From a MCDS  $D$ , we can obtain a solution for ST-MSN problem with terminals  $I$  as follows. We can find a spanning tree in  $G[D]$ ; add an edge between each vertex in  $I \setminus D$  and some vertex in  $D$ ; and remove any leaf which is not a terminal in the resulting tree. The Steiner nodes in this solution are contained in  $D$ . Hence in the optimal solution to the ST-MSN problem, the number of Steiner nodes is at most  $\gamma_c(G)$ .

In the approach taken in [48], first a maximal independent set  $I$  is found such that every subset of  $I$  and its complement are exactly distance two apart. The authors develop and use a 3-approximate algorithm for the ST-MSN problem on UDGs given terminals  $I$  (see [48] for details). Denote the Steiner nodes in the 3-approximate solution for the ST-MSN problem by  $S_I$ , then its size is at most  $3\gamma_c(G)$ . Thus, the CDS  $S_I \cup I$  has size at most  $6.8\gamma_c(G) + 1.2$ . This appears to be the approach with best performance guarantee available presently.

The weighted version of the MDS and MCDS problems, where the vertices of the UDG  $G$  are weighted and the objective is to find a dominating or a connected dominating set of minimum weight (sum of the weights of the selected vertices) have only been studied recently and the first constant factor approximation algorithms have been developed in [3]. A factor 72 approximation for MWDS and a factor 89 approximation for MWCDS are available and these problems appear to be more complicated than their unweighted counterparts.

A PTAS for the MDS problem given the disk representation was developed in [39], along similar lines as the schemes proposed for maximum independent set and minimum vertex cover problems. MCDS problem also has a PTAS developed in [17] for UDGs when the UDG is presented in its disk representation. In this work, an approximation algorithm running in time  $n^{O((s \log s)^2)}$  is presented that constructs a CDS of size no larger than  $(1 + 1/s)\gamma_c(G)$ . The algorithm uses a grid based divide-and-conquer approach in combination with the shifting strategy. A robust PTAS for the MDS problem on UDGs was proposed recently in [52].

We briefly describe the robust PTAS for MDS on UDGs from [52]. Given a graph  $G = (V, E)$ , the authors define a 2-separated collection of subsets  $S$ , as

$$S = \{S_1, \dots, S_k\} \text{ with } S_i \subset V, i = 1, \dots, k \text{ satisfying}$$

$$\forall i \neq j, d(s, t) > 2, \forall s \in S_i, \forall t \in S_j .$$

If  $D(S)$  denotes a MDS of  $G[S]$ , the authors show that for a 2-separated collection  $S$  in  $G$ ,

$$\gamma(G) = |D(V)| \geq \sum_{i=1}^k |D(S_i)| .$$

Furthermore, if we have subsets  $T_i$  such that  $S_i \subset T_i, i = 1, \dots, k$  and a bound  $\rho \geq 1$  such that

$$|D(T_i)| \leq \rho |D(S_i)|, \forall i = 1, \dots, k, \tag{4}$$

and

$$D' = \bigcup_{i=1, \dots, k} D(T_i) \text{ dominates } G, \tag{5}$$

then  $D'$  is a  $\rho$ -approximate MDS of  $G$ . This is true since,

$$|D'| \leq \sum_{i=1}^k |D(T_i)| \leq \rho \sum_{i=1}^k |D(S_i)|$$

$$\leq \rho |D(V)| = \rho \gamma(G) .$$

Given a UDG  $G = (V, E)$  and an  $\epsilon > 0$ , the algorithm in [52] constructs in polynomial time (for fixed  $\epsilon$ ), a 2-separation  $S_i$  and the supersets  $T_i$  with  $\rho = 1 + \epsilon$  satisfying the required properties (4), (5). This is accomplished as follows. First, we start with an arbitrary vertex  $v_1 \in V_1 := V$  and compute a MDS  $D(N_k(v_1))$  of  $N_k(v_1)$  for  $k = 0, 1, 2, \dots$  until the condition

$$|D(N_{k+2}(v_1))| > \rho |D(N_k(v_1))|$$

is violated. Denote by  $r_1$  the smallest  $k$  for which the above condition is violated, i.e.,  $|D(N_{r_1+2}(v_1))| \leq \rho |D(N_{r_1}(v_1))|$ . Then we iterate this procedure for the graph induced by  $V_{i+1} := V_i \setminus N_{r_1+2}(v_i)$  until  $V_{i+1} = \emptyset$ . Note that in the subsequent iterations, the  $k$ -neighborhood is defined with respect to the current graph  $G[V_{i+1}]$ . Suppose this procedure terminates after  $K$  iterations, let  $T_i = N_{r_1+2}(v_i)$  and let  $S_i = N_{r_1}(v_i)$  for  $i = 1, \dots, K$ . The authors then show that  $S_1, \dots, S_K$  is a 2-separated collection and  $\bigcup_{i=1}^K D(T_i)$  dominates  $G$ . The termination condition for each iteration,  $|D(T_i)| \leq \rho |D(S_i)|$ , guarantees the required approximation ratio.

It is noted in [52] that  $G$  needs not be a UDG to derive the approximation ratio, however it is necessary to show polynomial time solvability. The running time guarantee is provided by the following results from [52]. Firstly, the number of iterations  $K \leq n$  and in each iteration  $i$ , the MDS in each  $k$ -neighborhood  $N_k(v_i)$  can be found in polynomial time since its size is shown to be bounded by a polynomial function of  $k$ , and finally the number of  $k$ -neighborhoods considered is also bounded since  $r_i \leq c(\rho)$  where  $c(\rho)$  is a constant that depends only on the desired approximation factor  $\rho$ . Finally, this PTAS can be made robust by utilizing the same certification approach to show the graph is not a UDG used for the MIS problem developed by the same authors, described in Sect. “Independent Sets”.

### Coloring and Clique Partitioning

The graph coloring problem on UDGs is known to be NP-hard. In [18], 3-colorability of UDGs is shown to be NP-complete and hence it follows that no approximation algorithm can achieve a ratio within  $4/3$ , unless  $P = NP$ . In fact  $k$ -colorability of UDGs is NP-complete for any fixed  $k \geq 3$  [31]. A simple 3-approximation algorithm for the problem was presented in [45] based on results from [37,58]. Let

$$p(G) = \max_{H \subseteq G} \delta(H),$$

the largest  $p$  such that  $G$  contains a subgraph  $H$  of minimum degree  $p$ . Then

$$\chi(G) \leq p(G) + 1 [58]$$

and  $p(G)$  can be found in  $O(m + n)$  steps [37,58] as follows. Let  $p := 0$  and let  $v$  be a vertex of minimum degree in  $G$ . Repeating the steps,  $p := \max\{p, \delta(G)\}$  followed by  $G := G - v$  until no vertices remain in  $G$ , finds  $p(G)$ . If we denote by  $v_i$ , the vertex removed in step  $i$ , each  $v_i$  then has at most  $p(G)$  neighbors in  $v_{i+1}, \dots, v_n$ . Processing the vertices in the order  $v_n, \dots, v_1$ , and coloring each vertex with the smallest color not yet assigned to any of its neighbors already colored, guarantees a coloring of  $G$  with at most  $p(G) + 1$  colors. If  $G$  is a UDG, then it is proven in [45] that

$$\frac{p(G)}{3} + 1 \leq \chi(G).$$

Using similar approaches, it has also been shown in [54] that a UDG  $G$  can be colored using no more than  $3\omega(G) - 2$  colors. A 3-approximate algorithm for coloring UDGs using network flow and matching techniques is also available from [31].

Clique partitioning is NP-complete even when restricted to *coin graphs* (UDGs where all overlaps are tangential) [15]. A polynomial time 3-approximate algorithm for this problem that uses the disk representation is available from [15]. The algorithm proceeds by first partitioning the plane into horizontal strips of width  $\sqrt{3}$ . A disk belongs to strip  $i$  if its center lies on the strip. A disk with its center on the boundary is assigned to the strip on top. Let  $G_i$  denote the UDG induced by disks in strip  $i$  and  $V(G_i)$  are vertex disjoint. Solve the minimum clique partitioning problem exactly on each  $G_i$  and let  $Z_i$  denote the collection of cliques. The authors observe that this can be accomplished in polynomial time by coloring the complement since each  $G_i$  is a *cocomparability graph* [9,15]. The clique partition returned by the algorithm is  $Z := \bigcup_i Z_i$  and it can be shown that  $|Z| \leq 3\bar{\chi}(G)$  as follows. Let  $Z^*$  denote a minimum clique partition of UDG  $G$  and let  $Z_i^*$  be the restriction of  $Z^*$  to  $G_i$  obtained by excluding the vertices not in  $V(G_i)$  from the cliques in  $Z^*$ .  $Z_i^*$  is a valid clique partition of  $G_i$  and hence  $|Z_i^*| \geq |Z_i|$ . If  $C$  is a clique in  $Z^*$ , the authors observe that based on geometric arguments, the centers of disks in  $C$  must lie inside three consecutive strips. Hence, each  $C$  in  $Z^*$  is a union of at most 3 disjoint cliques from  $Z_{j-1}^*, Z_j^*$ , and  $Z_{j+1}^*$  for some  $j$ . Hence we have,

$$|Z| = \sum_i |Z_i| \leq \sum_i |Z_i^*| \leq 3|Z^*|.$$

The running time of the approximation algorithm is dominated by the exact solution step on each strip resulting in  $O(n + \bar{m})$  where  $\bar{m}$  denotes the number of edges in  $\bar{G}$ .

### Related Results

A survey of on-line and off-line approximation algorithms for independent set and coloring problems on UDGs and general *disk graphs* (intersection graphs of disks of arbitrary radii) can be found in [23]. A short survey of results for cliques, independent sets and coloring of disk graphs is also available in [27]. A survey

of complexity results on recognizing several variants of UDGs can be found in [36]. PTAS for *maximum weighted independent set* and *minimum weighted vertex cover* problems on intersection models of disks are available in [24].

A notion of *thickness* of UDGs is introduced and *fixed parameter tractability* of maximum independent set, minimum vertex cover and minimum (connected) dominating set problems (with thickness as parameter) is established in [59]. A parameterized algorithm running in  $n^{O(\sqrt{k})}$  for finding an independent set of size  $k$  on *bounded ratio disk graphs* (the ratio of maximum diameter to minimum diameter is bounded by a constant) are presented in [1].

Several variants of the classical vertex coloring problem have been considered on UDGs, primarily motivated by different frequency assignment problems that arise in wireless networks. Apart from natural generalizations of UDGs such as general disk graphs, and bounded ratio disk graphs mentioned before, other generalizations of UDGs such as *Quasi UDGs* [42], *bisected UDGs* [53] and *double disk graphs* [44] have also been developed motivated by wireless applications. Coloring problems have been studied in the context of these generalizations.

Algorithms for *distance constrained labeling*, which is a generalization of the well-known vertex coloring problem, for disk graphs are presented in [26]. Another variant of coloring called the *multicoloring* problem on UDGs is considered in [49]. The notion of *conflict-free coloring* is introduced and studied in the context of disk graphs in [25]. A  $k$ -improper coloring of a graph is one in which each color class induces a subgraph of maximum degree  $k$ . Note that 0-improper coloring is a proper coloring by the standard definition. For fixed  $k$ , the  $k$ -improper coloring problem has been shown to be NP-complete in [35]. Coloring and other problems on *bisected unit disk graphs*, which generalize UDGs to allow for the phenomenon of *cell sectorization* in wireless communication are studied in [53]. Another generalization of UDGs motivated by frequency assignment problems in wireless networks are *double disk graphs*. Here, two concentric disks of arbitrary radii are associated with each vertex, and two vertices are adjacent if the inner disk of one intersects the outer disk of the other. For instance, one could think of the inner disk as the receiver range and the outer disk as the

transmission range. Coloring problems on these graphs are studied and constant factor approximation algorithms are developed in [22,44]. Hierarchical models of UDGs formed by a sequence of labeled UDGs is considered in [46]. PTAS for the maximum independent set, minimum dominating set, minimum clique cover, and minimum vertex coloring problems for UDGs specified hierarchically are developed in [46].

The notion of *well-separated pair decomposition* [13] with applications in geometric proximity problems is studied in the context of UDGs and algorithms for the same are developed in [29]. In [41], the hardness of approximately embedding UDGs is considered. Given a UDG  $G = (V, E)$ , let  $L(c_u, c_v)$  denote the Euclidean distance between centers  $c_u, c_v$  of discs  $u, v \in V$  in an embedding  $emb(G)$ . The authors define the quality of an embedding  $emb(G)$  as

$$q(emb(G)) = \frac{\max_{(u,v) \in E} L(c_u, c_v)}{\min_{(u,v) \notin E} L(c_u, c_v)}.$$

Note that for any proper unit disk embedding  $emb(G)$ , the numerator of  $q(emb(G))$  is at most 1 and the denominator is more than 1. The authors of [41] then show that finding an embedding  $emb(G)$  for a UDG  $G$  such that  $q(emb(G)) \leq \sqrt{3}/2 - \epsilon$  where  $\epsilon \rightarrow 0$  as  $n \rightarrow \infty$  is NP-hard.

A data structure referred to as *extended doubly connected edge list* is developed in [43] for representing UDGs which facilitate faster implementation of routing algorithms in mobile wireless networks.

*Max-cut* and *max-bisection* problems in UDGs are shown to be NP-hard in [21].

## Conclusions

In this chapter, we have surveyed results from literature on classical combinatorial optimization problems such as the maximum clique, maximum independent set, minimum vertex cover, minimum (connected) domination, graph coloring and minimum clique partitioning on unit-disk graphs. Brief descriptions of the approaches taken to solve these problems and the key ideas involved have been explained. Several recent results from literature have also been presented. A summary of important results surveyed can be found in Table 1.

### Keywords

Mathematical software; Optimization; High performance computing

The origin of the term *mathematical software* can be traced back to J.R. Rice, who organized a symposium on this topic in 1969 [20,21]. Today, the term ‘mathematical software’ refers to accurate, efficient and reliable software for the solution of mathematical problems that

arise in scientific and engineering applications. Different applications are described by similar mathematical models, leading to common computational kernels. Mathematical software provides solutions to these kernels, and supplies building blocks for the development of application software. Therefore, the availability of mathematical software simplifies the solution of application problems by relieving users from having to deal with details related to basic algorithms and their implementations, while exploiting the experience and know-how of mathematical software developers that is needed to produce reliable, accurate and robust modules. Mathematical software is therefore the result of the collaboration of experts in different fields of scientific computing, as it is confirmed by the existence of organized mathematical software repositories and cross-indexed catalogs [1,10,18].

The production of mathematical software is a complex process, ranging from the development of algorithms, to their implementation in specific environments, to the development of user-friendly interfaces, and to intensive testing and quality assurance of the final product. Moreover, this activity is largely influenced by the evolution of computer architectures.

To solve real world problems, hardware must be ‘dressed’ with a suitable suite of software products. This software can be grouped into three main layers that we refer to as *low-level*, *medium-level* and *high-level*. These terms indicate how close the software is to the hardware (with low-level referring to the closest layer), and, at the same time, how close the software is to the real-world problem (with high-level software referring to the layer closest to the application).

We divide mathematical software into the following main categories [23]:

- a) *individual routines*, sometimes gathered into *collections*,
- b) *packages of basic routines*,
- c) *packages for specific mathematical areas*,
- d) *general-purpose libraries*,
- e) *problem solving environments (PSE)*.

Note that problem solving environments have been included among the above categories although they do not consist only of mathematical software, in order to give an idea of the trends in the development of scientific software and of the role of mathematical software in such contexts.

In the field of optimization, a lot of sequential software is available within each one of the above categories. The continuing evolution of most optimization algorithms and software makes hard both the task to give an exhaustive overview of the current (1999) state-of-the-art and the process to rapidly individuate a software among the existing ones which is able to take advantage of the special nature of the particular problem to be solved.

A first step along such direction should be to formulate the optimization problem as one of the standard *optimization paradigms*. This usually leads to a taxonomy, according to which most optimization problems can be classified. One of the most complete classifications can be found in [17]. It provides an up-to-date (1999) online optimization tree guide to the different subfields of optimization and includes an overview of the major algorithms in each area, with pointers to software packages where appropriate. The first two branches of such optimization tree provide pathways through continuous and discrete problems. Following these pathways we are able to meet the most relevant classes of optimization problems, ranging from nonlinear equations and nonlinear least squares for the unconstrained continuous optimization, to linear programming and general nonlinearly constrained problems for the constrained continuous optimization.

The choice of an algorithm, and related software, to solve an optimization problem has to be made taking into account either some intrinsic properties of the problem, such as:

- type of the objective function and constraints,
- size (number of variables and constraints),
- sparsity degree,

or the main factors that determine the computational cost of the algorithm, such as:

- evaluation of objective functions, constraints, and/or derivatives,
- number of evaluations of objective functions, constraints, and/or derivatives,
- number of variables or constraints,
- number of iterations (optimization algorithms are essentially iterative).

We point out that a large number of available optimization software belongs to category c), that is it consists of packages which are specifically aimed to optimization problems and that can be divided into the following two

groups:

- *single-class*, that is packages which address a specific problem class;
- *multiple-class*, that is packages that cover more than one class of problems.

Among the software collections belonging to the first group, we mention WHIZARD [25] for linear programming which uses primal, dual and network simplex algorithms, and L-BFGS-B [5] for bound-constrained optimization problems, which uses a limited memory BFGS algorithm and it is suitable for solving large problems.

Among the packages belonging to the multiple-class we mention MINPACK-1 [14] which is intended to solve systems of nonlinear equations and nonlinear least squares problems, and it is based on the trust region concept.

One of the most recently developed packages of the multiple-class group is LANCELOT [6,12], which provides solvers for unconstrained optimization problems, systems of nonlinear equations, bound-constrained optimization problems, and general nonlinearly constrained optimization problems.

We observe that in many cases software packages which can be used for more than one problem class would sacrifice some efficiency by handling some special nature of the main target problem as the general one.

We also mention three general numerical software libraries, NAG, Harwell and IMSL (category d)), which contain optimization capabilities.

In the 1990s, much research effort has been addressed to develop modeling languages and *optimization systems* (category e), that is PSEs). The basic idea of a modeling programming language is to provide user with common notation and familiar concepts to formulate optimization models and examine solutions, while computer manages communication with an appropriate solver. One of the most used modeling languages is AMPL [9], which offers an interactive command environment for setting up and solving linear and nonlinear optimization problems, in continuous or discrete variables.

An optimization system is a complete system formed by modeling languages to formulate the optimization problem, as well as by easy-to-use user interfaces to solve it and other utilities, like report writing,

model management and execution control. An example of currently available optimization systems is the NEOS Server [17] which allows to solve optimization problems automatically over the Internet, with minimal input from the user and with state-of-the-art optimization software without downloading and linking code. Furthermore, the NEOS Server provides derivatives and sparsity patterns determined automatically with ADIFOR, which is a tool for the automatic differentiation of Fortran programs [3].

Finally, we observe that, as pointed out in [7,26], computational kernels that frequently appear in numerical optimization are those of dense and sparse linear algebra (matrix factorization, orthogonalization, preconditioning, etc.). In most optimization software computational kernels are solved by using efficient routines from standard packages designed for basic linear algebra problems (BLAS, LAPACK).

While the quality of mathematical software can be considered satisfactory for ‘traditional’ computing environments, the widespread and effective use of *high performance computing* (HPC) resources, required for the solution of the so-called *grand challenges*, is still inhibited by the lack of software suitable for such advanced computational environments [23].

Design and implementation of mathematical software for high performance computing environments has to take into account a number of issues in addition to the ones faced for sequential and vector systems. The new features to be dealt with include a variety of processor and memory system architectures, the lack of standard language features for specifying parallel operations or data distribution, and nondeterminism in execution.

The number of available *parallel optimization* packages is small if compared with the large number of sequential packages. Among them, we mention BTN (*block truncated Newton*) [16], for unconstrained minimization in shared and distributed memory computing environments and PDS, a collection of routines for solving unconstrained nonlinear optimization problems using direct search methods, which has been developed for distributed memory architectures [24]. Moreover, versions of GENOS (*generalized network optimization system*), for solving unconstrained optimization problems with network and generalized network constraints, are available for vector and parallel ma-

chines [8]. Routines for unconstrained nonlinear problems based on Newton-type methods, are included in the *NAG parallel library*. Other efforts to produce optimization software for HPC environments are gathered into a few projects currently under development. A well know project is MINPACK-2, aimed mainly at developing a version of MINPACK-1 suitable for advanced architectures [2].

Two basic strategies for introducing parallelism into optimization algorithms, and more generally into numerical algorithms, can be identified:

- parallelizing the computational kernels;
- parallelizing the methods.

One of the already mentioned computational kernel in optimization algorithms is the *evaluation of objective functions and/or derivatives*, which can dominate the overall execution time. If the evaluations are computationally intensive, one can exploit parallelism in each of them, and the exploitation depends on the type of the objective function. For example, in the case of partially separable functions, i. e. functions expressed as the sum of element functions on which small subsets of variables have disjoint effects, one can exploit parallelism by having different processors compute different element functions concurrently, as in [11].

With the strategy of ‘parallelizing the method’, parallelism is introduced at a level higher than computational kernels, often leading to new optimization methods. For example, in the context of quasi-Newton methods, parallelism has been introduced using line-searches that evaluate the objective function at multiple points concurrently. The basic idea consists in choosing several points along a search direction, evaluating the objective function in each of them concurrently, and using the point with the lowest function value at the next iterate.

A further example can be found in the area of global optimization. The idea is to partition the feasible region into subregions, where each processor searches for a local minimum; the global minimum is obtained by comparing the local results (see for example [4,19]).

Finally we observe that an effective implementation of the parallelization strategies described requires the use of *dynamic load balancing techniques*, to ensure as much as possible that the workload is uniformly distributed among the processors and, hence, to minimize processor idle time.

Interest in *dynamic simulation* and *optimization* of chemical processes has increased significantly during the 1980s– 1990s. Common problems include control and scheduling of batch processes; startup, upset, shut-down and transient analysis; safety studies and the evaluation of control schemes. Chemical processes are modeled dynamically using differential-algebraic equations (DAEs). The DAE formulation consists of differential equations that describe the dynamic behavior of the system, such as mass and energy balances, and algebraic equations that ensure physical and thermodynamic relations.

The general *dynamic optimization* problem can be stated as follows:

$$\min_{z(t), y(t), u(t), t_f, p} \varphi(z(t_f), y(t_f), u(t_f), t_f, p) \quad (1)$$

s.t. DAE model:

$$\frac{dz(t)}{dt} = F(z(t), y(t), u(t), t, p), \quad (2)$$

$$G(z(t), y(t), u(t), t, p) = 0, \quad (3)$$

initial conditions:

$$z(0) = z^0, \quad (4)$$

point conditions:

$$G_s(z(t_s), y(t_s), u(t_s), t_s, p) = 0, \quad (5)$$

bounds:

$$\begin{cases} z^L \leq z(t) \leq z^U, \\ y^L \leq y(t) \leq y^U, \\ u^L \leq u(t) \leq u^U, \\ p^L \leq p \leq p^U, \\ t_f^L \leq t_f \leq t_f^U, \end{cases} \quad (6)$$

where

$\varphi$	is a scalar objective function,
$F$	are differential equation constraints,
$G$	are algebraic equation constraints,
$G_s$	are additional <i>point conditions</i> at times $t_s$ ,
$z$	are differential state profile vectors,
$z^0$	are the initial values of $z$ ,
$y$	are algebraic state profile vectors,
$u$	are control state profile vectors,
$p$	is a time-independent parameter vector.

We assume, without loss of generality, that the index of the DAE system is one and that the objective function is in linear *Mayer form*. Otherwise, it is easy to reformulate most problems to this form. Dynamic optimization problems can be solved either by the variational approach or by applying some level of discretization that converts the original continuous time problem into a discrete problem. The first approaches are focused on obtaining a solution to the classical necessary conditions for optimality. These approaches are also known as *indirect methods*.

The methods that discretize the original continuous time formulation can be divided into two categories, according to the level of discretization. Here we distinguish between the methods that discretize only the control profiles (partial discretization) and those that discretize the state and control profiles (full discretization). Basically, the partially discretized problem can be solved either by dynamic programming or by applying a nonlinear programming (NLP) strategy (*direct-sequential*). A basic characteristic of these methods is that at every iteration a feasible solution of the DAE system, for given control values, is obtained by integration. The main advantage of these approaches is that they generate smaller discrete problems than full discretization methods.

The methods that fully discretize the continuous time problem also apply NLP strategies to solve the discrete system and are known as direct-simultaneous methods. These methods can use different NLP and discretization techniques but the basic characteristic is that they solve the DAE system only once, at the optimum. In addition, they have better stability properties than partial discretization methods, especially in the presence of exponentially increasing modes. On the other

hand, the discrete problem is larger and may require special solution techniques.

With this classification we take into account the degree of discretization used by the different methods. Some authors might prefer to classify the methods according to the solution strategy as indirect methods, methods based on *dynamic programming* and direct methods [41].

This article is organized as follows. In the next section we present the description of the *variational methods*. Following this we describe methods that partially discretize the dynamic optimization problem, and we then discuss full discretization methods as well. Finally, we conclude with a brief description of some of the emerging areas related to dynamic optimization such as *interior point methods* and the solution of *mixed integer dynamic optimization* problems and *multistage problems*.

**Variational Methods**

These methods are based on the solution of the first order necessary conditions for optimality that are obtained from *Pontryagin’s maximum principle* [37]. For the problem (1)–(4), the optimality conditions are formulated as a set of differential-algebraic equations

$$\frac{dz}{dt} = \frac{\partial H}{\partial \lambda} = F(z(t), y(t), u(t), p), \quad z(0) = z_0, \tag{7}$$

$$\frac{d\lambda}{dt} = -\frac{\partial H}{\partial z}, \quad \lambda(t_f) = \frac{\partial \varphi}{\partial z} + \frac{\partial G_f}{\partial z_f} v_f, \tag{8}$$

$$\frac{\partial H}{\partial y} = \frac{\partial F}{\partial y} \lambda + \frac{\partial G}{\partial y} \mu = 0,$$

$$\frac{\partial H}{\partial u} = 0, \tag{9}$$

$$\int_0^{t_f} \frac{\partial H}{\partial p} dt = 0,$$

$$G(z(t), y(t), u(t), t, p) = 0,$$

where the *Hamiltonian*,  $H$ , is a scalar function of the form

$$H(t) = \lambda(t)^T F(t) + \mu(t)^T G(t) \tag{10}$$

and  $\lambda, \mu$  are vectors of the *adjoint variables* and  $v_f$  is the multiplier associated with the final time constraint,  $G_f(z(t_f), y(t_f), u(t_f), t_f, p)) = 0$ .

The main problem in obtaining a solution to these equations are the boundary conditions. Normally the state variables are assigned initial conditions and the adjoint variables are assigned final conditions. This procedure leads to a *two-point boundary value problem* (TPBVP) that can be solved with different approaches: single shooting, invariant embedding, multiple shooting, *collocation* on finite elements and finite differences.

In the single shooting methods the missing initial conditions values are guessed. Then, an initial value solver integrates the DAE forward and a Newton iteration is applied to adjust the guessed initial conditions so that the final conditions are equal to the given values. The main disadvantage of this method is that in many cases the problem cannot be solved for a given set of guessed initial conditions, due to nonlinearities and instabilities of the DAE system.

Invariant embedding [45] is a procedure for converting the TPBVP to a initial value problem (IVP). It is based on assuming the structure of the solution, and results in solution procedures analogous to the Riccati matrix differential equation. The main disadvantage here is the high dimensionality of the resulting problem.

Multiple shooting methods follow the same idea as single shooting, but now the integration horizon is divided into smaller subintervals. In this way, state variable values are not only guessed at initial time, but also at several points in between. Then the system equations are decomposed by either solving a collocation system for each region or using a direct integrator along the nominal trajectory on each subinterval. The Newton iteration is also needed to enforce the continuity between subintervals. The discretization methods (or global methods) are known as the most stable. The solution to the TPBVP is obtained simultaneously for the whole horizon, so the initial conditions do not need to be guessed.

For the multiple shooting and discretization methods, special decomposition strategies are usually used to decompose the structured linear algebraic system that is obtained at every iteration of the solution procedure. Efficient factorizations schemes, based on structured Gaussian elimination [27,30] and structured orthogonal factorization [50] can be used in order to minimize the computational effort. Although these methods work well for problems without bounds, handling inequality

constraints is difficult, unless a priori information about the active constraints is known.

## Partial Discretization

### Dynamic Programming

The use of *iterative dynamic programming* (IDP) for the solution of dynamic optimization problems has been limited largely because of the high dimensionality usually associated with it. This problem is often avoided by allowing a very coarse grid, which in some cases can be accurate enough [13]. Although the IDP algorithm is slower than most gradient-based algorithms, it can be useful to cross-check results of relatively small problems ( $n < 100$ ). This is especially true when the global optimum is unknown, as the probability of obtaining the global optimum is usually high once the grid is not poorly chosen [20]. For these techniques the time horizon is divided into  $P$  time stages, each of length  $L$ . Then, the control variables are usually represented as piecewise constant or piecewise linear functions in each interval. The piecewise linear functions in each interval  $(t_k, t_{k+1})$ , usually takes the form

$$u(t) = u_i + \left( \frac{u_{i+1} - u_i}{L} \right) (t - t_i) ,$$

where  $u_i$  and  $u_{i+1}$  are the values of  $u$  at  $t_i$  and  $t_{i+1}$ , respectively.

The dynamic optimization problem is to find  $u_i$ ,  $i = 0, \dots, P-1$ , that minimize a given objective function. The basic search algorithm is the following [33]:

- 1) Divide the time interval  $[0, t_f]$  into  $P$  time stages, each of length  $L$ .
- 2) Choose the number of allowable values  $M$  for  $u$ .
- 3) Choose an initial profile for each  $u_i$ , initial region size  $r_i$ , and the contraction factor  $\gamma$ .
- 4) By using the initial control policy, integrate the system from  $t = 0$  to  $t_f$  to generate the state trajectory and store the values of the states at the beginning of each time stage, so that the states at  $(i-1)$  corresponds to the value of the states at the beginning of stage  $i$ .
- 5) Starting at stage  $P$ , integrate the system from  $t_f - L$  to  $t_f$  using as initial value the states at  $P-1$  from step 4 once with each of the allowable values for the control vector. Choose the control  $u_{P-1}$  that gives the minimum value for the objective function, and store the value.
- 6) Step back to stage  $P-1$ , corresponding to time  $t_f - 2L$ . For each allowable value of  $u_{P-2}$  integrate the system by using as initial value the states at  $P-2$  chosen from step 4 and the given control policy (constant or linear). Continue integration until  $t = t_f$  using for the last stage the value  $u_{P-1}$  from step 5. Compare the  $M$  values of the objective function and choose the  $u_{P-2}$  that gives the smallest value.
- 7) Continue the procedure until stage 1, corresponding to the initial time  $t = 0$ .
- 8) Reduce the region for allowable control,  $r^{k+1} = \gamma r^k$ , where  $k$  is the iteration index. Use the control policy from step 7 as the midpoint for the allowable values for the control  $u$  at each stage.
- 9) Increment the iteration index and go to step 5. Continue the procedure for a specified number of iterations and examine the results.

This algorithm works well when the dynamic optimization problem does not include bounds on state variables. In order to include them, a penalty term has to be added into the objective function to penalize the constraint violation. This can be done by adding a state variable for each inequality that measures the constraint violation over time [35] or by computing the constraint violation at given points in time [20].

### Sequential Methods

In the sequential methods, only the control variables are discretized. This is why these techniques are also known as *control parametrization* methods. Given the initial conditions and a given set of control parameters, the DAE system is solved with a differential algebraic equation solver at each iteration. This produces the value of the objective function, which is used by a nonlinear programming solver to find the optimal parameters in the control parametrization. The sequential method is of the feasible path type, that is, in every iteration the DAE system is solved. This procedure is very robust when the system contains only stable modes. If this is not the case, finding a feasible solution for a given set of control parameters can be difficult.

The time horizon is divided into  $P$  time stages and at each stage the control variables are represented with a piecewise constant, a piecewise linear or a polynomial approximation [22,48]. Also, a common practice is to use a set of Lagrange polynomials. So, in each stage  $i$ ,

the control variables can be written as:

$$u_i(t) = \sum_{q=1}^{\text{ncol}} \psi_q \left( \frac{t - t_{i-1}}{L_i} \right) u_{i,q}, \quad (11)$$

where  $u_{i,q}$  represent the values of the control variables, in stage  $i$  at collocation point  $q$ . Here,  $\psi_q$  is a Lagrange polynomial of order ncol satisfying,

$$\psi_q(\rho_r) = \delta_{q,r}.$$

The gradients of the objective function with respect to the control parameters can be calculated with the sensitivity equations of the DAE system or by integration of the adjoint equations.

### Sensitivity-Based Gradients

The *sensitivity equations* are found by differentiating the DAE system after the control has been discretized with the parameter set  $\theta$  [21,45], and for each element,  $\theta_j$ , we write:

$$\begin{aligned} \frac{\partial \left( \frac{dz}{dt} \right)}{\partial \theta_j} &= \frac{d \left( \frac{\partial z}{\partial \theta_j} \right)}{dt} \\ &= \left( \frac{\partial F}{\partial z} \right)^\top \left( \frac{\partial z}{\partial \theta_j} \right) + \left( \frac{\partial F}{\partial y} \right)^\top \left( \frac{\partial y}{\partial \theta_j} \right) + \left( \frac{\partial F}{\partial \theta_j} \right), \\ \left( \frac{\partial G}{\partial z} \right)^\top \left( \frac{\partial z}{\partial \theta_j} \right) + \left( \frac{\partial G}{\partial y} \right)^\top \left( \frac{\partial y}{\partial \theta_j} \right) + \left( \frac{\partial G}{\partial \theta_j} \right) &= 0. \end{aligned}$$

The solution of the sensitivity equations is simplified because the Jacobians in the sensitivity equations ( $\partial F / \partial z$ ,  $\partial G / \partial z$ ,  $\partial F / \partial y$ ,  $\partial G / \partial y$ ) are equal to the DAE system Jacobians calculated at each step (or given number of steps) of the integration. The computational effort is reduced to one matrix multiplication per parameter per Jacobian evaluation. Once the sensitivities of the states with respect to the parameters are known, the gradient of the objective function and the constraints  $c$ , can be calculated as follows [21,45]:

$$\begin{aligned} \frac{d\varphi}{d\theta} &= \left( \frac{\partial \varphi}{\partial \theta} \right) + \left( \frac{\partial z}{\partial \theta} \right) \left( \frac{\partial \varphi}{\partial z} \right) + \left( \frac{\partial y}{\partial \theta} \right) \left( \frac{\partial \varphi}{\partial y} \right), \\ \frac{dc}{d\theta} &= \left( \frac{\partial c}{\partial \theta} \right) + \left( \frac{\partial z}{\partial \theta} \right) \left( \frac{\partial c}{\partial z} \right) + \left( \frac{\partial y}{\partial \theta} \right) \left( \frac{\partial c}{\partial y} \right). \end{aligned}$$

Although there have been a lot of advances in solving sensitivity equation more efficiently [23], the computational effort of solving them is still an expensive part of the optimization algorithms. The cost of solving these equations is strongly dependent on the number of input variables. Current directions for handling the computational load include exploitation of faster computer hardware and parallel computer programming architectures, as well as more efficient solution strategies that avoid repeated factorization of Jacobians [5].

The methods that are based in this approach cannot treat the bounds on state variables directly, because the state variables are not included in the nonlinear programming problem. Special methods have been developed to address this problem. Most of the techniques for dealing with inequality path constraints rely on defining a measure of the constraint violation over the entire horizon, and then penalizing it in the objective function, or forcing it directly to zero through an end-point constraint [49].

An alternative is to transform the inequality constraints into equalities by adding a square slack variable [26]. The slack variables can then be treated as control variables and the proper bounds can be imposed in the NLP. The problem of this approach is that it can generate high-index problems, and special index reduction techniques have to be applied at the same time.

In [49], inequality path constraints are handled through a hybrid approach which is the result of the combined application of the discretization of these constraints at a finite number of points, and forcing an integral measure of their violation to zero. Each inequality path constraint requires the introduction of an additional ordinary differential equation, and it is converted to  $2P$  ( $P$  = number of stages) point constraints and one end-point constraint.

The use of initial value solvers that can handle directly the path constraints has also been studied [22]. The main idea is to use an algorithm for constrained dynamic simulation so that any admissible combination of the control parameters produces an initial value problem that is feasible with respect to the path constraints. The algorithm proceeds by detecting activation and deactivation of the constraints during the solution, and solving the resulting high-index DAE system and their related sensitivities.

## Adjoint-Based Gradients

The gradients can also be calculated through *adjoint methods* [14,25,40] at a cost independent of the number of input variables. The DAE adjoint equations are determined from the Hamiltonian function (10). The adjoint profiles  $\lambda$  and  $\mu$  form a semi-explicit index one DAE that can be solved easily. Once the adjoint system (8)–(9) is solved, the gradients are obtained from

$$\delta\varphi = \int_0^{t_f} \left( \frac{\partial F}{\partial u} \lambda + \frac{\partial G}{\partial u} \mu \right) \delta u \, dt.$$

If the control profile is discretized into piecewise constants  $u_i$ . The gradient with respect to  $u_i$  can be expressed as

$$\begin{aligned} \delta\varphi = & \int_0^{t_1} \left( \frac{\partial F}{\partial u} \lambda + \frac{\partial G}{\partial u} \mu \right) dt \, du_1 + \dots \\ & + \int_{t_{p-1}}^{t_p} \left( \frac{\partial F}{\partial u} \lambda + \frac{\partial G}{\partial u} \mu \right) dt \, du_p \end{aligned}$$

and

$$\frac{d\varphi}{du_i} = \int_{t_{i-1}}^{t_i} \left( \frac{\partial F}{\partial u} \lambda + \frac{\partial G}{\partial u} \mu \right) dt.$$

Adjoint methods are not difficult to automate, but they require the storage of the state profiles for the subsequent adjoint calculation. Also, Jacobians for system and adjoint equation integration can be evaluated at different times, in general, sparse LU factors of Jacobians from system equation integration are not used while solving adjoint equations. The use of implicit Runge–Kutta methods that transform the DAE system into discrete-time implicit equations [38] can solve this problem.

As in the sensitivity based methods, in the adjoint-based methods, the bounds of the states variables can not be treated directly. Usually, when state constraints are imposed a separate adjoint system is developed for each constraint. However, if path constraints are handled individually, we face a daunting task because of the number of adjoint systems that must be developed. Special techniques that reduce the number of adjoints variables have been developed to overcome this problem [38]. Other techniques approximate the constraint satisfaction (constraint aggregation methods) by introducing an *exact penalty function* [10,40] or a *Kreiselmeier–Steinhauser function* [10] into the problem.

## Full Discretization

Full discretization methods explicitly discretize all the variables of the DAE system and generate a large scale nonlinear programming problem that is usually solved with a *successive quadratic programming* (SQP) algorithm. These kinds of methods follow a simultaneous approach (or infeasible path approach); that is, the DAE system is not solved at every iteration. It is only solved at the optimum point. Because of the size of the problem, special decomposition strategies are used to solve the NLP efficiently. Despite this characteristic, the simultaneous approach has advantages for problems with state variable (or path) constraints and for systems where instabilities occur for a range of inputs. In addition, the simultaneous approach can avoid intermediate solutions that may not exist, be difficult to obtain, or require excessive computational effort.

There are two main different approaches to discretize the state variables explicitly, multiple shooting [12] and collocation on finite elements [19]. We briefly describe both of them in the following sections.

## Multiple Shooting

In these methods the control variables are approximated by suitable parametrizations using only a finite set of control parameters. Usually a piecewise constant or piecewise linear representation is used. On each stage  $i = 0, \dots, P-1$  a time transformation is used [29]

$$\theta_i(\tau, v) = t_i + \tau h_i, \quad t_i = t_0 + \sum_{k=0}^{i-1} h_k, \quad \tau \in [0, 1],$$

with  $v = (t_0, d_0, d_1, \dots, d_{p-1})$ , with a dimensionless discretization grid

$$0 = \tau_{i,0} < \tau_{i,1} < \dots < \tau_{i,m_i} = 1$$

such that  $\theta_i(\tau_{i,0}, v) = t_i$  and  $\theta_i(\tau_{i,m_i}, v) = t_{i+1}$ . A piecewise approximation  $u_i$  of the control  $u_i$  is then defined by

$$\hat{u}_i(\tau) = \varphi_{i,j}(\tau, q_{ij})$$

using local control parameters  $q_{ij}$ . The functions  $\varphi_{i,j}$  are given basic functions, typically vectors of polynomials. If a piecewise constant approximation is chosen, this function takes the form  $\varphi_{i,j}(\tau, q_{ij}) = q_{ij}$ . For a piecewise

linear approximation the functions are expressed as

$$\varphi_{i,j}(\tau, q_{ij}) = q_{ij}^1 + \frac{\tau - \tau_{ij}}{\tau_{i,j+1} - \tau_{ij}} \left( q_{ij}^2 - q_{ij}^1 \right),$$

$$q_{ij} = \begin{pmatrix} q_{ij}^1 \\ q_{ij}^2 \end{pmatrix}$$

by linear interpolation between the values  $q_{ij}^1$  and  $q_{ij}^2$  at the endpoints of the stage. With this representation, a continuous approximation can be obtained by imposing continuity equations between the stages.

After this, the DAE system is explicitly discretized on each stage  $i = 0, \dots, P - 1$  at the points  $\tau_{ij}$  of the discretization grid using multiple shooting [11,43]. At each grid point the values of the state variables  $s_{ij} = (s_{ij}^z, s_{ij}^y)$  are chosen as additional unknowns. In this way a set of relaxed decoupled initial value problems (IVP) is obtained:

$$\frac{dz_i}{d\tau} = f_i(z_i(\tau), y_i(\tau), \varphi_{i,j}(\tau, q_{ij}), p, \theta_i(\tau, v)) h_i,$$

$$0 = g_i(z_i(\tau), y_i(\tau), \varphi_{i,j}(\tau, q_{ij}), p, \theta_i(\tau, v)) - g_i(s_{ij}^z, s_{ij}^y, \varphi_{i,j}(\tau_{ij}, q_{ij}), p, \theta_i(\tau_{ij}, v)) \tag{12}$$

with initial conditions

$$z_i(\tau_{ij}) = s_{ij}^z, \quad y_i(\tau_{ij}) = s_{ij}^y.$$

By including into the NLP the continuity conditions for the differential variables and the consistency conditions

$$0 = g_i(s_{ij}^z, s_{ij}^y, \varphi_{i,j}(\tau_{ij}, q_{ij}), p, \theta_i(\tau_{ij}, v))$$

as equality constraints, the final solution satisfies the DAE system. With this approach, the inequality constraints for states and controls can be imposed directly at the grid points. For piecewise constant or linear controls this approximation is adequate, but path constraints for the states may not be satisfied between grid points. This problem can be avoided by applying special techniques to enforce feasibility, like the ones used in the sequential methods.

The resulting NLP is solved using an SQP-type method that requires at each iteration the calculation of the objective function gradient and the constraint Jacobians. For almost all the different functions explicit formulas are available, and the corresponding derivatives

can easily be calculated. The only exception is  $z_i(\tau_{i,j+1})$ , which is computed by numerical integration of the relaxed decoupled IVP, hence the sensitivities with respect to initial values and parameters must be determined. This task is performed with the same techniques used in sequential methods. The only difference is that they are applied at every stage, and this allows a parallel implementation of this kind of algorithm. The SQP-type methods used for the solution of the NLP are very similar to the algorithms used after the full discretization using collocation. For this reason, we consider the collocation methods next.

### Collocation

The continuous time problem is converted into an NLP by approximating the profiles as a family of polynomials on finite elements. Different polynomial representations are used in the literature. In [16,46] a monomial basis representation [4] for the differential profiles is used. This representation is recommended because of smaller condition number and smaller rounding errors:

$$z(t) = z_{i-1} + h_i \sum_{q=1}^{ncol} \Omega_q \left( \frac{t - t_{i-1}}{h_i} \right) \frac{dz}{dt}_{i,q}, \tag{13}$$

where  $z_{i-1}$  is the value of the differential variable at the beginning of element  $i$ ,  $h_i$  is the length of element  $i$ ,  $dz/dt_{i,q}$  is the value of its first derivative in element  $i$  at the collocation point  $q$ , and  $\Omega_q$  is a polynomial of order  $ncol$ , satisfying

$$\Omega_q(0) = 0, \quad \text{for } q = 1, \dots, ncol,$$

$$\frac{d}{dt} \Omega_q(\rho_r) = \delta_{q,r} \quad \text{for } q = 1, \dots, ncol,$$

where  $\rho_r$  is the collocation point within each element. One disadvantage of the representation (13) is that state path constraints can only be enforced directly at the mesh points dividing each element. However, we can solve this problem by adding bounded algebraic variables to the problem formulation. The control and algebraic profiles are approximated using Lagrange polynomials of the form

$$y(t) = \sum_{q=1}^{ncol} \psi_q \left( \frac{t - t_{i-1}}{h_i} \right) y_{i,q}, \tag{14}$$

$$u(t) = \sum_{q=1}^{ncol} \psi_q \left( \frac{t - t_{i-1}}{L_i} \right) u_{i,q}, \tag{15}$$

where  $y_{i,q}$  and  $u_{i,q}$  represent the values of the algebraic and control variables, respectively, in element  $i$  at collocation point  $q$ .

Here,  $\psi_q$  is a Lagrange polynomial of order  $ncol$  satisfying,

$$\psi_q(\rho_r) = \delta_{q,r}.$$

Other authors also prefer to use low order Lagrange polynomials [7,31] for the differential variables.

$$z(t) = \sum_{q=1}^{ncol} \psi_q \left( \frac{t - t_{i-1}}{h_i} \right) z_{i,q}. \quad (16)$$

### NLP Techniques

The large scale NLP problems that arise from the full discretization of the DAE system are usually solved using successive quadratic programming (SQP) methods. These methods can be classified into full space and reduced space approaches.

#### Full Space SQP Approaches

Full space methods take advantage of the DAE optimization problem structure and the sparsity of the model. They are very efficient for problems with many degrees of freedom [7,8] as the optimality conditions can be easily stored and factored. Two important disadvantages of these methods are that second derivatives of the objective function and constraints are usually required, and special precautions are necessary to ensure descent properties. In [1], a full space algorithm which exploits the almost block diagonal structure of the DAE optimization problem was developed. This approach decouples the optimality conditions for each block of the *quadratic programming* (QP) subproblem using an affine transform. This way, the first order conditions in the state and control variables can be solved recursively, making the effort of solving it increase linearly with the number of blocks. Also in [7,8] a full space method is presented. In this work, the sparsity and the block diagonal structure are also exploited, but the degrees of freedom of the problems solved are relatively large compared to the number of variables. reduced space SQP In process engineering problems, the degrees of freedom are relatively few, as the number of state variables is much larger than the number of control variables.

In these cases, a reduced space SQP approach (rSQP) can be very efficient. With this approach, either projected Hessian matrices or their quasi-Newton approximations may be used, avoiding the necessity of second derivatives. An efficient algorithm can be constructed by decoupling the search direction into its components in range and null spaces and solving a smaller QP subproblem at every iteration. When using collocation, this decomposition allows to exploit the structure of the collocation matrix [32] decreasing the computational effort of these methods.

A partially reduced strategy using multiple shooting was developed in [42] and more recently in [29]. In this strategy, the structured NLP is projected onto the reduced space of differential variables plus control parameters, utilizing the natural decomposition of the discretized states into differential and algebraic variables. This algorithm is particularly efficient for problems with relatively large number of algebraic constraints. In addition to these methods, specialized decomposition procedures that take advantage of the structure of the Hessian were explored in [44].

### Emerging Areas

In this final section we briefly summarize areas of research that emerge (as of 2000) for dynamic optimization. These extend the methods presented so far to larger and more challenging applications and can be classified as improvements to nonlinear programming solvers, extensions to include discrete decisions and the treatment of multistage dynamic systems.

#### Addressing Bottlenecks in NLP Solvers

Several features in the above NLP strategies lead to performance bottlenecks for dynamic optimization. As the problem size increases, the selection of the correct active set can be expensive, especially for tightly constrained NLPs. It has been noted that the normally efficient active set strategies in [7,8] can become time consuming as many state and control profiles become constrained by their bounds. To overcome this problem, *interior point* and *barrier methods* allow us to deal with many active constraints in an efficient manner. This advantage is rooted in improved complexity properties of interior point methods. Whereas active set strategies have an exponential worst-case complexity, inte-

rior point methods typically have a complexity proportional to a low power of the number of variable bounds. In actual practice the resulting performance for active set strategies exhibits a polynomial increase in the number of active set iterations, whereas the number of interior point iterations is independent of problem size.

The barrier (or interior point) method can be motivated by representing the NLP (resulting from a discretization of (1)–(6)):

$$\begin{cases} \min & f(x) \\ \text{s.t.} & c(x) = 0, \\ & x \geq 0 \end{cases}$$

as

$$\begin{cases} \min & f(x) - \mu \sum_i \ln(x_i) \\ \text{s.t.} & c(x) = 0 \end{cases}$$

and solving the equality constrained problem for a decreasing sequence of positive  $\mu$ . This transformation can be applied directly to the NLP or at the QP level for the subproblem derived from an SQP algorithm. In the latter case, an interior point method can be derived that follows a central path for decreasing  $\mu$ . Very efficient implementations (e.g., predictor corrector algorithms [34] have been developed for this purpose and these have desirable convergence rates. However, despite these properties, interior point QP solvers, embedded within SQP, are not competitive with active set strategies unless the number of active constraints is large. Here active set solvers take advantage of warm starts from previous QP solutions, while so far interior point solvers still require a fixed computational cost (typically about ten linear factorizations and solutions of the KKT system) regardless of the number of active constraints. To reduce this fixed cost to only one KKT factorization per NLP integration, it becomes advantageous to develop the barrier method at the NLP level. Recently efficient barrier NLP solvers have been developed, including the LOQO solver in [47] and the NITRO solver in [15]. For these methods there are still some limitations on convergence properties, due to nonconvex NLPs.

NLP methods based on interior point concepts allow us to exploit directly all of the features mentioned

above for dynamic systems. Examples that demonstrate the performance of these approaches include the solution of linear *model predictive control* (MPC) problems [39] and nonlinear MPC problems [1] using interior point QP solvers and the solution of large optimal control problems using barrier NLP solvers [17].

### Discrete Decisions In Dynamic Optimization

Along with the DAE models described in (2)–(3), it becomes important to consider the modeling of discrete events in many dynamic simulation and optimization problems. In chemical processes, examples of this phenomena include phase changes in vapor-liquid equilibrium systems, changes in modes in the operation of safety and relief valves, vessels running dry or overflowing, discrete decisions made by control systems and explosions due to accidents. These actions can be reversible or irreversible with the state profiles and should be modeled with appropriate logical constraints. An interesting presentation on modeling discrete events can be found in [6]. The simulation of these events is often triggered by an appropriate discontinuity function which monitors a change in the condition and leads to a change in the state equations. These changes can be reformulated either by using complementarity conditions (with positive continuous variables  $x$  and  $y$  alternately set to zero) [24] or as binary decision variables [6]. These additional variables can then be embedded within optimization problems. Here complementarity conditions can be reformulated through smoothing [18] to yield an NLP while the incorporation of integer variables leads to mixed integer optimization problems.

For the latter case, several studies have considered the solution of mixed integer dynamic optimization (MIDO) problems. In particular, [3] developed a complete discretization of the state and control variables to form a mixed integer nonlinear program. On the other hand, [2] apply a sequential strategy and discretize only the control profile. In this case, careful attention is paid to the calculation of sensitivity information across discrete decisions that are triggered in time.

### Multistage Applications

The ability to solve large dynamic optimization problems and to model discrete decisions allows the inte-

gration of multiple dynamic systems for design and analysis. Here different dynamic stages of operation can be considered with individual models for each dynamic stage. Multistage applications in process engineering include startups and transients in dynamic systems with different modes of operation, design and operation of periodic processes with different models (e. g., adsorption, regeneration, pressurization, in a dynamic cycle, [36]), synthesis of chemical reactor networks [28], changes in physical phenomena due to discrete changes (as seen above) and multiproduct and multiperiod batch plants where scheduling and dynamics need to be combined and different sequences and dynamic operations need to be optimized.

For these applications each stage is described by separate state variables and models as in equations (2)–(3). These stages include an overall objective function with parameters linking among stages and control profiles that are manipulated within each stage. Moreover, multistage models need to incorporate transitions between dynamic stages. These can include logical conditions and transitions to multiple models for different operation. Moreover, the DAE models for each stage require consistent initializations across profile discontinuities, triggered by discrete decisions.

The solution of multistage optimization problems has been considered in a number of recent studies. See [9] for the simultaneous design, operation and scheduling of a multiproduct batch plant by solving a large NLP. More recently (as of 2000), multistage problems have been considered as mixed integer problems using sequential strategies [2] as well as simultaneous strategies [3,28]. These applications only represent the initial stages of dynamic systems modeling, in order to deal with an integrated analysis and optimization of large scale process models. With the development of more efficient decomposition and solution strategies for dynamic optimization, much more challenging and diverse multistage applications will continue to be considered.

### Introduction

The 3D structure of molecules is important for a multitude of reasons, prominent in contemporary studies: structure-property relations, reaction kinetics and dynamics, and drug design. Determining these structures is not straight forward, however, and a variety of techniques have been developed, including X-ray diffraction, NMR spectroscopy, and electron spectroscopy. Despite the many techniques available, at least in the area of protein structures, more than 85% of structures present in the PDB have been solved using X-ray diffraction methods [10].

In a single-crystal X-ray diffraction experiment, X-rays are focused on a molecular structure which has been crystallized. The incident rays are then diffracted and their intensity is sampled using a detector. The resulting pattern is recorded and analyzed, yielding data which primarily includes a reciprocal space metric ( $h, k, l$ ), termed Miller index, followed by a diffraction intensity at each individual coordinate set. The coordinates ( $h, k, l$ ) describe an infinite set of parallel planes

through a given crystal using the primitive reciprocal lattice vectors as a basis.

An ideal crystal can be described as a periodic arrangement of atoms repeated infinitely in space. This allows for a characterization of 3-D crystal structure in terms of a Fourier series known as the density function:

$$\rho(\mathbf{x}) = \frac{1}{V} \sum_m F_{\mathbf{H}_m} \exp(-2\pi i \mathbf{H}_m \cdot \mathbf{x}), \quad (1)$$

where  $V$  is the unit cell volume,  $m$  is an index for the set of reflections,  $\mathbf{H}$  is a ( $h, k, l$ ) Miller index, and  $F_{\mathbf{H}}$  is a structure factor defined as:

$$F_{\mathbf{H}} = \sum_j f_j \exp(2\pi i \mathbf{H} \cdot \mathbf{x}_j), \quad (2)$$

where  $j$  is an index for the set of atoms in the structure,  $f_j$  is an atomic scattering factor for atom  $j$ , and  $\mathbf{x}_j$  is the position of atom  $j$ . A structure factor can also be written in terms of an amplitude and phase:

$$F_{\mathbf{H}} = |F_{\mathbf{H}}| \exp(i\phi_{\mathbf{H}}). \quad (3)$$

Hence, full characterization of a crystal structure requires both amplitude and phase data for a large number of reflections,  $\mathbf{H}$ . In a traditional X-ray diffraction experiment, the diffraction intensity measured,  $I_{\mathbf{H}}$ , is directly proportional to the structure factor amplitude,  $|F_{\mathbf{H}}|$ . Phase data, however, is not directly available, yet vital for reconstructing the density function of a crystal. It is therefore in the difficult task of phase retrieval, for which this article is concerned.

First, a discussion of the Patterson and MAD techniques is presented. Traditionally, these techniques do not directly rely on optimization. Thus, the treatment of these methods is brief, focusing on some interesting uses of optimization in their context. Then, two prominent direct methods are discussed, both of which rely on the solution of difficult nonconvex optimization formulations. Minimal principle methods are addressed first, with particular emphasis on the solution of centrosymmetric structures. Then, maximum entropy methods are presented, with a focus on the maximum determinant method.

### Patterson Methods

Derivation of an electron density map requires amplitude and phase information for a large number of reciprocal lattice vectors,  $\mathbf{H}$ . As mentioned previously in the

introduction, phase information is not directly measurable in a traditional X-ray diffraction experiment, a serious obstacle in calculation of a density map. In 1934, with this severe limitation in mind, it was Arthur Lindo Patterson, who first began to look at a Fourier transform of diffraction intensities instead of structure factors. Such a transform does not require any knowledge of phase information. Naturally, this image is not identical to the original density function. However, certain structural information is still contained in the resultant map. Hence, techniques based on a Fourier transform of intensity, still used in some contemporary structural solution methods, form the global class of Patterson methods.

The Patterson function is simply the convolution of the density function with its inverse:

$$P(\mathbf{u}) = \rho(\mathbf{x}) \star \rho(-\mathbf{x}). \quad (4)$$

The discrete form of the Patterson function is written as:

$$P(\mathbf{u}) = \frac{1}{V} \sum_m |F_{\mathbf{H}_m}|^2 \exp(-2\pi i \mathbf{H}_m \cdot \mathbf{u}). \quad (5)$$

A Patterson map can therefore be constructed from a sufficient set of diffraction intensities measured for a set of reciprocal lattice vectors,  $\mathbf{H}$ , in a single-crystal X-ray diffraction experiment.

The physical meaning of a Patterson map in relation to the original structure is easiest to interpret when atomic contributions to the density function are considered point-like. Hence, for the time, assume electron density is large at the exact position  $\mathbf{x}_j$  of each atom in the crystal and 0 at non-atomic site coordinates. Then, it is clear from (4) that the Patterson function at  $\mathbf{u}$  will only be substantial when it is a difference of two atomic position vectors, namely  $\mathbf{u} = \mathbf{x}_j - \mathbf{x}_i$ . Thus, for every possible combination of interatomic differences we observe a Patterson peak, with intensity proportionally to the product of the atomic scattering factors of the participant atoms. Consequently, a  $N$ -atom structure, without consideration of overlap, yields a Patterson map with  $N(N-1)$  peaks and a highly pronounced central peak. In other words, a Patterson map is the superposition of many copies of the original electron density map.

Solution by Patterson methods requires a technique for deconvolution of the density function from the Pat-

erson map. In traditional techniques [2], the Patterson function,  $P(\mathbf{u})$ , is displaced by two vectors,  $\mathbf{x}_i$  and  $\mathbf{x}_k$ . Then, the two shifted Patterson maps are superimposed,

$$P_{ik}(\mathbf{u}) = P(\mathbf{u} - \mathbf{x}_i) + P(\mathbf{u} - \mathbf{x}_k) \quad (6)$$

Ideally, the difference of the two vectors chosen to derive  $P_{ik}(\mathbf{u})$  represents an interatomic difference vector. In such a case, the structural image in  $P_{ik}(\mathbf{u})$  is enhanced. This procedure is repeated until sufficient information is available to construct the original density function. A Patterson map is particularly useful in the case of heavy atom structures since the atomic scattering factor of an atom is proportional to the atomic number of its composite element. Hence, when a heavy atom is present at position  $\mathbf{x}_k$ , all peaks at  $\mathbf{u} = \mathbf{x}_k - \mathbf{x}_j$  are pronounced in the map. Naturally, from such a Patterson map, it is much easier to deconvolute the original density function.

A function for the selection of appropriate displacement vectors, used for the solution of Patterson maps, is presented in [11] and [9]. The generalized symmetry minimum function,  $SMF$ , can be written as:

$$SMF(\mathbf{u}) = \sum_i \min_s P(R_s \mathbf{x}_i + \nu_s - \mathbf{u}), \quad (7)$$

where  $i$  is the set of sampled points,  $\mathbf{x}_i$ , in the Patterson map,  $R$  represents a symmetry rotation operator,  $\nu$  a translational operator, and  $s$  the set of symmetry relations present. This form of the  $SMF$  is applicable to the full space of the Patterson map. The positions of atoms are chosen from peaks in  $SMF(\mathbf{u})$ .  $SMF$  is still used in contemporary algorithms for displacement vector selection, and has yielded structural solutions for molecules containing up to 6,000 non-hydrogen atoms in the asymmetric unit [3]. The success, however, is still largely restricted to structures containing heavy atoms.

In terms of optimization, solution by Patterson methods is classically posed in terms of a search over a set of interatomic distance vectors calculated from a Patterson map. In [8] this was done for the solution of myoglobin, based on the 'minimum average' function:

$$\max Z = \sum_{m \in M} P_m / \sum_{m \in M} W_m \quad (8)$$

$$s.t. P_m = P(\mathbf{w}_m), \forall m \in M \quad (9)$$

$$W_m = W(\mathbf{w}_m), \forall m \in M \quad (10)$$

$$\mathbf{w} \in \Omega, \quad (11)$$

where  $M$  is a subset of all available ratios having the lowest values of  $P_m/W_m$ ,  $P_m$  and  $W_m$  are the values of the Patterson and test functions, and  $\mathbf{w}$  is a vector chosen from  $\Omega$ , the set of all possible orientations in the Patterson map. Traditionally, this problem is solved in a stochastic manner: a large set of trials is constructed with randomly generated orientations for  $\mathbf{w}$ . The merit function is then calculated for each trial, and the best solution is selected subject to further solution filtering.

### MAD

Multiple anomalous diffraction, MAD, directly solves the phase problem by means vector analysis of diffraction amplitudes sampled for at least three wavelengths. The list of available elements, which produce anomalous differences is limited by the set of experimentally available wavelengths. With the exception of sulfur, none of the elements commonly found in biological macromolecules yield sufficient anomalous scattering. Hence, some sort of chemical substitution is often required. The calculation of phases is straight forward and simply requires knowledge of the position of the anomalous scatterers in the unit cell.

Since most elements which anomalously scatter are heavier, Patterson methods are often sufficient to locate the substituted atoms. Determining the candidates for substitution and calculation of the heavy atom structure is, however, at times difficult when a large number of substitution sites exist. In [13], a figure of merit is proposed for automated selection of the correct trial heavy atom structures. This figure of merit is composed of four individual tests: Patterson function, difference Fourier, phasing figure of merit, and solvent location.

### Direct Methods

Direct methods refers to a class of techniques which rely on probability theory to determine phases in reciprocal space using data from a single-crystal X-ray diffraction experiment. These methods, revolutionary at the time they were introduced, pushed the limit of solvable structures substantially. Unfortunately, the accuracy of direct methods fall as the size of the asym-

metric unit increases. In addition, these methods typically rely on near atomic data resolution. Finally, since all direct methods operate primarily in reciprocal space, a Fourier transform of the phases derived is required to construct the electron density function. From this density function, atomic positions are then selected.

Most direct methods rely on the use of origin-independent combinations of phases, most prominent of which are the triplet phase relations:

$$\Phi = \phi_{\mathbf{H}} + \phi_{\mathbf{K}} + \phi_{-\mathbf{H}-\mathbf{K}}. \quad (12)$$

In the sequel, minimal principle methods for phasing are first discussed. These techniques rely on solution of a NLP, with triplets defining the constraint set. Then, focus is placed on the class of maximum entropy methods for phasing, with particular emphasis on maximum determinant methods.

### The Minimal Principle

The minimal principle methods are certainly some of the most well-known phasing techniques. Like all direct methods, they represent a phasing technique, which is applied in the reciprocal space of a crystal. Specifically, a phase solution is determined from the minimal principle by minimizing a merit function in the framework of a nonconvex NLP. The optimization program, first proposed by [5], is as follows:

$$\min R_{\min} = \sum_t A_t [\cos(\Phi_t) - \omega_t]^2 / \left( \sum_t A_t \right) \quad (13)$$

$$s.t. \phi_{\mathbf{H}_t} + \phi_{\mathbf{K}_t} + \phi_{-\mathbf{H}_t-\mathbf{K}_t} = \Phi_t, \quad \forall t \in T, \quad (14)$$

$$\phi_{\mathbf{H}_m} \in [0, 2\pi], \quad \forall m \in M, \quad (15)$$

where  $M$  denotes the total number of reflections from an X-ray diffraction experiment after all the symmetry equivalent reflections have been removed,  $T$  denotes the set of triplet phase invariants,  $A_t = 2N^{-1/2}|E_{\mathbf{H}}||E_{\mathbf{K}}||E_{-\mathbf{H}-\mathbf{K}}|$ ,  $\omega_t = I_1(A_t)/I_0(A_t)$ ,  $|E|$  is a normalized structure factor amplitude,  $N$  is the number of atoms in the unit cell,  $I_n$  is a modified Bessel function of order  $n$ , and  $\mathbf{H}$  and  $\mathbf{K}$  denote Miller indices.

In all practical cases, it has been demonstrated [7] that a set of phases which minimizes  $R_{\min}$  and satisfies atomicity constraints represent the true phase solution for a structure.

Most contemporary phasing algorithms, which make use of the minimal principle, rely on a combination of local search and stochastic optimization techniques. One commonly used direct methods package for phasing is known as SnB [16].

For centrosymmetric structures, an integer programming model of the minimal principle has been derived by [12]:

$$\min R_{\min} = \sum_t A_t [4\beta_t + 1 - 2\omega_t + \omega_t^2] / \left( \sum_t A_t \right) \quad (16)$$

$$s.t. \phi_{\mathbf{H}_t} + \phi_{\mathbf{K}_t} + \phi_{-\mathbf{H}_t - \mathbf{K}_t} = 2\alpha_t + \beta_t, \quad \forall t \in T, \quad (17)$$

$$\phi_{\mathbf{H}_m} + \phi_{\mathbf{H}_m \mathbf{R}_s} = 1, \quad \forall m \in M, \forall s \in S_m, \quad (18)$$

$$\phi_{\mathbf{H}_m} = \phi_{\mathbf{H}_m \mathbf{R}_u}, \quad \forall m \in M, \forall u \in U_m, \quad (19)$$

$$\alpha_t, \beta_t \in \{0, 1\}, \quad \forall t \in T, \quad (20)$$

$$\phi_{\mathbf{H}_m} \in \{0, 1\}, \quad \forall m \in M, \quad (21)$$

where  $M$ , as before, denotes the total number of reflections from an X-ray diffraction experiment after all the symmetry equivalent reflections have been removed,  $S_m$  is the set of shifted phases related to  $\mathbf{H}_m$  by rotational symmetry  $\mathbf{R}_s$ , and  $U_m$  is the set of unshifted phases related to  $\mathbf{H}_m$  by rotational symmetry  $\mathbf{R}_u$ . Solution of this model is nontrivial. In addition, it has been shown [17] that a global solution to the minimal principle model can in fact represent a false minimum, which does not correspond to a true phase solution. False minima result when a true structural solution contains triplet invariants, which sum to an odd multiple of  $\pi$ , termed ‘odd triplets’. Such odd triplets are typically absent from strong  $A$ -value triplet sets. This has motivated the formulation of a modified integer minimal principle, which solves over a subset,  $T'$  of the full triplet set  $T$ . The global minimum of this model can easily be obtained by simply finding a phase solution which satisfies the constraint set when all invariants are set to zero:

$$\phi_{\mathbf{H}_t} + \phi_{\mathbf{K}_t} + \phi_{-\mathbf{H}_t - \mathbf{K}_t} = 0, \quad \forall t \in T' \quad (22)$$

$$\phi_{\mathbf{H}_m} + \phi_{\mathbf{H}_m \mathbf{R}_s} = 1, \quad \forall m \in M, \forall s \in S_m \quad (23)$$

$$\phi_{\mathbf{H}_m} = \phi_{\mathbf{H}_m \mathbf{R}_u}, \quad \forall m \in M, \forall u \in U_m \quad (24)$$

$$\phi \in \{0, 1\}. \quad (25)$$

This model can be solved in polynomial time, and has been shown to greatly enhance computational efficiency for a variety of structures when compared to a standard crystallography package [12].

### Maximum Determinant

One of the first papers, which would lay a foundation for maximum entropy methods for phasing was published in 1950. By constructing the Hermitian forms of the structure factor function in terms of electron density and noting the positivity of electron density, [6] showed that a system of determinants containing certain  $F_{\mathbf{H}}$ 's must be non-negative. This yielded the concept of a Karle–Hauptman matrix, abbreviated as KH matrix.

Later, [14] proposed a method by which KH matrices could be utilized for phasing of crystal structures. First, consider the Sayre equation:

$$\langle E_{\mathbf{K}} E_{\mathbf{H} - \mathbf{K}} \rangle^{\mathbf{K}} = \theta E_{\mathbf{H}}, \quad (26)$$

where  $E$  is a normalized structure factor at a particular Miller index,  $\theta$  is a normalization constant, and the brackets around the left-hand side indicate an average over  $\mathbf{K}$ . If substitutions are made,  $\mathbf{H} = \mathbf{H}_i - \mathbf{H}_j$  and  $\mathbf{K} = \mathbf{L} + \mathbf{H}_j$ , in terms of the rows  $i \in r$  and columns  $j \in c$  of a KH matrix,  $\mathbf{L}$  a random vector, (26) reduces to:

$$\langle E_i E_j \rangle^* = \langle E_{\mathbf{L} + \mathbf{H}_i} E_{-\mathbf{L} - \mathbf{H}_j} \rangle^{\mathbf{L}} = \theta E_{\mathbf{H}_i - \mathbf{H}_j} \quad i, \forall j \in c. \quad (27)$$

The values of  $E_{\mathbf{H}_i - \mathbf{H}_j}$ , in the corresponding KH matrix, represent correlation coefficients, and consequently form a covariance matrix. If the following assumptions are then taken: a large number of atoms in the unit cell, the positions of which are mutually independent, then it is possible to derive a conditional joint probability law of the basic form:

$$p(E_1, \dots, E_m) = C \exp \left( N \frac{\delta_{m+1}}{D_m} \right), \quad (28)$$

where  $D_m$  is the determinant of a KH matrix of order  $m$ , denoted by  $\mathbf{A}_m$ , and  $\delta_{m+1}$  is the determinant of  $\mathbf{A}_m$

with one additional row and column appended. In this situation, the structure factors which compose the  $\mathbf{A}_m$  matrix are known, the phases of the appended structure factors are varied. Ultimately, (28), implies that the most probable value for the phases of the structure factors added to  $\mathbf{A}_m$  will maximize the determinant  $\delta_{m+1}$ . A generalized rule was also suggested by Tsoucaris [14]: given a KH matrix which contains structure factors with unknown phases, the most probably set of phases will maximize the determinant of the KH matrix. In terms of an optimization framework:

$$\max Z = \det \mathbf{A} \quad (29)$$

$$s.t. A > 0 \quad (30)$$

$$A = A(\phi) \quad (31)$$

$$\phi_{\mathbf{H}_m} \in \{0, 2\pi\}, \quad \forall m \in M. \quad (32)$$

CRUNCH is a well known crystallography package [4] in which the phasing is done primarily based on solution of the maximum determinant formulation. The determinant is maximized using a local search technique in combination with an expression of the derivative of the determinant of  $\mathbf{A}$  in terms of element  $i, j$ :

$$\frac{\delta \det \mathbf{A}}{\delta \alpha_{ij}} = 2|a_{ij}||b_{ij}| \sin(\beta_{ij} - \alpha_{ij}) \det \mathbf{A}, \quad (33)$$

where  $\alpha$  and  $\beta$  are phases of elements  $a_{ij}$  and  $b_{ij}$  respectively and  $b_{ij}$  is related to  $a_{ij}$  through the inverse of  $\mathbf{A}$ . In addition, programs such as CRUNCH will often maximize the determinant for a large number of small matrices until enough phase information is available to compose a full density function. Each of these matrices will typically contain a small amount of overlap to fix origin specification. It has also been shown by [15], that the eigenvalues of KH matrices can be used to assess phase set quality and for phase refinement.

### Entropy Maximization

The more general technique of entropy maximization is discussed in detail by [1]. Essentially, the optimization model described involves both entropy and physical considerations. In general, the solution is done by maximizing entropy defined as:

$$S(q) = - \int_V q(\mathbf{x}) \log [ q(\mathbf{x}) / m(\mathbf{x}) ] \mathbf{d}^3 \mathbf{x}, \quad (34)$$

where  $q$  is the probability density of atoms and  $m$  is a 'prior prejudice', typically taken as a uniform distribution. It then remains to write  $q$  in terms of the normalized structure factors  $U$  of the crystallography problem. In the space group P1, this is achieved as:

$$q(\mathbf{x}) = \frac{1}{V} \sum_M U_{\mathbf{H}_m} \exp(-2\pi i \mathbf{H}_m \cdot \mathbf{x}) \quad (35)$$

$$U_{\mathbf{H}} = \int_V q(\mathbf{x}) \exp(2\pi i \mathbf{H} \cdot \mathbf{x}) \mathbf{d}^3 \mathbf{x}. \quad (36)$$

Solution of the maximum entropy formulation will typically allow phasing of structures beyond the size limitations of other direct methods.

### Conclusion

Phase information is not directly measurable from a traditional X-ray diffraction experiment. Numerous techniques have been developed for phasing of crystal structures, most well-known are the Patterson, direct, and MAD methods. Typically Patterson methods rely on the presence of one or more heavy atoms in the structure. MAD methods require the presence of a measurable anomalous difference. Direct methods phase in reciprocal space and are typically subject to size and resolution limits. In the field of direct methods, much work with regard to optimization has been done. Still, despite the age of the crystallography field, many problems are still open in the area of robust and reliable determination of crystal structures.

### Problem Description

The complexity of water-related problems is escalating as the uses of water and the (environmental and others) objectives to fulfill continue to expand. Most of the easier structural solutions for greater water resources utilization have already been implemented and new projects, including interbasin transfers, find some opposition in the Society. In these circumstances the need for a rational water resources planning is becoming stronger than ever as a result of the impact of the changes in the general climatic conditions and the increasing demand of water resources using.

To ensure the successful catchment management of complex water resource systems (interaction of reservoirs and channels in the surface of rivers as well as aquifers and other groundwater resources), it is essential that the most reliable models and supporting tools can be used. In the field of *conjunctive use of water resource systems*, the reality is complex and, so, the models for planning are large (in terms of the number of decision variables) and stochastic (there are parameters such as the hydrological exogenous inflow and demand for different uses whose values cannot be controlled by the decision maker and are uncertain). The property of uncertainty makes the water resources planning difficult to tackle, but yet the solution is critical for a proper utilization of the (scarce) water resources.

The *multi-period optimization modeling framework* should aim to confer the ability to solve vital problems to water resources planning agencies. The problem consists of *water resources planning under uncertainty on hydrological exogenous inflow and demand* for a set of inter-related (and transboundary) basin systems along a given planning horizon. It should have a direct bearing on the assignment of water resources to the requirements of the different uses, by operating significant demand savings and *minimizing the degradation in qual-*

ity of both water environment and natural environment associated with its use. The main elements of the problem are the water resource sources (such as the *surface and groundwater systems*), the water demand centers to satisfy current and potential future needs (for hydropower generation, irrigation, industrial, domestic, recreative and ecological purposes among others) and the infrastructure of reservoirs and *water transportation systems* including artificial, natural and would-to-be basin and inter-basin channels.

A water resource system is included by a surface subsystem and a groundwater subsystem, both interconnected. The system can be viewed as a physical network whose nodes and arcs are as follows:

- 1) *Nodes with water storage capacity* (i. e., reservoirs including lakes), where evaporation and losses by infiltration to groundwater should be considered. This type of nodes can have associated hydropower generation units that make use of water but it does not reduced it practically.
- 2) *Physical junction nodes*. They are points in the river where the waterflow has some modification such as river confluences, hydrological inflows, diversions, etc.
- 3) *Demand nodes*. Other demand uses are irrigation, urban, industrial, recreation and for ecological purposes among others. They can be represented by consumptive and (partially) nonconsumptive water demand nodes.
- 4) *Return nodes*. They are nodes (points in the river) where water is (partially) returned from some demand nodes.
- 5) *On-the-river hydropower nodes*. They are nodes without water storage capacity, so, they can only make use of the waterflow for satisfying hydropower generation needs, but without regulating it, nor reducing it either.
- 6) *Surface water pumping facilities*. These nodes allow water pumping to upstream reservoirs.
- 7) *Natural stream arcs*. Different types of arcs can be modeled as network arcs, such as natural channels (i. e., river reaches in multireservoir systems), canals, ditches, interbasin transfers, etc.
- 8) *Aquifers*. They are nodes from the groundwater system with water storage capacity. Conjunctive use of surface water and groundwater is of great importance in many basins, given the scarcity of

water resources and the competition between conflicting uses.

- 9) *Controlled recharge facilities*. These nodes allow direct injection of surface water into the aquifers.
- 10) *Groundwater pumping facilities*. These nodes allow direct pumping of groundwater to the natural stream arcs.

The main purpose of optimization in the field consists of determining the water resources availability and demand balancing for each period of the planning horizon under study. In case of no balancing feasible solution, the approach should provide a water resources planning to minimize the weighted unbalancing deviation. The water flows through interbasin transfer channels along a given time planning horizon. Technically, the problem is converted to a *time replicated network*. Novel modeling schemes for *multistage linking constraints* to force upper bounds on the water demand cumulated deficit for given consecutive time periods should be considered, see [8]. This type of constraints force water management policies to avoid disastrous consequences of *drought out events*. For the same purpose a constraint type can be modeled to preserve 'earmarked' reserve stored water in (directly and nondirectly) upstream reservoirs along the river to satisfy potential future needs in selected demand centers at given time periods.

The decision maker should decide about the water volume to be stored at each reservoir and controlled aquifer and, then, the water volume to be released, such that physical structural constraints are satisfied and water utilization policies are prioritized and optimized. These policies are related to environmental objectives, hydroelectrical production, irrigation, urban and industrial demands and other uses, reservoirs' water levels, aquifers' artificial recharge and pumping policies, reserve stored water at reservoirs to satisfy potential future needs at selected demand centers during drought out events, etc. So, the objective function to minimize is the expected value of a composite function included by the penalization of the deficits on the satisfaction target levels, the weights of water flow through natural stream and surface pumping arcs and the weights of water pumping from aquifers along the planning horizon.

As an important byproduct the system should determine the risk of significant water deficiencies and to

mitigate the consequences of extreme events as droughts and floods. The assessment of the impact on water balancing due to water channelling infrastructure modifications, as well as modifications on water resource using policies for some demand types are some other useful results. See some approaches in [1,2,7,9] and [12] - [13] among others.

Other results from using optimization schemes for water resources planning are as follows.

- Assessing environment protection by enforcing lower bounds on the flow through natural stream arcs and water quality.
- Assessing the degree of systems' reliability.
- Determining the risk of significant water deficiencies even over very extended areas.
- Qualifying the water demand according to the requirements of the different uses, and assessing the impact on each other use.
- Advancing and quantifying the potential repercussions on the Environment and the Economy of certain water utilization policies at given time periods under a variety of potential scenarios.
- Determining the structural works and management changes that should be performed to mitigate disastrous consequences of drought out and flood events.
- Assessing the *rational use of groundwater* by helping to decide when and how much aquifer pumping should be performed (and when and how much aquifer artificial recharge should be commanded) to preserve their structural constitution, given the scenario tree that is foreseen (see below), and the ranking and weighting of the demand uses to consider.
- Assessing the need and timing of inter-basin transfers by considering the potential scenarios to occur and the demand uses in the different river basin areas. Similar impact for transboundary rivers.

### Stochastic Approach

The optimization problem described above can be expressed in the following model structuring,

$$\begin{cases} \min_v & c^T v \\ \text{s.t.} & Av = p \\ & v \geq 0, \end{cases} \quad (1)$$

where  $c$  is the vector of the objective function coefficients,  $A$  is the  $m \times n$  constraint matrix,  $p$  is the right-

hand side  $m$ -vector and  $v$  is the  $n$ -vector of the decision variables to optimise. It must be extended in order to deal properly with uncertainty in the values of some parameters, say,  $c$  and  $p$  in this case, hydrological exogenous inflow and demand in various uses. The class of optimization problems with uncertainty in the parameters is among the most intractable class in numerical computation.

In any case one needs to consider two additional features. In the first place, one must model the availability of hydrological information over time, and state what sort of water resource using decisions can be made at each of the various stages. Secondly, to compute an optimal water resources solution in the stochastic area any proposed solution should also be compared with other candidate solutions as it is done in the deterministic field. But, in the stochastic setting, the criteria by which this comparison can be performed are much less clear. Thus, one needs an approach to model the uncertainty in the problem data. The traditional approach is to make probabilistic distribution assumptions, estimate the parameters from historical data and, then, develop an stochastic model to take the uncertainty into account. Such an approach may not be appropriate if only limited information is available. In many such cases one may employ a technique so-called *scenario analysis*, where the uncertainty is modeled via a set of scenarios [6].

Let  $S$  denote the set of scenarios to consider, and  $w^s$  the likelihood that the decision maker assigns to scenario  $s$  for  $s \in S$ . So, in contrast to traditional mathematical programming approaches, state-of-the-art schemes model the uncertainty by using scenarios to characterize the uncertain parameters. A scenario tree is generated and, through the use of *full recourse* techniques, an implementable solution is obtained for the first time stage by considering all scenarios but without subordinating to any of them; additionally, a coordinated solution for each scenario group at the other time stages should also be provided. While this approach is used, the so-called deterministic equivalent model (DEM) has a huge number of constraints and variables. So, very often the problem structure (network-like and others) is lost as a consequence of the need to impose additional conditions on the value of the variables to ensure the coherence of the water resource using decisions taken at different time stages.

The minimization of the expected value of the composite function included by the penalization of the deficit on the satisfaction target levels can be expressed

$$\begin{cases} \min_v & \sum_{s \in S} w^s c^s \top v \\ \text{s.t.} & Av = p^s, \quad \forall s \in S, \\ & v \geq 0. \end{cases} \quad (2)$$

Note that (2) gives an implementable policy based on the so-called *simple recourse* scheme. (See that the whole vector of decision variables is anticipated at stage 1).

### Nonanticipative Water Resources Policies

Model (2) does anticipate decisions in  $v$  that for multistage environments may not be needed at stage  $r = 1$ . Very frequently the decisions for stage  $r = 1$  are the decisions to be made since at stage  $r = 2$  one may realize that some of the data has been changed, some scenarios vanish, etc. In this case, the model will be usually reoptimized in a rolling planning horizon mode. When only spot decisions (i. e., decisions for the first stage) are to be made, the information about future uncertainty is taken into account for a better spot decision making. This type of scheme is termed *full recourse*.

Let  $R$  denote the set of stages and  $v_r^s$  the vector of the variables related to stage  $r$  under scenario  $s$  for  $r \in R$  and  $s \in S$ , and  $v^s$  is the set of vectors  $v_r^s \forall r \in R$ . The so-called *nonanticipative principle* is stated as follows, see [15]: If two different scenarios, say,  $s$  and  $s'$  are identical up to stage  $r$  on the basis of the information available about them up to that stage, then the values of the  $v$ -variables must be identical up to stage  $r$ . This principle guarantees that the solution obtained from the model is not dependent at stage  $r$  on the information that is not yet available. To illustrate this concept, consider a so-called *scenario tree* where each node represents a point in time where a decision on water resource using can be made. Once a decision is being made several contingencies can happen, and information related to these contingencies is available at the beginning of the next stage. This information structure is visualized as a tree, where each root-to-leave path represents one specific scenario and corresponds to one realization of the uncertain parameters.

In order to introduce the implications of this principle, see [8], in water resources planning optimization, let us define a set of scenario groups, say,  $G_r$  for each stage  $r$ , such that all scenarios having the same realizations of the uncertainty up to stage  $r$  belong to the same scenario group, say,  $g$  for  $g \in G_r$ . Let  $S_{g,r}$  denote the set of scenarios that belong to group  $g$  at stage  $r$  for  $S_{g,r} \subseteq S$ . Let a node in the scenario tree be represented by the pair, say,  $(k, r)$  for  $k \in G_r, r \in R$ , such that the scenario tree is defined by the set of nodes  $\cup_k \in G_r, r \in R(k, r)$  and the set of directed arcs  $E$ , where  $(k, \ell) \in E$  if and only if  $S_\ell, r+1 \subseteq S_{k,r}$  for  $k \in G_r$  and  $\ell \in G_{r+1}$ . Let  $G_r^k \equiv \{\ell \in G_{r+1}\}(k, \ell) \in E$ . Finally, let  $N$  denote the set of solutions that satisfy the so-called *nonanticipativity constraints*. That is,

$$v \in N \equiv \left\{ v^s : \begin{array}{l} v_r^s = v_r^{s'}, \\ \forall s, s' \in S_{g,r}, \\ g \in G_r, r \in R \end{array} \right\}. \quad (3)$$

So, the DEM of the so-called *full recourse* version of model (1) can be expressed

$$\begin{cases} \min_v & \sum_{s \in S} w^s c^s \top v^s \\ \text{s.t.} & Av^s = p^s, \quad \forall s \in S, \\ & v \in N, \\ & v^s \geq 0, \quad \forall s \in S. \end{cases} \quad (4)$$

Model (4) has a nice structure that we may exploit. Two approaches can be used to represent the nonanticipativity constraints (3). One approach is based on a *compact representation*, where (3) is used to eliminate variables in (4) as well as for reducing model size, so that there is a single variable for each element at each scenario group of each stage, but any special structure of the constraints in (1) is destroyed. In this case let the variables vector  $v = (x, y, z)$  have the following structure:  $x_{g,r}$ , vector of variables with nonzero coefficients in the constraints related to stage  $r$  alone for  $g \in G_r, r \in R$ ;  $y_{g,r}$ , vector of variables with nonzero elements in the constraints related to the stages  $r$  and  $r+1$  (for the water resources planning problem this type of variables represent the stored water in the reservoirs and aquifers at the last time period of stage  $r$ ); and  $z_{g,r}$ , vector of variables with nonzero elements in the constraints related to stage  $r$  as well as in the constraints related to sets of stages to be defined below.

Introduce the following additional notation.  $U$  is the set of  $z$ -related constraint blocks through time stages, so-called *multistage linking constraints*,  $R_u$  is the set of time stages related to constraint block  $u$  for  $u \in U$ ,  $\underline{r}_u$  and  $\bar{r}_u$  are the smallest and largest elements from  $R_u$ , respectively, and  $N_{g,u}$  is the set of nodes in the directed path through the set of time stages (i. e., set  $R_u$ ) whose ending node is node  $(g, \bar{r}_u)$  and the unique origin node is, say,  $(i, \underline{r}_u)$ . So, the pair  $(k, r)$  index for variable  $z_{k,r}$  is such that  $(k, r) \in N_{g,u}$  for ending node  $(g, \bar{r}_u)$  and constraint block  $u$ . This type of constraint block can be represented as follows:

$$Z_{g,u} \begin{cases} \sum_{(k,\tau) \in N_{g,u}} D_{u,\tau} z_{k,\tau} = d_{g,u} \\ \forall g \in G_{\bar{r}_u}, \end{cases} \quad u \in U, \tag{5}$$

where  $D_{u,\tau}$  is the matrix for constraint block  $u$  related to the  $z$ -variables from stage  $\tau$ , and  $d_{g,u}$  is the right-hand side of constraint block  $u$  for scenario group  $g$  from stage  $\bar{r}_u$ ,  $u \in U$ . (See that constraint block  $u$  has  $|G_{\bar{r}_u}|$  versions.) For the water resources planning this type of constraints prevent that the cumulated water demand deficit in given nodes through consecutive time stages can violate given upper bounds under given scenario groups.

The compact representation of model (4) can be expressed as follows:

$$\begin{cases} \min_{x,y} & \sum_{r \in R} \sum_{g \in G_r} w_{g,r} \\ \text{s.t.} & \cdot (a_{g,r}^\top x_{g,r} + b_{g,r}^\top y_{g,r} + c_{g,r}^\top z_{g,r}) \\ & 0 \leq x_{g,r}, y_{g,r}, z_{g,r} \in X_{g,r} \\ & \forall g \in G_r, \quad r \in R, \\ & z_{g,r} \in Z_{g,u}, \quad \forall g \in G_{\bar{r}_u}, \quad u \in U, \end{cases} \tag{6}$$

such that

$$X_{g,r} \begin{cases} A_r x_{g,r} + B'_r y_{\ell,r-1} + B_r y_{g,r} \\ \quad + C_{g,r} z_{g,r} = p_{g,r} \\ \forall g \in G_r, \quad r \in R, \end{cases} \tag{7}$$

where  $w_{g,r}$  gives the weight for scenario group  $g$  at stage  $r$ , such that  $a_{g,r}$ ,  $b_{g,r}$  and  $c_{g,r}$  are the  $x$ -,  $y$ - and  $z$ -variables related objective function coefficients respectively, for the pair  $(g, r)$ ,  $A_r$ ,  $B_r$  and  $C_r$  are the appropriate constraint matrices and  $p_{g,r}$  is the right-hand side,

all with the conformable dimensions, and  $\ell: \{g \in G_{r-1} \text{ for } g \in G_r, r \in R\}$ , and

$$w_{g,r} = \sum_{s \in S_{g,r}} w^s. \tag{8}$$

One of the main inconveniences of the compact representation (5)–(7) is the inherent difficulty for its decomposition in smaller models. Given the large scale instances of the model, easy decomposition is a key for success. It can be obtained from the so-called *splitting variable representation*. It requires to produce *sibles* of the  $y$ - and  $z$ -variables.

For this purpose let  $N^{g,r}$  denote the set of pairs  $(k, \tau)$  such that  $k \in G_\tau$ ,  $\tau \in R$ ,  $\tau \geq r$  and  $\exists u \in \frac{U}{r} = \bar{r}_u$  for  $(g, r) \in N_{k,u}$ . That is,  $(g, r)$  and  $(k, \tau)$  for  $g \in G_r$  and  $k \in G_\tau$  are any two nodes in the scenario tree for  $r, \tau \in R$ , such that there is a constraint block  $u$  for  $u \in U$  where  $\tau \equiv \bar{r}_u$  and there is a path from some node, say,  $(i, \underline{r}_u)$  to node  $(k, \tau)$  through node  $(g, r)$ .

In order to introduce the new representation, let us rename the  $y$ - and  $z$ -variables such that  $y_{g,r}$  and  $z_{g,r}$  will be replaced by  $y_{g,r}^0$  and  $z_{g,r}^{g,r}$ , respectively, and add the new variables  $y_{\ell,r-1}^g$ , where  $\ell: g \in G_{r-1}$ , and  $z^{k,\tau,g,r}$ ,  $\forall (k, \tau) \in N^{g,r}$ ,  $g \in G_r$ ,  $r \in R$ . So, the splitting variable representation is as follows:

$$\begin{cases} \min_{x,y,z} & \sum_{r \in R} \sum_{g \in G_r} w_{g,r} \\ & \cdot (a_{g,r}^\top x_{g,r} + b_{g,r}^\top y_{g,r}^0 + c_{g,r}^\top z_{g,r}^{g,r}) \\ \text{s.t.} & X_{g,r}, \\ & Z_{g,u}, \\ & Y_{g,r}^\ell, \\ & Z_{g,r}^{k,\tau}, \\ & x, y, z \geq 0, \end{cases} \tag{9}$$

where

$$X_{g,r} : \begin{cases} A_r x_{g,r} + B'_r y_{\ell,r-1}^g + B_r y_{g,r}^0 \\ \quad + C_r z_{g,r}^{g,r} = p_{g,r}, \\ \forall g \in G_r, r \in R, \\ \ell : g \in G_{r-1}^{\ell} \end{cases}, \tag{10}$$

$$Z_{g,u} : \begin{cases} \sum_{(k,\tau) \in N_{g,u}} D_{u,\tau} z_{k,\tau}^{g,\bar{r}_u} = d_{g,u}, \\ \forall g \in G_{\bar{r}_u}, \quad u \in U, \end{cases}, \tag{11}$$

$$Y_{g,r}^\ell : \begin{cases} y_{g,r}^\ell - y_{g,r}^{\ell+1} = 0, \\ \forall \ell \in \{0\} \cup G_r^g, \quad g \in G_r, \quad r \in R \end{cases}, \tag{12}$$

$$z_{g,r}^{k,\tau} : \left\{ \begin{array}{l} z_{g,r}^{g,r} - z_{g,r}^{k,\tau} = 0, \\ \forall (k, \tau) \in N^{g,r}, g \in G_r, r \in R \end{array} \right\}. \quad (13)$$

*Remark 1* The two constraint blocks (12) and (13) in (9) are the expressions for the nonanticipativity constraints (3).

Different types of decomposition approaches can be used for solving model (8); namely, augmented Lagrangian and Benders [3] decomposition schemes, both being very amenable for using parallel computing approaches, see [4,5,10,11,14,16], and [17] among others.

## Conclusions

Full recourse based mathematical programming schemes have been used as the kernels of decision support systems for water resource planning under water exogenous inflow and demand uncertainty, where the uncertainty is treated via scenario analysis. This methodology results in a huge deterministic equivalent model (with hundreds of thousands of constraints and variables), where care should be taken to preserve the constraint structure of the original problem. Two very useful constraint types are considered for the demand centers, namely, upper bounds on the deficit of reserve stored water in (directly and nondirectly) upstream reservoirs to satisfy potential future needs, and upper bounds on the consecutive time periods cumulated water demand deficit (so-called *multistage linking constraints*).

A splitting variable scheme for the reservoirs and controlled aquifers stored water modeling representation can be used, as well as decomposition frameworks based on Benders and augmented Lagrangian approaches. On the other hand, given the separability of the subproblems attached to the nodes of the scenario tree as well as the reduced overhead required, one can be motivated to develop parallel computing versions of the decomposition approaches on a distributed environment. It will significantly help to solve large scale water resource planning problems under uncertainty in water exogenous inflow and demand parameters.

### Abstract

Finding the median (or minisum) point in continuous space relative to a set of weighted demand points (customers, markets, existing facilities) is a classical problem in location theory. We examine an extension of the problem where the existing facilities are modeled as fixed areas, and the median point is determined relative to the *closest* distances to these areas. Two popular distance metrics are considered: the Euclidean and rectangular norms. These demonstrate the differences between the classes of round (or smooth) norms and block norms. Mathematical properties of the new models are used to adapt existing solution methods to solve them.

### Keywords

Euclidean norm; Rectangular norm; Closest distance; Median

### Introduction

In continuous location theory, facilities to be optimally located are generally represented by points, and the customers or markets that they serve are also geometrical points in space. The objective is to find the optimal site of one or more facilities with respect to a specified performance measure such as the sum of transportation costs. This is one of the oldest formal optimization problems in mathematics and has a long and interesting history ([15] Section 1.3, [7,9,21]). Many variants of the problem exist. A very basic version of the location problem is to minimize:

$$W(x) = \sum_{i=1}^n w_i K(x - a_i), \tag{1}$$

where  $x = (x_1, x_2)$  is the unknown facility location in  $\mathbb{R}^2$ ,  $w_i$  is a positive weight representing transportation cost per unit distance for customer  $i$ , and  $K(x - a_i)$  is a norm measuring distance from the facility location  $x$  to the fixed location  $a_i = (a_{i1}, a_{i2})$  of demand point  $i$ . The most common distance measure is Euclidean or straight-line distance and in this case, the most common solution procedure is some form of non-linear optimization such as gradient descent.

A simple yet elegant solution procedure for the minimum problem (1) with Euclidean ( $\ell_2$ ) distances was proposed by Weiszfeld in 1937 [20]. Setting the first-order partial derivatives of  $W(x)$  to zero, we obtain the following system of equations for a stationary point:

$$\sum_{i=1}^n \frac{w_i(x_t - a_{it})}{\ell_2(x - a_i)} = 0, \quad t = 1, 2. \tag{2}$$

Since the objective function is convex, the above equations are both necessary and sufficient for any differentiable point to be a global solution of (1). However, since the system of equations cannot be solved explicitly, Weiszfeld developed the following one-point iterative scheme by isolating the coordinates on one side:

$$x_t^{q+1} = \frac{\sum_i w_i a_{it} / \ell_2(x^q - a_i)}{\sum_i w_i / \ell_2(x^q - a_i)}, \quad t = 1, 2, \tag{3}$$

where  $q = 0, 1, 2, \dots$ , denotes the iteration number.

The Weiszfeld procedure is equivalent to a gradient descent with predetermined step size. In a semi-

nal paper by Kuhn [14], global convergence of the procedure was proven provided that no iterate coincides with a fixed point  $a_i$ , where the iteration functions are undefined. The local convergence rate is always linear when the optimal solution occurs at a differentiable point; however, when the optimal solution coincides with a fixed point, the convergence rate may be sub-linear or quadratic under certain conditions [13]. The Weiszfeld procedure has been generalized to other distance functions, and convergence properties have been studied e. g. see [1,2] for  $\ell_p$  distances. We note that global convergence is guaranteed for the  $\ell_p$  norm if the parameter  $p \in [1, 2]$ , that is, for the rectangular norm ( $p = 1$ ), the Euclidean norm ( $p = 2$ ), and all  $\ell_p$  norms in between.

The  $\ell_p$  norm, with  $1 < p < \infty$ , belongs to the class of round norms that are characterized by unit circles with no ‘flat spots’. Block norms, on the other hand, have unit circles that are polygons in  $\mathbb{R}^2$  (or polyhedrons in higher dimensional space). With this property, the objective function in (1) becomes convex piecewise linear. Block norms play a useful role in location models (e. g., see [17,19]), as the search in continuous space may now be confined to a finite set of points, and linear programming or related techniques may be used. Similarly, many other types of problems become much easier to solve when absolute values occur in a certain form. Examples of block norms include the rectangular norm ( $p = 1$ ), Tchebycheff norm ( $p = \infty$ ), and a linear combination of the two that has been used to approximate the  $\ell_p$  norm [18].

When distances are rectangular, that is, when:

$$K(x - a_i) = (|x_1 - a_{i1}| + |x_2 - a_{i2}|), \quad (4)$$

minimizing  $W(x)$  is accomplished by simply finding weighted median locations separately along the  $x_1$  and  $x_2$  axes (e. g., see [15] Chapter 2, or [9]). For example, if the  $a_{i1}$ ’s are ordered from smallest to largest, with their weights attached, then the  $a_{i1}$  associated with the median of the weights would determine the optimal solution for  $x_1$ . The separability property of rectangular distances allows for the solution of more complex problems. For example, the demand points may be replaced by demand ‘areas’, and the distance becomes the expected distance between the facility and each demand for a given density function of space distributed demand [6,22].

## The Model

We now consider the problem of locating a new facility denoted by point  $x \in \mathbb{R}^2$  to service a set of  $n$  specified demand regions (or market areas) denoted by  $A_i \subset \mathbb{R}^2$ ,  $i = 1, \dots, n$ . The  $A_i$  are assumed to be fixed areas in the plane that are bounded and closed, with known demands again specified by weighting constants,  $w_i > 0$ ,  $i = 1, \dots, n$ . The objective is to find the point  $x$  that minimizes the weighted sum of distances to the  $n$  demand regions.

What makes our problem different from the well-studied minisum problem discussed above is that the travel distance separating the facility from a demand region  $A_i$  is now defined as the distance measured by norm  $K$  from  $x$  to the closest point in  $A_i$ . This may be interpreted as flow from the facility entering the given market at the closest entry point. Internal distribution costs within the market area are assumed to be unimportant or ‘someone else’s concern’ (see [4,5] for further discussion).

The idea of closest distances is well known in set theory (e. g. [11]). Area demands have been used many times in location problems, but along with the assumption that travel distances within areas are relevant: e. g. see [6,10,22]. If some form of aggregation is used, then the expected travel distance from the facility to some ‘mean’ point in the interior of the demand area determines the transportation cost.

Denote the closest point in  $A_i$  by  $a_i(x)$ . Since this point is determined by the intersection of the smallest possible circle of norm  $K$  centered at  $x$  with  $A_i$ , it follows that if  $A_i$  is a convex region, and  $K$  a round norm, then,  $a_i(x)$  is always uniquely defined. The travel distance now becomes:

$$d(x, A_i) = \min_{y \in A_i} K(x - y) = K(x - a_i(x)). \quad (5)$$

The single facility minisum problem with closest distance function then takes the form:

$$\min W(x) = \sum_{i=1}^n w_i d(x, A_i) = \sum_{i=1}^n w_i K(x - a_i(x)). \quad (6)$$

**Property 1 (Brimberg and Wesolowsky, [4])** If  $A_i$  is a convex region, then  $d(x, A_i)$  is a convex function of  $x$  for any norm  $K$ .

It follows that if all the  $A_i$  are given as convex regions, then  $W$  is a sum of convex functions that is itself convex. In this case a general descent algorithm may be used to obtain the optimal solution. However, more specialized methods may be devised based on properties of the particular model.

**Euclidean Closest Distances**

We now specify the norm  $K$  to be the Euclidean norm, that is,

$$d(x, A_i) = \ell_2(x - a_i(x))$$

$$= [(x_1 - a_{i1}(x))^2 + (x_2 - a_{i2}(x))^2]^{1/2}, \quad (7)$$

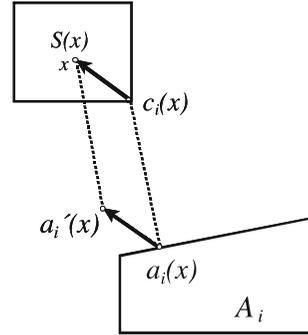

$$\forall x = (x_1, x_2), \quad a_i(x) = (a_{i1}(x), a_{i2}(x)) \in \mathbb{R}^2.$$

Let  $int(A_i)$  and  $B_i$  denote, respectively, the interior and boundary of  $A_i, i = 1, \dots, n$ . Let  $a_i(x)$  represent the ‘‘fixed point’’  $a_i(x)$  which is assumed to be unique. When  $x \in int(A_i)$ , it is clear that  $\partial(d(x, A_i))/\partial x_j$  exists, and is equal to 0 for all  $j$ . However, since the functional form of  $W(x)$  changes crossing from the interior to the exterior of  $A_i$ , it also follows that when  $x \in B_i, \partial(d(x, A_i))/\partial x_j$  is undefined for at least one direction  $j$ . The following result [5] provides an interesting relation when  $x$  is a point outside  $A_i$ .

**Property 2** Consider any  $x \notin A_i$ . Then the partial derivative  $\partial(d(x, A_i))/\partial x_j$  is defined  $\forall j$ ; its value at  $x$  is the same when  $a_i(x)$  is replaced by the fixed point  $a_i(x)$ .

It follows that if  $x$  is external to all the  $A_i$ , the gradient vector of  $W(x)$  may be calculated by replacing all the demand regions by the associated fixed points  $a_i(x)$ . Meanwhile if  $x$  is inside a region, we simply delete that region from the calculation. Thus the problem may be converted, at least locally, to the standard form given in (1). The basic idea behind the algorithm given in [5] may now be summarized as follows:

Given an initial location  $x^0$ , we determine the closest point  $a_i(x^0)$  for each demand region  $A_i$  not containing  $x^0$ . These  $a_i(x^0)$  are then treated as fixed points replacing the respective areas  $A_i$ . This allows us now to make use of the well-known Weiszfeld procedure introduced above. One Weiszfeld iteration produces a new location  $x^1$  with lower objective function value relative to the set  $\{a_i(x^0); i = 1, \dots, n\}$ , although reduction of the step size may be required if  $x^0$  falls within a demand

**Optimizing Facility Location with Euclidean and Rectilinear Distances, Figure 1**  
**Closest distances with an area facility**

region. Using the new location  $x^1$ , we then recalculate the closest points to obtain  $\{a_i(x^1); i = 1, \dots, n\}$ , and a further improvement in the objective function. The whole process is repeated to provide a sequence of descent moves. The algorithm will converge to the optimal solution if all the  $A_i$  are convex regions; otherwise, since the objective function is no longer convex, we are only guaranteed a local minimum.

Suppose now that instead of being a point, the new facility is represented by an area of fixed dimensions and orientation, denoted by  $S(x)$ , where  $x$  is a specified ‘center’ point. The closest distance between the facility and demand region  $A_i$  is then defined as:

$$d(x, A_i) = \min_{z \in S(x), y \in A_i} \{\ell_2(z - y)\} = \ell_2(c_i(x) - a_i(x)), \quad (8)$$

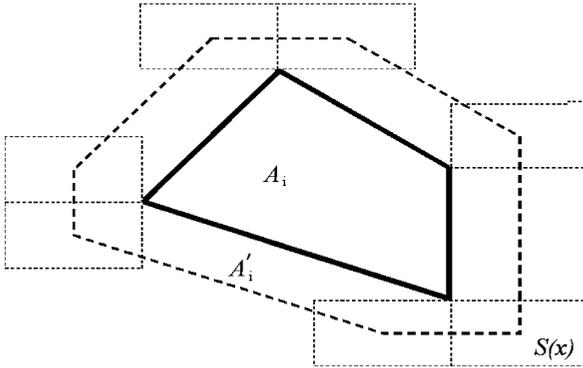

where  $c_i(x)$  and  $a_i(x)$  are the closest points in  $S(x)$  and  $A_i$ , respectively. As illustrated in Fig. 1, we may replace  $c_i(x)$  by  $x$  and  $a_i(x)$  by  $a'_i(x) = a_i(x) + (x - c_i(x))$ .

Using this insight, the problem may be converted to the original form by replacing each  $A_i$  by an enlarged area  $A'_i$  [5]. This is illustrated in Fig. 2, where  $S(x)$  is a rectangle, and  $A_i$  a polygon. Note that  $A'_i$  is also a polygon but with a larger number of sides.

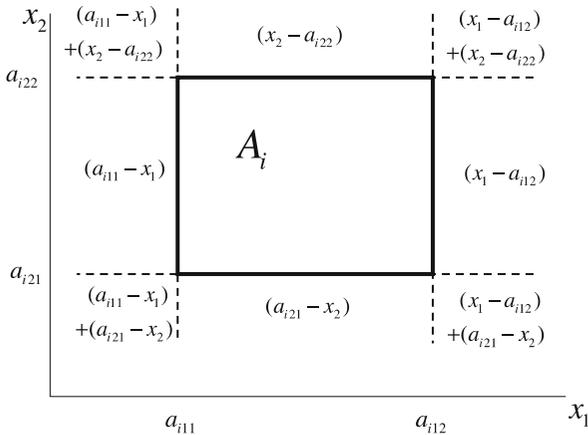

**Rectilinear Closest Distances**

The norm  $K$  is now specified by the rectangular norm; hence,

$$d(x, A_i) = \ell_1(x - a_i(x)) = |x_1 - a_{i1}(x)| + |x_2 - a_{i2}(x)|. \quad (9)$$

**Optimizing Facility Location with Euclidean and Rectilinear Distances, Figure 2**  
**Enlarged Area  $A'_i$**

**Optimizing Facility Location with Euclidean and Rectilinear Distances, Figure 3**  
**Distances from area  $A_i$**

The problem now becomes:

$$\min W(x) = \sum_{i=1}^n w_i (|x_1 - a_{i1}(x)| + |x_2 - a_{i2}(x)|). \quad (10)$$

If the area  $A_i$  is a rectangle, then the distance  $d(x, A_i)$  has a very convenient form. Referring to the notation and closest distances given in Fig. 3, it follows that

$$d(x, A_i) = \frac{1}{2} \sum_{j=1}^2 \sum_{k=1}^2 |x_j - a_{ijk}| - \tau_i, \quad (11)$$

where

$$\tau_i = \frac{a_{i12} - a_{i11}}{2} + \frac{a_{i22} - a_{i21}}{2} \quad (12)$$

from which we can conclude that this problem is equivalent to solving:

$$\min W(x) = \sum_{i=1}^n \sum_{j=1}^2 \sum_{k=1}^2 w_i |x_j - a_{ijk}| \quad (13)$$

This problem is now separable, and is very easily solvable by ordering coordinates and taking medians, as discussed previously (see [15], Chapter 2). The physical interpretation of this problem is also interesting. If each rectangle  $A_i$  with weight or demand  $w_i$  is replaced by two fixed points with the same weights  $w_i$  at diagonally opposing vertices, then the original problem becomes an equivalent problem with point demands.

In common with many location models using rectilinear distances,  $W(x)$  remains piecewise-linear along any straight line in the solution space when closest rectangular distances are in use. Specifically,  $W(x)$  is linear in segments of the plane marked off by lines drawn through the vertices of polygonal demand areas. This is particularly important in location problems, such as the maximin location problem, where the objective function is not convex. It means that the problem can be decomposed into a number of problems with linear objective functions [3,4,8,10,12].

Another characteristic of this problem in common with other rectilinear location problems (and block norms in general) is that it can be solved with linear programming; that is, optimizing  $W(x)$  can be expressed as a set of linear programming formulations.

The rectangular distance function has discontinuities in its derivatives, so that associated location problems provide difficulties for gradient descent based procedures. One way around this is to use hyperbolic approximations for the terms represented by absolute differences [16,23].

### Keywords

Ordered vector spaces; Vector lattice; Order complementarity

The introduction of the order complementarity problem in complementarity theory can be justified by the following two reasons:

- 1) In the study of some particular classical complementarity problems the essential fact is not the orthogonality in the sense of an inner-product, but important is the lattice orthogonality. It is very useful, in some circumstances, to represent the classical complementarity problem as an order complementarity problem.
- 2) In several practical problems the complementarity condition appears with more than one operator. We have this situation, for example in Economics, in Lubrication Theory, in Stochastic Optimal Control Theory, etc. [16]. The study of order complementarity problems is a new chapter in Complementarity Theory. This chapter is now in developing.

**Preliminaries**

Denote by  $E(\tau)$  (respectively, by  $(E, \|\cdot\|)$  and  $(E, \langle \cdot, \cdot \rangle)$ ) a locally convex space (respectively, a Banach space and a Hilbert space). Suppose that  $E$  is ordered by a *pointed convex cone*  $\mathbf{K} \subset E$ , i. e.,  $\mathbf{K}$  is a subset of  $E$  satisfying the following properties:

- 1)  $\mathbf{K} + \mathbf{K} \subseteq \mathbf{K}$ ;
- 2)  $\lambda \mathbf{K} \subseteq \mathbf{K}$  for all  $\lambda \in \mathbf{R}_+$ ; and
- 3)  $\mathbf{K} \cap (-\mathbf{K}) = \{0\}$ .

Denote by  $\leq$  the ordering defined by  $\mathbf{K}$ , that is,  $x \leq y$  if and only if  $y - x \in \mathbf{K}$ . Assume that the ordered vector space  $(E, \mathbf{K})$  is a *vector lattice*, i. e., for every pair  $(x, y) \in E \times E$ , the supremum  $\vee(x, y)$  and the infimum  $\wedge(x, y)$  with respect to the ordering  $\leq$  exist in  $E$ . In this case, for every  $x, y, z \in E$  we have:

- 1)  $\vee(x, y) + z = \vee(x + z, y + z)$ ;
- 2)  $\wedge(x, y) + z = \wedge(x + z, y + z)$ ;
- 3)  $\vee(x \vee y, z) = \vee[\vee(x, y), \vee(y, z)] = \vee(x, y, z)$ .

We can show that  $\vee(x, y) = -\wedge(-x, -y)$  for all  $x, y \in E$ .

Let  $E(\tau)$  be a locally convex space and  $\mathbf{K} \subset E$  a closed convex cone.

We say that  $\mathbf{K}$  is *regular* (respectively, *completely regular*) if all monotone increasing and order bounded (resp. topological bounded) sequences of elements of  $\mathbf{K}$  are  $\tau$ -convergent. Let  $D \subset E$  be a subset. An operator  $T: D \rightarrow E$  is said to be *isotone* (respectively, *antitone*) if  $x_1 \leq x_2$  ( $x_1, x_2 \in D$ ) implies  $T(x_1) \leq T(x_2)$  (respectively,

$T(x_2) \leq T(x_1)$ ). If  $S$  is a subset of  $D$ , we denote by  $\mu(S)$  the *measure of noncompactness* of  $S$  i. e.,  $\mu(S) = \inf\{r > 0: S \text{ can be recovered by a finite family of subsets of } E \text{ whose diameter } < r\}$ .

We say that  $T$  is a *k-set-contraction* ( $k \geq 0$ ) if it is continuous, bounded and  $\mu(T(S)) \leq k\mu(S)$  for any bounded set  $S \subset D$ . A *k-set-contraction* is called a *strict-set-contraction* if  $k < 1$ .  $T$  is called *condensing* if it is continuous, bounded and  $\mu(T(S)) < \mu(S)$  for any bounded set  $S \subset D$  with  $\mu(S) > 0$ . If  $\mathbf{K} \subset E$  is a pointed convex cone we say that a bilinear form  $\langle \cdot, \cdot \rangle$  on  $E$  is *K-local* if and only if  $\langle x, y \rangle = 0$ , whenever  $x, y \in \mathbf{K}$  and  $\wedge(x, y) = 0$ .

**Order Complementarity Problems**

The order complementarity problems represent a relatively new chapter in complementarity theory. The order complementarity problems are necessary since, in many situations some classical complementarity problems must be represented as a lattice orthogonality problem. Furthermore in some practical problems, we must use the complementarity condition simultaneously with respect to several operators.

Let  $(E, \mathbf{K})$  be a vector lattice with respect to the order defined by the pointed convex cone  $\mathbf{K}$ . Let  $D$  be a nonempty subset of  $E$ . In particular, the set  $D$  can be the cone  $\mathbf{K}$ . Given  $m$  linear or nonlinear functions  $f_1, \dots, f_m: E \rightarrow E$ , the *order complementarity problem* associated with the family of functions and with the set  $D$  is:

$$\text{OCP}(\{f_i\}_{i=1}^n; D) \left\{ \begin{array}{l} \text{find } x_0 \in D \\ \text{s.t. } \wedge(f_1(x_0), \dots, f_m(x_0)) \\ \quad = 0. \end{array} \right.$$

In [16] this problem is named the *implicit general order complementarity problem*. We have several interesting particular cases:

- 1) If  $m = 2, D = E, f_1 = \text{Id}$  (the identity mapping) and  $f_2(x) = Tx + q$ , where  $T: E \rightarrow E$  is a linear mapping and  $q$  an element in  $E$ , we have the *linear order complementarity problem* denoted by  $\text{LOCP}(T, q)$ . This problem was studied systematically for the first time in 1989 in [2] where several interesting new classes of linear operators were introduced. We find, for example, the operators of classes  $(H^+), (S), (Z), (K), (P)$  and  $(A)$ .

- 2) If  $m$  is arbitrary and the functions  $f_i$  ( $i = 1, \dots, m$ ) are affine mappings we have the *generalized linear order complementarity problem*. Several results about this problem are obtained in [9,16,25].
- 3) If  $m = 2$ ,  $D = \mathbf{K}$  and  $f_1, f_2$  are nonlinear mappings we have the *nonlinear order complementarity problem* studied for the first time in 1986, in [12].
- 4) If  $m = 3$ ,  $D = E$ ,  $f_1 = \text{Id}$  and  $f_2, f_3$  are nonlinear we have the order complementarity problem introduced in lubrication theory in 1986 in [22].
- 5) If  $m$  is arbitrary,  $D = \mathbf{K}$ ,  $f_1 = \text{Id}$  and  $f_2, \dots, f_m$  are nonlinear but having the form  $f_i(x) = x - T_i(x)$  ( $i = 1, \dots, m$ ), with every  $T_i$  a nonlinear mapping, we have the *generalized order complementarity problem* studied systematically in [17], and for set-valued mappings in [18].

**Order Complementarity Problem as Mathematical Model**

The order complementarity problems can be considered also as mathematical models for many practical problems. We indicate in this section some of such models.

**Mixed Lubrication Problem**

Consider the mixed lubrication in the context of a journal bearing with elastic support. The problem is to study the contact pressure  $X$ . In this case,  $E = H^1(\Omega)$  (defined over  $L^2(\Omega)$ ) and the cone is  $\mathbf{K} = \{\mu \in H^1(\Omega) : \mu \geq 0 \text{ a.e. on } \Omega\}$ . We have two operators,  $T_1(X)$  and  $T_2(X)$ , where  $T_1$  is generally an integral operator and  $T_2$  is the Reynolds’ partial differential operator. For the definition of these operators, the reader is referred to [16,17,22]. In this case, there are three distinct functions which cause the decomposition of the spatial area into three disjoint regions: the innermost region (solid-to-solid contact), the elasto-hydrodynamic lubrication region (solid-to-fluid contact), and the cavity region (in which the pressure returns to the ambient value). The complementarity formulation is based on the observation that the contact pressure  $X$  satisfies the following equations specified for every region:

- 1)  $X \geq 0$ ,  $T_1(X) = 0$ ,  $T_2(X) \geq 0$  (solid-to-solid contact);
- 2)  $X = 0$ ,  $T_1(x) \geq 0$ ,  $T_2(X) \geq 0$  (cavity point);
- 3)  $X \geq 0$ ,  $T_1(X) \geq 0$ ,  $T_2(X) = 0$  (lubrication point).

The problem to know the contact pressure  $X$  is equivalent to the solvability of the problem  $\text{OCP}(\text{Id}, T_1, T_2; \mathbf{K})$ . Initially, this problem was defined in [22] and until now it is not solved.

**Global Reproduction of an Economic System Working with Several Technologies**

Consider a nonlinear economic system which is a generalization of the classical linear input-output system defined by Leontief. Suppose that the system has  $n$  production sectors and every sector works with  $m$  technologies to produce one type of output. The number of technologies is the same for every sector. Every sector is constrained to use the production of the others. Let  $x_j$  be the level in units of the gross activity performed in the sector  $j$ . Suppose that to produce  $x_j$  units in the sector  $j$ ,  $f_{ij}^k(x_j)$  units from the technology  $k$  of sector  $i$  are needed as inputs. We make the following assumptions: for all  $i, j, k$ :

- 1) all  $f_{ij}^k(x_j)$  are continuous;
- 2)  $f_{ij}^k(0) = 0$ ;
- 3)  $0 \leq u_j \leq v_j$  implies  $f_{ij}^k(u_j) \leq f_{ij}^k(v_j)$ .

The balances between total activities and final demands for the technology  $k$  are given by  $x_i = \sum_{j=1}^n f_{ij}^k(x_j) + y_j$ ,  $i = 1, \dots, n$ , where  $y_i$  is the final demand for the sector  $i$ . Denote this system by  $S(\{f_{ij}^k\})$ . This is the classical Leontief nonlinear input-output system studied by several authors (see the references cited in [17]). We replace condition 3) by the following more realistic condition:

- 4) there exists a continuous mapping  $\Phi: \mathbf{R}^n \rightarrow \mathbf{R}^n$  such that:
  - i)  $\text{Id} + \Phi$  is invertible and  $(\text{Id} + \Phi)^{-1}$  is isotone (with respect to the ordering defined by  $\mathbf{R}_+^n$ );
  - ii)  $\Phi(x) + \sum_{j=1}^n f_j^k(x_j)$  is isotone for every  $k$ , where  $x = (x_1, \dots, x_n)^T$  and  $f_j^k(x_j) = [f_{ij}^k(x_j)]_{i=1}^n$ .

If  $S(\{f_{ij}^k(x_j)\})$  satisfies 1), 2) and 4) we say that it is a *tolerant system* and in this case  $\Phi$  is a *tolerance*. We define  $F^k(x) = x - \sum_{j=1}^n f_j^k(x_j)$  and for any  $y^0 > 0$ ,

$$S_{y^0} = \left\{ x \in \mathbf{R}_+^n : \begin{array}{l} F^1(x) - y^0 \geq 0 \\ \vdots \\ F^m(x) - y^0 \geq 0 \end{array} \right\}.$$

For this model, the problem is to show that given  $y^0 > 0$  with  $S_{y^0}$  nonempty, the problem  $\text{OCP}(T_1, \dots, T_m, \mathbf{R}_+^n)$

has a solution  $x^0 > 0$  which is the least element of  $S_{y^0}$ , where

$$T_1(x) = F^1(x) - y^0, \dots, T_m(x) = F^m(x) - y^0.$$

In this case we say that the *production*  $x^0$  is realizing  $y^0$  with a minimal social cost. This model was studied in [17]. In this paper it is shown that a tolerant economic system, which is locally nonlinear and with the functions  $f_{ij}^k$  not necessarily isotone, has a behavior similar to a classical Leontief model.

### Discrete Dynamic Complementarity Problem

One of the recent discoveries in complementarity theory is the *dynamic complementarity problem*. It seems that this problem was defined in [10] and it is a unifying framework for fluid and diffusion approximation of stochastic flow networks. Now we consider the *discrete dynamic complementarity problem* (DDCP). Let  $(\mathbf{R}^m, \langle \cdot, \cdot \rangle)$  be the Euclidean space ordered by  $\mathbf{R}_+^m$ . Let  $x = \{x(0), \dots, x(n), \dots\}$  be a sequence of vectors in  $\mathbf{R}^m$ . Assume that  $x(0) \geq 0$  and  $\mathcal{R}$  is a real  $(m \times m)$ -matrix. The problem (DDCP) is the following: given the sequence  $x$  and the matrix  $\mathcal{R}$  find the sequence  $y = \{y(0), \dots, y(n), \dots\}$  such that for all  $n \in \mathbf{N}$ :

- i)  $z(n) = x(n) + \mathcal{R}y(n) \geq 0$ ;
- ii)  $y(0) = 0, \Delta y(n) = y(n) - y(n-1) \geq 0$ ;
- iii)  $\langle z(n), \Delta y(n) \rangle = 0$ .

We assume by convention that  $y(-1) = 0$  and  $\mathbf{N} = \{0, 1, 2, \dots\}$ . Consider the vector space  $S = \{x: x: \mathbf{N} \rightarrow \mathbf{R}^m, \text{ ordered by the convex cone}$

$$\mathbf{K} = \{x \in S: x(n) \geq 0 \text{ for all } n \in \mathbf{N}\}$$

and endowed with the Fréchet locally convex topology defined by the family of seminorms  $\{p_r\}_{r \in \mathbf{N}}$ , where  $p_r = \sum_{n=0}^r \|x(n)\|$ . The space  $S$  is a vector lattice and  $\mathbf{K}$  is normal. We define the following operators from  $S$  into  $S$ :

$$T_1(y) = \{x(0) + \mathcal{R}y(0), \dots, x(n) + \mathcal{R}y(n), \dots\},$$

$$T_2(y) = \{0, y(1) - y(0), \dots, y(n) - y(n-1), \dots\},$$

We put  $A = \{y \in S: y(0) = 0\}$ . The solvability of problem DDCP is equivalent to the solvability of the problem  $\text{OCP}(T_1, T_2; A)$ . The study of dynamic complementarity problem is an interesting new research domain in Complementarity Theory. The reader can find other examples of order complementarity problems in [14,16],

where it is shown that the generalized linear complementarity problem in Cottle and Dantzig's sense or the Bellman routing problem can be reformulated as an order complementarity problem.

### Solution Methods

Let  $E(\tau)$  be a locally convex space ordered by a closed pointed convex cone  $\mathbf{K} \subset E$  suppose that  $E$  is a vector lattice. Given the operators  $T_1, \dots, T_m \in \mathcal{L}(E)$  and the set  $D \subset E$ , we consider the problem  $\text{OCP}(\{T_i\}_{i=1}^m, D)$ . Because the fact that the operator ' $\wedge$ ' is used in the definition of this problem, many classical methods applicable to the solvability of nonlinear equations or to the solvability of fixed point problems are not applicable. For example the operator ' $\wedge$ ' can destroy the compactness or the differentiability of operators  $T_i$  ( $i = 1, \dots, m$ ). However, some fixed point methods or some topological methods are applicable. In this sense several existence theorems and iterative methods for solvability of the problem  $\text{OCP}(\{T_i\}_{i=1}^m, D)$  are presented in the papers [12,13,14,15,16,17,18]. Several existence results can be obtained using the fixed point theory and the following result.

**Theorem 1** *If  $\Phi_0: E \rightarrow E$  is an arbitrary function such that  $(\text{Id} + \Phi_0)^{-1}$  exists, then  $x_* \in D$  is a solution of the problem  $\text{OCP}(\{T_i\}_{i=1}^m, D)$  if and only if  $x_*$  is a fixed point of the mapping  $\mathcal{H}(x)$  defined by*

$$\mathcal{H}(x) = (\text{Id} + \Phi_0)^{-1} \\ \times (\vee \{(\text{Id} + \Phi_0 - T_1)(x), \dots, (\text{Id} + \Phi_0 - T_m)(x)\})$$

for every  $x \in E$ .

The importance of this Theorem is the fact that for practical problems we can choose the mapping  $\Phi_0$  such that  $\mathcal{H}(x)$  has some good properties. We denote  $H(x) = \wedge (x - T_1(x), \dots, x - T_m(x))$ , for all  $x \in E$ .

**Definition 2** We say that  $H$  is  $\Phi_0$ -isotone on  $D$  if there exists a mapping  $\Phi: E \rightarrow E$  such that  $H + \Phi$  is isotone on  $D$ ,  $(\text{Id} + \Phi)$  is invertible and  $(\text{Id} + \Phi)^{-1}$  is isotone.

We recall that  $D$  is order convex if  $u, v \in D$  and  $u \leq w \leq v$  imply that  $w \in D$ .

**Theorem 3** *Let  $(E(\tau), \mathbf{K})$  be a locally convex vector lattice and  $D \subset E$  an ordered convex set. If the following assumptions are satisfied:*

- 1)  $\mathbf{K}$  is a regular cone;
- 2)  $H$  is  $\Phi$ -isotone;
- 3)  $(Id + \Phi)^{-1}(H + \Phi)$  is continuous;
- 4) there exist  $x_0, y_0 \in D$  such that  $x_0 \leq y_0$ ,  $x_0 \leq H(x_0)$  and  $H(y_0) \leq y_0$ ,

then the problem has a minimal and a maximal solutions, both computable by iterative methods.

*Proof* The proof is in [16].

Suppose that  $Id - T_i = R_i + S_i$ , where  $R_i$  is isotone and  $S_i$  antitone. In this case we can associate to the mapping  $H$  the mapping

$$\widehat{H}(x, y) = \wedge \{R_1(x) + S_1(y), \dots, R_m(x) + S_m(y)\}$$

for all  $x, y \in E$ . We obtain that  $H$  is a heterotonic operator in Opoitsev's sense (see [23]). We say that  $(x_*, y_*)$  is a coupled fixed point for  $H$  if  $\widehat{H}(x_*, y_*) = x_*$  and  $\widehat{H}(y_*, x_*) = y_*$ . We have the following result:

**Theorem 4** Let  $(E, \|\cdot\|)$  be a uniformly convex Banach space ordered by a regular pointed closed convex cone  $\mathbf{K} \subset E$ . If one of the following assumptions are satisfied:

- 1)  $\widehat{H}$  is nonexpansive;
- 2)  $\widehat{H}$  is condensing with respect to a measure of noncompactness;
- 3)  $\widehat{H}$  is continuous and  $\dim E < +\infty$ ,

then for very conical interval  $[x_0, y_0]$  strongly invariant for  $H$  (i. e.,  $x_0 \leq \widehat{H}(x_0, y_0)$  and  $\widehat{H}(y_0, x_0) \leq y_0$ ), there exists a coupled fixed point  $(x_*, y_*)$  for  $H$  and a solution  $\widehat{x}$  of the problem  $OCP(\{T_i\}_{i=1}^m, \mathbf{K})$  such that  $x_* \leq \widehat{x} \leq y_*$ . Moreover  $x_* = \lim_{k \rightarrow \infty} x_k$  and  $y_* = \lim_{k \rightarrow \infty} y_k$ , where  $x_k = \widehat{H}(x_{k-1}, y_{k-1})$  and  $y_k = \widehat{H}(y_{k-1}, x_{k-1})$ .

*Proof* The proof of this theorem is in [16].

Several interesting existence results based on a special topological index, defined on cones, are presented in [15]. This topological index was defined in [23]. The problem  $OCP(\{T_i\}_{i=1}^m, D)$  can be also studied by the topological degree. Several results in this sense have been obtained especially for the Linear Order Complementarity Problem [8,9,25]. The results obtained for the problem  $OCP(\{T_i\}_{i=1}^m, D)$  can be applied to the problem  $NCP(f, \mathbf{K})$  when  $E$  is a Hilbert space and the inner product is  $\mathbf{K}$ -local, since in this case the problem  $NCP(f, \mathbf{K})$  is equivalent to the problem  $OCP(Id, f, \mathbf{K})$ .

Matroids have been defined in 1935 as generalization of graphs and matrices.

Starting from the 1950s they have had increasing interest and the theoretical results obtained have been used for solving several difficult problems in various fields such as civil, electrical, and mechanical engineering, computer science, and mathematics. *Oriented matroids* are a special class of matroids. They can be viewed as a combinatorial abstraction of real hyperplanes arrangements, of point configurations over the reals, of convex polytopes, or of directed graphs. Scope of this article is to introduce the reader to the theory of oriented matroids, providing an extensive discussion of the axiom systems for them and illustrating the different aspects that characterize these objects.

### Historical Review

In 1935 H. Whitney in [35] studied the *linear dependence* and its important application in mathematics. A number of equivalent axiomatic systems for matroids is contained in his pioneering paper, that is considered the first scientific work about matroid theory.

In the 1950s and 1960s, starting from the Whitney's ideas, W. Tutte in [22,23,24,25,26,27,28,29,30] built a considerable body of theory about the structural properties of matroids, which became popular in the 1960s, when J. Edmonds in [7,8,9,10,11,12,13] introduced the matroid theory in combinatorial optimization. From 1965 on, a growing number of researchers

became interested in matroids. The origins of oriented matroids go back to these years due to R.G. Bland, J. Folkman, M. Las Vergnas, and Lawrence. Among the first results, see [17] and [15], which contains the fundamental topological representation theorem for oriented matroids. To the same years further notions of oriented matroids go back due to Bland, who was motivated by linear programming duality theory ([3,4]), and, independently, to Las Vergnas, who was motivated by graph theory ([31,32,33,34]). In 1978 appeared [5].

In the literature there are several other early papers, among them [16,19], and [21].

[2] contains a comprehensive and tutorial treatment of oriented matroids, whose current research updates are provided in [36].

**Axiom Systems for Oriented Matroids.**

Researchers from various mathematical areas arrived at four basic, equivalent, axiom systems:

- 1) circuit axioms;
- 2) orthogonality axioms;
- 3) chirotopes, or basis orientations;
- 4) vector axioms.

In order to understand these axiom systems, some notions and definition are needed.

**Definition 1** A *signed set*  $X$  is a set  $\underline{X}$  together with a partition  $(X^+, X^-)$  of  $\underline{X}$ .  $X^+$  is the positive set;  $X^-$  is the negative set.  $X$  is positive (negative), if  $X^+ = \emptyset$  ( $X^- = \emptyset$ ).  $\text{supp } X = X^+ \cup X^-$  is the support of  $X$ .

**Definition 2** Let  $X$  and  $Y$  be two signed sets,  $X$  is a restriction of  $Y$  if and only if  $X^+ \subseteq Y^+$  and  $X^- \subseteq Y^-$ .

**Definition 3** Let  $F$  be an unsigned set and  $X$  be a signed set. Then, the restriction of  $X$  to  $F$ , denoted  $X|_F$ , is a signed set  $Y = X \cup F$ , such that  $Y^+ = X^+ \cup F$  and  $Y^- = X^- \cup F$ .

**Definition 4** A signed set  $X$  can be defined also throughout a mapping  $\text{sg}_X: X \rightarrow \{-1, 1\}$ , such that  $X^+ = \{x: \text{sg}_X(x) = 1\}$  and  $X^- = \{x: \text{sg}_X(x) = -1\}$ .  $\text{sg}_X$  is called the *signature* of  $X$ .

In the following,  $X \setminus Y$  denotes the restriction of  $X$  to  $\underline{X} \setminus \underline{Y}$ .

**Definition 5** Let  $X$  and  $Y$  be two signed sets, their *composition*  $X \circ Y$  is a signed set such that  $(X \circ Y)^+ = X^+ \cup (Y^+ \setminus X^-)$  and  $(X \circ Y)^- = X^- \cup (Y^- \setminus X^+)$ .

Note that  $\circ$  is associative, while  $X \circ Y = Y \circ X$  if and only if the restrictions of  $X$  and  $Y$  to their intersection are equal.

**Definition 6** The *opposite* of a signed set  $X$ , denoted  $-X$ , is the signed set such that  $(-X)^+ = X^-$  and  $(-X)^- = X^+$ .

**Definition 7** Let  $X$  and  $Y$  be two signed sets.  $X$  and  $Y$  are called *orthogonal signed sets*, denoted by  $X \perp Y$ , if either  $X \cap Y = \emptyset$ , or the restrictions of  $X$  and  $Y$  to their intersection are neither equal nor opposite, i.e. there must exist  $x, y \in X \cap Y$  such that  $X(x)Y(x) = -X(y)Y(y)$ .

**Definition 8** Let  $E$  be any set. A *signed subset* of  $E$  is a signed set whose support is contained in  $E$ .

A signed subset of  $E$  can be identified with an element of  $\{-1, 0, 1\}^E$ , which is usually abbreviated by  $\{-, 0, +\}^E$ . If  $E = \{1, \dots, n\}$  and  $X \in \{-, 0, +\}^E$ ,  $X$  is a *sign vector* having  $n$  entries  $-$ ,  $0$ , or  $+$ .

**Circuits and Circuit Axioms.**

In this Section we provide the definition of an oriented matroid in terms of its signed circuits.

**Definition 9 (Circuit axioms)** A collection  $\mathcal{C}$  of signed subsets of a set  $E$  is the set of *signed circuits* of an oriented matroid  $\mathcal{M}$  on  $E$  if and only if  $\mathcal{C}$  satisfies the following axioms:

- 1)  $\emptyset \notin \mathcal{C}$ ;
- 2) symmetry:  $\mathcal{C} = -\mathcal{C}$ ;
- 3) incomparability:  $\forall X, Y \in \mathcal{C}$ , if  $\underline{X} \subseteq \underline{Y}$ , then  $X = Y$  or  $X = -Y$ ;
- 4) weak elimination:  $\forall X, Y \in \mathcal{C}$ ,  $X \neq -Y$ , and  $x \in X^+ \cap Y^-$  there exists a  $Z \in \mathcal{C}$  such that  $Z^+ \subseteq (X^+ \cup Y^+) \setminus \{x\}$  and  $Z^- \subseteq (X^- \cup Y^-) \setminus \{x\}$ .

