idea is to relax the binary condition on  $x$ , and instead make them continuous which leads to

$$0 \leq x_i \leq 1 \quad \forall v_i \in V. \quad (3)$$

The integer problem reduces to a linear program which can be solved in polynomial time. This relaxation leads to the so called stable set polytope relaxation

$$\begin{aligned} P_{\text{RSTAB}}(G) \\ := \{x \in \mathbb{R}^n \mid x_i + x_j \leq 1, 0 \leq x \leq 1 \forall ij \in E\}. \end{aligned} \quad (4)$$

From its construction, we get that  $P_{\text{STAB}}(G) \subseteq P_{\text{RSTAB}}(G)$ . For a complete graph with cardinality  $\geq 3$ , the  $x$  vector with value 1/2 in each component is a vertex of  $P_{\text{RSTAB}}(G)$ , but it cannot be contained in  $P_{\text{STAB}}(G)$  as a maximum cardinality stable set in a complete graph has cardinality one. This example shows that the relaxation above is very weak. Note, the vector whose entries are all 1/2 is always contained in  $P_{\text{RSTAB}}(G)$  – independent of the structure of the graph  $G$ . The following corollary generalizes this observation. It was first indicated by Balinski [11].

**Corollary 1** *The vertices of  $P_{\text{RSTAB}}(G)$  are  $(0, \frac{1}{2}, 1)$ -valued.*

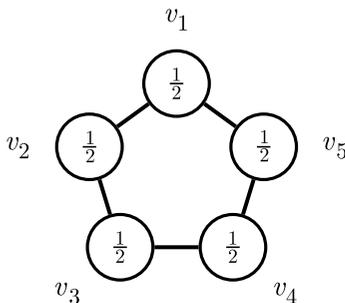

We saw that for a complete graph  $G$  with cardinality  $\geq 3$ ,  $P_{\text{STAB}}(G) \subset P_{\text{RSTAB}}(G)$ . The next theorem states

that this holds except for connected bipartite graphs. In this case the stable set polytope and the stable set polytope relaxation are equal, that is  $P_{\text{STAB}}(G) = P_{\text{RSTAB}}(G)$ .

**Theorem 2 [42]** *The non-negativity inequalities,  $x_i \geq 0 \ \forall v_i \in V$ , together with the edge inequalities (1) are sufficient to describe  $P_{\text{STAB}}(G)$ , iff  $G$  is bipartite and has no isolated nodes.*

Theorem 2 has the following important implication: It states that the maximum stable set problem for bipartite graphs can be solved in polynomial time by solving the stable set problem over (4). As a consequence, a Branch & Cut algorithm using the stable set polytope relaxation (4), will terminate for bipartite graphs in the root node of the branching tree after solving one linear program. However, we already have indicated that the stable set polytope relaxation is very weak and hence not a good choice in a Branch & Cut framework for general graphs. Obviously, it can be checked in linear time whether a graph is bipartite or not. Exact polynomial time algorithms for bipartite graphs can be found in [42,47].

As the restriction to bipartite graphs is very tough, we want to find some ways to strengthen the stable set polytope relaxation. One idea is to add additional valid inequalities to  $P_{\text{RSTAB}}(G)$ . Therefore, let us consider the Fig. 1. It shows a graph with the five nodes  $v_1, v_2, \dots, v_5$ . Such a graph is called odd-cycle. In general, whenever a (sub-)graph  $H$  has an odd number of nodes, say  $n$ , and there are  $n$  adjacent edges in the edge set such that each node is incident to exactly two nodes, then we call  $H$  an odd cycle. Notice that an odd cycle can have more than  $n$  edges. In this case, any additional edge is called chord. For the graph of the Fig. 1, the

**Stable Set Problem: Branch & Cut Algorithms, Figure 1**  
Odd cycle with five nodes

stable set polytope relaxation allows the fractional solution with all entries of  $1/2$ , as illustrated. This solution is optimal, and for the cardinality stable set problem, the objective function value is  $5/2$ , which is greater than any optimal stable set which has cardinality two. Now, summing up all edge inequalities corresponding to the five edges in the graph, one gets

$$2x_1 + 2x_2 + 2x_3 + 2x_4 + 2x_5 \leq 5.$$

In this case each node is incident to exactly two edges, giving the coefficients for the variables, and there are five edge inequalities, providing the right-hand side. This inequality can be divided by two and as all variables are binary, one gets

$$x_1 + x_2 + x_3 + x_4 + x_5 \leq \left\lfloor \frac{5}{2} \right\rfloor.$$

This inequality can be generalized to the so called odd-cycle inequalities

$$\sum_{v_i \in \widetilde{V}} x_i \leq \frac{|\widetilde{C}| - 1}{2} \tag{5}$$

for each odd cycle  $C = (\widetilde{V}, \widetilde{E}) \subseteq G$ .

From the construction above, it is obvious that the odd-cycle inequalities are valid for the stable set polytope. If, in addition, the stable set polytope relaxation satisfies all odd-cycle inequalities of  $G$ , then it is called a cycle-constraint stable set polytope and is denoted by

$$P_{\text{CSTAB}}(G) := \{x \in \mathbb{R}^{|V|} \mid x \text{ satisfies (1), (3) and (5)}\}.$$

If you consider, again, a complete graph, you see that there is no constant which relates the optimal solution over  $P_{\text{CSTAB}}(G)$  to an optimal stable set. However, the graphs for which  $P_{\text{CSTAB}}(G) = P_{\text{STAB}}(G)$  are called t-perfect; the “t” stands for “trou” – the French word for “hole”. Two examples for t-perfect graphs are bipartite graphs and almost bipartite graphs, where a graph  $G$  is called almost bipartite if there is a node  $v$  such that graph  $G$  without  $v$  is bipartite. The problem of checking whether a graph is t-perfect or not belongs to  $co - \mathcal{NP}$ . The special structure of t-perfect graphs helps to find a maximum stable set. This is stated by the next corollary.

**Corollary 3** *The maximum stable set problem in a t-perfect graph can be solved in polynomial time.*

We will see in Sect. “Separation” that the odd-cycle inequalities can be separated in polynomial time. This proves together with the Equivalence of Optimization and Separation the Corollary 3. Polynomial time algorithms for the class of  $t$ -perfect graphs can be found in [42,43].

We are mainly interested in facets of  $P_{STAB}(G)$  since they are not dominated by any valid inequality of  $P_{STAB}(G)$ . The odd-cycle inequalities can only be facet-defining if their odd cycles are chordless. If there is a chord, one gets a smaller odd cycle and an even cycle. The smaller odd-cycle inequality together with the edge inequalities dominate the odd-cycle inequality which shows that it cannot be facet-defining. A graph which is a chordless cycle is called a hole. If an odd cycle induces an odd hole, the corresponding odd-cycle inequality is called an odd-hole inequality. Consider the following

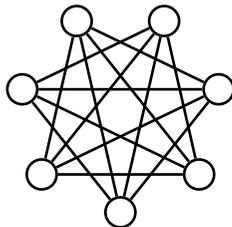

**Corollary 4 [57]** *Let  $G$  be an odd hole. Then  $\sum_{v_i \in V} x_i \leq \frac{|V|-1}{2}$  is facet-defining for  $P_{STAB}(G)$ .*

A counterpart of the odd-cycle inequalities are the antihole inequalities. They are valid for antiholes, which is the complement graph of an odd hole with at least five nodes. From the Fig. 2, we recognize that each stable set of an antihole with  $n$  nodes can contain at most two nodes as each node is adjacent to exactly  $n - 2$  nodes. Therefore, the following inequalities hold

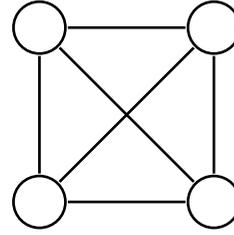

$$\sum_{v_i \in \tilde{V}} x_i \leq 2 \quad \text{for each antihole } A = (\tilde{V}, \tilde{E}) \subseteq G. \quad (6)$$

Note that an antihole with 5 nodes is isomorphic to an odd hole with 5 nodes. The separation problem for the antihole inequalities is not known whether it belongs to  $P$  or not.

Another group of inequalities for the stable set polytope builds the clique inequalities. From the Fig. 3 we

Stable Set Problem: Branch & Cut Algorithms, Figure 2  
Odd antihole

Stable Set Problem: Branch & Cut Algorithms, Figure 3  
Complete graph with four nodes a clique

get

$$\sum_{v_i \in Q} x_i \leq 1 \quad \text{for each clique } Q. \quad (7)$$

In 1979, Padberg showed the following important

**Theorem 5 [62]** *Let  $G$  be a graph with node set  $V$  and  $Q \subseteq V$ . Inequality (7) is valid for  $P_{STAB}(G)$ . An inequality  $\sum_{v_j \in Q} x_j \leq 1$  is a facet of  $P_{STAB}$ , iff  $Q$  is a maximal clique in  $G$ .*

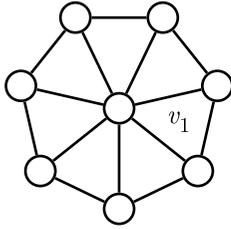

Theorem 5 shows that the edge inequalities (1) are only facet-defining for  $P_{STAB}(G)$ , if they build a maximal clique. Hence, they are dominated by the clique inequalities. We will use this observation later in Sect. “Implementation”. Note that for triangles, the clique inequality and the odd-cycle inequality are the same. We define the so called clique-constraint stable set polytope as

$$P_{QSTAB}(G) := \{x \in \mathbb{R}^{|V|} \mid x \text{ satisfies (1), (3) and (7)}\}.$$

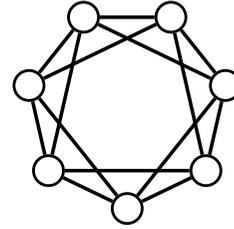

A graph  $G$  is called perfect if  $P_{QSTAB}(G) = P_{STAB}(G)$ . Originally, in 1961 Berge called a graph perfect if the coloring number is equal to the clique number. This definition is equivalent to the polyhedral one given above. The maximum clique and the stable set problem are very closely related. Therefore, it is not surprising that it is  $\mathcal{NP}$ -hard to separate the clique inequalities in an arbitrary graph. With this fact, it is quite remarkable that the following theorem holds.

**Theorem 6 [42]** *The maximum stable set problem for perfect graphs can be solved in polynomial time.*

We do not go into the details of the proof here, but nevertheless, we give a rough explanation. It is possible to generalize the clique inequalities to a class of so called orthonormal representation constraints which

Stable Set Problem: Branch & Cut Algorithms, Figure 4  
Odd wheel

Stable Set Problem: Branch & Cut Algorithms, Figure 5  
(7,3)-web

are polynomially separable. The convex set of all vectors satisfying them and the non-negativity inequalities build the so called theta body, [50,81]. In the case of perfect graphs, this theta body is a polytope which equals  $P_{\text{STAB}}(G)$ . This implies Theorem 6. However, it is even  $\mathcal{NP}$ -hard to determine an optimal solution over  $P_{\text{QSTAB}}(G)$ , in general. More about perfect graphs can be found, for instance, in [30,31,66].

If we consider the Fig. 4, we recognize an odd hole with cardinality seven with the additional node  $v_1$  which is adjacent to all other nodes. Such a graph is called wheel and node  $v_1$  is its hub. We see that if node  $v_1$  is contained in a stable set, no other node of the wheel can be contained in it. Hence, we get the following odd-wheel inequalities

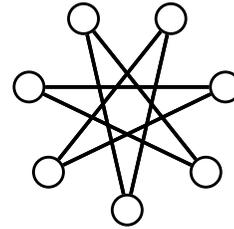

$$\sum_{v_i \in \tilde{V}} x_i + \frac{|C|-1}{2} x_u \leq \frac{|C|-1}{2} \tag{8}$$

for each odd wheel  $C = (\tilde{V}, \tilde{E}) \subseteq G$  with hub  $u$ .

From its construction, inequality (8) is valid for  $P_{\text{STAB}}(G)$ . It defines a facet if  $G$  is isomorphic to an odd wheel. Recognize that the wheel inequality dominates the odd-hole inequality. Generalizations of the wheel inequalities can be found in [27].

Another class of inequalities are the web and antiweb inequalities. Let  $p$  and  $q$  be integers satisfying  $p > 2q + 1$  and  $q > 1$ . A graph  $G$  is called a web if  $G$  is isomorphic to the graph consisting of the nodes  $\{v_1, \dots, v_p\}$  with an edge  $v_i v_j$ , iff  $|i - j| \equiv r < q$  modulo  $(n - 2)$ . A web is abbreviated with  $W(p, q)$ . A graph is called antiweb, denoted by  $AW(p, q)$ , iff  $AW(p, q)$  is isomorphic to  $\overline{W}(p, q)$ . Examples can be seen in the Fig. 5 and 6, respectively. The following inequalities

$$\sum_{v_i \in W(p,q)} x_i \leq q, \tag{9}$$

Stable Set Problem: Branch & Cut Algorithms, Figure 6  
(7,3)-antiweb

$$\sum_{v_i \in AW(p,q)} x_i \leq \left\lfloor \frac{p}{q} \right\rfloor \tag{10}$$

are called web inequalities and antiweb inequalities, respectively. Both types of inequalities are valid for  $P_{\text{STAB}}(G)$ . The web inequalities (9) define facets if  $p$  and  $q$  are relatively prime and  $G = W(p, q)$  - two natural numbers are called relatively prime if their greatest common divisor is 1, or in formula:  $\text{gcd}(p, q) = 1$ ; while the antiweb inequalities (10) are facet-defining for  $P_{\text{STAB}}(AW(p, q))$  if there is no  $k \in \mathbb{N}$  with  $p = k \cdot q$ . More details can be found, for instance, in [28,74].

Now, consider the following class of inequalities for a graph  $G = (V, E)$  and  $W \subseteq V$

$$x(W) := \sum_{v_i \in W} x_i \leq \alpha(G[W]). \tag{11}$$

They are called rank inequalities. From their construction, inequalities (11) are valid for  $P_{\text{STAB}}(G)$ . The edge, odd-cycle, clique, antihole, web and antiweb inequalities belong to this class. Therefore, these inequalities are not facet-defining for  $P_{\text{STAB}}(G)$  in general. For instance, an odd-wheel with 5 or more nodes does not lead to a rank inequality. Let us now have a closer look at the separation of the discussed inequalities.

## Separation

In order to separate the odd-cycle inequalities (5) for a graph  $G$  and a vector  $x^*$ , one has to find an odd cycle for which  $x^*$  violates the corresponding inequality, or one has to prove that such cycles do not exist. In other words, we have to find a minimum-weight odd cycle in a graph, with an appropriate weighting function. If this cycle satisfies the corresponding inequality (5), it is proven that all odd-cycle inequalities are satisfied. Otherwise, one has found a maximal violated odd-cycle inequality. Therefore, we first recognize

**Proposition 7** *A minimum-weight odd cycle in a graph  $G$  with edge weights can be computed in  $O(|V| \cdot |E| \cdot \log(V))$ .*

The idea is to construct an auxiliary bipartite graph  $H$ . This node set of  $H$  consists of two copies of the node set of the original graph  $G$ , and there is an edge between two nodes of  $H$  if the corresponding original nodes in  $G$  are adjacent. The edge weights are copied with the edges. From the construction of  $H$ , a minimum odd-cycle with respect to the edge weighting in  $G$  corresponds to a shortest path in  $H$  and vice versa. Hence, calculation of a shortest path for each node of the original graph  $G$  to its copy, gives a minimum weight odd cycle in  $G$ . Computing the shortest paths with Dijkstra's algorithm yields to the running time of Proposition 7. Now, define the following edge weighting of graph  $G$  depending on  $x^*$  as

$$c(v_i v_j) := \frac{1 - x_i^* - x_j^*}{2}. \quad (12)$$

With this weighting, it can be shown that an odd-cycle inequality in  $G$  is violated by vector  $x^*$ , if and only if

$$\exists C = (\tilde{V}, \tilde{E}) \subseteq G \text{ with } C \text{ odd cycle and} \\ \sum_{v_i v_j \in \tilde{E}} c(v_i v_j) < \frac{1}{2}.$$

This yields directly to the following theorem.

**Theorem 8** *The separation problem for the class of odd-cycle inequalities can be solved in  $O(|V| \cdot |E| \cdot \log(|V|))$ .*

One has to mention that  $x^*$  has to satisfy all inequalities (3) before the odd-cycle inequalities can be separated with the above procedure. Otherwise, the weights

defined in (12) can become negative, and the shortest path cannot be calculated with Dijkstra's algorithm anymore. More details and the description of the algorithms can be found in [27,38,67]. It is interesting to realize that, in general, there are exponentially many odd cycles in a graph, but on the contrary, the separation of them is polynomial. We want to mention that Grötschel and Pulleyblank introduced in 1981 another method to separate the odd-cycle inequalities with the use of perfect matchings resulting in a running time of  $O(|E|^4)$ , [41].

Finding a maximum clique is  $\mathcal{NP}$ -hard, while computing an arbitrary maximal clique as well as an arbitrary maximal stable set can be done in linear time. We want to point out that we distinguish between maximum and maximal. Maximal means that there is no better solution containing the particular one; so maximal can be seen as locally best while maximum is global. The separation problem for the clique inequalities asks to find a violated clique inequality in a particular graph  $G$  with a given linear program solution or to state that all clique inequalities are satisfied. This is equivalent to finding a maximum clique in  $G$  with the linear program solution as node-weighting  $c$ . Hence, the separation problem for the clique inequalities is  $\mathcal{NP}$ -hard. Computational tests show that the clique inequalities are very important for polyhedral approaches to the stable set problem, cf. [69]. As an exact separation cannot be considered, one idea could be to fix the size of the cliques to be separated, as then the problem becomes polynomially solvable. Another observation is that it is enough to consider maximal cliques. The reason is that the resulting clique inequality dominates all clique inequalities corresponding to contained cliques. Practically, it is more successful to separate over larger classes of inequalities containing the clique inequalities. We discuss that later for the case of rank inequalities. However, the best computational results, so far, are achieved with heuristic separation methods.

A separation algorithm for the wheel inequalities is given by Cheng and Cunningham, [26]. The appealing idea is to treat each node of the graph as a possible hub of an odd wheel and define appropriate weights for all nodes which are adjacent to this hub. Then, on the new graph, the odd-cycle inequalities can be separated. Hence, this algorithm results in a total running time of  $O(|V|^2 \cdot |E| \cdot \log(|V|))$  or  $O(|V|^4)$ , dependent on the

shortest path algorithm. For practical Branch & Cut algorithms, this complexity is already too high compared to the number of violated inequalities one can expect. Even more sophisticated are the separation routines for the web and antiweb inequalities. They are discussed by Cheng and Vries, [28]. Although they can also be separated in polynomial time, the complexity of the separation algorithms are again too large for practical use. In addition, these type of inequalities usually occur in graphs with high density, e.g. greater than 0.7, which makes its separation doubtful for graphs with low density; where the density of graph  $G = (V, E)$  is defined as  $\frac{2 \cdot |E|}{|V| \cdot (|V| - 1)}$ .

Next to the special type of inequalities for the stable set polytope discussed in the Sect. “**Stable Set Polytope**”, one can use general classes of inequalities. In this context, we want to mention two of such a type. The first are the so called mod- $k$  cuts which belong to the Chvátal-Gomory cuts with rank one. The appealing idea of the mod- $k$  cuts is to find a multiplier  $\mu$ , such that a particular inequality system  $Ax \leq b$  multiplied with this vector  $\mu$  can be strengthened by dividing it by a positive integer  $k$ . Therefore, let  $k > 1$  be integral, and suppose that we have given a system of linear inequalities  $Ax \leq b$  with integral coefficients. Let  $\mu$  be a vector with positive integer entries and appropriate dimension such that

$$\begin{aligned}\mu^\top A &\equiv 0 \pmod{k}, \\ \mu^\top b &\equiv k - 1 \pmod{k}.\end{aligned}$$

From this, one can obtain the mod- $k$  inequalities

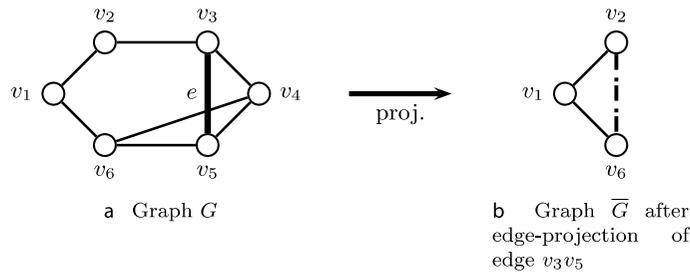

$$\frac{1}{k} \mu^\top Ax \leq \frac{1}{k} (\mu^\top b - (k - 1)).$$

Examples for the case of  $k = 2$  are the odd-cycle inequalities or the wheel inequalities. The separation of the mod- $k$  inequalities and more details can be found in [23,67].

The second class of general inequalities that we discuss here in brief are the so called local cuts. The principal idea was introduced by Applegate et al. in 2001 for the Traveling Salesman Problem, [1]. Suppose we have given the set of all  $m$  feasible solutions to the stable set problem, for instance of a subgraph with  $n$  nodes. The idea is to check if a given (solution) vector lies in its convex hull or if it lies outside, to compute a facet which separates this point from the convex hull. This

can be achieved by solving a linear program with  $m$  variables and  $n$  constraints. Its optimal objective function value provides the information if the point lies inside the polytope, and the optimal dual variables give the coefficients of the separation inequality, called local cut. Obviously, this method has some weaknesses. One first has to find a ‘good’ subgraph and then enumerate all stable sets. In addition, the linear program to be solved can be large, as the number of stable sets in a graph can be exponential. Nevertheless, the resulting cuts can be quite strong, especially if all other separation procedures do not bring new cuts. More details and computational results can be found in [67].

At the end of this subsection, we introduce the idea of separating rank inequalities. We do not go into full detail here but instead focus on the discussion of the principle ideas of the beautiful results of Mannino and Sassano, [52]. The appealing idea is to reduce the size of the graph and to make it denser at the same time. In general, any node of the graph can be selected and its two endnodes will be removed from the graph. In addition, new so called false edges are added to the graph and some other nodes may also be removed. Therefore, this procedure is called edge projection. Now, after a few iterations of this procedure, when the graph is small enough, one can separate any type of rank inequality, for instance, the clique inequalities or the odd-cycle inequalities. If a violated inequality has been found, it must be projected to be valid for the polytope of the original graph. This process is called anti-projection. We have to mention that it is possible that a projected inequality is no longer violated by a solution vector, even if it was in the projected graph. The edge-projection and the anti-projection can be done in linear time which makes this method very fast. Let us now consider a small example indicated in the Fig. 7. In Fig. 7a you see a small graph with six nodes. It is an odd hole with the additional node  $v_4$ . If we select edge  $e = v_3v_5$  to project on, then in this case, nodes  $v_3, v_5$  and, in addition,  $v_4$  are removed from the graph (the reason therefore is that  $v_4$  is the common neighbor of nodes  $v_3$  and  $v_5$ ); as well as all edges incident with any of these nodes. False edges are added between the set of nodes which are only neighbors of  $v_3$  and not of  $v_5$  and the set of nodes which are only neighbors of  $v_5$  and not of  $v_3$ . Hence, false edge  $v_2v_6$  is added, and one gets the triangle shown in Fig. 7b. We recognize that the re-

**Stable Set Problem: Branch & Cut Algorithms, Figure 7**  
Edge protection

sulting graph is smaller and, indeed, more dense. We realize that the triangle inequality

$$x_1 + x_2 + x_6 \leq 1$$

is valid for  $P_{\text{STAB}}(\bar{G})$  but not for  $P_{\text{STAB}}(G)$ . In most cases, the anti-projection adds the deleted nodes to the inequality and increases the right hand side by value one. In this case we get

$$x_1 + x_2 + x_3 + x_4 + x_5 + x_6 \leq 2,$$

which is a valid inequality for  $P_{\text{STAB}}(G)$ . We recognize that it is a lifted odd-hole inequality, which is facet-defining for  $P_{\text{STAB}}(G)$ ; where the extension of a valid inequality for  $P$  to a valid inequality for a higher dimensional polytope  $\bar{P} \supseteq P$  is called lifting. In general, it turns out that facet-defining inequalities for the polytope of the projected graph might not be facet-defining for the polytope of the original graph and vice versa. The method was successfully developed and implemented by Rossi and Smriglio, [69]. More details and polyhedral results can be found in [67].

### Branching

The branching strategy in a Branch & Cut algorithm influences the overall performance of the algorithm very much. In general, it is very difficult to find a good strategy. Various techniques have been explored and none of them can always outperform the others. But for special problems, there are different strategies that help to reduce the size of the Branch & Bound tree and speedup the algorithm. We start this section with a motivation for the need of special techniques and present the branching idea of Balas and Yu from 1986, [7]. It still remains the most successful strategy in practice.

One standard branching idea for a problem with binary variables is to generate two subproblems. One variable is set to value one in one subproblem and to value zero in the other one. However, this branching strategy leads to a very unbalanced Branch & Bound tree for the maximum stable set problem. This can be seen by the following argument. Setting a variable to value one sets all nodes of its neighborhood to value zero. In contrast, setting a variable to value zero has no consequence for all other variables of the graph. To avoid this drawback, one could think to set in each subproblem of the tree at least one variable to value one. Basically, this is the key property of the branching strategy by Balas and Yu.

Let  $G' = (V', E')$  be the subgraph induced by the set of nodes which are not fixed in a current subproblem. In each subproblem, the goal is to find a maximum stable set in the particular subgraph given by the tree, or to prove that  $\alpha(G') < LB$ , with the lower bound  $LB$ . Let  $W \subseteq V'$ , and assume that we can show that  $\alpha(G[W]) \leq LB$ . Clearly, if  $W = V'$ , the subproblem can be fathomed; otherwise, if  $\alpha(G') > LB$  any maximum stable set must contain at least one node of set  $Z := V' \setminus W = \{v_1, \dots, v_p\}$ . Based on this observation, Balas and Yu showed that every maximum-cardinality stable set with greater weight than the lower bound must be contained in one of the sets

$$V'_i := \{v_i\} \cup V' \setminus (\Gamma(v_i) \cup \{v_{i+1}, \dots, v_p\})$$

for  $i = 1, \dots, p$ .

Note, that this strategy is also true for the weighted case with  $c \neq 1$ . This branching leads to  $p$  new subproblems in one branching step. In each subproblem, node  $v_i$  is set to value one, and all nodes of  $\Gamma(v_i) \cup \{v_{i+1}, \dots, v_p\}$  are set to value zero.

Let us now discuss some properties of this strategy. The size of  $W$  and the ordering of the nodes in  $Z$  can affect the total number of subproblems to be solved. Of course, the larger  $W$  is, the fewer subproblems will be generated in that state. The size of  $W$  is strongly effected by the quality of the computed lower bound. Determining  $W$  is quite crucial and can be done for the cardinality stable set problem, for instance, with a clique covering, cf. [7,69]. Also other methods such as matchings or holes [71] have been considered. In addition, the choice of the branching variable also has a great impact on the number of subproblems being solved. The size of the tree can be reduced by branching on nodes with a high degree, which was empirically shown by Carraghan and Pardalos [25]. The reason is the previously mentioned observation that with the branching node its neighborhood is also set. To sort the nodes in each subproblem in ascending order of degree seems to be computationally expensive as the degree of all nodes has to be calculated in each branching step prior to sorting. However, Sewell [71] showed experimentally that for sparse graphs this is still convenient.

### Implementation Aspects

In general, when implementing a solver for the stable set problem, the following two things are crucial. First, one has to obtain a good lower bound, which means in the case of maximization, a feasible solution. One should use one of the many suggested heuristics in literature. We refer to the article ► [heuristics for maximum clique and independent set](#). Second, it is recommended to have a strong preprocessing. This becomes even more important when the graphs result from applications. Many contributions have been made for this purpose. Among them are, for instance, fixing of nodes, fixing of cliques and treating connected components separately, [56,67,72].

For the case of a Branch & Cut algorithm in particular, one first needs a formulation of the stable set problem. We discussed some of the relaxations in Sect. “[Stable Set Polytope](#)”. For practical efficiency, it is not recommended to start with the optimization over  $P_{\text{RSTAB}}(G)$ . The reasons are that this relaxation is very weak and contains relatively many constraints. A better idea is to start with maximal cliques which contain all edges. Such a covering can be found in linear time. The

resulting relaxation is stronger, as each maximal clique is facet-defining and dominates all the edge inequalities contained. Recognize that for bipartite graphs the relaxations is the same for both methods.

If one decides to separate several classes of inequalities within a Branch & Cut framework, one needs an order in which the separation routines are called. It is recommended to first call the polynomial separation routines, then the ones which take higher computational effort. However, practical tests show that the clique inequalities are very important. Therefore, a Branch & Cut solver should focus on fast heuristic separation of the clique inequalities combined with the very powerful tool of edge-projection. This leads to the best computational results so far.

Moreover, it is recommended to focus on facet-defining inequalities. Therefore, each clique should be lifted to a maximal clique before its inequality is added to the formulation. Accordingly, each odd-cycle should be checked not to contain any chords, and if so, the smaller odd-cycle would be added instead. These transformations can be done in linear time.

More details regarding implementation and Branch & Cut modules for the stable set problem can be found, for instance, in [10,24,67,69].

### Conclusion

Many contributions have been made to solve the stable set problem exactly. One of the exact algorithms is based on the Branch & Cut method. However, the stable set polytope is not yet fully understood, and the known inequalities are either easy to separate with little impact, or they can only be separated with a large amount of computational effort and are very crucial for polyhedral approaches to the stable set problem. Therefore, it is not a surprise that there are some stable set instances with less than 1000 nodes which cannot be solved exactly with current methods.

a (global) quadratic optimization problem of the form

$$\max \{f(\mathbf{x}) = \mathbf{x}^\top R\mathbf{x} : \mathbf{x} \in \Delta\}, \quad (1)$$

where  $R$  is an arbitrary symmetric  $n \times n$  matrix. Quadratic optimization problems like (1) are *NP*-hard [2], even regarding the detection of local solutions. Nevertheless, there are several procedures which try to exploit favorable data constellations in a systematic way, and to avoid the worst-case behavior whenever possible. Examples for this type of algorithms are specified below.

First we concentrate on the evolutionary approach to finding local solutions of StQPs. To this end, consider the following *dynamical system* operating on  $\Delta$ :

$$\begin{aligned} \dot{x}_i(\tau) &= x_i(\tau)[(R\mathbf{x}(\tau))_i - \mathbf{x}(\tau)^\top R\mathbf{x}(\tau)], \\ i &\in N, \end{aligned} \quad (2)$$

where a dot signifies derivative w.r.t. time  $\tau$ , and a discrete time version

$$x_i(\tau + 1) = x_i(\tau) \frac{[R\mathbf{x}(\tau)]_i}{\mathbf{x}(\tau)^\top R\mathbf{x}(\tau)}, \quad i \in N. \quad (3)$$

The *stationary points* under (2) and (3) coincide, and all local solutions of (1) are among these (see below). A stationary point  $\mathbf{x}$  is said to be *asymptotically stable*, if every solution to (2) or (3) which starts close enough to  $\bar{\mathbf{x}}$ , will converge to  $\bar{\mathbf{x}}$  as  $\tau \nearrow \infty$ . Now the following results hold (for proofs and further characterization results linking optimization theory, evolutionary game theory, and qualitative theory of dynamical systems, see [1] and the references therein):

- the objective  $f(\mathbf{x}(\tau))$  increases strictly along non-constant trajectories of (2) and (3);
- all trajectories converge to a stationary point;
- all Karush–Kuhn–Tucker points and hence all local solutions of (1) are stationary points under (2) and (3);
- if no principal minor of  $R = R^\top$  vanishes, then with probability one (regarding the choice of  $\mathbf{x}(0)$ , the starting point), any trajectory of (2) converges to one of the strict local solutions  $\bar{\mathbf{x}}$  of (1), which coincide with the asymptotically stable points under (2) and (3);
- further,  $\mathbf{y}^\top R\mathbf{y} < \bar{\mathbf{x}}^\top R\bar{\mathbf{x}}$  for all  $\mathbf{y} \in \Delta$  with  $\mathbf{y} \neq \bar{\mathbf{x}}$  but  $y_i = 0$  if  $\bar{x}_i = 0$ .

## Standard Quadratic Optimization Problems: Algorithms

Global optimization; Interior point; Copositivity; Escape step; Replicator dynamics

A *standard quadratic optimization problem* (StQP) consists of finding (global) maximizers of a quadratic form over the *standard simplex*  $\Delta$  in  $n$ -dimensional Euclidean space  $\mathbf{R}^n$ ,

$$\Delta = \{\mathbf{x} \in \mathbb{R}^n : x_i \geq 0 \text{ for all } i \in N, \mathbf{e}^\top \mathbf{x} = 1\},$$

where  $N = \{1, \dots, n\}$ ;  $\mathbf{a}^\top$  denotes transposition; and  $\mathbf{e} = [1, \dots, 1]^\top \in \mathbf{R}^n$ . Hence a StQP can be written as

- 1 Given a local solution  $\bar{\mathbf{x}}$  to (1), remove all alleles which are not unfit, i.e. all  $i \in S = \{i \in N : \bar{x}_i > 0\}$ ;
- 2 determine a (local) *fitness minimizer*  $\mathbf{y}$  in the reduced problem, i.e. consider problem (1) with  $R$  replaced by

$$\tilde{R} = [\gamma s - r_{ij}]_{i,j \in N \setminus S},$$

- 3 where  $\gamma s = \max_{i,j \in N \setminus S} r_{ij}$  with a local solution  $\mathbf{y}$  of this auxiliary problem, put

$$J = \{j \in N \setminus S : y_j > 0\}$$

- 4 and denote by  $m$  the cardinality of  $J$ ;  
for all  $s \in S$  and  $t \in J$ , consider the reduced problem  $\mathcal{P}_{t \rightarrow s}$ , i.e. problem (1) in  $n - m$  variables for the  $(n - m) \times (n - m)$  matrix  $R_{t \rightarrow s}$  obtained from  $R$  as follows: replace  $r_{si}$  with  $r_{ti}$  and remove all other  $j \in J$ ;
- 5  $\bar{\mathbf{x}}$  is a global solution to the master problem (1) if and only if for all  $(s, t) \in S \times J$ , the maximum of  $\mathcal{P}_{t \rightarrow s}$  does not exceed the current best value  $\bar{\mathbf{x}}^\top R \bar{\mathbf{x}}$ ;
- 6 in the negative, i.e. if  $\mathbf{u}^\top R_{t \rightarrow s} \mathbf{u} > \bar{\mathbf{x}}^\top R \bar{\mathbf{x}}$  for some  $\mathbf{u} \in \Delta \subset \mathbf{R}^{n-m}$ , and if  $j \in J$  is chosen such that for all  $q \in J$

$$\sum_{p \notin J \cup \{s\}} (r_{jp} - r_{qp})u_p \geq \frac{1}{2}(r_{qq} - r_{jj})u_s,$$

then a strictly improving feasible point  $\bar{\mathbf{x}}$  is obtained as follows:

$$\bar{x}_q = \begin{cases} u_t & \text{if } q = j, \\ 0 & \text{if } q \in J \cup \{s\} \setminus \{j\}, \\ u_q & \text{if } q \in N \setminus J. \end{cases}$$

**GENF procedure to escape from inefficient local solutions in StQPs**

Although strictly increasing objective values are guaranteed as trajectories under (2) or (3) are followed, one could get stuck in an inefficient local solution of (1). One possibility to escape is the *genetic engineering via negative fitness* (GENF) approach [1] described in the sequel. From the properties above, a strict local solution  $\bar{\mathbf{x}}$  of (1) must be a global one if all  $\bar{x}_i > 0$ . Consequently,

at an inefficient local solution necessarily  $\bar{x}_i = 0$  for some  $i$ . In the usual genetic interpretation of the dynamics (2) and (3), this means that some alleles die out during the natural selection process, and these are therefore unfit in the environment currently prevailing. The escape step now artificially re-introduces some alleles which would have gone extinct during the natural selection process, and restarts with a smaller subproblem which will yield an improvement if  $\bar{\mathbf{x}}$  is inefficient, see the table above.

In view of the possible combinatorial explosion in effort with increasing number of variables, this dimension reducing strategy seems to be promising: if  $k$  is the size of  $S$ , the above result yields a series of  $km$  StQPs in  $n - m$  variables rather than in  $n$ . We are now ready to describe the algorithm which stops after finitely many repetitions, since it yields strict local solutions with strictly increasing objective values [1].

- |   |   |
|---|---|
| 1 | Start with $\mathbf{x}(0) = [1/n, \dots, 1/n]^\top$ or nearby, iterate (3) until convergence;   |
| 2 | the limit $\bar{\mathbf{x}} = \lim_{r \rightarrow \infty} \mathbf{x}(r)$ is a strict local solution with probability one; call the GENF procedure to improve the objective, if possible; denote the improving point by $\tilde{\mathbf{x}}$ ; |
| 3 | repeat 1), starting with $\mathbf{x}(0) = \tilde{\mathbf{x}}$   |

**Replicator dynamics algorithm for StQPs**

A different approach towards global solutions of StQPs uses familiar branch and bound schemes. For ease of exposition, now consider the minimization StQP

$$\min \{ \mathbf{x}^\top Q \mathbf{x} : \mathbf{x} \in \Delta \}, \tag{4}$$

and assume without loss of generality that  $Q$  has only positive entries (otherwise replace  $Q$  with  $Q + \gamma \mathbf{e}\mathbf{e}^\top$  where  $\gamma$  is suitably large). If one applies a usual simplicial partition [2] (cf. also **Simplicial decomposition**) to  $\Delta$ , all subproblems are again StQPs. To obtain lower bounds for these problems, convex minorants for the objective  $\mathbf{x}^\top Q \mathbf{x}$  on  $\Delta$  may be used, e.g. quadratic forms  $\mathbf{x}^\top F \mathbf{x}$  with  $F$  positive semidefinite (or some related matrix  $\hat{F}$  which ensures that the minorant is convex necessarily over  $\Delta$  only), where  $F$  is chosen such that the gap between the objectives is small. This can be accomplished by requiring  $\text{diag } F = \text{diag } Q$  and that  $\sum_i^j [q_{ij} -$

$f_{ij}]$  is small, while the minorant condition is guaranteed by the requirement  $f_{ij} \leq q_{ij}$  for all  $i, j \in N$ . Therefore one arrives at a semidefinite optimization problem (SDP; cf.

► **Semidefinite programming: Optimality conditions and stability**) which can be solved by the usual methods. The resulting matrix  $F$  then gives a convex problem, so that the desired lower bound for (4),  $\{\min_{\mathbf{x} \in \Delta} \mathbf{x}^\top F \mathbf{x}\}$  can be obtained efficiently, e. g. via local search techniques or linear complementarity approaches (cf. also ► **Interval analysis: Eigenvalue bounds of interval matrices**). For details and results see [3].

Maximum weight clique; Portfolio selection; Simplicial partition; Branch and bound

A *standard quadratic optimization problem* (StQP) consists of finding (global) maximizers of a quadratic form over the *standard simplex* in  $n$ -dimensional Euclidean space  $\mathbf{R}^n$ ,

$$\Delta = \{\mathbf{x} \in \mathbf{R}^n : x_i \geq 0 \text{ for all } i \in N, \mathbf{e}^\top \mathbf{x} = 1\},$$

where  $N = \{1, \dots, n\}$ ;  $\mathbf{a}^\top$  denotes transposition; and  $\mathbf{e} = \sum_{i \in N} \mathbf{e}_i = [1, \dots, 1]^\top \in \mathbf{R}^n$ , with  $\{\mathbf{e}_i : i \in N\}$  the vertices of  $\Delta$ . Hence a StQP can be written as a (global) quadratic optimization problem of the form

$$\max \{\mathbf{x}^\top R \mathbf{x} : \mathbf{x} \in \Delta\}, \quad (1)$$

where  $R$  is an arbitrary symmetric  $n \times n$  matrix.

An important application for StQPs is the search for a maximum weight clique arising in computer vision, pattern recognition and robotics (see [2] for a more detailed account): consider an undirected graph  $\mathcal{G} = (N, \mathcal{E})$  with  $n$  nodes, and a weight vector  $\mathbf{w} = [w_1, \dots, w_n]^\top$  of positive weights  $w_i$  associated to the nodes  $i \in N$ . A *clique*  $S$  is a subset of  $N$  which corresponds to a complete subgraph of  $\mathcal{G}$  (i. e. any pair of different nodes in  $S$  is an edge in  $\mathcal{E}$ ). A clique  $S$  is said to be *maximal* if there is no larger clique containing  $S$ . Every clique  $S$  in  $\mathcal{G}$  has a weight  $W(S) = \sum_{i \in S} w_i$ . The *maximum weight clique problem* (MWCP) consists of finding a clique in the graph which has largest total weight. The classical (unweighted) *maximum clique problem* is a special case with  $\mathbf{w} = \mathbf{e}$ . To reformulate the MWCP as a StQP, one may exploit an idea of L. Lovász in considering the following class of symmetric  $n \times n$  matrices: let

$$\mathcal{C}(\mathcal{E}) = \{(c_{ij})_{i,j \in N} : c_{ij} = 0 \text{ if } (i, j) \in \mathcal{E}\},$$

as well as  $\mathcal{C}_+(\mathcal{G}) = \{C \in \mathcal{C}(\mathcal{E}) : C^\top = \{C \text{ and } c_{ij} \geq c_{ii} + c_{jj} \text{ if } (i, j) \notin \mathcal{E}\}$ , and form the class

$$\mathcal{C}(\mathcal{G}, \mathbf{w}) = \left\{ C \in \mathcal{C}_+(\mathcal{G}) : c_{ii} = \frac{1}{2w_i} \text{ for all } i \right\}.$$

Now consider the (minimization) StQP

$$\min \{\mathbf{x}^\top C \mathbf{x} : \mathbf{x} \in \Delta\} \quad (2)$$

for some matrix  $C \in \mathcal{C}(\mathcal{G}, \mathbf{w})$ . Given a subset  $S \subseteq N$ , define the  $S$ -face of  $\Delta$  as

$$\Delta_S = \{\mathbf{x} \in \Delta: x_i = 0 \text{ if } i \notin S\}$$

and its *weighted barycenter* as  $\mathbf{x}^S = \sum_{i \in S} (w_i/W(S))\mathbf{e}_i \in \Delta_S$ . Then the following assertions hold [2]:

- A point  $\mathbf{x} \in \Delta$  is a local solution to problem (2) if and only if  $\mathbf{x} = \mathbf{x}^S$ , where  $S$  is a maximal clique.
- A vector  $\mathbf{x} \in \Delta$  is a global solution to problem (2) if and only if  $\mathbf{x} = \mathbf{x}^S$ , where  $S$  is a maximum weight clique.
- Moreover, all local (and hence global) solutions to (2) are strict.

Note that a different class used in [3] does not share these properties. The class  $\mathcal{C}(\mathcal{G}, \mathbf{w})$  is isomorphic to the positive orthant in  $\binom{n}{2} - e$  dimensions where  $e$  is the cardinality of  $\mathcal{E}$ . This class is a polyhedral pointed cone with its apex given by the matrix  $C^{\mathcal{G}, \mathbf{w}}$  with entries

$$c_{ij}^{\mathcal{G}, \mathbf{w}} = \begin{cases} \frac{1}{2w_i} & \text{if } i = j, \\ \frac{1}{2w_i} + \frac{1}{2w_j} & \text{if } i \neq j \text{ and } (i, j) \notin \mathcal{E}, \\ 0 & \text{otherwise.} \end{cases}$$

In the unweighted case  $\mathbf{w} = \mathbf{e}$ , we get  $C^{\mathcal{G}, \mathbf{e}} = (\frac{1}{2})I + A_{\bar{\mathcal{G}}}$  where  $A_{\bar{\mathcal{G}}}$  is the adjacency matrix of the complement graph  $\bar{\mathcal{G}}$ , and  $I$  the  $n \times n$  identity matrix. Therefore (2) can be seen as a regularized generalization of the original approach of T.S. Motzkin and E.G. Straus [7].

Another application of StQP is concerned with the mean/variance *portfolio selection* problem (see, e.g. [6]; ► **Portfolio selection and multicriteria analysis**) which can be formalized as follows: suppose there are  $n$  securities to invest in, at an amount expressed in relative shares  $x_i \geq 0$  of an investor's budget. Thus, the budget constraint reads  $\mathbf{e}^T \mathbf{x} = 1$ , and the set of all feasible portfolios (investment plans) is given by  $\Delta$ . Now, given the expected return  $m_i$  of security  $i$  during the forthcoming period, and an  $n \times n$  covariance matrix  $V$  across all securities, the investor faces the multi-objective problem to maximize the expected return  $\mathbf{m}^T \mathbf{x}$  and simultaneously minimize the risk  $\mathbf{x}^T V \mathbf{x}$  associated with her decision  $\mathbf{x}$ .

One of the most popular approaches to such type of problems in general applications is that the user pre-specifies a parameter  $\beta$  which in her eyes balances the benefit of high return and low risk, i.e. consider the

parametric QP

$$\max \{f_\beta(\mathbf{x}) = \mathbf{m}^T \mathbf{x} - \beta \mathbf{x}^T V \mathbf{x}: \mathbf{x} \in \Delta\}.$$

For fixed  $\beta$ , this is a StQP. Anyhow, the question remains how to choose  $\beta$ . In finance applications, the notion of market portfolio is used to determine a reasonable value for this parameter. This emerges more or less from an exogenous artefact, namely by introducing a completely risk-free asset which is used to scale return versus risk [5]. An alternative, purely endogenous derivation of market portfolio could use a result of M.J. Best and B. Ding [1] who consider the problem

$$\max_{\beta > 0} \max_{\mathbf{x} \in \Delta} \frac{1}{\beta} f_\beta(\mathbf{x}), \tag{3}$$

and show how optimal solutions  $(\beta^*, \mathbf{x}^*)$  for (3) emerge from a single StQP (1) with, e.g.  $R = 2\mathbf{m}\mathbf{m}^T - V$ .

A general application of StQPs arises if one applies branch and bound schemes with simplicial partitions [4] (cf. also ► **Simplicial decomposition**) to general quadratic problems of the form

$$\max \left\{ g(\mathbf{x}) = \frac{1}{2} \mathbf{x}^T Q \mathbf{x} + \mathbf{c}^T \mathbf{x}: \mathbf{x} \in M \right\},$$

where  $M = \{\mathbf{x} \in \mathbf{R}^n: A\mathbf{x} \leq \mathbf{b}\}$  with  $A$  an  $m \times n$  matrix and  $Q$  a symmetric  $n \times n$  matrix. A subproblem then is of the form  $\max\{g(\mathbf{x}): \mathbf{x} \in P\}$  with  $P \cap M \neq \emptyset$  and  $P = \text{conv}\{\mathbf{v}_0, \dots, \mathbf{v}_n\}$  for some points  $\mathbf{v}_i \in \mathbf{R}^n$  (if all vertices of  $M$  are easy to determine, one could even take them rather than the  $\mathbf{v}_i$ ). With the  $n \times (n + 1)$  matrix  $U = [\mathbf{v}_0, \dots, \mathbf{v}_n]$ , the subproblem reduces to the StQP

$$\max \{ \mathbf{y}^T R \mathbf{y}: \mathbf{y} \in \Delta \}$$

where  $R = U^T Q U + \mathbf{e}\mathbf{c}^T U + U^T \mathbf{c}\mathbf{e}^T$  is a symmetric  $(n + 1) \times (n + 1)$  matrix and  $\Delta \subseteq \mathbf{R}^{n+1}$ . Efficient bounds can thus be obtained with one of the algorithms for obtaining (local) solutions to a StQP.

Global optimization; Interior point; Copositivity

A *standard quadratic optimization problem* (StQP) consists of finding (global) maximizers of a (possibly indefinite) quadratic form over the *standard simplex*  $\Delta$  in  $n$ -dimensional Euclidean space  $\mathbf{R}^n$ ,

$$\Delta = \{ \mathbf{x} \in \mathbf{R}^n : x_i \geq 0 \text{ for all } i \in N, \mathbf{e}^\top \mathbf{x} = 1 \},$$

where  $N = \{1, \dots, n\}$ ;  $\mathbf{a}^\top$  denotes transposition; and  $\mathbf{e} = [1, \dots, 1]^\top \in \mathbf{R}^n$ . Hence a StQP can be written as a (global) quadratic optimization problem of the form

$$\max \{ \mathbf{x}^\top R \mathbf{x} : \mathbf{x} \in \Delta \}, \quad (1)$$

where  $R$  is an arbitrary symmetric  $n \times n$  matrix. Since the maximizers of (1) remain the same if  $R$  is replaced with  $R + \gamma \mathbf{e} \mathbf{e}^\top$  where  $\gamma$  is an arbitrary constant, one may assume without loss of generality that all entries of  $R$  are positive. Furthermore, the question of finding maximizers of a general quadratic function  $\mathbf{x}^\top Q \mathbf{x} + 2\mathbf{c}^\top \mathbf{x}$  over  $\Delta$  can be homogenized in a similar way by considering the rank-two update  $R = Q + \mathbf{e} \mathbf{e}^\top + \mathbf{c} \mathbf{c}^\top$  in (1) which has the same objective values on  $\Delta$ .

StQPs arise in procedures which enable an escape from inefficient local solutions of general quadratic optimization problems (QPs): consider the general quadratic maximization problem

$$\max \left\{ f(\mathbf{x}) = \frac{1}{2} \mathbf{x}^\top Q \mathbf{x} + \mathbf{c}^\top \mathbf{x} : \mathbf{x} \in M \right\}, \quad (2)$$

where  $M = \{ \mathbf{x} \in \mathbf{R}^n : A \mathbf{x} \leq \mathbf{b} \}$  with  $A$  an  $m \times n$  matrix and  $Q$  a symmetric  $n \times n$  matrix. To formulate a characterization of global optimality of a Karush–Kuhn–Tucker point  $\bar{\mathbf{x}}$  for (2), first add a trivial non-binding constraint, i. e. the most elementary strict inequality  $0 < 1$ , to obtain slacks  $\bar{\mathbf{u}}$  as follows: denote by  $\mathbf{a}_i^\top$  the  $i$ th row of  $A$  and put  $\mathbf{a}_0 = \mathbf{o}$ . Similarly put  $b_0 = 1$  and enrich  $\bar{A} = [\mathbf{a}_0 | A^\top]^\top = [\mathbf{o}, \mathbf{a}_1, \dots, \mathbf{a}_m]^\top$  as well as  $\bar{\mathbf{b}} = [b_0 | \mathbf{b}^\top]^\top = [1, b_1, \dots, b_m]^\top$ . Finally, define  $\bar{\mathbf{u}} = \bar{\mathbf{b}} - \bar{A} \bar{\mathbf{x}} \geq \mathbf{o}$ . Then perform, for any  $i \in \{0, \dots, m\}$ , a rank-one update of  $\bar{A}$  and a rank-two update of  $Q$ , using the current gradient  $\mathbf{g} = \nabla f(\bar{\mathbf{x}}) = Q \bar{\mathbf{x}} + \mathbf{c}$  of the objective:

$$\begin{aligned} D_i &= \bar{\mathbf{u}} \mathbf{a}_i^\top - \bar{u}_i \bar{A}, \\ Q_i &= -\mathbf{a}_i \mathbf{g}^\top - \mathbf{g} \mathbf{a}_i^\top - \bar{u}_i Q. \end{aligned}$$

This gives a symmetric  $n \times n$  matrix  $Q_i$  and a matrix  $D_i$  which is effectively  $m \times n$  since its  $i$ th row is zero. Denoting by  $J(\bar{\mathbf{x}})$  the set of all nonbinding constraints, the following result is proved in [1]:

**Theorem 1** A Karush–Kuhn–Tucker point  $\bar{\mathbf{x}}$  of (2) is a global solution if and only if for all  $i \in J(\bar{\mathbf{x}}) = \{i \in N \cup \{0\} : \bar{u}_i > 0\}$ ,

$$\mathbf{v}^\top Q_i \mathbf{v} \geq 0 \quad \text{if } D_i \mathbf{v} \geq \mathbf{o}. \quad (3)$$

If  $\mathbf{v}^\top Q_i \mathbf{v} < 0$  for some  $\mathbf{v}$  with  $D_i \mathbf{v} \geq \mathbf{o}$ , then

$$\tilde{\mathbf{x}} = \bar{\mathbf{x}} + \lambda \mathbf{v} \quad (4)$$

is an improving feasible point for  $\lambda = \bar{u}_i / (\mathbf{a}_i^\top \mathbf{v})$  (if  $\mathbf{a}_i^\top \mathbf{v} = 0$ , i. e.  $\lambda = +\infty$ , this means that (2) is unbounded).