Note that the Axioms 1), 3), and 4) of Definition 9 are the circuit axioms of an ordinary matroid.

**Corollary 10** The circuit supports  $\underline{\mathcal{C}} = \{\underline{X}: X \in \mathcal{C}\}$  in an oriented matroid  $\mathcal{M}$  are the circuits of a matroid  $\underline{\mathcal{M}}$ , called *underlying matroid* of  $\mathcal{M}$ .

**Definition 11**  $C$  is called a *circuit orientation* of  $\underline{\mathcal{M}}$ , which has the same rank of  $\mathcal{M}$ .

An ordinary matroid  $M$  is *orientable* if it has a circuit orientation.

Deciding the orientability of a matroid is a difficult problem. Bland and Las Vergnas [5] proved that a binary matroid is orientable if and only if it is regular.

**Definition 12** Let  $\mathcal{M}$  be an oriented matroid on a set  $E$  and let  $x \in E$ . Then  $x$  is a loop of  $\mathcal{M}$  if  $(\{x\}, \emptyset) \in \mathcal{C}$ .

If  $x \notin X$  for every  $X \in \mathcal{C}$ ,  $x$  is called *coloop* of  $\mathcal{M}$ .

Bland and Las Vergnas [5] and, independently, Folkman and Lawrence [15] obtained the following result.

**Theorem 13** Let  $\mathcal{C}$  be a collection of signed subsets of a set  $E$  satisfying 1), 2), and 3) of Definition 9. Then 4) of Definition 9 is equivalent to

4') strong elimination:  $\forall X, Y \in \mathcal{C}, x \in X^+ \cap Y^-$ , and  $f \in (X^+ \setminus Y^-) \cup (X^- \setminus Y^+)$ , there is a  $Z \in \mathcal{C}$  such that  $f \in Z, Z^+ \subseteq (X^+ \cup Y^+) \setminus \{x\}$ , and  $Z^- \subseteq (X^- \cup Y^-) \setminus \{x\}$ .

**Minors**

As for the ordinary case also for an oriented matroid  $\mathcal{M}$  on a set  $E$ , it is possible to define *submatroids* or *minors* induced by a subset  $F$  of  $E$  by *deletion* and/or *contraction*.

For any  $\mathcal{S} \subseteq \{-, 0, +\}^E$ , let  $\text{Min}\mathcal{S}$  be the collection of nonempty signed sets in  $\mathcal{S}$  with inclusion-minimal support and let  $\text{Max}\mathcal{S}$  be the collection of signed sets in  $\mathcal{S}$  with inclusion-maximal supports. Then the following properties hold.

**Proposition 14 (Deletion)** Let  $\mathcal{M}$  be an oriented matroid on a set  $E$  with set of signed circuits  $\mathcal{C}$ , and let  $F \subseteq E$ . Then  $\mathcal{C}' = \{X \in \mathcal{C}: \underline{X} \subseteq F\}$  is the set of circuits of an oriented matroid on  $F$  called the *submatroid of  $\mathcal{M}$  induced on  $F$*  and denoted by  $\mathcal{M}(F)$ .

**Proposition 15 (Contraction)** Let  $\mathcal{M}$  be an oriented matroid on a set  $E$  with set of signed circuits  $\mathcal{C}$ , and let  $F \subseteq E$ . Then  $\text{Min}\{X|_F: X \in \mathcal{C}\}$  is the set of circuits of an oriented matroid on  $F$  called the *contraction of  $\mathcal{M}$  to  $F$*  and denoted by  $\mathcal{M}/A$ , where  $A = E \setminus F$ .

**Proposition 16** Let  $\mathcal{M}$  be an oriented matroid on a set  $E$ , and let  $A, B$  be two disjoint subsets of  $E$ . It holds

$$(\mathcal{M} \setminus A) \setminus B = \mathcal{M} \setminus (A \cup B),$$

$$\frac{\binom{\mathcal{M}}{A}}{B} = \frac{\mathcal{M}}{(A \cup B)},$$

$$\frac{(\mathcal{M} \setminus A)}{B} = \left(\frac{\mathcal{M}}{B}\right) \setminus A.$$

**Definition 17** A circuit signature of a matroid assigns to each circuit  $C$  two opposite signed sets  $X$  and  $-X$  supported by  $C$ .

**Theorem 18** Let  $M$  be a matroid on a set  $E$ , and let  $\mathcal{S}$  be a circuit signature of  $M$ . Suppose that for all  $x \in E$  the induced circuit signatures  $\mathcal{S} \setminus \{x\}$  and  $\mathcal{S}/\{x\}$  are circuit orientations of  $M \setminus \{x\}$  and  $M/\{x\}$ , respectively. Then, one of the following condition holds:

- 1)  $\mathcal{S}$  is a circuit orientation of  $\mathcal{M}$ ;
- 2)  $|E| = 3$ ;
- 3)  $|E| = 4$ .

**Duality.**

Let  $\mathcal{M}$  be an oriented matroid on a set  $E$ ,  $B$  a basis of  $\underline{\mathcal{M}}$ , and  $x \in E \setminus B$ , then there is a unique circuit  $c(x, B)$  of  $\underline{\mathcal{M}}$ .  $\underline{c}(x, B)$  is contained in  $B \cup \{x\}$  and supports a unique signed circuit of  $\mathcal{M}$ . Let  $c(x, B)$  be the basic circuit of  $x$  with respect to  $B$ , the signed circuit supported by  $\underline{c}(x, B)$  which has  $x$  in its positive part. On the other hand, given  $x \in B$ ,  $\underline{c}^*(x, B)$  denotes a unique cocircuit of  $\underline{\mathcal{M}}$  disjoint from  $B \setminus \{x\}$ .  $c^*(x, B)$  denotes the corresponding signed cocircuit of  $\mathcal{M}$  which is positive on  $\{x\}$  with respect to  $B$ . The existence and uniqueness of  $c^*(x, B)$  is proved in the following Proposition.

**Proposition 19** Let  $\mathcal{M}$  be an oriented matroid on a set  $E$  with set of circuits  $\mathcal{C}$ . Then the following three properties hold.

- 1) There exist a unique signature  $\mathcal{C}^*$  of the cocircuits of  $\underline{\mathcal{M}}$  such that  $X \perp Y$ , for all  $X \in \mathcal{C}$  and  $Y \in \mathcal{C}^*$ .
- 2) The collection  $\mathcal{C}^*$  is the set of signed circuits of an oriented matroid on  $E$  called the *dual matroid* (or *orthogonal matroid*) of  $\mathcal{M}$ , denoted by  $\mathcal{M}^*$ .
- 3)  $\mathcal{M}^{**} = \mathcal{M}$ .

The following Theorem, proved in [5], states the axiomatic definition of an oriented matroid in terms of its dual.

**Theorem 20 (Orthogonality axioms)** Let  $M$  be a matroid,  $\mathcal{C}$  be a circuit signature of  $M$ , and  $\mathcal{C}^*$  be a cocircuit signature of  $M$ . Then the following properties are equivalent.

- 1)  $\mathcal{C}$  and  $\mathcal{C}^*$  are the circuit collections of a pair of dual matroids.
- 2)  $X \perp Y, \forall X \in \mathcal{C}, \forall Y \in \mathcal{C}^*$ .
- 3)  $X \perp Y, \forall X \in \mathcal{C}, \forall Y \in \mathcal{C}^*$ , with  $|\underline{X} \cap \underline{Y}| \leq 3$ .

Bland and Las Vergnas have given [5] and [6] a further axiom system, called *painting axioms* by them, expressed in the following theorem.

**Theorem 21 (Painting axioms)** *Let  $C$  and  $C^*$  be two collections of signed subsets of a set  $E$ . Then,  $C$  is the set of circuits and  $C^*$  is the set of cocircuit of an oriented matroid on  $E$  if and only if they satisfy the conditions 1)–3) in Definition 9 and one of the two following equivalent properties.*

- 1) *3-painting: For all 3-partitions  $E = B \cup G \cup R$  and  $x \in B$  either there exists an  $X \in C$  such that  $x \in \underline{X} \subseteq B \cup G$  and  $\underline{X} \cap B \subseteq X^+$ , or there exists a  $Y \in C^*$  such that  $x \in \underline{Y} \subseteq B \cup R$  and  $\underline{Y} \cap B \subseteq Y^+$ , but not both.*
- 2) *4-painting: For all 4-partitions  $E = B \cup W \cup G \cup R$  and  $x \in B \cup W$  either there exists an  $X \in C$  such that  $x \in \underline{X} \subseteq B \cup W \cup G$ ,  $\underline{X} \cap B \subseteq X^+$ , and  $\underline{X} \cap W \subseteq X^-$ , or there exists a  $Y \in C^*$  such that  $x \in \underline{Y} \subseteq B \cup W \cup R$ ,  $\underline{Y} \cap B \subseteq Y^+$ , and  $\underline{Y} \cap W \subseteq Y^-$ , but not both.*

**Corollary 22** *Each element of an oriented matroid belongs either to a positive circuit or to a positive cocircuit, but not to both.*

The previous Corollary is helpful to define a special type of oriented matroid, called *acyclic oriented matroid*.

**Definition 23** An oriented matroid  $\mathcal{M} = (E, C)$  is *acyclic* if it does not contain a positive circuit.

$\mathcal{M}$  is *totally acyclic* if all its elements are contained in a positive circuit.

The identification of the minors of  $\mathcal{M}^*$  with the duals of the minors of  $\mathcal{M}$  follows from Theorem 20, as showed in the following proposition.

**Proposition 24** *Let  $\mathcal{M}$  be an oriented matroid on a set  $E$  and  $A$  be a subset of  $E$ . Then,*

$$(\mathcal{M} \setminus A)^* = \mathcal{M}^* / A,$$

$$(\mathcal{M} / A)^* = \mathcal{M}^* \setminus A.$$

**Chirotopes and Basis Orientations**

An oriented matroid can be also defined by giving a sign to its bases. In the following are reported some definitions, needed to understand how to construct a basis orientation of a given oriented matroid, which becomes characterized in terms of signed bases, as shown in [32] and [34].

**Definition 25** The basis signature of an oriented matroid is called *chirotope*.

**Definition 26** Let  $\mathcal{M}$  be an oriented matroid on a set  $E$  with signed circuits  $C$ . The *bases* of  $\mathcal{M}$  are those maximal subsets of  $E$  that do not contain any circuit, i. e. they are the bases of  $\underline{\mathcal{M}}$ .

**Definition 27** A *basis orientation* of an oriented matroid  $\mathcal{M}$  is a mapping  $\chi$  of the set of ordered bases of  $\mathcal{M}$  to  $\{-1, 1\}$  such that

- 1)  $\chi$  is alternating;
- 2) for each two ordered bases of  $\mathcal{M}$  of the form  $(a, x_2, \dots, x_r)$  and  $(b, x_2, \dots, x_r)$ ,  $a \neq b$ , it holds that

$$\chi(b, x_2, \dots, x_r) = -C(a)C(b)\chi(a, x_2, \dots, x_r),$$

where  $C$  is one of the two opposite signed circuits of  $\mathcal{M}$  in the set  $(a, b, x_2, \dots, x_r)$ .

Condition 2) in Definition 27 is also known as *pivoting property*.

Las Vergnas [32] and [34] has proved that every oriented matroid  $\mathcal{M}$  has exactly two basis orientations, which are opposite. He also showed that if  $\chi$  is a basis orientation of  $\mathcal{M}$ , then  $\mathcal{M}$  is uniquely determined by  $\underline{\mathcal{M}}$  and  $\chi$ .

The pivoting property 2) in Definition 27 can be rewritten also as follows.

**Definition 28** A *basis orientation*  $\chi$  of an oriented matroid  $\mathcal{M}$  is such that

- 2\*) for each two ordered bases of  $\mathcal{M}$  of the form  $(a, x_2, \dots, x_r)$  and  $(b, x_2, \dots, x_r)$ ,  $a \neq b$ , it holds that

$$\chi(b, x_2, \dots, x_r) = D(a)D(b)\chi(a, x_2, \dots, x_r),$$

where  $D$  is one of the two opposite signed cocircuits complementary to the hyperplane spanned by  $\{x_2, \dots, x_r\}$  in  $\mathcal{M}$ .

Conditions 2 and 2\* of Definitions 27 and 28, respectively, are equivalent for a map  $\chi$ , if  $\mathcal{M}$  is an oriented matroid.

**Definition 29 (Chirotope axioms)** Let  $E$  be a finite set and let  $r \geq 1$  be an integer. A *chirotope* of rank  $r$  is a mapping  $\chi: E^r \rightarrow \{-1, 0, 1\}$  satisfying the following three properties:

- 1)  $\chi$  is not identically zero;

2)  $\chi$  is alternating, i. e.

$$\chi(x_{\sigma_1}, \dots, x_{\sigma_r}) = \text{sign}(\sigma)\chi(x_1, \dots, x_r),$$

for each permutation  $\sigma$  and each  $x_1, \dots, x_r \in E$ ;

3) for all  $x_1, \dots, x_r, y_1, \dots, y_r \in E$  such that for  $i = 1, \dots, r$ ,  $\chi_1 \cdot \chi_2 \geq 0$ , where

$$\chi_1 = \chi(y_i, x_2, \dots, x_r),$$

$$\chi_2 = \chi(y_1, \dots, y_{i-1}, x_1, y_{i+1}, \dots, y_r),$$

it holds that

$$\chi(x_1, \dots, x_r) \cdot \chi(y_1, \dots, y_r) \geq 0.$$

J. Lawrence [18] proved the following result.

**Theorem 30** *Let  $E$  be a set and let  $r \geq 1$  be an integer. Then, a mapping  $\chi: E^r \rightarrow \{-1, 0, 1\}$  is a basis orientation of an oriented matroid of rank  $r$  on  $E$  if and only if it is a chirotope.*

**Vectors and Covectors**

The concept of vectors and covectors for oriented matroids has been introduced in 1978 by Bland and Las Vergnas [5].

**Definition 31** A vector of an oriented matroid is any composition of circuits.

A covector of a vector of the dual oriented matroid, i. e. any composition of cocircuits.

The set of vectors  $\mathcal{V}$  of an oriented matroid  $\mathcal{M}$  can be viewed as partially ordered set. The partial order ' $\leq$ ' is given by

$$Y \leq X \quad \text{if } Y \text{ is a restriction of } X.$$

$(\mathcal{V}, \leq)$  is a pure ordered set of rank  $\rho^* = \rho(\mathcal{M}^*)$ . It has a unique minimal element 0 and its atoms (covering 0) are the circuits of  $\mathcal{M}$ . Note that all above definitions and properties of vectors can be easily dualized for covectors.

The formal characterization of the set of vectors of an oriented matroid is contained in the following theorem due to Edmonds and A. Mandel in 1982 [14].

**Theorem 32 (Vectors axioms)** *A collection  $\mathcal{V}$  of signed subsets of a set  $E$  is the set of vectors of an oriented matroid if and only if the following properties hold:*

- 1)  $\emptyset \in \mathcal{V}$ .
- 2) *symmetry:*  $\mathcal{V} = -\mathcal{V}$ ;
- 3) *composition:*  $\forall X, Y \in \mathcal{V}, X \text{ circ } Y \in \mathcal{V}$ ;
- 4) *strong vector elimination:*  $\forall X, Y \in \mathcal{V}, a \in X^+ \cap Y^-$  and  $b \in (\underline{X} \setminus \underline{Y}) \cup (\underline{Y} \setminus \underline{X}) \cup (X^+ \cap Y^+) \cup (X^- \cap Y^-)$ , there exists  $Z \in \mathcal{V}$  such that
  - i)  $Z^+ \subseteq (X^+ \cup Y^+) \setminus \{a\}$ ;
  - ii)  $Z^- \subseteq (X^- \cup Y^-) \setminus \{a\}$ ;
  - iii)  $b \in \underline{Z}$ .

In Theorem 32, condition 3) can be replaced by one of the following two conditions:

- 3') *vector elimination:*  $\forall X, Y \in \mathcal{V}$  and  $a \in X^+ \cap Y^-$ , there exists  $Z \in \mathcal{V}$  such that
  - i)  $Z^+ \subseteq (X^+ \cup Y^+) \setminus \{a\}$ ;
  - ii)  $Z^- \subseteq (X^- \cup Y^-) \setminus \{a\}$ ;
  - iii)  $(\underline{X} \setminus \underline{Y}) \cup (\underline{Y} \setminus \underline{X}) \cup (X^+ \cap Y^+) \cup (X^- \cap Y^-) \subseteq \underline{Z}$ .
- 3) *Y-approximation of X:*  $\forall X, Y \in \mathcal{V}$  with  $\underline{Y} \subseteq \underline{X}$  and  $X^+ \cap Y^- \neq \emptyset$ , there is a proper restriction  $Z$  of  $X$  such that
  - i)  $Z \in \mathcal{V}$ ;
  - ii)  $(X^+ \setminus Y^-) \cup (X^- \setminus Y^+) \subseteq \underline{Z}$

The oriented matroid operations of deletion and contraction, and the duality concept can be formulated in terms of vectors as formalized in the following two propositions.

**Proposition 33** *Let  $\mathcal{M}$  be an oriented matroid on  $E$  with set of circuits  $C$  and set of vectors  $\mathcal{V}$ , and let  $A \subseteq E$ .*

- *The set of vectors of the deletion matroid  $\mathcal{M} \setminus A$  is the set*

$$\mathcal{V} \setminus A = \{X \in \mathcal{V} : \underline{X} \cap A = \emptyset\}.$$

- *The set of vectors of the contraction matroid  $\mathcal{M}/A$  is the set*

$$\mathcal{V}/A = \{X \setminus A : X \in \mathcal{V}\}.$$

**Proposition 34** *Let  $\mathcal{M}$  be an oriented matroid on  $E$  with set of circuits  $C$  and set of vectors  $\mathcal{V}$ . Then the set of vectors of its dual matroid  $\mathcal{M}^*$  is the set  $\mathcal{L} = \{Y \in \{+, -, 0\}^E : X \perp Y, \forall X \in C\} = \{Y \in \{+, -, 0\}^E : X \perp Y, \forall X \in \mathcal{V}\}$ .*

**General Topics**

This Section is devoted to showing how the oriented matroids collocate in both pure and applied mathematics and how their four axioms systems arise from the following four topics:

- directed graphs;
- orthogonal pairs of real vector subspaces;
- point configurations and convex polytopes;
- real hyperplane arrangements.

**Directed Graphs**

Let  $D = (V, E)$  be a digraph and let  $C$  be the set of its simple cycles. Each cycle  $c \in C$  is associated with an orientation, i. e. each of them consists of some forward (positive) edges and some backward (negative) edges. Therefore, any  $c \in C$  can be viewed as a signed subset of  $E$  with positive and negative parts. A signed subset of  $E$  deriving from a cycle  $c \in C$  is called a *signed circuit* of  $D$  and all signed circuits of  $D$  form the collection

$$C = \{X = (X^+, X^-) : X \text{ a signed circuit of } D\} .$$

The oriented matroid  $\mathcal{M} = \mathcal{M}_D$  of  $D$ , also denoted by  $\mathcal{M} = \mathcal{M}(E)$ , is given by the pair  $(E, C)$ .

For a digraph  $D$  it is also possible to define the set of its signed cocircuits as follows. Let  $V = (V_1, V_2)$  be a *minimal cut* of  $D$ , i. e. a partition of the nodes of  $D$  such that the removing of the edges connecting elements in  $V_1$  to elements in  $V_2$  increases by one the number of components of the underlying undirected graph. Let  $Y^+$  be the set of edges in  $D$  from  $V_1$  to  $V_2$  and  $Y^-$  be the set of edges from  $V_2$  to  $V_1$ , then the sets  $Y = (Y^+, Y^-)$  are signed sets called *signed cocircuits* of  $D$ , which form the collection

$$C^* = \left\{ Y = (Y^+, Y^-) : \begin{array}{l} Y \text{ a signed} \\ \text{cocircuit of } D \end{array} \right\} ,$$

where  $C^*$  provides the collection of circuits of the dual oriented matroid of  $\mathcal{M}_D$ .

It is quite easy to show that the digraph  $D$  satisfies the properties 1)–4) of circuit axioms expressed by Definition 9 and that all properties of  $D$  are reflected in  $C$  and  $C^*$ . For example, if  $D$  does not contain any oriented cycle, then  $C$  will contain no positive circuit, i. e. the matroid corresponding to  $D$  will be an acyclic oriented matroid.

**Real Vectors Spaces**

In this Section the two most important ways to relate oriented matroids to real vector spaces are considered: point configurations and hyperplane arrangements.

**Vector Configurations**

Generally speaking, given an arbitrary field  $F$  and a finite set of vectors that spans a vector space of dimension  $r$  over  $F$ , the minimal linear dependences generate the circuits of a matroid of rank  $r$ . In order to get an oriented matroid, the field  $F$  must be ordered. In more detail, given a finite set  $E = \{v_1, \dots, v_n\}$  of vectors that spans a vector space of dimension  $r$  over an ordered field  $\{v_1, \dots, v_n\} \subseteq \mathbf{R}^r$ , then a minimal linear dependence is such that

$$\sum_{i=1}^n \lambda_i v_i = 0 ,$$

with  $\lambda_i \in \mathbf{R}$  and the circuits of the associated oriented matroid  $\mathcal{M} = (E, C)$  of a vector configuration  $E$  are the sets  $X = (X^+, X^-)$  such that

$$X^+ := \{i : \lambda_i > 0\}, \quad X^- := \{i : \lambda_i < 0\}$$

for all the minimal dependences among the vectors  $v_i$ .

The bases of the matroid corresponding to a vector configuration  $E$  are the subsets of  $E$  that form vector space bases, i. e. all subsets  $\{v_{i_1}, \dots, v_{i_r}\}$  of  $E$  such that  $\det(\{v_{i_1}, \dots, v_{i_r}\}) \neq 0$ .

For a vector configuration over the real field  $\mathbf{R}$ , let consider the signs of the determinants of ordered  $r$ -subsets of  $\{v_1, \dots, v_n\}$ , then the basis orientation or chirotope of the vector configuration is defined as

$$\chi(i_1, \dots, i_r) := \text{sign } \det\{v_{i_1}, \dots, v_{i_r}\} ,$$

where  $\chi(i_1, \dots, i_r) \in \{+, -, 0\}$ .  $\chi$  is an asymmetric function and satisfies the properties 1)–3) of chirotope axioms expressed in Definition 29.

**Point Configurations**

In the following, starting from the observation that every vector configuration in  $\mathbf{R}^r \setminus \{0\}$  corresponds to an affine point configuration in an  $(r - 1)$ -dimensional affine space, it will be showed how any point configuration in a real affine space leads to an acyclic oriented matroid. In fact, after choosing a linear form  $l_0(v_i) \neq 0$  for all  $i$  it is possible to define an  $(r - 1)$ -dimensional affine space as

$$\mathcal{A}^{r-1} := \{x \in \mathbf{R}^r : l_0(x) = 1\} ,$$

and to associate with each vector  $v_i$  the point  $1/l_0(v_i)v_i \in \mathcal{A}^{r-1}$ . Vectors  $v_i$  with  $l_0(v_i) < 0$  correspond to points called ‘points with negative weight’. If the given vector configuration does not contain any positive linear dependences, i. e.

$$\sum_i \lambda_i v_i = 0, \quad \lambda_i \geq 0,$$

then it is possible to choose  $l_0$  such that  $l_0(v_i) > 0$  for all  $i$ . This corresponds to the situation where the oriented matroid is acyclic, which can be always achieved by simply replacing some of the vectors  $v_i$  by their negatives. The circuits of the corresponding acyclic oriented matroid are given by the signs of the coefficients in the minimal affine dependences ( $\sum_i \lambda_i v_i = 0, \lambda_i \geq 0$ ). For example, the vertices of a complex polytope describe an acyclic oriented matroid.

The sign patterns of arbitrary (possibly non minimal) affine dependences can be derived from the circuits by compositions as follows. Given two signed sets  $X$  and  $Y$ ,

$$X \circ Y = (X^+ \cup (Y^+ \setminus X^-), X^- \cup (Y^- \setminus X^+)).$$

The signed sets so obtained are called *vectors* of the oriented matroid.

### Hyperplane Arrangements.

A real hyperplane arrangement  $\mathcal{H} = \{H_1, \dots, H_n\}$  is a finite set of hyperplanes through the origin in  $\mathbf{R}^r$ . Since every hyperplane is defined by giving a linear function  $l_i(x) = \sum_{j=1}^r a_{ij}x_j$ , any hyperplane can be defined as  $H_i = \{x \in \mathbf{R}^r: l_i(x) = 0\}$ . Since  $l_i$  can be viewed as vectors in the dual space  $(\mathbf{R}^r)^*$ , they form a vector configuration in  $(\mathbf{R}^r)^*$ , which determines an oriented matroid. In fact, once chosen the vectors  $l_i$ , a positive side  $H_i^+ = \{x \in \mathbf{R}^r: l_i(x) \geq 0\}$  of  $H_i$  is distinguished and the oriented matroid corresponds to the arrangement of halfspaces  $\{H_i^+: 1 \leq i \leq n\}$  in  $\mathbf{R}^r$ .

As showed below in Theorem 36, not only every real arrangement of hyperplanes gives rise to an oriented matroid, but the inverse is also ‘nearly’ true.

### Topological Representation Theorem

In [15] Folkman and Lawrence showed that each oriented matroid has a pseudosphere representation. This

property, expressed in the so called *topological representation theorem*, is a generalization of the hyperplane arrangement model to arbitrary oriented matroids. In this Section the topological representation theorem will be treated superficially, giving only its meaning and some of the most important consequences that it implies. For more details about this fundamental result in the theory of oriented matroids, see [2].

Let  $E$  be a finite, parallel-free, spanning set of nonzero vectors in  $\mathbf{R}^{r+1}$ , and let  $C \subseteq \{+, -, 0\}^E$  be the set of signed circuits of the corresponding oriented matroid. For each  $e \in E$ , let  $S_e = \{x \in \mathbf{R}^{r+1}: \langle x, e \rangle = 0, \|x\| = 1\}$ . The positive and negative parts of  $S_e$  are respectively  $S_e^+ = \{x \in \mathbf{R}^{r+1}: \langle x, e \rangle \geq 0, \|x\| = 1\}$  and  $S_e^- = -S_e^+$ . It is easy to prove that

- 1)  $S_e^+$  and  $S_e^-$  are subsets of the unit  $r$ -sphere  $S^r = \{x \in \mathbf{R}^{r+1}: \|x\| = 1\}$ ;
- 2)  $S_e$  is a linear  $(r - 1)$ -sphere;
- 3)  $S_e^+$  and  $S_e^-$  are the two closed hemispheres of  $S_e$ , which is the intersection of  $S^r$  and the hyperplane orthogonal to  $e$ , so that the arrangement of spheres  $\mathcal{A} = (S_e)_{e \in E}$  is equivalent to an arrangement of hyperplane discussed above.

In fact, once established the arrangement of spheres  $\mathcal{A}$  and distributed the signs  $+$  and  $-$  to the hemispheres, such signed arrangements of  $(r - 1)$ -spheres in  $S^r$  identify an oriented matroid of rank  $r + 1$ . In more details, the signed circuits  $C$  in this case are the vectors  $X \in \{+, -, 0\}^E$  such that

- $c_1)$   $\cup_{e \in \underline{X}} S_e^{X_e} = S^r$ , where  $S_e^{X_e}$  is either  $S_e^+$  or  $S_e^-$ ;
- $c_2)$   $\underline{X} = \{e \in E: X_e \neq 0\}$  is minimal with property  $c_1$ .

A subset  $S$  of  $S^r$  is called a *pseudosphere* if there exists a homomorphism  $h: S^r \rightarrow S^r$  such that  $S = h(S^{r-1})$ , where  $S^{r-1} = \{x \in S^r: x_{r+1} = 0\}$ .

**Definition 35** An arrangement of pseudospheres  $\mathcal{A} = (S_e)_{e \in E}$  is a finite set of pseudospheres  $S_e$  in  $S^r$  such that

- for  $A \subseteq E$  each  $S_A = \cap_{e \in A} S_e \neq \emptyset$ , is homeomorphic to a sphere of some dimension;
- for every  $e \in E$  and every nonempty intersection  $S_A$  such that  $S_A \not\subseteq S_e$ , the intersection  $S_A \cap S_e$  is a pseudosphere in  $S_A$  with sides  $S_A \cap S_e^+$  and  $S_A \cap S_e^-$ .

**Theorem 36 (Topological representation)** *Let  $\mathcal{A}$  be a signed arrangement of pseudospheres, and let  $C(\mathcal{A})$  be the family of the sign vectors  $X \in \{+, -, 0\}^E$  that satisfy  $c_1$  and  $c_2$ , then*

- tr<sub>1</sub>) if  $A = (S_e)_{e \in E}$  is a signed arrangement of pseudospheres in  $S^r$ , then  $C(A)$  is the family of circuits of an oriented matroid on  $E$  and whose rank is  $r + 1$ ;
- tr<sub>2</sub>) if  $(E, C)$  is an oriented matroid of rank  $r + 1$ , then there exists a signed arrangement of pseudospheres  $A$  in  $S^r$  such that  $C = C(A)$ ;
- tr<sub>3</sub>) given two signed arrangements  $A$  and  $A'$ , then  $C = C(A) = C = C(A')$  if and only if  $A' = h(A)$  for some self-homomorphism  $h$  of  $S^r$ .

**Corollary 37** *There is a 1-to-1 correspondence between arrangement of pseudospheres in  $S^r$  and oriented matroid of rank  $r + 1$ .*

## Conclusions

Starting from the 1950s, matroids and oriented matroids have had increasing interest. A huge number of scientific works have been published on those subjects and a large collection of matroid theorems and theoretical results exists.

This article has introduced the combinatorial theory of oriented matroids, providing their axiomatic definitions and their basic properties.

QR factorization; Rank revealing factorization;  
Complete orthogonal factorization

Triangularization is a process of reducing a square (rectangular) matrix into upper-triangular (upper-trapezoidal) form by applying a series of *elementary transformations*. There are basically two types of elementary transformations: orthogonal and nonorthogonal. Examples of nonorthogonal transformations include classical Gaussian transforms, and Gauss–Jordan transforms.

### Orthogonal Factorization

Here the matrix  $A \in \mathbf{R}^{m \times n}$  is reduced to an upper-trapezoidal form using a sequence of elementary orthogonal transformations (such as Householder or Givens transformations; see ► [QR factorization](#) for more details).

### Rank Revealing Factorizations

Orthogonal factorizations can also be used effectively for computing the *numerical rank* [2] of a matrix. The general idea is to identify the independent columns of the matrix and permute them to the left-hand side; i. e. find a permutation matrix  $\Pi$  such that

$$Q^T A \Pi = \begin{matrix} & r & n-r \\ \begin{matrix} r \\ m-r \end{matrix} & \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix} \end{matrix}, \quad (1)$$

where  $R_{11}$  is nonsingular, upper triangular and  $\|R_{22}\| < \epsilon$ . It is said that the  $\epsilon$ -rank of  $A$  is  $r$ . The following *QR factorization with column-pivoting* computes factorization in (1). Given  $A \in \mathbf{R}^{m \times n}$  with  $m \geq n$ , the following algorithm computes  $r = \text{rank}(A)$  by permuting columns while computing the QR factorization (see [2] for details).

```

for  $j = 1 : n$ 
     $c(j) = A(1 : m, j)^T A(1 : m, j)$ ;
end;
 $r = 0$ ;
find  $k$  s.t.  $c(k) = \max(c(1 : n))$ ;
     $t = c(k)$ ;
while  $t > \epsilon$ 
     $r = r + 1$ ;
    exchange columns  $i$  and  $k$ ;
    exchange  $c(k)$  and  $c(i)$ ;
     $v = \text{house}(A(r : m, r))$ ;
    Apply to rest of the columns;
    for  $i = r + 1 : n$ 
         $c(i) = c(i) - A(r, i)^2$ ;
    end;
    if  $r < n$ 
        find  $k$  such that
         $c(k) = \max(c(r + 1 : n))$ ;
         $t = c(k)$ ;
    else  $t = 0$ ;
end;
```

### Complete Orthogonal Factorization

Sometimes, it is desirable to reduce the matrix  $A \in \mathbf{R}^{m \times n}$  to the following form

$$Q^T A Z = \begin{pmatrix} T_{11} & 0 \\ 0 & 0 \end{pmatrix},$$

where  $T_{11} \in \mathbf{R}^{r \times r}$  is nonsingular and upper triangular. Such a factorization is rank revealing and the rank of  $A$  will be  $r$ . Such factorizations are very useful in rank-deficient optimization problems (such as rank-deficient least squares) [1].

The first step towards complete orthogonal factorization is to apply QR factorization with column pivoting. Thus,

$$Q^T A \Pi = \begin{pmatrix} R_{11} & R_{12} \\ 0 & 0 \end{pmatrix}.$$

Then apply a series of orthogonal transformations on the right-hand side so that  $R_{12}$  is zeroed. While  $R_{12}$  is being zeroed, values in  $R_{11}$  will change, and let us call the modified  $R_{11}$  as  $T_{11}$ . The only trick here is make sure that while  $R_{12}$  is being zeroed, zeros that are already in  $R_{11}$  are not disturbed.

Let us consider an example of a matrix  $A \in \mathbf{R}^{5 \times 6}$  whose rank is three. After the QR with column pivoting, let

$$Q^T A \Pi = \begin{pmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} & a_{16} \\ 0 & a_{22} & a_{23} & a_{24} & a_{25} & a_{26} \\ 0 & 0 & a_{33} & a_{34} & a_{35} & a_{36} \\ 0 & 0 & 0 & a_{44} & a_{45} & a_{46} \\ 0 & 0 & 0 & a_{54} & a_{55} & a_{56} \end{pmatrix},$$

where

$$\left\| \begin{pmatrix} a_{44} & a_{45} & a_{46} \\ a_{54} & a_{55} & a_{56} \end{pmatrix} \right\|_2 < \epsilon$$

and  $Q$  is orthogonal and  $\Pi$  is some permutation matrix. The following sequence of Givens transformations,

$$Q^T A \Pi G_{36}^3 G_{35}^3 G_{34}^3 G_{26}^2 G_{25}^2 G_{24}^2 G_{16}^1 G_{15}^1 G_{14}^1$$

will zero  $R_{12}$  without disturbing the zeros that are already present in  $R_{11}$ .

MCDM; ELECTRE; Outranking; Concordance; Discordance; Preference modeling

A classical problem in the field of *multiple criteria decision making* (MCDM) is to build a preference relation on a set of multi-attributed alternatives on the basis of preferences expressed on each attribute and ‘inter-attribute’ information such as weights. Based on this

preference relation (or, more generally, on various relations obtained following a robustness analysis) a recommendation is elaborated (e.g. exhibiting a subset likely to contain the ‘best’ alternatives).

A common way [20] to do so is to attach a number  $v(x)$  to each alternative  $x \in X$  and to declare that  $x$  is ‘at least as good as’  $y$  if and only if  $v(x) \geq v(y)$ . The number  $v(x)$  depends on the evaluations  $x_1, \dots, x_n$  of  $x$  on the  $n$  attributes and we have  $v(x) = V(x_1, \dots, x_n)$ . The most common form for  $V$  is an additive value function in which  $V(x_1, \dots, x_n) = \sum_{i=1}^n k_i v_i(x_i)$ ; in that case the task of the analyst reduces down to assessing the partial value functions  $v_i$  and the scaling constants  $k_i$ . The preference relation that is built using this *value function approach* is a *weak order*, i.e. a complete and transitive binary relation. Using such information it is not difficult, in general, to elaborate a recommendation. The definition of the aggregation function  $V$  may not always be simple however. Making all alternatives comparable in a ‘nice transitive way’ requires much information and, in particular, a detailed analysis of trade-offs between attributes.

*Outranking methods* (OMs) were first developed in France in the late 1960s following difficulties experienced with the value function approach in dealing with practical problems. They are closely associated with the name of B. Roy, who developed the well-known family of ELECTRE methods. A large part of the literature on OMs was written in French which has been prejudicial to their international diffusion; good accounts in English are [18,32,38,39,46,53,56,57], while detailed references in French include [24,31,41,47,48].

### Basic Ideas

As in the value function approach, OMs build a preference relation, usually called an *outranking relation*, among alternatives evaluated on several attributes. Roy defines an outranking relation as a binary relation  $S$  on the set  $X$  of alternatives such that  $xSy$  if, given what is known about the preferences of the decision-maker, the quality of the evaluations of the alternatives and the nature of the problem, there are enough arguments to decide that  $x$  is at least as good as  $y$ , while there is no essential reason to refute that statement.

In most OMs the outranking relation is built through a series of *pairwise comparisons* of the alter-

natives (this implies that these methods deal with *finite sets of the alternatives*; their underlying principles may however be adapted in order to deal with infinite sets [19]). Although pairwise comparisons can be done in many ways, the *concordance-discordance* principle is prevalent in most OMs (exceptions include [2,50]). It consists in declaring that an alternative  $x$  is at least as good as an alternative  $y(xSy)$  if:

- a *majority* of the attributes supports this assertion (*concordance condition*); and
- the opposition of the other attributes (the *minority*) is not ‘too strong’ (*nondiscordance condition*).

This principle is at variance with the ones underlying the value function approach. It rests on a ‘voting’ analogy and may be used without having recourse to a subtle analysis of trade-offs between attributes. It mainly uses *ordinal* considerations and has a strong *noncompensatory* flavor [3,11]. The application of this principle gives rise, in general, to binary relations which are neither complete (i.e. it is possible that  $\text{Not}(xSy)$  and  $\text{Not}(ySx)$ ) nor transitive (i.e. we may have  $xSy, ySz$  and  $\text{Not}(xSz)$ ). Exploiting an outranking relation in order to arrive at a recommendation is therefore not an easy task and calls for the application of specific techniques [41,53].

We briefly describe below ELECTRE I [35], which is the oldest and simplest OM before coming to some extensions and comments.

### ELECTRE I

Consider a finite set of alternatives  $X$  evaluated on a family  $N = \{1, \dots, n\}$  of attributes. A first step in the comparison of two alternatives  $x = (x_1, \dots, x_n)$  and  $y = (y_1, \dots, y_n)$  is to know how they compare on each attribute. ELECTRE I uses a traditional preference model for this purpose: a weak order (i.e. a complete and transitive binary relation)  $S_i$  is supposed to be defined on each  $i \in N$ ,  $x_i S_i y_i$  meaning that  $x$  is judged at least as good as  $y$  on attribute  $i$ . Dealing with a finite set, it is not restrictive (see [15]) to assume the existence of a real valued function  $g_i$  such that

$$x_i S_i y_i \Leftrightarrow g_i(x_i) \geq g_i(y_i).$$

Quite often in practice, numbers are used to evaluate the alternatives on the various attributes and the relations  $S_i$  stem from the comparison of these numbers [4].

In ELECTRE I, the analysis of the proposition  $xSy$  rests on the partition of the set  $N$  of attributes into a *concordant coalition*  $C(xSy) = \{j \in N: g_j(x_j) \geq g_j(y_j)\}$  and a *discordant coalition*  $D(xSy) = \{j \in N: g_j(x_j) < g_j(y_j)\}$ . The proposition  $xSy$  will be accepted if the concordant coalition  $C(xSy)$  is ‘sufficiently important’ (concordance condition) and if on any of the attributes in  $D(xSy)$  the ‘difference of preference’ in favor of  $y$  is not considered to be ‘large’ (condition of nondiscordance). In order to implement the concordance condition, a positive *weight*  $k_j$  is assigned to each attribute  $j \in N$  and the importance of a coalition is supposed to be represented by the sum of the weights of the attributes belonging to that coalition. Thus the concordance index  $c(x, y) = \sum_{j \in C(xSy)} k_j / \sum_{j \in N} k_j$  represents the relative importance of the coalition  $C(xSy)$  in the set  $N$  of all attributes; we have  $c(x, y) \in [0, 1]$ . Whether or not  $C(xSy)$  is ‘sufficiently important’ is then judged comparing  $c(x, y)$  to a *concordance level*  $s \in [1/2, 1]$ . It is worth noting that the partition of  $N$  into  $C(xSy)$  and  $D(xSy)$  and the computation of the concordance index  $c(x, y)$  rest on purely ordinal comparisons: altering the functions  $g_j$  without altering the binary relations  $S_j$  will not change the values of the concordance index. Suppose that  $c(x, y) \geq s$ . Concluding that  $xSy$  would give no power to the attributes in  $D(xSy)$ . If on any of these attributes the, positive, preference difference between  $y$  and  $x$  is ‘large’ there are good reasons to reject the proposition  $xSy$ ). The definition of ‘large’ preference differences is done in ELECTRE I via the definition of nonnegative *veto thresholds*  $v_j$  (which may vary with  $g_j$ ) on each attribute; a preference difference is declared ‘large’ as soon as  $g_j(y_j) - g_j(x_j) > v_j$ . It should be noticed that the implementation of the nondiscordance principle through the definition of veto thresholds  $v_j$  linked to a particular functions  $g_j$  is a matter of commodity only; what is in fact looked for is a subset of the asymmetric part of  $S_j$  corresponding to ‘large’ preference differences, which may be done independently of any numerical representation. In summary, we have in ELECTRE I:

$$\begin{aligned}
 &xSx \\
 &\Updownarrow \\
 &c(x, y) \geq s \\
 &\text{and} \\
 &g_j(y_j) - g_j(x_j) < v_j, \forall j \in D(xSy) .
 \end{aligned}$$

When  $s = 1$  (which amounts to requiring unanimity of the attributes in order to accept outranking) or  $v_j = 0$  for all  $j$  (implying that all positive preference differences are ‘large’), the outranking relation  $S$  is nothing but the so-called *dominance relation*  $\Delta$  defined by

$$x\Delta y \Leftrightarrow [x_j S_j y_j \text{ for all } j \in N] .$$

It is not difficult to see that it is always true that  $\Delta \subseteq S$ . An outranking relation may be usefully seen as an enrichment of the dominance relation  $\Delta$  in which unanimity of the attributes is not required and not all positive preference differences are considered ‘large’; decreasing the value of  $s$  and/or increasing the values of the  $v_j$  results in a richer but somewhat riskier outranking relation. Although, the dominance relation  $\Delta$  is clearly reflexive and transitive (but not complete), simple examples, inspired by *Condorcet’s paradox* [49], show that, in general,  $S$  is neither complete nor transitive when  $s < 1$  and  $v_j > 0$ .

It is important to note that in ELECTRE I, the weights  $k_j$  cannot be interpreted as substitution rates or *trade-offs*; they are thus fundamentally different from the scaling constants that are used in the *value function approach*. In line with the voting analogy underlying the concordance-discordance principle, it is useful to interpret  $k_j$  as the ‘number of votes’ given to attribute  $j$  (this number of votes being independent of the choice of the function  $g_j$ ), the concordance threshold  $s$  specifying a level of ‘qualified majority’.

ELECTRE I was originally designed to lead to ‘choice-type’ results. Since  $S$  may not be complete or transitive, the set  $\{x \in X: xSy \text{ for all } y \in X\}$  of *maximal alternatives* (in  $X$  given  $S$ ) can be empty. In order to overcome this difficulty, ELECTRE I determines the minimal (with respect to inclusion) set of alternatives not outranking each other such that all the alternatives outside of this set are outranked by at least one alternative from this set. Technically, this leads to the determination of the *kernel of the graph*  $(X, S)$  after the detection and elimination by reduction of possible circuits (a well-known result in graph theory proves the existence and unicity of kernels in graphs without circuits).

**Extensions**

Besides ELECTRE I, many other OMs have been proposed in the literature [13,14,23,33,36,40,42,45,58].

They mainly differ on:

- the type of result that is looked for (e. g. one may wish to use  $S$  to rank order alternatives or to sort them into pre-defined categories);
- the way the outranking relation is built. It is indeed possible to implement the concordance-discordance principle in various ways (e. g. allowing for synergy effects in  $D(xSy)$ ). Moreover, varying the values of  $s$  and of the thresholds  $v_j$  lead to several different relations  $S$ ; such variations are incorporated in methods which use several nested outranking relations (as in [40,42]) or a *fuzzy outranking relation* in which a ‘credibility’ is attached to each arc in the graph  $(X, S)$  as in ([13,14,36,58]) (on the notion of fuzzy outranking relation see ([17,28]));
- the way alternatives are compared on each attribute. In ELECTRE I it is postulated that alternatives can be compared on each attribute according to a weak order. This traditional preference model may be inappropriate considering the inevitable elements of imprecision, uncertainty and inaccurate determination entering the evaluations of the alternatives. Indifference on each attribute may not be fully transitive; moreover there may exist cases in which the transition from indifference to strict preference is not without ambiguity giving rise to models involving ‘weak preference’ relations (such models involve *indifference* and/or *preference thresholds* [34,37,51,52]).

The following table summarizes the main characteristics of the existing ELECTRE methods and might help in choosing an appropriate OM. See [41] and [56] for a complete description of these methods and of many others in a similar vein, in particular the TACTIC method [54] and the family of PROMETHEE methods [13,14].

### Practical Considerations

We give here some indications on how to give a value to the parameters used in ELECTRE I: weights  $k_j$ , veto thresholds  $v_j$  and the concordance threshold  $s$  (they may be transposed to all ELECTRE methods; for a more detailed account see [24,26,41,48] and for an alternative approach [21]). Before doing so, it is important to note that the underlying philosophy of OMs is not to describe as accurately as possible the preferences of

Outranking Methods, Table 1

Main characteristics of existing ELECTRE methods; adapted from [41]

Electre methods	Preference model on each attribute	Use of weights	No. of outrank. rel. used	Type of result
I [35]	trad.	yes	1	Choice
IS [45]	nontrad.	yes	1	Choice
II [40]	trad.	yes	2	Ranking (partial)
III [36]	nontrad.	yes	1 (fuzzy)	Ranking (partial)
IV [42]	nontrad.	no	up to 5	Ranking (partial)
Tri [41] [58]	nontrad.	yes	1	Assignm. into predef. categ.

a decision-maker. This decision-maker is often a remote abstract entity (the state, the region, the firm); when this is not the case he/she is frequently not very accessible and his/her preferences may be only very partially structured. Searching for the ‘true’ values of  $k_j$ ,  $v_j$  or  $s$  makes little sense under these conditions. The *concordance-discordance* principle is best seen as a useful and easily understandable convention to help structuring preferences. The ‘assessment’ of the parameters of the method should therefore aim at transforming what appears to be the stable basic judgements of the actors to be helped into numerical values. Needless to say that, under these conditions, the elaboration of a recommendation should be preceded by a thorough robustness analysis.

In order to give a numerical value to the weights  $k_j$  it is useful to envisage imaginary but realistic alternatives combining plausible evaluations on the various attributes. Consider two such alternatives  $x$  and  $y$  such that  $g_j(x_j) > g_j(y_j)$  for all  $j \in J \subset N$  and  $g_i(y_i) > g_i(x_i)$  for all  $i \notin J$ . If the differences between the evaluations of  $x$  and  $y$  have been chosen in such a way as to avoid ‘large’ preference differences and if it may be agreed that  $x$  is at least as good as  $y$  while  $y$  is not at least as good as  $x$ , we

can then infer that  $\sum_{j \in J} k_j \geq s$  and  $\sum_{i \notin J} k_i < s$ , supposing without loss of generality that  $\sum_{j \in N} k_j = 1$ . Combining several questions of this type gives rise to a polyhedron of plausible values for  $k_j$  and  $s$  to be explored during the robustness analysis, see [43,44]. It should be noted here that the precise numerical values of  $k_j$  and  $s$  are irrelevant in ELECTRE I as long as they imply a similar partition of subsets of attributes into ‘winning’ coalitions (for which the sum of the weights exceed the concordance threshold) and ‘losing’ ones.

Consider now two imaginary alternatives  $x$  and  $y$  such that  $g_j(x_j) > g_j(y_j)$  for all  $j \in N \setminus \{i\}$  and choose  $g_i(y_i)$  to be one of the best evaluations on attribute  $i$  and  $g_i(x_i)$  to be one of the worst. We have  $D(xSy) = \{i\}$ . If it can be accepted that  $xSy$ , then it is clear that no veto power should be conferred to attribute  $i$ , which amount to setting  $v_i$  to an arbitrarily large number. If not, attribute  $i$  has a veto power; in order to give a value to  $v_i$  one can then increase  $g_i(x_i)$  and/or decrease  $g_i(y_i)$  till  $xSy$  is accepted. A slightly larger value than the difference  $g_i(y_i) - g_i(x_i)$  leading to the acceptance of  $xSy$  gives a plausible value for  $v_i$  (note that before choosing a constant value of  $v_i$  it should be checked that the maximum difference  $g_i(y_i) - g_i(x_i)$  on attribute  $i$  compatible with  $xSy$  does not vary along the scale of  $g_i$ ; when this is the case variable thresholds can be easily used).

### Theoretical Appraisal

OMs have often been criticized for their lack of axiomatic foundations; ELECTRE I was proposed on a more or less ad hoc basis and subsequent methods aimed at extending it. The situation has changed dramatically in recent years giving rise to a variety of studies investigating the foundations of these methods. In particular, it is worth mentioning that:

- the links between concordance-discordance principle leading to possibly intransitive and incomplete outranking relations and classical aggregation problems in social choice theory (exemplified by Arrow’s impossibility theorem; see [49]) has been studied in depth [1,5,27];
- outranking methods may be axiomatised in more or less the same way as the various instances of the value function approach (see [3,10,11,30,54]), the axioms emphasizing the ‘ordinal’ and ‘noncompensatory’ features of the methods;
- the structural properties of outranking relations have been studied in depth [7], this problem having strong links with the classical problems of the construction of voting paradoxes [25] and the binary choice probabilities problem [16];
- various ways of exploiting outranking relations have been carefully analyzed and/or axiomatized see [6,8,9,12,22,29,55].

This literature on the foundations of OMs while still being in its early stages has already greatly contributed to a better understanding of these methods and their underlying hypotheses.

### Practical Applications

OMs have been applied in real-world studies since their creation. It is impossible to give here a complete list of applications and references. We only mention a few significant applications in various fields (detailed bibliographical indications may be found in [41]).

#### Environment

Forestry management (Canada), Nuclear waste management (Belgium), Pollution prevention and control (France), Solid waste management (Finland, Greece), Water resource management (France, Hungary, USA);

#### Finance

Allocation of grants (Belgium), Analysis of the international diversification of portfolios (Canada), Equitable burden sharing in international institutions (Belgium), Investment planning (France), Portfolio management (Canada);

#### Health

Computer-aided diagnosis (France), Epidemiology (France), Identification of bacteria (Belgium), Management of hospitals (Canada);

#### Location

Airports (Canada, the Netherlands), High voltage electric lines (France, Canada), Schools (France), Thermal power plants (Algeria);

## Transportation

Choice of a highway route (France), Planning the renovation of metro stations (France), Selection of suburban metro extensions projects (France);

## Miscellaneous

Analysis of tenders (France, Portugal), Choice between forecasting models (Belgium), Choice of a marketing strategy (France), Inventory management (France), Production planning in a job-shop (Canada), Promotion of navy officers (Portugal), Regional planning (The Netherlands).

Parameter estimation; Optimization; Approximation

Consider a set of experimental observations represented by a vector  $b \in \mathbf{R}^n$ . The goal is to estimate a set of parameters  $x \in \mathbf{R}^m$  with the help of a matrix of independent input conditions represented by  $A \in \mathbf{R}^{n \times m}$ . In other words, one wishes to express  $b$  in terms of  $A$ . However, one may have a larger number of experimental observations than parameters to be estimated, i. e., it may be the case that  $n \gg m$ . The problem described above is a typical estimation problem which gives rise to an overdetermined system of linear equations:

$$Ax = b. \quad (1)$$

In general one cannot expect to obtain a vector  $x$  which satisfies (1) even if  $A$  has  $m$  linearly independent columns. This feature of the problem leads to the search for a vector  $x$  which makes  $Ax$  as close as possible to  $b$ . The closeness is measured in some suitable norm which is usually either the 2-norm, or the 1-norm, or the  $\infty$ -norm. The most common is the 2-norm which yields the well-known linear *least squares problem*:

$$\min_x \|Ax - b\|_2 = \sqrt{(Ax - b)^\top (Ax - b)}. \quad (2)$$

The linear least squares approach is usually preferred because it leads to a simpler problem. More precisely, it admits a closed-form solution which can be obtained by solving the linear system of equations:

$$A^\top Ax = 2A^\top b. \quad (3)$$

Since  $A^\top A$  is a symmetric positive (semi)definite matrix (it is positive definite when  $A$  has  $m$  linearly independent columns, in which case the solution is unique) it can be decomposed in the form of  $LDL^\top$  (or, Choleski factorization) where  $L$  is unit lower triangular, and  $D$  is diagonal. The factored form can then be used to solve (3) which has always a solution. However, this method is only reliable when  $A$  is a well-conditioned matrix. A more numerically stable way to solve (3) is to use an orthogonal factorization (e. g., QR) combined with a pivoting strategy. A detailed treatment of the linear least squares problem can be found in [8].

In some instances, the set of observations includes gross inaccuracies or wild points. In such cases, it may be preferable to use the 1-norm which leads to the following estimation problem

$$\min_x \|Ax - b\|_1 = \sum_{i=1}^n |(Ax - b)_i|, \quad (4)$$

where  $(Ax - b)_i$  is used to represent the  $i$ th component of  $Ax - b$ . The function in (4) is not differentiable at those points where  $(Ax - b)_i = 0$  for some  $i \in \{1, \dots, n\}$ . The problem is commonly referred to as the  $\ell_1$  *estimation problem*. The parameter values obtained from the minimization problem (4) will not be as adversely affected by the presence of wild points as the estimates obtained using (3). On the other hand, in contrast to the linear least squares problem (4) is a combinatorial optimization problem because it can be shown that a minimizing point  $x$  has the property that some of the components of the *residual vector*  $Ax - b$  are equal to zero, some are positive and some are negative (this property is what makes this approach immune to wild points). Hence, if one had access to the information as to which components are zero, positive, and negative, respectively, one could find a minimizing point  $x$  by solving the following linear program:

$$\begin{cases} \min_x & \sum_{i \in \mathcal{A}^c} s_i^* (Ax - b)_i \\ \text{s.t.} & (Ax - b)_i = 0, \quad \forall i \in \mathcal{A}, \end{cases}$$

where  $\mathcal{A}$  is the set of indices corresponding to zero components of  $Ax - b$ ,  $\mathcal{A}^c$  is its complement with respect to  $\{1, \dots, n\}$ , and  $s_i^*$  is the *sign function* which assumes the value  $+1$  for positive residuals, and  $-1$  for negative residuals, respectively.

Unfortunately, one has a priori no idea about  $s_i^*$  and  $A$ . An alternative way to pose (4) leads to the following problem:

$$\begin{cases} \min_{\substack{c \geq 0 \\ d \geq 0 \\ u \geq 0 \\ v \geq 0}} \sum_{i=1}^n (u_i + v_i) \\ \text{s.t.} \quad u - v + A(c - d) = b, \end{cases}$$

with  $(Ax - b)_i = u_i + v_i$  and  $x_j = c_j - d_j$ . The equivalence of (4) and the above linear program is discussed in [17]. The most successful attempts at solving (4) were based on the above reformulation and its dual problem. Notably, I. Barrodale and F.D.K. Roberts [4] specialized the simplex algorithm of linear programming to the above formulation by taking advantage of the complementarity between the  $u_j$  and  $v_j$  variables in the pivoting process. R.D. Armstrong, E.L. Frome and D.S. Kung [1] developed a revised simplex algorithm for the linear programming formulation of the problem. A different algorithm which aims at minimizing the nondifferentiable 1-norm function (4) was given in [6].

A more recent idea for solving the  $\ell_1$  estimation problem was given in [12]. This idea is quite different from those mentioned above in that it replaces the original function with a once continuously differentiable function, and leads to the following problem:

$$\min_x \sum_{i=1}^n \rho((Ax - b)_i), \tag{5}$$

where

$$\rho(t) = \begin{cases} \frac{t^2}{2\gamma} & \text{if } |t| \leq \gamma, \\ |t| - \frac{\gamma}{2} & \text{if } |t| > \gamma, \end{cases} \tag{6}$$

with  $t$  being a knock-off variable, and  $\gamma$  a positive scalar. This function is known as *Huber's M-estimator function* ([9]) in the statistics literature as it was introduced by P.J. Huber as a *robust estimator* in the face of *inaccuracies in the observations*. K. Madsen and H.B. Nielsen observed that they can obtain a solution (4) by repeatedly solving (5) for decreasing values  $\gamma$  tending to zero. They were also able to avoid the potentially ill-conditioning effects of driving  $\gamma$  to zero.

As far as obtaining a set of parameters 'immune' to grossly inaccurate observations, one has the option to

use the 1-norm or (4), or the Huber problem (5). It is interesting that Huber's problem was used as a subproblem to solve (4). The relationship between problems (4) and (5) were further explored in [13] and [11].

Another popular choice for the solution of overdetermined systems of linear equations is to compute a solution to minimize the  $\infty$ -norm of the residual vector. This approach yields the problem

$$\min_x \max_i |(Ax - b)_i| . \tag{7}$$

The problem is commonly known as the *Chebyshev problem*. Here, one faces again a problem of a combinatorial nature as it can be proved that a solution to (7) has certain residual values equal to the maximum in absolute value, and others smaller than this value in modulus, respectively. This partition of the residuals at a minimizing point is obviously unknown. Hence, one must resort to some algorithm to compute a solution to (7) much the same way as in the case of (4). Here, again there exist approaches based on minimizing the nondifferentiable function in (7) (nondifferentiable at points where at least two residuals attain the maximum value in modulus). The most notable of such methods are that of Bartels–Golub [7], Bartels–Conn–Charalambous [5]. There exist also methods based on the linear programming formulation which is given as follows in [17]:

$$\begin{cases} \min_{x,z} z \\ \text{s.t.} \quad -z \leq (Ax - b)_i \leq z, \quad \forall i = 1, \dots, n. \end{cases}$$

Some of the approaches based on linear programming favored the above primal formulation for use in a penalty function algorithm [10,15]. Some others used the dual formulation:

$$\begin{cases} \min_{\substack{v \geq 0 \\ w \geq 0}} (v - w)^T b \\ \text{s.t.} \quad A^T(v - w) = 0 \\ e^T(v + w) = 1, \end{cases}$$

where  $e$  represents a vector of all ones. Among these approaches, the most successful is the simplex adaptation of [2].

A survey of the use of the 2-norm, 1-norm and  $\infty$ -norm criteria in linear regression in statistics is given in [14], but contains only developments until 1981.

Some of the algorithms mentioned above are available as software packages. In particular, the 1-norm algorithms of Barrodale–Roberts and of Bartels–Conn–Sinclair are available in the NAG (Numerical Algorithms Group) software library. The 1-norm and Huber algorithms of Madsen–Nielsen are available from the authors. The Chebyshev algorithm of Barrodale–Phillips is available in the NAG library, and also in the ACM collection [3]. The Chebyshev algorithm of Pinar–Elhedhli is available from the authors. A copy of the Bartels–Golub algorithm for the Chebyshev problem can be obtained from [16].

Optimization; Annealing; Hierarchical; Smoothing;  
Macrostate; Statistical mechanics; Trajectory diagrams

The packet annealing method [1,7,9] was motivated and developed specifically for thermodynamic global minimization problems such as those encountered in protein structure prediction [3], but it may be applicable to other global minimization problems as well. It uses the intrinsic variable-scale coarse-grained hierarchical structure [11] of the potential energy (objective function) landscape to guide a deterministic search to the global minimum. The method is similar to simulated annealing [4] in that it assumes that each point in the search space, parameterized by multidimensional vector  $R$ , corresponds to a conformation of a physical system whose motion is governed by the potential energy  $V(R)$ . According to statistical mechanics, at temperature  $T$ , the conformational probability distribution is the Gibbs-Boltzmann distribution [5],

$$p_B(T; R) = \frac{\exp[-\beta V(R)]}{\int \exp[-\beta V(R)] dR},$$

where  $\beta \equiv 1/k_B T$  is the inverse temperature ( $k_B$  is Boltzmann's constant which relates the energy and temperature scales). As  $T \rightarrow 0$ , all probability is concentrated in the vicinity of the global minimum,  $R_g$ , of  $V$ . Simulated annealing attempts to find  $R_g$  by following  $p_B(\beta; R)$  as the system is cooled using the Metropolis [6] or other (e. g., molecular dynamics) search procedures to simultaneously search the entire space. In contrast, during cooling, packet annealing recursively subdivides conformation space into a sequence of compact macrostate regions which are separated from each other by potential energy barriers that are large compared to the current  $T$ . By this means, the space is subdivided into a growing number of smaller and smaller macrostates which are searched in parallel. The hierarchical relationships between the macrostates are represented in tree-like macrostate trajectory diagrams which describe the thermodynamic properties of the macrostates as functions of temperature. This allows computational effort to be focussed on the most promising subregions of conformation space. A key feature is that both the characteristic energetic and spatial scales of each macrostate are computed during the search process so that each macrostate can be searched using appropriately coarse-grained energetic and spatial variables. The nature of the linkage between these scales, the scaling properties of the system, determines the difficulty of finding the minimum.

For illustration, consider the problem of finding the global minimum of the two-dimensional potential shown in Fig. 1a. At a high temperature where  $k_B T$  exceeds the internal energy barriers (right panel, Fig. 1b), the probability distribution is spread fairly smoothly over a compact region and can be coarsely approximated by a single Gaussian characteristic packet  $\phi_\alpha^0$  (right panel, Fig. 1c) which is characterized by its

**Packet Annealing, Figure 1**  
**Packet annealing analysis**

centroid (vector  $R_\alpha^0$ ) and root-mean-square size (tensor  $\Lambda_\alpha^0$ ) (Fig. 1d). As  $T$  is reduced to the point where the central energy barrier becomes larger than  $k_B T$ , the distribution bifurcates into two lobes  $\beta$  and  $\gamma$  which can be approximated by two child packets (center panels, Fig. 1b, Fig. 1c, Fig. 1d). As temperature is further decreased,  $\beta$  bifurcates into two children  $\delta$  and  $\epsilon$  (left panels). By this temperature it is evi-

dent that the peak within the  $\phi_\delta^0$  packet corresponds to the global minimum of  $V$ . While this could be found by a random search (as in simulated annealing), it is clear that it would be more efficient to use the hierarchically coarse-grained structure manifested by the characteristic packet analysis to direct the search.

- A model two-dimensional potential,  $V(r_1, r_2)$ .

- The corresponding Gibbs–Boltzmann probability distribution  $p_B$  at three temperatures  $T_{hi} > T_{med} > T_{lo}$ .
- Superposition of the Gaussian packets that are solutions of the characteristic packet equations at the three temperatures (a large number of characteristic packets, corresponding to the very small-scale fluctuations of  $V$ , will appear at lower temperatures).
- The characteristic packets are characterized by the positions of their center-of-masses ( $R^0$ ) and by their root-mean-square fluctuation tensors ( $\Lambda^0$ ), represented here by ellipses.
- Free-energy vs. temperature trajectory diagram for this temperature range. Solid lines represent metastable macrostate trajectories and dotted lines represent transitions. The discontinuities in the trajectories correspond to branch points at which packets bifurcate (from [1])

The characteristic packets are computed by solving a coupled set of self-consistent equations identifying Gaussian distributions which are metastable in the stochastic physical system having potential  $V(R)$  [10]. This is equivalent to finding which locally minimize, the Hellinger distance, between  $p_B$  and [2]. The characteristic packets only coarsely approximate  $p_B$ ; their main role is to determine the boundaries of the macrostate regions and thus dissect conformation space. Thermodynamic properties such as entropy and free energy can then be computed for each macrostate region and compactly represented in trajectory diagrams (Fig. 1e). All trajectories are tracked in this simple example, so finding the global minimum is guaranteed. This is not the case in more complicated problems where the number of branches exceeds computational capacity, and it is necessary to prune the trajectory diagram and pursue only a limited subset of branches. These are selected by a branch selection algorithm which uses the macrostate thermodynamic properties to predict those which are most likely to contain the global minimum. While the global minimum in Fig. 1 could be found by following only the trajectory having the lowest free-energy at each bifurcation, in general, multiple trajectories will have to be followed. The efficiency of the method will largely be determined by the ability of the branch selection algorithm to minimize the number of needed search trajectories. This is problem-dependent and requires the existence of underlying regularities within the class of

potentials being studied. It has been suggested that such regularities do exist for protein potential functions [1]; this is an active area of research.

A key feature is that reduced accuracy is sufficient until the final (low) temperature is reached—it is only necessary that each trajectory remain within the catchment region of its macrostate. Within each macrostate region  $V(R)$  can be replaced with an approximation which has been spatially smoothed on a scale commensurate with the size of the macrostate. The use of smoothing is somewhat analogous to that occurring in the diffusion equation [8] and Gaussian density annealing [12] methods [11].

### Unrestricted Parallelism

For simplicity, complexity theory usually focuses on decision problems. A *complexity class* consists of all decision problems solvable with given resource bounds.

The *depth of a Boolean circuit* is the most obvious measure of parallel time, because all gates can work in parallel. Problems solvable by uniform families of circuits of depth  $O(\log n)$  have long been recognized as an important complexity class. Here  $n$  always denotes the length of an input, and it is assumed that the family contains one circuit for each  $n$ .

Complexity theory for parallel computations really started with the observation of the strong correspondence between parallel time and Turing machine space complexity discovered by A. Borodin [1]. In terms of circuit complexity, this means that not only is the depth of a Boolean circuit equal to the parallel time, but for every narrow circuit there is an equivalent shallow circuit. The close relationship between space in sequential machines and time in parallel machines is known as the *parallel computation thesis* [8].

This relationship between space and time complexity classes has been strengthened by the introduction of *alternating Turing machines* [2] as a computing model with unbounded parallelism. These machines have universal states in addition to the existential states present in nondeterministic machines. For universal configurations, all successor configurations must lead to acceptance, while for existential configurations at least one successor must lead to acceptance.

For time functions  $T(n)$  and space functions  $S(n)$ , alternating Turing machines define the complexity classes  $ATIME(T(n))$  and  $ASPACE(S(n))$ . With  $ALOGSPACE = ASPACE(\log n)$  and  $APTIME = \cup_c ATIME(n^c)$ , the correspondence between sequential and parallel complexity classes is  $ALOGSPACE = P$  (polynomial time) and  $APTIME = PSPACE$  (polyno-

mial space). Similar relations hold at higher levels of the time and space hierarchy.

### Restricted Amount of Hardware, Circuits

More practical complexity classes (for parallel computing) simultaneously restrict the parallel time and the amount of hardware used. S.A. Cook [3] has proposed to consider complexity classes obtained by simultaneously bounding the time and space of Turing machines. The most important of these classes has later been named SC (Steve's class).  $SC^k$  consists of all decision problems that can be solved simultaneously in polynomial time and  $O(\log^k n)$  space. Finally, SC is defined as  $SC = \cup_k SC^k$ .

Similarly, N. Pippenger has studied the complexity classes (later called  $NC^k$ ) consisting of all problems that can be solved by uniform families of Boolean circuits such that the size of the  $n$ th circuit is polynomial in  $n$  and its depth is  $O(\log^k n)$  (see [9]). Again, NC is defined as  $NC = \cup_k NC^k$ . The classes NC and  $NC^k$  are much more widely used than the classes SC and  $SC^k$ , because NC directly measures the parallel time. Informally, it consists of all decision problems that can be solved very fast (in *polylogarithmic time*) on a parallel machine with only a moderate (polynomial) amount of hardware. It is an open problem (as of 2000) whether  $NC = SC$  [1].

If Boolean circuits are allowed to have 'AND' and 'OR' gates with an arbitrary number of inputs, then the restriction to polynomial size and depth  $O(\log^k n)$  defines the class  $AC^k$ . It is easy to see that  $NC^k \subseteq AC^k \subseteq NC^{k+1}$ .

By allowing randomized computations, NC extends to RNC. Formally, these circuits may contain gates (without inputs) producing independent random outputs 0 and 1 (representing false or true) with equal probability. Such a randomized circuit solves a problem, if it rejects every negative instance, while accepting every positive instance with probability at least 1/2. Deciding whether a graph has a perfect matching is in RNC, but is not known to be in NC.

For good reasons, practical parallel computing has initially focused on utilizing the obvious parallelism present in many scientific computations due to the presence of matrices, vectors or simple loops. At the same time, theoretical research has tried to classify

problems according to their efficient solvability by parallel algorithms, the central question being whether a problem is in NC.

### Restricted Amount of Hardware, PRAMs

To show membership in NC, and for designing any parallel algorithm while abstracting from all communication issues, the PRAM model of parallel computing has been defined. A PRAM [6,13] consists of many cooperating processors, each being a random access machines (RAM, [4]). Each processor can do local computations consisting of additions, subtractions, shifts, conditional and unconditional jumps, as well as indirect addressing. Arbitrary long shifts and multiplications of large numbers are not allowed in one step, as these operations would make a single processor impractically powerful.

The processors in a PRAM are synchronized, and communication between processors is accomplished by a global memory. The intention is not to suggest that synchronized operation and global memory are easy to realize, but that it simplifies programming of a parallel machine. Simulation of global memory (by local memory and communication) can be handled by a compiler or even directly implemented in hardware ([10]). Several flavors of PRAM have been defined.

- In an *EREW PRAM*, different processors are not allowed to access the same memory location simultaneously.
- In a *CREW PRAM*, only writing to memory is so restricted.
- In a *CRCW PRAM*, simultaneous reading and writing is allowed.

There are three kinds of CRCW PRAMs with different ways to handle concurrent writing.

- In the *COMMON* model, all processors writing to the same location simultaneously, are required to write the same data.
- In the *ARBITRARY* model, an arbitrary processor succeeds (i. e., it writes last).
- In the *PRIORITY* model, the lowest numbered processor succeeds with writing.

Interesting complexity classes are obtained by restricting computations to be *uniform*. Technically, it is assumed that a *logspace Turing machine* produces the programs for all processors. Then the complexity

classes  $EREW^k$ ,  $CREW^k$  and  $CRCW^k$  are defined as the classes of problems solved by a uniform PRAM of the given type in time  $O(\log^k n)$  with polynomially many processors. (For  $CRCW^k$  the most powerful type PRIORITY is assumed.) It is known that  $NC^k \subseteq EREW^k \subseteq CREW^k \subseteq CRCW^k = AC^k \subseteq NC^{k+1}$  (see [9]).

Besides minimizing the parallel time, a key issue in parallel computing is to minimize the *work*, which is the product of the parallel time with the number of processors. An algorithm is said to be *optimal* if the ratio between the work and the optimal sequential time is bounded by a constant, and it is said to be *efficient* if that ratio is bounded by a polylogarithmic factor.

While the PRAM model abstracts from *communication* issues, another branch of research has focused exactly on communication for various interesting arrangements of processors, like arrays, trees and hypercubes [11].

Theoretically, it has been shown that PRAM algorithms can be implemented by some fixed networks of communicating processors with very little loss of speed [7,14]. Yet, it has been felt that the constant factors in the speed loss could be too big to warrant the restriction of the algorithm designer to simply program a PRAM and let the compiler handle all communication.

## BSP and LogP

Several parallel machine models have been proposed with two goals in mind.

- Programs (like PRAM programs) are portable to various types of physical parallel machines.
- The programmer (unlike a PRAM programmer) has some control over the communication between processors in order to obtain high efficiency.

These two somewhat contradicting goals can be achieved by letting the programmer choose the source and target, but not the path and detailed timing of each message. The two most influential such models are the *BSP model* (*bulk synchronous parallel model*) of L.G. Valiant [15,16] and the *LogP model* [5].

The BSP model is called a *bridging model*, because it is intended to bridge the gap between hardware and software for parallel computing, as the von Neumann model did for sequential computing. Thanks to compilers, the programmer does not have to know too many details of the actual machine.

The BSP model performs a sequence of supersteps, each consisting of three phases, local computation, global communication and a barrier synchronization. The latter is a global check that all components have finished a superstep. The BSP model is characterized by two parameters,  $L$  and  $g$ . The time unit is the duration of a local operation. The periodicity parameter  $L$  measures the length of a superstep, while  $g$  measures the length of a global operation.

The LogP model has basically the same goals as the BSP model, but intends to give the programmer slightly more flexibility to address important performance issues without having to deal with unnecessary details. The LogP model is characterized by four parameters, the latency  $L$ , the overhead per message  $o$ , the time gap between messages  $g$  (for each processor) and the ratio  $P$  between the number of processors and the number of memory modules. This allows each parallel machine to be characterized by only a few parameters. The algorithm designer can prescribe different methods for different ranges of the parameters. Then such an algorithm can compile efficiently on various parallel machines.

The BSP and LogP models, as well as the QSM (*queueing shared-memory model*), are actually quite closely related as indicated by various simulation results (e. g., [12]).

### Keywords

Models for parallel computing; Parallel algorithm; Algorithm design; BSP; CGM; PRAM; Grid; Hypercube; Bulk synchronous parallel computer; Coarse grained multicomputer; Parallel random access machine; PC clusters; Shared memory parallel machines; Distributed memory parallel machines

The rapid growth and large availability of high speed networking have brought *high performance computing systems* (HPCS) to the reach of many people wishing to process very large data and difficult problems as fast as possible. Such systems evolve at an incredible pace and different machines with new architectures, programming models and paradigms, and computation granularity are proposed every year. For instance, the use of personal computers (PC) clusters interconnected by high performance local networks with raw throughput close to 1Gb/s and latency smaller than

10  $\mu$ s yielded, in the late 1990s, parallel systems whose computing power was close to or even better than the one of super-computers of the middle of the 1980s, for a hundredth to a tenth of their nominal price. Their local networks were either realized with off-the-shelf ware (e.g. Myrinet and Fast Ethernet), or application-driven devices, in which case additional functionalities were built-in, mainly at the memory access level. Such clusters supported the Linux operational system, among others, and offered a system level virtualization for user-friendly programming environments like multi-threading, communication libraries, automatic load-balance, I/O systems, etc.

When using an HPCS to solve computationally intensive problems, the first aspect to be understood is the level of concurrency existing in the problem, i.e., which tasks can be executed simultaneously and which cannot. For instance, there are cases where a problem is not adapted at all to the parallel setting and only very small benefit from parallelism can be obtained. Therefore, the choice of a model for *parallel computing* is of primeval importance.

## Models

Parallel computing models can be roughly divided into those which implicitly hide or assume the value of its parameters and those which explicitly set these values, as follows. The machine *size* can be defined by a parameter  $p$  or be (implicitly) connected to the problem input size  $n$ . The *topology* of the communication network is either explicit (ring, grid, hypercube, etc.) and the processors communicate only with neighbors, or hidden, i.e., the processors can communicate with any other processor through a high speed interconnection medium. The *communication costs* may depend on the size of the messages sent and on the distance they travel, or be fixed by message or even by set of messages sent. Finally, although *parallel computers* are asynchronous, and some models take this into consideration, most of the existing models suppose a synchronized *mode*, with some kind of barrier of synchronization – even light ones, based on *rendez-vous* communications. In the following, we briefly describe the most important models for parallel computing and the way they deal with the parameters above. For more details, we refer to [11,12,14,22,23,24,29].

## Atomic Models

In these models, a parallel machine consists of a large set of atomic processors communicating by the exchange of atomic messages at a constant cost per message. The number of processors is usually taken as a function of  $n$ , the input size of the problem to be solved.

### PRAM

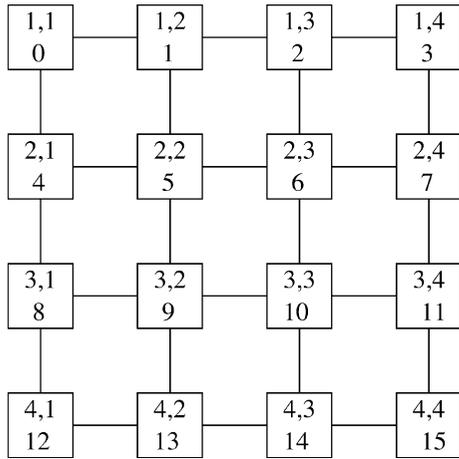

The shared memory model known as *parallel random access machine* (PRAM) [19,22,23] is the best known *model for parallel algorithm design*, because of its high abstraction level. In this model, a parallel machine consists of a large set of atomic processors. They communicate through a shared memory, where any position can be accessed in constant time. In order to design an algorithm we just have to describe a sequence of synchronous parallel operations executed by the processors on the shared memory, without worrying about scheduling the communications between the processors. This model is perfectly adapted to determine the level of parallelism inherent to a problem, since all parameters are implicit or hidden [10,21]. Unfortunately, however, only small shared-memory parallel computers have been built so far, because of technological constraints regarding the concurrent access to the memory in constant time, when the number of processors is large.

### Atomic GRAM

One way to solve the problem raised by the fully connected shared memory was to consider distributed memory machines and make explicit the topology through which the atomic processors communicate. Among the most used *GRAMs* (where  $G$  stands for the graph defining the topology of the communication network), we find grids and hypercubes [11,24], whose definitions follow.

### The 2-dimensional grid

The *2-dimensional grid* (called grid in the remainder) of size  $N$  is composed of  $N$  processors  $PE_{i,j}$ ,  $1 \leq i, j \leq \sqrt{N}$ , such that processor  $PE_{i,j}$  is linked to processors  $PE_{i-1,j}$ ,  $PE_{i+1,j}$ ,  $PE_{i,j-1}$ ,  $PE_{i,j+1}$ , for  $2 \leq i, j \leq \sqrt{N} - 1$ . The grid has degree 4, diameter  $O(\sqrt{N})$  (a longest

**Parallel Computing: Models, Figure 1**  
A  $4 \times 4$  grid

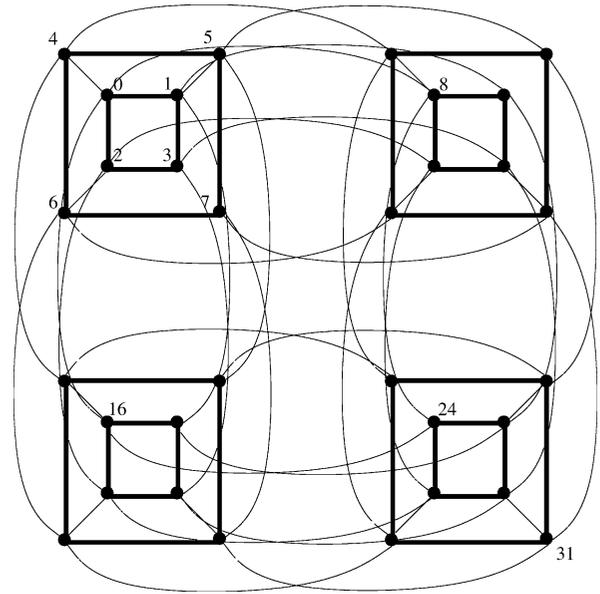

path existing between processors  $PE_{1,1}$  and  $PE_{\sqrt{N},\sqrt{N}}$ , for instance), and bisection width  $\sqrt{N}$  (which can be obtained by deleting all links between processors  $PE_{i,\frac{\sqrt{N}}{2}}$  and  $PE_{i,\frac{\sqrt{N}}{2}+1}$ , for  $1 \leq i \leq \sqrt{N}$ ).

Grids can be generalized in two ways. The first one is to consider  $d$ -dimensional grids which are defined on  $N$  processors  $PE_{i_1, \dots, i_d}$ ,  $1 \leq i_k \leq N^{1/d}$ , with links between  $PE_{i_1, \dots, i_k, \dots, i_d}$  and  $PE_{i_1, \dots, i_k \pm 1, \dots, i_d}$ , for  $1 \leq k \leq d$ . The second classic generalization is to add links in the 2-dimensional grid between processors  $PE_{1,j}$  and  $PE_{\sqrt{N},j}$  and between  $PE_{i,1}$  and  $PE_{i,\sqrt{N}}$  for  $1 \leq i, j \leq \sqrt{N}$ . The obtained structure is called a *2-dimensional torus*. As 2-dimensional grids, 2-dimensional tori can be generalized to *d-dimensional tori*.

Processors of a grid are usually numbered in a row major order by using a unique index.  $PE_{i,j}$  is then denoted by  $PE_{(i-1)\sqrt{N}+j-1}$ , that is, processors are linearly numbered from left to right and from top to bottom, with indices in the range  $0, \dots, N - 1$ .

**The Hypercube**

An interconnection network with the topology of a *d-dimensional hypercube*, denoted  $H(d)$ , is composed of  $N = 2^d$  processors, labeled from 0 to  $N - 1$ , and  $dN/2$  communication links. Let  $(i)_2$  be the binary string representing  $i$  and  $i_k$  denote the  $k$ -th digit, from right to left, in  $(i)_2$ . Then, the neighbors of  $PE_i$  are all  $PE_j$  such that  $(i)_2$  and  $(j)_2$  differ in exactly one bit position, say  $k$ ,

**Parallel Computing: Models, Figure 2**  
A Hypercube  $H(5)$  with 32 nodes and diameter 5. We can see its decomposition in four  $H(3)$ , in bold

$0 \leq k < d$ , implying that its degree is  $d$ . In this case, we say that  $PE_i$  and  $PE_j$  are neighbors along dimension  $k$ . It is not difficult to see that the maximum distance in a hypercube is given by those pairs of processors whose binary string differ in all  $d$  positions, implying that its diameter is  $d = \log N$ . Finally, the bisection width of a hypercube is  $N/2$ .

Figure 2 shows that processors are the vertices of a hypercube of dimension  $d$ , each connected to  $d$  neighbors. Notice further that, for instance,  $PE_0$  and  $PE_4$  are neighbors along dimension 2 in any  $d > 2$ -dimensional hypercube.

A hypercube  $H(d)$  can be decomposed in  $d$  different ways into two copies of  $H(d - 1)$ , with  $N/2$  edges connecting them. In order to find one such decomposition, it suffices to fix any one bit position in the processors' addresses, say position  $k$ ,  $0 \leq k < d$ . Then, the two copies of  $H(d - 1)$  are composed of the vertices  $i_{d-1} \dots i_{k+1} 0 i_{k-1} \dots i_0$  and  $i_{d-1} \dots i_{k+1} 1 i_{k-1} \dots i_0$ , respectively. It is interesting to notice that one can use these decompositions in order to implement divide and conquer algorithms in hypercubes.

Let us further remark that the hypercube is vertex and edge symmetric, making it easy to use. Very informally, we could say that, as far as the neighbors are con-

cerned, the hypercube looks the same from every node. Note that this is also true for the torus, but false for the grid.

### Bulk Models

Parallel algorithm designers who dealt with real problems to solve, soon discovered that they needed not only to determine a problem's inherent parallelism, but also to write algorithms that could be efficiently implemented. Hence, atomic models were not of help, since parallel computers cannot expand endlessly in order to reflect the size of the problem at hand, and distributed memory bulk models appeared.

In opposition to the atomic models, the number of processors,  $p$ , becomes a parameter and each processor is supposed to be able to hold  $n/p$  data. A *parallel algorithm* is then a sequence of *supersteps*, composed of local computations followed by a communication round, where messages are exchanged among the processors. Notice that such an algorithm, where the number of supersteps is small and independent of  $n$ , will be efficient in any HPCS, provided that the communication procedures are implemented in an efficient manner, what is usually the case.

### Bulk GRAM

One difference between bulk and atomic GRAMs is the number of processors, that here is set to an independent value  $p$ . In each communication phase, processors can then send a message of varying length to their neighbors. The cost of these communications is also modeled, according to a value proportional to the initialization of the communication channel plus the time spent by the message to arrive at the destination [5,11,20].

### BSP

The BSP model (for *bulk synchronous parallel*) [28], uses slackness in the number of processors and memory mapping via hash functions to hide communication latency and provide for the efficient execution of atomic PRAM algorithms on existing hardware.

An input of size  $n$  is distributed evenly across a  $p$ -processor parallel computer. In a single superstep each processor may send  $h$  and receive  $h'$  messages (called an  $(h, h')$ -relation) and then perform an internal computation on its internal memory cells using the messages it

has just received. To avoid any conflicts that might be caused by asynchronies in the network (whose topology is left undefined) the messages sent out in a round  $t$  by some processor cannot depend upon any messages that the processor receives in round  $t$  (but, of course, they may depend upon messages received in round  $t - 1$ ).

Communication costs depend on two parameters, namely the latency  $L$  and the throughput  $g$ . The cost of an  $(h, h')$ -relation performed by a processor is then  $L + \max(h, h')g$ , and the total cost of a communication round is  $\max_{i=1, \dots, p} L + \max(h_i, h'_i)g$  where  $h_i$  (respectively,  $h'_i$ ) represents the amount of data sent (respectively, received) by processor  $i$ . Precise models of parallel computers can be obtained by assigning realistic values to  $L$  and  $g$ . More detailed BSP models and algorithms can be found in [2,3,27,29].

### CGM

The *coarse grained multicomputer* model, or CGM( $n, p$ ) for short, was introduced in [7]. The CGM( $n, p$ ) is a BSP model consisting of a set of  $p$  processors with  $O(n/p)$  local memory each, in which each superstep has  $h = h' = O(n/p)$ .

The originality of CGM stems from its cost model. The algorithm designer will no longer try to minimize the overall amount of data exchanged, as in the BSP, but rather design algorithms with a small number of supersteps, independent of the input size  $n$ . As a consequence, these algorithms will be very efficient in practice. Ideally, algorithms should run for a constant number of supersteps, as it is the case for sorting [27] and many problems in image processing [17,18], computational geometry [13,15], and optimization [8,16]. On the other hand, graph problems seem to be somewhat more complex, some of them requiring  $O(\log p)$  communication rounds to be solved [4].

### LogP

This model uses the BSP model as a starting point and focuses on the technological trend from fine-grained parallel machines towards coarse-grained systems, advocating portable parallel algorithm design [6]. It characterizes a *distributed memory parallel computer* by four parameters (whence its name), as follows.

- $L$ : the latency of a small message being communicated from user-space to user-space.

- $o$ : the overhead incurred in a communication. It is defined as the time interval during which a processor cannot do anything else because it is communicating.
- $g$ : the gap between two consecutive message transmissions (or receptions) by one processor. It is defined as the inverse of the bandwidth of the communication processing element.
- $P$ : the number of processors.

Memory resources are considered finite. Hence, only  $L/g$  messages can be at the same time in the network. The cost to communicate an elementary packet between two processors is  $L + 2o$ . If a reception acknowledgment is required, this cost becomes  $2L + 2o$ . Designing algorithms in LogP may become an elaborate task, because of the several parameters involved, and the asynchronous character of the models [1,9,26]. It is also very interesting to notice that work on LogP algorithms are very similar to those on bulk GRAM algorithms, done some 10 years earlier [5,25].

### Optimization – Parallel Search Algorithms – Heuristics

Many applications in the field of artificial intelligence and operations research rely on heuristic search (cf. Heuristic search) as their primary solution method. Because these applications often spawn very large decision trees, the design of efficient parallel algorithms is of prime importance. Depending on the level of parallelism (fine-grained or coarse-grained) and the degree of parallelism (moderately or massively parallel), the techniques used in parallel heuristic search can be categorized into one of three classes:

- task partitioning
- parallel window search
- tree partitioning

### Task Partitioning

The method of task partitioning (or operator partitioning) provides a fine-grained parallelism at the lowest level, the operator level. It speeds up the processing of individual nodes by performing repetitive steps like successor generation, node evaluation, and bookkeeping in parallel.

Task partitioning is especially popular in the field of computer chess, where special purpose hardware was built to assist in the move generation and board evaluation. The world computer chess champions Deep Thought [3] and Deep Blue, for example, employ special-purpose coprocessors for generating all moves of a position and for evaluating all 64 fields of a board in parallel. In the early years, hardware implementations were only feasible for simple operators that could be easily implemented in silicon. With the advent of programmable hardware accelerator chips like FPGAs (field programmable gate arrays), more complex parts of the tree search could be implemented in hardware, which dramatically improved the performance of computer chess programs, most notably that of the world champion Shredder.

## Parallel Window Search

In parallel window search, all processors examine the entire tree, but each with another search bound. This method was originally developed to speed up game playing programs. As first suggested by Baudet [1], the total range of values in a game tree is subdivided into  $p$  nonoverlapping alpha-beta windows (where  $p$  is the number of processors), so that approximately one third is covered. The advantage is, that the processor having the true minimax value in its window will find it faster by virtue of starting with a narrow search window instead of using the full-width window. Even the unsuccessful processors are productive: They determine whether the minimax value lies below or above their assigned search interval. If the true minimax value does not lie in one of the initial  $p$  windows, the processors are re-scheduled to cover some of the remaining intervals. The iterative re-scheduling process is continued (like in binary search) until the final solution is found by one of the processors.

In some favorable cases, parallel window search may even cause superlinear speedup  $s(p) > p$  when the minimax value is found early in the search. Moreover, the communication and synchronization overheads are quite low, allowing efficient execution on loosely coupled parallel systems. On the negative side, however, is the limited scalability of parallel window search. Even with an infinite number of processors, a maximal speedup of five or six can be attained in chess trees, because in the best case all  $w^{\lceil d/2 \rceil} + w^{\lfloor d/2 \rfloor} - 1$  nodes of the minimal tree (with width  $w$  and depth  $d$ ) must be examined by the 'successful' processor returning the minimax value. For this reason, parallel window search is suitable for small systems with up to three processors only.

Parallel window search can also be applied to single-agent searches like iterative-deepening A\* (IDA\*) [7]. Here, different processors are used to search the entire tree up to different thresholds (windows), hoping that one of them would find a solution. If not, a global administration scheme determines the next larger threshold, and the node expansion starts over again. Note, that this scheme works only in applications where the increments in the threshold are known a priori. In the 15-puzzle, for example, the first processor's threshold would be set to the heuristic estimate  $h(n)$  of the ini-

tial position  $n$ , the next processor gets the threshold  $h(n) + 2$ , and so on.

As in adversary game tree search, the maximum scalability is limited to the maximum number of iterations. Because the iterations with consecutive thresholds are not explored in sequential order, the first solution may not be optimal. Optimality can, however, be guaranteed by completing all shallower iterations than that of the best solution found so far. The better the node ordering, the faster the solution speed. In the extreme case, superlinear speedup can be achieved when the solution is found early in some 'left' part of the tree.

Because of its nonoptimality and its limited scalability, parallel window search is mainly used for quickly determining a (possibly suboptimal) solution which is then improved by other means [7].

## Tree Partitioning

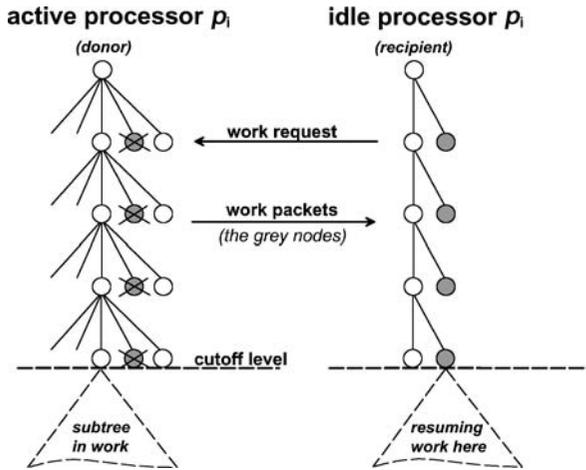

In tree partitioning, the total search space is split into smaller parts (subtrees) for simultaneous exploration by different processors. Once the subtrees have been distributed among the processors, only little communication is necessary for broadcasting improved bound values and for termination detection.

Compared to the other two techniques, tree partitioning is the only parallelization strategy that allows (in principle) to employ an unlimited number of processors. This is especially true for the use of tree partitioning in parallel depth-first search (DFS). Here, applications have been successfully tested on massively parallel systems with more than a thousand processors.

Because DFS trees tend to be highly irregular in practice, i. e. they exhibit varying branching degrees and search depths, static tree partitioning methods are insufficient to keep all processors busy during the whole computation. Two dynamic work partitioning methods have been proposed: stack splitting and search-frontier splitting.

## Stack Splitting

In the stack splitting scheme [5], the local work is partitioned by splitting the donor's search stack into two, one of which is given to the requester. Care must be taken to select a suitable amount of work for shipment. On the one hand, the transferred work must be large enough to vindicate the communication costs, and on

Parallel Heuristic Search, Figure 1  
Stack splitting

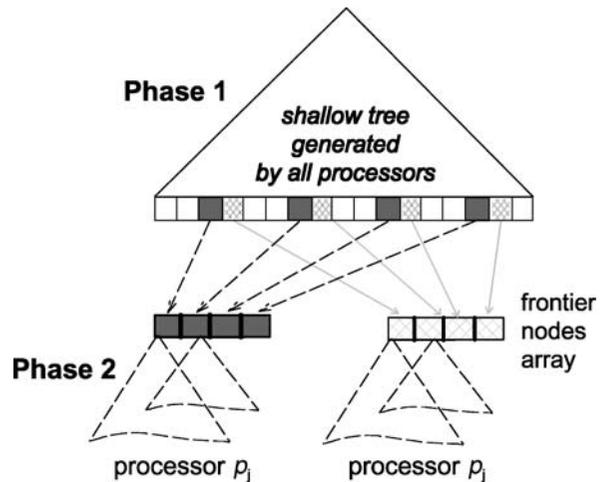

the other hand, not too much work should be sent to avoid thrashing effects. Several strategies for selecting nodes from a donor's stack have been proposed:

- Removing nodes from the tree levels near the root give coarse-grained work packets, which are likely to be splitted a second time during the search.
- Removing nodes near a cut-off level deep in the tree give fine-grained work packets, making it sometimes necessary to send more requests for obtaining enough work.
- Removing a 'vertical slice of nodes', one from each level, may be useful in trees with large branching factors and irregular search depths.

Stack-splitting works for simple DFS as well as for iterative DFS. The iterative-deepening search PIDA\* (Parallel IDA\*, [4]) starts a new iteration with an increased cost-bound when all processors have finished their current iteration without success. The end of an iteration is determined by a barrier synchronization, e. g., the distributed termination detection algorithm of Dijkstra [2].

### Search-Frontier Splitting

Rather than subdividing a processor's stack, search-frontier splitting initially generates a suitable number of 'work packets'. A work packet is a node from a 'search-frontier' in the tree, containing nodes  $n$  with the same cost value  $f(n)$ . Search-frontier splitting has two phases:

Parallel Heuristic Search, Figure 2  
Search-frontier splitting

- In an initialization phase, the nodes of a search-frontier are distributedly generated by a cost-bounded BFS or an iterative DFS. The bound is incrementally increased until at least  $p$  nodes with the same cost  $f(p)$  are generated and stored in the local memories. Each frontier forms the root of a subtree that represents an indivisible piece of work used in the second phase.
- In the main asynchronous search phase, each processor expands its own frontier nodes in DFS or DFBB fashion. When a processor gets idle, it sends a request for a work packet (unprocessed frontier node) to another processor.

The initialization phase is only short. A suitable amount of frontier nodes is generated to provide a fine work granularity. As before, the work packets must neither be too small (to pay off for the communication costs) nor too large (to avoid thrashing effects).

In practice, little load balancing is required, because the expansion of the local frontier nodes keep the processors busy for most of the time. Search-frontier splitting is applicable to DFS and iterative DFS. The iterative-deepening variant AIDA\* (asynchronous IDA\* [8]) starts a new iteration on the previously used frontier nodes. This has the effect of a self-improving load balancing scheme, because all subtrees tend to grow at approximately the same rate when searching to the next larger cost-bound. In practice, the communication overhead decreases with increasing search time.

## Work Distribution

The work distribution is either initiated by the sender (donor) or by the receiver (recipient). In the sender initiated work distribution, the generation of subtasks is independent from idle processors. It is based on the rationale that the local work-load of any two processors in the system should not differ by a factor  $\geq \delta$  [6]. Work packets are delivered to weakly loaded processors either on demand (when they become idle) or when imbalances occur. In conjunction with a node priority scheme, sender initiated work distribution may help avoiding speedup anomalies, but at the cost of a reduced execution speed.

The receiver initiated work distribution scheme, also known as work stealing, is more popular. Work requests are only sent by processors that became idle. When a donor has work to share, it returns a work packet, otherwise it notifies the requester accordingly. More sophisticated variants start issuing work requests as soon as there are fewer than  $\delta$  work packets left on their stack, thereby reducing communication latency by overlapping communication and computation.

But which processor should best be addressed to obtain a work packet? The answer depends on the topology and characteristic of the interconnection network of the parallel system. Four receiver initiated work distribution methods have been extensively tested and analysed:

- ARR: In the asynchronous round robin strategy, each processor maintains a local variable target pointing to the next donor. Whenever a processor runs out of work, it sends a work request to the target processor and increments target (modulo  $p$ ) thereafter.
- GRR: The global round robin method works similar to ARR, but with a global target variable instead. Whenever a processor runs out of work, it looks up the global target variable, increments it, and sends a work request to the assigned donor. Hence, four messages are sent for a single work request. Memory contention can be reduced by introducing a hierarchy of distributed target variables.
- RP: In random polling, idle processors send work requests to randomly chosen processors. Each donor is selected with the same probability.
- PF: In packet forwarding, unsuccessful work requests are not returned to the sender, but forwarded to the next neighbor. On ring topologies, work requests are forwarded until a processor responds with a work packet, or the message makes a full round through the ring, thereby indicating that no work is available.

Which of the work distribution schemes to choose depends on the interconnection topology of the target platform. On systems with a small communication diameter (e.g. hypercube), RP and ARR give best speedups, while PF performs better on systems with a large communication diameter (e.g. ring, torus) [4,8].

## Table Driven Search

In many domains, application-specific heuristics and search enhancements introduce interdependencies between the generated states, making efficient parallelization a challenging task. Much of this information is stored in memory tables (e.g. transposition tables or refutation lists), which are essentially large caches in which the generated nodes and some book-keeping information are stored. Before expanding a new node, a table lookup is performed to check whether information on that node is available. This is especially useful when a node can have multiple predecessors, i.e. when the search space is a graph rather than a tree.

In parallel implementations the transposition table is partitioned among the processors. Each time a processor extends a new node, it first does a remote lookup by sending a message to the processor responsible for that portion of the table and waiting for the result. This results in a large time-overhead – even with asynchronous message passing. As an efficient alternative, transposition-driven work scheduling (TDS) [9] was introduced, which migrates the node to be expanded to the processor that may contain the corresponding transposition table entry. From that moment on, the receiving processor is responsible for the table lookup and, depending on the result, for extending the subtree of that node to the given search depth. TDS was introduced for parallel single-agent search (like IDA\*) but can also be applied to multi-agent search.

Trap-door point

For finite-dimensional optimization problems with infinitely many inequality constraints ('semi-infinite' optimization), the topological concept of global stability and its algebraic characterization are introduced in the following. Global stability refers to perturbations of the defining functions and their derivatives up to second order. Then, transitions between stable problems via one-parametric families are considered. Necessarily, certain unstable situations will be met and they will be discussed by means of the underlying singularities.

The considered optimization problems are of the following type:

$$(\text{SIP}) \begin{cases} \min & f(x) \\ \text{s.t.} & x \in M[h, g], \end{cases}$$

where

$$M[h, g] = \left\{ x \in \mathbf{R}^n : \begin{array}{l} h_i(x) = 0, \quad i \in A, \\ g(x, y) \geq 0 \\ \text{for all } y \in Y \end{array} \right\},$$

$$Y = \left\{ y \in \mathbf{R}^r : \begin{array}{l} u_i(y) = 0, \quad i \in I, \\ v_j(y) \geq 0, \quad j \in J \end{array} \right\},$$

$h = (h_i, i \in A), u = (u_i, i \in I), v = (v_j, j \in J), |A| < n, |I| < r, |J| < \infty$ . The index set  $Y$  is assumed to be *compact*. All defining functions are assumed to be of class  $C^k$  ( $k \geq 2$ ), i. e.,  $f \in C^k(\mathbf{R}^n, \mathbf{R}), g \in C^k(\mathbf{R}^n \times \mathbf{R}^r, \mathbf{R})$ , etc.

**The Reduction Ansatz**

Under certain assumptions it is possible to reduce (SIP) *locally* to an optimization problem with a *finite* number of inequality constraints. In fact, put  $Y_0(x) = \{y \in Y: g(x, y) = 0\}$  and let  $\bar{x} \in M[h, g]$ . Then, all points of  $Y_0(\bar{x})$  are *global minima* for  $g(\bar{x}, \cdot)|_Y$ . Consequently, if  $Y_0(\bar{x}) = \{\bar{y}_1, \dots, \bar{y}_p\}$  are ‘nondegenerate’ respectively ‘strongly stable’ (cf. [16]), then the implicit function theorem guarantees the existence of local  $C^1$ - respectively Lipschitz continuous, mappings  $y_j(x)$ , where  $y_j(x)$  is a *local minimum* for  $g(x, \cdot)|_Y, j = 1, \dots, p$ . But then, in a neighborhood of  $\bar{x}$ , we can describe the feasible set  $M[h, g]$  by means of the equalities  $h_i = 0, i \in A$ , and the *finite* number of  $C^2$ -, respectively  $C^{1,1}$ -, inequality constraints  $\varphi_j(x) \geq 0, j = 1, \dots, p$ , where  $\varphi_j(x) = g(x, y_j(x))$  (*local marginal function*) (cf. [4]).

**Global (Structural) Stability**

In this section, global (structural) stability of (SIP) will be introduced and characterized by using the concept of topological stability of the feasible set  $M[h, g]$  and the concept of strong stability of stationary points for (SIP). Throughout this section assume that for all  $y \in Y$  the gradients  $Du_i(\bar{y}), i \in I, Dv_j(\bar{y}), j \in J_0(\bar{y})$  are linearly independent, where  $J_0(\bar{y}) = \{j \in J: v_j(\bar{y}) = 0\}$ .

**Topological Stability of  $M[h, g]$**

The set  $M[h, g]$  is called *topologically stable* with respect to the strong  $C^2$ -topology (briefly:  $C^2_s$ -stable) if there exists a  $C^2_s$ -neighborhood  $\mathbf{U}$  of  $(h, g)$  in  $C^2$  such that  $M[h, g]$  is homeomorphic with  $M[\tilde{h}, \tilde{g}]$  for every  $(\tilde{h}, \tilde{g}) \in \mathbf{U}$ . Here, a  $C^2_s$ -neighborhood of  $(h, g)$  is generated by perturbations of  $(h, g)$  and their derivatives up to second order which are controlled by a positive continuous function  $\varepsilon(\cdot): \mathbf{R}^n \rightarrow \mathbf{R}$  (for details, cf. [6]).

The topological stability of  $M[h, g]$  is closely related with the *Mangasarian–Fromovitz constraint qualification* (MFCQ). The (MFCQ) is said to hold at  $\bar{x} \in M[h, g]$  if the (row) vectors  $Dh_i(\bar{x}), i \in A$  are linearly independent and if there exists a vector  $\xi \in \mathbf{R}^n$  satis-

fying  $Dh_i(\bar{x}) \cdot \xi = 0, i \in A$  and  $D_x g(\bar{x}, \bar{y}) \cdot \xi > 0$  for all  $\bar{y} \in Y_0(\bar{x})$ . In [12] it is shown that topological stability of  $M[h, g]$  can be characterized by an equivalent algebraic condition: If  $M[h, g]$  is compact, then  $M[h, g]$  is  $C^2_s$ -stable if and only if (MFCQ) holds at all  $\bar{x} \in M[h, g]$ . This equivalence was proved first in [2] for finite optimization problems (i. e. for those with finitely many constraints) and, then, it was generalized for semi-infinite problems in [12]. A generalization to noncompact feasible sets  $M[h, g]$  under a stronger constraint qualification is presented in [9].

**Strong Stability of Stationary Points**

The strong stability of a stationary point for a finite problem and its equivalent algebraic characterization have been introduced in [16].

A point  $\bar{x} \in M[h, g]$  is called a *stationary point* for (SIP) if there exist  $\bar{y}_1, \dots, \bar{y}_p \in Y_0(\bar{x})$ , and reals  $\bar{\beta}_i, i \in A, \bar{\gamma}_j \geq 0, j = 1, \dots, p$  such that

$$Df(\bar{x}) = \sum_{i \in A} \bar{\beta}_i Dh_i(\bar{x}) + \sum_{j=1}^p \bar{\gamma}_j D_x g(\bar{x}, \bar{y}_j).$$

A stationary point can be a local minimum or a saddle point for (SIP). Let  $SIP(f, h, g)$  denote the semi-infinite problem that is generated by the function vector  $(f, h, g)$ . The *strong stability of a stationary point*  $x(f, h, g)$  for  $SIP(f, h, g)$  is a local property; it means the existence and local uniqueness of a stationary point  $x(\tilde{f}, \tilde{h}, \tilde{g})$  for  $SIP(\tilde{f}, \tilde{h}, \tilde{g})$  where all local sufficiently small perturbations of  $(f, h, g)$  and their derivatives up to second order are considered and where  $x(\tilde{f}, \tilde{h}, \tilde{g})$  depends continuously on the perturbed function vector  $(\tilde{f}, \tilde{h}, \tilde{g})$ . Here, the function vector  $(f, h, g)$  is considered as a parameter, and under certain assumptions equivalent algebraic conditions for strong stability can be obtained by using the implicit function theorem in the corresponding function space. This was done first in [16] for finite problems, a generalization to semi-infinite problems is given in [17] where the following three cases are distinguished for the considered point  $\bar{x} = x(f, h, g)$ .

- 1) The set  $Y_0(\bar{x})$  is finite with  $Y_0(\bar{x}) = \{\bar{y}_1, \dots, \bar{y}_p\}$ , and all points  $\bar{y}_1, \dots, \bar{y}_p$  are strongly stable local minima for  $g(\bar{x}, \cdot)|_Y$ . Furthermore, the *linear independence constraint qualification* (LICQ) holds at  $\bar{x} \in M[h, g]$ , i. e. the vectors  $Dh_i(\bar{x}), i \in A, D_x g(\bar{x}, \bar{y}_j), j = 1, \dots, p$  are linearly independent.

- 2)  $Y_0(\bar{x}) = \{\bar{y}_1, \dots, \bar{y}_p\}$ , and all points  $\bar{y}_1, \dots, \bar{y}_p$  are strongly stable local minima for  $g(\bar{x}, \cdot)|_Y$ . Furthermore, (MFCQ) holds at  $\bar{x} \in M[h, g]$  but not (LICQ).
- 3) Not all points from  $Y_0(\bar{x})$  are strongly stable local minima for  $g(\bar{x}, \cdot)|_Y$ .

In Case 1 and Case 2 the reduction Ansatz is fulfilled at  $\bar{x} \in M[h, g]$  can be described locally by means of finitely many  $C^{1,1}$ -constraints. Therefore, the Karush–Kuhn–Tucker system (written as a system of equations as in [16,17]) is Lipschitz continuous and has a generalized Jacobian. Then, an equivalent algebraic characterization for the strong stability of  $\bar{x} \in M[h, g]$  in Case 1 and Case 2 is a condition on a certain subset of this generalized Jacobian (for details, cf. [17]): In Case 1 one obtains a condition on coherent orientation; here, all elements (matrices) of this subset of the generalized Jacobian restricted to the corresponding tangent space have a nonvanishing determinant with a common sign. In Case 2, all elements of this subset restricted to the corresponding tangent space are positive definite. In particular, in Case 2 a strongly stable stationary point  $\bar{x} \in M[h, g]$  has to be a local minimum for  $SIP(f, h, g)$ .

In Case 3 the active index set  $Y_0(\bar{x})$  might contain infinitely many points! The equivalent algebraic characterization for strong stability in that case is also a positive definiteness condition but a rather technical one (for details, see [17]). In Case 3 a strongly stable stationary point  $\bar{x} \in M[h, g]$  has to be a local minimum for  $SIP(f, h, g)$  as well.

**Global (Structural) Stability of  $SIP(f, h, g)$**

Two problems  $SIP(f, h, g)$  and  $SIP(\tilde{f}, \tilde{h}, \tilde{g})$  are called *equivalent* if there exist continuous mappings  $\varphi: \mathbf{R}^n \rightarrow \mathbf{R}^n$ ,  $\psi: \mathbf{R} \rightarrow \mathbf{R}$  with the following properties:

- 1) The mapping  $\varphi(t, \cdot): \mathbf{R}^n \rightarrow \mathbf{R}^n$  is a homeomorphism for each  $t \in \mathbf{R}$ .
- 2) The mapping  $\psi$  is a homeomorphism and monotonically increasing.
- 3) For all  $t \in \mathbf{R}$ :  $\varphi_t[\mathbf{L}^t(f, h, g)] = \mathbf{L}^{\psi(t)}(\tilde{f}, \tilde{h}, \tilde{g})$ , where  $\varphi_t := \varphi(t, \cdot)$  and  $\mathbf{L}^t(f, h, g) = \{x \in M[h, g]: f(x) \leq t\}$ .

The semi-infinite problem  $SIP(f, h, g)$  is called *structurally stable* if there exists a  $C^2_s$ -neighborhood  $\mathbf{V}$  of the defining triple  $(f, h, g)$  such that  $SIP(\tilde{f}, \tilde{h}, \tilde{g})$  and  $SIP(f, h, g)$  are equivalent for all  $(f, h, g) \in \mathbf{V}$ .

The structural stability of  $SIP(f, h, g)$  can be characterized by means of the introduced topological stability

of  $M[h, g]$  as well as the strong stability of stationary points as follows. If  $M[h, g]$  is compact, then  $SIP(f, h, g)$  is structurally stable if and only if (MFCQ) holds at all  $x \in M[h, g]$ , every stationary point for  $SIP(f, h, g)$  is strongly stable and different stationary points have different  $f$ -values. This result was proved first in [1,4] for finite problems and, then, it was (partially) generalized to semi-infinite problems in [8,20].

**Generic Transitions**

In this section one-parametric families  $(SIP)_t$  of semi-infinite optimization problems are considered:

$$(SIP)_t \begin{cases} \min_x & f(x, t), \\ \text{s.t.} & x \in M(t), \end{cases}$$

where all defining functions  $f, h, g, u, v$  depend on one additional variable  $t$  (the parameter), i. e., one considers  $f(x, t), h_i(x, t), i \in I, g(x, t, y)$ , etc. Note that, in particular, the index set  $Y(t)$  now also depends on the parameter  $t$ . This is in contrast to one-parametric *finite* optimization problems (i. e.,  $Y(t)$  finite), where the index set of inequality constraints is not assumed to be parameter-dependent (i. e.,  $Y(t)$  constant; cf., e. g., [5,7,13,15]). It is assumed (in the sequel briefly referred to by  $A_{CUSC}$ ) that each set  $Y(t) \subset \mathbf{R}^r, t \in \mathbf{R}$ , is compact, and that the set-valued mapping  $t \rightarrow Y(t)$  is upper semicontinuous at each  $t \in \mathbf{R}$ .

A point  $\bar{x} \in M(\bar{t})$  is called a *generalized critical point* (shortly, g.c.point) for  $(SIP)_{\bar{t}}$  if the family of vectors  $D_x f(\bar{x}, \bar{t}), D_x h_i(\bar{x}, \bar{t}), i \in I, D_x g(\bar{x}, \bar{t}, y), y \in Y_0(\bar{x}, \bar{t})$  is linearly dependent. Here,  $D_x f$  stands for the row vector of first partial derivatives, and  $Y_0(\bar{x}, \bar{t})$  denotes the parameter-dependent set of active inequality constraints, i. e.,  $Y_0(x, t) = \{y \in Y(t): g(x, t, y) = 0\}$ . The *generalized critical point set* is defined to be the set  $\Sigma = \{(x, t) \in \mathbf{R}^n \times \mathbf{R}: x \text{ is a g.c.point for } (SIP)_t\}$ . By the well-known first order necessary optimality condition of F. John, for every local minimizer  $\bar{x}$  of  $(SIP)_{\bar{t}}$  one has  $\bar{z} = (\bar{x}, \bar{t}) \in \Sigma$ .

The main idea for the investigation of parameter-dependent local minimizers is to study the larger set  $\Sigma$  which contains also local maximizers and several kinds of saddle points. For a fixed generic problem, these different classes of g.c.points can easily be distinguished by algebraic conditions which use the so-called linear

and quadratic (co-)indices. In particular, the *linear (co-)index* refers to the number of (positive) negative Lagrange multipliers corresponding to active inequality constraints; the *quadratic (co-)index* counts the number of (positive) negative eigenvalues of the restriction of the Hessian of a Lagrangian to the tangent space. For a one-parametric problem, these numbers may only change at *singularities* in  $\Sigma$ . The nonsingular points in  $\Sigma$  are termed *nondegenerate critical points* (for details, cf. [13]). In the finite case, i. e., when  $Y(t)$  is a constant and finite set, a nondegenerate critical point is a local minimizer if and only if its linear as well as its quadratic index vanish. Moreover, at a non-degenerate critical point  $\bar{z}$ , the set  $\Sigma$  can locally be described by the implicit function theorem which yields a regular parametrization of  $\Sigma$  by  $t$ . Since the quadruple of linear and quadratic (co-)indices remains constant in a neighborhood of  $\bar{z}$ , a nondegenerate local minimizer remains stable under small perturbations of the parameter  $t$ .

In [5,7], H.Th. Jongen, P. Jonker, and F. Twilt showed for one-parametric finite optimization problems that, apart from non-degenerate critical points (points of type 1) generically there occur exactly four different types of singularities in  $\Sigma$  (points of type 2, 3, 4, and 5). At each singularity the change of the index quadruple is completely described by certain characteristic numbers which can be computed from the problem data at the singularity. Results about the topological structure of  $\Sigma$  around the singular points yield the fundamentals for the design of numerical path following methods (for details, cf. [3]).

In *one-parametric semi-infinite optimization*, generically three additional singularities come into play. Let all defining functions of  $(SIP)_t$  be three times continuously differentiable and define the set CUSC to be the subset of  $C^3(\mathbf{R}^r \times \mathbf{R}, \mathbf{R})^{|I|+|J|}$  consisting of all functions  $(u, v)$  which define index sets  $Y(t)$  such that  $A_{CUSC}$  holds. Then there exists a  $C_s^3$ -open dense subset  $\mathbf{F}$  of  $C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})^{|A|+1} \times C^3(\mathbf{R}^n \times \mathbf{R} \times \mathbf{R}^r, \mathbf{R}) \times \text{CUSC}$ , such that for all  $(f, h, g, u, v) \in \mathbf{F}$  each point of the corresponding g.c.point set  $\Sigma$  is one of eight types. The latter result is given in [10] and proved in detail in [18].

In the remainder of the present section, this type classification is motivated and the local structure of  $\Sigma$  at the typically semi-infinite singularities is discussed. Since in the generic case the number of active indices at a point  $(\bar{x}, \bar{t}) \in \Sigma$  cannot exceed  $n+1$  (cf. [10]), one

deals with finitely many solutions of the so-called *lower level problem*  $\min g(x, t, \cdot)|_{Y(t)}$ , as well as with the *upper level problem*  $f(\cdot, t)|_{M(t)}$ . The idea of the type classification in the semi-infinite case is that in exactly one of these finitely many *finite* optimization problems a singularity of codimension one occurs.

First, assume that all active indices are nondegenerate global minimizers of the lower level problem. Then a local reduction of the semi-infinite to a finite one-parametric optimization problem can be performed, as described in the previous section about the Reduction Ansatz. Here, the assumption  $A_{CUSC}$  is needed. In this reduced problem, all five types from one-parametric finite programming can occur. In particular,  $(\bar{x}, \bar{t})$  is a nondegenerate critical point of  $(SIP)_{\bar{t}}$  if it is of type 1 for the reduced problem. Moreover, this shows that the four singularities from the finite case persist in the semi-infinite setting.

The typically semi-infinite singularities arise if exactly one of the active indices in  $Y_0(\bar{x}, \bar{t}) = \{\bar{y}_1, \dots, \bar{y}_p\}$  is degenerate. Let this be the index  $\bar{y}_p$ . In the generic case, the degeneracy can only be due to situations such as at points of type 2, 3, 4, and 5. As points of type 3 are never local minimizers (cf. [10]), one is left with three possibilities which give rise to the typically semi-infinite singularities of type 6, 7, and 8. The present survey will not handle all details of the type definitions and of the local structures of  $\Sigma$ . For locally simplified problems these definitions are given in [10], whereas the definitions in terms of the original problem data are given in [18]. In the following a one-dimensional manifold  $\Gamma$  in  $\mathbf{R}^n \times \mathbf{R}$  is said to exhibit a *turning point* at  $\bar{z} = (\bar{x}, \bar{t}) \in \Gamma$  if the function  $\Phi(x, t) \equiv t$ , restricted to  $\Gamma$ , possesses a local extremum at  $\bar{z}$ . If, additionally,  $\Gamma$  is locally a  $C^2$ -manifold and the extremum of  $\Phi$  is nondegenerate, then  $\bar{z}$  is called a *quadratic turning point*.

A g.c.point  $\bar{z}$  of type 6 can roughly be characterized by the fact that the gradients of constraints which are active at  $\bar{y}_p$  in the lower level problem are linearly independent, and exactly one of the multipliers corresponding to active inequality constraints vanishes. Now consider two auxiliary problems  $(SIP)_t^e$  and  $(SIP)_t^d$  where this inequality constraint is treated as an equality constraint, respectively deleted as a constraint. It can be shown that  $\bar{z}$  is a non-degenerate critical point of both  $(SIP)_t^e$  and  $(SIP)_t^d$ , which gives rise to two solu-

tion curves  $\Psi^e$  and  $\Psi^d$  in  $\mathbf{R}^n \times \mathbf{R}$ , both being regularly parametrized by  $t$ . Exactly one branch  $\Psi_+^e$  and  $\Psi_+^d$  of each curve belongs to  $\Sigma$ , so that at  $\bar{z}$  the set  $\Sigma$  is locally a one-dimensional manifold which is piecewise of differentiability class  $C^2$ . In the case  $|A| + p = n$ , the curves  $\Psi^e$  and  $\Psi^d$  meet tangentially, and  $\Sigma$  does not exhibit a turning point at  $\bar{z}$ , whereas in the case  $|A| + p < n$  the curves  $\Psi^e$  and  $\Psi^d$  meet under a nonvanishing angle. Moreover, it can be shown that the linear index and co-index remain constant when passing a point of type 6 along  $\Sigma$ , whereas the quadratic index and co-index change if and only if  $\Sigma$  exhibits a turning point at  $\bar{z}$ . In the latter case, the quadratic index changes by one, and characteristic numbers determine the direction of change. In particular, a local minimizer can only be lost at a point of type 6, if  $\Sigma$  exhibits a turning point there. In this case, a feasible direction of quadratic descent (i. e., a *jump direction*) can be given (cf. [3,11,18]).

At a g.c.point  $\bar{z}$  of type 7, the number of active constraints at  $\bar{y}_p$  in the lower level problem does not exceed  $r$ , and their gradients are linearly dependent. It turns out that necessarily a component of the index set  $Y(\bar{t})$  vanishes under perturbations of the parameter (cf. also [8]). As a consequence, the feasible set mapping  $t \rightarrow M(t)$  is not upper semicontinuous at  $\bar{t}$ , and a branch of  $\Sigma$  emanates, respectively ends at  $\bar{z}$ . More precisely,  $\Sigma$  coincides locally with one branch of a one-dimensional  $C^2$ -manifold which exhibits a quadratic turning point at  $\bar{z}$ . A feasible direction of linear descent can be given if  $\Sigma$  consists locally of local minimizers (cf. [11,18]).

At a g.c.point  $\bar{z}$  of type 8, the number of active constraints at  $\bar{y}_p$  in the lower level problem equals  $r + 1$ . If the Mangasarian–Fromovitz constraint qualification holds at  $\bar{y}_p$ , one calls  $\bar{z}$  to be of type 8a, else of type 8b. First consider points of type 8a. Similarly to the situation at points of type 6, there are two auxiliary problems which give rise to two  $C^2$ -curves  $\Psi^1, \Psi^2$  of nondegenerate critical points, both being regularly parametrized by  $t$ , where exactly one branch of each curve belongs to  $\Sigma$ . Since  $\Psi^1$  and  $\Psi^2$  meet in  $\bar{z}$  under a nonvanishing angle,  $\Sigma$  is locally a one-dimensional manifold which is piecewise of differentiability class  $C^2$ . It can be shown that  $\Sigma$  does not exhibit a turning point at  $\bar{z}$  and that the index quadruple remains constant when passing  $\bar{z}$  along  $\Sigma$ . Now let  $\bar{z}$  be a g.c.point of type 8b. Similarly to the situation at points of type 7, a component of the index set  $Y(\bar{t})$  vanishes under perturbations of the param-

eter, and a branch of  $\Sigma$  emanates, respectively ends at  $\bar{z}$ . More precisely,  $\Sigma$  coincides locally with one branch of a one-dimensional  $C^2$ -manifold which can be regularly parametrized by  $t$ . Again a feasible direction of linear descent can be given if  $\Sigma$  consists locally of local minimizers (cf. [11,18]).

Finally, there is a remarkable phenomenon concerning the global structure of  $\Sigma$ . In contrast to the case of one-parametric finite programming where the singular points form the (relative) boundary of the set of nondegenerate critical points (cf. [5,7]), in the semi-infinite case there appears an additional type of boundary point which does not belong to  $\Sigma$ . This so-called *trap-door point* occurs when a new component of  $Y(t)$  is born at a parameter value  $\bar{t}$  (recall that at points of type 7 and type 8b such a component vanishes). The occurrence of trap-door points as well as of points of type 7 and 8b can be avoided if the mapping  $t \rightarrow Y(t)$  is not only assumed to be upper but also lower semicontinuous. In this case, the singular points form the (relative) boundary of the set of non-degenerate critical points. For details, cf. [18,19].

Parametric linear programming; Critical region; Sensitivity analysis with respect to changes in cost coefficients

In this article, we describe solution approaches for two types of linear problems involving uncertain parameters. The first problem that is discussed, involves a single uncertain parameter present on the right-hand side of the constraints, and the second problem involves uncertainty in coefficients of the objective function. The significance of solving these problems is that, while the first problem takes into account the case when a parameter associated with the model equations, such as demand and supply is uncertain, the second problem incorporates uncertainty in the coefficients of variables which define the objective function, such as cost of raw materials and selling price of products. Mathematically, the former problem depicts the value of objective function as the feasible region shrinks (or enlarges), and

Parametric Linear Programming: Cost Simplex Algorithm, Figure 1  
Right-hand side parametrization

Parametric Linear Programming: Cost Simplex Algorithm, Figure 2  
Objective function parametrization

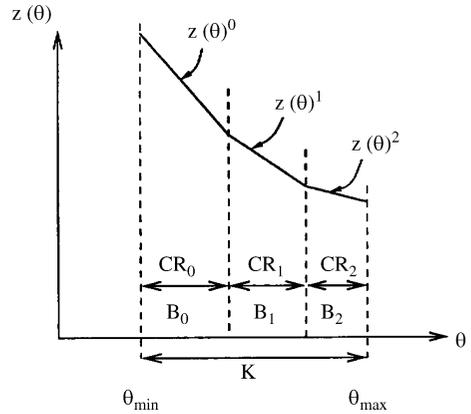

the latter characterizes the ‘fixed’ feasible region with a number of regions corresponding to different sets of active and inactive constraints.

For the first problem, in Fig. 1, PQRS represents an initial feasible region corresponding to the value  $\theta_1$  of the uncertain parameter, and C represents the constraint involving  $\theta$ . As  $\theta_1$  changes from  $\theta_1$  to  $\theta_2$ , the feasible region and the set of active constraints changes. For a given range of  $\theta$ , the aim is then to identify intervals of  $\theta$  within which the optimal value function function,  $z(\theta)$ , preserves its optimality. For the second problem, in Fig. 2, where  $z(\phi)$  represents the objective function and  $\phi$  represents the vector of uncertain parameters in the objective function coefficients, although the feasible region PQRS remains constant, the slope of objective function changes with change in  $\phi$ . The aim in this case is to identify regions rather than the intervals of uncertain parameter space. Next we will describe solution approaches for both the problems.

**Parametric Linear Programming**

Consider the following parametric linear programming problem:

$$\left\{ \begin{array}{l} z(\theta) = \min_x c^T x \\ \text{s.t. } Ax = b + f\theta, \\ x \geq 0, \\ \theta_{\min} \leq \theta \leq \theta_{\max}, \\ x \in \mathbf{R}^n, \end{array} \right. \quad (1)$$

Parametric Linear Programming: Cost Simplex Algorithm, Figure 3  
Optimal value function (right-hand side case)

where  $x$  is a vector of continuous variables;  $A$  is a constant matrix, and  $c$ ,  $b$  and  $f$  are constant vectors of appropriate dimensions;  $\theta$  is a scalar uncertain parameter. The solution of (1) is approached by incorporating the uncertain parameter,  $\theta$ , in the simplex tableau. The solution procedure consists of two phases. In the first phase, an optimal solution for any  $\theta$  in  $[\theta_{\min}, \theta_{\max}]$  is obtained. Let  $B_1$  denote the corresponding optimal basis, and  $x_B^1(\theta) = B^{-1}(b + f\theta)$ , the vector of corresponding basic variables. The *critical region*,  $CR_1$  (Fig. 1), associated with this basis is given by the condition of *primal feasibility*,  $x_B^1(\theta) \geq 0$ , together with the condition that  $\theta_{\min} \leq \theta \leq \theta_{\max}$ . The optimal value function,  $z(\theta)^1$ , is given by  $z(\theta)^1 = c_B^T x_B^1(\theta)$ . This completes the first phase. In the second phase, the *neighboring bases* ( $B_0$  or  $B_2$ ) are identified by one dual step. The procedure is

repeated until the complete range of  $\theta$  has been characterized by critical regions and corresponding optimal value functions. While solving problems of the form given in (1) is usually computationally expensive, it is better than exhaustively obtaining the optimal solutions for all the values of  $\theta$  that lie within  $\theta_{\min}$  and  $\theta_{\max}$ . However, in the worst case the computational requirements for solving (1) are not bounded by a polynomial in the size of the problem [10]. Some other references on the subject are [1,2,3,11] and [12].

### Objective Function Parametrization

Consider the following linear programming problem with uncertain objective function coefficients:

$$\begin{cases} z(\phi) = \min_x c^\top(\phi)x \\ \text{s.t.} & Ax = b, \\ & x \geq 0, \\ & x \in \mathbf{R}^n, \quad \phi \in \mathbf{R}^s, \end{cases} \quad (2)$$

where  $c(\phi) = c + H\phi$ , such that  $c$  is a constant vector and  $H$  is a constant matrix;  $b$  is a constant vector;  $\phi$  is a vector of uncertain parameters, such that for each  $\phi \in K$ ,  $\phi \in \mathbf{R}^s$ , (2) has a finite optimal solution, and has no optimal solution for  $\phi \in \mathbf{R}^s - K$ . Further, consider the following restriction on  $\phi \in \Psi$ ,  $\Psi = \{\phi: G\phi \leq g\}$ , where  $G$  is a constant matrix and  $g$  is a constant vector. By defining new variables  $v$  and  $z$ , (2) can be rewritten as:

$$\begin{cases} z(\phi) = \min_x \phi^\top v + z \\ \text{s.t.} & Ax = b, \\ & v = H^\top x, \\ & z = c^\top x, \\ & x \geq 0, \\ & x \in \mathbf{R}^n, \quad \phi \in \mathbf{R}^s. \end{cases} \quad (3)$$

In the simplex based solution algorithm [4], associated with each optimal basis is a region of  $\phi$  which can be uniquely defined for that basis. The basic idea of the solution approach is then to identify all such bases so that  $\Psi$  is completely characterized by a number of regions, and the corresponding value of the objective function. This can be achieved as follows.

Let  $B$  denote an optimal basis and  $x_B$  denote the corresponding optimal solution; also let  $\rho$  denote the cor-

responding index, also let the basic variables in  $H$  be denoted by  $H_B$ , then we can write:

$$\begin{aligned} \rho H^\top &= H_B^\top Y - H^\top, \\ \rho z^\top &= c_B^\top Y - c^\top, \\ h_{N+1} &= H_B^\top x_B, \\ z^{(\rho)} &= c_B^\top x_B, \end{aligned} \quad (4)$$

where

$$Y = B^{-1}A, \quad x_B = B^{-1}b.$$

The set of equations in (3) can now be rewritten as follows:

$$\begin{aligned} Ax &= b, \\ v + \rho H^\top x &= h_{N+1}, \\ z + \rho z^\top x &= z^{(\rho)}, \end{aligned}$$

where  $\rho z = c_B^\top Y$ , and using appropriate transformation, the objective function can be written as:

$$z(\phi) = -(\rho z^\top + \phi^\top \rho H^\top)x + \phi^\top h_{N+1} + z^{(\rho)}. \quad (5)$$

By denoting  $c_B(\phi) = c_B + H_B\phi$ , and substituting in (4) the following is obtained:

$$\rho z(\phi) = \rho z + \rho H\phi. \quad (6)$$

As described later, this is an important relation for characterizing the region of  $\phi$  associated with the optimal basis  $B$ . In order to obtain parametric solution and the corresponding regions of  $\phi$ , we first need the following:

- The optimal value function,  $z_{\min}(\phi)$ , is concave, linear and continuous over  $K$ .
- Two bases are said to be *neighboring bases* if and only if

- there exists  $\phi^* \in K$  such that both bases are optimal bases for  $\phi^* \in K$ , and
- it is possible to pass from one bases to the another by one primal simplex step.

- The critical region where the basis  $B$  remains optimal is given by the following condition of *dual feasibility*:  $\rho z(\phi) \geq 0$ , or  $-\rho H\phi \leq \rho z$ , together with the restriction on  $\phi$  given by  $G\phi \leq g$ .
- item Two critical regions are said to be neighbors (or *neighboring critical regions*) if their correspond-

ing optimal bases are neighbors (or neighboring bases).

The solution algorithm then relies on finding an initial optimal solution and the corresponding critical region, and then identifying all the critical regions by passing from one region to its neighbor by a primal simplex step. The procedure is continued until the complete space of  $\phi$ , along with the corresponding optimal value function, has been characterized. Also see [5,6,7,8,9,13,14] and [3] for further details.

Parametric upper and lower bounds; Decomposition algorithms

In this article we will present some developments in the subject of parametric programming for problems involving 0–1 integer variables and nonlinearities in the model. For pure quadratic integer problems, [13] proposed an algorithm by extending some of the concepts described in [10] for the case of linear models. The problem they considered can be stated as follows:

$$\begin{cases} z(\theta) = \min_y p(y) \\ \text{s.t.} & Ay \geq b + r\theta, \\ & 0 \leq \theta \leq 1, \\ & y \in \{0, 1\}^m, \end{cases} \quad (1)$$

where  $\theta$  is a scalar uncertain parameter;  $p(y) \equiv y^T Q y$ ;  $r$  is a nonnegative  $n$ -vector, such that only  $r_1 \geq 0$ ;  $Q$  is an  $(m \times m)$  matrix;  $A$  is an  $(n \times m)$  matrix. The solution procedure is based upon the observation that as  $\theta$  is increased from 0 to 1, it results in shrinking of the feasible region (because  $r \geq 0$ ) of (1) and hence only a solution worse than (greater than or equal to) the solution at 0 can be obtained, i. e.,  $z(\theta)$  is a nondecreasing function of  $\theta$  (see Fig. 1). Another interesting feature of the formulation in (1) is that since  $\theta$  is bounded between lower and upper bounds, there is a finite number of (integer) solutions that will lie between these bounds. Further, because the optimal solution of (1) at a fixed value of  $\theta$  corresponds to lattice points of a polyhedron, it remain optimal for a range of  $\theta$  until another lattice point becomes optimal (this results in a finite number of intervals of  $\theta$  corresponding to the finite number of solutions that lie in  $[0, 1]$ ; Fig. 1). [13] proposed the following procedure for identifying these (critical) intervals and corresponding optimal solutions:

Parametric Mixed Integer Nonlinear Optimization, Figure 1  $z(\theta)$  is a discontinuous nondecreasing step function

grams to nonlinear programs. They also discussed the extension of their results to the mixed integer case. We next consider the following parametric mixed integer nonlinear programming problem:

$$\begin{cases} z(\theta) = \min_{y,x} c^T y + f(x) \\ \text{s.t.} & h(x) = 0, \\ & B y + g(x) \leq b + r\theta, \\ & \theta_{\min} \leq \theta \leq \theta_{\max}, \\ & x \in X, \quad y \in \{0, 1\}^m, \end{cases} \quad (2)$$

where  $f$  and  $g$  are continuously differentiable and convex on the  $n$ -dimensional compact polyhedral convex set  $X = \{x: x \in \mathbf{R}^n, A_1 x \leq a_1\}$ ;  $h$  is affine with respect to  $x$ ;  $\theta$  is a scalar uncertain parameter;  $c$ ,  $b$  and  $r$  are constant vectors and  $B$  is a constant matrix.

- The solution of (2) can be approached by using
- i) outer-approximation (OA) [3]; or,
  - ii) generalized Benders decomposition (GBD) principles [9].

See [7] for details and some applications of these algorithms. The basic idea in both the approaches is to decompose the problem into a *primal* and a *master subproblem*, and the basic difference between the two approaches is in the formulation of the master subproblem. The solution of primal subproblem, which is obtained for fixed  $y$ , represents a parametric upper bound, whereas, the solution of master subproblem, which is obtained for a relaxation of the initial problem, represents a parametric lower bound. The solution algorithm is based upon iterating between these two subproblems (upper and lower bounds).

0	Set $k = 1$ and let $\theta = 0$ .
1	For (1) find the optimum solution $y_k$ and the corresponding $p(y_k)$ . Also find $\theta_k$ using:
	$\theta_k = \frac{a_1 y_k - b_1}{r_1},$
	where $a_1$ denotes the first row of $A$ . IF no such $y_k$ exists, THEN go to 3, ELSE go to 2.
2	Set $k = k + 1$ and let $\theta = \theta_{k-1} + \delta$ , where
	$\theta = \frac{a_1 y_{k-1} - b_1 + g}{r_1} = \theta_{k-1} + \delta,$
	where $\delta = g/r_1$ and $g$ is the greatest common divisor of the elements of $a_1$ . IF $\theta \leq 1$ , THEN go to 1, else go to 3.
3	Stop, all critical solutions have been found.

[2] extended their previous work on dynamic programming to present a solution procedure for pure integer nonlinear programming problems. [18] extended the branch and bound technique of [17] for linear pro-

The primal subproblem is formulated by fixing  $y = \bar{y}$  in (2) to obtain a parametric NLP (pNLP) of the following form:

$$\begin{cases} z(\bar{y}, \theta) = \min_x c^\top \bar{y} + f(x) \\ \text{s.t.} & h(x) = 0, \\ & B\bar{y} + g(x) \leq b + r\theta, \\ & \theta_i \leq \theta \leq \theta_{i+1}, \\ & x \in X. \end{cases} \quad (3)$$

Under appropriate continuity and convexity properties ([4,5,6,11]), the solution of (3) is approximated by creating linear parametric upper and lower bounds at the extreme points of the interval  $[\theta_i, \theta_{i+1}]$ . A *parametric upper bound* is given by:

$$\widehat{z}(\bar{y}, \theta) = \alpha z^*(\bar{y}, \theta_i) + (1 - \alpha)z^*(\bar{y}, \theta_{i+1}), \quad \alpha \in (0, 1) \quad (4)$$

and a *parametric lower bound* is given by:

$$\begin{aligned} \bar{z}(\bar{y}, \theta) &= \max\{\text{LB}_i, \text{LB}_{i+1}\}, \\ \text{LB}_i &= z^*(\bar{y}, \theta_i) + \nabla_\theta z^*(\bar{y}, \theta_i)(\theta - \theta_i), \\ \text{LB}_{i+1} &= z^*(\bar{y}, \theta_{i+1}) + \nabla_\theta z^*(\bar{y}, \theta_{i+1})(\theta - \theta_{i+1}), \end{aligned} \quad (5)$$

where  $z^*(\bar{y}, \theta_i)$  and  $z^*(\bar{y}, \theta_{i+1})$  are the solutions of (3) at  $\theta_i$  and  $\theta_{i+1}$ , respectively;  $\nabla_\theta z^*$  is evaluated through the Lagrange multipliers. The parametric upper and lower bounds are tightened at the intersection point (in  $\theta$ ) of  $\text{LB}_i$  and  $\text{LB}_{i+1}$  breaking the interval of  $\theta$  into two smaller intervals, within which another set of upper and lower bounds are obtained. This approximation is continued until the difference between upper and lower bounds is within  $\epsilon$ . If an infeasibility is found at an extreme point, the following problem is solved to obtain the feasible interval:

$$\begin{cases} \min_{x, \theta} \theta \quad (\text{or } \max_{x, \theta} \theta) \\ \text{s.t.} & h(x) = 0, \\ & B\bar{y} + g(x) - r\theta \leq b, \\ & x \in X, \\ & \theta_i \leq \theta \leq \theta_{i+1}. \end{cases} \quad (6)$$

The final solution of a primal subproblem is given by parametric upper bounds obtained in their corresponding intervals of  $\theta$ .

The master subproblem can then be constructed by using either OA or GBD principles. Using OA principles, master subproblem is formulated as follows ([1,15,16]):

$$\begin{cases} z'(\theta) = \min_{y, x, \mu} c^\top y + \mu \\ \text{s.t.} & T(\lambda)[h(x^*) + \nabla h(x^*)(x - x^*)] \leq 0, \\ & By + g(x^*) + \nabla g(x^*)(x - x^*) \\ & \quad \leq b_0 + r\theta, \\ & f(x^*) + \nabla f(x^*)(x - x^*) - \mu \leq 0, \\ & \sum_{j \in J} y_j - \sum_{j \in L} y_j \leq |J| - 1, \\ & \theta_i \leq \theta \leq \theta_{i+1}, \\ & x \in X, \quad y \in \{0, 1\}^m, \end{cases} \quad (7)$$

where  $\mu$  is a scalar variable;  $T(\lambda)$  is a diagonal matrix with elements

$$t_{p,p} = \begin{cases} -1, & \lambda_p < 0, \\ 0, & \lambda_p = 0, \\ 1, & \lambda_p > 0, \end{cases}$$

where  $\lambda_p$  is the Lagrange multiplier of equation  $h_p, p = 1, \dots, P$ , [12];  $x^*$  are the solutions of (3) obtained at the extreme points of intervals of  $\theta$  while solving the primal subproblem;  $J = \{j: y = 1\}$  and  $L = \{j: y = 0\}$ , and  $|J|$  is the cardinality of  $J$ .

Alternatively, using GBD principles, the master subproblem is formulated as follows [14]:

$$\begin{cases} z'(\theta) = \min_{y, \mu} \mu \\ \text{s.t.} & \mu \geq c^\top y + f(x^*) + \lambda^\top [h(x^*)] \\ & \quad + \tau^\top [By + g(x^*) - b - r\theta], \\ & \lambda_{\text{inf}}^\top [h(x^*)] \\ & \quad + \tau_{\text{inf}}^\top [By + g(x^*) - b - r\theta] \leq 0, \\ & \theta_i \leq \theta \leq \theta_{i+1}, \\ & y \in \{0, 1\}^m, \end{cases} \quad (8)$$

where  $\lambda$  and  $\tau$  are Lagrange multipliers obtained at extreme points of intervals of  $\theta$  in the primal subproblem; and the subscript inf corresponds to the Lagrange multipliers in the infeasible interval of  $\theta$ , where following

relaxed problem is solved:

$$\left\{ \begin{array}{l} \min_{x, s_1, s_2, \phi} \quad (s_1 + s_2 + \phi) \\ \text{s.t.} \quad h(x) + s_1 - s_2 = 0, \\ \quad \quad By + g(x) - b - r\theta_{\text{inf}} \leq \phi, \\ \quad \quad s_1, s_2, \phi \geq 0, \\ \quad \quad x \in X, \end{array} \right. \quad (9)$$

where  $s_1, s_2$  and  $\phi$  are positive slack variables and the subscript inf corresponds to infeasible  $\theta$  points.

Note that (7) and (8) are parametric mixed integer linear programming (pMILP) problems, which can be solved using the following algorithm proposed by [15]. The solution is approached by fixing  $\theta$  at the lower value of the interval, in the master subproblem. This results in a deterministic MILP, which is then solved to obtain an integer solution given by  $y'$ . Fixing  $y = y'$  in the master subproblem results in a parametric LP (pLP) problem. The solution of this pLP, obtained by using an algorithm described by [8], is given by a linear parametric profile,  $\hat{z}'(\theta)$ , and represents an upper bound on the solution of master subproblem. Another MILP is formulated, to obtain a *breakpoint*  $\theta_{\text{bp}}$ , where some other integer solution is lower than the upper bound,  $\hat{z}'(\theta)$ , as follows:

$$\left\{ \begin{array}{l} \theta_{\text{bp}} = \min_{x, \theta} \\ \text{s.t.} \quad T(\lambda)[h(x^*) + \nabla h(x^*)(x - x^*)] \leq 0, \\ \quad \quad By + g(x^*) + \nabla g(x^*)(x - x^*) \\ \quad \quad \leq b_0 + r\theta, \\ \quad \quad f(x^*) + \nabla f(x^*)(x - x^*) - \mu \leq 0, \\ \quad \quad \sum_{j \in I} y_j - \sum_{j \in L} y_j \leq |I| - 1, \\ \quad \quad \mu \leq \hat{z}'(\theta), \\ \quad \quad \theta_i \leq \theta \leq \theta_{i+1}, \\ \quad \quad x \in X, \\ \quad \quad y \in \{0, 1\}^m, \quad y \neq y'. \end{array} \right. \quad (10)$$

For the interval  $[\theta_i, \theta_{\text{bp}}]$  the solution is given by  $z'(\theta) = \hat{z}'(\theta)'$ , and for the rest of the interval,  $[\theta_{\text{bp}}, \theta_{i+1}]$  the procedure is repeated until (10) is infeasible. The final solution is given by a set of parametric profiles valid in their corresponding intervals.

0	(initialization) Define an interval of $\theta$ ; tolerance, $\epsilon$ ; an upper bound $\hat{z}^*(\theta) = \infty$ ; initial $y = \bar{y}$ .
1	(primal problem) For each interval with a new integer structure, $\bar{y}$ :
1a	Solve problem (3) to obtain $\hat{z}(\bar{y}, \theta)$ such that tolerance, $\epsilon$ , is satisfied.
1b	If $\hat{z}(\bar{y}, 0) \leq \hat{z}^*(\theta)$ update the best upper bound function, and the corresponding integer solutions, $y^*$ .
2	(master problem) For each interval, solve either (7) or (8) to obtain a lower bound $z'(\theta)$ and the corresponding break points. Define the new set of intervals.
3	(convergence) If for some interval $\hat{z}^*(\theta) \leq z'(\theta)$ , or the master problem is feasible, the solution is given by the current solution, otherwise return to primal problem with new integer solution.

This solution of the master subproblem represents a parametric lower bound. If in an interval the lower bound,  $z'(\theta)$ , exceeds the upper bound,  $\hat{z}(\bar{y}, \theta)$ , or the master subproblem is infeasible the algorithm stops with the current solution in those intervals as the final solution, otherwise, the new vector  $y$  along with the corresponding interval obtained from the solution of the master subproblem is returned back to the primal subproblem.

The main steps of the algorithm are summarized above.

These algorithms have been tested on a number of applications including process synthesis and planning, heat exchanger network synthesis, multi-objective optimization and simultaneous product and process design ([1,14,15]).

Introduction

The principle of *embedding* for nonlinear equations has been known for more than 40 years (cf. e. g. [9, Chapt. 11], and the historical remarks there, [10]). We consider the nonlinear system of equations

$$F(x) = 0 \tag{1}$$

defined by  $F: \mathbf{R}^n \rightarrow \mathbf{R}^n$  (e. g.  $F \in C^2(\mathbf{R}^n, \mathbf{R}^n)$ ) and equation (1) is embedded by

$$H(x, t) = 0, \quad t \in [0, 1],$$

with the following properties:

$$H(x^0, 0) = 0, \quad H(x, 1) = F(x),$$

where  $H: \mathbf{R}^n \times \mathbf{R} \rightarrow \mathbf{R}^n$ ,  $x^0 \in \mathbf{R}^n$  arbitrarily chosen and fixed.

The following so-called standard embedding is one example:

$$H(x, t) := F(x) + (t - 1)F(x^0).$$

Moreover, there are many practical examples, in particular from mechanics and electrotechnics, which, a priori, depend on one real parameter  $t$ . Then the function  $H$  is given explicitly. In order to find a solution for (1), we have to find a discretization of the interval  $[0, 1]$ :

$$0 = t_0 < \dots < t_i < t_{i+1} < \dots < t_N = 1 \tag{2}$$

and corresponding  $(x(t_i), t_i)$  with  $H(x(t_i), t_i) = 0$ ,  $i = 1, \dots, N$ , using the starting point  $x^0$ . The main tools for finding such a discretization are *path following* methods (also called *homotopy methods* or *continuation methods*). The general principle will be explained under the following assumptions:

E1)  $H \in C^2(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})$ .

E2) There exists a function  $x \in C^1([\underline{t}, \bar{t}], \mathbf{R}^n)$  such that  $H(x(t), t) = 0$ .

If we denote by  $r(t)$  the radius of convergence, for instance for the Newton method solving  $H(x, t) = 0$  in a neighborhood of  $x(t)$ , then we have (cf. [3])

**Theorem 1** Assume E1) and E2). Then there exists a real number  $r > 0$  such that  $r(t) \geq r$  for all  $t \in [\underline{t}, \bar{t}]$ .

Path following methods are realized by so-called predictor-corrector schemes. The main idea of such a scheme is the following:  $t_i \rightarrow t_{i+1}$  beginning at some  $t$  with known  $x(t)$  is the predictor, and the Newton method is the corrector. More precisely, using the known point  $(\tilde{x}^i, t_i)$  as an approximation of  $(x(t_i), t_i)$ , we compute an approximation  $(\tilde{x}^{i+1}, t_{i+1})$  of  $(x(t_{i+1}), t_{i+1})$  by a finite number of Newton steps, where  $t_{i+1}$  has to be chosen in such a way that  $\tilde{x}^i$  lies in the convergence region of the problem

$$H(x, t_{i+1}) = 0$$

if  $|t_{i+1} - t_i|$  is chosen sufficiently small.

For example, consider  $H(x, t) = 3/x + t - 4.5$ . The point  $(\tilde{x}^i, t_i) = (0.7499, 0.5)$  is an approximation of  $(x(t_i), t_i)$  and for  $t_{i+1} = 0.6$ ,  $\tilde{x}^i$  lies in the convergence region of  $H(x, 0.6) = 0$ , starting at  $\tilde{x}^{i+1} = 0.7692$ .

Let  $\bar{t}$  be the endpoint of the scheme. In case of  $[\underline{t}, \bar{t}] = [0, 1]$ , we obtain, in a finite number of steps, a point lying in  $r(1)$  and having at least superlinear convergence.

Concerning parameter-dependent equations we refer to [1] and the very good and informative bibliography therein.

Now we consider a nonlinear optimization problem:

$$(P) \min \left\{ f(x): \begin{array}{l} h_i(x) = 0, \quad i \in I, \\ g_j(x) \leq 0, \quad j \in J \end{array} \right\},$$

(where  $I := \{1, \dots, m\}$ ,  $J = \{1, \dots, s\}$  and assume that  $f, h_i, g_j \in C^k(\mathbf{R}^m, \mathbf{R})$ ,  $i \in I, j \in J$ , and  $k \geq 1$  will be specified later) and the corresponding Karush–Kuhn–

Tucker system (shortly KKT-system)

$$\begin{cases} Df(x) + \sum_{i \in I} \lambda_i Dh_i(x) \\ + \sum_{j \in J} \mu_j Dg_j(x) = 0, \\ h_i(x, t) = 0, & i \in I, \\ g_j(x) \leq 0, & j \in J, \\ \mu_j \geq 0, & j \in J, \\ \mu_j \cdot g_j(x) = 0, & j \in J \end{cases} \quad (3)$$

(here  $Df(x) := (\partial f / \partial x_1, \dots, \partial f / \partial x_n)$  is a row vector).

In the literature we can distinguish two general approaches to realize the idea explained above for nonlinear optimization problems.

- First approach: Transform the KKT system into a system of equations or into a generalized equation.
- Second approach: (P) will be embedded by a one-parametric optimization problem.

In the first approach, both transformations are well known. The KKT system (3) is a mixture of equations and inequalities. The reformulation to a system of equations is quite simple. For  $y \in \mathbf{R}$  we define

$$y^+ := \max\{y, 0\}, \quad y^- := \min\{y, 0\}.$$

We can formulate the KKT system as an equivalent system of equations:

$$\mathcal{H}(x, y) := \begin{bmatrix} D(f(x) + \sum_{i \in I} y_i Dh_i(x) \\ + \sum_{j \in J} y_j^+ Dg_j(x), \\ h_i(x), \quad i \in I, \\ y_j^- - g_j(x), \quad j \in J \end{bmatrix} = 0 \quad (4)$$

(cf. e.g. [3, Ref. 134 and 135]).  $\mathcal{H}(x, y)$  is called a *Kojima function*. We refer to the interesting article [7], and the references therein. Here,  $f, h_i, g_j \in C^{1,1}(\mathbf{R}^n, \mathbf{R})$ ,  $i \in I, j \in J$  (i.e., there exist derivatives which are locally Lipschitz). Two embeddings (parametrizations) of  $\mathcal{H}(x, y, t) = 0$  are investigated. In particular, this permits new interpretations of the related solution methods (penalty and a new *barrier* method) and allows for estimates of the solutions by using implicit function theorems.

There are also possibilities to reformulate the KKT system into a  $k$ -times ( $k \geq 1$ ) continuously differentiable nonlinear parameter-dependent system of equations (cf. e.g. [3, Ref. 62] and the references there). Then we can use standard methods for parameter-dependent equations (cf. the literature mentioned

above). Furthermore, we can also consider the KKT system as a generalized equation (cf. [3, Ref. 193] and the references there) and use the corresponding path following methods (cf. [3, Ref. 177]).

Before we come to the second approach, we introduce a general *one-parametric nonlinear optimization* problem

$$\begin{aligned} \min \{f(x, t) : x \in M(t)\}, \\ t \in \mathbf{R}, \quad \text{resp. } t \in [0, 1], \end{aligned}$$

$$M(t) = \left\{ x \in \mathbf{R}^n : \begin{array}{l} h_i(x, t) = 0, \quad i \in I, \\ g_j(x, t) \leq 0, \quad j \in J \end{array} \right\},$$

$$f, h_i, g_j \in C^k(\mathbf{R}^n \times \mathbf{R}, \mathbf{R}),$$

$$i \in I, \quad j \in J, \quad k \geq 2,$$

$$I := \{1, \dots, m\}, \quad J := \{1, \dots, s\}.$$

Furthermore, we introduce the following notations:

$$\Sigma_{\text{gc}} := \left\{ (x, t) \in \mathbf{R}^n \times \mathbf{R} : \begin{array}{l} x \text{ a generalized} \\ \text{critical point of} \\ P(t) \end{array} \right\},$$

$$\Sigma_{\text{stat}} := \left\{ (x, t) \in \mathbf{R}^n \times \mathbf{R} : \begin{array}{l} x \text{ a stationary} \\ \text{point of } P(t) \end{array} \right\},$$

$$\Sigma_{\text{loc}} := \left\{ (x, t) \in \mathbf{R}^n \times \mathbf{R} : \begin{array}{l} x \text{ a local} \\ \text{minimizer of} \\ P(t) \end{array} \right\},$$

(a generalized critical (g.c.) point is defined in [3] for instance).

We adapt the concept of embedding to the problem (P) using the problem  $P(t)$  with at least the following properties:

A1) A local minimizer  $x^0$  for  $P(0)$  is known;

A2)  $P(1)$  is equivalent to (P).

The conditions A1) and A2) are fulfilled if we choose e.g.  $P(t)$  defined by

$$\begin{aligned} f(x, t) &:= tf(x) + (1-t) \|x - x^0\|^2, \\ h_i(x, t) &:= h_i(x) + (t-1)h_i(x^0), \quad i \in I, \\ g_j(x, t) &:= g_j(x) + (t-1)|g_j(x^0)|, \quad j \in J, \end{aligned}$$

where  $x^0 \in \mathbf{R}^n$  is arbitrarily fixed.

Here too, we have to find a discretization (2) of the interval  $[0, 1]$  and corresponding points  $(x(t_i), t_i) \in \Sigma_{\text{loc}}$  ( $\Sigma_{\text{stat}}$  or  $\Sigma_{\text{gc}}$ ),  $i = 1, \dots, N$ . We can also use a predictor-corrector scheme applied to the full problem  $P(t)$  in some interval  $[t, \bar{t}] \subseteq [0, 1]$  (a modification

of the above Theorem holds, cf. [3]) or to a finite number of reduced problems with equality constraints only:

$$P^{J_0}(t) : \min \left\{ f(x, t) : \begin{array}{l} h_i(x, t) = 0, \quad i \in I, \\ g_j(x, t) = 0, \quad j \in J_0, \end{array} \right\}, \\ t \in [t_s, t_{s+1}],$$

where  $J_0$  is the index set of active constraints, which is constant in a certain interval  $[t_s, t_{s+1}] \subseteq [0, 1]$ . We call this procedure an active index set strategy. In order to understand how difficult it is to find such a discretization (2), we give a very brief summary on two classes of functions  $(f, H, G)$  ( $H = (h_1, \dots, h_m)^\top$ ,  $G = (g_1, \dots, g_s)^\top$ ), namely, the Jongen–Jonker–Twilt class  $\mathcal{F}$  (cf. [3] and the original articles [3, Ref. 115 and 118]) and the Kojima–Hirabayashi class (cf. [3, Ref. 135]).

### Generic Singularities, the Approach via Piecewise Differentiability and Topological Stability

First, we introduce two well-known constraint qualifications.

The *linear independence constraint qualification* (LICQ) is satisfied at  $\bar{x} \in M(\bar{t})$  if the vectors  $D_x h_i(\bar{x}, \bar{t})$ ,  $i \in I$ ,  $D_x g_j(\bar{x}, \bar{t})$ ,  $j \in J_0(\bar{x}, \bar{t})$ , are linearly independent ( $J_0(x, t) := \{j \in J : g_j(x, t) = 0\}$ ).

The *Mangasarian–Fromovitz constraint qualification* (MFCQ) is satisfied at  $\bar{x} \in M(\bar{t})$  if:

MF1)  $D_x h_i(\bar{x}, \bar{t})$ ,  $i \in I$ , are linearly independent

MF2) there exists a vector  $\xi \in \mathbf{R}^n$  with

$$\begin{aligned} D_x h_i(\bar{x}, \bar{t})\xi &= 0, \quad i \in I, \\ D_x g_j(\bar{x}, \bar{t})\xi &< 0, \quad j \in J_0(\bar{x}, \bar{t}). \end{aligned}$$

We consider the Kojima function  $\mathcal{H}(x, y, t)$  corresponding to  $P(t)$  and  $\mathcal{H}(x, y, t)$  is piecewise continuously differentiable (shortly  $PC^1$ ) (see [4]). The classical definition of a regular value of a continuously differentiable function is generalized for  $PC^1$  functions. Furthermore, it is shown that, if 0 is a regular value of  $\mathcal{H}$ , then the set  $\mathcal{H}^{-1}(0)$  is  $PC^1$  manifold (cf. [3, Ref. 135]).

Next, we cite our short characterization of the class  $\mathcal{F}$  introduced by H.Th. Jongen, P. Jonker and F. Twilt.

The space  $C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})$  will be endowed with the strong (or Whitney-)  $C_s^3$ -topology, the  $C_s^3$ -topology of the product of a finite number of copies of  $C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})$  being the induced product topology. A typical  $C_s^3$  base-neighborhood  $\mathcal{N}$  of the zero function in  $C^3(\mathbf{R}^n$

$\times \mathbf{R}, \mathbf{R})$  is induced by means of a continuous positive function  $\varepsilon: \mathbf{R}^n \times \mathbf{R} \rightarrow \mathbf{R}$  as follows:

$$\begin{aligned} \mathcal{N}_\varepsilon &= \{\phi \in C^3(\mathbf{R}^n \times \mathbf{R}) : \\ &\|\phi(z)\| + \sum \left\| \frac{\partial \phi}{\partial z_i}(z) \right\| + \sum \left\| \frac{\partial^2 \phi}{\partial z_i \partial z_j}(z) \right\| \\ &+ \sum \left\| \frac{\partial^3 \phi}{\partial z_i \partial z_j \partial z_k}(z) \right\| < \varepsilon(z) \\ &\text{for all } z \in \mathbf{R}^{n+1} \}, \end{aligned}$$

where  $z = (x, t) \in \mathbf{R}^n \times \mathbf{R}$ . A typical  $C_s^3$  base-neighborhood of  $f \in C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})$  will be the set  $f + \mathcal{N}_\varepsilon$ .

The local structure of  $\Sigma_{\text{gc}}$  is completely described if  $(f, H, G)$  belongs to a  $C_s^3$ -open and dense subset  $\mathcal{F}$  of  $C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})^{1+m+s}$ .

If  $(f, H, G) \in \mathcal{F}$  then  $\Sigma_{\text{gc}}$  can be divided into 5 types:

- *Type 1*: A point  $\bar{z} = (\bar{x}, \bar{t}) \in \Sigma_{\text{gc}}$  is of Type 1 if the following conditions are satisfied

$$\left( D_x f + \sum_{i \in I} \lambda_i D_x h_i + \sum_{j \in J_0(\bar{z})} \mu_j D_x g_j \right) \Big|_{z=\bar{z}} = 0, \quad (5)$$

$$\text{the LICQ is satisfied at } \bar{x} \in M(\bar{t}), \quad (6)$$

$$\mu_j \neq 0, \quad j \in J_0(\bar{z}), \quad (7)$$

$$D_x^2 L(\bar{x}) \Big|_{T(\bar{z})} \text{ is nonsingular.} \quad (8)$$

Here,  $D_x^2 L$  is the Hessian of the Lagrangian

$$L = f + \sum_{i \in I} \lambda_i h_i + \sum_{j \in J_0(z)} \mu_j g_j,$$

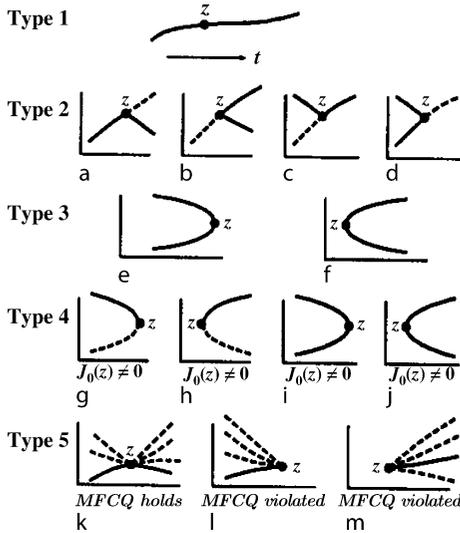

and the uniquely determined numbers  $\lambda_i \mu_j$  are taken from (5).

Furthermore,

$$T(z) = \left\{ \xi \in \mathbf{R}^n : \begin{array}{l} D_x h_i(z)\xi = 0, \quad i \in I, \\ D_x g_j(z)\xi = 0, \quad j \in J_0(z) \end{array} \right\}$$

is the tangent space at  $z$ .  $D_x^2 L(z) \Big|_{T(z)}$  represents  $V^\top D_x^2 L V$ , where  $V$  is a matrix whose columns form a basis of  $T(z)$ .

A point of Type 1 is called a *nondegenerate critical point*. The set  $\Sigma_{\text{gc}}$  is the closure of the set of all

Parametric Optimization: Embeddings, Path Following and Singularities, Figure 1

points of Type 1, the points of the Types 2–5 constitute a discrete subset of  $\Sigma_{gc}$ . The points of the Types 2–5 represent three basic degeneracies:

- Type 2: violation of (7).
- Type 3: violation of (8).
- Type 4: violation of (6) and

$$|I| + |J_0(\bar{z})| - 1 < n.$$

- Type 5: violation of (6) and

$$|I| + |J_0(\bar{z})| = n + 1.$$

For each of these five types Fig. 1 illustrates the local structure of  $\Sigma_{gc}$ . Let  $\Sigma_{gc}^v$ ,  $v \in \{1, \dots, 5\}$  be the set of g.c. points of Type  $v$ . Figure 2 illustrates the local structure of  $\mathcal{F}$  in  $\Sigma_{loc}$  and  $\Sigma_{stat}$ . The class  $\mathcal{F}$  is defined by

$$\mathcal{F} = \left\{ (f, H, G) \in C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R})^{1+m+s} : \Sigma_{gc} \subset \bigcup_{v=1}^5 \Sigma_{gc}^v \right\}.$$

The following theorem (cf. [4, Ref. 15]) provides a special perturbation of  $(f, H, G)$  with additional parameters that can be chosen arbitrarily small such that the perturbed function vector belongs to the class  $\mathcal{F}$ .

**Theorem 2** Let  $(f, H, G) \in C^3(\mathbf{R}^n \times \mathbf{R}, \mathbf{R}^{1+m+s})$ . Then, for almost all  $(b, A, c, D, e, F) \in \mathbf{R}^n \times \mathbf{R}^{n(n+1)/2} \times \mathbf{R}^m \times$

$\mathbf{R}^{mn} \times \mathbf{R}^s \times \mathbf{R}^{sn}$ , we have

$$(f(x, t) + b^T x + x^T A x, H(x, t) + c + D x, G(x, t) + e + F x) \in \mathcal{F}.$$

Here ‘almost all’ means: each measurable subset of

$$\{(b, A, c, D, e, F) : (f(x, t) + b^T x + x^T A x, H(x, t) + c + D x, G(x, t) + e + F x) \notin \mathcal{F}\}$$

has Lebesgue-measure zero.

**Remark 3** There is also a perturbation theorem for the Kojima–Hirabayashi class with a linear perturbation in the objective and scalar perturbations in the constraints (cf. [3, Ref. 135])

**Remark 4** (cf. [3]) Considering  $\Sigma_{stat}$  we note that the condition  $(f, H, G) \in \mathcal{F}$  implies that zero is a regular value of the Kojima-mapping  $\mathcal{H}$ .

**Definition 5** Let  $K \subseteq \mathbf{R} \cup \{\pm\infty\}$ .

- i) The problem  $P(t)$  is called *regular in the sense of Jonken–Jonker–Tiwit* (briefly: *JJT-regular*) (with respect to  $K$ ) if

$$(f, H, G) \in \mathcal{F} \left( \mathbf{R}^n \times K \cap \Sigma_{gc} \subset \bigcup_{v=1}^5 \Sigma_{gc}^v \right).$$

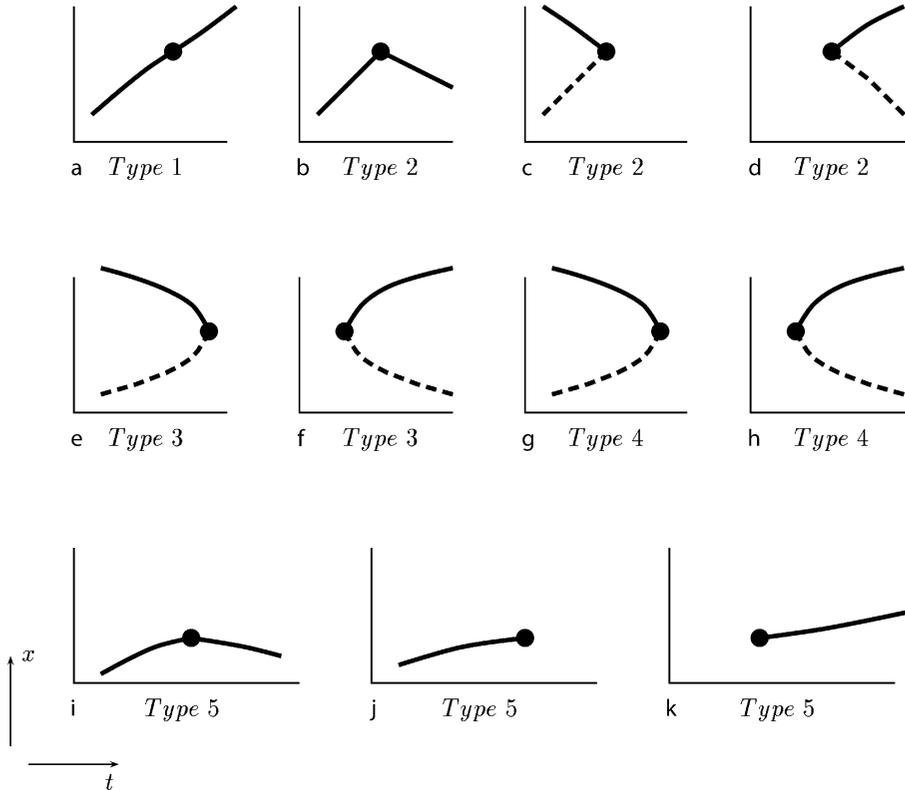

- ii) The problem  $P(t)$  is called *regular in the sense of Kojima–Hirabayashi* (briefly: *KH-regular*) (with respect to  $K$ ) if  $0 \in \mathbf{R}^{n+m+s}$  is a regular value of  $\mathcal{H}$  ( $\mathcal{H}|_{\mathbf{R}^n \times \mathbf{R}^m \times \mathbf{R}^s \times K}$ ).

Now, we present some facts about path following methods (for more details see [3]). For this, we assume A1), A2) and that  $(f, H, G) \in \mathcal{F}$ . The algorithm PATH III (cf. [3, Chap. 4]) computes a numerical description of a compact connected component in  $\Sigma_{gc}$  and  $\Sigma_{stat}$ , respectively.

In the last part of this section we present two theorems that are essential for the analysis of considered embeddings in the literature and for modifying embeddings that are successful under certain assumptions.

**Theorem 6** ([3, Ref. 71]) We assume

- C1)  $M(t)$  is nonempty and there exists a compact set  $C$  with  $M(t) \subseteq C$  for all  $t \in [0, 1]$ .
- C2)  $P(t)$  is *KH-regular* with respect to  $[0, 1]$ .
- C3) There exists a  $t_1 > 0$  and a continuous function  $x: [0, t_1] \rightarrow \mathbf{R}^n$  such that  $x(t)$  is the unique stationary point for  $P(t)$  for  $t \in [0, t_1]$ .

Parametric Optimization: Embeddings, Path Following and Singularities, Figure 2

The full curve stands for the curve of local minimizers and the dotted curve represents a curve of stationary points

C4) MFCQ is satisfied for all  $x \in M(t)$  for all  $t \in [0, 1]$ . Then there exists a  $PC^1$ -path in  $\Sigma_{stat}$  that connects  $(x^0, 0)$  with some point  $(x^*, 1)$ .

Applying our first Remark we obtain

**Corollary 7** We assume C1), C3), C4) and D2)  $P(t)$  is JJT-regular with respect to  $[0, 1]$ . Then there exists a  $PC^2$ -path  $K(x^0, 0)$  in  $\Sigma_{stat}$  connecting  $(x^0, 0)$  with some point  $(x^*, 1)$ . Furthermore, if  $(x, t) \in K(x^0, 0)$ , then  $(x, t)$  belongs to  $\cup_{v \in \{1, 2, 3, 5\}} \Sigma_{gc}^v$ .

Finally we present a consequence of a general topological stability result given in [3, Ref. 87]:

**Theorem 8** We assume C1) and C4). Then  $M(t_1)$  is homeomorphic with  $M(t_2)$  for all  $t_1, t_2 \in [0, 1]$ .

**Remark 9** We see that the MFCQ plays an important role in both theorems above. Unless the MFCQ is satisfied, we do not attain a point  $(\hat{x}, 1) \in \Sigma_{stat}$  by path following methods only, g.c. points of the Types 4 and 5 may appear and the path ends in  $\Sigma_{stat}$ .

From this point of view we refer to the analysis of possible jumps from one connected component to another in  $\Sigma_{stat}$  and  $\Sigma_{gc}$ , respectively (cf. [3, Chap. 5]). In the worst case we have to find all connected components in  $\Sigma_{gc}$ . Since we do not have jumps in all cases, this problem has not been solved yet. This is not surprising because, in case we surely find a discretization (1) and a corresponding point  $(x^i, t_i) \in \Sigma_{gc}$ ,  $i = 1, \dots, N$ , the problem of global optimization is solved (cf. e. g. [3, Sect. 6.3]).

**Concluding Remarks**

- i) We have restricted ourselves to *parametric optimization* problems in  $\mathbf{R}^n$  so far. We refer to semi-infinite problems (cf. e. g. [6, pp. 161–176], and the references in that article).
- ii) The theory and methods described in the section above are used for an analysis and appropriate modifications of the standard embedding (cf. [6, pp. 59–

84]), the penalty, exact penalty, and Lagrange multiplier embeddings (cf. [4] and [4, Refs. 2, 3, 6]), and for constructing new methods [2]. Summarizing, we have now more clearness concerning the problem of what kind of difficulties (mainly singularities) may appear and how to overcome them in some cases (see also [5]).

- iii) We refer to further applications: One *parametric optimization* problems arising for instance in practical problems, multi-objective optimization, stochastic optimization etc. (cf. [3, Chap. 1]). Of course, on the one hand, the applications described there are not complete and, on the other hand, there is a stormy development in several fields.
- iv) Finally, we would like to refer to so-called interior point methods, which are path following methods, too (cf. e. g. [8]).

#### Introduction

Peptide and protein identification is of fundamental importance in the study of proteomics. Tandem mass spectrometry (MS/MS) coupled with high performance liquid chromatography (HPLC) has emerged as a powerful protocol for high-throughput and high sensitivity peptide and protein identification experiments. In

recognition of the extensive amount of sequence information embedded in a single mass spectrum, tandem MS has served as an impetus for the recent development of numerous computational approaches formulated to sequence peptides robustly and efficiently with particular emphasis on the integration of these algorithms into a high throughput computational framework. The two most frequently reported computational approaches in the literature are (a) de novo and (b) database search methods, both of which can utilize deterministic, probabilistic and/or stochastic solution techniques.

The majority of peptide identification methods used in practice are database search methods [2,11,19,21,30,31,32,36,37] due to their accuracy and ease of implementation. A variety of techniques for peptide identification via databases are currently available. One approach, as implemented in the SEQUEST algorithm [11,36,37], uses cross-correlation to mathematically determine the similarity between a theoretical tandem mass spectrum predicted from a peptide sequence in the database and the experimental tandem mass spectrum under investigation. The more frequently used technique, known as probability-based matching, utilizes a probabilistic model to determine whether an ion peak match between the experimental and theoretical tandem mass spectrum is actual or random [2,19,30,32]. Various models have been formulated for this purpose, ranging from a likelihood ratio hypothesis test [2,19] to the null hypothesis that peptide matches are random [32]. The major limitation of database methods is they are ineffective if the database in which the search is conducted does not contain the corresponding protein responsible for generating the tandem mass spectrum.

De novo methods are advantageous over database techniques since they can be used to find novel proteins, amino acid mutations and study the proteome before the genome. A prominent methodology for the de novo peptide identification problem is the spectrum graph approach [3,4,5,6,8,12,18,22,25,34,35]. In the majority of spectrum graph representations, the peaks in the tandem mass spectrum as translated as nodes on a directed graph, where the nodes are connected by edges if the mass difference between them is equal to the weight of an amino acid. The nodes or edges of the spectrum graph are typically assigned

scores based on empirically-derived weights. Various alternative techniques to the spectrum graph approach have also been developed. For example, the de novo algorithm PEAKS [26] generates 10,000 potential sequences using a dynamic programming algorithm and then in a subsequent step reevaluates the predicted sequences using a stricter confidence scorer. Another technique addresses the peptide identification problem via stochastic optimization using genetic algorithms to solve multi-objective models and can empirically test for independence between scoring functions [20,27,28]. The algorithm NovoHMM [13] uses a hidden Markov model to solve the peptide identification problem, where the observable random variables are the observed mass peaks and the hidden variables correspond to the unknown peptide sequence. Despite the vast potential of de novo methods, they can be computationally demanding and may exhibit variable prediction accuracies.

In this work, we present a novel mixed-integer linear optimization (MILP) approach to efficiently address the de novo peptide identification problem so as to form a basis for a high-throughput computational framework for peptide identification [9,10]. This framework is denoted as **PILOT**, which stands for **Peptide identification via Mixed-Integer Linear Optimization and Tandem mass spectrometry**.

## Formulation

This section provides a thorough description of the mathematical model and algorithmic framework for the de novo identification of peptides of spectra resulting from tandem mass spectrometry.

## Mathematical Model for Peptide Identification

The essential components of the mixed-integer linear programming problem formulation are the parameters, sets, binary variables, constraint equations and objective function [10].

**Parameters** Each tandem mass spectrum of a peptide contains the mass of the parent peptide, its charge state, and a list of mass-to-charge ratios and their corresponding intensities of the fragment ions of the peptide. It is important to note that the mass of the parent peptide and the masses of the ion peaks in the tandem mass

spectra are subject to a certain degree of experimental error [8]. The parameters are:

$m_p$	mass of parent peptide
$mass(\text{ion peak } i)$	mass of ion peak $i$
$\lambda_i$	intensity of ion peak $i$

**Set Definitions** The first set to consider is the mass difference between all of the peaks in the tandem mass spectrum, which we denote by the matrix  $M$  defined in Eq. (1).

$$M = \{M_{i,j} = mass(\text{ion peak } j) - mass(\text{ion peak } i) : mass(\text{ion peak } j) > mass(\text{ion peak } i)\} \quad (1)$$

The index  $i$  corresponds to the rows and the index  $j$  corresponds to the columns of the matrix  $M_{i,j}$ . The construction of the peptide sequence should be restricted to using only those peaks whose mass difference is equal to the weight of an amino acid. The indices corresponding to these peak pairs are stored in the matrix  $S$ , defined in Eq. (2).

$$S = \{S_{i,j} = (i, j) : M_{i,j} = \text{mass of an amino acid}\} \quad (2)$$

Thus, the mass difference between peak  $i$  and peak  $j$  is equal to the weight of some amino acid for every  $(i, j) \in S_{i,j}$ . The subsequent problem formulation will only be considered over this set,  $S_{i,j}$ .

The physical relationships between fragment ions can be used to construct additional sets. The sequencing of a candidate peptide must be done using ions from the *same* ion series (i. e., **b**, **y**, etc.). While it is not known a priori of what ion type a given mass peak is, there do exist important relationships among the different ions. As the charged parent peptide undergoes collision-induced dissociation (CID), it primarily fragments into two ion pairs: either **a** and **x**, **b** and **y**, or **c** and **z**, where all three pairs are what are known as *complementary ions* by definition. These ion pairs are easily identified a priori since the sum of two complementary ions is equal to the weight of the parent peptide,  $m_p$ , as determined experimentally. The indices of peak pairs which satisfy this relationship are stored in the set  $C$ ,

defined in Eq. (3).

$$C = \{C_{i,j} = (i, j) : mass(\text{ion peak } i) + mass(\text{ion peak } j) = m_p + 2; i \neq j\} \quad (3)$$

This set will be useful for eliminating certain ions in the sequencing calculations. However, one should note that further fragmentation of these ions is possible and frequently observed, which places limitations on how many complementary ions are actually detected in a tandem mass spectrum.

Different types of ion series begin and end at different  $m/z$  values in the tandem mass spectrum. For instance, a candidate peptide derived using the **y**-ion series must begin at the weight of water (19 Daltons) and terminate at the weight of the parent peptide ( $m_p + 1$ ), whereas deriving the same sequence using the **b**-ion series, the appropriate bounds become zero mass (1 Dalton) and the weight of the parent peptide subtracted by the weight of water ( $m_p - 17$ ), in respective order. To model this mathematically, two new sets are created which correspond to the boundary conditions at the “head” of the peptide and the “tail” of the peptide. Note that the sets presented below consider *only* the possibility for **b**- or **y**-ions in the candidate sequence.

$$BC_i^{\text{head}} = \{1, 19\} \text{ Daltons} \quad (4)$$

$$BC_j^{\text{tail}} = \{m_p - 17, m_p + 1\} \text{ Daltons} \quad (5)$$

**Binary Variables** Binary {0-1} variables are utilized in the problem formulation to model which peaks ( $p_i$ ) and paths connecting peaks ( $w_{i,j}$ ) are used in the construction of the candidate sequence. The use of binary variables also allows us to invoke logical inference when formulating the model constraints.

$$p_i = \begin{cases} 1, & \text{if peak } (i) \text{ is selected} \\ 0, & \text{otherwise} \end{cases}$$

$$w_{i,j} = \begin{cases} 1, & \text{if peaks } (i) \text{ and } (j) \text{ are connected by} \\ & \text{a path (i. e., } p_i = p_j = 1) \\ 0, & \text{otherwise} \end{cases}$$

**Constraints** Several constraints derived from ion properties and graph theory are formulated in terms of the binary variables via logical inference. The first constraint exploits the fact that the candidate peptide

must be sequenced using ions of the same type and that complementary ions are of different type by definition. Thus, if peak  $i$  is used to construct a candidate sequence and the peak pair  $(i, j)$  belong to the complementary ion set defined in Eq. (3), then peak  $j$  should be eliminated from consideration in the sequencing calculations. This is modeled mathematically by Eq. (6).

$$p_i + p_j \leq 1 \quad \forall (i, j) \in C_{i,j} \quad (6)$$

An obvious but important constraint to impose on the candidate sequence is that the summation of the weights of its amino acids is equal to the mass of the parent peptide ( $m_P$ ). It is well-known that the experimentally measured parent peptide mass is subject to a certain degree of experimental error [8], which is dependent on the resolution of the mass spectrometer used. Thus, exact conservation of mass cannot be achieved but must be relaxed by some tolerance of error, as shown in Eq. (7).

$$\sum_{(i,j) \in S_{i,j}} M_{i,j} \cdot w_{i,j} \leq (m_P - 18) + \textit{tolerance} \quad (7)$$

$$\sum_{(i,j) \in S_{i,j}} M_{i,j} \cdot w_{i,j} \geq (m_P - 18) - \textit{tolerance} \quad (8)$$

The algorithm typically uses a tolerance of error of  $\pm 2$  Daltons above and below the parent peptide mass. It is also possible to formulate the *tolerance* term as a variable and then incorporate it into the model such that its value is minimized.

The sequencing of the candidate peptide is best envisioned as connecting peaks in the tandem mass spectrum with paths that correspond to weights of amino acids. To ensure that the paths selected are continuous and non-degenerate, we use the *flow conservation law* from graph theory which has been used extensively in process synthesis problems [1,15,16,17,24,29,33], as shown in Eq. (9).

$$\sum_{j \in S_{j,i}} w_{j,i} - \sum_{k \in S_{i,k}} w_{i,k} = 0 \quad \forall i, i \notin BC_i^{\text{head}}, i \notin BC_i^{\text{tail}} \quad (9)$$

The above constraints ensure that the number of input paths entering a peak is equal to the number of output paths leaving that peak.

To anchor the beginning and end of the candidate sequence, the peaks denoted as the boundary conditions for the sequencing are activated, as shown in Eqs. (10) and (11).

$$\sum_{i \in BC_i^{\text{head}}} \sum_{j \in S_{i,j}} w_{i,j} = 1 \quad (10)$$

$$\sum_{j \in BC_j^{\text{tail}}} \sum_{i \in S_{i,j}} w_{i,j} = 1 \quad (11)$$

One should note that the existence for certain boundary condition elements (contained in the sets  $BC^{\text{head}}$  and  $BC^{\text{tail}}$ ) are checked for by the preprocessing algorithm (described in a subsequent section) and can be adjusted if information is missing from the tandem mass spectrum. Furthermore, these constraints enforce the non-degeneracy of paths since *only one* path can initiate and terminate the sequence, respectively.

The final set of constraints constitutes the mathematical relationship between the binary variables representing the peaks,  $p_i$ , and the paths connecting the peaks,  $w_{i,j}$ :

$$\sum_{j \in S_{\{i,j\}}} w_{i,j} = p_i \quad \forall i \in BC_i^{\text{head}} \quad (12)$$

$$\sum_{j \in S_{i,j}} w_{j,i} = p_i \quad \forall i \notin BC_i^{\text{head}} \quad (13)$$

These constraints ensure that if there exists a path entering and leaving a peak  $k$  (i. e.,  $w_{i,k} = 1$  and  $w_{k,j} = 1$ ), then peak  $k$  will be activated in the construction of the candidate sequence (i. e.,  $p_k = 1$ ). These constraints also allow the option for removing peaks (and the paths connected to these peaks) from the sequencing calculations by simply deactivating the binary variables that represents those peaks ( $p_i$ ). For instance, this is useful for eliminating the precursor ion and multiply-charged ions from consideration.

**Objective Function** The **b**- and **y**-ion peaks are on average the most abundant in intensity throughout the entire  $m/z$  range [23]. Based on this observation, the objective function is postulated as an explicit function of the peak intensities in attempt to maximize the number of **b**- and **y**-ions used in constructing the candidate

sequence.

$$\text{MAX}_{p_k, w_{i,j}} \sum_{(i,j) \in S_{i,j}} \lambda_j \cdot w_{i,j} \quad (14)$$

Equations (1–14) comprise the entire mathematical model for the de novo peptide sequencing problem using tandem mass spectrometry. The entire problem formulation is summarized in problem (P).

$$\begin{aligned} & \text{MAX}_{p_k, w_{i,j}} \sum_{(i,j) \in S_{i,j}} \lambda_j \cdot w_{i,j} \\ & \text{s.t.} \quad \sum_{(i,j) \in S_{i,j}} M_{i,j} \cdot w_{i,j} \leq m_p + \textit{tolerance} \\ & \quad \sum_{(i,j) \in S_{i,j}} M_{i,j} \cdot w_{i,j} \geq m_p - \textit{tolerance} \\ & \quad p_i + p_j \leq 1 \quad \forall (i, j) \in C_{i,j} \\ & \quad \sum_{j \in S_{i,j}} w_{i,j} = p_i \quad \forall i \in BC_i^{\text{head}} \\ & \quad \sum_{j \in S_{i,j}} w_{j,i} = p_i \quad \forall i \notin BC_i^{\text{head}} \\ & \quad \sum_{i \in BC_i^{\text{head}}} \sum_{j \in S_{i,j}} w_{i,j} = 1 \\ & \quad \sum_{j \in BC_j^{\text{tail}}} \sum_{i \in S_{i,j}} w_{i,j} = 1 \\ & \quad \sum_{j \in S_{j,i}} w_{j,i} - \sum_{k \in S_{i,k}} w_{i,k} = 0 \\ & \quad \forall i, i \notin BC_i^{\text{head}}, i \notin BC_i^{\text{tail}} \\ & \quad w_{i,j}, p_k = \{0, 1\} \quad \forall (i, j), (k) \end{aligned} \quad (P)$$

The resulting problem (P) is a mixed-integer linear programming (MILP) problem and can be solved to optimality using existing methods (e. g., CPLEX [7]). To generate a rank-ordered list of candidate sequences, integer cuts are used to exclude previous solutions from being revisited. That is, for every solution, an integer cut is incorporated into the model using the following general form[14]:

$$\sum_{(i,j) \in B} w_{i,j} - \sum_{(i,j) \in NB} w_{i,j} \leq |B| - 1 \quad (15)$$

where  $B = \{(i, j) : w_{i,j} = 1\}$

$NB = \{(i, j) : w_{i,j} = 0\}$

$|B|$  is the cardinality of B

Peptide Identification via Mixed-Integer Optimization, Table 1  
Ions identified by the preprocessing algorithm

Ion Type	Relation to the $\mathbf{b}_2$ -ion
$\mathbf{y}_{n-2}$	$m_p + 2 - \mathbf{b}_2$
$\mathbf{a}_2$	$\mathbf{b}_2 - 28$
$\mathbf{b}_1$	$AA_1$ or $AA_2$ where $AA_1 + AA_2 + 1 = \mathbf{b}_2$
$\mathbf{y}_{n-1}$	$m_p + 2 - AA_1$ or $m_p + 2 - AA_2$ where $AA_1 + AA_2 + 1 = \mathbf{b}_2$

### Algorithmic Framework

The overall algorithm PILOT is comprised of: (1) a preprocessing algorithm used to identify certain peaks and to validate boundary conditions, (2) a two-stage mixed-integer linear optimization framework to address missing ion peaks due to residue-dependent fragmentation characteristics, and (3) a post-processing technique for selecting the most probable sequence by cross-correlating the theoretical tandem mass spectra of the candidate sequences with the experimental tandem mass spectrum [9].

**Preprocessing of Spectral Data** Before formulating the MILP problem, the raw tandem mass spectrum is analyzed using a preprocessing algorithm to elucidate key spectral features that can be exploited in the sequencing calculations. In particular, certain ion peaks are sought to confirm the proposed boundary conditions previously mentioned. First, the raw spectrum is examined for the existence of the typically abundant in intensity  $\mathbf{b}_2$ -ion [23], whose validity can be confirmed by its complementary  $\mathbf{y}_{n-2}$ -ion. If the corresponding  $\mathbf{y}_{n-2}$ -ion also exists in the spectrum, then the two possible  $\mathbf{y}_{n-1}$ -ions are back-calculated using the mass of the parent peptide ( $m_p$ ) and the weights of the amino acids which constitute the  $\mathbf{b}_2$ -ion (see Table 1), and the spectrum is once again searched to confirm these ions.

Every  $\mathbf{b}_2$ -ion amino acid pair found by the algorithm is then ranked based on the intensities of their supporting ions (i. e.,  $y_{\{n-2\}}$ ,  $y_{\{n-1\}}$ ,  $a_{\{2\}}$  and their isotopic offsets and neutral losses of water and ammonia). The highest scoring  $\mathbf{b}_2$ -ion amino acid pair is then selected to represent N-terminal boundary conditions for the sequencing calculations. The preprocessing algorithm is also used to identify the C-terminal amino

acid based on known ion peaks. For example, if the peptide is a result of tryptic digestion, then its C-terminal amino acid must be lysine (indicated by an ion peak at 147 Da) or arginine (indicated by an ion peak at 175 Da). Multiply-charged ions and immonium ions are also searched for in the experimental tandem mass spectrum to guide the interpretation process.

### Missing Ion Peaks: Two-Stage Algorithmic Approach

In the mixed-integer linear optimization model (see problem P), the algorithm attempts to derive several candidate sequences using only *single* amino acid weights to connect mass peaks. However, if the spectrum is missing certain mass peaks then it might not be possible to fully construct the correct sequence in this fashion. To accommodate this issue, the sequencing problem is split into two stages: stage one derives the candidate peptides using only single amino weights and stage two allows for the possibility of using *two* amino acid weights. That is to say, in the second stage the additional option is available to connect two peaks via the weight of any two combined amino acids. In this stage the emphasis is again placed on primarily using the weights of single amino acids to construct the candidate sequences by penalizing the use of combined amino acid weights. This is accomplished in the objective function by multiplying the path variable corresponding to multiple residues by a penalty weighting fraction which is less than one and decreases with increasing mass error. As a result, the driving force for the algorithm is the single residue weights, while the double residue weights are utilized only to bridge the gap between disjoint single residue segments of the candidate sequence.

### Postprocessing: Scoring Candidate Sequences

A subsequent scoring of the candidate peptide sequences is necessary in order to: (a) assign amino acids to regions of the peptide not considered in the sequencing calculations due to boundary condition adjustments, (b) resolve doublet and triplet amino acid combinations due to missing peaks, and (c) validate the “b” or “y” ions used to construct the candidate sequence by looking for other supporting ions in the raw tandem mass spectrum. For cases (a) and (b), the weight in the candidate sequence is replaced by permutations of amino acids consistent with this mass. This results in

a super set of candidate sequences whose theoretical tandem mass spectra can be predicted and compared to the experimental tandem mass spectrum for validity.

Since only the y- or b- ion series were used in constructing the peptide sequences, it would be beneficial to utilize various other types of ions when scoring these candidate peptides in order to exploit as much information from the tandem mass spectrum as possible. In particular, the assignment of a peak as a b- or y- ion can be confirmed by the existence of supporting isotopes, neutral losses of small molecules (i. e., -H<sub>2</sub>O, -NH<sub>3</sub>, -H<sub>2</sub>O-NH<sub>3</sub>, -H<sub>2</sub>O-H<sub>2</sub>O) and multiply-charged ions. To introduce dependencies among the ion series, a reward/penalty system was created. For instance, a match between a predicted y-ion and a peak in the experimental spectrum is more probable if the corresponding y-ions isotopes and offsets are also found in the experimental spectrum [18]. Thus, the score from a match between b- or y-ion is assigned a reward proportional to the number of its corresponding isotopes and offsets that also match with the experimental spectrum. Conversely, the existence of isotopic offsets and neutral loss ions *without* a corresponding y- or b-ion are penalized in the score. These conventions address the likelihood that the peaks used in the construction of the candidate sequence are actually of the b- or y-ion series.

### Cases

The proposed framework is for the de novo identification of doubly-charged tryptic peptides that were ionized via electrospray ionization. A comparative study is presented with several existing de novo peptide identification methods to demonstrate the predictive capabilities of the proposed framework, PILOT. The de novo peptide identifications algorithms Lutefisk, LutefiskXP, PepNovo, PEAKS, EigenMS, NovoHMM, were selected on the basis of availability and reported performance. Tandem MS for quadrupole time-of-flight mass spectrometers were analyzed in the comparative study.

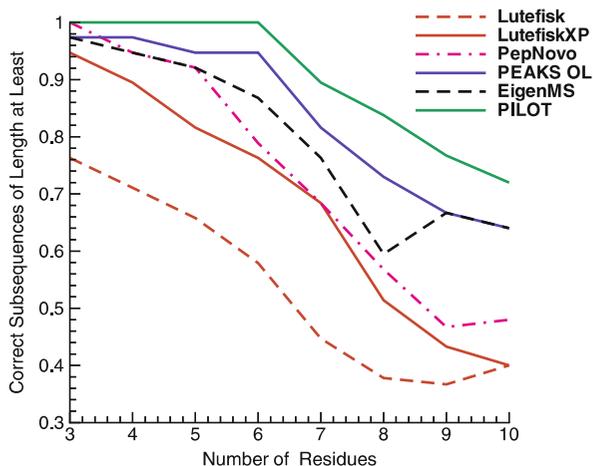

### Quadrupole Time-of-Flight, QTOF, Spectra

To test the method's performance on quadrupole time-of-flight tandem mass spectra, we selected an existing data set that is publicly available [26]. These spectra were collected with Q-TOF2 and Q-TOF-Global

mass spectrometers for a control mixture of four known proteins: alcohol dehydrogenase (yeast), myoglobin (horse), albumin (bovine, BSA), and cytochrome C (horse). A total of 38 doubly-charged tryptic peptides were examined using Lutefisk, LutefiskXP, PepNovo, PEAKS, EigenMS and PILOT [9]. The top-ranked sequence reported from each of these methods is used in the comparison.

The results of the comparison can be summarized using various measures. First, consider the overall peptide identification accuracy of the de novo methods, which is reported in Table 2. In terms of correct identifications, PILOT is superior to the other de novo methods with an identification rate of about 66%, followed by PEAKS and EigenMS, both at about 53%. A common limitation of de novo methods is the inability to assign the correct N-terminal amino acid pair or resolve isobaric residues (i. e., Q or GA, W or SV, etc.). To accommodate this limitation in the comparison, we also reported the percentage of predictions for which there are only one, two, or three *incorrect* amino acid assignments in the entire sequence. In Table 2, it is seen that allowing for up to three *incorrect* amino acids increases the identification rate for all methods on the order of 30%, which supports the hypothesis that these limitations are inherent in all the de novo methods. The last entry in Table 2 reports the number of correctly assigned residues normalized by the total number of actual residues (which is 418 for the 38 doubly-charged peptides considered). PILOT outperforms the other de novo methods with a residue accuracy of 91%.

Another alternative metric of performance is the percentage of correct continuous subsequences of a given number of amino acids [13,18]. These trends are summarized in Fig. 1 for all of the de novo methods. This alternative metric reveals that although LutefiskXP has a lower overall identification rate than Lutefisk, it exhibits a much better accuracy over subsequences of varying length (as shown in Fig. 1). Note that some of the trends in Fig. 1 exhibit an increase in accuracy for correct subsequences greater than 8 consecutive amino acids in length. This is because these counts are normalized by the total number of peptides that are of *at least* the length specified, which decreases from 37 for subsequences of length 8 to 30 for subsequences of length 9 to 25 for subsequences of length 10. For each of the 38 QTOF peptides, PILOT predicts at least 6 consecutive

Peptide Identification via Mixed-Integer Optimization, Figure 1

Comparison of correct subsequences of varying length for quadrupole time-of-flight predictions

amino acids correctly for every peptide and performs consistently better than the other de novo methods over the entire range of subsequences considered.

## Conclusions

A novel mixed-integer linear optimization (MILP) framework, PILOT, was proposed for the de novo identification of peptides using tandem mass spectrometry data. PILOT is the first reported mixed-integer linear optimization formulation for the peptide identification problem which can introduce integer cuts to generate a rigorous rank-ordered list of candidate sequences, introduce complementary ions directly into the sequencing calculations and allow for the error tolerance to be introduced as a variable term. For a given experimental MS/MS spectrum, PILOT generates a rank-ordered list of potential candidate sequences and a cross-correlation technique is employed to select the most probable peptide by assessing the degree of similarity between the theoretical tandem mass spectra of the predicted sequences and the experimental tandem mass spectrum. A comparative study using tandem mass spectra from quadrupole time-of-flight was presented to benchmark the performance of the proposed framework with several existing de novo methods.

## Introduction

Conjugate-gradient methods represent an important class of unconstrained optimization algorithms with strong local and global convergence properties and modest memory requirements. An excellent survey of the development of different versions of nonlinear conjugate-gradient methods, with special attention to global convergence properties, is presented by Hager and Zhang [22]. This family of algorithms includes a lot of variants, well known in the literature, with important convergence properties and numerical efficiency. The purpose of this chapter is to present these algorithms as well as their performances to solve a large variety of large-scale unconstrained optimization problems.

For solving the nonlinear unconstrained optimization problem

$$\min \{f(x) : x \in R^n\} , \quad (1)$$

where  $f : R^n \rightarrow R$  is a continuously differentiable function bounded from below, starting from an initial guess

## Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization

NECULAI ANDREI<sup>1,2</sup>

<sup>1</sup> Research Institute for Informatics, Center for Advanced Modeling and Optimization, Bucharest, Romania

$x_0 \in R^n$  a nonlinear conjugate-gradient method generates a sequence  $\{x_k\}$  as

$$x_{k+1} = x_k + \alpha_k d_k, \tag{2}$$

where  $\alpha_k > 0$  is obtained by line search, and the directions  $d_k$  are generated as

$$d_{k+1} = -g_{k+1} + \beta_k s_k, \quad d_0 = -g_0. \tag{3}$$

In (3)  $\beta_k$  is known as the conjugate-gradient parameter,  $s_k = x_{k+1} - x_k$  and  $g_k = \nabla f(x_k)$ . Consider  $\|\cdot\|$  the Euclidean norm and define  $y_k = g_{k+1} - g_k$ . The line search in the conjugate-gradient algorithms is often based on the standard Wolfe conditions:

$$f(x_k + \alpha_k d_k) - f(x_k) \leq \rho \alpha_k g_k^T d_k, \tag{4}$$

$$g_{k+1}^T d_k \geq \sigma g_k^T d_k, \tag{5}$$

where  $d_k$  is a descent direction and  $0 < \rho \leq \sigma < 1$ . For some conjugate-gradient algorithms, stronger versions of the Wolfe conditions are needed to ensure convergence and to enhance stability. According to the formula for  $\beta_k$  computation, the conjugate-gradient algorithms can be classified as classical, hybrid, scaled, modified and parametric. In the following we shall present these algorithms and insist on their numerical Dolan and Moré’s performances profiles for solving large-scale unconstrained optimization problems.

The history of conjugate-gradient method begins with the seminal paper of Hestenes and Stiefel [23], who presented an algorithm for solving symmetric, positive-definite linear algebraic systems. In 1964 Fletcher and Reeves [18] extended the domain of application of conjugate-gradient method to nonlinear problems, thus starting the nonlinear conjugate-gradient research direction. The main advantages of the conjugate-gradient method are its low memory requirements and its convergence speed. A large variety of nonlinear conjugate-gradient algorithms are known. For each of them convergence results have been proved in mild conditions which refer to the Lipschitz and boundedness assumptions. To prove the global convergence of nonlinear conjugate-gradient methods, often the Zoutendijk condition is used combined with analysis showing that the sufficient descent condition  $g_k^T d_k \leq -c \|g_k\|^2$  holds, and that there exists a constant  $\delta$  such that  $\|d_k\|^2 \leq \delta k$ . Often, the convergence analysis of conjugate-gradient

algorithms, for general nonlinear functions, follows insights developed by Gilbert and Nocedal [19]. The idea is to bound the change  $u_{k+1} - u_k$  in the normalized direction  $u_k = d_k / \|d_k\|$ , which is used to conclude, by contradiction, that the gradients cannot be bounded away from zero.

### Classical Conjugate-Gradient Algorithms

These algorithms are defined by (2) and (3), where the parameter  $\beta_k$  is computed as in Table 1. Observe that these algorithms can be classified as algorithms with  $\|g_{k+1}\|^2$  in the numerator of  $\beta_k$  and algorithms with  $g_{k+1}^T y_k$  in the numerator of parameter  $\beta_k$ .

The FR, CD and DY methods (see the tables for the definitions of the acronyms used for the algorithms throughout the text), with  $\|g_{k+1}\|^2$  in the numerator of  $\beta_k$ , have strong convergence theory, but all

Classical conjugate-gradient algorithms

No.	Formula	Author(s)
1.	$\beta_k^{HS} = \frac{y_k^T g_{k+1}}{y_k^T s_k}$	Hestenes and Stiefel [23] (HS). The first conjugate-gradient algorithm for linear algebraic systems
2.	$\beta_k^{FR} = \frac{g_{k+1}^T g_{k+1}}{g_k^T g_k}$	Fletcher and Reeves [18] (FR). The first conjugate-gradient algorithm for nonlinear functions
3.	$\beta_k^{PRP} = \frac{y_k^T g_{k+1}}{g_k^T g_k}$	Polak-Ribiere [31] and Polyak [32] (PRP)
4.	$\beta_k^{PRP+} = \max \left\{ 0, \frac{y_k^T g_{k+1}}{g_k^T g_k} \right\}$	Polak-Ribiere and Polyak + (PRP+) suggested by Powell [33]
5.	$\beta_k^{CD} = -\frac{g_{k+1}^T g_{k+1}}{g_k^T d_k}$	Conjugate descent (CD) introduced by Fletcher [17]
6.	$\beta_k^{LS} = -\frac{y_k^T g_{k+1}}{g_k^T d_k}$	Liu and Storey [26] (LS)
7.	$\beta_k^{DY} = \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k}$	Dai and Yuan [13] (DY)

these methods are susceptible to jamming. They begin to take small steps without making any significant progress to the minimum. On the other hand, the HS, PRP and LS methods, with  $g_{k+1}^T y_k$  in the numerator of parameter  $\beta_k$ , have a built-in restart feature that addresses the jamming phenomenon. When the step  $s_k$  is small, the factor  $y_k = g_{k+1} - g_k$  in the numerator of  $\beta_k$  tends to zero. Therefore,  $\beta_k$  becomes small and the new direction  $d_{k+1}$  in (3) is essentially the steepest descent direction  $-g_{k+1}$ . With other words, the HS, PRP and LS methods automatically adjust  $\beta_k$  to avoid jamming, and their performances are better than the performance of methods with  $\|g_{k+1}\|^2$  in the numerator of  $\beta_k$ .

### Hybrid Conjugate-Gradient Methods

These algorithms have been devised to exploit the attractive features of the classical conjugate-gradient algorithms. They are defined by (2) and (3), where the parameter  $\beta_k$  is as in Table 2. There are two classes of hybrid algorithms. The first class of the hybrid algorithms combines in a *projective* manner the algorithms having  $\|g_{k+1}\|^2$  in the numerator of  $\beta_k$  with the algorithms having  $g_{k+1}^T y_k$  in the numerator of  $\beta_k$ . The second class of hybrid algorithms, more recently established, considers *convex combinations* of algorithms with  $\|g_{k+1}\|^2$  in the numerator of  $\beta_k$  and the algorithms having  $g_{k+1}^T y_k$  in the numerator of  $\beta_k$ . In general, the performances of hybrid conjugate-gradient algorithms are better than the performances of classical conjugate-gradient algorithms.

### Scaled Conjugate-Gradient Algorithms

The algorithms in this class generate a sequence  $x_k$  of approximations to the minimum  $x^*$  of  $f$ , in which

$$x_{k+1} = x_k + \alpha_k d_k, \quad (6)$$

$$d_{k+1} = -\theta_{k+1} g_{k+1} + \beta_k s_k, \quad (7)$$

where  $\theta_{k+1}$  is a parameter. The iterative process is initialized with an initial point  $x_0$  and  $d_0 = -g_0$ . Observe that if  $\theta_{k+1} = 1$ , then we get the classical conjugate-gradient algorithms according to the value of the scalar parameter  $\beta_k$ . On the other hand, if  $\beta_k = 0$ , then we get another class of algorithms according to the selection of the parameter  $\theta_{k+1}$ . Considering  $\beta_k = 0$ , there are two possibilities for  $\theta_{k+1}$ : a positive scalar or

a positive-definite matrix. If  $\theta_{k+1} = 1$ , then we have the steepest-descent algorithm. If  $\theta_{k+1} = \nabla^2 f(x_{k+1})^{-1}$ , or an approximation of it, then we get the Newton or the quasi-Newton algorithms, respectively. Therefore, we see that in the general case, when  $\theta_{k+1} \neq 0$  is selected in a quasi-Newton manner, and  $\beta_k \neq 0$ , (7) represents a combination between the quasi-Newton and the conjugate-gradient methods. However, if  $\theta_{k+1}$  is a matrix containing some useful information about the inverse Hessian of function  $f$ , we are better off using  $d_{k+1} = -\theta_{k+1} g_{k+1}$  since the addition of the term  $\beta_k s_k$  in (7) may prevent the direction  $d_k$  from being a descent direction unless the line search is sufficiently accurate. Therefore, in the following we shall consider  $\theta_{k+1}$  as a positive scalar which contains some useful information on the inverse Hessian of function  $f$ .

To determine  $\beta_k$  consider the following procedure [1,2,3,4]. As we know, the Newton direction for solving (1) is given by  $d_{k+1} = -\nabla^2 f(x_{k+1})^{-1} g_{k+1}$ . Therefore, from the equality

$$-\nabla^2 f(x_{k+1})^{-1} g_{k+1} = -\theta_{k+1} g_{k+1} + \beta_k s_k,$$

we get

$$\beta_k = \frac{s_k^T \nabla^2 f(x_{k+1}) \theta_{k+1} g_{k+1} - s_k^T g_{k+1}}{s_k^T \nabla^2 f(x_{k+1}) s_k}. \quad (8)$$

Using the Taylor development, after some algebra, we get

$$\beta_k = \frac{(\theta_{k+1} y_k - s_k)^T g_{k+1}}{y_k^T s_k}, \quad (9)$$

where  $y_k = g_{k+1} - g_k$ . Birgin and Martínez [10], who first introduced scaled conjugate-gradient algorithms, arrived at the same formula for  $\beta_k$ , but using a geometric interpretation of quadratic function minimization. The parameter  $\beta_k$  in (7) can be defined, as in Table 3, where the scaling parameter  $\theta_k$  is computed as

$$\theta_{k+1} = \frac{s_k^T s_k}{y_k^T s_k}. \quad (10)$$

Another scaled conjugate-gradient algorithm was presented by Andrei [1,2,3,4]. This is a scaled memoryless Broyden-Fletcher-Goldfarb-Shanno (BFGS) preconditioned conjugate-gradient algorithm. The basic idea is to combine the scaled memoryless BFGS method and the preconditioning technique in the frame of the conjugate-gradient method. The preconditioner, which

is also a scaled memoryless BFGS matrix, is reset when the Powell restart criterion holds. The parameter scaling the gradient is selected as the spectral gradient (10).

**SCALCG Algorithm**

*Step 1. Initialization.* Select  $x_0 \in R^n$ , and the parameters  $0 < \rho \leq \sigma < 1$ . Compute  $f(x_0)$  and  $g_0 = \nabla f(x_0)$ . Set  $d_0 = -g_0$  and  $\alpha_0 = 1/\|g_0\|$ . Set  $k = 0$ .

*Step 2. Line search.* Compute  $\alpha_k$  satisfying the Wolfe conditions (4) and (5). Update the variables  $x_{k+1} = x_k + \alpha_k d_k$ . Compute  $f(x_{k+1})$ ,  $g_{k+1}$  and  $s_k = x_{k+1} - x_k$ ,  $y_k = g_{k+1} - g_k$ .

*Step 3. Test for continuation of iterations.* If this test is satisfied the iterations are stopped, else set  $k = k + 1$ .

*Step 4. Scaling factor computation.* Compute  $\theta_k$  using (10).

*Step 5. Restart direction.* Compute the (restart) direction  $d_k$  as

$$d_{k+1} = -\theta_{k+1} g_{k+1} + \theta_{k+1} \left( \frac{g_{k+1}^T s_k}{y_k^T s_k} \right) y_k - \left[ \left( 1 + \theta_{k+1} \frac{y_k^T y_k}{y_k^T s_k} \right) \frac{g_{k+1}^T s_k}{y_k^T s_k} - \theta_{k+1} \frac{g_{k+1}^T y_k}{y_k^T s_k} \right] s_k .$$

*Step 6. Line search.* Compute the initial guess  $\alpha_k = \alpha_{k-1} \|d_{k-1}\|_2 / \|d_k\|_2$ . Using this initialization compute  $\alpha_k$  satisfying the Wolfe conditions. Update the variables  $x_{k+1} = x_k + \alpha_k d_k$ . Compute  $f(x_{k+1})$ ,  $g_{k+1}$  and  $s_k = x_{k+1} - x_k$ ,  $y_k = g_{k+1} - g_k$ .

*Step 7. Store:*  $\theta = \theta_k$ ,  $s = s_k$  and  $y = y_k$ .

*Step 8. Test for continuation of iterations.* If this test is satisfied the iterations are stopped, else set  $k = k + 1$ .

*Step 9. Restart.* If the Powell restart criterion  $|g_{k+1}^T g_k| \geq 0.2 \|g_{k+1}\|^2$  is satisfied, then go to step 4 (a restart step), otherwise continue with step 10 (a standard step).

*Step 10. Standard direction.* Compute the direction  $d_k$  as

$$d_{k+1} = -v + \frac{(g_{k+1}^T s_k)w + (g_{k+1}^T w)s_k}{y_k^T s_k} - \left( 1 + \frac{y_k^T w}{y_k^T s_k} \right) \frac{g_{k+1}^T s_k}{y_k^T s_k} s_k ,$$

where  $v$  and  $w$  are computed as

$$v = \theta g_{k+1} - \theta \left( \frac{g_{k+1}^T s}{y^T s} \right) y + \left[ \left( 1 + \theta \frac{y^T y}{y^T s} \right) \frac{g_{k+1}^T s}{y^T s} - \theta \frac{g_{k+1}^T y}{y^T s} \right] s ,$$

3.	$\beta_k^{YT} = \frac{g_{k+1}^T(z_k - ts_k)}{d_k^T z_k},$ where $z_k = y_k + \frac{\delta \xi_k}{s_k^T u_k} u_k,$ $\xi_k = 6(f_k - f_{k+1}) + 3(g_k + g_{k+1})^T s_k,$ $\delta \geq 0 \text{ is a constant and } u_k \in R^n \text{ satisfies}$ $s_k^T u_k \neq 0;$ for example $u_k = d_k$	Suggested by Yabe and Takano [38] (YT) based on a modified secant condition given by Zhang et al. [39]
4.	$\beta_k^{YT+} = \max \left\{ 0, \frac{g_{k+1}^T z_k}{d_k^T z_k} \right\} - t \frac{g_{k+1}^T s_k}{d_k^T z_k}$	Suggested by Yabe and Takano plus [38] (YT+)
5.	$\beta_k = \frac{\ g_{k+1}\ ^2}{\lambda_k \ g_k\ ^2 + (1 - \lambda_k) d_k^T y_k}, \quad \lambda_k \in [0, 1].$ The FR algorithm corresponds to $\lambda_k = 1.$ The DY algorithm corresponds to $\lambda_k = 0$	Suggested by Dai and Yuan [14]
6.	$\beta_k = \frac{\mu_k \ g_{k+1}\ ^2 + (1 - \mu_k) g_{k+1}^T y_k}{\lambda_k \ g_k\ ^2 + (1 - \lambda_k) d_k^T y_k}, \quad \lambda_k, \mu_k \in [0, 1]$	Suggested by Nazareth [28]. This two-parameter family includes the methods FR, DY, PRP and HS in extreme cases
7.	$\beta_k = \frac{\mu_k \ g_{k+1}\ ^2 + (1 - \mu_k) g_{k+1}^T y_k}{(1 - \lambda_k - \omega_k) \ g_k\ ^2 + \lambda_k d_k^T y_k - \omega_k d_k^T g_k},$ $\lambda_k, \mu_k \in [0, 1] \text{ and } \omega_k \in [0, 1 - \lambda_k]$	Suggested by Dai and Yuan [14] This three-parameter family includes the six classical conjugate-gradient algorithms, as well as the previous one-parameter and two-parameter families

and

$$w = \theta y_k - \theta \left( \frac{y_k^T s}{y^T s} \right) y + \left[ \left( 1 + \theta \frac{y^T y}{y^T s} \right) \frac{y_k^T s}{y^T s} - \theta \frac{y_k^T y}{y^T s} \right] s,$$

with saved values  $\theta, s$  and  $y$ .

*Step 11. Line search.* Compute the initial guess  $\alpha_k = \alpha_{k-1} \|d_{k-1}\|_2 / \|d_k\|_2$ . Using this initialization compute  $\alpha_k$  satisfying the Wolfe conditions. Update the variables  $x_{k+1} = x_k + \alpha_k d_k$ . Compute  $f(x_{k+1}), g_{k+1}$  and  $s_k = x_{k+1} - x_k, y_k = g_{k+1} - g_k$ .

*Step 12. Test for continuation of iterations.* If this test is satisfied the iterations are stopped, else set  $k = k + 1$  and go to step 9.

To a great extent, the SCALCG algorithm [1,2,3,4] is very close to the Perry-Shanno computational scheme [30,34,35]. SCALCG is a scaled memory-less BFGS preconditioned algorithm where the scaling factor is the inverse of a scalar approximation of the Hessian. If the Powell restart criterion  $|g_{k+1}^T g_k| \geq 0.2 \|g_{k+1}\|^2$  is used, for general functions  $f$  bounded from below with bounded second partial derivatives and bounded level set, using the same arguments considered by Shanno in [35], one can prove that either the iterates converge to a point  $x^*$  satisfying  $\|g(x^*)\| = 0$  or the iterates cycle.

**Modified Conjugate-Gradient Algorithms**

We know a large variety of modified conjugate-gradient algorithms. All of them are designed to improve the

performances of the classical computational schemes using the idea of preconditioning or the modification of classical schemes in order to satisfy the sufficient-descent condition. The algorithms in this class are characterized by (2) and (3), where the parameter  $\beta_k$  is computed as in Table 4.

Maximization in the formula for the  $\tilde{\beta}_k^N$  computation scheme by Hager and Zhang plays the role of the truncation operation like in the PRP+ scheme, for example. Hager and Zhang obtained this algorithm by deleting a term from the search direction for the memoryless quasi-Newton scheme of Perry [30] and Shanno [34]. Hager and Zhang [20] proved the global convergence with inexact line search, showing that for any line search and any function, the sufficient-descent condition  $g_k^T d_k \leq -(7/8) \|g_k\|^2$  is satisfied and the jamming is avoided essentially owing to the  $y_k^T g_{k+1}$  term in the formula for  $\beta_k^N$ .

The ACGA and ACGA+ computational schemes are a modification of the DY conjugate-gradient algorithm, designed to satisfy the sufficient-descent condition. Andrei [9] proved that for uniformly convex functions under a strong Wolfe condition the ACGA is globally convergent. The CGSD algorithm is also a modification of the Dai and Yuan conjugate-gradient algorithm. Andrei [9] proved the global convergence of CGSD for general nonlinear functions under the Wolfe conditions.

One of the best conjugate-gradient algorithms in this class is CONMIN by Shanno [34] and Shanno and Phua [36]. Using the Hestenes and Stiefel formula for updating  $\beta_k$ , Perry [30] suggested a formula for computing the search direction  $d_{k+1}$  which satisfies a system of linear equations, similar but not identical to the quasi-Newton equation. Shanno [34] reconsidered the method of Perry and interpreted it as a memoryless BFGS updating formula. In this algorithm  $g_{k+1}$  is modified by a positive-definite matrix which best estimates the inverse Hessian, without any additional storage requirements. For convex functions, under inexact line search, Shanno [35] proved the global convergence of CONMIN.

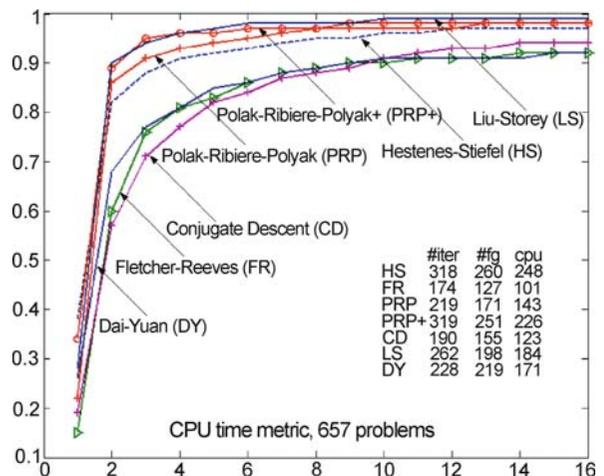

### Parametric Conjugate-Gradient Algorithms

The parametric conjugate-gradient algorithms were introduced in the same way as the quasi-Newton methods

were combined to get the Broyden or the Huang families. These algorithms are defined by (2) and (3), where the parameter  $\beta_k$  is as in Table 5.

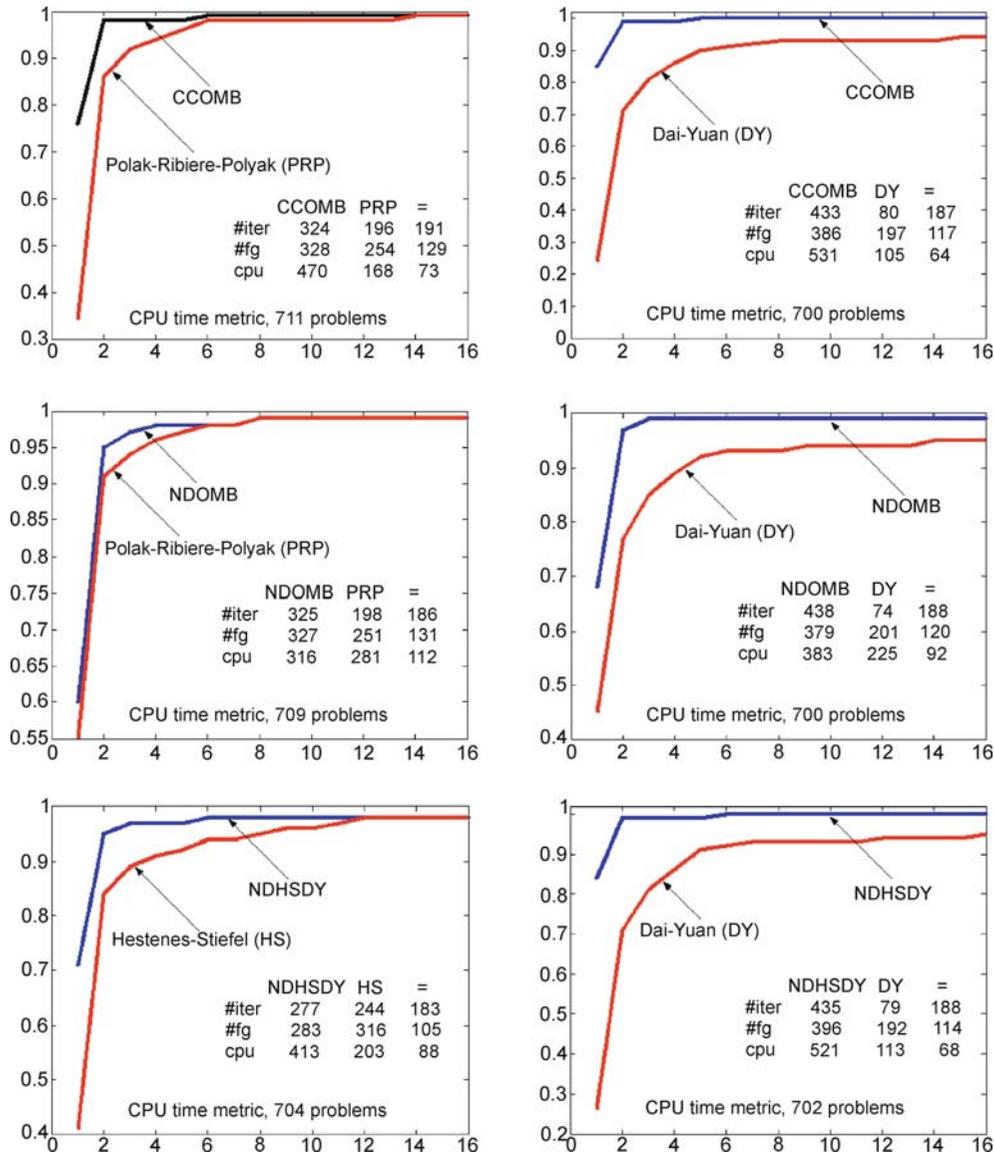

### Performance Profiles

In this section we present the computational performance of a Fortran implementation of conjugate-gradient algorithms on a set of 750 unconstrained optimization test problems. The test problems are the unconstrained problems in the CUTE [11] library, along with other large-scale optimization problems presented in [6]. We selected 75 large-scale unconstrained optimization problems in extended or generalized form. For each function we have considered ten numerical experiments with the number of variables  $n = 1000, 2000, \dots, 10000$ . CG\_DESCENT was authored by Hager and Zhang [20,21], CONMIN by Shanno and Phua [36]. The CG\_DESCENT code contains the variant CG\_DESCENT(w) implementing the Wolfe line search and the variant CG\_DESCENT(aw) implementing an approximate Wolfe line search. The Wolfe conditions implemented in CG\_DESCENT(w) can compute a solution with an accuracy on the order of the square root of machine epsilon. In contrast, the approximate Wolfe line search implemented in CG\_DESCENT(aw) can compute a solution with

Performance profiles of the HS, FR, PRP, PRP+, CD, LS and DY methods. See the tables for the definitions of the acronyms used for the algorithms referred to in all the figures

Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 2  
 Performance profiles of some hybrid conjugate-gradient algorithms (continued on next page)

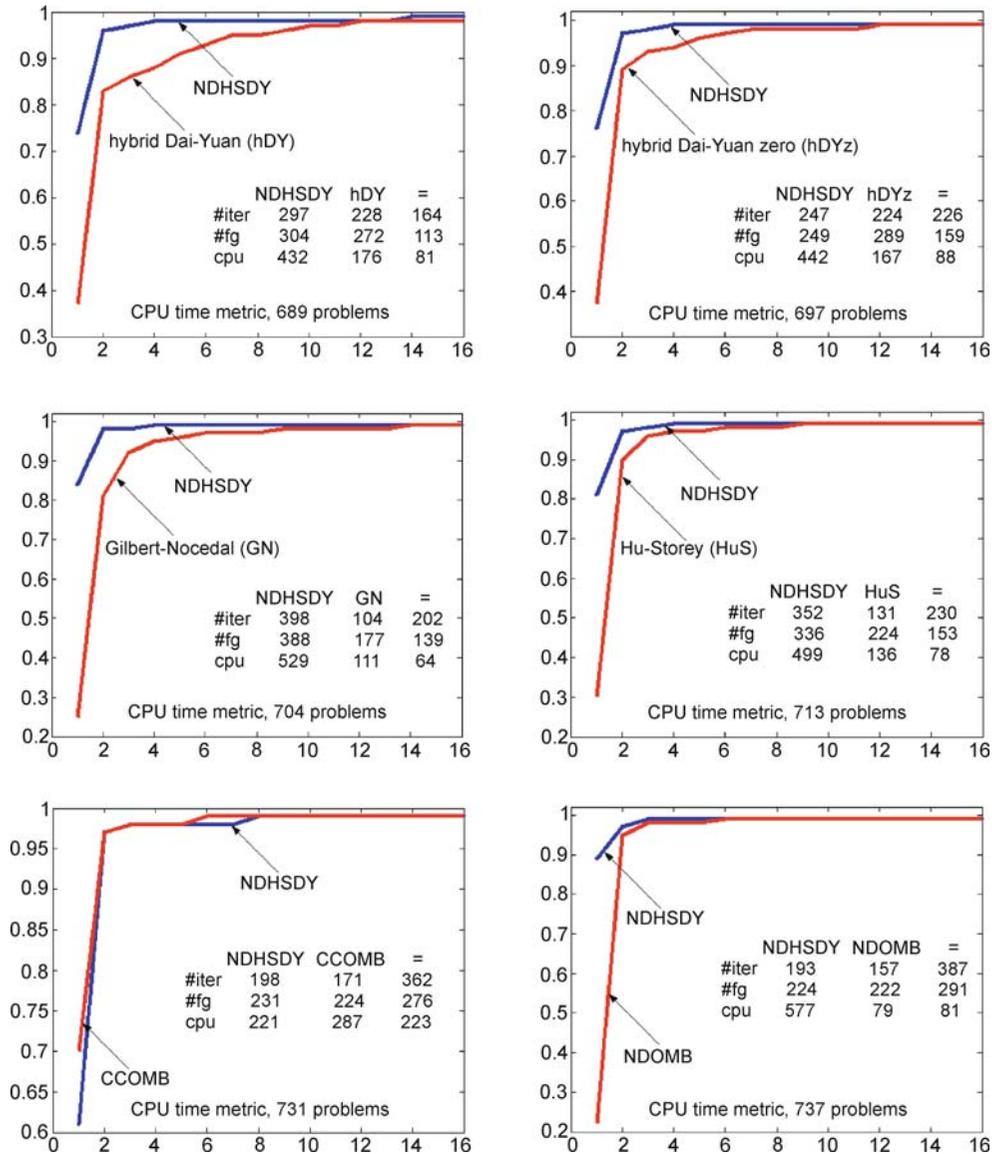

an accuracy on the order of machine epsilon. The rest of the algorithms considered in this study are authored by Andrei. All codes were written in double-precision Fortran and compiled with f77 (default compiler settings) on an Intel Pentium 4, 1.8 GHz workstation.

All algorithms implement the Wolfe line search conditions with  $\rho = 0.0001$  and  $\sigma = 0.9$ , and the same stopping criterion  $\|g_k\|_\infty \leq 10^{-6}$ , where  $\|\cdot\|_\infty$  is the maximum absolute component of a vector.

The comparisons of the algorithms are given in the following context. Let  $f_i^{\text{ALG1}}$  and  $f_i^{\text{ALG2}}$  be the optimal value found by ALG1 and ALG2, for problem  $i = 1, \dots, 750$ , respectively. We say that, in the particular problem  $i$ , the performance of ALG1 was better than the performance of ALG2 if

$$|f_i^{\text{ALG1}} - f_i^{\text{ALG2}}| < 10^{-3}$$

and the number of iterations, or the number of function-gradient evaluations, or the CPU time of ALG1

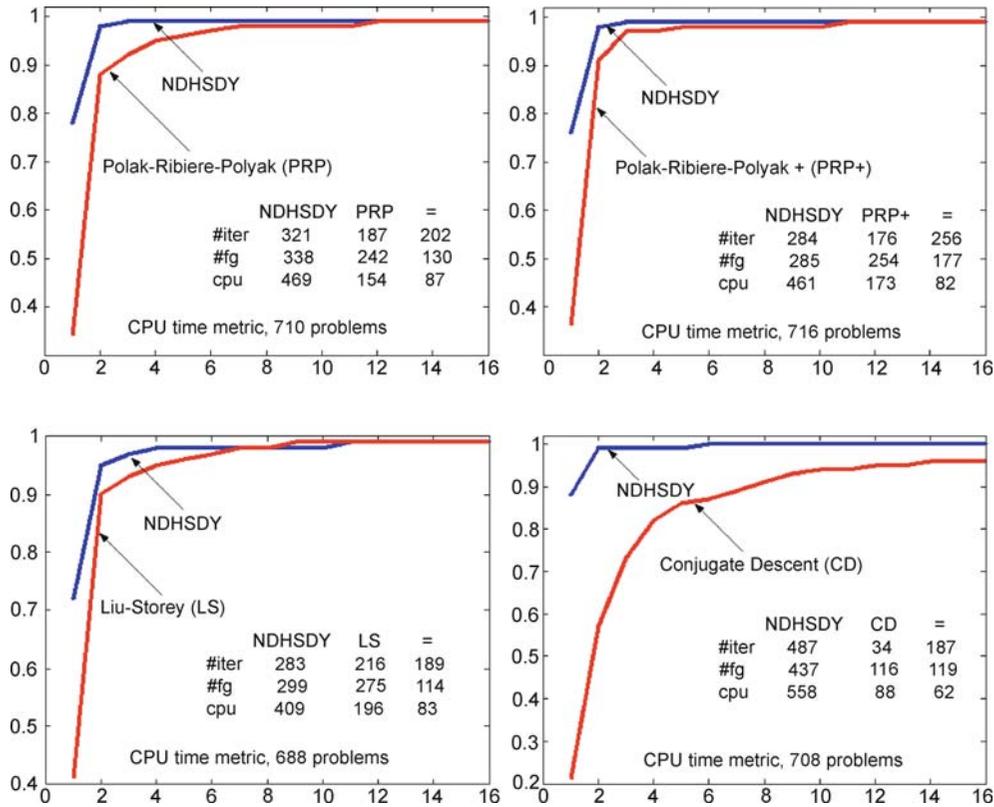

Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 2 (continued)

was less than the number of iterations, or the number of function-gradient evaluations, or the CPU time corresponding to ALG2, respectively.

The performances of these algorithms were evaluated using the profiles of Dolan and Moré [16] corresponding to this set of 750 test problems we extracted from the CUTE collection [11] and from [6]. For each algorithm, we plot the fraction of problems for which the algorithm is within a factor of the best CPU time. The left side of the figures gives the per-

centage of the test problems, out of 750, for which an algorithm is more performant; the right side gives the percentage of the test problems that were successfully solved by each of the algorithms. Mainly, the right side represents a measure of an algorithm's robustness.

In the first set of numerical experiments we compare the classical conjugate-gradient algorithms. Figure 1 shows the CPU time performance profiles of these algorithms.

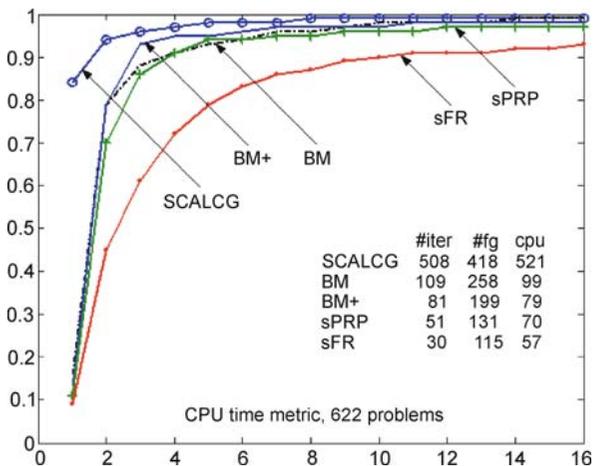

**Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 3**  
 Performance profiles of the NDHSDY algorithm compared with those of some classical conjugate-gradient algorithms

From Fig. 1 we see that the FR, CD and DY methods, although they have strong convergence properties, may not perform well in practice owing to jamming. In contrast, although the HS, PRP and LS methods in general may not converge, they often perform better than the FR, CD and DY methods.

Figure 2 presents the performance profiles of some hybrid conjugate-gradient algorithms.

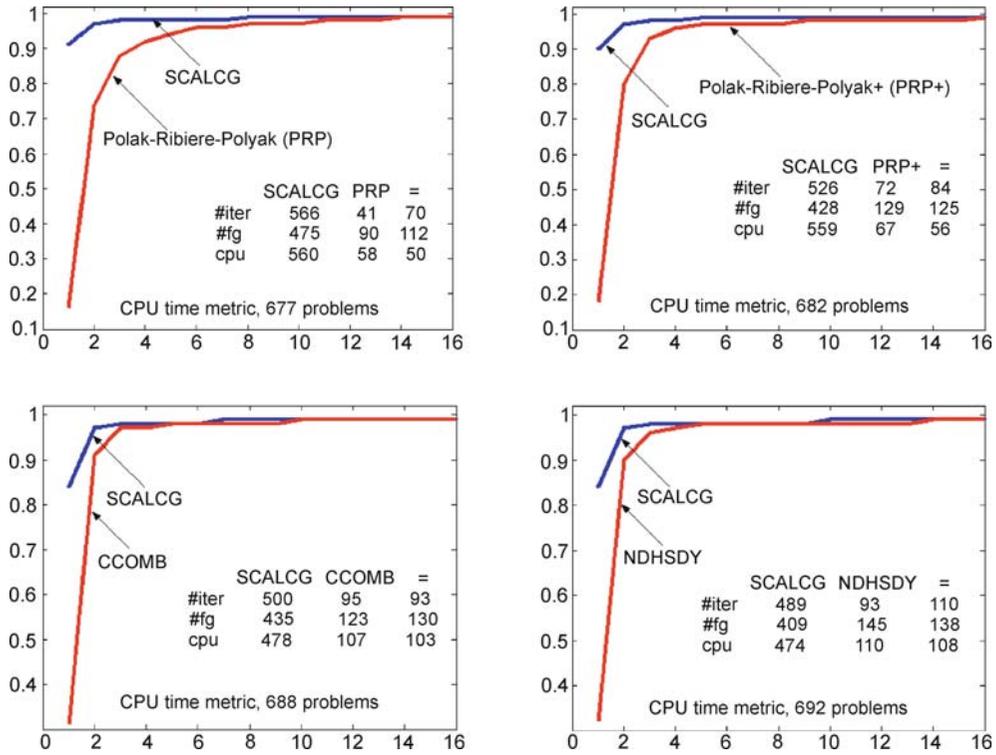

Figure 3 presents the performance profiles of the NDHSDY algorithm compared with those of the classical conjugate-gradient algorithms: PRP, PRP+, LS and CD. It seems that the best algorithm is the hybrid algorithm NDHSDY given by a convex combination of HS and DY, where the parameter in the convex combination is obtained using the Newton direction.

In the next set of numerical experiments we compare the scaled conjugate-gradient algorithms. Figure 4 shows the performance profiles of SCALCG, BM, BM+, sPRP and sFR. We see that the SCALCG algorithm is

**Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 4**  
 Performance profiles of scaled conjugate-gradient algorithms

top performer among the scaled conjugate-gradient algorithms.

Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 5  
 Performance profiles of the SCALCG algorithm compared with those of the PRP, PRP+, CCOMB and NDHSDY algorithms

Figure 5 shows the performance profile of the SCALCG algorithm compared with those of the classical conjugate-gradient algorithms PRP and PRP+, as well as the hybrid algorithms CCOMB and NDHSDY.

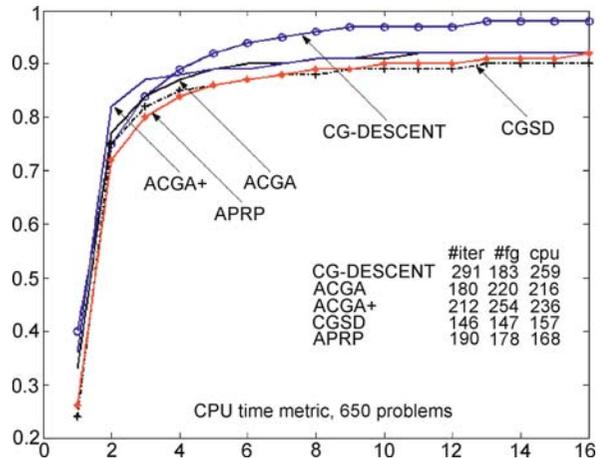

In the following we compare the modified conjugate-gradient algorithms CG\_DESCENT(w), ACGA, ACGA+, CGSD and APRP. Figure 6 presents the performance profiles of these algorithms.

Figure 7 presents the performance profiles of the CG\_DESCENT(w) algorithm compared with those of the PRP, PRP+, NDHSDY and SCALCG algorithms.

Now, comparing CONMIN with some other modified conjugate-gradient algorithms, ACGA, ACGA+, CGSD and APRP, we obtained the performance profiles as in Fig. 8.

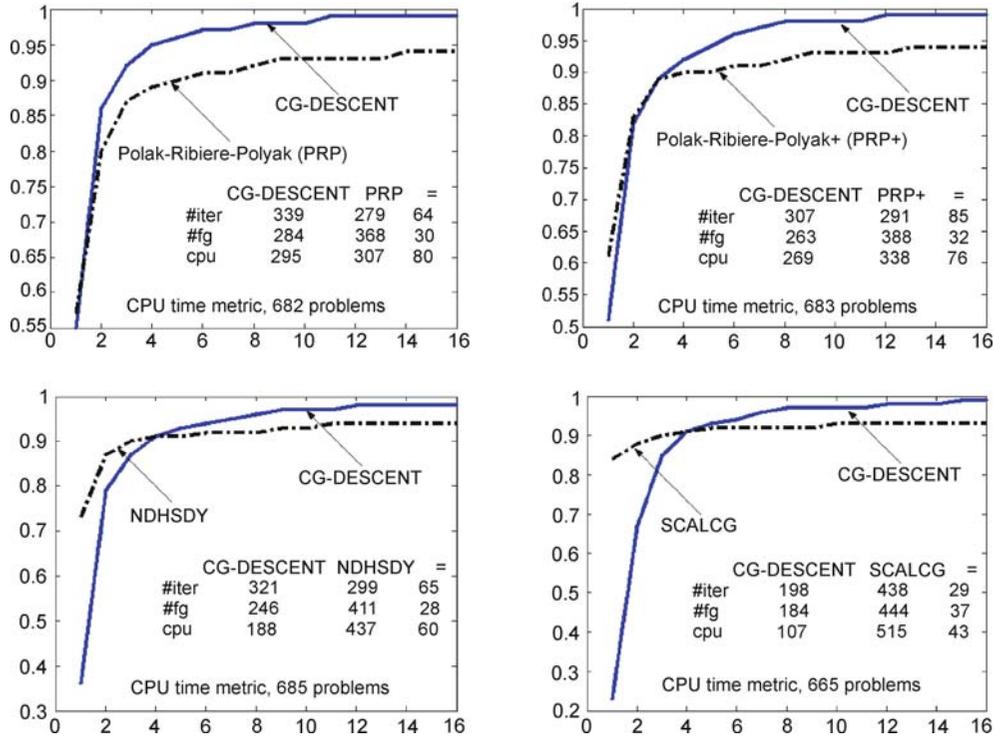

We see that CONMIN is the top performer. Figure 9 presents the performances profiles of the CONMIN algorithm compared with those of the PRP, NDHSDY, SCALCG and CG\_DESCENT algorithms.

Finally, let us consider the parametric conjugate-gradient algorithms DL(t=1) and DL+(t=1). Figure 10

**Conclusion and Discussion**

Conjugate-gradient algorithms are one of the most elegant and probably the simplest algorithms for computational nonlinear optimization. Their theory is well established [22] and they have proved to be surprisingly effective in solving real practical applications. The computational study presented here, which include 29 conjugate-gradient algorithms, shows that the most effective are CONMIN, CG\_DESCENT and SCALCG. Close to these algorithms is NDHSDY, a convex combination of HS and DY conjugate-gradient algorithms in which the parameter is computed using the Newton direction. Concerning the robustness, CG\_DESCENT is in first place.

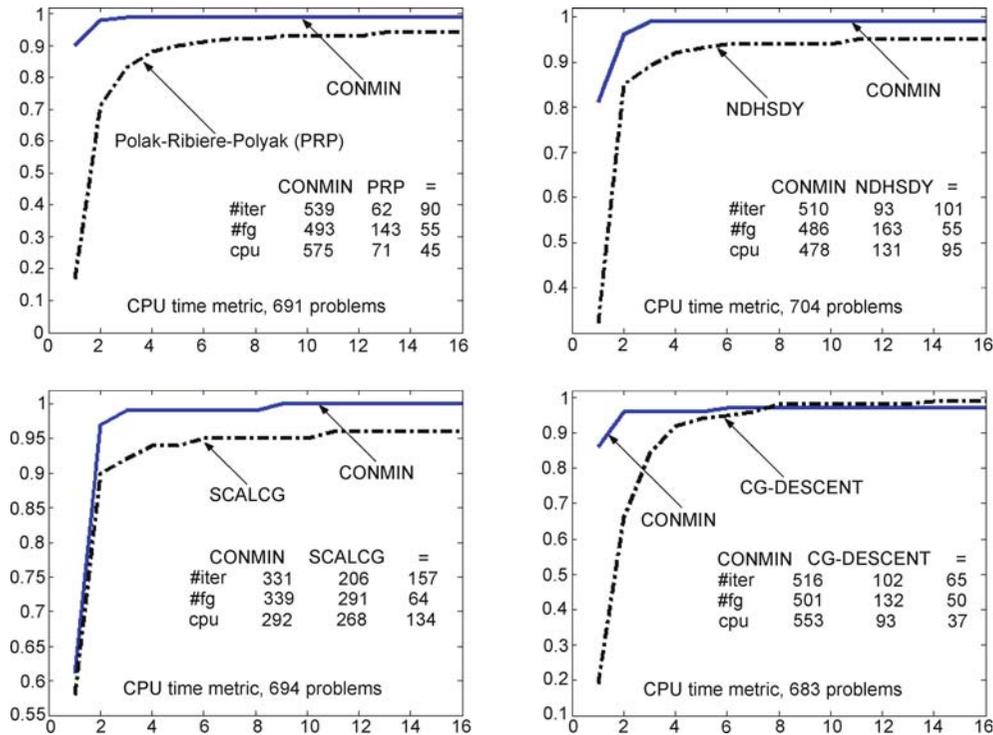

This computational study involved a large variety of nonlinear test functions. However, to draw conclusions about the effectiveness of these algorithms, the test functions must be organized on some classes with well-established characteristics, and one must see which conjugate-gradient algorithm is more successful. This remains to be explored.

Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 8

Performance profiles of the CONMIN, ACGA, ACGA+, CGSD and APRP algorithms

It is worth seeing a comparison between the most successful conjugate-gradient algorithms and the quasi-

Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 9

Performance profiles of the CONMIN algorithm compared with those of the PRP, NDHSDY, SCALCG and CG\_DESCENT algorithms

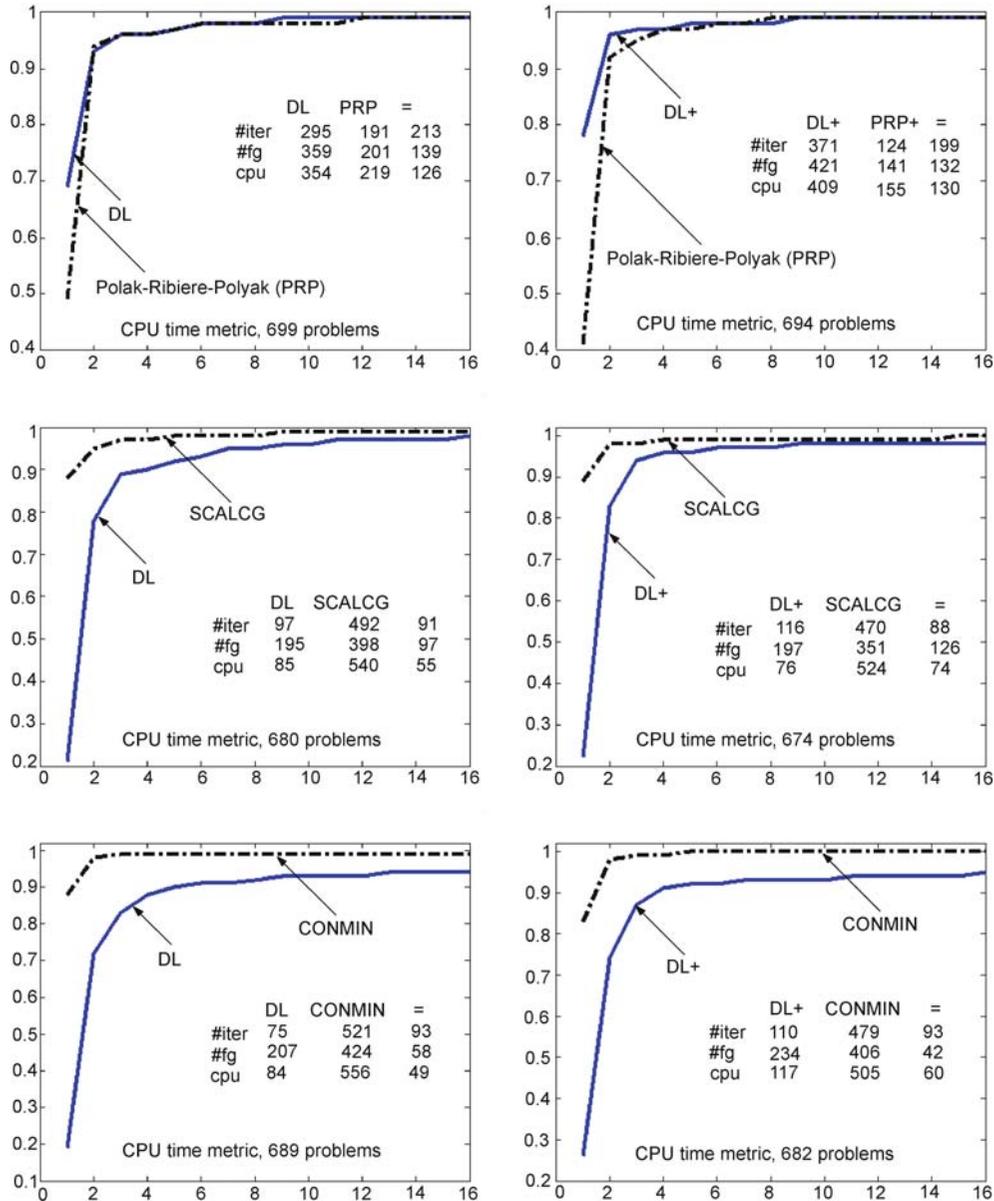

Newton limited BFGS (LBFGS) algorithm of Nocedal [29]. Figure 11 shows the performance profiles of the CONMIN, SCALCG, CG\_DESCENT and NDHSDY algorithms compared with those of the LBFGS ( $m=3$ ) algorithm, an implementation given by Liu and Nocedal [25] using the line search of Moré and Thuente [27].

From Fig. 11 we see that LBFGS ( $m=3$ ) is way more successful than any conjugate-gradient algorithm. Closest to LBFGS is CONMIN.

Even though conjugate-gradient methods are relevant nonlinear optimization methods, there are some open problems which deserve additional research:

1. In contrast to the quasi-Newton methods for which the step length for the vast majority of iterations is equal to 1, the step length in conjugate gradient methods differs from 1, being larger or smaller up by two order of magnitude depending on how the problem is scaled. In conjugate-gradient methods the size of  $\alpha_k$  varies in a very unpredictable way.

2. Another open problem is the preconditioning of conjugate-gradient algorithms. The scaled conjugate-gradient algorithms by Birgin and Martínez [10] and Andrei [1,2,3,4] introduce a scaling of  $g_{k+1}$  in the direction  $d_{k+1}$  computation. However, if the definition of  $\theta_{k+1}$  in (7) does not contain enough information about the inverse Hessian of the minimizing function, then it is better to use the search direction  $d_{k+1} = -\theta_{k+1}g_{k+1}$ , since the addition of the term  $\beta_k s_k$  in (7) may prevent  $d_{k+1}$  from being a descent direction unless the line search is sufficiently accurate. In scaled conjugate-gradient algorithms there is a very delicate balance between  $-\theta_{k+1}g_{k+1}$  and  $\beta_k s_k$ , which brings to attention the preconditioning question.
3. Another open problem with conjugate-gradient methods is that the structure of the minimizing problem is not taken into account to design more efficient computational schemes. This is in sharp contrast to quasi-Newton or truncated Newton methods.

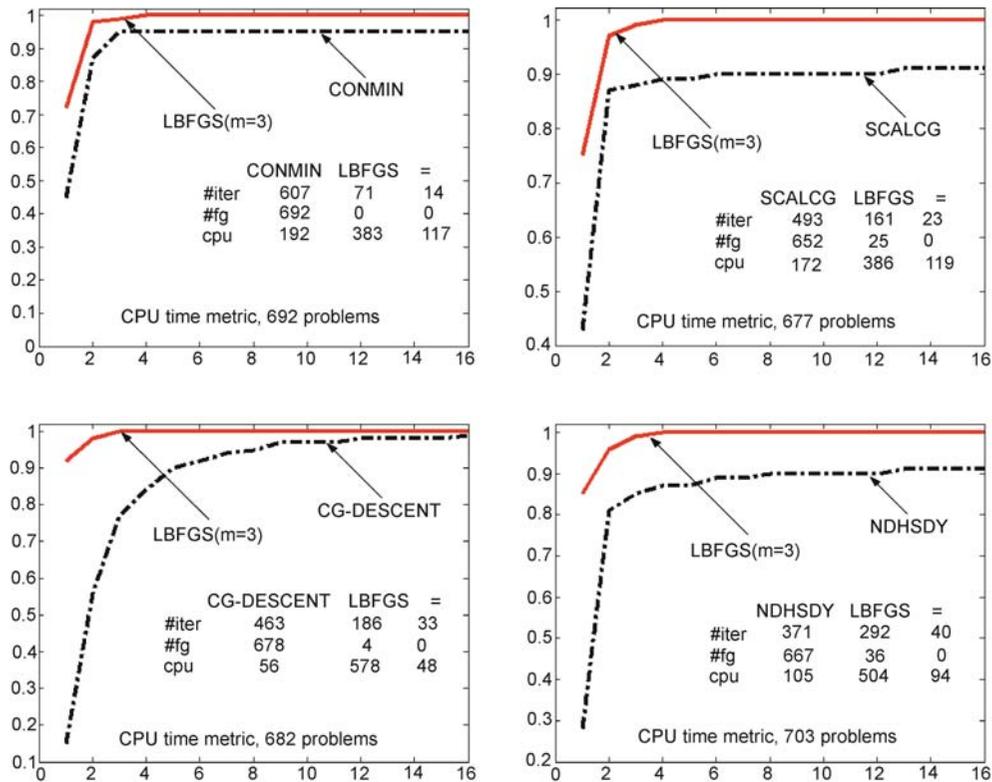

Performance Profiles of Conjugate-Gradient Algorithms for Unconstrained Optimization, Figure 10

Performance profiles of the DL( $t=1$ ) and DL+( $t=1$ ) algorithms compared with those of the PRP, SCALCG and CONMIN algorithms

Global optimization; Phase problem; Normalized structure factors; Structure invariants; Minimal function; Minimal principle; Shake and bake algorithm

The *phase problem* of X-ray crystallography is formulated as one in constrained global minimization. The problem of reaching this minimum is solved by the *Shake and Bake algorithm* which effectively by-passes the myriad of (unconstrained) local minima. The function whose constrained global minimum is sought is known as the *minimal function*.

### Introduction

When a beam of monochromatic X-rays strikes a crystal, the crystal scatters the incident beam in different directions and with different intensities determined by the crystal structure, that is the arrangement of the atoms in the unit cell of the crystal. From the intensities of the scattered X-rays, the directions of which are labeled by the so-called reciprocal lattice vectors  $H$ , a set of numbers  $|E_H|$  may be derived, one corresponding to each scattered X-ray. The phases  $\phi_H$  of the scattered X-rays are lost in the scattering (diffraction) experiment, that is to say cannot be measured. However, the elucidation of the crystal structure requires a knowledge of

the complex numbers

$$E_{\mathbf{H}} = |E_{\mathbf{H}}| \exp(i\phi_{\mathbf{H}}), \quad (1)$$

the so-called *normalized structure factors*, of which only the magnitudes  $|E_{\mathbf{H}}|$  can be determined from experiment. Thus the phase  $\phi_{\mathbf{H}}$ , unobtainable from the diffraction experiment, must be assigned to each  $|E_{\mathbf{H}}|$ . The problem of determining the phases  $\phi_{\mathbf{H}}$  when only the magnitudes  $|E_{\mathbf{H}}|$  are available, is called the ‘phase problem’. A major advance in the early 1950s was the recognition that the lost phase information was to be found in the measurable intensities of the diffraction pattern. In fact, owing to the known atomicity of crystal structures and the redundancy of observed magnitudes  $|E_{\mathbf{H}}|$ , the phase problem is not only solvable in principle but is a greatly overdetermined one.

The phase problem is here formulated as one in constrained global minimization. The ability to impose constraints, in the form of identities among the phases which must, of necessity, be satisfied, even if only incompletely and approximately, enables one to avoid the countless local minima of the minimal function and to arrive at the unique constrained global minimum. The shake and bake algorithm, which implements the minimal principle formulated here, provides a routine and completely automatic solution of the phase problem when diffraction intensities to atomic resolution (1.2Å or better) are available.

### Identities Among the Phases

The relationship between the crystal structure and the diffraction pattern, in the case that the structure consists of  $N$  identical atoms in the unit cell (the only case to be considered here), is given by the pair of equations

$$E_{\mathbf{H}} = \frac{1}{\sqrt{N}} \sum_{j=1}^N \exp(2\pi i\mathbf{H} \cdot \mathbf{r}_j), \quad (2)$$

$$\langle E_{\mathbf{H}} \exp(-2\pi i\mathbf{H} \cdot \mathbf{r}) \rangle_{\mathbf{H}} = \begin{cases} \frac{1}{\sqrt{N}} & \text{if } \mathbf{r} = \mathbf{r}_j, \\ 0 & \text{if } \mathbf{r} \neq \mathbf{r}_j, \end{cases} \quad (3)$$

where  $|E_{\mathbf{H}}|$  is obtained directly from the intensity of the X-ray scattered in the direction labeled by the reciprocal lattice vector  $\mathbf{H}$ , whose three components are integers,  $\mathbf{r}$  is an arbitrary three-dimensional vector, and  $\mathbf{r}_j$  is the position vector of the atom labeled  $j$ . Thus

the positions of the maxima of the triple Fourier series (3), a function of the position vector  $\mathbf{r}$ , yield the crystal structure directly. However, in order to calculate (3) both the phases  $\phi_{\mathbf{H}}$  and magnitudes  $|E_{\mathbf{H}}|$  (in (1)) are needed. Since only the magnitudes  $|E_{\mathbf{H}}|$  are obtainable from the measured intensities in the diffraction experiment while the phases  $\phi_{\mathbf{H}}$  are lost, (3) makes clear why the phase problem has historically been regarded as the central problem of X-ray crystallography.

The system of equations (2) implies the existence of relationships among the normalized structure factors  $E_{\mathbf{H}}$  since the (relatively few) unknown atomic position vectors  $\mathbf{r}_j$  may, at least in principle, be eliminated. In this way one obtains a system of equations among the normalized structure factors  $E_{\mathbf{H}}$  alone, that is, among the phases  $\phi_{\mathbf{H}}$  and magnitudes  $|E_{\mathbf{H}}|$ :

$$F(E) = G(\phi; |E|) = 0 \quad (4)$$

which depends on  $N$  but is independent of the atomic position vectors  $\mathbf{r}_j$ . For a specified crystal structure the magnitudes  $|E|$  are determined (by (2)). Thus the system of equations (4) leads directly to a system of identities among the phases  $\phi$  alone:

$$G(\phi; |E|) \rightarrow H(\phi ||E|) = 0 \quad (5)$$

dependent now on the presumed known magnitudes  $|E|$ , which must of necessity be satisfied. The direct methods are those which exploit these relationships to go directly from known magnitudes  $|E_{\mathbf{H}}|$  to the desired phases  $\phi_{\mathbf{H}}$

### Structure Invariants

Equation (3) implies that the normalized structure factors  $E_{\mathbf{H}}$ , that is to say magnitudes  $|E_{\mathbf{H}}|$  and phases  $\phi_{\mathbf{H}}$ , determine the crystal structure. Equation (2) however does not imply that, conversely, the crystal structure determines unique values for the normalized structure factors  $E_{\mathbf{H}}$  since the atomic position vectors  $\mathbf{r}_j$  depend not only on the crystal structure but on the choice of origin as well. As it turns out, however, the magnitudes  $|E_{\mathbf{H}}|$  are in fact uniquely determined by the crystal structure independently of the choice of origin, but the values of the individual phases depend on the choice of origin as well as on the crystal structure. Nevertheless there exist special linear combinations of the phases, the so-called *structure invariants*, whose values

are uniquely determined by the crystal structure and are independent of the choice of origin. The most important class of structure invariants, the so-called triplets, are the linear combinations of three phases

$$\phi_{\mathbf{HK}} = \phi_{\mathbf{H}} + \phi_{\mathbf{K}} + \phi_{-\mathbf{H}-\mathbf{K}} \quad (6)$$

where  $\mathbf{H}$  and  $\mathbf{K}$  are arbitrary reciprocal lattice vectors.

### Probabilistic Background

It is assumed that the atomic position vectors  $r_j$  are random variables which are uniformly and independently distributed. Under this assumption the normalized structure factors  $E_{\mathbf{H}}$ , as functions ((2)) of the primitive random variables  $r_j$ , are themselves random variables. Since the magnitudes  $|E_{\mathbf{H}}|$  are known from the diffraction experiment, (1) and (2) imply that the phases  $\phi_{\mathbf{H}}$  also are random variables. Hence it makes sense to ask for the conditional probability distribution of the special linear combinations of three phases, (6), the triplets  $\phi_{\mathbf{HK}}$ , assuming that the values of an appropriate set of observed magnitudes  $|E|$  have been given.

### For Fixed $\mathbf{H}$ and $\mathbf{K}$ , the Conditional Probability Distribution of the Triplet $\Phi_{\mathbf{HK}}$

Under the assumptions of the previous section, the conditional probability distribution of the triplet  $\phi_{\mathbf{HK}}$ , (6), given the three magnitudes  $|E_{\mathbf{H}}|$ ,  $|E_{\mathbf{K}}|$ ,  $|E_{\mathbf{H}+\mathbf{K}}|$  is

$$P\left(\frac{\Phi}{A_{\mathbf{HK}}}\right) = \frac{1}{2\pi I_0(A_{\mathbf{HK}})} \exp(A_{\mathbf{HK}} \cos \Phi), \quad (7)$$

where  $\Phi$  represents the triplet  $\phi_{\mathbf{HK}}$ , the parameter  $A_{\mathbf{HK}}$  is defined by

$$A_{\mathbf{HK}} = \frac{2}{\sqrt{N}} |E_{\mathbf{H}} E_{\mathbf{K}} E_{\mathbf{H}+\mathbf{K}}| > 0 \quad (8)$$

and  $I_0$  is the modified Bessel function. Since  $A_{\mathbf{HK}} > 0$ , the distribution (7) implies that the mode of  $\phi_{\mathbf{H}}$  is zero and the conditional expectation (or average) of  $\cos \phi_{\mathbf{H}}$ , given  $A_{\mathbf{HK}}$ , is

$$E(\cos \phi_{\mathbf{HK}}) = \frac{I_1(A_{\mathbf{HK}})}{I_0(A_{\mathbf{HK}})} > 0, \quad (9)$$

where  $I_1$  is the modified Bessel function. It is also readily confirmed that the larger the value of  $A_{\mathbf{HK}}$  the smaller is the conditional variance of  $\cos \phi_{\mathbf{HK}}$ , given  $A_{\mathbf{HK}}$ . It is to be stressed that the conditional expected value of the cosine, (9), is always positive since  $A_{\mathbf{HK}} > 0$ .

### Minimal Principle

It is assumed that a crystal structure consisting of  $N$  identical atoms in the unit cell is fixed, but unknown, that the magnitudes  $|E|$  of the normalized structure factors  $E$  are known, and that a sufficiently large base of phases, corresponding to the largest magnitudes  $|E|$ , is specified. In view of (9), one is led to construct the so-called minimal function:

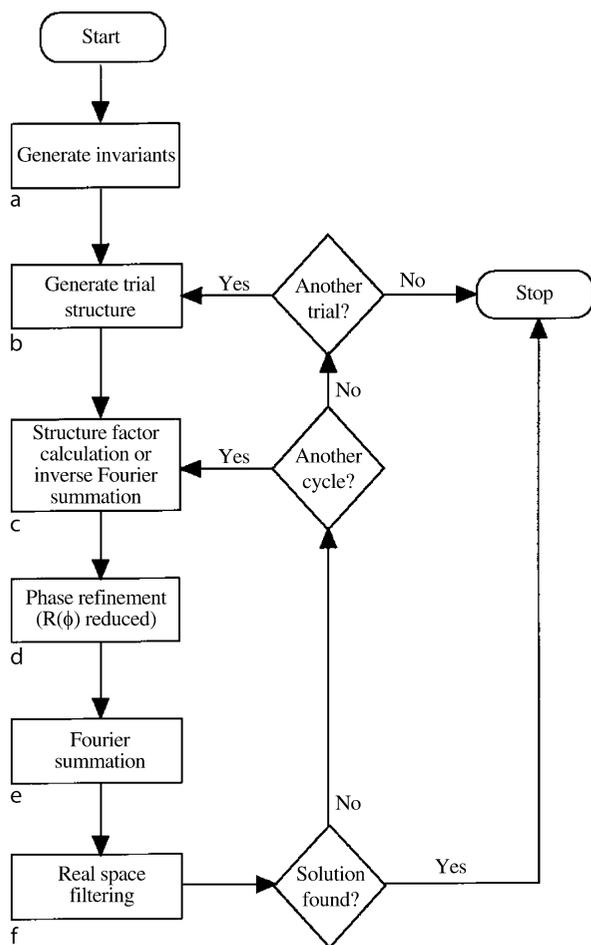

$$R(\phi) = \frac{1}{\sum_{\mathbf{H}, \mathbf{K}} A_{\mathbf{HK}}} \times \sum_{\mathbf{H}, \mathbf{K}} A_{\mathbf{HK}} \left\{ \cos \phi_{\mathbf{HK}} - \frac{I_1(A_{\mathbf{HK}})}{I_0(A_{\mathbf{HK}})} \right\}^2 \quad (10)$$

which, because of (6), is seen to be a function of the phases  $\phi$ , dependent on known magnitudes  $|E|$ . Again in view of (9), one is led to conjecture that the global minimum of  $R(\phi)$  constrained to satisfy the identities (5) yields the correct values of all the phases (the *minimal principle*). It is to be emphasized that the unconstrained global minimum of  $R(\phi)$  does not give us the answer we seek, nor do any of the (innumerable) local minima.

### Computer Program 'Shake and Bake'

The six-part shake and bake phase determination procedure, shown by the flow diagram in Fig. 1, combines minimal-function phase refinement and real-space filtering. It is an iterative process that is repeated until a solution is achieved or a designated number of cycles have been performed. With reference to Fig. 1, the major steps of the algorithm are described next.

- A) Generate invariants. Normalized structure-factor magnitudes ( $|E|$ 's) are generated by standard scaling methods and the triplet invariants that involve the largest corresponding  $|E|$ 's are generated. Parameter choices that must be made at this stage include the numbers of phases and triplets to be used. The total number of invariants is ordinarily chosen to be at least 100 times the number of atoms whose positions are to be determined.
- B) Generate trial structure. A trial structure or model is generated that is comprised of a number of randomly positioned atoms equal to the number of atoms in the unit cell. The starting coordinate sets

**Phase Problem in X-ray Crystallography: Shake and Bake Approach, Figure 1**  
Flow chart for Shake and Bake, the minimal-function phase refinement and real-space filtering procedure

are subject to the restrictions that no two atoms are closer than a specified distance (normally  $1.2\text{\AA}$ ) and that no atom is within bonding distance of more than four other atoms.

- C) Structure-factor calculation. A normalized structure-factor calculation based on the trial coordinates is used to compute initial values for all the desired phases simultaneously. In subsequent cycles, peaks selected from the most recent Fourier series are used as atoms to generate new phase values.
- D) Phase refinement. The values of the phases are perturbed by a parameter-shift method in which  $R(\phi)$ , which measures the mean-square difference between estimated and calculated structure invari-

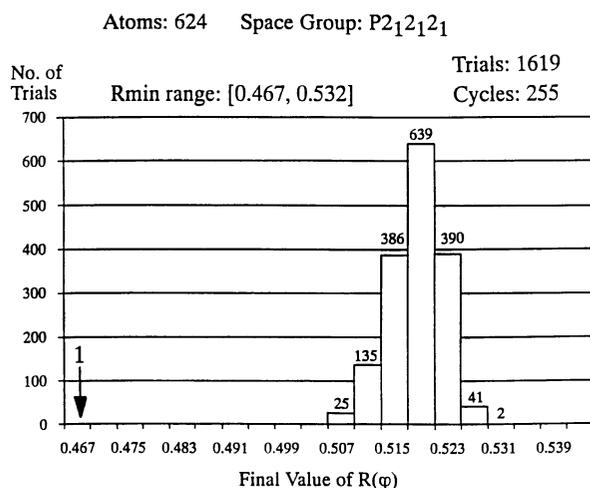

ants, is reduced in value.  $R(\phi)$  is initially computed on the basis of the set of phase values obtained from the structure-factor calculation in step C. The phase set is ordered in decreasing magnitude of the associated  $|E|$ 's. The value of the first phase is incremented by a preset amount and  $R(\phi)$  is recalculated. If the new calculated value of  $R(\phi)$  is lower than the previous one, the value of the first phase is incremented again by the preset amount. This is continued until  $R(\phi)$  no longer decreases or until a predetermined number of increments has been applied to the first phase. A completely analogous course is taken if, on the initial incrementation,  $R(\phi)$  increases, except that the value of the first phase is decremented until  $R(\phi)$  no longer decreases or until the predetermined number of decrements has been applied. The remaining phase values are varied in sequence as just described. Note that, when the  $i$ th phase value is varied, the new values determined for the previous  $i - 1$  phases are used immediately in the calculation of  $R(\phi)$ . This process, when convergent, often, but not always, yields the constrained global minimum of  $R(\phi)$ . The stepsize and number of steps are variables whose values must be chosen.

- E) Fourier summation. Fourier summation is used to transform phase information into an electron-density map (refer to (3)). The grid size must be specified.
- F) Real-space filtering (identities among phases imposed). Image enhancement has been accomplished by a discrete electron-density modification consisting of the selection of a specified number of the largest peaks on the Fourier map for use in the next structure-factor calculation. The simple choice, in each cycle, of a number of the largest peaks corresponding to the number of expected atoms has given satisfactory results. No minimum-interpeak-distance criterion is applied at this stage.

### Applications

Shake and Bake has been tested successfully, with no failure, using experimentally measured atomic resolution data for some 30 structures, many of which had been difficult to solve with existing techniques or had defeated all previous attempts. These structures range in size from 25 to 1000 independent nonhydrogen

atoms. Although a number of these structures had been previously known, this fact was not used in these applications. In all cases those trials which led to solutions were readily identified by the behavior of the minimal function  $R(\phi)$  (See Fig. 2; Fig. 3).

## A Notable Application: Determination by Shake and Bake of the Previously Known Crystal Structure of Toxin II From the Scorpion

*Androctonus australis* Hector. This structure, consisting of 64 amino acid residues (512 protein atoms, the heaviest comprising four disulfide bridges) and 112 water molecules (a total of 624 atoms), crystallizes in the space group  $P2_12_12_1$  and diffracts to a resolution of 0.96 Å. A total of 50,000 triplets having the largest values of  $A_{\text{HK}}$  were generated from the 5,000 phases with the largest values of  $|E|$  and used in the definition of the minimal function  $R(\phi)$ . A total of 1619 Shake and Bake trials were run, each for 255 cycles. The final value of  $R(\phi)$  for the trial which led to the solution was 0.467, the value of the constrained global minimum of  $R(\phi)$ . The range of final values of  $R(\phi)$  for the remaining 1618 trials was [0.507, 0.532] (see histogram, Fig. 2), clearly nonsolutions.

Figure 3 shows the course of the minimal function  $R(\phi)$ , as a function of cycle number, for the trial which led to the solution and for a typical nonsolution trial. Both trials show almost identical behavior for some 130 cycles when  $R(\phi)$  for the solution trial drops precipitously from a value of about 0.50 to 0.467 and remains at about that level for all remaining cycles. For the nonsolution trial however,  $R(\phi)$  oscillates between 0.51 and 0.52 for all remaining cycles.

Piecewise linear arc cost; Fixed charge; Minimum cost network flow; Global optimization

In this article, the minimum cost network flow problems [38] are considered with piecewise linear arc costs, so called *piecewise linear minimum cost network flow problem (PLNFP)*. As a special subclass of minimum cost network flow problems, general piecewise linear network problems can be classified according to the

type of piecewise cost functions. Using general network flow constraints, PLNFP can be stated as follows:

Given a directed graph  $G = (N, A)$  consisting of a set  $N$  of  $m$  nodes and a set  $A$  of  $n$  arcs, then solve [PLNFP]:

$$\text{minimize } f(x) = \sum_{(i,j) \in A} f_{ij}(x_{ij})$$

subject to

$$\sum_{(k,i) \in A} x_{ki} - \sum_{(i,k) \in A} x_{ik} = b_i, \quad \forall i \in N, \quad (1)$$

$$0 \leq x_{ij} \leq u_{ij}, \quad \forall (i, j) \in A, \quad (2)$$

where  $f$  is separable and each  $f_{ij}$  is piecewise linear. For instance, the arc cost  $f_{ij}(x_{ij})$  can be defined as follows:

$$f_{ij}(x_{ij}) = \begin{cases} c_{ij}^1 x_{ij} + s_{ij}^1, & 0 \leq x_{ij} < \lambda_{ij}^1, \\ c_{ij}^2 x_{ij} + s_{ij}^2, & \lambda_{ij}^1 \leq x_{ij} < \lambda_{ij}^2, \\ \vdots & \vdots \\ c_{ij}^{r_{ij}} x_{ij} + s_{ij}^{r_{ij}}, & \lambda_{ij}^{r_{ij}-1} \leq x_{ij} \leq \lambda_{ij}^{r_{ij}}, \end{cases}$$

where  $\lambda_{ij}^k$  for  $k = 1$  to  $r_{ij} - 1$  are breakpoints in the given interval  $[0, u_{ij}]$ . The constraints in (1) are called the *conservation of flow equations*. The constraints in (2) are called *capacity constraints on the arc flows*. The problem is *uncapacitated* if  $u_{ij} = \infty, \forall (i, j) \in A$ .

Three specific classes of PLNFP are identified based on the arc costs,  $f_{ij}$  as follows:

- 1) Convex PLNFP.
- 2) Concave PLNFP.
- 3) Indefinite PLNFP.

In some cases, indefinite PLNFP is called discontinuous PLNFP, since it usually results from a set of discontinuities in the arc cost functions. Since the *fixed charge network flow problem (FCNFP)* has a very close relation to the PLNFP, it is important to understand the special structure of FCNFP to solve PLNFP. Due to the global optimality property of *concave minimization* [19,33], global solutions can be obtained at extreme points of feasible regions for the cases of FCNFP and concave PLNFP. A recent survey on minimum concave-cost network flow problems can be found in [16].