Determining whether or not (3) is satisfied, amounts to the question whether or not  $\max\{\mathbf{v}^\top (-Q_i) \mathbf{v} : D_i \mathbf{v} \geq \mathbf{o}\} \leq 0$ . Now this homogeneous problem is decomposable [2,3] into problems of the form  $\max\{\mathbf{x}^\top R \mathbf{x} : \mathbf{x} \geq \mathbf{o}\}$ , where the constraint  $\mathbf{e}^\top \mathbf{x} = \sum_i x_i = 1$  can be added without loss of generality, rendering a StQP. In fact, in order to determine an improving feasible direction (4) it is not necessary to solve the latter problem to optimality, but rather sufficient to determine a feasible point  $\mathbf{x} \in \Delta$  with  $\mathbf{x}^\top R \mathbf{x} > 0$ .

If the original problem (2) is itself already a StQP, then all checks of (3) can be reduced to a single one: if  $\bar{\mathbf{x}} \in \Delta$  is any feasible point, then  $\bar{\mathbf{x}}$  is a global maximizer of  $\mathbf{x}^\top Q \mathbf{x}$  over  $\Delta$  if and only if the matrix  $\bar{Q} = (\bar{\mathbf{x}}^\top Q \bar{\mathbf{x}}) \mathbf{e} \mathbf{e}^\top - Q$  satisfies  $\mathbf{v}^\top \bar{Q} \mathbf{v} \geq 0$  if  $\mathbf{v} \geq \mathbf{o}$ , i. e.  $\bar{Q}$  is copositive.

The close connection between StQPs and copositivity becomes evident if the usual semidefinite programming (SDP) approach is enlarged to recast a StQP into a linear optimization problem on a cone  $\mathcal{K}$  which is the (pre) dual of the cone  $\mathcal{K}^*$  of all copositive symmetric  $n \times n$  matrices, with respect to the duality  $\langle R, S \rangle = \text{trace}(RS)$  operating on pairs  $(R, S)$  of such matrices. This formulation allows to employ interior point algorithms (cf. also ► [Sequential quadratic programming: Interior point methods for distributed optimal control problems](#); ► [Interior point methods for semidefinite programming](#)), similar to the methods used in SDP. Both cones  $\mathcal{K}^*$  and  $\mathcal{K}$  have nonempty interiors, and the latter can be described as follows [4,6]:

$$\mathcal{K} = \text{conv} \{ \mathbf{x} \mathbf{x}^\top : \mathbf{x} \geq \mathbf{o} \},$$

the convex hull of all symmetric rank-one matrices, i. e. dyadic products, generated by nonnegative vectors. Note that dropping the nonnegativity requirement, we would arrive at the positive semidefinite case. Now let  $E = \mathbf{e} \mathbf{e}^\top$  be the  $n \times n$  matrix of all ones. Since the extremal points of the set  $\mathcal{L} = \{X \in \mathcal{K} : \langle E, X \rangle = 1\}$  are exactly the dyadic products  $\mathbf{x} \mathbf{x}^\top$  with  $\mathbf{x} \in \Delta$ , a maximizer of  $\langle R, X \rangle$  over  $\mathcal{L}$  can be found which is of this form, and hence

the StQP (1) is equivalent to the linear problem

$$\max \{ \langle R, X \rangle : X \in \mathcal{K}, \langle E, X \rangle = 1 \}.$$

It is easy to see that the dual formulation [5] of this problem is

$$\min \{ y \in \mathbf{R} : yE - R \in \mathcal{K}^* \},$$

which is the task to find the smallest  $y$  such that  $yE - R$  is copositive. Thus the dual problem is related to the question of eigenvalue bounds (replace  $E$  with the identity matrix and ‘copositive’ with ‘positive semidefinite’).

### Introduction

Historically, the use of new technologies in agriculture and related sciences has been relatively behind that in the industrial sector. Usually, for a technology that is already part of the mainstream technologies in the industrial sector, it takes time to be accepted by the community of researchers in agriculture-related areas. One of the reasons for the technological gap between the industrial and agricultural sectors could be related to the modest amounts of investment made in the field of agriculture compared with the impressive amounts and efforts the industrial sector invests in new technologies. Another reason could be the relatively slow pace of updating the student curriculum with the new technologies in university departments that prepare the future specialists in the field of agriculture [19].

The level of complexity of the problems researchers in agriculture-related areas need to address is constantly increasing. The advent of the Internet forces researchers to move their models and applications in new programming platforms. As agriculture occurs in time and space, aside from the technical issues presented by the particular problem, researchers need to take into account spatial and temporary considerations related to the problem. Therefore, researchers in agriculture-related fields are obliged to address more and more

complex problems and their solution requires a wide collaboration between specialists of different disciplines and the integration of different technologies. Thus, the software systems they need to develop and maintain are complex and challenging.

In order to successfully overcome the challenges of developing flexible and complex agricultural systems, researchers are required to master and use modern software engineering disciplines. The following is a short inventory of some of the most advanced software engineering techniques used in developing software systems in agriculture and related fields.

### The Unified Modeling Language

The Unified Modeling Language (UML) was born as a support for modeling software using the object-oriented programming paradigm. Before UML, several object-oriented modeling languages were used, each with its own set of notations, and there was some confusion among the object-oriented community about which language to use [4]. By the mid-1990s, an important event had occurred that impacted the development of object-oriented modeling languages in a very positive manner. Grady Booch, Ivar Jacobson and James Rumbaugh joined Rational Rose (<http://www-306.ibm.com/software/rational/>) with the goal of creating a standard modeling language for specifying, visualizing, constructing, and documenting all the artifacts of a software system [4].

According to Wikipedia, in the field of software engineering, the UML is a nonproprietary specification language for object modeling. UML is a general-purpose modeling language that includes a standardized graphical notation used to create an abstract model of a system, referred to as a UML model. UML is extendable, offering the following mechanisms for customization: profiles and stereotype ([http://en.wikipedia.org/wiki/Unified\\_Modeling\\_Language](http://en.wikipedia.org/wiki/Unified_Modeling_Language)). The current version, UML2.0, contains 13 types of diagrams that can be grouped in three categories such as structure, behavior, and interaction diagrams; they are used to express static and dynamic aspects of the system under study. UML is the Object Management Group's most-used specification, and the way the world models not only application structure, behavior, and architecture, but also business process and data structure.

### Examples of UML Models in Agriculture

The use of UML in modeling agricultural systems is a recent phenomenon. Initially, the use of UML was to make a general presentation of the application's model. Hutchings used a simple class diagram to represent relationships between classes in a framework for grazing livestock. Drouet and Pages [7] discussed the benefits of using the object-oriented paradigm and UML to express the relationships between growth and assimilate partitioning from plant organs to the whole plant. This use of UML was limited as the diagrams presented lacked many details, which make it difficult to understand the role of classes/objects and their behavior. A good model should represent not only the relationships between classes, but also their structure and behavior and the role of each class involved in an association.

Later, a number of authors made UML part of their modeling approach [21] used UML to analyze several irrigation-scheduling models and water-balance models to identify common elements and relationships in order to propose a general template for creating new models and maintaining existing ones. Papajorgji and Pardalos [19] presented a detailed UML and object-oriented approach to model software for agricultural systems. Pinet et al. [22] used UML and Object Constraint Language (OCL) to model spatial constraints of an environmental information system monitoring the spreading of organic matter. Hasenohr and Pinet [12] used UML and OCL to develop a spatial decision support system to implement common agricultural policy. Martin and Vigler [13] used UML to set up a shared geographic information system for agricultural quality and environmental management. Miralles [15] used UML to present geographic information system (GIS) patterns that express relationships between spatial and temporal concepts and to automatically generate the corresponding code. Figure 1 shows the class diagram of the irrigation-scheduling model as presented in [21].

### The OCL

OCL is a notational language, a subset of UML that allows specifying constraints over entities representing concepts from the problem domain [17,27]. It integrates notations close to a spoken language to ex-

press constraints. OCL was first developed by a group of IBM scientists around 1995 during a business modeling project. It was influenced by Syntropy, which is an object-oriented modeling language that makes heavy use of mathematical concepts. OCL is now part of the UML standard supported by the OMG and it plays a crucial role in the model-driven architecture (MDA) approach [24].

### Examples of Using OCL in Agriculture

OCL is used to express spatial constraints in an environmental information system developed by researchers at Cemagref, France, and is described in detail in [22]. This system monitors the spreading of organic matter in France.

Spreading on the croplands is an excellent way of recycling organic matter (manure, sewage sludge, etc.) but the agricultural practices used require a fastidious monitoring system. An excessive and ill-planned spreading practice could lead to damage to soils owing to pollution. It is very important to model a set of spatial constraints that define precisely where spreading of organic matter can take place; as an example, organic matter can never be spread inside certain protected natural areas. Designing an environmental information system that controls the spreading of organic matter requires some spatial constraints be strictly respected. Figure 2 shows the UML model for the spreading problem.

The *Allowed\_Area* class models the area on which the regulation allows the spreading of organic matter. The *Spread\_Area* class models the area on which the spreading has already been carried out by the farmers. In the ideal case, the organic matter is organized into groups before being spread on the fields; each group has an ID in order to improve traceability. The spreading model presented in this example includes only one of the potential organic matter providers (*Purification\_Station*).

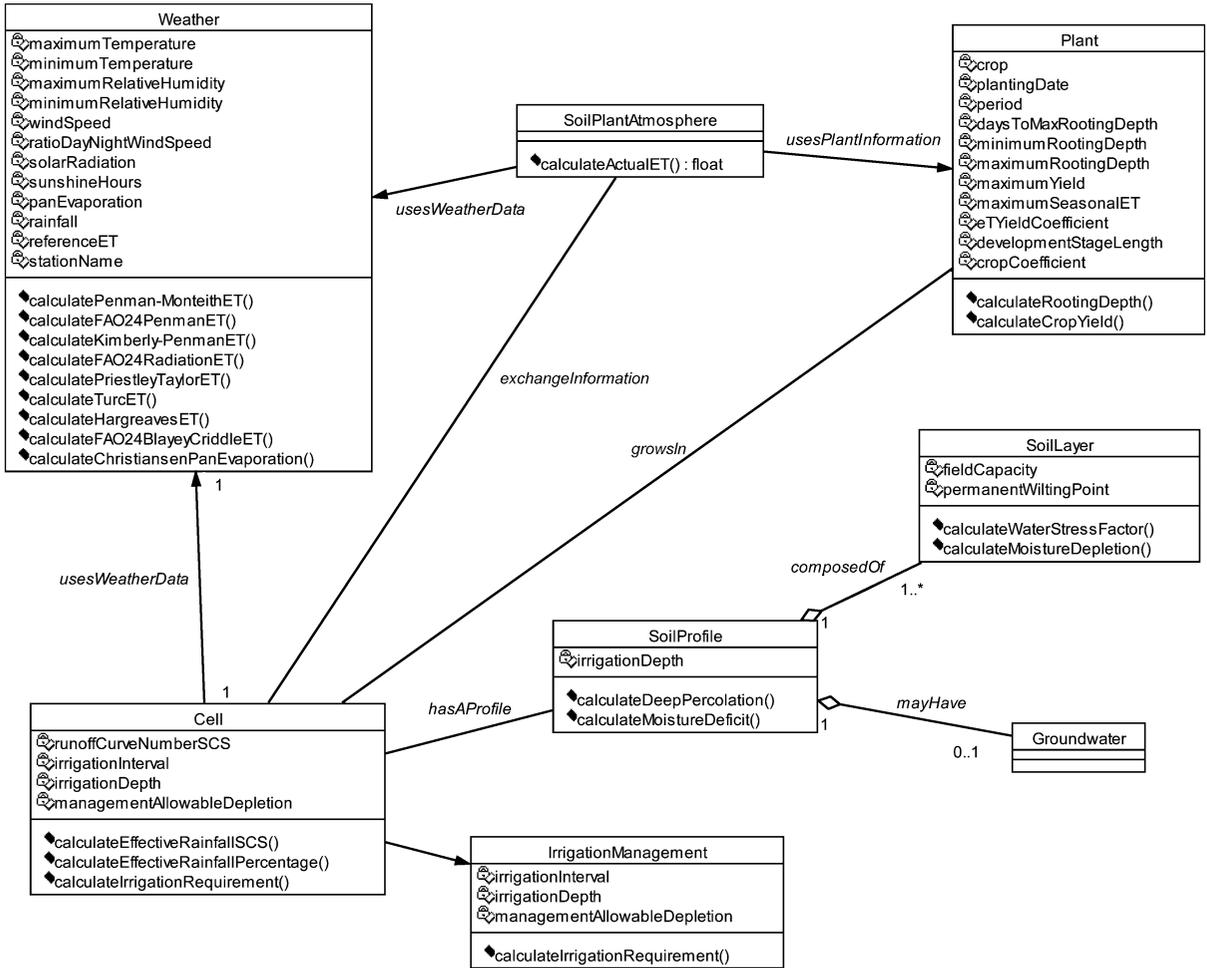

Constraints can be expressed using OCL. The following constraint says that a spread area should not overlap with its associated allowed area:

**context** Spread\_Area **inv:**

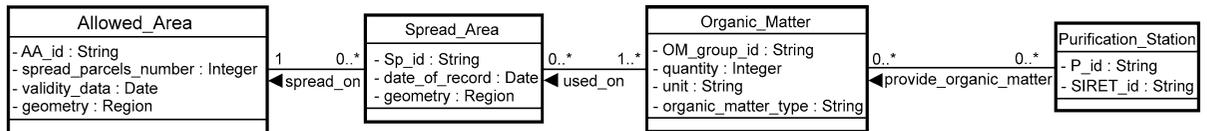

not (self.geometry.overlap(self.spread\_on.geometry))

The following constraint says that all allowed areas must be spatially disjoint from built areas:

**context** Allowed\_Area **inv:**

State of the Art in Modeling Agricultural Systems, Figure 1  
Class diagram representation of the irrigation-scheduling model

State of the Art in Modeling Agricultural Systems, Figure 2  
Agricultural spreading model

1. `Built_Area.allInstances->forAll`  
(`built_area_instance`)
  2. `built_area_instance.geometry->forAll`(`building`)
  3. `self.geometry.disjoint`(`building`))
- In the above constraint, the use of set-based operation is needed because the geometry of a built area can be composed of several simple regions (i.e., several buildings). A complete expression in natural language

of this constraint is “1. for each built\_area\_instance in the Built\_Area class and 2. for each building in the built\_area\_instance geometry, 3. the geometry of an Allowed\_Area instance (denoted by self) must always be spatially disjoint from building.” Code can be automatically generated from OCL constraints [6,22]. This code allows also the evaluation of the quality of the data stored in the database; i.e., verify if the data

stored in the database satisfy the constraints defined using OCL.

## The Design Patterns

Well before software engineers started using patterns, an architect named Christopher Alexander wrote two books that describe the use of patterns in building architecture and urban planning. The first book is titled *A Pattern Language: Towns, Buildings, Construction* [1], published in 1977. The second one is titled *The Timeless Way of Building* [2], published in 1979. These two books not only changed the way structures were built, but they had a significant impact in another not closely related field, the field of software engineering. According to Alexander [1], a pattern describes a problem which occurs over and over again in our environment, and then describes the core of the solution to that problem, in such a way that one can use this solution a million of times over, without ever doing it the same way twice. Although Alexander refers to buildings and towns, his conclusion can be successfully applied in the process of object-oriented design.

Design patterns are well-thought solutions for a large number of problems that have been built by experienced designers to be easily used by novice programmers. They started being used in the mid-1990s, when a group of four software engineers [10] wrote the book titled *Design Patterns Elements of Reusable Object-Oriented Software*. The book had a significant impact on the way software design was carried out. A design pattern names, abstracts, and identifies the key aspects of a common design structure that make it useful for creating a reusable object-oriented design [10]. The same way an architect uses prefabricated blocks for building complex constructions, a programmer will use patterns to develop complex software. Using patterns makes the process of designing complex systems easier.

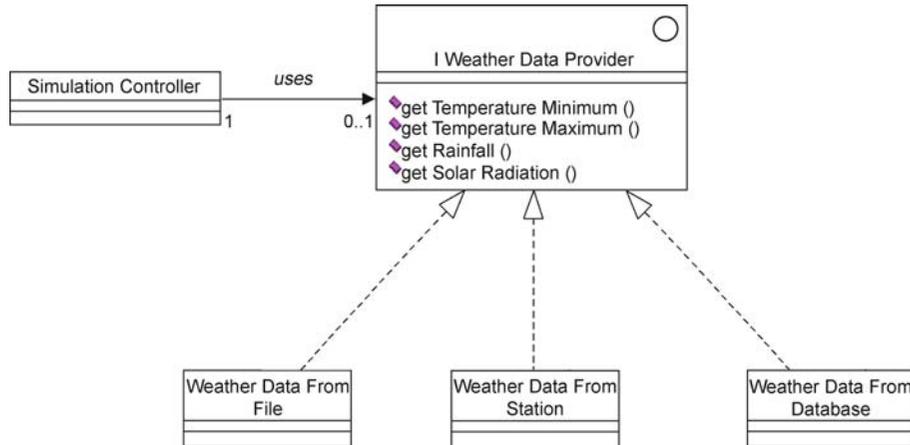

Design patterns are divided into three categories: creational, structural, and behavioral patterns. Creational patterns deal with the process of creating objects. They describe optimal ways of creating new objects. Structural patterns describe how to compose classes or objects. Behavioral patterns describe how to distribute behavior among classes and how classes interact with each other.

## Example 1 of Using Design Patterns in Agriculture

Very often programmers have to solve the same problem that occurs in different applications regardless of the problem domain. An example of this type of problem could be providing an application with the same type of data using different data sources and the system has to decide at run time what the particular data source is. Such a problem can be solved using the *strategy pattern*.

The intent for the *strategy pattern* is to define a family of algorithms, encapsulate each one, and make them interchangeable [10]; therefore, algorithms can vary independently from the clients that use them. This pattern is useful in cases where several strategies are available for use and the choice of the right strategy is done at run time. To better understand the context in which the strategy pattern can be used, let us consider a simple simulation model as presented in [20]. In a crop simulation model the weather data can be obtained using different sources, such as using a text file, reading them from a database system, or using an on-line system of weather stations. In a system developed in a traditional programming language such as FORTRAN, the ability to choose between several options requires the use of complex *if-then-else* or *switch* statements. All the options available are hardwired into code. As new data sources are available, their use will require changes to the code. Therefore, traditional programming languages offer rather limited and rigid solutions to this problem. A well-thought system should not only provide access to several sources of data, but additionally it should provide for ways of obtaining them when available in the future without affecting the existing system.

The object-oriented paradigm and the design patterns solve this problem by offering a flexible and elegant solution. Figure 3 shows classes that are involved in the strategy pattern as described in [19]. The *SimulationController* is a client that uses the weather data. The *IWeatherDataProvider* is an interface that represents the common behavior of all classes providing access to a particular source of weather data. *SimulationController* has a unidirectional association with *IWeatherDataProvider*. The multiplicity of this association allows one controller to use one or no weather data provider. Classes *WeatherDataFromFile*, *WeatherDataFromStation*, and *WeatherDataFromDatabase*

State of the Art in Modeling Agricultural Systems, Figure 3  
Class diagram for the strategy pattern

provide behavior for extracting data from a particular source such as a text file, a network of weather stations, or a database. These classes implement the same interface, the *IWeatherDataProvider*; therefore, any one of them can be used to provide the weather data requested by *SimulationController*. Note that the user of the data, in this case *SimulationController*, does not have access to or knowledge of the data providers; therefore, the data providers can change the data extraction algorithm without affecting the data user.

### Example 2 of Using Design Patterns in Agriculture

While developing a GIS, designers pay particular attention to the spatial properties of thematic concepts such as *Plot*, *Spread\_Area*, etc. In GIS-based systems the spatial concepts that are manipulated the most are *Point*, *Line*, and *Polygon*. These concepts have their own characteristics and some of them can be combined to create other concepts; as an example, a *Line* can be represented as a set of *Point* and a *Polygon* can be considered as a set of *Point* or as a succession of *Line*. Furthermore, the nature of the relationship between *Point*, *Line*, and *Polygon* is static; it never changes over time. The relationship between these spatial concepts can be represented by design patterns as described in [10].

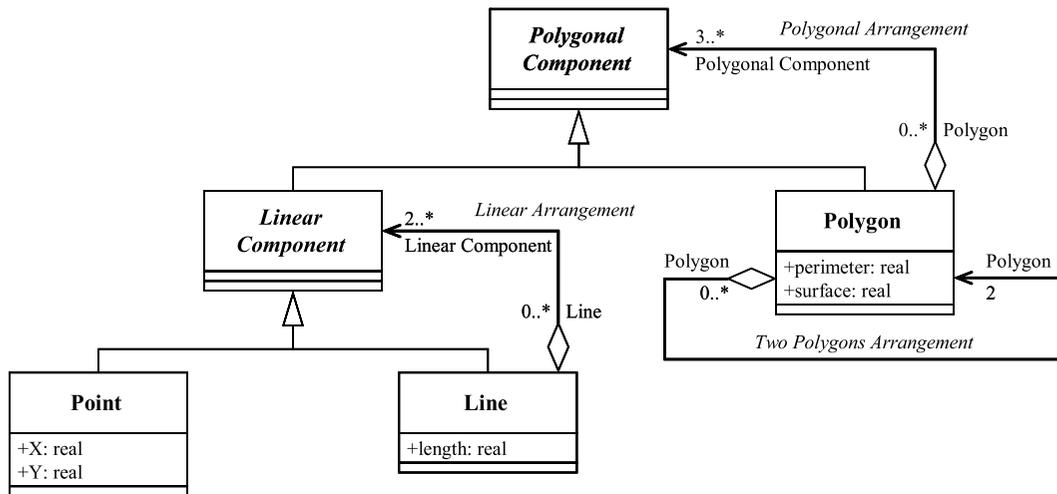

Miralles [15] described a *GIS design pattern based model* that is a recurrent model for a coordinate system: 1D, 2D, and 3D. Figure 4 shows the specific design pattern for a 2D coordinate system. This GIS model

is structured around two composite patterns. The first composite pattern depicts the relationship between the spatial properties *Point* and *Line*. A *Line* is composed at least of two *Linear Component*, which can be *Point*, *Line*, or a mixture of *Point* and *Line*. The *Point* has two properties: an abscissa and an ordinate. The *Line* has as property its length. The second composite pattern provides the possibility of representing a *Polygon* as *Polygonal Component*, which can be either *Linear Component* or *Polygon* or even a combination of the latter. The polygonal properties are the perimeter and the surface. Like the simplest polygon (triangle) is composed of three points or three line segments, the cardinality of the *Polygonal Arrangement* association should be at least equal to (3 or more). In this case, the polygonal arrangement of two polygons cannot be done. In order to do it, the *Two Polygons Arrangement* association has been added.

The *GIS design pattern based model* describing the spatial properties currently used for GIS modeling could be considered as a structural pattern. Considering the static nature of the relationships among concepts involved in the pattern, code can be easily generated in any programming language.

### The MDA Approach

The MDA is a framework for software development defined by the OMG [25]. At the center of this approach are models; the software development process is driven

State of the Art in Modeling Agricultural Systems, Figure 4  
Geographical information system design pattern based model for a 2D coordinate system

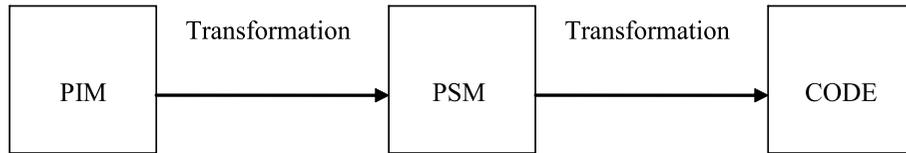

by constructing models representing the software under development. The MDA approach is often referred to as a model-centric approach as it focuses on the business logic rather than on implementation technicalities of the system in a particular programming environment. This separation allows both business knowledge and technology to continue to be developed without necessitating a complete rework of existing systems [14].

MDA uses UML to construct visual representations of models. UML is an industry standard for visualizing, specifying, constructing, and documenting the artifacts of a software-intensive system [4], and it has a set of advantages that makes it fit to be the heart of the MDA approach. First, by its nature, UML allows for developing models that are platform-independent. These models depict concepts from the problem domain and the relationships between them and then represent the concepts as objects provided with the appropriate data and behavior. A model specified with UML can be translated into any implementation environment. The valuable business and systems knowledge captured in models can then be leveraged, reused, shared, and implemented in any programming language [5]. A second advantage is that UML has built-in extension mechanisms that allow the creation of specialized, UML-based languages referred to as UML profiles [8]. If modelling agricultural systems requires special modelling artifacts, then an agricultural UML profile would be created and plugged into the UML core system.

The MDA approach consists of three levels of models as shown in Fig. 5. As shown in this figure, a set of transformations are needed to transform a model from the current level to the next one.

The approach starts with construction of a *conceptual diagram* that represents our knowledge of the problem domain expressed through concepts, abstractions, and their relationships. Conceptual diagrams are the result of an activity referred to as *conceptual modeling*. Conceptual modeling can be defined as the process of organizing our knowledge of an application domain into hierarchical rankings or ordering of abstractions, in order to obtain a better understanding of the phenomena under consideration [7]. Conceptual diagrams have the advantage of presenting concepts and relationships in an abstract way, independent of any computing platform or programming language that may be used for their implementation. During this phase, the focus is on depicting the concepts of the system and providing them with the right data and behavior. The fact that the implementation technology may be Java, a relational database, or .NET is irrelevant at this point. Therefore, the intellectual capital invested in the model is not affected by changes in the implementation technologies. A conceptual model thus is a platform-independent model (PIM).

Because of the nature of a PIM (no implementation details are considered at this phase) and because the model construction is done visually using UML,

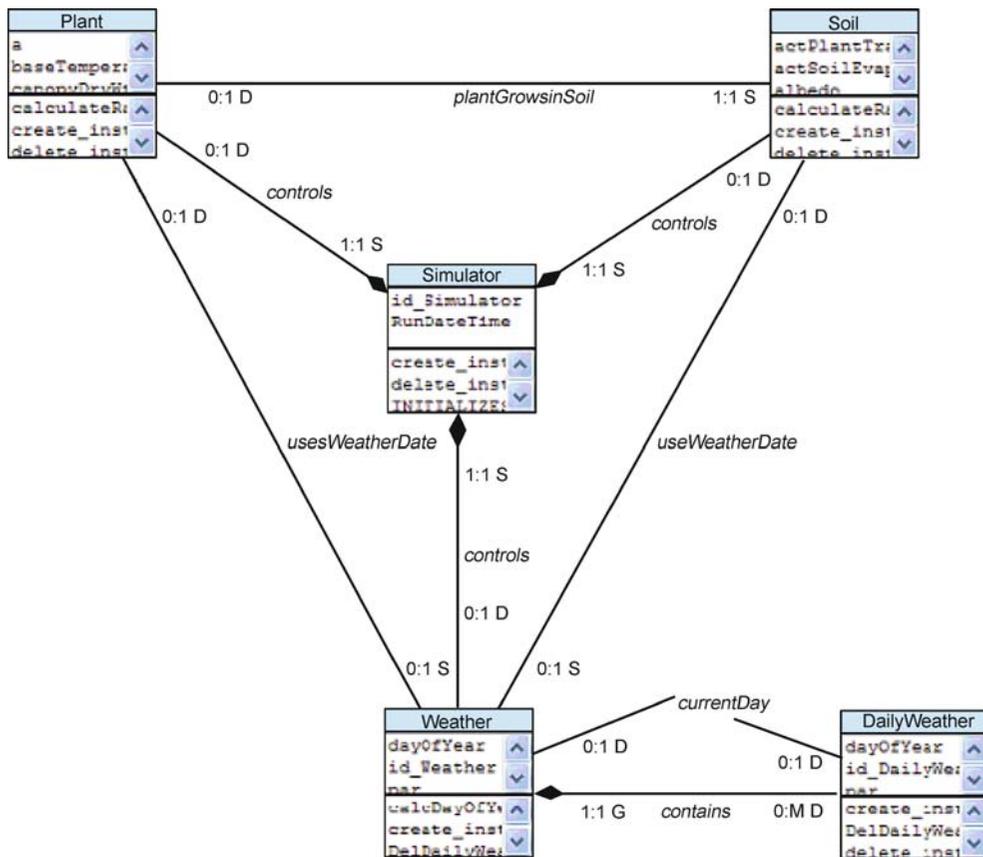

State of the Art in Modeling Agricultural Systems, Figure 5

Transformations are applied to a model level to obtain the next level. *PSM* platform-specific model

the participation of domain specialists in the model construction process is greatly facilitated. The MDA approach frees domain specialists from the necessity of knowing a programming language in order to be an active participant. PIMs are developed in UML, which is visual and uses plain English that can be easily understood by programmers and nonprogrammers alike [21]. A PIM is the only model that developers will have to create “by hand.” Executable models will be ob-

tained automatically by applying a set of transformations to the PIM.

Figure 6 shows a PIM for a simple crop simulation model. Details on the implementation of this model can be found at <http://mda.ifas.ufl.edu>. Concepts from the simulation domain are depicted in an abstract manner and their relationships are presented. At the center of the model is the *Simulator* object, which has access to entity objects *Plant*, *Soil*, and *Weather*. The na-

State of the Art in Modeling Agricultural Systems, Figure 6

Conceptual model for the crop simulation model

ture of these relationships is a composition, meaning that it is *Simulator*'s responsibility to create instances of these objects and destroy them at the end of the simulation. *Simulator* is provided with a method named *simulate(list of parameters)* that runs the simulation using as initial values the list of parameters. *Simulator* plays the role of a control class; it sends the right message to the right object to carry out the simulation [19].

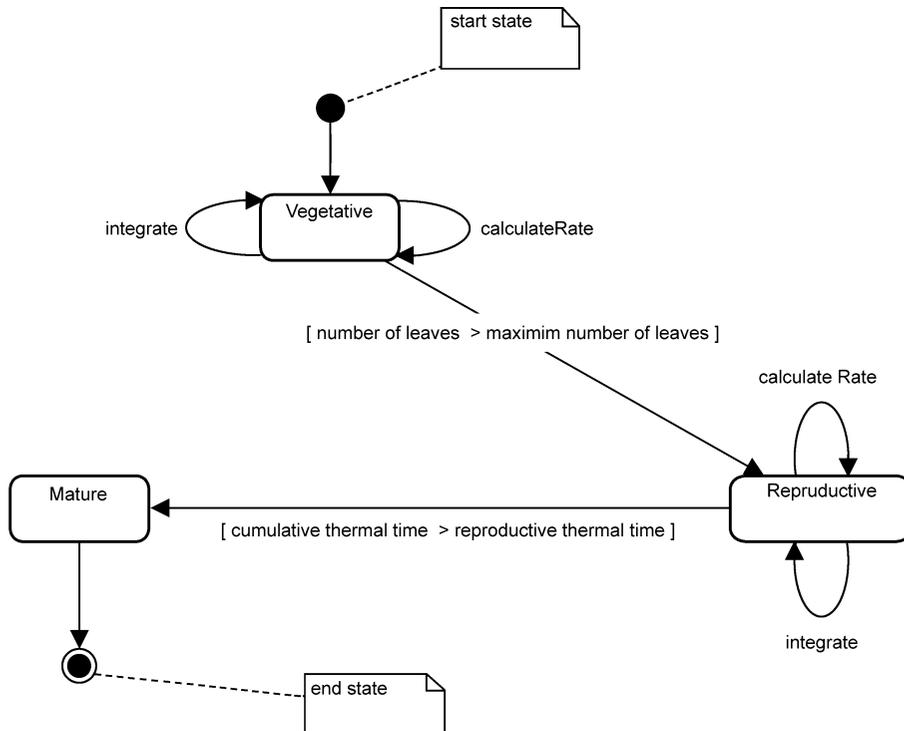

Providing objects of the conceptual diagram with behavior is one of the most exciting features of the MDA approach. In the world of the simulation models, most of the behavior that objects should provide is expressed in the form of equations. Equations are constructed in a declarative way using attributes of objects participating in the conceptual diagram.

The simulation process is controlled by the behavior of the object *Plant*. A state-transition diagram is used to model the behavior of *Plant* [4]. This diagram shows the valid execution order of the services of the class and the set of possible lifecycles of *Plant*. Figure 7 shows the state-transition diagram of *Plant*. The diagram has

two types of elements: *states* and *transitions*. States represent the different situations through which an object of type *Plant* can pass, depending on the value of its attributes. Transitions represent executed services, events, or transactions, which produce state changes and modify the value of the object's attributes.

According to the state-transition diagram, *Plant* will remain in the state *vegetative* and will continue to receive messages *calculateRate* and *integrate* as long as the guard condition *number of leaves > maximum number of leaves* is not satisfied. When the guard condition is satisfied *Plant* will move to state *reproductive*. For this transition, the source state is *vegetative* and the target state is *reproductive*. *Plant* will remain in the state *reproductive* as long as the guard condition *cumulative thermal time > reproductive thermal time* is not satisfied. When the guard condition is satisfied, *Plant* will move to state *mature* and the simulation will terminate.

MDA-based tools provide ample capabilities to check the correctness of the conceptual model, the behavior of its objects, and the relationships between them.

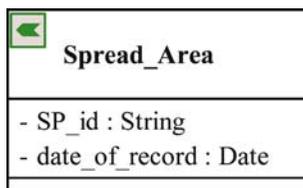

State of the Art in Modeling Agricultural Systems, Figure 7  
State chart describing the behavior of *Plant*

An XML file is created that contains a detailed specification for the model that can be used by code engines to generate code in several programming languages. Several scenarios can be considered as different parts of the system can be implemented in different languages. For example, the user can choose the C# environment for developing the user interface and a CORBA-EJB, Java-based environment for the implementation of the server. Because the conceptual model is detailed and precise, code generators can find all the information needed to translate the model into several programming environments. Besides the code representing objects of the conceptual model, code generators will provide all the wiring code that links the client and the server applications.

In the domain of GIS there are several modeling formalisms to express the spatial properties of thematic concepts: Aigle [16], CONGOO [18], GeoFrame [9], MADS [23], Perceptory [3], POLLEN [11], etc. Some of these formalisms use a visual language based on pictograms (Perceptory, MADS, Aigle, etc.). The visual language was introduced to improve the communication between the GIS designer and users.

Similarly, Miralles [15] has implemented the visual language of Perceptory in a professional case tool using the profile mechanism, a mechanism that extends the UML metamodel. Pictograms are attached as annotations to the UML notation of *Class*. For example, the polygonal geometry of the thematic concept *Spread\_Area* showed in Fig. 8 can be expressed by a polygonal pictogram. Figure 8 shows the UML notation for class *Spread\_Area* using the Perceptory language [3]. The polygonal pictogram used in *Spread\_Area* shows that *Spread\_Area* is kind of *Polygon*.

The GIS design formalisms are used during the analysis phase of the GIS development, the phase dur-

State of the Art in Modeling Agricultural Systems, Figure 8  
*Spread\_Area* concept annotated with a polygonal pictogram

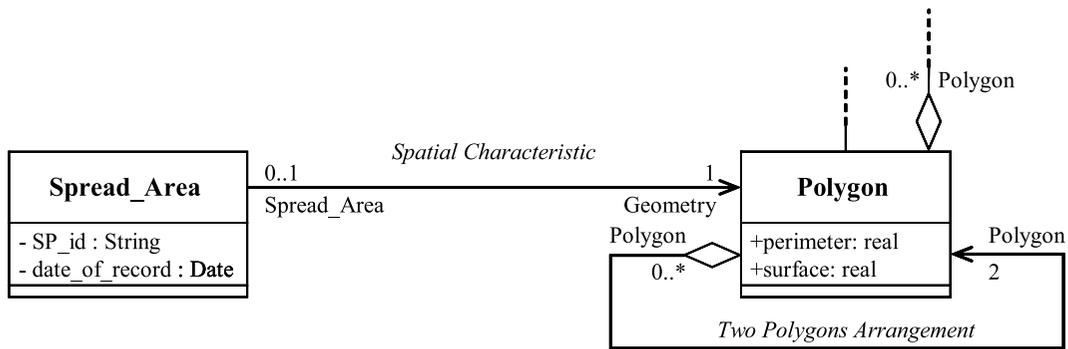

ing which the model is created “by hand.” So, the model built is a PIM. Miralles [15] provided two transformations on the PIM to convert a pictogram into model elements used by code generators. The first one is a transformation that generates the *GIS design pattern based model* presented in “The Design Patterns” (Fig. 4). It automatically creates classes (*Point*, *Line*, and *Polygon*), the corresponding attributes (*X*, *Y*, *length*, *perimeter*, and *surface*), and also the generalization and the association links (*Linear Arrangement*, *Polygonal Arrangement*, and *Two Polygons Arrangement*). This transformation is called *GIS design pattern based model generation*. At this step, the thematic concept *Spread\_Area* and the spatial concept *Polygon* are totally disassociated. The second transformation implements the relationship between these two concepts and is also a PIM/PIM transformation. This transformation is referred to as *pictogram translation mapping technique*. The goal of this transformation is to automatically establish an association between *Spread\_Area* and *Polygon* (Fig. 9) referred to as *Spatial Characteristic*.

By default, the role of *Polygon* is set to *Geometry* and its cardinality is set to 1. At the other end of the association *Spatial Characteristic*, the class, and its role share the same name, *Spread\_Area*, and its cardinality is set to (0 or 1). These default values can be modified later by the designer if necessary. Once the association has been created, the pictogram is not used any longer as the information it conveys becomes redundant.

The two transformations described above, GIS design pattern based model generation and pictogram translation mapping technique are examples of application of the MDA principles in the domain of GIS.

## Conclusion

Developing a successful software project in agriculture requires the collaboration of researchers from different scientific domains with different scientific backgrounds. Therefore, it is very important for a team of different backgrounds to have a common communication language. UML is an excellent tool for analyzing, designing, and documenting software projects. Models are developed visually using plain English (or any other spoken language for that matter) and can be understood by programmers and nonprogrammers alike. Thus, collaboration between team members is greatly

**State of the Art in Modeling Agricultural Systems, Figure 9**  
**Association spatial characteristic created by the pictogram translation mapping technique**

improved by increasing the number of specialists involved in project development. Furthermore, the advent of MDA makes the process of design and analysis more accessible to specialists, as MDA is a specialist-centric approach. The model is developed visually using knowledge from the problem domain, thus making the specialist of the domain the center of the application development.

### Introduction

This review paper considers the resource constrained project-scheduling problem (RCPSp) with static nature and renewable resources and aims to provide a recent survey of related work and heuristics employed. ‘Static scheduling’ refers to determining a solution to a scheduling problem instance with fixed resources and precedence constraints. ‘Renewable resources’ implies that resources may be used during the whole scheduling process and planning timespan without degradation in capacity or work pace. Thus, the resources are not single-use type. The solutions will basically consist of starting times of a known set of activities. For an introduction and overview of different formulations of project scheduling problems the reader is referred to [7,16,17,25]. Ozdamar and Ulusoy [30] provide an elaborate review of RCPSp with both renewable and non-renewable resource constraints and time/cost based objectives.

The RCPSp is known to be NP-hard. Thus only instances with a very limited number of activities can currently be solved to optimality. For larger problems, heuristics are utilized that provide robust, high performance, extensible and easy to apply solutions. Some benchmark results are also available in the literature and among those, the most recent are the ones supplied by [1,15,23,24]. Bouleimen and Lecocq [6] (along with [1] and [13]) give the best performing results to supplied benchmark instances.

The activity-on-node (AON) based flow representation of the RCPSp is given in the next section. Following the formulation, a brief summary of the recent approaches proposed is provided.

### Formulation

Artigues et al. [2] provide the following AON-flow network based formulation for the static case of RCPSp with renewable resources:

It is assumed that a project composed of a set of activities  $V = 1, \dots, n$  has to be scheduled on a set of renewable resources  $\mathfrak{R} = 1, \dots, m$ . Each resource  $k \in \mathfrak{R}$  has a finite capacity  $R_k$ . Precedence constraints of activities within the project are modeled by a set of project arcs  $E$  such that  $(i, j) \in E$  means that activity  $j$  has to start after completion of activity  $i$ . Each activity  $i \in V$  requires a non-negative amount  $r_{ik}$  of each resource

$k \in \mathfrak{R}$  and has a duration  $p_i$ . The scheduling problem lies in characterizing an  $n$ -tuple  $S = \{S_1, \dots, S_n\}$  where  $S_i$  is the starting time of the activity  $i$ , while minimizing the total project duration (makespan) denoted by  $C_{max}$ . This problem, known as the RCPSP may be defined by the triple  $(V, E, \mathfrak{R})$ . Its difficulty comes from the resource limitation constraints that prevent some activities requiring the same resources from being scheduled simultaneously. These constraints can be modeled by defining each resource  $k$  as the union of  $R_k$  resource units, such that a given resource unit cannot be allocated to more than one activity at the same time. In other words, each resource is assumed to have a capacity of one activity. If a resource has a capacity greater than one activity, then it is divided into several resources each with a capacity of one. Hence, in any feasible solution, a resource unit allocated to an activity  $i$  has to be directly transferred after the completion of  $i$  to a unique activity  $j$ . However, since all the units of the same resource are equivalent, one only has to know the number of units directly transferred from one activity to another. For an elaborate discussion of the model, the graphical representation, and the mathematical formulation of the problem, refer to [2].

There are two main classifications for the objective function: time based and cost based. Time based objectives in the literature comprise instances such as minimizing makespan, mean lateness, mean completion time, and weighted tardiness in an environment where multiple projects are dealt simultaneously. However, cost based objectives don't necessarily yield the same results as time based objective functions. Maximizing the net present value of a project, minimizing total cost of a project considering all costs including variable costs due to resource consumption and other overhead summed with tardiness costs, and finally maximizing the efficient usage of cash over the project span are some instances of cost based objectives we can observe in the contemporary literature. Ozdamar and Ulusoy [30] study these different objective functions in greater detail.

Brucker et al. [7] introduce a classification scheme and a common notation for the RCPSP. The need for such an effort is to remove the widening gap between the contemporary machine scheduling literature and the RCPSP literature in terms of notation and classification. Indeed, both problems have so many common-

alities that one may be converted to the other with ease (both are *NP*-hard in nature). Due to these commonalities, notation and heuristics developed for one can easily be adapted for the other. Brucker et al. [7] also try to form a standard structural base to maintain future research within a coherent literature.

## Methods

The surveys by Herroelen et al. [16] and Kolisch and Padman [25] provide detailed descriptions of the characteristics, representations and classification schemes for the solution approaches proposed for the RCPSP. Bouleimen and Lecocq [6] group the suggested solution methods into three, as follows:

1. priority rules ([4,12,21,22,26]);
2. exact methods ([8,10,11,28]); and
3. metaheuristics such as tabu search ([2,3,31]) genetic algorithms ([1,13,20]), and simulated annealing method ([5,6]).

Brucker et al. [7] claim that the first heuristic methods are the priority-rule based scheduling methods. In these methods, the main idea is extending a partially generated schedule by stepwise insertions of new activities either in sequential or parallel order. At each step, a set of feasible nodes for insertion is generated based on starting time constraints, priority constraints, or other resource constraints. The selection of the next activity for insertion (from the decision set) is based on a priority assessment mechanism, usually specific to the problem type and objectives. Brucker et al. [7] emphasize the advantage of priority-based heuristics as being intuitive, easy to implement and fast in computational effort. However, a shortcoming of these methods is that they do not excel with respect to the average deviation from the optimal objective function value. Brucker et al. [7] also point out that recent effort has shifted to exact methods, local search [32] and meta-heuristics. They also provide an overview of computational results by reporting the size of the problems solved and giving details about computational specifications.

Among the exact algorithms proposed for the RCPSP, most promising progress has been attained using the branch-and-bound mechanism. Herroelen et al. [16] highlight seven points in the conclusion of their review on usage of branch-and-bound methods for solving the RCPSP. They comment that those seven

points reveal a number of desirable attributes of an efficient optimal solution procedure for the RCPSP. It is also added that the seven points constitute the very basis of computational efficiency of a method they introduce for the RCPSP. Herroelen et al. [16] and Icmeli et al. [19] list instances of exact applications from the literature while providing an extensive review of solution methods used for different versions of RCPSP.

Kolisch and Padman [25] cluster heuristic approaches for the RCPSP with makespan minimization objective basically to four different solutions methodologies: (1) priority-rule based scheduling, (2) truncated branch-and-bound, (3) disjunctive arc concepts, and (4) meta-heuristic techniques. However, for their efficiency, robustness and improvement potential, heuristic algorithms and meta-heuristic approaches (rather than exact algorithms) will be addressed.

Meta-heuristic techniques for solving combinatorial optimization problems have emerged in recent years. Kolisch and Padman [25] address that all heuristic approaches encode the solution as a list with length equal the number of jobs. The generated list can be mapped into a schedule using priority-based approaches. For a detailed study in encoding schemes one may refer to Kolisch and Hartmann [24].

In the procedure of Sampson and Weiss [32] each element of the generated list is an integer. In their scheduling mechanism, each element starts at the maximum of the completion times of its immediate predecessors plus a specific integer value. This ensures feasibility in the time domain. To prevent excess usage of renewable resources they also add a penalizing mechanism.

Hartmann [14], Leon and Ramamoorthy [27], Naphade et al. [29], Lee and Kim [26], Cho and Kim [9], and Kohlmorgen et al. [20] basically encode the solution as a list of numbers that assigns each task a priority value. By using these priority values within a schedule-generating scheme, one obtains a feasible schedule and the associated objective function value. This encoding has the potential to be applied to meta-heuristics such as simulated annealing, tabu search and genetic algorithms.

Baar et al. [3], Bouleimen and Lecocq [6], Hartmann [13], and Pinson et al. [31] use an 'activity list' where a schedule is generated by scheduling the activities in the order prescribed by the list. Baar et al. [3]

use two different neighborhood search mechanisms for a tabu-search procedure. The first one encodes a solution as an activity list which is mapped to a schedule with the serial scheduling scheme. The neighborhood is defined as all activity lists which can be reached by shifting a resource-critical job to a new position. The second neighborhood builds up on the exact solution procedure of Brucker et al. [8]. Essentially, activity pairs are either forced or let to be processed in parallel via the so called 'parallelity relations'. For a fixed parallelity relation a schedule is obtained by forward recursion. Bouleimen and Lecocq [6] use simulated annealing together with a shift operator. Hartmann [13] uses a genetic algorithm with two-point crossover. Pinson et al. [31] propose a tabu-search with pair wise interchange and shift within a neighborhood.

An alternative objective function for the RCPSP is to maximize the net present value of the project. Kolisch and Padman [25] provide a classification of heuristics developed for the RCPSP. They group heuristics into three categories: (1) optimization guided, (2) parameter based, and (3) meta-heuristic approaches.

Icmeli and Erenguc [18] apply a tabu-search procedure to a starting feasible solution generated using a simple, single-pass algorithm. They improve the initial solution over several iterations by moving each activity one time unit early or late from its current completion time without violating the earliest and latest completion time constraints for the activity. They also test the usage of long time memory concept in their algorithm. The computational results are found to be both efficient and close to optimal.

Zhu and Padman [33,34] introduce a notion of replacing single pass complex optimization-based heuristics with a blend of multiple but simple heuristics. They report superior performance of their method to other works employing unique but more complex heuristics. In their initial work [33], they utilize a multi-agent based approach with six simple rules used in random order to exploit changing conditions of the project environment. In their latter work [34], they use distributed computation concepts through the use of an Asynchronous Team (A-team) approach. This approach facilitates cooperation of multiple heuristic algorithms so that together they produce better results than if they were acting alone.

Kolisch and Hartmann [24] provide an updated and extended version of their previous [23] review on solution methods for project scheduling problems. They review existing solution methods under priority based rules, classical metaheuristics, non-standard metaheuristics, and other heuristics. They test different algorithms they picked from the literature on problem sets generated and report average deviation from critical path lower bound.

## Conclusion

In this study, the reader is provided with a brief introduction to the RCPSP and supplied with most recent improvements in solution mechanisms based on heuristics. With the potential of providing high quality solutions within reasonable time frames, heuristics and meta-heuristics seem to be one step ahead of the exact algorithms. Thus, this work aims to focus its inquiry domain within the meta-heuristics field. While trying to keep the content brief, the reader is provided with guides to elaborate and most cited references.

Individual probabilistic constraints; Joint probabilistic constraint; Programming under probabilistic constraint; Recourse model; Hybrid model

Stochastic programming is the science that offers solutions for problems in connection with stochastic systems, where the resulting numerical problem to be solved is a mathematical programming problem. When formulating a stochastic programming problem, in most cases we start from a deterministic mathematical programming problem that we call base problem or underlying deterministic problem. Then, observing that some of the parameters in it are random, we formulate another decision problem, the stochastic programming problem, by taking into account the probability distribution of the random variables involved.

Any stochastic programming problem formulation depends on a decision-observation scheme that tells us in what order decisions and observations follow each other. If this scheme is: decision making on the system design or control variables (usually contained in the decision vector  $\mathbf{x}$ ), observation of the random variables influencing the system performance, then the model is called static. If there is at least one observation of random variables followed by a decision making, then the model is called dynamic. From another point of view, a stochastic programming problem (static or dynamic) may contain reliability provision or allows for the violation of the constraints with some penalty that is included into the objective function. The reliability provision typically manifests itself in the use of probabilistic constraint(s), where we prescribe that the random constraint(s) should hold (when the random variables realize and can be observed) with prescribed probability (probabilities). The first type of stochastic programming model is called probabilistic constrained model while the second type is called recourse model. The two model construction principles can be used simultaneously in a hybrid model. The use of probabilistic constraints is an old statistical decision principle. For example, A. Wald used it in the sequential analysis context [6]. Its combined use with mathematical programming, however, appeared first in [1]. The general form of a static probabilistic constrained model has the form:

$$\begin{cases} \min & h(\mathbf{x}) \\ \text{s.t.} & h_0(\mathbf{x}) \geq 0, \dots, h_m(\mathbf{x}) \geq 0, \end{cases}$$

## Static Stochastic Programming Models

### Keywords

Stochastic programming problem; Underlying deterministic problem; Probabilistic constraint;

where  $h, h_1, \dots, h_m$  are some functions of  $\mathbf{x} \in \mathbf{R}^n$ ,

$$h_0(\mathbf{x}) = P(g_1(\mathbf{x}, \boldsymbol{\xi}) \geq 0, \dots, g_r(\mathbf{x}, \boldsymbol{\xi}) \geq 0) - p,$$

$\boldsymbol{\xi} \in \mathbf{R}^q$  is a random vector,  $g_1, \dots, g_r$  are functions in  $\mathbf{R}^{n+q}$  and  $p$  is a prescribed probability. In practice,  $p$  is chosen near 1, e. g.,  $p = 0.9, 0.95, 0.99$ .

In the simplest case  $g_i(\mathbf{x}, \boldsymbol{\xi}) = T_i \mathbf{x} - y_i$ ,  $i = 1, \dots, r$ , where  $T_i$  is the  $i$ th row of an  $r \times n$  matrix  $T$  and  $h, h_1, \dots, h_m$  are linear functions. This model can be written as

$$\begin{cases} \min & \mathbf{c}^\top \mathbf{x} \\ \text{s.t.} & A\mathbf{x} \geq \mathbf{b}, \quad \mathbf{x} \geq \mathbf{0}, \\ & P(T\mathbf{x} \geq \boldsymbol{\xi}) \geq p. \end{cases}$$

The probabilistic constraints in the above models are joint constraints. Sometimes instead of  $P(T\mathbf{x} \geq \boldsymbol{\xi}) \geq p$ , the individual probabilistic constraints  $P(T_i \mathbf{x} \geq \xi_i) \geq p_i$ ,  $i = 1, \dots, r$ , are used. This was the case in the originating paper [1]. Joint probabilistic constraint was first used by L.B. Miller and H. Wagner [2]. They assumed, however, that in  $P(T\mathbf{x} \geq \boldsymbol{\xi})$  the components of the random vector  $\boldsymbol{\xi}$  are stochastically independent. General probabilistic constrained stochastic programming models have been formulated in [3,4].