### Convex PLNFP

Firstly, let us consider a convex PLNFP. Suppose constraints are all linear, and the cost function to be mini-

mized is separable and piecewise linear. Then the proportionality assumption is violated for the cost function. However, if the piecewise linear function is convex, the problem can still be modeled as an LP [29].

Let  $f_{ij}(x_{ij})$  denote the contribution of  $x_{ij}$  to the separable objective function. Suppose that there are  $r_{ij} - 1$  breakpoints at which  $f_{ij}(x_{ij})$  changes slope, such that

$$0 = \lambda_{ij}^0 < \lambda_{ij}^1 < \dots < \lambda_{ij}^{r_{ij}-1} < \lambda_{ij}^{r_{ij}} = u_{ij}.$$

Let the slope in the subinterval  $\lambda_{ij}^{k-1} \leq x_{ij} \leq \lambda_{ij}^k$  be  $c_{ij}^k$  for  $k = 1$  to  $r_{ij}$ , and let  $y_{ij}^k$  be the portion of  $x_{ij}$  lying in the  $k$ th subinterval,  $\lambda_{ij}^{k-1}$  to  $\lambda_{ij}^k$ , (i. e.,  $y_{ij}^k$  is the length of the overlap of the interval  $0$  to  $x_{ij}$  with the subinterval  $\lambda_{ij}^{k-1}$  to  $\lambda_{ij}^k$ ),  $k = 1$  to  $r_{ij}$ . When defined in this manner, the new variables  $y_{ij}^1, \dots, y_{ij}^{r_{ij}}$  partition  $x_{ij}$  such that

$$x_{ij} = y_{ij}^1 + \dots + y_{ij}^{r_{ij}}. \tag{3}$$

These variables are subject to the constraints:

$$\begin{cases} y_{ij}^1 \leq \lambda_{ij}^1 \\ 0 \leq y_{ij}^2 \leq \lambda_{ij}^2 - \lambda_{ij}^1 \\ \vdots \\ 0 \leq y_{ij}^{r_{ij}-1} \leq \lambda_{ij}^{r_{ij}-1} - \lambda_{ij}^{r_{ij}-2} \\ 0 \leq y_{ij}^{r_{ij}} \leq \lambda_{ij}^{r_{ij}} - \lambda_{ij}^{r_{ij}-1} \end{cases} \tag{4}$$

and:

for every  $t$ , if  $y_{ij}^t > 0$ , then each of  $y_{ij}^k$  is equal to its upper bound

$$\lambda_{ij}^k - \lambda_{ij}^{k-1}, \quad \forall k < t. \tag{5}$$

Defining the new variables as shown above, it is clear that  $f_{ij}(x_{ij})$  is equal to  $c_{ij}^1 y_{ij}^1 + \dots + c_{ij}^{r_{ij}} y_{ij}^{r_{ij}}$ . If the original separable piecewise linear objective function to be minimized is continuous and convex so that it holds the following *increasing* conditions

$$c_{ij}^1 < \dots < c_{ij}^{r_{ij}}, \tag{6}$$

constraints on the new variables of the type (5) can be ignored in the transformed model. Since convex PLNFP is reformulated as an LP using the above technique and has specially structured network constraints, it can be solved efficiently in polynomial time. If  $f_{ij}$

is not continuous the slopes do not satisfy the condition (6), then the constraints (5) must be specifically included in the model. Since these constraints are not linear, the transformed model is no longer an LP.

**FCNFP**

Due to the similarity of its structure with the piecewise linear case, the fixed charge network flow problem (FCNFP) has close relations to PLNFP. It is very important and useful to investigate some features of FCNFP even if FCNFP does not belong to the class of PLNFP.

The FCNFP is a special case of minimum concave cost network flow problems (MCNFP) [19], whose arc cost function has a discontinuity at the origin. The arc cost function  $f_{ij}(x_{ij})$  of the FCNFP has a form

$$f_{ij}(x_{ij}) = \begin{cases} 0 & \text{if } x_{ij} = 0 \\ s_{ij} + c_{ij}x_{ij} & \text{if } x_{ij} > 0, \end{cases} \tag{7}$$

where  $s_{ij} \geq 0$  is a fixed cost for arc  $(i, j) \in A$ .

In many practical problems, the cost of an activity is the sum of a fixed cost and a cost proportional to the level of the activity. FCNFP is obtained by imposing a fixed cost of  $s_{ij} \geq 0$  if there is positive flow on arc  $(i, j)$  and a variable cost  $c_{ij}$ . Due to the discontinuity of  $f_{ij}$ , the problem can be transformed to a 0-1 mixed integer programming problem by introducing  $n$  binary variables, indicating whether the corresponding activity is being carried out or not. Assuming  $s_{ij} > 0$ ,  $f_{ij}$  can be replaced by

$$f_{ij} = c_{ij}x_{ij} + s_{ij}y_{ij}$$

with

$$x_{ij} \geq 0 \quad \text{and} \quad y_{ij} = \begin{cases} 0 & \text{if } x_{ij} = 0 \\ 1 & \text{if } x_{ij} > 0. \end{cases} \tag{8}$$

The above condition (8) can be incorporated into the capacity constraints to yield

$$0 \leq x_{ij} \leq u_{ij}y_{ij}, \quad y_{ij} \in \{0, 1\}.$$

Hence we obtain the following formulation of the fixed charge network flow problem FCNFP<sub>MIP</sub>:

$$\min \sum_{(i,j) \in A} (c_{ij}x_{ij} + s_{ij}y_{ij})$$

subject to

$$Mx = b \tag{9}$$

$$0 \leq x_{ij} \leq u_{ij}y_{ij}, \quad (i, j) \in A, \tag{10}$$

$$y_{ij} \in \{0, 1\}, \quad (i, j) \in A, \tag{11}$$

where  $M$  is an  $m \times n$  node-arc incidence matrix and  $b$  is an  $m$ -dimensional column vector. This FCNFP<sub>MIP</sub> can be solved by using any type of classical branch and bound algorithms that use LP relaxations [30]. These LP relaxations can be solved efficiently by existing linear network algorithms exploiting the special structure of their feasible domain [18].

As we can see later, many concave and indefinite PLNFPs can be reduced to a FCNFP model by introducing new variables and modifying problem structures. It is noticed that FCNFP models reduced from original PLNFPs can be also transformed to a 0-1 mixed integer programming problem. Consequently, the size of the resulting model grows very fast even if the original PLNFP is just of medium size. This stimulates the reason that many researchers have developed new efficient schemes to improve their exact methods (especially the *branch and bound method*). Indeed, the computational effort and memory requirement to solve large scale FCNFP models have been gradually reduced in various application areas. Yet, since there is a limitation for improving exact solution methods to solve the problem in practical sense, developing a effective approximate method is still in need.

### Concave PLNFP

As different from the convex case, concave PLNFPs are more difficult to solve since we cannot use the same technique in the convex case to reduce the problem into an LP. However, a concave PLNFP can be transformed to a fixed charge network problem in an extended network. The size of the extended network depends on the number of linear pieces in each arc cost function. An *arc separation procedure* (ASP) is required to solve the problem in this way and ASP can be valid due to the concavity of arc cost functions.

Let us consider an arc  $(i, j) \in A$  and its arc cost  $f_{ij}$ , and suppose  $f_{ij}$  has  $r_{ij}$  linear pieces as defined previously. Then arc  $(i, j)$  can be separated into  $r_{ij}$  arcs be-

tween nodes  $i$  and  $j$  for  $(i, j) \in A$ . Each separated arc  $(i, j)^k$  for  $k = 1$  to  $r_{ij}$  has a fixed charge cost function  $f_{ij}^k$  (see Fig. 1) defined by

$$f_{ij}^k(x_{ij}) = \begin{cases} 0 & \text{if } x_{ij} = 0 \\ s_{ij}^k + c_{ij}^k x_{ij} & \text{if } x_{ij} > 0. \end{cases}$$

This extended network is denoted by  $G_e(N, A_e)$  where the number of arcs  $|A_e|$  is given by

$$n_e = |A_e| = \sum_{(i,j) \in A} r_{ij}.$$

After the ASP modification shown in Fig. 2, the original concave piecewise linear objective function can be expressed as a sum of fixed charge arc cost functions as follows:

$$\begin{aligned} f(x) &= \sum_{(i,j) \in A} f_{ij}(x_{ij}) \\ &= \sum_{(i,j) \in A} \sum_{k=1}^{r_{ij}} f_{ij}^k(x_{ij}^k) \\ &= \sum_{(i,j) \in A} \sum_{k=1}^{r_{ij}} (c_{ij}^k x_{ij}^k + s_{ij}^k). \end{aligned} \tag{12}$$

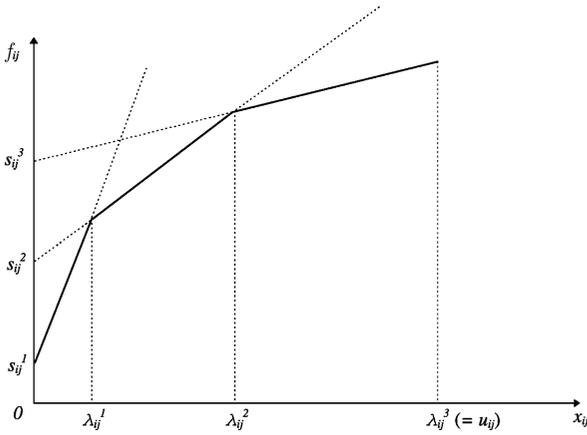

It is easy to see that the equality in (12) can not be true in general cases without a set of constraints to restrict a domain for each separated arc cost function. However, due to the following property from the concavity of arc cost functions:

$$c_{ij}^1 > \dots > c_{ij}^{r_{ij}} > 0, \tag{13}$$

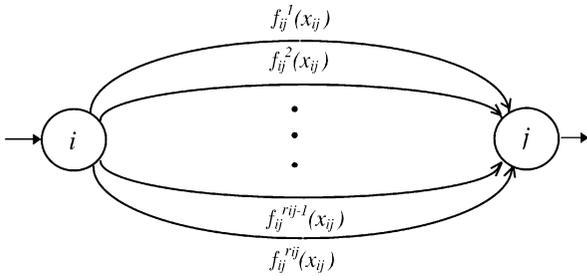

the equality holds for true in this case. More precisely,  $f_{ij}(x_{ij})$  is equal to at most one of arc cost among all separated arc costs between node  $i$  and  $j$  at the optimality of minimization problems. This argument can be generalized as the following property.

**Proposition 1** *Given an extended network described above, if a positive flow  $x_{ij}^*$  is optimal for a minimum concave PLNFP and if  $\lambda_{ij}^{q-1} < x_{ij}^* \leq \lambda_{ij}^q$  for  $1 \leq q \leq r_{ij}$ , then it takes only one arc,  $(i, j)^q$  (i. e.  $q$ th arc) among all separated arcs between node  $i$  and  $j$ ,  $(i, j)^k$  for  $k = 1, \dots, r_{ij}$ .*

Based on this, the original concave PLNFP can be reduced to a FCNFP with the objective function given

**Piecewise Linear Network Flow Problems, Figure 1**  
**Example of a concave piecewise linear arc cost function**

**Piecewise Linear Network Flow Problems, Figure 2**  
**Arc separation procedure**

in (12) and some extended network constraints corresponding to the constraints in (1). The resulting formulation of a concave PLNFP is shown as follows:

$$\min f(x) = \sum_{(i,j) \in A} \sum_{k=1}^{r_{ij}} f_{ij}^k(x_{ij}^k)$$

subject to

$$\sum_{(l,i) \in A} \sum_{k=1}^{r_{ij}} x_{li}^k - \sum_{(i,l) \in A} \sum_{k=1}^{r_{ij}} x_{il}^k = b_i, \quad \forall i \in N,$$

$$\sum_{k=1}^{r_{ij}} x_{ij}^k = x_{ij}, \quad \forall (i, j) \in A,$$

$$x_{ij}^k \geq 0, \quad \forall (i, j) \in A, \quad k = 1, \dots, r_{ij},$$

$$0 \leq x_{ij} \leq u_{ij}, \quad \forall (i, j) \in A. \quad (14)$$

In the formulation, it is clear that any other set of constraints is not necessary to specify lower and upper

bounds for separated arcs  $(i, j)^k \in A_e, \forall i, j \in N$ , due to the above proposition.

As a result, the solution of concave PLNFP can be found by solving the fixed charge network problem formulated as above. Thus, developing an efficient algorithm to solve a FCNFP (*exactly or approximately*) is a key to solve PLNFPs in this approach.

**Indefinite PLNFP**

Lastly, we consider a PLNFP with indefinite arc cost functions, which is the most difficult case in this class. The major difficulty to find exact solutions for indefinite PLNFPs is originated from the structure of their arc cost function. Obviously such cost functions are neither convex nor concave, and possibly have a finite set of discontinuities. However, due to the nature of real world applications of the model, we focus on two certain types of arc cost function in indefinite PLNFP models, so called *staircase arc cost function* [6,17,26] and *sawtooth arc cost function* [26] arc cost functions, respectively.

Both arc cost functions have a very similar structure in overall shape, however, they have a different aspect at breakpoints. It can be described in mathematical form as follows:

- ‘Staircase’ arc cost function (see Fig. 3):

$$f_{ij}^{k-1}(\lambda_{ij}^{k-1}) < f_{ij}^k(\lambda_{ij}^{k-1} + \varepsilon),$$

for any  $\varepsilon > 0$  and  $k = 2, \dots, r_{ij}$ .

- ‘Sawtooth’ arc cost function (see Fig. 4):

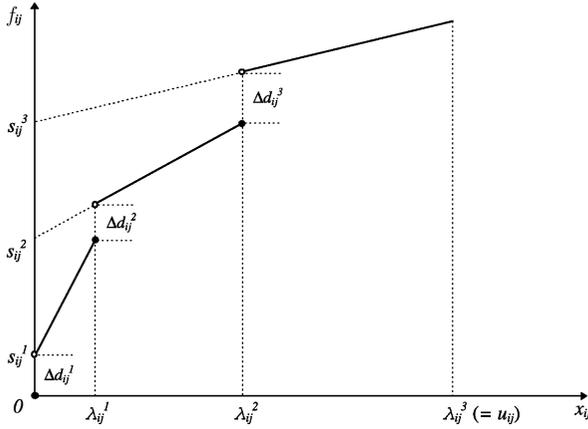

$$f_{ij}^{k-1}(\lambda_{ij}^{k-1} - \varepsilon) > f_{ij}^k(\lambda_{ij}^{k-1}),$$

for any  $\varepsilon > 0$  and  $k = 2, \dots, r_{ij}$ .

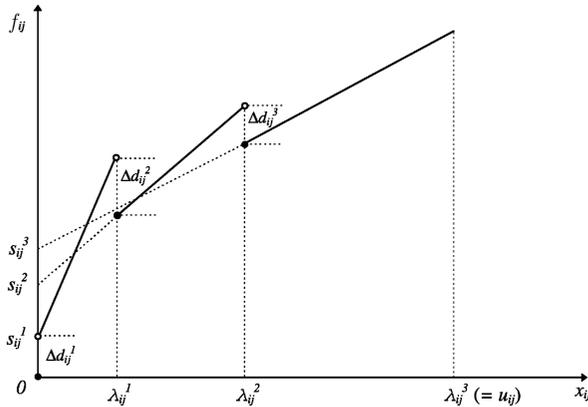

Moreover, it is assumed that the property of slopes shown in (13) is still valid since it is a very general phenomenon in real applications. Note that extreme point solutions are not guaranteed in this cases since objective functions are no longer concave.

Now, we introduce an equivalent (FCNFP)<sub>MIP</sub> formulation of the problem with some additional parameters and binary variables. Let us define the size of interval between adjacent breakpoints as

$$\Delta \lambda_{ij}^k = \lambda_{ij}^k - \lambda_{ij}^{k-1}, \quad \forall (i, j) \in A, \quad k = 1, \dots, r_{ij}, \quad (15)$$

Piecewise Linear Network Flow Problems, Figure 3  
Staircase arc cost function

Piecewise Linear Network Flow Problems, Figure 4  
Sawtooth arc cost function

and define the gap of function values at each breakpoint in arc cost functions as

$$\begin{aligned} \Delta d_{ij}^k &= (c_{ij}^k \lambda_{ij}^{k-1} + s_{ij}^k) - (c_{ij}^{k-1} \lambda_{ij}^{k-1} + s_{ij}^{k-1}) \\ &= s_{ij}^k - s_{ij}^{k-1} + (c_{ij}^k - c_{ij}^{k-1}) \lambda_{ij}^{k-1}, \quad \forall (i, j) \in A, k, \end{aligned} \tag{16}$$

where  $s_{ij}^0 = 0$  and  $c_{ij}^0 = 0$  (also clearly  $\Delta d_{ij}^1 = s_{ij}^1$ ). We now let  $x_{ij}^k$  be the part of  $x_{ij}$  that lies within level  $k$  (i. e.  $k$ th subinterval), in the following sense,

$$x_{ij}^k = \begin{cases} 0 & \text{if } x_{ij} \leq \lambda_{ij}^{k-1}, \\ x_{ij} - \lambda_{ij}^{k-1} & \text{if } \lambda_{ij}^{k-1} < x_{ij} \leq \lambda_{ij}^k, \\ \Delta \lambda_{ij}^k & \text{if } x_{ij} \geq \lambda_{ij}^k, \end{cases} \tag{17}$$

and we obtain the following equation for substitution into  $(FCNFP)_{MIP}$  model. We then introduce new binary variables defined by

$$y_{ij}^k = \begin{cases} 1 & \text{if } \lambda_{ij}^{k-1} < x_{ij} \\ 0 & \text{otherwise.} \end{cases} \tag{18}$$

Using (15)–(18), the indefinite PLNFP under consideration can be formulated as an MIP version of FCNFP as follows:

$$\min \sum_{(i,j) \in A} \sum_{k=1}^{r_{ij}} (c_{ij}^k x_{ij}^k + \Delta d_{ij}^k y_{ij}^k)$$

subject to constraints in (1) and

$$x_{ij} = \sum_{k=1}^{r_{ij}} x_{ij}^k \quad \forall (i, j), \tag{19}$$

$$x_{ij}^k \leq \Delta \lambda_{ij}^k y_{ij}^k \quad \forall (i, j), k = 1, \dots, r_{ij}, \tag{20}$$

$$x_{ij}^{k-1} \geq \Delta \lambda_{ij}^{k-1} y_{ij}^k \quad \forall (i, j), k = 2, \dots, r_{ij}, \tag{21}$$

$$x_{ij}^k \geq 0 \quad \forall (i, j), k = 1, \dots, r_{ij}, \tag{22}$$

$$y_{ij}^k \in \{0, 1\} \quad \forall (i, j), k = 1, \dots, r_{ij}. \tag{23}$$

It is noticed that combining one constraint from (20) and one from (21) yields  $\Delta \lambda_{ij}^{k-1} y_{ij}^k \leq x_{ij}^{k-1} \leq \Delta \lambda_{ij}^{k-1} y_{ij}^{k-1}$ , which implies  $y_{ij}^k \leq y_{ij}^{k-1}, \forall (i, j), k > 1$ .

There is another approach to formulate the problem as a concave minimum cost network flow problem (MCNFP) model. In [26], B.W. Lamar described an equivalent formulation of MCNFP with general nonlinear arc costs (including the problem considered in this section) as a concave MCNFP on an extended network. The equivalence between the problems is based on converting each arc with an arbitrary cost function in the original problem into an arc with a concave piecewise linear cost function in series with a set of parallel arcs, each with a linear arc cost function (cf. [26] for details). Thus, the resulting problem is a concave MCNFP, which is different from the FCNFP formulation model shown above.

## Applications

Piecewise linear network models have a number of applications in various areas such as transportation problems, location problems, distribution problems, communication network design problems, and economic lot-sizing problems. Due to the structure of objective functions (especially in concave and indefinite PLNFP models), many real-world situations listed above can be modeled as PLNFP. There are major applications in the following two fields which have been studied extensively by researchers.

### Transportation Problems

The first major field is transportation-related problems with concave cost functions including fixed charge cost functions. The concave cost functions in this field are usually assumed to be piecewise linear in many cases. A number of algorithms developed with different schemes and their computational results have been reported. These can be found in a limited list of references [2,3,4,7,11,15,20,21,24,25,31,34,35].

The category of exact solution approach contains diverse techniques based on extreme point ranking, branch and bound, and dynamic programming methods. Since the problems can be formulated as MIP models, branch and bound approach with various branching schemes has been a major interest in the literature.

K.G. Murty [28] introduced an extreme point ranking method for solving fixed charge problems. P. McKeown [27] extended Murty's method to avoid some degeneracy of the problem. Recently, Pardalos [32] discussed a range of enumerative techniques based on vertex enumeration or extreme point ranking.

P. Rech and L.G. Barton [34] investigated a nonconvex transportation algorithm using branch and bound approach to problems with piecewise linear cost functions. These functions are approximated by a convex envelope and solved using out-of-kilter method. C.T. Bornstein and R. Rust [6] specialized this approach to the problem with staircase cost function, using successive linearizations of the objective function. P.T. Thach [37] proposed a method for decomposing the problem with a staircase structure into a sequence of much smaller subproblems.

Lamar [25] developed a branch and bound approach for cases of capacitated MCNFP in which the

costs consist of piecewise linear segments. The problem is formulated an MIP, with the branching variables determining which linear cost region an arc flow falls into.

Recently, D. Kim and P.M. Pardalos [23] developed a heuristic procedure for solving general FCNFP without formulating it as an MIP. The procedure is consist of solving a series of LPs to update slopes and searching extreme points of the convex feasible region with the updated slopes. This approach provides a potential possibility of parallel implementation with different initial solutions to improve the quality of solutions. Some heuristic approaches can be found in [8,11,21,24].

### Location Problems

Another major application area is to solve location problems. Since the problem in this field is to locate facilities and determine the size of facilities to minimize total cost [13], it naturally involves fixed costs and/or piecewise linear costs. Since solution methods in this field have used network formulation in many cases, they are quite similar to those for solving FCNFP or PLNFP [1,10,12,22,36]. However, exploiting their certain problem structures, there are some Lagrangian approaches [5,14] to the problems.

Recently, K. Holmberg [17] proposed a decomposition and linearization approach for solving the facility location problem with staircase costs. A comparison of heuristic and relaxation approaches in this field can be found in [9].

### Concluding Remarks

In this article, three categories of PLNFP are identified and formulated in general formats. Some properties of problems in each category are investigated to show the insight of problems including FCNFP. The concave PLNFP is formulated as a FCNFP in MIP structure exploiting the concavity of arc cost functions. Moreover, the indefinite (nonconvex) PLNFP is also transformed to a FCNFP with a reduced feasible region. This implies that the extreme point solution of the transformed FCNFP may not be an extreme point solution of the original indefinite PLNFP.

A major advantage of the formulations introduced in the paper is that solutions can be found by solving fixed charge problems instead of solving difficult nonconvex optimization problems. As we can see in the

transformation to FCNFP, the size of FCNFP is usually quite large because of new binary variables introduced in the model. Thus, developing an efficient algorithm for large scale FCNFP can provide a key to solve concave and indefinite PLNFP in practice.

### Keywords

Simplex algorithm; Interior point algorithms; Exterior point method

We present a new class of *simplex type algorithms* for solving general linear problems. The distinguished characteristic of the new algorithms is their capability of generating two paths to the optimal solution. One path is of simplex type while the other is not. The basic solutions of the simplex path are not feasible. The nonsimplex path consists of feasible segments the endpoints of which lie on the boundary of the feasible region. Preliminary computational results indicate that the new algorithms are substantially faster than the classical simplex algorithm.

### Introduction

The classical simplex algorithm [6] had been the most efficient method for solving practical linear problems until the middle of 1980s. Then N.K. Karmarkar [9] developed the first *interior point algorithm*. Subsequent research led to the development of efficient interior point algorithms which outperform the simplex algorithm on large linear problems. Despite this fact the development of pivoting algorithms that clearly outperform the classical simplex method remained of great interest. It seems that a new class of pivoting algorithms developed recently is more efficient than the simplex method.

The new algorithms differ radically from the classical simplex algorithm. The basic solutions generated are not feasible. In that sense the algorithms are *exterior point methods*. However, the algorithms generate a second path, which consists of feasible points. In fact, it consists of line segments the end point of which lie on the boundary of the feasible region. As a result, the movement between adjacent basic feasible solutions is avoided. The geometry reveals that the new algorithms are faster than the well known simplex method, a fact that is verified by the available preliminary computational results, see [2,5,8]. However, more computational results are needed to draw more safe conclusions.

The first exterior point simplex type algorithm developed by K. Paparrizos [11] for the assignment problem. Other exterior point algorithms for network flow

problems can be found in [1,10,15]. Paparrizos [12] generalized his exterior point method to the general linear problem by developing a dual in nature algorithm. Independently, a similar primal algorithm solving a sequence of linear subproblems is developed in [3]. The algorithms in [12] and [3] generate two paths. One path is feasible, the other is not. However, both paths are of simplex type. In [13] the algorithms in [12] and [3] are generalized, so that the feasible path is not of simplex type. The main algorithm presented in this paper is very similar to the algorithm described in [13]. The algorithm in [5] also generates two paths of simplex type. One path is feasible to the primal problem while the other is feasible to the dual problem. A generalization to this algorithms can be found in [14].

**Algorithm Description**

We will describe the algorithm using the linear problem in the standard form

$$(P_1) \begin{cases} \min & c^T x \\ \text{s.t.} & Ax = b \\ & x \geq 0 \end{cases}$$

where  $c, x \in \mathbf{R}^n, b \in \mathbf{R}^m, A \in \mathbf{R}^{m \times n}$  and  $T$  denotes transposition. Without loss of generality we assume that  $A$  is of full row rank, i. e., the row rank of  $A$  is  $m$  (with  $m < n$ ).

A submatrix of  $A$  consisting of  $m$  independent columns is called *basic matrix*. The  $j$ th column of a matrix or tableau  $A$  is denoted by  $a_j$  and the  $i$ th row by  $A_i$ . A column in a basic matrix  $B$  is called *basic*. The columns not in  $B$  are called *nonbasic*. The submatrix of  $A$  consisting of all the nonbasic variables is called a *non-basic matrix* and it is denoted by  $N$ . Also, with  $B$  and  $N$  we denote the sets  $B = \{j : a_j \text{ is basic}\}, N = \{j : a_j \text{ is non-basic}\}$ . The basic and nonbasic components of a vector  $x$  (respectively,  $c$ ) are denoted by  $x_B, x_N$  (respectively,  $c_B, c_N$ ). Setting  $x_N = 0$  in the equality constraints of (P1) we have  $Bx_B = b$ . From the last equation we have

$$x_B = B^{-1}b$$

The solution  $x_B = B^{-1}b, x_N = 0$  is called *basic*. A solution that satisfies all the constraints of (P1) is called *feasible*. Clearly, a basic solution is feasible if and only if  $x_B \geq 0$ .

Given a basic matrix  $B$  we can use the equality constraints of (P1) to express the basic components  $x_B$  as a function of the nonbasic components  $x_N$ :

$$x_B = B^{-1}b - B^{-1}Nx_N.$$

Substituting in the objective function of (P1) we have

$$\begin{aligned} z &= c^T x = c_B^T x_B + c_N^T x_N \\ &= c_B^T (B^{-1}b - B^{-1}Nx_N) + c_N^T x_N \\ &= c_B^T B^{-1}b + (c_N^T - c_B^T B^{-1}N)x_N. \end{aligned}$$

We set

$$z_j = c_j - c_B^T B^{-1}a_j$$

and

$$H = -B^{-1}N.$$

The current basis  $B$  is *optimal* if  $z_j \geq 0, j \in N$ .

Now, we are ready to describe an exterior point algorithm. Let  $B$  be a nonoptimal basic matrix not necessarily feasible to (P1), i. e.,  $x_B = B^{-1}b \not\geq 0$ . Set  $Q = \{j: z_j < 0, j \in N\}$  and  $R = N \sim Q = \{j: z_j \geq 0, j \in N\}$ . If  $Q = \emptyset$ , then  $B$  is an optimal basis and  $x_B, x_N$  is an optimal solution to (P1). In this case the algorithms stops. Otherwise, a leaving variable  $x_{B_r} = x_k$  is determined as follows.

First an improving direction  $d$  ( $c^T d < 0$ ) such that  $d_R = 0$  and  $d_Q > 0$  is constructed. The direction  $d$  is constructed in such a way so that the ray  $\{\bar{x}: \bar{x} = x + td, t > 0\}$  must intersect the feasible region of problem (P1). In the case  $x_B \geq 0, d$  is very easily computed. Just set  $d_R = 0, d_Q > 0$  and

$$d_B = \sum_{j \in Q} h_j d_j, \tag{1}$$

where  $h_j = -B^{-1}a_j$ . The leaving variable is determined by the following minimum ratio test,

$$\frac{x_{B_r}}{-d_{B_r}} = \min \left\{ \frac{x_{B_i}}{-d_{B_i}} : d_{B_i} < 0 \right\}. \tag{2}$$

Observe that the above minimum ratio test is precisely that used by the primal simplex algorithm. However, keep in mind that our algorithm is an exterior point method and, hence, the basic solutions are not feasible in general. Similar to the simplex method, the exterior

point algorithm stops in the case  $d_B \geq 0$ . In this case, it can be easily shown that problem (P1) is unbounded.

After the choice of the leaving variable  $x_{B_r} = x_k$ , we proceed to the choice of the entering variable  $x_l$ . It is worth mentioning that the exterior point algorithm, although of primal nature, chooses the entering and leaving variables in the reverse order of that of the primal simplex algorithm. First the leaving variable is chosen and then the entering one. In that sense, the exterior point algorithm resembles to the dual simplex method. The entering variable is chosen as follows. It is set

$$\frac{-z_p}{-h_{rp}} = \min \left\{ \frac{-z_j}{-h_{rj}} : h_{rj} < 0, j \in Q \right\} \quad (3)$$

and

$$\frac{-z_s}{-h_{rs}} = \min \left\{ \frac{-z_j}{-h_{rj}} : h_{rj} > 0, j \in R \right\}. \quad (4)$$

Then it is set  $l = p$ , if

$$\frac{-z_p}{-h_{rp}} \geq \frac{-z_s}{-h_{rs}}, \quad (5)$$

and  $l = s$ , otherwise. From the way the entering variable is chosen, it is easily seen that priority is given to the variables in  $Q$ .

Let  $\hat{y}$  be the feasible point from which the ray  $\{\bar{x} : x + td, t \geq 0\}$  exits the feasible region. Let  $\hat{B}$  be the new basis,  $\hat{B} = (B \sim \{k\}) \cup \{l\}$ . Also, let  $\hat{x}$  be the new basic solution. The new direction is  $\hat{d} = \hat{y} - \hat{x}$  and a new iteration can be initiated.

Formally, the algorithm can be described as follows.

- [0] (*Initialization*) Start with a feasible basis  $B$ . Set  $N = \{1, \dots, n\} \sim B$ ,  $Q = \{j \in N : z_j < 0, R = N \sim Q$ . Construct the improving direction  $d$ , where  $d_R = 0$ ,  $d_Q = 1$  and  $d_B = \sum_{j \in Q} h_j$ . Set also  $d_0 = \sum_{j \in Q} z_j$ .
- [1] (*Test of optimality*) If  $Q = \emptyset$ , STOP. The current basic solution is optimal.
- [2] (*Choice of the leaving variable*) If  $d_B \geq 0$ , STOP. Problem (P1) is unbounded. Otherwise, choose the leaving variable  $x_{B_r} = x_k$  from relation (2).
- [3] (*Choice of the entering variable*) Choose the entering variable  $x_l$  using the following two relations. Set

$$\frac{-z_p}{-h_{rp}} = \min \left\{ \frac{-z_j}{-h_{rj}} : h_{rj} < 0, j \in Q \right\}$$

and

$$\frac{-z_s}{-h_{rs}} = \min \left\{ \frac{-z_j}{-h_{rj}} : h_{rj} > 0, j \in R \right\}$$

If

$$\frac{-z_p}{-h_{rp}} \geq \frac{-z_s}{-h_{rs}},$$

then set  $l = p$ . Otherwise, i. e., if

$$\frac{-z_p}{-h_{rp}} < \frac{-z_s}{-h_{rs}},$$

set  $l = p$ .

- [4] (*Pivot operation*) Set  $B \leftarrow (B \sim \{k\}) \cup \{l\}$ . If  $l \in Q$ , then  $Q \leftarrow Q \sim \{l\}$  and  $R \leftarrow R \cup \{k\}$ . If  $l \in R$  then  $Q \leftarrow Q$  and  $R \leftarrow (R \sim \{l\}) \cup \{k\}$ . Let  $y$  be the boundary point from which  $d$  exits the feasible region and  $\bar{x}$  the new basic solution. Set  $d \leftarrow y - \bar{x}$ ,  $x \leftarrow \bar{x}$  compute  $d_0 = \sum_{j \in Q} z_j$  and go to Step 1.

*Example 1* We further illustrate the algorithm by applying it to the following linear problem.

$$\begin{cases} \min & z = -2x_1 - 3x_2 + x_3 + 4x_4 \\ \text{s.t.} & x_1 + 4x_2 + 2x_3 + x_4 + x_5 = 8 \\ & x_1 + 3x_2 - 4x_3 - x_4 + x_6 = 8 \\ & x_1 + 3x_2 + 2x_3 - x_4 + x_7 = 10 \\ & x_1, x_2, x_3, x_4, x_5, x_6, x_7 \geq 0. \end{cases}$$

In Step 0 we set  $B = [5, 6, 7]$ . It is easily seen that  $Q = [1, 2]$  and  $R = [3, 4]$ . Also,  $(x_B)^T = (x_5, x_6, x_7) = (8, 8, 10)$ . We set  $d_3 = d_4 = 0$  and  $d_1 = d_2 = 1$ . Then, we have  $(d_B)^T = (d_5, d_6, d_7) = (-1 - 4, -1 - 3, -1 - 3) = (-5, -4, -4)$ . Finally, we have  $z_1 = -2, z_2 = -3, z_4 = 1, z_5 = 4$ , and  $z_6 = z_7 = z_8 = 0$ .

The algorithm does not stop in Step 1 because  $Q \neq \emptyset$ . As  $d_B \not\geq 0$  we can choose the leaving variable. It is

$$\begin{aligned} & \min \left\{ \frac{x_5}{-d_5}, \frac{x_6}{-d_6}, \frac{x_7}{-d_7} \right\} \\ & = \min \left\{ \frac{8}{-5}, \frac{8}{-4}, \frac{10}{-4} \right\} = \frac{8}{-5} = \frac{x_5}{-d_5}. \end{aligned}$$

Hence,  $r = 1$  and  $k = 5$  ( $B[1] = 5$ ). Variable  $x_k$  is leaving.

For the choice of the entering variable we first compute

$$\min \left\{ \frac{-z_1}{-h_{11}}, \frac{-z_2}{h_{12}} \right\} = \min \left\{ \frac{2}{1}, \frac{3}{4} \right\} = \frac{-z_2}{h_{12}}.$$

There is no  $j \in R$  such that  $h_{1j} > 0$ . Hence,  $l = 2 \in Q$ . The new sets  $B, Q$  and  $R$  are  $B = [2, 6, 7]$ ,  $Q = [1]$  and

$R = [3, 4, 5]$ . The point  $y$  from which the improving direction exits the feasible region is given by  $y = x + \bar{t}d$ , where  $\bar{t} = \frac{x_5}{(-d_5)} = \frac{8}{5}$ . Hence,  $y^T = (0, 0, 0, 0, 8, 8, 10) + 8/5(1, 1, 0, 0, -5, -4, -4) = (8/5, 8/5, 0, 0, 0, 8/5, 18/5)$ . It is easily verified that the new basic solution is  $\bar{x}^T = (0, 2, 0, 0, 0, 2, 4)$ . The new direction is

$$\bar{d}^T = (y - \bar{x})^T = \left( \frac{8}{5}, \frac{-2}{5}, 0, 0, 0, \frac{-2}{5}, \frac{-2}{5} \right).$$

Observe that  $c^T \bar{d} < 0$ ,  $\bar{d}_Q > 0$  and  $\bar{d}_R = 0$ .

The algorithm is initialized with a basic feasible solution. As a result a two phase or a *big-M* method very similar to that of the primal simplex algorithm can be used to solve general linear problems.

### Algorithm Justification

In this section we show that the algorithm correctly solves linear problems. We also show that the algorithm is finite under the usual non degeneracy assumptions.

**Lemma 2** *If the algorithm stops at step 1, then the last basic solution is optimal.*

*Proof* The proof is by induction on the number of iterations. Assume that  $z_j \geq 0$  for  $j \in R$ . It is easily seen that this induction hypothesis is satisfied by the initial basis. Let  $\bar{B}$  be the next basis,  $\bar{R}$  the updated set  $R$  and  $\bar{z}_j$  the corresponding reduced costs. Then we have

$$\bar{z}_j = z_j - \frac{z_l}{h_{rl}} h_{rj} \geq 0, \quad j \neq k, \quad j \in \bar{R}. \tag{6}$$

Because of the choice of the entering variable  $x_l$  we have  $z_l/h_{rl} \geq 0$ . If  $h_{rj} \leq 0$ , then  $\bar{z}_j \geq 0$ . If  $h_{rj} > 0$ , (6) is equivalent to

$$\frac{z_j}{h_{rj}} \geq \frac{z_l}{h_{rl}},$$

which holds because of the choice of the entering variable. If  $j = k$ , then  $\bar{z}_k = \frac{z_l}{h_{rl}} \geq 0$ . Hence,  $\bar{z}_j \geq 0$  for  $j \in \bar{R}$ .

Denote now by  $\bar{B}$  the basis just before the last basis  $B$ . From the stopping condition  $Q = \emptyset$ , we conclude that  $\bar{Q} = \{l\}$ . A simple induction on the number of iterations shows that  $\bar{d}_{\bar{R}} = 0$  and  $\bar{d}_l > 0$ . Let  $\bar{d}$  be the direction corresponding to the increase of the entering variable  $x_l$ ,  $l \in \bar{Q}$ . Then  $\bar{d} = \lambda \bar{d}$ , where  $\lambda > 0$ . Let  $y$  be

the boundary point from which  $\bar{d}$  exits the feasible region. It is easily concluded that  $x = y \geq 0$ . Hence, the last basic solution  $x$  is feasible. By the well known Theorem of duality we conclude that  $x$  is optimal.

**Lemma 3** *If the algorithm stops at Step 2, problem (P1) is unbounded.*

*Proof* From  $d = y - x$  we conclude that  $Ad = 0$ . From  $d_R = 0$  we have

$$c^T d = \sum_{j \in Q} z_j d_j$$

From relation (6) and a simple induction we conclude that  $z_j < 0$  for  $j \in Q$ . As  $d_j \geq 0$  we have  $c^T d < 0$ . This concludes the proof.

We show finiteness of the algorithm under the assumption that the dual problem of (P1) is nondegenerate, i. e.,  $z_j \neq 0$ , for  $j \in N$ . We also assume that the initial basic feasible solution  $x$  is nondegenerate.

**Theorem 4** *The algorithm solves problem (P1) correctly after a finite number of iterations.*

*Proof* The correctness of the algorithm is an immediate consequence of Lemmas 2 and 3. Let  $B$  be the current basis and  $\bar{B}$  the previous one. Let  $\bar{d}$  correspond to  $\bar{B}$  and  $\bar{y}$  be the boundary point from which  $\bar{d}$  exits the feasible region. Then  $d = \bar{y} - x$ , where  $x$  is the basic solution corresponding to  $B$ . Also  $\bar{x} = x + td \geq 0$  for  $1 \leq t \leq x_{b_r}/(-d_{b_r})$ . Indeed, for  $t = 1$  we have  $\bar{x} = \bar{y} \geq 0$ . We conclude that  $x_{B_r} > 0$ . From the nondegeneracy assumption we have  $z_l \neq 0$ . Hence, the objective function decreases strictly from iteration to iteration. The decrease is  $(-z_l/h_{rl}) x_{B_r} < 0$ . This concludes the proof.

The algorithm cycles on degenerate problems, see [12]. The primal-dual pivoting rule [5] also cycles, see [8]. However, refinements of these algorithms employing the least index rule [4] or the lexicographic rule are cycling free, see [3,12] and [8].

### Computational Improvements

The algorithm performs two minimum ratio tests; one for choosing the entering and one for choosing the leaving variable. This fact may mislead someone to con-

clude that no modifications of the algorithm are possible. This is not true. Consider the current basis  $B$ . From the previous iteration, a boundary point  $y$ , which is used to construct the current direction  $d$ , is available. In [17] several heuristics for improving the point  $y$  and, hence, reducing the number of iterations, have been developed.

The algorithm is capable of choosing the entering variable  $x_l$  so that  $l \in R$ . Consequently, a minimum ratio test involving all the nonbasic variables is necessary. We can reduce the work per iteration by choosing the entering variable among those belonging to  $Q$ . Then, a variant consisting of stages is constructed. The minimum ratio test of this variant is restricted to the set  $Q$ . As a result the condition  $z_j \geq 0, j \in R$  is not satisfied. However, the objective function improvement per iteration is larger.

As long as the basic solutions are exterior the boundary points  $y$  must satisfy  $y_R = 0$ . This restriction does not permit computation of good boundary point. One way to cure this computational deficiency is to force the basic solutions to be feasible to the dual problem of (P1). This way a new primal dual algorithm is constructed. This algorithm can be seen as a generalization of the primal dual pivoting rule discussed in [5].

The pivoting algorithms that generate two paths seem to be more efficient than the classical simplex algorithm. Preliminary computational results reported in [1,7] and [5] support this belief. It is worth mentioning that the algorithm is up to 10 times faster than the simplex algorithm employing the maximum coefficient rule on some specially structured linear problems of rather small size ( $n \leq 1000$ ), see [2]. In all computational results we are aware of the computational superiority of two path pivoting algorithms over the simplex method increases as the size of the problems increases. This fact is very encouraging for the new algorithms. Certainly, more computational results, particularly on benchmark problems, are required to draw more safe conclusions. A computational study of this type is now under way in [16].

### Introduction

Since there has been tremendous progress in planning in the process industry during the last 25 years, it might be worthwhile to give an overview of the current state-of-the-art of planning problems in the process industry. This is the purpose of the current contribution, which has the following structure. We start with some conceptual thoughts and some comments on special features of planning in the process industry. What is said in this article applies to the chemical but also to the pharmaceutical as well as to the food industry. The reader will find an orientation on production planning, strategic and design planning, planning under uncertainty and multiobjective planning. In the Sect. “**Model Features in Planning Problems**” the focus is on planning features one would expect in a process industry planning model. The Sect. “**Planning Under Uncertainty**” and “**Multi-Criteria Planning Problems**” address planning under uncertainty and multi-criteria planning.

### A Definition of Planning

A definition of the term “planning” leads to a group of related terms such as “strategic planning,” “design planning,” “master planning,” “operative planning,” and

“production planning.” Planning needs also be distinguished from scheduling.

A starting point could be Pochet and Wolsey (p. 3 in [21]) in their definition of production planning: *Production planning is defined as the planning of the acquisition of the resources and raw materials, as well as the planning of the production activities, required to transform raw materials into finished products meeting customer demand in the most efficient or economical way.* Note that this does not say anything about the length of the time horizon. Their definition of supply chain planning is similar to that of production planning, but extends its scope by considering and integrating procurement and distribution decisions. They distinguish supply chain design problems which cover a longer time horizon and include additional decisions such as the selection of suppliers, the location of production facilities, and the design of the distribution system.

In this article we use planning for any type of strategic, design, or operative planning. We always assume that we are dealing with multisite production networks. Operative planning includes production planning within multisite production networks and scheduling of individual sites. While in production planning the focus is rather on optimizing the trade-off between economic objectives such as cost minimization or maximization of contribution and the less tangible objective of customer satisfaction, in scheduling due dates, makespan, or machine utilization becomes more relevant. So, instead of the term “production planning” we use the term “operative planning” (or just, “planning”), with the target of supporting decisions which have an operative impact on a time scale of several months, maybe up to a year. Planning involves the determination of operational plans that support different short- or mid-term objectives for the current business and for a given multisite topology. Planning covers a horizon from a few months to 12 months, and can be extended to cover years (when it comes to strategic or design planning) and time-discrete models are used. If the time horizon becomes smaller we are in the realm of scheduling where time-continuous models become more efficient. When we extend the time horizon we are dealing with strategic planning or design planning covering 1 year up to 20 years. Design planning includes those parts of the Pochet–Wolsey definition given earlier that allow beyond the topology also for the design of

production units, or the capacity of warehouses. Strategic planning is more concerned with product and customer portfolio optimization but also with the acquisition of whole production sites. Kallrath [16] elaborates more on the concept of operative planning and the design planning problem and promotes the idea of combining both in one single model.

### Special Planning Features in the Process Industry

In the process industry *continuous* and *batch production systems* can be distinguished. There exists also semibatch production, which combines features from both. Plants producing only a limited number of products each in relatively high volume typically use special purpose equipment allowing a continuous flow of materials in *long campaigns*, i. e., there is a continuous stream of input and output products with no clearly defined start or end time. Alternatively, small quantities of a large number of products are preferably produced using multipurpose equipment which is operated in *batch mode*. Batch production is characterized by *well-defined start-ups*, e. g., filling in some products and follow-up steps defined by specific tasks for heating, mixing, and reaction, and a *clearly defined end* for extracting the finished product. Batch production involves an integer number of batches, where a batch is the smallest quantity to be produced; the batch size may also vary between a lower and an upper bound. Several batches of the same product following each other immediately establish a *campaign*. Production may be subject to certain constraints, e. g., campaigns are built up by a discrete number of batches, or a minimal campaign length (or minimal production quantity) has to be observed. Within a fixed planning horizon, a certain product can be produced in several campaigns; this implies that campaigns have to be modeled as individual entities. One might argue that details of the batch production could be rather found in a scheduling model than in scheduling. However, the model provided in Kallrath and Maindl (Chap. 8 in [17]) is a clear example where batch and campaign features have been incorporated into a time-discrete planning model enhancing it by some continuous time aspects. This problem was solved first by Kallrath [10]. An elegant and numerically more efficient formulation to add time continuity to discrete-time models was developed more re-

cently by Sürle [24]. However, it seems that this formulation still needs to be extended to support multistage production.

Chemical products produced using different production equipment could lead to different performance when used. Therefore, customers might require that a product always is produced using one particular machine, or at least it is always produced using the same machine. This feature is called *origin tracing* and is treated in Kallrath [15]. Certain performance chemicals or goods in the food industry have a limited shelf-life and are subject to an expiration date, or can only be used after a certain aging time. To trace those time stamps requires that individual storage means are considered, e. g., containers or drums, which carry the time stamp or the remaining shelf-life. A model formulation is provided in Kallrath [15].

Another special feature in the refinery or petrochemical industry or process industry in general is the *pooling* problem (see, for instance, [1], or Chap. 11 in [18]). This is an almost classic problem in nonlinear optimization. It is also known as the *fuel mixture problem* in the refinery industry but it also occurs in blending problems in the food industry. The pooling problem refers to the intrinsic nonlinear problem of forcing the same (unknown) fractional composition of multicomponent streams emerging from a pool, e. g., a tank or a splitter in a mass-flow network. Structurally, this problem contains indefinite bilinear terms (products of variables) appearing in equality constraints, e. g., mass balances. The pooling problem occurs in all multicomponent network flow problems in which the conservation of both mass flow and composition is required and both the flow and composition quantities are variable.

Nonlinear programming (NLP) models have been used by the refining, chemical, and other process industries for many years. These nonlinear problems are nonconvex and either approximated by linear ones which can be solved by linear programming (LP) or approximated by a sequence of linear models. This sequential LP technique is well established in the refinery industry but suffers from the drawback of yielding only locally optimum solutions. Although many users may identify obviously suboptimal solutions from experience, there is no validation of nonobvious suboptimal

solutions, as this would require truly globally optimal solutions. Recent advances in optimization algorithms have yielded experimental academic codes which do find globally optimal solutions to large scale pooling NLP models [20]. Nonconvex nonlinear models are not restricted to the oil refining and petrochemical sector, but arise in logistics, network design, energy, environment, and waste management as well as in finance and their solution requires global optimization.

### Some Comments on Planning and Scheduling in the Process Industry

Planning and scheduling is part of company-wide logistics and supply chain management. Planning and scheduling are often treated as separate approaches to avoid mathematical complexity. Depending on the level of detail required, the borderlines between planning and scheduling are diffuse. There could be strong overlaps between scheduling and planning in production, distribution, or supply chain management and strategic planning. The main structural elements of planning and scheduling in the process industry are:

- Multipurpose (multi-product, multi-mode) reactors,
- Sequence-dependent set-up times and cleaning cost,
- Combined divergent, convergent, and cyclic material flows,
- Non-preemptive processes (no interruption), buffer times,
- Multistage, batch, and campaign production using shared intermediates,
- Multicomponent flow and nonlinear blending,
- Finite intermediate storage, dedicated, and variable tanks.

Structurally, in scheduling these features often lead to allocation and sequencing problems, knapsack structures, or to the pooling problem. Although the horizon of scheduling problems is usually only days to a few weeks, time-discrete models lead to too many binary variables. Thus, time-continuous formulations are preferable; see Janak et al. [8] or the reviews by Floudas and Lin [4] or Floudas [2]. The largest scheduling problem using a continuous-time approach was solved by Janak et al. [6,7]. It includes over 80 pieces of equipment, considers the processing recipes of hundreds of different products and leads to a linear mixed integer

programming (MILP) problem with up to 463,025 constraints, 55,531 variables, among them 8,981 binary variables, and 1,472,365 non-zeroes.

In production or supply chain planning, we usually consider material flow and balance equations connecting sources and sinks of a supply network avoiding some of the complicating details of scheduling. Time-indexed models using a relative coarse discretization of time, e. g., a year, quarters, months, or weeks, are usually accurate enough. LP, MILP and nonlinear mixed integer programming (MINLP) technologies are often appropriate and successful for problems with a clear quantitative objective function as outlined in the section “**Model Features in Planning Problems**” or quantitative multicriteria objectives. A typical size planning problem with four sites, 800 different products, 1,500 different combinations of product and production plant, 10,000 different combinations of customer, product, package and month is reported in Sect. 5.1 in Kallrath [15]. This problem leads to over 200,000 variables, 380,000 nonzero elements, 400 integer variables, and 900 semi-continuous variables. The number of discrete variables usually can reach a few thousand.

### Model Features in Planning Problems

In the literature and in available software packages we usually find *discrete-time models* supporting multi-period analysis, i. e., nearly all the data may vary over time and allow one to evaluate scenarios that involve time-dependent aspects such as seasonal demand patterns, new product introductions, and shutdown of production facilities for maintenance periods. These models include the following main structural objects which are represented by the corresponding indices of the model:

- **Locations** can be production or storage sites, hosting plants and tanks, or demand points hosting tanks.
- **Facilities** are typically production, wrapping, or inventory units that are characterized by their functional properties. Especially, in the process industry we find multistage production systems involving units with general product-mode relationships. Their functional properties are attributes such as capacity, throughput rates, product recipes, yields, minimum production utilization rates, fixed and

variable costs, or storage limitations. Facilities can be existing or potential (for design studies). Production facilities may be subject to batch and campaign constraints across periods.

- **Demand points** may represent customers, regional warehouse locations, or distributors who specify the quantity of a product they request. A demand point can be also seen as a sink of the planning model, i. e., a point where a product leaves the system and is not traced further. Demand may be subject to certain constraints, e. g., satisfying a minimum quantity of demand, observing origins of production, or supplying a customer always from the same origin.
- **Inventories** may be physically fixed entities such as tanks or warehouses but also moveable entities (e. g., drums, containers, boxes). They can be defined as:
  1. Dedicated to a single product from one production source,
  2. Dedicated to a specific product,
  3. Free to accept any product from any source or origin.

We may encounter tank farms, and especially *multi-purpose storage entities*, i. e., variable and multiproduct tanks.
- **Products** may be classified as raw materials, intermediates, finished, and salable products. A product may have several of these attributes, and it can be purchased from suppliers, produced, or sold. Products are produced according to the capabilities at the facilities and the recipes assigned; they may establish a product group, e. g., additives. Product requirements are based on market demand, which is characterized by volume, selling price, package type, time, origin, and location or by other products in which they are used as intermediate products.
- **Suppliers or vendors** may provide products for purchase under different offering schemes. This includes the ability to link the product supply to locations and describe contractual pricing mechanisms or availability. The solver may choose the optimal supplier.

Regarding the overall business and strategic objectives the model needs to incorporate data describing the:

- Costs, i. e., certain fixed costs, variable costs (production, transportation, inventory, external product purchase, energy, resources and utilities), and other costs,

- Commercial aspects: financial aspects such as depreciation plans, discount rates, investment plans, foreign currency exchange rates, duties and tariffs, as well as site-dependent taxes,

*Maximize operating cash flow* and *maximize net present value* (NPV) objective functions are used to determine the financial and operating impacts of mergers, acquisitions, consolidation initiatives, and capital spending programs affecting business. In detail this may include:

1. Maximize the net profit (free design reactors; open and close facilities),
2. Maximize the contribution margin for a fixed system of production units,
3. Maximize the contribution margin while satisfying a minimum percentage of demand,
4. Minimize the cost while satisfying full demand (allow external purchase of products),
5. Maximize total sales neglecting cost,
6. Maximize total production for a fixed system of production reactors,
7. Maximize total production of products for which demand exists,
8. Minimize energy consumption or the usage of other utilities,
9. Minimize the deviation of the usage of resources from their average usage,
10. Multicriteria objectives, e. g., maximize contribution margin and minimize total volume of transport.

Objective functions 2–10 support different short- or mid-term objectives for the current business. By using different objective functions, one can create operational plans that support strategies such as market penetration, top-line growth, or maximization of cash flow to support other business initiatives.

If, besides this broad structure, the focus is on a more detailed representation of physical entities, we find that planning models and their constraints may involve the following features (in alphabetic order):

- **Batch production** (see Kallrath [10]): The quantity of a specific product being produced in a campaign possibly over several periods must be an integer multiple of some pre-defined batch size.
- **Buy, build, close, or sell specific production assets** (see Kallrath [12]): This feature is used for closing, or selling acquisition, consolidation and capacity planning to determine the NPV and operational

impacts of adding or removing specific assets or groups of assets to the network.

- **Campaign production** (see Kallrath [10]): This allows one to impose a lower and/or an upper bound on a contiguous production run (campaign) possibly across periods; this feature is also known under the name *minimal runs*.
- **Delay cost**: Penalty costs apply if customer orders are delivered after the requested delivery date.
- **Minimum production requirements**: Minimum utilization rates modeled as semicontinuous variables have to be observed for specific production units and/or entire production locations for each production time period.
- **Multilocations**: These can be production sites, storage sites, and demand points.
- **Multipurpose production units** (see Kallrath and Wilson [18] or Chap. 8 in Kallrath and Maindl [17]): If a unit is fixed to a certain mode, several products are produced (with different mode-dependent daily production rates), and vice versa, a product can be produced in different modes. Daily production can be less than the capacity rates. A detailed mode-changing production scheme may be used to describe the cost and time required for sequence-dependent mode changes.
- **Multistage production** (see Chap. 8 in Kallrath and Maindl [17]): Free and fixed recipe structures can be used for the production of multiple intermediate products before the production of the final product with convergent and divergent product flows. The recipes may depend on the mode of the multipurpose production unit.
- **Multitime periods** (see Timpe and Kallrath [25]): Nonequidistant time period scales are possible for commercial and production needs. For instance, demand may be forecast weekly for the first quarter of the year and then quarterly for the remainder of the year.
- **Nonlinear pricing** for the purchase of products [12] or utilities (energy, water, etc.) or nonlinear cost for inventory or transportation may lead to convex and concave structures in order to model volume and price discount schemes for the products or services purchased, while, in addition, contract start-up and cancellation fees may lead to additional binary variables.
- **Order lost cost**: Penalty costs are incurred if products are not delivered as requested and promised.
- **Packaging** machines are optimized to increase machine throughput and ensure that priority is given to the most profitable products.
- **Product swaps**: With the objective of saving transportation and other costs companies often arrange joint supply agreements called *swaps*. For example, company 1 based in Europe as well in the USA has a production shortage of product A in the USA and thus purchases a defined quantity of product A in the USA from company 2. Company 2 (also located in the USA and Europe) has a customer in Europe requesting product A and thus purchases a defined quantity of product A from company 1 in Europe. Both companies get product A where they need it and avoid the cost of shipping the product. Without this type of supply agreement company 1 would have to ship product A from its European plant to the USA, and company 2 would have to ship product A from its US manufacturing plant to Europe.
- **Production origin tracing** (see Kallrath [15]): It is possible to define fixed, free, or unique origins for specific demands. For example, a customer may require that his demand is satisfied only from a specific plant in the network, or it may not be supplied from a set of plants, or the customer only requests that he is supplied from one unique plant during the whole planning horizon.
- **Shelf-life** (see Kallrath [15]): Product aging time can be traced. This allows for the application of constraints such as maximum shelf-life, disposal costs for time-expired products, and the setting of selling prices as a function of product life.
- **Transportation and logistics** (see Kallrath [13]): Transportation quantities are appropriately modeled by the use of semicontinuous variables. This allows minimum and maximum shipment quantities to be defined for each source location, destination location, product, and transport means combination. The logistics involves the costs, lead times, and constraints (minimum shipment quantities) associated with moving intermediate and finished products between facilities and demand points. The means of transport may be chosen by the optimizer and nonlinear cost functions have to be considered as well.

This list covers many features but may be enhanced depending on the planning problem at hand. A model supporting these features caters to the overall business and strategic objectives. The model incorporates data describing the variable costs for production, transportation, inventory, external product purchase, energy, resources, utilities, and further commercial aspects: financial aspects such as depreciation plans, discount rates, investment plans, foreign currency exchange rates, duties and tariffs, as well as site-dependent taxes. Maximize operating cash flow and maximize NPV objective functions can also be used to determine the financial and operating impacts of mergers, acquisitions, consolidation initiatives, and capital spending programs affecting business. One would expect that a planning model supports various objective functions, among them net profit (free design reactors; open and close facilities), contribution margin, cost, sales, total production, or multicriteria objectives, e. g., maximize contribution margin and minimize total transportation volume.

A possible extension which could relatively easily be connected to such a model is customer or product portfolio features as described in Kallrath [15].

### Planning Under Uncertainty

In many instances, the data are not in a deterministic form and this naturally leads to optimization under uncertainty, that is, optimization problems in which at least some of the input data are subject to errors or uncertainties, or in which even some constraints hold only with some probability or are just soft. Those uncertainties can arise from many reasons:

1. Physical or technical parameters which are only known to a certain degree of accuracy. Usually, for such input parameters safe intervals can be specified.
2. Process uncertainties, e. g., stochastic fluctuations in a feed stream to a reactor, processing times.
3. Demand and price uncertainties occur in many situations: supply chain planning, investment planning, or strategic design optimization problems involving uncertain demand and price over a long planning horizon of 10–20 years.

For planning, the third point is most relevant. It is difficult to predict demand and prices, especially in strategic or design planning problems where the time horizon

covers several years. Scenario-based optimization in the sense of stochastic optimization leads to large number of variables. A decision taker might be more inclined to hedge against certain risks than to find the most probable scenario. Therefore, the robust optimization framework developed by Lin et al. [9,19] seems to be more appropriate. It provides (1) an explicit trade-off between the effect of uncertainties on the objective function of choice, (2) the unified treatment of uncertainties in product demands, processing times, processing rates, prices of products, and prices of raw materials, and (3) the alternative deterministic equivalent models for a variety of types of representations of uncertainties through bounded, symmetric, normal, difference of normal, binomial, discrete, and Poisson probability distributions.

### Multi-Criteria Planning Problems

In planning we may encounter the situation that there are conflicting objectives. Maximizing the contribution margin and minimizing the amount of stocked material might conflict. The novice might think if the storage costs are appropriately included in the objective function both objectives would go along with each other very well. However, some promising sales could be lost because not enough material had been stocked. Thus, the goal to minimize the amount of stock is different from maximizing the contribution margin. At least in this example it might be possible to measure both goals in the same unit of measure, in this case a monetary unit. The more general situation is that we are facing conflicting goals which cannot even be measured on a common scale.

Multiobjective optimization, also called multicriteria optimization or vector minimization problems, allows one to involve several objective functions. A simple approach to solve such problems is to express all objectives in terms of a common measure of goodness leading to the problem how to compare different objectives on a common scale. Basically, one can distinguish two cases. Either the search is for *Pareto optimal* solutions, or the problem has to be *solved for every objective function separately*.

When minimizing several objective functions simultaneously the concept of Pareto optimal solutions turns out to be useful. A solution is said to be Pareto op-

timal if no other solution exists that is at least as good according to every objective, and is strictly better according to at least one objective. When searching for Pareto optimal solutions, the task might be to *find one*, *find all*, or *cover the extremal set*.

A special solution approach to multiple objective problems is to require that all the objectives should come close to some target, measured each in its own scale. The targets we set for the objectives are called *goals*. Our overall objective can then be regarded as to minimize the overall deviation of our goals from their target levels. The solutions derived are Pareto optimal.

Goal programming can be considered as an extension of standard optimization problems in which targets are specified for a set of constraints. There are two basic approaches for goal programming: the preemptive (*lexicographic*) approach and the *Archimedean* approach. In the Archimedean approach weights or penalties are applied for not achieving targets. A linear combination of the violated targets weighted by some penalty factor is added, or establishes the objective function. We consider only the first approach.

In preemptive goal programming, goals are ordered according to importance and priorities. Especially, if there is a ranking between incommensurate objectives available, this method might be useful. The goal at priority level  $i$  is considered to be infinitely more important than the goal at the next lower level,  $i + 1$ . But they are relaxed by a certain absolute or relative amount when optimizing for the level  $i + 1$ . In a reactor design problem we might have the following ranking: reactor size ( $i = 1$ ), safety issues ( $i = 2$ ), and production output rate ( $i = 3$ ).

Here we provide an illustrative example for *preemptive* (lexicographic) goal programming with two variables  $x$  and  $y$  subject to the constraint  $42x + 13y \leq 100$  as well as the trivial bounds  $x \geq 0$  and  $y \geq 0$ . We are given

Name	Criterion	Type	A/P	$\Delta$
Goal 1 (OBJ1):	$5x + 2y - 20$	Max	P	10
Goal 2 (OBJ3):	$-3x + 15y - 48$	Min	A	4
Goal 3 (OBJ2):	$1.5x + 21y - 3.8$	Max	P	20

where the attribute A or P indicates whether we have to interpret  $\Delta$  as an absolute value or percentage-wise. The multi-criteria LP or MILP problem is converted to a sequence of LP or MILP problems. The basic idea is

to work down the list of goals according to the priority list given. Thus, we start by maximizing the LP with respect to the first goal. This gives us the objective function value  $z_1^*$ . Using this value  $z_1^*$  enables us to convert goal 1 into the constraint

$$5x + 2y - 20 \geq Z_1 = z_1^* - \frac{10}{100}z_1^* . \quad (1)$$

Note how we have constructed the target  $Z_1$  for this goal (P indicates that we work percentage-wise). In the example we have three goals with the optimization sense {max, min, max}. Two times we apply a percentage-wise relaxation, one time an absolute one. Solving the original problem with the additional inequality (1) we get:

$$\begin{aligned} z_1^* &= -4.615385 \\ \Rightarrow 5x + 2y - 20 &\geq -4.615385 - 0.1 \times (-4.615385) \end{aligned} \quad (2)$$

Now we minimize with respect to goal 2 adding (2) as an additional constraint. We obtain

$$\begin{aligned} z_2^* &= 51.133603 \\ \Rightarrow -3x + 15y - 48 &\geq 51.133603 + 4 \end{aligned} \quad (3)$$

Similarly as for the first goal, we now have to convert the second goal into a constraint (3) (here we allow a deviation of 4) and maximize according to goal 3. Finally, we get  $z_3^* = 141.943995$  and the solution  $x = 0.238062$  and  $y = 6.923186$ . To be complete, we could also convert the third goal into a constraint, giving

$$\begin{aligned} 1.5x + 21y - 3.8 &\geq 141.943995 - 0.2 \cdot 141.943995 \\ &= 113.555196 . \end{aligned}$$

Note that lexicographic goal programming based on objective functions provides a useful technique to tackle multicriteria optimization problems. The great advantage is that the absolute or percentage-wise deviations used in lexicographic goal programming based on objectives are easy to interpret. However, we have to keep in mind that the sequence of the goals influences the solution strongly. Therefore, the absolute or percentage deviations have to be chosen with care. It is very important that the optimization problem can be solved to exact optimality or at least closely to optimality because

otherwise the interpretation of the permissible deviation from targets becomes difficult if not impossible.

Goal programming offers an alternative approach but should not be regarded as without defects. The specific goal levels selected greatly determine the answer. Therefore, care is needed when selecting the targets. It is also important in which units the targets are measured. Detailed treatment of goal programming appears in such books as those by Ignizio [5] and Romero [22], who introduce many variations on the basic idea, as well as in that by Schniederjans [23].

### Solution Approaches

Most of the planning problems in the process industry lead to MILP or MINLP models and contain the following building blocks: *tracing the states of plants, modeling production, balance equations for material flows, transportation terms, consumption of utilities, cost terms, and special model features*. Mode changes, start-up and cancellation features, and nonlinear cost structures require many binary variables. Minimum utilization rates and transportation often require semicontinuous variables. Special features such as batch and campaign constraints across periods require special constraints to implement the concept of contiguity [10,24]. The model, however, remains linear in all variables. Only if the pooling problem occurs, e. g., in the refinery industry or the food industry, we are really facing a MINLP problem. For a review on algorithms used in LP, MILP, NLP, and MINLP the reader is referred to [11]. State-of-the art global solution techniques to nonconvex nonlinear problems were reviewed by Floudas et al. [3].

It is very convenient and saves a lot of maintenance work if the planning model is implemented in an algebraic modeling language. In modeling languages one stores the *knowledge* about a model. A model coded in a modeling language *defines the problem*; it usually does not specify how to solve it. Unlike procedural languages such as Fortran or C, modeling languages are *declarative languages* containing the problem in a declarative form by specifying the properties of the problem. *Algebraic modeling languages* [14] are a special subclass of declarative languages, and most of them are designed for specifying *optimization problems*, i. e., the model can be written in a form which is close to the mathematical notation. Usually they are capable of describing

problems of the form

$$\text{Minimize } f(x) \quad (4)$$

$$\text{subject to } g(x) = 0 \quad (5)$$

$$h(x) \geq 0, \quad (6)$$

where  $\mathbf{x}$  denotes a subset of  $X = \mathbb{R}^m \times \mathbb{Z}^n$ .

The problem is flattened, i. e., all variables and constraints become essentially one-dimensional, and the model is written in an *index-based* formulation, using *algebraic expressions* in a way which is close to the mathematical notation. Typically, the problem is declared using *sets, indices, parameters, and variables*.

In a modeling language, model and model data are kept separately. There is a clear cut between the model structure and the data. Thus, many different instances of the same model class with varying data can be solved. Many systems provide an open database connectivity (ODBC) interface for automatic database access and an interface to the most widely used spreadsheet systems. This relieves the user from the laborious duty of searching for the relevant data every time the model is used. A second advantage of this concept is that during the development phase of the model (in the cycle) the approach can be tested on *toy problems* with small artificial data sets, and later the model can be applied without change for large scale industry-relevant instances with real data.

In an algebraic modeling language, the formulation of the model is *independent of solver formats*. Different *solvers* can be connected to the modeling language, and the translation of models and data to the solver format is done automatically. This has several advantages. The formerly tedious and error-prone translation steps are done by the computer, and after thorough testing of the interface errors are very unlikely. There is a clean cut between the problem definition and the solution approach, i. e., between the modeling and the numerical, algorithmic part. In addition, for hard problems *different solvers* can be tried, making it more likely that a solution algorithm is found which produces a useful result.

Modern algebraic modeling languages such as AIMMS, GAMS, LINGO, MPL, Mose1, or OPL studio are well suitable to implement such models (see Kallrath [14] to get a flavor of all of them), use state-of-

the art commercial solvers, e.g., XPressMP (by Dash Optimization, <http://www.dashoptimization.com>) or CPLEX (by ILOG, <http://www.ilog.com>), and allow one to solve even huge MILP problems with several hundred thousand variables and constraints quite efficiently. In the case of MINLP, the solution efficiency depends strongly on the individual problem and the model formulation. However, as stressed in [11] for both problem types, MILP and MINLP, it is recommended that the full mathematical structure of a problem is exploited, that appropriate reformulations of models are made, and that problem-specific valid inequalities or cuts are used. Software packages may also differ with respect to the ability of *presolving techniques*, *default strategies* for the branch-and-bound algorithm, *cut generation* within the branch-and-cut algorithm, and last but not least *diagnosing and tracing infeasibilities*, which is an important issue in practice.

There is great progress in solving planning problems more efficiently by constructing efficient valid inequalities for certain substructures of planning problems. The well-written books by Wolsey [26] and Pochet and Wolsey [21] contain many examples. These inequalities may a priori be added to a model, and in the extreme case they would describe the complete convex hull. As an example we consider the mixed-integer inequality

$$x \leq C\lambda, \quad 0 \leq x \leq X; \quad x \in \mathbb{R}_0^+, \quad \lambda \in \mathbb{N}, \quad (7)$$

which has the valid inequality

$$x \leq X - G(K - \lambda), \quad \text{where } K := \left\lceil \frac{X}{C} \right\rceil \quad \text{and} \\ G := X - C(K - 1). \quad (8)$$

This valid inequality (8) is the more useful, the more  $K$  and  $X/C$  deviate. A special case arising often is the situation  $\lambda \in \{0, 1\}$ . Another example, taken from ([26], p. 129) is

$$A_1\alpha_1 + A_2\alpha_2 \leq B + x; \quad x \in \mathbb{R}_0^+, \quad \alpha_1, \alpha_2 \in \mathbb{N}, \quad (9)$$

which for  $B \notin \mathbb{N}$  leads to the valid inequality

$$\lfloor A_1 \rfloor \alpha_1 + \left( \lfloor A_2 \rfloor \alpha_2 + \frac{f_2 - f}{1 - f} \right) \leq \lfloor B \rfloor + \frac{x}{1 - f}, \quad (10)$$

where the following abbreviations are used:

$$f := B - \lfloor B \rfloor, \quad f_1 := A_1 - \lfloor A_1 \rfloor, \quad f_2 := A_2 - \lfloor A_2 \rfloor. \quad (11)$$

The dynamic counterpart of valid inequalities added a priori to a model leads to cutting plane algorithms which avoid adding a large number of inequalities a priori to the model (note this can be equivalent to finding the complete convex hull). Instead, only those useful in the vicinity of the optimal solution are added dynamically.

With use of these techniques, for some BASF planning problems including up to 100,000 constraints and up to 150,000 variables with several thousand binary variables, good solutions with integrality gaps below 2% have been achieved within 30 min on standard Pentium machines [11].

## Conclusions

Planning is strongly based on mathematical optimization exploiting large MILP problems. Strategic, design, and operative planning models including several hundred thousand variables and constraints can be solved efficiently using commercial algebraic modeling languages and attached MILP solvers. These models are connected to company-wide databases.

### Introduction

Increased competition leads contractors and chemical companies to look for potential savings at every stage of the design process. Process plant layout is an important part of the design or retrofit of chemical plants, and involves decisions concerning the spatial allocation of equipment items and the required connections between them [21]. Equipment items are allocated to one floor (single-floor case) or many floors (multifloor case) considering a number of cost and management or engineering drivers such as:

- Connectivity cost, which involves the cost of piping and other required connections between equipment items. In addition, other related network operating costs such as pumping may also be taken into account.
- Construction cost, which leads to the design of compact plants. The trade-off between the cost of occu-

pied area (land) and height (multifloor plants) must also be considered here.

- Retrofit, i. e. fitting new equipment items within an existing plant layout.
- Operation, which involves scheduling issues (e. g. pipeless plants).
- Safety, which introduces constraints with respect to the minimum allowable distance between equipment items.

Trade-offs between connectivity, pumping, construction, financial risk and installation of potential protection devices are necessary. In order to resolve these trade-offs optimally, computer-aided methods are needed to support engineers in the identification of optimal layouts subject to multiple design criteria.

Traditionally, process plant layout decisions are either ignored or do not receive appropriate attention during the design or retrofit of chemical plants. Furthermore, safety aspects are usually not considered systematically within process layout, design and operation frameworks, thus resulting in inefficient and unsafe plants. It is critical that systematic and efficient computer-aided methods are developed to support engineers in the rapid generation of alternative, safe, chemical process plant layouts.

The process plant layout problem shares many similarities with the facility layout problem, which has been the center of interest for industrial engineers for several years (for comprehensive reviews, see [14,18,22,36]). Here, we focus on the chemical process plant layout, which has attracted attention within the research community because of the particular production, environmental and safety considerations of the process industries. Such considerations affect both the objective functions and the constraints of any optimization model used.

In this chapter, a brief review of chemical plant layout research is given for the process plant layout problem and this is followed by a detailed description of an optimization-based framework. Illustrative research is presented by integrating traditional plant layout frameworks with sustainability aspects. Special attention is given to aspects associated with land use, safety and plant location. Issues related to design/operation, production organization and pipe routing are also discussed. Finally, other applications based on plant layout principles are presented.

## Approaches to Process Plant Layout

The initial approaches to the process plant layout problem were based on heuristics [2,35]. Although heuristic approaches may be efficient from the computational point of view, they do not offer any guarantee for the optimality of the solution obtained. Graph-theoretic approaches have been applied to the problem of organizing equipment items into sections for single-floor plants [15]. A method to aid decisions concerning the assignment of equipment items to floors in multifloor arrangements was proposed [16], albeit with no consideration of the detailed layout within each floor. Application of stochastic optimization techniques to the process plant layout problem was demonstrated [6,7] by developing software tools capable of tackling larger problems.

Recently, a number of mathematical programming approaches have emerged based either on land space discretization [11,12,34] or continuous-domain representation [3,9,13,23,24,30]. Most of these models accommodate various important issues of the layout problem, such as rectangular equipment footprints, rectilinear distances, equipment orientation, restrictions on available space, layout organization into production sections and some safety aspects (e. g. minimum distances between equipment items).

The process plant layout problem is well known as a hard computational problem. Most literature approaches, which are based on mathematical programming and use branch-and-bound solution procedures, can usually tackle flowsheets with up to 12 equipment items. It has been demonstrated that the solution performance can greatly be improved with additional simple constraints to eliminate symmetrical layout solutions and/or tighten mathematical formulation [8,9,33,37]. Furthermore, iterative optimization-based procedures have recently been developed using construction and/or improvement solution phases, which are suitable for larger flowsheets [17,28,40].

Next, a representative mathematical programming framework is described, based on a continuous-domain representation.

## A Continuous-Domain Mathematical Model

A mathematical programming model for the optimal single-floor process plant layout problem in a two-

Plant Layout Problems and Optimization, Table 1  
Notation

Indices	
$i, j$	Equipment items
Parameters	
$\alpha_i, \beta_i$	Dimensions of item $i$
$C_{ij}$	Connection cost between items $i$ and $j$
$X^{\max}$	Maximum x coordinate
$Y^{\max}$	Maximum y coordinate
Decision variables	
$O_i$	1 if length of item $i$ (parallel to the x axis) is equal to $\alpha_i$ ; 0 otherwise
$E1_{ij}, E2_{ij}$	Nonoverlapping binary variables
$l_i$	Length of item $i$
$d_i$	Depth of item $i$
$X_i, Y_i$	Coordinates of the geometrical center of item $i$
$R_{ij}$	Relative distance in x coordinates between items $i$ and $j$ , if $i$ is to the right of $j$
$L_{ij}$	Relative distance in x coordinates between items $i$ and $j$ , if $i$ is to the left of $j$
$A_{ij}$	Relative distance in y coordinates between items $i$ and $j$ , if $i$ is above $j$
$B_{ij}$	Relative distance in y coordinates between items $i$ and $j$ , if $i$ is below $j$
$D_{ij}$	Total rectilinear distance between items $i$ and $j$

dimensional continuous space is described here as proposed previously by Papageorgiou and Rotstein [24]. In the formulation presented here, rectangular shapes are assumed for equipment items following current industrial practice. Rectilinear distances between the equipment items are used for a more realistic estimate of piping costs as either aerial or underground corridors are usually used for the piping and instrumentation network. Equipment items, which are allowed to rotate 90°, are assumed to be connected through their geometrical centers.

Overall, the single-floor process plant layout problem can be stated as follows:

*Given*

- A set of  $N$  pieces of equipment and their dimensions
- Connectivity network and associated costs
- Space and equipment allocation limitations
- Minimum safety distances, if any, between equipment items
- Production sections

*Determine*

- The allocation of each equipment item (i. e. coordinates and orientation)

So as to optimize a suitable criterion (here, minimize equipment connection cost).

The indices, parameters and decision variables (binary and continuous) associated with the mathematical model are listed in Table 1.

Next, the main mathematical constraints of the single-floor process plant layout model are described.

**Equipment Orientation Constraints** The values of length,  $l_i$ , and depth,  $d_i$ , of equipment item  $i$  depend on its orientation in the space and can be determined by

$$l_i = \alpha_i O_i + \beta_i (1 - O_i) \quad \forall i, \quad (1)$$

$$d_i = \alpha_i + \beta_i - l_i \quad \forall i. \quad (2)$$

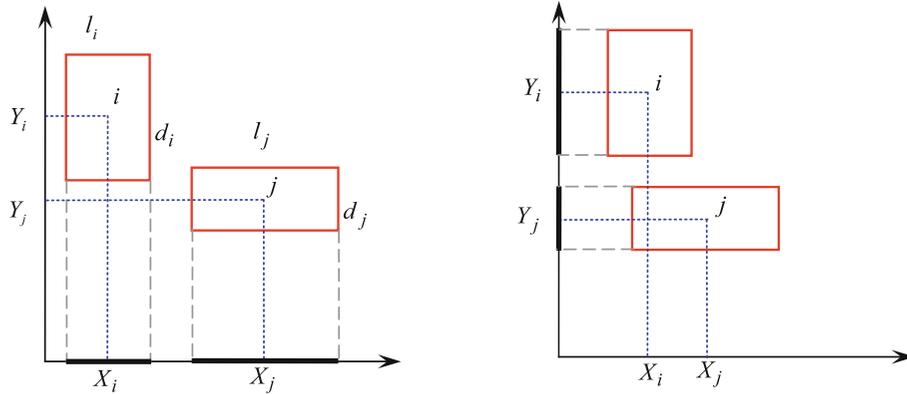

**Distance Constraints** The relative distances between items  $i$  and  $j$  are given by the following equalities:

$$R_{ij} - L_{ij} = X_i - X_j \quad \forall (i, j): C_{ij} > 0, \quad (3)$$

$$A_{ij} - B_{ij} = Y_i - Y_j \quad \forall (i, j): C_{ij} > 0, \quad (4)$$

$$D_{ij} = R_{ij} + L_{ij} + A_{ij} + B_{ij} \quad \forall (i, j): C_{ij} > 0. \quad (5)$$

It should be noted that the above constraints (3–5) are written only for those equipment pairs whose relative distance occurs in the objective function (i. e. terms

**Plant Layout Problems and Optimization, Figure 1**  
**Equipment nonoverlapping**

with nonzero connection costs,  $C_{ij} > 0$ ), which is minimized. As a consequence, it is guaranteed that *at most* one variable of each pair  $(R_{ij}, L_{ij})$  and  $(A_{ij}, B_{ij})$  will be nonzero at the optimal solution of each linear programming problem during the branch-and-bound solution procedure.

**Nonoverlapping Constraints** In order to avoid the overlapping of the two equipment items  $i$  and  $j$  occupying the same physical location, appropriate mathematical constraints should be included in the model to prohibit overlapping of the projections of each equipment footprint either in the  $x$  or  $y$  in the dimension as clearly shown in Fig. 1

Nonoverlapping is guaranteed if *at least* one of the following conditions is active:

$$X_i - X_j \geq \frac{(l_i + l_j)}{2} \tag{6}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N,$$

$$X_j - X_i \geq \frac{(l_i + l_j)}{2} \tag{7}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N,$$

$$Y_i - Y_j \geq \frac{(d_i + d_j)}{2} \tag{8}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N,$$

$$Y_j - Y_i \geq \frac{(d_i + d_j)}{2} \tag{9}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N.$$

These nonoverlapping disjunctive conditions can mathematically be modelled by including appropriate “big M” constraints and introducing two additional sets of binary variables;  $E1_{ij}$  and  $E2_{ij}$ . Each pair of values (0 or 1) for these variables determines which constraint from (6) to (9) is active. For every pair  $(i, j)$  such that  $i < j$ , we have:

If constraint (6) is active, then  $E1_{ij} = 0, E2_{ij} = 0$ .

If constraint (7) is active, then  $E1_{ij} = 1, E2_{ij} = 0$ .

If constraint (8) is active, then  $E1_{ij} = 0, E2_{ij} = 1$ .

If constraint (9) is active, then  $E1_{ij} = 1, E2_{ij} = 1$ .

In summary, the nonoverlapping constraints included in the mathematical model are:

$$X_i - X_j + M(E1_{ij} + E2_{ij}) \geq \frac{(l_i + l_j)}{2} \tag{10}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N$$

$$X_j - X_i + M(1 - E1_{ij} + E2_{ij}) \geq \frac{(l_i + l_j)}{2} \tag{11}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N$$

$$Y_i - Y_j + M(1 + E1_{ij} - E2_{ij}) \geq \frac{(d_i + d_j)}{2} \tag{12}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N$$

$$Y_j - Y_i + M(2 - E1_{ij} - E2_{ij}) \geq \frac{(d_i + d_j)}{2} \tag{13}$$

$$\forall i = 1, \dots, N - 1, j = i + 1, \dots, N,$$

where  $M$  is a suitable upper bound on the distance between two equipment items. Note that the above constraints can easily be modified to include minimum/maximum distances between specific items

for safety and/or operational reasons (see, for example, [24]). More systematic frameworks to account for safety aspects are described in Sect. “Other Applications”.

**Additional Layout Design Constraints** Lower-bound constraints on the coordinates of the geometrical center of each equipment item should be included in order to avoid intersection of items with the origin of axes, achieved by

$$X_i \geq \frac{l_i}{2} \quad \forall i, \quad (14)$$

$$Y_i \geq \frac{d_i}{2} \quad \forall i. \quad (15)$$

Similarly, upper-bound constraints can be used to force all equipment items to be allocated within a rectangular shape of land area defined by the corners (0,0) and  $(X^{\max}, Y^{\max})$ :

$$X_i + \frac{l_i}{2} \leq X^{\max} \quad \forall i, \quad (16)$$

$$Y_i + \frac{d_i}{2} \leq Y^{\max} \quad \forall i. \quad (17)$$

**Objective Function** The objective function considered in this model is the minimization of the total connection cost:

$$\text{Min} \sum_i \sum_{j \neq i} C_{ij} D_{ij}. \quad (18)$$

Other cost terms can be considered, such as land area, construction/building, vertical/horizontal pumping, protection devices and accident property damage.

All continuous variables in the formulation are defined as nonnegative. Overall, the single-floor process plant layout problem has been formulated as a mixed-integer linear programming (MILP) model (constraints 1–5, 10–18). This model has also been extended for multifloor process plant layout problems [26], combined with safety aspects [25] and integrated with design/operation of pipeless batch plants [29].

### Integration Aspects

In this section, additional important aspects are discussed with respect to their integration into traditional plant layout frameworks.

### Use of Land

The cost of land is an important component that should be included in the mathematical model of the process plant layout problem. Land cost has been implicitly taken into account [30] where the surface area has been assumed to be proportional to the land occupied by equipment items and not the space around items. A stochastic optimization technique [7] includes explicitly the cost of land in the objective function. Both previous efforts [7,30] refer to single-floor layouts problems.

For the multifloor plant layout case, the trade-off between the cost of occupied area (land) and that of construction (multiple floors) should be considered and resolved in an optimal manner. Mathematical programming models that have crucially addressed such issues have been developed by Georgiadis et al. [12] and Patsiatzis and Papageorgiou [26].

Sole consideration of land cost (and possibly together with construction, connection and pumping costs) may result in quite a compact layout and consequently a conservative layout solution from a safety point of view. Therefore, sufficient integration of safety aspects into existing frameworks is necessary. Such representative research efforts are described next.

### Safety

Safety aspects should be considered during the early stages of the design process by using appropriate quantitative indices. Such aspects are either ignored or considered through rather simplistic terms (e.g. minimum distances [3,24]). The safety of a chemical plant can further be improved by either putting the plant equipment items far apart from each other or by installing protection devices at additional capital cost, which would reduce the area of exposure and consequently reduce the propagation of a potential accident. Various trade-offs should be considered simultaneously within the process plant layout, such as:

- Piping, pumping and land costs that increase as the distance between equipment items increases;
- Financial risk component cost, which decreases as equipment items are put far apart or by installing extra protection devices; and
- Cost of protection devices, which eliminate accident escalation.

Along the above directions, a mathematical programming model-based approach was introduced by Pen-teado and Ciric [30], which resulted in mixed-integer nonlinear programming (MINLP) models determining simultaneously the process plant layout, the number and the type of protection devices and the financial risk associated with accidents and their propagation to neighboring units, assuming circular equipment footprints. An alternative MINLP model has also been proposed [27] by adopting rectangular shapes and rectilinear distances between units. Both these studies were based on a risk representation related to accidents propagating from a source to a target unit utilizing the equivalent TNT method [19]. An evolutionary procedure was proposed by Fuchino et al. [10] for the arrangement of equipment models in the early design phase by considering simultaneously the position and the orientation of equipment modules, as both affect the propagation of an accident.

Two widely used indices for risk assessment and safety evaluation are the Mond Index [20] and the Dow Fire and Explosion Index [1]. The use of the Mond Index was illustrated by Castell et al. [7] by adding a penalty term in the objective function, which minimizes any violations of Mond safety distances. User intervention is crucial in this work to ensure the feasibility of all separation distance requirements. Finally, the use of the Dow Fire and Explosion Index was demonstrated by Patsiatzis et al. [25] by proposing an MILP approach to safe process plant layout. This index determines the realistic maximum loss occurring under the most adverse operating conditions and is applicable to processes where flammable, combustible or reactive material is stored or processed. It is based on historic loss data, the energy potential of the processed materials in the chemical plants and the current application of loss-prevention practices.

### Location Information

Integration of location-specific information with the decision-making procedure for the process plant layout problem was successfully demonstrated by Ozyurt and Realf [23]. Such information is related to existing infrastructure, geographic aspects, climate conditions, elevation and soil characteristics. The location-specific information system is first used to derive conclusions

about the plant environment, and these are then translated into additional mathematical constraints on the process plant layout problem by restricting some equipment locations.

### Design and Operation

The process plant layout decisions are traditionally considered after the plant design stage has been completed. However, it is obvious that strong interactions exist between plant layout and plant design and therefore significant benefits could be gained by developing systematic, simultaneous approaches. Such an approach was proposed by Barbosa-Povoa et al. [4], where an MILP model was shown to be particularly suitable for cases with equipment of rectangular and irregular shapes as well as flexible equipment input/output point locations. The latter model has been integrated with operating aspects and applied to multipurpose batch plants [5].

It should be noted that layout considerations are of particular significance for pipeless plants as they determine the vessel transfer times, which can then affect the schedule of the plant. Simultaneous optimization-based approaches have also been developed for pipeless batch plants, which offer enhanced production flexibility and piping-free cleaning requirements, by considering plant design, layout and operation aspects [29,31].

### Layout Organization into Production Sections

The organization of the plant layout problem into well-defined production sections is often required for various reasons, such as safety, efficient material handling and workforce management. The boundaries of these sections are drawn by walls or corridors, which facilitate the movement of materials and/or operators.

The organization of the plant layout into sections can formally be incorporated into the process plant layout mathematical model presented in Sect. "A Continuous-Domain Mathematical Model". The basic assumption is that the equipment items are partitioned into subsets by using either rule-based/intuitive techniques or algorithmic approaches (see, for example, [15]). Each subset of equipment items constitutes a *section*, and then each section can then be represented by a well-defined rectangular box. New constraints must be introduced to guarantee that no overlapping occurs

(1) among different sections and (2) among the footprints *within* each section [24]. The aim of the optimization is then to determine the location of both production sections and equipment items within each section so that the total layout cost is minimized.

### Pipe Routing

The design of the piping system in a chemical plant constitutes an important part of deriving an efficient plant layout (apart from pipeless plants) and should be considered as early as possible in the design process. A number of factors should be taken into account, such as cost, safety, operability and structural/mechanical aspects. A pipe-routing method was proposed by Schmidt-Traub et al. [32] using grid and vector router algorithms. Optimization-based and graph theory methods have also been described by Guirardello and Swaney [13], which could include capacity constraints, pipes with branches and stress analysis.

### Other Applications

This section demonstrates the application of basic plant layout principles to two interesting problems: allocation and data classification.

### Allocation

Allocation problems, which include plant layout problems, with different numbers of dimensions have been research topics of great activity for many years. Most allocation problems are large-scale combinatorial optimization problems, occurring in several different industrial applications. A general purpose MILP model for allocation problems in any given number of dimensions has been presented [38]. This mathematical formulation utilizes a type of nonoverlapping constraints similar to those presented in Sect. “A Continuous-Domain Mathematical Model”. The proposed model deals with the allocation of items in an  $N$ -dimensional space. Several problems, previously presented in the literature, have been solved using the proposed model, such as one-dimensional scheduling problems, two-dimensional cutting problems, as well as plant layout problems and three-dimensional packing problems. Problems defined in four dimensions are also presented and solved using the model described above.

### Data Classification

Beyond chemical plant design, basic plant layout principles can also be applied to data classification problems as illustrated here. Data classification, a fundamental problem in data mining and machine learning, deals with the identification of patterns and the assignment of new samples into known groups. A rigorous mixed-integer optimization model for multiclass data classification problems has been proposed [39] using a hyperbox representation. The optimal location and dimension of each box is determined by minimizing the total number of misclassifications. Special constraints are introduced to avoid overlapping of boxes that belong to different classes. These constraints simply represent an extension of those described in Sect. “A Continuous-Domain Mathematical Model” to cover more than two dimensions.

### Concluding Remarks

In this chapter, a comprehensive review of the chemical plant layout research has been presented. Systematic, optimization-based frameworks for plant layout have the potential to offer contractors and chemical companies significant savings and increase business competitiveness. The future will show additional benefits if issues related to dynamic plant layout, uncertainty and more efficient solution procedures for larger problems are resolved.

Phase space; Optimal control; Hamiltonian system; Optimality conditions

It is considered that the behavior of an object at any instant of time is characterized by  $n$  real numbers  $x^1, \dots, x^n$ . The vector space  $X$  of the vector variable  $x = (x^1, \dots, x^n)$  is the phase space of the object under consideration. The motion of the object consists of the fact that the variables  $x^1, \dots, x^n$  change with time. It is assumed that the object's motion can be controlled, i. e., that the object is equipped with certain controllers on whose position the motion of the object depends. The positions of the controllers are characterized by points  $u = (u^1, \dots, u^r)$  of a certain control region  $U$ , which may be any set in some  $r$ -dimensional Euclidean space. In applications, the case where  $U$  is a closed region in the space is especially important.

In the statement of the problem it is assumed that the object's law of motion can be written in the form of a system of differential equations

$$\frac{dx^i}{dt} = f_i(x, u), \quad i = 1, \dots, n, \quad (1)$$

or in vector form

$$\frac{dx}{dt} = f(x, u), \quad (2)$$

where the functions  $f_i$  are defined for  $x \in X$  and  $u \in U$ . They are supposed to be continuous in the variables  $x^1, \dots, x^n, u$  and continuously differentiable with respect to  $x^1, \dots, x^n$ .

If the control law is given, i. e., a certain admissible control  $u = u(t)$  is chosen, (2) takes the form

$$\frac{dx}{dt} = f(x, u(t)), \quad (3)$$

from which, for any initial condition  $x(t_0) = x_0$ , the motion of the object  $x = x(t)$  is uniquely determined, i. e., the solution of (3) is defined for a certain time interval. The solution  $x(t)$  is called the solution of (2) corresponding to the control  $u(t)$  for the initial condition  $x(t_0) = x_0$ . The solution may not be defined on the entire interval  $t_0 \leq t \leq t_1$  on which  $u(t)$  is given as it may run off to infinity.

It is said that the admissible control  $u(t)$ ,  $t_0 \leq t \leq t_1$  transfers the phase point from the position  $x_0$  to the position  $x_1$  if the corresponding solution  $x(t)$  of (2), satisfying the initial condition  $x(t_0) = x_0$ , is defined for all  $t$ ,  $t_0 \leq t \leq t_1$ , and passes through the point  $x_1$  at the time  $t_1$ .

It is supposed that an additional function  $f_0(x, u)$ , which is defined and continuous together with its partial derivatives  $\partial f_0 / \partial x^i$ ,  $i = 1, \dots, n$ , on all of  $X \times U$ , is given. The fundamental problem of finding the optimal controls is formulated as follows [1].

In the phase space  $X$  two points  $x_0$  and  $x_1$  are given. Among all the admissible controls  $u = u(t)$  which transfer the phase point from the position  $x_0$  to the position  $x_1$  (if such controls exist), find one for which the functional

$$J = \int_{t_0}^{t_1} f_0(x(t), u(t)) dt \quad (4)$$

takes on the least possible value. Here  $x(t)$  is the solution of (2) with initial condition  $x(t_0) = x_0$  corresponding to the control  $u(t)$  and  $t_1$  is the time at which this solution passes through  $x_1$ . The control  $u(t)$  which yields the solution of the problem is called an *optimal control* corresponding to a transition from  $x_0$  to  $x_1$ . The corresponding trajectory  $x(t)$  is called an *optimal trajectory*.

An important special case of the fundamental problem is the one where  $f_0(x, u) \equiv 1$ . In this case, the functional (4) takes the form

$$J = t_1 - t_0$$

and the optimality of the control  $u(t)$  signifies minimality of the transition time from  $x_0$  to  $x_1$ . The problem of

finding the optimal controls and trajectories in this case is called the time-optimal problem.

In order to formulate the necessary optimality condition it is convenient to adjoin a new coordinate  $x^0$  to the phase coordinates  $x^1, \dots, x^n$ , which vary according to (1). Let  $x^0$  vary according to the law

$$\frac{dx^0}{dt} = f_0(x^1, \dots, x^n, u(t))$$

and consider the system of differential equations

$$\frac{dx^i}{dt} = f_i(x, u), \quad i = 0, \dots, n, \tag{5}$$

whose right-hand sides do not depend on  $x^0$ . Introducing the vector

$$\bar{x} = (x^0, \dots, x^n)$$

in the  $(n + 1)$ -dimensional vector space  $\bar{X}$ , system (5) may be rewritten in vector form

$$\frac{d\bar{x}}{dt} = \bar{f}(x, u),$$

where  $\bar{f}(x, u)$  is the vector in  $\bar{X}$  with coordinates  $f_0(x, u), \dots, f_n(x, u)$ . Note that  $\bar{f}(x, u)$  does not depend on the coordinate  $x^0$  of the vector  $\bar{x}$ .

To formulate the theorem, which yields the solution of the fundamental problem, in addition to the fundamental system (5) another system of equations

$$\frac{d\psi_i}{dt} = - \sum_{j=0}^n \frac{\partial f_j(x, u)}{\partial x^i} \psi_j, \quad i = 0, \dots, n, \tag{6}$$

in the auxiliary variables  $\psi_0, \dots, \psi_n$  is considered.

If we choose an admissible control  $u(t)$ ,  $t_0 \leq t \leq t_1$ , and have the corresponding phase trajectory  $x(t)$  of system (5) with initial condition  $x(t_0) = x_0$ , system (6) takes the form

$$\frac{d\psi_i}{dt} = - \sum_{j=0}^n \frac{\partial f_j(x(t), u(t))}{\partial x^i} \psi_j, \tag{7}$$

where  $i = 0, \dots, n$ .

This system is linear and homogeneous. Therefore, for any initial condition it admits the unique solution

$$\bar{\psi} = (\psi_0, \dots, \psi_n)$$

for the  $\psi_i$ , which is defined on the entire interval  $t_0 \leq t \leq t_1$ . Just as the solution  $\bar{x}(t)$  of (5), the solution of (7) consists of continuous functions  $\psi_i(t)$  which have everywhere, except at a finite number of points, i. e., at the points of discontinuity of  $u(t)$ , continuous derivatives with respect to  $t$ . For any initial condition each solution of (7) is called the solution of (6) corresponding to the chosen control  $u(t)$  and phase trajectory  $\bar{x}(t)$ .

Systems (5) and (6) are combined into one entry. To do so the function

$$H(\bar{\psi}, x, u) = (\bar{\psi}, \bar{f}(x, u)) = \sum_{j=0}^n \psi_j f_j(x, u)$$

of the variables

$$x^1, \dots, x^n, \psi_0, \dots, \psi_n, u^1, \dots, u^r$$

is considered.

The systems (5) and (6) may be rewritten with the aid of the function  $H$  in the form of the Hamiltonian system

$$\frac{dx^i}{dt} = \frac{\partial H}{\partial \psi^i}, \quad i = 0, \dots, n, \tag{8}$$

$$\frac{d\psi_i}{dt} = - \frac{\partial H}{\partial x^i}, \quad i = 0, \dots, n. \tag{9}$$

Thus, taking an arbitrary admissible, i. e., piecewise continuous, control  $u(t)$ ,  $t_0 \leq t \leq t_1$ , and the initial condition  $\bar{x}(t_0) = \bar{x}_0$ , the corresponding trajectory  $\bar{x}(t) = (x^0(t), \dots, x^n(t))$  can be found. After that the solution of (9),

$$\bar{\psi}(t) = (\psi_0(t), \dots, \psi_n(t)),$$

corresponding to the functions  $u(t)$  and  $\bar{x}(t)$  can be found. It should be emphasized that the vector functions  $\bar{x}(t)$  and  $\bar{\psi}(t)$  are continuous and have everywhere, except at a finite number of points, continuous derivatives with respect to  $t$ .

For fixed values of  $\bar{\psi}$  and  $x$  the function  $H$  becomes a function of the parameter  $u \in U$ . The least upper bound of the values of this function is denoted by

$$M(\bar{\psi}, x) = \sup_{u \in U} H(\bar{\psi}, x, u).$$

If the continuous function  $H$  achieves its upper bound on  $U$ , then  $M(\bar{\psi}, x)$  is the maximum of the values of  $H$  for fixed  $\bar{\psi}$  and  $x$ .

A necessary condition for optimality is given by Theorem 1, which is called the *maximum principle* [1].

**Theorem 1** Let  $u(t)$ ,  $t_0 \leq t \leq t_1$ , be an admissible control such that the corresponding trajectory  $\bar{x}(t)$  which begins at the point  $\bar{x}_0$  at the time  $t_0$  passes at some time  $t_1$  through a point on a line  $\Pi$ . In order that  $u(t)$  and  $\bar{x}(t)$  be optimal it is necessary that there exist a nonzero continuous vector function  $\bar{\psi}(t) = (\psi_0(t), \dots, \psi_n(t))$  corresponding to  $u(t)$  and  $\bar{x}(t)$  such that

1) for every  $t$ ,  $t_0 \leq t \leq t_1$ , the function  $H(\bar{\psi}(t), x(t), u)$  of the variable  $u \in U$  attains its maximum at the point  $u = u(t)$ ,

$$H(\bar{\psi}(t), x(t), u(t)) = M(\bar{\psi}(t), x(t)); \quad (10)$$

2) at the terminal time  $t_1$  the relations

$$\psi_0(t_1) \leq 0, \quad M(\bar{\psi}(t_1), x(t_1)) = 0 \quad (11)$$

are satisfied. Furthermore, it turns out that if  $\bar{\psi}(t)$ ,  $\bar{x}(t)$  and  $u(t)$  satisfy system (8)–(9) and condition 1), the time functions  $\psi_0(t)$  and  $M(\bar{\psi}(t_1), x(t_1))$  are constant. Thus, (11) may be verified at any time  $t$ ,  $t_0 \leq t \leq t_1$ , and not just at  $t_1$ .

From Theorem 1 an analogous necessary condition for time optimality can be derived. To do this, it is necessary to set  $f_0(x, u)$  of Theorem 1 equal to 1. The function  $H$  then takes the form

$$H = \psi_0 + \sum_{j=1}^n \psi_j f_j(x, u).$$

Introducing the  $n$ -dimensional vector  $\psi = (\psi_1, \dots, \psi_n)$  and the function

$$H'(\psi, x, u) = \sum_{j=1}^n \psi_j f_j(x, u),$$

equations (1) and (6) can be rewritten in the form of the Hamiltonian system

$$\frac{dx^i}{dt} = \frac{\partial H'}{\partial \psi_i}, \quad i = 1, \dots, n, \quad (12)$$

$$\frac{d\psi_i}{dt} = -\frac{\partial H'}{\partial x^i}, \quad i = 1, \dots, n. \quad (13)$$

For fixed values of  $\psi$  and  $x$ ,  $H'$  is a function of  $u$ . The upper bound of the values of this function is denoted by

$$M'(\psi, x) = \sup_{u \in U} H'(\psi, x, u).$$

Because

$$H'(\psi, x, u) = H(\bar{\psi}, x, u) - \psi_0,$$

then

$$M'(\psi, x) = M(\bar{\psi}, x) - \psi_0,$$

and therefore (10) and (11) now take the form

$$\begin{aligned} H'(\psi(t), x(t), u(t)) &= M'(\psi(t), x(t)) \\ &= -\psi_0 \geq 0. \end{aligned}$$

Thus, the following theorem is valid [1].

**Theorem 2** Let  $u(t)$ ,  $t_0 \leq t \leq t_1$ , be an admissible control which transfers the phase point from  $x_0$  to  $x_1$  and let  $x(t)$  be the corresponding trajectory, so that  $x(t_0) = x_0$ ,  $x(t_1) = x_1$ . In order that  $u(t)$  and  $x(t)$  be time-optimal it is necessary that there exist a nonzero, continuous vector function  $\psi(t) = (\psi_1(t), \dots, \psi_n(t))$  corresponding to  $u(t)$  and  $x(t)$  such that

1) for all  $t$ ,  $t_0 \leq t \leq t_1$ , the function  $H'(\psi(t), x(t), u)$  of the variable  $u \in U$  attains its maximum at the point  $u = u(t)$ ,

$$H'(\psi(t), x(t), u(t)) = M'(\psi(t), x(t));$$

2) at the terminal time  $t_1$  the relation

$$M'(\psi(t_1), x(t_1)) \geq 0 \quad (14)$$

is satisfied. Furthermore, it turns out that if  $\psi(t)$ ,  $x(t)$  and  $u(t)$  satisfy system (12)–(13) and condition 1), the time function  $M'(\psi(t), x(t))$  is constant. Thus, (14) may be verified at any time  $t$ ,  $t_0 \leq t \leq t_1$ , and not just at  $t_1$ .

From among all the trajectories which start at  $\bar{x}_0$  and end on some point of  $\Pi$  (as well as the corresponding controls), Theorem 1 allows us to single out those separate, isolated trajectories and controls which satisfy all the formulated conditions. In fact, there are  $2n + 3$  relations (8)–(10) for  $2n + 3$  variables  $x^j$ ,  $\psi_j$  and  $u$ . Furthermore, since (10) is not differential and the number of differential equations equals  $2n + 2$ , the solutions of the system (8)–(10) in general depend on  $2n + 2$  parameters. However, one of these parameters is redundant as the functions  $\psi_j(t)$  are defined only up to a common multiple. In addition, one of the parameters is determined by the condition that

$$\max_{u \in U} H(\bar{\psi}(t_0), x(t_0), u)$$

vanishes.

Thus, there are  $2n$  parameters, on which the whole manifold of solutions of (8)–(10) depends. It follows that  $2n$  parameters must be chosen in such a way that the trajectory  $\bar{x}(t)$  passes through  $\bar{x}_0$  at the given time  $t = t_0$  and through a point of  $\Pi$  for some  $t > t_0$ . The number  $t_1 - t_0$  is also a parameter, so that there are altogether  $2n + 1$  essential parameters. The condition that the trajectory must pass through the point  $\bar{x}_0$  and the line  $\Pi$  gives rise to  $2n + 1$  relations. Hence, one can expect that there exist only separate, isolated trajectories joining the point  $\bar{x}_0$  with the line  $\Pi$ , which satisfy the conditions of Theorem 1. Only these separate, isolated trajectories can turn out to be optimal.

### Portfolio Selection Problem

The heart of the portfolio problem is the selection of an optimal set of investment assets by rational economic agents. Elements of portfolio problems were discussed in the 1930's and 1940's by J.R. Hicks, [19], J. Marschak [46], D.H. Leavens [37], J.B. Williams [62], and others; see [45] for a survey of these early contributions. However, the first formal specification of such a selection model was by H.M. Markowitz [40,42] who defined a mean-variance model for calculating optimal portfolios; see also A.D. Roy [51], whose first safety model is very close to the mean value model. Following [55,58,59] and [50], this portfolio selection model may be stated as:

$$\begin{cases} \min & x'Vx \\ \text{s.t.} & x'r = r_p \\ & x'e = 1, \end{cases} \quad (1)$$

where  $x$  is a column vector of investment proportions in each of the risky assets,  $V$  is a positive semidefinite variance-covariance matrix of asset returns,  $r$  is a column vector of expected asset returns,  $r_p$  is the investor's target rate of return and  $e$  is a column unit vector. An explicit solution for the problem can be found using the procedures described in [47,66], or [50].

Restrictions on short selling can be modeled by augmenting (1) by the constraints:

$$x \geq 0, \quad (2)$$

where  $0$  is a column vector of zeros. The problem now becomes a classic example of quadratic mathematical

programming; indeed, the development of the portfolio problem coincided with early developments in non-linear programming. Markowitz's [41] critical line algorithm is a systematic solution procedure. Formal investigations of the properties of both formulations, and variants, appear in [22,57], and the references above.

**The Use of Mean And Variance**

The economic justification for this model is based on the von Neumann–Morgenstern expected utility results, discussed in this context by Markowitz [42]. The model can also be viewed in terms of consumer choice theory together with the characteristics model developed by K. Lancaster [36]. His argument is that goods purchased by consumers seldom yield a single, well defined service; instead, each good may be viewed as a collection of attributes each of which gives the consumer some benefit (or dis-benefit). Thus preference is defined over those characteristics embodied in a good rather than over the good itself. The analysis focusses attention on the attributes of assets rather than on the assets per se. This requires the assumption that utility depends only on the characteristics. With  $k$  characteristics,  $C_k$ , we need

$$U = f(W) = g(C_1, \dots, C_k),$$

where  $U$  and  $W$  represent utility and wealth. Modeling too few characteristics will yield apparently false empirical results. Clearly, the benefits of this approach increase as the number of assets rises relative to the number of characteristics. The objects of choice are the characteristics  $C_1, \dots, C_k$ . In portfolio theory, these are taken to be payoff (return) and risk.

At Markowitz's suggestion, when dealing with choice among risky assets, payoff is measured as the expected return of the distribution of returns, and risk by the standard deviation of returns. Apart from minor exceptions, see [66], this pair of characteristics form a complete description of assets which is consistent with expected utility theory in only two cases: assets have normal distributions, or investors have quadratic utility of wealth functions. The adequacy of these assumptions has been investigated by a number of authors (e.g., [5,16,60]). Although returns have been found to be nonnormal and the quadratic utility has a number of objectionable features (not least diminish-

ing marginal utility of wealth for high wealth), several authors demonstrate approximation results which are sufficient for mean variance analysis ([39,49,52]).

A number of authors, including Markowitz [42], consider alternatives to the variance and suggest the use of the semivariance. This suggestion has been extended into workable portfolio selection rules. E. Fama [14] and S. Tsiang [61] have argued the usefulness of the semi-interquartile range as a measure of risk. A. Kraus and R.F. Litzenberger [35] and others have examined the effect of preferences defined in terms of the third moment which allows investor choice in terms of skewness. J.G. Kallberg and W.T. Ziemba [31,32] show that risk aversion preferences are sufficient to determine optimal portfolio choice if assets have normally distributed returns whatever the form of the assumed, concave, utility function.

**Solution of Portfolio Selection Model**

In the absence of short sales restrictions, (1) can be rewritten as

$$\min L = \frac{1}{2}x'Vx - \lambda_1(x'r - r_p) - \lambda_2(x'e - 1). \quad (3)$$

The first order conditions are

$$Vx = \lambda_1 r + \lambda_2 e,$$

which shows that, for any efficient  $x$ , there is a linear relation between expected returns  $r$  and their covariances,  $Vx$ .

Solving for  $x$ :

$$x = \lambda_1 V^{-1}r + \lambda_2 V^{-1}e = V^{-1}[r \ e]A^{-1}[r_p \ 1]', \quad (4)$$

where

$$A = \begin{bmatrix} a & b \\ b & c \end{bmatrix} = \begin{bmatrix} r'V^{-1}r & r'V^{-1}e \\ r'V^{-1}e & e'V^{-1}e \end{bmatrix}.$$

Substituting (4) into the definition of portfolio variance,  $x'Vx$ , yields

$$V_p = [r_p \ 1]A^{-1}[r_p \ 1]',$$

$$S_p = \left[ \frac{cr_p^2 - 2br_p + a}{ac - b^2} \right]^{\frac{1}{2}}, \quad (5)$$

where  $V_p$  and  $S_p$  represent portfolio variance and standard deviation, respectively. This defines the efficient

set, which is a hyperbola in mean/standard-deviation space (or a parabola in mean/variance space). The minimum risk is at  $S_{\min} = c^{1/2}$  and  $r_{\min} = b/c$  (both strictly positive). Rational risk averse investors will hold portfolios lying on this boundary with  $r \geq r_{\min}$ .

Each efficient portfolio,  $p$ , has an orthogonal portfolio  $z$  (i. e., such that  $\text{Cov}(r_p, r_z) = 0$ ) with return

$$r_z = \frac{a - br_p}{b - cr_p}.$$

Using this, the efficient set degenerates into the straight line tangent to the hyperbola at  $p$  which has intercept  $r_z$ :

$$r = r_z + \lambda s, \quad (6)$$

where  $r$  and  $s$  represent vectors of the expected return and risks of efficient portfolios, and  $\lambda = (r_p - r_z)/S_p$  can be interpreted as the additional expected return per unit of risk. This is known as the *Sharpe ratio* [54,56]. Equation (6) shows a two-fund separation theorem, that linear combinations of only two portfolios are sufficient to describe the entire efficient set.

Under the additional assumptions of *homogeneous beliefs* (so that all investors perceive the same parameters) and equilibrium, (6) becomes the *capital market line*. The *security market line* (i. e. the relationship between expected returns and systematic risk or beta), which is the outcome of the capital asset pricing model (CAPM), can be derived by premultiplying (4) by  $V$  and simplifying using the definitions of  $V_p$  and  $r_z$ :

$$r = r_z e + (r_p - r_z)\beta, \quad \text{where } \beta = \frac{Vx}{V_p}. \quad (7)$$

If it exists, the risk-free rate of interest may be substituted for  $r_z$  (definitionally, the risk-free return will be uncorrelated with the return on all risky assets). Equation (7) then becomes the original CAPM in which expected return is calculated as the risk-free rate plus a risk premium (measured in terms of an asset's covariance with the market portfolio). The CAPM forms one of the cornerstones of modern finance theory and is not addressed here. Discussion of the CAPM can be found in [22] and [17], while systematic fundamental and seasonal violations of the theory are presented in [63] and [34].

## Short Selling

The assumption that assets may be sold short (i. e.,  $x_i < 0$ ) is justified when the model is used to derive analytical results for the portfolio problem. Also, when considering equilibrium (e. g., the CAPM), none of the short selling constraints should be binding (because in aggregate, short selling must net out to zero). However, significant short selling restrictions do face investors in most real markets. These restrictions may be in the form of absolute prohibition, the extra cost of deposits to back short selling or self imposed controls designed to limit potential losses. For example, the NYSE imposes the 'uptick rule' under which short sales are allowed only if the price of the immediately preceding trade was higher than, or equal to, the trade preceding it (as short selling is profitable when the market is falling), this rule substantially limits its attractiveness.

The set of quadratic programming problems to find the efficient frontier when short sales are ruled out can be formulated as either minimising the portfolio risk for a specified sequence of portfolio returns ( $r_p$ ) by repeatedly solving equations (1) and (2), or maximising the weighted sum of portfolio risk and return for a chosen range of risk-return trade-off parameters ( $\mu$ ) by repeatedly solving (8). This latter approach has the advantages of locating only points on the efficient frontier and, for evenly spaced increments in  $\mu$ , locating more points on the efficient frontier where its curvature is greatest.

$$\begin{cases} \max & \alpha = x'Vx - \mu(x'r - r_p) \\ \text{s.t.} & x \geq 0 \\ & x'e = 1. \end{cases} \quad (8)$$

When short sales are permitted, a position (long or short) is taken in every asset, while when short selling is ruled out, the solution involves long positions in only about 10% of the available assets. When short selling is permitted, about half the assets are required to be sold short, often in large amounts, and sometimes in amounts exceeding the initial value of the investment portfolio. Indeed, this is the main activity of 'short seller' funds.

In contrast, most models based on portfolio theory, in particular the CAPM, ignore short selling constraints [43,44]. This change is consistent with the development of equilibrium models for which institutional restric-

tions are inappropriate (and if imposed would not be binding). However, when short selling is permitted, the number of asset return observations is required to exceed the number of assets, while complementary slackness means that this condition need not be met when short selling is ruled out. Computational procedures to solve mean-variance models with various types of constraints, and the optimal combination of safe and risky assets for various utility functions are discussed in [65].

### Estimation Problems

The model (1) requires estimates of  $r$  and  $V$  for the period during which the portfolio is to be held. This estimation problem has been given relatively little attention, and many authors, both practitioners and academics, have used historical values as if they were precise estimates of future values. However, S.D. Hodges and R.A. Brealey [21], among others, demonstrate the benefits obtained from even slight improvements on historical data.

Estimation risk can be allowed for either by using different methods to forecast asset returns, variances and covariances, which are then used in place of the historical values in the portfolio model, or by using the historical values in a modified portfolio selection technique [2]. Since the portfolio selection model of Markowitz takes these estimates as parametric, there is no theoretical guidance on the estimation method and a variety of methods have been proposed to provide the estimates. The *Sharpe single index market model* [53] has been widely applied to forecast the covariance matrix. Originally proposed to reduce the computation required by the full model, it assumes a linear relation between stock returns and some measure of the market,  $r = \alpha + \beta' m + \varepsilon$  (for market index  $m$  and residuals  $\varepsilon$ ). This uses historical estimates of the means and variances; however, the implied covariance matrix is  $V_1 = v_m \beta \beta' + V$ , where  $v_m$  is the variance of the index,  $\beta$  is a column vector of slope coefficients from regressing each asset on the market index and  $V$  is a diagonal matrix of the variances of the residuals from each of these regressions. A number of studies have found that models based on the single index model outperform those based on the full historical method, see e. g. [4].

The *overall mean method*, first proposed in [12], is based on the finding that, although historical esti-

mates of means are satisfactory, data are typically not stable enough to allow accurate estimation of the  $N(N - 1)/2$  covariance terms. The crudest solution is to assume that the correlations between all pairs of assets expected in the next period are equal to the mean of all the historic correlations. An estimate of  $V$  can then be derived from this. E.J. Elton, M.J. Gruber and T.J. Urich [13] compared the overall mean method of forecasting the covariance matrix with forecasts made using historical values, and four alternative versions of the single index model. They concluded that the overall mean model was clearly superior. A simplified procedure for estimating the overall mean correlation appears in [1].

In recent years, statisticians have shown increasing interest in *Bayesian methods* [20] and particularly *James–Stein estimators* ([10,11,30,48]). The intuition behind this approach is that returns which are far from the norm have a higher chance of containing measurement error than those close to it. Thus, estimates of returns, based on individual share data, are cross-sectionally ‘shrunk’ towards a global estimate of expected returns which is based on all the data. Although these estimators have unusual properties, they are generally expected to perform well in large samples.

P. Jorion [27,28] examined the performance of Bayes–Stein estimation using both simulated and small real data sets and concluded that the Bayes–Stein approach outperformed the use of historical estimates of returns and the covariance matrix. However, he found [29] that the index model outperformed Stein and historical models. J.L.G. Board and C.M.S. Sutcliffe [4] applied these and other methods to large data sets. They found that, in contrast to earlier studies, the relative performance of Bayes–Stein was mixed. While it produced reasonable estimates of the mean returns vector, there were superior methods (e. g., use of the overall mean) for estimating the covariance matrix when short sales were permitted. They also found that, when short sales were prohibited, actual portfolio performance was clearly improved, although there was little to choose between the various estimation methods.

An alternative approach is to try to control for errors in the parameter estimates by imposing additional constraints on (1). Clearly, ex-ante the solution to such a model cannot dominate (1), however,

ex-post, dominance might emerge (i. e., what seems, in advance, to be an inferior portfolio might actually perform better than others). The argument is that adding constraints to (1) to impose lower bounds (i. e., prohibiting short sales) and/or upper bounds (forcing diversification) can be used as an ad hoc method of avoiding the worst effects of estimation risk. Of course, extreme, but possibly desirable, corner solutions will also be excluded by this technique. K.J. Cohen and J.A. Pogue [8] imposed upper bounds of 2.5% on any asset. Board and Sutcliffe [3] studied the effects of placing upper bounds on the investment proportions, which may be interpreted as a response to estimation risk. Using historical forecasts of returns and the covariance matrix, and with short sales excluded, they found that forcing diversification leads to improved actual performance over the unconstrained model. C.R. Hensel and A.L. Turner [18] have also studied adjusting the inputs and outputs to improve portfolio performance.

V.R. Chopra and Ziemba [7], following the work of Kallberg and Ziemba [33], showed that errors in the mean values have a much greater effect than errors in the variances, which are in turn more important than errors in the covariances. Their simulations show errors of the order of 20 to 2 to 1. This quantifies the earlier findings and stresses the importance of having good estimates of the asset means. Chopra [6] shows that mean, variance and covariance errors affect turnover in the same way.

Another approach is to use fundamental analysis to provide external information to modify the estimates [21]. Clearly, among the simplest external data to add are the seasonal (e. g., turn of the year, and month and weekend) effects which have been found in most stock markets around the world. Incorporation of these into the parameter estimates can substantially improve the performance of the model. Ziemba [63] demonstrated the benefits of factor models to estimate the mean returns.

## Summary

We have considered only the single period mean-variance portfolio theory model. Although recent developments have focussed on extending the model to multiple periods, most of these models which as-

sume frictionless capital markets require the solution of a sequence of instantaneous mean-variance models in which the existence of transactions costs adds enormously to the complexity of the problem. Surveys covering dynamic portfolio theory appear in [9,22,66], and [23]; see also [64].

Portfolio selection concerns the problem of finding the most attractive stocks and the determination of their

proportions in a portfolio, which is essentially a matter of arbitration between the risk and the return. In 1952 H.M. Markowitz [17] proposing the mean-variance model gives the start of a theory that had known since a great development. According to this approach, an investor follows two conflicting objectives that are the maximization of the expected return and the minimization of the risk measured by the variance of the return. On the same basis (essentially measuring the risk by the variance or another measure of the variation of the return) several other models were developed. A complete overview of these models can be found in [5], including the single-index models, the multi-index models, the average correlation models, the mixed models, the utility model and models using different criteria such as the geometric mean return, stochastic dominance, safety first and skewness.

However, an analysis of risk nature in *portfolio management* shows that the latter comes from various origins and then its nature is multidimensional. The traditional theoretical approach mentioned above does not take into account this multidimensional measure of risk. Also, individual goals and investor's preferences cannot be incorporated in these models. *Multiple criteria decision making* (MCDM) provides the methodological basis to resolve the inherent multicriteria nature of portfolio selection problem. Additionally, it builds realistic models by taking into account, apart of the two basic criteria of return and risk (mean-variance model), a number of important criteria, such as marketability, price earning ratio (PER), growth of the dividends, and others. Furthermore, MCDM, have the advantage of taking into account the preferences of any particular investor. Recently, several authors have developed a new approach, using MCDM for portfolio management.

In this article we develop some arguments for the use of MCDM in portfolio management and we present a brief review of the existing articles concerning this new approach (Section 2). Then, we propose a multicriteria methodological framework in two stages (Section 3). In the first stage the ELECTRE TRI [28] method and the MINORA ([24,25]) systems are used to select attractive stocks. In the second stage, the ADELAIS [23] system is used to construct a portfolio of the attractive stocks chosen in the first stage. This methodological framework is illustrated on a case study. Finally,

we summarize the used methodological framework and underline its advantages then give some concluding remarks.

## MCDM and Portfolio Selection

### Portfolio Selection: A Multicriteria Problem

To manage efficiently portfolio selection, it is necessary to take into account all the factors that influence the financial markets. Then, portfolio management is a multicriteria problem. Effectively, multifactor models and APT (arbitrage pricing theory) point out the existence of several influence factors for the determination of the stock prices. Furthermore, fundamental analysis models, commonly used in practice, underlines that stock prices are also dependent on the firm health and its capacity to pay dividends. The latter problem itself is a multicriteria problem because, in order to solve it, we must appreciate the profitability of the firm, its debt level (in the short and long terms) and quality of management. Finally, in practice, an investor has a personal attitude and particular objectives.

By reducing the risk to its probabilistic dimension, the classical approach cannot take into account its multidimensional nature and risk measures that do not have a concrete and practical economical meaning. In addition, this approach imposes a norm to the investor's behavior that can be restrictive. Also, it cannot take into account the personal attitude and preferences of a real investor confronted with a given risk in a particular situation. However, experience has proved that the classical approach is useful, for instance concerning the diversification principle and the use of the beta as measure of risk. Thus, the use of the classical approach seems to be necessary but not sufficient, to manage portfolio selection efficiently. Some additional criteria must be added to the classical risk-return criteria. In practice, these additional criteria can be found in fundamental analysis or constructed following the personal goals of the investor.

Note that the application of the above principles is difficult because of the complexity of multicriteria problems on the one hand and the use of criteria from different origins and of conflicting nature on the other hand. Furthermore MCDM will facilitate and favor the analysis of compromise between the criteria. It equally permits to manage the heterogeneity of criteria scale

and the fuzzy and imprecise nature of the evaluation that it will contribute to clarify. (Here the words fuzzy and imprecise refer to: a) the delicacy of an investor's judgement (the human nature and the lack of information), that will not always allow to discriminate between two close situations; and b) the use of a representation model, which is a simplification of reality that expresses itself in an error term.)

Linking the multicriteria evaluation of an asset portfolio and the research of a satisfactory solution to the investor's preferences, the MCDM methods allow to take into account the investors' specific objectives. Furthermore, these methods do not impose any normative scheme to the comportment of the investors. The use of MCDM methods allows to synthesize in a single procedure the theoretical and practical aspects of portfolio management, then it allows a non normative use of theory.

The originality of MCDM provides the possibility to obtain a gain of time and/or to increase the number of stocks considered by the practitioner by systematizing the decision process. Moreover, in a market close to efficiency, as are all the big markets, it is the good and fast use of all available information that ensures informational efficiency of capital markets and will permit the investor to compete.

### Review of Existing Study

In this section we present a brief review of articles concerning MCDM and portfolio management. An analysis and a more complete presentation of most of these papers can be found in [7] or [12]. T.L. Saaty, P. Rogers and R. Pell [22] proposed in 1980 to construct a portfolio using the analytic hierarchy process (AHP) methodology. They consider that stocks must be compared following the investor objectives and the criteria that influence the prices. In addition, the latter criteria are themselves influenced by some global economic factors. In AHP, factors, criteria and stocks are successively weighed following their relative importance. Finally, the weight of each stock gives its proportion in the portfolio.

S.M. Lee and L. Chesser [16] present a goal programming (GP) model to construct a portfolio. The used objectives are the research of a minimum return, minimization of risk (using  $\beta$ ), various diversification

objectives and some specific objectives to the investors. In GP, the investor can set his desires in preference order in a simple and natural way.

A. Rios-Garcia and S. Rios-Insua [20] construct a portfolio using multi-attribute utility theory (MAUT) and *multi-objective linear programming* (MOLP). Particularly, the authors propose the use of Bayesian econometrics to update the investor multi-attribute utility function, and examine the problem posed by the nonlinear criteria in MOLP.

Y. Evrard and R. Zisswiller [6] use MAUT to perform a valuation of some stocks. The aim is to show how it is possible to construct models that link the attributes of the stocks (return, risk, PER and earnings per share) and the investors' preferences.

H. Nakayama, T. Takeguchi and M. Sano [19] propose a graphics interactive methodology to construct a portfolio using the expected return, the variance and the evolution of the return in the past.

J.M. Martel, N.T. Khoury and M. Bergeron [18] perform a portfolio selection using the outranking methods ELECTRE I and ELECTRE II. From the stocks included in two portfolios selected by a real investor, they generate 50 portfolios. These portfolios are compared using ELECTRE I and II and follow four criteria: the return, the logarithmic variance, the PER, and the liquidity. The aim is to determine which portfolio fits well to the decision criteria.

G. Colson and C. De Bruyn [1] propose a system that performs a stock valuation and allows the construction of a portfolio. The heart of this system is the confrontation of the following objectives:

- 1) Obtain a minimum level of gain.
- 2) Maintain the risk under a predetermined level.
- 3) Obtain a minimum level of gain as dividends and interests.
- 4) Insure a sufficient level of diversification, firm control or liquidity.

This system is subdivided between two subsystems, the single decision model (SDM) and the simultaneous management model (SMM). The SDM ranks the stocks using various statistics criteria and information coming from correspondents. The SMM is a GP model as in [16].

A. Szala [26] performs stock evaluation in collaboration with a French investment company. For the financial analyst of the company, that examines a small

number of stocks using numerous criteria, Szala uses the outranking method ELECTRE III to obtain a ranking of the stocks. For traders or portfolios managers, it is not realistic to use many criteria because they generally manage a great number of stocks. Then, concerning traders and portfolio managers, Szala decided to amalgamate the financial criteria in a synthesis criterion obtained by using the PREFCALC system (PREFCALC is an interactive system of the same nature as MINORA that will be presented in the following section of this paper).

Khoury, Martel and Bergeron [14] use the outranking methods ELECTRE IS and ELECTRE III to select international index portfolios. They generate 19 index portfolios from the indexes of 16 countries. The criteria that have been used are: return, standard deviation, transaction costs, country risk, available cover for foreign currencies and exchange risk.

The purpose of Colson and M. Zeleny ([2,29]) is to construct an efficient frontier in concordance with the principles of stochastic dominance. To achieve their aim, they propose to use a three-dimensional vector, the 'prospect ranking vector' (PRV), as a measure of risk. The first component of the PRV is the probability not to achieve a minimal return, the second component is the expected return and the third component is the probability to exceed a maximum return. We find an interest updating the PRV in order to perform a portfolio selection rather than construct an efficient frontier [9]. To achieve this result, it is necessary to modify the PRV in order to obtain more complete measures of risk. Then, the first component is divided into two components: the first is destined to protect the investor against strong losses and the second is used to take into account the other possible losses (not so strong but significant). Concerning the third component, the probability to exceed a maximum level of return is changed in the probability to significantly exceed the expected return. Then, this new version of the PRV can be associated to other criteria to perform a multicriteria portfolio selection. In [9] portfolio selection is managed by using the MINORA system that will be presented in the following section.

C. Zopounidis, D.K. Despotis and I. Kamaratou [31] propose the use of the ADELAI system to construct a portfolio using some diversification constraints, some constraints representing the investor's personal pref-

erences and the following criteria: return, dividends,  $\beta$ , earnings per share growth, marketability, PER. The ADELAIS system is also used in our methodology that will be presented later.

M. Tamiz, R. Hasham and D.F. Jones [27] propose to use GP for portfolio evaluation and selection. The proposed method consists of two stages: the first stage estimates the sensitivity of the stocks to specific factors using GP and regression analysis. They use twelve factors: UK, US and German interest rates, US and German inflation rates, Dow Jones index, Nikkei average index, Hang Sang index, oil price, gold price, house price and sterling index. The sensitivities obtained by the GP model and those of the regression analysis are compared. In the second stage, a portfolio is selected by using a GP model based on the decision maker's scenarios and preferences.

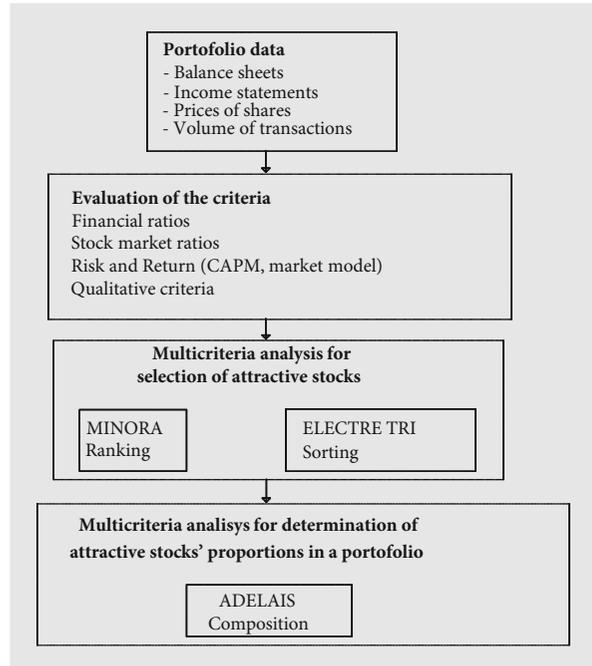

C. Dominiak [4] presents a procedure for security selection that uses a multicriteria discrete analysis method based on the idea of reference solution. The criteria he used are divided into three groups:

- 1) Valuation measures that contain Price book value ratio and PER.
- 2) Fundamental variables that contain profit margin ratio and changes in quarterly net profits.
- 3) Technical indicators that contain rate of change, relative strength index and price appreciation during the last 3 months.

Ch. Hurson and N. Ricci [8] propose to combine arbitrage pricing theory (APT) and MCDM to model the portfolio management process. First, APT is used to construct some efficient portfolios, to estimate their expected return and to identify influence factors and risk origins. Then, two multicriteria decision methods: the ELECTRE TRI outranking method and the MINORA interactive system are used to select attractive portfolios, using APT factors as selection criteria. This methodology is illustrated by an application to the Greek market.

### Methodological Framework

In this section we will present our methodology and illustrate it on a case study. For a more detailed presentation and applications on Greek and Belgium market, see [7,10,11,12,32]. A first application of MINORA to portfolio management can also be found in [30].

Portfolio Selection and Multicriteria Analysis, Figure 1  
Basic components of the methodological framework

### Basic Components

The basic components of the proposed methodological framework are presented in Fig. 1.

### Portfolio Data and Criteria

For the analysis and the selection of stocks, it is necessary to possess the following basic information for at least three consecutive years: balance sheets, income statements and stock market information, i.e. prices of shares and volume of transactions. This consecutive financial information allows the investor or portfolio manager to evaluate the evolution of the stock's situation, and to form financial and stock market ratios relevant to portfolio management.

On the basis of the portfolio data one can calculate financial and stock market ratios (return on equity, return on investment, current ratio, interest charges/sales, earnings per share, price earnings ratio, dividend per share, etc.), the pair risk/return from the theoretical portfolio models capital assets pricing model (CAPM) and market model. Apart from the quantitative criteria, the investor or portfolio manager

needs to have more general information so that his evaluation would be as objective and complete as possible. Such information about a stock may be its quality of management, image, security of information, position on the market, etc. This qualitative information is sometimes more important than the financial, because, for example, if the firm does not have good managers, its financial results (sales, net income, return) will not be satisfactory.

Financial and stock market ratios have become an accepted evaluation technique of financial analysts and portfolio managers. They provide a quantitative view of every element that concerns the internal operation of a firm as well as its relations with the outer world, and permit fast processing of a large volume of financial data. The financial ratios have already been used in many fields of financial management. C.F. Lee [15] has grouped every financial ratio that has been used in the forecasting of firm failure, bond rating, market return and mergers. The risk and the return issue of theoretical portfolio models (CAPM and market model) are the basic criteria in portfolio selection. Qualitative criteria are modeled according to the preferences of each user (portfolio manager) with the aid of an ordinal scale (3 better than 2 and 2 better than 1).

### Multicriteria Analysis for the Selection of Attractive Stocks

In this step the two MCDM methods MINORA and ELECTRE TRI are used to help the portfolio manager in the selection of a set of attractive stocks taking into consideration his preferences and experiences. Here, only a short description of the two methods is given.

#### MINORA System

MINORA is an interactive multicriteria decision making system that ranks a set of alternatives from the best ones to the worst ones using several criteria. In this purpose the MINORA system uses the UTA ranking algorithm [13]. From the ranking by the decision maker of a subset of well-known alternatives, UTA uses *ordinal regression* to estimate a set of separable *additive utility functions* of the following form:

$$u(g) = u_1(g_1) + \dots + u_k(g_k),$$

where  $g = (g_1, \dots, g_k)$  is the performance vector of an alternative and  $u_i(g_i)$  is the marginal utility function of criteria  $i$ , normalized between 0 and 1. The ordinal regression is performed using linear programming (for more details see [3]). In MINORA the interaction takes the form of an analysis of inconsistencies between the ranking established by the decision maker and the ranking obtained from the utility function estimated by UTA. Two measures of these inconsistencies are used in MINORA:

- 1) The  $F$  indicator which is the sum of the deviations of the ordinal regression curve (global utility versus decision maker's ranking), e.g. the sum of estimation errors.
- 2) The Kendall's  $t$  that gives a measure, from  $-1$  to  $1$ , of the correlation between the decision maker ranking and the ranking resulting from the utility function.

At optimality, when the two rankings are similar, the  $F$  indicator is equal to 0 and the Kendall's  $t$  to 1. The interaction is organized around four questions presented to the decision maker:

- 1) Is he ready to modify his ranking?
- 2) Does he wish to modify the relative importance of a criterion, its scale or the marginal utilities (trade-off analysis)?
- 3) Does he wish to modify the family of criteria used: to add, cancel, modify, divide or join some criteria?
- 4) Does he wish to modify the whole formulation of the problem?

These questions send back to the corresponding stages of MINORA and the method stops when an acceptable compromise is determined. Then the result (a utility function) is extrapolated to the whole set of alternative to give a ranking of them.

The MINORA system presents two main advantages:

- It furnishes a ranking of stocks that is a natural pre-occupation frequently used by portfolio managers.
- The form of the interactivity, all the originality of the MINORA system can be found in the inconsistencies analysis in an interactive way. It allows to help the decision maker to construct his own model in a non normative way and organizes, in a unique procedure, all the activity of decision making, from the model formulation to the final result (a ranking of the alternatives from the best to the worst in the

case of MINORA). At the same time the decision maker is constantly integrated to the resolution processes and can control its evolution at any moment. Finally, it should be noted that the MINORA system has been used successfully to solve numerous management problems.

### The ELECTRE TRI Outranking MCDM Method

ELECTRE TRI is an outranking method specially conceived for *sorting problems*. In our methodology the ELECTRE TRI method is used to sort the stocks in three categories: attractive stocks, uncertain stocks (to be studied further) and nonattractive stocks. ELECTRE TRI deals only with ordered categories (complete order). The categories are defined by some reference alternatives or reference profiles (one down profile and one up profile) which are themselves defined by their values on the criteria. Next we can define the categories  $C_i$ ,  $i = 1, \dots, c$ , where  $C_1$  is the worst category and  $C_c$  the best one. We can also define the profiles  $r_i$ ,  $i = 1, \dots, c - 1$ , where  $r_1$  and  $r_{c-1}$  are the lower and the upper profile respectively. Then, the profile  $r_i$  is the theoretical limit between two categories  $C_i$  and  $C_{i+1}$  and  $r_i$  represents a fictitious stock which is strictly better than  $r_{i-1}$  on each criterion. In ELECTRE TRI, the information asked from the decision maker about his preferences takes the form, for each criterion and each profile, of a relative weight and an indifference, preference and veto thresholds. To sort the stocks, ELECTRE TRI compares each of them to the profiles using the concepts of indifference, preference and veto thresholds in order to construct a concordance index, a discordance index and finally a valued outranking relation as in ELECTRE III method (cf. [21]). This valued outranking relation  $s_s(a, b) \in [0, 1]$  measures the strength of the relation 'a outranks b' ( $a$  is at least as good as  $b$ ). This valued outranking relation is transformed in a 'net' outranking relation in the following way:  $s_s(a, b) \geq \lambda \Leftrightarrow aSb$ , where  $S$  represents the net outranking relation,  $a$  and  $b$  two stocks and  $\lambda$  a 'cut level' ( $0.5 \leq \lambda \leq 1$ ) above which the relation  $a$  outranks  $b$  is considered as valid. Then the preference  $P$ , the indifference  $I$  and the incomparability  $R$  are defined as follows:

- $aIb \Leftrightarrow aSb$  and  $bSa$ ,
- $aPb \Leftrightarrow aSb$  and no  $bSa$ ,
- $aRb \Leftrightarrow$  no  $aSb$  and no  $bSa$ .

In ELECTRE TRI there are two non total compensation sorting procedures (the pessimistic one and the optimistic one) to assign each alternative into one of the categories defined in advance. In the sorting procedure, stock  $a$  is compared at first to the worst profile  $r_1$  and in the case of  $aPr_1$ ,  $a$  is compared to the second profile  $r_2$ , etc., until one of the following situations appears:

- i)  $aPr_i$  or  $aIr_{i+1}$  and  $r_{i+1}Pa$ ;
- ii)  $aPr_i$  and  $r_{i+1}Ra, \dots, r_{i+m}Ra, r_{i+m+1}Pa$ .

In situation i) both the procedures assign stock  $a$  to category  $i + 1$ . In situation ii), the pessimistic procedure classifies stock  $a$  to category  $i + 1$ , while the optimistic procedure classifies stock  $a$  to category  $i + m + 1$ . When the value of  $\lambda$  gradually decreases, the pessimistic procedure becomes less compulsive and the optimistic procedure less permissive. Evidently the optimistic procedure tends to classify the stocks to the higher possible category, in contrast to the pessimistic procedure that tends to classify the stocks to the lower possible category. In general, the pessimistic procedure is applied when a policy of prudence is necessary or when the available means are very constraining. The optimistic procedure is applied to problems where the decision maker desires to favor the alternatives that present some particular interest or some exceptional qualities. In portfolio management the optimistic procedure will be well adapted to an optimistic investor with a speculative investment policy, while a prudent investor, following a passive investment policy, will prefer the pessimistic procedure.

ELECTRE TRI manages incomparability in such a way that it will point out the alternatives that have particularities in their evaluations. In cases where some alternatives belong to different categories in both procedures, the conclusion is that they are incomparable with one or more reference profiles (as the number of categories between the two assignments is increasing, the 'particularities' of the alternatives are becoming more important). This is because these alternatives have good values for some criteria and, simultaneously, bad values for other criteria; moreover, these particular alternatives must be examined with attention. In this way the notion of incomparability included in ELECTRE TRI brings an important information to the decision maker and for this reason the best way to employ ELECTRE TRI is to use the two assignments procedures and to

compare the results. The advantages of ELECTRE TRI are the following:

- ELECTRE TRI by sorting the stocks is well adapted to the purpose of portfolio management (acceptable stocks, stocks to be studied further and unacceptable stocks).
- ELECTRE TRI, as all the methods of the ELECTRE family, accepts intransitivity and incomparability. In ELECTRE TRI this is done in such a way that the method will point out the alternatives that have particularities in their evaluation.
- The ELECTRE family uses techniques that are easily understandable by the decision maker.

The methods from the ELECTRE family are very popular and they have been used with success in a great number of studies [21].

### Multicriteria Analysis for the Determination of Attractive Stocks' Proportions in a Portfolio: The ADELAIS System

MINORA and ELECTRE TRI give the possibility to the portfolio manager to select the most attractive stocks he desires to include in his final portfolio. Then, the ADELAIS system helps him to determine the proportions (percentage) of capital invested in the above attractive stocks. ADELAIS is an interactive computer system developed to support the search for a satisfactory solution in MOLP problems of the general form:

$$\begin{cases} \max & \{f_1(\mathbf{x}), \dots, f_n(\mathbf{x})\} \\ \text{s.t.} & \mathbf{x} \in A, \end{cases}$$

where  $\mathbf{x} = (x_1, \dots, x_m)$  is the vector of decision variables,  $f_1(\mathbf{x}), \dots, f_n(\mathbf{x})$  are linear functions of the decision variables and  $A$  is the set of the feasible solutions defined by linear constraints  $A \subseteq \mathbf{R}^m$ . The system provides extensive data management capabilities and concerning the solution process it provides a 'two level' interaction: interactive assessment of the portfolio manager's utility function and interactive modification of the satisfaction levels. The system operates in two phases: a preliminary phase that is performed once and an iterative phase. In the preliminary phase, ADELAIS provides the upper and lower bounds for each objective function, the pay-off matrix, the starting efficient solution in a minimax sense and its rate of

closeness to the ideal values (upper bounds). At each iteration of the iterative phase a new efficient solution is presented the portfolio manager with the upper and lower bounds for each objective, the achievement percentages with respect to the upper bounds, the satisfaction levels (i. e., the revised lower bounds) established in previous iterations. Then, the system asks the portfolio manager to indicate the objectives he desires to improve and if he intends to decrease some other objectives in compensation. The portfolio manager's answers, combined with relative answers of previous iterations, form the basis for the establishment of new satisfaction levels. The new satisfaction levels limit the feasible set but the system provides the portfolio manager with the possibility to relax them if desired by analyzing the local trade-offs among the objectives. If the portfolio manager does not intend to decrease some objectives the system stops on the current efficient solution (best compromise), otherwise a reference set of decision alternatives (i. e. a set of vectors that might be assumed by the objectives) is constructed and the UTA method is used to estimate an additive utility function as in the MINORA system. Once a satisfactory utility function is assessed, this is maximized over the set  $A$  in order to obtain a new efficient solution taking into account the portfolio manager's preferences.

The advantages of the ADELAIS system for the portfolio manager, are the following:

- It allows determining the proportions of the attractive stocks in the portfolio that is not possible with ranking or sorting methods.
- The interactive analysis of the inconsistencies as in the MINORA system, which helps the portfolio manager to understand the portfolio selection problem.
- The interactive revision of the satisfaction levels orientates in a way easy to understand the research of the best compromise that is well adapted to the portfolio manager's preferences.

*Example 1* We will illustrate our methodology by a case study coming from [10]. The sample considered in the study consists of 40 stocks coming from the financial and commercial sectors of the Athens Stock Exchange (ASE). These stocks are evaluated using the 7 following criteria:

- $g_1$ : Return that must be maximized.
- $g_2$ : Marketability (percentage of shares traded) that must be maximized.
- $g_3$ : Beta risk that must be minimized.
- $g_4$ : Price earnings ratio (price of the share/earnings per share). Since there are negative values of earnings (losses), we choose to maximize the inverse of this criterion
- $g_5$ : Growth of dividend per share that must be maximized.
- $g_6$ : Acid test (current assets minus inventories/current liabilities) that must be maximized.
- $g_7$ : Return on equity (i. e. net income/stockholder equity) that must be maximized.

All the stocks of the sample have been evaluated on the five stock market criteria  $g_1, \dots, g_5$ , while, in order to obtain most significant results, the criterion  $g_6$  is used for the stocks of the commercial sector (CS1 to CS20) and the criterion  $g_7$  for the stocks of the financial sector (FS1 to FS20).

Table 1 presents the multicriteria evaluation for the stocks of the commercial sector. Qualitative criteria are not included because they are dependent to the portfolio manager's personal information that was not available in this application.

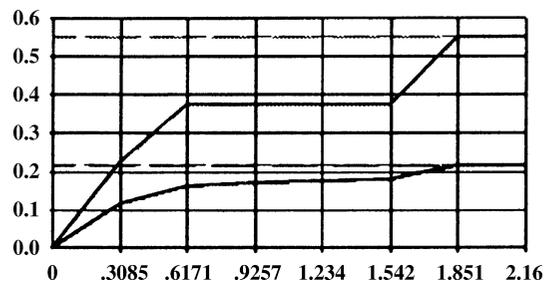

### Ranking of Stocks Using the MINORA System

The reference set and its ranking for the commercial sector is the following: CS16; CS18; CS12, CS19; CS9, CS3; CS7, CS8; CS1; CS20; for this purpose the portfolio manager can use a graphic help. The MINORA system provides two basic results: the criteria's graphics (i. e. marginal utilities, Fig. 2 and the ordinal regression curve (ranking versus global utility, Fig. 3). An important graphic help is at the disposal of the portfolio manager in order to interpret these results. In Fig. 2 there are three utility curves for the return criterion (min, middle and max). The middle one corresponds to the above presented model of additive utility and, also, gives the relative weight for the criterion. The two others show the entire range of the possible marginal utility functions and gives an idea of the sensitivity of the criteria. Figure 3 shows the ordinal regression curve (stocks' ranking versus global utility).

Table 2 presents the pre-ordering of the portfolio manager (D.R.), the stock names (Actions), the global

utility of every stock (G.U.) and the ordering from MINORA (M.R.).

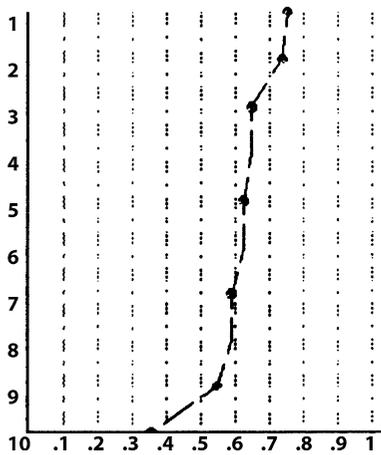

### Sorting of Stocks Using the ELECTRE TRI Method

The objective is to sort the stocks in the following three categories: attractive stocks (C3), uncertain stocks to be studied further (C2), non attractive stocks (C1). The reference profiles and the thresholds related to the concordance and discordance indices are fixed by the port-

comparison. The stocks that belong to the best category (C3) in both optimistic and pessimistic sorting are proposed without hesitation to the portfolio manager for selection. The stocks that belong to the worst category (C1) in both optimistic and pessimistic sorting are not proposed to the portfolio manager. When the stocks belong to the uncertain category (C2) for both optimistic and pessimistic sorting, this means that these have moderate values on all criteria and, consequently,

**Portfolio Selection and Multicriteria Analysis, Table 4**  
Sorting of stocks

	Optimistic	Pessimistic
C1	CS4, CS13, CS20, FS1, FS7, FS11, FS12, FS13	CS1, CS4, CS13, CS19, CS20, FS1, FS7, FS9, FS11, FS12, FS13, FS14
C2	CS1, CS2, CS3, CS5, CS6, CS8, CS14, CS15, CS17, FS8, FS9, FS14, FS19	CS2, CS3, CS5, CS6, CS7, CS8, CS9, CS12, CS14, CS15, CS17, FS3, FS8, FS10, FS16, FS19
C3	CS7, CS9, CS10, CS11, CS12, CS16, CS18, CS19, FS2, FS3, FS4, FS5, FS6, FS10, FS15, FS16, FS17, FS18, FS20	CS10, CS11, CS16, CS18, FS2, FS4, FS5, FS6, FS15, FS17, FS18, FS20

they must be studied further. In the cases where some stocks belong to different categories in both optimistic and pessimistic sorting, this means that they are incomparable with one or two reference profiles. This is due to the fact that these stocks have good values for some criteria and, simultaneously, bad values for other criteria. Thus, the notion of incomparability underlies the particularities of these stocks that must be examined further and brings an important information to the portfolio manager. Comparing the ranking results of the MINORA system with the sorting results of the ELECTRE TRI method, one can remark, generally, that there is an agreement, that is, the stocks which are well ranked (i. e. top of the ranking) by MINORA are in the best category C3 by ELECTRE TRI, and vice versa. This agreement between these two methods asserts the interest of the methodology and allows the portfolio manager to be confident with their results.

#### Determination of the Attractive Stocks' Proportions in a Portfolio Using the ADELAIS System

According to the results obtained above, the portfolio manager can choose a subset of the best stocks from

each sector and then, using the ADELAIS system, determine the proportions invested in each selected stock. The chosen set is the following: FS10, FS5, FS20, FS6, FS2 from the financial sector and CS16, CS18, CS12, CS11, CS9 from the commercial sector.

The decision variables,  $X_i$ , are the percentages of capital invested in each stock. For the needs of the study we note:  $X_1 = \text{FS10}$ ,  $X_2 = \text{FS5}$ ,  $X_3 = \text{FS20}$ ,  $X_4 = \text{FS6}$ ,  $X_5 = \text{FS2}$ ,  $X_6 = \text{CS16}$ ,  $X_7 = \text{CS18}$ ,  $X_8 = \text{CS12}$ ,  $X_9 = \text{CS11}$ ,  $X_{10} = \text{CS9}$ .

Since, the return, the marketability, the beta, the price earnings ratio and the growth dividend per share of the constructed portfolio are directly related to the percentages of capital invested in each stock, only these five criteria are used in the application of the ADELAIS system. On the other hand, the acid test ratio and the return on equity can only be used as evaluation criteria of the financial soundness of each stock, and they do not characterize the constructed portfolio. Consequently, the objective functions are:

- Maximize the return ( $g_1$ ):  $\max R_1X_1 + \dots + R_{10}X_{10}$ .
- Maximize the marketability ( $g_2$ ):  $\max M_1X_1 + \dots + M_{10}X_{10}$ .
- Minimize the beta ( $g_3$ ):  $\min B_1X_1 + \dots + B_{10}X_{10}$ .
- Maximize the price earnings ratio ( $g_4$ ):  $\max \text{PER}_1X_1 + \dots + \text{PER}_{10}X_{10}$ .
- Maximize the growth of dividends per share ( $g_5$ ):  $\max \text{GD}_1X_1 + \dots + \text{GD}_{10}X_{10}$ .

Here,  $R_i$ ,  $M_i$ ,  $B_i$ ,  $\text{PER}_i$ , and  $\text{GD}_i$  are the values of the corresponding objective for the stock  $i$ . The constraints are:

- $X_1 + \dots + X_{10} = 1$ , all the available capital must be invested.
- $0.05 < X_1 < 0.2, \dots, 0.05 < X_{10} < 0.2$  upper and lower limits of the amount to be invested in each stock (% of capital).

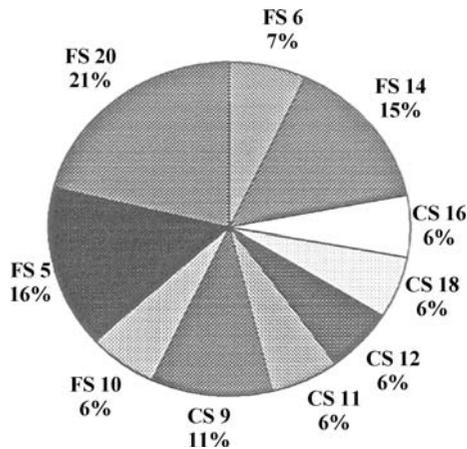

At the beginning (preliminary phase) ADELAIS proceeded to the estimation of an initial efficient portfolio of stocks (compromise) and presents it as in Table 5. A pay-off table for the objectives was also given to the portfolio manager.

With respect to the initial solution, the portfolio manager being satisfied by the attained values of the marketability and the growth of dividends per share asked for an improvement of the other objectives. On the basis of this information the system generated a set of portfolios, and asked

Best compromise solution

Solution	$g_1$	$g_2$	$g_3$	$g_4$	$g_5$
Attained values	1.47	0.52	0.73	11.9	47.22
$R_c$	65%	61.9%	65.8%	57.5%	95.2%

the portfolio manager to rank them. On the basis of these data, ADELAIS assesses an additive utility model and use it to determine a new reference solution. Finally, after three iterations ADELAIS determines the best compromise solution that could not be improved. Table 6 presents the values of the objectives and the rate of closeness to the ideal point, the corresponding portfolio appears in Fig. 4.

## Concluding Remarks

In this article a review of articles is presented concerning MCDM and portfolio management and a methodological framework for portfolio selection. MCDM is a new supportive tool for portfolio selection. The use of multicriteria decision making methods allows to take into consideration the investors personal preferences and all the relevant criteria, whatever their origins, for portfolio selection. In our methodology, the conjoined use of the MINORA system and the ELECTRE TRI method have shown some advantages as the complementarity and the similarity of the obtained results that state the portfolio manager's confidence in the constitution of his portfolio; also, they satisfy one of the portfolio managers' preoccupation which is the ranking and the sorting of stocks in portfolio selection. Secondly, ELECTRE TRI with the notion of incomparability brings an important information to the portfolio manager, especially when the evaluation of stocks appears difficult. Thirdly, ADELAIS and MINORA systems provide a considerable aid to the portfolio manager to construct his own model of portfolio selection in an interactive way. This portfolio selection model is without any normative consideration proposed by the classical portfolio theory. Finally, the topic of portfolio management also covers the portfolio diversification by categories of securities (stocks, bonds, options, international securities, etc.), in order to compensate the risks. The construction of a portfolio for each of these securities and the diversification problem also are multicriteria. Thus, it will be interesting to look at the contribution that MCDM can bring to these problems. The final aim is to regroup these problems in order to formalize and improve all the processes of portfolio management.

### Keywords

Linear programming; Primal-dual; Potential function; Potential reduction

Consider the *linear programming* (LP) problem in the standard form:

$$\begin{cases} \min & c^\top x \\ \text{s.t.} & Ax = b, \\ & x \geq 0, \end{cases} \quad (1)$$

where the given matrices  $A \in \mathbf{R}^{m \times n}$ ,  $c \in \mathbf{R}^n$ ,  $b \in \mathbf{R}^m$ , and the unknown vector  $x \in \mathbf{R}^n$ . The dual of (LP), (DLP), can be written as:

$$\begin{cases} \max & b^\top y \\ \text{s.t.} & A^\top y + s = c, \\ & s \geq 0, \end{cases} \quad (2)$$

where the unknown vector  $y \in \mathbf{R}^m$ . Let  $\mathcal{F}$  be the *feasible set* of  $(x, y, s)$ , and let the *interior* of  $\mathcal{F}$  be denoted by  $\text{int } \mathcal{F}$ , i. e., this is the set of feasible  $(x, y, s)$  such that  $x > 0$  and  $s > 0$ .

*Potential reduction algorithms* for linear programming are generally equipped with various *potential functions* that are solely used to measure the solution's progress. There is no restriction on either path following or stepsize during the iterative process; the greater the reduction of the potential function, the faster the convergence of the algorithm. These potential functions represent the *logarithmic volumes* of certain *coordinate-aligned ellipsoids* containing the optimal solution set. There are three types of potential functions (see the references). For  $(x, y, z) \in \text{int } \mathcal{F}$ , the first is the *primal-dual potential function*

$$\psi(x, s) = \rho \log(x^\top s) - \sum_{j=1}^n \log(x_j s_j),$$

where  $\rho \geq n$ . This function is also called *Tanabe-Todd-Ye potential function*. Note that for  $\rho = n$

$$\psi(x, s) = n \log(x^\top s) - \sum_{j=1}^n \log(x_j s_j) \geq n \log n.$$

Thus, for  $\rho > n$ ,  $\psi(x, s)$  approaching  $-\infty$  implies  $x^\top s$  converging to 0.

Let  $z = b^\top y$  and  $\bar{z} = c^\top x$  for some strictly feasible  $x$  and  $(y, s)$ , respectively. Then, consider

$$\phi_p(x, \underline{z}) = \rho \log(c^\top x - \underline{z}) - \sum_{j=1}^n \log(x_j)$$

and

$$\phi_d(y, s, \underline{z}) = \rho \log(\bar{z} - b^\top y) - \sum_{j=1}^n \log(s_j).$$

$\phi_p$  is called *Karmarkar's potential function* or the *primal potential function*, and  $\phi_d$  is called the *dual potential function*. The three functions are closely related:

$$\psi(x, s) = \phi_p(x, \underline{z}) - \sum_{j=1}^n \log s_j,$$

and

$$\psi(x, s) = \phi_d(y, s, \bar{z}) - \sum_{j=1}^n \log x_j.$$

Thus, the reduction in  $\phi_p(x, z)$  or  $\phi_d(y, s, \bar{z})$ , when  $(y, s)$  or  $x$  is fixed, implies the same reduction in  $\psi(x, s)$ .

Depending on which potential being used as the primary reduction, there are also three types of potential reduction algorithms. Here, we describe the primal and primal-dual algorithms.

### Primal Potential Reduction Algorithm

Consider a pair of  $(x^k, y^k, s^k) \in \text{int } \mathcal{F}$ . Fix  $z^k = b^\top y^k$ , then the *gradient vector* of the primal potential function with respect to  $x^k$  is

$$\begin{aligned} \nabla \phi_p(x^k, z^k) &= \frac{\rho}{(s^k)^\top x^k} c - (X^k)^{-1} e \\ &= \frac{\rho}{c^\top x^k - z^k} c - (X^k)^{-1} e. \end{aligned}$$

We directly solve the *ball-constrained linear problem* for direction  $d_x$ :

$$\begin{cases} \min & \nabla \phi_p(x^k, z^k)^\top d_x \\ \text{s.t.} & A d_x = 0, \\ & \|(X^k)^{-1} d_x\| \leq \alpha. \end{cases}$$

Let the minimizer be  $d_x$ . Then

$$d_x = -\alpha \frac{X^k p^k}{\|p^k\|},$$

where

$$\begin{aligned} p^k &= p(z^k) \\ &:= \left( I - X^k A^\top (A(X^k)^2 A^\top)^{-1} A X^k \right) \\ &\quad \times X^k \nabla \phi_p(x^k, z^k). \end{aligned}$$

Update

$$x^{k+1} = x^k + d_x = x^k - \alpha \frac{X^k p^k}{\|p^k\|}, \quad (3)$$

and we have

$$\phi_p(x^{k+1}, z^k) - \phi_p(x^k, z^k) \leq -\alpha \|p^k\| + \frac{\alpha^2}{2(1-\alpha)}.$$

Thus, as long as  $\|p^k\| \geq \eta > 0$ , we may choose an appropriate  $\alpha$  such that

$$\phi_p(x^{k+1}, z^k) - \phi_p(x^k, z^k) \leq -\delta$$

for some positive constant  $\delta$ . By the relation between  $\psi_\rho(x, s)$  and  $\phi_p(x, z)$ , the primal-dual potential function is also reduced. That is,

$$\psi_\rho(x^{k+1}, s^k) - \psi_\rho(x^k, s^k) \leq -\delta.$$

However, even if  $\|p^k\|$  is small, we will show that the *primal-dual potential function* can be reduced by a constant  $\delta$  by increasing  $z^k$  and updating  $(y^k, s^k)$ .

We focus on the expression of  $p^k$ , which can be rewritten as

$$\begin{aligned} p^k &= \left( I - X^k A^\top (A(X^k)^2 A^\top)^{-1} A X^k \right) \\ &\quad \times \left( \frac{\rho}{c^\top x^k - z^k} X^k c - e \right) \\ &= \frac{\rho}{c^\top x^k - z^k} X^k s(z^k) - e, \end{aligned} \quad (4)$$

where

$$s(z^k) = c - A^\top y(z^k) \quad (5)$$

and

$$\begin{aligned} y(z^k) &= y_2 - \frac{c^\top x^k - z^k}{\rho} y_1, \\ y_1 &= (A(X^k)^2 A^\top)^{-1} b, \\ y_2 &= (A(X^k)^2 A^\top)^{-1} A(X^k)^2 c. \end{aligned} \quad (6)$$

One can show that, when  $\|p(z^k)\|$  is small, then  $(x^k, y(z^k), s(z^k))$  is in the neighborhood of the *central path* and  $b^\top y(z^k) > z^k$ . Thus, we can increase  $z^k$  to  $b^\top y(z^k)$ . Moreover,  $\phi(x^k, s(z^k))$  is reduced from  $\phi(x^k, s^k)$  by a constant. Overall, we have the following potential reduction theorem to evaluate the progress.

**Theorem 1** *Given  $(x^k, y^k, s^k) \in \text{int } \mathcal{F}$ . Let  $\rho = n + \sqrt{n}$ ,  $z^k = b^\top y^k$ ,  $x^{k+1}$  be given by (5), and  $y^{k+1} = y(z^k)$  in (6) and  $s^{k+1} = s(z^k)$  in (5). Then, either*

$$\psi(x^{k+1}, s^k) \leq \psi(x^k, s^k) - \delta$$

or

$$\psi(x^k, s^{k+1}) \leq \psi(x^k, s^k) - \delta,$$

where  $\delta > 1/20$ .

This theorem establishes an important fact: the *primal-dual potential function* can be reduced by a constant no matter where  $x^k$  and  $y^k$  are. In practice, one can perform the line search to minimize the primal-dual potential function. This results in the following primal-dual potential reduction algorithm.

```

Given   a central path point  $(x^0, y^0, s^0) \in \text{int } \mathcal{F}$ .
Let      $z^0 = b^\top y^0$ .
Set      $k := 0$ .
WHILE    $(s^k)^\top x^k \geq \epsilon$  DO
1       Compute  $y_1$  and  $y_2$  from (6).
2       IF there exists  $z$  such that  $s(z) > 0$ ,
        THEN compute

             $\bar{z} = \arg \min_z \psi_p(x^k, s(z))$ ,

        FI
        IF  $\psi_p(x^k, s(\bar{z})) < \psi_p(x^k, s^k)$ ,
        THEN  $y^{k+1} = y(\bar{z})$ ,  $s^{k+1} = s(\bar{z})$  and
             $z^{k+1} = b^\top y^{k+1}$ ;
        ELSE  $y^{k+1} = y^k$ ,  $s^{k+1} = s^k$  and  $z^{k+1} = z^k$ .
        FI
3       Let  $x^{k+1} = x^k - \bar{\alpha} X^k p(z^{k+1})$  with  $\bar{\alpha} =$ 
         $\arg \min_{\alpha \geq 0} \psi_p(x^k - \alpha X^k p(z^{k+1}), s^{k+1})$ .
4       Set  $k := k + 1$  and return to Step 1.

```

#### Primal algorithm

The performance of the algorithm results from the following corollary.

**Corollary 2** *Let  $\rho = n + O(\sqrt{n})$ . Then, the primal algorithm terminates in at most  $O(\frac{\sqrt{n} \log((x^0)^\top s^0)}{\epsilon})$  iterations with*

$$c^\top x^k - b^\top y^k \leq \epsilon.$$

#### Primal-Dual Potential Reduction Algorithm

Another technique for solving linear programs is the symmetric primal-dual algorithm. Once we have a pair  $(x, y, s) \in \text{int } \mathcal{F}$  with  $\mu = x^\top s/n$ , we can generate a new iterate  $x^+$  and  $(y^+, s^+)$  by solving for  $d_x, d_y$  and  $d_s$  from the system of linear equations:

$$\begin{aligned} Sd_x + Xd_s &= \gamma \mu e - Xs, \\ Ad_x &= 0, \\ -A^\top d_y - d_s &= 0. \end{aligned} \quad (7)$$

Let  $d := (d_x, d_y, d_s)$ . To show the dependence of  $d$  on the current pair  $(x, s)$  and the parameter  $\gamma$ , we write  $d = d(x, s, \gamma)$ . Note that  $d_x^\top d_s = -d_x^\top A^\top d_y = 0$  here.

The system (7) is the *Newton step* starting from  $(x, s)$  which helps to find the point on the central path with duality gap  $\gamma n\mu$ . If  $\gamma = 0$ , it steps toward the optimal solution characterized by the optimality conditions of (LP) and (DLP); if  $\gamma = 1$ , it steps toward the central path point of  $\mu$ ; if  $0 < \gamma < 1$ , it steps toward a central path point with a smaller complementarity gap. In the algorithm presented here, we choose  $\gamma = n/\rho < 1$ . Each iterate reduces the primal-dual potential function by at least a constant  $\delta$ , as does the previous potential reduction algorithm.

Let the direction  $d = (d_x, d_y, d_s)$  be generated by equation (7) with  $\gamma = n/\rho$ , and let

$$\theta = \frac{\alpha \sqrt{\min(Xs)}}{\left\| (XS)^{-\frac{1}{2}} \left( \frac{x^\top s}{\rho} e - Xs \right) \right\|}, \quad (8)$$

where  $\alpha$  is a positive constant less than 1. Let

$$\begin{aligned} x^+ &= x + \theta d_x, \\ y^+ &= y + \theta d_y, \\ s^+ &= s + \theta d_s. \end{aligned}$$

Then, we should have  $(x^+, y^+, s^+) \in \text{int } \mathcal{F}$  and

$$\begin{aligned} & \psi_\rho(x^+, s^+) - \psi_\rho(x, s) \\ & \leq -\alpha \sqrt{\min(Xs)} \left\| (XS)^{-\frac{1}{2}} \left( e - \frac{\rho}{x^\top s} Xs \right) \right\| \\ & \quad + \frac{\alpha^2}{2(1-\alpha)}. \end{aligned}$$

Let  $v \in \mathbf{R}^n$  be a positive vector and  $\rho \geq \sqrt{n}$ . Then, we can prove

$$\sqrt{\min(v)} \left\| V^{-\frac{1}{2}} \left( e - \frac{\rho}{e^\top v} v \right) \right\| \geq \sqrt{\frac{3}{4}}.$$

Combining these we have

$$\psi_\rho(x^+, s^+) - \psi_\rho(x, s) \leq -\alpha \sqrt{\frac{3}{4}} + \frac{\alpha^2}{2(1-\alpha)} = -\delta$$

for a constant  $\delta$ . This result will provide a competitive theoretical iteration bound, but a faster algorithm may be again implemented by conducting a line search along the direction  $d$  to achieve the greatest reduction in the primal-dual potential function. This leads to the following algorithm.

```

Given    $(x^0, y^0, s^0) \in \text{int } \mathcal{F}$ .
Set      $\rho \geq \sqrt{n}$  and  $k := 0$ .
WHILE   $(s^k)^\top x^k \geq \epsilon$  DO
1       Set  $(x, s) = (x^k, s^k)$  and  $\gamma = n/p$ ;
        compute  $(d_x, d_y, d_s)$  from (7).
2       Let  $x^{k+1} = x^k + \bar{\alpha} d_x$ ,  $y^{k+1} = y^k + \bar{\alpha} d_y$ ,
        and  $s^{k+1} = s^k + \bar{\alpha} d_s$ , where  $\bar{\alpha} =$ 
         $\arg \min_{\alpha \geq 0} \psi_\rho(x^k + \alpha d_x, s^k + \alpha d_s)$ .
3       Set  $k := k + 1$  and return to Step 1.
    
```

**Primal-dual algorithm**

**Theorem 3** *Let  $\rho = n + O(\sqrt{n})$ . Then, the primal-dual algorithm terminates in at most  $O\left(\sqrt{n} \log\left(\frac{(x^0)^\top s^0}{\epsilon}\right)\right)$  iterations with*

$$c^\top x^k - b^\top y^k \leq \epsilon.$$

Potential reduction methods have been successively extended to solving nonlinear *conic programs*, see, e. g., [13].

Gradient-free minimization; Powell method; Line search methods; Pattern search

The Powell method in its basic form can be viewed as a *gradient-free minimization algorithm*. It requires repeated line search minimizations, which may be carried out using *univariate gradient free*, or *gradient based procedures*. It was introduced by M.J.D. Powell [1]. The procedure is described in the algorithm steps below.

The minimization problem considered is:

$$\min_{\mathbf{x}} f(\mathbf{x}).$$

#### 1. Initialization

Select an accuracy  $\epsilon > 0$ , and a starting point  $\mathbf{x}^{(0)}$ . Set the initial search directions  $\mathbf{s}^{(i)}$  to be the unit vectors along each coordinate axis, for  $i = 1, \dots, n$ . Set the main iteration counter to  $k = 0$ , and the cycle counter  $i = 1$ . Initialize  $\mathbf{z}^{(1)} = \mathbf{x}^{(0)}$ . Set counter  $j = 0$  for the case where step 2.2a is used.

#### 2. Directional univariate minimization

2.1 Determine a univariate minimizer  $\lambda_i^*$  for the problem  $f(\mathbf{z}^{(i)} + \lambda_i \mathbf{s}^{(i)})$ . Set  $\mathbf{z}^{(i+1)} = \mathbf{z}^{(i)} + \lambda_i^* \mathbf{s}^{(i)}$ , and increment  $i \leftarrow i + 1$ . Repeat step 2.1 until  $i = n + 1$ . Check for termination (i.e. use the criterion in step 3). Go to step 2.2a if the original version is desired, or go to step 2.2b if the variant avoiding linearly dependent directions is chosen

2.2a New direction selection (pattern search directions)  
*(Original version of the method)*  
 Set  $j \leftarrow j + 1$ .  
 IF  $j \leq n$   
 THEN replace  $\mathbf{s}^{(j)}$  by  $\mathbf{z}^{(n+1)} - \mathbf{x}^{(k)}$ .  
 ELSE reset search direction set to the coordinate directions.  
 END IF  
 Set  $\mathbf{x}^{(k+1)} = \mathbf{z}^{(n+1)}$ ;  
 initialize  $\mathbf{z}^{(1)} = \mathbf{x}^{(k+1)}$ ;  
 increment counter  $k \leftarrow k + 1$ ;  
 set  $i = 1$ , go to step 2.1.

2.2b New direction selection  
(Modified variant to avoid linearly dependent directions)

At the present  $k$ th main iteration calculate  $\Delta = \max_{1, \dots, n} \{f(\mathbf{z}^{(i)}) - f(\mathbf{z}^{(i+1)})\}$  and the index  $m$  for which this occurs. The corresponding direction for which this occurs is designated as  $\mathbf{s}^{(m)}$ .

Calculate  $f_1 = f(\mathbf{x}^{(k)})$ ,  $f_2 = f(\mathbf{z}^{(n+1)})$ ,  $f_3 = f(2\mathbf{z}^{(n+1)} - \mathbf{x}^{(k)})$ .

IF either  $f_3 \leq f_1$  and/or  $(f_1 - 1 - 2f_2 + f_3)(f_1 - f_2 - \Delta)^2 \geq 0.5\Delta(f_1 - f_2)^2$

THEN

use the old set of directions  $[\mathbf{s}^{(1)}, \dots, \mathbf{s}^{(n)}]$ ;

set  $\mathbf{x}^{(k+1)} = \mathbf{z}^{(n+1)}$  or  $\mathbf{x}^{(k+1)} = 2\mathbf{z}^{(n+1)} - \mathbf{x}^{(k)}$ , whichever yields the lowest value of  $f(x)$ ;

initialize  $\mathbf{z}^{(1)} = \mathbf{x}^{(k+1)}$ ;

increment counter  $k \leftarrow k + 1$ ;

set  $i = 1$ , go to step 2.1.

ELSE define the search direction (pattern)

$\mathbf{s} = \mathbf{z}^{(n+1)} - \mathbf{x}^{(k)}$ ;

find the value  $\lambda^*$  minimizing the function  $f(\mathbf{z}^{(n+1)} + \lambda\mathbf{s})$ .

define the new set of directions  $[\mathbf{s}^{(1)}, \dots, \mathbf{s}^{(m-1)}, \mathbf{s}^{(m+1)}, \dots, \mathbf{s}^{(n)}, \mathbf{s}]$ ;

set  $\mathbf{x}^{(k+1)} = \mathbf{z}^{(n+1)} + \lambda^*\mathbf{s}$ ;

initialize  $\mathbf{z}^{(1)} = \mathbf{x}^{(k+1)}$ ;

increment counter  $k \leftarrow k + 1$ ;

set  $i = 1$ , go to step 2.1.

END IF

### 3. Termination check

A satisfactory termination criterion is generally to stop whenever at any stage of the algorithm the change in the variables is less than the required accuracy, that is when  $\|\mathbf{z}^{(n+1)} - \mathbf{x}^{(k)}\| \leq \epsilon$ .

In terms of the termination criterion, Powell [1] gives a more elaborate termination check procedure. This is defined by the following steps:

- Specify a set of accuracies, for each variable independently,  $\epsilon_1, \dots, \epsilon_n$ , each of which is greater than zero.
- Apply the standard Powell's method until a complete cycle of  $n$  directional minimizations causes a change of less than 1/10th of the desired accuracy

in the variables, individually. Call the resulting point  $\mathbf{y}^{(A)}$ .

- Increase every variable by 10 times the corresponding specified accuracy.
- Apply the standard Powell's method from this point until a complete cycle of  $n$  directional minimizations causes a change of less than 1/10th of the desired accuracy in the variables, individually. Call the resulting point  $\mathbf{y}^{(B)}$ .
- Define a search direction  $\mathbf{s}^{(AB)} = \mathbf{y}^{(A)} - \mathbf{y}^{(B)}$ . Calculate  $\lambda^*$  minimizing  $f(\mathbf{y}^{(A)} + \lambda \mathbf{s}^{(AB)})$ . Set  $\mathbf{y}^{(C)} = \mathbf{y}^{(A)} + \lambda \mathbf{s}^{(AB)}$ .
- Assume that the process has converged if the components (individually) of the vectors  $(\mathbf{y}^{(A)} - \mathbf{y}^{(C)})$  and  $(\mathbf{y}^{(B)} - \mathbf{y}^{(C)})$  are less than 1/10th of the set accuracies. If this does not hold, proceed to the next step.
- Replace the search direction  $\mathbf{s}^{(1)}$  by  $(\mathbf{y}^{(A)} - \mathbf{y}^{(C)})$  and restart the procedure from step 2 onwards (present termination control procedure).

The termination procedure proposed above by Powell is expected to be more reliable, but it is more expensive since the entire minimization problem has to be resolved at least twice, until the tight convergence criteria are satisfied.

The method has a quadratic termination property, minimizing quadratic functions in predetermined number of operations, requiring  $n^2 + O(n)$  line searches. The directions generated also by the method can be shown to be conjugate (e. g. [2]).

To remedy the case where directions will tend gradually to become linearly dependent (in the original version, step 2.2a) a modification, originally proposed by Powell, is also given in step 2.2b.

### Introduction

We are concerned with Nonlinear Programming problems defined in the following way:

$$\begin{aligned} & \text{Minimize} && f(x) \\ & \text{subject to} && h(x) = 0 \\ & && g(x) \leq 0 \\ & && x \in \Omega, \end{aligned} \quad (1)$$

where  $h : \mathbb{R}^n \rightarrow \mathbb{R}^m$ ,  $g : \mathbb{R}^n \rightarrow \mathbb{R}^p$ ,  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  are continuous and  $\Omega \subset \mathbb{R}^n$  is a closed set. From now on  $\|\cdot\|$  represents the Euclidean norm and  $v_+$  means  $\max\{0, v\}$ . The set  $\mathbb{R}_+$  will be the set of nonnegative real numbers.

The Powell–Hestenes–Rockafellar (PHR) Augmented Lagrangian [42,54,56] is given by:

$$L_\rho(x, \lambda, \mu) = f(x) + \frac{\rho}{2} \left\{ \sum_{i=1}^m \left[ h_i(x) + \frac{\lambda_i}{\rho} \right]^2 + \sum_{i=1}^p \left[ \left( g_i(x) + \frac{\mu_i}{\rho} \right)_+ \right]^2 \right\}, \quad (2)$$

for all  $x \in \mathbb{R}^n$ ,  $\lambda \in \mathbb{R}^m$ ,  $\mu \in \mathbb{R}_+^p$ .

PHR-based Augmented Lagrangian methods for solving (1) are based on the iterative (approximate) minimization of  $L_\rho$  with respect to  $x \in \Omega$ , followed by the updating of the penalty parameter  $\rho$  and the Lagrange multipliers approximations  $\lambda$  and  $\mu$ . The most popular practical Augmented Lagrangian method gave rise to the LANCELOT package [24,25,26]. LANCELOT does not use inequality constraints  $g(x) \leq 0$  in its problem formulation. When an inequality constraint  $g_i(x) \leq 0$  appears in a practical problem, it is replaced by  $g_i(x) + s_i = 0$ ,  $s_i \geq 0$ . The convergence of the LANCELOT algorithm to KKT points was proved in [24] using regularity assumptions. Under weaker assumptions that involve the Constant Positive Linear Dependence (CPLD) constraint qualification [4,55], KKT-convergence was proved in [2] for a variation of the LANCELOT method. In the original LANCELOT method  $\Omega$  was a box. A generalization where  $\Omega$  is a polytope may be found in [23].

The motivation of (2) comes from the classical External Penalty method [27,34,36]. In this method one minimizes the function given by

$$\Phi_\rho(x) = f(x) + \frac{\rho}{2} \left[ \sum_{i=1}^m h_i(x)^2 + \sum_{i=1}^p [g_i(x)_+]^2 \right], \quad (3)$$

for successive values of  $\rho$  that tend to infinity. If, after minimizing (3) for a given  $\rho$ , a satisfactory feasibility is not achieved, the External Penalty philosophy leads to increase the value of  $\rho$ . If  $\rho$  is very large, the problem of minimizing  $\Phi_\rho$  may become very difficult for ordinary minimization solvers.

The Augmented Lagrangian philosophy is different. Assume that the result of minimizing  $\Phi_\rho$ , for a given  $\rho$  is not satisfactory, in terms of feasibility. Then, instead of increasing  $\rho$  (or, perhaps, besides increasing  $\rho$ ) one modifies the origin with respect to which infeasibility

is penalized. For example, suppose that, after the minimization of  $\Phi_\rho$  we obtain  $x$  such that  $h_i(x) = c \neq 0$ . A common sense conjecture would be that this “disappointing” result was obtained because we punished the deviation of  $h_i(x)$  with respect to 0, whereas the correct strategy would be to punish the deviation with respect to  $-c$ . This leads to the Shifted Penalty idea, in which, instead of  $\Phi_\rho$ , one uses the Shifted Penalty function:

$$\Phi_\rho(x, c, d) = f(x) + \frac{\rho}{2} \left[ \sum_{i=1}^m (h_i(x) + c_i)^2 + \sum_{i=1}^p [(g_i(x) + d_i)_+]^2 \right]. \quad (4)$$

Writing  $c_i = \lambda_i/\rho$  and  $d_i = \mu_i/\rho$  we observe that the Shifted Penalty strategy coincides with the Augmented Lagrangian one. The naive modification of the shifts  $c_i, d_i$  sketched above gives rise to the best known (first-order) updating formula for the Lagrange multipliers in the Augmented Lagrangian method. It is interesting to observe that this intuitive reasoning is independent of the smoothness of  $f, h$  and  $g$ . In this article we give preference to matrix-free updating procedures, which excludes the consideration of higher order estimates [28,35].

In [3] a new PHR-like algorithm was introduced that does not use slack variables to complete inequality constraints and admits general constraints in the lower-level set  $\Omega$ . In the box-constraint case, subproblems are solved using a technique introduced in [13], which improves the GENCAN algorithm [12]. CPLD-based convergence and penalty-parameter boundedness were also proved in [3] under suitable conditions on the problem.

In addition to its intrinsic adaptability to the case in which arbitrary constraints are included in  $\Omega$ , the following positive characteristics of the Augmented Lagrangian approach for solving (1) must be mentioned:

1. Augmented Lagrangian methods proceed by sequential resolution of simple problems. Progress in the analysis and implementation of simple-problem optimization procedures produces an almost immediate positive effect on the effectiveness of Augmented Lagrangian algorithms. Box-constrained optimization is a dynamic area of practical optimization from which we can expect Augmented Lagrangian improvements.
2. Global minimization of the subproblems implies convergence to global minimizers of the Augmented Lagrangian method [11]. There is a large field for research on global optimization methods for box-constraint optimization. When the global box-constraint optimization problem is satisfactorily solved in practice, the effect on the associated Augmented Lagrangian method for the Nonlinear Programming problem is immediate.
3. Most box-constrained optimization methods are guaranteed to find stationary points. In practice, good methods do more than that. The line-search procedures of [12], for example, include extrapolation steps that are not necessary at all from the point of view of KKT convergence. However, they enhance the probability of convergence to global minimizers. As a consequence, the probability of convergence to Nonlinear Programming global minimizers of a practical Augmented Lagrangian method is enhanced too.
4. The global convergence theory of Augmented Lagrangian methods [11] does not need differentiability of the functions that define the Nonlinear Programming problem. In practice, this indicates that the Augmented Lagrangian approach may be successful in situations where smoothness is dubious.
5. The Augmented Lagrangian approach can be adapted to the situation in which analytic derivatives are not computed. See [47] for a derivative-free version of LANCELOT.
6. In many practical problems the Hessian of the Lagrangian is structurally dense (in the sense that any entry may be different from zero at different points) but generally sparse (given a specific point in the domain, the particular Lagrangian Hessian is a sparse matrix). As an example of this situation, consider the following formulation [18,19] of the problem of fitting circles of radii  $r$  within a circle of radius  $R$  without overlapping:
 
$$\begin{aligned} \text{Min } & \sum_{i < j} \max \{0, 4r^2 - \|p_i - p_j\|_2^2\}^2 \\ & \text{subject to } \|p_i\|_2^2 \leq (R - r)^2. \end{aligned}$$

The Hessian of the objective function is structurally dense but sparse at any point such that points  $p_i$  are “well distributed” within the big circle, since

only pairs of overlapping small circles appear in the expression of the objective function. Newtonian methods usually have difficulties with this situation, both in terms of memory and computer time since the sparsity pattern of the matrix changes from iteration to iteration. This difficulty is almost irrelevant for the Augmented Lagrangian approach if one uses a low-memory box-constraint solver.

7. Independently of the Lagrangian Hessian density, the structure of the KKT system may be very poor for sparse factorizations. This is a serious difficulty for Newton-based methods but not for suitable implementations of the Augmented Lagrangian PHR algorithm.
8. If the Nonlinear Programming problem has many inequality constraints the usual slack-variable approach of Interior-Point methods (also used in [2,24]) may be inconvenient. There are several approaches to reduce the effect of the presence of many slacks, but they may not be as effective as not using slacks at all.
9. Huge problems have obvious inconvenients in terms of storage requirements. The Augmented Lagrangian approach provides a radical remedy: problem data may be computed “on the flight”, used when required in the subproblem, and not stored at all. This is not possible if one uses matrixial approaches, independently of the sparsity strategy adopted.
10. If, at the solution of the problem, some strong constraint qualification fails to hold, the performance of Newton-like algorithms could be severely affected. The Augmented Lagrangian is not as sensitive to this type of inconvenient.

The amount of research dedicated to Augmented Lagrangian methods decreased in the 21th century. Modern methods, based on interior-point techniques, sequential quadratic programming, trust regions, restoration, nonmonotone strategies and advanced sparse linear algebra procedures attracted much more attention.

A theoretical reason, and its practical consequence, seems to be behind this switch of interest. Roughly speaking, under suitable assumptions, Interior-Point Newtonian techniques converge quadratically (or, at least, superlinearly) whereas practical Augmented Lagrangian generally converge only linearly. Therefore, if both methods converge to the same point, and the pre-

cision required is strict enough, an Interior-Point Newtonian method will require less computer time than an Augmented Lagrangian method, independently of the work per iteration. Several attempts have been made to alleviate both the slow-convergence behavior as the ill-conditioning of the subproblems [14,21,32,33,39,49]. Behind these attempts is the fact that the optimality conditions of the Augmented Lagrangian (and Penalty) subproblems may be decomposed in such a way that, for  $\rho$  large, resemble the KKT conditions of the original problem. This fact may be exploited in several ways and makes it possible that good implementations of the Augmented Lagrangian method be quite competitive with Interior-Point Newtonian techniques, even when high precision is the main requirement at the solution.

The general form of the Augmented Lagrangian method based on the PHR formula considered in this article is the following.

#### Algorithm 1

Let  $\lambda_{\min} < \lambda_{\max}$ ,  $\mu_{\max} > 0$ ,  $\gamma > 1$ ,  $0 < \tau < 1$ . Let  $\{\varepsilon_k\}$  be a sequence of nonnegative numbers such that  $\lim_{k \rightarrow \infty} \varepsilon_k = 0$ . Let  $\lambda_i^1 \in [\lambda_{\min}, \lambda_{\max}]$ ,  $i = 1, \dots, m$ ,  $\mu_i^1 \in [0, \mu_{\max}]$ ,  $i = 1, \dots, p$ , and  $\rho_1 > 0$ . Initialize  $k \leftarrow 1$ .

#### Step 1. Solving the subproblem.

Compute  $x^k \in \mathbb{R}^n$  an approximate solution of

$$\text{Minimize } L_{\rho_k}(x, \lambda^k, \mu^k) \text{ subject to } x \in \Omega. \quad (5)$$

#### Step 2. Define

$$V_i^k = \max \left\{ g_i(x^k), -\frac{\mu_i^k}{\rho_k} \right\}, i = 1, \dots, p.$$

If  $k = 1$  or

$$\max \left\{ \|h(x^k)\|_{\infty}, \|V^k\|_{\infty} \right\} \leq \tau \max \left\{ \|h(x^{k-1})\|_{\infty}, \|V^{k-1}\|_{\infty} \right\}, \quad (6)$$

define  $\rho_{k+1} = \rho_k$ . Otherwise, define  $\rho_{k+1} = \gamma \rho_k$ .

**Step 3.** Compute  $\lambda_i^{k+1} \in [\lambda_{\min}, \lambda_{\max}]$ ,  $i = 1, \dots, m$  and  $\mu_i^{k+1} \in [0, \mu_{\max}]$ ,  $i = 1, \dots, p$ . Set  $k \leftarrow k + 1$  and go to Step 1.

In the practical implementation of Algorithm 1, we will compute  $\lambda_i^{k+1} = \min\{\max\{\lambda_{\min}, \lambda_i^k + \rho_k h_i(x^k)\}, \lambda_{\max}\}$  and  $\mu_i^{k+1} = \min\{\max\{0, \mu_i^k + \rho_k g_i(x^k)\}, \mu_{\max}\}$ . These are safeguarded first-order estimations of the Lagrange multipliers. The safeguards defined by  $\lambda_{\min}, \lambda_{\max}$  and  $\mu_{\max}$  are necessary to prove the global convergence results. Some authors prefer to define Augmented Lagrangian algorithms without safeguards for the Lagrange multipliers [9,26]. However, boundedness of the multiplier estimates are necessary to prove the main convergence results and, if this boundedness is not algorithmically forced, it may be guaranteed only by means of strong problem assumptions.

Different Augmented Lagrangian algorithms will differ only in Step 1. In each case we will need a precise definition for the approximate solution of (5).

**Cases**

**Augmented Lagrangians and Global Optimization**

In this section we will only assume continuity of the functions  $f, h$  and  $g$ . Throughout the section we will assume that a global minimizer of (1) exists. Several versions of the Augmented Lagrangian method generate sequences that converge to global minimizers, provided that global minimizers of the subproblems are available. This property is inherited from the analogous property of the External Penalty method. A practical consequence of this property is the fact that Augmented Lagrangian methods tend to find feasible points with lower objective function values than other nonlinear programming solvers, when clever aggressive algorithms are used for solving the subproblems.

Here we will assume we are able to find an approximate global minimizer defined by the tolerance  $\varepsilon_k$ . At each iteration,  $x^k$  will belong to  $\Omega \cap P_k$ , where  $P_k$  is an auxiliary set to which a global minimizer of (1) necessarily belongs. For example,  $P_k$  may be a set that contains the feasible region of (1). The presence of the constraints defined by  $P_k$  helps in the global resolution of the subproblems. Obviously, in the absence of algorithmic advantages,  $P_k$  may be defined as being  $\mathbb{R}^n$ . Algorithm 2 will be Algorithm 1, where Step 1 is defined as follows.

**Step 1.** Let  $P_k \subset \mathbb{R}^n$  be a closed set such that a global minimizer  $z$  (the same for all  $k$ ) belongs to  $P_k$ . Find an  $\varepsilon_k$ -global minimizer  $x^k$  of the problem

Min  $L_{\rho_k}(x, \lambda^k, \mu^k)$  subject to  $x \in \Omega \cap P_k$ . That is  $x^k \in \Omega \cap P_k$  is such that:

$$L_{\rho_k}(x^k, \lambda^k, \mu^k) \leq L_{\rho_k}(x, \lambda^k, \mu^k) + \varepsilon_k, \quad (7)$$

for all  $x \in \Omega \cap P_k$ . The  $\varepsilon_k$ -global minimum can be obtained using a deterministic global optimization approach, such as the  $\alpha$ BB method [37].

In most deterministic global optimization methods for solving (7) the point  $x^{k-1}$  is not used as “initial approximation” as most local optimization solvers do. In fact, the concept of “initial point” has no meaning at all in this case. The information used by the Outer iteration  $k$  is the set of approximate Lagrange multipliers computed after iteration  $k - 1$ , and nothing else.

Theorems 2 [11] is the main convergence result related to Algorithm 2. Limit points of sequences generated by this algorithm are feasible global minimizers.

**Theorem 2** *Assume that the sequence  $\{x^k\}$  is well defined and admits a limit point  $x^*$ . Then,  $x^*$  is a global minimizer of (1). If, instead of  $\varepsilon_k \rightarrow 0$  we assume only that  $\varepsilon_k \rightarrow \varepsilon \geq 0$ ,  $x^*$  will be feasible and  $f(x^*) \leq f(x) + \varepsilon$  for all feasible  $x$ .*

The problem of finding  $x^k \in \Omega \cap P_k$  satisfying (7) consists of finding an  $\varepsilon_k$ -global solution of the problem:

$$\text{Minimize } L_{\rho_k}(x, \lambda^k, \mu^k) \text{ subject to } x \in \Omega \cap P_k. \quad (8)$$

When  $\Omega$  and  $P_k$  are defined by linear equality and/or inequality constraints and  $f, h, g$  admit continuous second derivatives, this problem has been solved in [11] using the  $\alpha$ BB algorithm [37].

The practical results presented in [11] corroborate the theory and give hints on the effectivity of the Augmented Lagrangian method for global optimization.

**Augmented Lagrangian Algorithm with Arbitrary Lower-Level Constraints**

In [2,3] safeguarded Augmented Lagrangian methods were defined that converge to KKT points under the CPLD constraint qualification and exhibit good properties in terms of penalty parameter boundedness. ALGENCAN, which is publicly available in the TANGO Project web page <http://www.ime.usp.br/~egbirgin/tango/>, is the application of the main algorithm in [3] to problem (1).

In this section we will assume that  $f, h, g$  admit continuous first (and, sometimes, second) derivatives. Observe that the function  $L_{\rho}$ , defined in (2) has continuous first derivatives with respect to  $x$ , but second derivatives are not defined at the points such that  $g_i(x) + \mu_i/\rho = 0$ .

In Algorithm 3 we will assume that the set  $\Omega$  is defined by

$$\Omega = \{x \in \mathbb{R}^n \mid \underline{h}(x) = 0, \underline{g}(x) \leq 0\}, \quad (9)$$

where  $\underline{h} : \mathbb{R}^n \rightarrow \mathbb{R}^m, \underline{g} : \mathbb{R}^n \rightarrow \mathbb{R}^p$  are as smooth as necessary. The constraints defined by  $\Omega$  are called *lower-level* constraints. Algorithm 3 is identical to Algorithm 1 except at Step 1. The subproblem resolution at Algorithm 3 is as given below.

**Step 1.** Compute (if possible)  $x^k \in \mathbb{R}^n$  such that there exist  $v^k \in \mathbb{R}^m, u^k \in \mathbb{R}^p$  satisfying

$$\begin{aligned} \|\nabla L_{\rho_k}(x^k, \lambda^k, \mu^k) + \sum_{i=1}^m v_i^k \nabla \underline{h}_i(x^k) \\ + \sum_{i=1}^p u_i^k \nabla \underline{g}_i(x^k)\| \leq \varepsilon_k, \end{aligned} \quad (10)$$

$$u_i^k \geq 0, \underline{g}_i(x^k) \leq \varepsilon_k \text{ for all } i = 1, \dots, p, \quad (11)$$

$$\underline{g}_i(x^k) < -\varepsilon_k \Rightarrow u_i^k = 0 \text{ for all } i = 1, \dots, p, \quad (12)$$

$$\|\underline{h}(x^k)\| \leq \varepsilon_k. \quad (13)$$

The conditions (10)–(13) are approximate KKT conditions for the minimization of  $L_{\rho_k}$  subject to the lower level constraints. If  $\Omega = \mathbb{R}^n$  these conditions reduce to  $\|\nabla L_{\rho_k}(x^k, \lambda^k, \mu^k)\| \leq \varepsilon_k$ .

The CPLD (Constant Positive Linear Dependence) condition defined by Qi and Wei [55] is a crucial tool in the convergence theory of Algorithm 3. In [4] it has been proved that CPLD is a constraint qualification and its relation with other constraint qualifications have been reported.

A First-Order Constraint Qualification is a property of feasible points of a Nonlinear Programming problem such that, when verified at a local minimizer, implies that the local minimizer is a KKT point. The Linear-Independence Constraint Qualification (LICQ),

also called *regularity*, says that the gradients of the active constraints at the feasible point  $x$  are linearly independent.

Assume that the feasible set of a nonlinear programming problem is given by  $\bar{h}(x) = 0, \bar{g}(x) \leq 0$ , where  $\bar{h} : \mathbb{R}^n \rightarrow \mathbb{R}^m$  and  $\bar{g} : \mathbb{R}^n \rightarrow \mathbb{R}^p$ . Let  $I(x) \subset \{1, \dots, p\}$  be the set of indices of the active inequality constraints at the feasible point  $x$ . Let  $I_1 \subset \{1, \dots, m\}, I_2 \subset I(x)$ . The subset of gradients of active constraints that correspond to the indices  $I_1 \cup I_2$  is said to be *positively linearly dependent* if there exist multipliers  $\lambda, \mu$  such that

$$\sum_{i \in I_1} \lambda_i \nabla \bar{h}_i(x) + \sum_{i \in I_2} \mu_i \nabla \bar{g}_i(x) = 0, \quad (14)$$

with  $\mu_i \geq 0$  for all  $i \in I_2$  and  $\sum_{i \in I_1} |\lambda_i| + \sum_{i \in I_2} \mu_i > 0$ . Otherwise, we say that these gradients are *positively linearly independent*.

The Mangasarian–Fromovitz Constraint Qualification MFCQ says that, at the feasible point  $x$ , the gradients of the active constraints are positively linearly independent [48,57].

The CPLD Constraint Qualification says that, if a subset of gradients of active constraints is positively linearly dependent at the feasible point  $x$  (i.e. (14) holds), then there exists  $\delta > 0$  such that the vectors

$$\{\nabla \bar{h}_i(y)\}_{i \in I_1}, \{\nabla \bar{g}_j(y)\}_{j \in I_2}$$

are linearly dependent for all  $y \in \mathbb{R}^n$  such that  $\|y - x\| \leq \delta$ .

The main convergence theorems related to Algorithm 3 were proved in [3]. Theorem 3 says that, if a limit point satisfies the CPLD condition with respect to the lower-level constraints, then this point is stationary with respect to a natural infeasibility measure. In other words, this theorem says that, if the limit point is not feasible, then (very likely) it is a local minimizer of the upper-level infeasibility, subject to lower-level feasibility.

**Theorem 3** *Let  $\{x^k\}$  be a sequence generated by Algorithm 3. Let  $x^*$  be a limit point of  $\{x^k\}$ . Then, if the sequence of penalty parameters  $\{\rho_k\}$  is bounded, the limit point  $x^*$  is feasible. Otherwise, at least one of the following possibilities hold:*

(i)  $x^*$  is a KKT point of the problem

$$\text{Minimize } \frac{1}{2} \left[ \sum_{i=1}^m h_i(x)^2 + \sum_{i=1}^p [g_i(x)_+]^2 \right] \quad (15)$$

subject to  $x \in \Omega$ .

(ii)  $x^*$  does not satisfy the CPLD constraint qualification associated with  $\Omega$ .

From the point of view of optimality, we are interested in the status of feasible limit points. Theorem 4 says that, under the CPLD constraint qualification, feasible limit points are stationary (KKT) points of the original problem. Since CPLD is strictly weaker than the Mangasarian–Fromovitz (MF) constraint qualification, it turns out that Theorem 4 is stronger than results where KKT conditions are proved under MF or regularity assumptions.

**Theorem 4** *Let  $\{x^k\}$  be a sequence generated by Algorithm 3. Assume that  $x^*$  is a feasible limit point of (1)–(9) that satisfies the CPLD constraint qualification related to set of all the constraints. Then,  $x^*$  is a KKT point of the problem (1)–(9).*

Theorems 3 and 4 are interesting and useful but they do not explain why it is better to use the Augmented Lagrangian instead of a pure penalty method. In fact, if we define  $\lambda^k = 0, \mu^k = 0$  for all  $k$  these two theorems remain valid and we are in presence of a variation of the External Penalty method. The use of Lagrange multipliers estimates is justified in Theorem 5, which is also proved in [3]. Theorem 5 says that, under appropriate conditions, the sequence of penalty parameters  $\{\rho_k\}$  do not tend to infinity. In practice, this means that the minimization subproblems tend to remain well-conditioned and that minimization algorithms for solving the subproblems will not face difficulties associated to very large values of  $\rho_k$ .

**Theorem 5** *Assume that:*

1. *The sequence  $\{x^k\}$  is generated by the application of Algorithm 3 to problem (1)–(9) and  $\lim_{k \rightarrow \infty} x^k = x^*$ .*
2. *In Algorithm 3 we use the updating rules  $\lambda_i^{k+1} = \max\{\lambda_{\min}, \min\{\lambda_i^k + \rho_k h_i(x^k), \lambda_{\max}\}\}$  and  $\mu_i^{k+1} = \max\{0, \min\{\mu^k + \rho_k g_i(x^k), \mu_{\max}\}\}$ .*
3. *The point  $x^*$  is feasible ( $h(x^*) = 0, \underline{h}(x^*) = 0, g(x^*) \leq 0$  and  $\underline{g}(x^*) \leq 0$ ).*

4. *The gradients of the active constraints at  $x^*$  are linearly independent. The associated (unique) Lagrange multipliers are  $\lambda^*, \mu^*, u^*, v^*$ .*
5. *The functions  $f, h, g, \underline{h}$  and  $\underline{g}$  admit continuous second derivatives in a neighborhood of  $x^*$ .*
6. *Define the tangent subspace  $T$  as the set of all  $z \in \mathbb{R}^n$  such that  $\nabla h(x^*)^T z = \nabla \underline{h}(x^*)^T z = 0, \nabla g_i(x^*)^T z = 0$  for all  $i$  such that  $g_i(x^*) = 0$  and  $\nabla \underline{g}_i(x^*)^T z = 0$  for all  $i$  such that  $\underline{g}_i(x^*) = 0$ . Then, for all  $z \in T, z \neq 0$ ,*

$$z^T \left[ \nabla^2 f(x^*) + \sum_{i=1}^m \lambda_i^* \nabla^2 h_i(x^*) + \sum_{i=1}^p \mu_i^* \nabla^2 g_i(x^*) + \sum_{i=1}^m \nu_i^* \nabla^2 \underline{h}_i(x^*) + \sum_{i=1}^p u_i^* \nabla^2 g_i(x^*) \right] z > 0.$$

7. *For all  $i = 1, \dots, m, j = 1, \dots, p, \lambda_i^* \in (\lambda_{\min}, \lambda_{\max}), \mu_j^* \in [0, \mu_{\max})$ .*
8. *For all  $i$  such that  $g_i(x^*) = 0$ , we have  $\mu_i^* > 0$ . (Strict complementarity in the upper level.)*
9. *There exists a sequence  $\eta_k \rightarrow 0$  such that  $\varepsilon_k \leq \eta_k \max\{\|h(x^k)\|, \|V^k\|\}$  for all  $k = 0, 1, 2, \dots$ . Then, the sequence of penalty parameters  $\{\rho_k\}$  is bounded.*

Observe that strict complementarity is imposed only to the constraints in the upper-level set. In the lower-level set it is admissible that  $\underline{g}_i(x^*) = u_i^* = 0$ . Observe, too, that the assumption on the reduced positive definiteness on the Hessian of the Lagrangian is weaker than the usual second-order sufficiency assumption [36], since the subspace  $T$  is orthogonal to the gradients of all active constraints, and no exception is made with respect to active constraints with null multiplier  $u_i^*$ . In fact, this is not a second-order sufficiency assumption for local minimizers. It holds for the problem of minimizing  $x_1 x_2$  subject to  $x_2 - x_1 \leq 0$  at  $(0, 0)$  although  $(0, 0)$  is not a local minimizer of this problem.

The last hypothesis of Theorem 5 imposes that the precision in which subproblems are solved should tend to zero faster than the measure of infeasibility-noncomplementarity. Some authors [30,31,40,41], in slightly different contexts, also used convergence toler-

ances that depend on the degree of infeasibility of the current inner iterate.

The Augmented Lagrangian method is the only efficient nonlinear programming algorithm that can take obvious advantage of the existence of case-oriented optimization solvers for problems whose constraints are a subset of the original problem constraints. The partition of the constraints in “easy” and “complicate” is very common in engineering applications. In the Augmented Lagrangian framework, easy constraints go to the lower level and complicate constraints contribute to the Augmented Lagrangian function. The most common situation is the one in which lower level constraints are linear. Location problems of this type are described in [3]. Problems with more than  $3 \times 10^6$  variables and  $14 \times 10^6$  constraints are solved in this way, using moderate computer time. The codes are free for download through the TANGO Project web page <http://www.ime.usp.br/~egbirgin/tango/>. The key for the efficiency of the Augmented Lagrangian method in these problems is the use of the Spectral Projected Gradient method [15,16,17] for solving the subproblems.

### Augmented Lagrangian Algorithm with Lower-Level Box Constraints

In most applications, the definition of the lower level set  $\Omega$  in (1) is:

$$\Omega = \{x \in \mathbb{R}^n \mid a \leq x \leq b\}, \quad (16)$$

where  $a, b \in \mathbb{R}^n$ ,  $a \leq b$ . In other words,  $\Omega$  is an  $n$ -dimensional box. By the continuity of the Augmented Lagrangian function and the compactness of  $\Omega$ , this definition guarantees that a global minimizer of the subproblem exists. Many times one adds bound constraints in the lower level of a nonlinear programming problem in order to guarantee solubility of the subproblems and boundedness of the sequence  $\{x^k\}$ .

Obviously, the constraints (16) may be written in the form (9) and, so, Algorithm 3 may be applied and Theorems 3, 4 and 5 hold. However, many specific algorithms for box-constrained optimization exist that use stronger convergence criteria than the one given in (10)–(13). Namely, in box-constrained minimization one usually declares convergence when

$$x^k \in \Omega \text{ and } \|P_{\Omega}(x^k - \nabla L_{\rho_k}(x^k, \lambda^k, \mu^k))\|_k \leq \varepsilon_k, \quad (17)$$

where  $P_{\Omega}$  denotes the Euclidean projection on  $\Omega$ . The condition (17) implies (10)–(13). This leads us to define Algorithm 4 as Algorithm 1 where Step 1 is defined by (17). Theorems 3, 4 and 5 obviously apply to Algorithm 4. It must be observed, however, that, since all the points of  $\Omega$  satisfy CPLD, Theorem 3 guarantees that the limit points of the generated sequence  $\{x^k\}$  are KKT points of  $\sum_{i=1}^m h_i(x)^2 + \sum_{i=1}^p [g_i(x)_+]^2$  subject to  $x \in \Omega$ .

Algorithm 4, with the subproblems solved by the box-constraint solver GENCAN [12], with the modifications introduced in [13], is called ALGENCAN. The code that implements ALGENCAN is free for download in the TANGO Project web page <http://www.ime.usp.br/~egbirgin/tango/>. It is written in Fortran 77 (double precision) and interfaces with AMPL, CUTEr, C/C++, Python and R (language and environment for statistical computing) are available.

The default version of ALGENCAN uses  $\tau = 0.5$ ,  $\gamma = 10$ ,  $\lambda_{\min} = -10^{20}$ ,  $\mu_{\max} = \lambda_{\max} = 10^{20}$ ,  $\varepsilon_k = 10^{-4}$  for all  $k$ ,  $\lambda_1 = 0$ ,  $\mu_1 = 0$  and  $\rho_1 = \max\{10^{-6}, \min\{10, (2|f(x^0)|)/(\|h(x^0)\|^2 + \|g(x^0)_+\|^2)\}\}$ . The default convergence criterion is  $\max\{\|h(x^k)\|_{\infty}, \|V^k\|_{\infty}\} \leq 10^{-4}$ . The condition  $\|V^k\|_{\infty} \leq 10^{-4}$  guarantees that, for all  $i = 1, \dots, p$ ,  $g_i(x^k) \leq 10^{-4}$  and that  $(\mu_i^k + \rho_k g_i(x^k))_+ = 0$  whenever  $g_i(x^k) < -10^{-4}$ . This means that, approximately, feasibility and complementarity hold at the final point. Dual feasibility with tolerance  $10^{-4}$  is guaranteed by (17) and the choice of  $\varepsilon_k$ .

The celebrated package LANCELOT also solves the basic Nonlinear Programming problem with box constraints, but each inequality constraint is completed with a slack variable to become an equality constraint plus a lower-level bound.

A comparison between the default versions of ALGENCAN and LANCELOT B using all the (1023) problems of the CUTEr collection was reported in [3]. The executions were stopped when the precision  $10^{-4}$  was achieved or when the allowed CPU time (5 min on an 1.8 GHz AMD Opteron 244 processor, 2 Gb of RAM memory and Linux operating system) was exhausted. Codes are in Fortran 77 and the compiler option “-O” was adopted.

Given a fixed problem, for each method  $M \in \{\text{LANCELOT}, \text{ALGENCAN}\}$ ,  $x_{\text{final}}^M$  was defined in [3] as the final point obtained by  $M$  when solving the given problem.

**Practical Augmented Lagrangian Methods, Table 1**  
 Efficiency means number of times that method M obtained the best  $r^M$ . Robustness means the number of times in which  $r^M < \infty$

	ALGENCAN	LANCELOT B
Efficiency	692	544
Robustness	809	763

The point  $x_{\text{final}}^M$  is considered to be *feasible* if

$$\max \left\{ \|h(x_{\text{final}}^M)\|_{\infty}, \|g(x_{\text{final}}^M)_+\|_{\infty} \right\} \leq 10^{-4}.$$

Define

$$f_{\text{best}} = \min_M \{ f(x_{\text{final}}^M) \mid x_{\text{final}}^M \text{ is feasible} \}.$$

It is said that the method  $M$  found a solution of the problem if  $x_{\text{final}}^M$  is feasible and

$$f(x_{\text{final}}^M) \leq f_{\text{best}} + 10^{-3}|f_{\text{best}}| + 10^{-6}$$

or  $\max \{ f_{\text{best}}, f(x_{\text{final}}^M) \} \leq -10^{20}.$

Finally, let  $t^M$  be the computer CPU time that method M used to arrive to  $x_{\text{final}}^M$ . Define

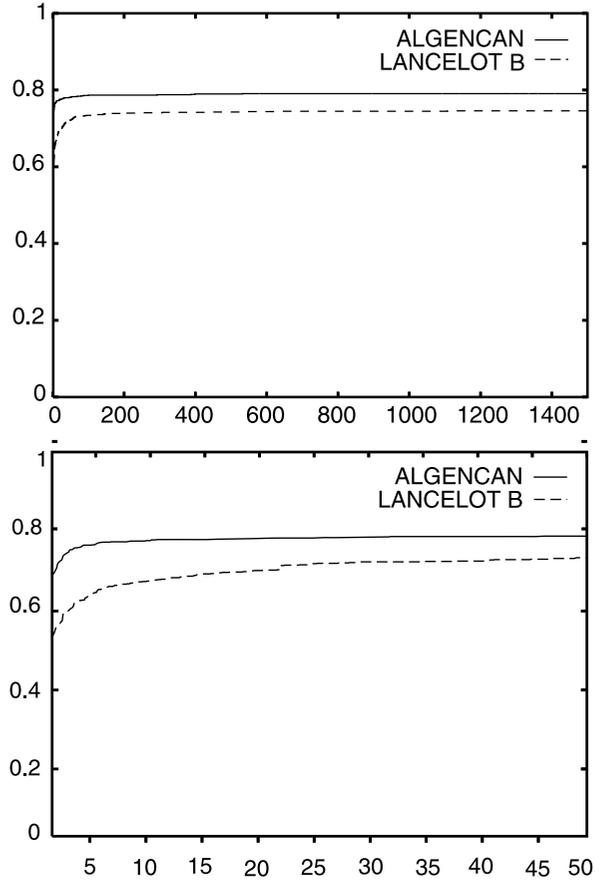

$$r^M = \begin{cases} t^M, & \text{if method M found a solution,} \\ \infty, & \text{otherwise.} \end{cases}$$

The quantity  $r$  was used as performance measurement in [3]. The results of the comparison are reported in the form of performance profiles [29] and a small numerical table. See Fig. 1 and Table 1.<sup>1</sup>

### Alternative Augmented Lagrangians

The main drawback of the PHR formula (2) is that the objective function of the subproblems is not twice

<sup>1</sup>When LANCELOT B solves a feasibility problem (problem with constant objective function), it minimizes the squared infeasibility instead of addressing the original problem. As a result, it sometimes finishes without satisfying the user required stopping criteria (feasibility and optimality tolerances on the the original problem). In 35 feasibility problems, LANCELOT B stopped declaring convergence but the user-required feasibility tolerance was not satisfied at the final iterate. 16 of the 35 problems seem to be problems in which LANCELOT B converged to a stationary point of the infeasibility (large objective function value of the reformulated problem). In the remaining 19 problems (less than 2% of the total number of problems), LANCELOT B seems to stop prematurely. This easy-to-solve inconvenient may slightly deteriorate the robustness of LANCELOT B reported here.

**Practical Augmented Lagrangian Methods, Figure 1**  
 Performance profiles of ALGENCAN and LANCELOT B in the problems of the CUTE collection. Note that there is a CPU time limit of 5 min for each pair method/problem. The second graphic is a zoom of the left-hand side of the first one

continuously differentiable. This is the main motivation for the introduction of many alternative Augmented Lagrangian methods. See, for example, [1,5,6,7,8,22,38,43,45,46,50,51,52,53,58]. Most of them have interesting interpretations as proximal point methods for solving the dual problem, when the original nonlinear programming problem is convex [44]. In [10] a comparison of many different Augmented Lagrangian formulae within an algorithmic framework similar to the one of Algorithm 1 has been performed using the CUTE collection [20]. In general, the PHR formula seems to be more efficient than the alternative ones for the resolution of the selected problems.

### Introduction

The protein folding question is one of the most challenging problems in computational biology. Although the structures of approximately 40,000 proteins have been determined via experimental techniques and cataloged in the Protein Data Bank (PDB) [3], there are thousands more to be discovered. Modeling proteins with computational techniques is especially critical for

proteins that do not easily crystallize or cannot be addressed by NMR techniques.

Protein structure prediction requires searching through a vast conformational space for the native structure. This challenge can be met through the application of powerful algorithms, such as the  $\alpha$ BB global optimization method [1,2,11]. Many ab initio protein structure prediction methods rely on databases and statistical methods to predict short peptide fragments which are subsequently assembled using scoring functions [8,9,23,37,38,39,40,41,44,45]. Other successful approaches apply detailed physics-based force fields and search for the minimum free energy of a protein [5,6,16,17,18,19,20,21,24,25,26,27,28,29,30,31,34,36,42]. For a detailed summary of protein structure prediction methods, the reader is directed to two recent reviews [12,13].

The prediction of residue contacts within  $\alpha$ -helical bundles is critical to the prediction of the overall tertiary structure of these proteins. Predicted interhelical distance restraints can be used to significantly reduce the conformational search space in the protein folding problem. Both modeling [22] and experiments [35] have shown that the residues that define the hydrophobic core are most crucial for folding, limiting the conformational search space. The preference of nonpolar atoms for nonaqueous environments is called the hydrophobic effect [4]. This occurrence is due to the inability of nonpolar molecules to participate in hydrogen bonding in an aqueous environment. The hydrophobic effect is a major stabilization factor for proteins, nucleic acids, and membranes. Because of the dominance of such hydrophobic interactions in protein folding, this paper focuses upon predicting specific hydrophobic residue pair contacts in protein structure. The important contributions of electrostatic, van der Waals, hydrogen bonded, torsional, and solvation energetic terms are included using secondary and tertiary structure prediction methods (e. g., the ASTRO-FOLD approach [16,17,18]).

## Methods

There are three main aspects of the overall approach to the helical topology prediction problem. First a dataset of helical proteins was assembled. This dataset is then used to develop hydrophobic residue-based interheli-

cal contact probabilities. Two optimization models are then presented to minimize these contact probabilities subject to constraints that enforce physically realistic topologies. A summary of the important details of the approach are presented here. A more detailed description of the method is available elsewhere [32].

## Dataset Selection

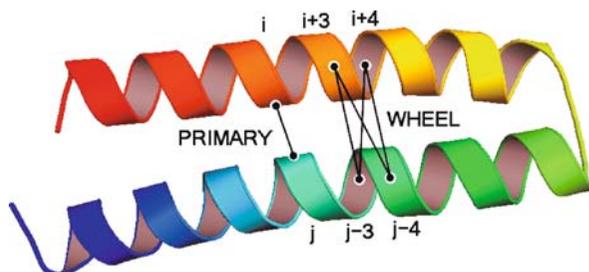

A database PDB set of 318 helical protein structures was compiled to generate probabilities for specific hydrophobic-to-hydrophobic PRIMARY residue contacts and associated hydrophobic-to-hydrophobic WHEEL residue contacts between helices of the same helical protein (this terminology is explained below). They were taken from the following sources: 20 from Table 2 of Zhang et al. [43]; 7 from Table 1 of Huang et al. [15]; 62 from the CATH database [33]; and 229 from the PDB Select 25 Database [14].

## Probability Generation and Probability Sets

The probabilities will be established for both a contact at position  $i$  (denoted as a PRIMARY contact) and any associated contacts in the helical wheel position (denoted as WHEEL contacts). For the purpose of calculating the PRIMARY probabilities, two helices of a given protein in the database PDB set were considered to interact if they had a contact between a pair of residues with a PRIMARY distance between 4.0 Å and 10.0 Å. Unless otherwise specified, distances in this paper refer to  $C^\alpha$ - $C^\alpha$  distances.

For a parallel helix-to-helix interaction, WHEEL contacts include the following residue combinations:  $(i+3)$  to  $(j+3)$ ;  $(i+3)$  to  $(j+4)$ ;  $(i+4)$  to  $(j+3)$ ;  $(i+4)$  to  $(j+4)$ ;  $(i-3)$  to  $(j-3)$ ;  $(i-3)$  to  $(j-4)$ ;  $(i-4)$  to  $(j-3)$ ; and  $(i-4)$  to  $(j-4)$ . For an antiparallel helix-to-helix interaction, the following are the possible WHEEL contacts:  $(i+3)$  to  $(j-3)$ ,  $(i+3)$  to  $(j-4)$ ;  $(i+4)$  to  $(j-3)$ ;  $(i+4)$  to  $(j-4)$ ;  $(i-3)$  to  $(j+3)$ ;  $(i-3)$  to  $(j+4)$ ;  $(i-4)$  to  $(j+3)$ ; and  $(i-4)$  to  $(j+4)$ . Figure 1 illustrates the PRIMARY and WHEEL contacts for an antiparallel helical interaction. Two residues  $k$  and  $l$  that were WHEEL residues of  $i$  and  $j$ , respectively, were considered to interact if the WHEEL distance between them was greater than or equal to 4.0 and less than 12.0 Å.

Formulating the problem as a set of PRIMARY and WHEEL contacts provides a significant advantage over

**Predictive Method for Interhelical Contacts in Alpha-Helical Proteins, Figure 1**

Two interacting  $\alpha$ -helices in the test set protein 1rop (PDB). The helices here interact in an antiparallel manner, hydrophobic residues  $i$  and  $j$  form a PRIMARY contact, and the residues  $(i+3)$ ,  $(i+4)$  can each interact with  $(j-3)$ ,  $(j-4)$  to form WHEEL contacts if both residues of a given pair are hydrophobic. This figure was created with PyMol [7]

other methods. Instead of making assumptions about the form of the helix, such as representing the helix as a simple cylinder, the proposed method is able to address irregular helices. By selecting a set of interhelical point contacts within a specified distance range, the approach can handle the most difficult cases, including those containing helices that bend or kink.

Two helices may interact in one of three possible ways. They may be parallel or antiparallel to one another. The third type of possible interaction will be labeled unclassified. These are cases for which neither the parallel nor the antiparallel label applies. For the model prediction section of this paper, only parallel and antiparallel helical interactions were predicted.

The occurrence frequencies of each of the 36 possible hydrophobic pairs were determined by counting the number of occurrences of hydrophobic-to-hydrophobic minimum interhelical distances within the 4.0 to 10.0 Å distance range. The frequency for each pair was then split into two groups, parallel and antiparallel, based on the relative direction of the interacting helices. The total number of hydrophobic-to-hydrophobic minimum distance contacts was identified as the sum of these 36 occurrence frequencies. The PRIMARY probabilities are then established as the occurrence frequency of a specific hydrophobic pair for a specific directionality divided by the total number of hydrophobic-to-hydrophobic contacts.

Conditional WHEEL probabilities were generated for interacting helices in the database PDB set. Given

that two  $\alpha$ -helices have an interaction with a corresponding hydrophobic-to-hydrophobic minimum interaction distance within 4.0 to 10.0 Å the conditional probability that the residues on the same side of the helical wheel form any hydrophobic-to-hydrophobic contact within 4.0 to 12.0 Å was determined. These probabilities were calculated by considering the number of hydrophobic-to-hydrophobic WHEEL contacts and the total number of possible WHEEL contacts for every specific helix to helix interaction individually, calculating the probability for each interhelical residue contact by averaging over the total number of such contacts after the entire database PDB set has been considered.

### Interhelical Contact Prediction Model

Given the locations of helices in a protein's primary sequence, the next step in the proposed method is to predict the interhelical PRIMARY and WHEEL residue contacts. This is done in order to impose distance constraints upon such contacts in the tertiary structure prediction section of the framework.

To accomplish this task, two mixed-integer linear programming (MILP) optimization problems were formulated. The first MILP problem, denoted as the Level 1 Model, identifies a set of the most probable interhelical PRIMARY contacts. The PRIMARY contacts selected by the Level 1 Model are enhanced by the presence of the most probable WHEEL contacts predicted in the Level 2 Model. This second model also provides a method to distinguish between equally likely results of the Level 1 model.

**Level 1 Model: PRIMARY Interhelical Contacts** In the Level 1 problem, the binary variables  $y_{mn}^a$  and  $y_{mn}^p$  are activated if the helices  $m$  and  $n$  of the same protein interact in an antiparallel or a parallel fashion, respectively. In addition, the binary variables  $w_{ij}^{mn}$  are defined as active when the hydrophobic residue pair  $(i, j)$  forms a PRIMARY contact, where  $i$  is in helix  $m$  and  $j$  is in helix  $n$ .

**Objective Function:** The objective function of Level 1, Eq. (1), corresponds to maximizing the sum of the most probable hydrophobic contacts  $(i, j)$  for the given primary sequence by considering the product of the binary variable  $w_{ij}^{mn}$ , representing the existence of a residue-residue contact, the binary variables  $y_{mn}^a$  and

$y_{mn}^p$ , representing the existence of a helix-helix contact, and the probability of a parallel or antiparallel contact,  $P_{ij;mn}^p$  or  $P_{ij;mn}^a$ , respectively.

$$\max \sum_m \sum_n y_{mn}^a \cdot \sum_i \sum_j w_{ij}^{mn} \cdot P_{ij;mn}^a + \sum_m \sum_n y_{mn}^p \cdot \sum_i \sum_j w_{ij}^{mn} \cdot P_{ij;mn}^p \quad (1)$$

$$y_{mn}^a, y_{mn}^p, w_{ij}^{mn} = \{0, 1\} \quad (2)$$

This objective function is nonlinear due to the products of binary variables that result. The objective function can be reformulated as a linear objective function by introducing a second pair of variables, as described elsewhere [10].

**Residue Contact Rules:** Every hydrophobic amino acid of helix  $m$ ,  $i$ , can have at most one PRIMARY contact with another hydrophobic amino acid of helix  $n$ ,  $j$ , and this is given by Eq. (3). The two terms in this equation are necessary due to the model formulation; it is assumed that the second index is always larger than the first index for any potentially active variables  $w_{ij}$  in order to reduce the number of binary variables.

$$\sum_{j:j>i} w_{ij} + \sum_{j:j<i} w_{ij} \leq 1 \quad (3)$$

Equation (4) prevents any pairs of contacts  $(i, j)$  and  $(i', j')$  from both being specified if either the number of residues between  $i$  and  $i'$  or  $j$  and  $j'$  is less than five or the number of residues between  $i$  and  $i'$  is different than the number of residues between  $j$  and  $j'$  by more than two residues. This requires that  $(i', j')$  cannot be a WHEEL contact to the PRIMARY contact  $(i, j)$  and also limits the size of kinks in the protein backbone that result from a differing separation between  $(i$  and  $i')$  and  $(j$  and  $j')$ .

$$w_{ij}^{mn} + w_{i'j'}^{mn} \leq 1$$

$$\forall(i, i', j, j'): |\text{diff}(i, i') - \text{diff}(j, j')| > 2$$

$$\text{or either } |\text{diff}(i, i')| < 5$$

$$\text{or } |\text{diff}(j, j')| < 5 \quad (4)$$

In this equation,  $\text{diff}(i, i')$  refers to the difference in sequence numbering between  $i$  and  $i'$ .

Equation (5) states that if a PRIMARY contact  $(i, j)$  occurs, then none of the WHEEL residues for  $i$  can also

be part of a PRIMARY contact themselves.

$$w_{kl}^{mn} + w_{ij}^{mn} \leq 1 \quad \forall(i, j, k, l): i, k \in m \text{ and } k \text{ is in a WHEEL position of } i \quad (5)$$

**Helix Contact Rules:** For every helix  $m$ , Eq. (6) establishes the maximum number of PRIMARY contacts that can be specified involving  $m$ . The parameter  $\text{counth}(m)$  is established based upon the number of hydrophobic residues within a helix that are not WHEEL residues to each other.

$$\sum_n (y_{mn}^a + y_{mn}^p) \leq \text{counth}(m) \quad \forall m \quad (6)$$

Equations (7)–(8) require a minimum number of loop residues between two  $\alpha$ -helices to yield helical interactions of a given orientation.

$$y_{mn}^p = 0 \quad \forall(m, n): \text{loop between } (m, n) \text{ has less than 6 AA} \quad (7)$$

$$y_{mn}^a = 0 \quad \forall(m, n): \text{loop between } (m, n) \text{ has less than 1 AA} \quad (8)$$

Equation (9) states that two helices  $m$  and  $n$  can either interact in a parallel or antiparallel fashion, if they interact at all, but in only one manner.

$$y_{mn}^a + y_{mn}^p \leq 1 \quad \forall(m, n) \quad (9)$$

Equations (10)–(13) restrict the topology of helical interactions based upon transitive rules.

$$y_{mn}^a + y_{np}^a + y_{mp}^a \leq 2 \quad \forall(m, n, p): m \neq n \neq p, \text{nhel} \geq 3 \quad (10)$$

$$y_{mn}^p + y_{np}^a + y_{mp}^p \leq 2 \quad \forall(m, n, p): m \neq n \neq p, \text{nhel} \geq 3 \quad (11)$$

$$y_{mn}^a + y_{np}^p + y_{mp}^p \leq 2 \quad \forall(m, n, p): m \neq n \neq p, \text{nhel} \geq 3 \quad (12)$$

$$y_{mn}^p + y_{np}^p + y_{mp}^a \leq 2 \quad \forall(m, n, p): m \neq n \neq p, \text{nhel} \geq 3 \quad (13)$$

**Relating Residue Contacts to Helix Contacts:** A direct link between the  $w_{ij}$  PRIMARY contact variables and the  $y_{mn}^a$  and  $y_{mn}^p$  helical interaction variables is provided by Eqs. (14)–(15).

$$w_{ij}^{mn} \leq y_{mn}^a + y_{mn}^p \quad (14)$$

$$y_{mn}^a + y_{mn}^p - \sum_i \sum_j w_{ij}^{mn} \leq 0 \quad (15)$$

Equations (16)–(17) require the PRIMARY contact predictions,  $w_{ij}^{mn}$ , to be consistent with the variables representing the interaction directions,  $y_{mn}^a$  and  $y_{mn}^p$ .

$$\begin{aligned} w_{ij}^{mn} + w_{i'j'}^{mn} + y_{mn}^a \leq 2 \quad \forall (i, j, i', j') : \\ i' > i, j' > j \text{ and} \\ |i' - i| < |j' - j| + 3 \text{ or} \\ |i' - i| > |j' - j| - 3 \end{aligned} \quad (16)$$

$$\begin{aligned} w_{ij}^{mn} + w_{i'j'}^{mn} + y_{mn}^p \leq 2 \quad \forall (i, j, i', j') : \\ i' > i, j > j' \text{ and} \\ |i' - i| < |j' - j| + 3 \text{ or} \\ |i' - i| > |j' - j| - 3 \end{aligned} \quad (17)$$

Equations (18) and (19) specify that a PRIMARY contact pair  $(i, j)$  may be predicted only if it results in an overlap between the two helices of at least two-thirds of the length of the shorter helix.

$$w_{ij}^{mn} + y_{mn}^a \leq 1 \quad \text{if } m, n \text{ overlap} < 2/3 \\ \text{of shorter helix} \quad (18)$$

$$w_{ij}^{mn} + y_{mn}^p \leq 1 \quad \text{if } m, n \text{ overlap} < 2/3 \\ \text{of shorter helix} \quad (19)$$

**Additional Features:** Obtaining a rank-ordered list of the most likely sets of helical contacts is more desirable than a single solution. Equation (20) introduces the idea of integer cut constraints into the model. After each successive solve of the above model, the previous solution can be excluded from the feasible solution

space using this equation. Here  $A$  is the set of active variables,  $I$  is the set of inactive variables and  $\text{card}(A)$  is the cardinality of set  $A$ .

$$\begin{aligned} \sum_{(m,n),(i,j) \in A} (y_{mn}^a + y_{mn}^p + w_{ij}^{mn}) \\ - \sum_{(m,n),(i,j) \in I} (y_{mn}^a + y_{mn}^p + w_{ij}^{mn}) \leq \text{card}(A) - 1 \end{aligned} \quad (20)$$

Equation (21) indicates an upper limit on the number of PRIMARY contacts that two interacting helices  $m$  and  $n$  can have specified. This upper contact limit is shown as *max\_contact* in Eq. (21).

$$\sum_i \sum_j w_{ij}^{mn} \leq \text{max\_contact} \cdot (y_{mn}^a + y_{mn}^p) \quad \forall (m, n) \quad (21)$$

Equation (22) eliminates a number of helical interactions from the Level 1 solutions equal to the value of the parameter *subtract*. The *subtract* parameter effectively loosens the helical packing, which may be desired in predicting only the most essential and hopefully smallest distance contacts.

$$\sum_m \sum_n (y_{mn}^a + y_{mn}^p) \leq \left( \sum_m \text{counth}(m)/2 \right) - \text{subtract} \quad (22)$$

Equations (1)–(22) represent the Level 1 mathematical model which is a mixed-integer linear optimization problem (MILP).

**Level 2 Model: WHEEL Interhelical Contacts** The Level 2 MILP problem serves as a check on the ordering of the solutions found in Level 1.

**Objective Function:** The Level 2 objective function, Eq. (23), maximizes the most probable hydrophobic  $(k, l)$  WHEEL contacts based on probabilities calculated using the database PDB set. Although this was done with the  $(i, j)$  pairs and parallel or antiparallel orientations already fixed from Level 1, the model could be altered to allow for only fixing the helical orientations after Level 1, for example. The parameters  $p_{kl;ij;mn}^a$  and  $p_{kl;ij;mn}^p$  give the probabilities that any hydrophobic  $(k, l)$  pair will occur on the same side of the helical

wheel as a specific PRIMARY pair  $(i, j)$  for antiparallel or parallel orientations, respectively. The Level 2 objective function must be based upon not only the  $p_{kl;ij;mn}^a$  and  $p_{kl;ij;mn}^p$  probabilities, but also upon the probabilities  $p_{ij;kl;mn}^a$  and  $p_{ij;kl;mn}^p$  as shown in Eq. (23). These latter probabilities treat the  $(k, l)$  WHEEL contacts as PRIMARY contacts themselves, and the values reflect the relative weights of the different  $(i, j)$  WHEEL contacts to these  $(k, l)$  PRIMARY contacts. This approximation allows for distinguishing between the possible  $(k, l)$  hydrophobic contacts that may be specified when there is a choice of more than one pair.

$$\begin{aligned} \max \sum_{m,n} \sum_{i,j} \sum_{k,l} w_{kl;ij}^{mn} \cdot [p_{kl;ij;mn}^a + p_{ij;kl;mn}^a] \\ \cdot y_{mn}^a \cdot w_{ij}^{mn} \\ + \sum_{m,n} \sum_{i,j} \sum_{k,l} w_{kl;ij}^{mn} \cdot [p_{kl;ij;mn}^p + p_{ij;kl;mn}^p] \\ \cdot y_{mn}^p \cdot w_{ij}^{mn} \end{aligned} \quad (23)$$

$$y_{mn}^a, y_{mn}^p, w_{ij}^{mn}, w_{kl;ij}^{mn}, y_{ijmn}^a, y_{ijmn}^p = \{0, 1\} \quad (24)$$

Like the objective function in the Level 1 model, Eq. (23) is also nonlinear due to the products of binary variables that result. It can be linearized in a similar fashion [10].

**Wheel Residue Contact Rules:** Equation (25) states that a maximum of one WHEEL contact is allowed to be specified per primary contact.

$$\sum_k \sum_l w_{kl;ij}^{mn} \leq w_{ij}^{mn} \quad \forall (m, n, i, j) : y_{mn}^a + y_{mn}^p = 1 \quad (25)$$

## Applications

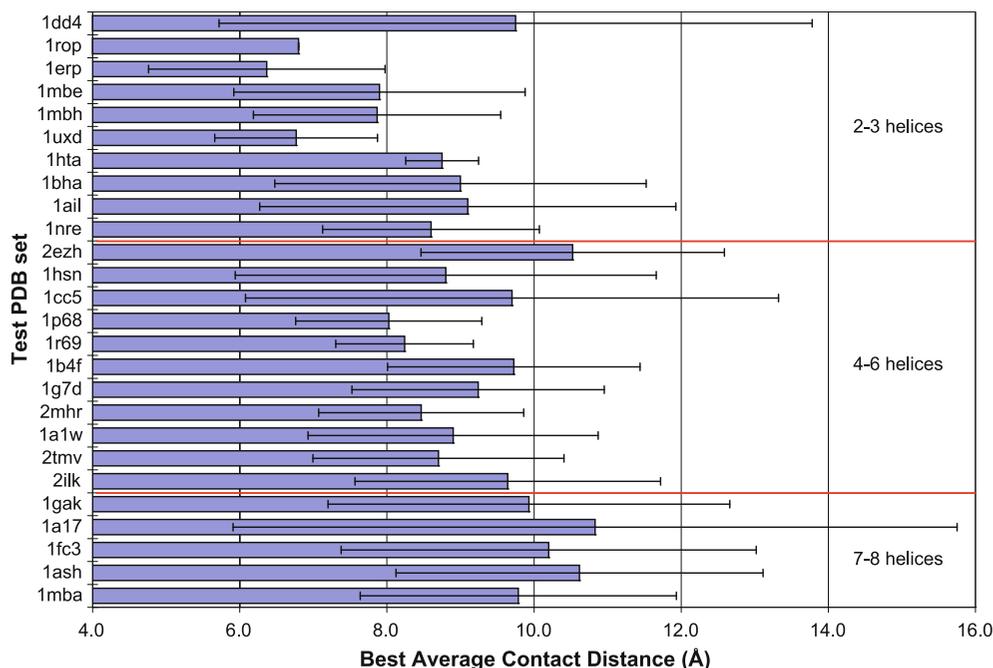

The Level 1 and Level 2 MILP optimization problems were applied to 26 target proteins with known structures in the PDB, termed the test PDB set. For each of these proteins, only the primary amino acid sequence and the experimentally-determined locations of the helices were presented to the model. The model predicted the interhelical hydrophobic residue contacts between such helices using the PRIMARY and WHEEL probabilities developed from globular helical proteins.

A predicted set of interhelical contacts (a solution) was evaluated by computing the average of the distances of these contacts from the experimentally-determined structure. The proposed framework was used to generate 20 solutions for each protein and each parameter value by applying integer cuts. The solutions in this list are ranked by objective value, from best to worst. The best contact distance average value is defined as the lowest contact distance average value identified for a specific protein. An upper limit of 14 Å was identified as a goal for the average distance corresponding to a contact prediction, since such a distance constraint would significantly improve the structure refinement.

Figure 2 displays the lowest combined PRIMARY and WHEEL contact distance averages for every test protein. For the parameters given, these are the best solutions: the experimentally-determined distance averages corresponding to contacts predicted by the model are lower for those solutions than for all other solutions in each protein system. Figure 2 demonstrates that the predictive results of the model are highly encouraging. A general goal of 5.0 to 14.0 Å for the actual distance range of contacts predicted by the model was set, since such a distance range would significantly improve the structure refinement. This goal was attained and surpassed for the entire set of the test proteins.

The error bars of one standard deviation for the distance averages indicate that 1fc3, 1ash, 1cc5, and 2ezh may fall close to this limit and that 1a17 is beyond this target. The averages for a large number of the target proteins fall far below 14.0 Å, suggesting that lower distance restraints such as 12.0 Å or even 10.0 Å and below, may be appropriate in some or even most cases.

The successful predictions of this model using both experimentally-determined helix locations as well as predicted helical regions support the thesis that hydrophobic-to-hydrophobic interactions are key to the folding of the native structures of  $\alpha$ -helical globular proteins. Despite the variety of structural motifs present in the test PDB set, the hydrophobic-to-hydrophobic interactions based model was able to identify low distance interhelical PRIMARY and WHEEL contacts for each of the 26 proteins analyzed. This observation is also supported by the success of the *subtract* parameter in identifying the most essential contacts and further reinforces the utility of the probability values developed for the model.

**Predictive Method for Interhelical Contacts in Alpha-Helical Proteins, Figure 2**

Lowest contact distance averages for identified solutions to the target proteins as explained in the text. Error bars for one standard deviation of the contact distances are given

Multicriteria analysis; Preference disaggregation;  
Linear programming; Decision support system

In decision making involving to multiple criteria, the basic problem stated by analysts and decision mak-

ers concerns the way that the final decision should be made. In many cases, however, this problem is posed in the opposite way: assuming that the decision is given, how is it possible to find the rational basis through which the decision was made? Or equivalently, how is it possible to assess the decision maker’s preference model leading to the exact same decision as the actual one or at least the most ‘similar’ decision? The philosophy of preference disaggregation in multicriteria analysis is to assess/infer preference models from given preferential structures and to address decision-aiding activities through operational models within the aforementioned framework.

### Definitions and Notations

Under the term *multicriteria analysis* two basic approaches have been developed involving:

- a) a set of methods or models enabling the aggregation of multiple evaluation criteria to choose one or more actions from a set  $A$ ;
- b) an activity of decision-aid to a well-defined decision maker (individual, organization, etc.).

In both cases the set  $A$  of potential actions or decisions is analysed in terms of multiple criteria in order to model all the possible impacts, consequences or attributes related to the set  $A$  (for instance, see [11,27,47,49,69]).

B. Roy [47] outlines a general modeling methodology of decision making problems, which includes four modeling steps beginning with the definition of the object of the decision and ending with the activity of decision aid, as follows:

- Level 1: Object of the decision, including the definition of the set of potential actions  $A$  and the determination of a problematic on  $A$  (see below).
- Level 2: Modeling a consistent family of criteria assuming that these criteria are nondecreasing value functions, exhaustive and nonredundant.
- Level 3: Development of a global preference model, to aggregate the marginal preferences on the criteria.
- Level 4: Decision-aid or decision support, based on the results of level 3 and the problematic in level 1.

In level 1, Roy [47] distinguishes four referential problematics, each of which does not necessarily preclude the others. These problematics can be employed sepa-

rately or in a complementary way in all phases of the decision making process. The four problematics are the following:

- Problematic  $\alpha$ : Choosing one action from  $A$  (choice).
- Problematic  $\beta$ : Sorting the actions in well defined categories which are given in a preference order (sorting).
- Problematic  $\gamma$ : Ranking the actions from the best one to the worst one (ranking).
- Problematic  $\delta$ : Describing the actions in terms of their performances on the criteria (description).

In level 2, the modeling process must conclude on a consistent family of criteria  $\{g_1, \dots, g_n\}$ . Each criterion is a nondecreasing real valued function defined on  $A$ , as follows:

$$g_i: A \rightarrow [g_{i*}, g_i^*] \subset \frac{\mathbf{R}}{a} \rightarrow g(a) \in \mathbf{R}, \quad (1)$$

where:

- $[g_{i*}, g_i^*]$  is the criterion evaluation scale;
- $g_{i*}$  is the worst level of the  $i$ th criterion;
- $g_i^*$  is the best level of the  $i$ th criterion;
- $g_i(a)$  is the evaluation or performance of action  $A$  on the  $i$ th criterion;
- $g(a)$  is the vector of performances of action  $A$  on the  $n$  criteria.

From the above definitions the following preferential situations can be determined:

$$g_i(a) > g_i(b) \Leftrightarrow a > b \quad (a \text{ is preferred to } b),$$

$$g_i(a) = g_i(b) \Leftrightarrow a \sim b \quad (a \text{ is indifferent to } b).$$

In multicriteria analysis four types of criteria are used with the following properties:

- *Measurable criterion*: The criterion enables the preferential comparison of intervals of the evaluation scale. It can be distinguished in the following subtypes [69]:
  - true criterion (without any threshold);
  - semicriterion (with indifference threshold);
  - pseudocriterion (with indifference and preference thresholds).
- *Ordinal criterion*: The criterion defines only an order on  $A$ ; thus the evaluation scale is discrete (qualitative criterion);

- *Probabilistic criterion*: It covers the case of uncertainty in the actions' performances modeled by probability distributions (see the Section 'Disaggregation Under Uncertainty' below);
- *Fuzzy criterion*: The actions' performances are intervals of the criterion's evaluation scale.

The modern theoretical steams in the field of multiple criteria decision-aid (MCDA) can be distinguished into four groups:

- 1) Multi-objective optimization (see the Section 'Disaggregation in Multi-objective Optimization');
- 2) Value-focused approaches ([29,30]);
- 3) Outranking methods ([1,49])
- 4) Disaggregation methods.

Roy and D. Bouyssou [48] point out the major conceptual and methodological differences distinguishing value-focused approaches from outranking methods using the classical example regarding the location of a thermo-nuclear electrical production plant. On the conceptual level, the authors characterize the value-focused approach as descriptive of the decision maker's preferences, while outranking methods are characterized as a constructive way of building these preferences. On the methodological level, the value-focused approach proposes a value or utility function to model the decision maker's global preference (functional systems), whereas outranking methods propose outranking relations (relational systems).

## Outline of the Article

The development of disaggregation methods has actually begun in 1978, with the presentation of the UTA method in the 'Cahiers du LAMSADE' series. We will summarise all the progress made in this scientific field from that moment.

The subsequent sections include: the background of the UTA method through the use of goal programming techniques in regression analysis; some thoughts about the usefulness of the disaggregation; a brief presentation of the UTA algorithm; variants of UTA; other disaggregation methods; methods for decision making under uncertainty; multi-objective optimization. Finally, the last two sections show the implementation of disaggregation methods through decision support systems and potential real-world applications.

## History

The history of the disaggregation principle in multi-dimensional/multicriteria analyses begins with the use of goal programming techniques, a special form of linear programming structure, in assessing/infering preference/aggregation models or in developing linear or nonlinear multidimensional regression analyses [52].

A. Charnes, W.W. Cooper and O. Ferguson [9] proposed a lineal model of optimal estimation of executive compensation by analysing or disaggregating pairwise comparisons and given measures (salaries); the model was estimated so that it could be as consistent as possible with the data from the goal programming point of view.

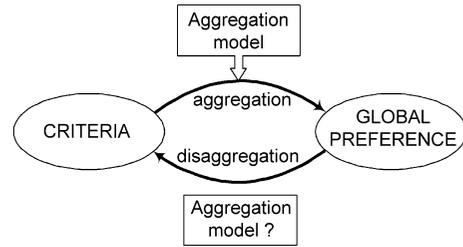

O.J. Karst [28] minimized the sum of absolute deviations via goal programming in linear regression with one variable, while H.M. Wagner [70] generalises Karst's model in the multiple regression case. Later, J.E. Kelley [31] proposed a similar model to minimize Tchebycheff's criterion in linear regression.

Later, V. Srinivasan and A.D. Shoker [65] outlined the ORDREG ordinal regression model to assess a linear value function by disaggregating pairwise judgements. N. Freed and G. Glover [17] proposed goal programming models to infer the weights of linear value functions in the frame of discriminant analysis (problematic  $\beta$ ).

The research on handling ordinal criteria has begun with the studies [71] and [25]. Both research teams faced the same problem: to infer additive value functions by disaggregating a ranking of reference alternatives. F.W. Young, J. de Leeuw and Y. Takane [71] proposed alternating least squares techniques, without ensuring, however, that the additive value function is optimally consistent with the given ranking. In the case of the UTA method proposed by E. Jacquet-Lagrèze and J. Siskos [25] optimality is ensured through linear programming techniques.

## The Disaggregation Paradigm in MCDA

In the traditional aggregation paradigm, the criteria aggregation model is known a priori, while the global preference is unknown. On the contrary, the philosophy of disaggregation involves the inference of preference models from given global preferences (Fig. 1).

**Preference Disaggregation, Figure 1**  
The aggregation and disaggregation paradigms in MCDA

## Global Preference As Datum

The clarification of the decision maker's global preference necessitates the use of a reference set of actions  $A_R$ . Usually, this set could be:

- 1) a set of past decision alternatives ( $A_R$ : past actions);
- 2) a subset of decision actions, especially when  $A$  is large ( $A_R \subset A$ );
- 3) a set of fictitious actions, consisting of performances on the criteria which can be easily judged by the decision maker to perform global comparisons  $A_R$ : fictitious actions).

In each of the above cases the decision maker is asked to externalise and/or confirm his/her global preferences on the set  $A_R$  taking into consideration the performances of the reference actions on all criteria. Usually, the form of the global preference follows the following typology:

- Measurable judgements on  $A_R$ ;
- Ranking (weak order relation) on  $A_R$  (problematic  $\gamma$ );
- Pairwise relation;
- Sorting of reference actions (problematic  $\beta$ ).

## The 'Famous' UTA Method

### Objective of the Method

The UTA method proposed by Jacquet-Lagrèze and Siskos [26] aims at inferring one or more additive value functions from a given ranking on the reference set  $A_R$ . The method uses special linear programming techniques to assess these functions so that the ranking(s) obtained through these functions on  $A_R$  is (are) as consistent as possible with the given one.

**The Additive Value Model**

The criteria aggregation model in UTA is assumed to be an additive value function of the following form [30]:

$$u(\underline{g}) = \sum_{i=1}^n p_i u_i(g_i) \tag{2}$$

subject to normalization constraints:

$$\begin{aligned} u_i(g_i^*) &= 0, \quad u_i(g_i^*) = 1, \\ \forall i &= 1, \dots, n, \\ \sum_{i=1}^n p_i &= 1, \end{aligned} \tag{3}$$

where  $u_i, i = 1, \dots, n$ , are nondecreasing real valued functions, named marginal value or utility functions, which are normalized between 0 and 1, and  $p_i$  is the weight of  $u_i$ .

Both the marginal and the global value functions have the monotonicity property of the true criterion. For instance, in the case of the global value function the following properties hold:

$$\begin{aligned} u[\underline{g}(a)] > u[\underline{g}(b)] &\Leftrightarrow a > b \quad (\text{preference}), \\ u[\underline{g}(a)] = u[\underline{g}(b)] &\Leftrightarrow a \sim b \quad (\text{indifference}). \end{aligned}$$

The UTA method infers an unweighted form of the additive value function, equivalent to the form defined from relations (2)–(3), as follows:

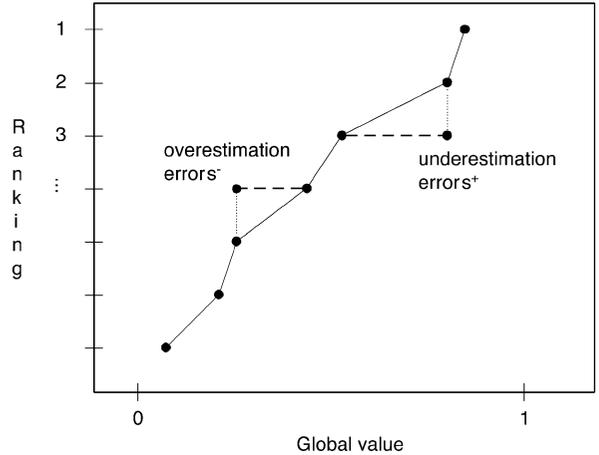

$$u(\underline{g}) = \sum_{i=1}^n u_i(g_i) \tag{4}$$

subject to normalization constraints:

$$u_i(g_i^*) = 0, \quad \forall i = 1, \dots, n, \tag{5}$$

$$\sum_{i=1}^n u_i(g_i^*) = 1. \tag{6}$$

Of course, the existence of such a preference model assumes the preferential independence of the criteria for the decision maker [30], although this assumption does not pose significant problems in a posteriori analyses such as disaggregation analysis.

**Preference Disaggregation, Figure 2**  
Ordinal regression curve (ranking versus global value)

**The UTASTAR Algorithm.**

In order to assess every marginal value function, the evaluation scales of each criterion (especially in the case of measurable criteria) is discretised in a limited set of points:

$$G_i = \{g_i^* = g_i^1, g_i^2, \dots, g_i^{a_i} = g_i^*\}. \tag{7}$$

On the other hand, the set of reference actions  $A_R = \{a_1, \dots, a_k\}$  is ‘rearranged’ in such a way that  $a_1$  is the head of the ranking and  $a_k$  its tail. Since the ranking has the form of a weak order, for each pair of consecutive actions  $(a_j, a_{j+1})$  one of the two following relations holds:

$$\begin{aligned} a_j > a_{j+1} &\quad (\text{preference}), \\ a_j \sim a_{j+1} &\quad (\text{indifference}). \end{aligned}$$

In the original version of UTA [26], for each packed action  $a \in A_R$  a single error  $\sigma(a)$  is introduced to be minimised. Later, Y. Siskos and D. Yannacopoulos [60] introduced two errors leading to better results (Fig. 2). This variant of UTA, is now called UTASTAR.

The main computational procedure employed in UTASTAR employs linear programming techniques to find additive value functions which are as consistent as possible with the ranking on  $A_R$ :

- 1) Express the global value of reference actions  $u[\underline{g}(a_j)], j = 1, \dots, k$ , first in terms of marginal val-

ues  $u_i(g_i)$ , then in terms of variables:

$$w_{il} = u_i(g_i^{l+1}) - u_i(g_i^l) \geq 0, \quad i = 1, \dots, n; \\ l = 1, \dots, \alpha_i - 1,$$

by means of the relations

$$u_i(g_i^l) = \sum_{t=1}^{l-1} w_{it}, \quad u_i(g_i^1) = 0, \quad \forall i \text{ and } l > 1.$$

- 2) Introduce two error functions  $\sigma^+$  and  $\sigma^-$  on  $A_R$  by writing for each pair of consecutive actions in the ranking, the analytic expressions:

$$\Delta(a_j, a_{j+1}) = u[\underline{g}(a_j)] - \sigma^+(a_j) + \sigma^-(a_{j+1}) \\ - u[\underline{g}(a_{j+1})] + \sigma^+(a_{j+1}) - \sigma^-(a_{j+1}). \quad (8)$$

- 3) Solve the linear program

$$\min z = \sum_{j=1}^k [\sigma^+(a_j) + \sigma^-(a_j)]$$

subject to the set of constraints:

$$\begin{cases} \Delta(a_j, a_{j+1}) \geq \delta & \text{if } a_j \succ a_{j+1}, \\ \Delta(a_j, a_{j+1}) = 0 & \text{if } a_j \sim a_{j+1}, \end{cases} \quad \forall j = 1, \dots, k-1, \quad (9)$$

$$\sum_{i=1}^n \sum_{l=1}^{\alpha_i-1} w_{il} = 1, \quad (10)$$

$$w_{il} \geq 0,$$

$$i = 1, \dots, n; \quad l = 1, \dots, \alpha_i - 1,$$

$$\sigma^+(a_j) \geq 0, \quad \sigma^-(a_j) \geq 0, \quad j = 1, \dots, k, \quad (11)$$

$\sigma$  being a small positive number.

- 4) Test the existence of multiple or near optimal solutions of the linear program in step 3 (stability analysis); in case of nonuniqueness, find the mean additive value function of those (near) optimal solutions which maximise the objective functions  $p_i = u_i(g_i^*) = \sum_l w_{il}$  for all  $i = 1, \dots, n$  on the polyhedron (9)–(11) bounded by the new constraint:

$$\sum_{j=1}^k [\sigma^+(a_j) + \sigma^-(a_j)] \leq z^* + \varepsilon, \quad (12)$$

$z^*$  being the optimal value of the linear program in step 3 and  $\varepsilon$  a very small positive number.

### Variants and Meta-UTA Techniques

After the development of the UTA method several variants have been developed incorporating different forms of global preference or different forms of optimality criteria used in the linear programming formulation. The main variants include:

- Inferring  $u$  from pairwise comparisons [26].
- Maximising Kendall's  $\tau$ , a consistency measure between the two rankings, via a mixed linear programming formulation [26].
- Inferring  $u$  from assignment examples in the case of problematic  $\beta$  ([14,22,26,78]).
- Optimising lexicographic criteria without discretization of criteria scales  $G_i$  [41].
- Inferring  $u$  in the presence of nonmonotonic preferences on the criteria evaluation scales [13].

Other techniques, named meta-UTA, aimed at the improvement of the value function with respect to near optimality analysis or to its exploitation for decision support.

D.K. Despotis, Yannacopoulos and C. Zopounidis [12] propose to minimise the error's dispersion (Tchebycheff criterion) within the UTA's step 4. In the case where UTA gives a sum of error equal to zero ( $z^* = 0$ ), M. Beuthe and G. Scanella [5] propose the meta-UTA techniques UTAMP1 maximising  $\delta$  (minimum difference between the global value of two consecutive reference actions) in near optimality analysis, and UTAMP2 maximising  $\delta$  plus the minimum of marginal value step  $w_{il}$  of UTA's step 1.

Beuthe and Scanella [7] propose similar techniques for the case of  $z^* > 0$  and provide some comparative analysis results for different UTA variants.

Finally, Siskos [51] suggests the construction of fuzzy outranking relations based on multiple value functions  $u$  provided by UTA's near optimality analysis.

### Other Disaggregation Methods

The disaggregation logic has been employed almost in all aggregation models in multicriteria analysis. Of course, in some cases, it is not easy to infer aggregation models or procedures from their output.

A first attempt to infer ELECTRE III from a given ranking was made in [45] without satisfactory results. L.N. Kiss et al. [33] developed the ELECCALC system

that estimates indirectly the parameters of the ELECTRE II method from the decision maker's responses to questions of the system regarding his/her global preferences. V. Mousseau and R. Slowinski [40] and Mousseau et al. [39] present linear programming formulations to infer the parameters of ELECTRE TRI, except the veto thresholds, from assignment example in the case of problematic  $\beta$ .

P. Spiliopoulos [63] and Siskos and N.F. Matsatsinis [55] employ the UTA method iteratively as a model to analyse consumers' behavior, through the MARKEX system providing decision support during new product development [37].

The disaggregation of measurable judgements in order to infer additive value functions for prediction purposes is proposed in [32]. Siskos et al. [58] developed an ordinal regression formulation to measure customer satisfaction by disaggregating multiple satisfaction judgements. The method was implemented in the MUSA system and it was applied in several real-world studies (for instance, see [38]).

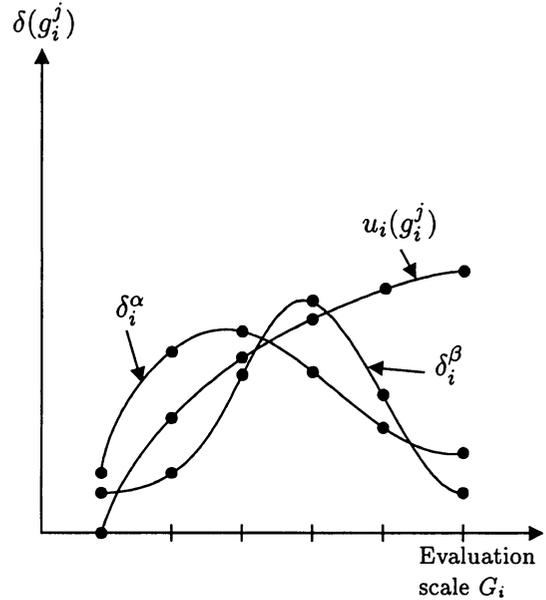

UTA was used in several works for conflict resolution in multi-actor decision situations ([8,24,36]).

Additive value functions are usually assessed in two phases: in the first phase the marginal value functions are assessed under the preferential independence conditions and in the second phase their weights are assessed by disaggregating a ranking of a small number of reference actions [50]. Two-phase disaggregation methods were implemented through the MACBETH system ([2,3]) and the MIIDAS system ([59,64]).

The general scheme of the disaggregation philosophy is also employed in other approaches, including rough sets ([16,43,62,72]), machine learning [44] and neural networks ([35,66]). All these approaches are used to infer some form of decision model (a set of decision rules or a network) from given decision results involving assignment examples, ordinal or measurable judgements.

### Disaggregation Under Uncertainty

Within the framework of multicriteria decision aid under uncertainty, Siskos [52] developed a specific version of UTA (Stochastic UTA), in which the aggregation model to infer from a reference ranking is an addi-

Preference Disaggregation, Figure 3  
Distributional evaluation and marginal value function

tive utility function of the form:

$$u(\underline{\delta}^a) = \sum_{i=1}^n \sum_{j=1}^{a_i} \delta_i^a(g_i^j) u_i(g_i^j) \quad (13)$$

subject to normalization constraints (5)–(6), with the following additional notation (see also Fig. 3):

- $\delta_i^a$  is the distributional evaluation of action  $A$  on the  $i$ th criterion;
- $\delta_i^a(g_i^j)$  is the probability that the performance of action  $A$  on the  $i$ th criterion is  $g_i^j$ ;
- $u_i(g_i^j)$  is the marginal value of the performance  $g_i^j$ ;
- $\underline{\delta}^a$  is the vector of distributional evaluations of action  $A$ ;
- $u(\underline{\delta}^a)$  is the global utility of action  $A$ .

Of course, the additive utility function (13) has the same properties as the value function:

$$u(\underline{\delta}^a) > u(\underline{\delta}^b) \Leftrightarrow a > b \text{ (preference),}$$

$$u(\underline{\delta}^a) = u(\underline{\delta}^b) \Leftrightarrow a \sim b \text{ (indifference).}$$

Similarly to the case of the UTA described above, the stochastic UTA method disaggregates a ranking of reference actions [53]. The algorithmic procedure could be expressed in the following way:

- 1) Express the global expected utilities of reference actions  $u(\underline{g}^{a_j})$  in terms of variables  $w_{il} = u_i(g_i^{l+1}) - u_i(g_i^l) \geq 0$ .
- 2) Introduce two error functions  $\sigma^+$  and  $\sigma^-$ :

$$\Delta(a_j, a_{j+1}) = u(\underline{g}^{a_j}) - \sigma^+(a_j) + \sigma^-(a_j) \quad (14)$$

$$-u(\underline{g}^{a_{j+1}}) + \sigma^+(a_{j+1}) - \sigma^-(a_{j+1}). \quad (15)$$

- 3) Solve the linear program:

$$\min z = \sum_{j=1}^k [\sigma^+(a_j) + \sigma^-(a_j)]$$

subject to the set of constraints:

$$\begin{cases} \Delta(a_j, a_{j+1}) \geq \delta & \text{if } a_j > a_{j+1}, \forall j = 1, \dots, k-1, \\ \Delta(a_j, a_{j+1}) = 0 & \text{if } a_j \sim \tilde{a}_{j+1}, \end{cases} \quad (16)$$

$$\begin{aligned} \sum_i \sum_l w_{il} &= 1, \\ w_{il} &\geq 0, \\ i &= 1, \dots, n; \quad l = 1, \dots, \alpha_i - 1, \\ \sigma^+(a_j) &\geq 0, \quad \sigma^-(a_j) \geq 0, \\ j &= 1, 2, \dots, k, \end{aligned} \quad (17)$$

$\delta$  being a small positive number.

- 4) Test the existence of multiple or near optimal solutions.

Of course, the ideas employed in all variants of the UTA method are also applicable in the same way in the case of the stochastic UTA.

### Disaggregation in Multi-objective Optimization

The disaggregation approach is also applicable in the specific field of multi-objective optimization, mainly in the field of linear programming with multiple objective functions. For instance, in the classical methods of [18] and [73] the weights of the linear combinations of the objectives are inferred locally from trade-offs or pairwise judgements given by the decision maker at each iteration of the methods.

T.J. Stewart [67] proposed a procedure of pruning the decision alternatives using the UTA method, while

Jacquet-Lagrèze, R. Meziari and Slowinski [23] developed a disaggregation method, similar to UTA, to assess a whole value function of multiple objectives for linear programming systems.

Siskos and Despotis [54] proposed an interactive method named ADELAIS that uses UTA iteratively, in order to optimise an additive value function within the feasible region defined on the basis of the satisfaction levels determined during each iteration. Finally, A. Tangian and M.J. Gruber [68] propose a different form of disaggregation techniques for the assessment of quadratic multi-objective functions.

### Interactive Disaggregation Systems

Except for the normative features that a disaggregation approach provides, it also constitutes a basis for the interaction between analysts and decision makers. The issues involved during this interactive dialog and negotiation include:

- the consistency between the assessed preference model and the a priori preferences of the decision maker;
- the assessed values (values, weights, utilities, etc.); and
- the overall evaluation of potential actions (extrapolation output).

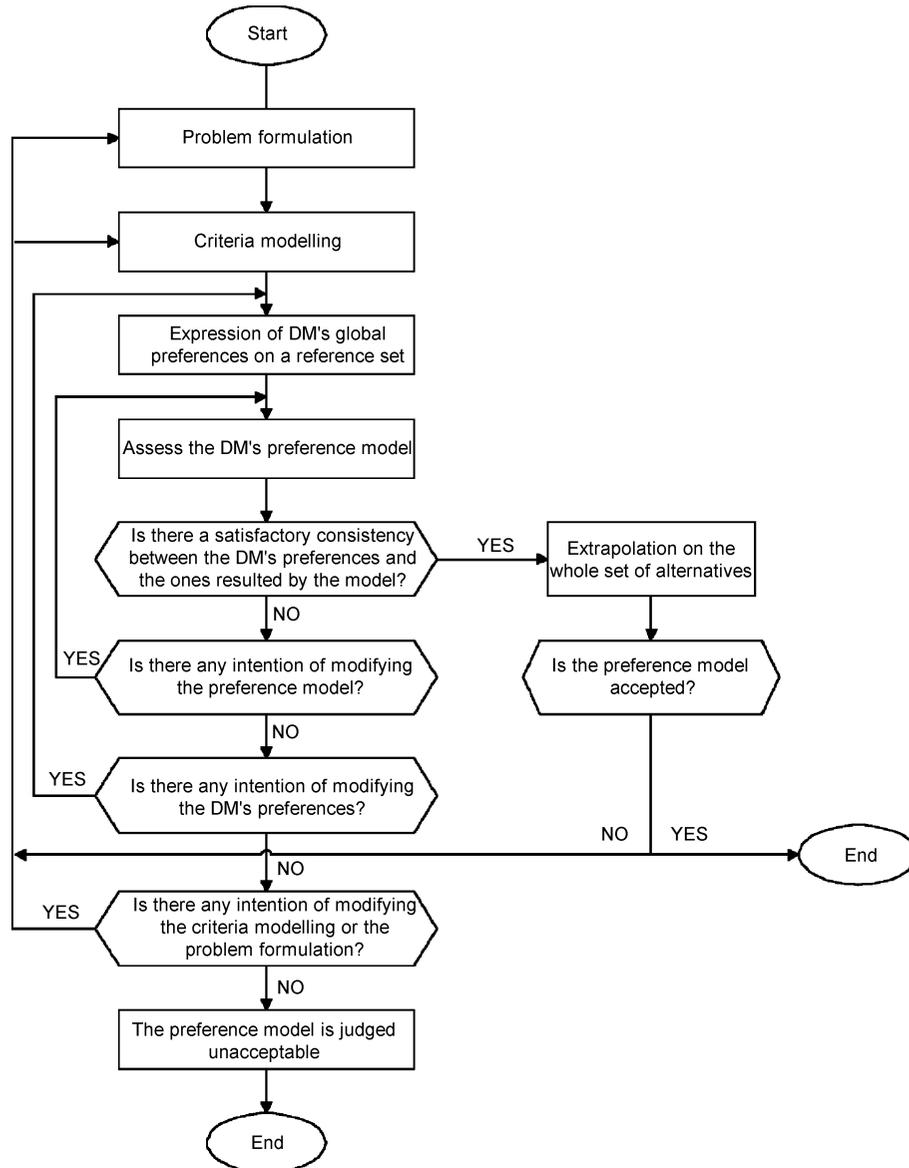

A general interaction scheme is given in Fig. 4.

Several decision support software have been developed on the basis of disaggregation methods, most of them being UTA based. They include: PREF-CALC [21], MINORA-MIIDAS [59], ADELAIS [54], MARKEX [55], UTA+ [34], FINEVA [81], FINCLAS [75], PREFDIS [77], MUSTARD [6].

### Applications and Conclusions

From their first appearance in 1978 onwards, preference disaggregation methods have been applied in several real-world decision making problems from the fields of financial management, marketing, environmental management, as well as human resources management. The following list reports some of these applications (list not exhaustive):

- financial management
  - venture capital [56];

**Preference Disaggregation, Figure 4**  
Simplified decision support process based on disaggregation analysis

- portfolio selection and management ([20,79]);
- business failure prediction ([74,76]);
- business financing ([61,75,81]);
- country risk assessment ([10,42,80]);
- marketing
  - marketing of new products ([4,55,63]);
  - sales strategy problems ([46,57]);
  - customer satisfaction ([38,58]);
- environmental management ([15,19,53]);

- industrial project evaluation [22];
- job evaluation [64].

The above applications have provided insight on the applicability of preference disaggregation analysis in addressing real-world decision problems and its efficiency. The future research developments on this field required to explore further the potentials of the preference disaggregation philosophy within the context of multicriteria decision aid, include:

### Inference of More Sophisticated Aggregation Models by Disaggregation

Currently most preference disaggregation methods lead to the assessment of additive value functions. However, in many cases such additive models fail to comprise the decision maker's preference in a satisfactory way, either because their underlying assumptions do not hold (preferential independence), or because they do not consider the existing interactions between the criteria. In that respect it is worth examining the development of alternative aggregation models, for instance in the form of multiplicative value functions or even outranking relations.

### Evaluation of the Aggregation-Disaggregation Relationship

Both aggregation and disaggregation procedures share the same objective: to aggregate all criteria into a global preference model that will support decision making. Of course, as this paper has demonstrated, there are significant differences in the process employed in both approaches to accomplish this objective. However, it would be interesting to explore the relationship of aggregation and disaggregation procedures in terms of similarities and/or dissimilarities regarding the evaluation results obtained by both approaches. This will enable the identification of the reasons and the conditions under which aggregation and disaggregation procedures will lead to different or the same results.

### Experimental Evaluation of Disaggregation Procedures

Real-world applications can be used to illustrate the decision support provided by preference disaggregation approaches in practice. However, a thorough investigation of their performance and ability to capture the decision maker's preferences requires the conduct of experimental studies. Through such studies it is possible to examine how different data conditions and preferential structures affect the efficiency of preference disaggregation approaches and the aggregation models used.

### Implementation of Disaggregation Methods into DSSs and Group DSSs

Preference disaggregation procedures operate on an interactive and iterative way. The decision maker inter-

acts with the procedure to achieve a consistent representation of his/her preferences in the aggregation model through an iterative trial and error process. The DSSs technology is well adapted to both these features, enabling the decision maker to take full advantages that preference disaggregation approaches provide, in real-time. Furthermore, this framework could be extended bearing in mind the fact that many crucial decisions are taken by a group of decision makers working in a negotiating or cooperative environment to conclude to a consensus decision. Group DSSs provide the means required in supporting such decision making situations.

*Multicriteria decision aid* (MCDA) has emerged during the last three decades as a promising scientific field in operations research and management science, and today it has consolidated its position with a wide set of methods and tools confronting in a realistic and flexible way decision problems where multiple conflicting criteria should be considered. The tools provided by MCDA are not just some mathematical models, which aggregate several criteria, points of view or attributes, but furthermore they are decision support oriented. Actually, ‘support’ is a key issue in MCDA, implying that the models are not developed through a straightforward sequential process where the decision maker’s role is passive. Instead an iterative process is employed to analyze the preferences of the decision maker and represent them as consistently as possible in an appropriate decision model. Throughout this process the interaction of the decision maker with the analyst is essential, providing significant preferential information to the analyst. This decision support nature of MCDA is the basic feature that distinguishes it from the classical models that the optimization approach employs.

Within the methods and tools provided by MCDA, several approaches and theoretical disciplines can be defined, although their distinction and the existing boundaries among them are often difficult to determine. In fact several authors provided different categorizations of the MCDA approaches ([19,21,34,36]). Following the proposal of P.M. Pardalos et al. [15] and C. Zopounidis [40], one can identify four major streams in MCDA:

- 1) *multi-objective programming* ([30,32,35]),
- 2) *multi-attribute utility theory* [11],
- 3) *outranking relations* ([18,20]),
- 4) *preference disaggregation analysis* [10].

The differences among these approaches can be identified in terms of the types of problems that they address, in terms of the preference models that they develop, as well as in term of the process that is employed to develop these models. As far as the type of problem is concerned, multi-objective programming addresses decision problems where there is not a finite set of alternative solutions, but instead the possible alternatives are determined implicitly through a set of constraints imposed by the nature of the problem. On the other hand, multi-attribute utility theory, outranking relations, and preference disaggregation analysis are used

to study decision problems involving the evaluation of a well-defined finite set of alternatives.

Concerning the form of the model that is employed, in multi-objective programming the decision problem is formulated as a mathematical programming model, with more than one objective functions representing the objectives of the decision maker. In both multi-attribute utility theory and preference disaggregation analysis the model is a utility function either additive or multiplicative. Finally, outranking relations are based on pairwise judgments between the alternatives of the form 'alternative  $a$  is at least as good as alternative  $b$ '.

Although there are significant differences between the four MCDA approaches regarding the types of problems that they address and the model formulation, the most significant differences involve the information that they require from the decision maker, and the procedure that is used to elicit this information. In multi-objective programming the process employed to develop the model and to obtain the best compromise solution is an interactive one. Once the decision problem has been consistently formulated as a mathematical programming problem, the efficient (nondominated) set of solutions is determined. The decision maker is then asked to provide some preferential information usually in terms of some reference points, indicating the way that the efficient set should be investigated. In multi-attribute utility theory, a direct interrogation process is employed to elicit information from the decision maker concerning the trade-offs among the conflicting criteria, attributes or points of view. These trade-offs are then used to construct the global preference model in the form of a utility function that the decision maker implicitly uses to make decisions. The modeling of the decision makers preferences in outranking relations is achieved similarly to the process used in multi-attribute utility theory (direct interrogation of the decision maker), although the type of information required differ (the decision maker must determine the weights of the evaluation criteria, as well as preference, indifference and veto thresholds). Compared to the other three approaches, preference disaggregation requires the minimal amount of information from the decision maker. The weights, trade-offs, reference points, or any other preferential information does not have to be determined a priori by the decision

maker. Instead, the decision maker, based on his/her past experience is asked to provide some characteristic examples of his decision making policy through the evaluation of a 'reference' set of alternatives. Then using ordinal regression techniques, the utility function that has been implicitly used by the decision maker is estimated.