A related model construction contains maximization of a probability subject to some constraints. Programming under probabilistic constraint and maximizing a probability under constraints have many applications in many engineering (power systems, water resources, telecommunication, engineering structures, etc.) and economic (insurance, finance, economic planning, etc.) problems. For the mathematical theory, solution techniques and applications of these models, see [5].

Conditional expectation constraint; Integrated probabilistic constraint

Given the constraints  $g_i(\mathbf{x}, \xi) \geq 0, i = 1, \dots, r$ , where  $\xi$  is a random vector, one way to create part of a stochastic programming problem, based on them, is to introduce the constraints involving conditional expectations:

$$g_i(t) = E\{g_i(\mathbf{x}, \xi) | g_i(\mathbf{x}, \xi) < 0\} \leq d_i, \\ i = 1, \dots, r,$$

where  $d_i, i = 1, \dots, r$ , are some bounds chosen by ourselves. In the simplest and from the practical point of view most important case  $g_i(\mathbf{x}, \xi) = T_i\mathbf{x} - y_i$ , where  $T_i$  is the  $i$ th row of a matrix. In this case the above constraints take the form:

$$g_i(T_i\mathbf{x}) = E\{\xi_i - T_i\mathbf{x} | \xi_i - T_i\mathbf{x} > 0\} \leq d_i, i = 1, \dots, r.$$

The practical meaning of these constraints is that violations of the stochastic constraints  $T_i\mathbf{x} \geq \xi_i, i = 1, \dots, r$ , are allowed but the average magnitude of violation,

given that violation occurs, is bounded from above, in each constraint. If, e. g.,  $T_i\mathbf{x} \geq \xi_i$  means in a diet problem that the meal composition should satisfy the demand for the  $i$ th nutrient in a population (where the randomness of the nutrient demand is due to the inhomogeneous nature of the population), then  $E\{\xi_i - T_i\mathbf{x} | \xi_i - T_i\mathbf{x} > 0\}$  is the average unsatisfied demand for nutrient  $i$ , among those whose demands are not satisfied. Constraints of this type have been introduced first in [2]; see also [3]. The conditional expectation constraint is closely related to the expected residual lifetime in reliability theory or total remaining life in insurance, these being defined as  $g(t) = E\{\eta - t | \eta - t > 0\}$ , in connection with the random lifetime  $\eta$ . It is well-known (see, e. g., [3]) that if  $\eta$  has continuous distribution with logconcave probability distribution function, then  $g(t)$  is a decreasing function. Using this fact, we can convert the conditional expectation constraints into linear ones, provided that  $\xi_i$  has continuous distribution with logconcave probability distribution function, and  $g_i(\mathbf{x}, \mathbf{y}) = T_i\mathbf{x} - y_i$ , for every  $i = 1, \dots, r$ . The equivalent constraints are:

$$T_i\mathbf{x} \geq g_i^{-1}(d_i), \quad i = 1, \dots, r.$$

A closely related stochastic programming constraint formulation, based on the stochastic constraints  $T_i\mathbf{x} - \xi_i \geq 0, i = 1, \dots, r$ , provides us with the following:

$$E\{\xi_i - T_i\mathbf{x} | \xi_i - T_i\mathbf{x} > 0\} P(\xi_i - T_i\mathbf{x} > 0) \leq d_i, \\ i = 1, \dots, r.$$

These are equivalent to

$$l_i(T_i, \mathbf{x}) = \int_{T_i\mathbf{x}}^{\infty} (1 - F_i(z)) dz \leq d_i, \\ i = 1, \dots, r,$$

where  $F_i(z)$  is the distribution function of the random variable  $\xi_i, i = 1, \dots, r$ . The new constraints are called *integrated probabilistic constraints* and have been introduced in [1]. In the above-mentioned diet problem these constraints mean that the average unsatisfied demand is taken in the whole population and is limited form above, in each nutrient.

The advantage of the integrated probabilistic constraints is that the functions  $l_i, i = 1, \dots, r$ , are decreasing, regardless of the type of probability distributions

involved, and the constraints are equivalent to

$$T_i \mathbf{x} \geq l_i^{-1}(d_i), \quad i = 1, \dots, r.$$

Statistical classification; Mathematical programming

*Statistical classification* is used when it is of interest to partition a set of subjects or observations into groups or categories, based on observed attributes that are associated with each of the subjects. For example, a lending institution may wish to partition a set of loan applicants into one of the two categories of probable payers and defaulters, based on observed characteristics for the applicants. The characteristics might include: size of the loan requested, total available income, total amount of credit available to the applicant at other sources, number of years with current employer, and others.

To give a formal definition to the problem, there are  $n$  subjects to be partitioned into  $k$  categories, based on  $m$  different observed characteristics. The proper category of classification is assumed to be known for each of these subjects, and  $X_{ij}$  denotes the measured value

of characteristic  $j$  for subject  $i$ . A *classification function* is to be obtained for each category of classification to represent the strength of association of any subject with that category. Let  $F_a(X_{i\cdot})$  denote the classification function for a given category  $a$  with  $1 \leq a \leq k$ , for any given subject, say for subject  $i$ . We assume a linear form for  $F_a(X_{i\cdot})$  and

$$F_a(X_{i\cdot}) = c_0^a + \sum_{j=1}^m c_j^a X_{ij}.$$

The  $n$  known observations are used as a training set to obtain coefficients for the classification functions that accurately model the relationship between the strength of association of the classification functions and the actual group membership for the given observations. These functions are then used in the future to classify subjects for which the proper category is not known, and for which a prediction of category membership is being sought. In particular, a future observation, with associated measured values for  $X_{ij}$ s, will be predicted to be a member of category  $a$  when  $F_a(X_{i\cdot}) > F_b(X_{i\cdot})$ , for all  $1 \leq b \leq k$  with  $b \neq a$ . R.A. Fisher [1] and C.A.B. Smith [3] developed classical statistical techniques to approach this problem, with standard assumptions about the distributions of the  $X_{ij}$ s.

More recently, optimization approaches have been used to develop techniques to obtain coefficients for the classification functions that directly maximize the number of correct classifications in the training set. A. Stam [4] presents an exhaustive survey of most of the early work in this area. Most of these approaches are based on mathematical programming techniques. These approaches are of interest since they will maximize the number of correct classifications in the training set, which standard statistical approaches will not necessarily do. In addition, the mathematical programming techniques are very useful when standard statistical assumptions about the distributions of  $X_{ij}$ s are not valid.

W.V. Gehrlein [2] presents elementary mathematical programming formulations of the generalized classification problem to obtain classification functions that directly maximize the number of correct classifications in the training set. The primary variables in these formulations are the given  $c_i^a$  coefficients that should be used in the classification functions.

Each of the observations in the training set will have a binary (0–1) variable,  $I_i$ , associated with it, such that observation  $i$  will be correctly categorized when  $I_i = 0$  and observation  $i$  will be incorrectly categorized when  $I_i = 1$ . The objective function is given by

$$\text{Minimize } \sum_{i=1}^n I_i.$$

There are  $k - 1$  constraints that are associated with the categorization of each observation. Observation  $i$  is known to be a member of some category, say  $a$ . Then for each  $b$  with  $1 \leq b \leq k$  and  $b \neq a$  there is a constraint of the form

$$c_0^a + \sum_{j=1}^m c_j^a X_{ij} - c_0^b - \sum_{j=1}^m c_j^b X_{ij} + MI_i \geq e,$$

in which  $M$  is a very large number and  $e$  is a very small number. The values of  $M$  and  $e$  remain the same in all constraints. By the nature of  $M$  and  $e$ , this constraint will be met trivially if  $I_i = 1$ , and we must have  $F_a(X_{i\cdot}) > F_b(X_{i\cdot})$  if  $I_i = 0$ .

It is also possible to develop a classification procedure that has only one classification function. The category of group membership is then determined by where the value of the computed classification function value falls on the number line. That is, the number line is partitioned into  $k$  segments, with each of the segments corresponding to an associated group membership. The line segments are established for each group, say  $a$ , with an upper limit  $UL_a$  and a lower limit  $LL_a$ . As above, a binary variable,  $I_i$ , is associated with each observation such that observation  $i$  is correctly categorized when  $I_i = 0$  and observation  $i$  will be incorrectly categorized when  $I_i = 1$ . The objective function remains the same as above. With this formulation there are only two constraints that are associated with the categorization of each observation. Observation  $i$  is known to be a member of some category, say  $a$ , and the associated constraints are of the form

$$c_0^a + \sum_{j=1}^m c_j^a X_{ij} - MI_i \leq UL_a,$$

$$c_0^a + \sum_{j=1}^m c_j^a X_{ij} + MI_i \geq LL_a.$$

As above,  $M$  is a very large number, and  $e$  will be a very small number. These constraints will be met trivially if

$I_i = 1$ , and we must have  $LL_a \leq F_a(X_i) \leq UL_a$  whenever  $I_i = 0$ . Additional constraints are needed to ensure a logical consistency of the line segment partition. For each  $a$  with  $1 \leq a \leq k$ , we need a constraint of the form

$$UL_a - LL_a \geq e.$$

To be certain that there is no overlap of the line segments, each combination of groups, say  $a$  and  $b$ , has two binary variables  $I_{ab}$  and  $I_{ba}$  defined for them, with associated constraints of the form

$$\begin{aligned} LL_a - UL_b + MI_{ab} &\geq e, \\ LL_b - UL_a + MI_{ba} &\geq e, \\ I_{ab} + I_{ba} &= 1. \end{aligned}$$

Extensions of these elementary formulations of optimization techniques go in several different directions. A particularly useful variation deals with the notion of minimizing the total cost of misclassification, when there are different costs or penalties that are associated with the different ways in which a subject could be incorrectly classified. Multiple stage classification schemes are also considered, in which a subject is initially either placed in a category with existing information, or no classification is made. If a classification is not made in the first stage, then additional information is used to make a classification in a second stage. In addition, specialized heuristic techniques have been developed to obtain solutions to these mathematical programming formulations in an efficient manner, when the number of possible categories of classification is restricted. Much of the current work on these extensions is given in [5].

Turnpike; Statistical convergence; Asymptotical stability; Optimal trajectories

### Introduction

This article considers the application of the notion of statistical convergence in turnpike theory. The first results have been obtained recently [14,15,19]. We briefly discuss the importance of this conjunction, present some results obtained and, finally, we formulate a challenging problem for future investigations.

We will consider discrete dynamical systems. Trajectories of these systems are some sequences of real numbers. Turnpike property, in a simple case, states that there is a certain stationary point that attracts all optimal trajectories not depending on the initial state. In other words, all optimal trajectories converge to this

stationary point. We can say that any optimal trajectory spends “almost” all time in some  $\varepsilon$ -neighborhood of that point. The term “almost” in this case means that only a finite number of elements of optimal trajectory may remain outside the  $\varepsilon$ -neighborhood of that point ( $\varepsilon$  is any small number).

It turns out that, for some practical problems this property does not hold. The relaxation of the term “almost” might be helpful to extend the class of problems that the turnpike property holds. One such a relaxation is the use of statistical convergence instead of an ordinary convergence. In this case, an infinite number of elements of optimal trajectory may remain outside the  $\varepsilon$ -neighborhood of a stationary point; however, the number of these elements in comparison with the number of elements in the  $\varepsilon$ -neighborhood is so small that we can say the optimal trajectory “almost” remains in this neighborhood.

This article adopts the notion of statistical convergence to describe the turnpike property.

## Turnpike Theory

Turnpike theory studies asymptotical behavior (often stability) of optimal trajectories of dynamical systems. It has many applications in economics and engineering. We refer to [8,16,18,25] for more detailed information about this theory and its various applications.

The first result in this area was obtained by J. von Neumann, in 1945. However, the main meaning of this result that led to turnpike property was discovered by Paul A. Samuelson, in 1948–1949, who also introduced this terminology. A clearer description of this property was provided by Dorfman et al. [3] in the chapter “Efficient Programs of Capital Accumulation” of *Linear Programming and Economic Analysis*. The following is the famous quote from [3], p. 331, that describes the meaning of the turnpike property:

*“Thus in this unexpected way, we have found a real normative significance for steady growth – not steady growth in general, but maximal von Neumann growth. It is, in a sense, the single most effective way for the system to grow, so that if we are planning long-run growth, no matter where we start and where we desire to end up it will pay in the intermediate stages to get into a growth phase of this kind. It is exactly like a turnpike paralleled by a network of minor roads. There is a fastest route*

*between any two points; and if the origin and destination are close together and far from the turnpike, the best route may not touch the turnpike. But if origin and destination are far enough apart, it will always pay to get on to the turnpike and cover distance at the best rate of travel, even if this means adding a little mileage at either end. The best intermediate capital configuration is one which will grow most rapidly, even if it is not the desired one, it is temporarily optimal”.*

After this book, theorems about the asymptotic behavior of optimal (or efficient) trajectories of dynamical systems are called “turnpike theorems.” Asymptotic behavior of optimal trajectories may be described in different ways.

In this article, we consider trajectories that are sequences of numbers from  $\mathbb{R}^m$ . The turnpike property in this case can be formulated as a convergence of optimal trajectories to some stationary point. We reformulate this property using statistical convergence instead of an ordinary convergence.

## Statistical Cluster Points and Statistical Convergence

The idea of statistical convergence was introduced by Steinhaus [23] and also independently by Fast [4] and Buck [1] for sequences of real and complex numbers. Later, this notion was developed by Salat [22], Maddox [7], Connor [2], Fridy [5,6] and others.

Fridy [6] introduced the notion of a statistical limit point and a statistical cluster point and gave some properties of a set of statistical limit and cluster points. In particular, it was shown that the set of statistical cluster points of a bounded sequence is not empty; moreover, if this set consists of one point, then the sequence is statistically convergent to this point. Because of this property, the notion of statistical cluster points, and, consequently, the statistical convergence, became a suitable tool that could be used in turnpike theory.

First we present some notations. We denote by  $|A|$  the cardinality of a subset  $A \subset \{1, 2, \dots\}$ . Consider a sequence  $(x_k)$ , where  $x_k \in \mathbb{R}^m$ ,  $k = 1, 2, \dots$

**Definition 1** The sequence  $(x_k)$  is said to be statistically convergent to  $x^* \in \mathbb{R}^m$  if for every  $\varepsilon > 0$

$$\limsup_{n \rightarrow \infty} \frac{1}{n} |\{k \leq n : \|x_k - x^*\| \geq \varepsilon\}| = 0.$$

We use the notation  $\text{st} - \lim_{k \rightarrow \infty} x_k = x^*$  in this case.

**Definition 2**  $\xi \in \mathbb{R}^m$  is said to be a cluster point of sequence  $(x_k)$  if for every  $\varepsilon > 0$

$$\limsup_{n \rightarrow \infty} \frac{1}{n} |\{k \leq n : \|x_k - \xi\| < \varepsilon\}| > 0 .$$

Given a sequence  $x = (x_k)$ , we denote by  $\Gamma_x$  the set of all statistical cluster points. If this set consists of one point, then the sequence is statistically convergent to that point [6].

The set of ordinary limit points is defined as

$$L_x = \{\xi \in \mathbb{R}^m : \text{there exists a subsequence } x_{k_n} \rightarrow \xi \text{ as } k_n \rightarrow \infty\} .$$

It is clear that if  $x$  is a bounded sequence, then  $L_x$  is a nonempty compact set and for every  $\varepsilon > 0$  there exists a number  $N_\varepsilon < +\infty$  such that

$$\rho(L_x, x_k) < \varepsilon \text{ for every } k \geq N_\varepsilon .$$

Here  $\rho(A, \xi) = \min_{y \in A} \|y - \xi\|$  is the distance from  $\xi$  to the closed set  $A$ .

It turns out that the set  $\Gamma_x$  possesses a similar property. The following is a very useful and important result proved in [6] for the case  $m = 1$ . It is not difficult to generalize it for  $m > 1$ .

**Lemma 1.** Assume that  $x = (x_k)$  is a bounded sequence. Then:

1. There exists a sequence  $y = (y_k)$  such that
  - $\Gamma_x = L_x$ ,
  - $\lim_{n \rightarrow \infty} \frac{1}{n} |\{k \leq n : x_k \neq y_k\}| = 0$ .
2. The set of statistical cluster points  $\Gamma_x$  is not empty and compact.
3.  $\lim_{n \rightarrow \infty} \frac{1}{n} |\{k \leq n : \rho(\Gamma_x, x_k) < \varepsilon\}| = 0$  for all  $\varepsilon > 0$ .

Let  $\alpha = (\alpha_k)$  be a sequence of bounded real numbers and  $\Gamma_\alpha$  be the set of statistical cluster points on this sequence. From Lemma 1. we know that the set  $\Gamma_\alpha$  has a minimal element. We denote by  $C - \liminf_{k \rightarrow \infty} \alpha_k$  the minimal element in  $\Gamma_\alpha$ .

This notation is similar to the notion of  $\liminf_{k \rightarrow \infty} \alpha_k$  being equal to a minimal number of the set of ordinary limit points  $L_\alpha$ .

Let  $g : \mathbb{R}^m \rightarrow \mathbb{R}$  be a continuous function and  $x = (x_k), x_k \in \mathbb{R}^m$ , be a given bounded sequence. Then

the sequence of real numbers  $\gamma = (g(x_k))$  is bounded. We define the following functional

$$J(x) = C - \liminf_{k \rightarrow \infty} g(x_k) \doteq \min \Gamma_\gamma \tag{1}$$

as a minimal number of  $\Gamma_\gamma$ . We have the following useful representation: given any bounded sequence  $x = (x_k)$

$$C - \liminf_{k \rightarrow \infty} g(x_k) = \min_{\xi \in \Gamma_x} g(\xi) . \tag{2}$$

Below we consider two problems where the turnpike theorems are formulated in terms of statistical convergence. For details see [14,15,19].

**Problem 1**

Consider the problem

$$x_{k+1} \in a(x_k) + x_k, k = 1, 2, \dots ; \tag{3}$$

$$J(x) = C - \liminf_{k \rightarrow \infty} g(x_k) \rightarrow \max . \tag{4}$$

We assume that set-valued mapping  $a : \mathbb{R}^m \rightarrow \Pi_c(\mathbb{R}^m)$  is continuous in the Hausdorff metric and  $g : \mathbb{R}^m \rightarrow \mathbb{R}$  is a continuous function. Here  $\Pi_c(\mathbb{R}^m)$  stands for the set of all compact subsets of  $\mathbb{R}^m$ .

A sequence  $x = (x_k)$  satisfying (3) will be called a trajectory of this system. From Lemma 1. we know that the functional (4) is well defined for bounded trajectories.

**Definition 3**  $\xi \in \mathbb{R}^m$  is called a stationary point if  $0 \in a(\xi)$ .

Note that if  $\xi$  is a stationary point, then the sequence  $(x_k)$ , where  $x_k = \xi$  for all  $k = 1, 2, \dots$ , is a stationary trajectory to system (3). Throughout this article, we denote the set of stationary points by  $\mathcal{M}$ :

$$\mathcal{M} = \{x : 0 \in a(x)\} .$$

The set  $\mathcal{M}$  may be empty or unbounded. If it is not empty, then it is a closed set as mapping  $a$  is continuous. Denote

$$J^* = \sup_{\xi \in \mathcal{M}} g(\xi) .$$

**Definition 4** Trajectory  $x = (x_k)$  is called optimal if  $J(x) \geq J(\tilde{x})$  holds for all trajectories  $\tilde{x}$  starting from the same initial state:  $\tilde{x}_0 = x_0$ .

We use the notation  $a(A) = \cup_{x \in A} a(x)$ . The following is the main condition imposed on mapping  $a$ .

**Condition A:** Given any set  $A \subset \mathbb{R}^m$

$$\text{if } 0 \in \text{co } a(A) \text{ then } 0 \in a(\text{co } A). \quad (5)$$

If mapping  $a$  has a convex graph then this condition holds. The main results are presented in the following two theorems.

**Theorem 1** Assume that Condition A holds and  $g$  is concave. Then for every bounded trajectory  $x = (x_k)$  to system (1) the inequality  $J(x(\cdot)) \leq J^*$  is satisfied.

Now assume that the set  $\mathcal{M}$  is convex and bounded, and function  $g$  is strictly concave. Then there is a unique point  $\xi^*$  such that  $g(\xi^*) = J^*$ .

**Condition B:** The set  $a(\xi^*)$  is a strictly convex body; that is,  $\int a(\xi^*) \neq \emptyset$ , and for every two points  $\xi_1, \xi_2 \in \partial a(\xi^*)$  and for all  $\lambda \in (0, 1)$  the following holds

$$\lambda \xi_1 + (1 - \lambda) \xi_2 \in \int a(\xi^*).$$

Here  $\partial(\cdot)$  and  $\int(\cdot)$  stand for the boundary and the interior of a set, respectively.

**Theorem 2** Assume that  $\mathcal{M}$  is convex and bounded, function  $g$  is strictly concave and Conditions A and B hold. If a bounded trajectory  $x = (x_k)$  such that  $J(x) = J^*$ , then  $\Gamma_x = \{\xi^*\}$ ; that is, trajectory  $x$  is statistically convergent to  $\xi^* : \text{st} - \lim_{k \rightarrow \infty} x_k = \xi^*$ .

If  $J(x) = J^*$  then from the first theorem it follows that trajectory  $x = (x_k)$  is optimal. The second theorem provides the turnpike property: all optimal trajectories satisfying  $J(x) = J^*$  statistically converge to  $\xi^*$ .

The proof of these theorems based on techniques developed for continuous systems in [9,10,11,12]. These studies did not use an assumption similar to Condition B. The following example shows that Condition B is necessary when dealing with discrete systems.

*Example 1.* Let mapping  $a$  and function  $g$  be defined on the box given by  $\{(x_1, x_2) : |x_i| \leq 1, i = 1, 2\}$  as follows

$$\begin{aligned} a(x_1, x_2) &= \{(y_1, y_2) : y_1 = x_2(x_2 - 1), \\ y_2 &= [-2x_2, 1 - 2x_2]\}; \\ g &= -x_1^2 - (1 - x_2)^2. \end{aligned}$$

We have

$$\mathcal{M} = \{(x_1, x_2) : |x_1| \leq 1, x_2 = 0\};$$

$$J^* = \max_{\xi \in \mathcal{M}} g(\xi) = g(0, 0) = -1, \quad \xi^* = (0, 0).$$

It is not difficult to see that all the conditions of Theorem 2 hold except Condition B. Consider the sequence  $x = (x^k)$  where  $x^k = (0, 0)$  for  $k = 1, 3, 5, \dots$ , and  $x^k = (0, 1)$  for  $k = 2, 4, 6, \dots$ . It is a trajectory to (3) because  $(0, 1) \in a(0, 0)$  and  $(0, -1) \in a(0, 1)$ . Moreover, the set  $\Gamma_x = \{(0, 0), (0, 1)\}$  consists of two points. We have

$$J(x) = \min_{\xi \in \Gamma_x} = -1 = J^*,$$

however  $x^k$  is not statistically convergent to  $\xi^* : \text{st} - \lim_{k \rightarrow \infty} x^k \neq \xi^*$ .

## Problem 2

Consider the problem

$$x_{k+1} = f(x_k, u_k), x_1 = \xi^0, u_k \in U; \quad (6)$$

$$J(x) = C - \liminf_{k \rightarrow \infty} g(x_k) \rightarrow \max. \quad (7)$$

Here  $\xi^0$  is a fixed initial point, function  $f(x, u) : \mathbb{R}^m \times \mathbb{R}^r \rightarrow \mathbb{R}^m$  is continuous,  $U \subset \mathbb{R}^r$  is a compact set and  $g : \mathbb{R}^m \rightarrow \mathbb{R}$  is a continuous function.

The pair  $(u, x)$  is called a process if the sequences  $x = (x_k)$  and  $u = (u_k)$  satisfy (6) for all  $k = 1, 2, \dots$ ;  $x = (x_k)$  is called a trajectory and  $u = (u_k)$  is called a control.

We assume that there is a bounded closed set  $C \subset \mathbb{R}^m$  such that  $x_k \in C$  for all trajectories; that is, we assume that trajectories are uniformly bounded.

**Definition 5**  $\xi \in \mathbb{R}^m$  is called a stationary point if there exists  $u \in U$  such that  $f(\xi, u) = \xi$ .

We denote the set of stationary points by  $M$ . It is clear that  $M$  is a closed set.

We formulate the main conditions as follows:

**Condition 1.** Function  $g$  has a unique maximizer on set  $M$  denoted by  $\xi^* : \max_{\xi \in M} g(\xi) = g(\xi^*)$ .

**Condition 2.** There exists a process  $(u^*, x^*)$  such that  $x_k^* \rightarrow \xi^*$  as  $k \rightarrow \infty$ .

Denote  $B = \{\xi \in C : g(\xi) \geq g(\xi^*)\}$ .

**Condition 3.** There exists a vector  $p \in \mathbb{R}^m$  such that  $p f(x, u) < p x$  for all  $x \in B, x \neq \xi^*$  and  $u \in U$ .

The turnpike property is formulated in the following theorem.

**Theorem 3** *Let Conditions 1–3 hold and  $(u, x)$  be an optimal process in problem (6) and (7). Then*

1.  $\Gamma_x = \{\xi^*\}$ ; that is,  $st - \lim_{k \rightarrow \infty} x_k = \xi^*$ .
2. If  $u^* \in U$  is a unique point in  $U$  such that  $f(\xi^*, u^*) = \xi^*$ , then we also have  $st - \lim_{k \rightarrow \infty} u_k = u^*$ .

In this theorem, turnpike property is established not only for optimal trajectories but also for optimal controls. In both cases this property is satisfied in terms of statistical convergence.

**A Challenging Problem**

The functional in the above problems is defined by statistical cluster points (see (4)). The following functional would be of great interest in terms of turnpike theory and statistical convergence

$$J(x) = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=1}^n g(x_k) \rightarrow \max . \tag{8}$$

In the literature on turnpike theory many functional have been considered, including terminal functionals, integral (summation) functionals with and without discount factors [3,8,9,10,11,12,13,16,18,20,21,24,25]. They usually are defined by utility functions ( $g$  in our case).

The functional (8) also has a useful meaning: it aims to maximize the limit of average utilities. However, this functional is not considered in the literature; the reason is very simple – for functional (8) the turnpike property in terms of (ordinary) convergence is in order not true!

We explain how this may happen in the following example.

*Example 2.* Consider the system  $x_{k+1} \in a(x_k), k = 1, 2, \dots$ , where  $x_k \in (-\infty, +\infty)$ . We only require that sets  $a(0)$  and  $a(1)$  contain at least points 0 and 1:  $\{0, 1\} \in a(0), \{0, 1\} \in a(1)$ . Function  $g$  is defined as  $g(x) = -x^2$ .

It is clear that a stationary trajectory  $\xi_k^* = 0, k = 1, 2, \dots$ , is an optimal trajectory and  $J^* = 0$ . For any other trajectory  $\tilde{x} = (\tilde{x}_k)$  we have  $J(\tilde{x}) \leq J^*$ .

Consider a sequence  $x = (x_k)$ , where  $x_k = 1$  for all  $k = i^2, i = 1, 2, \dots$ , and  $x_k = 0$  otherwise. We know that

$$\lim_{k \rightarrow \infty} x_k \text{ does not exist; however, } st - \lim_{k \rightarrow \infty} x_k = 0 .$$

It is easy to see that this sequence is a trajectory to the system. Moreover, it is not difficult to show that

$$\frac{1}{n} \sum_{k=1}^n g(x_k) \rightarrow 0 \text{ as } n \rightarrow \infty .$$

Therefore,  $x$  is an optimal trajectory and it does not converge to 0; meanwhile, the statistical convergence to 0 is valid.

This example shows that the turnpike property for functional (8) should use something different from ordinary convergence. We believe that the statistical convergence will be suitable for this aim.

To prove the turnpike property, in terms of statistical convergence, for a wide range of systems with functional (8) would be a challenging problem.

### Introduction

The careful observation of protein data banks [6] has been one of the motivations for modelling the biomolecular structure. The present development of this subject led to the conviction that the placement of some atoms in the structure of a protein is the same as that of Steiner points of a minimal Steiner Tree [3,4]. The experimental internal radius of a DNA molecule and a molecular aggregate like the tobacco mosaic virus as well as the pitch of the helices in a helical model of the placement of their atoms have also been in good agreement with this Steiner modelling. It seems that there is a deep correlation between the potential energy of the molecular configuration and the length of the Steiner Tree. The search for the minima of the energy could then be conducted by solving the associated Steiner problem. Even molecular clusters can be studied with this approach by starting from an existing correlation of their potential energies with the length of a generic Fermat problem. It can be thought that Nature is following mathematical principles of local energy minimization in order to build the present form of these structures and to keep them looking for stability through unstable stages of molecular evolution [5].

### The Steiner Ratio of a Metric Manifold

We consider a finite set of points  $A$  in a metric manifold  $M$ . Let us consider the subsets of  $A$  such that each pair of points on them could be connected by an edge of minimal length of a subset. These edges are geodesic arcs of the manifold  $M$ . A tree is a collection of points and their connecting edges. A tree that connects all the points of a subset is a spanning tree (SP) of this subset. Among all the possible STs  $s$  of a set  $A$  with length  $l_{SP}(s, A)$ , there is at least one whose overall length is minimum. This will be the minimal SP of

set  $A$ ,  $MST(A)$ . Its length will be given by

$$l_{MST(A)} = \min_{(s\text{-trees})} l_{SP}(s, A). \quad (1)$$

If we allow for the introduction of additional points of the manifold  $M$  on each set  $A$ , we get SPs of smaller overall length. A Steiner tree (ST) is obtained with the additional requirement of three tangent lines to only three geodesic edges meeting at an angle of  $120^\circ$  on each additional (Steiner) point. Among all these Steiner trees  $t$  of a set  $A$  with length  $l_{ST}(t, A)$ , there is one whose overall length is minimum. This is called the Steiner minimal tree of set  $A$ ,  $SMT(A)$ . Its length is

$$l_{SMT(A)} = \min_{(t\text{-trees})} l_{ST}(t, A). \quad (2)$$

The minimum spanning tree  $MST(A)$  is the worst approximation to the Steiner minimal tree,  $SMT(A)$ , or the “worst cut” for each set  $A \subset M$ . A common measure of this approximation is the Steiner ratio of the set  $A \subset M$

$$\rho(A) = \frac{l_{SMT(A)}}{l_{MST(A)}}. \quad (3)$$

The Steiner ratio  $\rho_n$  of the manifold  $M$  is then defined as the infimum of all values  $\rho(A)$  for all sets  $A$ , or

$$\rho_n = \inf_{ACM} \rho(A). \quad (4)$$

We henceforth adopt the three-dimensional Euclidean space as the metric manifold  $M$ .

### Evenly Spaced Consecutive Points – Spanning and Steiner Trees

For each set  $A$  of points in  $\mathbb{R}^3$  we suppose a continuous and differentiable curve to pass by all these points. If the points along the curve are evenly spaced in terms of the Euclidean metric, we have for their position vectors

$$\|\vec{r}_{j+2} - \vec{r}_{j+1}\| = \|\vec{r}_{j+1} - \vec{r}_j\|, \quad (5)$$

where  $\|\cdot\|$  represents the Euclidean norm.

A convenient representation of these vectors will be

$$\vec{r}_j = (r(\omega) \cos(j\omega), r(\omega) \sin(j\omega), jh(\omega)), \quad 0 \leq j \leq n-1. \quad (6)$$

The functions  $r(\omega)$  and  $h(\omega)$  are continuous and twice differentiable.

The position vectors  $\vec{r}_j$  above have an interesting property: four of them are enough to generate all the others, or

$$\vec{r}_{j+4} = \mu\vec{r}_{j+3} + \nu\vec{r}_{j+2} + \xi\vec{r}_{j+1} + \zeta\vec{r}_j, \quad 0 \leq j \leq n-1, \quad (7)$$

where  $\mu, \nu, \xi, \zeta$  are functions to be found.

This is a well-posed problem with a unique solution. We write the corresponding relations for the coordinates of the vectors in Eq. (7) as

$$\begin{aligned} (j+4)h &= \mu(j+3)h + \nu(j+2)h + \xi(j+1)h + \zeta jh, \\ 0 \leq j \leq n-1 \end{aligned} \quad (8)$$

and with an Argand representation in the  $x^1 - x^2$  plane,

$$rz_{j+4} = \mu rz_{j+3} + \nu rz_{j+2} + \xi rz_{j+1} + \zeta rz_j, \quad 0 \leq j \leq n-1, \quad (9)$$

where

$$z_j = (z)^j = e^{ij\omega}. \quad (10)$$

From Eq. (9) we have

$$z^4 - \mu z^3 - \nu z^2 - \xi z - \zeta = 0. \quad (11)$$

We write Eq. (8) for two points  $j$  and  $j+l$ , and we get

$$\mu + \nu + \xi + \zeta = 1. \quad (12)$$

From Eqs. (12) and (8) we can write

$$\mu + 2\nu + 3\xi + 4\zeta = 0. \quad (13)$$

The two last equations are enough for the existence of a double  $z = 1$  root of Eq. (11), or

$$(z-1)^2(z^2 + (2-\mu)z + 3-2\mu-\nu) = 0. \quad (14)$$

For complex roots of unit modulus  $|z| = 1$  according to Eq. (10), we have

$$\mu^2 + 4\mu + 4\nu - 8 < 0 \quad (15)$$

$$\mu = 2(1 + \cos \omega); \quad 0 \leq \mu \leq 4. \quad (16)$$

Equations (15) and (16) lead us to write

$$2\mu + \nu = 2. \quad (17)$$

From Eqs. (11), (12), (13) and (17) we get

$$\nu = 2 - 2\mu, \quad \xi = \mu; \quad \zeta = -1. \quad (18)$$

We can then write

$$\vec{r}_{j+4} = \mu \vec{r}_{j+3} + 2(1 - \mu)\vec{r}_{j+2} + \mu \vec{r}_{j+1} - \zeta \vec{r}_j. \quad (19)$$

This relation will give us the motivation of thinking about tetrahedra as the fundamental pieces of this modelling. There are  $n_T = (n - 3)$  tetrahedra for  $n$  points.

The values

$$\omega = \omega_R = \pi \pm \arccos\left(\frac{2}{3}\right) \quad (20)$$

correspond to vertices of two sequences of regular tetrahedra joined together at common faces. In the literature, it is known usually by the name “3-sausage” [2]. Actually, these two values correspond to the same structure. It is itself chiral for  $n \geq 6$ , since for  $n = 3, 4, 5$  (0, 1, 2 tetrahedra) there is a two-fold ( $n = 3$ ) or a three-fold ( $n = 4, 5$ ) axis of symmetry. The structures correspond to  $\omega$  and  $-\omega$ , with  $\omega \neq \omega_R$  being sequences of non-regular tetrahedra and they are chiral themselves and chiral to each other for all  $n \geq 3$ .

After this digression, we go back to the problem of constructing SPs for the set of  $n$  vertices of Eq. (5). A first candidate is the sequence itself. Its total length is given by

$$l_{SP} = (n - 1)[h^2 + r^2(A + 1)]^{1/2}, \quad (21)$$

where

$$A = 1 - 2 \cos \omega. \quad (22)$$

There is a necessary restriction on this spanning tree if we require that the STs to be formed below be full STs ( $n - 2$  Steiner points). The smallest angle between consecutive edges with the points  $\vec{r}_j$  of Eq. (6) as vertices should be less than  $120^\circ$ . We write

$$-\frac{1}{2} < \cos \theta = -1 + \frac{r^2(A + 1)^2}{2[h^2 + r^2(A + 1)]}, \quad (23)$$

or

$$h^2 < r^2 A(A + 1). \quad (24)$$

This is the first restriction imposed on the position vectors  $\vec{r}_j$ . Actually,  $r(\omega)$  is an arbitrary function for the present modelling, as will be seen in the forthcoming development.

A generalization of the last formula can be obtained by introducing subsequences of evenly spaced but non-consecutive points [4]. These subsequences are given by

$$(P_j)_{m, l_{P_j \max}} : \vec{r}_j, \vec{r}_{j+m}, \vec{r}_{j+2m}, \dots, \vec{r}_{j+l_{P_j \max} m}, \quad (25)$$

where  $(m - 1)$  is the number of skipped points necessary to form this sequence. The indices of the subsequences above should be restricted by

$$j + l_{P_j \max} m \leq n - 1. \quad (26)$$

We can write

$$l_{P_j \max} = \left[ \frac{n - j - 1}{m} \right]. \quad (27)$$

The square brackets  $[x]$  stand for the greatest integer value  $\leq x$ .

There are  $m$  subsequences  $P_j$ ,  $0 \leq j \leq m - 1$ , and each subsequence has  $(l_{P_j \max} + 1)$  points. We now define a new sequence by the union set of the sequences above or

$$\mathbb{P}_m = \bigcup_{j=0}^{m-1} (P_j)_{m, l_{P_j \max}}. \quad (28)$$

As a check of the consistency of this scheme we can see that each sequence  $\mathbb{P}_m$  has  $n$  points, like the original sequence, Eq. (6). From Eq. (27) and a mathematical identity we have

$$\begin{aligned} \sum_{j=0}^{m-1} (l_{P_j \max} + 1) &= m + \sum_{j=0}^{m-1} \left[ \frac{n - j - 1}{m} \right] \\ &= m + n - m = n. \end{aligned} \quad (29)$$

By completeness, the scheme should also include the original sequence of consecutive points, given by Eq. (6). It is effectively given by  $\mathbb{P}_1 = (P_0)_{1, n-1}$ .

Each sequence  $\mathbb{P}_m$  (Eq. 28) has an associated SP. We shall proceed now to the calculation of its length. We stress that the union of subsequences of the definition

of  $\mathbb{P}_m$  is accomplished by joining two subsequences by an edge of consecutive points as far as the calculation of length is concerned.

The scheme is valid for a generic set of points on a given curve. We should write a generic Ansatz for the coordinates of the subsequences instead of Eq. (6). We have

$$\vec{r}_{j+l_P m} = (r(\omega) \cos(j + l_P m), r(\omega) \sin(j + l_P m), \\ \cdot (j + l_P m)h(\omega)). \quad (30)$$

With the prescriptions above, the length of the SP for a sequence  $\mathbb{P}_m$  is

$$l_{\text{SP}}^{(m)} = [m^2 h^2 + r^2(A_m + 1)]^{1/2} \sum_{j=0}^{m-1} \left[ \frac{n-j-1}{m} \right] \\ + (m-1)[h^2 + r^2(A_1 + 1)]^{1/2}, \quad (31)$$

where

$$A_1 = A \text{ and } A_m = 1 - 2 \cos(m\omega). \quad (32)$$

After using the mathematical identity in the last equality of Eq. (29), we get

$$l_{\text{SP}}^{(m)} = (n-m)[m^2 h^2 + r^2(A_m + 1)]^{1/2} \\ + (m-1)[h^2 + r^2(A_1 + 1)]^{1/2}. \quad (33)$$

There is an analogous restriction to Eq. (24) on the angles between edges of subsequences. It is written as

$$m^2 h^2 < r^2 A_m (A_m + 1), \quad \forall m. \quad (34)$$

The length of the MST will be given by

$$l_{\text{SP}} = \min_{(m)} \left\{ l_{\text{SP}}^{(m)} \right\}. \quad (35)$$

The  $\min_{(m)} \{ \dots \}$  process above should be understood in the sense of formation of a piecewise function by the functions corresponding to values  $m = 1, 2, 3, \dots$

We can apply the same scheme to Steiner points and their connecting edges. The original sequence is

$$\vec{S}_k = (R(\omega) \cos k\omega, R(\omega) \sin k\omega, kH(\omega)), \\ 1 \leq k \leq n-2, \quad (36)$$

where  $R(\omega)$  and  $H(\omega)$  are also continuous and twice differentiable functions.

We now form the subsequences

$$(S_k)_{m, l_{S_k \max}} : \\ \vec{S}_k, \vec{S}_{k+m}, \vec{S}_{k+2m}, \dots, \vec{S}_{k+l_S m}, \dots, \vec{S}_{k+l_S j_{\max} m}, \quad (37)$$

where  $(m-1)$  is the number of skipped points.

The restriction on the indices is

$$k + l_S m \leq n-2, \quad (38)$$

and we have

$$l_{S_k \max} = \left[ \frac{n-k-2}{m} \right]. \quad (39)$$

We also have  $m$  subsequences  $S_k$ ,  $1 \leq k \leq m$ , each of which has  $(l_{S_k \max} + 1)$  points. We define a new sequence of Steiner points by the union set of the sequences  $S_k$ ,  $1 \leq k \leq m$ :

$$\mathbb{S}_m = \bigcup_{k=1}^m (S_k)_{m, l_{S_k \max}}. \quad (40)$$

These new sequences have  $(n-2)$  points each. This can be checked by using Eq. (38), or

$$\sum_{k=1}^m (l_{S_k \max} + 1) = m + \sum_{k=1}^m \left[ \frac{n-k-2}{m} \right] \\ = m + n - m - 2 = n - 2. \quad (41)$$

The scheme includes trivially the original sequence of Eq. (36). It is given by  $\mathbb{S}_1 = (S_1)_{1, n-1}$ .

The coordinates of these subsequences should be written generically as

$$\vec{S}_{k+l_S m} = (R_m(\omega) \cos(k + l_S m), R_m(\omega) \\ \cdot \sin(k + l_S m), (k + l_S m)H_m(\omega)), \quad (42)$$

where  $R_m(\omega)$  and  $H_m(\omega)$  are continuous and twice differentiable functions.

### Steiner Trees

The ST for each subsequence will be organized as follows: first the points  $\vec{S}_{k+l_S m}$  of the subsequence  $(S_k)_{m, l_{S_k \max}}$  for a given  $m$  will be connected consecutively to each other. The first of these points,  $\vec{S}_{k+m}$ , will be connected to the first two points,  $\vec{r}_j$  and  $\vec{r}_{j+m}$ , of the

subsequence  $(P_j)_m, l_{p_j \max}$ . The last point,  $S_{k+l_{S_k \max} m}$ , will be connected to the last two points,  $\vec{r}_{j+(l_{p_j \max}-1)m}$  and  $\vec{r}_{j+l_{p_j \max} m}$ . All the intermediary points  $\vec{S}_{k+l_{S_m}}$  will be connected to the intermediary points  $r_{j+l_{p_j} m}$ , for  $j = k$ . This means that we assume a path topology [2] for each subsequence.

The requirement of edges meeting at an angle of  $120^\circ$  on each Steiner point leads to the following relations:

$$H_m = h; \quad m^2 H_m^2 = R_m^2 A_m (A_m + 1), \quad \forall m. \quad (43)$$

From Eqs. (34) and (43) we have trivially,

$$R_m < r. \quad (44)$$

From Eq. (44) the length of the ST corresponding to the sequences  $\mathbb{P}_m$  and  $\mathbb{S}_m$  and a path topology will be given by

$$\begin{aligned} l_{\text{ST}}^{(m)} &= (r - R_m) \left( m + \sum_{k=1}^m \left[ \frac{n - k - 2}{m} \right] \right) \\ &+ [m^2 H_m^2 + R_m^2 (A_m + 1)]^{1/2} \sum_{k=1}^m \left[ \frac{n - k - 2}{m} \right] \\ &+ 2 [m^2 H_m^2 + (r - R_m)^2 + r R_m (A_m + 1)]^{1/2}. \end{aligned} \quad (45)$$

From Eqs. (43) and the mathematical identity used in Eq. (41) we write

$$\begin{aligned} l_{\text{ST}}^{(m)} &= n(r - R_m) + (n - m - 2)R_m(A_m + 1) \\ &+ 2 [(r - R_m)^2 + R_m(r + R_m A_m)(A_m + 1)]^{1/2}. \end{aligned} \quad (46)$$

Actually, we have used Eq. (43) for the two ends of the tree. Their contribution to the length is the last term in Eq. (46). In order to satisfy the condition of meeting edges at  $120^\circ$  there, we need to take a special limit  $R_m \rightarrow r$ . It is worthwhile for future modelling applications to notice that this procedure leads to the same result as the limit for  $l_{\text{ST}}^{(m)}$  for large numbers  $n$  of atoms. This is easy to see from Eq. (46).

$$l_{\text{ST}}^{(m)} (n \gg 1 \text{ or } \underbrace{R_m \rightarrow r}_{\text{at ends}}) = nr + [(n - m)A_m - m]R_m. \quad (47)$$

## The Steiner Ratio Function

We follow the prescription of Eq. (3) for writing an expression for the Steiner ratio function. It will be given by

$$\begin{aligned} \rho &= \frac{\min_{(m)} \{n + (A_m(A_m + 1))^{-1/2}\}}{\min_{(m)} \{(n - m)[A_m + 1 + m^2(F(\omega))^2]^{1/2}\}} \cdots \\ &\cdots \frac{[(n - m)A_m - m]mF(\omega)}{+(m - 1)[A_1 + 1 + (F(\omega))^2]^{1/2}} \end{aligned} \quad (48)$$

where  $F(\omega) \equiv \frac{h(\omega)}{r(\omega)}$  is a function restricted by

$$F(\omega) < \min_{(m)} \left\{ \frac{1}{m} [A_m(A_m + 1)]^{1/2} \right\}. \quad (49)$$

The application to protein modelling could be done by classifying the minimum energy values (minima of  $\rho$ ) of protein structures on protein data banks [6] after choosing a convenient function  $F(\omega)$ .

For application to the Steiner ratio problem of discrete mathematics, we can see that for very large set of points ( $n \gg 1$ ), the ratio function Eq. (48) can be written

$$\rho(n \gg 1) = \frac{\min_{(m)} \left\{ 1 + mF(\omega) \left( \frac{A_m}{A_m + 1} \right)^{1/2} \right\}}{\min_{(m)} \left\{ [A_m + 1 + m^2(F(\omega))^2]^{1/2} \right\}}. \quad (50)$$

Let the function  $F(\omega)$  be chosen such that the  $\min_{(m)}$  process in the numerator of Eq. (49) is dominated by the term corresponding to a fixed value of  $m = \bar{m}$ . The problem of Eq. (49) will then be solved by

$$\rho(\omega, F, \bar{m}) = \text{Max}_{(m)} \left\{ \frac{1 + \bar{m}F(\omega) \left( \frac{A_{\bar{m}}}{A_{\bar{m}} + 1} \right)^{1/2}}{[A_m + 1 + m^2(F(\omega))^2]^{1/2}} \right\}. \quad (51)$$

For  $\bar{m} = 1$  the function of Eq. (50) has the global minimum

$$\omega_1 = \pi - \arccos \frac{2}{3}; \quad F(\omega_1) = \frac{\sqrt{30}}{9} \quad (52)$$

and

$$\begin{aligned} \rho(\omega_1, F(\omega_1), \bar{m} = 1) &= \frac{1}{10} (3\sqrt{3} + \sqrt{7}) \\ &= 0.78419037337. \end{aligned} \quad (53)$$

This is the value that was conjectured in the literature [2] as the best upper bound of the Steiner ratio for three-dimensional Euclidean space.

We also report that the value  $m = \bar{m} = 1$  can be selected by a linear function  $F(\omega) = \alpha\omega$ , which means right circular helices for the geometrical locus of the points  $\vec{r}_j$  and  $\vec{S}_k$  of our modelling. Furthermore, the function  $\rho$  obtained by taking also  $m = \bar{m} = 1$  in the denominator is a convex envelope in this case.

### Concluding Remarks

The successful application of the scheme introduced in the foregoing pages reinforce the idea of studying their consequences as well as classifying biomolecular structures in terms of associated Steiner trees. It is a geometrical approach to the fundamental problem of energy minimization of these structures, and it can shed some light on the problem of biomolecular formation and evolution. Some additional knowledge of protein structure [1,7] should be introduced into our analysis, like amide planes and their twisting angles and a residual Fermat problem already solved by Nature for the placement of  $\alpha$ -carbon atoms. The only information we used was the placement of carbon and nitrogen atoms as Steiner points. We hope that the scheme developed here can be extended to create a useful definition of molecular chirality and a well-posed optimization problem.

Combinatorial optimization; Steiner tree; Steiner ratio; Approximation algorithms; variations of Steiner trees

The Steiner tree is an *NP*-hard combinatorial optimization problem [50] with a long history [11,66,93]. The study of Steiner trees received great attention in the 1990s since many important open problems, including

the *Gilbert–Pollak conjecture* on the *Euclidean Steiner ratio*, the existence of better approximation, and the existence of polynomial time approximation schemes (PTAS), have been solved with influence in the general theory of designs and analysis of approximation algorithms for combinatorial optimization, and also, many new important applications in VLSI designs, optical networks, wireless communications, etc. have been discovered and studied extensively. Those applications usually require some modifications on classical Steiner tree problems and hence require new techniques for solving them. Therefore, studying various variations of Steiner trees became an exciting activity recently. In this article, we will review important developments in the 1990s and discuss some open problems which may motivate important developments in this century.

### On the Proof of Gilbert–Pollak’s Conjecture

Given a set of points in a metric space, the problem is finding a shortest network interconnecting the points in the set. Such a shortest network is called a *Steiner minimum tree* on the point set. The Steiner tree problem can be seen as a generalization of *Fermat’s problem*. Around 1700, P. Fermat proposed a problem of finding a point to minimize the total distance from this point to three given points in the Euclidean plane; its solution is exactly the Steiner minimum tree on the three points. The general form of Steiner minimum tree problem was proposed by C.F. Gauss [26]. However, R. Courant and H. Robbins [27] referred to it as the Steiner problem. The popularity of their book was responsible for bringing the Steiner tree problem to people’s attention. Two important papers in the 1960s further laid a solid groundwork for additional study. Z.A. Melzak [75] first gave a finite algorithm for the Euclidean Steiner trees. E.N. Gilbert and H.O. Pollak [52] produced an excellent survey of the problem, raised many new topics including Steiner ratio problem, and extended the problem to other metric space. Since then, more than three hundred research papers have been written contributing to the Steiner tree problem. For an excellent survey, see [55].

An important development on the Steiner tree problem that took place in the beginning of the 1990s is the proof of Gilbert–Pollak’s conjecture on the Euclidean Steiner ratio [32,33]. This new development is

based on the discovery of a new approach with a new *minimax theorem*.

A *minimum spanning tree* on a set of points is the shortest network interconnecting the points in the set with all edges between the points. While the Steiner tree problem is intractable, the minimum spanning tree can be computed pretty fast. The Steiner ratio in a metric space is the largest lower bound for the ratio between lengths of a minimum Steiner tree and a minimum spanning tree for the same set of points in the metric space, which is a measure of performance for the minimum spanning tree as a polynomial time approximation of the minimum Steiner tree. Determining the Steiner ratio in each metric space is a traditional problem on Steiner trees. In 1976, F.K. Hwang [54] determined that the Steiner ratio in a rectilinear plane is  $2/3$ . However, it took 22 years to complete the story of determining the Steiner ratio in the Euclidean plane. In 1968, Gilbert and Pollak conjectured that the Steiner ratio in the Euclidean plane is  $\sqrt{3}/2$ . Through efforts made by several authors [14,24,31,31,36,48,53,80,86,87], and [23], the conjecture was finally proved by D.-Z. Du and Hwang [32,33] in 1990. The significance of their proof stems also from the potential applications of the new approach included in the proof.

In their approach, the central part is a new minimax theorem about minimizing the maximum value of several concave functions over a simplex as follows.

**Theorem 1 (Du–Hwang minimax theorem)** *Let  $f(x) = \max_{i \in I} g_i(x)$ , where  $I$  is a finite set and  $g_i(x)$  is a continuous, concave function in a polytope  $X$ . Then the minimum value of  $f(x)$  over the polytope  $X$  is achieved at some critical point, namely, a point satisfying the following property:*

\*) *There exists an extreme subset  $Y$  of  $X$  such that  $x \in Y$  and the index set  $M(x) (= \{i: f(x) = g_i(x)\})$  is maximal over  $Y$ .*

The Steiner ratio problem is first transferred to such a minimax problem ( $g_i(x) =$  (the length of a Steiner tree)–(the Steiner ratio)·(the length of a spanning tree with graph structure  $i$ ), where  $x$  is a vector whose components are edge-lengths of the Steiner tree) and the minimax theorem reduces the minimax problem to the problem of finding the minimax value of the concave functions at critical points. Then each critical point is transferred back to an input set of points with special

geometric structure; it is a subset of a lattice formed by equilateral triangles. This special structure enables us to verify the conjecture corresponding to the nonnegativeness of minimax value of the concave functions.