This indirect estimation of the decision makers' preferences in preference disaggregation analysis is a quite appealing characteristic compared to the direct interrogation procedures employed in multi-objective programming, multi-attribute utility theory and outranking relations.

The preference disaggregation analysis found an appropriate field of applications in the domain of *financial decision making*. Most financial decision making problems such as corporate failure prediction, credit granting, portfolio selection and management, venture capital investment, country risk assessment, etc., have a repetitive character [37], while the decisions have to be taken in real time. These two characteristics of financial decision making problems are in accordance with the general methodological framework of preference disaggregation analysis. The repetitive character of financial decision problems enables the decision analyst to exploit the experience and the past decisions of the decision maker (financial/credit analyst, portfolio manager, etc.) in order to develop the appropriate decision model. Once this model is validated, it can be used to support real time financial decision making. Zopounidis [40] provides a comprehensive discussion of the applications of preference disaggregation analysis and multicriteria analysis in general in the study of financial decision making problems, while the books ([38,39]) and [7] illustrate the application of preference disaggregation analysis in venture capital investments, business failure prediction, and portfolio selection and management.

The rest of this article will focus with more details on the basic concepts, principles and techniques used in preference disaggregation analysis. More specifically, Section 2 describes the foundations of preference disaggregation analysis, while Sections 3, 4 and 5 illustrate how the preference disaggregation analysis can be applied in the study of ranking, sorting and choice problems respectively using simple illustrative examples from the field of credit granting. Finally, Section 6

concludes the article and discusses some possible future research direction in this field.

### Preference Disaggregation Analysis

The preference disaggregation approach refers to the analysis (disaggregation) of the global preferences of the decision maker to deduce the relative importance of the evaluation criteria, using ordinal regression techniques based mainly on *linear programming* formulations.

The preference disaggregation analysis is based on the simple finding that generally, in real world situations, decision makers are either unable or unwilling to provide in a direct way specific information regarding their preferences including weights or trade-offs. Even if this is possible, the procedure that will be employed to elicit such information from the decision maker is time consuming which may prevent its practical applications in real decision problems where decisions have to be taken in real time.

On the contrary, instead of describing the procedure that leads to the final decision, it would be easier for the decision maker to provide the analyst with the actual decision he/she would take considering the specific characteristics and conditions of the problem at hand.

For instance, when a committee of professors investigates the profiles of candidates for a graduate course, in order to rank them from the most appropriate to the less appropriate ones, the past evaluations that the committee has made can be used. These evaluations can either have the form of a ranking or they may express the intense of preference between two candidates (how many times an alternative is preferred compared to another alternative) [12]. Furthermore, it is even possible to consider more detailed information that the decision maker can provide, for instance the ranking of the alternatives on each evaluation criterion combined with the ranking of the criteria according to their significance [1].

The purpose of gathering such information from the decision maker is to have some representative examples of decisions taken by the decision maker. These examples reflect the decision policy and the preferences that the decision maker has implicitly used in making the decision. Consequently, through the analysis of

such decision instances, the analyst can derive useful information concerning the global preference system of the decision maker.

Decision makers when making decisions evaluate each alternative over a set of factors, criteria, attributes or points of view that affect the overall evaluation of the alternatives. Then, these partial evaluations are aggregated to derive the final decision. Following the same approach, the aim of the preference disaggregation analysis is to disaggregate the overall decision into the partial evaluations on each one of the evaluation criteria. The disaggregation should be performed in such a way so that the aggregation of partial evaluations will lead to the overall evaluation that the decision maker provided. If this is not possible then the deviations that occur should be minimized.

In such a disaggregation process it is clear that the form that the partial evaluations will have, as well as the selection of the model which will be used to aggregate the partial evaluations are two key issues. The first preference disaggregation approaches employed a simple weighted sum model of the form:

$$\sum w_j d_{ij},$$

where  $w_j$  denotes the weight of each criterion and  $d_{ij}$  denotes the distance of the evaluation of an alternative  $i$  on criterion  $j$  from the ideal point for this criterion ([6,16,31]). However, such a model is just an oversimplification of real world situations, which suffers from two major drawbacks.

- Firstly, it is obvious that this formulation implies both the overall value (score) of an alternative as well as the partial value of the alternative on an evaluation criterion, are linear functions (the weights of the evaluation criteria are independent on the criteria's values).
- Furthermore, this model is not appropriate for considering criteria which are measured through a qualitative scale. This would require the transformation of this qualitative scale into a numerical one, which can not be unique and it may not be in accordance with the preferential information that a qualitative scale provides.

To overcome such limitations, utility functions may be used. *Utility functions* are nonlinear increasing or decreasing functions of the criteria's values, indicating the value of the alternatives in the global preference system

of the decision maker. The most common forms of utility functions used in practice include the additive form and the multiplicative form. An additive utility function can be expressed as:

$$U(\bar{g}) = \sum_j u_j(g_j),$$

whereas a multiplicative utility function can be expressed as:

$$U(\bar{g}) = \frac{\prod_j (ku_j(g_j) + 1) - 1}{k},$$

where  $U(\bar{g})$  denotes the global utility of an alternative described by the vector of criteria  $\bar{g}$ ,  $u_j(g_j)$  is the partial or marginal utility of an alternative on criterion  $g_j$ , and  $k$  is a scaling factor. R.L. Keeney and H. Raiffa in their book [11] provide a comprehensive discussion of utility theory and the underlying assumptions of the several types of utility functions.

The aim of preference disaggregation analysis is to estimate the marginal utilities of each evaluation criterion so that their aggregation using either an additive or a multiplicative utility function results in an evaluation of the alternatives which is consistent with the decision maker's preferences and judgement policy. This estimation is achieved through mathematical programming techniques with the objective being the optimization of a measure of consistency. Multiplicative utility functions can generally be more appropriate for modeling decision makers' preferences in real world decisions taking into account possible interactions among the decision makers' preference on several criteria [14]. However, their estimation results in nonlinear programs that are computationally intensive and difficult to solve. Consequently, in practice additive utility functions are commonly used instead of multiplicative ones, since they provide a simple but also powerful approach for modeling decision makers' preference in multiple criteria decision making problems.

A well known preference disaggregation method which incorporates additive utility functions to model decision maker's preferences is the UTA method (UTilités Additives) proposed in [10]. The subsequent three subsections illustrate the UTA method as it has been proposed in [10], as well as some of its variants which have been proposed for the study of ranking, sorting and choice decision problems. More specifically

the UTASTAR method [28] for ranking problems, the UTADIS method ([3,9,42]) for *sorting problems*, as well as two methodologies proposed in [22] and [33] for choice problems are presented.

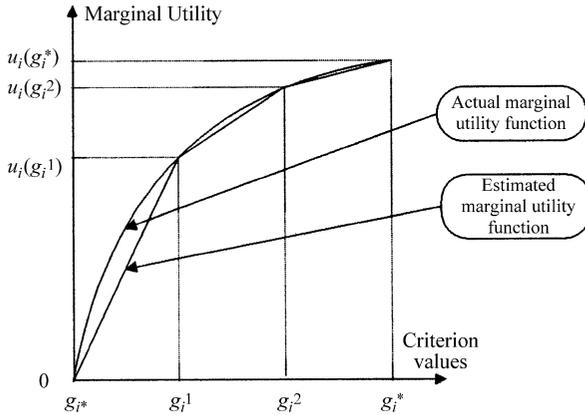

### Preference Disaggregation Analysis in Ranking Problems

The UTA method performs an ordinal regression based on the preference disaggregation approach of MCDA. Following the general methodological framework of preference disaggregation analysis, the decision maker is asked to provide a ranking (pre-ordering) of a reference set of alternatives which will be used to construct the additive utility model. This reference set may consist of examples of past decisions, or of a subset of the alternatives under consideration for which the decision maker can express a global evaluation.

Given this pre-ordering, the aim of the UTA method is to estimate a set of additive utility functions which are as consistent as possible with the decision maker's preferences (pre-ordering). The marginal utilities are piecewise linear (Fig. 1). The range of values of each criterion is divided into  $a_{i-1}$  equal intervals. The number of these subintervals can be specified by the decision maker, or it can be determined by the analyst so that there is at least one alternative falling into each subinterval. The estimation of the marginal utilities is achieved through the following linear programming formulation:

$$\left\{ \begin{array}{l} \min \quad F = \sum_{a \in A} \sigma(a) \\ \text{s.t.} \quad U(a) - U(b) + \sigma(a) - \sigma(b) \geq \delta \\ \quad \quad \text{if } aPb, \forall a, b \in A, \\ \quad \quad U(a) - U(b) + \sigma(a) - \sigma(b) = 0 \\ \quad \quad \text{if } aIb, \forall a, b \in A, \\ \quad \quad u_i(g_i^{j+1}) - u_i(g_i^j) \geq 0, \\ \quad \quad \sum_i u_i(g_{i*}) = 1, \quad u_i(g_{i*}) = 0, \quad \forall i, \end{array} \right.$$

where  $P$  and  $I$  represent the preference and the indifference relations, respectively,  $A$  is the set of reference alternatives used to develop the additive utility model,  $U(a) = \sum_{i=1}^n u_i[g_i(a)]$  is the global utility of an alternative  $a \in A$ ,  $\sigma(a)$  is an error function ( $\sigma(a) \geq 0$ ), and  $\delta$  is a threshold used to ensure the strict preference of an alternative  $a$  over an alternative  $b$  ( $\delta \geq 0$ ).

**Preference Disaggregation Approach: Basic Features, Examples from Financial Decision Making, Figure 1**  
**Piecewise linear form of marginal utilities**

Solving the above linear program a utility function is estimated which minimizes the deviations  $\sigma(a)$ . However, it has been observed that in many cases this utility function is not the most consistent one with the pre-ordering provided by the decision maker. On the contrary, utility functions that correspond to sub-optimal solutions of the above linear program often provide a more consistent representation of the decision maker's preferences. Furthermore, the above linear program has often multiple optimal solutions (degeneracy). Therefore, in order to examine these two essential issues, in a second stage the UTA method proceeds to a post-optimality analysis, trying to find some characteristic sub-optimal or multiple optimal solutions. A heuristic post-optimality procedure that has been proposed by E. Jacquet-Lagrèze and Y. Siskos [10] finds the solutions which correspond to extreme weights of the evaluation criteria. This is achieved by incorporating an additional constraint of the form:  $F \leq F^* + k(F^*)$ , where  $F^*$  is the optimal value of the objective function obtained by solving the above linear program and  $k(F^*)$  is a small portion of it. The new linear program that is obtained is solved with the objective being the minimization or the maximization of the weight of each criterion:

$$\begin{cases} \min \text{ (or max)} & \sum_{i=1}^n \rho_i u_i(g_{i*}) \\ \text{with } \rho_i = 0 \text{ or } 1, & \forall i. \end{cases}$$

Siskos and D. Yannacopoulos [28] proposed the UTASTAR method, an improved variant of the UTA method. The differences between the two methods can be identified in the following two aspects:

- 1) Instead of using the marginal utilities  $u_i(g_i^j)$  as decision variables, the difference  $w_{ij}$  between the marginal utilities of two successive values of a criterion is used:  $w_{ij} = u_i(g_i^{j+1}) - u_i(g_i^j) \geq 0$ . In this way the constraints  $u_i(g_i^{j+1}) - u_i(g_i^j) \geq 0$  are transformed in nonnegativity constraints  $w_{ij} \geq 0$ .
- 2) Two error functions are used instead of one. The two error functions denoted as  $\sigma^+(a)$  and  $\sigma^-(a)$  represent the overestimation or underestimation error that may occur in the decision maker's pre-ordering. The overestimation error involves alternatives that have been ranked by the decision maker higher than their rank according to the additive utility model, while the underestimation error involves alternatives which have been ranked by the decision maker lower than their rank according to the additive utility model.

Considering these two differences the new linear program that is solved is the following:

$$\left\{ \begin{array}{l} \min \quad \sum_{a \in A} [\sigma^+(a) - \sigma^-(a)] \\ \text{s.t.} \quad U(a) - U(b) + \sigma^+(a) - \sigma^-(a) \\ \quad \quad -\sigma^+(b) + \sigma^-(b) \geq \delta \\ \quad \quad \text{if } aPb, \\ \quad \quad U(a) - U(b) + \sigma^+(a) - \sigma^-(a) \\ \quad \quad -\sigma^+(b) + \sigma^-(b) = 0 \\ \quad \quad \text{if } aIb, \\ \quad \quad \sum_i \sum_j w_{ij} = 1, \\ \quad \quad w_{ij}, \sigma^+(a), \sigma^-(a) \geq 0, \quad \forall a \in A, \forall i, j, \\ \quad \quad u_i(g_i^k) = \sum_{k=1}^{a_i-1} w_{ik}, \quad \forall i, j, k. \end{array} \right.$$

The UTA and the UTASTAR methods have been applied successfully in a variety of decision problems, including environmental decisions [24], marketing decisions and sales strategy problems ([13,17,23]), customer satisfaction [25], venture capital investments [29], country risk assessment [2], evaluation of bankruptcy risk [37], as well as research and development decisions [5].

**Preference Disaggregation Approach: Basic Features, Examples from Financial Decision Making, Table 1**  
Evaluations of the firms

	EBIT/TA	NU/NW	TL/TA	(CA-I)/CL
$F_1$	10%	24%	33%	2.97
$F_2$	5%	9%	78%	1.11
$F_3$	13%	18%	80%	0.84
$F_4$	15%	-8%	72%	0.85
$F_5$	8%	-30%	93%	0.60

In the subsequent subsection, a simple example is used to illustrate how the UTASTAR method can be applied in the study of ranking problems.

*Example 1* Consider a decision problem concerning credit granting. Five firms ( $F_1, F_2, F_3, F_4, F_5$ ) are seeking financing by a bank. The credit managers of the bank evaluate the firms along four financial ratios:

- 1) earnings before interest and taxes/total assets (EBIT/TA);
- 2) net income/net worth (NI/NW);
- 3) total liabilities/total assets (TL/TA); and
- 4) (current assets-inventories)/current liabilities [(CA-I)/CL].

For the ratios EBIT/TA, NI/NW and (CA-I)/CL the preferences of the credit managers are increasing functions of their values. Hence, the higher the values of these ratios the more creditworthy a firm is. On the contrary, for the ratio TL/TA the preference of the credit managers is a decreasing function of its value, since high values of this ratio mean that the firm is highly indebted. Table 1 illustrates the evaluations of the firms along these four criteria.

According to the credit policy of the bank, the following preferential structure (pre-ordering) is defined:

$$F_1 P F_2 P F_3 P F_4 P F_5 .$$

The first step of the UTASTAR method consists of making explicit the utilities of the alternatives (firms). The range of values of each criterion (financial ratio) is divided into a number of subintervals, so that there is at least one firm belonging to each interval. Following this

rule the following scales are retained:

$$\begin{aligned} [g_{1*}, g_1^*] &= [5\%, 7.5\%, 10\%, 12.5\%, 15\%], \\ [g_{2*}, g_2^*] &= [-30\%, -16.5\%, -3\%, 10.5\%, 24\%], \\ [g_{3*}, g_3^*] &= [93\%, 73\%, 53\%, 33\%], \\ [g_{4*}, g_4^*] &= [0.6, 1.785, 2.97]. \end{aligned}$$

Using linear interpolation the global utilities of the firms can be written as follows:

$$\begin{aligned} U(F_1) &= u_1(10\%) + u_2(24\%) + u_3(33\%) + u_4(2.97), \\ U(F_2) &= u_1(5\%) + 0.11u_2(-3\%) + 0.89u_2(10.5\%) \\ &\quad + 0.25u_3(93\%) + 0.75u_3(73\%) \\ &\quad + 0.57u_4(0.6) + 0.43u_4(1.785), \\ U(F_3) &= 0.8u_1(12.5\%) + 0.2u_1(15\%) \\ &\quad + 0.44u_2(10.5\%) + 0.56u_2(24\%) \\ &\quad + 0.35u_3(93\%) + 0.65u_3(73\%) \\ &\quad + 0.80u_4(0.6) + 0.20u_4(1.785), \\ U(F_4) &= u_1(15\%) + 0.37u_2(-16.5\%) \\ &\quad + 0.63u_2(-3\%) \\ &\quad + 0.95u_3(73\%) + 0.05u_3(53\%) \\ &\quad + 0.79u_4(0.6) + 0.21u_4(1.785), \\ U(F_5) &= 0.8u_1(7.5\%) + 0.2u_1(10\%) \\ &\quad + u_2(-30\%) + u_3(93\%) + u_4(0.6). \end{aligned}$$

Using the transformation  $u_i(g_i^k) = \sum_{k=1}^{a_i-1} w_{ik}$ , the global utilities can be expressed as:

$$U(F_1) = w_{11} + w_{12} + w_{21} + w_{22} + w_{23} + w_{24} + w_{31} + w_{32} + w_{33} + w_{41} + w_{42}, \quad (1)$$

$$U(F_2) = w_{21} + w_{22} + 0.89w_{23} + 0.75w_{31} + 0.43w_{41}, \quad (2)$$

$$\begin{aligned} U(F_3) &= w_{11} + w_{12} + w_{13} + 0.20w_{14} \\ &\quad + w_{21} + w_{22} + w_{23} + 0.56w_{24} \\ &\quad + 0.65w_{31} + 0.20w_{41}, \end{aligned} \quad (3)$$

$$\begin{aligned} U(F_4) &= w_{11} + w_{12} + w_{13} + w_{14} + w_{21} \\ &\quad + 0.63w_{22} + w_{31} + 0.05w_{32} + 0.21w_{41}, \\ U(F_5) &= w_{11} + 0.2w_{12}. \end{aligned} \quad (4)$$

Taking into account the pre-ordering that was defined, and the global utilities of the firms the following linear program is formulated ( $\delta = 0.05$ ):

$$\begin{aligned} \min\{ & \sigma^+(F_1) + \sigma^-(F_1) + \sigma^+(F_2) + \sigma^-(F_2) \\ & + \sigma^+(F_3) + \sigma^-(F_3) + \sigma^+(F_4) + \sigma^-(F_4) \\ & + \sigma^+(F_5) + \sigma^-(F_5) \} \end{aligned}$$

s.t.

$$\begin{aligned} & w_{11} + w_{12} + 0.11w_{23} + w_{24} \\ & + 0.25w_{31} + w_{32} + w_{33} + 0.57w_{41} + w_{42} \\ & + \sigma^+(F_1) - \sigma^-(F_1) - \sigma^+(F_2) + \sigma^-(F_2) \geq 0.05, \end{aligned} \quad (5)$$

$$\begin{aligned} & -w_{11} - w_{12} - w_{13} - 0.2w_{14} - 0.11w_{23} \\ & - 0.56w_{24} + 0.1w_{31} + 0.23w_{41} \\ & + \sigma^+(F_2) - \sigma^-(F_2) - \sigma^+(F_3) + \sigma^-(F_3) \geq 0.05, \end{aligned} \quad (6)$$

$$\begin{aligned} & -0.8w_{14} + 0.37w_{22} + w_{23} + 0.56w_{24} \\ & - 0.35w_{31} - 0.05w_{32} - 0.01w_{41} \\ & + \sigma^+(F_3) - \sigma^-(F_3) - \sigma^+(F_4) + \sigma^-(F_4) \geq 0.05, \end{aligned} \quad (7)$$

$$\begin{aligned} & 0.8w_{12} + w_{13} + w_{14} + w_{21} + 0.63w_{22} \\ & + w_{31} + 0.05w_{32} + 0.21w_{41} \\ & + \sigma^+(F_4) - \sigma^-(F_4) - \sigma^+(F_5) + \sigma^-(F_5) \geq 0.05, \end{aligned} \quad (8)$$

$$\begin{aligned} & w_{11} + w_{12} + w_{13} + w_{14} + w_{21} + w_{22} \\ & + w_{23} + w_{24} + w_{31} + w_{32} + w_{33} + w_{41} + w_{42} = 1. \end{aligned} \quad (9)$$

Constraint (5) involves the pairwise comparison of  $F_1$  with  $F_2$ , constraint (6) involves the pairwise comparison of  $F_2$  with  $F_3$ , constraint (7) involves the pairwise comparison of  $F_3$  with  $F_4$ , constraint (8) involves the pairwise comparison  $F_4$  with  $F_5$ , while constraint (9) is used to normalize the global utilities between 0 and 1. The optimal solution to this linear problem is as follows. (The solver of Microsoft Excel has been used to solve all the presented linear programs. Since most of the solutions presented are not unique, different solutions may be obtained through other linear programming packages depending upon their particulari-

ties and vagaries.)

$$\begin{aligned} w_{13} &= 0.0152, w_{14} = 0.0357, \\ w_{21} &= 0.0758, w_{22} = 0.0786, \\ w_{23} &= 0.0959, w_{24} = 0.011, \\ w_{31} &= 0.1301, w_{32} = 0.0754, w_{33} = 0.0758, \\ w_{41} &= 0.3306, w_{42} = 0.0758. \end{aligned}$$

This solution is fully consistent with the predefined pre-ordering. More specifically, the global utilities obtained through this solution are:

$$\begin{aligned} U(F_1) &= 0.9491, U(F_2) = 0.4795, \\ U(F_3) &= 0.4295, U(F_4) = 0.3795, \\ U(F_5) &= 0. \end{aligned}$$

In a second stage, through the post-optimality analysis, the existence of multiple optimal solutions is investigated. In order to find the most characteristic solutions the weight of each criterion is maximized. This is achieved by solving four new linear programs with the objectives being the maximization of  $w_{11} + w_{12} + w_{13} + w_{14}$ ,  $w_{21} + w_{22} + w_{23} + w_{24}$ ,  $w_{31} + w_{32} + w_{33}$ , and  $w_{41} + w_{42}$ , respectively. For instance, the linear program to maximize the weight of the first criterion (EBIT/TA) would be the following:

$$\max\{w_{11} + w_{12} + w_{13} + w_{14}\}$$

s.t.

$$\begin{aligned} & w_{11} + w_{12} + 0.11w_{23} + w_{24} + 0.25w_{31} + w_{32} \\ & + w_{33} + 0.57w_{41} + w_{42} \geq 0.05, \\ & -w_{11} - w_{12} - w_{13} - 0.2w_{14} - 0.11w_{23} \\ & - 0.56w_{24} + 0.1w_{31} + 0.23w_{41} \geq 0.05, \\ & -0.8w_{14} + 0.37w_{22} + w_{23} + 0.56w_{24} \\ & - 0.35w_{31} - 0.05w_{32} - 0.01w_{41} \geq 0.05, \\ & 0.8w_{12} + w_{13} + w_{14} + w_{21} + 0.63w_{22} \\ & + w_{31} + 0.05w_{32} + 0.21w_{41} \geq 0.05, \\ & w_{11} + w_{12} + w_{13} + w_{14} + w_{21} + w_{22} + w_{23} \\ & + w_{24} + w_{31} + w_{32} + w_{33} + w_{41} + w_{42} = 1. \end{aligned}$$

Solving this linear program the obtained solution is:  $w_{14} = 0.2296$ ,  $w_{23} = 0.2390$ ,  $w_{41} = 0.5314$ . Similarly solving the other three linear programs the following solutions are obtained:

For  $\max\{w_{21} + w_{22} + w_{23} + w_{24}\}$ :

$$w_{21} = 0.4297, w_{22} = 0.3529, w_{41} = 0.2174 .$$

For  $\max\{w_{31} + w_{32} + w_{33}\}$ :

$$w_{23} = 0.0524, w_{33} = 0.7051, w_{41} = 0.2425 .$$

For  $\max\{w_{41} + w_{42}\}$ :

$$w_{23} = 0.0524, w_{41} = 0.2425, w_{42} = 0.7051 .$$

A simple way to select a unique utility function is to consider the mean of all the solutions obtained through the post-optimality stage:

$$w_{14} = 0.0574, w_{21} = 0.1074 ,$$

$$w_{22} = 0.0882, w_{23} = 0.0860 ,$$

$$w_{33} = 0.1763, w_{41} = 0.3084, w_{42} = 0.1763 .$$

Consequently, the marginal utilities of the financial ratios are:

$$u_1(5\%) = u_1(7.5\%) = u_1(10\%) = u_1(12.5\%) = 0 ,$$

$$u_1(15\%) = 0.0574 ,$$

$$u_2(-30\%) = 0, u_2(-16.5\%) = 0.1074 ,$$

$$u_2(-3\%) = 0.1957 ,$$

$$u_2(10.5\%) = 0.2816 u_2(24\%) = 0.2816 ,$$

$$u_3(93\%) = u_3(73\%) = u_3(53\%) = 0 ,$$

$$u_3(33\%) = 0.1763 .$$

$$u_4(0.6) = 0, u_4(1.785) = 0.3084 ,$$

$$u_4(2.97) = 0.4847 .$$

According to this solution the global utilities of the firms are:

$$U(F_1) = 0.9426, U(F_2) = 0.4048 ,$$

$$U(F_3) = 0.3548, U(F_4) = 0.2852, U(F_5) = 0 .$$

It is obvious that the ranking of the firms according to their global utilities is fully consistent with the predefined pre-ordering. Furthermore, the bank can use the obtained additive utility function to evaluate any new firm.

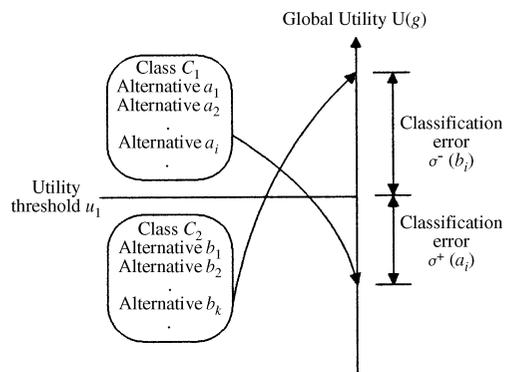

### Preference Disaggregation Analysis in Sorting Problems

The preference disaggregation analysis except for the study of ranking problems can also be used to study

sorting problems. In this case, the primary objective is not to rank a set of alternatives from the best ones to the worst ones, but instead the aim is to sort the alternatives into two or more predefined ordered homogeneous classes denoted as  $C_1, \dots, C_q$  ( $C_1$  is the class of the best alternatives, and  $C_q$  is the class of the worst alternatives). The sorting of the alternatives can be accomplished in several ways. The most simple and common one is based on the comparison of the score of each alternative with some thresholds ( $u_1, \dots, u_{q-1}$ ) which distinguish the classes. Following the methodological framework of the UTA method the score of each alternative is its global utility  $U(a)$ . The sorting of an alternative  $a$  is accomplished through the following comparisons:

$$\begin{aligned} U(a) \geq u_1 &\Rightarrow a \in C_1 , \\ u_2 \leq U(a) < u_1 &\Rightarrow a \in C_2 , \\ &\dots \\ u_k \leq U(a) < u_{k-1} &\Rightarrow a \in C_k , \\ &\dots \\ U(a) < u_{q-1} &\Rightarrow a \in C_q . \end{aligned}$$

J.M. Devaud et al. [3] (see also [9] and [42]) proposed the UTADIS method (UTilités Additives DIScriminantes) a variant of the UTA method which is especially conceived for the study of sorting problems. The objective of the method is to estimate a global utility model (additive utility function) and the utility thresholds in order to minimize the classification error. The classification error is measured through two error

Preference Disaggregation Approach: Basic Features, Examples from Financial Decision Making, Figure 2 Classification errors

functions denoted as  $\sigma^+(a)$  and  $\sigma^-(a)$ , representing the deviations of a misclassified alternative from the utility threshold. Figure 2 illustrates these two types of errors for the two-group (class) sorting problem.

In the UTADIS method the additive utility model and the utility thresholds are estimated through the following linear program (using the transformation  $w_{ij} = u_i(g_i^{j+1}) - u_i(g_i^j)$  proposed in [28]):

$$\left\{ \begin{array}{l} \min \quad F = \sum_{a \in C_1} \sigma^+(a) + \dots \\ \quad + \sum_{a \in C_k} [\sigma^+(a) + \sigma^-(a)] + \dots \\ \quad + \sum_{a \in C_q} \sigma^+(a) \\ \text{s.t.} \quad U(a) - u_1 + \sigma^+(a) \geq 0, \quad \forall a \in C_1, \\ \quad U(a) - u_{k-1} - \sigma^-(a) \leq -\delta, \quad \forall a \in C_k, \\ \quad U(a) - u_k + \sigma^+(a) \geq 0, \quad \forall a \in C_k, \\ \quad U(a) - u_{q-1} - \sigma^-(a) \leq -\delta, \quad \forall a \in C_q, \\ \quad \sum_{i=1}^m \sum_{j=1}^{a_i-1} w_{ij} = 1, \\ \quad u_{k-1} - u_k \geq s, \quad k = 2, \dots, q-1, \\ \quad w_{ij} \geq 0, \quad \sigma^+(a) \geq 0, \quad \sigma^-(a) \geq 0. \end{array} \right.$$

The first constraint implies that the global utility of an alternative  $a \in C_1$  should be greater or equal to the utility threshold  $u_1$ . If this is not possible, then an amount of utility equal to  $\sigma^+(a)$  should be added to the global utility of this alternative, indicating that the alternative is classified to a lower class than the one it actually belongs (cf. Fig. 2). The second set of constraints is used for alternatives that are classified by the decision maker in an intermediate class  $C_k$ . In such cases, the global utility of the alternative should be strictly lower than the utility threshold  $u_{k-1}$  (a positive small real number  $\delta$  is used to ensure the strict inequality) and greater or equal to the utility threshold  $u_k$ . If either of these two conditions is not satisfied then the corresponding amount of utility  $\sigma^+(a)$  or  $\sigma^-(a)$  should be added (subtracted) to the global utility of the alternative. Similarly, the third constraint is used for alternatives which belong to the worst class  $C_q$ . The global utility of these alternatives should be strictly lower than the utility threshold  $u_{q-1}$ ; otherwise an amount of utility equal to  $\sigma^-(a)$  should be subtracted from the global utility of the alternatives, indicating that these alternatives are classified by the

model to a higher (better) class than the one they actually belong (cf. Fig. 2). The fourth constraint is used as a normalization constraint, so that the global utilities and the utility thresholds are normalized between 0 and 1. Finally, the fifth constraint is used to ensure that  $u_1 > \dots > u_{q-1}$  (a positive real number  $s > \delta > 0$  is used to ensure the strict inequality between the utility thresholds). The post-optimality analysis stage is performed similarly to the UTA method.

In [4] and [41] three variants of the UTADIS method were proposed to improve the classification accuracy of the obtained additive utility models. The first variant (UTADIS I) except for the classification errors also incorporates the distances of the correctly classified alternatives from the utility thresholds which have to be maximized. The second variant (UTADIS II) is based on a mixed integer programming formulation minimizing the number of misclassifications instead of their magnitude, while the third variant (UTADIS III) combines UTADIS I and II, and its aim is to minimize the number of misclassifications and maximize the distances of the correctly classified alternatives from the utility thresholds.

Except for the classification of the alternatives in the predefined classes, the global utilities of the alternatives that are estimated through the family of the UTADIS methods can be used to rank the alternatives belonging in each class. Hence, the decision maker is provided with an additional information that can be used to identify the best and the worst alternatives within each class. The applications of the UTADIS method include sales strategy problems [3], the evaluation of research and development projects [9], and several financial decision problems such as credit risk and bankruptcy risk evaluation, country risk assessment, credit card evaluation, evaluation of bank branches' efficiency, and portfolio selection and management ([4,41,42]). In the subsequent subsection, a simple example is used to illustrate how the UTADIS method can be applied in the study of sorting problems.

*Example 2* Let us consider again the credit granting problem which has been used previously to illustrate the application of the UTASTAR method. In this case we assume that the credit managers of the bank are not interested in ranking the firms from the most creditworthy to the less creditworthy ones, but instead they

are interested in sorting them in two classes: the credit-worthy firms which could be financed by the bank (class  $C_1$ ), and the untrustworthy firms which should not be financed (class  $C_2$ ). Suppose according to the credit policy of the bank, that the firms  $F_1, F_2$  and  $F_3$  can be considered as creditworthy firms, whereas the firms  $F_4$  and  $F_5$  can be considered as risky (untrustworthy) firms. The global utilities of the firms have the same form as in the case of the UTASTAR method (1)–(4). The new linear program that is used to estimate the additive utility model is the following:

$$\min \sigma^+(F_1) + \sigma^+(F_2) + \sigma^+(F_3) + \sigma^-(F_4) + \sigma^-(F_5)$$

s.t.

$$\begin{aligned} &w_{11} + w_{12} + w_{21} + w_{22} + w_{23} + w_{24} \\ &+ w_{31} + w_{32} + w_{33} \\ &+ w_{41} + w_{42} - u_1 + \sigma^+(F_1) \geq 0, \end{aligned} \quad (10)$$

$$\begin{aligned} &w_{21} + w_{22} + 0.89w_{23} + 0.75w_{31} \\ &+ 0.43w_{41} - u_1 + \sigma^+(F_2) \geq 0, \end{aligned} \quad (11)$$

$$\begin{aligned} &w_{11} + w_{12} + w_{13} + 0.20w_{14} \\ &+ w_{21} + w_{22} + w_{23} + 0.56w_{24} \\ &+ 0.65w_{31} + 0.20w_{41} - u_1 + \sigma^+(F_3) \geq 0, \end{aligned} \quad (12)$$

$$\begin{aligned} &w_{11} + w_{12} + w_{13} + w_{14} \\ &+ w_{21} + 0.63w_{22} + w_{31} + 0.05w_{32} \\ &+ 0.21w_{41} - u_1 - \sigma^-(F_4) \leq 0.001, \end{aligned} \quad (13)$$

$$w_{11} + 0.2w_{12} - u_1 - \sigma^-(F_5) \leq 0.001, \quad (14)$$

$$\begin{aligned} &w_{11} + w_{12} + w_{13} + w_{14} \\ &+ w_{21} + w_{22} + w_{23} + w_{24} \\ &+ w_{31} + w_{32} + w_{33} + w_{41} + w_{42} = 1. \end{aligned} \quad (15)$$

Constraints (10)–(12) involve the firms  $F_1, F_2$  and  $F_3$  which belong in class  $C_1$  and consequently their global utility should be greater or equal to the utility threshold  $u_1$ . On the contrary, constraints (13)–(14) involve the firms  $F_4$  and  $F_5$  which belong in class  $C_2$  and con-

sequently their global utilities should be strictly lower than the utility threshold  $u_1$  (a small positive number  $\delta = 0.001$  is used to ensure the strict inequality). Constraint (15) is used similarly to the UTASTAR method for normalization purposes. Solving the above linear program the following solution is obtained:

$$w_{22} = 0.1779, w_{23} = 0.8018, w_{31} = 0.0203 .$$

The estimated utility threshold is  $u_1 = 0.9067$ . According to this solution the global utilities of the firms are:

$$\begin{aligned} &U(F_1) = 1, U(F_2) = 0.9067, \\ &U(F_3) = 0.9929, U(F_4) = 0.1324, U(F_5) = 0 . \end{aligned}$$

Obviously, all the firms are correctly classified into their original class, however the obtained solution is not unique. Consequently, the method proceeds to the post-optimality analysis stage to identify the most characteristic multiple optimal solutions. This is achieved similarly to the UTASTAR method. However in this case, five new linear programs are solved. The first four correspond to the maximization of the criteria's weights (as in the UTASTAR method), while the fifth corresponds to the maximization of the utility threshold  $u_1$ . For example, the linear programming formulation for maximizing the weight of the ratio EBIT/TA is the following:

$$\min\{w_{11} + w_{12} + w_{13} + w_{14}\}$$

s.t.

$$\begin{aligned} &w_{11} + w_{12} + w_{21} + w_{22} + w_{23} + w_{24} \\ &+ w_{31} + w_{32} + w_{33} \\ &+ w_{41} + w_{42} - u_1 \geq 0, \end{aligned}$$

$$\begin{aligned} &w_{21} + w_{22} + 0.89w_{23} \\ &+ 0.75w_{31} + 0.43w_{41} - u_1 \geq 0, \end{aligned}$$

$$\begin{aligned} &w_{11} + w_{12} + w_{13} + 0.20w_{14} \\ &+ w_{21} + w_{22} + w_{23} + 0.56w_{24} \\ &+ 0.65w_{31} + 0.20w_{41} - u_1 \geq 0, \end{aligned}$$

$$\begin{aligned} &w_{11} + w_{12} + w_{13} + w_{14} + w_{21} + 0.63w_{22} \\ &+ w_{31} + 0.05w_{32} + 0.21w_{41} - u_1 \leq -0.001, \end{aligned}$$

$$w_{11} + 0.2w_{12} - u_1 \leq -0.001,$$

$$w_{11} + w_{12} + w_{13} + w_{14}$$

$$+ w_{21} + w_{22} + w_{23} + w_{24}$$

$$+ w_{31} + w_{32} + w_{33} + w_{41} + w_{42} = 1 .$$

The solution to this linear program is:

$$w_{14} = 0.4704, w_{23} = 0.5296,$$

and the utility threshold is  $u_1 = 0.4714$ .

Similarly solving the other four linear programs the following solutions are obtained.

For  $\max\{w_{21} + w_{22} + w_{23} + w_{24}\}$ :

$$w_{21} = 0.2772, w_{22} = 0.1619,$$

$$w_{23} = 0.2837, w_{24} = 0.2772,$$

$$u_1 = 0.3802.$$

For  $\max\{w_{31} + w_{32} + w_{33}\}$ :

$$w_{23} = 0.0011, w_{33} = 0.9989, u_1 = 0.001.$$

For  $\max\{w_{41} + w_{42}\}$ :

$$w_{23} = 0.0010, w_{41} = 0.0005,$$

$$w_{42} = 0.9985, u_1 = 0.0011.$$

For  $\max\{u_1\}$ :

$$w_{21} = 0.9861, w_{22} = 0.0139,$$

$$u_1 = 1.$$

Similarly to the UTASTAR method, the mean of these solutions is considered as a unique solution:

$$w_{14} = 0.0941, w_{21} = 0.2527,$$

$$w_{22} = 0.0352, w_{23} = 0.1631,$$

$$w_{24} = 0.0554, w_{33} = 0.1998,$$

$$w_{41} = 0.0001, w_{42} = 0.1997.$$

The utility threshold is  $u_1 = 0.3707$ . Consequently, the marginal utilities of the financial ratios are:

$$u_1(5\%) = u_1(7.5\%) = u_1(10\%) = u_1(12.5\%) = 0,$$

$$u_1(15\%) = 0.0941.$$

$$u_2(-30\%) = 0, u_2(-16.5\%) = 0.2527,$$

$$u_2(-3\%) = 0.2878, u_2(10.5\%) = 0.4509,$$

$$u_2(24\%) = 0.5064.$$

$$u_3(93\%) = u_3(73\%) = u_3(53\%) = 0,$$

$$u_2(33\%) = 0.1998.$$

$$u_4(0.6) = 0, u_4(1.785) = 0.0001,$$

$$u_4(2.97) = 0.1998.$$

According to this solution the global utilities of the firms are:

$$U(F_1) = 0.9059, U(F_2) = 0.4330,$$

$$U(F_3) = 0.5008, U(F_4) = 0.3689, U(F_5) = 0.$$

It is obvious that the sorting of the firms according to their global utilities is fully consistent with the predefined classification. The utility function that has been constructed through the above procedure is the following:

$$U(g) = 0.0941u_1(g_1) + 0.5064u_2(g_2) \\ + 0.1998u_3(g_3) + 0.1998u_4(g_4).$$

### Preference Disaggregation Analysis in Choice Problems

Except for the study of ranking and sorting problems the preference disaggregation analysis is also applicable in choice problems. In this case the decision maker is concerned with the selection of the most appropriate alternative. T.J. Stewart [33] demonstrated how the preference disaggregation analysis could be applied in such types of problems. The methodology that he proposes combines the UTA method with an interactive pruning of the alternatives until the best alternative is selected. The proposed approach proceeds in five steps:

- 1) Initially, a subset of the alternatives under consideration is selected.
- 2) Following the methodology of the UTA method, the decision maker is asked to provide a ranking (pre-ordering) of the subset of the alternatives that was selected in step 1.
- 3) According to the ranking defined in the previous step and using the UTA method the corresponding utility function is estimated. In the same step, for each alternative  $a$  not belonging to the reference set used to construct the additive utility model, a linear program is solved in order to investigate the existence of a utility function for which  $U(a) > U(o)$  (where  $o$  is the best alternative among the alternatives belonging to the reference set) while retaining the correct (consistent) ranking of the other alternatives of the reference set. If such a utility function does not exist, then  $a$  can be eliminated from further consideration.

- 4) If such a utility function exists then, in step 4, the utilities of all the alternatives (based on the utility function developed on the reference set of alternatives) are presented to the decision maker along with all the alternatives not belonging to the reference set that can be considered as best alternatives (for which there is a utility function that makes them the best alternatives).
- 5) If the decision maker is satisfied with the best solution then the process stops, otherwise in step 5 the decision maker selects the alternative not belonging to the reference set which outperforms the current best alternative among the reference set. This new alternative is included in the initial reference set and the decision maker is asked to provide a new ranking of the alternatives in the new reference set. The methodology proceeds from step 3, until all the alternatives not belonging into the reference set have been considered.

Another way of applying the preference disaggregation approach in choice problems has been proposed in [22]. This approach is based on constructing a fuzzy outranking relation [20] using the set of utilities estimated through the post-optimality analysis performed through the UTA method. The relation suggested is based on the calculation of the percentage of utilities for which an alternative is better than another. In this way the degree of credibility of the affirmation 'alternative  $a$  is at least as good as alternative  $b$ ' is estimated. The construction of this outranking relation enables the decision maker to identify the best alternative(s) which are not outranked by any other alternative(s), while furthermore, the incomparabilities which may occur among the alternatives due to their dissimilar characteristics are identified.

### Conclusions and Future Research

In this article the main features, disciplines and characteristics of the preference disaggregation approach of MCDA were presented. Furthermore, the applicability of the preference disaggregation analysis in the study of several types of problems (ranking, sorting, and choice) was demonstrated through the description of the UTA method and several of its variants.

Preference disaggregation analysis using minimal information from the decision maker constitutes

a promising and powerful approach for modeling the decision makers' preference and developing a global preference model through an interactive and iterative procedure.

Multicriteria decision support systems (MCDSSs) implementing this MCDA approach can be very helpful tools both for decision analysts as well as for decision makers in making decisions in real world situations where the time is limited while the cost of taking a decision is a very significant factor. Researchers in this field have already explored the potentials of MCDSSs incorporating preference disaggregation procedures. Some representative examples are the PREFCALC system [8], the MINORA system [26], the MIIDAS system [27], the PREFDIS system [44], the FINCLAS system [43] and the FINEVA system [45] for corporate assessment, as well as the MARKEX system [13] for marketing decisions. Recently (1998), researchers have also investigated the contribution of artificial intelligence techniques in the framework of an integrated decision support system (intelligent multicriteria decision support systems), combining the preference disaggregation approach as well as other MCDA approaches with the capabilities provided by expert systems and neural networks. The appealing features of such an integration, constitute a significant field of further research both in preference disaggregation analysis as well as in MCDA in general.

Preference; Ordered set; Valued relation; Utility; Measurement

Preference modeling is an inevitable step in a lot of fields, that include economy, psychology, sociology, operational research, decision support systems.

This step is sometimes implicit, as in operational research and economy, where the preferences of the decision-maker are often represented by a function to be optimized; sometimes it is studied in detail and based on experiments or inquiries, as in psychophysics or multicriteria analysis. Of course, people coming from different disciplines will, in general, have different points of view on preference modeling. It is useful to distinguish the *normative perspective* (attitude which consists in defining how to take a decision in order to satisfy predefined norms or properties; here the main questions are: how to be rational? how must be the preferences in order to reach that goal?), the *descriptive perspective* (attitude which consists in modeling, as realistically as possible, the behavior of a decision-maker; how do people take decisions?) and the *prescriptive* one (attitude which consists in helping a decision-maker to be as coherent as possible with his own goals and preferences; how to help somebody to decide?).

However, people working on preferences, even they come from different fields and have different perspectives, use more or less the same tools. The purpose of this article is to give a brief overview of these tools.

### Basic Preference Relations

Let  $A$  be the set of elements (decisions, candidates for a job, commodities, consumption levels, locations, ...) to be compared or evaluated. It is often assumed that, comparing two elements  $a$  and  $b$ , the decision-maker can have three attitudes: *preference* for one element (a decision-maker prefers a decision  $a$  over a decision  $b$  (eventually according to a particular point of view) if, in a situation where he has to select one of them, he

chooses  $a$ ), *indifference* between  $a$  and  $b$  (a decision-maker is indifferent between two decision  $a$  and  $b$  (eventually according to a particular point of view) if both decisions are equally acceptable for him), and *incomparability* between them (two decisions  $a$  and  $b$  are incomparable (at a given moment of a decision process) if the decision-maker is not able or refuse to express a preference or an indifference, due to a lack of data or contradictory information). We will denote:

$$\begin{cases} aPb & \text{if } a \text{ is preferred to } b, \\ bPa & \text{if } b \text{ is preferred to } a, \\ aIb & \text{in case of indifference,} \\ aJb & \text{in case of incomparability.} \end{cases}$$

The basic preference relations  $P$ ,  $I$  and  $J$  are the sets of couples  $(a, b)$  such that, respectively,  $aPb$ ,  $aIb$  and  $aJb$ . These relations are used in most of the works devoted to preference modeling. Moreover, it is traditionally accepted that these relations are mutually exclusive and verify the following basic properties:  $\forall a, b \in A$ ,

$$\begin{cases} aPb \Rightarrow b \not Pa & (P \text{ is asymmetric}), \\ aIa & (I \text{ is reflexive}), \\ aIb \Rightarrow bIa & (I \text{ is symmetric}), \\ a \not J a & (J \text{ is irreflexive}), \\ aJb \Rightarrow bJa & (J \text{ is symmetric}). \end{cases}$$

Defining the 'preference-indifference relation'  $S$  by  $aSb$  if and only if  $aPb$  or  $aIb$ , it is not difficult to see that all the above situations can be characterized using only relation  $S$ :

$$\begin{cases} aPb & \text{if and only if } aSb \text{ and } b \not Sa, \\ aIb & \text{if and only if } aSb \text{ and } bSa, \\ aJb & \text{if and only if } a \not Sb \text{ and } b \not Sa. \end{cases}$$

### Traditional Preference Model

A usual attitude is to associate numbers (valuations) to the elements of  $A$  and to declare that  $a$  is preferred to  $b$  if the 'value' of  $a$  is greater (or smaller if the 'value' is a cost for example) than the value of  $b$  and that there is indifference if the values are equal. This is the traditional approach in operational research, decision theory, economy or finance, where decision problems are considered as optimization ones. This attitude leads to

a preference model with the following strong assumptions:  $\forall a, b, c \in A$ ,

$$\begin{cases} aPb \text{ and } bPc \Rightarrow aPc & (P \text{ transitive}), \\ aIb \text{ and } bIc \Rightarrow aIc & (I \text{ transitive}), \\ aPb \text{ and } bIc \Rightarrow aPc, \\ aIb \text{ and } bPc \Rightarrow aPc, \end{cases}$$

and  $J$  is empty (there is no incomparability).

In terms of relation  $S$ , this means that,  $\forall a, b, c \in A$ ,

$$\begin{cases} aSb \text{ and } bSc \Rightarrow aSc & (S \text{ transitive}), \\ a \not Sb & \Rightarrow bSa & (S \text{ complete}), \end{cases}$$

characterizing what is usually called a *weak order* (i. e., a transitive and complete relation). In this case, indifference  $I$  is an *equivalence* (i. e., a reflexive, symmetric and transitive relation) and the set of equivalence classes is totally ordered by relation  $P$ .

When  $A$  is finite or enumerable, the weak order structure is sufficient to represent preferences by numbers as explained here above; in the nonenumerable case, some topological conditions have to be added (see [7]).

### Extensions of the Traditional Model

The transitivity of indifference is incompatible with the existence of a 'sensitivity threshold' under which the decision-maker does not feel any difference between two elements or refuses to accept a strict preference for one of the elements. Moreover, the frontier between indifference and preference is not always clear, leading to new situations (and new relations) called 'hesitation between indifference and preference' or 'weak, strong, very strong, ... preferences'. Finally it is also necessary to extend the traditional model by taking into account incomparability situations ( $J$  is not always empty). All these considerations have led to new models called *semi-orders*, *interval orders*, *partial orders*, *pseudo-orders*, *suborders*, *embedded families of preferences*, ..., which were extensively studied in the literature. The interested reader can consult [5,6,8,11,14,20,22,26].

### Valued Preferences

Modelers sometimes want to quantify preferences to express either an intensity of preference, either a num-

ber (or a percentage) of votes in favor of an element over another, either a probability of preference, or a 'degree' (without any specific property). In this case, a number is associated to each couple  $(a, b)$ , leading to so-called valued, fuzzy, probabilistic relations. The study of the properties of these relations, of their representations by numerical functions and of their use in decision models, is illustrated, for instance, by [9] or [12].

### Preferences on Structured Sets

The set  $A$  may have a special structure: the elements of  $A$  are sometimes points in a topological space (as in economy), vectors of evaluations on several dimensions (as in multicriteria analysis), probability distributions on a set of consequences (as in decision-making under risk), sets of possible consequences depending on the states of the nature (as in decision-making under uncertainty). All these situations have led to a lot of models, concepts or methodologies that include value theory, utility theory, multi-attribute utility theory, multiple criteria decision analysis, subjective expected utility theory and conjoint measurement theory.

Some references in this abundant literature are [7,10,15,16,18,19,23,25,28,29].

### Other Topics Connected to Preference Modeling

We briefly mention in this section some topics which cannot be ignored by people interested in preference modeling:

- the 'art' of collecting preference information from subjects (see for example [30]),
- the statistical analysis of preferences (see [4] or [13]),
- the geometrical representation of preferences (see for example [2]),
- the problem of meaningfulness ([21]),
- the evolution of preferences over time (see [17]),
- the philosophical aspects of preference modeling ([3,31])
- the social choice theory ([24]),
- the preference aggregation problem ([1,27]).

## Keywords

Stochastic programming; Preprocessing; Feasibility; Gale–Hoffman inequalities

A two-stage stochastic linear program with random right-hand side (and with discrete random variables) is normally written as follows

$$\begin{cases} \min_{x \geq 0} & cx + Q(x) \\ \text{s.t.} & Ax = b \end{cases}$$

where

$$Q(x) = \sum_j p_j Q(x, \xi_j),$$

and

$$Q(x, \xi) = \min_{y \geq 0} \{qy : Wy = h(\xi) - T(\xi)x\}.$$

Here,  $p_j$  is the probability that the random vector  $\tilde{\xi}$  takes on its  $j$ th possible value  $\xi_j$ , and  $W$  is an  $(m \times n)$  matrix. This way of formulating a two-stage stochastic program is partly motivated by solution procedures ([1,8]), partly by the time structure of the problem. For this article, the latter is the most important. The interpretation of the problem is that first (now) we make a decision  $x$ , then we observe a value of  $\tilde{\xi}$ , and finally we make a *recourse decision*  $y$  based on our earlier decision  $x$  and the observed value of  $\tilde{\xi}$ .

Many aspects of preprocessing (pre-analysis) are in no way particular to multistage stochastic problems. For example, the issue of removing redundant rows and columns, as well as that of consistency, are well discussed for deterministic (one-stage) problems, see for example the work on preprocessing in linear programming by H.J. Greenberg [5]. Details referring to stochastic programs are found in [10], and in [7, Chapt. 5; 6]. The one major point to make for stochastic programs is that since, for example, the matrix  $W$  shows up

in the formulation as many times as there are possible values of  $\tilde{\xi}$ , it may be worthwhile to spend a lot of effort just to simplify the matrix a little. This may not be true for deterministic LPs, as it may cost more to simplify the matrix than to solve the problem to optimality without simplifications. Hence, although *technically* the issues are the same, the *motivation* for simplifications may be rather different.

An  $x_0 \geq 0$  satisfying  $Ax_0 = b$  may produce a *recourse problem*  $Q(x_0, \xi_j)$  which is infeasible for some  $j$ . In other words, the requirement that  $Q(x, \xi)$  be feasible for all  $\xi$  produces *implied constraints* on the *first-stage decisions*  $x$ . The cone  $\text{pos } W$  is a cone containing all vectors which are such that if they are put as right hand sides in the second-stage problem, they produce a feasible problem. Formally,

$$\text{pos } W = \{t: t = Wy, y \geq 0\}.$$

If  $\text{pos } W = \mathbf{R}^m$  we say that we have *complete recourse*. That is easy to test for [10]. If  $h(\xi) - T(\xi) x \in \text{pos } W$  for all possible  $\xi$  and all  $x \geq 0$  satisfying  $Ax = b$ , we have *relatively complete recourse*. This is hard to test, but possible to generate. The rest of this article will discuss the generation of relatively complete recourse. The clue is that if we find all implied constraints, and add them to  $Ax = b$ , the expanded set of constraints will imply relatively complete recourse by construction. These implied constraints are useful in two directions, a) when solving the stochastic program we can use methods requiring relatively complete recourse, and b) the implied constraints will show the modeler things he has assumed, but never written down explicitly. Hence, the constraints are useful for both error detection and increased understanding. A small numerical example can be found in [7, Sect. 6.4].

To find an implied constraint for a given  $x_0$  is equivalent to finding a *feasibility cut* in Benders decomposition (cf. also ► **Generalized Benders decomposition**). However, the purpose of preprocessing is not to find just one, but to find all implied constraints (feasibility cuts). More formally, we look for a *polar matrix*  $W^*$  (with a minimal number of columns), which is such that

$$y \in \text{pos } W \Leftrightarrow y^T W^* \leq 0.$$

```

PROCEDURE support( $W, W^*$ );
BEGIN
  frame( $W$ );
  done:=false;
  FOR  $i = 1$  TO  $n$  DO
    IF NOT done THEN BEGIN
       $\alpha := W_i^T W^*$ ;
       $I_+ := \{k : \alpha(k) > 0\}$ ;
       $I_- := \{k : \alpha(k) < 0\}$ ;
       $I_0 := \{k : \alpha(k) = 0\}$ ;
      done:= ( $I_+ \cup I_- = \emptyset$ );
      IF done THEN  $W^* := 0$ ;
      IF  $I_+ \neq \emptyset$  AND NOT done THEN
        BEGIN
          IF  $I_- = \emptyset$  THEN  $W^* := W_{I_-}^*$ 
          ELSE BEGIN
            FOR ALL  $k \in I_+, j \in I_-$  DO
               $C_{kj} := W_k^* - (\alpha(k)/\alpha(j)) W_j^*$ ;
               $W^* := W_{I_+}^* \cup W_{I_-}^* \cup_{kj} C_{kj}$ ;
            frame( $W^*$ );
          END; (*ELSE*)
        END; (*IF*)
      END; (*FOR*)
    END support;
  
```

#### Pseudocode for finding the polar matrix $W^*$

Finding  $W^*$  is a problem of exponential complexity, equivalent to extreme point enumeration. An algorithm tailored to the problem is found in [10], and presented above. For reasonably large LPs one cannot, in general, expect to be able to find all implied constraints. However, if there are few implied constraints (and that is in any case the more interesting situation) the algorithm will find them quickly. Hence, this procedure may in some situations yield a lot of insight into a problem, in other cases it leads nowhere. Only by checking can that be found out. A pseudocode for the algorithm is given below. Two calls are made to a procedure  $\text{frame}(W)$ . This procedure finds a *frame* of  $\text{pos } W$ , i.e., it removes all columns from  $W$  that are nonnegative linear combinations of other columns. The variable  $\text{done}$  is boolean. The recourse matrix  $W$  is input to the procedure, and the polar matrix  $W^*$  is output. An illustrated example of the use of this procedure is found in [7, Sect. 5.2].

For networks there are some more specific results. The starting point is the well known result by D. Gale [2] and A.J. Hoffman [6]. Let a network be given by a set of arcs  $\mathcal{A} = \{1, \dots, n\}$  and a set of nodes  $\mathcal{N} = \{1, \dots, m\}$ . An arc  $k$  may be described by its start node  $i$  and end node  $j$  by  $k \sim (i, j)$ . We let  $\beta(i)$  be the external flow in node  $i$  (with a positive number meaning supply), and let  $\gamma(k)$  be the capacity of arc  $k$ . By  $Q^+ = [Y, \mathcal{N} \setminus Y]^+$  we understand the set of arcs starting in a node in  $Y$  and ending in  $\mathcal{N} \setminus Y$ . We define  $Q^-$  similarly, and define  $Q = Q^+ \cup Q^-$  as a *cut*. Finally, we let  $G(Y)$  be the graph consisting of the nodes in  $Y$ , and the arcs connecting nodes in  $Y$ . The Gale–Hoffman (GH) result says that a capacitated network flow problem is feasible if and only if for every cut  $Q = [Y, \mathcal{N} \setminus Y]$ , the net supply in  $Y$  is less than or equal to the capacity of  $Q^+$ , i. e. if the GH-inequality

$$\sum_{i \in Y} \beta(i) \leq \sum_{k \in Q^+} \gamma(k) \quad (1)$$

is satisfied. Following [11] this has been strengthened to show that a GH-inequality is needed if and only if  $G(Y)$  and  $G(\mathcal{N} \setminus Y)$  are both connected. If either of them is disconnected, the GH-inequality is not needed as it is implied by other GH-inequalities. This is an interesting result as it shows that a linear dependency argument can be obtained by looking only at one inequality at a time.

An algorithm for finding all necessary GH-inequalities can be found in [12], and one for updating the inequalities when new arcs or nodes are introduced is given in [3]. The latter can be seen as a network interpretation of procedure support. These results are shown for uncapacitated networks in [4,9]. They can be found directly or deduced from the capacitated case by observing that (1) will always be satisfied as long as  $Q^+ \neq \emptyset$ . Hence, we keep only those GH-inequalities for which  $Q^+ = \emptyset$ . The result that  $G(Y)$  and  $G(\mathcal{N} \setminus Y)$  both must be connected still applies.

If the recourse problem is a network flow problem, the  $W$ -matrix is the node-arc incidence matrix (with a row removed), and both external flows and arc capacities are functions of the first stage decisions  $x$  and the random variables  $\xi$ . If  $\beta$  and  $\gamma$  in (1) are replaced by the appropriate expressions in  $x$  and  $\xi$ , and the results added to  $Ax = b$ , we obtain relatively complete recourse, which was our goal. Since this must be true for all  $\xi_j$  for

a given  $x$ , we can normally perform a worst-case analysis with respect to  $\xi_j$ , and add this result to the first case constraints.

If a capacitated network flow problem is formulated as an LP, with the upper bounds written explicitly as constraints, and procedure support is applied, the columns of  $W^*$  will correspond to an index vector for  $\beta$  and  $\gamma$  (with negative signs on the index vector for  $\gamma$ ) in (1).

### Introduction

The classical paradigm in mathematical programming is to develop a model that assumes that the input data is precisely known and equal to some nominal values. This approach, however, does not take into account the influence of data uncertainties on the quality and feasibility of the model. It is therefore conceivable that as the data takes values different than the nominal ones several constraints may be violated, and the optimal solution found using the nominal data may be no longer optimal or even feasible. In a numerical case study on linear optimization problems from the Net Lib library, Ben-Tal and Nemirovski [1] concluded that in real-world applications of linear optimization problems, one cannot ignore the possibility that a small uncertainty in the data can make the usual optimal solution completely meaningless from a practical viewpoint. This observation raises the natural question of designing solution approaches that are immune to data uncertainty, that is they are “robust”. Modern robust linear optimization models are proposed by Ben-Tal and Nemirovski [1], Bertsimas and Sim [2] and Chen, Sim and Sun [3]. While the proposals of Ben-Tal and Nemirovski [1] and Chen, Sim and Sun [3] lead to second order cone optimization problems (SOCP), the proposal of Bertsimas and Sim [2] preserves the linearity of the model. We focus on the results of Bertsimas and Sim [2].

**Formulation**

We consider the following nominal linear optimization problem,

$$\begin{aligned} & \text{maximize} && \mathbf{c}'\mathbf{x} \\ & \text{subject to} && \tilde{\mathbf{a}}_i'\mathbf{x} \leq \tilde{b}_i \quad i = 1, \dots, m \end{aligned} \tag{1}$$

in which the data at every constraint,  $(\tilde{\mathbf{a}}_i, \tilde{b}_i)$ ,  $i = 1, \dots, m$  are potentially uncertain at the time when the decision  $\mathbf{x} \in \mathfrak{R}^n$  needs to be made. For simplicity of our exposition, we assume without loss of generality that the data at the objective  $\mathbf{c}$  is not subject to uncertainty, since we can use the objective maximize  $t$  and add the constraint  $t - \mathbf{c}'\mathbf{x} \leq 0$  to the model.

**Affine Data Dependency**

We focus on constraint-wise uncertainties. Clearly, uncertainties appearing at various parts of the data in any  $i$ th constraint  $(\tilde{\mathbf{a}}_i, \tilde{b}_i)$  may be correlated. To capture such correlation, we assume that the uncertain data at the  $i$ th constraint is affinely dependent on some primitive uncertainty vector,  $\tilde{\mathbf{z}}^i \in \mathfrak{R}^{N_i}$  as follows

$$\begin{aligned} \tilde{\mathbf{a}}_i &= \mathbf{a}_i(\tilde{\mathbf{z}}^i) = \mathbf{a}_i^0 + \sum_{j=1}^{N_i} \mathbf{a}_i^j \tilde{z}_j^i, \\ \tilde{b}_i &= b_i(\tilde{\mathbf{z}}^i) = b_i^0 + \sum_{j=1}^{N_i} b_i^j \tilde{z}_j^i, \end{aligned}$$

where  $(\mathbf{a}_i^j, b_i^j) \in \mathfrak{R}^{n+1}$ ,  $j = 1, \dots, N_i$  are non zeros vectors. Note that we can always define a bijection mapping from a vector space of  $\tilde{\mathbf{z}}^i \in \mathfrak{R}^{N_i}$  at the  $i$ th constraint to the corresponding data space of  $(\tilde{\mathbf{a}}_i, \tilde{b}_i)$ . Therefore, under the affine data dependency, it is always possible to map all the data uncertainties affecting the  $i$ th constraint to the primitive uncertainty vector,  $\tilde{\mathbf{z}}^i$ . The affine data mapping can easily represent linear relations among data entries. As an illustration,

$$\begin{pmatrix} a_1 \\ a_2 \\ b \end{pmatrix} (z_1, z_2) = \begin{pmatrix} 100 \\ 200 \\ 300 \end{pmatrix} + \begin{pmatrix} 2 \\ -5 \\ 0 \end{pmatrix} z_1 + \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} z_2,$$

the data is a vector in  $\mathfrak{R}^3$  and has two primitive uncertainties. The first and second elements are related such that when  $a_1$  increases by two units,  $a_2$  decreases

by five units. The values of  $b$  can change independently of  $a_1$  or  $a_2$  and it is controlled by another primitive uncertainty,  $z_2$ . For the case when all data entries in  $(\tilde{\mathbf{a}}_i, \tilde{b}_i)$  are independently distributed, we would have  $N_i = n + 1$  and that the vector  $(\mathbf{a}_i^j, b_i^j)$ ,  $j = 1, \dots, n + 1$  is a vector taking a non-zero value only at the  $j$ th row. We assume that the distributions of the primitive uncertainty vector,  $\tilde{\mathbf{z}}^i$ ,  $i = 1, \dots, m$  are mildly characterized as follows:

**Model of Data Uncertainty U** We assume that  $\tilde{z}_j^i$ ,  $j = 1, \dots, N_i$  are independently (but not necessarily identically) distributed random variables with zero means and support in  $[-1, 1]$ .

Under the model of data uncertainty U, the nominal value of  $\tilde{\mathbf{z}}^i$  is a zero vector. Hence, it follows naturally that  $(\mathbf{a}_i^0, b_i^0)$  is the nominal value of the uncertain data  $(\mathbf{a}_i(\tilde{\mathbf{z}}^i), b_i(\tilde{\mathbf{z}}^i))$ . Similarly,  $(\mathbf{a}_i^j, b_i^j)$ ,  $j = 1, \dots, N_i$  is the direction of data perturbation under the influence of the primitive uncertainty  $\tilde{z}_j^i$ .

In robust optimization, we represent data uncertainty using uncertainty sets instead of probability distributions. At each constraint, we allow the primitive uncertainty vector,  $\tilde{\mathbf{z}}^i$  to vary within an uncertainty set,  $\mathcal{U}_i$  without having to violate the  $i$ th constraint. We call the following problem the *robust counterpart* of Problem (1)

$$\begin{aligned} & \text{maximize} && \mathbf{c}'\mathbf{x} \\ & \text{subject to} && \mathbf{a}_i(\mathbf{z}^i)'\mathbf{x} \leq b_i(\mathbf{z}^i) \\ & && \forall \mathbf{z}^i \in \mathcal{U}_i \quad i = 1, \dots, m. \end{aligned} \tag{2}$$

Indeed, given any solution to the robust counterpart, we are able to guarantee deterministically that the solution will remain feasible if the primitive uncertainty vector,  $\tilde{\mathbf{z}}$  lies within the uncertainty set  $\mathcal{U}_i$ . Under the model of data uncertainty U, we are able to design uncertainty sets that guarantee feasibility in constraints with high probability without being overly conservative.

Although the robust counterpart (2) has possibly exponential or even infinite number of constraints, it is nevertheless a convex optimization problem with respect to its decision variable,  $\mathbf{x}$ . In fact, the computational complexity of the robust counterpart depends on the nature of the uncertainty set,  $\mathcal{U}_i$ . Here, we focus on polyhedral uncertainty sets in which the robust counterparts are computationally tractable in the form of

linear optimization problems that are moderately larger in size as compared to the nominal problems.

Using linear programming duality, we show how to convert the robust counterpart (2) into a concise linear optimization problem. We focus on the following polyhedral uncertainty set,

$$\mathcal{P}_i = \{z \in \mathbb{R}^{N_i} : S_i z + T_i u \leq r_i \text{ for some } u\}.$$

**Theorem 1** *The robust counterpart*

$$a_i(z^i)'x \leq b_i(z^i) \quad \forall z^i \in \mathcal{P}_i, \tag{3}$$

is equivalent to

$$\begin{cases} \exists p : \\ r_i'p \leq b_i^0 - a_i^{0'}x \\ S_i'p = \begin{pmatrix} a_i^{1'}x - b_i^1 \\ \vdots \\ a_i^{N_i'}x - b_i^{N_i} \end{pmatrix} \\ T_i'p = 0 \\ p \geq 0. \end{cases} \tag{4}$$

*Proof 1* For notational convenience, we ignore the constraint index  $i$ . Under the affine data dependency, we can represent the constraint (3) as

$$\sum_{j=1}^N (a^j'x - b^j)z_j \leq b^0 - a^{0'}x \quad \forall z \in \mathcal{P}$$

or equivalently as

$$\max_{z \in \mathcal{P}} \left\{ \sum_{j=1}^N (a^j'x - b^j)z_j \right\} \leq b^0 - a^{0'}x. \tag{5}$$

By standard linear programming duality, the objective of the following problem

$$\begin{aligned} &\text{maximize } d'z \\ &\text{subject to } Sz + Tu \leq r \end{aligned}$$

is the same as

$$\begin{aligned} &\text{minimize } r'p \\ &\text{subject to } S'p = d \\ &\quad T'p = 0 \\ &\quad p \geq 0. \end{aligned}$$

Hence, the constraint (5) is equivalent to

$$\begin{aligned} &\text{minimize } r'p && \leq b^0 - a^{0'}x \\ &\text{subject to } S'p = \begin{pmatrix} a^1'x - b^1 \\ \vdots \\ a^{N'}x - b^N \end{pmatrix} \\ &\quad T'p = 0 \\ &\quad p \geq 0. \end{aligned} \tag{6}$$

Finally, to ensure the feasibility of  $x$ , we only need to find a vector  $p$  feasible in the left hand side optimization problem of constraint (6) such that  $r'p \leq b^0 - a^{0'}x$ . If such vector,  $p$  exists, the corresponding minimizer,  $p^*$  should also satisfy  $r'p^* \leq b^0 - a^{0'}x$ .  $\square$

Hence, the robust counterpart (2) in which  $U_i = \mathcal{P}_i, i = 1, \dots, m$  is equivalent to

$$\begin{aligned} &\text{maximize } c'x \\ &\text{subject to } r_i'p_i \leq b_i^0 - a_i^{0'}x && i = 1, \dots, m \\ &\quad S_i'p_i = \begin{pmatrix} a_i^{1'}x - b_i^1 \\ \vdots \\ a_i^{N_i'}x - b_i^{N_i} \end{pmatrix} && i = 1, \dots, m \\ &\quad T_i'p_i = 0 && i = 1, \dots, m \\ &\quad p_i \geq 0 && i = 1, \dots, m. \end{aligned} \tag{7}$$

**Worst Case Uncertainty Set**

Under the model of data uncertainty  $U$ , the primitive uncertainty vector  $\tilde{z}^i$  at the  $i$ th constraint has support in  $[-1, 1]^{N_i}$ . Hence, we define the following worst case uncertainty set

$$\mathcal{W}_i = \{z \in \mathbb{R}^{N_i} : -1 \leq z \leq 1\}$$

for the primitive uncertainty corresponding to the  $i$  constraint. Such uncertainty set is first considered by Soyster [4].

**Theorem 2** *The robust counterpart*

$$a_i(z^i)'x \leq b_i(z^i) \quad \forall z^i \in \mathcal{W}_i,$$

is equivalent to

$$\begin{cases} \exists \mathbf{p}, \mathbf{q} : \\ \mathbf{1}'(\mathbf{p} + \mathbf{q}) \leq b_i^0 - \mathbf{a}_i^{0'} \mathbf{x} \\ \mathbf{p} - \mathbf{q} = \begin{pmatrix} \mathbf{a}_i^{1'} \mathbf{x} - b_i^1 \\ \vdots \\ \mathbf{a}_i^{N_i'} \mathbf{x} - b_i^{N_i} \end{pmatrix} \\ \mathbf{p}, \mathbf{q} \geq \mathbf{0} . \end{cases} \quad (8)$$

The robust counterpart (2) in which  $\mathcal{U}_i = \mathcal{W}_i$ ,  $i = 1, \dots, m$  is equivalent to

$$\begin{aligned} & \text{maximize } \mathbf{c}' \mathbf{x} \\ & \text{subject to } \mathbf{1}'(\mathbf{p}_i + \mathbf{q}_i) \leq b_i^0 - \mathbf{a}_i^{0'} \mathbf{x} \quad i = 1, \dots, m \\ & \mathbf{p}_i - \mathbf{q}_i = \begin{pmatrix} \mathbf{a}_i^{1'} \mathbf{x} - b_i^1 \\ \vdots \\ \mathbf{a}_i^{N_i'} \mathbf{x} - b_i^{N_i} \end{pmatrix} \quad i = 1, \dots, m \\ & \mathbf{p}_i, \mathbf{q}_i \geq \mathbf{0} \quad i = 1, \dots, m . \end{aligned} \quad (9)$$

**Uncertainty Set with a Budget**

Under the model of data uncertainty  $\mathcal{U}$ , the worst case uncertainty set is can be over conservative. Speaking intuitively, when  $N_i$  is large, it may be unlikely for the primitive uncertainty vector  $\tilde{\mathbf{z}}^i$  to deviate unanimously towards the violation of the constraint. Bertsimas and Sim [2] consider an uncertainty set that is able to withstand parameter uncertainty without excessively affecting the objective function as follows:

$$\mathcal{B}_i(\Gamma_i) = \left\{ \mathbf{z} \in \Re^{N_i} : -\mathbf{1} \leq \mathbf{z} \leq \mathbf{1}, \sum_{j=1}^{N_i} |z_j| \leq \Gamma_i \right\} .$$

The goal is to be protected against all cases that up to  $\Gamma_i$  of the primitive uncertainties  $\tilde{z}_j^i$ ,  $j = 1, \dots, N_i$  are allowed to to change deviate maximally in  $[-1, 1]$ . In other words, Bertsimas and Sim stipulate that nature will be restricted in its behavior, in that only a subset of the primitive uncertainties will change in order to adversely affect the solution. They propose an approach, that has the property that if nature behaves like this, then the robust solution will be feasible deterministically.

The parameter  $\Gamma_i$ , commonly known as the *budget of uncertainty* controls the size of the uncertainty set,

$\mathcal{B}_i(\Gamma_i)$  such that  $\mathcal{B}_i(0) = \{\mathbf{0}\}$  and  $\mathcal{B}_i(N_i) = \mathcal{W}_i$ . Note that the uncertainty set is a polytope as follows

$$\mathcal{B}_i(\Gamma_i) = \left\{ \mathbf{z} \in \Re^{N_i} : \mathbf{u} \leq \mathbf{1}, \mathbf{1}' \mathbf{u} \leq \Gamma_i, -\mathbf{u} \leq \mathbf{z} \leq \mathbf{u}, \text{ for some } \mathbf{u} \right\} .$$

**Theorem 3** *The robust counterpart*

$$\mathbf{a}_i(\tilde{\mathbf{z}}^i)' \mathbf{x} \leq b_i(\tilde{\mathbf{z}}^i) \quad \forall \tilde{\mathbf{z}}^i \in \mathcal{B}_i(\Gamma_i),$$

is equivalent to

$$\begin{cases} \exists t, \mathbf{s}, \mathbf{p}, \mathbf{q} : \\ \Gamma_i t + \mathbf{1}' \mathbf{s} \leq b_i^0 - \mathbf{a}_i^{0'} \mathbf{x} \\ \mathbf{s} + \mathbf{1} t = \mathbf{p} + \mathbf{q} \\ \mathbf{p} - \mathbf{q} = \begin{pmatrix} \mathbf{a}_i^{1'} \mathbf{x} - b_i^1 \\ \vdots \\ \mathbf{a}_i^{N_i'} \mathbf{x} - b_i^{N_i} \end{pmatrix} \\ \mathbf{p}, \mathbf{q}, \mathbf{s} \geq \mathbf{0}, t \geq 0 . \end{cases} \quad (10)$$

The robust counterpart (2) in which  $\mathcal{U}_i = \mathcal{B}_i(\Gamma_i)$ ,  $i = 1, \dots, m$  is equivalent to

$$\begin{aligned} & \text{maximize } \mathbf{c}' \mathbf{x} \\ & \text{subject to } \Gamma_i t_i + \mathbf{1}' \mathbf{s}_i \leq b_i^0 - \mathbf{a}_i^{0'} \mathbf{x} \quad i = 1, \dots, m \\ & \mathbf{s}_i + \mathbf{1} t_i = \mathbf{p}_i + \mathbf{q}_i \quad i = 1, \dots, m \\ & \mathbf{p}_i - \mathbf{q}_i = \begin{pmatrix} \mathbf{a}_i^{1'} \mathbf{x} - b_i^1 \\ \vdots \\ \mathbf{a}_i^{N_i'} \mathbf{x} - b_i^{N_i} \end{pmatrix} \quad i = 1, \dots, m \\ & \mathbf{p}_i, \mathbf{q}_i, \mathbf{s}_i \geq \mathbf{0}, t_i \geq 0 \quad i = 1, \dots, m . \end{aligned} \quad (11)$$

If more than  $\Gamma_i$  of the primitive uncertainties  $\tilde{z}_j^i$ ,  $j = 1, \dots, N_i$  change, the robust solution will be feasible **with very high probability**.

**Theorem 4** *Under the model of data uncertainty  $\mathcal{U}$ , if  $\mathbf{x}$  is feasible in the robust counterpart (10) then*

$$\Pr(\mathbf{a}_i(\tilde{\mathbf{z}}^i)' \mathbf{x} > b_i(\tilde{\mathbf{z}}^i)) \leq \exp\left(-\frac{\Gamma_i^2}{2N_i}\right) . \quad (12)$$

Note the original bound proposed in Bertsimas and Sim [2] require symmetrically bounded distribution. However, this condition is relaxed by Chen, Sim and Sun [3]. Nevertheless, tighter bounds can be achieved if the distributions are also symmetrically distributed.

**Theorem 5**

1. Suppose  $\tilde{z}_j^i, j = 1, \dots, N_i$  are independent symmetrically distributed random variables in  $[-1, 1]$ , then if  $\mathbf{x}$  is feasible in the robust counterpart (10), we have

$$\Pr(\mathbf{a}_i(\tilde{\mathbf{z}}^i)' \mathbf{x} > b_i(\tilde{\mathbf{z}}^i)) \leq B(n, \Gamma_i), \tag{13}$$

where

$$B(n, \Gamma_i) = \frac{1}{2^{N_i}} \left\{ (1 - \mu) \binom{N_i}{\lfloor v \rfloor} + \sum_{l=\lfloor v \rfloor+1}^{N_i} \binom{N_i}{l} \right\}, \tag{14}$$

where  $v = \frac{\Gamma_i + N_i}{2}$  and  $\mu = v - \lfloor v \rfloor$ .

2. For  $\Gamma_i = \theta \sqrt{N_i}$ ,

$$\lim_{N_i \rightarrow \infty} B(N_i, \Gamma_i) = 1 - \Phi(\theta), \tag{15}$$

where

$$\Phi(\theta) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\theta} \exp\left(-\frac{y^2}{2}\right) dy$$

is the cumulative distribution function of a standard normal.

We next compare the bounds: (12) (Bound 1), (13) (Bound 2), and the approximate bound (15). Table 1 illustrates the choice of  $\Gamma_i$  as a function of  $N_i$  so that the probability that a constraint is violated is less than 1%, where we used Bounds 1 and 2 and the approximate bound to evaluate the probability. It is clear that using Bounds 2 or the approximate bound gives essentially identical values of  $\Gamma_i$ , while using Bound 1 leads to unnecessarily higher values of  $\Gamma_i$  when the primitive uncertainties are symmetrically distributed. For  $N_i = 200$ , we need to use  $\Gamma = 33.9$ , i.e., only 17% of the number of uncertain data, to guarantee violation probability of less than 1%. For constraints with fewer number of uncertain data such as  $N_i = 5$ , it is necessary to ensure full protection, which is equivalent to the worst case or the Soyster’s method. Clearly, for constraints with large number of uncertain data, the proposed approach is capable of delivering less conservative solutions compared to the Soyster’s method.

**Applications**

Most of the practical optimization problems are in the form of a mixed integer programming (MIP) model,

**Price of Robustness for Linear Optimization Problems, Table 1**

Choice of  $\Gamma_i$  as a function of  $N_i$  so that the probability of constraint violation is less than 1%.

$N_i$	$\Gamma_i$ from Bound 1	$\Gamma_i$ from Bounds 2	$\Gamma_i$ from Approx.
5	5	5	5
10	9.6	8.2	8.4
100	30.3	24.3	24.3
200	42.9	33.9	33.9
2000	135.7	105	105

i.e., some of the variables in the vector  $\mathbf{x}$  take integer values. Fortunately, the robust model (11) in the case in which the nominal problem is a MIP is still a MIP formulation, and thus can be solved in the same way that the nominal problem can be solved. Moreover, both the deterministic guarantee as well as the probabilistic guarantee (Theorem 2) is still valid. As a result, the robust approach applies for addressing data uncertainty for MIPs. In our computational studies, we apply the robust formulation to a zero-one knapsack problems that are subject to data uncertainty. We examine whether this approach is computationally tractable, and whether it succeeds in reducing the price of robustness.

The zero-one knapsack problem is the following discrete optimization problem:

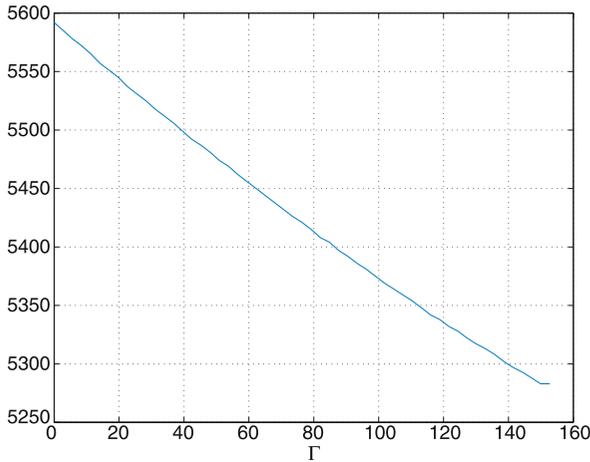

$$\begin{aligned} & \text{maximize} && \mathbf{c}' \mathbf{x} \\ & \text{subject to} && \mathbf{w}' \mathbf{x} \leq b \\ & && \mathbf{x} \in \{0, 1\}^n \end{aligned}$$

Although the knapsack problem is NP-hard, for problems of moderate size, it is often solved to optimality using state-of-the-art MIP solvers. For this experiment, we use CPLEX 6.0 to solve to optimality a random knapsack problem of size,  $n = 200$ .

Regarding the uncertainty model for data, we assume the weights  $\tilde{w}_i$  are uncertain, independently distributed and follow symmetric distributions in  $[\tilde{w}_i - \delta_i, \tilde{w}_i + \delta_i]$ . Hence, under the affine data dependency, we have

$$w_i(\tilde{\mathbf{z}}) = \tilde{w}_i + \delta_i \tilde{z}_i \quad i = 1, \dots, n$$

in which  $\tilde{z}_i, i = 1, \dots, n$  are independently distributed and follow symmetric distributions in  $[-1, 1]$ . An application of this problem is to maximize the total value

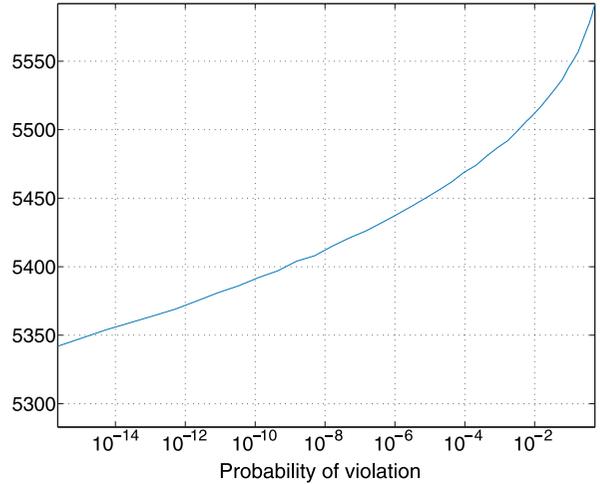

**Price of Robustness for Linear Optimization Problems, Figure 1**  
 Optimal value of the robust knapsack formulation as a function of  $\Gamma$

of goods to be loaded on a cargo that has strict weight restrictions. The weight of the individual item is assumed to be uncertain, independent of other weights and follows a symmetric distribution. In our robust model, we want to maximize the total value of the goods but allowing a maximum of 1% chance of constraint violation. The robust model is as follows:

$$\begin{aligned} & \text{maximize} && c'x \\ & \text{subject to} && \tilde{w}'x + \sum_{i=1}^n \delta_i x_i \tilde{z}_i \leq b \quad \forall z \in \mathcal{B}(\Gamma) \\ & && x \in \{0, 1\}^n. \end{aligned}$$

For the random knapsack example, we set the capacity limit,  $b$  to 4000, the nominal weight,  $w_i$  being randomly chosen from the set  $\{20, 21, \dots, 29\}$  and the cost  $c_i$  randomly chosen from the set  $\{16, 17, \dots, 77\}$ . We set the weight uncertainty  $\delta_i$  to equal 10% of the nominal weight. The time to solve the robust discrete problems to optimality using CPLEX 6.0 on a Pentium II 400 PC ranges from 0.05 to 50 s.

Figure 1 illustrates the effect of the protection level on the objective function value. In the absence of protection to the capacity constraint, the optimal value is 5592. However, with maximum protection, that is admitting the Soyster’s method, the optimal value is reduced by 5.5% to 5283. In Fig. 2, we plot the optimal value with respect to the approximate probability bound of constraint violation. In Table 2, we present

**Price of Robustness for Linear Optimization Problems, Figure 2**  
 Optimal value of the robust knapsack formulation as a function of the probability bound of constraint violation given in (13)

**Price of Robustness for Linear Optimization Problems, Table 2**  
 Results of Robust Knapsack Solutions

$\Gamma$	Probability Bound	Optimal Value	Reduction
2.8	$4.49 \times 10^{-1}$	5585	0.13%
14.1	$1.76 \times 10^{-1}$	5557	0.63%
25.5	$4.19 \times 10^{-2}$	5531	1.09%
36.8	$5.71 \times 10^{-3}$	5506	1.54%
48.1	$4.35 \times 10^{-4}$	5481	1.98%
59.4	$1.82 \times 10^{-5}$	5456	2.43%
70.7	$4.13 \times 10^{-7}$	5432	2.86%
82.0	$5.04 \times 10^{-9}$	5408	3.29%
93.3	$3.30 \times 10^{-11}$	5386	3.68%
104.7	$1.16 \times 10^{-13}$	5364	4.08%
116.0	$2.22 \times 10^{-16}$	5342	4.47%

a sample of the objective function value and the probability bound of constraint violation.

It is interesting to note that the optimal value is marginally affected when we increase the protection level. For instance, to have a probability guarantee of at most 0.57% chance of constraint violation, we only reduce the objective by 1.54%.

## Conclusions

The robust methodology provides solutions that ensure deterministic and probabilistic guarantees that constraints will be satisfied as data change. Moreover, the protection level determines probability bounds of constraint violation, which do not depend on the solution of the robust model. As the robust model remains a linear optimization problem, the method naturally applies to discrete optimization problems. It is also possible to build uncertainty sets that are mapped from asymmetrical distributions. The interested reader may refer to Chen, Sim and Sun [3].

## LCP

Linear complementarity problems in the general form are given as follows (cf. also ► [Linear complementarity problem](#)):

$$\begin{aligned} -Mu + v &= q, \\ u, v &\geq 0, \\ u_i v_i &= 0, \quad i = 1, \dots, n, \end{aligned}$$

where  $M$  is a given  $(n \times n)$  matrix,  $q \in \mathbf{R}^n$ . The non-negative variables  $u_i$  and  $v_i$ ,  $i = 1, \dots, n$ , should be non-negative and complementary. The solvability of LCPs depend on the special properties of the coefficient matrix  $M$ . For illustration we will give some well solvable classes in the sequel.

LCPs are natural generalizations of linear programming (linear optimization) and quadratic programming. In the first case

$$M = \begin{pmatrix} 0 & A \\ -A^\top & 0 \end{pmatrix} \quad \text{and} \quad q = \begin{pmatrix} -b \\ c \end{pmatrix},$$

where the matrix  $A$  and the vectors  $b$  and  $c$  are the problem data of the linear optimization problem

$$\min \{c^\top x : Ax \geq b, x \geq 0\}.$$

This way a block diagonal *skew-symmetric matrix*  $M$  is obtained. When the LCP is obtained from the convex quadratic optimization problem

$$\min \left\{ c^\top x + \frac{1}{2} x^\top Q x : Ax \geq b, x \geq 0 \right\},$$

where  $Q$  is a *positive semidefinite symmetric matrix*, then

$$M = \begin{pmatrix} 0 & A \\ -A^\top & Q \end{pmatrix} \quad \text{and} \quad q = \begin{pmatrix} -b \\ c \end{pmatrix}.$$

Here  $M$  is a positive semidefinite *bisymmetric matrix*. Bisymmetry means that the matrix has a block diagonal structure, and it is the sum of a symmetric block diagonal positive semidefinite, and a skew-symmetric block diagonal matrix.

Some other classes of solvable LCPs occur when  $M$  is

- a  $P$ -matrix,
  - a *sufficient matrix* or, equivalently, a  $P_*$ -matrix [21].
- LCPs are solvable by using *pivot methods* or interior point methods (cf. also ► **Linear programming: Interior point methods**). Here the basics of some of the most popular principal pivot methods are discussed.

**Principal Pivoting**

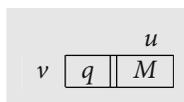

When one solves an LCP by using pivoting, then the equality constraints  $-Mu+v = q$  always hold. The coefficient matrix of the vector  $v$ , the unit matrix might serve as a natural initial basis. Then the basic solution  $u = 0$  and  $v = q$  is complementary as well. A basis is called *complementary* when exactly one of the complementary variables  $(u_i, v_i)$ , for all  $i = 1, \dots, n$ , is a basis variable.

In a pivot algorithm, because we are working with basic solutions, the equality constraints always hold. We strive for nonnegativity while some variables leave the basis and others enter. Because the initial basis is complementary, it is a natural idea to preserve the complementarity property. This imposes that, if a set of variables leaves the basis, then precisely the variables in the complementary set must enter the basis. Such a step is called *principal pivoting*.

Principal pivoting was introduced by A.W. Tucker [19,20]. The theory of principal pivoting, or *complementary pivot theory*, was extensively studied [4,5,6,7,13,14,16].

**Principal Pivot Algebra**

When we write the basis (or simplex) tableau of the LCP down, then by leaving out the basis part we get the tableau:

Let  $(\gamma, \bar{\gamma})$  be a partition of the index set  $\{1, \dots, n\}$  and let us assume that the *principal submatrix*  $M_{\gamma\gamma}$

is nonsingular. Then the current representation of the LCP can be written as

$$\begin{aligned} v_\gamma &= q_\gamma + M_{\gamma\gamma}u_\gamma + M_{\gamma\bar{\gamma}}u_{\bar{\gamma}}, \\ v_{\bar{\gamma}} &= q_{\bar{\gamma}} + M_{\bar{\gamma}\gamma}u_\gamma + M_{\bar{\gamma}\bar{\gamma}}u_{\bar{\gamma}}. \end{aligned}$$

This in the usual tableau form can be written as A principal pivot, when the variables  $v_\gamma$  leave the basis and their complementary pair  $u_\gamma$  enters the basis can be explained both in the equation and tableau form as follows. Using the assumption that  $M_{\gamma\gamma}$  is nonsingular, we may write

$$\begin{aligned} u_\gamma &= q'_\gamma + M_{\gamma\gamma}^{-1}v_\gamma - M_{\gamma\gamma}^{-1}M_{\gamma\bar{\gamma}}u_{\bar{\gamma}}, \\ v_{\bar{\gamma}} &= q'_{\bar{\gamma}} + M_{\bar{\gamma}\gamma}M_{\gamma\gamma}^{-1}v_\gamma + M'_{\bar{\gamma}\bar{\gamma}}u_{\bar{\gamma}} \end{aligned}$$

where

$$\begin{aligned} M'_{\bar{\gamma}\bar{\gamma}} &= M_{\bar{\gamma}\bar{\gamma}} - M_{\bar{\gamma}\gamma}M_{\gamma\gamma}^{-1}M_{\gamma\bar{\gamma}}, \\ q'_\gamma &= -M_{\gamma\gamma}^{-1}q_\gamma, \\ q'_{\bar{\gamma}} &= q_{\bar{\gamma}} - M_{\bar{\gamma}\gamma}M_{\gamma\gamma}^{-1}q_\gamma. \end{aligned}$$

This representation corresponds to the tableau Further, the matrix

$$M' = \begin{pmatrix} M_{\gamma\gamma}^{-1} & -M_{\gamma\gamma}^{-1}M_{\gamma\bar{\gamma}} \\ M_{\bar{\gamma}\gamma}M_{\gamma\gamma}^{-1} & M_{\bar{\gamma}\bar{\gamma}} - M_{\bar{\gamma}\gamma}M_{\gamma\gamma}^{-1}M_{\gamma\bar{\gamma}} \end{pmatrix}$$

is called a *principal pivotal transform* of the matrix  $M$ . If we define

$$u' = \begin{pmatrix} v_\gamma \\ u_{\bar{\gamma}} \end{pmatrix}, \quad v' = \begin{pmatrix} u_\gamma \\ v_{\bar{\gamma}} \end{pmatrix}, \quad q' = \begin{pmatrix} q'_\gamma \\ q'_{\bar{\gamma}} \end{pmatrix},$$

then the LCP can equivalently be reformulated as

$$\begin{aligned} -M'u' + v' &= q', \\ u', v' &\geq 0, \\ u'_i v'_i &= 0, \quad i = 1, \dots, n. \end{aligned}$$

This way, without loss of generality, we may assume that the current principal pivot transform of the LCP contains  $v'$  as the vector of basis variables;  $u' = 0$ ,  $v' = q'$  as the current complementary solution; and,  $M'$  is the coefficient matrix of the nonbasic variables.

When only one variable leaves the basis, i. e.  $\gamma = \{k\}$  for some index, while its complementary pair enters, then this operation is called a *simple principal pivot*, or *diagonal pivot*, because in this case  $M_{\{k\}\{k\}} = m_{kk}$ , the  $k$ th diagonal element of the matrix  $M$ . When two variables are coming in and at the same time their pairs leave the basis, then this  $2 \times 2$  principal pivot is called an *exchange pivot* or *double pivot*.

## Invariant Matrix Classes

Let a class of matrices  $K$  be given. Then one say that the matrix class is *invariant under principal pivoting*, if for all  $M \in K$  and for all principal pivot transforms  $M'$  of  $M$  the relation  $M' \in K$  holds.

It is known, that several matrix classes enjoy the invariance property. The most important invariant matrix classes are the following:

- the class of  $P$ -matrices;
- the class of  $P_0$ -matrices;
- the class of *positive definite matrices*;
- the class of *positive semidefinite matrices*;
- the class of *bisymmetric positive semidefinite matrices*;
- the class of *column sufficient matrices*;
- the class of *row sufficient matrices*;
- the class of *sufficient matrices*;
- the class of  $Q$ -matrices.

Detailed discussion on matrix classes, their characterization, invariance and other properties can be found in [7,16].

## Simple Principal Pivoting Methods

Simple principal pivoting methods are using only simple principal pivots, i. e. principal pivots of order one. The best known variant of this method is due to Y. Bard [1] and G. Zoutendijk [22].

Let us assume that the matrix  $M$  is a  $P$ -matrix. Then all of its principal submatrices, in particular all of its  $1 \times 1$  principal submatrices are nonsingular.

Due to the  $P$ -matrix property, the steps of the algorithm are executable, however there is no guarantee that the method in this form is finite. The finiteness of a variant of this most simple principal pivoting algorithm was proved by K.G. Murty [15]. *Murty's least-index refinement* is as follows:

- Let an ordering of the pairs of the complementary variables be fixed.
- In Step 1, choose the least indexed infeasible basic variable, i. e. let  $k = \min\{i: v_i' < 0, i = 1, \dots, n\}$ .

Finally, remark that a finite variant of the Zoutendijk–Bard principal pivot rule can also be developed by using an appropriate lexicographic pivot selection rule (cf. also ► [Lexicographic pivoting rules](#)).

## Principal Pivoting Methods for Linear Complementarity Problems, Table 1

		$u_\gamma$	$u_{\bar{\gamma}}$
$v_\gamma$	$q_\gamma$	$M_{\gamma\gamma}$	$M_{\gamma\bar{\gamma}}$
$v_{\bar{\gamma}}$	$q_{\bar{\gamma}}$	$M_{\bar{\gamma}\gamma}$	$M_{\bar{\gamma}\bar{\gamma}}$

## Principal Pivoting Methods for Linear Complementarity Problems, Table 2

		$v_\gamma$	$u_{\bar{\gamma}}$
$u_\gamma$	$q'_\gamma$	$M_{\gamma\bar{\gamma}}^{-1}$	$-M_{\gamma\bar{\gamma}}^{-1}M_{\gamma\bar{\gamma}}$
$v_{\bar{\gamma}}$	$q'_{\bar{\gamma}}$	$M_{\bar{\gamma}\gamma}M_{\gamma\bar{\gamma}}^{-1}$	$M_{\bar{\gamma}\bar{\gamma}} - M_{\bar{\gamma}\gamma}M_{\gamma\bar{\gamma}}^{-1}M_{\gamma\bar{\gamma}}$

- 0 (Initialization)  
Let the unit matrix, the coefficient matrix of the  $v$  variables be the initial complementary basis.
- 1 (Leaving variable selection)  
IF no infeasible variable exist,  
THEN stop; the LCP is solved.  
Choose an infeasible basis variable, say  $v'_k$ .
- 2 (Principal pivot)  
Do a simple principal pivot on  $m'_{kk} \neq 0$ . The chosen infeasible variable leaves the basis while its complementary pair enters.  
Go to Step 1.

## Zoutendijk–Bard principal pivot rule

## General Principal Pivoting Methods

As mentioned earlier, general principal pivoting methods use not only simple principal pivots of order one, but also use larger pivot blocks. Frequently, these blocks are not determined at once, the principal blocks are build-up step-by step.

Three variants of more general principal pivoting methods will be described. The (complementary) basis tableaus will be considered in the form as given in Table 1 and Table 2.

## Criss-Cross Methods

The first one is the *least-index criss-cross method* [3,9,10,12], which uses first and second order principal

0	(Initialization) Let the unit matrix, the coefficient matrix of the $v$ variables be the initial complementary basis. Let an ordering of the pairs of the complementary variables be fixed.
1	(Leaving variable selection) IF no infeasible variable exist, THEN stop; the LCP is solved. Choose the least indexed infeasible basis variable, say $v'_k$ , where $k = \min\{i : v'_i < 0, i = 1, \dots, n\}$ .
2	(Entering variable selection) IF the pivot ( $v'_k, u'_k$ ) is possible, i.e. $m'_{kk} \neq 0$ , THEN go to Step 3a. IF $m'_{kk} = 0$ , THEN look for positive coordinates in row $k$ of $M'$ . IF all coordinates in row $k$ are nonpositive, THEN stop; the LCP is infeasible. Choose the least indexed positive coordinate, say with index $r$ , in row $k$ : $r = \min\{i : m'_{ki} > 0, i = 1, \dots, n\}$ . Go to Step 3b.
3a	(Diagonal pivot) Do a simple principal pivot on $m'_{kk}$ . Then chosen infeasible variable $v'_k$ leaves the basis while its complementary pair $u'_k$ enters. Go to Step 1.
3b	(Exchange pivot) Do a $2 \times 2$ principal pivot on the principal submatrix $\begin{pmatrix} m'_{kk} & m'_{kr} \\ m'_{rk} & m'_{rr} \end{pmatrix}$ . The variables $v'_k$ and $v'_r$ leave the basis while their complementary pairs $u'_k$ and $u'_r$ enter. Go to Step 1.

#### Least-index criss-cross pivot rule for sufficient LCPs

pivots. During the execution of the algorithm all the basis solutions are complementary.

Let us assume that the matrix  $M$  is a sufficient matrix. As it was mentioned above, the class of sufficient matrices is closed under principal pivot transforms.

Due to the assumption that the matrix  $M$  is sufficient and the class of sufficient matrices is closed under principal pivoting, the steps of the algorithm are executable. It is also known that this least index criss-

cross method solves sufficient LCPs in a finite number of steps [3,9,10,11,12].

Observe, that if the matrix  $M$  is a  $P$ -matrix, then only simple principal pivots are executed. Thus, the least index criss-cross rule reduces to the simple principal pivoting algorithm with Murty's least index refinement.

#### Lemke's Algorithm

The second algorithm is the complementary pivoting algorithm of C.E. Lemke [13,14]. This algorithm can be interpreted on different ways, here only the simplest version is presented.

If  $q \geq 0$ , then the vector  $u = 0, v = q$  solves the LCP. If  $q \not\geq 0$ ; then let  $d = (-1, \dots, -1)^T \in \mathbb{R}^n$  and let consider the augmented LCP:

$$\begin{aligned} -Mu + v + d\lambda &= q, \\ u, v, \lambda &\geq 0, \\ u_i v_i &= 0, \quad i = 1, \dots, n. \end{aligned}$$

The solution  $u = 0, v = q - d\lambda$ , where  $\lambda = \min\{q_i : 1 \leq i \leq n\}$  has the following properties:

- $-Mu + v + d\lambda = q$  holds;
- all coordinates are nonnegative;
- it is complementary, i. e.  $u_i v_i = 0, \forall i$ ;
- there is an index  $k$  with both  $u_k$  and  $v_k$  are nonbasic, and thus zero, further  $\lambda = q_k$ .

Those solutions of the augmented LCP, which satisfy these properties, will be referred to as *almost complementary solutions*. Lemke's complementary pivot algorithm traverses through a sequence of almost complementary solutions. At the last step the variable  $\lambda$  reaches the value zero, and, this way a complementary solution of the original LCP is obtained.

Lemke's algorithm builds-up a big principal pivot block via a series of pivots which produce almost complementary basic solutions. It does not make explicit use of any special property of the coefficient matrix, however the conclusion, at Step 2, that the LCP is infeasible might not always be valid. For large classes of LCPs, e. g. if  $M$  is a *copositive matrix*, the infeasibility conclusion is true. For detailed discussions see e. g. [7].

The algorithm in this form terminates in a finite number of steps only for instances when all almost complementary basis of the augmented LCP are nonde-

0	(Initialization) Form the augmented LCP as discussed above. The initial almost complementary feasible basis is given by $v_1, \dots, v_{k-1}, \lambda, v_{k+1}, \dots, v_n$ . (The actual basis variables, and the variable that just have left the basis will again be denoted by $v'_*$ , while their complementary non-basic pairs by $u'_*$ .)
1	(Entering variable selection) The entering variable is $u'_k$ , the complementary pair of the variable which just have left the basis.
2	(Leaving variable selection) IF all coordinates in the column of $u'_k$ are nonnegative, THEN stop; the LCP is infeasible. Make a primal simplex ratio test in the column of $u'_k$ . IF the pivot $(\lambda, u'_k)$ comes out of the ratio test, THEN go to Step 3a. IF for some $r$ the pivot $(v'_r, u'_k)$ comes out of the ratio test, THEN go to Step 3b.
3a	(Solution) Do a pivot on $(\lambda, u'_k)$ , stop. The resulting feasible basis is complementary; the LCP is solved.
3b	(Pivot) Do a pivot on $(v'_r, u'_k)$ and let $k := r$ . Go to step 1.

### Lemke's algorithm

generate. Degeneracy resolution is possible on the basis of *lexicographic pivot selection* [7,18] as well as by using least index resolution [3]. A particularly interesting result is the lexicographic Lemke rule of M.J. Todd [18]. To date (2000), this is the only simplex method for oriented matroid programming [2] and, it is a particularly interesting simplex algorithm for linear optimization [17].

### Symmetric PPM

Finally, a general form of the symmetric principal pivoting method is presented. In the major cycles the PPM

0	(Initialization) Let the unit matrix, the coefficient matrix of the $v$ variables be the initial complementary basis; thus the initial solution is $u = 0, v = q$ . Let $\lambda < \min\{q_i : 1 \leq i \leq n\}$ .
1	(The distinguished variable) IF no infeasible variable exist, THEN stop; the LCP is solved. Choose an infeasible variable as the distinguished variable which has, let say, index $k$ . We have two cases:
1i	The distinguished variable is $u'_k = \lambda < 0$ .
1ii	The distinguished variable is $v'_k < 0$ . In both cases we use $u'_k$ as the <i>driving variable</i> .
2	(Blocking variable selection) Increase the value of $u'_k$ . Let $\vartheta_k$ be the largest possible value of $u'_k$ satisfying the following two conditions:
2a	IF $v'_k$ is the distinguished variable THEN $v'_k$ stays nonpositive;
2b	for all basic variables $v'_i \geq \lambda$ holds. IF $\vartheta_k = \infty$ , THEN stop; the LCP is infeasible. IF $\vartheta_k = 0$ , THEN no pivot is needed; let $u'_k := 0, u'_i$ for all $i \neq k$ remain unchanged and let $v' := q + Mu'$ . Go to Step 1.
3a	(Diagonal pivot if $m'_{rr} > 0$ ) IF $m'_{rr} > 0$ THEN do a simple principal pivot on $m'_{kk}$ and make $v'_r$ nonbasic at its blocking lower bound value. IF $r = k$ , THEN go to Step 1. IF $r \neq k$ , THEN go to Step 2.
3b	(Exchange pivot if $m'_{rr} = 0$ ) IF $m'_{rr} = 0$ THEN do a $2 \times 2$ principal pivot on the principal submatrix $\begin{pmatrix} m'_{kk} & m'_{kr} \\ m'_{rk} & m'_{rr} \end{pmatrix}$ . The variables $v'_k$ and $v'_r$ leave the basis while their complementary pairs $u'_k$ and $u'_r$ enter. Let $k := r$ and go to Step 2.

### Symmetric principal pivot algorithm

drives an infeasible variable, called the *distinguished variable* to zero. In this process an artificial lower bound  $\lambda < 0$  is used. The nonbasic variables  $u'_i$  are either zero,

or equal to  $\lambda < 0$ . This way, the ‘complementary’ basic solution  $v' = q + Mu'$ , in fact, will not be complementary. Let  $M$  be a *row sufficient matrix*.

Although the symmetric principal pivoting algorithm is not finite for nondegenerate problems, it also can be turned into a finite one by using least index resolution [3] or lexicographic pivot selections [7].

Several variants of the principal pivoting method – symmetric, parametric, asymmetric etc. – were developed in the last decades. Good surveys of this extensive theory can be found in [7,16].

### Complexity

Finally, some notes are due on worst-case behavior. As it was mentioned, and was proved in the cited literature, the presented algorithms are finite when they are furnished with either least-index resolution or lexicographic selection rules. However, in the worst case they may require exponentially many pivots to solve the LCP. The best known exponential example is due to Murty. The data is given as follows:  $q_i = -1, \forall i$ , and

$$m_{ij} = \begin{cases} 0 & \text{if } i > j, \\ 1 & \text{if } i = j, \\ 2 & \text{if } i < j. \end{cases}$$

Clearly the matrix  $M$  is an upper triangular  $P$ -matrix. Further, the vector  $u^T = (0, \dots, 0, 1)$  and  $v^T = (1, \dots, 1, 0)$  is the unique solution of this LCP. It can be shown that, e.g., Murty’s simple principal pivoting method and the least-index criss-cross method needs  $2^{n-1}$  steps to solve this LCP. On the other hand, although it is not proved in general, the results of the paper [8] indicate, that analogously to simplex methods, principal pivoting methods need a polynomial number of iteration in average.

Linear programming; Average case complexity of algorithms; Stochastic geometry

Solving linear programming problems (cf. also ► [Linear programming](#)) is of enormous relevance in real world applications, which contain a lot of data and

of unknown variables. Hence, the computational efficiency of solution methods is a crucial criterion for their applicability.

Today, we have a competition between the simplex method (invented around 1947 by G.B. Dantzig) and interior point methods (starting with Karmarkar’s algorithm in 1984; cf. also ► [Sequential quadratic programming: Interior point methods for distributed optimal control problems](#)).

This article concentrates on simplex methods and on an investigation of their arithmetical effort, measured in terms of the *average number of pivot steps*.

Throughout the paper we discuss the following type of linear programming problems:

$$\begin{cases} \text{maximize} & v^\top x \\ \text{subject to} & a_1^\top x \leq b^1, \dots, a_m^\top x \leq b^m \\ \text{where} & v, a_1, \dots, a_m \in \mathbf{R}^n, b \in \mathbf{R}^m \\ \text{and} & m \geq n. \end{cases} \quad (1)$$

For abbreviation we use

$$A := \begin{pmatrix} a_1^\top \\ \vdots \\ a_m^\top \end{pmatrix} \in \mathbf{R}^{m \times n} \quad \text{and} \quad b = \begin{pmatrix} b^1 \\ \vdots \\ b^m \end{pmatrix}.$$

The matrix  $A$  collects the  $m$  gradient vectors to the restrictions as row vectors, and the vector  $b$  gives the  $m$  capacities.  $X := \{x : Ax \leq b, x \in \mathbf{R}^n\}$  is the feasible region, respectively the feasible polyhedron, to the problem (1), which can also be written in the form

$$\text{maximize } v^\top x \quad \text{subject to } Ax \leq b. \quad (2)$$

Other types of programs as

$$\text{maximize } v^\top x \quad \text{subject to } Ax \leq b, x \geq 0, \quad (3)$$

$$\text{maximize } v^\top x \quad \text{subject to } Ax = b, x \geq 0 \quad (4)$$

and hybrids or variations of such forms can easily be translated into (1). But for form (1) our discussion on the influence of distributions, dimensions and variants can be made much better in geometrical, verbal terms. All the stated results hold – after adaption – for the other forms, too.

If  $X$  has vertices and if there are optimal solutions to (1), then there is a vertex in the optimal set. In each vertex of  $X$  at least  $n$  restrictions of (1) will be active or tight. And in each edge of  $X$  at least  $n - 1$  restrictions are active. Every nonoptimal vertex is incident to an

edge improving the objective. And if an optimal vertex exists, every iterative construction of a connected path over such improving edges leads to the optimal vertex after a finite number of steps. These facts are exploited in the design of the simplex method, which works in two phases:

- I Find a vertex  $x_0 \in X$ ;  
IF there is no vertex,  
THEN STOP.
- II Construct a sequence of vertices  $x_0, \dots, x_s \in X$ , such that for  $i = 0, \dots, s-1$  the vertices  $x_i$  and  $x_{i+1}$  are adjacent and  $v^T x_i < v^T x_{i+1}$ .  
IF  $x_s$  is optimal OR  
IF at  $x_s$  the nonexistence of an optimal solution becomes obvious,  
THEN STOP at  $x_s$ .

Phase I works in a similar manner to Phase II. Since Phase II admits a better geometrical explanation, and is simpler to analyze, we concentrate (for the beginning) on Phase II.

Note that our definition of Phase II still gives the freedom, how we determine the successor vertex (if more than one are possible). A rule for that decision will fix a ‘variant’ of the simplex algorithm. The complexity of Phase II (the so-called ‘simplex algorithm’) is mainly determined by the number  $s$ . Less difficult to analyze is the effort to perform a single pivot step, which costs at most  $O(mn)$  arithmetic operations for updating an  $(m \times n)$ -tableau under all reasonable variants.

In this article we are interested in the average case behavior of the random number  $s$ , when our problems (I) follow a given distribution. Since nobody knows the ‘real world distribution’, we have to introduce and to use a self-made *stochastic model* about the appearance of special instances of (I).

Based on that model, we will evaluate the stochastic behavior of  $s$ . It is clear that this will massively depend on

- the variant under use;
- the stochastic model, respectively distribution, chosen.

A *probabilistic analysis* of the behavior of an algorithm consists of three essential steps:

- a study of the way the algorithm is working on given, deterministic problem-instances including a charac-

terization of the desired figures (e. g.  $s$ ) for that instance;

- a consensus about an underlying stochastic model on the distribution of occurring problem-instances;
- a cumulation over all possible instances, weighted with their occurrence probability, leading to stochastic information on the *random behavior*.

So, we study the procedure of a deterministic algorithm, which is employed to solve random problem-instances.

This stands in contrast to the situation with *randomized algorithms*, where random parameters decide how the algorithm shall proceed in solving a given, deterministic problem.

Throughout the paper we shall rely on a *nondegeneracy assumption*: All submatrices of  $(A, b)$  and of  $(A)^T$ ,  $v$  are of full (i. e., maximal) rank.

This is compatible with our models either by direct conditioning or by the fact that in such a probabilistic model the set of degenerate problems is a nullset.

In this paper, we shall briefly report on experiments and their (limited) information-value. After that we come to two different stochastic models which admitted a successful probabilistic analysis. The first is the sign-invariance model, whose analysis reached its summit in the middle of the 1980s. And the second is the rotation-symmetry model, whose evaluation had started even earlier. But the refinement of that approach is still going on.

## Numerical Experiments and Comparison of Variants

The first idea to learn more about the *average case behavior* of  $s$  is to carry out controlled numerical (Monte-Carlo) experiments. For that purpose, one has to fix several dimension-pairs  $(m, n)$ , to use a stochastic model for generating the data, and to solve the created problem-instances by application of a given variant.

These experiments can be employed for a variety of purposes, as for forecasting the number of pivot steps  $s$  (on the basis of  $(m, n)$  for a fixed variant and model) or for comparing different variants or for recognizing the different influences of stochastic models.

All of that had been done and tried in the past. Studying the huge number of reports on such experiments leads to a very confusing and frustrating im-

pression. Since stochastic models, employed variants, dimensions and problem-types vary excessively, the results and methods can hardly be compared. In particular, it is not possible to summarize the outcome briefly, since all the test parameters would have to be mentioned exactly. So, we refer to the very informative survey by R. Shamir in [19], who comes to the following overall conclusion:

The smaller dimension  $n$  (respectively, the dimension of the polyhedra) enters the mean value function of  $s$  in a slightly superlinear way and the larger dimension  $m$  (respectively, the number of inequality restrictions, including sign-constraints) has only a significantly sublinear influence.

Easier to understand and to interpret are experiments, when they are done parallel to a theoretical study, because then both results, the empirical and the theoretical one, can be checked whether they justify and confirm each other. This has been achieved in experiments for the so-called *rotation-symmetry model* (RSM):

- Let  $b = \vec{1}$  and let  $a_1 \dots, a_m, v$  (and an auxiliary vector  $u$ ) be distributed independently, identically and symmetrically under rotations on  $\mathbf{R}^n \setminus \{0\}$ .

Note that only  $b > 0$  is essential. Choosing  $b = \vec{1}$  (i.e. the vector of ones) means a simplifying standardization only.

The experiments could more or less confirm the theoretical results on  $E_{m,n}(s)$  (the expected number of pivot steps required for  $(m, n)$  problems). These theoretical results will be presented later. Rather informative was the comparison of the behavior of different variants and of the influence of different stochastic distributions. In [11] we tested seven variants belonging to three categories (A, B, C), whose geometric description can be given as follows.

Note that in each vertex a decision has to be made, which one of the (exactly)  $n$  tight restrictions should be de-activated. This means that a choice among the subset of the improving edges (originating from that vertex) is made. The current basis is the set of the  $n$  gradients  $(a_i)$  corresponding to the active restrictions at the current vertex.

- *Category A:* Variants exploiting information on the shape of  $X$  and on the objective  $v^T x$ .

- (*rule of steepest ascent*) Choose that incident improving edge with smallest angle to the gradient of the objective function.
- (*rule of greatest improvement*) Take that edge which leads to the maximal improvement of  $v^T x$  in the next step.
- *Category B:* Variants exploiting information on the objective only.
  - (*Dantzig's rule*) Since a vertex  $x$  is optimal if and only if  $v$  is in the cone of the gradients  $a_i$  of the current basis, we can calculate in each step the representation of  $v$  by that basis of  $\mathbf{R}^n$ . So every basis-gradient is associated with its  $v$ -representation coordinate. Since optimality requires a completely nonnegative representation, Dantzig's rule suggests to take the edge that deactivates the restriction whose gradient has the most negative coordinate.
  - (*shadow-vertex algorithm* or *parametric rule*) This is the variant for which theoretical studies worked very well. The results will be presented in the following sections. Therefore, we explain it in detail. This variant leads from a vertex optimizing an alternative objective  $u^T x$  to the optimal solution for  $v^T x$  (or an unbounded edge), by providing all optimal vertices to the family of objectives  $(\lambda v + u)^T x$  with  $\lambda \in [0, \infty)$ . For  $\lambda$  starting at 0 and increasing, the sequence of optimal vertices gives just the parametric simplex path, which had also been constructed in the early parametric variant of S.I. Gass and T.L. Saaty. They had introduced the parametric concept for another type of problems and without the geometric shadow-vertex interpretation: If we project  $X$  on  $\text{Span}(u, v)$ , then our variant constructs a path starting in the  $u^T x$ -optimum visiting only *shadow-vertices*. These are vertices which keep their vertex-property even after the projection. The projection-image of the constructed path is again a path along the boundary of the two-dimensional image of  $X$ . The choice of the right edge is organized by calculation of the basis representations of  $v$  and  $u$  (as in Dantzig's rule) and by minimizing the quotient of corresponding coordinates.
- *Category C:* Rules evaluating combinatorial principles only.

- (rule of random choice) Select randomly one of the improving edges.
- (rule of justice) De-activate the tight restriction that had been active most often.
- (rule of Bland) De-activate the tight restriction that has the least original index.

These variants were compared under three different rotation-symmetric distributions for the vectors  $a_i$ :

- uniform distribution on  $\omega_n$  (the unit sphere of  $\mathbf{R}^n$ );
- uniform distribution on  $\Omega_n$  (the full unit ball of  $\mathbf{R}^n$ );
- Gaussian distribution on  $\mathbf{R}^n$ .

In general, it turned out that results for Gaussian distribution were better (smaller) than for unit ball and the latter were better than the unit sphere results. This effect is simply caused by different ‘redundancy-rates’. A restriction is *redundant*, if its existence or nonexistence has no impact on the shape of  $X$ . Here, the  $i$ th restriction is redundant if and only if  $a_i$  belongs to  $\text{Conv}(0, a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_m)$ . This will never happen when all points come from  $\omega_n$  and rather seldom when all points come from  $\Omega_n$ , but very often when the points are Gaussian distributed. And, it is obvious, that under normal circumstances a problem becomes easier, if more restrictions are redundant, respectively if the redundancy rate is high.

The quality of the different variants can be ordered consistently. The best performance shows the rule of steepest ascent. It is slightly better than the rule of greatest improvement. These two variants show a very good performance in particular when the current vertex is still far away from the optimal one.

A bit worse are the variant of Dantzig and the shadow-vertex algorithm. The reason may be that they do not exploit information on the polyhedron itself (which may make the edge-choice more ineffective, but saves computation time in the single pivot step).

Considerably worse is the performance of the combinatorial variants. The best among these is random choice, followed by rule of justice, and finally comes Bland’s rule.

The overall impression is that the differences between Category A and Category B are not dramatic, but that the differences between Category B and Category C are striking.

We have also tested the standard deviation of  $s$  and the more meaningful quotient between standard deviation and mean value (for the number of pivot steps).

This quotient was less, but close to 1, when  $m$  was in the order of  $n$ . But the quotient became quite small for  $m \gg n$ . We understand this as a hint that in the RSM for  $m \rightarrow \infty$  and fixed  $n$  (the ‘asymptotic case’) the shape of  $X$ , the number of facets as well as their size, and the length of edges will stabilize more and more.

However, all these experiments and their outcome are not at all satisfactory for a final judgement. One reason is that the computation time for a sufficient number of repetitions of the experiments is irresponsibly high. Hence we cannot advance to reasonably high dimensions. Also complexity theory investigations cannot be settled by limited experiments. A third argument concerns potential regression analysis attempts based on the data of the results. It is almost impossible to modelize the qualitative structure of  $E_{m,n}(s)$  as a function of  $m$  and  $n$  with parameters to be specified by the regression, as long as we do not understand (theoretically) the interaction between  $m$ ,  $n$  and the stochastic model. Many such attempts failed as the model structures did always fit only in a bounded range of  $m$  and  $n$ .

Much more meaningful is the outcome of theoretical (arbitrary dimension) considerations. In the following, we present two successful approaches.

### Results Under the Sign-Invariance Model

The first investigation under this kind of model was done by S. Smale [20]. He analyzed problems of type (3):

$$\text{maximize } v^\top x \quad \text{subject to } Ax \leq b, x \geq 0$$

and treated this problem as a special case of the linear complementarity problem (cf. ► **Linear complementarity problem**)

$$\left\{ \begin{array}{l} \text{Find } w, z \in \mathbf{R}^{m+n} \\ \text{such that for given } q \in \mathbf{R}^{m+n}, \\ M \in \mathbf{R}^{(m+n) \times (m+n)}, \\ w - Mz = q, w^\top z = 0, \\ w \geq 0, z \geq 0. \end{array} \right. \quad (5)$$

When

$$M = \begin{pmatrix} 0 & -A \\ A^\top & 0 \end{pmatrix} \quad \text{and} \quad q = \begin{pmatrix} b \\ -v \end{pmatrix},$$

then a solution of (5) yields a solution of (3) and its dual.

As solution procedure, Smale employs the *Lemke algorithm*. One starts with a solution for  $\bar{1}$  replacing  $q$ . Then one moves on  $[\bar{1}, q]$  forward and performs pivot steps whenever one of the coordinates of the vector  $w$  reaches the value 0, in order to keep all components nonnegative.

The analysis amounted to the question, how many cones of a special type will be intersected by a line segment. This is a typical question for a parametric algorithm. The *expected number of pivot steps*  $E_{m,n}(s^L)$  was analyzed under the following stochastic model:

- 1)  $(A, b, v)$  is distributed absolutely continuous.
- 2) The columns of  $(A, b)$  and  $v$  are independent.
- 3) The measure of  $(A, b)$  is invariant under coordinate permutations in columns of  $(A, b)$ .

Smale proved for problems distributed under that model:

**Theorem 1 ([20])**

$$E_{m,n}(s^L) \leq C(n) (1 + \ln(m + 1))^{n(n+1)} .$$

This shows polynomiality in  $m$  (for fixed  $n$ ), but not in  $n$ .  $C(n)$  is an (exponential) function of  $n$ .

Smale’s studies gave a motivation for the analysis of the so-called *sign-invariance model* (SIM). It is extremely simple and only relies on a finite number of reflections and symmetries.

Let  $A, b$  and  $v$  define a nondegenerate dataset for problem (3). Let the occurrence of  $\begin{pmatrix} A & b \\ v^T & 0 \end{pmatrix}$  and of  $\begin{pmatrix} S_1 A S_2 & S_1 b \\ v^T S_2 & 0 \end{pmatrix}$  be equiprobable for every sign matrix  $S_1 \in \mathbf{R}^{m \times m}$  and  $S_2 \in \mathbf{R}^{n \times n}$ . (A *sign matrix* is a diagonal matrix with +1 or -1 in the diagonal entries). To explain the impact of that model, it suffices to consider a somehow relaxed version of sign-invariance, the so-called *flipping model*, where we consider only the sign matrix  $S_1$  and deal with problem instances of form (1):

$$\begin{cases} \max & v^T x \\ \text{s.t.} & a_1^T x \leq b^1, \dots, a_m^T x \leq b^m. \end{cases} \quad (6)$$

Here,  $\leq \geq$  indicates that one of the relations  $\leq$  or  $\geq$  shall be valid in the formulation of the instance. We get  $\leq$  if  $s_{ii} = 1$  and  $\geq$  if  $s_{ii} = -1$  in (6), respectively in  $S_1$ . Since all sign matrices  $S_1$  shall be equiprobable, this means that we independently determine the  $m$  direc-

tions of the relations, each one with probability  $\frac{1}{2}$  for  $\leq$  and with probability  $\frac{1}{2}$  for  $\geq$ .

By the way, we generate exactly  $2^m$  problem-instances out of one data set. The idea of averaging is to solve all  $2^m$  instances, to sum up the required pivot steps and to divide by the number of instances.

This set of problem instances can be solved (as far as Phase II is concerned) by application of the shadow-vertex algorithm explained in the section above. There we realize a simplex-path over all (temporarily) optimal vertices when we traverse the set of objectives  $(u + \lambda v)^T x$  for  $\lambda \geq 0$ .

If we add the corresponding set of (optimal) vertices for negative values of  $\lambda$ , then the total set will be called the set of *co-optimal vertices*.

With  $s$  for the number of pivot steps,  $S_{coop}$  for the number of co-optimal vertices and  $S$  for the number of shadow-vertices, the following relation is obvious:  $s \leq S_{coop} \leq S$ .

Using simple combinatorial enumeration arguments, I. Adler and M. Haimovich [13] showed

**Theorem 2 ([13])** For type (1) under SIM:

$$E_{m,n}(S_{coop} | \text{a co-optimal path exists}) \leq n \frac{m - n + 2}{m + 1} \leq n .$$

So far, the analysis considers only the procedure of moving from a  $u^T x$ -optimum to a  $v^T x$ -optimum. But this does not fit exactly into a probabilistic analysis of a complete solution method (as Smale’s method), because the  $u^T x$ -optimum is not given beforehand and calculating it would be as troublesome as calculating the  $v^T x$ -optimum.

In 1983–1984, the combination of this result with a design of a complete algorithm was done in three papers by M.J. Todd [21], Adler and N. Megiddo [3], Adler, R.M. Karp, Shamir [2]. They all came to the same result for  $E_{m,n}(s^t)$ , the expected number of pivot steps required to solve the LP completely (including Phases I and II).

**Theorem 3 ([2,3,21])** For problems of type (1), respectively of type (3), distributed under SIM, the expected number of pivot steps for the complete solution by a lexicographic version of Lemke’s algorithm ( $s^t$ ) is

$$E_{m,n}(s^t) \leq 2(n + 1)^2 ,$$

(respectively,  $\leq 2 \min(m^2, n^2)$ ).

In the first two papers, analyzing type-(3) problems, the proof was based – as in Smale’s analysis – on the evaluation of a probability that a typical cone is intersected by a line. But this time, this is the line

$$[d, \vec{1}]$$

with  $0 < d = (\delta, \delta^2, \dots, \delta^{m+n})^\top$  and  $\delta$  as small as desired.

Closer to our geometrical interpretation and easier to explain is the third approach in [2].

To explain the solution process of a type-(1) problem, we use

$$X^{(n+k)} := \left\{ x \in \mathbf{R}^n : a_1^\top x \leq b^1, \dots, a_{n+k}^\top x \leq b^{n+k} \right\}$$

for  $0 \leq k \leq m - n$  and  $X^{(m)} = X$ .

The following *complete* algorithm works directly in the space  $\mathbf{R}^n$  and is called the *lexicographic variant of the constraint-by-constraint method*:

#### Initialization

Determine the unique vertex  $\bar{x} \in X^{(n)}$  and choose  $u$  as  $u = \delta^1 a_1 + \dots + \delta^n a_n$  with  $\delta > 0$  sufficiently small.

#### Stage $k$ ( $1 \leq k \leq m - n$ )

START at  $\bar{x}$ , the maximal vertex for  $u^\top x$  on  $X^{(n+k-1)}$ .

IF  $\bar{x} \in X^{(n+k)}$

THEN go to stage  $k + 1$ .

ELSE

use the shadow-vertex algorithm to improve the value of  $a_{n+k}^\top x$  (note that so far  $a_{n+k}^\top \bar{x} > b^{n+k}$ ),

START at  $\bar{x}$  and minimize  $a_{n+k}^\top x$  on  $X^{(n+k-1)}$ .

STOP as soon as  $a_{n+k}^\top x \leq b^{n+k}$ .

On the last traversed edge find a point  $\tilde{x}$  with  $a_{n+k}^\top \tilde{x} = b^{n+k}$ .

ENTER stage  $k + 1$  with  $\tilde{x}$ ; replace  $\bar{x}$ .

This is possible, because we have moved on a co-optimal path, hence  $\tilde{x}$  maximizes  $u^\top x$  on  $X^{(n+k)}$ .

STOP if it is impossible to achieve  $a_{n+k}^\top x \leq b^{n+k}$ , because then the original problem is infeasible.

#### Stage $m - n + 1$

START at  $\bar{x}$ , which maximizes  $u^\top x$  on  $X^{(m)} = X$ .

Apply the shadow-vertex algorithm to find the optimal point for  $v^\top x$  or discover that  $v^\top x$  is unbounded on  $X$ .

In principle, this amounts to solving  $(m - n + 1)$  problems, for which the average number of steps is less than  $n$  each (Theorem 2). But now, due to the lexicographical choice of  $u$ , it can be exploited that (when we enter stage  $k + 1$ ) most of the work to optimize the current objective has already been done in earlier stages. Thus, the effort of stage  $k + 1$  becomes much smaller than  $n$ .

Finally, the order of the total average number of steps is  $O(n^2)$  instead of  $O(mn)$ .

With slight additional conditions on the distributions of the  $A$  entries, Adler and Megiddo [3] could establish also a lower bound of type  $C \cdot n^2$ .

They argued that for  $m \leq 2n$ , since the share of feasible problems is at least  $n^{-1/2}$ , the conditional expected number of pivot steps for solving LP’s of that model, under the condition that the problem instance is feasible, is  $O(n^{2.5})$ .

As for every probabilistic model, one should ask about the direct impact of the model on the results.

An important feature of SIM is the fact that many instances will be infeasible, precisely

$$\frac{\text{number of feasible instances}}{\text{number of generated problems}} = \frac{\binom{m}{0} + \dots + \binom{m}{n}}{2^m} \rightarrow 0$$

as  $m \rightarrow \infty$  while  $n$  is fixed.

Only conditioning on feasible problem instances avoids averaging over a lot of easy problems. But even if we do so, we meet a remarkably small expected number of vertices:

$$E_{m,n}(\text{vertices per feasible instance}) = \frac{2^n \binom{m}{n}}{\binom{m}{0} + \dots + \binom{m}{n}},$$

which is less than  $2^n$  and converges to that value for  $m \rightarrow \infty$ ,  $n$  fixed.

Now it is not astonishing, that for a large class of variants the average number of pivot steps for the complete solution will be bounded from above by a function of  $n$  only (cf. [1]).

But the most important cause for simplification of problem instances with  $m \gg n$  is the *average redundancy rate* (the share of the restrictions without impact on  $X$ ). This expected number (conditioned on feasible

problems) is

$$\frac{\binom{m-1}{n}}{\binom{m}{0} + \dots + \binom{m}{n}} \rightarrow 1$$

as  $m \rightarrow \infty$  while  $n$  is fixed.

Simultaneously, the absolute number of nonredundant constraints (conditioned on feasibility) tends to  $2n$  for  $m \rightarrow \infty$  and fixed  $n$ .

So, for  $m \gg n$ , even for the feasible instances, the *average nonredundancy rate* will be very small. This will of course make these problems easy. And it says that the sign-invariance model gives reasonable and meaningful information only for  $m = O(n)$ .

SIM relies on symmetries and reflections only. The combinatorial methods for evaluation make it unlikely that a calculation of higher moments of the  $s$ -distribution can easily be done. Besides that, the model is somehow inflexible. For every set of data, the reflection procedure leads to exactly the same cumulated statistical characteristics in the total set of the  $2^m$  instances. There is no way to choose a desired redundancy share or a size of the expected number of vertices and to parametrize certain figures in order to study their impact.

Apparently (in particular for  $m \gg n$ ), the small upper bounds in Theorem 2 and Theorem 3 do rather reflect the special properties of the model than confirm the efficiency of the simplex method, which had been pointed out in [1].

**Results Under the Rotation-Symmetry Model**

The theoretical analysis based on the rotation-symmetry model RMS above started in 1977 [4] by work of K.H. Borgwardt and is still (1998) developing. The most important among his results, a *polynomial upper bound* for the *expected number of shadow-vertices*, was derived in 1996–1997 [10] and it had predecessors with slightly cruder bounds in 1987 [6] and 1982 [5].

**Theorem 4 ([10])** *For every rotation-symmetry distribution as in RMS and for every pair  $(m, n)$  with  $m \geq n$ , the expected number  $S$  of shadow-vertices (and of pivot steps  $s$  in Phase II) satisfies*

$$4E_{m,n}(s) \approx E_{m,n}(S) \leq \text{const} \cdot m^{\frac{1}{(n-1)}} \cdot n^2 .$$

This result and its predecessors have been derived by translating the question about  $S$  into the dual space of the vectors  $a_i$ . Candidates for being a vertex are only the  $\binom{m}{n}$  basic solutions  $x_\Delta$  solving a system of  $n$  equations

$$a_{\Delta^1}^\top x = 1, \dots, a_{\Delta^n}^\top x = 1$$

with

$$\Delta = \{\Delta^1, \dots, \Delta^n\} \subset \{1, \dots, m\} .$$

$x_\Delta$  is actually a vertex if all other restrictions are satisfied, i. e.  $a_i^\top x_\Delta \leq 1$  for all  $i \notin \Delta$ .

It becomes a shadow-vertex if the projection on  $\text{Span}(u, v)$  preserves its vertex property.

Now there is a one-to-one correspondence

$$x_\Delta \leftrightarrow \Delta = \{\Delta^1, \dots, \Delta^n\} \leftrightarrow \text{Conv}(a_{\Delta^1}, \dots, a_{\Delta^n}) .$$

Besides  $X = \{x : Ax \leq b\}$  we consider its *polar polyhedron*  $Y = \text{Conv}(0, a_1, \dots, a_m)$ .

The following equivalences enable us to derive the average number of shadow-vertices directly from the input data:

**Lemma 5**

- 1)  $x_\Delta$  is a vertex of  $X$  if and only if  $\text{Conv}(a_{\Delta^1}, \dots, a_{\Delta^n})$  is a facet of  $Y$ .
- 2) A vertex  $x_\Delta$  is a shadow-vertex of  $X$  if and only if

$$\text{Conv}(a_{\Delta^1}, \dots, a_{\Delta^n}) \cap \text{Span}(u, v) \neq \emptyset .$$

The addition theorem for expectation values and the symmetry of index choices yield

$$E_{m,n}(S) = \binom{m}{n} \text{P} \left( \begin{array}{l} \text{Conv}(a_1, \dots, a_n) \text{ is a facet} \\ \text{intersected by Span}(u, v) \end{array} \right) .$$

Here, one integrates over all possible configurations of  $a_1, \dots, a_m, u, v$  and weights with regard to the underlying distribution. The resulting multiple integral is very hard to evaluate. For the case of moderate dimensions ( $m, n$  arbitrary), we could only compare our integral with known results about a closely related integral. Much more efficient are the tools for evaluating the so-called *asymptotic case* ( $m \rightarrow \infty, n$  fixed), because there the integrals behave like Laplace integrals and can conveniently be evaluated. So it was much easier to derive *asymptotic results* for specific RSM-distributions.