Clearly, in order to use the minimax approach, for each problem three questions will be addressed:

- 1) How do we transfer the problem to such a minimax problem meeting the condition that the functions are concave?
- 2) How do we determine the critical geometric structure?
- 3) How do we verify the function value on the critical structure?

Developing techniques for answering these three questions will enable us to solve more open problems. Let us explain it by some examples in the following.

### Chung–Gilbert’s Conjecture

Steiner trees in Euclidean spaces have an application in constructing phylogenetic trees [17]. It was also conjectured by Gilbert and Pollak [52] that in any Euclidean space the Steiner ratio is achieved by the vertex set of a regular simplex. F.R.K. Chung and Gilbert [22] constructed a sequence of Steiner trees on regular simplices. The lengths of constructed Steiner trees goes decreasingly to  $\sqrt{3}/(4 - \sqrt{2})$ . Although the constructed trees are not known to be Steiner minimum trees, Chung and Gilbert conjectured that  $\sqrt{3}/(4 - \sqrt{2})$  is the best lower bound for Steiner ratios in Euclidean spaces. Clearly, if  $\sqrt{3}/(4 - \sqrt{2})$  is the limiting Steiner ratio in  $d$ -dimensional Euclidean space as  $d$  goes to infinity, then *Chung–Gilbert’s conjecture* is a corollary of Gilbert and Pollak’s general conjecture. However, this general conjecture of Gilbert and Pollak has been disproved by J.M. Smith [92] for dimension from three to nine and by Du and Smith for dimension larger than two. Now, interesting questions which arise in this situation are about Chung and Gilbert’s conjecture. Could Chung–Gilbert’s conjecture also be false? If the conjecture is not false, can we prove it by the minimax approach?

First, we claim that Chung–Gilbert’s conjecture could be true. In fact, we could get rid of Gilbert–Pollak’s general conjecture, and use another way to reach the conclusion that the limiting Steiner ratio for regular simplex is the best lower bound for Steiner ratios in Eu-

clidean spaces. To support our viewpoint, let us analyze a possible proof of such a conclusion as follows.

Consider  $n$  points in  $(n - 1)$ -dimensional Euclidean space. Then all of  $n(n - 1)/2$  distances between the  $n$  points are independent. Suppose that we could do a similar transformation and the minimax theorem could apply to these  $n$  points to obtain a similar result in the proof of Gilbert–Pollak’s conjecture for Euclidean plane, i. e. a point set with critical geometric structure has the property that the union of all minimum spanning trees contains as many equilateral triangles as possible. Then such a critical structure must be a regular simplex.

The above observation tells us two facts:

- a) Chung–Gilbert’s conjecture can follow from the following two conjectures.

*Conjecture 2* The Steiner ratio for  $n$  points in a Euclidean space is not smaller than the Steiner ratio for the vertex set of  $(n - 1)$ -dimensional regular simplex.

*Conjecture 3 (Smith’s conjecture [92])*  $\sqrt{3}/(4 - \sqrt{2})$  is the limiting Steiner ratio for simplex.

- b) It may be possible to prove Conjecture 2 by the minimax approach if we could find the right transformation.

One may wonder why we need to find a right transformation. What happens to the transformation used in the proof of Gilbert–Pollak’s conjecture in the Euclidean plane? Here, we remark that such a transformation does not work for Conjecture 2. In fact, in the Euclidean plane, with a fixed graph structure, all edge-lengths of a full Steiner tree can determine the set of original points and furthermore the length of a spanning tree for a fixed graph structure is a convex function of the edges-lengths of the Steiner tree. However, in Euclidean spaces of dimension more than two, edge-lengths of a full Steiner tree are not enough to determine the set of original points. Moreover, adding other parameters may destroy the convexity of the length of a spanning tree as a function of the parameters.

Smith [92] showed by an exhaustive computation that for  $d = 3, \dots, 7$ , the Steiner trees constructed by Chung and Gilbert are actually minimum Steiner trees, but, for  $d = 8$ , their Steiner tree is not minimum. He also conjectured that the trees of Chung and Gilbert are minimum if  $d$  is of the form  $d = 3 \cdot 2^p$ . Conjecture 3 is a corollary of this more specific conjecture.

From the above, we see that proving Chung–Gilbert’s conjecture requires a further development of the minimax approach.

### Graham–Hwang’s Conjecture

A Steiner tree with rectilinear distance is called a *rectilinear Steiner tree*. While rectilinear Steiner trees in plane have many applications on CAT and VLSI, rectilinear Steiner trees in high-dimensional space can be found in biology [17,47] and optimal traffic multicasting for some communication networks [13,18]. Although the Steiner ratio in rectilinear plane was determined by Hwang [54] in an earlier stage of the study of Steiner trees, there is still (as of 2000) no progress on the Steiner ratio in rectilinear spaces by now. The Steiner ratio in a  $d$ -dimensional rectilinear space was conjectured to be  $d/(2d-1)$  by Graham and Hwang [53]. The difficulty for extending Hwang’s approach to proving *Graham–Hwang’s conjecture* is due to the lack of knowledge on the full rectilinear Steiner trees in high-dimensional spaces. (A full Steiner tree has a property that all original points are leaves.) In fact, for a full rectilinear Steiner tree in plane, all Steiner points lie on a path. However, it is not known whether a similar result holds for full rectilinear Steiner trees in a space of dimension more than two.

Graham–Hwang’s conjecture can be easily transferred to a minimax problem required by our minimax approach. For example, choose lengths of all straight segments of a Steiner tree. When the connection pattern of the Steiner tree is fixed, the set of original points can be determined by such segments-lengths, the length of the Steiner tree is a linear function and the length of a spanning tree is a convex function of such segment-lengths, so that  $g_i$  is a concave function of such segment-lengths. However, for this transformation, it is hard to determine the critical structure. To explain the difficulty, we notice that in general the critical points could exist in both the boundary and interior of the polytope. (See the minimax theorem.) In the proof of Gilbert–Pollak’s conjecture in plane, a crucial fact is that only interior critical points need to be considered in a contradiction argument. The critical structure of interior critical points are relatively easy to be determined. However, for the current transformation on Graham–Hwang’s conjecture, we have to consider

some critical points on the boundary. It requires a new technique, either determine critical structure for such critical points or eliminate them from our consideration.

One possible idea is to combine the minimax approach and Hwang’s method. In fact, by the minimax approach, we may get a useful condition on the set of original points. With such a condition, the point set can have only certain type of full Steiner trees. This may reduce the difficulty of extending Hwang’s method to high dimension.

The significance of developing techniques for determining critical structure corresponding to critical points on the boundary is not only for solving Graham–Hwang’s conjecture, but also for solving some other problems. For example, it can be immediately applied to some packing problems. One of the typical packing problems is to find the maximum number of objects which can be put in a certain container. When the objects are discs or spheres, the problem can be transferred to a minimax problem that meets our requirement. To determine such a number exactly, we have also to deal with critical points on the boundary of the polytope.

### The Steiner Ratio in Banach Spaces

Examining the proof of Gilbert–Pollak’s conjecture in the Euclidean plane, we observe that the proof has nothing concerning the property of Euclidean norm except the last part, verification of the conjecture on point sets of critical structure. This means that using the minimax approach to determine the Steiner ratio in *Minkowski plane* (2-dimensional Banach space), we would have no problem in finding a transformation and determining critical structures. We would meet only a problem on verification for point sets with critical structure.

Steiner minimum trees in Minkowski planes have been studied by [1,25,30,34,70,91]. In these papers, some fundamental properties of Steiner minimum trees in Minkowski planes have been established. Two nice conjectures about the Steiner ratio in Minkowski planes were proposed respectively by [25,30] and [30] as follows:

*Conjecture 4* In any Minkowski plane, the Steiner ratio is between  $2/3$  and  $\sqrt{3}/2$ .

*Conjecture 5* The Steiner ratio in a Minkowski plane equals that in its dual plane.

With new techniques in the critical structures, B. Gao, Du and Graham [49] proved the first half of Conjecture 4 that in any Minkowski plane, the Steiner ratio is at least  $2/3$ , and P.-J. Wan, Du and Graham [97] showed that Conjecture 5 is true for three, four, and five points. With a different approach, Du and others [30] also proved that in any Minkowski plane, the Steiner ratio is at most 0.8766.

The Chung–Gilbert conjecture and Conjecture 5 can be extended to high-dimensional Banach spaces as follows.

*Conjecture 6* In any infinite-dimensional Banach space, the Steiner ratio is between  $1/2$  and  $\sqrt{3}/(2 - \sqrt{2})$ .

*Conjecture 7* The Steiner ratio in any Banach space equals that in its dual space.

Significant results on these two conjectures could be produced by further developments of minimax approach from a successful application in two-dimensional problems to high-dimension.

### On Better Approximations

Starting from a minimum spanning tree, improve it by adding Steiner points. This is a natural idea to obtain an approximation solution for the Steiner minimum tree. Every approximation solution obtained in this way would have a performance ratio at most the inverse of the Steiner ratio. The problem is how much better than the inverse of the Steiner ratio one can make.

From the 1980s onwards numerous heuristics [6,13,19,44,61,63,64,65,67,94,100] for Steiner minimum trees have been proposed for points in various metric spaces. Their superiority over minimum spanning trees were often claimed by computation experiments. But no theoretical proof of superiority was ever given. It was a long-standing problem whether there exists a polynomial time approximation with a performance ratio better than the inverse of the Steiner ratio or not. For simplicity, a polynomial time approximation with performance ratio smaller than the inverse of the Steiner ratio will be called a *better approximation*. The first significant work on better approximations was

made by M.W. Bern [10]. He proved that for the rectilinear metric and Poisson distributed regular points, a greedy approximation obtained by a very simple improvement over a minimum spanning tree has a shorter average length. Later, Hwang and Y.C. Yao [56] extended this result to the usual case when the number of regular points is fixed.

In 1991, A.Z. Zelikovsky [102] made the first breakthrough to the problem by giving a better heuristic for the Steiner minimum trees in graph. This is the second important development on Steiner trees in 1990s. To explain his idea and review further development from his work, let us start from comparing his work with a previous work with a similar idea.

### Chang's Idea

Chang [18,19] proposed the following approximation algorithm for Steiner minimum trees in the Euclidean plane: Start from a minimum spanning tree and at each iteration choose a Steiner point such that using this Steiner point to connect three vertices in the current tree could replace two edges in the minimum spanning tree and this replacement achieves the maximum saving among such possible replacements.

Smith, D.T. Lee and J.S. Liebman [90] also use the idea of the greedy improvement. But, they start with Delaunay triangulation instead of a minimum spanning tree. Since every minimum spanning tree is contained in Delaunay triangulation, the performance ratio of their approximation algorithm can also be bounded by the inverse of the Steiner ratio. The advantage of Smith–Lee–Liebman algorithm is on the running time. While Chang's algorithm runs in  $O(n^3)$  time, Smith–Leeh–Liebman algorithm runs only in  $O(n \log n)$  time.

A. Kahng and G. Robin [60] proposed an approximation algorithm for Steiner minimum trees in the rectilinear plane by using the same idea as that of Chang. For these three algorithms, it can be proved that for any particular set of points, the ratio of lengths of the approximation solution and the Steiner minimum tree is smaller than the inverse of the Steiner ratio. Some experimental results also show that the approximation solution obtained by these algorithms are very good. However, no proof has been found to show any one of them being a better approximation.

### Zelikovsky's Idea

Zelikovsky's idea [102] is based on the decomposition of a Steiner tree (namely, a tree, not necessarily minimum, interconnecting original points): An original point in a Steiner tree can be either a leaf or a junction. In the latter case, the Steiner tree can be decomposed at this point. In this way, every Steiner tree can be decomposed into edge-disjoint union of several Steiner trees for subsets of original points; each of them has no junction being an original point. A Steiner tree with no original point being a junction is called a *full Steiner tree*. The full Steiner trees in the decomposition are called *full components*. The size of a full component is the number of original points in the component.

Clearly, for any  $k \geq 3$ , a  $k$ -size Steiner minimum tree usually has shorter length compared with a minimum spanning tree. It is natural to think about using a minimum  $k$ -size Steiner tree to approximate the Steiner minimum tree. However, this does not work because computing a  $k$ -size Steiner minimum tree is still an intractable problem. Zelikovsky's idea is to approximate the Steiner minimum tree by a 3-size Steiner tree generated by a polynomial time greedy algorithm. The key fact is that the length of such a heuristic is smaller than the arithmetic mean of lengths of a minimum spanning tree and a 3-size Steiner minimum tree; that is, the performance ratio of his approximation satisfies

$$\text{PR} \leq \frac{\rho_2^{-1} + \rho_3^{-1}}{2},$$

where  $\rho_k$  is the  $k$ -Steiner ratio. Thus, if the 3-Steiner ratio  $\rho_3$  is bigger than the Steiner ratio  $\rho_2$ , then this greedy algorithm is a better approximation for the Steiner minimum tree. Zelikovsky was able to prove that 3-Steiner ratio in graphs is at least  $3/5$  which is bigger than  $1/2$ , the Steiner ratio in graphs [61]. So, he solved the better approximation problem in graphs. Zelikovsky's idea has been extensively studied in the literature.

Du, Zhang, and Q. Feng [40] generalized Zelikovsky's idea to the  $k$ -size Steiner tree. They showed that a generalized Zelikovsky's algorithm has performance ratio

$$\text{PR} \leq \frac{(k-2)\rho_2^{-1} + \rho_k^{-1}}{k-1}.$$

P. Berman and V. Ramaiyer [9] employed a different idea to generalize Zelikovsky's result. They obtained an algorithm with the performance ratio satisfying

$$\text{PR} \leq \rho_2^{-1} - \sum_{i=3}^k \frac{\rho_{i-1}^{-1} - \rho_i^{-1}}{i-1}.$$

They also showed that in the rectilinear plane, the 3-Steiner ratio is at least  $72/94$  which is bigger than  $2/3$  [54], the Steiner ratio in rectilinear plane. So, they solved the better heuristic problem in rectilinear plane.

Du, Zhang, and Feng [40] proved a lower bound for the  $k$ -Steiner ratio in any metric space. This lower bound goes to one as  $k$  goes to infinity. So, in any metric space with the Steiner ratio less than one, there exists a  $k$ -Steiner ratio bigger than the Steiner ratio. Thus, they proved that the better heuristic exists in any metric space satisfying the following conditions:

- 1) the Steiner ratio is smaller than one;
- 2) the Steiner minimum tree on any fixed number of points can be computed in polynomial time.

These metric spaces include Euclidean plane and Euclidean spaces.

Zelikovsky [104] used a different potential function in his greedy approximation and obtained an approximation with performance ratio satisfying

$$\text{PR} \leq \rho_k^{-1}(1 - \ln \rho_2).$$

Although Zelikovsky's idea starts from a point different from Chang's one, the two approximations are actually similar. To see this, let us describe Zelikovsky's algorithm as follows: Start from a minimum spanning tree and at each iteration choose a Steiner point such that using this Steiner point to connect three regular points could replace two edges in the minimum spanning tree and this replacement achieves the maximum saving among such possible replacements.

Clearly, they both start from a minimum spanning tree and improve it step by step by using a greedy principle to choose a Steiner point to connect a triple of vertices. The difference is only that this triple in Chang's algorithm may contain some Steiner points while it contains only regular points in Zelikovsky's algorithm. This difference makes Chang's approximation difficult to be analyzed. Which one will give a better approximation solution? This is an interesting problem.

### The $k$ -Steiner Ratio $\rho_k$

While the determination of the  $k$ -Steiner ratio plays an important role in estimation of the performance ratio of several recent better approximations, A. Borchers and Du [15] completely determined the  $k$ -Steiner ratio in graphs that for  $k = 2^r + h \geq 2$ ,

$$\rho_k = \frac{r2^r + h}{(r + 1)2^r + h}$$

and Borchers, Du, Gao, and Wan [16] completely determined the  $k$ -Steiner ratio in the rectilinear plane that  $\rho_2 = 2/3$ ,  $\rho_3 = 4/5$ , and for  $k \geq 4$ ,  $\rho_k = (2k - 1)/(2k)$ . However, the  $k$ -Steiner ratio in the Euclidean plane for  $k \geq 3$  is still (as of 2000) an open problem. Du, Zhang, and Feng [40] conjectured that the 3-Steiner ratio in the Euclidean plane is

$$\frac{(1 + \sqrt{3})\sqrt{2}}{1 + \sqrt{2} + \sqrt{3}}.$$

They also analyzed that the  $k$ -Steiner ratio in the Euclidean plane might be determined in a similar way to the proof of Gilbert–Pollak conjecture. The difficulty appears only in the description of ‘critical structure’.

### Variable Metric Method

Berman and Ramaiyer [9] introduced an interesting approach to generalize Zelikovsky’s greedy approximation. Let us call the Steiner minimum tree for a subset of  $k$  regular points as a  $k$ -tree. Their approach consists of two steps. The first step processes all  $i$ -trees,  $3 \leq i \leq k$ , sequentially in the following way: For each  $i$ -tree  $T$  with positive saving in the current graph, put  $T$  in a stack and if two leaves  $x$  and  $y$  of  $T$  are connected by a path  $p$  in a minimum spanning tree without passing any other leaf of  $T$ , then put an edge between  $x$  and  $y$  with weight equal to the length of the longest edge in  $p$  minus the saving of  $T$ . In the second step, it repeatedly pops  $i$ -trees from the stack remodeling the original minimum spanning tree for all regular points and keeping only  $i$ -trees with the current positive saving. Adding weighted edges to a point set would change the metric on the points set. Let  $E$  be an arbitrary set of weighted edges such that adding them to the input metric space makes all  $i$ -trees for  $3 \leq i \leq k$  have nonpositive saving in the resulting metric space  $M_E$ . Denote by  $t_k(P)$  a supremum of the length of a minimum spanning tree

for the point set  $P$  in metric space  $M_E$  over all such  $E$ . Then Berman–Ramaiyer’s algorithm produces a  $k$ -size Steiner tree with total length at most

$$\begin{aligned} t_2(P) - \sum_{i=3}^k \frac{t_{i-1}(P) - t_i(P)}{i-1} \\ = \frac{t_2(P)}{2} + \sum_{i=3}^{k-1} \frac{t_i(P)}{(i-1)i} + \frac{t_k(P)}{k-1}. \end{aligned}$$

The bound for the performance ratio of Berman–Ramaiyer’s approximation above is obtained from this bound and the fact that  $t_k(P) \leq \rho_k^{-1} \text{SMT}(P)$  where  $\text{SMT}(P)$  is the length of the Steiner minimum tree for point set  $P$ .

Based on the above observation, we may have the following questions. Could we find another way to vary metric for a better bound? Could we forget the greedy idea and design a better approximation with only a variable metric idea? Answering these questions requires deeper understanding of the variable metric method. We attempt to obtain new algorithms from this study.

M. Karpinski and Zelikovsky [62] proposed a preprocessing procedure to improve existing better approximations. First, they use this procedure to choose some Steiner points and then run a better approximation algorithm on the union of the set of regular points and the set of chosen Steiner points. This preprocessing improves the performance ratio for every known better approximation that we mentioned previously.

The preprocessing procedure is similar to the algorithm of Berman and Ramaiyer. But, it uses a ‘related gain’ instead of the saving as the greedy function. One of our current ideas is to modify Chang’s algorithm in the following way: At each iteration, if a Steiner point is introduced, then computes its related gain, and later consider only triples of regular points and Steiner points with positive related gain. Would this approximation perform better? We attempt to get the answer.

Although many better approximations have been found in recent years, none of them has performance ratio smaller than the inverse of 3-Steiner ratio. The inverse of the 3-Steiner ratio seems to be the limit for the performance ratio of polynomial time approximations for Steiner minimum trees to be able to reach.

S. Arora and others [5] conjectured that their backtrack greedy technique gives a polynomial time approx-

imation scheme to 3-size Steiner minimum trees. If their conjecture is true, then their algorithms also give approximations for Steiner minimum trees with performance ratio approach to the inverse of the 3-Steiner ratio. This probably is the best possible performance ratio. Thus, the conjecture of Arora and others is an attractive problem to our further research.

A more accurate analysis [62,101,104] for the performance ratios of Berman–Ramaier’s algorithm and Karpinski–Zelikovsky’s preprocessing requires bounds for  $t_k$  and a similar number  $t^k$ . The techniques in [15,16] for determining the  $k$ -Steiner ratio seems very promising for establishing tight upper bounds for  $t_k$  and  $t^k$ .

The knowledge for the lower bound of the performance ratio is an open problem (as of 2000). One knows only that for Steiner minimum trees in graphs, if  $NP \neq P$ , then a lower bound larger than one exists, because the problem in this case is MAX SNP-complete [12].

### On PTAS

T. Jiang and others [58,59] brought a quite different idea from previous ones to Steiner minimum trees. They decompose the set of regular points based on the lengths of edges in a minimum spanning tree. By an interesting analysis, they proved that if the ratio of lengths between the longest edge and the shortest edge in a minimum spanning tree is bounded by a constant, then there is a polynomial time approximation scheme (PTAS) for Steiner minimum trees in the rectilinear plane and in the Euclidean plane. This idea can also be used in other geometric optimization problems, in particular, some variations of Steiner tree problems described in the next section.

In 1995, Arora and J.S.B. Mitchell independently discovered powerful techniques to establish polynomial time approximation schemes for geometric optimization problems, including Euclidean and rectilinear Steiner tree problems. Their results constitute the third important development on Steiner trees in 1990s. The significance of their results is not only on Steiner trees, but also on the design and analysis of approximation algorithms in combinatorial optimization. Let us review these two remarkable techniques in the following.

### Arora’s PTAS

It is quite interesting to note that Arora [4] appeared only one week before Mitchell [76]. Any way, they use very different techniques to reach the same goal. Therefore, both are very interesting. Arora’s technique is based on recursive partition. In Jiang and others [58,59], although partition can be moved parallelly, the size of each cell is fixed. It cannot be varied according to local information about distribution of terminals. Therefore, only in case that terminals are distributed almost evenly, could the partition work well. This is why such a condition that the ratio of lengths between the longest edge and the shortest edge in a minimum spanning tree is bounded by a constant is required.

However, in Arora’s recursive partition, each big cell is partitioned into small cells independently from other big cells. How to cut only depends on the situation inside of itself. This advantage enables him to discard the condition in Jiang and others [58,59].

### Mitchell’s PTAS

Mitchell’s technique was initiated from studying a minimum length *rectangular partition problem*. Given a rectilinear region  $R$  surrounded by a rectilinear polygon and some rectilinear holes, a *rectangular partition* of  $R$  is a set of segments in  $R$ , which divide  $R$  into small rectangles each of which does not contain any hole in its interior. The problem is to find such a rectangular partition with the minimum total length. This problem is  $NP$ -hard.

Du and others [38] introduced a concept of *guillotine subdivision*. A guillotine subdivision is a sequence of cuts performed recursively such that each cut partitions a piece into at least two. Du and others [38] showed that the minimum length guillotine rectangular partition can be computed in polynomial time. However, they were only able to show that this guillotine subdivision is an approximation of the minimum length rectangular partition problem with performance ratio two in a special case that the region  $R$  is surrounded by a rectangle with some points as holes in it. Mitchell [77] showed that this is actually true in general. He also successfully utilized this technique to obtain constant approximations for other geometric optimization problems. With the same technique, C. Mata [74] obtained a constant-factor approximation algo-

rithm for red-blue separation problem improving previous result  $O(\log n)$ .

Inspired by this success, Mitchell [76] extended guillotine subdivision to  $m$ -guillotine subdivision, a rectangular polygonal subdivision such that there exists a cut whose intersection with the subdivision edges consists of a small number ( $O(m)$ ) of connected components and the subdivisions on either side of the cut are also  $m$ -guillotine. With a minor change of the proof of [77], Mitchell established a PTAS for minimum length rectangular partition problem. Mitchell [78,79] further extended this  $m$ -guillotine subdivision technique to other geometric optimization problems, including Euclidean and rectilinear Steiner tree problems, and obtained PTAS for them.

### Variations of Steiner Trees

Successful researches on classical Steiner tree problems encourage extensive study on variations of Steiner trees with various application backgrounds. Currently, they form a quite active research direction in Steiner trees.

In VLSI design, one considers several sets of terminals and finds a minimum total length packing of Steiner trees for these sets under the following situation [82]: The edges of the Steiner trees are required to lie in channels between cells. Each channel has a capacity which tells at most how many edges can run through it.

A complicated computer network usually consists of several nets of different speeds. The following problem was proposed based on such a background: Consider an undirected network with multiple edge weights  $(c_1(e), \dots, c_k(e))$  ( $c_1(e) > \dots > c_k(e)$ ). Given a subset  $N$  of vertices and a partition  $\{N_1, \dots, N_k\}$  of  $N$  with  $|N_1| \geq 2$ , find a subnetwork interconnecting  $N$  with minimum total weight such that the length of any edge  $e$  on a path between a pair of vertices in  $N_j$  is at least  $c_j(e)$  [43,57].

To construct roads of minimum total length to interconnect  $n$  highways under the constraint that the roads can intersect each highway only at one point in a designated interval which is a line-segment, a generalization of Euclidean Steiner trees has been proposed and studied. Du, Hwang, and Xue [35] presented a set of optimality conditions for the problem and showed how to construct a solution to meet this set of optimality conditions.

Constructing phylogenetic trees is an important topic in computer biology. One of formulations is as follows: For a fixed alphabet  $A$ , let  $d$  denote the Hamming distance on  $A^n$ , i.e.  $d((a_1, \dots, a_n), (b_1, \dots, b_n))$  equals the number of indices  $i$  such that  $a_i \neq b_i$ . Given a set  $P$  of points in the metric space  $(A^n, d)$ , find a Steiner minimum tree for  $P$ . This problem is known to be NP-hard. (See [47].)

When a new customer is out of original telephone network, the company has to build a new line to connect the customer into the network. This situation brings us an on-line Steiner tree problem as follow: Assume that a sequence of points in a metric space are given step by step. In the  $i$ th step, only locations of the first  $n_i$  points in the sequence are known. The problem is to construct a shorter network at each step based on the network constructed in previous steps. The study of on-line problems was initiated by [89] and [73]. A criterion for the performance of an on-line algorithm is to compare the solution generated by the on-line algorithm with the solution of corresponding off-line problem. In the Euclidean plane, it has been known that the worst-case ratio of lengths between on-line solution and off-line solution is between  $O(n \log n / \log \log n)$  and  $O(n \log n)$  [2,96,99].

Listing all variations and reviewing each of them would take tremendous time and space. It should not be the purpose of this short article. Therefore, we next review a few for which some significant results have been recently obtained.

### Steiner Arborescence

Given a weighted directed graph  $G$ , a vertex  $r$ , and a subset  $P$  of  $n$  vertices, a *Steiner arborescence* is a directed tree with root  $r$  such that for each  $x \in P$  there exists a path from  $r$  to  $x$ . The shortest Steiner arborescence is also called a *minimum Steiner arborescence*. Computing minimum Steiner arborescence is an NP-hard problem. Also, one knows that if  $NP \neq P$ , then the best possible performance ratio of polynomial time approximation for this problem is  $O(\log n)$ . This means that although, like the minimum spanning tree, the minimum arborescence as a shortest arborescence tree without Steiner points can be computed in polynomial time, the Steiner ratio (the maximum lower bound for the ratio of lengths between the minimum Steiner arbores-

cence and the minimum arborescence for the same set of given points) in directed graphs is zero. Z. Dai and others [20,28] applied Arora's techniques to this problem and obtained the best known result that for any  $\varepsilon > 0$  there exists a polynomial time approximation with performance ratio  $O(n^\varepsilon)$ . An open problem (as of 2000) remains for closing the gap between the lower bound and the upper bound for the performance ratio.

A version of this problem in the rectilinear plane has a great interest in VLSI designs and an interesting story in the literature. Given a set  $P$  of  $n$  points in the first quadrant of the rectilinear plane, a *rectilinear Steiner arborescence tree* is a directed tree rooted at the origin, consisting of all paths from the root to points in  $P$  with horizontal edges oriented in left-to-right direction and vertical edges oriented in bottom-up direction. What is the complexity of computing the minimum rectilinear arborescence? First, it was claimed that a polynomial time algorithm was found. However, S.K. Rao, P. Sadayappan, Hwang, and P.W. Shor [84] found a serious flaw in this algorithm. Although they could not show the *NP*-completeness of the problem, they pointed out the difficulties of computing the minimum rectilinear arborescence in polynomial time. They also showed that while the ratio of lengths between a minimum arborescence tree and a minimum Steiner tree for the same set of points tends to infinity, there is a polynomial time approximation with performance two. Recently (2000), W. Shi and C. Su [88] showed that computing the minimum rectilinear arborescence is *NP*-hard. B. Lu and L. Ruan [72] showed, by employing Arora's techniques, that there is a polynomial time approximation scheme for the problem.

### Edge-length and Number of Steiner Points

In wavelength-division multiplexing (WDM) optical network design [68,83], suppose we need to connect  $n$  sites located at  $p_1, \dots, p_n$  with WDM optical network. Due to the limit in transmission power, signals can only travel a limited distance (say  $R$ ) for guaranteed correct transmission. If some of the intersite distances are greater than  $R$ , we need to provide some amplifiers or receivers/transmitters at some locations in order to break it into shorter pieces. This situation requires us

to consider the problem of minimizing the maximum edge-length and the number of *Steiner points* in design of WDM optical network. To do so, two variations of Steiner trees have been studied.

The first is to minimize the number of Steiner points under upper bound for edge-length. That is, given a set of  $n$  terminals  $X = \{p_1, \dots, p_n\}$  in the Euclidean plane  $R^2$ , and a positive constant  $R$ , the problem is to compute a tree  $T$  spanning a superset of  $X$  such that each edge in the tree has a length no more than  $R$  and with the minimum number  $C(T)$  of points other than those in  $X$ , called *Steiner points*. This problem is called *Steiner tree problem with minimum number of Steiner points*, denoted by *STP-MSP* for short. G.-L. Lin and G.H. Xue [69] showed that the STP-MSP problem is *NP*-hard. They also showed that the approximation obtained from the minimum spanning tree by simply breaking each edge into small pieces within the upper bound (called *steinerized spanning tree*) has a worst-case performance ratio at most five. D. Chen and others [21] showed that this approximation has a performance ratio exactly four. They also presented a new polynomial time approximation with a performance ratio at most three and a polynomial time approximation scheme under certain conditions. Lu and others [71] studied the STP-MSP in rectilinear plane. They showed that in the rectilinear plane, the steinerized spanning tree has performance ratio exactly three and there exists a polynomial time approximation two.

The second is to minimize the maximum edge-length under an upper bound on the number of Steiner points. That is, given a set  $P = \{p_1, \dots, p_n\}$  of  $n$  terminals and an positive integer  $k$ , we want to find a Steiner tree with at most  $k$  Steiner points such that the length of the longest edges in the tree is minimized. This is one of the bottleneck Steiner tree problems. Wang and Du [98] showed that:

- a) if  $NP \neq P$ , then the performance ratio of any polynomial time approximation for the problem in the Euclidean plane is at least  $\sqrt{2}$ ;
- b) if  $NP \neq P$ , then the performance ratio of any polynomial time approximation for the problem in the rectilinear plane is at least two;
- c) there exists a polynomial time approximation with performance ratio two for the problem in both rectilinear and Euclidean planes.

## Multiphase

Given an edge-weighted complete graph with vertex set  $X$  ( $|X| = n$ ) and subsets  $X_1, \dots, X_m$  of vertices, the problem is to find a minimum weighted subgraph  $G$  such that for every  $i = 1, \dots, m$ ,  $G$  contains a spanning tree for  $X_i$ . This problem is called *subset interconnection designs* or *multiphase spanning network* problem [29,37]. Du and others [41] showed that if  $NP \neq P$ , then the best performance ratio of polynomial time approximation for this problem is  $\ln n + O(1)$ .

Given an edge-weighted graph  $B$  with vertex set  $X$  and subsets  $X_1, Y_1, \dots, X_m, Y_m$  of  $X$  with  $X_i \cap Y_i = \emptyset$ , the problem is to find a minimum weighted subgraph  $G$  such that for every  $i = 1, \dots, m$ ,  $G$  contains a Steiner tree for  $X_i$  without using vertices not in  $Y_i$ . This problem is called *multiphase Steiner network* problem. Both multiphase spanning network and Steiner network problems arose in communication network design [81] and vacuum system design [37]. For the former one, when the solution is a forest, the system  $(X_1, \dots, X_m)$  is called *subtree hypergraph*. Such a system has various applications in computer database schemes [7] and statistics. It is also related to chordal graphs [42,45]. R.E. Tarjan and M. Yannakakis [95] gave a  $O(m+n)$ -time algorithm to tell whether a set system is a subtree hypergraph or not.

Comparing the phylogenetic tree problem with multiphase Steiner network problem, we would find some similarities between them if we look at each coordinate like a phase. For multiphase Steiner tree problem, if the solution is a tree, then we have either a good heuristic or a polynomial time computable exact solution [37]. This suggests that studying the relationship between the two problems will hopefully find a new construction of phylogenetic trees.

L. Ruan and others [85] found that multiweight Steiner tree problem can be transformed to multiphase Steiner tree problem. This initiates new line to study both problems.

### Keywords

Stochastic programming; Mathematical program with equilibrium constraints; Stackelberg game;

Hierarchical optimization; Variational inequality problem; Nondifferentiable nonconvex program

A stochastic bilevel program (SBP) is a generalization of an ordinary bilevel program (BP; cf. ► [Bilevel programming: Introduction, history and overview](#)), which allows the uncertainty in the values of the problem parameters to be expressed by a probability distribution on some or all of the variables of the model. The introduction of these random variables in the BP modifies some of its properties, both its mathematical properties, as well as the resolution time needed to find a satisfactory solution.

Nevertheless, a stochastic BP is essentially a bilevel program, and it is therefore important to summarize the essential features of this class of models before moving on to the effects of incorporating uncertainty.

### Principal Features of Bilevel Programs

Bilevel programs are optimization problems with two objectives, one at each level, which interact through the sharing of some of the problem variables. BP can be perhaps most easily understood through comparison with the leader-follower (or Stackelberg) paradigm in game theory. In this context, the leader is represented through the upper level optimization problem. In particular, the leader seeks to optimize a function of two vectors, one which he explicitly controls,  $x$ , and another vector which describes the reactions of the followers to his actions. These reactions are described by  $y$ . Since the reactions of the followers have an impact on the objective of the leader, the leader's optimization problem is to solve  $\min f(x, y)$ , subject to  $x \in \mathcal{X}$ ,  $y \in \mathcal{Y}$ . Note that the leader may be subject to constraints on his action, given by  $\mathcal{X}$ . In addition, in some cases, there is more than one possible reaction  $y$  from the followers in response to a given  $x$ ; if this happens, the leader may take different strategies for accepting a single  $y$  when he decides on the optimal  $x$ , or  $y$  will be restricted to a set,  $\mathcal{Y}$ .

Just as the leader seeks to minimize a function,  $f(x, y)$ , the followers' behavior is also described by an optimization process,  $t(x, y)$ . In this case, the followers accept the leader's decision,  $x$ , as a parameter, and seek to optimize their objective over  $y$ , subject to some constraints, described by the set  $\mathcal{Z}(x)$ , which may also depend on the parameter  $x$ . That is, the lower level, fol-

lowers' problem is given by  $\min t(x, y), y \in Z(x)$ , which is clearly a parametric program with  $x$  as a parameter.

In summary, then, BP is expressed by a pair of optimization programs, coupled through the passing of an upper-level variable as a parameter to the lower level problem. One can express quite generally the vector  $y$  as a possibly nonunique solution to the lower-level problem, whose (parametric) solution set is given by  $S(x)$ :

$$\begin{cases} \min_{\substack{x \in X \\ y \in Y}} f(x, y) \\ \text{s.t. } y \in S(x), \end{cases}$$

where  $S(x) = \{y: y \in \operatorname{argmin}_{z \in Z(x)} t(x, z)\}$ .

The definition of BP in terms of a generic, lower-level parametric solution set  $S(x)$  allows us to introduce a further generality into the model: in many interesting applications, the lower-level, or followers' behavior, cannot be expressed as an optimization problem, but can be described by an *equilibrium process*, which is given mathematically by a *variational inequality problem* (VIP). That is,  $S(x) = \{y \in Z(x): T(x, y)^\top (y - \hat{y}) \leq 0, \hat{y} \in Z(x)\}$ . These bilevel programs are often referred to as *mathematical programs with equilibrium constraints*, (MPEC). In fact, MPEC can be considered as a more general form of BP, since any optimization problem can be expressed as a VIP, but the converse is true only when  $T(x, \cdot) = \nabla_y t(x, \cdot)$ .

Bilevel programs have a number of mathematical and computational particularities with respect to standard one-level optimization programs. The most striking characteristic of BP is that the upper-level function is not differentiable, even in the case where the lower-level response vector,  $y$ , is unique as a function of  $x$ , that is  $y = S(x)$ . Indeed,  $y$  is an implicit function in terms of  $x$ . A further observation of BP shows that, for each evaluation of  $f(x, y)$ , it is necessary to solve the lower-level problem, just to obtain an iterate for  $y$ . The computational complexity of BP is thus increased dramatically, since each iteration in the resolution of  $f$  requires the resolution of  $t$ .

### Examples of Bilevel Programs

While the leader-follower paradigm is useful for illustrating the hierarchical nature of the two levels in a bilevel program, it does not provide a sufficient scope of the range of problems included in the class of bilevel

programs. Indeed, bilevel programs describe problems in many areas of engineering and management, as well as problems in game theory. Following are a few examples of bilevel programs, which will furthermore help illustrate how uncertainty can be explicitly taken into account. (See also [10].)

*Example 1 (Optimal pricing problem)* In a number of application areas, especially the *transportation* and *telecommunications* sectors, a central operator seeks to maximize profit, given that the market that he is targeting is competitive, and furthermore that his potential clients can refuse to participate should the price be set too high, or service quality too low. These problems have an inherent bilevel form. Determining the optimal tolls to set on a highway, or the price of a long-distance phone service are problems of this type.

The upper-level describes the manager's problem: it may consist in determining the prices so as to achieve profit maximization, or the problem of determining the level of service to offer on the infrastructure which optimizes a given performance criterion, perhaps taking into account the cost of offering such a service level. The policy instrument,  $x$ , is then the price to be set by the manager for use of the infrastructure, and/or the service level of the infrastructure (capacity, travel time, or access time improvements, etc.). The feasible set  $X$  generally contains bounds on the possible values of  $x$ . When the manager seeks to determine the optimal level of capacity improvements to an existing infrastructure, the resulting bilevel problem is known as the *network design problem*.

The lower-level problem describes the users' responses to the prices and/or service levels set by the manager. The users' response is given by the level of use on each link of the infrastructure,  $y$ . In general, one assumes that the users' behavior follows an equilibrium principle, given by an cost operator (or utility function),  $T(x, y)$ . The cost operator gives the cost of using the infrastructure as a function of the price vector  $x$  and the amount of use  $y$ . The interpretation of (Nash) *equilibrium* is the following: A usage pattern  $y$  is in equilibrium (stable) if no single user can reduce his own cost (or increase his utility) by modifying his current usage pattern. The lower-level feasible set,  $Z(x)$  will then include demand satisfaction constraints (where the total demand level may be a function of the price or service

level,  $x$ ) and may include capacity constraints on the infrastructure.

The deterministic bilevel pricing model is then given by:

$$\begin{cases} \max_{x \in X} & f(x, y), \\ \text{s.t.} & y \in S(x), \end{cases} \quad (1)$$

where  $S(x) := \{y \in Z(x) : T(x, y)^\top (y - \hat{y}) \leq 0, \hat{y} \in Z(x)\}$ .

Permitting the incorporation of random variables into the optimal infrastructure pricing model can be quite useful for increasing the realism of the model. In particular, the demand for the use of the infrastructure can be estimated through historical data or surveys, but generally with some random error. In this case, demand can be expressed as a random variable, and then  $Z(x) := Z(x, \omega)$ , where  $\omega$  belongs to a probability space  $(\Omega, \mathcal{A}, \mathcal{P})$ . Similarly, the maximum usage level of the infrastructure, that is, the link capacities included in  $Z(x)$ , can depend on a number of factors which cannot be described precisely, but whose effect is to modify upper usage limits according to a known probabilistic law. In addition, the user's cost function on the infrastructure,  $T(x, y) := T(x, y, \omega)$  can vary according to a known distribution.

*Example 2 (Stackelberg–Nash equilibrium)* The game theoretic model of a *Stackelberg–Nash* (or *Stackelberg–Nash–Cournot*) equilibrium permits representing a number of important market phenomena. The model assumes a market in which  $N$  firms produce a single good, each competing for maximum market share. In addition, there is a single firm (or government) that also produces the good, but is capable of reacting to the  $N$  other firms' production when determining how to set its own production level.

This paradigm is successfully applied, for example, to utility markets, in which both private and public firms compete to sell the same utility; power generation is one such example. The upper-level optimization problem,  $\max_x f(x, y)$  represents the leader's profit function, and  $x$  the leader's production level. The lower-level represents the Nash equilibrium problem among the  $N$  firms, known as the followers, with  $y := y(x)$  being the followers' production levels, given the leader's production decision. Each follower then solves  $\max_{y_i} t_i(x, y)$ ; and the equilibrium of the noncoopera-

tive Nash game can therefore be expressed as a VIP, as in the example above.

The incorporation of uncertainty in the Stackelberg–Nash model would then take the form of a randomly varying demand from the market, and possibly uncertainty in the profit functions themselves.

*Example 3 (Structural optimization)* Among the large number of potential applications of bilevel optimization in engineering, one which has been the subject of much research attention is that of finding the design of a mechanical structure which has the best performance under the influence of external forces: structural optimization.

As is the case in the examples above, *structural optimization* problems also have an inherent bilevel form. The upper level objective function  $f(x, y)$  measures some characteristic of the structure, such as its construction cost, weight, or stiffness, with  $y$  representing the performance measure. This objective function is optimized by selecting design parameters,  $x$ , which express the shape of the structure, and the choice and amount of material to be used in the design. In addition, the structure may be subject to behavioral constraints within the upper-level problem, such as bounds on the displacements, stresses and contact forces. These constraints define the feasible region  $\mathcal{Y}$ . Budget limits on the amount of available material, if present, would be included in a set  $\mathcal{X}$ .

The lower-level problem describes the behavior of the structure given the choices of the design variables, possible contact conditions with foundations or boundaries, (the set  $Z$ ), and the external forces acting on it,  $F$ . For elastic structures, the behavior is given by the equilibrium law of minimal potential energy,  $\Pi(x, y)$ , which determines the values of the (lower-level) state variables, that is, the displacements, stresses and contact forces,  $y$ . The matrix  $K(x)$  represents the stiffness of the material, and is symmetric and positive semidefinite.

The deterministic structural optimization problem thus described then is:

$$\begin{cases} \min_{\substack{x \in \mathcal{X} \\ y \in \mathcal{Y}}} & f(x, y), \\ \text{s.t.} & y \in \operatorname{argmin}_{z \in Z} \Pi(x, z), \end{cases} \quad (2)$$

where  $\Pi(x, y) := (1/2)y^\top K(x)y - F^\top y$ .

The introduction of uncertainty into the structural optimization model can be of great use in permitting the modeler to take into account variations in external forces (due for example to wind and other weather conditions, varying traffic on a bridge, etc.) and variations in the material properties. In the first case, the variation in external forces can be described by setting  $F = F(\omega)$ , where  $\omega \in \Omega$ . Note that a failure to take this variability into account may lead to structures with unwanted vibration under certain weather conditions, as the topology optimization will assign bars only where needed to sustain the described forces; hence random forces left out of the optimization will not be accounted for by the resulting structure. Note further that the structure that will result from this stochastic bilevel optimization will be one that responds best ‘on average’ to the range of possible forces. In certain cases, where any failure is unacceptable (e.g., when designing bridges), it may be preferable to use a *worst-case approach*, which will result in more costly designs that minimize however the risk of failure (rather than minimizing cost or some other characteristic of the structure).

Uncertainty in other problem parameters can be accommodated in a similar manner. Taking into account the variability in material properties, one would set  $K(x) = K(x, \omega)$ .

**Properties of the Stochastic Bilevel Program**

The presence of random variables in the bilevel program means that one can no longer calculate exactly the vectors  $x$  and  $y$ , since their values depend on parameters which vary randomly. Instead, one can calculate the values of  $x$  and  $y$  that optimize  $f$  on average; the objective is then to minimize the expected value of  $f(x, y, \omega)$ . The stochastic bilevel program is defined below, with the more general lower-level VIP:

$$\text{SBP} \quad \begin{cases} \min & E_\omega [f(x, y, \omega)] \\ \text{s.t.} & x \in X, \\ & y(\omega) \in S(x, \omega), \quad \omega \in \Omega, \end{cases}$$

where  $S(x, \omega) := \{y \in Z(x, \omega) : T(x, y, \omega)^\top (y - \widehat{y}) \leq 0, \widehat{y} \in Z(x, \omega)\}$  denotes the set of solutions to the lower-level variational inequality defined by the parameterized mapping  $T(x, \cdot, \omega)$  and feasible set  $Z(x, \omega)$  (presumed convex). The random variable  $\omega$  is defined on a probability space  $(\Omega, \mathcal{A}, \mathcal{P})$ .

In its general form, the objective function of the stochastic bilevel program can be a multiple integral when  $\omega$  is a vector of continuous random variables. That is,  $E[f(x, y, \omega)] := \int_\Omega f(x, y, \omega) dF(\omega)$ . However, this integral is in most cases very difficult to evaluate. For that reason, as is the case in the majority of stochastic programs at this time, a discretization of the random distributions is used: one lets  $\mathcal{L}$  represent the discrete set of random observations obtained from  $\Omega$ , numbered  $\ell = 1, \dots, |\mathcal{L}|$ , and  $\rho_\ell$  the probability of each scenario  $\ell \in \mathcal{L}$ , with  $\sum_{\ell \in \mathcal{L}} \rho_\ell = 1$ . This allows one to express the expected value in the objective function as a sum:  $E[f(x, y_\ell)] := \sum_{\ell \in \mathcal{L}} \rho_\ell f(x, y_\ell)$ . The resulting problem is referred to as SBP- $\mathcal{L}$ .

In what follows, it is assumed that the set of random observations has been expressed as a discrete set. (For information on the additional assumptions needed in the case of a continuous distribution, see [1,12,16]).

Consider the following assumptions:

- i)  $X$  is nonempty and closed.
- ii) The lower-level constraint set is of the form  $Z_\ell(x) := \{y : g_\ell^i(x, y) \leq 0, i = 1, \dots, k\}$ ,  $\ell \in \mathcal{L}$ , where each function  $g_\ell^i$  is continuous and convex in  $y$  for each  $x \in X$ . Further, either  $g_\ell^i(x, \cdot) = g_\ell^i(\cdot)$ ,  $i = 1, \dots, k$ ,  $\ell \in \mathcal{L}$ , that is,  $Z_\ell(x) = Z_\ell$ , or for each  $x \in X$ ,  $\ell \in \mathcal{L}$ , there is a  $y$  such that  $g_\ell^i(x, y) < 0$ ,  $i = 1, \dots, k$ .
- iii) There exists an  $(x, y_\ell) \in \mathcal{P}_\ell := \{(x, y) \in \text{gr } S_\ell : x \in X\}$  with  $f(x, y_\ell) < \infty$  for all  $\ell \in \mathcal{L}$ , where  $\text{gr } S_\ell := \{(x, y) : y \in S_\ell\}$  is the graph of  $S_\ell$ .
- iv) (Inf-compactness)  $f$  is lower semicontinuous, proper, and has bounded level sets on  $\cup_{\ell \in \mathcal{L}} \mathcal{P}_\ell$ .

Perhaps the first property of interest is that of the existence of a solution.

**Theorem 4 (Existence of optimal solutions to SBP- $\mathcal{L}$ )** *Let the assumption ii) hold, and the mapping  $T_\ell$  be continuous. Then, the graph of  $S_\ell$ ,  $\text{gr } S_\ell$ , is closed for each  $\ell \in \mathcal{L}$ . Hence, under the additional assumptions i), iii), and iv), there exists at least one optimal solution to SBP- $\mathcal{L}$ .*

*Proof* If  $\text{gr } S_\ell$  is closed for each  $\ell \in \mathcal{L}$ , then the assumptions imply the inf-compactness of the extended function  $f + \delta_{\widehat{Z}}$ , where  $\widehat{Z} := \cup_{\ell \in \mathcal{L}} Z_\ell$ . From this, the existence of a solution follows from Weierstrass’ theorem. But by condition ii), either  $Z_\ell(x) = Z_\ell$ , in which case the closedness of  $\text{gr } S_\ell$  follows from the continuity

of  $T_\ell$ , or the Slater condition holds, in which case the closedness of  $Z_\ell$  follows from [7, Lemma 1].

The conditions required in the preceding existence result are weaker than those of some previously considered requirements on bilevel model formulations, and as such, may be particularly interesting for a number of important applications. One such example can be found in (stochastic or deterministic) structural optimization problems; in this case, for example, it can be shown, that there exists an optimal solution even in the presence of zero design bounds. (See [2] for further details.)

A second property of interest is whether or not the problem is a *convex optimization problem*. In most cases, neither deterministic nor stochastic bilevel problems will be convex. However, there is a special form of the stochastic bilevel program which may possess the desired convexity property.

Consider the following special case of SBP, in which the upper-level objective function  $f$  depends on the lower-level solution only in the sense of its optimal value. The deterministic form of this problem has been analyzed in great detail in [15], and is defined as follows:

$$\text{SBPOV} \quad \begin{cases} \min & E_\omega [f(x, p(x, \omega))], \\ \text{s.t.} & x \in \mathcal{X}, \\ & p(x, \omega) := \inf_{y \in Z(x, \omega)} t(x, y, \omega). \end{cases}$$

The discretized formulation, SBPOV- $\mathcal{L}$ , of this special case is analogous to that of the general bilevel program.

**Theorem 5 (Convexity of SBPOV- $\mathcal{L}$ )** *In addition to the assumptions i)–iv), assume, for each  $\ell \in \mathcal{L}$ , that  $t_\ell$  is convex and continuous, and  $g_\ell^i$ ,  $i = 1, \dots, k$ , are convex. Then, each function  $p_\ell := \inf_{y \in Z_\ell(x)} t_\ell(x, y)$  is convex on  $\mathcal{X}$ . Further, assume that  $\mathcal{X}$  is convex, and that the function  $f$  is convex and increasing in its second argument. Then, the implicit upper-level objective function  $x \mapsto \sum_{\ell \in \mathcal{L}} \rho_\ell f(x, p_\ell(x))$  is convex on  $\mathcal{X}$ , so that SBPOV- $\mathcal{L}$  is a convex problem.*

*Proof* One needs only to establish the convexity of  $p_\ell$  on  $\mathcal{X}$  for every  $\ell \in \mathcal{L}$ , but this result follows from the assumptions and [5, Thm. 5].

Note that two-stage stochastic programs are in fact equivalent to the problem SBPOV: two-stage stochastic

linear programs (2S-SLP) are obtained as a particular form of this problem, that is, the *right-hand side perturbation model*, as discussed by [15, p. 189], in which the upper-level variable is located only on the right-hand side of the lower-level constraints. Consequently, the convexity of the two-stage stochastic programs can be obtained directly from the preceding result on SBPOV. (These and other such relations are explored in [12].)

A third property of interest for the resolution of the model concerns the differentiability of the upper-level objective function.

Let us first present some additional (and stronger) assumptions, that, among other things, will guarantee the uniqueness of the lower-level solution,  $y_\ell$  for each  $x \in \mathcal{X}$  and each  $\ell \in \mathcal{L}$ .

- $f$  is continuously differentiable.
- The lower-level constraint set is of the form  $Z_\ell(x) := \{y: g_\ell^i(x, y) \leq 0, i = 1, \dots, k\}$ , where each function  $g_\ell^i$  is twice continuously differentiable and convex in  $y$  for each  $x \in \mathcal{X}, \ell \in \mathcal{L}$ . Furthermore, for each  $x \in \mathcal{X}, \ell \in \mathcal{L}$ ,  $Z_\ell(x) \neq \emptyset$ , and  $Z_\ell(x) \subset B_\ell$ , for some open and bounded set  $B_\ell$ .
- Let  $\mathcal{I}_\ell(x, y) := \{i = 1, \dots, k: g_\ell^i(x, y) = 0\}$ . Then, for each  $x \in \mathcal{X}, \ell \in \mathcal{L}$ , and  $y \in S_\ell(x)$ , the partial gradients  $\nabla_y g_\ell^i(x, y)$ ,  $i \in \mathcal{I}_\ell(x, y)$ , are linearly independent.
- $T_\ell$  is continuously differentiable and strongly monotone in  $y_\ell$  for each  $x \in \mathcal{X}, \ell \in \mathcal{L}$ .

**Theorem 6 (Directional differentiability of SBP- $\mathcal{L}$ )** *Suppose that SBP- $\mathcal{L}$  has a solution and let the assumptions a)–d) be satisfied. Then, the implicit function  $x \mapsto \sum_{\ell \in \mathcal{L}} \rho_\ell f(x, y_\ell(x))$  of SBP- $\mathcal{L}$  is locally Lipschitz continuous and directionally differentiable on  $\mathcal{X}$ .*

*Proof* By [13, Thm. 2.1], the assumptions imply that the implicit mapping  $x \mapsto S_\ell(x)$  is locally Lipschitz continuous, for each  $\ell \in \mathcal{L}$ . Then, the result follows directly from [14].

## Algorithms for Stochastic Bilevel Programs

The last essential ingredient needed in order to study and apply stochastic bilevel programs to real problems is an efficient algorithm for solving the model. As mentioned earlier, the deterministic bilevel problem is already quite difficult and time-consuming to solve; the introduction of a discrete random distribution on some

or all of its parameters causes an even greater increase in the problem size. For this reason, the development of efficient methods is primordial, as are the use of *decomposition* and *parallel strategies*, whenever possible.

Next, one method for generating subgradients of  $f$  is presented (based on [11]). Note that the algorithm utilizes the local Lipschitz continuity and directional differentiability of the implicit function  $f$ , and thus requires the additional assumptions presented above. Then, a penalty method making use of a merit function reformulation of the VIP is discussed, followed by a perturbation method which uses the *Karush–Kuhn–Tucker conditions* (KKT) of the VIP.

For a given  $x \in X$  and  $\ell \in \mathcal{L}$ , let  $y_\ell$  be the (unique) solution to the lower-level problem, and let  $\mathcal{I}(x, \ell) := \{i = 1, \dots, m: g_i^j(x, y) = 0\}$ . One then introduces the subsets  $\mathcal{I}_+(x, \ell)$  and  $\mathcal{I}_0(x, \ell)$  of  $\mathcal{I}(x, \ell)$  for the active constraints whose (unique) multipliers satisfy  $\lambda_i > 0$  and  $\lambda_i = 0$ , respectively. In the event that  $\mathcal{I}_0(x, \ell)$  is nonempty (that is, strict complementarity does not hold at  $y_\ell$ ) one can further introduce a subset  $\mathcal{J}(x, \ell)$  of  $\mathcal{I}(x, \ell)$  for which the requirement is that  $\mathcal{I}(x, \ell) \supseteq \mathcal{J}(x, \ell) \supseteq \mathcal{I}_+(x, \ell)$  holds. Let  $g_{\mathcal{J}}$  and  $d_{\mathcal{J}}$  denote the subvector of  $g$  and subvector of  $d$  where only rows  $i \in \mathcal{J}$  are included.

Applying the analysis of [11], a subgradient of  $f$  can be calculated as follows.

First, for each  $\ell \in \mathcal{L}$ , solve the following linear system of equations:

$$\begin{pmatrix} \nabla_y L_\ell(x, y_\ell, \lambda_\ell) & -\nabla_y g_{\mathcal{J}(x, \ell)}(x, y_\ell)^\top \\ \nabla_y g_{\mathcal{J}(x, \ell)}(x, y_\ell) & 0^{m \times |\mathcal{J}(x, \ell)|} \end{pmatrix} \times \begin{pmatrix} d_{y_\ell} \\ d_{\lambda_{\mathcal{J}(x, \ell)}} \end{pmatrix} = \begin{pmatrix} -\nabla_y f(x, y_\ell) \\ 0^m \end{pmatrix}$$

in order to obtain  $d_{y_\ell}$ , where  $L_\ell(x, y_\ell, \lambda_\ell) := T_\ell(x, y_\ell) + \nabla_y g(x, y_\ell)^\top \lambda_\ell$ , and  $y_\ell := y_\ell(x)$ .

Then, a subgradient of  $f$  at  $x$  is given by the formula  $\xi_f(x) := \sum_{\ell \in \mathcal{L}} \rho_\ell [\nabla_x f(x, y_\ell) + \nabla_x L_\ell(x, y_\ell, \lambda_\ell)^\top d_{y_\ell} - \nabla_x g_{\mathcal{J}(x, \ell)}(x, y_\ell)^\top d_{\lambda_{\mathcal{J}(x, \ell)}}]$ .

The subgradient can be used in an algorithm for the heuristic solution of the problem or embedded within a more sophisticated algorithm. The following *subgradient projection algorithm* utilizes the fact that  $f$  is differentiable almost everywhere and in particular when the  $y_\ell, \ell \in \mathcal{L}$ , are strictly complementary:

Given  $x \in X$

An initial step in the direction of an arbitrary element  $-\xi_f(x) \in -\partial f(x)$  is taken, followed by a Euclidian projection onto  $X$ : a backtracking line search in this steplength is made so that either the resulting feasible solution has a sufficiently lower objective value, or a predetermined steplength is applied, whichever is greater.

**Subgradient projection method**

Note that, at points of nondifferentiability, the traditional projection method may break down because the negative of the subgradient may then not be a descent direction; in order to obtain a well-defined iteration at such points, one therefore utilizes a steplength which is the maximum of the one supplied by the backtracking line search and the result of a predetermined steplength formula used in traditional *subgradient optimization* techniques.

See [11] for the deterministic analog of the above analysis for calculating subgradients in a *bundle method* for the solution of a deterministic bilevel problem. This can be viewed as a more advanced technique than the above which ensures convergence to a stationary point.

Consider the following parallel resolution strategy for this model. In some cases, one may identify a cluster of scenarios with similar values. Then, by allocating these to the same processor, one may solve the corresponding lower-level problems utilizing efficient re-optimization procedures given that any of them have been solved to optimality, since the optimal solution to any one of them is feasible and near-optimal to all the others. Further, for scenarios with slightly differing sets,  $\mathcal{J}(x, \ell)$ , consider sorting the scenarios in each set so that  $|\mathcal{J}(x, \ell)|$  is increasing. Then one may solve the preceding linear systems in sequence, expanding the matrix with the necessary rows and columns and utilizing the solution to the former system as a starting point in the search for the next. The fact that the choice of  $\mathcal{J}(x, \ell)$  is arbitrary in the range of active constraints may be used to minimize the number of scenarios with distinct values of  $\mathcal{J}(x, \ell)$ .

By reformulating the variational inequality in the lower level through the use of a *merit* (or *gap*) func-

tion and introducing a penalty parameter, it is possible to devise a different method for solving the stochastic bilevel program. The merit function is defined as follows: Assume that for each scenario,  $\ell \in \mathcal{L}$ , one can find a continuous function  $\psi_\ell$  that satisfies the following criteria:

$$\psi_\ell \geq 0$$

for every  $x \in \mathcal{X}$  and all  $y$ , and

$$\psi_\ell = 0 \Leftrightarrow y \in S_\ell(x).$$

Then, the method is based on including the new function  $\psi_\ell$  in the objective with a penalty parameter forcing it to zero, that is, for  $\eta_\ell > 0$ , one solves

$$\begin{cases} \min & \sum_{\ell \in \mathcal{L}} \rho_\ell [f(x, y_\ell) + \eta_\ell \psi_\ell(x, y_\ell)], \\ \text{s.t.} & x \in \mathcal{X}. \end{cases}$$

Note that the objective function remains separable with respect to the scenarios and can thus be decomposed and solved in parallel. For more details on this method and possible merit functions see [4,6,8,9].

A still different approach for solving MPEC or bilevel programs involves rewriting the solution set mapping of the lower-level variational inequality in terms of its KKT conditions. Letting  $\lambda_\ell$  be the (unique, under the assumptions above) vector of multipliers for the lower-level constraint set  $Z_\ell(x)$ , the KKT conditions are, for every  $\ell \in \mathcal{L}$ :

$$\begin{aligned} T_\ell(x, y) - \nabla_y g_\ell(x, y) \lambda_\ell &= 0, \\ g_\ell(x, y) &\leq 0, \quad \lambda_\ell \geq 0, \quad \lambda_\ell^\top g_\ell(x, y) = 0. \end{aligned}$$

Then, the stochastic bilevel program is written as before with the constraints above replacing the constraints  $y_\ell \in S_\ell(x)$ .

The resulting program is an equivalent one-level reformulation of SBP, but is intractable due to the presence of the complementarity constraints. In [3] the above model was reformulated by expressing the lower-level constraints as  $g_\ell(x, y) \geq 0$ ,  $\ell \in \mathcal{L}$ , and then writing the complementarity constraints as

$$g_\ell(x, y) - z_\ell = 0, \quad -2 \min(z_\ell, \lambda_\ell) = 0,$$

for every  $\ell \in \mathcal{L}$ , where  $z_\ell$  is a vector of the same dimension as  $\lambda_\ell$ , and the min operator is applied to the vectors componentwise.

The resulting problem is tractable but nonsmooth, due to the min operator. The authors in [3] then reformulated the *nonsmooth optimization* problem by using a *perturbative approximation* to the min operation. This results in a sequence of smooth optimization problems converging to the nonsmooth problem as the perturbation parameters,  $\eta_\ell$ , tend to zero.

Since the equations above are all separable with respect to the scenarios  $\ell \in \mathcal{L}$ , the same decomposition approaches can be applied to this method.

It should be noted that decomposition across scenarios may still prove insufficient for permitting the resolution of realistic stochastic bilevel programs. The use of *random sampling*, such as has been used in *stochastic quasigradient methods* and *stochastic decomposition*, as well as the development of approximation strategies, are lines of research that should be pursued in the future.

Global optimization; Random sampling; Optimal stopping; Look-ahead rules; Bayesian stopping rule

Every well-designed *global optimization* algorithm is usually equipped with three main components:

- 1) a sampling (or global) phase, whose aim is to investigate as thoroughly as possible the feasible region;
- 2) a local phase, designed to approximate good local optima;
- 3) a stopping rule, through which the algorithm is terminated either with a certificate of optimality (or an estimate of the error incurred) or with some kind of probabilistic measure of the error itself.

Many deterministic algorithm for global optimization problems are equipped with stopping criteria which enable to prove global optimality or to give a precise error bound. Unfortunately, from one side those algorithms are applicable only to strongly structured problems, like, e.g., the optimization of Lipschitz-continuous functions (with known Lipschitz constant), the minimization of concave functions (cf. ► [Concave programming](#)), or of functions which are explicitly representable as the difference of two convex functions (cf. ► [D.C. programming](#)); thus those stopping rules, based upon duality results and lower-bounding techniques, as well as the algorithms designed for those problems, cannot be applied to problems which do not possess that specific structure. On the other side, even for those strongly structured problems, it has been frequently observed that, in practice, it is quite likely that an algorithm will find the global optimum relatively quickly, but the vast majority of computational time is devoted to the proof of optimality. So, in some situations, it might be advisable to relax the requirement of certificated optimality, and to stop an algorithm as soon as there is sufficient evidence that the optimum has been found.

Stopping criteria based upon this idea are usually built after a stochastic model and are inspired from classical stopping rules developed within the field of statistical decision theory. Most, if not all, of the research in statistical stopping rules is based on the assumption that the algorithm used is either the *pure random search* or *pure Monte-Carlo* method, or *multistart*. The former is the most basic global optimization algorithm which consists only in generating a uniform ran-

dom sample in the feasible region and keeping track of the best observed function value (the record). The latter, multistart, differs from pure random sampling as it prescribes to apply a local optimization routine from each sampled point (thus it implements an effective, although computationally inefficient, local phase). Extension of the stopping rules built for these algorithms to different methods, like e. g. other two-phase methods (cf. also ► **Stochastic global optimization: Two-phase methods**) known as *multilevel single-linkage*, or *simple linkage*, has to be considered just as an heuristic.

It is possible to distinguish three main types of stopping rules, which mainly differ upon the criteria for stopping and the sophistication of the underlying stochastic model:

- 1) global exploration: stop as soon as there is sufficient evidence that all of the feasible region has been sampled;
- 2) enumeration of local optima: stop as soon as there is sufficient evidence that all local optima have been observed;
- 3) enumeration of good local optima: stop as soon as there is sufficient evidence that no local optimum better than the best so far will be observed.

It can be easily understood that the last criterion is the best one, but its practical realization poses very difficult modelization problems. In what follows, a brief account of the main models and methods for each of the three models will be given.

Let  $S \subseteq \mathbf{R}^d$  ( $d \in \mathbf{N}$ ) be the feasible region for the global optimization problem

$$f^* = \min_{x \in S} f(x). \quad (1)$$

It is assumed that the Lebesgue measure  $\mu(S)$  of  $S$  is finite and strictly positive. From elementary probability, it is easy to derive that, after  $N$  uniform points have been sampled, the probability that at least a point in the sample falls within a prescribed subset of  $S$  whose Lebesgue measure is  $\epsilon$  is given by

$$1 - \left(1 - \frac{\epsilon}{\mu(S)}\right)^N; \quad (2)$$

thus, given a prefixed probability level  $p \in (0, 1)$ , if sampling is terminated as soon as

$$N \geq \frac{\log(1-p)}{\log\left(1 - \frac{\epsilon}{\mu(S)}\right)} \quad (3)$$

then every region of volume greater than  $\epsilon$  will contain a sample point with probability at least  $p$ . Letting

$$L^\eta := \{x \in S: f(x) \leq f^* + \eta\} \quad (4)$$

be the  $\eta$ -level set of  $f$ , it is in principle possible, although extremely difficult in practice, once an error level  $\eta$  has been chosen, to let  $\epsilon = \mu(L^\eta)$ . The main disadvantage of this very simple stopping rule is that it usually prescribes to stop very late, when every region of volume  $\epsilon$ , and not just  $L^\eta$ , has been observed. In principle, this method might be applied with success to multistart: this algorithm can be seen as a pure random search method applied to the composition of the objective function  $f$  and the mapping of  $S$  into itself which arises associating to each feasible point  $x \in S$  the point which is obtained starting a local optimization routine from  $x$ . This way, being the resulting composite function piecewise constant, a (usually much) larger value of  $\epsilon$  can be safely used. Unfortunately no practical method is known which enables to approximate the correct value of  $\epsilon$ . Some attempts have been reported in the literature (see e. g. [6]), but the rules proposed, although quite simple, seem to be very inefficient in providing a quick and reliable stopping time.

The second class of methods for stopping, designed for the complete enumeration of local optima through multistart, originates from ideas introduced in [9]. If the starting points in multistart are stochastically independent, then, letting the local optima be arbitrarily numbered as  $1, \dots, T$ , the probability of hitting  $n_1$  times the first,  $n_2$  times the second, and so on, is given by

$$\frac{n!}{n_1! \dots n_T!} \theta_1^{n_1} \dots \theta_T^{n_T}. \quad (5)$$

Parameters  $\theta_j$  in (5) represent the *share* of the  $j$ th local optimum, that is, the relative volume of its *region of attraction*, or, equivalently, the probability that a local search started from a point in the sample leads to the  $j$ th local minimum. In practice, neither  $T$ , nor the shares are known. A *Bayesian decision-theoretic framework* is used, in which a prior probability distribution is given on the unknown parameters of the probabilistic model; after each observation is made, through a Bayesian updating, an a posteriori distribution is quite easily computed. Based upon this model, several rules can be obtained for stopping, depending upon different cost structures. Following a standard procedure in

Bayesian sequential decision theory, a loss function is defined which gives a measure of the trade-off between stopping and continuing sampling; then, sequentially, at each iteration the posterior expected loss is computed and the alternatives of stopping and continuing are compared. For example, one might define a loss by specifying a price to be paid either for stopping before all local optima have been found or for continuing after the global optimum has been observed. Alternatively, one can define a cost for each local search and a gain (a negative loss) incurred if a new local optimum is discovered. Stopping rules derived from this framework have the advantage of being very simple to implement; unfortunately, the model and the resulting stopping rules just depend on the number of different local optima discovered; the value of the objective function at the local optima never plays a role, so that these criteria tend to be quite conservative and highly sensible to the total number of local optima, irrespective of their value. Well known and widely used results in this framework can be found in [3]; an ingenious trick is presented in [8] which consists in ordering the observed function values at local optima; a term which takes into account the desire to stop if no optima better than the best so far is observed is thus included in the loss. Here again function values do not explicitly enter neither the model nor the stopping rules, but the relative rank of each local optimum is considered. The resulting rules, although more complex than those in [3], display a significantly better behavior.

In all of the above methods for stopping, a prior distribution has to be given on the total number of local optima and the shares; while it is quite natural to assume a Dirichlet distribution for the shares, the question of choosing a sensible prior for  $T$  is still to be answered; a seemingly interesting choice, consisting of an improper prior, giving constant weight to all positive integers, was proven to give incorrect results in [8].

The last generation of stopping rules for multistart derive from even more complex models. The idea of explicitly including function values in the model raises extremely difficult theoretical problems. In fact it is very hard to identify a sensible stochastic models for the observed function values at randomly chosen points or, even worse, at local optima obtained by starting a local optimization routine from a random starting point. Again, the best one can hope, is to define a prior

model and adapt the resulting probability distribution by means of Bayes' theorem. An attempt in this direction can be found in [1] and [2]; there it is assumed that function values at local optima obtained from multi-start follow a probability distribution which is largely unknown. Thus this probability distribution is modeled as one out of an infinite class of possible probability distributions: the prior knowledge is made explicit in the definition of a prior probability distribution over a class of distribution functions. From the literature on Bayesian nonparametric inference the so called *simple homogeneous process* [5] was selected, due to its representativeness (its realizations are dense in the space of continuous distributions) and to its computational manageability. Accordingly, stopping rules were derived which prescribe to stop as soon as

$$\int_{-\infty}^{f_n^*} (f_n^* - y) d\widehat{F}_n(y) \leq c, \quad (6)$$

where  $f_n^*$  is the record value observed after the first  $n$  samples (more precisely, after the first  $n$  local searches),  $\widehat{F}_n$  is the expected posterior distribution, computed through the prior process and the  $n$  observations of local optima,  $c$  is a threshold. The left-hand side in (3) is the expected improvement after the the next observation with respect to the current record. The effectiveness of the resulting stopping rules has been tested and very good computational results have been reported; unfortunately the rules are quite cumbersome to implement and require the setting of several parameters in the definition of the prior.

An alternative approach is described in [4], where the problem of specifying a prior distribution on the set of probability distributions is simplified assuming that function values are discretized; this way the underlying probabilistic model becomes a parametric one, although with a possibly huge number of parameters, namely the global minimum and global maximum values of  $f$ , and the probability of observing any of the discretized values between them. Although the resulting rules are attractively simple, the idea of discretizing the range is far from being a satisfactory one, as a discretization which is too large might lead to incorrect decisions on the global optimum, while a narrow one enlarges the dimension of the parameter space. Again the problem of specifying a prior on the parameters, in particular of

the global minimum and maximum, is a difficult one; moreover the sensitivity of the rules to function values is questionable: the authors prove that, using a loss function which is the difference between a cost associated to sampling and the ratio between the possible improvement over the record value and the range of values for  $f$ , the optimal stopping rule depends only on the iteration number; thus no information on the observed function values is used, thus easily leading to incorrect decisions.

Unfortunately the main difficulty in stopping a stochastic global optimization algorithm is not any of the above mentioned ones, like e. g., the difficulty of choosing parameters, the insensibility of some rules to function values or the cumbersome implementation. The real weakness of all the above mentioned approaches is the fact that all of them are based upon the analysis of stochastically independent samples in the feasible region. While this assumption is natural for pure random search and for multistart, it becomes false as soon as more refined methods are used, notably two-phase methods. Thus all of these rules become simply heuristic stopping criteria. What is worse is that they do not provide a reliable estimate of the error incurred after stopping; the user is thus left with a heuristic rule with no guarantee. It is not a surprise that most stochastic global optimization users just let their algorithm run until some time limit is exhausted. Unfortunately deriving stopping rules for more clever algorithms is an extremely hard task; some attempts have been reported in [7] when dealing with Bayesian global optimization methods (cf. ► [Bayesian global optimization](#)), but even if good stopping rules can be derived in that framework, the results are again only heuristic, as they are based upon models of the objective function which are usually not justifiable.

In conclusion, while stopping is a crucial component in stochastic global optimization and late stopping is generally the main cause of inefficiency, research in this field seems to have stopped in the last years; there is still a need for good criteria for general algorithms, capable of producing a reliable estimate of the error.

Global optimization; Random sampling; Acceptance/rejection; Multilevel methods

*Two-phase methods* are *global optimization* algorithms which consist of sampling (*global phase*) coupled with refinement or approximation of local optima (*local phase*). Although this definition is extremely general, as to encompass virtually all known methods of global optimization, the term ‘two-phase’ is generally used in connection with methods based upon random sampling and local optimization started from selected points in the sample.

To fix the notation, let the problem under consideration be that of finding

$$f^* = \min_{x \in S} f(x), \quad (1)$$

where  $S \subseteq \mathbf{R}^d$  is a  $d$ -dimensional set (usually closed, often compact) and  $f: S \rightarrow \mathbf{R}$  is a continuous objective function. On  $f$  no other special assumption is generally made except that a local search algorithm is available, which is capable of producing a *local optimum* once started from a *feasible point*. Thus, depending on the local optimization routine employed,  $f$  might, for example, be required to be continuously differentiable.

Two-phase methods are best suited for *global optimization problems* with no special structure, while different, often deterministic, methods are preferred when dealing with strongly structured global optimization problems like, e. g., concave minimization (cf. also ► [Concave programming](#)), d.c. problems (cf. also ► [D.C. programming](#)), Lipschitz continuous problems; for a general reference on these particular classes of structured global optimization problems, besides this volume, the reader might wish to consult [3].

Two-phase methods display sufficiently good behavior when the following conditions are met:

- sampling in the feasible set is not too difficult (frequently  $S$  is assumed to be a hyper-rectangle);
- the dimension  $d$  is not too high: until a few years ago  $d = 10$  seemed already to be a high dimension; more

recent developments pushed this limit to more than 60;

- the Lebesgue measure of the *region of attraction* of the global optima is not too small. The ‘region of attraction’ of a local (and, hence, also the global) optimum is defined as the maximal subset  $A \subseteq S$  characterized by the fact that a local search started from any point in  $A$  leads to that local optimum;
- the computational cost of evaluating  $f$  at a feasible point is substantially lower than that of performing a local search, and it is not extremely expensive by itself.

For low-dimensional problems, when the last condition is not met and function observation is a computationally demanding task it is preferable to switch to methods based upon approximate models of the objective function, the most well-known representative of which is the class of Bayesian algorithms (cf. also ► [Bayesian global optimization](#)).

What has come to be known as the class of *two-phase* methods consists of the following very general optimization scheme:

```

PROCEDURE two-phase()
  let  $k := 1$ ;
  WHILE (StoppingRule() == FALSE) do:
    choose  $N_k > 0$ ;
    (Begin Phase I):
    sample a set  $S_k$  of  $N_k$  points from  $S$ ;
    let  $S^k := \bigcup_{h=1}^k S_h$ 
    (Begin Phase II):
    choose  $S^* \subseteq S^k$ ;
    FOR EACH  $x \in S^*$  DO
      start a local search from  $x$ ;
    END FOR;
    let  $k := k + 1$ ;
  END WHILE;
END two-phase;

```

In practice Phase I, or *global phase*, aims at exploring as thoroughly as possible the feasible region, while in Phase II, or *local phase*, the approximation of good local optima is carried out. It can be easily seen that most methods for global optimization can be seen as special instances of the above scheme.

Phase I usually consists of *uniform random sampling*, even if some attempts have been made to use

*quasirandom* sequences which have, among others, the advantage of producing smaller gaps between sampled points.

As the main computational burden is assumed to be connected with local searches, it is natural that the main distinction between different two-phase methods lies in the decision regarding the choice of  $S^*$ , the set of starting points for local optimization. The following are some of the most well-known strategies for defining such a set:

- *pure random search*:  $S^* = \emptyset$ , that is, no local searches are performed. This method is a basic, although very inefficient, global optimization strategy. It is also known as the *pure Monte-Carlo method*;
- *best start*:  $S^* \subseteq S_k$  is equal to the set of new ‘record points’, i. e. to the set of points at which, during the current iteration, a function value strictly lower than the best so far has been observed;
- *multistart*:  $S^* = S_k$ . This method prescribes that a local search is started from every sampled point;
- *clustering*:  $S^*$  is defined as the set of record points in suitable subsets of the sample built according to a clustering procedure. The idea of clustering for global optimization dates back to two papers in the 1970s, [2] and [10], where the idea of concentrating the sample in order to approximate the regions of attraction of low-level local optima was introduced. Concentration of the sample is achieved either by discarding a fixed fraction of the points with highest function value, or by performing a single, or just a few, descent steps from points in the sample. These procedures transform the sample into a nonuniform one: clustering techniques are then employed to identify subsets of the sample with a higher-than-average concentration of points. This idea is further exploited in *density clustering* methods (see [9] and [7]) where clusters are grown around suitable ‘seed points’ by progressively enlarging an ellipsoidal set until the relative density of points of the transformed sample which fall inside the ellipsoid becomes smaller than a threshold;
- *multilevel single-linkage* (in short: MLSL). In this method the user specifies a constant sample size  $N_k = N$  and two positive reals  $\sigma$  and  $\nu$ . Then  $S^*$  is defined as follows: a point  $x \in S^k$  (the whole sample) is included in  $S^*$  if no point  $y \neq x$  in the sample  $S^k$

exists such that:

$$f(y) \leq f(x) \quad \text{and} \quad \|x - y\| \leq r_{N,k,\sigma}.$$

It is moreover required that points in  $S^*$  are ‘sufficiently far’ from the boundary, that is, given the threshold  $\nu > 0$ , it is required that

$$\text{dist}(x, \partial S) \geq \nu, \quad \forall x \in S^*,$$

and that neither a local search had been already applied to  $x$ , nor  $x$  is too near to a previously discovered local optimum.

Here  $\text{dist}$  is the Euclidean distance and  $\partial S$  denotes the boundary of  $S$ ; the variable threshold  $r_{N,k,\sigma}$  is defined as:

$$\pi^{-1/2} \left( \Gamma \left( 1 + \frac{d}{2} \right) \mu(S) \sigma \frac{\log kN}{kN} \right)^{1/d}. \quad (2)$$

In (2),  $\Gamma$  is the gamma function,  $\mu$  represents the Lebesgue measure,  $\sigma$  is a positive constant. The basic idea of this method, which was analyzed in [8], is that, instead of building clusters with prescribed shape (e.g., ellipsoidal), points are clustered by means of a distance criterion. In particular a point is clustered to another in the sample if this latter is near enough and has a better function value. Local searches are started only from unclustered points. This way, ideally linking points which are clustered together, a forest is built and local searches are started only from the root of each tree; it is hoped that each tree in the forest connects points within the region of attraction of a single local optimum. As the threshold in (2) decreases to 0, a single tree will eventually be broken into two or more connected components, and it may happen that local searches are started also from points which, in previous iterations, were not considered to be good candidates.

- *simple linkage* (in short: SL). Here  $N_k = 1$  and either  $S^* = \emptyset$  or  $S^* = S_k$  (a single point). In particular a local search will be started from the most recently sampled point  $x$  if and only if no point  $y \neq x$  in the sample  $S^k$  exists such that:

$$f(y) \leq f(x) + \epsilon \quad \text{and} \quad \|x - y\| \leq r_{k,\sigma},$$

where  $r_{k,\sigma}$  is defined as

$$\pi^{-1/2} \left( \Gamma \left( 1 + d/2 \right) \mu(S) \sigma \frac{\log k}{k} \right)^{1/d}. \quad (3)$$

Symbols used in (3) have the same meaning as before;  $\epsilon$  is a small positive constant. This method was introduced in [5] and theoretically compared with MLSL in [4]. The main differences with MLSL are in the choice of sampling a single point at each iteration and of letting the possibility of starting a local search only from the last single sampled point, instead of having the necessity, at each iteration, of reconsidering the whole sample again;

- *Topographical search.*  $S^*$  is defined as the set of local record points in the sample: given an integer  $m \geq 1$  a point is a local record if its functional value is lower than that of its  $m$  nearest neighbors. A variant of this idea was presented in [11].

In all these methods, provided that sampling produces a dense set of points in  $S$ , convergence of the best observed function value to the global optimum is achieved with probability 1. It was proven in [1] that producing a dense set of observations is, in a certain sense, also necessary. Moreover, if a prefixed accuracy  $\eta > 0$  is given and if it is assumed that the level set

$$L^\eta = \{x \in S: f(x) \leq f^* + \eta\}$$

has a positive Lebesgue measure, then all of the above algorithms will almost surely place an observation in  $L^\eta$  in a finite number of iterations. What distinguishes poorly performing methods like Pure Random Search from MLSL or Simple Linkage is the fact that, through local searches, these methods attempt to place observations in  $L^\eta$  as soon as a point is sampled in the (hopefully much larger) region of attraction of the global optimum.

Multistart succeeds in reaching this goal, starting a local search from *every* sampled point. This has the negative effect of wasting a huge quantity of computational power both during local searches leading to local (nonglobal) optima, and in discovering each local optimum more than once. Both MLSL and Simple Linkage try to reach a compromise between Pure Random Search and Multistart by starting a few local searches only from a selected set of promising points. The main theoretical properties of MLSL and SL are the following:

- the probability of starting a local search at iteration  $k$  decreases to 0 provided that  $\sigma > 2$  in MLSL and  $\sigma > 0$  in SL;
- the total expected number of local searches started, even if the algorithm is run forever without stop-

ping, is finite, provided that  $\sigma > 4$  in MLSL and  $\sigma > 2^d/d$  in SL (these results hold when  $S$  is the  $d$ -dimensional hypercube).

These two properties are crucial in evaluating the efficiency of MLSL and SL: they state that the total effort devoted to local searches is kept at a low level. The different conditions imposed on  $\sigma$  in the last property come from an important difference in the assumptions of MLSL and SL: while the former forbids local searches to be started from sampled points which are within a prefixed distance from the boundary, the latter allows local searches to be started from any point in  $S$ , including the boundary. As the dimension  $d$  increases, given, as prescribed in MLSL,  $\nu > 0$ , the probability of sampling a point whose distance from the boundary is less than  $\nu$  increases. This fact might help to explain the fact that MLSL was successfully applied only to quite low-dimensional global optimization problems. On the other hand SL was applied with success to high-dimensional global optimization problems like, e. g., the minimization of *Lennard–Jones potential energy function*, a classical test for global optimization derived from computational chemistry, characterized by the presence of a number of local optima which increases exponentially with the dimension of the problem.

Recent developments in two-phase methods aim at:

- analyzing their finite time behavior (all of the properties mentioned above were asymptotic ones), possibly leading to different definitions of the thresholds used for deciding whether to start or not local searches;
- improving the sampling phase, in order to avoid the possibility that a local search is started from a point just because no other point was sampled in a suitable neighborhood.

This last point can be tackled by building the sample in such a way that large gaps between sampled points are avoided; as an example, *quasirandom* sequences might be employed (for a general reference see [6]). It should be observed however that the substitution of pseudorandom points with quasirandom ones needs a thorough redefinition of the criteria used for starting local searches. As an alternative, the idea itself of using a threshold might be abandoned, leading to methods similar to Topographical Search.

As a concluding remark, it should be observed that all the effort in these methods is devoted to placing, at relatively low computational cost, observations in a small neighborhood of the global optimum. This effort is wasted if the algorithm is not equipped with a good stopping rule (cf. also ► [Stochastic global optimization: Stopping rules](#)). Unfortunately, no stopping rule is sensible for such poorly structured problems; the only possibility up to now has been that of using heuristic stopping criteria, some of which particularly complex, derived from simplified stochastic models. Regrettably, research in the field of stopping rules for two phase methods seems to have stalled in the last few years, probably as a consequence of the low confidence users put into statistical stopping rules which never can give a guarantee, or even an estimate, about the error in approximating the global optimum.

Stochastic integer programming; Stability analysis

As in many other branches of mathematical optimization, stochastic programming theory and algorithms have to be rethought completely when including integer requirements. Among stochastic integer programs so far the *linear two-stage model* is best understood, both structurally and algorithmically. It is the problem

$$\min \left\{ cx + Q(x, \mu) : Bx = b, x \in \mathbf{Z}_+^n \times \mathbf{R}_+^{n'} \right\},$$

where

$$Q(x, \mu) = \int_{\mathbf{R}^s} \Phi(z - Ax)\mu(d(z, A))$$

and

$$\Phi(t) = \min \left\{ qy + q'y' : \begin{array}{l} Wy + W'y' = t, \\ y' \in \mathbf{R}_+^{s'}, y \in \mathbf{Z}_+^s \end{array} \right\}.$$

Structural properties of the above model are mainly determined by the interaction of the second-stage value function  $\Phi$  and the integrating probability measure  $\mu$ . Due to the integer requirement on  $y$  the value function  $\Phi$  is no longer convex, as would have been the case with the integer-free counterpart model. Studies of the *mixed integer value function*  $\Phi$  date back to the 1970s [5]. Under mild assumptions including in particular the rationality of  $W$  and  $W'$  it holds that  $\Phi(t) \in \mathbf{R}$  for all  $t$ , and the function  $\Phi$  is lower semicontinuous. Moreover, the following properties of  $\Phi$  (established in [3,5]) are useful prerequisites for the analysis of the above model:

- 1) There exists a countable partition  $\cup_{i=1}^\infty T_i$  of the domain of  $\Phi$  such that the restrictions of  $\Phi$  to  $T_i$  are piecewise linear and Lipschitz continuous with a uniform constant  $L > 0$  not depending on  $i$ .
- 2) Each of the sets  $T_i$  has a representation  $T_i = \{t_i + K\} \cup_{j=1}^N \{t_{ij} + K\}$ , where  $K$  denotes the polyhedral cone  $W'(\mathbf{R}_+^{s'})$ ,  $t_i, t_{ij}$  are suitable points from the argument space, and  $N$  does not depend on  $i$ .
- 3) There exist positive constants  $\beta, \gamma$  such that  $|\Phi(t_1) - \Phi(t_2)| \leq \beta \|t_1 - t_2\| + \gamma$  for arbitrary  $t_1, t_2$ .

Although discontinuous, the function  $\Phi$  hence is not ‘too bad’: discontinuities only occur in subsets of hyperplanes, in its continuity regions the function is even Lipschitzian with uniform modulus, and the overall growth of the function is bounded by an affine expression.

The combination of these properties with tools from probability theory leads to statements on the *joint continuity* of  $Q$  as a function both of the decision variable  $x$  and the integrating probability measure  $\mu$ . The latter, of course, needs a proper convergence notion in the space of probability measures. Here *weak convergence of probability measures* [4] has turned out to be sufficiently broad to cover relevant applications and sufficiently strict to allow substantial conclusions. Continuity of  $Q$  both in  $x$  and  $\mu$  has direct consequences for the *stability* of the stochastic integer program when perturbing the underlying probability measure  $\mu$ . Such perturbations are motivated by two reasons: In practical modeling the probability distribution of the random parameters is always subjective. The modeler hence wants to

be sure that slight modifications of the distribution do not lead to drastic changes in the solution. Secondly, the integral defining  $Q$  is multivariate with a dimension governed by the dimension of the underlying random vector which usually is quite big. Numerical integration hence fails if  $\mu$  is nondiscrete. Approximating  $\mu$  by discrete measures then turns integrals into sums which are numerically feasible. Of course, this has to be accompanied by the safeguard that ‘close’ approximations of model data (the measure  $\mu$ ) end up in ‘close’ approximations of the model output (the optimal value and the solution set).

Under mild technical assumptions that basically ensure  $\Phi$  and  $Q$  to be well defined real-valued functions the following results on continuity, stability and rates of convergence for stochastic integer programs are known.

Fatou’s lemma and the lower semicontinuity of  $\Phi$  imply lower semicontinuity of  $Q(\cdot, \mu)$  [11,13]. Via Lebesgue’s dominated convergence theorem this extends to continuity of  $Q(\cdot, \mu)$  at a given  $x$  provided the exceptional set  $E(x)$  of all  $(z, A)$  such that  $\Phi$  is discontinuous at  $z - Ax$  has  $\mu$ -measure zero [11,13]. Since discontinuities of  $\Phi$  are located in a set of Lebesgue measure zero (cf. property 2) above) the condition on  $E(x)$  is fulfilled if  $\mu$  has a density. This also covers the first continuity result in the field obtained by L. Stougie [15]. Adding boundedness and monotonicity assumptions on densities of one-dimensional marginal distributions of linear transforms of  $\mu$  leads to *Lipschitz continuity* of  $Q(\cdot, \mu)$  [12,13]. Here the above properties 1) and 3) of  $\Phi$  are essential for the proof.

A particular problem class is given by *two-stage stochastic programs with simple integer recourse*. Here, the function  $Q$  is much better understood since it enjoys separability properties and essential parts of the analysis can be done in dimension one. Results comprise sufficient conditions for differentiability of  $Q(\cdot, \mu)$ , an algorithm for constructing the convex hull of the epigraph of  $Q(\cdot, \mu)$  and convexification procedures for  $Q(\cdot, \mu)$  based on proper modifications of  $\mu$  [6,7,8,16].

Continuity of  $Q$  as a function jointly in  $x$  and  $\mu$  can be obtained by adding elements from the theory of weak convergence of probability measures [4]. Using Rubin’s theorem on weak convergence of image measures induced by discontinuous transformations [4] it is possible to show that  $Q(\cdot, \cdot)$  is continuous at  $(x, \mu)$  if the

above mentioned exceptional set  $E(x)$  has  $\mu$ -measure zero [13]. In [1] the authors study upper and lower semicontinuity of integral functionals with discontinuous integrands of which  $Q(\cdot, \cdot)$  is a special case. The role of the discontinuity set  $E(x)$  is then taken by properly defined exceptional sets of missing upper and lower semicontinuity. *Semicontinuity* of the integral functional then essentially follows if the corresponding exceptional set has  $\mu$ -measure zero.

When heading for *rates of quantitative continuity* of  $Q$  as a function of  $\mu$ , e. g., Lipschitz or Hölder continuity, it is essential to select a metric on the space of probability measures (*probability metric*, [9]) that, on the one hand, fits to the discontinuous integrand and, on the other hand, metrizes weak convergence of probability measures under mild assumptions. In [14] a specific variational distance meeting these requirements is proposed and a Hölder continuity result for  $Q(x, \cdot)$  is established. The polyhedral cone  $K$  arising in the above property 2) of  $\Phi$  enters the definition of the variational distance as a crucial ingredient.

By standard arguments from the *stability analysis of optimization problems* with parameters in general topological or metric spaces [2,10] the above continuity statements for  $Q$  can be turned into stability results for the optimal value and the set of optimal solutions of the underlying stochastic integer program. In particular, results of this type were obtained for (Hölder) continuity of the optimal value and for upper semicontinuity of the solution set mapping [1,11,13,14].

Combinatorial optimization; Stochastic programming

A *stochastic linear program with recourse* is a program of the form

$$\begin{cases} \min & cx + Q(x) \\ \text{s.t.} & x \in X \end{cases}$$

where  $Q(x) = \mathcal{E}_\xi Q(x, \xi)$ ,  $Q(x, \xi) = \min_{y(\xi) \in Y(\xi)} qy(\xi)$  and  $\mathcal{E}_\xi$  denotes the mathematical expectation with respect to  $\xi$ .  $X$  and  $Y(\xi)$  are usually polyhedral convex sets. In recourse programs, some decisions ( $x$ ), called *first-stage decisions*, must be taken before knowing the particular values taken by the random variables ( $\xi$ ) while some other decisions ( $y(\xi)$ ), called *second-stage decisions* or *recourse actions*, can be taken after the realizations of the random variables are known. In this representation,  $Q(x, \xi)$  is the second-stage value function for a given  $\xi$  and  $Q(x)$  the expected value-function or expected recourse.

A *stochastic integer program with recourse* (SIP) is a stochastic program, where some of the decisions are restricted to be integer, either in the first-or in the second-stage problem. It is an extension of integer programming or combinatorial optimization, where some of the problem data are random variables. Any application of combinatorial optimization can thus be extended to a stochastic integer program. Typical applications are in the energy sector [16], resource acquisition [1], location problems [10], stochastic scheduling [2], stochastic knapsack for yield management [15]. We

concentrate here on the *recourse* formulation of SIP although some models incorporate instead probabilistic constraints.

SIPs are notoriously difficult unless the only integrality requirements are restricted in the first-stage. Indeed, the *expected recourse function* is known to be nonconvex, discontinuous (with some exceptions when the random variables are absolutely continuous [10,13]). Similarly, the set of first-stage decisions that yield second-stage feasible solutions is in general nonconvex. It follows that the available methods and properties are scarce for this problem. Research has thus concentrated on some specific problems.

One major situation where some properties are available is the *simple integer recourse* problem, defined as follows:

$$Q(x, \xi) = \min \left\{ q^+ \cdot y^+ + q^- \cdot y^- : \begin{array}{l} y^+ \geq h - Tx, \\ -y^- \leq h - Tx, y^+, \\ y^- \geq 0 \text{ and integer} \end{array} \right\},$$

where  $\xi$  is formed by the stochastic components of  $q^+$ ,  $q^-$ ,  $h$  and  $T$ . Here, any difference in  $h - Tx$  with respect to zero must be compensated by an integer quantity  $y^+$  or  $y^-$ . This compensation is calculated componentwise. The expected value of a simple integer recourse problem can be computed either exactly or by an approximation whose error bound can be controlled. Moreover, a componentwise convexity property can be derived between points that are at an integer distance so that an exact algorithm can be obtained, in particular in the case where the first-stage variables are integer [11]. Also, in several cases, the convex hull of the expected recourse can be obtained [6].

Another line of approach is to use the hierarchy between aggregate level decisions, which are typically those restricted to be integer, and detailed level decisions, which are very often continuous. *Hierarchy* has been used either through *Benders decomposition* [9] or within the framework of *asymptotic analysis* [8].

Bender's decomposition has also been applied to the case when the first-stage variables are binary variables [7]. Those methods sometimes use the terminology 'integer *L-shaped*' to stress the similarity with what is done in linear (continuous) stochastic programs. Applications have mainly been in the routing area as many ex-

amples exist where the expected second-stage recourse functions is computable. Of particular importance, is the possibility to develop lower bounding functionals that are also valid at fractional solutions (see ► [Fractional combinatorial optimization](#)).

A description of Bender's decomposition for SIP in a more general framework is available in [5]. An interesting alternative is to combine *dual decomposition* and *Lagrangian relaxation* [4].

Clearly, this field is only in its infancy (as of 1999) so that we may expect many more results in the coming years. A bibliography is available in [14] and a general presentation in [3].

Cutting plane algorithm; Stochastic programming

Stochastic linear programs are typically characterized as extremely large scale linear programs. In general, they cannot be solved without the use of specialized methods that are designed to exploit their special structure. In this chapter, we describe a commonly used decomposition technique due to J.F. Benders, and discuss the manner in which it is used to solve stochastic linear programs. We also discuss the manner in which statistical techniques can be used in combination with Benders' decomposition. This combination forms the basis of the stochastic decomposition algorithm, which is a powerful mechanism for solving large scale stochastic linear programs.

### Introduction

In deterministic activity analysis, planning consists of choosing activity levels which satisfy resource constraints while maximizing total profit (or minimizing total cost). Note that all the information necessary for decision making is assumed to be available at the time of planning. Under uncertainty, not all the information is available, and parameters such as resources are often modeled by random variables. However, in the absence of appropriate modeling and algorithmic tools for planning under uncertainty, practitioners have often resorted to using deterministic methodology by replacing the random variables by their expected values. In general, this is inappropriate. In circumstances where all the information is not known with certainty, it is advisable to plan only those activities that cannot be postponed to a future date, while some others may be postponed until better information becomes available. Since information is revealed sequentially over time, decision making under uncertainty naturally becomes a multi-stage process. The earliest LP models for planning under uncertainty may be credited to G.B. Dantzig [3] and E.M.L. Beale [1], and are often referred to as *two-stage stochastic programs with recourse*.

A two-stage stochastic linear program with recourse may be stated as

$$(SLP) \begin{cases} \min & cx + E[h(x, \tilde{\omega})] \\ \text{s.t.} & Ax = b, \\ & x \geq 0, \end{cases}$$

where  $\tilde{\omega}$  is a random variable defined on the probability space  $(\Omega, \mathcal{A}, P)$ , and for each  $\omega \in \Omega$ ,

$$h(x, \omega) = \begin{cases} \min & g_{\omega} y \\ \text{s.t.} & W_{\omega} y = r_{\omega} - T_{\omega} x \\ & y \geq 0. \end{cases} \quad (1)$$

Note that the randomness in data elements appears in the second stage, whereas data in the first stage is assumed to be known with certainty.

Two-stage stochastic linear programs arise in a variety of settings. They commonly appear in situations in which the first-stage decision,  $x$ , corresponds to a long term, or 'planning', decision that must be made immediately (i. e., prior to any realization of  $\tilde{\omega}$ ). Following the implementation of this decision, one is faced with a collection of short term, or 'operational', decisions, which vary with the outcome of  $\tilde{\omega}$ . Thus, for example, in a manufacturing environment one might make decisions regarding the acquisition of productive capacity. These, of course, are long term decisions made prior to knowing the precise nature of the demand profile. Actual production decisions are made after information regarding demand has been revealed. As such, these decisions are short term. Naturally, the objective function will attempt to strike a balance between the two types of costs.

Note that the explicit representation of  $E[h(x, \tilde{\omega})]$  requires the solution of (1) for each possible outcome of  $\tilde{\omega}$ . Thus, problems such as SLP are typically quite large – too large to solve directly as linear programs. It follows that the efficient solution of SLP requires the development of specialized solution procedures that exploit the structure of the problem. In order to bring the problem to a computationally viable size, decomposition schemes are used. As problem size increases, these schemes are often used in conjunction with statistically motivated methods. Thus, in this article, we will explore the development of cutting plane methods based on a Benders' decomposition of SLP, and will discuss

the development of deterministic cutting planes, as well as their statistically motivated counterparts.

**Decomposition of SLP**

For brevity in exposition, we assume throughout that  $h(x, \tilde{\omega}) < \infty$  with probability one. This is equivalent to assuming that for all  $x$  satisfying  $Ax = b, x \geq 0$ , (1) is almost surely feasible. In the stochastic programming literature, this property is known as ‘relatively complete recourse’. As stated in (1), the function  $h(x, \omega)$  is easily verified as a convex function of  $x$  (see [9]). It follows that the recourse function,

$$E[h(x, \tilde{\omega})] = \int_{\Omega} h(x, \omega) P(d\omega)$$

is also a convex function of  $x$ . As such, it lends itself to solution via Kelley’s cutting plane algorithm [7]. Define

$$f(x) = cx + E[h(x, \tilde{\omega})]$$

$$X = \{x: Ax = b, x \geq 0\}.$$

Assuming  $X$  is bounded, Kelley’s algorithm may be stated as:

- 0  $x^1 \in X$  is given,  $f^0(x) = -\infty, k \leftarrow 0$ .
- 1  $k \leftarrow k + 1$ .  
Find  $(\alpha^k, \beta^k)$  such that  $\forall x \in X$ :  
 $f(x^k) = \alpha^k + (c + \beta^k)x^k,$   
 $f(x) \geq \alpha^k + (c + \beta^k)x.$
- 2  $f_k(x) = \max\{f_{k-1}(x), \alpha^k + (c + \beta^k)x\}.$
- 3 Solve  $\min_{x \in X} f_k(x)$  to obtain  $x^{k+1}$ .  
Repeat from Step 1.

**Kelley’s cutting plane algorithm**

While it is not difficult to include a stopping rule in Kelley’s method, we have not done so in the above statement because we wish to draw parallels between deterministic and stochastic cutting plane methods. We note that stopping rules for stochastic methods are beyond the scope of this article.

The manner in which  $(\alpha^k, \beta^k)$  are specified in Step 1 of the algorithm is critical to ensuring that an optimal solution to  $\min\{f(x): x \in X\}$  is eventually identified through Step 3 of the algorithm. Coefficients of the supporting hyperplane required in Step 2 may be obtained

from a dual solution of (1). That is, assuming that (1) has a finite optimum, we have

$$h(x, \omega) = \begin{cases} \max & \pi(r_\omega - T_\omega x) \\ \text{s.t.} & \pi W_\omega \leq g_\omega. \end{cases} \tag{2}$$

Thus, if  $\bar{x} \in X$  is given and if we let  $\pi_\omega \in \arg \max \{\pi(r_\omega - T_\omega \bar{x}): \pi W_\omega \leq g_\omega\}$  then

$$h(x, \omega) \geq \pi_\omega(r_\omega - T_\omega x), \quad \forall x \in X,$$

with equality ensured if  $x = \bar{x}$ . Note that  $\pi_\omega$  actually depends on both  $\bar{x}$  and  $\omega$ . Thus, given  $x^k$  and  $\omega$ , let

$$\pi_\omega^k \in \arg \max \left\{ \pi(r_\omega - T_\omega x^k): \pi W_\omega \leq g_\omega \right\}$$

and note that we may obtain the subgradient coefficients in Step 2 of Kelley’s method using

$$\alpha^k = \int_{\Omega} \pi_\omega^k r_\omega P(d\omega),$$

$$\beta^k = - \int_{\Omega} \pi_\omega^k T_\omega P(d\omega),$$

or equivalently

$$\alpha^k = E[\pi_\omega^k r_\omega], \quad \beta^k = -E[\pi_\omega^k T_\omega]. \tag{3}$$

Note that this algorithm can be interpreted as a decomposition method for block angular linear programs. Hence it is sometimes referred to as Benders’ decomposition [2]. In the stochastic programming literature, this is also known as the *L-shaped method* [8].

In order to appreciate the computational challenges inherent to the solution of SLP, it is important to recognize the magnitude of the requirements associated with (3). Specifically, note that the subgradient coefficients specified in (3) require the implicit solution of the linear program in (1)-(2) for every possible realization of the random variable  $\tilde{\omega}$ . If there are only a few possible realizations, this poses no computational burden. However, in most cases this exact evaluation easily exceeds computational capabilities. For example, if there are only 10 independent random variables with 3 outcomes each, then there are a total of  $3^{10}$  or 59,049 possible outcomes. This figure represents the number of linear programs that would have to be solved in each iteration of Kelley’s method. To solve problems of realistic sizes, it is

necessary to resort to approximations of the subgradient coefficients. Given their representation as expected values in (3), it is natural to resort to statistically based approximation schemes.

### Statistical Representation of Cutting Plane Coefficients

The most simplistic use of sampled data within the cutting plane coefficients is quite straightforward and easily implemented. Unfortunately, it is prone to substantial error, and should not, in general be used except with caution. We present it here only as an introduction to a more stable methodology.

We begin by noting that one may obtain statistical estimates of the cutting plane coefficients by using randomly sampled observations of  $\tilde{\omega}$  and computing the appropriate sample means. That is, suppose that  $\{\omega^t\}_{t=1}^n$  is a collection of independent and identically distributed observations of  $\tilde{\omega}$  and  $\pi_t^k \in \arg \max\{\pi(r^t - T^t x^k: \pi W^t \leq g^t)\}$ , where  $(r^t, T^t, g^t, W^t) = (r_{\omega^t}, T_{\omega^t}, g_{\omega^t}, W_{\omega^t})$ . Then the sample means

$$\hat{\alpha}^k = \frac{1}{n} \sum_{t=1}^n \pi_t^k r^t, \quad \hat{\beta}^k = \frac{-1}{n} \sum_{t=1}^n \pi_t^k T^t$$

can be used as estimates of the cutting plane coefficients. Application of Kelley's method using these estimated cut coefficients is equivalent to solving

$$\begin{cases} \min & cx + \frac{1}{n} \sum_{t=1}^n h(x, \omega^t) \\ \text{s.t.} & Ax = b, \\ & x \geq 0. \end{cases} \quad (4)$$

If we let  $\bar{x}_n$  denote an optimal solution to (4), then it is clear that  $\bar{x}_n$  need not be an optimal solution to SLP. Moreover, it is also clear that  $\bar{x}_n$  will depend on the sample used – different sets of observations will lead to different solutions.