In the sequel, we write  $E_{m,n}(S) \sim f(m, n)$  as  $m \rightarrow \infty$ ,  $n$  fixed, when we mean that

$$C_1 \leq \liminf_{\substack{m \rightarrow \infty \\ n \text{ fixed}}} \frac{E_{m,n}(S)}{f(m, n)} \leq \limsup_{\substack{m \rightarrow \infty \\ n \text{ fixed}}} \frac{E_{m,n}(S)}{f(m, n)} \leq C_2$$

for certain constants  $C_1, C_2 > 0$ . Besides that, we speak of an *RSM-distribution on  $\Omega_n$  with algebraically decreasing tail* if

$$P(\|x\| \geq r) \sim (1 - r)^\gamma$$

for  $r \rightarrow 1$  for a  $\gamma > 0$ .

**Theorem 6** ([4,6,14,16,18]) *For fixed  $n$  and  $m \rightarrow \infty$ , the following distributions lead to the following behavior of  $E_{m,n}(S)$ :*

- *Gaussian distribution on  $\mathbb{R}^n$ :*

$$E_{m,n}(S) \sim \sqrt{\ln mn}^{\frac{3}{2}}.$$

- *Uniform distribution on  $\Omega_n$ :*

$$E_{m,n}(S) \sim m^{\frac{1}{(n+1)}} n^2.$$

- *Uniform distribution on  $\omega_n$ :*

$$E_{m,n}(S) \sim m^{\frac{1}{(n-1)}} n^2.$$

- *There are RSM-distributions such that*

$$E_{m,n}(S) \sim C(n).$$

- *For RSM-distributions on  $\Omega_n$  with algebraically decreasing tail:*

$$E_{m,n}(S) \sim m^{\frac{1}{(n-1+2\gamma)}} n^2.$$

These results should be compared with corresponding results on the average number of vertices of  $X$ , respectively facets of  $Y$ , denoted by  $E_{m,n}(V)$  in our model.

**Theorem 7** ([6,8,16]) *For fixed  $n$  and  $m \rightarrow \infty$ , the following distributions lead to the following behavior of  $E_{m,n}(V)$ :*

- *Gaussian distribution on  $\mathbb{R}^n$ :*

$$E_{m,n}(V) \sim [\ln m]^{\frac{(n-1)}{2}} 2^n \cdot \pi^{\frac{(n-1)}{2}} \cdot \frac{1}{\sqrt{n}}.$$

- *Uniform distribution on  $\Omega_n$ :*

$$E_{m,n}(V) \sim m^{\frac{(n-1)}{(n+1)}} 2^{\frac{n}{2}} \times \pi^{\frac{n}{2}} n^{-\frac{1}{4}} (n+1)^{\frac{(n-1)}{2}}.$$

- *Uniform distribution on  $\omega_n$ :*

$$E_{m,n}(V) \sim m^{\frac{(n-1)}{(n-1)}} 2^{\frac{n}{2}} \times \pi^{\frac{n}{2}} n^{-\frac{5}{4}} (n-1)^{\frac{(n-1)}{2}}.$$

- *For distributions on  $\Omega_n$  with algebraically decreasing tail:*

$$E_{m,n}(V) \sim m^{\frac{(n-1)}{(n-1+2\gamma)}} 2^{\frac{n}{2}} \pi^{\frac{n}{2}} n^{-\frac{3}{4}} \times (n-1+2\gamma)^{\frac{(n-1)}{2}} \left(\frac{n}{2}\right)^{-\frac{(n-1)}{2(n-1+2\gamma)}}.$$

Obviously, the simplex method is able to select a rather short path through the huge set of vertices. Hereby it visits (on the average and approximately) only the  $n$ th root of the total number of available vertices.

Another very important point is the *variance of the number of shadow-vertices*, respectively of the number of required pivot steps. Due to the technical difficulties mentioned above, so far (1998) only the asymptotic case has been analyzed. K. Küfer [17] showed

**Theorem 8** ([17]) *For distributions with algebraically decreasing tail on  $\Omega_n$ , the quotient of variance and square of expected value behaves asymptotically as follows:*

$$\frac{\text{Var}_{m,n}(s)}{E_{m,n}^2(s)} \sim \frac{1}{n},$$

$$\frac{\text{Var}_{m,n}(S)}{E_{m,n}^2(S)} \sim m^{\frac{-1}{(n-1+2\gamma)}}.$$

Here,  $s$  is the number of pivot steps of the shadow-vertex algorithm (Phase II) and  $S$  is the number of shadow-vertices.

So far, we have dealt only with a fictive Phase II algorithm, starting at an optimal vertex for an auxiliary objective. But this vertex is impracticable to find. Now let us talk about a safe Phase I.

A special feature of our problems is the feasibility of the origin, which makes (in contrast to the sign-invariance model) every instance feasible. Based on that information, we can employ a method (cf. [5] and [6]), which applies the shadow-vertex algorithm  $n-1$  times, and each time the dimension of the problem is increased. In each of these stages all the stochastic requirements of our model are satisfied.

Here we introduce

$$X^{(k)} = \left\{ x: Ax \leq \vec{1}, x^{k+1} = \dots = x^n = 0 \right\},$$

and formulate the *dimension-by-dimension algorithm*:

*Initialization*(Stage  $k=1$ )  
 Starting from the origin, find a vertex of  $X^{(1)}$  maximizing  $v^\top x = v^1 \cdot x^1$ .  
 IF this maximal vertex does not exist,  
 THEN STOP.

Stage  $k, 2 \leq k \leq n$ ,  
 Use the optimal point  $(\bar{x}^1, \dots, \bar{x}^{k-1}, 0, \dots, 0)^\top$  for  $v^\top x$  on  $X^{(k-1)}$ , which is located on an edge of  $X^{(k)}$ .

1. Find an adjacent vertex in  $X^{(k)}$  to that edge.
2. Apply the shadow-vertex algorithm using  $e_k^\top x$  and  $v^\top x$  as pair of objectives for maximizing  $v^\top x$  on  $X^{(k)}$ .  
 IF  $v^\top x$  turns out to be unbounded on  $X^{(k)}$ , STOP.
3. IF  $k < n$ , set  $k = k+1$  and enter the next stage.  
 IF  $k = n$ , PRINT the optimal vertex for  $X$ .

One can derive an upper bound for this cumulation of  $n - 1$  applications of the shadow-vertex algorithm by summing up all the expected numbers of shadow-vertices. But this would significantly overestimate the actual number of pivot steps in this algorithm, since we would ignore that the original distribution comes from  $\mathbf{R}^n$  and that only projection distributions (from  $\mathbf{R}^n$  to  $\mathbf{R}^k$ ) can determine the behavior in stage  $k$ . Since the set of projection distributions is only a small subset of the RSM-distributions in dimension  $k$ , the corresponding bound for the expected number of steps in stage  $k$  is much better. Consequently, we obtain the following result, which also holds for problems of type (3), including sign-constraints:

**Theorem 9 ([9,10])** *For every pair  $(m, n)$  with  $m \geq n$  and every RSM-distribution on  $\mathbf{R}^n$ , the expected total number of pivot steps for the dimension-by-dimension algorithm satisfies*

$$E_{m,n}(s^t) \leq m^{\frac{1}{(n-1)}} \cdot n^3 \cdot C,$$

as well for problems of type (1) as for problems of type (3).

But, as observed in the analysis of the constraint-by-constraint method (cf. Theorem 3), it is plausible that most work of optimizing in stage  $k + 1$  has already been prepared in prior stages, such that the actual number of steps in stage  $k + 1$  is much smaller. This was precisely clarified by G. Höfner [14] for the asymptotic case:

**Theorem 10 ([14])** *For every RSM-distribution the expected total number of pivot steps in the dimension-by-dimension algorithm satisfies*

$$E_{m,n}(s^t) \sim m^{\frac{1}{(n-1)}} \cdot n^{\frac{5}{2}}$$

when  $m \rightarrow \infty$  and  $n$  is fixed for problems of type (1) and (3).

It must be clear that this algorithm is crude and lengthy and has been introduced only for meeting the conditions of RSM and for making the probabilistic analysis possible.

In order to confirm the ‘folklore’ observation, that Phase I can be done with an effort not exceeding that of Phase II, Höfner analyzed another complete algorithm. But unfortunately, this method is assured to work only in the asymptotic case.

1) Solve the problem

$$\max \vec{1}^\top x \quad \text{subject to } Ax \leq \vec{1}, x \geq 0$$

by use of the shadow-vertex algorithm starting at the vertex 0. The optimal vertex  $\bar{x}$  will (in the asymptotic case) with extremely high probability be a vertex of  $X = \left\{ x: Ax \leq \vec{1} \right\}$ .

2) Start the shadow-vertex algorithm at  $\bar{x}$ , forget about the sign constraints and optimize  $v^\top x$  on  $X$ .

It can be shown that both applications of the shadow-vertex algorithm require (on the average) at most  $m^{1(n-1)} \cdot n^2 \cdot \text{const}$  pivot steps.

So, this is an algorithm with a Phase I effort not exceeding that of Phase II.

So far, the plausible and natural very good behavior of Phase I can only be guaranteed in the asymptotic case. In the moderate cases, the situation is similar to that of the sign-invariance results, where the constraint-by-constraint method needs a factor  $n$  more pivot steps than Phase II does.

As we have discussed the advantages and drawbacks of SIM, we now consider similar questions for RSM. Seemingly it is a tremendous advantage of RSM that it

generates only (the hard) feasible problems. But simultaneously it turns out to be a drawback that the given Phase I algorithms are designed in a way such that they exploit this fact and are dependent on the guarantee of ‘0 being feasible’.

One way to overcome that drawback lies in the following idea. Remember that we want to solve all problem instances of the type

$$\begin{cases} \max & v^\top x \\ \text{s.t.} & a_1^\top x \leq b^1, \dots, a_m^\top x \leq b^m \end{cases}$$

with arbitrary values of  $b^i$  (not necessarily positive).

For integrating all these problems in our analysis, we use a ‘homogenization method’. We introduce the notation  $P_n := \{x : Ax \leq b\}$  and reformulate our restrictions as

- $a_i^\top x \leq b^i$  corresponds to  $a_i^\top x \leq 1 - \widetilde{b}^i$  when  $b^i = 1 - \widetilde{b}^i$ .

So we can demand that

$$a_1^\top x + \widetilde{b}^1 \cdot 1 \leq 1, \dots, a_m^\top x + \widetilde{b}^m \cdot 1 \leq 1$$

and define a polyhedron in  $\mathbf{R}^{n+1}$  by

$$\left( a_1^1, \dots, a_n^n, \widetilde{b}^i \right) \begin{pmatrix} x^1 \\ \vdots \\ x^{n+1} \end{pmatrix} \leq 1,$$

which means that  $a_i^\top \bar{x} + \widetilde{b}^i x^{n+1} \leq 1 (\bar{x} \in \mathbf{R}^n)$  for  $i = 1, \dots, m$ .

This system defines a new polyhedron  $P_{n+1} \subset \mathbf{R}^{n+1}$ . The set of feasible points with  $x^{n+1} = 0$  is a one-to-one copy of  $\{x : Ax \leq \bar{1}\}$ . The set of feasible points with  $x^{n+1} = 1$  corresponds one-to-one to the set of points in  $P_n$ .

It is now clear that in level  $\{x^{n+1} = 0\}$  the problem satisfies all RSM-requirements. So we can solve the optimization problem for  $v^\top x$  on that artificial polyhedron. But then we can use one further stage ( $n + 1$ ) of the dimension-by-dimension algorithm to reach level  $\{x^{n+1} = 1\}$  (by maximizing  $x^{n+1} = e_{n+1}^\top x$  on  $P_{n+1}$ ). If we use the shadow-vertex algorithm starting at the level  $\{x^{n+1} = 0\}$ -optimum, then we walk on a *co-optimal path* all the time. And there will be two possible outcomes:

- 1)  $\max\{x^{n+1} : x \in P_{n+1}\} < 1$ .

Then level  $\{x^{n+1} = 1\}$  has no feasible points and  $P_n$  is proven to be empty, respectively infeasible.

- 2)  $\max\{x^{n+1} : x \in P_{n+1}\} \geq 1$ .

Then the shadow-vertex path in stage  $n + 1$  will traverse the desired level. We calculate the intersection point, drop the last coordinate 1 and have the optimal point for  $\max \mu^\top x$  subject to  $Ax \leq b$ . This results from the co-optimality of our path.

Now the following probabilistic result is obvious:

**Theorem 11 ([7])** *If  $\left(\frac{a_1}{\widetilde{b}^1}\right), \dots, \left(\frac{a_m}{\widetilde{b}^m}\right)$  are distributed on  $\mathbf{R}^{n+1}$  according to the RSM, then general problems of type (1) can be solved for every  $(m, n)$  with an expected total number of pivot steps as*

$$E_{m,n}(s^t) \leq m^{\frac{1}{n}}(n + 1)^3 \cdot C.$$

But this condition has a quite artificial flavor, because the RSM-distribution of the augmented vectors may lead to dependencies between the gradients  $a_i$  and the capacities  $b^i$ .

We know of one special distribution where both wishes (RSM-distribution and independency) can be combined, namely the Gaussian distribution on  $\mathbf{R}^{n+1}$ . This is the only RSM-distribution where the components of the generated vectors are independent. We obtain:

**Theorem 12 ([7])** *If the vectors*

$$\left(\frac{a_1}{\widetilde{b}^1}\right), \dots, \left(\frac{a_m}{\widetilde{b}^m}\right)$$

*are independent and Gaussian distributed, then*

$$E_{m,n}(s^t) \leq m^{\frac{1}{n}}(n + 1)^3 \cdot \text{const.}$$

For more general independent distributions of the right sides (the capacities), as for uniform distribution, we could not derive satisfactory bounds so far (1998). However, this seems to be caused by technical difficulties only. The special results in Theorems 11 and 12 indicate that general problems with arbitrary independent capacity distribution may be solvable on the average with the same effort.

We conclude our report with a look on general variants. In [15] and [12] P. Huhn proved a *lower bound* on the average number of pivot steps, which is valid for all variants. Assume that Phase I has provided us with

a vertex  $x_0$  of  $X$ , and that the objective  $v^\top x$  had no impact on Phase I. Then we start at  $x_0$  with Phase II and try to reach the optimal vertex  $x_{\text{opt}}$ . To bridge the distance, every variant has to use edges of the polyhedron  $X$ . Now *stochastic geometry* can provide information on the distribution of the length of these edges. If one can show that there are extremely few ‘long’ edges, then a large number of ‘small’ edges has to be used for our walk. This has been done in [15] and [12] and it gave a guarantee that no variant can (on the average) do its job with less than a certain (computable) number of steps. Quantitatively, this reads as follows. We present only the result for a special distribution, the uniform distribution on  $\omega_n$  (corresponding results have been derived for a large class of distributions).

**Theorem 13** [15] *In a typical RSM problem with uniform distribution on  $\omega_n$ , every variant of the simplex algorithm will, on the average, require a certain number  $E_{m,n}^{\text{av}}(s)$  of pivot steps, and*

$$E_{m,n}^{\text{av}}(s) \geq C \cdot m^{\frac{1}{(n-1)}} \cdot n^0 \quad \text{with } C > 0.$$

Despite the fact that here the  $n$ -order is  $n^0$  (compare with  $n^2$  for the shadow-vertex algorithm), this shows that no variant can perform substantially better. This means that there is no algorithm (variant) running essentially faster than the shadow-vertex algorithm, which can exploit the increasing number of options with  $n$ , and which avoids the typical order  $m^{1/(n-1)}$  in the RSM.

Thus, a posteriori, the results on the shadow-vertex algorithm have proved to be quite representative. It is not the very best variant, but not much worse than the very best.

Note that the lower bound in Theorem 13 is meaningful only when  $m \gg n$ , because only then it becomes significantly greater than 1, although the inequality is valid for all  $(m, n)$ . This is different from the results about the variance (Theorem 8) and the speedup for Phase I (Theorem 10), where it is uncertain, whether these results will be valid in moderate dimensions, too. (Perhaps not the technical difficulties are to blame.) It may as well be possible that these results essentially rely on a regularization effect of the polyhedra for large number of points, as we know it from the approximation of a ball from inside by the convex hull of a huge number of random points.

To clarify these questions, remains an important challenge for future research.

### Keywords

Probabilistic constrained linear programming; Duality;  
Linear programming; Optimization

When formulating stochastic programming problems one usually starts from an underlying deterministic

problem which, in case of *probabilistic constrained linear programming* (PCLP), is the *linear programming* (LP) problem. In game theoretical formulation, the LP primal-dual pair of problems is the following:

$$\begin{cases} \sup_{y \in Y'} \{yAx\} \rightarrow \min, \\ x \in X' = \{x \in \mathbf{R}^n : Ax \geq b, x \geq 0\}, \end{cases}$$

and

$$\begin{cases} \inf_{x \in X'} \{yAx\} \rightarrow \max, \\ y \in Y' = \{y \in \mathbf{R}^m : yA \leq c, y \geq 0\}, \end{cases}$$

where  $A$  is a given matrix of dimension  $m \times n$ ,  $b$  and  $c$  are given vectors of dimension  $m$  and  $n$ , and  $x$  and  $y$  are decision vectors of dimension  $n$  and  $m$ , respectively. In order to extend the *LP duality* concept [2] we reformulate the feasibility sets of the two problems by introducing probability constraints as follows:

$$\begin{cases} \sup_{y \in Y} \{yAx\} \rightarrow \min, \\ x \in X = \{x \in \mathbf{R}^n : P(Ax \geq \beta) \geq p, x \geq 0\}, \end{cases} \quad (1)$$

and

$$\begin{cases} \inf_{x \in X} \{yAx\} \rightarrow \max, \\ y \in Y = \{y \in \mathbf{R}^m : P(yA \leq \tau) \geq q, y \geq 0\}. \end{cases} \quad (2)$$

Here  $\beta$  and  $-\tau$  are random vectors of dimension  $m$  and  $n$  with given joint continuous probability distribution functions  $F$  and  $G$ ,  $p$  and  $q$  are reliability levels in  $(0, 1)$ ;  $A$ ,  $x$ ,  $y$  are defined as above.

The pair of problems (1) and (2) was introduced in [3]. Each of them is a generalization of problems with probabilistic constraints and linear objective, introduced by A. Charnes and W.W. Cooper [1], by B.L. Miller and H.M. Wagner [6], and by A. Prékopa [7]. The formulation of a dual problem can be of help in elaborating a solution method, in analysing sensitivity of a solution, in assessing the closeness of the objective function value at a solution at hand from the optimal value.

Because of the presence of the bilinear function  $yAx$ , the objective functions of both (1) and (2) directly depend on the feasibility set of the other problem. It is desirable, therefore, to find objective functions for Problems (1) and (2) such that either of them could be interpreted in itself. The idea is similar to that applied

in LP where  $cx$  and  $yb$  can replace the corresponding objective functions. The argumentation leading to such a pair of self-contained problems follows.

Define the following sets:

$$\begin{aligned} B &= \{b \in \mathbf{R}^m : F(b) \geq p, b \in \text{supp } F\}, \\ X(b) &= \{x \in \mathbf{R}^n : Ax \geq b, x \geq 0\}, \\ \text{for given } b \in \mathbf{R}^m, \\ C &= \{c \in \mathbf{R}^n : G(-c) \geq q, -c \in \text{supp } G\}, \\ Y(c) &= \{y \in \mathbf{R}^m : yA \leq c, y \geq 0\}, \\ \text{for given } c \in \mathbf{R}^n. \end{aligned}$$

The sets  $X(b)$  and  $Y(c)$  are *convex polyhedral sets*. The sets  $B$  and  $C$  are closed because  $F$  and  $G$  are assumed to be continuous, and their interiors are not empty because  $p, q < 1$ ,  $B$  (respectively,  $C$ ) is convex if  $F$  (respectively,  $G$ ) is quasiconcave. The set  $B$  is bounded if the *support set*  $\text{supp } F$  (the smallest closed subset of  $\mathbf{R}^m$  whose probability measure generated by  $F$  is 1) is bounded. Similarly, the set  $C$  is bounded if  $\text{supp } G$  is bounded. Assume, in the course of the transformation below, that  $B$  and  $C$  are bounded. Obviously,

$$\begin{aligned} X &= \{x \in \mathbf{R}^n : x \in X(b), b \in B\}, \\ Y &= \{y \in \mathbf{R}^m : y \in Y(c), c \in C\}, \end{aligned}$$

so (1) and (2) can be rewritten in the following equivalent form:

$$\min_{b \in B} \left\{ \min_{x \in X(b)} \left\{ \sup_{c \in C} \left\{ \sup_{y \in Y(c)} yAx \right\} \right\} \right\}, \tag{3}$$

and

$$\max_{c \in C} \left\{ \max_{y \in Y(c)} \left\{ \inf_{b \in B} \left\{ \inf_{x \in X(b)} yAx \right\} \right\} \right\}. \tag{4}$$

Observe that

$$\sup_{y \in Y(c)} yAx = \inf_{x' \in X(Ax)} \{cx'\},$$

for any given  $c \in \mathbf{R}^n$  and  $x \in \mathbf{R}^n$ , with  $\inf_{x' \in X(Ax)} \{cx'\} = -\infty$  if  $Y(c) = \emptyset$ , by the LP duality theorem. It means that

$$\sup_{c \in C} \left\{ \sup_{y \in Y(c)} yAx \right\} = \sup_{c \in C} \left\{ \inf_{x' \in X(Ax)} \{cx'\} \right\},$$

and both sides are defined to be  $-\infty$  if  $Y(c) = \emptyset$  for all  $c \in C$ . The function  $cx'$  is convex in  $c$ , concave in  $x'$ , and

continuous on the product set  $C \otimes X(Ax)$  provided  $C$  is convex. Assume that  $C$  is convex. Then the *saddle value* of  $cx'$  exists with respect to minimizing over  $X(Ax)$  and maximizing over  $C$  [9]:

$$\sup_{c \in C} \left\{ \inf_{x' \in X(Ax)} cx' \right\} = \inf_{x' \in X(Ax)} \left\{ \sup_{c \in C} cx' \right\}.$$

In fact,  $cx'$  has a *saddle point* if  $\{c \in C : Y(c) \neq \emptyset\}$  satisfies the *Slater condition*: its interior is nonempty. The reason is that  $\inf_{x' \in X(Ax)} cx'$  as a function of  $c$  is closed, convex hence continuous over its domain  $\{c : Y(c) \neq \emptyset\}$  [10]. Therefore, it attains its maximum over the compact set  $\{c \in C : Y(c) \neq \emptyset\}$ , say at  $c^\circ$ . Then, by the LP duality theorem,  $\inf_{x' \in X(Ax)} c^\circ x'$  is attained, say at  $x^\circ$ . It implies that, in the presence of the Slater condition,  $(c^\circ, x^\circ)$  is a saddle point, with respect to minimizing over  $X(Ax)$  and maximizing over  $C$  [5]. This fact is needed to ensure that not all the optimal solutions of (1) are lost during the transformation.

Relax the minimization of  $\sup_C \sup_{Y(c)} yAx$  over  $X(b)$  in (3) and use infimum instead. Observe that  $X(b) = \{x' \geq 0 : \exists x \in X(b) \text{ such that } Ax' \geq Ax\}$  for any fixed  $b \in \mathbf{R}^m$ , so that

$$\inf_{x \in X(b)} \left\{ \inf_{x' \in X(Ax)} \left\{ \sup_{c \in C} cx' \right\} \right\} = \inf_{x \in X(b)} \left\{ \sup_{c \in C} cx \right\},$$

where both sides are defined to be  $+\infty$  if  $X(b) = \emptyset$ . Then restore the minimization over  $X(b)$  and obtain the following problem which corresponds to (1):

$$\left\{ \begin{array}{l} \sup_{c \in C} cx \rightarrow \min, \\ x \in X = \left\{ x : \begin{array}{l} Ax \geq b, x \geq 0, \\ F(b) \geq p, b \in \text{supp } F \end{array} \right\}. \end{array} \right. \tag{5}$$

By assuming that  $B$  is convex, a similar argumentation leads to the following problem which corresponds to (2):

$$\left\{ \begin{array}{l} \inf_{b \in B} yb \rightarrow \max, \\ y \in Y = \left\{ y : \begin{array}{l} yA \leq c, y \geq 0, \\ G(-c) \geq q, -c \in \text{supp } G \end{array} \right\}. \end{array} \right. \tag{6}$$

Next, we summarize the relation between (1) and (5), and (2) and (6), respectively.

If the probability distribution function  $G$  is quasiconcave,  $\text{supp } G$  is bounded,  $(b^\circ, x^\circ)$  is optimal for (5),

then  $x^\circ$  is optimal for (1). If the probability distribution function  $G$  is quasiconcave,  $\text{supp } G$  is bounded, the set  $\{c \in C : Y(c) \neq \emptyset\}$  fulfills the Slater condition,  $x^\circ$  is optimal for (1), then  $(b^\circ, x^\circ)$  is optimal for (5), where  $b^\circ = Ax^\circ$ .

If the probability distribution function  $F$  is quasiconcave,  $\text{supp } F$  is bounded,  $(c^\circ, y^\circ)$  is optimal for (5), then  $y^\circ$  is optimal for (2). If the probability distribution function  $F$  is quasiconcave,  $\text{supp } F$  is bounded,  $\{b \in B : X(b) \neq \emptyset\}$  fulfills the Slater condition,  $y^\circ$  is optimal for (2), then  $(c^\circ, y^\circ)$  is optimal for (6), where  $c^\circ = y^\circ A$ .

It remains to state the duality theorem, the proof of which can be found in [4].

**Theorem 1** (Duality theorem) *Suppose that the probability distribution functions  $F$  and  $G$  are quasiconcave, that  $F$  is a strictly increasing function of its components, that  $\text{supp } G$  is bounded, and that the Slater condition  $\text{int } \{b \in B : X(b) \neq \emptyset\} \neq \emptyset$  holds. If (5) is unbounded in value, then (6) is inconsistent. Otherwise, (6) is consistent, their values are equal, and that value is attained in (6).*

*Suppose that the probability distribution functions  $F$  and  $G$  are quasiconcave, that  $G$  is a strictly increasing function of its components, that  $\text{supp } F$  is bounded, and that the Slater condition  $\text{int } \{c \in C : Y(c) \neq \emptyset\} \neq \emptyset$  holds. If (6) is unbounded in value, then (5) is inconsistent. Otherwise, (5) is consistent, their values are equal, and that value is attained in (5).*

*Suppose that the probability distribution functions  $F$  and  $G$  are quasiconcave, that each of them is a strictly increasing function of its components, that  $\text{supp } F$  and  $\text{supp } G$  are bounded, and that the following regularity conditions hold:  $\text{int } \{b \in B : X(b) \neq \emptyset\} \neq \emptyset$  and  $\text{int } c \in C : Y(c) \neq \emptyset \neq \emptyset$ . Then (1) has an optimal solution  $x^\circ$ , and (2) has an optimal solution  $y^\circ$  such that  $(x^\circ, y^\circ)$  is a saddle point of  $yAx$  with respect to minimizing over  $X$  and maximizing over  $Y$ .*

The rich class of *quasiconcave probability distribution* functions includes, among others, the multidimensional normal, exponential, uniform, gamma distributions [8]. In practical problems, the support set of the probability distribution in question is usually bounded. Although the approximating theoretical distribution often has an unbounded support, reasonable truncation can be applied.

Probabilistic constraint; Logconcave probability density function; Logconcave function; Multivariate normal distribution

The general form of a probabilistic constraint is the following:

$$P(g_1(\mathbf{x}, \xi) \geq 0, \dots, g_r(\mathbf{x}, \xi) \geq 0) \geq p,$$

where  $g_r(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{x} \in \mathbf{R}^n$ ,  $\mathbf{y} \in \mathbf{R}^q$ ,  $i = 1, \dots, r$ , are some functions,  $\xi$  is a  $q$ -variate random vector and  $p$  is a fixed probability. In the simplest case  $g_r(\mathbf{x}, \mathbf{y}) = T_i\mathbf{x} - y_i$ , where  $T_i$  is the  $i$ th row of a matrix  $T$ ,  $i = 1, \dots, r$ . In this case the above constraint take the form:  $P(T\mathbf{x} \geq \xi) \geq p$ .

The most important theorem in connection with the probabilistic constraint states that if  $g_1, \dots, g_r$  are concave, or quasiconcave functions in  $\mathbf{R}^{n+q}$  and  $\xi$  has a continuous probability distribution with logconcave probability distribution function, then  $P(g_i(\mathbf{x}, \xi) \geq 0, i = 1, \dots, r)$  is a logconcave function in  $\mathbf{R}^n$  ([4,5]).

There are, however, important cases where the functions  $g_i(\mathbf{x}, \mathbf{y})$  are not concave or quasiconcave. S. Kataoka [2] and C. van de Panne and W. Popp [3] considered the probabilistic constraint of the form:

$$P(\xi_1 x_1 + \dots + \xi_n x_n \geq b) \geq p,$$

where  $\xi = (\xi_1, \dots, \xi_n)^T$  has a multivariate normal distribution and  $b$  is constant. The practical problems were investment and animal feed problems, respectively. If  $\mu = E(\xi)$ ,  $C = E[(\xi - \mu)(\xi - \mu)^T]$ , then the above probabilistic constraint is shown to be equivalent to

$$\mu^T \mathbf{x} + \Phi^{-1}(1 - p) \sqrt{\mathbf{x}^T C \mathbf{x}} \geq b,$$

where  $\Phi$  is the univariate standard normal probability distribution function. If  $p \geq 1/2$ , then  $\Phi^{-1}(1 - p) \leq 0$  and the set of  $\mathbf{x}$  vectors satisfying the probabilistic constraint is convex.

Generalizations of this result have been given in [1,4]. We look at the joint probabilistic constraint:

$$P(\xi_{i1} x_1 + \dots + \xi_{in} x_n \geq b_i, i = 1, \dots, r) \geq p,$$

where we assume that the altogether  $rm$  random variables  $\xi_{ij}$  have a joint normal distribution. The statement is that if the covariance matrices of the rows  $(\xi_{i1}, \dots, \xi_{in})$ ,  $i = 1, \dots, r$ , are constant multiples of a fixed covariance matrix  $C_1$ , or the covariance matrices of the columns  $(\xi_{1j}, \dots, \xi_{rj})^T$ ,  $j = 1, \dots, n$ , are constant multiples of a fixed covariance matrix  $C_2$ , then the set of  $\mathbf{x}$

vectors satisfying the probabilistic constraint is convex, provided that  $p \geq 1/2$ . For further convexity statements see [5].

### Introduction

Management of a firm's production-distribution system involves tactical and operational decisions along with strategic ones. The policies that enable a firm to

meet its strategic goals comprise a collection of structural and infrastructural decisions, which typically involve long-term commitments with regards to the configuration and coordination of its supply chain. These structural decisions, a.k.a., facility design decisions include location, capacity, product range, and production or operating technologies at various facilities. The usual objective is minimizing costs or maximizing gross profits while leaving other manufacturing tasks (e.g., goals set for quality, flexibility, etc.) for prior or subsequent analysis. Mathematical models of this nature are generally called as “production-distribution system design problems” (PDSDP).

Traditionally, location, capacity, technology, and product range decisions have been dealt with separately. Facility location models, in general, ignore the geographical differences in capacity and technology acquisition/operation costs. Whereas, capacity expansion models mostly deal with the temporal aspects of market demand and do not incorporate location decisions with regards to the establishment of new plants. The interactions between facility design decisions, however, can be significant and PDSDP research takes its motivation from these interactions. The governments of many countries provide subsidies to support economic activities of specific sectors or regions with high rate of unemployment. In taking advantage of the capital and/or employment subsidies, preferential tax rates, and free trade zones provided by governments, firms, especially multinationals need to take interdependencies between their location, capacity and technology decisions into account. These decisions could further be complicated due to varying scale and scope economies inherent in different technologies.

A production-distribution network provides an effective representation of the manufacturing and logistics activities of a firm and assists researchers with a framework to study various systems. In a typical network, nodes represent suppliers, manufacturing facilities, distribution centers, warehouses and customers of the firm. The arcs on the network delineate the flow of items between nodes. An example network of five echelons is depicted in Fig. 1. There are mainly two important features that define the difficulty of PDSDP: first, is the number of echelons in the system and second, is the number of different types of configurational, most notably locational, decisions that need to be made.

**Production-Distribution System Design Problem, Figure 1**  
A production-distribution network

Our objective is to provide an overview of the prevailing methodology for designing production-distribution systems. The remainder of this article is organized as follows: In the next section we give an overview and taxonomy of the prevailing PDSDP models. Subsequently, an overview of PDSDP in practice is given. The paper concludes with our remarks.

### Prevailing Models

Location decisions have been attracting researchers since the end of nineteenth century. But a rigorous methodology for production-distribution systems did not come out until sixties during which two competing approaches have appeared. For a warehouse location problem, Shycon and Maffei [71] propose a simulation model claiming that, a proper model should be descriptive, whereas Kuehn and Hamburger [46] favor prescriptive models and propose a mixed integer linear program (MILP) and a heuristic solution procedure. After these two pioneering works, MILP formulations received considerably more attention in both practice and theory.

It is evident that PDSDP refers to a family of problems. The purpose here is to provide an overview of production-distribution system design literature, rather than an exhaustive review. The uncapacitated facility location problem (UFLP) is the simplest type of PDSDP, with a single-commodity, a network of two echelons (i.e., facilities and customers) of which only a single echelon of nodes (i.e. facilities) is to be located. The following is the most popular formulation known

in the literature:

$$\min \sum_{i \in I} f_i y_i + \sum_{i \in I} \sum_{j \in J} c_{ij} x_{ij} \quad (1)$$

$$\text{s.t. } \sum_{i \in I} x_{ij} = 1, \quad j \in J, \quad (2)$$

$$x_{ij} \leq y_i, \quad i \in I, \quad j \in J, \quad (3)$$

$$x_{ij} \geq 0, \quad i \in I, \quad j \in J, \quad (4)$$

$$y_i \in \{0, 1\}, \quad i \in I \quad (5)$$

$x_{ij}$  : proportion of customer  $j$ 's demand satisfied by facility  $i$ ,

$y_i$  : 1 if facility  $i$  is opened, 0 otherwise,

$c_{ij}$  : the total production and distribution costs for supplying all of the customer  $j$ 's demand from facility  $i$ ,

$f_i$  : fixed cost of opening facility  $i$ ,

$I, J$  : the set of candidate facility sites and customers.

The objective is to minimize the sum of the fixed setup costs of opening facilities and the variable costs of serving the customers. Constraints (1) guarantee that each customer's demand is satisfied, and (2) ensure that only open plants can make shipments.

Beginning with Kuehn and Hamburger, most research has been directed towards devising more efficient solution procedures to UFLP. Efraymson and Ray [19] propose an LP based branch-and-bound algorithm. However, in order to solve the arising LPs more efficiently and to minimize the memory requirements, they devised a more compact but weaker formulation of UFLP by replacing constraints (2) with the following equivalent set of constraints:

$$\sum_{j \in J} x_{ij} \leq n_i y_i, \quad i \in I, \quad (6)$$

where  $n_i$  is the number of customers that facility  $i$  can serve. Later, Spielberg [75] proposed another branch-and-bound (implicit enumeration) algorithm using the same weaker formulation. The largest stride towards an efficient solution procedure came in late seventies. Bilde and Krarup [8] and Erlenkotter [22], independent from each other, took advantage of the tighter formulation and proposed one of the most remarkable solution pro-

cedures. Instead of solving LPs at nodes to optimally, they devised quick procedures to obtain good solutions to the dual of LPs. Using these "good" dual solutions, they generated integer feasible primal solutions using complementary slackness conditions and a heuristic. Erlenkotter reports that most of the time the optimal solution is found after single pass. If there is a gap left, it is eliminated by branch-and-bound. After these works, this type of procedure (called dual-based branch-and-bound) has been repeatedly applied to other location problems.

The normative work on UFLP has been extended in several ways so as to analyze more realistic production-distribution systems. One of the earliest attempts was to incorporate the limited availability of land and other production factors at the alternative sites. The formulation of the capacitated version is quite similar to UFLP, where capacity constraints are appended to the formulation. Using identical formulations, Akinc and Khumawala [2] and Nauss [55] propose linear programming and Lagrangean relaxation based branch-and-bound solution techniques, respectively. On the other hand, Geoffrion and McBride [28] solve a generalization of the capacitated model in which there are lower as well as upper bounds and arbitrary constraints over structural variables ( $y_i$ ).

Multicommodity models have also been widely studied in the literature (e.g. Warszawski [88], Neebe and Khumawala [56], and Karkazis and Boffey [41]). The problem is an immediate generalization of UFLP where there are multiple products. Even though they offered different formulations, all of them assumed that only one product can be assigned to a facility. This assumption is later relaxed in Klincewicz and Luss [43]. Quite a few researchers have focused on increasing the number of echelons to be located. This line of research constitutes a major stride towards the development of analytical models that are capable of representing PDSDPs of the size managers typically encounter in real life. Kaufman, Eede, and Hansen [42] and Tcha and Lee [76] are among the earlier works. The former deals with location of plants and warehouses to minimize that total cost of respective fixed costs and production and distribution costs. Tcha and Lee however deals with arbitrary number of echelons. The commonality between both models is that they ignore any cost that might arise from the interaction be-

tween plants and warehouses. Later, Gao and Robinson [26] propose an efficient dual-based branch-and-bound algorithm and Barros and Labbe [6] present a profit maximization version of the same problem. They proposed various heuristics and an exact Lagrangian relaxation-based branch-and-bound algorithm.

Thus far, works on UFLP and some of its immediate generalizations are reviewed. Arguably one of the most influential model in PDSDP literature is proposed and solved by Geoffrion and Graves [27]. Their model consists of three echelons; plants, warehouses, and customers. The objective is to minimize the total costs of production, transportation, warehousing and total fixed costs of opening the warehouses. The capacity restrictions over DCs can be both from above or below, which enables modeling piecewise linear concave DC throughput costs. Furthermore, each customer is to be supplied from one DC and there may be certain restrictions on the configurational decisions. They proposed a solution procedure based on Benders' decomposition.

The most important contribution of Geoffrion and Graves [27] is the paradigm change triggered by this paper. In multi-echelon models, the usual practice was to represent flow between neighbor echelons by different sets of variables and impose flow conservation at the nodes. Geoffrion and Graves [27] represent the flows on the network by a single set of variables from nodes in the first echelon to the nodes in the last (i. e. using more indices). With this modeling technique the number of variables grow considerably with the size but the formulation becomes tighter, which could be useful in devising more efficient algorithms.

Later, Moon [54] extended the model and solution procedure considering economies of scale in DC throughput costs. In this case the DC throughput costs are represented by general concave cost functions. Pirkul and Jayaraman [59] propose a similar model that differs in the following aspects:

- i) The opening decisions are not only for warehouses but also for plants,
- ii) The capacity limitations are only from above, and
- iii) There are upper bounds on the number of plants and warehouses that can be opened. They devise a Lagrangean relaxation based heuristic solution procedure. In a subsequent paper [60], they also include supplier

selection. Elhedli and Goffin [20] present one of the most recent advances in this area.

In designing an production-distribution system, it is crucial to optimize the configurational decisions simultaneously because a sequential approach is bound to produce suboptimal results especially when the interactions between these decisions and scope and scale economies are present. One of the earliest attempts to develop a model that consider scale economies is due to Soland [73]. His model is a simple extension of UFLP where fixed facility costs are replaced by a concave function of the size of the facility. Later, Holmberg [37] and Holmberg and Ling [38] propose a capacitated facility location problem where capacity acquisition cost is an arbitrary piecewise linear function. Verter and Dincer [85] propose alternative model where capacity costs are assumed to be general concave functions of total acquisition. More recently, Dasci and Verter [17] and Verter and Dasci [84] extend these models to a multi-product environment and selection of various dedicated and flexible technologies that display different forms of scale and scope economies. A number of authors propose models that integrate inventory control and logistics decisions into a PDSDP framework. The inventory related costs also display scale economies and therefore, necessitate a concave or non-linear cost modeling, as in the aforementioned works. Shen [69] present a unifying work on this issue. Sneyder et al. [77] and Sourirajan et al. [74] present more recent location models that consider logistics related costs.

Since the mid-eighties, the world witnessed the emergence of global manufacturing firms, which diversify their operations to different countries. Globalization provides the firm with many advantages, such as access to cheap labor, raw material and other production factors, presence at regional markets, and access to locally available technological resources and know-how. The arising supply chain structures, however, are usually more challenging from the perspective of the manager. The strategic management of international production-distribution networks are further complicated due to the price and exchange rate uncertainties. In a series of papers, Hodder and Jucker [35,36] and Hodder and Dincer [34] propose scenario based approaches to model these uncertainties. Their models maximize expected profit less a constant portion of the

variability of the profit, which is an appropriate way to represent a risk-averse decision-maker. Later, Gutierrez and Kouvelis [31] also used a scenario-based approach to find robust solutions under all possible scenario realizations. More recently, Canel and Khumawala [11] and Kouvelis et al. [45] proposed models that include subsidies and tariffs. The prevailing studies in this field suggest that the scenario-based approach is a popular way of modeling the various types of uncertainties that characterize the international environment. The number of possible scenarios however quickly proliferate as the problem size increases, making not only the evaluation of the scenarios but also the generation of them a formidable task.

As we have seen, there are families of PDS-DPs involving capacity limitation on sites, multiple products, multiple echelons, or time phased system design models. Almost all of these models are formulated as mixed integer programs and are solved usually by branch and bound. In general, Lagrangean relaxation, linear programming (LP) relaxation, and dual-based procedures (see for example, Erlenkotter [22]) are the most common lower bounding techniques. While dual-based procedures are usually shown to be computationally more efficient than the former two, it is very much dependent on the special structures of the problems. On the other hand, Lagrangean and LP relaxation techniques can essentially be used for any formulation. Starting with Geoffrion and Graves [27], Bender's decomposition, which is able to handle arbitrary side constraints on structural variables, has been used few times. Nevertheless, it is among the less popular solution methods like dynamic programming. From the perspective of heuristic solution techniques, Lagrangean relaxation based and pairwise improvement type procedures are the most commonly used techniques.

While the match between a formulation and a solution procedure is certainly the defining factor in the efficiency of a solution method, tighter formulations usually lead to more efficient solutions procedures. For example in UFLP, while constraints (2) and (6) are interchangeable, the former provides a tighter formulation, which eventually led to very efficient dual-based solution procedures. Similarly, as pioneered by Geoffrion and Graves [27], defining the flows on a network by a single set of variables from nodes in the first ech-

elon to the nodes in the last. While this formulation causes the number of decision variables to propagate, it leads to tighter formulation.

While we try to give an overview of the prevailing PDS-DP models and solution methodologies, space prohibits us from mentioning tens if not hundreds other works. Therefore, we have devised a classification of the prevailing analytical models along differentiating PDS-DP features in Table 1. This table gives a quick snapshot of PDS-DP literature in the last 40 years. This classification is intended to reveal the strengths and weakness of the existing methodology as well as the major trends in the literature. Analytical approaches have been such a focus of research that even the table is far from exhaustive. Therefore, we refer the interested reader to the following review and critique papers: Aikens [1], Verter and Dincer [86], Vidal and Goetschalckx [87], Goetschalckx et al. [30], Klose and Drexel [44], Meixell and Gargeya [51], Snyder [72], Sahin and Sural [64], and Shen [70].

### PDS-DP in Practice

In this section, we provide an overview PDS-DP application in practice. In their seminal paper, Geoffrion and Graves [27], have not only provided one of the most influential models on PDS-DP, but also reported arguably the first industrial implementation. They assisted Hunt-Wesson Foods, Inc in re-locating their distribution centers (DCs). The firm had been producing several hundred commodities at 14 sites and distributing through a dozen DCs. They recommended five changes in the configuration of DCs as well as the establishment of a new DC.

After this work PDS-DP implementations have started to appear in the literature. Arguably, the most comprehensive implementation is presented by Arntzen et al. [4]. This paper reports on the development and use of Global Supply Chain Management (GSCM), a large scale optimization model that contributed to the re-organization of the Digital Equipment Corporation (DEC) in the late 80s and early 90s. Although its development had started as a small project, GSCM has become an essential tool to examine all aspects of supply chain management in DEC. GSCM is arguably the most comprehensive system that considers production, inventory, material handling, taxes, fa-

cility fixed charges, production line fixed charges, transportation costs, duty costs, duty drawbacks and duty avoidance. In an effort to establish the optimal supply chain structure, GSCM reduced the number of plants from 31 to 12, which enabled the major customer regions (America, Europe, and Pacific Rim) to become self-contained. Estimated savings as of 1995 were \$1.2 billion. GSCM was also used to determine the optimal network structure for distribution of spare parts and collection of defective items. Repair center facility locations and capacities were determined. Total savings of this project were estimated to be \$200 million.

A set of published industrial applications are summarized in Table 2. While such works appear at a steady pace, the literature on the applications of PDSDP is quite sparse. There seem to be a few possible explanations: First, (re)-configuration of a firm's supply chain is a long-term process, which requires a genuine commitment by top management. In many cases, the pos-

sibility of success in adopting an analytical approach for (re)-designing the supply chain is severely diminished due to the lack of support from top management. Second, we are aware of many firms who choose not to report their experiences in production-distribution system design simply due to the strategic nature of these decisions. Finally, the level of many industrial projects might not justify publication in academic journals.

Most of the models developed in these projects are different from each other and the past models appeared in the literature. This might be taken as a negative sign on the applicability of generic models. However, there are several commercial software packages that have built-in functions and off-the-shelf generalized programs. The companies developing these software packages report hundreds of firms in their client roster.

One such software package is called, Strategic Logistics Integrative Modeling System (SLIM). It is an

advanced decision support system that is used to evaluate strategic production and distribution planning problems. SLIM is developed by Prof. B. Shapiro of MIT and his associates, who have collaborated with over 100 companies in the US, Canada, Europe, and Australia [68]. Another software package is called Strategic Analysis of Integrated Logistics System (SAILS), which was developed by A. Geoffrion and his colleagues at the Insight Inc. In this package, extensive data management functions and optimization tools are integrated. Geoffrion and Powers [29] report that there have been 50 or more studies done by SAILS or one of its earlier versions. The projects result with 5–15% reduction in total transportation costs.

Generic models have the advantage of having a shorter development time and lower costs whereas custom-made models have the advantage of ability to incorporate various firm specific practices. Either generic or custom-made, above studies have shown that there are considerable savings possible from (re)designing production-distribution systems through an analytical model.

## Concluding Remarks

At the time, the first edition of the encyclopedia has appeared, we stressed that the development of analytical models that could effectively represent supply chains of the sizes that are typically encountered in real life was crucial. Recent advances in PDSDP research and computing enabled researchers to analyze more complex systems and achieve this objective. A quick glance at Table 1 would show that the advances made in the last 10 years are far greater than the advances made earlier. The existing methodology on PDSDP however still needs to be improved. We see two general directions the methodology should be improved: integration of strategic and tactical decisions and including international features in PDSDPs.

It is well known that structural decisions would restrict how the firms make their tactical decisions subsequently. Therefore, integration of this decisions in a PDSDP framework should help firms improve their profits. Although few works have recently appeared in the literature that integrates these decisions [74,77], the literature still has gaps.

While issues such as globalization, outsourcing, international plant location have been around quite some time, the literature is still scant on the issue. Among the 56 works that we have classified in Table 1, only six papers consider international features such as subsidies, tariffs, and exchange rate uncertainty explicitly. There has also been a skepticism as to the impact of certain aspects globalization on firms' configuration decisions. For example, according to one survey, conducted among the plant managers of 73 large multinational firms, subsidies and free trade zones are ranked among the least important factors. However, a number of studies, mostly conducted in the US National Bureau of Economic Research, report that both international and domestic firms have been quite responsive to subsidies, free trade zones, taxes, and labor costs in deciding their plant locations. For example, Head, Ries, and Swenson [32], in their investigation of location patterns of Japanese manufacturing establishments, conclude that these firms have been quite responsive to trade zones. Similarly, Coughlin and Segev [15], in their study of foreign investment in the US, concludes that higher average labor density (as a surrogate measure of average wage rate) and higher taxes in a state are found to deter foreign investment. Finally, both Fuest and Huber [25] and Bergman, Fuss, and Regev [7] provide anecdotal and empirical evidence about how subsidies alter the location choices of domestic firms in the Eastern Germany and Israel respectively.

We can conclude that the interactions between facility design decisions are especially important for international companies. They face not only a multitude of location and technology choices but also a complex array of cost structures due to regional differences as well as governments' tax, subsidy, and free trade policies. These decisions are further complicated by manufacturing strategy options and scale and scope economies. Therefore, it is important that analytical approaches for PDS DP incorporate demand and exchange rate uncertainties as well as the other distinguishing features of the international environment.

## Abstract

We briefly review the development of generalized-ensemble optimization techniques and their application since publication of “Protein Folding: Generalized-Ensemble Algorithms” was published in the first edition of this book.

## Keywords

Energy landscape sampling; Model hopping; Parallel tempering

“Protein Folding: Generalized-Ensemble Algorithms” was submitted to the editors in February 1999 as a contribution for the “Encyclopedia of Optimization.” While the article has remained useful as a short and concise introduction, the remarkable success over the last 8 years in the forming and application of generalized-ensemble techniques to optimization problems warrants some comments. New generalized-ensemble algorithms have been developed, and the simulation of small proteins (of order  $\approx 50$  residues) has become feasible.

One example for the recent algorithmic developments is energy landscape paving (ELP) [5]. Like all successful stochastic optimization techniques, it aims at avoiding entrapment in local minima and to continue the search for further solutions. For this purpose, one performs in ELP low-temperature Monte Carlo simulations with an effective energy:

$$w(\tilde{E}) = e^{-\tilde{E}/k_B T} \quad \text{with} \quad \tilde{E} = E + f(H(q, t)). \quad (1)$$

Here,  $T$  is a (low) temperature and  $f(H(q, t))$  a function of the histogram  $H(q, t)$  in a prechosen “order parameter”  $q$ . The weight of a local minimum state decreases with the time the system stays in that state, i. e., ELP deforms the energy landscape locally till the local minimum is no longer favored, and the system will explore higher energies. It will then either fall in a new local minimum or walk through this high-energy region till the corresponding histogram entries all have

similar frequencies and the system again has a bias toward low energies. Note that for  $f(H(q, t)) = f(H(q))$  ELP reduces to the older *generalized-ensemble* methods. We have evaluated the efficiency of ELP in simulations of the 20-residue *trp*-cage protein whose structure we could “predict” within a root-mean-square deviation (rmsd) of 1 Å [8].

Note also that ELP allows even the possibility of zero-temperature simulations [8]. For  $T \rightarrow 0$  only moves with  $\Delta\tilde{E} \leq 0$  will be accepted. If we choose  $\tilde{E} = E + cH(E, t)$ , we find as acceptance criterion:

$$\Delta E + c\Delta H(q, t) \leq 0 \Leftrightarrow c\Delta H(q, t) \leq -\Delta E, \quad (2)$$

where  $E$  is the physical energy. Hence, within ELP the system can overcome even at  $T = 0$  any energy barrier. The waiting time for such a move is proportional to the height of the barrier that needs to be crossed. Factor  $c$  sets now only the time scale, and in this sense the  $T = 0$  form of ELP is parameter free.

Today, the most popular generalized-ensemble technique in protein science is parallel tempering (also known as replica exchange) [1,3]. In its most common form, one considers  $N$  *noninteracting* copies of the molecule, each at a different temperature  $T_i$ . In addition to standard Monte Carlo [3] or molecular dynamics moves [3,9] that affect only one copy, parallel tempering introduces a new *global* update [1]: the exchange of conformations between two copies  $i$  and  $j = i + 1$  with probability

$$w(\mathbf{C}^{\text{old}} \rightarrow \mathbf{C}^{\text{new}}) = \min(1, \exp(-\beta_i E(C_j) - \beta_j E(C_i) + \beta_i E(C_i) + \beta_j E(C_j))). \quad (3)$$

This exchange of conformations leads to a faster convergence than is observed in regular low-temperature canonical simulations. Note that parallel tempering does not require Boltzmann weights but can be combined easily with other generalized-ensemble techniques [3].

A variant of parallel tempering is “model hopping” [6], where sampling of low-energy configurations is enhanced by performing a random walk through an ensemble of systems with slightly altered energy functions. In that way, information is exchanged between varying stages of coarse graining or different local environments. We assume that the energy function can be divided into two terms:  $E = E_A + aE_B$ . As in parallel

tempering, “model hopping” considers  $N$  noninteracting copies of the molecule, but adjacent copies are now exchanged with probability

$$w(\mathbf{C}^{\text{old}} \rightarrow \mathbf{C}^{\text{new}}) = \min(1, \exp\{-\beta[E_A(C_j) + a_i E_B(C_j) + E_A(C_i) + a_j E_B(C_i) - E_A(C_i) - a_i E_B(C_i) - E_A(C_j) - a_j E_B(C_j)]\}) . \quad (4)$$

Here,  $\Delta a = a_j - a_i$  and  $\Delta E_B = E_B(C_j) - E_B(C_i)$ . Configurations perform a random walk on a ladder of models with  $a_1 = 1 > a_2 > a_3 > \dots > a_N$  that differ by the relative contributions of  $E_B$  to the total energy  $E$  of the molecule. For instance, barriers in the energy landscape of proteins often arise from van der Waals repulsion between atoms that come too close. Hence, we have considered an implementation of “model hopping” with successively smaller contributions from the van der Waals energy. While the “physical” system is on one side of the ladder (at  $a_1 = 1$ ), the (nonphysical) model on the other end of the ladder (at  $a_N \ll 1$ ) may allow atoms to share the same position in space. As the protein “tunnels” through energy barriers, sampling of low-energy configurations is enhanced in the “physical” model (at  $a_1 = 1$ ). With this realization of “model hopping” we could “predict” the structure of a 46-residue protein A in an all-atom simulation within a root mean square deviation (rmsd) of 3.2 Å [6]

Model hopping also allows guiding a simulation by information obtained from homologous structures [2]. Usually, such spatial constraints introduce an additional roughness into the energy landscape and therefore often lead to extremely slow convergence of the simulation. This problem is circumvented in our approach through a random walk in an ensemble of replicas that differ by the strength with which the constraints are coupled to the system. We have demonstrated the usefulness of this approach on some examples of the CASP6 competition [2].

Generalized ensemble, as discussed in “Protein Folding: Generalized-Ensemble Algorithms” and in this addendum, now allows the *in silico* study of small proteins (built out of  $\approx 50$  amino acids) using all-atom models. Examples include the 34-residue human parathyroid hormone fragment PTH(1-34) [4], the 28-residue FSD, the 36-residue villin headpiece

subdomain [5,7,10], and fragment B of protein A (46 residues)[6]. Current work aims at extending the applicability of these methods to all-atom simulations of proteins built out of 50 to 100 residues.

## Introduction

One of the most demanding problems in computational biology is the so-called *ab initio* protein structure prediction problem. In *ab initio* prediction the objective is to predict protein structure solely from physically based force fields that describe the interactions between the amino acids and interactions between amino acids and the protein's environment. The *ab initio* protein structure prediction problem can be cast as an optimization problem in which the minimum free energy of the molecule is sought, because this configuration corresponds to the most stable structure of the protein.

In this contribution the problem of protein loop structure prediction is addressed. By the term loops we refer to any amino acid subsequence within a protein that is not of the geometrically regular type of an  $\alpha$ -helix or a  $\beta$ -strand. The importance of loops for the overall three-dimensional structure and function of proteins has been pointed out before (see, e.g., Fiser et al. [5]). Even though loops are short amino acid subsequences, they are of major importance to the overall structure. Loops are often exposed to the surface and contribute to active and binding sites. Without loops, many proteins could not fold into compact structures.

Unfortunately, loop structure is considerably more difficult to predict than the geometrically regular  $\beta$ -strands and  $\alpha$ -helices, since loops possess greater structural flexibility than strands and helices, and since they have relatively few contacts with the remainder of the structure.

Methods for loop structure prediction have been investigated for at least two decades [2]. Recent progress in loop structure prediction has been achieved with approaches that combine dihedral angle sampling, steric clash detection, clustering, and scoring or energy function evaluation to build up ensembles of loop conformations.

In the so-called loop *reconstruction* problem, the anchor geometry of the protein into which the loop must fit is assumed to be known. Here we address the problem of loop structure prediction when no information on the anchor geometry is available. More precisely, we assume the secondary structure of the stem residues is assumed to be known, but the geometry of the protein into which the loop must fit is considered to be unknown in our methodology. This loop structure prediction with flexible stems must be considered more difficult than the loop reconstruction problem.

Ultimately, the optimization based method for loop structure prediction summarized here is going to be embedded in an existing *ab initio* protein structure prediction method [10,11,12,13,14,15,16,17,18,19].

## Method and Applications

This section first introduces a new methodology for loop structure prediction for loops with flexible stems. Subsequently, results are summarized that have been obtained for a large test set of 3215 loops of known structure.

## Method

The loop prediction method proceeds along the following steps: (i) generating conformers by high-resolution dihedral angle sampling, (ii) structure optimization with a physically based energy function, (iii) iterative clustering of ensembles to discard conformers that are likely to have a large rmsd with respect to the native loop structure, and (iv) strategies for selecting optimal loops from the ensemble that remains after step (iii). These steps are briefly described. For details we refer to [20].

The description of the geometry of a loop consists of two elements. The geometry of the backbone is described in terms of the dihedral angles,  $\phi$  and  $\psi$ . Correspondingly, the side chains of each amino acids are described by side chain dihedral angles. The number of the side chain dihedral angles depends on the type of amino acid. Step (i) generates a large number of candidate backbone conformations by sampling  $n - 1$  dihedral angle pairs  $(\phi_i, \psi_i)$ ,  $i = 1, \dots, n - 1$  from appropriate probability distributions for a loop that consists of  $n$  amino acids. Conformers are generated with probability functions in a discretized  $(\phi, \psi)$ -space [20]. In

this approach the  $(\phi, \psi)$  space is divided into  $72^2$  angular bins of size  $5^\circ \times 5^\circ$ . Functions for the probability to find a  $(\phi, \psi)$  pair in any of the  $5^\circ \times 5^\circ$  bins are derived for each of the 20 amino acids in each of three types of secondary structure, resulting in 60 probability functions. The three types considered are  $\alpha$ -helical,  $\beta$ -strand, and loop. More precisely, helical and strand-type amino acids are defined by the DSSP classification codes H, E [9]. To qualify as a loop, an amino acid sequence must not be at either terminal of the protein and must be located between strands or helices. Probability functions are derived by counting occurrences of  $(\phi, \psi)$ -pairs for each amino acid in each bin for a reference set of known protein structures. The reference set is chosen to be all proteins with experimental resolution of 2.2 Å or better in the PdbSelect25 set (<http://www.cmbi.kun.nl/gv/dssp/>) [9]. This results in a set of 939 reference proteins, and an overrepresentation of angular bins due to considering structures that are too similar is avoided. Similar dihedral angle bin sets have successfully been used before [3,4]. Compact and computationally efficient representations of the dihedral angle bin sets and their sampling for conformer generation exist. We refer to [20] for details.

Having generated a backbone geometry by dihedral angle sampling, side chain angles are optimized for each amino acid by looping over the amino acids and identifying the lowest energy conformation that can be achieved with any combination of angles from a well-established library of side chain conformations (the Dunbrack rotamer library [1]). While determining the optimal side chain configuration for an amino acid, the backbone and side chain angles of the remaining amino acids are fixed. The side chain optimization iterates over the sequence of amino acids that constitute the protein and terminates when no further improvement can be achieved. Energies are calculated with a physically based force field, the ECEPP/3 force field [21]. Covalent bond lengths and bond angles are fixed at their equilibrium values, so that the conformation is a function of the torsional angles only. The energy comprises electrostatic, nonbonded, hydrogen-bonded, and torsional contributions. After backbone generation by dihedral angle sampling, and after side chain optimization, the entire structure is subjected to an energy minimization in which all degrees of freedom, both all backbone angles, and all side chain angles, are optimized si-

multaneously. For this purpose a sequential quadratic programming algorithm [6] is used.

Using the approach described so far, a sufficiently large number  $n_c^{(0)}$  of geometrical conformations is generated and the resulting ensemble is subjected to clustering. In all results reported here, the ensemble size was chosen to be  $n_c^{(0)} = 2000$ . Before introducing the clustering algorithm we need the following definitions. The cluster size  $N_i$  is defined by

$$N_i = \# \{j \mid r(i, j) \leq r_{\text{thresh}}\}. \quad (1)$$

In Eq. (1)  $r(i, j)$  denotes the root mean square deviation (rmsd) between conformer  $i$  and  $j$ , and the pound symbol is the cardinality operator. For details on the rmsd calculation we refer to [20]. Note that the number of conformers  $n_c$  must be chosen with care, as the complexity of the pairwise rmsd calculation is  $O(n_c^2)$ . In the algorithm the upper index  $k$  is introduced to count the number of iterations. The symbols  $n_c^{(k)}$ ,  $N_{i,\text{max}}^{(k)}$  and  $r_{\text{max}}^{(k)}$  denote the number of conformers in the ensemble in iteration  $k$ , the number of conformers  $N_i$  as defined in Eq. (1) in the largest cluster found in iteration  $k$

$$N_{i,\text{max}}^{(k)} = \max_{i=1,\dots,n_c^{(k)}} N_i \quad (2)$$

and the largest pairwise rmsd found in the ensemble in iteration  $k$

$$r_{\text{max}}^{(k)} = \max_{i,j=1,\dots,n_c^{(k)}} r(i, j). \quad (3)$$

The relative rmsd threshold  $r_{\text{thresh,rel}} \in (0, 1)$  and the relative critical cluster size  $N_{\text{crit,rel}} \in (0, 1)$  are used to express  $r_{\text{thresh}}$  and  $N_{\text{crit}}$  in terms of the largest pairwise rmsd  $r_{\text{max}}^{(k)}$  and the largest cluster  $N_{i,\text{max}}^{(k)}$  in each iteration,

$$r_{\text{thresh}}^{(k)} = r_{\text{thresh,rel}} r_{\text{max}}^{(k)} \quad (4)$$

$$N_{\text{crit}}^{(k)} = N_{\text{crit,rel}} N_{i,\text{max}}^{(k)}. \quad (5)$$

The algorithm can now be stated as follows [20].

### 1. Initialization

Reset the iteration counter,  $k = 0$ . Choose the ensemble size  $n_c^{(0)}$  and generate the ensemble. Choose relative thresholds  $r_{\text{thresh,rel}}$  and  $N_{\text{crit,rel}}$ . Sample values are  $r_{\text{thresh,rel}} = 0.5$  and  $N_{\text{crit,rel}} = 0.5$ .

2. *Determination of rmsd threshold*  $r_{\text{thresh}}^{(k)}$   
Calculate pairwise rmsds  $r(i,j)$  for  $i = 1, \dots, n_c^{(k)}$ ,  $j = 1, \dots, n_c^{(k)}$ .  
Determine  $r_{\text{max}}^{(k)}$  from Eq. (3) and set  $r_{\text{thresh}}^{(k)}$  according to Eq. (4).
3. *Determination of clusters size threshold*  $N_{\text{crit}}^{(k)}$   
Calculate cluster sizes  $N_i^{(k)}$  for all conformers  $i = 1, \dots, n_c^{(k)}$  according to Eq. (1), where  $r_{\text{thresh}} = r_{\text{thresh}}^{(k)}$  in Eq. (1).  
Calculate  $N_{i,\text{max}}^{(k)}$  according to Eq. (2). Set  $N_{\text{crit}}^{(k)}$  according to Eq. (5).
4. *Termination criterion*  
If  $N_i \geq N_{\text{crit}}^{(k)}$  for all  $i = 1, \dots, n_c^{(k)}$ , stop.
5. *Discarding far-from-native conformations*  
Increment the iteration counter  $k$ .  
Discard conformations  $i$  for which  $N_i < N_{\text{crit}}^{(k)}$ . Consider the remaining conformations to constitute the new ensemble. Set  $n_c^{(k)}$  to the number of conformers in the new ensemble, re-enumerate the conformers in the new ensemble with numbers  $i = 1, \dots, n_c^{(k)}$ , and go to step 2.

We stress that the clustering algorithm is based on the idea of discarding structures that are likely not to be close to the native structure. In contrast, existing clustering algorithms are based on selecting structures that are close to native [3,4,7,8,22].

For test cases with known three-dimensional structure, the quality of the sampling approach can be assessed by identifying the lowest rmsd to the known structure in an ensemble. This check reveals that sampling is not restricting the overall prediction strategy [20].

Ultimately, a valid strategy is needed for selecting one or a few conformers from an ensemble that are likely to have a small rmsd with respect to the native structure when the native structure is not known. The potential energy has been reported not to be a useful criterion [8,22]. Among other things, this can be accounted to the fact that the potential energy does not take entropic contributions into account. As a remedy, the so-called colony energy has been suggested as an approximate approach to taking entropic contributions into account [22]. Alternatively one can disregard potential energy completely and identify conformers that are likely to be close to native based on the size of clusters they form

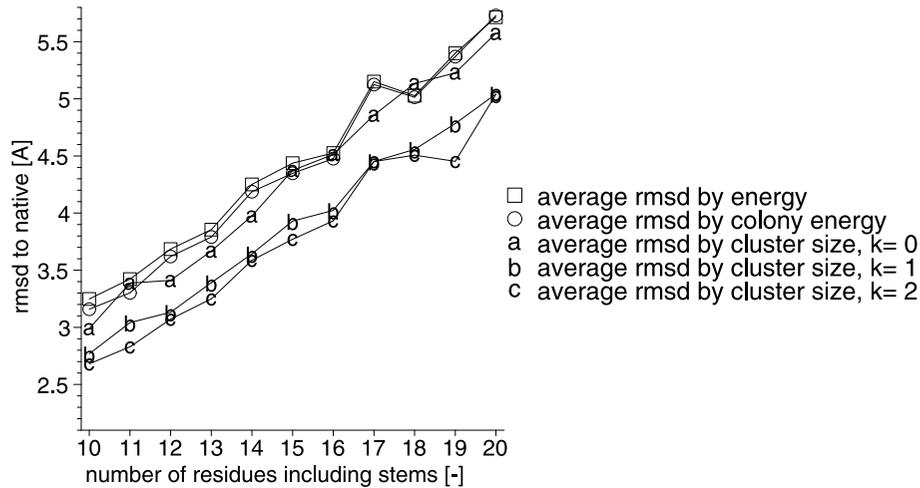

within the ensemble. We tested the potential energy, colony energy, cluster size, and a hybrid approach on a large set of 3215 loops with known structure.

## Applications

In this section we summarize the results that have been obtained for a large test set of loops with known structure. Using the PdbSelect25 we identified a test set of 716 loops of total length 10 (4 loop residues and 6 stem residues), 656 loops of length 11 (5 loop residues and 6 stem residues), 387 loops of length 12 (6 loop residues and 6 stem residues), 366 loops of length 13 (7 loop residues and 6 stem residues), 283 loops of length 14 (8 loop residues and 6 stem residues), 223 loops of length 15 (9 loop residues and 6 stem residues), 176 loops of length 16 (10 loop residues and 6 stem residues), 138 loops of length 17 (11 loop residues and 6 stem residues), 115 loops of length 18 (12 loop residues and 6 stem residues), 75 loops of length 19 (13 loop residues and 6 stem residues), and 80 loops of length 20 (14 loop residues and 6 stem residues). To our knowledge, this is the largest dataset for which loop structure prediction results have been reported to date. We refer to [20] for details.

The results are summarized in Fig. 1. The results labeled *average rmsds by energy* are obtained by identifying the lowest ECEPP/3 energy conformer in each ensemble, recording its rmsd to native, and subsequently averaging over the rmsds for all ensembles of loops of a given length. The average rmsds by colony energy results when using the colony energy [22] instead of the ECEPP/3 energy. The remaining data shown in Fig. 1 is obtained with the clustering algorithm. For all of the loops reported here, the clustering algorithm terminated after  $k = 2$  steps.

Figure 1 shows that the conformer that generates the largest cluster after any clustering step  $k = 0, 1, 2$  is on average a better prediction for the native structure than both the lowest energy and lowest colony energy conformer. From this we infer that the cluster size is a better criterion for the identification of conformers than energy or colony energy. Furthermore, the largest cluster conformer found after step  $k + 1$  of the clustering algorithm is as good as, or better than, the largest cluster conformer found in step  $k$ . In this sense,

**Protein Loop Structure Prediction Methods, Figure 1**

Average of rmsds as a function of total loop length for the loops from the PdbSelect25 proteins. Lines are added as a guide to the eye. Results are reproduced from [20]

repeatedly applying the clustering algorithm improves the largest cluster conformer on average.

In order to assess the computational demand created by the suggested approach, we measured the cpu times needed by our approach for 20 randomly selected loops of each sequence length. The resulting average times are 1.5 h, 5 h, and 11.25 h for a single loop with 4 loop and 6 stem residues, 10 loop and 6 stem residues, 14 stem and 6 loop residues, respectively, when the ensemble size is chosen to be 2000 conformers. These times were obtained on a single Intel Xeon 3 GHz machine running RedHat Linux 9.0.

The ensemble generation step needs a negligible fraction of the total time. The second step, energy minimization, is the computationally most demanding step. The times needed for pairwise rmsd calculations contribute between 3.5 min and 7 min to the total times given above. The time needed for the application of the clustering algorithm detailed in Sect. “Method” is independent of the loop length and contributes about 4 min per loop to the total times given above. The time-consuming step of energy minimization is amenable to parallelization, since the loops in an ensemble can be treated separately.

## Introduction/Background

Pseudomonotone maps were introduced by Karamardian as a generalization of monotone maps [22]. Other generalizations include various kinds of quasimonotone maps (quasimonotone, strictly quasimonotone, semistrictly quasimonotone ...). These generalizations, the relations between them, as well as the relation to generalized convexity are discussed in other articles of the Encyclopedia (see ► [generalized monotone single valued maps](#) and ► [generalized monotone multivalued maps](#) and in [16].

It should be noted that the same term a “pseudomonotone map” has been introduced by Brezis to denote a totally different class of maps [4]. The main difference between the two classes is that pseudomonotone maps in the sense of Brézis are defined through a kind of continuity property, whereas Karamardian used only the order relation of real numbers in his definition. For this reason some authors, starting by Gwinner [12], use the term “topologically pseudomonotone” for pseudomonotone maps in the Brezis sense. Although it is possible to give a definition that includes both kinds of pseudomonotonicity [11], we will use the term “pseudomonotone” only in the sense defined by Karamardian.

Pseudomonotone maps have the advantage that they lead to generalizations of existence theorems for the Stampachia variational inequality problem (VIP), without imposing additional assumptions, and with practically the same proof as for monotone maps [16]. However, this quasi-identical treatment of the VIP is not extended to other topics, and the properties of the two classes of maps are often quite dissimilar. For instance, while the sum of two monotone maps is mono-

tone, this is false for pseudomonotone maps. A vast theory has been developed for monotone maps, based on the concept of maximal monotonicity. By contrast, until recently it was believed that maximality plays no rôle for pseudomonotone maps. Consequently, some algorithms for finding the solution of VIP with maximal monotone maps have no extension to the pseudomonotone case.

This article will present some recent developments that can be considered as a first step towards filling the lacunae in the theory of pseudomonotone maps. In particular, maximal pseudomonotonicity will be discussed. The main tool is the definition of an equivalence relation in the set of all pseudomonotone maps. Also, a generalization of paramonotone maps and their use in cutting plane algorithms will be described. Finally, recent results on pseudoaffine maps and on the relation to monotone maps will be presented.

## Definitions

Let  $X$  be a real Banach space and  $X^*$  be its dual. Given  $x, y \in X$ ,  $[x, y]$  denotes the line segment  $\{(1-t)x + ty : t \in [0, 1]\}$ . For  $K \subseteq X^*$ ,  $\mathbb{R}_{++}K$  will be the set  $\bigcup_{t>0} tK$ . A multivalued map  $T : X \rightarrow 2^{X^*}$  is a map whose values are subsets of  $X^*$ , possibly empty. The *domain*  $D(T)$  of  $T$  is the set  $\{x \in X : T(x) \neq \emptyset\}$ , its graph the set  $\text{gr}(T) = \{(x, x^*) \in X \times X^* : x^* \in T(x)\}$  and its set of zeros is the set  $Z_T = \{x \in X : 0 \in T(x)\}$ . The map  $T$  is called upper sign-continuous [13] if for all  $x \in D(T)$  and  $v \in X$ , the following implication holds:

$$\left( \forall t \in (0, 1), \inf_{x^* \in T(x+tv)} \langle x^*, v \rangle \geq 0 \right) \\ \Rightarrow \sup_{x^* \in T(x)} \langle x^*, v \rangle \geq 0.$$

If  $T$  is upper hemicontinuous (i. e., its restriction on line segments is upper semicontinuous with respect to the weak\* topology in  $X^*$ ), then it is upper sign-continuous.

The map  $T$  is called monotone if for every  $(x, x^*), (y, y^*) \in \text{gr}(T)$ ,  $\langle y^* - x^*, y - x \rangle \geq 0$ ; it is called maximal monotone if its graph is not strictly contained in the graph of any other monotone map. Also,  $T$  is called  $D$ -maximal monotone if its graph is not strictly contained in the graph of any other monotone map with the same domain.

The map  $T$  is called pseudomonotone if for every  $(x, x^*), (y, y^*) \in \text{gr}(T)$ , the following implication holds.

$$\langle x^*, y - x \rangle \geq 0 \Rightarrow \langle y^*, y - x \rangle \geq 0.$$

Obviously, every monotone map is pseudomonotone.

Given a locally Lipschitz function  $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$ , we denote by  $\partial^0 f$  its Clarke subdifferential [7]. The locally Lipschitz function  $f$  is called pseudoconvex if for every  $x \in \text{dom}(f)$  and  $x^* \in \partial^0 f(x)$  the following implication holds:

$$\langle x^*, y - x \rangle \geq 0 \Rightarrow f(y) \geq f(x).$$

It is known that a locally Lipschitz function  $f$  is pseudoconvex if and only if  $\partial^0 f$  is a pseudomonotone map [23].

## Formulation

### Maximal Pseudomonotonicity

In order to introduce maximal pseudomonotone maps, one first defines an equivalence relation in the set of pseudomonotone maps. Two pseudomonotone maps  $T_1$  and  $T_2$  are called equivalent if they have the same domain, the same set of zeros, and for each  $x$  which is not a common zero, the elements of  $T_1(x)$  are positive multiples of the elements of  $T_2(x)$  and vice versa. In other words,

- (a)  $D(T_1) = D(T_2)$
- (b)  $Z_{T_1} = Z_{T_2}$ ,
- (c) for every  $x \in X \setminus Z_{T_1}$ ,  $\mathbb{R}_{++}T_1(x) = \mathbb{R}_{++}T_2(x)$ .

In this case we write  $T_1 \sim T_2$ . This is an equivalence relation. Another aspect of this equivalence is provided by the Stampacchia variational inequality. Given a map  $T$  and a convex subset  $K$  of  $X$ , we denote by  $S(T, K)$  the set of all  $x \in K$  which are solutions of the VIP:

$$\forall y \in K, \exists x^* \in T(x) : \langle x^*, y - x \rangle \geq 0.$$

The following result holds [14].

**Proposition 1** *Let  $T_1, T_2$  be pseudomonotone maps. If  $T_1 \sim T_2$ , then  $S(T_1, K) = S(T_2, K)$  for every convex set  $K \subseteq X$ . Conversely, if  $S(T_1, K) = S(T_2, K)$  for every line segment  $K$  and  $T_1, T_2$  have weak\*-compact convex values, then  $T_1 \sim T_2$ .*

Since all equivalent maps provide the same solutions to VIP, one can choose any element of the equivalence class to study or even find the solutions.

Given a pseudomonotone map  $T$ , its equivalence class has a maximum with respect to graph inclusion. This is simply the map  $\hat{T}$  defined by  $\hat{T}(x) = \cup_{S \sim T} S(x)$  for all  $x \in D(T)$ . It can be shown [13] that  $\hat{T}$  is also given by the formula

$$\hat{T}(x) = \begin{cases} \emptyset, & \text{if } x \notin D(T) \\ \mathbb{R}_{++}T(x), & \text{if } x \in D(T) \setminus Z_T \\ N_{L_{T,x}}, & \text{if } x \in Z_T \end{cases}$$

where  $N_{L_{T,x}}$  is the normal cone at  $x$  to the set  $L_{T,x} = \{y \in X : \exists y^* \in T(y), \langle y^*, y - x \rangle \leq 0\}$ .

A pseudomonotone map  $\hat{T}$  is called  $D$ -maximal pseudomonotone, if the graph of  $\hat{T}$  is not properly contained in the graph of any other map with the same domain. When the domain of  $T$  is convex, there is an equivalent, more appealing definition for  $D$ -maximal pseudomonotonicity [14]:

**Proposition 2** *Let  $T$  be pseudomonotone and such that  $D(T)$  is convex. Then  $T$  is  $D$ -maximal pseudomonotone if, and only if, every pseudomonotone extension of  $T$  with the same domain is equivalent to  $T$ .*

Some properties of the set of zeros of  $T$  are provided by the following proposition [14].

**Proposition 3** *Let  $T$  be  $D$ -maximal pseudomonotone. Then  $Z_T$  is weakly closed in  $D(T)$ . If in addition  $D(T)$  is convex, then  $Z_T$  is also convex, and  $z \in Z_T$  is equivalent to*

$$\forall (y, y^*) \in \text{gr}(T), \langle y^*, y - z \rangle \geq 0.$$

The following proposition provides a simple criterion for showing the  $D$ -maximal pseudomonotonicity of a map [13].

**Proposition 4** *Assume that  $T$  is pseudomonotone, upper-sign continuous, with weak\*-compact, convex values and open domain  $D(T)$ . Then  $T$  is  $D$ -maximal pseudomonotone.*

A simple consequence of the above proposition is:

**Corollary 5** *The Clarke subdifferential  $\partial^0 f$  of a locally Lipschitz, pseudoconvex function  $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$  is a  $D$ -maximal pseudomonotone map.*

As was explained before, from the point of view of VIP one can use any element of the equivalence class. This is fortunate, since in many cases instead of showing that a  $D$ -maximal pseudomonotone map has a “nice” property (as is the case with maximal monotone maps), one shows that an equivalent map has this property. For instance, one has:

**Proposition 6** *If  $T$  is  $D$ -maximal pseudomonotone, then  $\hat{T}(x)$  is convex for every  $x \in D(T)$ . If in particular the assumptions of Proposition 4 are satisfied, then  $\hat{T}(x) \cup \{0\}$  is weak\*-closed.*

Here is a case where one can find an equivalent map with a better continuity property [13]:

**Proposition 7** *Let  $T : \mathbb{R}^n \rightarrow 2^{\mathbb{R}^n}$  be a pseudomonotone map, upper sign-continuous, with compact convex values. If  $D(T)$  is open and convex, then there exists an equivalent upper semicontinuous map  $T_1$  with compact convex values.*

For instance let  $T$  be a single-valued pseudomonotone map defined on an open convex subset of  $\mathbb{R}^n$ . If  $T$  is hemicontinuous (i. e., continuous along line segments) then the above proposition guarantees that there exists an equivalent map which is continuous. Likewise, one can show that under some fairly general assumptions,  $T$  is equivalent to a map which is generically single-valued (i. e., is single valued except on a set of the first category). See Corollary 3.10 in [13].

### A Generalization of Paramonotone Maps

A monotone multivalued map  $T$  is called paramonotone if for every  $(x, x^*), (y, y^*) \in \text{gr}(T)$ ,  $\langle y^* - x^*, y - x \rangle = 0$  implies that  $x^* \in T(y)$  and  $y^* \in T(x)$ . It can be shown that the subdifferential of a proper lsc convex function is paramonotone [5]. Other examples of paramonotone maps are given in [21]. Paramonotone maps have been extensively used in algorithms for the solution of VIP [5,6,24]. The main reason is that these maps have the following “cutting plane property”:

$$\left. \begin{array}{l} x \in S(T, K) \\ y \in K \\ \langle y^*, x - y \rangle \geq 0 \\ \text{for some } y^* \in T(y) \end{array} \right\} \Rightarrow y \in S(T, K). \quad (1)$$

Assume that a map has property (1). If at the  $n$ th iteration of an algorithm one finds a point  $y_n$  that is not a solution of VIP, then all solutions of VIP belong to the intersection of  $K$  with the halfspace  $\{x \in X : \langle y_n^*, x - y_n \rangle < 0\}$  where  $y_n^*$  is an arbitrary element of  $T(y_n)$ .

Let  $K \subseteq X$  be nonempty, closed and convex. A single valued pseudomonotone map  $T : K \rightarrow X^*$  is called pseudomonotone $_*$  if for all  $x, y \in K$ ,

$$\langle T(x), y - x \rangle = \langle T(y), y - x \rangle = 0$$

implies that  $T(x) = kT(y)$ , for some  $k > 0$  [8]. Note that single-valued pseudomonotone $_*$  maps are a generalization of single-valued paramonotone maps. To extend this generalization to the multivalued case, one needs the tools presented in the previous subsection.

**Definition 8** [17] A map  $T : X \rightarrow 2^{X^*}$  is pseudomonotone $_*$  on  $K$  if it is pseudomonotone and for every  $x, y \in K$  and  $x^* \in T(x)$ ,  $y^* \in T(y)$ ,  $\langle x^*, y - x \rangle = \langle y^*, y - x \rangle = 0$  imply  $x^* \in \hat{T}(y)$  and  $y^* \in \hat{T}(x)$ .

It is easy to see that every paramonotone map is pseudomonotone $_*$ . Other classes of pseudomonotone $_*$  maps is provided by the following propositions [17].

**Proposition 9** *The Clarke subdifferential  $\partial^0 f$  of a locally Lipschitz pseudoconvex function  $f$  is pseudomonotone $_*$ .*

**Proposition 10** *If the map  $T$  is pseudomonotone $_*$ , then any map equivalent to  $T$  is pseudomonotone $_*$ .*

Proposition 9 is a particular case of a more general situation. A map  $T$  is called cyclically pseudomonotone [9,10] if for every  $(x_i, x_i^*) \in \text{gr}(T)$ ,  $i = 1, 2, \dots, n$ , the following implication holds:

$$\begin{aligned} \langle x_i^*, x_{i+1} - x_i \rangle &\geq 0, \quad \forall i = 1, 2, \dots, n-1 \\ \Rightarrow \langle x_n^*, x_1 - x_n \rangle &\leq 0. \end{aligned}$$

**Proposition 11** *If  $T$  is  $D$ -maximal pseudomonotone and cyclically pseudomonotone with convex domain, then it is pseudomonotone $_*$ .*

Since the Clarke subdifferential of a locally Lipschitz pseudoconvex function is  $D$ -maximal pseudomonotone and cyclically pseudomonotone, we see that the previous proposition implies Proposition 9.

We saw that paramonotone maps have the cutting plane property (1). The same is true for

pseudomonotone $_*$  maps; what is more interesting is that these maps are characterized in some sense by the cutting plane property:

**Proposition 12** *Let  $T$  be pseudomonotone on the convex set  $K$ . If  $T$  is pseudomonotone $_*$ , then property (1) holds on every subset of  $K$ . Conversely, if property (1) holds on every convex, compact subset of  $K$  and  $T$  has convex, weak\*-compact values, then  $T$  is pseudomonotone $_*$  on the interior of  $K$ .*

If  $T$  is single-valued, the assumption of pseudomonotonicity becomes redundant:

**Proposition 13** *Let  $T : K \rightarrow X^*$  be hemicontinuous. If  $T$  has property (1) on each convex compact subset of  $K$ , then  $T$  is pseudomonotone on  $K$  and pseudomonotone $_*$  on its interior.*

In Sect. “**Methods/Applications**” we will show how to apply pseudomonotone $_*$  maps for the solution of variational inequalities.

### Pseudoaffine Maps

Given a convex subset  $K$  of  $\mathbb{R}^n$ , a single-valued map  $T : K \rightarrow \mathbb{R}^n$  is called pseudoaffine (or PPM, as in [3]) if both  $T$  and  $-T$  are pseudomonotone. These maps were studied in [3] in connection with VIP. It is easy to see that a differentiable function  $f : K \rightarrow \mathbb{R}$  is pseudolinear (i. e., both  $f$  and  $-f$  are pseudoconvex) if and only if  $\nabla f$  is pseudoaffine. It is not hard to show that pseudolinear functions defined on the whole space  $\mathbb{R}^n$  have a very particular form [2,25]:

**Proposition 14** *A differentiable function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is pseudolinear if and only if there exist a vector  $u \in \mathbb{R}^n$  and a one-variable differentiable function  $h$  whose derivative is always positive or identical to zero, such that  $f(x) = h(\langle u, x \rangle)$ .*

If  $T = \nabla f$  in this case, then  $T(x) = h'(\langle u, x \rangle)$ , i. e.,  $T$  is equal to a positive multiple of a constant vector. For general pseudoaffine maps (i. e., those that are not necessarily equal to a gradient) that are defined on the whole space, the following elegant characterization has been shown:

**Proposition 15** *A map  $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$  is pseudoaffine if and only if there exists a positive function  $g : \mathbb{R}^n \rightarrow \mathbb{R}$ , a skew-symmetric linear map  $A$  and a vector  $u$  such that*

$$\forall x \in \mathbb{R}^n, T(x) = g(x)(Ax + u).$$

The proof of the above result needs some “global” arguments provided by algebraic topology and by projective geometry [2].

### Pseudomonotone vs. Monotone Maps

One of the basic differences between the class of monotone maps and the class of pseudomonotone maps has to do with their stability with respect to some operations. For instance, the class of monotone maps is stable with respect to addition (i. e., the sum of two monotone maps is monotone), while this is not the case for pseudomonotone maps. By contrast, the product of a pseudomonotone map with a positive function produces a pseudomonotone map while this is not the case for monotone maps.

In particular, it was noted in [1] that a map  $T : X \rightarrow 2^{X^*}$  is monotone if and only if for every  $x^* \in X^*$  the map  $T + x^*$  is pseudomonotone. More recently He [18] and Isac and Motreanu [20] obtained another result in this direction. Assume that  $X$  is a Hilbert space (in [18] one considered  $X = \mathbb{R}^n$ ) and  $K \subseteq X$  is a convex set with nonempty interior. Let further  $T : K \rightarrow X^*$  be a continuous single-valued map which is Gâteaux differentiable in the interior of  $K$ . Then  $T$  is monotone if and only if  $T + x^*$  is pseudomonotone for all  $x^*$  in a straight line of  $X^*$ . The differentiability assumption is essential in the argument of both papers [18,20] because the proof is based on a first-order characterization of generalized monotonicity.

In a recent paper [15] it was shown that the differentiability assumption is redundant, and one can also weaken considerably the assumption that the interior of  $K$  is nonempty. Given  $x^* \in X^*$  and a set  $K \subseteq X$ , one says that  $x^*$  is perpendicular to  $K$  if the value of  $x^*$  is constant on  $K$ , i. e.,  $\langle x^*, y - x \rangle = 0$  for all  $x, y \in K$ . The following proposition holds.

**Proposition 16** *Let  $K \subseteq X$  be nonempty and convex and  $T : K \rightarrow 2^{X^*}$  be a map with nonempty values. Assume that there exists a straight line  $S = \{x_0^* + tx^* : t \in \mathbb{R}\}$  in  $X^*$  such that  $x^*$  is not perpendicular to  $K$ , and for all  $z^* \in S$ ,  $T + z^*$  is pseudomonotone. Then  $T$  is monotone.*

In case  $K$  has nonempty interior or, more generally, nonempty quasi-interior, the assumption “ $x^*$  is not perpendicular to  $K$ ” is automatically fulfilled. It should also be noted that the results of this subsection are also

true if we replace “pseudomonotone” by “quasimonotone” (see the article ► [generalized monotone multi-valued maps](#) in this Encyclopedia for the definition).

### Methods/Applications

Many of the algorithms used to find a solution of a variational inequality with a paramonotone map, can be also used in the more general case of a pseudomonotone $_*$  map. We illustrate this by an example of a perturbed auxiliary problem method. Let  $K$  be a closed convex subset of a Hilbert space  $H$ ,  $T : K \rightarrow 2^H$  a map with nonempty values. Choose a Gâteaux differentiable strongly convex function  $M : H \rightarrow \mathbb{R}$  with a weakly continuous derivative (we can take for instance  $M(x) = \|x\|^2/2$ ). Construct a sequence  $\{x_k\}_{k \in \mathbb{N}}$  by the following algorithm.

- (i) Choose an arbitrary  $x_0 \in K$ .
- (ii) Having chosen  $x_k$ , find  $x_{k+1} \in K$  and  $x_{k+1}^* \in T(x_{k+1})$  such that

$$\forall y \in K, \langle \mu_k x_{k+1}^* + M'(x_{k+1}) - M'(x_k), y - x_{k+1} \rangle \geq 0$$

where  $\{\mu_k\}_{k \in \mathbb{N}}$  is a sequence of positive constants bounded from below. Note that finding  $x_{k+1}$  amounts to solving VIP for the perturbed map  $T_{k+1}(\cdot) = \mu_{k+1}T(\cdot) + M'(\cdot) - M'(x_k)$ . This problem can be much easier than the original one, since for instance if  $T$  is weakly monotone and  $\mu_{k+1}$  is small, then  $T_{k+1}$  is strongly monotone.

Assume that VIP has a solution and that the sequence  $\{x_k\}_{k \in \mathbb{N}}$  is well-defined. Then it can be shown that if  $T$  is pseudomonotone $_*$  and satisfies a fairly general continuity condition, then the sequence  $\{x_k\}_{k \in \mathbb{N}}$  converges weakly to a solution of VIP for  $T$ . Details can be found in [17].

### Conclusions

The theory of pseudomonotone maps is far from been developed to a satisfactory level. By contrast, the theory of monotone maps has reached a high level of maturity [19]. It is hoped that some of the recent advances presented here, and in particular the ideas on maximality of pseudomonotone maps, will provide a firm background for the study of pseudomonotone maps. This is illustrated by the ease and naturalness with

which notions like paramonotonicity can be generalized to pseudomonotone maps, a task that seemed almost impossible before the introduction of maximal pseudomonotone maps. In addition, the new notion of a pseudomonotone\* map seems to be ideally fit the cutting plane property (see Proposition 12) and this adds some confidence that the definition of maximality is on the right way.

### Introduction

Most problems of process design, process control, process operations, and molecule design are determined by the optimal solutions; however, those problems are mainly characterized by the existence of multiple minima and maxima, as well as first-, second-, and higher-order saddle points. During the last decade we

have experienced a rapid development of new methods for deterministic global optimization as well as the application of available global optimization algorithms in important engineering fields [1,2,9,10,11,12,13,14]. Recently, in order to locate the global solutions to the nonconvex phase stability analysis problems [3,4,5], a quadratic underestimation function based branch-and-bound algorithm, i. e., QBB, was developed for twice-differentiable nonlinear programs (NLPs) in terms of the simplicial partition of the constrained region [6,7].

### Formulation

The nonconvex optimization problem considered in this section can be formulated as

$$(P) \begin{cases} \min_{\mathbf{x}} & f(\mathbf{x}) \\ \text{subject to} & g_i(\mathbf{x}) \leq 0 \quad i = 1, \dots, m, \\ & \mathbf{x} \in \mathbf{S}^0 \subset \mathfrak{R}^n, \end{cases}$$

where  $f$  and  $\mathbf{g}_i$  belong to  $C^2$ , the set of twice-differentiable functions, and  $\mathbf{S}^0$  is a simplex defined by

$$\mathbf{S}^0 = \left\{ \mathbf{x} \in \mathfrak{R}^n : \mathbf{x} = \sum_{i=1}^{n+1} \lambda_i \mathbf{V}^i, \lambda_i \geq 0, \sum_{i=1}^{n+1} \lambda_i = 1 \right\},$$

where  $\mathbf{V}^i \in \mathbf{V} \subset \mathfrak{R}^n$ ,  $i = 1, 2, \dots, n+1$  are the  $n+1$  vertices of the simplex  $\mathbf{S}^0$ , and  $\mathbf{V}$  is the set of its vertices. Let  $D_g$  be a subset of  $\mathfrak{R}^n$  defined by

$$D_g = \{ \mathbf{x} \in \mathfrak{R}^n : \mathbf{g}_i(\mathbf{x}) \leq 0, i = 1, 2, \dots, m \}.$$

In general, the set  $D_g$  is nonconvex and even disconnected. We assume throughout this section that problem (P) has an optimal solution, unless otherwise stated. For any nonconvex optimization problem, i. e., (P), the QBB algorithm proposed in this section belongs

to a branch-and-bound scheme. During each iteration of this framework, a branching step and a bounding step must be finished simultaneously.

### Simplicial Partition

For the branching procedure, the simplex  $\mathbf{S}^0$  will be divided into refined subregions by using simplicial partition. For such kind of branching, it is a simple matter to check that for every  $i \in I$ , where  $I$  is the vertex set of  $\mathbf{S}^0$ , the points  $\mathbf{V}^1, \dots, \mathbf{V}^{i-1}, \mathbf{U}, \mathbf{V}^{i+1}, \dots, \mathbf{V}^{n+1}$  are vertices of a simplex  $\mathbf{S}_i \subset \mathbf{S}$ ,  $\mathbf{S}$  is the current simplex, and that

$$(\text{int } \mathbf{S}_i) \cap (\text{int } \mathbf{S}_j) = \emptyset \quad \forall j \neq i; \quad \bigcup_{i \in I} \mathbf{S}_i = \mathbf{S}.$$

Then, the simplexes  $\mathbf{S}_i$ ,  $i \in I$ , form a subdivision of the simplex  $\mathbf{S}$  via  $\mathbf{U}$ . Each  $\mathbf{S}_i$  will be referred to as a sub-simplex of  $\mathbf{S}$ . An important special case is the bisection where  $\mathbf{U}$  is a point of the longest edge of the simplex  $\mathbf{S}$ , for example,  $\mathbf{U} \in [\mathbf{V}^m, \mathbf{V}^n]$ , i. e.

$$\|\mathbf{V}^m - \mathbf{V}^n\| = \max_{\substack{i < j \\ i, j = 1, \dots, n+1}} \{\|\mathbf{V}^i - \mathbf{V}^j\|\},$$

where  $\|\cdot\|$  denotes any given norm in  $\mathfrak{R}^n$ , and  $\mathbf{U} = a\mathbf{V}^m + (1-a)\mathbf{V}^n$  with  $0 < a \leq 1/2$ . Adjiman et al. [9] proved that this simplicial bisection is exhaustive since  $\delta(\mathbf{S}_k) \rightarrow 0$  as  $k \rightarrow +\infty$ .

### Quadratic Underestimation Function for General Non-convex Structures

In the bounding step of a branch-and-bound algorithm, a lower bound is always obtained by constructing a valid convex underestimation problem for the original one appearing in the problem (P), and solving the relaxed convex NLP to global optimality. For the current simplex given by

$$\mathbf{S} = \left\{ x \in \mathfrak{R}^n : x = \sum_{i=1}^{n+1} \lambda_i \mathbf{V}^i, \lambda_i \geq 0, \sum_{i=1}^{n+1} \lambda_i = 1 \right\}, \quad (1)$$

where  $\mathbf{V}^i \in \mathbf{V} \subset \mathfrak{R}^n$ ,  $i = 1, 2, \dots, n+1$  are the  $n+1$  vertices of the current simplex  $\mathbf{S}$ , and  $\mathbf{V}$  is the set of these vertices. Then, we intend to compute a lower bound  $\mu(\mathbf{S})$  of the objective function  $f$  on  $\mathbf{S} \cap D_g$ . In other words, we compute a lower bound for the optimal

value of the problem

$$(P(\mathbf{S})) \quad \begin{cases} \min_{\mathbf{x}} & f(\mathbf{x}) \\ \text{subject to} & g_i(\mathbf{x}) \leq 0 \quad i = 1, \dots, m, \\ & \mathbf{x} \in \mathbf{S} \subset \mathfrak{R}^n. \end{cases}$$

As mentioned above,  $f$  and  $g_i$  are generic nonconvex functions belonging to  $C^2$ , then the main idea for computing a lower bound  $\mu(\mathbf{S})$  is to construct from problem (P(S)) a convex problem by replacing all those nonconvex functions with their respective convex underestimation functions, then solving the resulting relaxed convex problem. In order to achieve this, we see the following definition:

**Definition 1** Given any nonconvex function  $f(\mathbf{x}): S \rightarrow \mathfrak{R}$ ,  $\mathbf{x} \in S \subseteq \mathfrak{R}^n$  belonging to  $C^2$ , the following quadratic function is defined by

$$F(\mathbf{x}) = \sum_{i=1}^n a_i x_i^2 + \sum_{i=1}^n b_i x_i + c, \quad (2)$$

where  $\mathbf{x} \in \mathbf{S} \subseteq \mathfrak{R}^n$  and  $F(\mathbf{x}) = f(\mathbf{x})$  holds at all vertices of  $\mathbf{S}$ . The  $a_i$ 's are nonnegative scalars and are large enough such that  $F(\mathbf{x}) \leq f(\mathbf{x})$ ,  $\forall \mathbf{x} \in \mathbf{S}$ .

It is trivial to see that  $F(\mathbf{x})$  is convex since all quadratic coefficients, i. e.,  $a_i$ 's, are nonnegative. Theorem 2.2.1 in [7] ensures that  $F(\mathbf{x})$  defined by Definition 1 is a convex underestimator of  $f(\mathbf{x})$  if the difference function between them, i. e.,  $D(\mathbf{x}) = F(\mathbf{x}) - f(\mathbf{x})$ , is a convex function. It is well known that  $D(\mathbf{x})$  is convex if and only if its Hessian matrix  $H_D(\mathbf{x})$  is positive semidefinite in the current simplex. A useful convexity condition is derived by noting that  $H_D(\mathbf{x})$  is related directly to the Hessian matrix  $H_f(\mathbf{x})$  of  $f(\mathbf{x})$ ,  $\mathbf{x} \in \mathbf{S}$  by the following equation:

$$\mathbf{H}_D(\mathbf{x}) = 2\Delta - \mathbf{H}_f(\mathbf{x}),$$

where  $\Delta$  is a diagonal matrix whose diagonal elements are  $a_i$ 's defined in Definition 1. Analogous to the "diagonal shift matrix" defined in [9],  $\Delta$  here is referred to as the *diagonal underestimation matrix*, since these parameters guarantee that  $F(\mathbf{x})$  defined by Eq. 2 is a rigorous underestimator of the generic nonconvex function  $f(\mathbf{x})$ .  $D(x)$ , as defined, is convex if and only if  $2\Delta - H_f(\mathbf{x}) = 2\text{diag}(a_i) - H_f(\mathbf{x})$  is positive semidefinite for all  $\mathbf{x} \in \mathbf{S}$ .

In order to simplify the parameter calculation, the underestimator  $F(\mathbf{x})$  is reformulated by using a single nonnegative  $a$  value, as follows:

$$F(\mathbf{x}) = a \sum_{i=1}^n x_i^2 + \sum_{i=1}^n b_i x_i + c. \quad (3)$$

Then, all diagonal elements of the diagonal underestimation matrix  $\Delta$  are therefore equal to the uniform quadratic coefficient  $a$  defined by Eq. 3. Some interval arithmetic approaches are provided in [5,7] to estimate the quadratic coefficients with theoretical guarantee in the current simplex.

After the quadratic coefficients have been identified, the linear and constant coefficients of  $F(\mathbf{x})$  defined by Eqs. 2 or 3, i. e.,  $b_i$ 's and  $c$ , can be given by the quadratic coefficients  $a_i$ 's and the current simplex. In view of Definition 1, we know  $F(\mathbf{x}) = f(\mathbf{x})$  holds at all vertices of  $\mathbf{S}$ , so the following linear equation group can be obtained as

$$\mathbf{V}^k T \Delta \mathbf{V}^k + \mathbf{b}^T \mathbf{V}^k + c = f(\mathbf{V}^k) \quad k = 1, \dots, n+1,$$

where  $\Delta \in \Re^{n \times n}$  is the diagonal underestimation matrix whose diagonal elements are the quadratic term coefficients,  $a_i$ 's defined in Eqs. 2 or 3.  $\mathbf{b} \in \Re^n$  is the linear coefficient vector whose elements are  $b_i$ 's defined in Eqs. 2 or 3, and  $c$  is a scalar:

$$\mathbf{b}^T \mathbf{V}^k + c = f(\mathbf{V}^k) - \mathbf{V}^k T \Delta \mathbf{V} \quad k = 1, \dots, n+1.$$

The vector  $\mathbf{b} \in \Re^n$  is augmented as  $(\mathbf{b}, c) \in \Re^{n+1}$ , in order to include the scalar  $c$ . In the same way, the matrix  $\mathbf{V} \in \Re^{(n+1) \times n}$  is augmented as  $(\mathbf{V}, \mathbf{1}) \in \Re^{(n+1) \times (n+1)}$ , where  $\mathbf{1}$  is a column unity matrix of  $\Re^n$ .  $(\mathbf{V}, \mathbf{1}) \in \Re^{(n+1) \times (n+1)}$  is a regular square matrix since  $\mathbf{V} \in \Re^{(n+1) \times n}$  is the coordinate matrix of the simplex which is linearly independent. Then we have

$$(\mathbf{b}, c)^T = (\mathbf{V}, \mathbf{1})^{-1} [f(\mathbf{V}) - \mathbf{V}^T \Delta \mathbf{V}],$$

where  $[f(\mathbf{V}) - \mathbf{V}^T \Delta \mathbf{V}] \in \Re^{n+1}$  is a column vector for the  $n+1$  vertices of the current simplex. By virtue of this equation, it is obvious that the linear and constant coefficients defined by Eqs. 2 or 3 are determined uniquely by the quadratic coefficients and the current simplex.

By replacing all the nonconvex functions in problem (P(S)) with their corresponding quadratic function

based convex underestimators described by Eq. 3, we have the following relaxed convex programming problem (QP(S)):

$$(QP(S)) \left| \begin{array}{l} \min_{\mathbf{x}} \quad F(\mathbf{x}) \\ \text{subject to} \quad G_i(\mathbf{x}) \leq 0 \quad i = 1, \dots, m, \\ \mathbf{x} \in \mathbf{S} \subset \Re^n, \end{array} \right.$$

where

$$\begin{aligned} F(\mathbf{x}) &= \sum_{i=1}^n a_i^f x_i^2 + \sum_{i=1}^n b_i^f x_i + c^f, \\ \mathbf{G}_j(\mathbf{x}) &= \sum_{i=1}^n a_i^{g_j} x_i^2 + \sum_{i=1}^n b_i^{g_j} x_i + c^{g_j} \\ & \quad j = 1, 2, \dots, m. \end{aligned}$$

Let  $D_G$  be a subset of  $\Re^n$  defined by

$$D_G = \{x \in \Re^n : \mathbf{G}_i(\mathbf{x}) \leq 0, \quad i = 1, 2, \dots, m\}.$$

Obviously, the set  $D_G$  is convex and compact. It should be noted that only additional  $m+1$  quadratic parameters, i. e.,  $a^f$  and  $a^{g_i}$  for  $i = 1, 2, \dots, m$ , are introduced during the above transformation process if the uniform underestimation function is used, since all other linear and constant coefficients can be calculated by those quadratic parameters and the current simplex.

### QBB Underestimators for Special Structures

For the concave function structure, denoted by  $f^{CA}(\mathbf{x})$ , whose eigenvalues are all nonpositive, i. e.,  $\lambda_{i, \mathbf{x} \in \mathbf{S}} \leq 0$ . Then, the quadratic coefficient of its underestimator defined by Eq. 2 is zero, so the valid lower bound of the concave function structure over the current simplex is a linear function. In fact, the valid bound constructed by Eq. 2 is equivalent to the convex envelope of the concave function over a simplex [7]. Let  $\mathbf{S}$  be a simplex generated by the vertices  $\mathbf{V}^1, \mathbf{V}^2, \dots, \mathbf{V}^{n+1}$ , i. e.,  $\mathbf{S} = \{\mathbf{x} \in \Re^n : \mathbf{x} = \sum_{i=1}^{n+1} \lambda_i \mathbf{V}^i, \lambda_i \geq 0, \sum_{i=1}^{n+1} \lambda_i = 1\}$ , and let  $f^{CA}(\mathbf{x})$  be a concave function defined on  $\mathbf{S}$ . Then the convex envelope of  $f^{CA}(\mathbf{x})$  over  $\mathbf{S}$  is the affine function  $L^{CA}(\mathbf{x}) = \mathbf{b}^T \mathbf{x} + c$  that is uniquely determined by the system of linear equations  $f^{CA}(\mathbf{V}^i) = \mathbf{b}^T \mathbf{V}^i + c$  for  $i = 1, \dots, n+1$ .

For the general quadratic function presented by

$$f(\mathbf{x}) = \mathbf{x}^T \mathbf{Q} \mathbf{x} + \mathbf{q}^T \mathbf{x}$$

(note  $\mathbf{H}_f(\mathbf{x}) = \mathbf{Q}$ ), we have the *diagonal underestimation matrix*,  $\Delta$ , constructed on the basis of interval arithmetic [7], as

$$a = \max_i \left\{ 0, \frac{1}{2} \lambda_i^{\mathbf{Q}} \right\}$$

for the uniform case, and for the nonuniform case, we get

$$a_i = \max \left\{ 0, \frac{1}{2} \left( \mathbf{Q}_{ii} + \sum_{j \neq i} |\mathbf{Q}_{ij}| \right) \right\}.$$

Then, we have the quadratic underestimation function as

$$F(\mathbf{x}) = \mathbf{x}^T \Delta \mathbf{x} + \mathbf{b}^T \mathbf{x} + c,$$

where the linear and constant coefficients, i. e.,  $(\mathbf{b}, c)$ , can be determined uniquely by the quadratic coefficients calculated above and the current simplex.

### Properties of the QBB Underestimator

For construction of the QBB underestimator, only quadratic coefficients need to be calculated since the linear and constant ones defined by Eqs. 2 or 3 can be determined uniquely by the quadratic coefficients and the current simplex. Another important property of the QBB algorithm is that the quadratic function based underestimator is always convex throughout the problem space. A potential benefit of this property is that it allows the convex solver applied to get the solution to the underestimator to have a feasible or an infeasible convergence path. Geometrically speaking, the QBB uses a convex quadratic function to approximate the convex part of a general nonconvex function directly, which can bypass the concave parts and avoid the overestimation for them.

### Function Decomposition

It should be noted that the relaxed convex programming problem (QP(S)) can contain not only the quadratic underestimation functions for the generic nonconvex terms, but also the convex function terms which are not necessarily transformed into the quadratic underestimators. Then, the final underestimation strategy of the relaxed problem (QP(S)) can

be slightly decomposed into the following convex programming formulation, as

$$(QP(S')) \left| \begin{array}{l} \min_{\mathbf{x}} \quad F'(\mathbf{x}) \\ \text{subject to} \quad G'_i(\mathbf{x}) \leq 0 \quad i = 1, \dots, m, \\ \mathbf{x} \in \mathbf{S} \subset \mathbb{R}^n, \end{array} \right.$$

where

$$\begin{aligned} F'(\mathbf{x}) &= f^L(\mathbf{x}) + f^C(\mathbf{x}) + L_f^{CA}(\mathbf{x}) + F^{NC}(\mathbf{x}), \\ G'_i(\mathbf{x}) &= g_i^L(\mathbf{x}) + g_i^C(\mathbf{x}) + L_{g_i}^{CA}(\mathbf{x}) + G_i^{NC}(\mathbf{x}) \\ & \quad i = 1, 2, \dots, m, \end{aligned}$$

and  $f^L(\mathbf{x})$ ,  $f^C(\mathbf{x})$ ,  $L_f^{CA}(\mathbf{x})$ ,  $g_i^L(\mathbf{x})$ ,  $g_i^C(\mathbf{x})$ , and  $L_{g_i}^{CA}(\mathbf{x})$  represent the linear terms, convex terms, and the linear underestimation functions for the concave terms in the objective function and the constraints, respectively.  $F^{NC}(\mathbf{x})$  and  $G_i^{NC}(\mathbf{x})$  represent the quadratic convex underestimation functions for the generic nonconvex terms. Compared with the relaxed problem (QP(S)), the relaxed problem (QP(S')) contains not only quadratic function terms, but also the generic convex terms of the original problem.

### Algorithmic Procedure of QBB

At the start of this section, problem (P) is formulated over an initial simplex  $\mathbf{S}^0$  which can be easily obtained by using an outer approximation approach. Now, we are in a position to present the proposed algorithm for solving problem (P) by using the basic operations described in previous sections.

**Step 1 – Initialization.** A convergence tolerance,  $\varepsilon_c$ , and a feasibility tolerance,  $\varepsilon_f$ , are selected and the iteration counter  $k$  is set to be zero. The global lower and upper bounds  $\mu_0$  and  $\gamma_0$  of the global minimum of problem (P) are initialized and an initial current point  $\mathbf{x}^{k,c}$  is randomly selected.

**Step 2 – Local solution of problem (P) and update of upper bound.** The nonconvex and nonlinear optimization problem (P) is solved locally within the current simplex  $\mathbf{S}$ . If the solution  $f_{\text{local}}^k$  of problem (P) is  $\varepsilon_f$ -feasible, the upper bound  $\gamma_k$  is updated as  $\gamma_k = \min(\gamma_k, f_{\text{local}}^k)$ .

**Step 3 – Partitioning of the simplex.** The current simplex,  $\mathbf{S}^k$ , is partitioned into the following two sim-

plexes ( $r = 1, 2$ ):

$$S^{k,1} = \left( \mathbf{V}^{k,0}, \dots, \mathbf{V}^{k,m}, \dots, \frac{\mathbf{V}^{k,m} + \mathbf{V}^{k,l}}{2}, \mathbf{V}^{k,n} \right),$$

$$S^{k,2} = \left( \mathbf{V}^{k,0}, \dots, \frac{\mathbf{V}^{k,m} + \mathbf{V}^{k,l}}{2}, \dots, \mathbf{V}^{k,l}, \mathbf{V}^{k,n} \right),$$

where,  $k, m$  and  $k, l$  correspond to the vertices with the longest edge in the current simplex, i.e.,  $(k, m)$ ,  $(k, l) = \arg \max_{i < j} \{ \|\mathbf{V}^{k,j} - \mathbf{V}^{k,i}\| \}$ .

**Step 4 - Update of  $a_{k,f}^r, b_{k,f}^r, c_{k,f}^r$  and  $a_{k,g_i}^r, b_{k,g_i}^r, c_{k,g_i}^r$  inside both subsimplexes  $r = 1, 2$ .** The nonnegative parameters  $a_{k,f}^r$  and  $a_{k,g_i}^r$  of the general nonconvex terms in the objective function and the constraints are updated inside both simplexes  $r = 1, 2$  according to the methods presented in former sections, and the corresponding linear and constant coefficients, i.e.,  $b_{k,f}^r, c_{k,f}^r$  and  $b_{k,g_i}^r, c_{k,g_i}^r$ , are renewed accordingly.

**Step 5 - Solutions inside both subsimplexes  $r = 1, 2$ .** The convex programming problem (QP(S)') is solved inside both subsimplexes ( $r = 1, 2$ ) by using some nonlinear programming solver. If a solution  $F_{sol}^{k,r}$  is feasible and less than the current upper bound,  $\gamma_k$ , then it is stored along with the solution point  $\mathbf{x}_{sol}^{k,r}$ .

**Step 6 - Update iteration counter  $k$  and lower bound  $\mu_k$ .** The iteration counter increases by 1,

$$k \leftarrow k + 1,$$

and the lower bound  $\mu_k$  is updated to the minimum solution over the stored ones from the previous iterations. Furthermore, the selected solution is erased from the stored set:

$$\mu_k = F_{sol}^{k',r'},$$

where,  $F_{sol}^{k',r'} = \min_{r,I} \{ F_{sol}^{I,r}, r = 1, 2, I = 1, \dots, k - 1 \}$ . If the set  $I$  is empty, set  $\mu_k = \gamma_k$  and go to step 8.

**Step 7 - Update the current point  $\mathbf{x}^{k,c}$  and the current simplex  $S^k$ .** The current point is selected to be the solution point of the previously found minimum solution in step 6,

$$\mathbf{x}^{k,c} = \mathbf{x}_{sol}^{I',r'},$$

and the current simplex becomes the subsimplex containing the previously found solution,

$$S^k = \left( \mathbf{V}^{k',0}, \dots, \mathbf{V}^{k',m}, \dots, \frac{\mathbf{V}^{k',m} + \mathbf{V}^{k',l}}{2}, \dots, \mathbf{V}^{k',n} \right), \quad \text{if } r' = 1,$$

$$S^k = \left( \mathbf{V}^{k',0}, \dots, \frac{\mathbf{V}^{k',m} + \mathbf{V}^{k',l}}{2}, \dots, \mathbf{V}^{k',l}, \dots, \mathbf{V}^{k',n} \right), \quad \text{otherwise.}$$

**Step 8 - Check for convergence.** If  $(\gamma_k - \mu_k) > \varepsilon_c$ , then return to step 2. Otherwise,  $\varepsilon_c$ -convergence has been reached. The global minimum solution and the solution point are given as

$$f^* \leftarrow f^{c,k''},$$

$$\mathbf{x}^* \leftarrow \mathbf{x}^{c,k''},$$

where,  $k'' = \arg_I \{ f^{c,I} = \gamma_k \}, I = 1, \dots, k$ .

### Conclusion

The QBB algorithm is guaranteed to identify the global optimum solution of problems belonging to the broad class of twice-differentiable NLPs. For any such problem, the ability to generate progressively tighter convex lower bounding problems in a branch-and-bound framework guarantees the convergence of this algorithm to within  $\varepsilon$  of the global optimum solution under the exhaustive simplicial partition of the initial simplex. Different methods [7] have been developed for the construction of the convex valid underestimators for special function structures and the generic nonconvex function structures, where the maximal eigenvalue analysis of the interval Hessian matrix provides the rigorous guarantee for the QBB algorithm to converge to the global solution.

Orthogonal factorization; QR decomposition;  
Complete orthogonal factorization

QR factorization is a process of reducing a square (rectangular) matrix into upper triangular (upper trapezoidal) form by applying a series of *elementary orthogonal transformations*.

### Properties of Orthogonal Transforms

*Orthogonal transforms* are where the transformation matrices are orthogonal. Orthogonal matrices are square matrices where each column is a unit vector and each column is mutually orthogonal to every other column. This implies that  $Q \in \mathbf{R}^{n \times n}$  is orthogonal if and only if  $Q^T Q = QQ^T = I$  (i. e. the transpose of an orthogonal matrix is its inverse). Orthogonal transformations are invariant under the 2-norm; i. e.  $\|Qx\|_2 = \|x\|_2$ . More details can be found in [8]. There are two popular orthogonal transformations: Householder and Givens.

### Householder Transformations

These are named after A.S. Householder, who popularized their use in matrix computations. However, the properties of these matrices have been known for quite some time. For any nonzero  $v \in \mathbf{R}^n$ , a matrix  $H$  of the form

$$H = I - 2 \frac{vv^T}{v^T v}$$

is called *Householder transformation*. It is easy to verify that  $H$  is symmetric, and orthogonal (which also means that it is its own inverse). Identity matrices are not Householder matrices. Geometrically, Householder matrices merely rotate a given vector in  $n$ -dimensions (without stretching or shrinking). Given any two vectors  $x$  and  $y$  such that  $\|x\|_2 = \|y\|_2$ , there exists

$v_{ij}$  is the  $i$ th component of vector  $v$  produced by the above algorithm during the  $j$ th iteration. Note that the matrix  $Q$  is available in the lower triangular portion of the matrix in a factored form.

### Givens Rotations

These rotations are named after W. Givens; they are also referred to as *Jacobi iterations*. C.G. Jacobi devised a symmetric eigenvalue algorithm based on these transformations in 1846. Consider the following  $2 \times 2$  matrix of the form

$$G(\theta) = \begin{pmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{pmatrix}$$

applied to a vector  $x \in \mathbf{R}^2$ . It is easy to see that  $G^T x$  is a mere rotation of  $x$  by an angle of  $\theta$  in counterclockwise direction. Such transformations are called rotations and as such are orthogonal. A straightforward extension that applies to an  $n$ -vector is given by matrices of the following form

$$G(i, j, \theta) = \begin{matrix} & & i & & j & & \\ & & & & & & \\ & & & & & & \\ i & \begin{pmatrix} 1 & \cdots & 0 & \cdots & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & & \vdots & & \vdots \\ 0 & \cdots & c & \cdots & s & \cdots & 0 \\ \vdots & & \vdots & \ddots & \vdots & & \vdots \\ j & 0 & \cdots & -s & \cdots & c & \cdots & 0 \\ \vdots & & \vdots & & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 1 \end{pmatrix} & & & & \end{matrix}$$

with  $c^2 + s^2 = 1$ . Here  $G^T(i, j, \theta) x$  is a rotation of  $x \in \mathbf{R}^n$  by an angle  $\theta$  in counterclockwise direction in the  $(i, j)$ -plane. It is easy to verify that  $G^T(i, j, \theta)$  only modifies the rows  $i, j$  of the vector that is applied to and the remaining entries are unaffected; i. e.

$$G^T(i, j, \theta)x = \begin{cases} cx_i - sx_j & i\text{th component,} \\ sx_i + cx_j & j\text{th component,} \\ \text{unchanged} & \text{otherwise.} \end{cases}$$

Given any vector  $x \in \mathbf{R}^n$ ,  $G^T(i, j, \theta)$  can be constructed such that only the rows  $i, j$  are affected and that  $x_j$  is zeroed. Solving the following equations

$$sx_i + cx_j = 0 \quad \text{and} \quad c^2 + s^2 = 1$$

will yield

$$c = \frac{x_i}{\sqrt{x_i^2 + x_j^2}}, \quad s = \frac{-x_j}{\sqrt{x_i^2 + x_j^2}}. \quad (3)$$

Let  $G_{ij}^{(k)}$  denote the application of a Givens rotation that uses rows  $i$  and  $j$  and zeros  $A_{jk}$  entry. The first column below the first row can be zeroed using a sequence of Givens rotations such as

$$Q_1 = G_{1m}^{(1)} \cdots G_{12}^{(1)}.$$

Similarly, the second column can be zeroed below the diagonal by

$$Q_2 = G_{2m}^{(2)} \cdots G_{23}^{(2)}.$$

Repeating this process for each column,  $A$  is reduced to upper-trapezoidal form, as in

$$Q_n \cdots Q_1 A = R.$$

The beauty about using Givens rotations is that there are various ways of applying these rotations and yet getting the same final QR factorization. In fact, this fact can be exploited in parallel processing very effectively. Detailed parallel QR factorization algorithms can be found in [6,7] and [3].

### Fast Givens Transformations

*Fast Givens Transformations* involve half the number of multiplications compared to Givens rotations and they can be used to zero without an explicit square root computation. They are also referred to as *square-root-free Givens transformations*. Details can be found in [1,2,4].

Finally, it can be shown that if  $A$  has full rank, then it has a unique QR factorization if we make the diagonal elements of  $R$  positive [8].

## Keywords

Combinatorial optimization; Quadratic assignment problem; Nonlinear assignment problems; Facility location

The quadratic assignment problem (QAP) is a combinatorial optimization problem, that although there is a substantial amount of research devoted to it, it is still, up to this date, not well solvable in the sense that no exact algorithm can solve problems of size  $n > 20$  in reasonable computational time. The QAP can be viewed as a natural extension of the linear assignment problem (LAP; cf. also ▶ [Assignment and matching](#)). Let  $\mathcal{S}_n$  denote the set of all permutations  $\phi: N \rightarrow N$ , where  $N = \{1, \dots, n\} \in \mathbf{Z}^+$ . Given a cost matrix  $C = (c_{ij}) \in \mathbf{R}^{n \times n}$  we can formulate the LAP using permutations as:

$$\min_{\phi \in \mathcal{S}_n} \sum_{i=1}^n \sum_{j=1}^n c_{\phi(i)\phi(j)} = \min_{\phi \in \mathcal{S}_n} \sum_{i=1}^n c_{i\phi(i)}. \quad (1)$$

The general formulation of the QAP as introduced by E.L. Lawler in [88] is obtained by increasing the dimension of the cost array  $C$ :

$$\min_{\phi \in S_n} \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n \sum_{l=1}^n c_{\phi(i)\phi(j)\phi(k)\phi(l)} \\ = \min_{\phi \in S_n} \sum_{i=1}^n \sum_{j=1}^n c_{ij\phi(i)\phi(j)}. \quad (2)$$

Formulation (2) will be referred to as the general QAP, while an instance will be denoted by QAP( $C$ ). The most widely used formulation of the QAP, and its first appearance in the literature, is that of T.C. Koopmans and M.J. Beckmann [85] which is a special case of (2). Used as a mathematical model for the location of a set of indivisible economical activities, the formulation of Koopmans and Beckmann involves three  $n \times n$  input matrices with real elements  $F = (f_{ij})$ ,  $D = (d_{kl})$  and  $B = (b_{ik})$ , where  $f_{ij}$  is the flow between the facility  $i$  and facility  $j$ ,  $d_{kl}$  is the distance between the location  $k$  and location  $l$ , and  $b_{ik}$  is the cost of placing facility  $i$  at location  $k$ . The objective is to assign each facility to a location such that the total cost is minimized. The *Koopmans–Beckmann* QAP formulation is given as follows:

$$\min_{\phi \in S_n} \sum_{i=1}^n \sum_{j=1}^n f_{ij} d_{\phi(i)\phi(j)} + \sum_{i=1}^n b_{i\phi(i)}. \quad (3)$$

In the context of facility location (cf. also ► **Facilities layout problems**) the matrices  $F$  and  $D$  are symmetric with zeros in the diagonal, and all the matrices are nonnegative. An instance of a QAP with input matrices  $F$ ,  $D$  and  $B$  will be denoted by QAP( $F$ ,  $D$ ,  $B$ ), while we will denote an instance by QAP( $F$ ,  $D$ ), if there is no linear term (i.e.,  $B = 0$ ). It can be seen that (3) is a special case of (2) by setting  $c_{ijkl} = f_{ij}d_{kl}$  for all  $i, j, k, l$  with  $i \neq j$  or  $k \neq l$  and  $c_{ikik} = f_{ii}d_{kk} + b_{ik}$ , otherwise. In terms of computational complexity (cf. also ► **Complexity theory**; ► **Computational complexity theory**), S. Sahni and T. Gonzalez [129] have shown that the QAP is NP-hard and that even finding an approximate solution within some constant factor from the optimal solution cannot be done in polynomial time unless  $P = NP$ .

## Formulations

The QAP can be formulated as the following 0-1 integer programming problem with quadratic objective function (hence the name ‘quadratic assignment problem’):

$$\left\{ \begin{array}{l} \min \quad \sum_{\substack{i,j=1 \\ i \neq j}}^n \sum_{\substack{k,l=1 \\ k \neq l}}^n c_{ijkl} x_{ik} x_{jl} + \sum_{i,j=1}^n c_{ijij} x_{ij} \\ \text{s.t.} \quad \sum_{i=1}^n x_{ij} = 1, \quad j = 1, \dots, n, \\ \sum_{j=1}^n x_{ij} = 1, \quad i = 1, \dots, n, \\ x_{ij} \in \{0, 1\}, \quad i, j = 1, \dots, n. \end{array} \right. \quad (4)$$

The above formulation is a direct consequence of formulation (2), where the constraints imposed by the permutations are expressed algebraically. A QAP in Koopmans–Beckmann form can be formulated in a more compact way using the inner product between two matrices:

$$\left\{ \begin{array}{l} \min \quad \langle F, XDX^T \rangle + \langle B, X \rangle \\ \text{s.t.} \quad X \in \mathbf{X}_n, \end{array} \right. \quad (5)$$

where  $\mathbf{X}_n$  is the set of all *permutation matrices*  $X = (x_{ij})$  such that their elements satisfy the constraints in (4). In the objective function of (4), let the coefficients  $c_{ijkl}$  be the entries of an  $n^2 \times n^2$  matrix  $S$ , such that  $c_{ijkl}$  is on row  $(i-1)n+k$  and column  $(j-1)n+l$ . Now let  $Q := S - \alpha I$ , where  $I$  is the  $(n^2 \times n^2)$  unit matrix and  $\alpha$  is greater than the row norm  $\|S\|_\infty$  of matrix  $S$ . The subtraction of a constant from the entries on the main diagonal of  $S$  does not change the optimal solutions of the corresponding QAP, it simply adds a constant to the objective function. Hence we can consider a QAP with coefficient array  $Q$  instead of  $S$ . Let  $x = (x_{11}, \dots, x_{1n}, x_{21}, \dots, x_{nn})^T = (x_1, \dots, x_{nn})^T$ . Then we can rewrite the objective function of the QAP with array of coefficients  $Q$  as a quadratic form  $x^T Qx$ , where it can be shown that  $Q$  is symmetric and negative definite. Therefore we have a quadratic concave minimization problem (cf. also ► **Concave programming**) and can formulate the

QAP as:

$$\begin{cases} \min & x^\top Qx \\ \text{s.t.} & \sum_{i=1}^n x_{ij} = 1, \quad j = 1, \dots, n, \\ & \sum_{j=1}^n x_{ij} = 1, \quad i = 1, \dots, n, \\ & x_{ij} \geq 0, \quad i, j = 1, \dots, n, \end{cases} \quad (6)$$

The above formulation was introduced in [14], and was used to derive cutting plane procedures (cf. also ► **Integer programming: Cutting plane algorithms**). By adding the term  $\alpha I$  to the matrix  $Q$  instead of subtracting it, we could always assume that the objective function of the QAP is convex. This leads to the formulation of the QAP as a quadratic convex minimization problem. The QAP can also be formulated using the trace of a matrix as:

$$\begin{cases} \min & \text{tr}(FXD^\top + B)X^\top \\ \text{s.t.} & X \in \mathbf{X}_n. \end{cases} \quad (7)$$

The trace formulation of the QAP first appeared in [47], and was used in [51] to introduce eigenvalue lower bounding techniques for symmetric QAPs.

Let  $\text{vec}(X) \in \mathbf{R}^{n^2}$  be the vector formed by the columns of a permutation matrix  $X$ . The QAP can be formulated using the Kronecker product as

$$\begin{cases} \min & \text{vec}(X)^\top (F \otimes D) \text{vec}(X) \\ & + \text{vec}(B)^\top \text{vec}(X) \\ \text{s.t.} & X \in \mathbf{X}_n. \end{cases} \quad (8)$$

Using the Kronecker product, Lawler [88] provided an alternative formulation for the QAP as an  $n^2 \times n^2$  LAP. An  $n^2 \times n^2$  matrix  $C$  is constructed from the  $n^4$  costs  $c_{ijkl}$ , such that the  $(ijkl)$ th element corresponds to the  $((i-1)n+k, (j-1)n+l)$ th element of  $C$ . The QAP then is equivalent to an LAP of dimension  $n^2$  with  $C$  as the cost matrix, and with the additional constraint that the  $n^2 \times n^2$  permutation matrix which defines a feasible solution, must be the Kronecker product of two permutation matrices of dimension  $n$ . In other words the QAP is equivalent to

$$\begin{cases} \min & \langle C, Y \rangle \\ \text{s.t.} & Y = X \otimes X, \\ & X \in \mathbf{X}_n. \end{cases} \quad (9)$$

The resulting LAP however cannot be solved efficiently (i. e., in  $O(n^6)$  time) because  $Y$ , although it is an  $n^2 \times n^2$  permutation matrix, is constrained to have a special structure.

### Linearizations

Linearization is a technique which involves the elimination of the nonlinear term in a given objective function, in order to make it linear, through the introduction of new variables and new linear (binary) constraints. The objective is to transform a 0–1 nonlinear integer program into a provably equivalent 0–1 linear integer program, such that existing methods for linear integer programs will provide a relaxed problem where lower bounds may be computed. Though there are several ways to linearize a given nonlinear integer program, it is desirable to have a linearization that will introduce the least amount of new variables and constraints. Moreover, the ‘tightness’ of the relaxation of the resulting linear integer program is very important.

The first attempt to devise solution techniques for solving the QAP had to do with the elimination of the quadratic term in the objective function of (4), in order to transform the problem into a 0–1 linear program. Four such linearizations of the QAP will be presented in this section. The first is due to Lawler [88], which is the first linearization suggested for the QAP, and the second by Kaufman and F. Broeckx [80] which is the smallest with regard to the number of new variables and constraints introduced. The third is a more recent (1983) one that is due to A.M. Frieze and J. Yadegar [56], which unifies most of the previous linearizations for the QAP, and is closely related to the fourth linearization presented in this section due to W.P. Adams and T.A. Johnson [2].

### Lawler’s Linearization

Lawler [88] replaces the quadratic terms  $x_{ij}x_{kl}$  in the objective function of (4), with  $n^4$  variables

$$y_{ijkl} := x_{ij}x_{kl}, \quad i, j, k, l = 1, \dots, n,$$

which results in a 0–1 linear program of  $n^4 + n^2$  binary variables and  $n^4 + 2n^2 + 1$  constraints. More specifically, it is proved in [88] that the QAP is equivalent to the

following 0–1 linear program

$$\left\{ \begin{array}{l} \min \quad \sum_{i,j=1}^n \sum_{k,l=1}^n c_{ijkl} y_{ijkl} \\ \text{s.t.} \quad (x_{ij}) \in \mathbf{X}_n, \\ \quad \sum_{i,j=1}^n \sum_{k,l=1}^n y_{ijkl} = n^2, \\ \quad x_{ij} + x_{kl} - 2y_{ijkl} \geq 0, \\ \quad y_{ijkl} \in \{0, 1\}, \\ \quad \text{for } i, j, k, l = 1, \dots, n. \end{array} \right.$$

### Kaufman–Broeckx Linearization

Rearranging terms in the objective function (4) we obtain

$$\sum_{i,j=1}^n x_{ij} \sum_{k,l=1}^n c_{ijkl} x_{kl}.$$

Kaufman and Broeckx [80] defined  $n^2$  new real variables

$$w_{ij} := x_{ij} \sum_{k,l=1}^n c_{ijkl} x_{kl}, \quad i, j = 1, \dots, n,$$

resulting in an equivalent linear objective function

$$\sum_{i,j=1}^n w_{ij}.$$

Introducing  $n^2$  constants  $a_{ij} := \sum_{k,l=1}^n c_{ijkl}$  for  $i, j = 1, \dots, n$ , the QAP becomes equivalent to the following mixed 0–1 linear program:

$$\left\{ \begin{array}{l} \min \quad \sum_{i,j=1}^n w_{ij} \\ \text{s.t.} \quad (x_{ij}) \in \mathbf{X}_n, \\ \quad a_{ij} x_{ij} + \sum_{k,l=1}^n c_{ijkl} x_{kl} - w_{ij} \leq a_{ij}, \\ \quad w_{ij} \geq 0, \\ \quad i, j = 1, \dots, n. \end{array} \right.$$

The above formulation employs  $n^2$  new real variables,  $n^2$  binary variables and  $n^2 + 2n$  constraints. The elements  $c_{ijkl}$  are all assumed to be nonnegative, which is a valid assumption since the addition of a constant to each element will not affect the optimal solution. The proof of equivalence of the QAP to the above linear integer program can be found in [80].

### Frieze–Yadegar Linearization

In [56] the products of the binary variables are replaced by continuous variables (i. e.  $y_{ijkl} := x_{ij}x_{kl}$ ), and the QAP(C) is proved to be equivalent to the following mixed 0–1 linear program:

$$\left\{ \begin{array}{l} \min \quad \sum_{i,j=1}^n \sum_{k,l=1}^n c_{ijkl} y_{ijkl} \\ \text{s.t.} \quad (x_{ij}) \in \mathbf{X}_n, \\ \quad \sum_{i=1}^n y_{ijkl} = x_{kl}, \\ \quad \quad \quad \forall j, k, l, \\ \quad \sum_{j=1}^n y_{ijkl} = x_{kl}, \\ \quad \quad \quad \forall i, k, l, \\ \quad \sum_{k=1}^n y_{ijkl} = x_{ij}, \\ \quad \quad \quad \forall i, j, l, \\ \quad \sum_{l=1}^n y_{ijkl} = x_{ij}, \\ \quad \quad \quad \forall i, j, k, \\ \quad y_{ijij} = x_{ij}, \\ \quad \quad \quad \forall i, j, \\ \quad 0 \geq y_{ijkl} \leq 1, \\ \quad \quad \quad \forall i, j, k, l, \end{array} \right. \quad (10)$$

where  $i, j, k, l = 1, \dots, n$ . The above program has  $n^4$  new real variables,  $n^2$  binary variables, and  $n^4 + 4n^3 + n^2 + 2n$  constraints. Note that the constraint  $y_{ijij} = x_{ij}$  is redundant since it follows from the definition of the  $y_{ijkl}$  variables. Frieze and Yadegar considered a Lagrangian relaxation of the above 0–1 linear program, and established a relationship between the lower bounds derived by the solution of the relaxation, and the lower bounds derived from decomposition techniques applied to the Gilmore–Lawler bound for the QAP.

### Adams–Johnson Linearization

Adams and Johnson presented in [2] a new 0–1 linear integer formulation for the QAP, which resembles the one of Frieze and Yadegar described previously. It is based on the general linearization technique for general 0–1 polynomial programs introduced by Adams and

H.D. Sherali [3,4]. The QAP(C) is proved to be equivalent to the following mixed 0–1 linear program:

$$\left\{ \begin{array}{l} \min \quad \sum_{i,j=1}^n \sum_{k,l=1}^n c_{ijkl} y_{ijkl} \\ \text{s.t.} \quad (x_{ij}) \in \mathbf{X}_n, \\ \sum_{i=1}^n y_{ijkl} = x_{kl}, \quad \forall j, k, l, \\ \sum_{j=1}^n y_{ijkl} = x_{kl}, \quad \forall i, k, l, \\ y_{ijkl} = y_{klij}, \quad \forall i, j, k, l, \\ y_{ijkl} \geq 0, \quad \forall i, j, k, l, \end{array} \right. \quad (11)$$

where  $i, j, k, l = 1, \dots, n$ , and each  $y_{ijkl}$  represents the product  $x_{ij}x_{kl}$ . The above formulation contains  $n^2$  binary variables  $x_{ij}$ ,  $n^4$  continuous variables  $y_{ijkl}$ , and  $n^4 + 2n^3 + 2n$  constraints excluding the nonnegativity constraints on the continuous variables. Although as noted in [3] a significant smaller formulation in terms of both the number of variables and constraints could be obtained, the structure of the relaxation of the above formulation is favorable for solving it. As noted in [2], the constraint set of the above relaxation describes a solution matrix  $Y$  which is the Kronecker product of two permutation matrices (i.e.  $Y = X \otimes X$  where  $X \in \mathbf{X}_n$ ), showing clearly the equivalence of the above formulation with the QAP as formulated in (9). The theoretical strength of the above linearization of the QAP lies on the fact that, as shown in [2] and [73], the constraints of the relaxations derived from all previous linearizations, can be expressed as a linear combination of the constraints of the continuous relaxation of the above linearization. Moreover, many of the previously published lower-bounding techniques, can be explained based on the dual-space of this relaxation.