The drawback to simply solving (4) in place of SLP lies in the inability to judge the quality of the solutions produced. That is, if  $x^*$  denotes an optimal solution to SLP, one would naturally be interested in assessing  $f(\bar{x}_n) - f(x^*)$ . This turns out to be a fairly difficult undertaking, and can be computationally intensive (see

[5]). In addition, we note that cutting plane algorithms commonly generate cuts in early iterations which support the objective function 'peripherally' (i.e., in regions that are far removed from the optimal solution). With that observation, we note that it is possible to ease the computational effort required by using less accurate cuts in the early iterations. The *stochastic decomposition algorithm* [4] was designed to circumvent these drawbacks.

### Stochastic Decomposition

Recognizing that cutting planes derived early in the iterative process will tend to have little bearing on the optimal solution, stochastic decomposition (SD) iterates with a variable sample size. As iterations progress, the sample size used increases. That is, in the  $k$ th iteration,  $k$  observations are used. This requires the generation of one new observation of  $\tilde{\omega}$  in each iteration. In addition, SD creates computational efficiencies by using approximation of the subproblem (2).

In the  $k$ th iteration, the SD algorithm approximates one support of the following function:

$$\frac{1}{k} \sum_{t=1}^k h(x, \omega^t).$$

Note that cuts generated in earlier iterations were based on fewer observations of  $\tilde{\omega}$ . In order to ensure that all cuts are asymptotically valid (i.e., underestimate the actual objective function, as required in Step 2 of Kelley's method), the SD algorithm updates previous cuts by including a lower bounding constant. For example, suppose that  $h(x, \tilde{\omega}) \geq 0$  (with probability 1). Then

$$\begin{aligned} & \frac{1}{k} \sum_{t=1}^k h(x, \omega^t) \\ &= \frac{k-1}{k} \left\{ \frac{1}{k-1} \sum_{t=1}^{k-1} h(x, \omega^t) \right\} + \frac{1}{k} h(x, \omega^k) \quad (5) \\ &\geq \frac{k-1}{k} \left\{ \frac{1}{k-1} \sum_{t=1}^{k-1} h(x, \omega^t) \right\}. \end{aligned}$$

Now, suppose that in the first  $k-1$  iterations we have accumulated a collection of cutting plane coefficients,

$\{(\alpha_t^{k-1}, \beta_t^{k-1})\}_{t=1}^{k-1}$ , such that

$$\frac{1}{k-1} \sum_{t=1}^{k-1} h(x, \omega^t) \geq \alpha_t^{k-1} + \beta_t^{k-1} x,$$

$$\forall x \in \mathbf{X}, \quad t = 1, \dots, k-1.$$

Combining the above inequality with (5), we have

$$\frac{1}{k} \sum_{t=1}^k h(x, \omega^t) \geq \frac{k-1}{k} \{\alpha_t^{k-1} + \beta_t^{k-1} x\},$$

$$\forall x \in \mathbf{X}, \quad t = 1, \dots, k-1.$$

This leads to a simple mechanism for updating previously derived cutting plane coefficients which preserves the required lower bounding nature as iterations progress (and hence, as the sample size increases). That is, we simply require

$$\alpha_t^k \leftarrow \frac{k-1}{k} \alpha_t^{k-1}, \quad \beta_t^k \leftarrow \frac{k-1}{k} \beta_t^{k-1},$$

$$t = 1, \dots, k-1.$$

Of course, if the lower bound is given as  $\ell \neq 0$ , then we use

$$\alpha_t^k \leftarrow \frac{k-1}{k} \alpha_t^{k-1} + \frac{1}{k} \ell,$$

and the update of  $\beta_t^k$  is not altered.

To illustrate the subproblem approximation, suppose that  $\tilde{g}_\omega$  and  $\tilde{W}_\omega$  are constant so that  $g_\omega = g$  and  $W_\omega = W$  for all  $\omega \in \Omega$ . In this case, the set of dual feasible solutions in (2) is the same for all  $\omega \in \Omega$ , so that

$$h(x, \omega) = \max \{ \pi(r_\omega - T_\omega x) : \pi W \leq g \}.$$

Noting that we may restrict our attention to extreme point solutions, let  $V$  denote the set of extreme points of  $\{ \pi : \pi W \leq g \}$ . Then

$$h(x, \omega) = \max \{ \pi(r_\omega - T_\omega x) : \pi \in V \}.$$

SD iteratively constructs a subset of  $V$  based upon observed dual solutions. Thus, if  $V_k \subset V$  is the subset as it appears in the  $k$ th iteration, then SD estimates the cutting plane coefficients using

$$\pi_t^k \in \arg \max \{ \pi(r^t - T^t x^k) : \pi \in V_k \}.$$

Unlike the simplistic sample-based method previously described, specific guarantees of optimality can be obtained through stochastic decomposition. The expository details associated with safeguards can be somewhat lengthy, and thus, [4] and [6] for a detailed explanation.

## Conclusions

The representation of uncertainty in linear programming models easily leads to problems of extremely large magnitude. As such, the ability to decompose stochastic linear programs is critical to the development of viable solution procedures. Indeed, Benders' decomposition, and the cutting planes derived from it, lie at the heart of a wide variety of stochastic linear programming solution methods. Moreover, as the number of possible outcomes associated with the random variables increases, it is necessary to incorporate additional techniques. One of the most promising avenues of exploration to date involves the incorporation of random sampling methods within a decomposition procedure. This provides a mechanism for combining proven methods for obtaining computational efficiencies. That is, the benefits of using decomposition techniques for large scale linear programs have been well established, as have the benefits of using statistical summaries of sampled data in the estimation of expected values. In the solution of large scale stochastic linear programs, their combination proves to be quite powerful.

### Keywords

Stochastic programming; Approximation; Bounding the expectation

Stochastic linear programs (SLPs) can be seen as a generalization of linear programming problems where at least some coefficients in the objective function and/or

the constraints are random. The motivation for such a formulation is that in many practical applications, the problem data are not known with certainty, for instance because they represent information about the future.

As an example, consider a problem statement from the area of production planning. Today (at a first stage), a decision maker has to decide upon an input plan  $x$  which yields goods  $Tx$  by means of some technological process in order to meet the uncertain demand  $h$  in the future (a second stage). Since it is likely that the number of produced goods fails to meet the demand, a recourse action  $y$  is required that allows to compensate the discrepancy ‘ $h - Tx$ ’ as soon as the demand is known. Such a correction induces additional cost  $q'y$  in the second stage. The objective is to find a decision  $x$  that minimizes the direct cost  $c'x$  of the first stage plus the expected cost  $Q(x)$  induced by  $x$  for compensations. Formally, this can be written as

$$\begin{cases} \min & c'x + Q(x) \\ \text{s.t.} & Ax = b \\ & x \geq 0 \end{cases} \quad (1)$$

where  $Q(x) = \int_{\mathcal{E}} Q(x, \xi) dF(\xi)$  is the expectation of the *recourse function*

$$Q(x, \xi) = \min_y \{q'y : Wy = h(\xi) - T(\xi)x\}. \quad (2)$$

The second-stage cost (2) depends on  $x$  and the realization of some  $K$ -dimensional random vector  $\xi$  with values in the compact convex set  $\mathcal{E} \subset \mathbf{R}^K$  and distribution function  $F$ . Note that  $Q(x, \xi) : \mathcal{E} \rightarrow \mathbf{R}$  is convex for all  $x$  satisfying the constraints in (1). While the recourse action  $y$  may be different for each  $\xi$ , the first-stage decision  $x$  is independent of which event actually occurs. This property is known as *nonanticipativity*. The meaning is that the current decision is only based on what is known today.

Throughout this article, it is assumed that the cost coefficients  $q$  as well as the recourse matrix  $W$  are fixed since the penalization for compensating the discrepancy  $h(\xi) - T(\xi)x$  is likely to be of a deterministic nature. The case of a nonrandom  $W$  is known as *fixed recourse*. In particular,  $W = (-I, I)$  with  $I$  being the identical matrix is called *simple recourse*, meaning that each deviation of  $h(\xi) - T(\xi)x$  from zero is penalized by its absolute value. However, in a more general formulation

both  $q$  and  $W$  may also depend on the realization of  $\xi$  (see [1,12] for a more thorough discussion). Furthermore, it is assumed that the demand  $h$  and the technology matrix  $T$  are linear-affine in  $\xi$ , i. e.

$$\begin{aligned} h(\xi) &= h_0 + h_1\xi_1 + \dots + h_K\xi_K, \\ T(\xi) &= T_0 + T_1\xi_1 + \dots + T_K\xi_K. \end{aligned}$$

If the distribution of  $\xi$  is discrete, the *stochastic linear program with recourse* given by (1) and (2) can be written as a large deterministic problem where the expectations are written as a finite sum, and all constraints are duplicated for each realization of  $\xi$ . The resulting *deterministic equivalent problem* may be solved by straightforward application of standard linear programming methods (provided that the discrete set of possible outcomes for  $\xi$  is of relatively low cardinality). However, it exhibits a typical block structure that can be exploited by special *decomposition algorithms* (see also [1,12] or [13]).

Otherwise, if the distribution of  $\xi$  is continuous, one can use *approximation techniques* ([2,10,11]) where the original random vector  $\xi$  is replaced by another one  $\widehat{\xi}$ . Typically,  $\widehat{\xi}$  is discrete, and the problem reduces to a discretely distributed stochastic program. These techniques take advantage of the convexity of the recourse function, yielding upper and lower bounds for the expected recourse cost. This allows to quantify the accuracy of the approximation and, if not sufficient, to improve it by constructing a better approximation to  $Q(x)$ .

### The Jensen Lower Bound

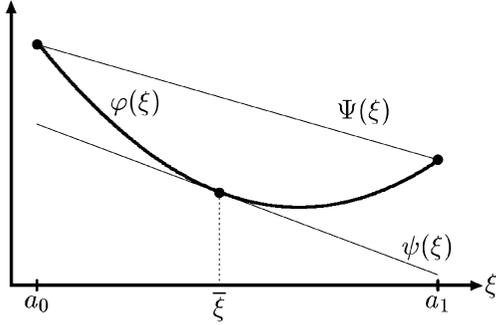

In order to outline the basic concepts (see e. g. [12]), assume that  $\xi$  is one-dimensional and denote the expectation by  $\bar{\xi} := E\xi = \int_{\mathcal{E}} \xi dF(\xi)$ . Recall that  $\varphi(\xi) := Q(\widehat{x}, \xi)$  is convex in  $\xi$  for any fixed  $\widehat{x}$ . Therefore, it can be bounded from below by a linear function  $\psi(\xi)$  that supports  $\varphi$  at some point  $\widehat{\xi}$ , i. e. (assuming that  $\varphi$  is (sub)differentiable in  $\widehat{\xi}$ )

$$\psi(\xi) = \varphi(\widehat{\xi}) + \varphi'(\widehat{\xi})(\xi - \widehat{\xi}).$$

Due to linearity, the expected value of this lower bound is given by

$$E\psi(\xi) = \varphi(\widehat{\xi}) + \varphi'(\widehat{\xi})(E\xi - \widehat{\xi}) = \psi(\bar{\xi}).$$

Obviously, the best lower bound is given by  $\widehat{\xi} = \bar{\xi}$  since no linear function supporting  $\varphi$  has a value larger than

Stochastic Linear Programs with Recourse and Arbitrary Multivariate Distributions, Figure 1

$\varphi(\bar{\xi})$  in  $\bar{\xi}$ . This is stated by *Jensen's inequality*  $\varphi(E\xi) \leq E\varphi(\xi)$  for convex functions of random variables. Applied to the situation where  $\varphi(\xi)$  is convex over the domain of  $\xi$ , one obtains a lower bound to the recourse function from

$$\varphi(\bar{\xi}) \leq \int_{\mathcal{E}} \varphi(\xi) dF(\xi). \quad (3)$$

Note that (3) also holds for multidimensional  $\xi \in \mathcal{E} \subset \mathbf{R}^K$ ,  $K \geq 1$ , regardless of any correlation between the components of  $\xi$ .

For one-dimensional random variables, the lower bounding function  $\psi(\xi)$  is illustrated in Fig. 1, together with an upper bound which can be derived as follows.

### The Edmundson–Madansky Upper Bound (Independent Case)

For simplicity, the one-dimensional case is considered first. Let the support of  $\xi$  be given by the interval  $\mathcal{E} = [a_0, a_1] \subset \mathbf{R}$ . The idea of the *Edmundson–Madansky upper bound* is to introduce a discrete random variable  $\widehat{\xi}$  with the same expectation, i. e.  $E\widehat{\xi} = \bar{\xi}$ , attaining the values  $a_0$  and  $a_1$  with probabilities

$$p_{a_0} := P(\widehat{\xi} = a_0) = \frac{a_1 - \bar{\xi}}{a_1 - a_0},$$

$$p_{a_1} := P(\widehat{\xi} = a_1) = \frac{\bar{\xi} - a_0}{a_1 - a_0} = (-1) \frac{a_0 - \bar{\xi}}{a_1 - a_0}.$$

Obviously, the linear function  $\Psi(\xi)$  through the points  $(a_0, \varphi(a_0))$  and  $(a_1, \varphi(a_1))$  is above  $\varphi(\xi)$  for all  $\xi \in \mathcal{E}$  due to convexity. This implies

$$\varphi(\xi) \leq \frac{a_1 - \xi}{a_1 - a_0} \cdot \varphi(a_0) + \frac{\xi - a_0}{a_1 - a_0} \cdot \varphi(a_1)$$

for all  $\xi \in \mathcal{E}$ , and integrating this inequality yields

$$\begin{aligned} & \int_{\mathcal{E}} \varphi(\xi) dF(\xi) \\ & \leq \frac{a_1 - \bar{\xi}}{a_1 - a_0} \cdot \varphi(a_0) + \frac{\bar{\xi} - a_0}{a_1 - a_0} \cdot \varphi(a_1) \\ & = p_{a_0} \cdot \varphi(a_0) + p_{a_1} \cdot \varphi(a_1) = E\varphi(\widehat{\xi}) \end{aligned}$$

as an upper bound for the expectation  $E\varphi(\xi)$ . The EM-bound on intervals can be extended easily to multivariate distributions, where  $\mathcal{E} = [a_{10}, a_{11}] \times \cdots \times [a_{K0}, a_{K1}] \subset \mathbf{R}^K$  is the rectangular support of  $\xi$ , if either  $Q(x, \cdot)$  is separable in the components of  $\xi$  or the elements of  $\xi$  are stochastically independent. In the former case, the bound may be applied to each component separately. Here, the more general latter case is of interest.

Denote the vertices of  $\mathcal{E}$  by  $a^v$ ,  $v = (v_1, \dots, v_K)$ ,  $v_i \in \{0, 1\}$ , such that  $a_i^{v_i} = a_{i v_i}$ . Analogously to the above,  $\widehat{\xi}$  is a discrete random vector with independent components and  $E\widehat{\xi}_i = \bar{\xi}_i$ , attaining values  $a^v$  with probability

$$\begin{aligned} p(a^v) & := P(\widehat{\xi} = a^v) \\ & = \frac{\prod_{i=1}^K (-1)^{v_i} (a_{i \bar{v}_i} - \bar{\xi}_i)}{\prod_{i=1}^K (a_{i1} - a_{i0})}, \quad (4) \end{aligned}$$

where  $\bar{v}_i = 1 - v_i$ , and the EM-inequality contains the product of all combinations of each interval bound, i. e.

$$\int_{\mathcal{E}} \varphi(\xi) dF(\xi) \leq \sum_v p(a^v) \cdot \varphi(a^v) = E\varphi(\widehat{\xi}).$$

### The Edmundson–Madansky Upper Bound (Dependent Case)

If the components of  $\xi$  are dependent, the EM-bound is more difficult to evaluate (unfortunately, the notation is also somewhat cumbersome). For  $\mathcal{B} := \{\Lambda: \Lambda \subset \{1, \dots, K\}\}$  and  $\delta_{\Lambda}(v) := \prod_{i \in \Lambda} (-1)^{v_i}$ ,  $\Lambda \in \mathcal{B}$ ,

$$m_{\Lambda} := \int_{\mathcal{E}} \left( \prod_{i \in \Lambda} \xi_i \right) dF(\xi)$$

are the crossmoments of  $\xi$  for any  $\Lambda \in \mathcal{B}$ , and  $\rho_{\Lambda} := m_{\Lambda} - \prod_{i \in \Lambda} \bar{\xi}_i$ . Using these definitions and  $\bar{\Lambda} = \{1, \dots, K\} \setminus \Lambda$ , it has been shown in [6], that the prob-

abilities of the discrete outcomes  $a^v$  are determined by

$$p(a^v) = \prod_{i=1}^K (a_{i1} - a_{i0})^{-1} \times \left[ \prod_{i=1}^K (-1)^{v_i} (a_{i\bar{v}_i} - \bar{\xi}_i) + \sum_{A \in \mathcal{B}} \left( \delta_{\bar{A}}(\bar{v}) \prod_{i \in \bar{A}} a_{i\bar{v}_i} \right) \delta_{\Delta}(v) \rho_{\Delta} \right]$$

Obviously,  $\rho_{\Delta} = 0$  if the components of  $\xi$  are independent which is equivalent to the bound in (4). The calculation of the EM-bound requires to evaluate  $2^K$  points and, in the dependent case, the same number of cross-moments. Therefore, for higher dimensions not only the computational effort but also the number of discrete outcomes increases exponentially, yielding a deterministic equivalent problem that might be too large to be solved.

**Bounds on Simplices**

Instead of rectangles, one can use a regular simplex  $\Delta \supset \mathcal{E}$  containing the support of  $\xi$ . In this case, Jensen’s inequality where  $\mathcal{E}$  is replaced by  $\Delta$  in (3) can be applied immediately to obtain a lower bound. To derive an upper bound, the affine independent vertices  $v_0, \dots, v_K$  of  $\Delta$  are considered as discrete outcomes. Since this are only  $K + 1$  points, the complexity is no longer exponential in the dimension of  $\xi$ . Note that for any  $\xi \in \Delta$ , the system of linear equations

$$p_0(\xi) + \dots + p_K(\xi) = 1, \\ v_0 p_0(\xi) + \dots + v_K p_K(\xi) = \xi$$

or briefly

$$Vp(\xi) = \begin{pmatrix} 1 \\ \xi \end{pmatrix} \quad \text{with } V = \begin{pmatrix} 1 & \dots & 1 \\ v_0 & \dots & v_K \end{pmatrix}$$

has the unique solution

$$p(\xi) = V^{-1} \begin{pmatrix} 1 \\ \xi \end{pmatrix}.$$

Analogously to the above, a discrete random variable  $\hat{\xi}$  is constructed attaining values  $v_0, \dots, v_K$  with probabilities  $p_0, \dots, p_K$  so that the expectation of the discrete

distribution is equivalent to those of the original one, i. e.  $E\hat{\xi} = p_0 v_0 + \dots + p_n v_n = \xi$ . This yields the following version of the Edmundson–Madansky inequality:

$$\int_{\Delta} \varphi(\xi) dF(\xi) \leq \sum_{i=0}^K p_i \varphi(v_i),$$

where the vector of probabilities is given by

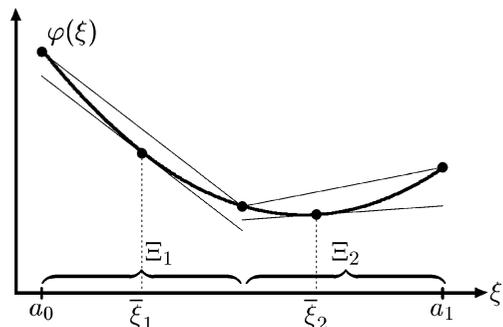

$$p = \int_{\Delta} V^{-1} \begin{pmatrix} 1 \\ \xi \end{pmatrix} dF(\xi) = V^{-1} \begin{pmatrix} 1 \\ \xi \end{pmatrix}$$

Note that this equation holds for both the independent and the dependent case.

**Improving Bounds**

The advantageous feature of approximation techniques is that the accuracy can be quantified by the difference between the Jensen and the Edmundson–Madansky bound. If not sufficient, the approximation can be improved by dividing the rectangular support  $\mathcal{E}$  (or the simplex  $\Delta$ , respectively) into convex disjunct subsets like in Fig. 2.

A finite collection of such subsets is called a *partition*. Dividing an element of an existing partition yields a ‘refined’ partition, and the associated bound is at least as good as the former one (monotonicity of bounds). If the subsets become arbitrary small, the approximated recourse function converges to the original one. However, for computational reasons the partition cannot become arbitrarily small. Also, dividing  $\mathcal{E}$  (or  $\Delta$ , respectively) without strategy may increase the computational effort dramatically. Hence, sophisticated refinement strategies are required that analyze the accuracy

Stochastic Linear Programs with Recourse and Arbitrary Multivariate Distributions, Figure 2

of the bounds for each subset and determine those that should be further divided. This yields a sequential approximation to the original problem.

### Generalizations and Alternative Methods

When deriving the upper and lower bounds, only randomness in the right-hand side was taken into account so far. If the latter are deterministic (i. e.  $h(\xi) := h_0$ ) but the coefficients  $q(\xi)$  in the objective are uncertain, one can apply the same procedure to the dual problem. Since this is a maximization problem with concave recourse function, the Jensen inequality provides an upper while the Edmundson–Madansky inequality yields a lower bound. For uncertainty in both the objective and the right-hand side of constraints, extensions of the approximation scheme described above are required (see e. g. [7]). It has to be mentioned that there are other concepts apart from the bounds derived here which are also applicable for noncompact support of the random data [4] or derive sharper lower bounds by exploiting second moment information [3].

Alternatively, one may approximate the original problem by sampling from continuous distributions to obtain a deterministic equivalent, or one may use *Benders decomposition* together with variance reduction techniques to handle a large number of scenarios [9]. Other sophisticated approaches like stochastic quasigradient methods [5] or stochastic decomposition [8] combine sampling with techniques known from convex optimization, for example subgradient or cutting plane procedures.

### Keywords

Stochastic programming; Optimization; Network

Stochastic programming provides a framework for sequential decision making, or planning, under uncertainty. Uncertainty naturally arises when the future consequences of present decisions are unknown, and is typically represented by a set of scenarios covering possible future events. A *stochastic program* (SP) seeks to find a decision which is, in some sense, optimal with respect to the scenario set. Depending upon the number of scenarios, and upon the size of the underlying (deterministic) model, an SP may become very large and computationally challenging to solve. Hence, there is an ongoing effort to devise efficient algorithms tailored to the special structures of SPs, and to exploit novel, parallel computer architectures in their solution.

This article focuses on two- and multistage SPs with generalized network structure. The two-stage SP is the simplest program which captures the dynamic decision process, while the network structure arises naturally in many applications, such as financial decision making (e. g., [11]). This problem structure was studied already in [24] and [25]. We first describe algorithms for the solution of network problems with strictly convex objective functions. These algorithms are then adapted to the specially structured stochastic network problems, and are also extended to general, convex (such as linear) objective functions.

### Problem Formulation

A *stochastic program* models a situation where a decision maker must make a decision here and now (time 0), facing future uncertainty (the first stage). At later time points,  $\tau_n$ , further corrective decisions are made. These decisions are made dependently on prior decisions and on the actual realizations of uncertain events between times 0 and  $\tau_n$ , but in the face of further uncertainty of events after  $\tau_n$ . The *two-stage* SP consists of the initial and one corrective decision and is naturally generalized to the *multistage* SP with an arbitrary number of decisions.

The two-stage SP where uncertainty is represented by a finite *scenario set*  $S = \{1, \dots, N\}$  with probabilities  $p^s > 0$ , can be formulated mathematically in the deter-

ministic, equivalent form, [26]:

$$\left\{ \begin{array}{l} \min \quad f(x) + \sum_{s \in S} p^s g^s(y^s) \\ \text{s.t.} \quad Ax = b, \\ \quad C^s x + B^s y^s = d^s, \quad \forall s \in S, \\ \quad 0 \leq x \leq u^x, \quad \forall s \in S, \\ \quad 0 \leq y^s \leq v^x, \quad \forall s \in S. \end{array} \right.$$

The first- and second-stage variables are denoted  $x$  and  $y^s$ , respectively. Any (scenario-independent) constraints on the first-stage decision are represented by the  $Ax = b$  constraint. The second-stage decisions  $y^s$  depend upon both the scenario (hence the superscript  $s$ ) and on the first-stage decisions  $x$  through the matrix  $C^s$ . All decision variable may be subject to simple bounds. The objective functions  $f$  and  $g^s$  are assumed to be convex, and continuously differentiable.

The L-shaped decomposition algorithm [21], based on Benders decomposition, applies directly to SP and is well-suited for course-grained, parallel solution, [17]. We consider here the equivalent *split-variable formulation*, obtained by replicating the first-stage variables  $x$  into copies  $x^s$  for each scenario, then adding *nonanticipativity constraints* (NA constraints)

$$x^1 = x^s, \quad \forall s \in \{2, \dots, N\} \quad (1)$$

to force the replicated variables to have the same value:

$$[RNLP] \left\{ \begin{array}{l} \min \quad \sum_{s \in S} p^s (f(x^s) + g^s(y^s)) \\ \text{s.t.} \quad Ax^s = b, \quad \forall s \in S, \\ \quad C^s x^s + B^s y^s = d^s, \quad \forall s \in S, \\ \quad 0 \leq x^s \leq u, \quad \forall s \in S, \\ \quad 0 \leq y^s \leq v^s, \quad \forall s \in S, \\ \quad x^1 = x^s, \quad \forall s \in \{2, \dots, S\}. \end{array} \right.$$

The advantage of this formulation is that the problem decomposes into  $N$  independent subproblems when the NA constraints are ignored. This fact is exploited algorithmically in the progressive hedging ([10,20]) and the diagonal quadratic approximation ([1,9]) algorithms, as well as in the row-action algorithms discussed above.

### Row-Action Algorithm

**Row-Action Algorithm** The row-action algorithm (RA algorithm) [4] is a primal-dual algorithm for solving the

general nonlinear optimization problem

$$[NLP] \left\{ \begin{array}{l} \min \quad F(z) \\ \text{s.t.} \quad Hz = r, \\ \quad 0 \leq z \leq u, \end{array} \right.$$

where the objective function  $F(z)$  is strictly convex and continuously differentiable,  $z \in \mathbf{R}^n$  and  $H \in \mathbf{R}^{m \times n}$ .

A solution to [NLP] consists of real vectors,  $z \in \mathbf{R}^n$ ,  $\pi \in \mathbf{R}^m$  and  $\lambda \in \mathbf{R}^n$ , which satisfy the standard optimality conditions:

- *primal feasibility*:  $Hz = r$  and  $0 \leq z \leq u$ ;
- *dual feasibility*:  $\nabla F(z) = -H^\top \pi - \lambda$ ;
- *complementary slackness*: for  $j = 1, \dots, n$ ,

$$\lambda_j > 0 \implies z_j = 0,$$

$$\lambda_j < 0 \implies z_j = u_j.$$

Starting from an initial primal-dual point  $(z, \pi, \lambda)$  that satisfies complementary slackness, the row-action algorithm iteratively operates on a single constraint (or row) at a time, simultaneously updating the primal variables occurring in the constraint, and the constraint's dual price. This update causes the constraint to be satisfied (primal feasibility) while maintaining complementary slackness. The algorithm terminates when primal feasibility is satisfied for all constraints, within some tolerance. The order in which the constraints are operated on is not formally important as long as no constraint is ignored indefinitely, although the ordering may influence the rate of convergence.

The algorithmic step can be viewed as a projection of the current primal iterate upon the hyperplane defined by a nonsatisfied constraint, with a simultaneous update of the constraint's dual price so that the three optimality conditions stated above are satisfied for that constraint. Indeed, let  $h_i$  denote the  $i$ th row of  $H$ , so that  $h_i^\top z = r_i$  is the  $i$ th constraint from  $Hz = r$ . Then the update is defined as the solution  $z^{\nu+1} \in \mathbf{R}^n$ ,  $\beta \in \mathbf{R}$  to the system

$$\nabla F(z^{\nu+1}) = \nabla F(z^\nu) + \beta \cdot h_i, \quad (2)$$

$$h_i^\top z^{\nu+1} = r_i \quad (3)$$

where  $\nu$  is the iteration counter,  $z^\nu$  is the current primal point and the *Bregman parameter*  $\beta$  is the change in the constraint's dual price,  $\pi_i$ . Under mild conditions

(strict convexity and *zone consistency* of  $F$ , see [4]), this system can be shown to have a uniquely determined solution that lies in the domain of  $F$ . The projection upon a simple bounds constraint is similar: For instance, if  $z_j > u_j$ , the system

$$\nabla F(z^{v+1}) = \nabla F(z^v) + \beta, \quad z_j^{v+1} = u_j$$

defines the next iterate. The algorithm is summarized below, where  $e_i$  denotes the  $i$ th unit vector.

#### Initialization

Set  $v = 0$ . Initialize  $(z^0, \pi^0, \lambda^0)$  such that  $\nabla F(z^0) = -H^\top \pi^0 - \lambda^0$ .

*Projection on equality constraint:*

To project on the  $i$ th equality constraint,  $h_i^\top z = r_i$ , solve the equations

$$\begin{aligned} \nabla F(z^{v+1}) &= \nabla F(z^v) + \beta \cdot h_i, \\ h_i^\top z^{v+1} &= r_i \end{aligned}$$

for  $z^{v+1} \in \mathbf{R}^n$  and  $\beta \in \mathbf{R}$ .

Update the dual price:  $\pi^{v+1} = \pi^v - \beta \cdot e_i$ .

*Projection on bounds:*

To project on the  $j$ th simple bound constraint,  $0 \leq z_j \leq u_j$ :

If  $z_j^v < 0$ , let  $\beta$  and  $z_j^{v+1}$  solve:

$$\begin{aligned} \nabla F(z^{v+1}) &= \nabla F(z^v) + \beta \cdot e_j, \\ z_j^{v+1} &= 0. \end{aligned}$$

If  $z_j^v > u_j$ , let  $\beta$  and  $z_j^{v+1}$  solve:

$$\begin{aligned} \nabla F(z^{v+1}) &= \nabla F(z^v) + \beta \cdot e_j, \\ z_j^{v+1} &= u_j. \end{aligned}$$

If  $0 < z_j^v < u_j$ , let  $\beta$  and  $z_j^{v+1}$  solve:

$$\begin{aligned} \nabla F(z^{v+1}) &= \nabla F(z^v) + \beta \cdot e_j, \\ \beta &= \lambda_j^v. \end{aligned}$$

Let  $\lambda^{v+1} = \lambda^v - \beta \cdot e_j$ .

*Termination:* IF convergence: STOP.

ELSE Set  $v \leftarrow v + 1$  and continue.

#### Row-action algorithm for [NLP]

We note that the initialization step is usually trivial, by setting  $\lambda^0 = -\nabla F(z^0) - H^\top \pi^0$  for any  $z^0$  in the domain of  $F$  and any  $\pi^0$ . The convergence test is based on a measure of violation of primal feasibility.

The RA algorithm has found application in a variety of areas, such as matrix estimation, image reconstruction and multicommodity network flow problems. For an extensive textbook treatment of these and related topics, and for further references, see [6].

#### Specialization to Quadratic Generalized Network Problems

We now specialize the RA algorithm to the case where [NLP] is a network problem with a quadratic objective function,

$$F(z) = \frac{1}{2} z^\top W z + q^\top z.$$

Let the network structure be defined by a graph  $G = (V, E)$  with a set  $V$  of nodes (or vertices), and a set  $E \subseteq V \times V$  of arcs (or edges). Let  $\delta_i^+ = \{j \in V: (i, j) \in E\}$  be the set of nodes having an arc coming from  $i$ , and  $\delta_j^- = \{i \in V: (i, j) \in E\}$  be the set of nodes having an arc going to  $j$ , respectively. The decision variables are then the flows  $z_{ij}$  from node  $i$  to node  $j$ , for  $(i, j) \in E$ . We allow the network to be generalized with arc multipliers  $m_{ij} > 0$ :

$$[QNP] \begin{cases} \min & \sum_{(i,j) \in E} \frac{1}{2} w_{ij} z_{ij}^2 + q_{ij} z_{ij} \\ \text{s.t.} & \sum_{j \in \delta_i^+} z_{ij} - \sum_{k \in \delta_i^-} m_{ki} z_{ki} = r_i, \\ & \forall i \in N, \\ & 0 \leq z_{ij} \leq u_{ij}, \quad \forall (i, j) \in E. \end{cases}$$

The elements of  $W$  are here denoted by  $w_{ij}$  and  $r_i$  is the supply at node  $i$  (demands are represented as negative supplies).

The algorithmic steps of the RA algorithm can now be stated for [QNP]. For the *flow conservation constraint* for node  $i$ ,

$$\sum_{j \in \delta_i^+} z_{ij} - \sum_{k \in \delta_i^-} m_{ki} z_{ki} = r_i,$$

(2)–(3) leads to the updating formula for  $z_{ij}$ :

$$\begin{cases} z_{ij}^{v+1} = z_{ij}^v + \frac{\beta}{w_{ij}} & \text{for } j \in \delta_i^+, \\ z_{ki}^{v+1} = z_{ki}^v - \frac{\beta \cdot m_{ki}}{w_{ki}} & \text{for } k \in \delta_i^-, \end{cases}$$

where

$$\beta = \frac{r_i - \left( \sum_{j \in \delta_i^+} z_{ij}^v - \sum_{k \in \delta_i^-} m_{ki} z_{ki}^v \right)}{\sum_{j \in \delta_i^+} \frac{1}{w_{ij}} + \sum_{k \in \delta_i^-} \frac{m_{ki}^2}{w_{ki}}}. \quad (4)$$

The dual variable for node  $i$  is updated by subtracting  $\beta$  from its current value,  $\pi_i^{v+1} = \pi_i^v - \beta$ .

Similarly, the simple bound constraints lead to the updates:

- if  $z_{ij}^v < 0$ : Let  $z_{ij}^{v+1} = 0$  and  $\beta = -w_{ij} z_{ij}^v$ ;
  - if  $z_{ij}^v > u_j$ : Let  $z_{ij}^{v+1} = u_j$  and  $\beta = w_{ij}(u_j - z_{ij}^v)$ ;
  - if  $0 < z_{ij}^v < u_j$ : Let  $z_{ij}^{v+1} = z_{ij}^v + \lambda_{ij}^v / w_{ij}$  and  $\beta = -\lambda_{ij}^v$ .
- In each case update  $\lambda_{ij}^{v+1} = \lambda_{ij}^v - \beta$ .

The *stochastic quadratic network problem*, is now obtained by adding NA constraints (1) to [QNP]:

[SQNP]

$$\left\{ \begin{array}{l} \min \quad \sum_{s \in S} \sum_{(i,j) \in E} p^s \left( \frac{1}{2} w_{ij} (z_{ij}^s)^2 + q_{ij} z_{ij}^s \right) \\ \text{s.t.} \quad \sum_{j \in \delta_i^+} z_{ij}^s - \sum_{i \in \delta_j^-} m_{ki} z_{ki}^s = r_i, \\ \quad \quad \forall i \in N, \\ \quad \quad z_{ij}^1 = z_{ij}^s, \quad \forall s \in \{2, \dots, N\}, \\ \quad \quad \forall (i, j) \in F, \\ \quad \quad 0 \leq z_{ij}^s \leq u_{ij}^s, \quad \forall (i, j) \in E. \end{array} \right.$$

As in [RNLP] the superscripts  $s$  denote scenario-dependent quantities. The NA constraints apply to the subset  $F$  of (replicated) first-stage variables. A specialization of (2)–(3) upon one such constraint changes the two components of the current iterate  $z_{ij}^{1,v}$  and  $z_{ij}^{s,v}$  to the common value

$$z_{ij}^{1,v+1} = z_{ij}^{s,v+1} = \frac{p^1 z_{ij}^{1,v} + p^s z_{ij}^{s,v}}{p^1 + p^s}$$

which is their probability-weighted average. However, it was shown in [13] that the values of first-stage variable  $(i, j)$  across all scenarios can be updated in a single step — equivalent to an infinite number of projections upon the NA-constraints for  $z_{i,j}$  — to their probability-weighted average:

$$z_{ij}^{s,v+1} = \sum_{s \in S} p^s z_{ij}^{s,v}, \quad \forall s \in S. \quad (5)$$

This observation leads to considerably faster agreement among scenarios.

## Proximal Minimization with $D$ -functions

The row-action algorithm only applies to problems with a strictly convex objective function. Consider the linear program

$$[LP] \left\{ \begin{array}{l} \min \quad c^\top z \\ \text{s.t.} \quad z \in X, \end{array} \right.$$

where the *feasible region* is denoted by

$$X = \{z \in \mathbf{R}^n : Hz = r \text{ and } 0 \leq z \leq u\}.$$

The *proximal minimization with  $D$ -functions algorithm* (PMD) solves linear programs by perturbing the objective into a strictly convex form, then solving the resulting subproblem using RA. The process is repeated with updated perturbations until the solution to the original LP is approached. PMD was proposed in [5], where its convergence was established.

Let  $S \neq \emptyset$  be an open convex set. Let  $f: \Lambda \subseteq \mathbf{R}^n \rightarrow \mathbf{R}$  be an *auxiliary function*. We assume that  $\bar{S} \subseteq \Lambda$ , where  $\bar{S}$  is the closure of  $S$ , and that  $f$  is strictly convex and continuous on  $\bar{S}$  and continuously differentiable on  $S$ . The set  $S$  is called the *zone* of  $f$ . The  *$D$ -function* corresponding to  $f$  is defined as

$$D_f(x, y) = f(x) - f(y) - \nabla f(y)^\top (x - y). \quad (6)$$

For some suitable choice of the auxiliary function  $f$  and a positive nondecreasing sequence  $\{\gamma^k\}_{k=0}^\infty$  with  $\liminf_{k \rightarrow \infty} \gamma^k = \gamma < \infty$ , the proximal minimization algorithm with  $D$ -functions proceeds from an arbitrary starting point,  $z^0 \in S$ , with the following iteration (the PMD algorithm):

$$z^{k+1} \leftarrow \arg \min_{z \in X \cap \bar{S}} F(z) + \frac{1}{\gamma^k} D_f(z, z^k). \quad (7)$$

PMD was used in [14] and [15] to solve linear and stochastic network problems using two auxiliary functions: the quadratic function,

$$f_Q(x) = \frac{1}{2} x^\top x, \quad (8)$$

with zone  $\mathbf{R}^n$  and  $D$ -function

$$D_{f_Q}(x, y) = \frac{1}{2} (x - y)^\top (x - y),$$

and the negative of Shannon's entropy function

$$f_E(x) = \sum_{j=1}^n x_j \cdot \log x_j \quad (9)$$

with the positive orthant  $S = \{x \in \mathbf{R}^n: x_j > 0\}$  as zone and with  $D$ -function

$$D_{f_E}(x, y) = \sum_{j=1}^n x_j \left[ \log \frac{x_j}{y_j} - 1 \right] + \sum_{j=1}^n y_j.$$

With the quadratic auxiliary function  $f_Q$ , PMD specializes to the familiar *quadratic proximal point algorithm* (QPP algorithm) of [18,19]:

$$z^{k+1} \leftarrow \arg \min_{z \in X} F_Q(z) \doteq e^T z + \frac{1}{2\gamma^k} \|z - z^k\|^2.$$

QPP hence consists of solving a series of quadratic programs (using, e. g., RA) while iteratively updating the proximal point  $z^k$ .

QPP and the corresponding algorithm obtained from PMD by using  $f_E$ , the *entropic proximal point algorithm* EPP, [7], were implemented and compared with exact algorithms for deterministic network problems in [15]. It was found that while neither algorithm was comparable to specialized, exact network algorithms (based on simplex or relaxation) for small or medium-sized problems, the PMD algorithms were able to solve extremely large problems, with up to 16 million variables, which could not be solved using the exact algorithms.

### Parallelism in the Row-Action Algorithm

The RA algorithm lends itself naturally to parallel execution on a computer with a large number of interconnected processors. In the context of stochastic network problems the potential for parallelism manifests itself at several levels. The key to parallelizing an algorithm is to identify parts of the algorithm which can be executed simultaneously without interfering with each other. Hence, two calculations can be executed simultaneously (by different processors) if they do not depend upon each other's results, that is, there are no data dependencies between them.

### Simple Bounds

The projection on simple bounds constraints is the simplest example of natural parallelism: Each projection changes the value of (at most) one primal and one dual variable. All the  $n$  bounds projections of a problem hav-

ing  $n$  variables can be executed in parallel without data dependencies.

### Disjoint Constraints

By *disjoint constraints* we mean constraints that do not have primary variables in common. Projections (2)-(3) upon a set of such constraints can be performed simultaneously since the data involved in each projection do not depend upon the other projections. For network problems, equality constraints correspond to nodes and are disjoint for sets of nonadjacent nodes, i. e., nodes that have no arcs in common. The identification of such sets is a graph-coloring problem [28], where nodes with the same 'color' can all be updated simultaneously.

### Stochastic Problems

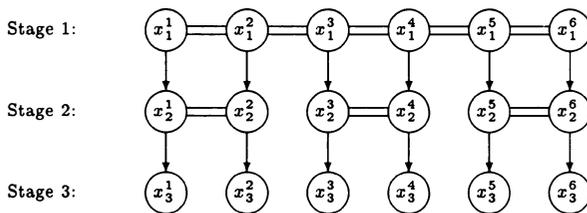

For a stochastic network it is evident that nodes belonging to different scenario subproblems are independent. This is true even for first-stage nodes within our framework of variable-splitting as in RNLP (and is our primary reason for using splitting). The NA projections (5) can in turn be executed in parallel for each (set of replicated) first-stage variable,  $z_{ij}^s, (i, j) \in F$ .

### Jacobi Algorithms

The kinds of parallelism mentioned so far all define algorithms which are equivalent to the strictly sequential RA algorithm, i. e., *Gauss-Seidel algorithms*. In contrast, *Jacobi algorithms* allow simultaneous operations on constraints even if they are not disjoint. This increases the potential for parallelism because projections on all the primal constraints can be calculated in parallel. However, projections on nondisjoint constraints will generally lead to conflicting updates of the (primal) variables common to the constraints. The conflict can be resolved by solving first for the projections for all constraints simultaneously, but retaining only the dual solutions and discarding the primal variables. Then, common values of the primal variables are calculated from the duals using dual feasibility. The convergence of this algorithm, using suitable underrelaxation, is established in [2]. Jacobi algorithms generally allow more parallelism than Gauss-Seidel algorithms but have poorer convergence properties because they operate on partially outdated data.

A scenario tree can be used to represent the way in which the stochastic variables  $\xi_t$  evolve: The root of the tree corresponds to the immediately observable, deterministic data,  $A_1$ ,  $B_1$ ,  $b_1$  and  $c_1$ . The nodes of the tree at level  $t \geq 2$  corresponds to possible realizations of  $\xi_t$ . In this tree, a scenario corresponds to a complete path from the root to a leaf. Similarly to the two-stage case, variables belonging to stages prior to the last are replicated for each scenario, and appropriate NA constraints used to enforce the proper correspondence among scenarios:

The nodes here represent sets of decision variables belonging to various stages (top to bottom) and scenarios (left to right). The double lines represent NA constraints; cf. the scenario tree above. This problem representation maps naturally upon a rectangular communication pattern, as on the CM-2, and was solved, [16], as in the two-stage case, by iterating alternately on scenario networks and NA constraints.

### Computational Experiments

The algorithms covered in this article were subjected to extensive numerical experimentation on the major types of stochastic network problems:

#### Nonlinear Two-stage Problems

The row-action algorithm was implemented on the CM-2 and used to solve large scale, quadratic problems in [13]. They report that the algorithm scales very effectively in problem size and number of processors: For instance, doubling both results in virtually the same solution time. The largest problem solved had 8, 192 scenarios and a deterministic, nonlinear equivalent of 868,367 constraints and 2,747,017 variables, and was solved to a tight primal tolerance in about 11 minutes using 32K processors, and achieving a computational rate of 276MFLOPS. The algorithm's performance is sensitive to the range of multipliers occurring in the

generalized networks, and deteriorates as this range increases.

Problems of this size could not be solved using any other available algorithm. The RA algorithm was, however, competitive with standard algorithms on smaller problems.

#### Linear Two-Stage Problems

The PMD algorithm in conjunction with the row-action algorithm was used in [14] on two-stage problems with linear objectives. They conclude that the relative advantage of this algorithm compared to standard codes (Minos 5.3 simplex and OSL interior point) is in the solution of large and very large problems. Solving the largest problems, with 2, 048 scenarios (deterministic equivalent of 217,103 constraints and 618,529 variables), took more than 3 hours of 32K CM-2 processing time, but a problem of this size could not be solved using the simplex or interior point algorithms. It also appears that the PMD/RA solution times scale nearly linearly in problem size, whereas the comparison codes had close to quadratic time complexity. It is apparent that the solution of linear, as opposed to strictly convex, problems takes substantially longer due to the overhead of the nested PMD/RA algorithms.

#### Multistage Problems

Finally, linear multistage problems with up to 9 stages were solved in [16]. Results mirror those stated above, namely effective scalability and the ability to make progress on very large scale problems, even with the complex nonanticipativity structure of a 9-stage problem. OSL is generally superior to the PMD/RA implementation for small to medium-sized problems, but cannot solve the large instances.

For further material on the parallel and massively parallel solution of large scale stochastic programs, see also [22] and [23].

### Article Outline

- [Introduction](#)
- [Discrete-Time Models](#)
- [Continuous-Time Models](#)
- [References](#)

### Introduction

A significant number of optimal stopping problems of practical interest may only be solved through numerical schemes. As many of them have surfaced in the area of mathematical finance, illustrations drawn from that field will be used to describe some of these numerical approaches. Specifically, we consider problems in the expected-value maximization form

$$\sup_{\tau \in \mathcal{T}} E[f(X_\tau, \tau)], \quad (1)$$

where  $\mathcal{T}$  is a set of stopping times,  $f$  a measurable function and  $\{X_t\}_{t \in I} \equiv X$  a Markov process, where  $I$  is a time index set that can be either discrete or continuous (see AitSahlia [1] for additional details).

Under technical conditions for its existence, a solution for (1) consists of

- the value function  $V(x, t) = \sup_{\tau \in \mathcal{T}_t} E[f(X_\tau, \tau) | X_t = x]$ , where  $\mathcal{T}_t$  is the set of stopping times subsequent to  $t$  in  $\mathcal{T}$
- the optimal stopping time  $\tau_t^* = \operatorname{argmax}_{\tau \in \mathcal{T}_t} E[f(X_\tau, \tau)]$ .

In this context, with  $E$  denoting the state space of  $X$ , the set  $E \times I$  is partitioned into a closed set  $S$  and its complement  $C$  labeled, respectively, stopping and continuation regions. Then

$$\tau_t^* = \inf\{s \geq t : X_s \in S\}. \quad (2)$$

### Discrete-Time Models

When  $\mathcal{T} = \{0, 1, \dots, N\}$  for some given  $N < \infty$ , the most straightforward numerical device is the back-

wards recursive dynamic algorithm

$$V(x, N) = f(x, N), \quad (3)$$

$$\begin{aligned} V(x, n) \\ = \max\{E[V(X_{n+1}, n+1)|X_n = x], f(x, n)\}, \\ 0 \leq n \leq N-1. \end{aligned} \quad (4)$$

An issue with the above might be implementing the proper numerical scheme to estimate  $E[V(X_{n+1}, n+1)|X_n = x]$ , especially in light of the so-called *curse of dimensionality* that makes this algorithm inefficient in high dimensions. There are potentially two remedies to this problem: one, for finite  $\mathcal{T}$ , based on Monte-Carlo simulation, and another, for infinite  $\mathcal{T}$ , based on large-scale linear programming (LP). For the former, an efficient and popular algorithm is that of Longstaff and Schwartz [10], which is now viewed within the wider context of approximate dynamic programming (see also [3,11]). The basic idea of this algorithm is to use Monte Carlo simulation and least-squares regression to estimate  $E[V(X_{n+1}, n+1)|X_n = x]$ .

For infinite  $\mathcal{T}$ , the value function is time-homogeneous when  $X$  and  $f$  are. In this case the value function solves

$$V(x) = \sup_{\tau \in \mathcal{T}_t} E[f(X_\tau)|X_t = x] \quad (5)$$

for all  $t \in \{0, 1, \dots\}$  and may be obtained through a LP algorithm thanks to its Snell envelope characterization [1]. Assuming a transition matrix  $P$  for  $X$  and a finite state space, which might be genuine or the result of a truncation, the resulting LP is

$$\text{Minimize } \sum_x V(x)$$

subject to

$$V(x) \geq \sum_y P(x, y)V(y),$$

$$V(x) \geq f(x),$$

$$V(x) \geq 0.$$

See Çinlar [4] and Dynkin and Yushkevich [5] for proofs and further details.

## Continuous-Time Models

When both  $X$  and its time index  $I$  are continuous, there are a number of numerical schemes to generate solutions for (1). Overall, they approximate either the underlying diffusion process  $X$  by a discrete version or the value function and its derivatives in its characterizing expression (e.g., integral representation, partial differential equation.)

- Weak-convergence approximation approach: The most general scheme concerning this approach is to approximate the infinitesimal operator  $\mathcal{L}$  of  $X$  in the free-boundary problem that characterizes the solution of (1). For example, a finite-differences approximation of derivatives in the free-boundary problem

$$\begin{aligned} \mathcal{L}V &= 0 \quad \text{in } C, \\ V &= f \quad \text{on } E \times \{T\}, \\ \frac{\partial V}{\partial x} &= \frac{\partial f}{\partial x} \quad \text{on } \partial S \end{aligned}$$

leads to the formulation of an optimal stopping problem for a Markov chain (see Kushner and Dupuis [8]).

If the process  $X$  is explicitly expressed in terms of Brownian motion, then random-walk approximations can directly be used on the latter. This is a fairly well understood procedure for which rates of convergence have been developed (see Lamberton [9]).

- Integral equation approach: In this scheme, one makes use of the Doob–Meyer decomposition formula for submartingales (see Karatzas and Shreve [7]) to express the value function  $V$  in terms of the boundary, which itself solves a related integral equation. For example, consider a case in American option pricing, with horizon  $T$ , payoff function  $f(x, t) = e^{-rt} \max(K - x, 0)$ , and  $X_t = X_0 \exp\{(r - \sigma^2/2)t + \sigma W_t\}$ , where  $K > 0$ ,  $r > 0$ , and  $\sigma > 0$  are given and  $\{W_t\}_t$  is a standard Brownian motion started at 0. Then the value function  $V$  can be decomposed as

$$\begin{aligned} V(x, t) &= U(x, t) \\ &+ \int_t^T [rK\Phi(-d(X, B(\tau), \tau - t))]d\tau, \end{aligned} \quad (6)$$

where  $\Phi$  is the cumulative standard normal distribution function,  $d(x, y, \tau) = (\ln(x/y) + (r +$

$\sigma^2/2)\tau)/\sigma\sqrt{\tau} - \sigma\sqrt{\tau}$ , and  $U(x, t) = Ke^{(T-t)}\Phi(-d(x, K, T - t))$ . This formula requires the knowledge of the boundary  $B = \partial S$ , where  $S$  is the stopping region that identifies the optimal stopping time (2), and which is obtained as the solution of the integral equation

$$\begin{aligned} (K - B(t)) \\ = U(B(t), t) \\ + \int_t^T [rK\Phi(-d(B(t), B(t), \tau - t))]d\tau. \quad (7) \end{aligned}$$

Efficient and accurate spline approximations of  $B$  can be found in AitSahlia and Lai [2].

- Linear complementarity approach: An alternative that does not require the explicit determination of the optimal stopping boundary relies on the variational inequality formulation

$$\begin{aligned} \min\{V, V - f\} = 0, \quad \text{on } E \times [0, T], \\ V = f, \quad \text{on } E \times \{T\}. \end{aligned}$$

Finite-difference approximations then lead to a linear complementarity problem (see Huang and Pang [6] and Wilmott et al. [12]).

### Introduction

A typical stochastic optimal stopping problem of practical interest consists of the following optimization:

$$\sup E[f(X_\tau, \tau)] \quad \text{s.t. } \tau \in \mathcal{T}, \quad (1)$$

where  $\{X_t\} \equiv X$  is a stochastic process known as the state process,  $E$  its associated expectation operator,  $f$  a function measurable with respect to the probability law induced by  $X$ , and  $\mathcal{T}$  a set of stopping times to be defined shortly. In many applications  $f(X_\tau, \tau)$  is interpreted as the gain resulting from stopping at time  $\tau$  when the state value is  $X_\tau$ .

A financial example that has been the subject of great interest in mathematical finance/financial engineering is one with  $f(x, t) = e^{-rt} \max(K - x, 0)$ , where  $K > 0$  is given, and  $X$  is the geometric Brownian process

$$X_t = X_0 \exp\{(r - \sigma^2/2)t + \sigma B_t\},$$

where  $r$  and  $\sigma$  are given positive constants and  $\{B_t\}$  is a standard Brownian motion started at 0. In finance  $f(X_t, t)$  represents the discounted payoff that results from the exercise at time  $t$  of a put stock option by its holder who is allowed to sell this stock at share price  $K$  when it is traded at price  $X_t$ . The option holder's prob-

lem is to find the best time to exercise this option, thus maximizing its payoff, a problem that is mathematically expressed as (1). As will be made precise soon, this optimal exercise time (or more generally stopping time) must be determined only on the basis of past observations. It should be mentioned here that  $\{B_t\}$  can also be considered the state process, instead of  $X$ .

Note that the payoff function  $f$  as expressed in (1) does include payoffs that are path-dependent through the usual introduction of additional variables to render a problem Markovian. For example, still in the financial realm, one may consider the payoffs  $e^{-rt}(M_t - X_t)$  or  $e^{-rt} \max(K - A_t, 0)$  that depend on the maximum process  $M_t = \max_{s \leq t} X_s$  or the average process  $A_t = (1/t) \int_0^t X_s ds$ .

Stochastic optimal stopping theory, or optimal stopping as it is customarily known, is a specialized type of the (stochastic) dynamic programming approach devised by Bellman [1] in the 1950s. However, actual optimal stopping problems originated in Wald's work on sequential statistical inference (Wald [4]), where the problem is to determine sequentially the sample size that will decide between two statistical hypotheses. Ever since these early days, this field has experienced several developments in both theory and applications as described for example in the book of Peskir and Shiryaev [3].

Optimal stopping problems are generally approached from a probabilistic perspective through martingales and Markov processes. When the underlying process  $X$  in (1) is a diffusion, they also lead to free-boundary problems for partial differential equations. Optimal stopping problems are rarely solved in closed-form and numerical methods abound, a topic addressed in a companion entry in this Encyclopedia.

## Definitions

This section sets up basic definitions that lead to the notion of stopping time. As mentioned before, the decision to stop at time  $t$  must be based only on information available up to  $t$ . In this respect the concept of information set in the form of filter is first formally presented, followed by that of stopping time.

- Discrete-time filtration  
Given a probability space  $(\Omega, \mathcal{F}, P)$ , a discrete-time filtration is a collection  $(\mathcal{F}_n)_{n \geq 0}$  where each  $\mathcal{F}_n$  is

a  $\sigma$ -algebra of subsets of  $\Omega$  such that  $\mathcal{F}_0 \subset \mathcal{F}_1 \subset \dots \subset \mathcal{F}$ .  $\mathcal{F}_n$  represents the information available up to time  $n$ . It generally consists of at least the set of events that have been determined by the realized values of  $X_t$  up to time  $n$ . The latter is called the natural filtration of  $X$  and is often augmented to form  $(\mathcal{F}_n)_{n \geq 0}$ .

- Continuous-time filtration

Here the definition is essentially identical to the previous modulo a technical condition. Given a probability space  $(\Omega, \mathcal{F}, P)$ , a continuous-time filtration is a collection  $(\mathcal{F}_t)_{t \geq 0}$  where each  $\mathcal{F}_t$  is a  $\sigma$ -algebra of subsets of  $\Omega$  such that  $\mathcal{F}_s \subset \mathcal{F}_t \subset \mathcal{F}$  for  $s \leq t$ . As in the discrete-time case,  $\mathcal{F}_t$  also represents information up to time  $t$ . Additionally, it is assumed that each  $\mathcal{F}_t$  contains all  $P$ -null sets in  $\mathcal{F}$  and that  $(\mathcal{F}_t)_{t \geq 0}$  is right-continuous; i. e.,  $\mathcal{F}_t = \bigcap_{s \leq t} \mathcal{F}_s$  for all  $t \geq 0$ .

- Stopping time

Let  $I = \{0, 1, 2, \dots\}$  and  $I = [0, \infty]$  when  $X$  is, respectively, a discrete-time process and a continuous-time process. A random variable  $\tau: \Omega \rightarrow I$  is a stopping time if  $P\{\tau < \infty\} = 1$  and  $\{\tau \leq t\} \in \mathcal{F}_t$  for all  $t \geq 0$ . Often the set  $I$  is bounded and therefore the former condition is obviously true. The latter condition expresses the fact that the decision to stop at time  $t$  must be based solely on information up to time  $t$ . In this case  $\tau$  is adapted to the filtration  $(\mathcal{F}_t)_{t \geq 0}$ .

## Solution Methods

There are generally two approaches to solving (1): one based on probabilistic tools and another on partial differential equations (PDE) techniques. However, both start by using the dynamic programming principle of optimality to derive the so-called Bellman equation. When the interval  $I$  is of the form  $[0, T]$  or  $\{1, 2, \dots, N\}$  define  $\mathcal{T}_t$  to be, respectively, the set of stopping times in  $[t, T]$  and  $\{t, t + 1, \dots, N\}$ . When  $I$  is infinite,  $\mathcal{T}_t$  is defined as the set of stopping times in  $I$  that are  $\geq t$ . Then solving (1) is tantamount to determining

- the value function  $V(x, t) = \sup_{\tau \in \mathcal{T}_t} E[f(X_\tau, \tau) | X_0 = x]$ , and
- the optimal stopping time  $\tau_t^* = \operatorname{argmax}_{\tau \in \mathcal{T}_t} E f(X_\tau, \tau)$ .

A sufficient condition guaranteeing the finiteness of the expectation in (1) is

$$E(\sup_{t \in I} |f(X_t, t)|) < \infty,$$

which can in fact be relaxed a number of ways.

- (I) The Probabilistic Approach: Martingales  
When  $I = \{0, 1, \dots, N\}$ , then by the optimality principle of dynamic programming we can write the recursion

$$V(x, N) = f(x, N) \tag{2}$$

$$V(x, n) = \max\{E[V(X_{n+1}, n+1)|X_n = x], f(x, n)\}, \quad 0 \leq n \leq N-1. \tag{3}$$

The solution for the system (2)–(3) induces a sequence of random variables  $S_n = V(X_n, n)$  that satisfies the following properties:

- (i)  $S_n = \max\{E[S_{n+1}|\mathcal{F}_n], f(X_n, n)\}$ ;
- (ii)  $(S_n)_{k \leq n \leq N}$  is the smallest super-martingale that dominates the gain process  $G_n = f(X_n, n)_{k \leq n \leq N}$  (i. e.;  $S_n \geq G_n$  P-a.s.);
- (iii) the stopping time  $\tau_n^* = \inf\{n \leq k \leq N : S_n = G_n\}$  is optimal for  $0 \leq n \leq N$ ;
- (iv) the stopped sequence  $(S_{k \wedge \tau_n^*})_{n \leq k \leq N}$  is a martingale.

We recall here that a discrete-time process  $(M_n)_n$  is a martingale with respect to a filtration  $(\mathcal{F}_n)_n$  (martingale for short) if  $E|M_n| < \infty$  for  $n \geq 0$  and  $E(M_{n+1}|\mathcal{F}_n) = M_n$ , P-a.s., for  $n \geq 0$ . Correspondingly,  $(M_n)_n$  is a super-martingale if  $E(M_{n+1}|\mathcal{F}_n) \leq M_n$ , P-a.s.,  $n \geq 0$ . The process  $(S_n)_{k \leq n \leq N}$  is called the Snell envelope and the above characterization is particularly useful to obtain the value function  $V$  through linear programming when the state space is finite (see Çinlar p. 212 in [2]).

The generalization of the above result to the case where  $I$  is countably infinite requires that the sequence  $S_n = V(X_n, n)$  be characterized differently through the concept of essential supremum below, which generalizes in some sense that of deterministic supremum.

**Essential Supremum.** Let  $I$  be an arbitrary set and  $(Z_n)_{n \in I}$  be a collection of random variables defined on the same probability space. Then

there exists a countable subset  $J \subset I$  such that  $Z^* = \sup_{n \in J} Z_n$  satisfies

- (a)  $Z_n \leq Z^*$  P-a.s. for each  $n \in I$ ;
- (b) for any other random variable  $\tilde{Z}$  such that  $Z_n \leq \tilde{Z}$  P-a.s. for each  $n \in I$ , we have  $Z^* \leq \tilde{Z}$  P-a.s.

The random variable  $Z^*$  is labeled *essential supremum* and is denoted by  $\text{esssup}_{n \in I} Z_n$ .

As a consequence, we can now rewrite the above Snell envelope when  $I = \{1, 2, \dots, N\}$  as

$$S_n = \text{esssup}_{\tau \in \mathcal{T}_n} E[f(X_\tau, \tau)|\mathcal{F}_n], \quad n \in I, \tag{4}$$

where  $\mathcal{T}_n$  is the set of stopping times in  $\{n, n+1, \dots, N\}$ . When  $I$  is countable infinite then  $S_n$  is correspondingly defined with  $\mathcal{T}_n$  as the set of stopping times in  $\{n, n+1, \dots\}$ . Similarly,  $S_n$  satisfies both conditions (a) and (b) and the optimality property (i) above for all  $n \geq 0$ .

For the continuous-time case, where  $I$  is an interval, the value function for problem (1) is the Snell envelope of the gain process  $(f(X_t, t))_t$  defined as

$$S_t = \text{esssup}_{\tau \in \mathcal{T}_t} E[f(X_\tau, \tau)|\mathcal{F}_t], \quad t \in I, \tag{5}$$

where  $\mathcal{T}_t$  is the set of stopping times in  $[t, T]$  for a finite horizon problem or  $[t, \infty)$  otherwise. The Bellman equation in its discrete form (3) is now replaced by

$$V(x, t) \geq \max\{E[V(X_s, s)|X_t = x], f(X_t, t)\}, \quad \text{for } s \geq t.$$

Formulation (1) has cast the problem of optimal stopping in a Markovian framework. This is in fact the most common situation in practice and the set-up is not too restrictive as it mirrors well the generic martingale situation fully described in Peskir and Shiryaev [3].

- (II) The Probabilistic Approach: Markov Property and Stopping Boundary

When  $X$  is a Markov process (in discrete- or continuous-time) with state space  $E$  the optimal stopping time is defined as

$$\tau^* = \inf\{t \in I : X_t \in S\},$$

where  $S$  is a closed subset in  $I \times E$ .  $S$  and its complement  $C$  in  $I \times E$  are such that

$$\begin{aligned} V(x, t) &> f(x, t) \text{ on } C, \\ V(x, t) &= f(x, t) \text{ on } S. \end{aligned}$$

$C$  and  $S$  are respectively called the continuation and stopping regions. The intersection  $B$  of their closures is called the stopping boundary. It is time-dependent when  $I$  is bounded and time-homogeneous when  $I$  is unbounded. When  $I$  is countably finite and  $E$  is discrete, then  $B$  can be obtained through the backward recursion (2)–(3).

### (III) The PDE Approach

When the state process  $X$  is a diffusion the boundary  $B$  and the value function  $V$  can be obtained by solving a free-boundary problem. Alternatively, when only the value function is of interest then it can be obtained as the solution of a variational inequality. If we let  $\mathcal{L}$  the infinitesimal operator associated with  $X$ , then assuming regularity and differentiability where necessary, the free-boundary problem when  $I = [0, \infty)$  is stated as

$$\begin{aligned} \mathcal{L}V &= 0 && \text{in } C, \\ \frac{\partial V}{\partial x} &= \frac{\partial f}{\partial x} && \text{on } B. \end{aligned} \quad (6)$$

The latter condition is called smooth-fit. It is in a sense the condition that characterizes the optimality of a solution  $V$  of the PDE (6). When  $I = [0, T]$  the free-boundary problem becomes:

$$\begin{aligned} \mathcal{L}V &= 0 && \text{in } C, \\ V &= f && \text{on } E \times \{T\}, \\ \frac{\partial V}{\partial x} &= \frac{\partial f}{\partial x} && \text{on } B. \end{aligned} \quad (7)$$

One way to avoid reference to the free boundary  $B$  is through the use of variational equality. For example, the latter problem with finite horizon  $T$  can be re-expressed as

$$\begin{aligned} \min\{V, V - f\} &= 0, && \text{on } E \times [0, T) \\ V &= f, && \text{on } E \times \{T\}. \end{aligned}$$

Stochastic programming; Incomplete information; Game theory; Minimax decision rule; Worst-case analysis; Bounds

In many applications of stochastic programming there is some uncertainty about the probability distribution  $P$  of the random parameters. The *incomplete knowledge of the probability distribution* can be described by assuming that  $P$  belongs to a specified class  $\mathcal{P}$  of probability distributions. This in turn suggests to use the *minimax decision rule*.

The first results were concerned with stochastic linear programs with recourse; they can be treated within the following more general framework

$$\begin{cases} \min & F(\mathbf{x}; P) := E_P f(\mathbf{x}; \omega) \\ \text{on} & \text{the set } \mathcal{X} \subset \mathbf{R}^n, \end{cases} \quad (1)$$

with  $\mathcal{X}$  a given set of decisions,  $P$  a probability distribution on  $(\Omega, \Sigma)$ ,  $\Omega \subset \mathbf{R}^m$  and  $P$  known to belong to a class  $\mathcal{P}$ . The random outcome of a decision  $\mathbf{x} \in \mathcal{X}$  is quantified by a function  $f$  defined on  $\mathcal{X} \times \Omega$ ,  $E_P$  denotes the expectation under  $P$ .

These results were formulated in terms of the *two-person zero-sum game*

$$(\mathcal{X}, \mathcal{P}, F(\mathbf{x}; P)). \quad (2)$$

M. Iosifescu and R. Theodorescu [11] suggested to use an optimal mixed strategy of the first player in the game (2). J. Žáčková [18] introduced the notion of *minimax solution* as an optimal pure strategy of the first player

in the game (2). Under quite general assumptions on  $\mathcal{P}$  and  $F$ , a minimax solution exists and

$$\inf_{\mathbf{x} \in X} \max_{P \in \mathcal{P}} F(\mathbf{x}; P) = \max_{P \in \mathcal{P}} \inf_{\mathbf{x} \in X} F(\mathbf{x}; P). \tag{3}$$

The minimax decision rule can be applied also in cases when the minimax theorem for the game (2) does not hold true. It means to solve the problem

$$\begin{cases} \min & \max_{P \in \mathcal{P}} F(\mathbf{x}; P) \\ \text{on} & \text{the set } X \subset \mathbf{R}^n \end{cases} \tag{4}$$

hence, to apply the best possible decision obtained for the most adverse considered circumstances. This provides a tool for the *worst-case analysis* for program (1) and allows for constructing bounds for the optimal value of (1) valid for all  $P \in \mathcal{P}$ .

Applicability of the results depends on the assumed form of the class  $\mathcal{P}$  which describes the level of the available information about the probability distribution of the random parameters and also on the properties of the random objective function  $f(\mathbf{x}; \omega)$ . Let us list some of the most frequent choices of  $\mathcal{P}$ :

- $\mathcal{P}$  consists of probability distributions carried by  $\Omega \subset \mathbf{R}^m$  which fulfill certain *moment conditions*, e. g.,

$$P = \{P: E_P g_j(\omega) = y_j, j = 1, \dots, J\} \tag{5}$$

with prescribed values  $y_j, \forall j, [4,6,8,17,18]$ .

- $\mathcal{P}$  contains probability distributions on  $(\Omega, \Sigma)$  with fixed marginals [15].
- Additional qualitative information, such as unimodality of  $P$ , is taken into account [6,8].
- $\mathcal{P}$  consists of probability distributions  $P$  with known finite support, i. e., to specify  $P$  means to fix the probabilities of the considered atoms (scenarios) taking into account a prior knowledge about their partial ordering, etc.; see e. g. [2].
- $\mathcal{P}$  is a neighborhood of a hypothetical probability distribution  $P_0$  [4].
- In principle,  $\mathcal{P}$  can be also a parametric family of probability distributions with an incomplete knowledge of parameter values.

For convex, compact  $\mathcal{P}$ , the expectation  $F(\mathbf{x}; P) = E_P f(\mathbf{x}; \omega)$  attains its maximal (and minimal) value at extremal points of  $\mathcal{P}$ ; the extremal probability distributions can be characterized independently of the form of the random objective  $f$ , however, the worst-case probability

distribution, say,  $P^* \in \mathcal{P}$  independent of  $f$  (and thus independent of the decisions  $\mathbf{x}$ ) appears only exceptionally. If this is possible the objective function in (4)  $\max_{P \in \mathcal{P}} F(\mathbf{x}; P) = F(\mathbf{x}; P^*)$  is just an objective function of a standard stochastic program which is relatively easy to solve due to a relatively simple structure of  $P^*$ . There are also instances when one can succeed to get the explicit form of  $\max_{P \in \mathcal{P}} F(\mathbf{x}; P)$  [6,12]. They relate to classes of one-dimensional probability distributions and to special functions  $f$ .

The general methodology for solution of the inner optimization problem  $\max_{P \in \mathcal{P}} F(\mathbf{x}; P)$  for a fixed decision  $\mathbf{x}$  has been elaborated in detail for the classes of probability distributions defined by moment conditions (5), both in the form of equations and inequalities: The extremal probability distributions have finite supports, cf. [14,17], and the solution of the inner problem

$$\max_P \int_{\Omega} f(\mathbf{x}; \mathbf{z}) dP \tag{6}$$

subject to

$$\begin{cases} \int_{\Omega} dP = 1, \\ \int_{\Omega} g_j(\mathbf{z}) dP = y_j, \quad j = 1, \dots, J, \end{cases} \tag{7}$$

reduces to solution of a generalized linear program (cf. [3,4,7,9,17]), provided that  $\Omega$  is compact and  $f(\mathbf{x}; \cdot), g_j, \forall j$ , are continuous on  $\Omega$ . The procedure provides both the atoms of the sought worst-case probability distribution and their probabilities. In some cases, it is expedient to analyze the dual program to (6), (7), which reads

$$\min_{\mathbf{u}} \sum_{j=1}^J u_j y_j + u_0 \tag{8}$$

subject to

$$u_0 + \sum_{j=1}^J u_j g_j(\mathbf{z}) \geq f(\mathbf{x}; \mathbf{z}), \quad \forall \mathbf{z} \in \Omega. \tag{9}$$

For details and various applications consult [3,4,5,6,7,8,9,13,17].

As an example, let  $f(\mathbf{x}; \cdot)$  be a convex function on a bounded convex polyhedron  $\Omega \subset \mathbf{R}^m$ , say,  $\Omega =$

$\text{conv}\{\omega^{(1)}, \dots, \omega^{(K)}\}$  and

$$\mathcal{P} = \{P: E_P \omega_j = y_j, j = 1, \dots, m\} \quad (10)$$

with  $\mathbf{y}$  a given interior point of  $\Omega$ . The constraints of (9),

$$u_0 + \sum_{j=1}^m u_j z_j \geq f(\mathbf{x}; \mathbf{z}),$$

hold true for all  $\mathbf{z} \in \Omega$  if and only if they are fulfilled for the extremal points  $\omega^{(1)}, \dots, \omega^{(K)}$ . Duality properties imply that only suitable subsets of the set of extremal points of  $\Omega$  need to be considered in construction the finite supports of the worst-case distributions. The generalized linear program (6), (7) reduces to the linear program

$$\max_P \sum_{k=1}^K p_k f(\mathbf{x}; \omega^{(k)}) \quad (11)$$

subject to

$$\begin{cases} \sum_{k=1}^K p_k \omega_j^{(k)} = y_j, & j = 1, \dots, m, \\ \sum_{k=1}^K p_k = 1, & p_k \geq 0 \quad \forall k. \end{cases} \quad (12)$$

Convexity of  $f$  with respect to  $\omega$  is essential for the above result. Generalization to piecewise convex functions  $f(\mathbf{x}, \cdot)$  (cf. [5]) is possible; on the other hand, the worst-case probability distribution from the class (10) for  $f$  concave in  $\omega$  is the degenerated distribution concentrated at the prescribed expected value  $E_P \omega$ . This degenerated distribution provides the best (i. e., the minimal possible) expectation for convex functions  $f(\mathbf{x}, \cdot)$  under  $P$  belonging to the class  $\mathcal{P}$ ; compare with the Jensen inequality.

If the set of feasible solutions of (12) is a singleton, the worst-case distribution  $P^*$  does not depend on  $f$  and we obtain bounds for the optimal values of the stochastic programs (12) under an arbitrary probability distribution  $P$  from the class (10) and an arbitrary function  $f$  which is convex in  $\omega$ :

$$\begin{aligned} \min_{\mathbf{x} \in X} f(\mathbf{x}, E_P \omega) &\leq \min_{\mathbf{x} \in X} E_P f(\mathbf{x}, \omega) \\ &\leq \min_{\mathbf{x} \in X} E_{P^*} f(\mathbf{x}, \omega), \quad \forall P \in \mathcal{P}, \end{aligned} \quad (13)$$

provided that the minima exist. Such bounds are numerically tractable, are tight and provide an information about sensitivity of the optimal value of stochastic program (1) on the choice of a probability distribution  $P$  belonging to the considered class  $\mathcal{P}$ . The well-known instance is the class of probability distributions carried by a closed interval  $[a, b]$  on the real line with a prescribed value  $y \in (a, b)$  of the expectation  $E_P \omega$ . The worst-case distribution is carried by the endpoints of the given interval  $[a, b]$  and the only solution of the system

$$p_1 a + p_2 b = y, \quad p_1 + p_2 = 1, \quad p_1, p_2 \geq 0$$

is  $p_1 = (b - y)/(b - a)$  and  $p_2 = 1 - p_1$ . The result agrees with the well-known Edmundson-Madansky inequality and the minimax approach guarantees that this bound is tight within the considered class of probability distributions and for convex functions  $f(\mathbf{x}, \cdot)$ .

There is a host of papers devoted to designing various bounds for the objective function  $F(\mathbf{x}, P)$  of stochastic programs (1) under various assumptions about the class  $\mathcal{P}$  and the function  $f(\mathbf{x}, \cdot)$ ; for a review of the related results see [3,4,6,13,17] and the references therein. These bounds proved to be useful also in designing algorithms and this is at present the main field of successful applications of the minimax approach.

On the other hand, to get minimax decisions is rather demanding, as it requires the solution of the full minimax problem (4). Except for the simple special cases, such as a unique feasible discrete distribution that fulfills (7) or the optimal value of the objective function (8) obtained in an explicit form, one has to rely on special numerical procedures such as the stochastic quasi-gradient methods designed for this purpose in [9,10]. The numerical difficulties are behind the fact that, in spite of a sound motivation, real life applications of the minimax approach have been rare and have consisted of the simple special cases e. g., [1,2,6,8,15,16].

Random objective function; Efficient point; Kataoka principle

We consider an objective function  $h(\mathbf{x}, \xi)$ , to be maximized in a mathematical programming problem, where  $\xi$  is a random vector. There are two prominent proposals to incorporate it into a stochastic programming model formulation. The first one is due to H.M. Markowitz [2,3] and it advocates for the maximization, with respect to  $\mathbf{x}$  and subject to the given constraints, of the function

$$\alpha E[h(\mathbf{x}, \xi)] - \beta \sqrt{\text{Var}[h(\mathbf{x}, \xi)]},$$

where  $\alpha > 0$  and  $\beta > 0$  are constants. We may choose  $\alpha = 1$ . Let  $\mu(\mathbf{x}) = E[h(\mathbf{x}, \xi)]$ ,  $\sigma(\mathbf{x}) = \sqrt{\text{Var}[h(\mathbf{x}, \xi)]}$ . An optimal solution  $\mathbf{x}_0$  can be characterized by the following two statements:

- a) there is no feasible  $\mathbf{x}$  such that  $\mu(\mathbf{x}) = \mu(\mathbf{x}_0)$ ,  $\sigma(\mathbf{x}) < \sigma(\mathbf{x}_0)$ ;
- b) there is no feasible  $\mathbf{x}$  such that  $\sigma(\mathbf{x}) = \sigma(\mathbf{x}_0)$ ,  $\mu(\mathbf{x}) > \mu(\mathbf{x}_0)$ .

We say that the pair  $(\mu(\mathbf{x}_0), \sigma(\mathbf{x}_0))$  is an *efficient point* among all pairs  $(\mu(\mathbf{x}), \sigma(\mathbf{x}))$ .

An important special case is the random objective function  $h(\mathbf{x}, \xi) = \xi^\top \mathbf{x}$  and it comes up in portfolio composition problems, where the components of  $\xi$  are the random returns of the assets. If we introduce the notations  $\mu = E(\xi)$ ,  $C = E[(\xi - \mu)(\xi - \mu)^\top]$ , then the objective function of the stochastic programming problem takes the form:

$$\mu^\top \mathbf{x} - \beta \sqrt{\mathbf{x}^\top C \mathbf{x}}.$$

Sometimes  $\mathbf{x}^\top C \mathbf{x}$  is replaced for  $\sqrt{\mathbf{x}^\top C \mathbf{x}}$ , in order to obtain a convex quadratic programming problem.

Sometimes  $\mu^\top \mathbf{x}$  is fixed (or a lower bound is prescribed for it) and  $\mathbf{x}^\top C \mathbf{x}$  is minimized, or  $\mathbf{x}^\top C \mathbf{x}$  is fixed (or an upper bound is prescribed for it) and  $\mu^\top \mathbf{x}$  is maximized.

The second principle to handle  $h(\mathbf{x}, \xi)$  is due to S. Kataoka [1]. In this case we formulate the problem

$$\begin{cases} \max & d \\ \text{s.t.} & P(h(\mathbf{x}, \xi) \geq d) \geq p, \\ & \mathbf{x} \in D, \end{cases}$$

where  $p$  is a prescribed probability and  $D$  is the set of feasible solutions in the original problem. In the special case  $h(\mathbf{x}, \xi) = \xi^\top \mathbf{x}$ , and under the assumption that  $\xi$  has a normal distribution, the above problem can be shown to be equivalent to

$$\begin{cases} \max & \left\{ \mu^\top \mathbf{x} + \Phi^{-1}(1-p) \sqrt{\mathbf{x}^\top C \mathbf{x}} \right\} \\ \text{s.t.} & \mathbf{x} \in D, \end{cases}$$

where  $\Phi$  is the univariate standard normal probability distribution function.

Decision making under uncertainty can often be formalized as a *stochastic program*, constrained not merely in material terms (by bounded resources, capacities, technological possibilities etc.), but also by limited information (*nonanticipativity*). The former type of constraints, accounting for material bounds, is usually described by inequalities required to hold almost surely. The latter type, reflecting informational restrictions, often assumes the form of linear equations involving conditional expectation operators. Each sort of constraint generates its own Lagrange multipliers. These Lagrange multipliers have various applications. In particular, they play key roles in algorithms for solving stochastic programs employing decomposition (cf. also ▶ [Stochastic linear programming: Decomposition and cutting planes](#)) or constraint relaxation techniques [[12](#),[13](#),[17](#),[19](#)]. Besides their computational role, these auxiliary variables also figure prominently in optimality conditions, duality theory and stability analysis (cf. also ▶ [Stochastic integer programming: Continuity, stability, rates of convergence](#)). Present randomness, they

take on specific features [1,3,4,9,11,15,16,18], which are reviewed in this article.

### The Basic Model

Stochastic programs often assume the following form. Minimize a functional  $f(x) = f(x(\cdot))$  over some given set in a linear space  $\mathcal{L}$  containing finite sequences  $x(\cdot) = (x_1(\cdot), \dots, x_T(\cdot))$  of random vectors  $x_t(\omega) \in \mathbf{R}^{n_t}$ . These vectors represent constrained choices (made sequentially, one at each stage or time  $t = 1, \dots, T < \infty$ ) under imperfect knowledge about the state  $\omega \in \Omega$  of the world. Although  $\omega$  is not known a priori, its probability distribution,  $\mathbb{P}$ , is given exogenously and defined on some *sigma-field*  $\mathcal{F}_{T+1}$  in  $\Omega$ . The knowledge of  $\omega$  increases over time. Specifically, there is an expanding family  $\mathcal{F}_1 \subseteq \dots \subseteq \mathcal{F}_{T+1}$  of sigma-fields which describes the information flow. At time  $t$  one may ascertain for any event in  $\mathcal{F}_t$  (and such events only) whether it has happened or not. In particular, a finite  $\mathcal{F}_t$  partitions  $\Omega$  into minimal events (atoms, information sets, decision nodes) on each of which  $x_t$  must be constant. The inclusion  $\mathcal{F}_t \subseteq \mathcal{F}_{t+1}$ ,  $t \leq T$ , reflecting progressive acquisition of knowledge, says that the partition becomes finer as time evolves.

At time  $t$  the decision-maker implements the part  $x_t$  of his overall decision  $x = (x_1, \dots, x_T)$ . That part is supposed to be an  $\mathcal{F}_t$ -measurable strategy (policy, behavioral rule)  $x_t: \Omega \rightarrow \mathbf{R}^{n_t}$ . This means that only available information is used any stage; decisions are based on realized rather than future events. If so, the process  $x = (x_1, \dots, x_T)$  is called *nonanticipative with respect to the filtration*  $\mathcal{F} = (\mathcal{F}_t)_{t=1}^T$ , and we write  $x \in \mathcal{F}$  for brevity. For example, let  $\theta_1, \dots, \theta_T$  be a stochastic process, defined on  $\Omega$ , and let  $\mathcal{F}_t$  be generated by  $\theta_1, \dots, \theta_t$ . Then  $x \in \mathcal{F}$  means that  $x_t$  depends on  $\theta_1, \dots, \theta_t$  only.

Besides the informational limitation  $x \in \mathcal{F}$ , there are other restrictions  $x \in \mathcal{G} \cap \mathcal{X}$  ‘material’ in nature, which are defined as follows:  $x \in \mathcal{L}$  belongs to the set  $\mathcal{G}$  (and is said to satisfy the *phase constraints*) if and only if

$$g_t(\omega, x(\omega)) := g_t(\omega, x_1(\omega), \dots, x_t(\omega)) \in -K_t(\omega) \quad (1)$$

almost surely (a.s.);  $x \in \mathcal{L}$  belongs to  $\mathcal{X}$  if and only if

$$x_t(\omega) \in X_t(\omega) \quad \text{a.s.} \quad (2)$$

for all  $t$ . Here,  $g_t: \Omega \times \mathbf{R}^{n_1 + \dots + n_t} \rightarrow \mathbf{R}^{m_t}$  is  $\mathcal{F}_t \times \mathcal{B}$ -measurable, and  $K_t(\omega) \subseteq \mathbf{R}^{m_t}$ ,  $X_t(\omega) \subseteq \mathbf{R}^{n_t}$  are  $\mathcal{F}_t$ -measurable random sets (see, e.g., [2] and [1]);  $\mathcal{B}$

stands for the Borel  $\sigma$ -algebra. Both  $X_t(\omega)$  and  $K_t(\omega)$  are nonempty and closed;  $K_t(\omega)$  is a convex cone. Define the relation  $\leq_{t,\omega}$  on  $\mathbf{R}^{m_t}$  by  $a \leq_{t,\omega} b \Leftrightarrow b - a \in K_t(\omega)$ . Then (1) can be written in the form

$$g_t(\omega, x(\omega)) \leq_{t,\omega} 0 \quad \text{a.s.} \quad (3)$$

The basic optimization problem is stated as follows.

$$(P) \quad \begin{cases} \text{Find} & \inf f(x) \\ \text{s.t.} & x \in \mathcal{F} \cap \mathcal{G} \cap \mathcal{X}. \end{cases}$$

Problem (P) is supposed to be feasible (i.e.,  $\mathcal{F} \cap \mathcal{G} \cap \mathcal{X} \neq \emptyset$ ) with finite optimal value.

Important examples of objective functionals include integral functionals of the form

$$f(x) := \mathbb{E}F(\omega, x(\omega)) = \int F(\omega, x(\omega))\mathbb{P}(d\omega), \quad (4)$$

where  $F$  is some  $\mathcal{F}_{T+1} \times \mathcal{B}$ -measurable integrand for which  $f(x)$ ,  $x \in \mathcal{X}$ , is well-defined and finite.

In the general setting, the objective  $f$  is a real-valued functional on the set  $\mathcal{X} \subseteq \mathcal{L}$ , where  $\mathcal{L}$  is the given linear space of  $\mathcal{F}_{T+1}$ -measurable vector functions  $x(\omega) = (x_1(\omega), \dots, x_T(\omega))$ . As  $\mathcal{L}$ , one often takes  $L^p(\mathcal{F}_{T+1}, \mathbb{P}; \mathbf{R}^n)$ ,  $n := \sum n_t$ , with  $p \in [1, +\infty]$ . This space consists of (equivalence classes of)  $\mathcal{F}_{T+1}$ -measurable functions  $x: \Omega \rightarrow \mathbf{R}^n$  with finite norm  $\|x\|_p := [\int |x(\omega)|^p \mathbb{P}(d\omega)]^{1/p}$  if  $p \in [1, +\infty)$ , and  $\|x\|_\infty := \text{ess sup } |x(\omega)|$ , where  $|\cdot|$  is any fixed norm on a finite-dimensional vector space.

It will be convenient to assume that all the  $\sigma$ -algebras  $\mathcal{F}_t$ , are completed by all subsets of null-sets in  $\Omega$ . In many applications, this assumption does not lead to a significant loss in generality.

### Results

For the most part, it will not be supposed that problem (P) has optimal solutions. For completeness, however, an existence result is provided.

**Theorem 1 (Existence of optimal solutions.)** *Suppose that, for each  $\omega$ , the set*

$$A(\omega) := \left\{ a = (a_1, \dots, a_T) : \begin{array}{l} a_t \in X_t(\omega), \\ g_t(\omega, a) \in -K_t(\omega), \\ \forall t \end{array} \right\}$$

is closed, convex and bounded in the norm  $|\cdot|$  by some number  $\beta(\omega) \geq 0$ , where  $E\beta < \infty$ . Assume  $\mathcal{L}$  contains a  $x \in \mathcal{F}$  such that  $x(\omega) \in A(\omega)$  a.s. Also, suppose  $f$  is convex and lower semicontinuous with respect to  $L^1$  convergence. Then problem (P) admits an optimal solution.

*Proof* The feasible set  $\mathcal{F} \cap \mathcal{G} \cap \mathcal{X}$  is convex, closed in  $L^1$  and uniformly integrable, hence weakly sequentially compact, while  $f$  is weakly lower semicontinuous [6].

Some notation must now be fixed. If  $\mathcal{Y}$  is a topological vector space, we write  $y^* \in \mathcal{Y}^*$  when  $y^*$  is a continuous linear mapping of  $\mathcal{Y}$  into  $\mathbf{R}$ . The value of  $y^* \in \mathcal{Y}^*$  at  $y \in \mathcal{Y}$  is denoted by  $y^*y$ . If  $\mathcal{K} \subseteq \mathcal{Y}$  is a convex cone, its dual cone is defined as  $\mathcal{K}^+ := \{y^* \in \mathcal{Y}^* : y^*y \geq 0, \forall y \in \mathcal{K}\}$ .

The following general fact will serve as the basis for further presentation.

**Proposition 2 (A Fritz John rule)** Consider an optimization problem:

$$(P1) \begin{cases} \text{Find} & \inf f(x) \\ \text{s.t.} & x \in \mathcal{X}, \\ & g(x) \in -\mathcal{K}, \\ & h(x) = 0, \end{cases}$$

having finite optimal value  $\inf(P1)$  for the given functions  $f: \mathcal{X} \rightarrow \mathbf{R}$ ,  $g: \mathcal{X} \rightarrow \mathcal{Y}$  and  $h: \mathcal{X} \rightarrow \mathcal{Z}$ . Here  $\mathcal{X}$  is a set,  $\mathcal{K} \subseteq \mathcal{Y}$  is a convex cone, and  $\mathcal{Y}, \mathcal{Z}$  are Hausdorff linear topological spaces. Suppose the convex hull  $\text{conv } C$  of the set

$$C := \left\{ \begin{array}{l} (r, y, z) \\ \in \mathbf{R} \times \mathcal{Y} \times \mathcal{Z} \end{array} : \begin{array}{l} f(x) \leq \inf(P1) + r, \\ g(x) \in -\mathcal{K} + y, \\ h(x) = z \\ \text{for some } x \in \mathcal{X} \end{array} \right\}$$

has nonempty interior and  $(0, 0, 0)$  at its boundary. Then there exists a nonzero continuous linear functional  $(r^*, y^*, z^*) \in \mathbf{R}_+ \times \mathcal{K}^+ \times \mathcal{Z}^*$  such that

$$\begin{aligned} & r^* \inf(P1) \\ & = \inf \{r^*f(x) + y^*g(x) + z^*h(x) : x \in \mathcal{X}\}. \end{aligned} \tag{5}$$

If  $\mathcal{Y}, \mathcal{Z}$  are both finite-dimensional, it suffices for (5) that  $(0, 0, 0)$  lies at the boundary of  $\text{conv } C$ .

*Proof* The convex hull of  $C$  has a closed supporting hyperplane through its boundary point  $(0, 0, 0)$ . Hence there is a nonzero  $(r^*, y^*, z^*) \in \mathbf{R}^* \times \mathcal{Y}^* \times \mathcal{Z}^*$  such that

$r^*r + y^*y + z^*z \geq 0$  for all  $(r, y, z) \in C$ . It is straightforward to see that  $r^* \geq 0$ , and that  $y^*$  must belong to the dual cone  $\mathcal{K}^+$ . Thus  $r^*[f(x) - \inf(P1)] + y^*g(x) + z^*h(x) \geq 0$  for all  $x \in \mathcal{X}$ , implying  $\inf\{r^*f(x) + y^*g(x) + z^*h(x) : x \in \mathcal{X}\} \geq r^* \inf(P1)$ . The reverse inequality holds trivially.

The above result can be employed, in particular, if

- a)  $C$  is convex, and
- b) the interior  $\text{int}C$  of the set  $C$  is not empty.

Observe that  $(0, 0, 0)$  is always on the boundary of  $C$ . Condition a) is fulfilled if, for any  $x^i \in \mathcal{X}$ ,  $y^i \in g(x^i) + \mathcal{K}$ ,  $z^i = h(x^i)$ ,  $i = 1, 2$ , and  $\rho \in [0, 1]$ , there exists  $x \in \mathcal{X}$  such that  $f(x) \leq \rho f(x^1) + (1 - \rho)f(x^2)$ ,  $g(x) \in -\mathcal{K} + \rho y^1 + (1 - \rho)y^2$ , and  $h(x) = \rho z^1 + (1 - \rho)z^2$ . In turn, this property holds if  $\mathcal{X}$  is a convex set in some linear space,  $f$  is a convex functional on  $\mathcal{X}$ ,  $h: \mathcal{X} \rightarrow \mathcal{Z}$  is affine, and the mapping  $g: \mathcal{X} \rightarrow \mathcal{Y}$  is convex with respect to the cone  $\mathcal{K}$ , i. e.,  $\rho g(x^1) + (1 - \rho)g(x^2) - g(\rho x^1 + (1 - \rho)x^2) \in \mathcal{K}$  for all  $x^1, x^2 \in \mathcal{X}$  and  $\rho \in [0, 1]$ .

In this article, Proposition 2 is applied to versions of problem (P1) in which one of the constraints  $g(x) \in -\mathcal{K}$  or  $h(x) = 0$  is not present. Observe that  $\text{int}C \neq \emptyset$  in any of the following cases:

- i)  $h$  is absent, and  $f$  is bounded above on a set  $\mathcal{X}_1 \subseteq \mathcal{X}$  with  $\text{int}[g(\mathcal{X}_1) + \mathcal{K}] \neq \emptyset$  (this is so if  $\text{int}\mathcal{K} \neq \emptyset$ );
- ii)  $g$  is absent and  $f$  is bounded above on some  $\mathcal{X}_2 \subseteq \mathcal{X}$  for which  $\text{int } h(\mathcal{X}_2) \neq \emptyset$ .

In the applications below, the functional  $f$  and the set  $\mathcal{X}$  will be those involved in the basic model (see the previous section). Furthermore, fix some  $q \in [1, +\infty]$  and set

$$\mathcal{Y} := \prod_{t=1}^T L^q(\mathcal{F}_t, \mathbf{P}; \mathbf{R}^{m_t}), \tag{6}$$

$$g(x) := (g_t(\cdot, x)),$$

$$\mathcal{K} := \{y \in \mathcal{Y} : y_t(\omega) \in K_t(\omega) \text{ a.s. } \forall t\}.$$

Suppose  $\|g(x)\|_q < \infty$  for all  $x \in \mathcal{X}$ . Also, following [16], define

$$h(x) := x - (E_1 x_1, \dots, E_T x_T), \tag{7}$$

and  $\mathcal{Z} := h(\mathcal{L})$ , assuming that  $h$  (when this operator comes into action) is well-defined on  $\mathcal{L} \supseteq \mathcal{X}$ . Here  $E_t$  stands for the conditional expectation given  $\mathcal{F}_t$ . Observe that  $x \in \mathcal{F}$  if and only if  $h(x) = 0$ .

In the subsequent analysis, the following hypothesis regarding problem (P) will be used:

FJ) There exists a nonzero  $(r^*, y^*, z^*) \in \mathbf{R}_+ \times \mathcal{K}^+ \times \mathcal{Z}^*$  such that the Fritz John condition (5) holds with  $\inf(P)$  finite.

It is understood that if some constraint  $g(x) \in -\mathcal{K}$  or  $h(x) = 0$  is absent in (P), or automatically satisfied, then the corresponding part of  $(y^*, z^*)$  should be omitted.

Conditions which guarantee applicability of Proposition 2, and hence the truth of FJ), are presented above. Hypothesis FJ) is especially well motivated for convex problems. Absent convexity, FJ) frequently obtains when  $\mathcal{X}$  is a neighborhood of some local optimum.

### Lagrange Multipliers for Phase Constraints

Throughout this subsection, it is assumed that  $\mathcal{L} \subseteq \mathcal{F}$ . The information constraint is thus satisfied automatically, and problem (P) reduces to finding  $\inf f$  over  $\mathcal{G} \cap \mathcal{X}$ . Associate the *Lagrangian*

$$L(x, \lambda) := f(x) + \lambda g(x), \quad x \in \mathcal{X}, \quad \lambda \in \mathcal{K}^+,$$

to constraint (3).

**Theorem 3 (Lagrange multipliers for the phase constraints.)** Assume FJ) and the following strict feasibility condition: For any  $y = (y_t)_{t=1}^T \in \mathcal{Y}$ , belonging to some neighborhood of 0, one can find  $x \in \mathcal{X}$  satisfying

$$g_t(\omega, x(\omega)) \leq_{t,\omega} y_t(\omega) \text{ a.s.}, \quad \forall t.$$

Then there exists  $\lambda = (\lambda_t)_{t=1}^T \in \mathcal{K}^+$  such that

$$\inf(P) = \inf_x L(\cdot, \lambda). \quad (8)$$

*Proof* The strict feasibility condition ensures that the number  $r^*$  involved in FJ) is strictly positive. Divide (5) by  $r^*$  and set  $\lambda := y^*/r^*$ .

It is often important to obtain an integral representation of  $\lambda$ ,

$$\lambda y = \mathbf{E} \lambda(\omega) y(\omega), \quad y \in \mathcal{Y}, \quad (9)$$

with an appropriate function  $\lambda(\omega)$ . This is immediate if  $q \in [1, +\infty)$  because then  $L^q(\mathcal{F}_t, \mathbf{P}; \mathbf{R}^{m_t})^* = L^q(\mathcal{F}_t, \mathbf{P}; \mathbf{R}^{m_t})$ , where  $q^* := q/(q-1)$ ,  $1^* = +\infty$ . However, not every functional in the dual of  $L^\infty$  is of the form (9) (those which admit representation (9) with  $\lambda(\cdot) \in L^1$  are called *absolutely continuous*). Therefore the case  $q = +\infty$  requires special consideration. The analysis of that case is based on the following continuity property of  $f$ :

• For any pair  $x, \tilde{x} \in \mathcal{X}$  and any sequence of  $\mathcal{F}_T$ -measurable indicators  $\chi^k \Omega \rightarrow \{0, 1\}$  satisfying  $\mathbf{E} \chi^k \rightarrow 0$ , we have

$$f(\chi^k \tilde{x} + (1 - \chi^k)x) \rightarrow f(x), \quad (10)$$

provided  $\chi^k \tilde{x} + (1 - \chi^k)x \in \mathcal{X}$ .

Clearly (10) holds when  $f$  is of the form (4) (with finite values).

One speaks of *complete recourse* if:

CR) for any  $x \in \mathcal{X}$  and  $1 \leq t \leq T$ , there exists  $\tilde{x}_t \in \mathcal{F}_t \cap \mathcal{X}_t$  such that

$$g_t(\omega, x_1(\omega), \dots, x_{t-1}(\omega), \tilde{x}_t(\omega)) \leq_{t,\omega} 0 \text{ a.s.} \quad (11)$$

and  $(x_1, \dots, (1 - \mathbf{1}_S)x_t + \mathbf{1}_S \tilde{x}_t, \dots, x_T) \in \mathcal{X}$  for each  $S \in \mathcal{F}_t$ .

Here  $\mathbf{1}_S(\omega) = 1$  if  $\omega \in S$  and 0 otherwise; the notation  $\tilde{x}_t \in \mathcal{F}_t \cap \mathcal{X}_t$  means that  $\tilde{x}_t$  is  $\mathcal{F}_t$ -measurable and satisfies (2).

**Theorem 4 (Absolutely continuous Lagrange multipliers for essentially bounded phase constraints.)** Consider the problem

$$\begin{cases} \min & f \\ \text{s.t.} & x \in \mathcal{G} \cap \mathcal{X}. \end{cases}$$

Assume FJ), CR), strict feasibility, and the continuity property (10). Then, there exists  $\lambda = (\lambda_t)_{t=1}^T \in \mathcal{K}^+$  with  $\lambda_t \in L^1(\mathcal{F}_t, \mathbf{P}; \mathbf{R}^{m_t})$  satisfying (8).

*Proof* By virtue of the Yosida-Hewitt theorem [20], any  $\lambda \in L^\infty$  admits a unique decomposition  $\lambda = \lambda^a + \lambda^s$  into an absolutely continuous component  $\lambda^a \in L^1$  and a *singular component*  $\lambda^s$ . The last notion means that there exist measurable sets  $S^1, S^2, \dots$  such that  $\mathbf{P}(S^k) \rightarrow 0$  and  $\lambda^s(\cdot) = \lambda^s(\chi^k \cdot)$ ,  $\forall k$ , where  $\chi^k := \mathbf{1}_{S^k}$ .

Consider  $\lambda = (\lambda_t) \in \mathcal{K}^+$  satisfying (8) and decompose  $\lambda_t$  into  $\lambda_t^a + \lambda_t^s$ . We claim that, in (8), one may replace  $\lambda$  by  $\lambda^a = (\lambda_t^a)$ , i. e., set all  $\lambda_t^s = 0$ . Indeed, by way of induction, suppose  $\lambda_\tau^s = 0$  for all  $\tau > t$ :

$$f(x) + \sum_{\tau \leq t} \lambda_\tau g_\tau(x) + \sum_{\tau \geq t+1} \lambda_\tau^a g_\tau(x) \geq \inf(P) \quad (12)$$

for any  $x \in \mathcal{X}$ , where  $1 < t < T$ . (If  $t = T$ , the last sum is zero.) Then the analogous inequality also holds for  $t - 1$ . To prove this, select a sequence  $S^1, S^2, \dots$  of  $\mathcal{F}_t$ -measurable sets such that  $P(S^k) \rightarrow 0$  and  $\lambda_i^s(\cdot) = \lambda_i^s(\chi^k \cdot)$ ,  $\forall k$ , where  $\chi^k$  is the indicator of  $S^k$ . Fix any  $x \in \mathcal{X}$ . Consider the function  $\tilde{x}_t \in \mathcal{F}_t \cap \mathcal{X}_t$  described in CR). Let  $x^k \in \mathcal{X}$  be obtained from  $x$  by substituting  $\chi^k \tilde{x}_t + (1 - \chi^k)x_t$  in place of  $x_t$  (in coordinate  $t$  only). Then

$$\begin{aligned} & f(x^k) + \sum_{\tau \leq t-1} \lambda_\tau g_\tau(x^k) + \sum_{\tau \geq t} \lambda_\tau^a g_\tau(x^k) \\ & \geq f(x^k) + \sum_{\tau \leq t-1} \lambda_\tau g_\tau(x^k) + \lambda_t^s g_t(x^k) \\ & \quad + \sum_{\tau \geq t} \lambda_\tau^a g_\tau(x^k) \geq \inf(P), \end{aligned}$$

because  $\lambda_t^s g_t(x^k) = \lambda_t^s(\chi^k g_t(x^k)) \leq 0$ . To obtain (12) for  $t - 1$ , it suffices to pass to the limit, employing the continuity property (10).

Finally, observe that  $\lambda^a = (\lambda_t^a) \in \mathcal{K}^+$ , since, for any  $y_t \geq t, \omega, 0$ , we have  $0 \leq \lambda_t[(1 - \chi^k)y_t] = \lambda_t^a[(1 - \chi^k)y_t] \rightarrow \lambda_t^a y_t \geq 0$ .

Methods using similar arguments were first proposed by A.Ya. Dubovitskii and A.A. Milyutin [5] in (deterministic) optimal control theory. Applications to stochastic extremal problems were developed in [8,9,10,14,15,16], and [1], where various versions and extensions of Theorem 4 can be found. Another approach, relying on a direct analysis of perturbation functions in  $L_1$  and yielding Lagrange multipliers representable as functions in  $L_\infty$ , was suggested by E.B. Dynkin [7].

**Lagrange Multipliers for Nonanticipativity Constraints**

In this subsection, let  $\mathcal{L} := L^p(\mathcal{F}_{T+1}, P; \mathbf{R}^n)$  for some  $p \in [1, +\infty]$  and  $\mathcal{Z} := \{z \in \mathcal{L} : (E_1 z_1, \dots, E_T z_T) = 0\} = h(\mathcal{L})$ , where  $h$  is given by (7).

The next goal is to relax the constraint  $x \in \mathcal{F} (\Leftrightarrow h(x) = 0)$ . Constraints of this type were first examined systematically by R.T. Rockafellar and R.J-B. Wets [16]. To separate different issues, suppose here that all the phase constraints of type (3) are absent, or already relaxed, as described above. Then (P) reduces to minimizing  $f$  over  $\mathcal{F} \cap \mathcal{X}$ . To deal with the constraint  $h(x) = 0$ ,

consider a different Lagrangian

$$\begin{aligned} \Lambda(x, \pi) & := f(x) + \pi h(x), \\ x & \in \mathcal{X}, \quad \pi \in \mathcal{Z}^*. \end{aligned} \tag{13}$$

**Theorem 5 (Lagrange multipliers for the nonanticipativity constraints.)** Consider the problem of minimizing  $f$  over  $\mathcal{F} \cap \mathcal{X}$ . Assume FJ). If  $\mathcal{X}$  has nonempty interior, then there is a linear functional  $\pi \in \mathcal{Z}^*$  such that

$$\inf(P) = \inf_x \Lambda(\cdot, \pi). \tag{14}$$

*Proof* Evidently the linear mapping  $h: \mathcal{L} \rightarrow \mathcal{Z}$  defined in (7) is surjective. Both spaces  $\mathcal{L}, \mathcal{Z}$  are Banach. Since the set  $\mathcal{U} := \text{int}\mathcal{X} \neq \emptyset$  is open, the open mapping theorem implies that  $h(\mathcal{U})$  is open. Furthermore,  $0 \in h(\mathcal{U})$  (see Remark 6), and so  $0 \in \text{int } h(\mathcal{X})$ . As a result,  $r^*$  must be strictly positive. Divide 5 by  $r^*$  and set  $\pi := z^*/r^*$ .

*Remark 6* Note that if  $\text{int } \mathcal{X} \neq \emptyset$  and  $p < \infty$ , then  $X_t(\omega) = \mathbf{R}^n$  a.s., and so  $\mathcal{X} = \mathcal{L}$ . Furthermore, if  $\text{int } \mathcal{X} \neq \emptyset$ , then, for any  $p, \mathcal{F} \cap \text{int } \mathcal{X} \neq \emptyset$ , which implies  $0 \in h(\text{int } \mathcal{X})$ .

*Remark 7* By the Hahn-Banach theorem, the functional constructed in Theorem 5 can be extended to a continuous functional  $\pi \in \mathcal{L}^*$ .

Again, it is of importance to obtain an integral representation of  $\pi$ . Like before, when  $p \in [1, +\infty)$ , this representation is immediate, since  $\mathcal{L}^* = L^{p^*}$  with  $p^* = p/(p - 1), 1^* = +\infty$ . Suppose  $p = +\infty$ .

**Theorem 8 (Absolutely continuous multipliers for the nonanticipativity constraints: the  $L^\infty$  case.)** Consider the problem

$$\begin{cases} \min & f \\ \text{over} & \mathcal{F} \cap \mathcal{X}. \end{cases}$$

Assume FJ) together with the continuity condition (10). Suppose that  $\mathcal{X}$  is convex and  $\text{int } \mathcal{X} \neq \emptyset$ . Then there exists an absolutely continuous functional on  $\mathcal{L} = L^\infty(\mathcal{F}_{T+1}, P; \mathbf{R}^n)$  satisfying (14).

*Proof* Let  $\pi$  be the functional described in Theorem 5 and Remark 7. By the Yosida-Hewitt theorem, each coordinate  $\pi_t$  of  $\pi$  decomposes into the sum  $\pi_t^a + \pi_t^s$ , where  $\pi_t^a \in L^1$  and  $\pi_t^s$  is singular. Let  $S^1, S^2, \dots \in \mathcal{F}_{T+1}, P(S^k) \rightarrow 0$  and  $\pi_i^s(\cdot) = \pi_i^s(\chi^k \cdot), \forall k$ , where  $\chi^k = \mathbf{1}_{S^k}$ . We

may assume, additionally, that  $\| (1 - \chi^k)E_t \chi^k \|_\infty \rightarrow 0$  [9]. Consider any  $x \in \mathcal{X}$ . Construct  $x^k$  from  $x$  by substituting  $\chi^k E_t x_t + (1 - \chi^k)x_t$  in place of  $x_t$  in coordinate  $t$  only. Then  $x^k \in \mathcal{X}$  by virtue of the convexity and  $\mathcal{F}_t$ -measurability of  $X_t(\omega)$  (see [1, App. II];  $X_t(\omega)$  is convex a.s. since  $\mathcal{X}$  is convex). Finally,  $f(x^k) \rightarrow f(x)$  and  $\pi_t(x_t^k - E_t x_t^k) \rightarrow \pi_t^a(x_t - E_t x_t)$ , because  $\pi_t^s(x_t^k - E_t x_t^k) = \pi_t^s[E_t x_t(\chi^k - E_t \chi^k)]$ , where  $E_t|\chi^k - E_t \chi^k| \leq 2E_t(1 - \chi^k)E_t \chi^k \rightarrow 0$  in  $\|\cdot\|_\infty$ . This shows that  $\Lambda(x, \pi^a) \geq \inf$  (P) for all  $x \in \mathcal{X}$ .

*Remark 9* If  $\pi = (\pi_t)$  admits an integral representation, then the Lagrangian (13) can be written

$$\begin{aligned} \Lambda(x, \pi) &= f(x) + E \sum_{t=1}^T E_t [\pi_t(x_t - E_t x_t)] \\ &= f(x) + E \sum_{t=1}^T [(\pi_t - E_t \pi_t)x_t]. \end{aligned}$$

This allows one to interpret  $\pi_t - E_t \pi_t$  as a ‘shadow price’ of information [3,4,9,16].

## Synthesis

Combination of the results presented above allows one to examine both the phase and the nonanticipativity constraints simultaneously. The next theorem provides a criterion of optimality in terms of pointwise minimization of a Lagrangian associated with the two constraints. Consider problem (P) with  $\mathcal{L} = L^p(\mathcal{F}_{T+1}, \mathbf{P}; \mathbf{R}^n)$  and  $f$  defined by (4). Suppose that the following hypotheses hold:

- C) For each  $\omega$ , the set  $X(\omega) := X_1(\omega) \times \cdots \times X_T(\omega)$  and the function  $F(\omega, a)$ ,  $a \in X(\omega)$ , are convex; the mapping  $g(\omega, a)$ ,  $a \in X(\omega)$ , is convex with respect to the cone  $K_1(\omega) \times \cdots \times K_T(\omega)$ .
- G) The functional  $f(x)$  is bounded above on some set  $\mathcal{X}_1 \subseteq \mathcal{X} \cap \mathcal{F}$  with  $\text{int}[g(\mathcal{X}_1) + \mathcal{K}] \neq \emptyset$ ; furthermore,  $0 \in \text{int}[g(\mathcal{X} \cap \mathcal{F}) + \mathcal{K}]$ .
- H) For any integral linear functional  $\lambda \in \mathcal{K}^+$ ,  $f(x) + \lambda g(x)$  is bounded above on some  $\mathcal{X}_2 \subseteq \mathcal{X}$  with  $\text{int} h(\mathcal{X}_2) \neq \emptyset$ , and we have  $\text{int} \mathcal{X} \neq \emptyset$ .

The sets of interior points involved in G),  $\text{int} h(\mathcal{X}_2)$ , and  $\text{int} \mathcal{X}$  are defined in terms of the spaces  $\mathcal{Y}, \mathcal{Z} = h(\mathcal{L})$ , and  $\mathcal{L}$ , respectively (for the definition of  $\mathcal{Y}$  and  $\mathcal{K}$  see (6)). Additionally, if  $q = \infty$ , assume CR).

**Theorem 10 (Pointwise optimality.)** *Let  $x \in \mathcal{X} \cap \mathcal{F} \cap \mathcal{G}$ . Then  $x$  is a solution to (P) if and only if there exist functionals  $\lambda \in \mathcal{K}^+$  and  $\pi \in L^p$  \* of integral form (9) such that a.s.*

$$\begin{aligned} x(\omega) &\in \arg \min \\ \left\{ \begin{array}{l} F(\omega, a) + \lambda(\omega)g(\omega, a) \\ + \sum_t [\pi_t(\omega) - E_t \pi_t(\omega)] a_t \end{array} : a_t \in X_t(\omega) \right\} & \quad (15) \end{aligned}$$

and  $\lambda(\omega)g(\omega, x(\omega)) = 0$ .

*Proof* Let  $x$  be a solution to (P). It is sufficient to construct functionals  $\lambda \in \mathcal{K}^+$  and  $\pi \in L^p$  \* of integral form such that

$$E(\omega, x) \leq E \left\{ \begin{array}{l} F(\omega, x') + \lambda(\omega)g(\omega, x') \\ + \sum_t [\pi_t - E_t \pi_t] x'_t \end{array} \right\}$$

for all  $x' \in \mathcal{X}$ . Then a suitable measurable selection argument (see, e.g., [1, App. I]) yields (15)). To construct  $\lambda$ , use Theorems 3 and 4. Then, to prove the existence of  $\pi$ , apply Theorems 5 and 8 to a modified optimization problem with the objective functional  $f(x) + \lambda g(x)$ . (The truth of FJ) follows from i) and ii). The ‘if’ statement is straightforward.

Stochastic programming, as presented above, can easily accommodate integral constraints of the form  $\int \varphi(\omega, x(\omega))P(d\omega) \in M$ , where  $\varphi: \Omega \times \mathbf{R}^n \rightarrow \mathbf{R}^d$  is an integrand satisfying appropriate conditions and  $M$  is a cone in  $\mathbf{R}^d$ .

Of course this article is only a brief glance at the large and rapidly developing field of study. Many relevant aspects have not been discussed. Perhaps the most important of such aspects is the tight connection between the theory of stochastic Lagrange multipliers and the theory of stochastic economic models. The former provides technical tools for the latter. The latter serves as a source of problems and often as a ‘proving ground’ for new developments regarding stochastic Lagrange multipliers. For an introduction into this subject, see [1].

Stochastic programming; Interior point methods;  
Structured matrix factorization; Parallel computing

Uncertainty is pervasive in many decision making problems on which it often plays a key role. Uncertainty in the input data of mathematical programs is generally modeled by postulating a probability distribution (usually discrete) for the unknown parameters which is then incorporated in an appropriate optimization model. Based on this approach, stochastic programs (SP) provide a constructive and prescriptive framework for incorporating, ex-ante, uncertainty in decision making models. *Stochastic programming* has evolved into an effective framework for modeling sequential decision problems under uncertainty in diverse applications: e. g., investment management, production and logistics, capacity and operational planning for electric power generation, management of natural resources, network design, etc.

Attention is focused here on two-stage stochastic linear programs with recourse which address the following situation: Certain decisions must be made at present in the face of uncertainty. At a later time uncertainty is resolved by observing a joint realization (outcome) of the values of all uncertain parameters. At that time, further corrective (recourse) actions can be taken in response to the outcome that materializes. Each postulated realization of the uncertain parameters constitutes a particular *scenario*. The objective is to minimize

the expected value of a total cost functional, which includes the direct cost of the initial decisions and the expected cost of the recourse actions.

### Problem Formulation

*Two-stage SP with recourse* distinguish between two sets of decision variables:

- $x_0 \in \mathbf{R}^{n_0}$  denotes the *first-stage decisions*. These decisions are made before the values of the random variables are observed, but they should anticipate the consequent cost of recourse actions.
- $y_s \in \mathbf{R}^{n_1}$  denotes the *second-stage decisions* under a particular scenario  $s$ . These are the adaptive decisions, representing *recourse* actions that are taken after the random variables have been observed. They depend on the first-stage decisions and on the realization of the random variables.

Uncertainty is represented by a discrete set of scenarios  $S = \{1, \dots, S\}$  with associated probabilities  $p_s > 0$ ,  $\sum_{s=1}^S p_s = 1$ . The two stage SP with recourse can then be stated in the following deterministic equivalent program, [13]:

$$\min_{x_0 \in \mathbf{R}_+^{n_0}, y_s \in \mathbf{R}_+^{n_1}} c^T x_0 + \sum_{s=1}^S p_s q_s^T y_s, \quad (1)$$

such that

$$A_0 x_0 = b, \quad (2)$$

$$T_s x_0 + W_s y_s = h_s, \quad \forall s \in S. \quad (3)$$

Any deterministic constraints on the first-stage decisions are depicted by equation (2) the coefficients of which (i. e., the  $m_0 \times n_0$  matrix  $A_0$  and the vector  $b \in \mathbf{R}^{m_0}$ ) are scenario invariant. Each scenario  $s \in S$  is associated with a corresponding instance of the input data, that is, the  $m_1 \times n_0$  technology matrix  $T_s$ , the  $m_1 \times n_1$  recourse matrix  $W_s$ , and the vectors  $q_s \in \mathbf{R}^{n_1}$  and  $h_s \in \mathbf{R}^{m_1}$ .

In this compact representation of the deterministic equivalent program, the constraints matrix has a *dual block-angular structure*:

$$\begin{pmatrix} A_0 & & & & \\ T_1 & W_1 & & & \\ \vdots & & \ddots & & \\ T_S & & & & W_S \end{pmatrix}. \quad (4)$$

The above formulation has  $n = n_0 + S \cdot n_1$  variables and  $m = m_0 + S \cdot m_1$  constraints. Hence, the inclusion of a large number of scenarios, so as to account for many possible contingencies, inevitably leads to very large optimization programs. Substantial research effort has been directed toward the development of effective solution methods that exploit the special block-structures of SP and capitalize on the capabilities of high-performance computing systems, including parallel multiprocessors.

Reformulations are sometimes applied to yield structures that are more suitable for some parallel algorithms. These reformulations employ variable-splitting to replicate the first-stage solutions into distinct vectors  $x_s \in \mathbf{R}^{n_1}$  for each scenario  $s \in S$ . Explicit *nonanticipativity constraints* are then added to the program in order to ensure that the values of these distinct vectors are scenario-invariant. Nonanticipativity constraints can be of a staircase form:

$$x_s - x_{s-1} = 0, \quad s = 2, \dots, S. \tag{5}$$

Similarly, the distinct vectors  $x_s$  may be equated with an auxiliary vector  $x_0$ , yielding a primal block-angular structure:

$$x_s - x_0 = 0, \quad s = 1, \dots, S. \tag{6}$$

Recent reviews of alternative parallel algorithms for solving stochastic programs can be found in [2,12].

### Interior Point Algorithm

*Interior point algorithms* directly address the deterministic equivalent program (1)-(3). Let us focus on the primal-dual, path following interior point method (e.g., [11]) which solves simultaneously the following pair of dual programs:

$$(P) \quad \min_{x \geq 0} c^T x \quad \text{s.t. } Ax = b,$$

$$(D) \quad \max_{z \geq 0} b^T y \quad \text{s.t. } A^T y + z = c.$$

The  $m \times n$  constraint matrix  $A$  is assumed to have full row rank. The method applies a logarithmic barrier to enforce the nonnegativity constraints. Each iteration involves a Newton step for the system of linear equations that represents first-order conditions for a critical point of the associated Lagrangian functions for the

barrier forms of (P) and (D). The algorithm is given below.

$X$  and  $Z$  are the  $n \times n$  positive definite diagonal matrices  $X = \text{diag}(x_1, \dots, x_n)$ ,  $Z = \text{diag}(z_1, \dots, z_n)$ . The steplengths  $\alpha_P, \alpha_D$  are computed so as to keep the primal variables ( $x$ ) and the dual slack iterates ( $z$ ) positive:

$$\alpha_P \doteq \delta \cdot \min_{\alpha_j > 0} \{ \alpha_j : x_j + \alpha_j \Delta x_j \geq 0 \}, \tag{7}$$

$$\alpha_D \doteq \delta \cdot \min_{\alpha_j > 0} \{ \alpha_j : z_j + \alpha_j \Delta z_j \geq 0 \}, \tag{8}$$

where  $\delta \in (0, 1)$ . A typical value of  $\delta$ , used in practice is 0.9995. An updating formula for setting the barrier parameter  $\mu^v$  that works well in practice is:

$$\mu^v = \frac{c^T x^v - b^T y^v}{n^2}.$$

#### Initialization

Set  $v=0$ . Start with an interior point ( $x^v \in \mathbf{R}_+^n, z^v \in \mathbf{R}_+^m, y^v \in \mathbf{R}^m$ ), and  $\mu^v > 0$ .

#### Iterative step

Solve for the dual step  $\Delta y$ :

$$(A\Theta A^T)\Delta y = \psi, \tag{9}$$

where  $\Theta = XZ^{-1}$ ,  $\psi = \rho + A\Theta(\sigma - X^{-1}\phi)$ ,  $\rho = b - Ax$ ,

$\sigma = c - A^T y - z$ ,  $\phi = \mu \mathbf{1} - XZ\mathbf{1}$ , and  $\mathbf{1}$  is a conformable vector of ones.

Compute the primal step  $\Delta x$ , and the slack variable step  $\Delta z$ , from

$$\Delta x = -\Theta(\sigma - X^{-1}\phi - A^T \Delta y), \tag{10}$$

$$\Delta z = -X^{-1}(\phi - Z\Delta x). \tag{11}$$

Update:

$$x^{v+1} = x^v + \alpha_P \Delta x, \tag{12}$$

$$y^{v+1} = y^v + \alpha_D \Delta y, \tag{13}$$

$$z^{v+1} = z^v + \alpha_D \Delta z, \tag{14}$$

where  $\alpha_P, \alpha_D \in (0, 1)$  are steplengths. reduce  $\mu^v$  to  $\mu^{v+1}$ , and increment the iteration counter  $v \leftarrow v + 1$ .

#### Primal-dual path following algorithm

Hence, the barrier parameter is kept large when far from the optimum (as measured by a large duality gap in the numerator) and the search direction points away from the boundary of the feasible region, so as to allow large steps. The barrier parameter is reduced as the optimum is approached so that the iterates may approach the boundary of the feasible region. Practically the same computations are applied – with fairly minor extensions – to solve separable, convex quadratic programs (see, e. g., [5,11]).

The major effort involves the solution of the  $n \times n$  symmetric, positive definite system of linear equations  $(A\Theta A^\top)\Delta y = \psi$ . This system is commonly encountered in interior point methods. So, the parallel matrix factorization procedures discussed here are directly applicable in other interior point algorithms as well. Interior point methods for stochastic programs are reviewed in [10].

The constraints matrix  $A$  of a two-stage SP has the dual block-angular structure (4). In the discussion above, the vector  $x$  encompasses all primal decision variables, that is, the first-stage decisions  $x_0$ , as well as the recourse decisions  $y_s$  for all scenarios. Also, the scenario probabilities  $p_s$  are incorporated by scaling the objective coefficients. Despite the sparsity of the constraints matrix  $A$ , the product matrix  $A\Theta A^\top$  can be very dense due to the presence of the coupling columns associated with the first-stage variables (see (4)). Hence, the direct application of interior point methods to stochastic programs is not particularly effective.

A first approach to overcoming this problem focuses on staircase formulations (cf. (5)). This significantly reduces fill-in and produces banded product matrices which can be factorized efficiently [8]. Schur complements have also been tested as a means for overcoming the problem with the dense columns of the first-stage variables [3,8]. These procedures can improve substantially the performance of interior point algorithms on SP. However, they can not be effectively parallelized. Moreover, the Schur complement approach suffers from numerical instabilities, particularly in problems with many dense columns [3].

An alternative, is to directly parallelize the matrix operations in interior point methods. Such procedures typically treat the optimization programs as fully dense and can not exploit the sparse block structure of SP.

Consequently, they are effective only for moderate-size problems [6,9].

A third approach is to specialize a *matrix factorization* procedure so as to capitalize on the structure of SP. The method is based on a generalization of the *Sherman–Morrison–Woodbury formula*. It was proposed for stochastic programs by J.R. Birge and L. Qi [4], and was further extended by Birge and D.F. Holmes [3], who also reported numerical experiments. Implementations of this factorization procedure on hypercubes and other parallel computers are reported in [7,14].

### Parallel Matrix Factorization

Partition the vectors  $\Delta y$  and  $\psi$  in (9) into subvectors  $[\Delta y_0^\top, \dots, \Delta y_S^\top]^\top$  and  $[\psi_0^\top, \dots, \psi_S^\top]^\top$ , respectively, with  $\Delta y_l, \psi_l \in \mathbf{R}^{m_l}$ , for  $l = 0, \dots, S$ . Here  $\Delta y_0$  represents the dual step corresponding to the first-stage constraints, and  $\Delta y_l$  represents the dual step corresponding to the second-stage constraints for the  $l$ th scenario. Hence,  $m_l = m_1$ , for  $l = 1, \dots, S$ ; also denote  $n_l = n_1$  for  $l = 1, \dots, S$ . The matrix factorization procedure that solves for the dual step  $\Delta y$  in (9) is based on the following lemma; for a proof of the lemma, see [4].

**Lemma 1** *Let  $M \doteq A\Theta A^\top$ , where  $\Theta$  is diagonal, and  $R \doteq \text{diag}_{l=0, \dots, S}(R_l)$ , where  $R_0 = I$  is an  $\mathbf{R}^{m_0} \times \mathbf{R}^{m_0}$  identity matrix,  $R_l = W_l\Theta_l W_l^\top \in \mathbf{R}^{m_l \times m_l}$ ,  $l = 1, \dots, S$ , and  $\Theta_l \in \mathbf{R}^{n_l \times n_l}$  is the (diagonal) submatrix of  $\Theta$  corresponding to the  $l$ th block. Also, let*

$$\begin{aligned} G_1 &\doteq \Theta_0^{-2} + A_0^\top A_0 + \sum_{l=1}^S T_l^\top R_l^{-1} T_l, \\ G &\doteq \begin{pmatrix} G_1 & A_0^\top \\ -A_0 & 0 \end{pmatrix} \\ U &\doteq \begin{pmatrix} A_0 & I \\ T_1 & 0 \\ \vdots & \vdots \\ T_S & 0 \end{pmatrix}, \quad V \doteq \begin{pmatrix} A_0 & -I \\ T_1 & 0 \\ \vdots & \vdots \\ T_S & 0 \end{pmatrix}. \end{aligned} \tag{9}$$

*If  $A_0$  and  $W_l$ ,  $l = 1, \dots, S$ , have full row rank then  $M$  and  $G_2 \doteq -A_0 G_1^{-1} A_0^\top$  are invertible, and*

$$M^{-1} = R^{-1} - R^{-1} U G^{-1} V^\top R^{-1}. \tag{10}$$

Equation (10) indicates that the solution of the linear system  $M\Delta y = (A\Theta A^\top)\Delta y = \psi$  can be expressed as  $\Delta y$

$= p - r$ , where  $p$  solves  $Rp = \psi$ , and  $r$  is obtained from the system

$$Gq = V^T p, \quad Rr = Uq. \quad (11)$$

The vector  $p$  can be computed componentwise by solving  $R_l p_l = \psi_l$ , for  $l = 0, \dots, S$ . The block structure of  $G$  is exploited in solving for  $q$ . One can write:

$$Gq = \begin{pmatrix} G_1 & A_0^T \\ -A_0 & 0 \end{pmatrix} \begin{pmatrix} q^1 \\ q^2 \end{pmatrix} = \begin{pmatrix} \widehat{p}^1 \\ \widehat{p}^2 \end{pmatrix},$$

where

$$\begin{pmatrix} \widehat{p}^1 \\ \widehat{p}^2 \end{pmatrix} \doteq V^T p = \begin{pmatrix} A_0^T p_0 + \sum_{l=1}^S T_l^T p_l \\ -p_0 \end{pmatrix}. \quad (12)$$

Hence,

$$q^2 = -G_2^{-1}(\widehat{p}^2 + A_0 G_1^{-1} \widehat{p}^1), \quad (13)$$

$$q^1 = G_1^{-1}(\widehat{p}^1 - A_0^T q^2). \quad (14)$$

Once  $q$  is known,  $r$  can be computed componentwise from (11).

The required operations rely extensively on matrix subblock computations that can be performed independently of one another. A parallel procedure for computing the dual step  $\Delta y$  is summarized in the following box (denote by  $A_i$  the  $i$ th row of  $A$ , and by  $A_j$  the  $j$ th column of  $A$ ).

Interprocessor data communication is necessary at only three points. After forming the terms  $T_l^T R_l^{-1} T_l$  in Steps 2a–2b the processors communicate to form the matrix  $G_1$  and the vectors  $\widehat{p}^1$  and  $\widehat{p}^2$ , in Step 2b. The results can be accumulated at a single master processor which executes serially the computations involving the dense matrices  $G_1$  and  $G_2$  in Steps 2c–2e. The computed vector  $q$  is then broadcasted to all other processors. Steps 3 and 4 require only the distributed data  $R_l$ ,  $T_l$ , and  $p_l$  on the  $l$ th processor and can be carried out with full parallelism. A final communication step accumulates the partial vectors  $\Delta y_l$  at the master processor to form  $\Delta y$ . This vector can then be made available to all processors for use in the subsequent calculation of the directions  $\Delta x$  and  $\Delta z$ ; these computations involve only matrix-vector products and vector additions that can be parallelized in a rather straightforward manner [14]. This algorithm is suitable for implementation on

Begin with the following data distribution. Processor  $l$  holds  $W_l$ ,  $T_l$ ,  $\Theta_l$ , and  $\psi_l$ ,  $l = 1, \dots, S$ . A designated master processor also holds  $A_0$ ,  $R_0$ ,  $\Theta_0$ , and  $\psi_0$ .

- 1 (Parallel solution of  $Rp = \psi$ .)  
The master processor sets  $R_0 p_0 = \psi_0$ . Processors  $l = 1, \dots, S$ , form  $R_l = W_l \Theta_l W_l^T$  and solve  $R_l p_l = \psi_l$  for  $p_l$ .
- 2 (Solution of  $Gq = V^T p$ .)
- 2a Processors  $l = 1, \dots, S$ , solve  $R_l (u_l)^i = (T_l)_{.i}$  for  $(u_l)^i$ ,  $i = 1, \dots, n_0$ , thus computing the columns of the matrix  $u_l = [(u_l)^1, \dots, (u_l)^{n_0}] = R_l^{-1} T_l$ .
- 2b Processors  $l = 1, \dots, S$ , multiply  $v_l = T_l^T u_l$  to form  $v_l = T_l^T R_l^{-1} T_l$  and also compute  $\zeta_l = T_l^T p_l$ . Communicate  $v_l \in \mathbf{R}^{n_0 \times n_0}$  and  $\zeta_l \in \mathbf{R}^{n_0}$  to form  $G_1$  (cf. (15)) and  $\widehat{p}^1$  (cf. (18)) on the master processor.  
The master processor sets  $\widehat{p}^2 = -p_0$ .
- 2c The master processor solves  $G_1 u = \widehat{p}^1$  for  $u$  and sets  $v = \widehat{p}^2 + A_0 u$  (cf. (19)).
- 2d The master processor forms  $G_2$  by solving  $(G_1) w^i = (A_0^T)_{.i}$  for  $w^i$ ,  $i = 1, \dots, m_0$ , and sets  $G_2 = -A_0 [w^1, \dots, w^{m_0}]$ .
- 2e The master processor solves  $G_2 q^2 = -v$  for  $q^2$  (cf. (19)), and solves  $G_1 q^1 = \widehat{p}^1 - A_0^T q^2$  for  $q^1$  (cf. (20)).  
Communicate to distribute  $q^1 \in \mathbf{R}^{n_0}$  to all processors.
- 3 (Parallel solution of  $Rr = Uq$ .)  
The master processor sets  $r_0 = A_0 q^1 + q^2$ . Processors  $l = 1, \dots, S$ , solve  $R_l r_l = T_l q^1$  for  $r_l$ .
- 4 (Form  $\Delta y$  in parallel.)  
The master processor sets  $\Delta y_0 = p_0 - r_0$ . Processors  $l = 1, \dots, S$ , set  $\Delta y_l = p_l - r_l$ .  
Communicate to gather the vector  $\Delta y$  on the master processor.

#### Parallel matrix factorization for dual step calculation

distributed memory, as well as on shared memory multiprocessors.

An alternative parallel implementation is to distribute the matrices  $G_1$  and  $G_2$  to all processors, and let the processors proceed locally (and redundantly) with all calculations involving these matrices. The master processor approach uses an all-to-one communication

step to accumulate the dense matrices at the master, followed by a one-to-all communication step to distribute the results to the processors. The alternative approach combines these two communication steps into a single all-to-all communication step that distributes the dense matrices to all processors which compute locally (and redundantly) their own copies of the vector  $q$ . Both of these alternatives are very efficient on present day distributed memory machines with high-bandwidth interconnections.

Yet another alternative is to distribute the dense matrices across processors, and use parallel dense linear algebra techniques for all calculations that involve these matrices. This approach is more suitable for shared-memory, tightly coupled multiprocessors, and when the dense matrices  $G_1$  and  $G_2$  are large.

A.J. Berger et al. [1] proposed another matrix factorization procedure that exploits the block-structure form of stochastic programs in interior point algorithms. The method, termed *tree dissection*, operates on the split-variable formulation and is applicable to multistage stochastic programs with recourse and convex, block-separable objective functions. A serial implementation of the method demonstrated very competitive computational performance on large scale problems in comparison to direct applications of interior point algorithms.

### Computational Experience

Interior point algorithms can be applied to solve SP with linear or separable, convex objective functions. Separability is important to maintain sparsity in the projection matrices. Nonseparable problems can yield full projection matrices, thus dramatically increasing the computational complexity. In such cases, it is possible to treat a problem as fully dense and directly parallelize the matrix operations involved in interior point methods without regard to problem structure [6,9]. However, such an approach is effective only for moderate size problems due to its substantial computational and storage requirements.

Interior point algorithms have proved very robust on two-stage SP with linear, or separable, convex quadratic objectives. The required number of iterations is neither particularly influenced in going from linear to separable quadratic SP, nor is it significantly affected

by the size of the problem or by the conditioning of the objective function. Hence, the algorithms can solve to a high accuracy very large SP in a moderate number of iterations. However, they may exhibit numerical difficulties if the constraint matrix does not have full row rank. Even if the entire constraint matrix has full row rank, the parallel factorization procedure may suffer from numerical instabilities if the recourse matrices  $W_s$  do not have full row rank as well. Thus, care must be exercised in implementations to test and account for situations in which the recourse matrices are rank deficient.

The parallel matrix factorization procedure presented in this article has been subjected to extensive numerical experimentation on hypercubes and other parallel computing systems [7,14], exhibiting a high level of scalability on large scale problems. In the implementations, each parallel task factorized the part of the projection matrix corresponding to a scenario. Moreover, the matrix operations involved in the factorization procedure, and throughout the interior point algorithm, can be executed efficiently on vector processors, or be further parallelized on massively parallel multiprocessors. Particularly, the operations on the small dense matrices that constitute the coordination step of the algorithm can be vectorized or parallelized to effectively eliminate any serial bottleneck.

Stochastic programming; Simple recourse; Integer recourse

The *simple integer recourse* model with fixed technology matrix is defined as

$$\inf_x \{cx + \bar{Q}(x) : Ax = b, x \in R_+^{m_1}\},$$

where the *expected value function*  $\bar{Q}$  is

$$\bar{Q}(x) = E_\xi v(\xi - Tx),$$

and  $v$  is the value function of the second-stage problem

$$v(s) = \inf_{y^+, y^-} \{q^+ y^+ + q^- y^- : y^+ \geq s, y^- \geq -s, y^+, y^- \in Z_+^{m_2}\}$$

for  $s \in R^{m_2}$ . Here  $c, A, b, q^+, q^-$  and  $T$  are vectors/matrices of the appropriate size,  $q^+, q^- \geq 0$ ,  $q^+ + q^- > 0$ , and  $\xi$  is a random vector in  $R^{m_2}$ .

As suggested by the name, this model has the same structure as the well-known continuous **simple recourse** model, in which the second-stage decision variables  $y = (y^+, y^-)$  are non-negative reals. These models are indeed the most simple **recourse models**, both analytically and conceptually. In both models the recourse actions (that is, the compensations for observed deviations from the constraints  $Tx = \xi$ ) are straightforward. For example, let  $Tx$  represent production to meet uncertain demand  $\xi$ . Then in the continuous model the recourse actions may represent buying or selling any shortage or surplus, whereas in the integer recourse model buying and selling is only possible in batches of a certain size. In both models the objective function reflects the direct costs  $cx$  and the expected recourse costs  $\bar{Q}(x)$ .

Using separability which is due to the simple recourse structure,  $\bar{Q}$  is completely characterized by the one-dimensional generic function  $Q$ , given by

$$Q(z) = q^+ E_\xi [\xi - z]^+ + q^- E_\xi [\xi - z]^- , z \in R ,$$

with  $q^+, q^- \in R_+$ ,  $q^+ + q^- > 0$ ,  $\xi$  a random variable, and  $[s]^+ = \max\{0, [s]\}$ ,  $[s]^- = \max\{0, -[s]\}$ ,  $s \in R$ . Below we present results for the one-dimensional function  $Q$ ; the extension to the  $n_1$ -dimensional case is straightforward.

In [11] structural properties of the function  $Q$  are presented. A closed-form expression for  $Q$  is given,

$$Q(z) = q^+ \sum_{k=0}^{\infty} \Pr\{\xi > z + k\} + q^- \sum_{k=0}^{\infty} \Pr\{\xi < z - k\} , z \in R ,$$

and conditions for (**Lipschitz**) continuity and (one-sided) differentiability are derived. (Corresponding results for the model in which also the technology matrix  $T$  is random are given in [4].) The function  $Q$  is continuous if and only if  $\xi$  follows a continuous distribution. If  $\xi$  is a discrete random variable with realizations  $\xi^j$ ,  $j = 1, \dots, r$ , then  $Q$  is **lower semicontinuous** with discontinuity points  $\cup_j \{\xi^j + Z\}$ . Moreover, even if  $Q$  is continuous, it is non-**convex** in general. This has led to

the study of conditions on the distribution of  $\xi$  such that the function  $Q$  is convex, and to the construction of convex approximations of  $Q$ .

Since  $Q$  is continuous (and finite) precisely if  $\xi$  is continuously distributed (with finite mean value), it follows that  $Q$  can only be convex if  $\xi$  has a probability density function, say  $f$ . In [9] it is shown that, under some mild technical conditions,  $Q$  is convex if and only if  $f(s) = G(s+1) - G(s)$ ,  $s \in R$ , where  $G$  is an arbitrary cumulative distribution function with finite mean value. For example, if  $G$  corresponds to the degenerate distribution in 1 then  $f$  is a probability density function of the **uniform distribution** on  $[0, 1]$ . Formulated in terms of random variables, we have that  $Q$  is convex if and only if there exists a random variable  $\eta$  with finite mean value, such that for all  $s \in R$  the conditional distribution of  $\xi$  given  $\eta = s$  is uniform on  $[s-1, s]$ . From this we see that the uniform distribution with unit support plays a central role here.

In [7] it is shown that any reasonable convex approximation of the function  $Q$  can be represented as a one-dimensional expected value function of a continuous simple recourse model, with a random right-hand side parameter whose distribution is known. Consequently, given a convex approximation of  $Q$ , the integer recourse model can be solved (at least approximately) by well-known algorithms for continuous simple recourse models (see e. g. [1,3,12,13,19]).

For the case that  $\xi$  follows a finite discrete distribution, a **strongly polynomial algorithm** to construct the **convex hull** of the function  $Q$  is given in [8]. In [6] it is shown that if the matrix  $T$  has full row rank, then the resulting one-dimensional functions can be used as building blocks for the convex hull of the  $n_1$ -dimensional expected value function  $\bar{Q}$ . If this condition is not satisfied, a convex lower bound for  $\bar{Q}$  is obtained.

If  $\xi$  is a continuous random variable, convex approximations of  $Q$  can be obtained by perturbing its distribution. In [9] a class of such approximations, defined by their probability density functions  $f_\alpha(s) = F(\lfloor s \rfloor_\alpha + 1) - F(\lfloor s \rfloor_\alpha)$ ,  $s \in R$ , is analyzed. Here  $F$  is the cumulative distribution function of  $\xi$ ,  $\alpha \in [0, 1)$  is a shift parameter, and  $\lfloor \cdot \rfloor_\alpha$  denotes round down with respect to the set  $\{\alpha + Z\}$  (the case  $\alpha = 0$  corresponds to the usual integer round down). For each  $\alpha \in [0, 1)$ , the function  $Q_\alpha(z) = q^+ E[\xi_\alpha - z]^+ + q^- E[\xi_\alpha - z]^-$ ,  $z \in R$ , with the random variable  $\xi_\alpha$  distributed accord-

ing to  $f_\alpha$ , is a piecewise linear convex approximation of  $Q$ . It is shown that

$$\|Q_\alpha - Q\|_\infty \leq (q^+ + q^-) \frac{|\Delta|f|}{4},$$

where  $|\Delta|f|$  is the **total variation** of  $f$ . By taking convex combinations this uniform error bound can be improved by a factor two at most, which is obtained by using  $f_{\alpha\beta} = (f_\alpha + f_\beta)/2$  with  $|\alpha - \beta| = 1/2$  as the approximating distribution. For many distributions the total variation of  $f$  decreases as the variance of the distribution increases. In these cases the approximation becomes better accordingly.

The continuous simple recourse representations of the approximations presented above have discretely distributed right-hand side parameters, and can therefore be solved efficiently. Algorithms to compute these distributions (and standard solution methods) are implemented in the model management system SLP-IOR [2].

Most results referred to above can be found in [17]. For an overview of the field of **stochastic (mixed-)integer programming** beyond the simple recourse case, we refer to [5,10,14,15,16]. An extensive *bibliography of stochastic programming* in general can be found in [18], which also contains a separate listing of stochastic integer programming literature.

Stochastic programming; Upper bound

A two-stage stochastic linear program with recourse (SLPR) with random right-hand sides and objective costs is normally written as follows:

$$\begin{cases} \min_{x \geq 0} & cx + Q(x) \\ \text{s.t.} & Ax = b \end{cases}$$

where

$$Q(x) = \int_{\Omega} Q(x, \omega) g(\omega) d\omega,$$

and

$$Q(x, \omega) = \min_{y \geq 0} \{q(\eta)y : Wy = h(\xi) - T(\xi)x\}.$$

Here,  $g(\omega)$  is the density function for the joint random vector  $\tilde{\omega} := (\tilde{\xi}, \tilde{\eta})$  whose support is the set  $\Omega$  and  $W$  is an  $(m \times n)$  matrix. This way of formulating a two-stage stochastic program is motivated partly by solution procedures, and partly by the time structure of the problem. For this article, the former is more important. The interpretation of the problem is that first (now) we make a decision  $x$ , then we observe a value of the joint vector  $\tilde{\omega}$ , and finally we make a *recourse decision*  $y$  based on our earlier decision  $x$  and the observed value of  $\tilde{\omega}$ .

In a direct approach for solution of the above problem, such as *Benders decomposition* [1] (or equivalently the *L-shaped decomposition* [12]), a master problem is created to determine a first stage solution  $x$  (say  $x_0$ ), along with a subproblem to determine the second stage value function  $Q(x_0)$  by integrating:

$$\int_{\Omega} Q(x_0, \omega) g(\omega) d\omega \equiv \int_{\Omega} f(\omega) g(\omega) d\omega.$$

For most functions  $f$  and densities  $g$  this is impossible to do exactly. Numerical integration when the dimension of the random vector  $\tilde{\omega}$  is beyond 5 or 6 is computationally intractable. Hence, one has to resort to bounds or approximations. Normally, the integral is replaced by a lower bounding expression, either by replacing  $f(\omega)$  by some simpler  $L(\omega)$ ,  $g(\omega)$  by some simpler  $l(\omega)$ , or both. Benders decomposition may then be applied to this simplified problem to arrive at an optimal lower bounding solution  $x_0$ . To check if this solution is good enough as an optimal solution to the given problem, an upper bound  $U$  to  $Q(x_0)$  must be found. Such upper bounds are usually determined by either relying on the solution of a certain moment problem that would essentially yield a discretization of the support  $\Omega$  or using a functional approximation  $U(\omega)$  that serves as an upper bounding function to  $f(\omega)$ . The latter case is discussed in this article. In this case, the resulting approximations may require either univariate integration on marginal domains, or simple discretizations of the support to allow efficient computation.

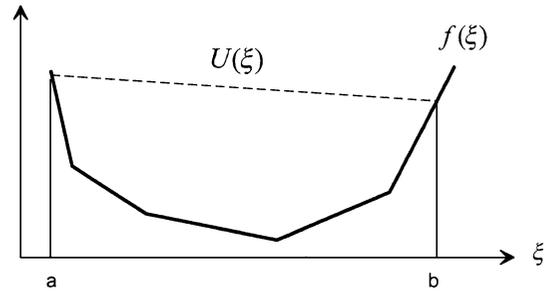

Upper bounds of interest here can be categorized depending on whether SLPR has randomness only in the right-hand sides, or it has randomness in both the objective costs and right-hand sides. In the former case, the function  $Q$  is convex in the random vector, while in the latter case, it is convex-concave in the random vectors.

We first consider the convex case, by restricting  $\eta$  to be a degenerate random vector, and thus, using the notation that  $\xi \equiv \omega$  and  $q \equiv q(\eta)$ . An easy upper bound in this case is available due to H.P. Edmundson and A. Madansky.

**The Edmundson–Madansky Upper Bound**

The *Edmundson–Madansky upper bound* (EM-bound) is based on articles by Edmundson [7] and Madansky [9]. This bound can be interpreted in terms of a moment problem with first moment condition, as well as in terms of an upper bounding function  $U(\xi)$  on  $f(\xi)$ . We consider the latter construction, as illustrated in Fig. 1.

The upper bound  $U(\xi)$  can be written as  $U(\xi) = r\xi + s$ , with  $r = (f(b) - f(a))/(b - a)$  and  $s = b/(b - a)f(a) - a/(b - a)f(b)$ . Upon integration, one obtains the upper

Stochastic Programs with Recourse: Upper Bounds, Figure 1  
The basis for the EM-bound

bound as

$$\int_a^b U(\xi)g(\xi) d\xi = f(a)\frac{b - \mathbb{E}\tilde{\xi}}{b - a} + f(b)\frac{\mathbb{E}\tilde{\xi} - a}{b - a}.$$

In other words, by integrating  $U(\xi)$  instead of  $f(\xi)$  one obtains an upper bound which amounts to just evaluating the function  $f$  at the extreme values of the support  $[a, b]$ , using the weights

$$p = \frac{b - \mathbb{E}\tilde{\xi}}{b - a} \quad \text{and} \quad 1 - p = \frac{\mathbb{E}\tilde{\xi} - a}{b - a}.$$

If the random vector  $\xi$  has  $K$  independent random components, the above reduction will leave us with a total of  $2^K$  points to evaluate. Hence, with more than about 10 random variables or so, this approximation scheme becomes computationally unattractive. Hence, there is a need for an upper bound whose complexity is not exponential in the number of random variables.

**The Piecewise Linear Upper Bound**

The *piecewise linear upper bound* (PL-bound) is based on the articles independently developed by S.W. Wallace [13] and J.R. Birge and R.J-B. Wets [4], later combined in [3]. Assume now that  $f(\xi)$  is given by

$$f(\xi) = \min_y \{qy : Wy = b + H\xi, 0 \leq y \leq c\},$$

that is,  $T(\xi) \equiv T, H$  is a deterministic matrix with  $n_1$  columns, the  $n_1$  random variables are independent, and there is no randomness in the upper limits,  $c$ . For simplicity, assume that the support of  $\xi$  is  $[0, B]$ , with  $B = (B_1, \dots, B_{n_1})$ . More complex situations can also be

treated. The goal is to find an upper bounding function

$$U(\xi) = f(0) + \sum_{i=1}^{n_1} d_i \xi_i.$$

This function  $U(\xi)$  is useful in that for most  $g(\xi)$  it is simple to integrate. We first solve

$$f(0) = \min_y \{qy : Wy = b, 0 \leq y \leq c\} = qy^0.$$

This is the base case, and we define  $\alpha^1 = -y^0$ , and  $\beta^1 = c - y^0$ . Define a counter  $r$  and let  $r := 1$ . Now, solve (letting  $H_r$  be column  $r$  of the matrix  $H$ )

$$\begin{aligned} \min_y \{qy : Wy = H_r B_r, \alpha^r \leq y \leq \beta^r\} \\ = qy^r = d^r B_r. \end{aligned}$$

Then, update the bounds to obtain

$$\begin{aligned} \alpha_i^{r+1} &= \alpha_i^r - \min\{y_i^r, 0\}, \\ \beta_i^{r+1} &= \beta_i^r - \max\{y_i^r, 0\}. \end{aligned}$$

Now, increment  $r$  by one and repeat until all  $n_1$  random variables have been treated. The PL-bound, as outlined here, requires the solution of  $n_1 + 1$  linear programs, in contrast to the EM-bound which needed  $2^{n_1}$  linear programs in the same setting. Many other versions of this bound exist, see, for example, [8, Sect. 3.4.4; 6.5.1].

Note that the EM-bound and the PL-bound are not comparable, in the sense that either one can be better than the other. The PL-bound bound may be infinite even if the true expected value is finite, whereas the EM-bound is finite if and only if the true value is finite. If the function  $f(\xi)$  turns out to be linear in  $\xi$ , both bounds are exact.

**Restrictions**

Upper bounds can be found by adding *restrictions* to the solution set of a problem. The PL-bound above is an example of that. In that case the restriction amounts to reserving certain parts of the upper limits for certain random variables. Another type of thinking about re-

strictions can be found in [10]. He points out that

$$\begin{aligned} &\int_a^b f(\xi)g(\xi) d\xi \\ &= \int_a^b \min_{y \geq 0} \{qy : Wy = b + h(\xi)\} g(\xi) d\xi \\ &\leq \min_{y \geq 0} \int_a^b \{qy : Wy = b + h(\xi)\} g(\xi) d\xi. \end{aligned}$$

The logic of this bound is that if we allow only one  $y$  for all values of  $\xi$ , rather than a function of  $\xi$ , we *restrict* the problem, and hence obtain an upper bound. The usefulness of this bound depends on our ability to evaluate the final expression. In [11] this expression is used in connection with another very useful observation, to arrive a *restricted-recourse bound*. Let

$$z_1^* = \min_{y \geq 0} \{qy : Wy \geq \xi\},$$

and define  $\pi^*$  to be an optimal dual solution to this problem. With  $\pi' \geq \pi^*$ , we get that  $z_1^* = z_2^*$  where

$$z_2^* = \min_{y \geq 0} \{qy + \pi'(\xi - Wy)^+\}.$$

Combining the two results we get that the following yields an upper bound:

$$\min_{y \geq 0} \left\{ qy + \pi' \int_a^b (\xi - Wy)^+ g(\xi) d\xi \right\}.$$

Solving this problem amounts to solving a stochastic program with simple recourse, and is not particularly hard. The quality of the bound depends to a large extent on the ability to find tight dual solutions. Note that this bound does not require convexity, namely, the matrix  $W$  is allowed to have random elements, and that it can be used for much more general situations than here.

As D.P. Morton and R.K. Wood noted, the restricted recourse bounds provide improvements over the penalty-based aggregation bounds developed in [2] and [6]. Restrictions are also used to bound a multistage problem in [14].

**Upper Bounds for a Convex-Concave Case**

When the right-hand side and objective cost vectors (of the second stage problem) are dependent random

vectors, upper bounds are developed in [5]. The first essential idea is to enclose the joint support  $\Omega$  within a known  $(K + L)$ -dimensional simplex  $\widehat{\Omega}$ , where  $K$  and  $L$  are, respectively, the number of  $\xi$  and  $\eta$  random variables. Such a simplex can generally be determined quite easily, however, the quality of the bound can be affected by a particular choice. Let the chosen simplex  $\widehat{\Omega}$  have the extreme points given by  $w^i \equiv (u^i, v^i)$  for  $i = 1, \dots, K + L + 1$ .

The second important idea is to develop an upper bounding function  $U(x, \omega)$  to  $Q(x, \omega)$  by using the convexity property of  $Q$  in  $\xi$  vector, given a fixed first stage decision  $x$ . Towards this, let  $\widehat{\Omega}_\eta$  be the conditional domain of  $\widehat{\Omega}$  for any fixed  $\eta$  value. Under the convexity, the following inequality holds:

$$Q(x, \omega) \leq U(x, \omega) := \sum_{i=1}^{K+L+1} p_i(\omega) Q(x, u^i, \eta), \quad \text{for } \omega \in \widehat{\Omega}_\eta,$$

where the nonnegative multipliers  $p_i(\omega)$  satisfy the convexity constraints for any  $\omega \in \widehat{\Omega}$ :

$$\sum_{i=1}^{K+L+1} w^i p_i(\omega) = \omega, \quad \sum_{i=1}^{K+L+1} p_i(\omega) = 1.$$

Taking expectations under the conditioning argument with respect to the ‘true’ density  $g(\omega)$  yields  $Q(x) \leq EU(x, \omega)$ . However,  $EU(x, \omega)$  in itself is not easy to evaluate. Hence, a simple inequality is utilized to upper bound the latter expectation. Notice that

$$EU(x, \omega) = \sum_{i=1}^{K+L+1} \int_{\Omega} G(\omega, x, i) g(\omega) d\omega,$$

where

$$G(\omega, x, i) = \min_{y^i \geq 0} \{p_i(\omega) q(\eta) y^i : Wy = h(u^i) - T(u^i)x\},$$

in which each minimization involves only random objective coefficients. Then, apply Jensen’s inequality on the inner minimization to obtain the upper bound as

$$Q(x) \leq \sum_{i=1}^{K+L+1} \widehat{p}_i \min_{y^i \geq 0} \{q(\widehat{\eta}^i) y^i : Wy = h(u^i) - T(u^i)x\},$$

provided the certainty equivalents  $\widehat{p}_i$  and  $\widehat{\eta}^i$  satisfy the condition:

$$\widehat{p}_i q(\widehat{\eta}^i) := \int_{\Omega} [p_i(\omega) q(\eta)] g(\omega) d\omega.$$

N.C.P. Edirisinghe [5] shows that the latter equivalent representation can be uniquely determined when the objective cost vector  $q(\eta)$  is linear affine in  $\eta$ . To compute these certainty equivalents, consider the (nonsingular) vertex matrix  $V$  of the simplex  $\widehat{\Omega}$ , whose  $i$ th column is given by

$$(w_1^i, \dots, w_{K+L}^i, 1)'$$

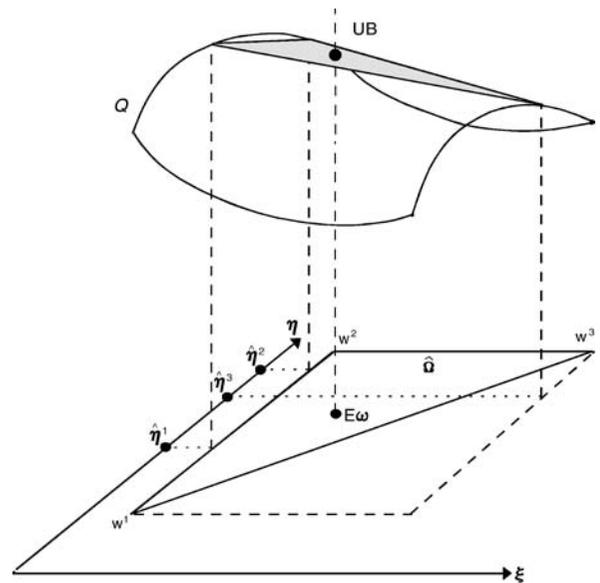

The inverse matrix of  $V$  is denoted by  $V^{-1}$  whose  $i$ th row is  $V_i^{-1}$ . Then, it can be shown that

$$\widehat{p}_i = V_i^{-1} (E[\xi_1], \dots, E[\xi_K], E[\eta_1], \dots, E[\eta_L], 1)'$$

Moreover,  $\widehat{\eta}^i$  is evaluated for each coordinate  $l$  ( $l = 1, \dots, L$ ) by  $\widehat{\eta}_l^i = r_l^i / \widehat{p}_i$ , where  $r_l^i$  is the  $i$ th element of the  $(K + L + 1)$ -column vector,

$$V^{-1} (E[\xi_1 \eta_l], \dots, E[\xi_K \eta_l], E[\eta_1 \eta_l], \dots, E[\eta_L \eta_l])'$$

Consequently, the upper bound requires all first moments and second order moments including the variance information of  $\eta$ . The upper bound computations

Stochastic Programs with Recourse: Upper Bounds, Figure 2 Convex-concave upper bound in two dimensions

require solving only  $K + L + 1$  linear programs. Therefore, the complexity of the bound does not grow exponentially with the number of random variables. This bound is illustrated in Fig. 2.

It can be verified through counterexamples that this upper bound is not associated with the solution of a moment problem having the concerned moment conditions. In contrast, generally, upper bounds in the convex-concave case are associated with solutions to moment problems. Also, when applied to the case of  $K = 1$  and  $L = 0$  – when only the right-hand side is random –, this upper bound reduces to the previously discussed Edmundson–Madansky upper bound.

### Introduction

Traditional deterministic optimization methods are used for well defined objective and constraint functions, i. e., when it is possible to calculate exactly  $F_0(x)$  to be minimized (or maximized) and to verify constraints

$$F_i(x) \leq 0, \quad i = 1 : m \quad (1)$$