### Complexity Issues

The first two parts of this section bring evidence to the fact that the QAP is a ‘very hard’ problem from the theoretical point of view. Not only the QAP cannot be solved to optimality efficiently but it even cannot be approximated efficiently within some constant approximation ratio. Furthermore, finding local optima is not a trivial task even for simply structured neighborhoods like the 2-opt neighborhood. The asymptotic behavior

of the QAP and polynomially solvable special cases of the QAP are mentioned in the last two parts of this section.

### Computational Complexity

Two early results obtained by Sahni and Gonzalez [129] in 1976 settled the complexity of solving and approximating the QAP. It was shown that the QAP is NP-hard and that even finding an  $\epsilon$ -approximate solution for the QAP is a hard problem, in the sense that the existence of a polynomial  $\epsilon$ -approximation algorithm implies  $P = NP$ .

**Theorem 1 [129]** *The quadratic assignment problem is strongly NP-hard. For an arbitrary  $\epsilon > 0$ , the existence of a polynomial time  $\epsilon$ -approximation algorithm for the QAP implies  $P = NP$ .*

The proof is done by a reduction from the Hamiltonian cycle problem [58].

M. Queyranne [121] derives an even stronger result which further confirms the widely spread belief on the inherent difficulty of the QAP in comparison with other difficult combinatorial optimization problems. It is well known and very easy to see that the traveling salesman problem (TSP) is a special case of the QAP. The TSP on  $n$  cities can be formulated as a QAP( $F, D$ ) where  $F$  is the distance matrix of the TSP instance and  $D$  is the adjacency matrix of a Hamiltonian cycle on  $n$  vertices. In the case that the distance matrix is symmetric and satisfies the triangle inequality, the TSP is approximable in polynomial time within 3/2 as shown in [37]. Queyranne [121] showed that, unless  $P = NP$ , QAP( $A, B$ ) is not approximable in polynomial time within some finite approximation ratio, even if  $A$  is the distance matrix of some set of points on a line and  $B$  is a symmetric block diagonal matrix.

A more recent result of S. Arora, Frieze and H. Kaplan [6] answers partially one of the open questions stated by Queyranne [121]. What happens if matrix  $A$  is the distance matrix of  $n$  points which are regularly spaced on a line, that is, points with abscissae given by  $x_p = p, p = 1, \dots, n$ ? This special case of the QAP is termed *linear arrangement problem* and is a well studied NP-hard problem. In the linear arrangement problem the matrix  $B$  is not restricted to have the block diagonal structure mentioned above, but is simply a symmetric 0–1 matrix. Arora, Frieze and Kaplan [6] give

a polynomial time approximation scheme (PTAS) for the linear arrangement problem in the case that the 0–1 matrix  $B$  is dense, that is, the number of ‘1’ entries in  $B$  is in  $\Omega(n^2)$ , where  $n$  is the size of the problem. They show that for each  $\epsilon > 0$  there exists an  $\epsilon$ -approximation algorithm for the dense linear arrangement problem with time complexity depending polynomially on  $n$  and exponentially on  $1/\epsilon$ , hence polynomial for each fixed  $\epsilon > 0$ .

### PLS-Complexity

Assume that an optimization problem  $P$  is given by specifying a ground set  $\mathcal{E}$ , a set  $\mathcal{F} \subseteq 2^{\mathcal{E}}$  of feasible solutions and an objective function  $f : \mathcal{F} \rightarrow \mathbf{R}$ . A globally optimal solution  $S^* \in \mathcal{F}$  of the problem  $P$  is defined as:

$$f(S^*) := \min_{S \in \mathcal{F}} f(S).$$

For any given  $S \in \mathcal{F}$  denote the *neighborhood* of  $S$  by  $\mathcal{N}(S) \subset \mathcal{F}$ . The neighborhood of  $S$  consists of other feasible solutions which are topologically ‘close’ to  $S$ . A *locally optimal solution* or a *local minimum*  $\bar{S} \in \mathcal{F}$  of the problem  $P$ , given the neighborhood  $\mathcal{N}$  is defined as:

$$f(\bar{S}) = \min_{S \in \mathcal{N}(\bar{S})} f(S).$$

Recently (as of 1999) it has been shown that even finding a locally optimal solution for the QAP can be prohibitively hard, that is, even local search is hard in the case of the QAP. Consider the following question ‘How easy it is to find a locally optimal solution for the QAP?’ Since local optimality is defined through a specific neighborhood structure, the answer depends on the involved neighborhood structure. If the neighborhood  $\mathcal{N}$  is replaced by new neighborhood  $\mathcal{N}'$ , one would generally expect changes in the local optimality status of a solution. The theoretical basis for facing this kind of problems was introduced by D.S. Johnson, C.H. Papadimitriou and Yannakakis [72]. They define the so-called *polynomial time local search problems*, shortly *PLS problems*. A pair  $(P, \mathcal{N})$ , where  $P$  is a (combinatorial) optimization problem and  $\mathcal{N}$  is an associated well defined neighborhood structure, defines a local search problem in which the objective is to find a locally optimal solution of  $P$  with respect to the neighborhood structure  $\mathcal{N}$ . Without going into technical details a problem in the PLS class is a local search problem

for which local optimality can be checked in polynomial time. In analogy with decision problems, there exist complete problems in the class of PLS problems. The PLS-complete problems, are – in the usual complexity sense – the most difficult among the PLS problems.

K.A. Murthy, Pardalos and Y. Li [103] introduce a neighborhood structure for the QAP which is similar to the neighborhood structure proposed by B.W. Kernighan and S. Lin [81] for the graph partitioning problem. For this reason we will call it a *K-L type neighborhood structure for the QAP*. Murthy, Pardalos and Li [103] show that the corresponding local search problem is PLS-complete. Consider a permutation  $\phi_0 \in \mathcal{S}_n$ . A swap of  $\phi_0$  is a permutation  $\phi \in \mathcal{S}_n$  obtained from  $\phi_0$  by applying a transposition  $(i, j)$  to it,  $\phi = \phi_0 \circ (i, j)$ . A *transposition*  $(i, j)$  is defined as a permutation which maps  $i$  to  $j$ ,  $j$  to  $i$ , and  $k$  to  $k$  for all  $k \notin \{i, j\}$ . A *greedy swap* of permutation  $\phi_0$  is a swap  $\phi$  which maximizes  $Z(F, D, \phi_0) - Z(F, D, \phi)$  over all swaps  $\phi$  of  $\phi_0$ , where  $Z(F, D, \phi)$  is the objective function value of QAP( $F, D$ ) with permutation  $\phi$  (see formulation (3)). Let  $\phi_0, \dots, \phi_l$  be a sequence of permutations in  $\mathcal{S}_n$ , each of them being a greedy swap of the preceding one. Such a sequence is called *monotone* if for all  $k = 0, \dots, l$ , in the pair  $(\phi_k, \phi_{k+1})$  where  $\phi_k = \phi_{k-1} \circ (i_k, j_k)$  and  $\phi_{k+1} = \phi_k \circ (i_{k+1}, j_{k+1})$ , we have  $\{i_k, j_k\} \cap \{i_{k+1}, j_{k+1}\} = \emptyset$ . The *neighborhood* of  $\phi_0$  consists of all permutations which occur in the (unique) maximal monotone sequence of greedy swaps starting with permutation  $\phi_0$ . Let us denote this neighborhood structure for the QAP by  $\mathcal{N}_{K-L}$ . It is not difficult to see that, given a QAP( $F, D$ ) of size  $n$  and a permutation  $\phi \in \mathcal{S}_n$ , the cardinality of  $\mathcal{N}_{K-L}(\phi)$  does not exceed  $\lfloor n/2 \rfloor + 1$ . It is easily seen that the local search problem (QAP,  $\mathcal{N}_{K-L}$ ) is a PLS problem. This result can be found in [112], where the authors show that the graph partitioning problem with the neighborhood structure defined in [81] is PLS-reducible to (QAP,  $\mathcal{N}_{K-L}$ ).

**Theorem 1 [112]** *The local search problem (QAP,  $\mathcal{N}_{K-L}$ ), where  $\mathcal{N}_{K-L}$  is the Kernighan–Lin type neighborhood structure for the QAP, is PLS-complete.*

The PLS-completeness of (QAP,  $\mathcal{N}_{K-L}$ ) implies that, in the worst case, a general local search algorithm as described above involving the Kernighan–Lin type neighborhood finds a local minimum only after a time which is exponential on the problem size. Numerical results,

however, show that such local search algorithms perform quite well when applied to QAP test instances, as reported in [103].

Another simple and frequently used neighborhood structure is the so-called *pair-exchange* (or *2-opt*) neighborhood  $\mathcal{N}_2$ . The pair-exchange neighborhood of a permutation  $\phi_0 \in \mathcal{S}_n$  consists of all permutations  $\phi \in \mathcal{S}_n$  obtained from  $\phi_0$  by applying some transposition  $(i, j)$  to it. Specifically,

$$\mathcal{N}_2(\phi) := \{\phi \circ (i, j) : i, j = 1, \dots, n, i \neq j\} .$$

It can also be shown that  $(\text{QAP}, \mathcal{N}_2)$  is PLS-complete. A.A. Schr affer and Yannakakis [130] have proven that the graph partitioning problem with a neighborhood structure analogous to  $\mathcal{N}_2$  is PLS-complete. A similar PLS-reduction as in [112] implies that the local search problem  $(\text{QAP}, \mathcal{N}_2)$  is PLS-complete.

Finally, let us mention that no local criteria are known for deciding how good a locally optimal solution is as compared to a global one. From the complexity point of view, deciding whether a given local optimum is a globally optimal solution to a given instance of the QAP is a hard problem, see [108].

### Asymptotic Behavior

Under certain probabilistic conditions on the coefficient matrices of the QAP, the ratio between its ‘best’ and ‘worst’ values of the objective function approaches 1, as the size of the problem approaches infinity. R.E. Burkard and U. Fincke [29] identify a common combinatorial property of a number of problems which, under certain probabilistic conditions on the problem data, behave as described above.

In an early work Burkard and Fincke [28] investigate the relative difference between the worst and the best values of the objective function for the Koopmans–Beckmann QAP. They first consider the case where the coefficient matrix  $D$  is the matrix of pairwise distances of points chosen independently and uniformly from the unit square in the plane. Then the general case where entries of the flow and distance matrices  $F$  and  $D$  are independent random variables taken from a uniform distribution on  $[0, 1]$  is considered. In both cases it is shown that the relative difference mentioned above approaches 0 with probability tending to 1 as the size of the problem tends to infinity.

Later Burkard and Fincke [29] consider the ratio between the objective function values corresponding to an optimal (or best) and a worst solution of a generic combinatorial optimization problem. They find that for each  $\epsilon > 0$ , the ratio between the best and the worst values of the objective function lies on  $(1 - \epsilon, 1 + \epsilon)$ , with probability tending to 1, as the size of the problem approaches infinity. Under additional combinatorial conditions, W. Szpankowski [132] strengthens this result and improves the range of the convergence to almost surely. In the almost sure convergence the probability that the above mentioned ratio tends to 1 is equal to 1. The asymptotic behavior of the QAP can be stated in the following theorem:

**Theorem 3** Consider a sequence of problems  $\text{QAP}(A^{(n)}, B^{(n)})$  for  $n \in \mathbf{N}$ , with  $n \times n$  coefficient matrices  $A^{(n)} = (a_{ij}^{(n)})$  and  $B^{(n)} = (b_{ij}^{(n)})$ . Assume that  $a_{ij}^{(n)}$  and  $b_{ij}^{(n)}$ ,  $n \in \mathbf{N}$ ,  $1 \leq i, j \leq n$ , are independently distributed random variables on  $[0, M]$ , where  $M$  is a positive constant. Moreover, assume that the entries  $a_{ij}^{(n)}$ ,  $n \in \mathbf{N}$ ,  $1 \leq i, j \leq n$ , have the same distribution, and the entries  $b_{ij}^{(n)}$ ,  $n \in \mathbf{N}$ ,  $1 \leq i, j \leq n$ , have also the same distribution, which does not necessarily coincide with that of  $a_{ij}^{(n)}$ . Furthermore, assume that these variables have finite expected values, variances and third moments. Let  $\phi_{opt}^{(n)}$  and  $\phi_{wor}^{(n)}$  denote an optimal and a worst solution of  $\text{QAP}(A^{(n)}, B^{(n)})$ , respectively, that is,

$$Z(A^{(n)}, B^{(n)}, \phi_{opt}^{(n)}) = \min_{\phi \in \mathcal{S}_n} Z(A^{(n)}, B^{(n)}, \phi) ,$$

and

$$Z(A^{(n)}, B^{(n)}, \phi_{wor}^{(n)}) = \max_{\phi \in \mathcal{S}_n} Z(A^{(n)}, B^{(n)}, \phi) .$$

Then the following equality holds almost surely:

$$\lim_{n \rightarrow \infty} \frac{Z(A^{(n)}, B^{(n)}, \phi_{opt}^{(n)})}{Z(A^{(n)}, B^{(n)}, \phi_{wor}^{(n)})} = 1 .$$

The above result suggests that the value of the objective function of the problem  $\text{QAP}(A^{(n)}, B^{(n)})$  (corresponding to an arbitrary feasible solution) gets somehow close to its expected value  $n^2 E(A)E(B)$ , as the size of the problem increases, where  $E(A)$  and  $E(B)$  are the expected values of  $a_{ij}^{(n)}$  and  $b_{ij}^{(n)}$ ,  $n \in \mathbf{N}$ ,  $1 \leq i, j \leq n$ , respectively. J.C.B. Frenk, M. van Houweninge, and A.G. Rinnooy

Kan [54] and W.T. Rhee [126,127] provide different analytical evaluations for this ‘getting close’, by imposing different probabilistic conditions on the data.

Results on the asymptotic behavior of the QAP have been exploited by M.E. Dyer, Frieze, and C.J.H. McDiarmid [46] to analyze the performance of branch and bound algorithms for QAPs with randomly generated coefficients as described above. They have shown that for such QAPs the optimal value of the continuous relaxation of Frieze–Yadegar linearization as stated in (10), is in  $O(n)$  with probability tending to 1 as the size  $n$  of the QAP tends to infinity. Hence the gap between the optimal value of this continuous relaxation and the optimal value of the QAP grows like  $O(n)$  with probability tending to 1 as  $n$  tends to infinity.

### Polynomially Solvable Cases

Since the QAP is  $NP$ -hard, restricted versions which can be solved in polynomial time are an interesting aspect of the problem. A basic question arising with respect to polynomially solvable versions is the identification of those versions and the investigation of the border line between hard and easy versions of the problem. There are two ways to approach this topic: first, find structural conditions to be imposed on the coefficient matrices of the QAP so as to obtain polynomially solvable versions, and secondly, investigate other combinatorial optimization or graph-theoretical problems which can be formulated as QAPs, and embed the polynomially solvable versions of the former into special cases of the later. These two approaches yield two groups of restricted QAPs which are briefly reviewed in this section. For a detailed information on this topic, see [35].

Most of the restricted versions of the QAP with specially structured matrices involve Monge matrices or other matrices having analogous properties. A matrix  $A = (a_{ij})$  is a *Monge matrix* if and only if the following *Monge inequalities* are fulfilled for each 4-tuples of indices  $i, j, k, l, i < k, j < l$ :

$$a_{ij} + a_{kl} \leq a_{il} + a_{kj}.$$

A matrix  $A = (a_{ij})$  is an *anti-Monge matrix* if and only if the following *anti-Monge inequalities* are fulfilled for each 4-tuples of indices  $i, j, k, l, i < k, j < l$ :

$$a_{ij} + a_{kl} \geq a_{il} + a_{kj}.$$

A simple example of Monge and anti-Monge matrices are the *sum matrices*; the entries of a sum matrix  $A = (a_{ij})$  are given as  $a_{ij} = \alpha_i + \beta_j$ , where  $(\alpha_i)$  and  $(\beta_j)$  are the generating row and column vector, respectively. A *product matrix*  $A$  is defined in an analogous way: its entries are given as  $a_{ij} = \alpha_i \beta_j$ , where  $(\alpha_i)$ ,  $(\beta_j)$  are the generating vectors. If the row generating vector  $(\alpha_i)$  and the column generating vectors  $(\beta_i)$  are sorted nondecreasingly, then the product matrix  $(\alpha_i \beta_j)$  is an anti-Monge matrix.

In contrast with the traveling salesman problem, it turns out that the QAP with both coefficient matrices being Monge or anti-Monge is  $NP$ -hard, whereas the complexity of a QAP with one coefficient matrix being Monge and the other one being anti-Monge is still open, see [23] and [35]. However, some polynomially solvable special cases can be obtained by imposing additional conditions on the coefficient matrices. These special cases involve very simple matrices like product matrices or so-called *chess-board matrices*. A matrix  $A = (a_{ij})$  is a chess-board matrix if its entries are given by  $a_{ij} = (-1)^{i+j}$ . These QAPs can either be formulated as equivalent LAPs, or they are *constant permutation QAPs* (see [23,35]), that is, their optimal solution can be given before hand, without knowing the entries of their coefficient matrices. A few other versions of the QAP involving Monge and anti-Monge matrices with additional structural properties can be solved by dynamic programming. Other restricted versions of the QAP involve matrices with a specific diagonal structure such as *circulant* and *Toeplitz matrices*. An  $n \times n$  matrix  $A = (a_{ij})$  is called a Toeplitz matrix if there exist numbers  $c_{-n+1}, \dots, c_{-1}, c_0, c_1, \dots, c_{n-1}$  such that  $a_{ij} = c_{j-i}$ , for all  $i, j$ . A matrix  $A$  is called a circulant matrix if it is a Toeplitz matrix and the generating numbers  $c_i$  fulfill the conditions  $c_i = c_{n-i}$ , for  $0 \leq i \leq n-1$ . In other words, a Toeplitz matrix has constant entries along lines parallel to the diagonal, whereas a circulant is given by its first row and the entries of the  $i$ -th row resembles the first row shifted by  $i-1$  places to the right.

In general versions of the QAP with one anti-Monge (Monge) matrix and one Toeplitz (circulant) matrix, remain  $NP$ -hard unless additional conditions, such as monotonicity, are imposed on the coefficient matrices. A well studied problem is the so called anti-

Monge–Toeplitz QAP where the rows and columns of the anti-Monge matrix are nondecreasing, investigated in [26]. It has been shown that this problem is NP-hard and contains as a special case the so-called turbine balancing problem (TBP) introduced in [99] and formulated as a QAP in [87]. In the TBP we are given a number of blades to be welded in regular spacing around the cylinder of the turbine. Due to inaccuracies in the manufacturing process the weights of the blades differ slightly and consequently the gravity center of the system does not lie on the rotation axis of the cylinder, leading to instabilities. In an effort to make the system as stable as possible, it is desirable to locate the blades so as to minimize the distance between the center of gravity and the rotation axis. The mathematical formulation of this problem leads to an NP-hard anti-Monge–Toeplitz QAP. (For more details and for a proof of NP-hardness see [26].) It is probably interesting that the maximization version of this problem is polynomially solvable. Further polynomially solvable special cases of the anti-Monge–Toeplitz QAP arise if additional constraints such as benevolence or  $k$ -benevolence are imposed on the Toeplitz matrix. These conditions are expressed in terms of properties of the generating function of these matrices, see [26]. The polynomially solvable QAPs with one anti-Monge (Monge) matrix and the other one Toeplitz (circulant) matrix described above, are all constant permutation QAPs. The techniques used to prove this fact and to identify the optimal permutation is called reduction to extremal rays. This technique exploits two facts: first, the involved matrix classes form cones, and secondly, the objective function of the QAP is linear with respect to each of the coefficient matrices. These two facts allow us to restrict the investigations to instances of the QAP with 0–1 coefficient matrices which are extremal rays of the above mentioned cones. Such instances can then be handled by elementary means (exchange arguments, bounding techniques) more easily than the general given QAP. The identification of polynomially solvable special cases of the QAP which are not constant permutation QAPs and can be solved algorithmically remains a challenging open question.

Another class of matrices similar to the Monge matrices are the *Kalmanson matrices*. A matrix  $A = (a_{ij})$  is a Kalmanson matrix if it is symmetric and its elements

satisfy the following inequalities for all indices  $i, j, k, l, i < j < k < l$ :

$$a_{ij} + a_{kl} \leq a_{ik} + a_{jl}, \quad a_{il} + a_{jk} \leq a_{ik} + a_{jl}.$$

For more information on Monge, anti-Monge and Kalmanson matrices, and their properties, see [32]. The Koopmans–Beckmann QAP with one coefficient matrix being a Kalmanson matrix and the other one a Toeplitz matrix, has been investigated in [44]. The computational complexity of this problem is an open question, but analogously as in the case of the anti-Monge–Toeplitz QAP, polynomially solvable versions of the problem are obtained by imposing additional constraints to the Toeplitz matrix.

Further polynomially solvable cases arise as QAP formulations of other problems, like the linear arrangement problem, minimum feedback arc set problem, packing problems in graphs and subgraph isomorphism, see [23,35]. Polynomially solvable versions of these problems lead to polynomially solvable cases of the QAP. The coefficient matrices of these QAPs are the (weighted) adjacency matrices of the underlying graphs, and the special structure of these matrices is imposed by properties of these graphs. The methods used to solve these QAPs range from graph theoretical algorithms (in the case of the linear arrangement problem and the feedback arc set problem), to dynamic programming (in the case of subgraph isomorphism).

### Lower Bounds

Lower bounding techniques are primarily used with implicit enumeration algorithms, such as branch and bound, to perform a limited search of the feasible region of a minimization problem, until an optimal solution is found. A more limited use of lower bounding techniques, is also for evaluating the performance of heuristic algorithms, by providing a relative measure of proximity of the suboptimal solution to the optimum. In comparing lower bounding techniques, the following criteria should be taken into consideration:

- complexity of computing the lower bound;
- tightness of the lower bound (i. e. closest to the optimum solution);
- efficiency in computing lower bounds for subsets of the primal feasible set.

Since there is no clear ranking of the performance of the lower bounds that will be discussed below, all of the above criteria should be kept in mind while reading the following paragraphs. Considering the asymptotic behavior of the QAP, it should be fair to assume that the tightness of the lower bound probably dominates all of the above criteria. That is, if there is a large number of feasible solutions close to the optimum, then a lower bound which is not tight enough, will fail to eliminate a large number of subproblems in the branching process.

### Gilmore–Lawler Type Lower Bounds

Based on the formulation of the general QAP as a LAP of dimension  $n^2$  stated in formulation (9), Lawler [88] derived lower bounds for the QAP, by constructing a solution matrix  $Y$  in the process of solving a series of LAPs. If the resulting matrix  $Y$  is a permutation matrix, then the objective function value is optimal, otherwise it is bounded from below by  $\langle C, Y \rangle$ . Specifically, consider an instance of  $\text{QAP}(C)$ , where the matrix  $C$  is partitioned into  $n^2$  minors,  $C^{(i,j)} = (c_{ijkl})_{n \times n}$  for  $i, j = 1, \dots, n$ . Each minor  $C^{(i,j)}$  essentially contains the costs associated with the assignment  $x_{ij} = 1$ . Partition the solution matrix  $Y$  also into  $n^2$  minors,  $Y^{(i,j)} = (y_{ijkl})_{n \times n}$  for  $i, j = 1, \dots, n$ , whose actual values are to be determined in the process. Solve the  $n^2$  LAPs associated with each minor  $C^{(i,j)}$ ,

$$\left\{ \begin{array}{l} l_{ij} = \min \sum_{k=1}^n \sum_{l=1}^n c_{ijkl} y_{ijkl} \\ \text{s.t.} \quad \sum_{k=1}^n y_{ijkl} = 1, \quad l = 1, \dots, n, \\ \sum_{l=1}^n y_{ijkl} = 1, \quad k = 1, \dots, n, \\ y_{ijij} = 1, \\ y_{ijkl} \in \{0, 1\}, \quad i, j = 1, \dots, n. \end{array} \right. \quad (12)$$

Observe that the last constraint essentially reduces the problem into an LAP of dimension  $(n - 1)$ , obtained by deleting the  $i$ th row and  $j$ th column of the matrix  $C^{(i,j)}$ . Denote the solution matrix for each of the above LAPs by  $Y^{(i,j)}$ . Using the values  $l_{ij}$  from above, solve the LAP to obtain the *Gilmore–Lawler lower bound* for general

QAPs:

$$\left\{ \begin{array}{l} \text{GLB}(C) = \min \sum_{i=1}^n \sum_{j=1}^n l_{ij} x_{ij} \\ \text{s.t.} \quad (x_{ij}) \in \mathbf{X}_n, \end{array} \right. \quad (13)$$

and denote its solution matrix by  $X^* = (x_{ij}^*)$ . If

$$\frac{1}{n} \sum_{ij} x_{ij}^* Y^{(ij)} \in \mathbf{X}_n,$$

then  $Y^* = (x_{ij}^* Y^{(ij)})_{n^2 \times n^2}$  is a Kronecker product of two permutation matrices of dimension  $n$ , and then it is also an optimal solution. Otherwise the optimal solution to the QAP is bounded below by  $\text{GLB}(C) = \langle C, Y^* \rangle$ . Considering that each LAP can be solved in  $O(n^3)$  time, the above lower bound for the general QAP of dimension  $n$  can be computed in  $O(n^5)$  time.

For the more special Koopmans–Beckmann formulation of the QAP (cf. formulation (3)) where the quadratic costs are derived by the pairwise product of two matrices  $F$  and  $D$ , the structure of the problem can be used to reduce the computational effort. Before we proceed, let us make some definitions. For vectors  $a, b \in \mathbf{R}^n$ , define the following extremal variations of the usual inner product between vectors, by imposing an ordering in the elements of the vectors:

$$\langle a, b \rangle^- := \sum_{i=1}^n a_i b_i, \quad (14)$$

where  $a_i \geq a_{i+1}, b_i \leq b_{i+1}, \forall i$ , and

$$\langle a, b \rangle^+ := \sum_{i=1}^n a_i b_i, \quad (15)$$

where  $a_i \geq a_{i+1}, b_i \geq b_{i+1}, \forall i$ . The following is a well known result:

**Proposition 4 [69]** For  $a, b \in \mathbf{R}^n$  the following inequalities hold for any  $\phi \in \mathcal{S}_n$ :

$$\langle a, b \rangle^- \leq \sum_{i=1}^n a_i b_{\phi(i)} \leq \langle a, b \rangle^+.$$

Consider an instance  $\text{QAP}(F, D, B)$ , and recall that this can be transformed into an instance of  $\text{QAP}(C)$  by assigning the values

$$c_{ijkl} = \begin{cases} f_{ik} d_{jl}, & \text{for } i \neq k, j \neq l, \\ f_{ii} d_{jj} + b_{ij}, & \text{for } i = k, j = l. \end{cases}$$

Each minor  $C^{(i,j)}$  in the partitioned matrix  $C$ , is now  $C^{(i,j)} = f_{(i,\cdot)} d_{(j,\cdot)}^T$ , where  $f_{(i,\cdot)}$  and  $d_{(j,\cdot)}$  is the  $i$ th and  $j$ th row of matrix  $F$  and  $D$  respectively. Therefore, using the result of Proposition 4, instead of solving  $n^2$  LAPs we can easily compute the values  $l_{ij}$  as

$$l_{ij} = f_{ii}d_{jj} + b_{ij} + \left\langle \widehat{f}_{(i,\cdot)}, \widehat{d}_{(j,\cdot)} \right\rangle, \tag{16}$$

where the vectors  $\widehat{f}_{(i,\cdot)}, \widehat{d}_{(j,\cdot)} \in \mathbf{R}^{n-1}$  are obtained by removing the  $i$ th and  $j$ th element of the vectors  $f_{(i,\cdot)}$  and  $d_{(j,\cdot)}$  respectively. Finally by solving the resulting LAP as in (12), we obtain the Gilmore–Lawler lower bound for the Koopmans–Beckmann QAPs, denoted by  $GLB(F, D)$ , in  $O(n^3)$  time. Its name is due to the fact that Lawler [88] and P.C. Gilmore [60] independently derived this lower bound, while the first author considered the case for general QAPs also. The simplicity of the Gilmore–Lawler lower bound makes it one of the most efficient to compute, although it deteriorates fast as  $n$  increases. The quality of the lower bound can be improved if the contribution of the quadratic term in the objective function is made to be smaller than that of the linear term. Consider the formulation of the general QAP where the linear and the quadratic terms are separated for clarity. By the above discussion the lower bound will be the solution to the LAP

$$\begin{cases} \min & \sum_{i=1}^n \sum_{j=1}^n (l_{ij} + c_{ijij})x_{ij} \\ \text{s.t.} & (x_{ij}) \in \mathbf{X}_n. \end{cases}$$

We want to decompose the cost coefficients in the quadratic term of (4) and transfer some of their value into the linear term such that  $c_{ijij} \gg l_{ij}$ , which will result in a tighter lower bound since the LAP can be solved exactly. This procedure known as *reduction* was introduced in [41], and it has been investigated by many researchers (see [18,47,56,128]). The general idea is to decompose each quadratic cost coefficient into several terms, which in turn will end up being linear cost coefficients and will be moved in the linear term of the objective function. Consider the following general decomposition for each quadratic cost coefficient in the objective function in (4):

$$D1) \quad c_{ijkl} = \bar{c}_{ijkl} + e_{ijk} + g_{ijl} + h_{ikl} + t_{jkl}, \quad i \neq k, j \neq l.$$

Here  $e, g, h, t \in \mathbf{R}^{n^3}$ . Substituting the above and separating terms, the objective function in (4) becomes

$$\begin{aligned} & \sum_{\substack{i=1 \\ i \neq k}}^n \sum_{\substack{j=1 \\ j \neq l}}^n \sum_{k,l=1}^n \bar{c}_{ijkl} x_{ij} x_{kl} \\ & + \sum_{\substack{i=1 \\ i \neq k}}^n \sum_{\substack{j=1 \\ j \neq l}}^n \sum_{k,l=1}^n (e_{ijk} + g_{ijl} + h_{ikl} + t_{jkl}) x_{ij} x_{kl} \\ & + \sum_{i,j=1}^n c_{ijij} x_{ij}. \end{aligned}$$

Consider now the term associated with the  $e_{ijk}$ :

$$\begin{aligned} & \sum_{i,j=1}^n \sum_{\substack{k=1 \\ k \neq i}}^n \sum_{\substack{l=1 \\ l \neq j}}^n e_{ijk} x_{ij} x_{kl} \\ & = \sum_{i,j=1}^n x_{ij} \left[ \sum_{\substack{k=1 \\ k \neq i}}^n e_{ijk} \left( \sum_{\substack{l=1 \\ l \neq j}}^n x_{kl} \right) \right]. \end{aligned}$$

We can add the term

$$\sum_{\substack{k=1 \\ k \neq i}}^n e_{ijk}$$

to the  $(i, j)$ th element of the LAP that composes the linear term of the objective function, since  $x_{ij} = 1 \Rightarrow x_{kj} = 0 \Rightarrow \sum_{l \neq j} x_{kl} = 1, \forall k$ . Using similar arguments for the vectors  $g, h$  and  $t$ , their costs become linear and the objective function with decomposed quadratic costs become

$$\sum_{\substack{i=1 \\ i \neq k}}^n \sum_{\substack{j=1 \\ j \neq l}}^n \sum_{k=1}^n \sum_{l=1}^n \bar{c}_{ijkl} x_{ij} x_{kl} + \sum_{i=1}^n \sum_{j=1}^n \widehat{c}_{ij} x_{ij},$$

where

$$\begin{aligned} \widehat{c}_{ij} &= c_{ijij} + \sum_{\substack{k=1 \\ k \neq i}}^n e_{ijk} \\ & + \sum_{\substack{l=1 \\ l \neq j}}^n g_{ijl} + \sum_{\substack{k=1 \\ k \neq i}}^n h_{kij} + \sum_{\substack{l=1 \\ l \neq j}}^n t_{lij}. \end{aligned}$$

Therefore we can apply the Gilmore–Lawler bound in the quadratic term of the decomposed objective function, whereas we can get an exact solution to the LAP that composes the linear term, and the sum of these two values will constitute a lower bound for the QAP. In the case of the Koopmans–Beckmann formulation of the QAP were we have two matrices  $F$  and  $D$ , the general decomposition scheme is:

D2)

$$\begin{cases} f_{ij} = \bar{f}_{ij} + \lambda_i + \mu_j, & i \neq j, \\ d_{kl} = \bar{d}_{kl} + \nu_k + p_l, & k \neq l. \end{cases}$$

Here  $\lambda, \mu, \nu, p \in \mathbf{R}^n$ . Substituting to the product  $f_{ij}d_{kl}$  it is easily seen that D2) reduces to the general decomposition D1) with vectors  $e, g, h, t \in \mathbf{R}^{n^3}$ . Frieze and Yadegar [56] showed that the inclusion of the vectors  $h$  and  $t$  in D1) does not affect the value of the lower bound, and therefore are redundant (similarly the vectors  $\mu$  and  $p$  for the Koopmans–Beckmann QAP are redundant in D2)). The same authors in [56] derived lower bounds for the QAP based on a Lagrangian relaxation (cf. also ► **Integer programming: Lagrangian relaxation**). Specifically, consider the Lagrangian relaxation of the 0–1 linear programming formulation of the QAP (see (10)), where the second and third constraints are included in the objective function, using as Lagrangian multipliers the elements of the vectors  $e$  and  $g$ . The Lagrangian function is thus defined as

$$\mathcal{L}(e, g) := \left\{ \begin{array}{l} \min \sum_{ijkl} c_{ijkl} y_{ijkl} \\ \quad + \sum_{jkl} e_{jkl} \left( x_{kl} - \sum_i y_{ijkl} \right) \\ \quad + \sum_{ikl} g_{ikl} \left( x_{kl} - \sum_j y_{ijkl} \right) \\ \quad = \sum_{ijkl} (c_{ijkl} - e_{jkl} - g_{ikl}) y_{ijkl} \\ \quad + \sum_{ij} \left( \sum_k e_{kij} + \sum_l g_{lij} \right) x_{ij} \\ \text{s.t.} \quad \text{first constraint in (10),} \\ \quad \text{fourth constraint in (10)} \\ \quad \dots \\ \quad \text{last constraint in (10).} \end{array} \right.$$

The authors prove in [56] that for any choice of  $e$  and  $g$ , the solution to the above minimization problem will equal the value of the Gilmore–Lawler lower bound as applied to the QAP, with decomposed quadratic cost coefficients, as dictated by using the vectors  $e$  and  $g$  only in D1). Therefore,  $\max_{e, g} \mathcal{L}(e, g)$  constitutes an upper bound on the lower bounds for the QAP, obtained by using the Gilmore–Lawler bound with decomposed quadratic cost coefficients. Using subgradient algorithms (cf. also ► **Nondifferentiable optimization: Subgradient optimization methods**) the authors derive near optimal solutions for  $\max_{e, g} \mathcal{L}(e, g)$  resulting in two lower bounds, denoted by  $FY1$  and  $FY2$ , corresponding to the two different solution approaches proposed. As suggested by the experimental results in [56], these bounds seem to be sharper than previously reported Gilmore–Lawler based lower bounds using reduction techniques. Almost all of the other approaches for obtaining lower bounds for the QAP with reduction techniques, are special cases of the general decomposition scheme D2) (see [18,47,128]).

**Variance Reduction Lower Bounds**

The variance reduction lower bounds were introduced in [93]. Consider an instance of the Koopmans–Beckmann formulation of the QAP, with input matrices  $F = (f_{ij}), D = (d_{ij}) \in \mathbf{R}^{n \times n}$ . Now partition both matrices into a sum of two matrices,  $F = F_1 + F_2$  and  $D = D_1 + D_2$ , where  $F_1 = (f_{ij}^{(1)}), F_2 = (f_{ij}^{(2)})$  and  $D_1 = (d_{ij}^{(1)}), D_2 = (d_{ij}^{(2)})$ . Construct an  $n \times n$  matrix  $L = (l_{ij})$ , by solving the following  $n^2$  LAPs:

$$l_{ij} = \min_{\phi \in S_n} \sum_{k=1}^n f_{ik}^{(1)} d_{j\phi(k)}^{(1)} + f_{ki}^{(1)} d_{\phi(k)j} + f_{ki} d_{\phi(k)j}^{(2)} - f_{ki}^{(2)} d_{\phi(k)j}^{(2)} \quad (17)$$

It is proved in [93] that the solution of the LAP with cost matrix  $L$  as constructed above, constitutes a lower bound for QAP( $F, D$ ). The problem of concern now, is to find a way to partition the matrices  $F$  and  $D$  such that the resulting lower bound is maximized. Observe that when  $F_1 = F$  and  $D_1 = D$  (i. e. no partitioning), we essentially derive the GLB( $F, D$ ).

Let  $M \in \mathbf{R}^{m \times n}$ , and denote its rows and columns respectively as  $m_{(i \cdot)}$ , and  $m_{(\cdot, j)}, i, j = 1, \dots, n$ . Think of  $M$

as a data set of  $mn$  elements  $m_{ij}$ , and define an average  $\gamma(M)$  and a variance  $V(M)$  as,

$$\gamma(M) := \frac{1}{mn} \sum_{i=1}^m \sum_{j=1}^n m_{ij},$$

$$V(M) := \sum_{i=1}^m \sum_{j=1}^n (\gamma(M) - m_{ij})^2.$$

Also define the total variance,

$$T(M, \lambda) := \lambda \sum_{i=1}^m V(m_{(i,\cdot)}) + (1 - \lambda)V(M),$$

where  $\lambda \in [0, 1]$ . The term  $V(m_{(i,\cdot)})$  stands for the variance of  $m_{(i,\cdot)}$ , treated as a  $1 \times n$  matrix. The authors observed that, as the variances of the matrices  $F$  and  $D$  decrease, the  $GLB(F, D)$  increases, while it is optimal if the variances of the rows of the matrices are zero. The partition scheme considered is of the form,  $F_1 = F + \Delta_F$ ,  $F_2 = -\Delta_F$ , and  $D_1 = D + \Delta_D$ ,  $D_2 = -\Delta_D$ . Considering only the matrix  $F$ , the problem is to find a matrix  $\Delta_F$ , such that the variances of  $F_1$  and  $F_2$  and the sum of the variances of the rows for each  $F_1$  and  $F_2$  are minimized. We will only describe how  $\Delta_F$  is obtained since  $\Delta_D$  is obtained in the same way. The problem of minimizing the variances can be stated mathematically as

$$\min_{\theta} \theta T(F + \Delta_F, \lambda) + (1 - \theta)T(-\Delta_F^T, \lambda), \quad (18)$$

where  $\Delta_F \in \mathbf{R}^{n \times n}$  and  $\theta \in [0, 1]$  is a parameter. Two approximate solutions were proposed in [93], corresponding to the two reduction schemes

R1)  $\delta_{ij} = \theta(f_{nm} - f_{ij}) + \delta_{nm}$ ,

R2)  $\delta_{ij} = \theta(\gamma(f_{(\cdot,n)}) - \gamma(f_{(\cdot,j)}))$ .

Here  $i, j = 1, \dots, n$ ,  $\Delta_F = (\delta_{ij})$ , and with  $\delta_{nm}$  being free to take any value (it was given a value of zero in the experiments conducted in [93]). In obtaining R2), the problem of minimizing the variances such that the matrix  $\Delta_F$  is constrained to have constant columns, is considered. The matrix  $\Delta_D$  is constructed in the same way. Based on the two reductions schemes above, the resulting lower bounds from the solution of (17) are denoted by  $LB1(\theta)$ , and  $LB2(\theta)$ . The above procedure for computing  $\Delta_F$ ,  $\Delta_D$  has  $O(n^2)$  computational complexity.

After the partitioning of the matrices  $F$  and  $D$ , the solution to the LAP with cost matrix  $L = (l_{ij})$ , where  $l_{ij}$  are defined in (17), will yield  $LB1(\theta)$  or  $LB2(\theta)$  according to

what reduction scheme used. If  $LB2(\theta)$  is used, the fact that the matrices  $F_2$  and  $D_2$  have constant columns can be exploited to compute the  $l_{ij}$ ,  $i, j = 1, \dots, n$ , efficiently as

$$l_{ij} = \langle \widehat{f}_{(i,\cdot)}^{(1)}, \widehat{d}_{(j,\cdot)}^{(1)} \rangle^- + f_{1i}^{(2)} \sum_{\substack{k=1 \\ k \neq j}}^n d_{kj}$$

$$+ d_{1j}^{(2)} \sum_{\substack{k=1 \\ k \neq i}}^n f_{kj} - (n-1)f_{1i}^{(2)}d_{1j}^{(2)} + f_{ii}d_{jj},$$

where  $\widehat{f}_{(i,\cdot)}^{(1)}, \widehat{d}_{(j,\cdot)}^{(1)} \in \mathbf{R}^{n-1}$  are the  $i$ th and  $j$ th row of  $F_1$  and  $D_1$  respectively, with the  $i$ th and  $j$ th elements removed from each, and  $\langle \cdot, \cdot \rangle^-$  is defined in (14). In the case that  $LB1(\theta)$  is used, the direct approach would be to solve the  $n^2$  LAPs defined in (17), which will require  $O(n^5)$  computational effort. A different approach is to calculate lower bounds for the values  $l_{ij}$ ,  $i, j = 1, \dots, n$ , as follows:

$$l_{ij} = \langle \widehat{f}_{(i,\cdot)}^{(1)}, \widehat{d}_{(j,\cdot)}^{(1)} \rangle^- + \langle \widehat{f}_{(\cdot,i)}^{(2)}, \widehat{d}_{(\cdot,j)}^{(2)} \rangle^- + \langle \widehat{f}_{(\cdot,i)}^{(2)}, \widehat{d}_{(\cdot,j)}^{(2)} \rangle^+ ,$$

where each vector in the above extremal inner products, is of dimension  $n - 1$ , and corresponds to the  $i$ th row or column of the indicated matrix, upon removal of the  $i$ th element. Similarly as before the extremal inner products  $\langle \cdot, \cdot \rangle^-$  and  $\langle \cdot, \cdot \rangle^+$  are defined in (14) and (15). Using the above approach would require  $O(n^3)$  time to compute lower bounds for the  $l_{ij}$ ,  $i, j = 1, \dots, n$ , thus the total computational complexity of the variance reduction lower bounds is  $O(n^3)$ . It is worth noting that there is also a closed form solution to problem (18) given in [71] which is

$$\delta_{ij} = \theta\lambda \frac{1 - \theta}{1 - \theta\lambda} \gamma(f_{(i,\cdot)}) + \frac{\theta(1 - \lambda) + \theta\lambda^2(1 - \theta) - \theta^2\lambda^2(1 - \theta)}{(1 - \theta\lambda)(1 - \lambda + \theta\lambda)} \gamma(F) - \frac{\theta\lambda(1 - \theta)}{1 - \lambda + \theta\lambda} \gamma(f_{(\cdot,j)}) - \theta f_{ij},$$

for  $i, j = 1, \dots, n$ . However it was reported in [93] that using the above closed form in the computation of the lower bounds, poses implementation obstacles.

The experimental results conducted in [93], also suggest that the settings of  $\theta = 0.5$  for  $LB1(\theta)$ , and  $\theta = 1$  for  $LB2(\theta)$  as best choices. Finally, these lower bounds perform well on QAPs with input matrices that have high variances, but their performance reduces to that of the Gilmore–Lawler bounds when the variance of the matrices is small.

### Eigenvalue Based Lower Bounds

These bounds were introduced in [50,51], and are applied to the Koopmans–Beckmann formulation of the QAP. This approach utilizes known results on permutation matrices and eigenvalues, and exploits the special structure of  $QAP(F, D)$ . Upon the introduction of the method in [50,51], many improvements and generalizations have appeared (see for example [65,66,67,68,123,124]). There is a resemblance with the Gilmore–Lawler based lower bounds, in the sense that, based upon a general lower bound, reduction techniques are applied to the quadratic terms of the objective function in order to improve its quality. The reduction techniques that applied to eigenvalue based lower bounds however, yield a significant improvement, which is not really the case with the Gilmore–Lawler bounds under certain reductions.

Considering the trace formulation of the QAP in (7), with  $F$  and  $D$  being real symmetric matrices, therefore with all their eigenvalues being real, the following result can be stated for the quadratic term [51]:

**Theorem 5 [51]** *Let  $F, D \in \mathbf{R}^{n \times n}$  be symmetric matrices, and denote by  $\lambda = (\lambda_1, \dots, \lambda_n)^\top$  and  $x_1, \dots, x_n$  the eigenvalues and eigenvectors of  $F$ , and by  $\mu = (\mu_1, \dots, \mu_n)^\top$  and  $y_1, \dots, y_n$  the the eigenvalues and eigenvectors of  $D$ . Then the following two relations are true for all  $X \in \mathbf{X}_n$ ,*

- i)  $\text{tr} FXDX^\top = \sum_{i=1}^n \sum_{j=1}^n \lambda_i \mu_j \langle x_i, Xy_j \rangle^2 = \lambda^\top S(X) \mu$ .  
Here  $S(X) = (\langle x_i, Xy_j \rangle^2)$  is a doubly stochastic matrix,
- ii)  $\langle \lambda, \mu \rangle^- \leq \text{tr} FXDX^\top \leq \langle \lambda, \mu \rangle^+$ .

Using Theorem 5ii) a lower bound for  $QAP(F, D)$  based on the eigenvalues of  $F$  and  $D$  is then

$$EVB = \langle \lambda, \mu \rangle^- + \min_{X \in \mathbf{X}_n} \text{tr} BX^\top,$$

where the second term is an ordinary LAP that can be solved exactly. Observe that in Theorem 5, the smaller

the interval  $[\langle \lambda, \mu \rangle^-, \langle \lambda, \mu \rangle^+]$  is, the closest  $\langle \lambda, \mu \rangle^-$  is to  $\text{tr} FXDX^\top$ . A possible way of making the interval smaller, is to decompose the matrices  $F$  and  $D$  such that some of their value will be transferred in the linear term, and the eigenvalues of the resulting matrices that compose the quadratic term, are as uniform in value as possible. Define the *spread* of the matrix  $F$  as

$$\text{spread}(F) := \max \{ |\lambda_i - \lambda_j| : i, j = 1, \dots, n \}.$$

Based on the above discussion, we want to minimize the spreads of the matrices that compose the quadratic term. There is no simple closed form for expressing  $\text{spread}(F)$  in terms of  $f_{ij}$ , however we can minimize instead a formula for the upper bound given in [98]:

$$\text{spread}(F) \leq m(F) = \left[ 2 \sum_{i=1}^n \sum_{j=1}^n f_{ij}^2 - \frac{2}{n} (\text{tr} F)^2 \right]^{\frac{1}{2}}. \quad (19)$$

The decomposition scheme that the authors use in [51], is the following:

$$f_{ij} = \bar{f}_{ij} + e_i + e_j + r_{ij}, \quad (20)$$

$$d_{kl} = \bar{d}_{kl} + g_k + g_l + s_{kl}, \quad (21)$$

where  $r_{ij} = s_{ij} = 0$ , for  $i \neq j$ .

Consider the decomposition for matrix  $F$  and let  $\bar{F} = (\bar{f}_{ij})$ . Minimizing the function  $f(e, r) = m(\bar{F})$  obtained by substituting the values of  $\bar{f}_{ij}$  in (19), the following values are obtained [51]:

$$z = \frac{1}{2(n-1)} \left( \sum_{i=1}^n \sum_{j=1}^n f_{ij} - \text{tr} F \right), \quad (22)$$

$$e_i = \frac{1}{n-2} \left( \sum_{j=1}^n f_{ij} - f_{ii} - z \right), \quad (23)$$

$$r_{ii} = f_{ii} - 2e_i, \quad (24)$$

for  $i = 1, \dots, n$ . Analogously we obtain the values for  $g$  and  $s$  for the decomposition of  $D$ . Replacing  $F$  and  $D$  in (7) we obtain

$$\text{tr}(FXD + B)X^\top = \text{tr}(\bar{F}X\bar{D} + \bar{B})X^\top,$$

where  $\bar{b}_{ij} = b_{ij} + f_{ii}d_{jj} + 2e_i \sum_{k=1, k \neq j}^n d_{jk}$ , and matrices  $\bar{F}$  and  $\bar{D}$  have respective eigenvalues  $\bar{\lambda} = (\bar{\lambda}_1, \dots, \bar{\lambda}_n)$  and  $\bar{\mu} = (\bar{\mu}_1, \dots, \bar{\mu}_n)$ . The corresponding eigenvalue lower bound is then

$$EVB1 = \langle \bar{\lambda}, \bar{\mu} \rangle^- + \min_{X \in X_n} \text{tr} \bar{B}X^T.$$

If we restrict ourselves only to pure quadratic ( $f_{ii} = d_{ii} = 0, \forall i, B = 0$ ) symmetric QAPs, the matrix  $\bar{B}$  in the above decomposition becomes  $\bar{B} = cw^T$ , where  $c = 2(e_1, \dots, e_n)^T$  and  $w = (\sum_j d_{1j}, \dots, \sum_j d_{nj})^T$ . Therefore  $\min_{X \in X_n} \text{tr} \bar{B}X^T = \langle c, w \rangle^-$ , and

$$EVB1 = \langle \bar{\lambda}, \bar{\mu} \rangle^- + \langle c, w \rangle^- \leq \min_{X \in X_n} \text{tr}(\bar{F}X\bar{D} + \bar{B})X^T.$$

We can however obtain further improvement as suggested by F. Rendl [123], who examined the linear term  $\langle c, w \rangle^-$ , and proposed a method where  $EVB1$  is iteratively improved, until some specified number of iterations is reached, or we have satisfied an optimality condition. More specifically, let  $S_k := \{X_1, \dots, X_k\} \subseteq X_n$ , and

$$L(X_i) := \min \{ \langle c, X_i w \rangle : X_i \in X_n \setminus S_{i-1} \},$$

so for any integer  $k \geq 1, L(X_1) \leq L(X_2) \leq \dots \leq L(X_k)$ . In other words the set  $S_k$  contains the  $k$  first solutions (permutation matrices) of the problem  $\min_{X \in X_n} \langle c, X_i w \rangle$ , where the first solution  $X_1 \ni L(X_1) = \langle c, w \rangle^-$ . Let

$$\text{QAP}(\bar{F}, \bar{D}, X_i) = \text{tr}(\bar{F}X_i\bar{D} + \bar{B})X_i^T,$$

and also define the following

$$Z(k) := \min \{ \text{QAP}(\bar{F}, \bar{D}, X_i) : i = 1, \dots, k \}.$$

The following inequalities [123] result:

$$Z(1) \geq \dots \geq Z(k) \geq \langle \bar{\lambda}, \bar{\mu} \rangle^- + L(X_k) \geq \dots \geq \langle \bar{\lambda}, \bar{\mu} \rangle^- + L(X_1),$$

where if  $Z(i) = \langle \bar{\lambda}, \bar{\mu} \rangle^- + L(X_i)$  for some  $i$ , then  $X_i$  is the optimal solution to the problem. So essentially, we try to close or reduce the gap between the optimal solution of the QAP and the lower bound  $EVB1$ , by

increasing the value of the linear term  $\langle c, w \rangle^-$  in the bound in  $k$  steps, where  $k$  is specified as a parameter. The generation of the set  $S_k$  or ranking as it is called, is a special case of the problem of ranking the  $k$  first solutions of an assignment problem with cost matrix  $(c_i w_j)$  where, as shown in [104], has time complexity  $O(kn^3)$ . Rendl [123] presents an  $O(n \log n + (n + \log k)k)$  for this special case. There are two issues regarding the effectiveness of the above ranking procedure, in improving the lower bound, addressed in [123]. First, observe that if the vectors  $c$  and  $w$  have  $m \leq n$  equal elements, then there are at least  $m!$  permutation matrices  $\{X_i\}$  such that the values  $\langle c, X_i w \rangle$  are equal. This in turn, implies that there will be none or small improvement in the lower bound while generating  $S_k$  for quite some number of iterations. As dictated by the decomposition in (22), (23),  $c$  and  $w$  will have equal elements if the row sums of  $F$  and  $D$  are equal. One condition then for applying the ranking procedure, is that most of the row sums of  $F$  and  $D$  are not equal. Secondly, Rendl [123] also defines a ratio called the *degree of linearity* based on the ranges of the quadratic and linear terms that compose the lower bound

$$L := \frac{\langle \bar{\lambda}, \bar{\mu} \rangle^+ - \langle \bar{\lambda}, \bar{\mu} \rangle^-}{\langle c, w \rangle^+ - \langle c, w \rangle^-}.$$

The influence of the linear term on the lower bound then is inversely proportional to the value of  $L$ . A small value of  $L$  suggests that the ranking procedure would be beneficial for the improvement of  $EVB1$  for symmetric, pure quadratic QAPs. For large values of  $L$ , we can expect that the quadratic term dominates the linear term in the objective function, and [51] suggest the following improvement on  $EVB1$ . Considering Theorem 5i) as applied to the reduced matrices  $\bar{F}$  and  $\bar{D}$ , denote the elements of the matrix  $S(X)$  by  $s_{ij} = \langle x_i, Xy_j \rangle^2$ . We can apply the bounds  $l_{ij} \leq s_{ij} \leq u_{ij}$  where

$$u_{ij} = \max\{(\langle x_i, y_j \rangle^-)^2, (\langle x_i, y_j \rangle^+)^2\},$$

$$l_{ij} = \begin{cases} 0 & \text{if } \langle x_i, y_j \rangle^-, \langle x_i, y_j \rangle^+ \text{ differ in sign,} \\ \min\{(\langle x_i, y_j \rangle^-)^2, (\langle x_i, y_j \rangle^+)^2\} & \text{otherwise.} \end{cases}$$

Recalling the fact that the  $s_{ij}$  are the elements of a doubly stochastic matrix, we can then form the *capacitated*

transportation problem

$$\text{CTP}^* \begin{cases} \min & \sum_{i=1}^n \sum_{j=1}^n \bar{\lambda}_i \bar{\mu}_j s_{ij} \\ \text{s.t.} & \sum_{i=1}^n s_{ij} = 1, \quad j = 1, \dots, n, \\ & \sum_{j=1}^n s_{ij} = 1, \quad i = 1, \dots, n, \\ & l_{ij} \leq s_{ij} \leq u_{ij}. \end{cases}$$

The new lower bound then would be

$$\text{EVB2} = \text{CTP}^* + \langle c, w \rangle^-.$$

A more generalized approach to eigenvalue based lower bounding techniques, was employed in [66], that led to new lower bounds. Consider the following sets of  $n \times n$  matrices, where  $I \in \mathbf{R}^{n \times n}$  is the identity matrix, and  $u := (1, \dots, 1)^\top \in \mathbf{R}^n$  is the vector of ones,

$$\mathcal{O} := \{X: X^\top X = I\},$$

$$\mathcal{E} := \{X: Xu = X^\top u = u\},$$

$$\mathcal{N} := \{X: X \geq 0\}.$$

It is a well known result that  $\mathbf{X}_n = \mathcal{O} \cap \mathcal{E} \cap \mathcal{N}$ , while the set of doubly stochastic matrices  $\Omega = \mathcal{E} \cap \mathcal{N}$ . Moreover, by Birkhoff's theorem [15] we know that  $\Omega$  is a convex polyhedron with a vertex set  $\mathbf{X}_n$ , that is,  $\Omega = \text{conv}\{X: X \in \mathbf{X}_n\}$ . Considering the above characterization of  $\mathbf{X}_n$ , we can see that any solution to a relaxation of the QAP obtained from excluding one or two of the matrix sets  $\mathcal{O}$ ,  $\mathcal{E}$  and  $\mathcal{N}$ , will yield a lower bound. Naturally the relaxation, and therefore the lower bound, will be tighter if only one of the matrix sets is excluded. In relation to Theorem 5, Rendl and Wolkowicz [124] showed that

$$\begin{aligned} \min_{X \in \mathcal{O}} \text{tr} FXDX^\top &= \text{tr} F \Lambda_F \Lambda_D^\top D \Lambda_D \Lambda_F^\top = \langle \lambda, \mu \rangle^-, \\ \max_{X \in \mathcal{O}} \text{tr} FXDX^\top &= \text{tr} F \Lambda_F \Lambda_D^\top D \Lambda_D \Lambda_F^\top = \langle \lambda, \mu \rangle^+, \end{aligned}$$

where  $\Lambda_F, \Lambda_D$  are the matrices with columns the eigenvectors of  $F$  and  $D$  respectively, in the order specified by the minimal (maximal) inner product of the eigenvalues. In other words, the lower bound on the quadratic part of the QAP as obtained from the EVB, is derived by relaxing the feasible set to that of orthogonal matrices. In [124] a new lower bound is derived, similar to EVB2 but using a different approach to decompose

the matrices  $F$  and  $D$ . More specifically, denote the decomposition scheme in (20) and (21) by the vector  $d := (e^\top, g^\top, r^\top, s^\top) \in \mathbf{R}^{4n}$ , where  $r = (r_{11}, \dots, r_{nn})^\top$  and  $s = (s_{11}, \dots, s_{nn})^\top$ , and consider EVB1 as a function of  $d$ . Maximizing this function with respect to  $d$  will result in a lower bound with the best possible decomposition that involves both the linear and quadratic terms. This leads to a nonlinear, nonsmooth, nonconcave function which is hard to solve, and a steepest ascent algorithm is proposed for maximizing it in [124]. The new bound, denoted EVB3, produces some of the best lower bounds for the QAP, with the expense however of high computational requirements.

All of the above discussed lower bounds, relax the set of permutation matrices to  $\mathcal{O}$ . A tighter relaxation was proposed in [67], where the set of permutation matrices was relaxed to  $\mathcal{O} \cap \mathcal{E}$ , by incorporating  $\mathcal{E}$  in the objective function, by exploiting the fact that the vector of ones  $u$  is both a left and right eigenvector with eigenvalue 1, for any  $X \in \mathbf{X}_n$ . More specifically define

$$P := [u/\|u\|; V],$$

where  $V^\top u = 0$ ,  $V^\top V = I_{n-1}$ . therefore  $V$  is an orthonormal basis for  $\{u\}^\perp$ , while  $Q := VV^\top$  is the orthogonal projection on  $\{u\}^\perp$ . The following characterization of the permutation matrices is given in [67]

**Lemma 6** [67] *Let  $X \in \mathbf{R}^{n \times n}$  and  $Y \in \mathbf{R}^{(n-1) \times (n-1)}$ . If*

$$X = P \begin{bmatrix} 1 & 0 \\ 0 & Y \end{bmatrix} P^\top, \quad (25)$$

then

$$X \in \mathcal{E},$$

$$X \in \mathcal{N} \Leftrightarrow VYV^\top \geq -\frac{uu^\top}{\|u\|},$$

$$X \in \mathcal{O} \Leftrightarrow Y \in \mathcal{O}_{n-1}.$$

Conversely if  $X \in \mathcal{E}$  then there exists a  $Y$  such that (25) holds.

Note that the above characterization of the permutation matrices, preserves the orthogonality and the trace structure of the problem. Substituting  $X = -uu^\top/\|u\|^2 + VYV^\top$  as suggested by (25), in the trace formulation of the QAP in (7), we have an equivalent projected problem (PQAP) of dimension  $n - 1$  on the variable

matrix  $Y$ . The new lower bound  $IVB$  is obtained by relaxing  $Y$  to  $O_{n-1}$ , therefore deriving a lower bound for the quadratic part of PQAP, while the linear part can be solved exactly as an LAP. Decompositions for improving the  $IVB$  are also considered in [67], where it is shown that the quadratic term in the projected problem is unaffected by  $e$  and  $g$  in the decomposition scheme in (20), (21). Obtaining a lower bound by considering both the quadratic and linear term is also considered in [78].

The symmetry assumption on the QAP is required by any of the eigenvalue based lower bounding techniques described above. Hadley, Rendl and Wolkowicz [68] show that any real QAP can be transformed into an equivalent QAP where the matrices  $F$  and  $D$  are Hermitian, which allows the application of eigenvalue based bounds.

### Bounds Based on Semidefinite Relaxations

Recently (as of 1999), semidefinite programming (SDP) relaxations for the QAP were considered [76,77,137]. The SDP relaxations considered in these papers are solved by interior point methods or cutting plane methods (cf. also ► **Linear programming: Interior point methods**; ► **Extended cutting plane algorithm**), and the obtained solutions are valid lower bounds for the QAP. In terms of quality the bounds obtained in this way are competitive with the best existing lower bounds for the QAP. For many test instances from QAPLIB [31] such as some instances of Hadley [26], Roucairol [128], Nugent et al. [105], and Taillard [133], they are the best existing bounds. However, due to prohibitively high computation time requirements, the use of such approaches as basic bounding procedures within branch and bound algorithms is up to now not feasible. See [77,78] for a detailed description of SDP approaches to the QAP and illustrate the idea by describing just one semidefinite programming relaxation for the QAP.

The set of  $n \times n$  permutation matrices  $\mathbf{X}_n$  is the intersection of the set of  $n \times n$  0-1 matrices, denoted by  $\mathcal{Z}_n$ , and the set  $\mathcal{E}_n$  of  $n \times n$  matrices with row and column sums equal to 1. Moreover,  $\mathbf{X}_n$  is also the intersection of  $\mathcal{Z}_n$  with the set of  $n \times n$  orthogonal matrices, denoted by  $\mathcal{O}_n$ . Hence

$$\mathbf{X}_n = \mathcal{Z}_n \cap \mathcal{E}_n = \mathcal{Z}_n \cap \mathcal{O}_n .$$

Recall that

$$\mathcal{O}_n = \{X \in \mathbf{R}^{n \times n} : XX^T = X^T X = I\}$$

and

$$\mathcal{E}_n = \{X \in \mathbf{R}^{n \times n} : Xu = X^T u = u\} ,$$

where  $I$  is the  $n \times n$  identity matrix and  $u$  is the  $n$ -dimensional vector of all ones. Then, the trace formulation of the QAP (7) with the additional linear term

$$-2 \sum_{i=1}^n \sum_{j=1}^n b_{ij} x_{ij} ,$$

can be represented equivalently as follows:

$$\text{QAP}_E \begin{cases} \min & \text{tr}(FXDX^T - 2BX^T) \\ \text{s.t.} & XX^T = X^T X = I, \\ & Xu = X^T u = u, \\ & x_{ij}^2 - x_{ij} = 0. \end{cases}$$

In order to obtain a semidefinite relaxation for the QAP from the formulation  $\text{QAP}_E$  above, we introduce first an  $n^2$ -dimensional vector  $\text{vec}(X)$ .  $\text{vec}(X)$  is obtained as a columnwise ordering of the entries of matrix  $X$ . Then the vector  $\text{vec}(X)$  is lifted into the space of  $(n^2 + 1) \times (n^2 + 1)$  matrices by introducing a matrix  $Y_X$ ,

$$Y_X = \begin{pmatrix} x_0 & \text{vec}(X)^T \\ \text{vec}(X) & \text{vec}(X) \text{vec}(X)^T \end{pmatrix} .$$

Thus,  $Y_X$  has some entry  $x_0$  in the left-upper corner followed by the vector  $\text{vec}(X)$  in its first row (column). The remaining terms are those of the matrix  $\text{vec}(X) \text{vec}(X)^T$  sitting on the right lower  $n^2 \times n^2$  block of  $Y_X$ . Secondly, the coefficients of the problem are collected in an  $(n^2 + 1) \times (n^2 + 1)$  matrix  $K$  given as

$$K = \begin{pmatrix} 0 & -\text{vec}(B)^T \\ \text{vec}(B) & D \otimes F \end{pmatrix} ,$$

where the operator  $\text{vec}$  is defined as above and  $D \otimes F$  is the Kronecker product of  $D$  and  $F$ .

It is easy to see that with these notations the objective function of  $\text{QAP}_E$  equals  $\text{tr}(KY_X)$ . By setting  $y_{00} := x_0 = 1$  as done in [77], one obtains two additional

constraints to be fulfilled by the matrix  $Y_X$ :  $Y_X$  is positive semidefinite and matrix  $Y_X$  is a rank-one matrix. Whereas the semidefiniteness and the equality  $y_{00} = 1$  can be immediately included in an SDP relaxation, the rank-one condition is hard to handle and is discarded in an SDP relaxation. In order to assure that the rank-one positive semidefinite matrix  $Y_X$  is obtained by an  $n \times n$  permutation matrix as described above, other constraints should be imposed to  $Y_X$ . Such conditions can be formulated as valid constraints of an SDP formulation for the QAP by means of some new operators, acting on matrices or vectors as introduced below. Given a matrix  $A \in \mathbf{R}^{n \times n}$ , the operator  $\text{diag}(A) \in \mathbf{R}^n$  produces a vector containing the diagonal entries of matrix  $A$  in their natural order, that is, from top-left to bottom-right. The adjoint operator  $\text{Diag}$  acts on a vector  $V \in \mathbf{R}^n$  and produces a matrix  $\text{Diag}(V) \in \mathbf{R}^{n \times n}$  with off-diagonal entries equal to 0 and the components of  $V$  on the main diagonal. For some matrix  $Y \in \mathbf{R}^{(n^2+1) \times (n^2+1)}$ , operator  $\text{arrow}(Y) \in \mathbf{R}^{(n^2+1)}$ , is defined as  $\text{arrow}(Y) := \text{diag}(Y) - (0, Y_{0,1:n^2})$ , where  $(0, Y_{0,1:n^2})$  is an  $n^2 + 1$ -dimensional vector with first entry equal to 0 and other entries coinciding with the entries of  $Y$  lying on the 0th row and in columns between 1 and  $n^2$ , in their natural order. The adjoint operator  $\text{Arrow}$  acts on an  $n^2 + 1$ -dimensional vector  $W$  and produces an  $(n^2 + 1) \times (n^2 + 1)$  matrix  $\text{Arrow}(W)$

$$\text{Arrow}(W) = \begin{pmatrix} w_0 & \frac{1}{2} W_{1:n^2}^\top \\ \frac{1}{2} W_{1:n^2} & \text{Diag}(W_{1:n^2}) \end{pmatrix},$$

where  $W_{(1:n^2)}$  is the  $n^2$ -dimensional vector obtained from  $W$  by removing its first entry  $w_0$ . Furthermore, we are going to consider an  $(n^2 + 1) \times (n^2 + 1)$  matrix  $Y$  as composed of its first row  $Y_{(0,\cdot)}$ , of its first column  $Y_{(\cdot,0)}$ , and of  $n^2$  submatrices of size  $n \times n$  each, which are arranged in an  $n \times n$  array of  $n \times n$  matrices and produce its remaining  $n^2 \times n^2$  block (this is similar to the structure of a Kronecker product of two  $n \times n$  matrices). The entry  $y_{\alpha\beta}$ ,  $1 \leq \alpha, \beta \leq n^2$ , will be also denoted by  $y_{(ij)(kl)}$ , with  $1 \leq i, j, k, l \leq n$ , where  $\alpha = (i - 1)n + j$  and  $\beta = (k - 1)n + l$ . Hence,  $y_{(ij)(kl)}$  is the element with coordinates  $(j, l)$  within the  $n \times n$  block with coordinates  $(i, k)$ .

With these formal conventions let us define the so-called *block-0-diagonal* and *off-0-diagonal* operators, acting on an  $(n^2 + 1) \times (n^2 + 1)$  matrix  $Y$ , and denoted by  $b^0 \text{diag}$  and  $o^0 \text{diag}$ , respectively.  $b^0 \text{diag}(Y)$  and  $o^0$

$\text{diag}(Y)$  are  $n \times n$  matrices given as follows:

$$b^0 \text{diag}(Y) = \sum_{k=1}^n Y_{(k,\cdot)(k,\cdot)},$$

$$o^0 \text{diag}(Y) = \sum_{k=1}^n Y_{(\cdot,k),(\cdot,k)},$$

where, for  $1 \leq k \leq n$ ,  $Y_{(k,\cdot)(k,\cdot)}$  is the  $k$ th  $n \times n$  matrix on the diagonal of the  $n \times n$  array of matrices, defined as described above. Analogously,  $Y_{(\cdot,k),(\cdot,k)}$  is an  $n \times n$  matrix consisting of the diagonal elements sitting on the position  $(k, k)$  of the  $n \times n$  matrices ( $n^2$  matrices altogether) which form the  $n^2 \times n^2$  lower right block of matrix  $Y$ . The corresponding adjoint operators  $B^0 \text{Diag}$  and  $O^0 \text{Diag}$  act on an  $n \times n$  matrix  $S$  and produce  $(n^2 + 1) \times (n^2 + 1)$  matrices as follows:

$$B^0 \text{Diag} = \begin{pmatrix} 0 & 0 \\ 0 & I \otimes S \end{pmatrix},$$

$$O^0 \text{Diag} = \begin{pmatrix} 0 & 0 \\ 0 & S \otimes I \end{pmatrix}.$$

Finally, let us denote by  $e_0$  the  $n^2 + 1$ -dimensional unit vector with first component equal to 1 and all other components equal to 0, and let  $R$  be the  $(n^2 + 1) \times (n^2 + 1)$  matrix given by

$$R = \begin{pmatrix} n & -u^\top \otimes u^\top \\ -u \otimes u & I \otimes E \end{pmatrix} + \begin{pmatrix} n & -u^\top \otimes u^\top \\ -u \otimes u & E \otimes I \end{pmatrix},$$

where  $E$  is the  $n \times n$  matrix of all ones. With these notations, a semidefinite relaxation for  $\text{QAP}_E$  is given as follows

$$\text{QAP}_{R0} \begin{cases} \min & \text{tr}(KY) \\ \text{s.t.} & b^0 \text{diag}(Y) = I, \\ & o^0 \text{diag}(Y) = I, \\ & \text{arrow}(Y) = e_0, \\ & \text{tr}(RY) = 0, \\ & Y \succeq 0, \end{cases}$$

where  $\preceq$  is the so-called *Löwner partial order*, that is,  $A \preceq B$  if and only if  $B - A \succeq 0$ , that is  $B - A$  is positive semidefinite. In [77] it was shown that an equivalent formulation for the considered QAP is obtained

from QAP<sub>R0</sub> by imposing one additional condition on the matrix  $Y$ , namely, the rank-one condition.

### Exact Solution Methods

Several exact solution approaches for solving the QAP will be presented in this section. Specifically the exact algorithms that have been used for the QAP are dynamic programming, cutting plane algorithms, and branch and bound which appears to be the most successful one.

### Branch and Bound

Branch and bound algorithms appear to be the most efficient exact algorithms for solving the QAP. For the QAP there are three types of branch and bound algorithms, namely:

- *Single assignment algorithms* ([60,88]).
- *Pair assignment algorithms* ([59,86,105]).
- *Relative positioning algorithm* ([97]).

All of the above algorithms work by iterative constructing an optimal permutation starting from an empty permutation. The single assignment algorithms seem to be the most efficient and the pair assignment algorithms do not have favorable computational results.

We will now describe a recent branch and bound algorithm for the QAP, that was proposed in [111]. In the description that follows we will consider the Koopmans–Beckmann formulation of the QAP. First let us define the necessary notation used in describing the branch and bound algorithm. A partial permutation for the set of integers  $S_n = \{1, \dots, n\}$  is denoted by

$$\phi_k := \begin{pmatrix} 1 & 2 & \dots & k \\ \phi_k(1) & \phi_k(2) & \dots & \phi_k(k) \end{pmatrix}$$

where  $k \leq n$ . From now we will write  $\phi_k = (\phi_k(1), \phi_k(2), \dots, \phi_k(k))$  for short. An assignment of a facility  $i$  to a location  $j$  will be denoted by  $i \rightarrow j$ , while if  $i$  must never be assigned to  $j$  we will write  $i \not\rightarrow j$ . Note that  $\phi_k$  is essentially a partial assignment of facilities to locations. If we want to add an extra assignment to some  $\phi_k$ , say  $k+1 \rightarrow j$ , we will write  $\phi_{k+1} = \phi_k \cup k+1 \rightarrow j$ , thereby  $\phi_{k+1}(i) = \phi_k(i)$  for  $i = 1, \dots, k$ , and  $\phi_{k+1}(k+1) = j$ . Given some  $\phi_k$  let its range be  $Q_k := \{\phi_k(i) : i = 1, \dots, k\}$ , and define the sets of nonpermissible assignments to be  $E_{k+1} := \{j \in S_n \setminus Q_k : k+1 \not\rightarrow j\}$ . Given an instance QAP( $F, D, B$ ),

a pair of  $\phi_k$  and  $E_{k+1}$  completely defines a subproblem  $P_i$  as

$$P_i \begin{cases} \min_{\phi \in S_n} & \sum_i \sum_j f_{ij} d_{\phi(i)\phi(j)} + \sum_i b_{i\phi(i)} \\ \text{s.t.} & \phi(i) = \phi_k(i), \quad i = 1, \dots, k, \\ & \phi(k+1) \notin E_{k+1}. \end{cases}$$

The original problem  $P_0$  is obtained for an empty partial permutation  $\phi_0$  and  $E_1 = \emptyset$ . For each  $P_i$  a lower bound  $g(P_i)$  can be computed, using any of the lower bounds described previously, and let the optimal solution to  $P_i$  be denoted by  $f(P_i)$ . In the branch and bound algorithm, a forest of  $n$  binary trees is constructed, where each node of the tree corresponds to a partial subproblem  $P_i$ . The *branching* process is as follows. Given a node  $P_i$  (i. e. a subproblem) defined by some  $\phi_k$  and  $E_{k+1}$ , two descendant nodes are created, the left child  $P_i^l$  and the right child  $P_i^r$ . For  $P_i^l$  we set  $\phi_{k+1}^l = \phi_k \cup k+1 \rightarrow j$  for some  $j \notin E_k$  and  $E_{k+2}^l = \emptyset$ , while for  $P_i^r$  we set  $\phi_k^r = \phi_k$  and  $E_{k+1}^r = E_{k+1} \cup j$ . A node which has  $\phi_k$  with  $k = n - 1$  cannot be decomposed further, and it is called a terminal node. Immediately we can identify the following properties

- $g(P_i) \leq f(P_i)$  for any node  $P_i$ ,
- $g(P_i) = f(P_i)$  if  $P_i$  is a terminal node,
- $g(P_j) \geq g(P_i)$  if  $P_j$  has descended from  $P_i$ .

A node defined by some  $\phi_k$  and  $E_{k+1}$  will have two terminal nodes as children if  $k = n - 2$ . Moreover, for any node  $|E_{k+1}| + k \leq n - 1$ , while if equality holds then there is only one  $j \notin E_{k+1}$  and only one left child is generated with  $\phi_{k+1} = \phi_k \cup k+1 \rightarrow j$  and  $E_{k+2} = \emptyset$ .

The branch and bound algorithm in [111] starts by computing an upper bound solution to the original subproblem  $P_0$  by means of a heuristic (cf. also ► **Heuristic search**). Let the corresponding permutation be  $\phi = (\phi(1), \phi(2), \dots, \phi(n))$ . Note that during the process of the algorithm the upper bound is continuously updated whenever a better feasible solution is found. Then  $n$  nodes are created, where for each  $P_i$  for  $i = 1, \dots, n$ , we set  $\phi_1 = \phi_0 \cup 1 \rightarrow \phi(i)$ ,  $E_2 = \emptyset$ , and  $g(P_i) = 0$ . Then the following steps are performed at each iteration

- 1) Selection: Here we choose which node to examine next, and we choose the node with the maximum  $g(P_i)$ .
- 2) Branching: Given the chosen node  $P_i$  from step 1, we create two new nodes  $P_i^l$  and  $P_i^r$ , based on

- the branching scheme described previously. We set  $g(P_i^r) = g(P_i)$  and we compute  $g(P_i^l)$ .
- 3) Elimination: If  $g(P_i^l)$  is less than or equal to the current upper bound, then the node  $P_i^l$  is pruned, that is, marked not to be considered in step 1) in the future.
  - 4) Termination: The algorithm stops if, and only if, there are no more nodes to be considered in step 1).
- The authors in [111] applied the above described branch and bound algorithm for the QAP in conjunction with the variance reduction lower bounds described previously.

### Traditional Cutting Plane Methods

Traditional cutting plane algorithms for the QAP have been developed by a different authors, [7,8,9,13,14], and [80]. These algorithms make use of mixed integer linear programming (MILP) formulations for the QAP which are suitable for Benders decomposition. In the vein of Benders, the MILP formulation is decomposed into a master problem and a subproblem, called also slave problem, where the master problem contains the original assignment variables and constraints. For a fixed assignment the slave problem is usually a linear program and hence, solvable in polynomial time. The master problem is a linear program formulated in terms of the original assignment variables and of the dual variables of the slave problem, and is solvable in polynomial time for fixed values of those dual variables. The algorithms work typically as follows. First, a heuristic is applied to generate a starting assignment. Then the slave problem is solved for fixed values of the assignment variables implied by that assignment, and optimal values of the primal and dual variables are computed. If the dual solution of the slave problem satisfies all constraints of the master problem, we have an optimal solution for the original MILP formulation of the QAP. Otherwise, at least one of the constraints of the master problem is violated. In this case, the master problem is solved with fixed values for the dual variables of the slave problem and the obtained solution is given as input to the slave problem. The procedure is then repeated until the solution of the slave problem fulfills all constraints of the master problem.

Clearly any solution of the master problem obtained by fixing the dual variables of the slave problem to some

feasible values, is a lower bound for the considered QAP. On the other side, the objective function value of the QAP corresponding to any feasible setting of the assignment variables is an upper bound. The algorithm terminates when the lower and the upper bounds coincide. Generally, the time needed for the upper and the lower bounds to converge to a common value is too large, and hence these methods may solve to optimality only very small QAPs. However, heuristics derived from cutting plane approaches produce good suboptimal solutions in early stages of the search, see for example, [21] and [14].

### Polyhedral Cutting Planes

Similarly to traditional cutting plane methods also polyhedral cutting planes or branch and cut algorithms (cf. also ► **Integer programming: Branch and cut algorithms**) make use of an LP or MILP relaxation of the combinatorial optimization problem to be solved, in our case the QAP. Additionally, polyhedral cutting plane methods make use of a class of (nontrivial) valid or facet defining inequalities known to be fulfilled by all feasible solutions of the original problem. If the solution of the relaxation is feasible for the original problem, we are done. Otherwise, some of the above mentioned valid inequalities are probably violated. In this case a ‘cut’ is performed, that is, one or more of the violated inequalities are added to the LP or MILP relaxation of our problem. The latter is resolved and the whole process is repeated. In the case that none of the valid inequalities is violated, but some integrality constraint is violated, the algorithm performs a branching step by fixing (feasible) integer values for the corresponding variable. The branching steps produce the search tree like in branch and bound algorithms. Each node of this tree is processed as described above by performing cuts and then by branching it, if necessary. Clearly, related elements of branch and bound algorithms like upper bounds, selection and branching rules play a role in branch and cut algorithms. Hence, such an approach combines elements of cutting plane and branch and bound methods. The main advantage of polyhedral cutting plane algorithms with respect to traditional cutting planes relies on the use of cuts which are valid for the whole polytope of the feasible solutions, and possibly facet defining. Traditional cutting planes

instead rely frequently on cuts which are not valid for the whole polytope of the feasible solutions. In this case the whole computation has to be done from scratch for different variable fixings. This requires additional running time and additional amounts of memory. Another and not less important drawback of traditional cutting plane algorithms is due to the ‘weakness’ of the cuts they involve. In contrast with cuts produced by facet defining inequalities, the weak cuts cannot avoid the slow convergence.

Polyhedral cutting plane methods for the QAP are not yet backed by a strong theory. However, some efforts to design branch and cut algorithms for the QAP have been made in [106] and [75]. M.W. Padberg and M.P. Rijal [106] have tested their algorithm on sparse QAP instances. The numerical results are encouraging, although the developed software is of preliminary nature, as claimed by the authors. V. Kaibel [75] has used branch and cut to compute lower bounds for QAP instances. His results are promising especially in the case where box inequalities are involved.

### Heuristics

There is a large amount of research directed toward heuristic algorithms for solving the QAP. This is partially due to the fact that, although substantial improvements have been done in the development of exact algorithms for the QAP, problems of dimension  $n > 20$  are still not practical to solve because of very high computer time requirements. The following types of heuristic algorithmic approaches have been applied towards the QAP:

- construction methods (CM);
- limited enumeration methods (LEM);
- improvement methods (IM);
- tabu search (TS);
- simulated annealing (SA);
- genetic algorithms (GA);
- greedy randomized adaptive search procedures (GRASP);
- ant systems (AS).

### Construction Methods

Construction methods were introduced in [60]. They are iterative approaches which usually start with an empty permutation, and iteratively complete a partial

permutation into a solution of the QAP by assigning some facility which has not been assigned yet to some free location.

```

PROCEDURE construction( $\phi_0, \Gamma$ )
 $\phi = \{\}$ ;
DO  $i = 1, \dots, n - 1 \rightarrow$ 
  IF  $(i, j) \notin \Gamma \rightarrow$ 
     $j = \text{heur}(i)$ ;
    update( $\phi_i, (i, j)$ );
     $\Gamma = \Gamma \cup (i, j)$ ;
  FI;
 $\phi = \phi_i$ ;
OD;
RETURN( $\phi$ )
END construction;

```

### Pseudocode for construction method

A generic construction method is presented in pseudocode under the name PROCEDURE construction ( $\phi_0, \Gamma$ ). Here  $\phi_0, \phi_1, \dots, \phi_{n-1}$  are partial permutations, and  $\text{heur}(i)$  is some heuristic procedure that assigns facility  $i$  to some location  $j$ , and returns  $j$ .  $\Gamma$  is the set of already assigned pairs of facilities to locations. The procedure update constructs a permutation  $\phi_i$  by adding the assignment  $(i, j)$  to  $\phi_{i-1}$ . The heuristic  $\text{heur}(i)$  employed by update could be any heuristic which chooses a location  $j$  for facility  $i$ ,  $(i, j) \notin \Gamma$ , in a greedy fashion or by applying local search. One of the oldest heuristics used in practice, the CRAFT heuristic, developed in [17], is a construction method. Another construction method which yields good results has been proposed in [100].

### Limited Enumeration Methods

It has been observed that often enumeration methods (e.g. branch and bound algorithms) find good solutions in early stages of the search, and then employ a lot of time to marginally improve that solution or prove its optimality. Based on this observation, limited enumeration methods impose a limit on the enumeration process, which can be either a maximum number of iterations or time limit, to produce a heuristic solution. Another strategy which serves the same goal is to manipulate the lower bound. This can be done by increasing the lower bound if no improvement in the solution

is achieved during a large number of iterations, and would yield deeper cuts in the search tree to speed up the process. Clearly, such an approach may cut off the optimal solution and hence should be used carefully, possibly in conjunction with certain heuristics that perform elaborate searches in the feasible space.

### Improvement Methods

These methods are otherwise called *local search algorithms*. For a comprehensive discussion of theoretical and practical aspects of local search in combinatorial optimization, see [1].

Basic ingredients of improvement methods are the neighborhood and the order in which the neighborhood is searched. A frequently used neighborhood for the QAP is the *k-exchange neighborhood* which we will define as follows. Let the difference between two permutations  $\phi$  and  $\psi$  be  $\delta(\phi, \psi) := \{i : \phi(i) \neq \psi(i)\}$ , and define the distance between the two permutations to be  $d(\phi, \psi) := |\delta(\phi, \psi)|$ . The *k-exchange neighborhood*  $N_k(\phi)$  for a permutation  $\phi \in \mathcal{S}_n$  is

$$N_k(\phi) := \{\psi : d(\phi, \psi) \leq k, 2 \leq k \leq n\} .$$

The size of the neighborhood used in the *k-exchange local search* is  $\binom{n}{k} = n!/k!(n-k)!$ . For the QAP the most frequently used values for *k* are 2 and 3, with  $N_2(\phi)$  producing better empirical results.

Another important ingredient of improvement methods is the order in which the neighborhood is scanned. This order can be either fixed previously or chosen at random. Given a neighborhood structure and a scanning order, a rule for the update of the current solution (from the current iteration to the subsequent one) should be chosen. The following update rules are frequently used:

- first improvement;
- best improvement;
- Heider's rule [70].

In the case of first improvement the current solution is updated as soon as the first improving neighbor solution is found. Best improvement scans the whole neighborhood and chooses the best improving neighbor solution (if such a solution exists at all). Heider's rule starts by scanning the neighborhood of the initial solution in a prespecified cyclic order. The current solution is updated as soon as an improving neighbor solution is found. The scanning of the neighborhood of the new

solution starts there where the scanning of the previous one was interrupted (in the prespecified cyclic order).

### Tabu Search

Tabu search was introduced in [62,63] as a technique to overcome local optimality. See [61] for a comprehensive introduction to tabu search algorithms.

Different implementations of tabu search have been proposed for the QAP, for example, a tabu search with fixed tabu list ([131]), the robust tabu search ([133]), where the size of the tabu list is randomly chosen between a maximum and a minimum value, and the reactive tabu search ([12]) which involves a mechanism for adopting the size of the tabu list. Reactive tabu search aims at improving the robustness of the algorithm. The algorithm notices when a cycle occurs, and increases the tabu list size according to the length of the detected cycle. The numerical results show that generally the reactive tabu search outperforms other tabu search algorithms for the QAP (see [12]). More recently, also parallel implementations of tabu search have been proposed, see for example, [36]. Tabu search algorithms allow a natural parallel implementation by dividing the burden of the search in the neighborhood among several processors.

### Simulated Annealing

Simulated annealing exploits the analogy between combinatorial optimization problems and problems from statistical mechanics. S. Kirkpatrick, C.D. Gelatt and M.P. Vecchi [82] and V. Černý [135] were among the first authors who recognized this analogy, and showed how the Metropolis algorithm (see [96]) used to simulate the behavior of a physical many-particle system can be applied as a heuristic for the traveling salesman problem.

Burkard and Rendl [33] showed that a simulated cooling process yields a general heuristic which can be applied to any combinatorial optimization problem, as soon as a neighborhood structure has been introduced in the set of its feasible solutions. In particular, they applied simulated annealing to the QAP. Other simulated annealing (SA) algorithms for the QAP have been proposed by different authors, see for example, [136] and [40]. All these algorithms employ the 2-exchange neighborhood. They differ on the way the cooling process or the thermal equilibrium is implemented. The

numerical experiments show that the performance of SA algorithms strongly depends on the values of the control parameters, and especially on the choice of the cooling schedule.

### Genetic Algorithms

The so-called genetic algorithms (GA) are a nature inspired approach for combinatorial optimization problems. The basic idea is to adapt the evolutionary mechanisms acting in the selection process in nature to combinatorial optimization problems. The first genetic algorithm for optimization problems was proposed by Holland [53] in 1975. For a good coverage of theoretical and practical issues on genetic algorithms, see [43] and [64].

A number of authors have proposed genetic algorithms for the QAP. Standard algorithms, like the one developed in [134], have difficulties to generate the best known solutions even for QAPs of small or moderate size. Hybrid approaches, such as combinations of GA techniques with tabu search as the one developed in [52] seem to be more promising. More recently another hybrid algorithm, the so-called greedy genetic algorithm proposed in [5], produced very good results on large scale QAPs from QAPLIB [31].

### Greedy Randomized Adaptive Search Procedure

The greedy randomized adaptive search procedure (GRASP) was introduced in [48] and has been applied successfully to different hard combinatorial optimization problems [49,83,84,125] and among them to the QAP [94,109,110] and the BiQAP [95]. See [48] for a survey and tutorial on GRASP, and to [117] for a comprehensive presentation of the implementation of GRASP to the QAP and related problems.

GRASP is a combination of greedy elements with random search elements in a two phase heuristic. It consists of a construction phase and a local improvement phase. In the construction phase good solutions from the available feasible space are constructed, whereas in the local improvement phase the neighborhood of the solution constructed in the first phase is searched for possible improvements. A pseudocode of GRASP is shown below. The input parameters are the size RCLsize of the restricted candidate list (RCL), a maximum number of iterations, and a random seed. RCL contains the candidates upon which the sampling

related to the construction of a solution in the first phase will be performed.

```

PROCEDURE
  GRASP(RCLSize,MaxIter,RandomSeed)
  InputInstance();
  DO k = 1, . . . , MaxIter →
    ConstructSolution(RCLSize,RandomSeed);
    LocalSearch(BestSolutionFound);
    UpdateSolution(BestSolutionFound);
  OD;
  RETURN BestSolutionFound
END GRASP;
    
```

### Pseudocode for generic GRASP

### Ant Systems

Ant systems (AS) is a recently developed heuristic for combinatorial optimization problems which tries to imitate the behavior of an ant colony in search for food. AS was originally introduced in [45] and [38] and has already produced good results for well known problems like the traveling salesman problem (TSP) and the QAP [39,57]. Numerical results in [39,57] show that ant systems are competitive heuristics especially for real life instances of the QAP with a few very good solutions clustered together. For randomly generated instances which have many good solutions distributed somehow uniformly in the search space, AS are outperformed by other heuristics, that is, genetic algorithms or tabu search approaches.

### Related Problems

Generalizations of the QAP appeared almost as soon as the problem itself. Specifically, Lawler [88] addressed the issue of extending to cubic, quartic, and *N-adic assignments problems* in general, in the same fashion as the LAP was extended to QAP in formulation (1). For the cubic assignment problem for example, we have  $n^6$  cost coefficients  $c_{ijklmp}$  where  $i, j, k, l, m, p = 1, \dots, n$ , and the problem is then defined to be

$$\begin{cases} \min & \sum_{i,j=1}^n \sum_{k,l=1}^n \sum_{m,p=1}^n c_{ijklmp} x_{ij} x_{kl} x_{mp} \\ \text{s.t} & (x_{ij}) \in \mathbf{X}_n. \end{cases}$$

As it is noted [88], we can construct an  $n^3 \times n^3$  matrix  $S$  containing the cost coefficients, such that the cubic

assignment problem is equivalent to the LAP

$$\begin{cases} \min & \langle S, Y \rangle \\ \text{s.t.} & Y = X \otimes X \otimes X, \\ & X \in \mathbf{X}_n. \end{cases}$$

In an analogous way the LAP can be extended to any  $N$ -adic assignment problem, by considering the solution matrix  $Y$  to be the Kronecker  $N$ th power of a permutation matrix in  $\mathbf{X}_n$ . In this section several generalizations and related problems of the QAP are presented, for which real applications have been found that initiated an interest in analyzing them and proposing solution techniques.

**Biquadratic Assignment Problem**

A generalization of the QAP is the biquadratic assignment problem (BiQAP), which is essentially a quartic assignment problem with cost coefficients formed by the products of two four-dimensional arrays. More specifically, consider two  $n^4 \times n^4$  arrays  $F = (f_{ijkl})$  and  $D = (d_{mpst})$ . The BiQAP can then be stated as:

$$\begin{cases} \min & \sum_{i,j,k,l=1}^n \sum_{m,p,s,t=1}^n f_{ijkl} d_{mpst} x_{im} x_{jp} x_{ks} x_{lt} \\ \text{s.t.} & \sum_{i=1}^n x_{ij} = 1, \quad j = 1, \dots, n, \\ & \sum_{j=1}^n x_{ij} = 1, \quad i = 1, \dots, n, \\ & x_{ij} \in \{0, 1\}, \quad i, j = 1, \dots, n. \end{cases}$$

The major application of the BiQAP arises in very large scale integrated (VLSI) circuit design. A detailed description of the mathematical modeling of the VLSI problem to a BiQAP can be found in [24]. Deterministic improvement methods and variants of simulated annealing and tabu search have been developed for the BiQAP in [22]. Computational experiments on test problems of size up to  $n = 32$ , with known optimal solutions (a test problem generator is presented in [24]), suggest that one version of simulated annealing is best among those tested. The GRASP heuristic has also been applied to the BiQAP in [95], and produced the optimal solution for all the test problems generated in [24].

**Multidimensional Assignment Problems**

A close relative to the class of  $M$ -adic assignment problems is that of the *multidimensional assignment problems* (MAPs), often referred to as *multi-index assignment problems*, that also arise as natural extensions from the LAP. The general formulation of the MAP is

$$\begin{cases} \min & \sum_{i_1=1}^{M_1} \dots \sum_{i_N=1}^{M_N} c_{i_1 \dots i_N} x_{i_1 \dots i_N} \\ \text{s.t.} & \sum_{i_2=1}^{M_2} \dots \sum_{i_N=1}^{M_N} x_{i_1 \dots i_N} = 1, \\ & \text{for } i_1 = 1, \dots, M_1, \\ & \sum_{i_1=1}^{M_1} \dots \sum_{i_{k-1}=1}^{M_{k-1}} \sum_{i_{k+1}=1}^{M_{k+1}} \dots \sum_{i_N=1}^{M_N} x_{i_1 \dots i_N} = 1, \\ & \text{for } i_k = 1, \dots, M_k, \quad k = 2, \dots, N - 1, \\ & \sum_{i_1=1}^{M_1} \dots \sum_{i_{N-1}=1}^{M_{N-1}} x_{i_1 \dots i_N} = 1, \\ & \text{for } i_N = 1, \dots, M_N, \\ & x_{i_1 \dots i_N} \in \{0, 1\} \\ & \text{for all } i_1 \dots i_N, \end{cases}$$

with  $n^N$  cost coefficients  $c_{i_1 \dots i_N}$ . A feasible solution to the above problem will be an  $N$ -dimensional permutation array. Multidimensional assignment problems in their general form have found many applications as a means of solving the data association problem. More specifically, the central problem in any multitarget tracking and multisensor surveillance is the data association problem of partitioning the observations into tracks and false alarms. General classes of these problems can be formulated as multidimensional assignment problems. For a detailed description on the application of MAPs for multiple target tracking applications, as well as for solution approaches, see [101,102,118].

Various applications are also contributed to special cases of the MAP. Specifically, the five-dimensional assignment problem has been successfully used for tracking elementary particles. By solving a five-dimensional assignment problem, physicists reconstruct tracks generated by charged elementary particles produced by the large electron-positron collider (LEP) at CERN institute [119]. The 3-index assignment problem is also a special case of the MAP.

### Bottleneck QAP

In the *bottleneck quadratic assignment problem* (BQAP) of size  $n$  we are given an  $n \times n$  flow matrix  $F$  and an  $n \times n$  distance matrix  $D$ , and wish to find a permutation  $\phi \in \mathcal{S}_n$  which minimizes the objective function

$$\max \{f_{ij}d_{\phi(i)\phi(j)} : 1 \leq i, j \leq n\}.$$

A more general BQAP analogous to the QAP in (2) is obtained if the coefficients of the problem are of the form  $c_{ijkl}$ ,  $1 \leq i, j, k, l \leq n$ :

$$\min_{\phi \in \mathcal{S}_n} \max_{1 \leq i, j \leq n} c_{ij\phi(i)\phi(j)}.$$

Besides the application in backboard wiring mentioned above, the BQAP has many other applications. Basically, all QAP applications give raise to applications of the BQAP because it often makes sense to minimize the largest cost instead of the overall cost incurred by some decision. A well studied problem in graph theory which can be modeled as a BQAP is the *bandwidth problem*. In the bandwidth problem we are given an undirected graph  $G = (V, E)$  with vertex set  $V$  and edge set  $E$ , and seek a labeling of the vertices of  $G$  by the numbers  $1, \dots, n$ , where  $|V| = n$ , such that the minimum absolute value of differences of labels of vertices which are connected by an edge is minimized. In other words, we seek a labeling of vertices such that the maximum distance of 1-entries of the resulting adjacency matrix from the diagonal is minimized, that is, the bandwidth of the adjacency matrix is minimized. It is easy to see that this problem can be modeled as a special BQAP with flow matrix equal to the adjacency matrix of  $G$  for some arbitrary labeling of vertices, and distance matrix  $D = (|i - j|)$ .

The BQAP is NP-hard since it contains the bottleneck TSP as a special case. Some enumeration algorithms to solve BQAP to optimality have been proposed in [19]. These algorithms employ a Gilmore–Lawler-like bound for the BQAP which involves in turn the solution of bottleneck linear assignment problems. The algorithm for the general BQAP involves also a threshold procedure useful to reduce to 0 as many coefficients as possible. Burkard and Fincke [27] investigated the asymptotic behavior of the BQAP and proved results analogous to those obtained for the QAP: If the coefficients are independent random variables taken from

a uniform distribution on  $[0, 1]$ , then the relative difference between the worst and the best value of the objective function approaches 0 with probability tending to 0 as the size of the problem approaches infinity.

The BQAP and the QAP are special cases of a more general quadratic assignment problem which can be called the *algebraic QAP* (in analogy to the algebraic linear assignment problem (LAP) introduced in [30]). If  $(H, *, <)$  is a totally ordered commutative semigroup with composition  $*$  and order relation  $<$ , the algebraic QAP with cost coefficients  $c_{ijkl} \in H$  is formulated as

$$\min_{\phi \in \mathcal{S}_n} c_{11\phi(1)\phi(1)} * \dots * c_{1n\phi(1)\phi(n)} * \dots * c_{nn\phi(n)\phi(n)}.$$

The study of the bottleneck QAP and more generally the algebraic QAP was the starting point for the investigation of a number of algebraic combinatorial optimization problem with coefficients taken from linearly ordered semimodules, that is, linear assignment and transportation problems, flow problems, and other. See [34] for a detailed discussion on this topic.

### Other Problems Which Can Be Formulated As QAPs

There are a number of other well known combinatorial optimization problems which can be formulated as QAPs with specific coefficient matrices. Of course, since QAP is not a well tractable problem, it does not make sense to use algorithms developed for the QAP to solve these other problems. All known solution methods for the QAP are far inferior compared to any of the specialized algorithms developed for solving these problems. However, the relationship between the QAP and these problems might be of benefit for a better understanding of the QAP and its inherent complexity.

Two well studied NP-hard combinatorial optimization problems which are special cases of the QAP, are the *graph partitioning problem* (GPP) and the *maximum clique problem* (MCP). In GPP we are given an (edge) weighted graph  $G = (V, E)$  with  $n$  vertices and a number  $k$  which divides  $n$ . We want to partition the set  $V$  into  $k$  sets of equal cardinality such that the total weight of the edges cut by the partition is minimized. This problem can be formulated as a QAP with distance matrix  $D$  equal to the weighted adjacency matrix of  $G$ , and flow matrix  $F$  obtained by multiplying with  $-1$  the adjacency matrix of the union of  $k$  disjoint complete

subgraphs with  $n/k$  vertices each. For more information on graph partitioning problems, see [90]. In the maximum clique problem we are again given a graph  $G = (V, E)$  with  $n$  vertices and wish to find the maximum  $k \leq n$  such that there exists a subset  $V_1 \subseteq V$  with  $|V_1| = k$ , which induces a clique in  $G$ , that is, all vertices of  $V_1$  are connected by edges of  $G$ . In this case consider a QAP with distance matrix  $D$  equal to the adjacency matrix of  $G$  and flow matrix  $F$  given as adjacency matrix of a graph consisting of a clique of size  $k$  and  $n - k$  isolated vertices, multiplied by  $-1$ . A clique of size  $k$  in  $G$  exists only if the optimal value of the corresponding QAP is  $-k^2$ . For a review on the maximum clique problem, see [114].

The traveling salesman problem (TSP) is another well known combinatorial optimization problem which is *NP-hard*, and much research has been devoted to finding efficient algorithms that will provide near-optimal solutions. In the TSP we are given a set of cities and the distances between them, and our task is to find the optimal tour that will visit each city once and will minimize the total distance traveled. In formulating the TSP as a QAP the distance matrix  $D$  is the corresponding distance matrix of the TSP, and the flow matrix  $F$  is the adjacency matrix of a complete cycle of length  $n$ . Without loss of generality the distance matrix  $D$  is considered to be symmetric. A complete cycle or tour is then defined by a permutation  $\phi$ . The traveling salesman problem (TSP) is a notorious *NP-hard* combinatorial optimization problem. Among the abounding literature on the TSP, [89] is a comprehensive reference.

In the *linear arrangement problem* we are given a graph  $G = (V, E)$  and wish to place its vertices at the points  $1, \dots, n$  on the line so as to minimize the sum of pairwise distances between vertices of  $G$  which are joined by some edge. If we consider the more general version of weighted graphs than we obtain the *backboard wiring problem*. This is an *NP-hard* problem as mentioned in [58]. It can be formulated as a QAP with distance matrix the (weighted) adjacency matrix of the given graph, and flow matrix  $F = (f_{ij})$  given by  $f_{ij} = |i - j|$ , for all  $i, j$ . In the *minimum weight feedback arc set problem* (FASP) a weighted digraph  $G = (V, E)$  with vertex set  $V$  and arc set  $E$  is given. The goal is to remove a set of arcs from  $E$  with minimum overall weight, such that all directed cycles, so-called *dicycles*, in  $G$  are

destroyed and an acyclic directed subgraph remains. Clearly, the minimum weight feedback arc set problem is equivalent to the problem of finding an acyclic subgraph of  $G$  with maximum weight. The unweighted version of the FASP, that is a FASP where the edge weights of the underlying digraph equal 0 or 1, is called the *acyclic subdigraph problem* and is treated extensively in [74]. An interesting application of the FASP is the so-called triangulation of input-output tables which arises along with input-output analysis in economics used to forecast the development of industries, see [91]. For details and a concrete description of the application of triangulation results in economics, see [41] and [122]. Since the vertices of an acyclic subdigraph can be labeled topologically, that is, such that in each arc the label of its head is larger than that of its tail, the FASP can be formulated as a QAP. The distance matrix of the QAP is the weighted adjacency matrix of  $G$  and the flow matrix  $F = (f_{ij})$  is a lower triangular matrix, that is,  $f_{ij} = -1$  if  $i \leq j$  and  $f_{ij} = 0$ , otherwise. The FASP is well known to be *NP-hard* (see [58,79]).

Another well known *NP-hard* problem which can be formulated as a QAP is the *graph packing problem* (cf. [16]). The graph packing problem can be formulated as a QAP with distance matrix equal to the adjacency matrix of  $G_2$  and flow matrix equal to the adjacency matrix of  $G_1$ . A packing of  $G_2$  into  $G_1$  exists if and only if the optimal value of this QAP is equal to 0. In the positive case the optimal solution of the QAP determines a packing.

### QAP Problem Generators

Since the QAP is a very hard problem from a practical point of view, often heuristics are the only reasonable approach to solve it, and so far there exists no performance guarantees for any of the algorithms developed for the QAP. One possibility to evaluate the performance of heuristics and to compare different heuristics is given by QAP instances with known optimal solution. Heuristics are applied to these instances and the heuristic solution is compared to the optimal one known before hand. The instances with known optimal solution should ideally have two properties: first, they should be representative in terms of their hardness, and secondly, they should not be especially easy for any of the heuristics.

Two generators of QAP instances with known optimal solution have been proposed so far: *Palubeckis' generator* [107] and the *Li–Pardalos generator* [92].

The first method for generating QAP instances with a known optimal solution was proposed by G.S. Palubeckis [107] in 1988. The input of the Palubeckis' algorithm consists of the size  $n$  of the instance to be generated, the optimal solution (permutation)  $\phi$  of the output instance, two control parameters  $w$  and  $z$ , where  $z < w$ , and the distance matrix  $A$  of an  $r \times s$  grid with  $rs = n$ .  $A$  contains rectilinear distances also called *Manhattan distances*, that is, the distance  $a_{ij}$  between two given knots  $i, j$  lying in rows  $r_i, r_j$  and in columns  $c_i, c_j$ , respectively, is given by  $a_{ij} = |r_i - r_j| + |c_i - c_j|$ . The output of the algorithm is a second matrix  $B$  such that  $\phi$  is an optimal solution of  $\text{QAP}(A, B)$ . The idea is to start with a matrix  $B$  such that  $\text{QAP}(A, B)$  is a trivial instance with optimal solution  $\phi$ . Then  $B$  is transformed such that  $\text{QAP}(A, B)$  is not any more trivial, but  $\phi$  continues to be its optimal solution.

Palubeckis starts with a constant matrix  $B = (b_{ij})$  with  $b_{ij} = w$ .  $\text{QAP}(A, B)$  is a trivial problem because all permutations yield the same value of the objective function and thus, are optimal solutions. Hence, also the identity permutation  $\text{id}$  is an optimal solution of  $\text{QAP}(A, B)$ . Then matrix  $B$  is iteratively transformed so that it is not a constant matrix any more and the identity permutation remains an optimal solution of  $\text{QAP}(A, B)$ . In the last iteration the algorithm constructs an instance  $\text{QAP}(A', B)$  with optimal solution  $\phi$  with the help of  $\text{QAP}(A, B)$  with optimal solution the identity permutation  $\text{id}$ , by setting  $A' = (a^{\phi^{(i)}\phi^{(j)}})$ . The optimal value of  $\text{QAP}(A', B)$  equals  $w \sum_{i=1}^n \sum_{j=1}^n a_{ij}$ . D. Cyganski, R.F. Vaz and V.G. Virball [42] have observed that the QAP instances generated by Palubeckis' generator are 'easy' in the sense that their optimal value can be computed in polynomial time by solving a linear program.

Another generator of QAP instances with known solution has been proposed by Li and Pardalos [92]. As Palubeckis' generator, Li and Pardalos starts with a trivial instance  $\text{QAP}(A, B)$  with the identity permutation  $\text{id}$  as optimal solution and iteratively transforms  $A$  and  $B$  so that the resulting QAP instance still has the optimal solution  $\text{id}$  but is not trivial any more. The transformations are such that for all  $i, j, i', j'$ ,  $a_{ij} \geq a_{i'j'}$  is equivalent to  $b_{ij} \leq b_{i'j'}$  at the end of each iteration.

If the coefficient matrices are considered as weighted adjacency matrices of graphs, each iteration transforms entries corresponding to some specific subgraph equipped with signs on the edges and hence called sign-subgraphs. The application of the Li–Pardalos algorithm with different sign-subgraphs yields different QAP generators. A number of generators involving different sign-subgraphs, for example, subgraphs consisting of a single edge, signed triangles and signed spanning trees have been tested. It is perhaps interesting and surprising that QAP instances generated by involving more complex sign-subgraphs are generally 'easier' than those generated by involving subgraphs consisting of single edges. Here a QAP instance is considered to be 'easy', if most heuristics applied to it find a solution near to the optimal one in a relatively short time. Nothing is known about the complexity of QAP instances generated by the Li–Pardalos generator, since the arguments used to analyze Palubeckis' generator do not apply in this case.

## Surveys and Books

In this concluding section a list of survey articles and books which cover all the aspects of the QAP in depth is given.

One of the early survey articles is [51] where the eigenvalue based lower bounds for the QAP are introduced. The survey papers [20,112] and [25] cover every aspect of the QAP. Specifically, the article [25] is the most recent one, and the most comprehensive. A collection of articles with theoretical and algorithmic contributions for the QAP can be found in the book [113]. The book [35] has a comprehensive introduction on the QAP, and focuses on special cases of the QAP which can be solved in polynomial time. Finally the book [106] focuses on polyhedral aspects of the QAP.

Global optimization; Fractional programming; Dinkelbach method

Given two continuous functions  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  and  $g: \mathbf{R}^n \rightarrow \mathbf{R}$  defined on a polyhedral set  $S \subseteq \mathbf{R}^n$  such that  $g(x) > 0$  for all  $x \in S$ , the *fractional programming problem* is to find some point  $x^*$  which satisfies

$$\frac{f(x^*)}{g(x^*)} = \max_{x \in S} \frac{f(x)}{g(x)}. \quad (1)$$

Applications and algorithms for fractional programs have been treated in considerable detail since the early work of J.R. Isbell and W.H. Marlow [5]. Included among the many applications are portfolio selection, stock cutting, game theory, and numerous decision problems in management science. See [3] for work known to up to 1971 and [1,4,12,13] for the most recent surveys.

If  $f(x)$  is concave and nonnegative and  $g(x)$  and  $S$  are convex (and  $S$  is bounded), then (1) is called a concave-convex fractional program. It was shown in [10] that such problems can be solved by a single concave problem using a simple variable transformation. This provides an efficient approach for solving a limited class of fractional programming problems. Unfortunately, even in some of the simplest cases (for example when  $f(x)$  and  $g(x)$  are quadratic) a new constraint, which may be nonlinear, must be added (to the transformed feasible region), and the transformed problem becomes very difficult to solve. In addition, if the problem is not concave-convex initially, then the transformation does not even necessarily yield a concave problem. In fact, in the most general case, Eq (1) may have many local maxima which are different from the optimal one, and hence determining the global maximum is very difficult (i. e., NP-hard).

A different and more recent method is to replace the nonlinear functions by suitable linear underestimators and then obtain the global optimum by a vertex ranking procedure. This method, due to P.M. Pardalos [6],

is applicable only when  $f(x)$  is a convex quadratic function and  $g(x)$  is linear (hence the ratio is quasiconvex).

Another well-known approach, and one of the oldest, is to consider the global optimization problem

$$\max_{x \in S} f(x) - \lambda g(x), \quad (2)$$

where  $\lambda \in \mathbf{R}$  is a constant. This ‘parametric’ approach, which was first proposed by W. Dinkelbach [2], generates a sequence of values  $\lambda_i$  that converges to the global optimum function value [11]. This method has since then been applied to many specific types of fractional programs including the concave-convex type, but very little work has been done to solve fractional programs where the ratio of two concave, two convex, or the ratio of a convex and a concave function is to be maximized. In addition, this method does not provide a sequence of improving upper bounds, and hence even though the sequence  $\lambda_i$  may be converging to the global optimum function value, no bound on the error is available at any iteration.

The method discussed here improves Dinkelbach’s algorithm by providing a means for obtaining a sequence of improving upper bounds which, along with the corresponding sequence of improving lower bounds, will provide a bound on the error at each iteration of the solution procedure. In addition, both the sequence of lower bounds and the sequence of upper bounds converge to the global optimum function value at a ‘superlinear’ rate. This algorithm is also appropriate for the class of quadratic fractional programs (i. e., one or both of  $f(x)$  and  $g(x)$  are quadratic) where the ratio may involve concave, convex, or even indefinite terms. It combines Dinkelbach’s approach with a method guaranteed to solve linearly constrained quadratic programming problems regardless of the definiteness of the quadratic form [8].

Two algorithms which are similar to the one presented here are given in [4,11]. *Schaible’s method* [11] first computes a sequence of improving upper and lower bounds using an efficient section method. *Dinkelbach’s algorithm* is then started as soon as the section method achieves a set of bounds that differ by some pre-specified tolerance. The algorithm presented here differs from Schaible’s method in that the upper and lower bounds are continuously improving throughout the procedure. Nevertheless, in both algorithms the se-

quence of upper and lower bounds converges superlinearly.

Likewise, [4] presents a variety of related algorithms which also provide upper and lower bounds. These algorithms combine Dinkelbach’s approach with various search techniques (e. g., Newton, binary, modified binary). The result is a set of related algorithms with convergence rates that vary depending on the search technique employed. T. Ibaraki [4] also provides a collection of computational results for the fractional knapsack problem and quadratic fractional programs.

**Problem Formulation and Properties**

The fundamental result which relates the global optimization problem (2) to the general fractional programming problem (1) is as follows:  $x^*$  solves the fractional programming problem (1) if and only if  $x^*$  solves the global optimization problem (2) with constant  $\lambda^* = f(x^*)/g(x^*)$ .

Dinkelbach’s original iterative algorithm is based on this theorem and can be described as follows:

```

1 | Select some  $x^{(0)} \in S$ .
   | Set  $\lambda^{(0)} = f(x^{(0)})/g(x^{(0)})$  and  $k = 0$ .
2 | Solve the constrained global optimization
   | problem (2) to get the optimal solution point
   |  $x^{(k+1)}$ .
3 | IF  $f(x^{(k+1)}) - \lambda^{(k)}g(x^{(k+1)}) = 0$ ,
   | THEN set  $x^* = x^{(k+1)}, \lambda^* = \lambda^{(k)}$ ,
   | STOP.
4 | IF  $f(x^{(k+1)}) - \lambda^{(k)}g(x^{(k+1)}) > 0$ ,
   | THEN set  $\lambda^{(k+1)} = f(x^{(k+1)})/g(x^{(k+1)})$  and  $k =$ 
   |  $k + 1$ .
   | Go to Step 2.
    
```

**Dinkelbach(S, f, g)**

The efficiency of this algorithm depends on the number of times the constrained global optimization problem must be solved, and on the time spent solving it during each iteration. Also note that a test of the form  $f(x^{(k+1)}) - \lambda^{(k)}g(x^{(k+1)}) < 0$  is not necessary since, for any fixed  $k$ ,

$$\begin{aligned}
 f(x^{(k+1)}) - \lambda^{(k)}g(x^{(k+1)}) &= \max_{x \in S} f(x) - \lambda^{(k)}g(x) \\
 &\geq f(x^{(k)}) - \lambda^{(k)}g(x^{(k)}) \\
 &= 0 .
 \end{aligned}$$

Now consider the function  $M(\lambda)$  defined as

$$M(\lambda) = \max_{x \in S} f(x) - \lambda g(x) . \tag{3}$$

The function  $M(\lambda)$  has two interesting properties that are important in guaranteeing convergence of upper and lower bounds to  $\lambda^*$  and in determining the rate of this convergence. The first of these properties is that for any lower bound  $\lambda$  of  $\lambda^*$ ,  $M(\lambda)$  is positive, and for any upper bound  $\lambda$  of  $\lambda^*$ ,  $M(\lambda)$  is negative. Secondly, the function  $M(\lambda)$  is convex. That is,

- 1)  $M(\lambda) > 0$  for all  $\lambda < \lambda^*$ , and  $M(\lambda) < 0$  for all  $\lambda > \lambda^*$ ; and
- 2)  $M(\lambda)$  is convex.

The sequence of iterates  $\lambda^{(0)}, \lambda^{(1)}, \dots$  generated by the algorithm Dinkelbach(S, f, g) is strictly monotone increasing, and satisfy  $M(\lambda^{(i)}) > 0$  for  $i = 0, 1, \dots$ [2]. Hence, by the properties of  $M(\lambda)$  listed above, they provide a strictly monotone increasing sequence of lower bounds for  $\lambda^*$ .

**Bounds and Convergence Rates**

The sequence of lower bounds  $\lambda^{(i)}$  converges superlinearly to  $\lambda^* \equiv f(x^*) : g(x^*) \rightarrow$  where  $x^*$  is any optimal solution for (1) as shown in [7]. However, as it now stands, the algorithm Dinkelbach(S, f, g) does not provide upper bounds on the global optimum function value  $\lambda^*$ . One way to obtain an initial upper bound is to solve the following two problems:

$$\max_{x \in S} f(x) \tag{3a}$$

to get the optimal solution  $f(x')$ , and

$$\min_{x \in S} g(x) \tag{4}$$

to get the optimal solution  $g(x'')$ . Then an initial upper bound is clearly given by  $\gamma^{(-1)} \equiv f(x')/g(x'')$ . In fact, according to the properties of  $M$  (part 1), any  $\gamma \in \mathbf{R}$  satisfying  $M(\gamma) < 0$  would also be an upper bound. Hence, if we define

$$\gamma^{(n)} \equiv \gamma^{(n-1)} - M(\gamma^{(n-1)}) \cdot \left( \frac{\gamma^{(n-1)} - \lambda^{(n)}}{M(\gamma^{(n-1)}) - M(\lambda^{(n)})} \right)$$

where  $\lambda^{(n)}$  is the most recent lower bound of  $\lambda^*$  and  $\gamma^{(n-1)}$  is the most recent upper bound of  $\lambda^*$ , then the new upper bound is given by  $\gamma^{(n)}$ . As Fig. 1 illustrates,

$\gamma^{(n)}$  is just the root of the line segment joining the points  $(\lambda^{(n)}, M(\lambda^{(n)}))$  and  $(\gamma^{(n-1)}, M(\gamma^{(n-1)}))$ .

This leads to an important modification of the algorithm Dinkelbach( $S, f, g$ ):

- 1 Select some  $x^{(0)} \in S$ .  
Set  $\lambda^{(0)} = f(x^{(0)})/g(x^{(0)})$ .
- 2 Solve the constrained global optimization problems (4) and (5) to get the optimal function values  $f(x')$  and  $g(x')$ , respectively.  
Set  $\gamma^{(-1)} = f(x')/g(x')$  and  $k = 0$ .  
IF  $\gamma^{(-1)} - \lambda^{(0)} \leq \delta$ ,  
THEN set  $\lambda^* = \lambda^{(0)}$  and  $x^* = x^{(0)}$ ;  
STOP.
- 3 Solve the constrained global optimization problem

$$M(\lambda^{(k)}) = \max_{x \in S} f(x) - \lambda^{(k)} g(x) \quad (6)$$

to get the optimal solution point  $x^{(k+1)}$ .

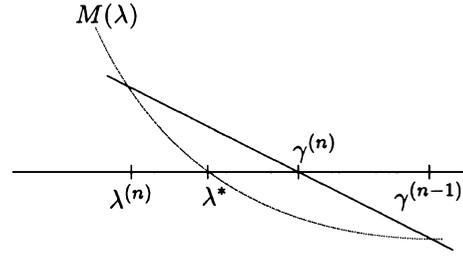

- 4 IF  $M(\lambda^{(k)}) = 0$ ,  
THEN set  $x^* = x^{(k+1)}$  and  $\lambda^* = \lambda^{(k)}$ ;  
STOP.
- 5 Solve the constrained global optimization problem

$$M(\gamma^{(k-1)}) = \max_{x \in S} f(x) - \gamma^{(k-1)} g(x) \quad (7)$$

to get the optimal solution point  $y^{(k)}$ .

- 6 IF  $M(\gamma^{(k-1)}) = 0$ ,  
THEN set  $x^* = y^{(k)}$  and  $\lambda^* = \gamma^{(k-1)}$ ;  
STOP.
- 7 Set
 
$$\gamma^{(k)} = \gamma^{(k-1)} - M(\gamma^{(k-1)}) \cdot \left( \frac{\gamma^{(k-1)} - \lambda^{(k)}}{M(\gamma^{(k-1)}) - M(\lambda^{(k)})} \right).$$
- 8 IF  $\gamma^{(k)} - \lambda^{(k)} \leq \delta$ ,  
THEN set  $\lambda^* = \lambda^{(k)}$  and  $x^* = x^{(k+1)}$ ;  
STOP.
- 9 Set  $\lambda^{(k+1)} = f(x^{(k+1)})/g(x^{(k+1)})$  and  $k = k + 1$ .  
Go to Step 3.

Fract( $S, f, g, \delta$ )

Quadratic Fractional Programming: Dinkelbach Method, Figure 1

Note that the parameter  $\delta \geq 0$  is a user supplied stopping tolerance. The following assertion from [7] shows that the sequence iterates  $\gamma^{(-1)}, \gamma^{(0)}, \gamma^{(1)}, \dots$  is, in fact, a sequence of upper bounds on  $\lambda^*$ , and that the sequence is strictly monotonically decreasing:

$$\lambda^* \leq \gamma^{(i+1)} \leq \gamma^{(i)} \quad \text{for } i = -1, 0, 1, \dots$$

In fact, the sequence of upper bounds  $\gamma^{(i)}$  also converges to  $\lambda^*$ , and this convergence is superlinear as well [7].

### Special Cases

If the feasible set  $S$  is polyhedral and the functions  $f(x)$  and  $g(x)$  are either linear or quadratic, then the algorithm solves a sequence of linear or quadratic programs, respectively. In particular, if  $f(x) = c^T x$  and  $g(x) = d^T x$  then the algorithm solves the sequence of linear programs

$$\max_{x \in S} (c - \lambda^{(k)} d)^T x \quad (8)$$

If both  $f(x)$  and  $g(x)$  are quadratic, i. e.,  $f(x) = (1/2) x^T Q x + c^T x$  and  $g(x) = (1/2) x^T P x + d^T x$ , then the algorithm solves the sequence of quadratic programs

$$\max_{x \in S} \frac{1}{2} x^T (Q - \lambda^{(k)} P) x + (c - \lambda^{(k)} d)^T x. \quad (9)$$

Notice that the matrix  $(Q - \lambda^{(k)} P)$  may be indefinite, in which case the algorithm is required to find the global maximum of a linearly constrained indefinite quadratic function. Even though this is an  $NP$ -hard problem (e. g., when  $(Q - \lambda^{(k)} P)$  is positive definite), the method developed by A.T. Phillips and J.B. Rosen [8] is guaranteed to find an  $\epsilon$ -approximate global maximum (i. e., the relative error is no larger than  $\epsilon$ ) for any specified  $\epsilon > 0$ .

Furthermore, if  $f(x)$  and  $g(x)$  are such that  $f(x) - \lambda g(x)$  is only ‘partially separable’, then the method developed in [9] can be used to find an  $\epsilon$ -approximate global maximum for any  $\epsilon > 0$ . Specifically, the method in [9] is guaranteed to find solutions to the sequence of subproblems (6) and (7) if  $x$  can be partitioned into two components  $x = (w, z)$  such that  $f(x) - \kappa g(x)$  (where the constant  $\kappa = \lambda^{(k)}$  or  $\gamma^{(k-1)}$ ) can be written in the form  $\phi(w) + \psi(z)$  where  $\phi(w)$  is a separable convex function of  $w$  and  $\psi(z)$  is a concave (but not necessarily separable) function of  $z$ . The applicability of these methods to the solution of these subproblems greatly extends the class of fractional programming problems that can be solved in practice.

## Introduction

In this paper we consider a quadratic programming (QP) problem of the following form:

$$\begin{aligned} \min \quad & f(x) = \frac{1}{2}x^T Qx + c^T x \\ \text{s.t.} \quad & x \in D \end{aligned} \quad (1)$$

where  $D$  is a polyhedron in  $\mathbb{R}^n$ ,  $c \in \mathbb{R}^n$ . Without any loss of generality, we can assume that  $Q$  is a real symmetric ( $n \times n$ )-matrix. If this is not the case, then the matrix  $Q$  can be converted to symmetric form by replacing  $Q$  by  $(Q + Q^T)/2$ , which does not change the value of the objective function  $f(x)$ . Note that if  $Q$  is positive semidefinite, then Problem (1) is considered to be a convex minimization problem. When  $Q$  is negative semidefinite, Problem (1) is considered to be a concave minimization problem. When  $Q$  has at least one positive and one negative eigenvalue (i. e.,  $Q$  is indefinite), Problem (1) is considered to be an indefinite quadratic programming problem. We know that in the case of convex minimization problem, every Kuhn-Tucker point is a local minimum, which is also a global minimum. In this case, there are a number of classical optimization methods that can obtain the globally optimal solutions of quadratic convex programming problems. These methods can be found in many places in the literature. In the case of concave minimization over polytopes, it is well known that if the problem has an optimal solution, then an optimal solution is attained at a vertex of  $D$ . On the other hand, the global minimum is not necessarily attained at a vertex of  $D$  for infinite quadratic programming problems. In this case, from second order optimality conditions, the global minimum is attained at the boundary of the feasible domain. In this research, without loss of generality, we are interested in developing solution techniques to solve general (convex, concave and indefinite) quadratic programming problems.

## Complexity of Quadratic Programming

In this section we discuss the complexity of quadratic programming problems. The complexity analysis can

give an idea of the possibility of developing efficient algorithms for solving the problem. In [10], the QP was shown to be  $\mathcal{NP}$ -hard in the case of a negative definite matrix  $Q$ . The QP was also proven to be  $\mathcal{NP}$ -hard by reduction to the satisfiability problem [11], and reduction to the knapsack feasibility problem [5]. Moreover, it has also been shown that checking local optimality for the QP itself is an  $\mathcal{NP}$ -hard problem [11]. In addition, checking for strict convexity (checking local optimality as part of the second order necessary conditions) in the QP was proven to be  $\mathcal{NP}$ -hard [8]. In fact, finding a local minimum and proving local optimality of such a solution to the QP may take exponential time. This is true even in the case of a small number of concave variables. For instance, although the matrix  $Q$  is of rank one with exactly one negative eigenvalue, the QP is still  $\mathcal{NP}$ -hard [9]. However, a large number of negative eigenvalues does not necessarily make the problem harder to solve. For example, consider the following problem:

$$\begin{aligned} \min \quad & \frac{1}{2}x^T Qx + c^T x \\ \text{s.t.} \quad & x \geq 0. \end{aligned}$$

If the matrix  $Q$  has  $(n - 1)$  negative eigenvalues, then there must be at least  $(n - 1)$  active constraints at the optimal solution [3]. Correspondingly, it is sufficient to solve  $(n - 1)$  different problems, in each case setting  $(n - 1)$  of the constraints to equalities, to find the optimal solution. In general, if the matrix  $Q$  has  $(n - k)$  negative eigenvalues, then we are required to solve  $\frac{n!}{k!(n-k)!}$  independent problems. In addition, the total computational time required to solve this problem is proportional to  $\frac{k^3 c^k n!}{k!(n-k)!}$ . Thus, if  $k$  is a constant and independent of  $n$ , then the computational time is bounded by a polynomial in  $n$ . On the other hand, if  $k$  grows with  $n$ , then the computational time can grow exponentially with  $n$  [3].

## Equivalence Between Discrete and Continuous Problems

Before we show the equivalence between discrete and continuous programs, it is important to discuss an equivalence property between two extremum problems [2]. Therefore, we refer to the following theorem (see [2] for a proof).

**Theorem 1** Let  $\bar{Z}$  and  $\bar{X}$  be compact sets in  $\mathbb{R}^n$ ,  $R$  be a closed set in  $\mathbb{R}^n$ , and let the following hypotheses hold.

- H<sub>1</sub>)**  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  is a bounded function on  $\bar{X}$ , and there exists an open set  $A \subset \bar{Z}$  and real number  $\alpha, L > 0$  such that, for any  $x, y \in S$ ,  $f$  satisfies the following Hölder condition:  $|f(x) - f(y)| \leq L\|x - y\|^\alpha$ .
- H<sub>2</sub>)** It is impossible to find  $\varphi: \mathbb{R}^n \rightarrow \mathbb{R}$  such that
  - (i)  $\varphi$  is continuous on  $\bar{X}$ ,
  - (ii)  $\varphi(x) = 0, x \in \bar{Z}; \varphi(x) > 0, x \in \bar{X} - \bar{Z}$ ,
  - (iii)  $\forall z \in \bar{Z}$ , there exists a neighborhood  $S(z)$  and a real  $\bar{\epsilon} > 0$  such that, for any  $x \in S(z) \cap (\bar{X} - \bar{Z})$ ,  $\varphi(x) \geq \bar{\epsilon}\|x - z\|^\alpha$ .

Then a real  $\mu_0$  exists such that for any real  $\mu \geq \mu_0$ ,  $\min f(x), x \in \bar{Z} \cap R$  is equivalent to  $\min[f(x) + \mu\varphi(x)], x \in \bar{X} \cap R$ .

Now we can show an equivalence between discrete and continuous programs from the following theorem [2].

**Theorem 2** Let  $e^T = (1, 1, \dots, 1)$ ,  $\bar{Z} = \mathbb{B}^n$ ,  $\bar{X} = \{x \in \mathbb{R}^n; 0 \leq x \leq e\}$ ,  $R = \{x \in \mathbb{R}^n; g(x) \geq 0\}$ . Consider the problem

$$\begin{aligned} \min \quad & f(x) \\ \text{s.t.} \quad & g(x) \geq 0, \quad x \in B^n, \end{aligned} \tag{2}$$

and the problem

$$\begin{aligned} \min \quad & [f(x) + \mu x^T(e - x)] \\ \text{s.t.} \quad & g(x) \geq 0, \quad 0 \leq x \leq e. \end{aligned} \tag{3}$$

Then we suppose that  $f$  verifies assumption  $H_1$  from Theorem 1 with  $\alpha = 1$ ; that is, it is bounded on  $\bar{X}$  and Lipschitz continuous on an open set  $A \supseteq \bar{Z}$ . Subsequently, there exists some  $\mu_0 \in \mathbb{R}$  such that  $\forall \mu < \mu_0$  Problems (2) and (3) are equivalent.

### Integer Programming Problems and Complementarity Problems

The connections between integer programs and complementarity problems can be exhibited by applying KKT conditions. The results can be generalized in the quadratic programming case [4].

**Theorem 3** Let us first assume

3a)  $f: \mathbb{R}^n \rightarrow \mathbb{R}, g: \mathbb{R}^n \rightarrow \mathbb{R}$  are continuously differentiable functions.

3b)  $g(x)$  satisfies a constraint qualification condition at  $x^0$  to ensure that KKT conditions are validated.

Then the nonlinear programming problem

$$\begin{aligned} \min \quad & f(x) \\ \text{s.t.} \quad & g(x) \geq 0, \quad x \geq 0, \end{aligned} \tag{4}$$

has an optimal solution  $x^0$  if there exist  $u^0 \in \mathbb{R}^n, y^0, v^0 \in \mathbb{R}^v$  such that  $(x^0, y^0, u^0, v^0)$  is an optimal solution to the following problem:

$$\begin{aligned} \min \quad & f(x) \\ \text{s.t.} \quad & f'(x) - y^T g'(x) - u = 0, \\ & g(x) - v = 0, \\ & y^T v = 0 \\ & x^T u = 0 \\ & x, y, u, v \geq 0. \end{aligned} \tag{5}$$

*Proof 1 Necessity.* If  $x^0$  is an optimal solution to Problem (4), from KKT conditions we obtain  $(y^0, u^0)$  such that

$$\begin{aligned} f'(x^0) - y^{0T} g(x^0) - u^0 &= 0, \\ g(x^0) &\geq 0, \\ x^{0T} u^0 &= 0, \\ x^0, y^0, u^0 &\geq 0. \end{aligned}$$

Let  $v^0 = g(x^0)$ , then  $(x^0, y^0, u^0, v^0)$  is an optimal solution to Problem (5).

*Sufficiency.* The proof is trivial. □

We now generalize the results of Theorem 3 to the quadratic programming case. Consider the following problem

$$\begin{aligned} \min \quad & \frac{1}{2} x^T Q x + c^T x \\ \text{s.t.} \quad & Ax \geq b, \\ & x \in B^n, \end{aligned} \tag{6}$$

where  $Q$  is a symmetric matrix. Using Theorem 2, Problem (6) is equivalent to

$$\begin{aligned} \min \quad & \left[ \frac{1}{2} x^T (Q - 2\mu I)x + (c^T + \mu e^T)x \right] \\ \text{s.t.} \quad & Ax \geq b, \\ & x \leq e, \\ & x \geq 0. \end{aligned} \tag{7}$$

Applying Theorem 3 to Problem (7), we then obtain

$$\min \left[ \frac{1}{2}x^T(Q - 2\mu I)x + (c^T + \mu e^T)x \right] \quad (8)$$

$$\text{s.t.} \quad c + Qx + \mu(e - 2x) - y^T A + t = u, \quad (9)$$

$$b - Ax = v, \quad (10)$$

$$e - x = w, \quad (11)$$

$$x^T u = 0, \quad (12)$$

$$y^T v = 0, \quad (13)$$

$$t^T w = 0, \quad (14)$$

$$x, y, t, u, v, w \geq 0. \quad (15)$$

Arrange the terms in (9), we then have  $Qx - 2\mu x = -(c + \mu e) + y^T A - t + u$ . Consequently, (8) becomes  $\min[\frac{1}{2}(c^T + \mu e^T)x + \frac{1}{2}(b^T y - e^T t)]$ . From (12), (13), and (14), we have

$$\begin{aligned} x^T u &= 0, \\ 0 &= y^T v = y^T b - y^T A x, \\ 0 &= t^T w = t^T e - t^T x; \end{aligned}$$

therefore,  $y^T b = y^T A x$  and  $t^T e = t^T x$ . Taken all together, Problem (6) is equivalent to the following problem.

$$\begin{aligned} \min \quad & \hat{c}^T \hat{x} \\ \text{s.t.} \quad & \hat{A} \hat{x} + \hat{u} = \hat{b}, \\ & \hat{x} \hat{u} = 0, \\ & \hat{x}, \hat{u} \geq 0, \end{aligned}$$

where

$$\begin{aligned} \hat{x}^T &= (x^T, y^T, t^T), \\ \hat{u}^T &= (u^T, v^T, w^T), \\ \hat{A} &= \begin{pmatrix} -Q + 2\mu I & A^T & -I \\ A & 0 & 0 \\ I & 0 & 0 \end{pmatrix}, \\ \hat{c}^T &= \frac{1}{2}(c^T + \mu e^T + e^T, b^T, e^T), \\ \hat{b}^T &= (c^T, b^T, e^T). \end{aligned}$$

Note that there are no restrictive assumptions made on  $Q$ , this transformation is applicable to the convex case as well as the nonconvex case.

### Integer Programming Problems and Quadratic Integer Programming Problems

Integer programming is used to model a variety of important practical problems in operations research, engineering, and computer science. Consider the following linear zero-one programming problem:

$$\begin{aligned} \min \quad & c^T x \\ \text{s.t.} \quad & Ax \leq b, \quad x_i \in \{0, 1\}, \quad (i = 1, \dots, n) \end{aligned}$$

where  $A$  is a real  $(m \times n)$ -matrix,  $c \in \mathbb{R}^n$  and  $b \in \mathbb{R}^m$ . Let  $e^T = (1, \dots, 1) \in \mathbb{R}^n$  denote the vector whose components are all equal to 1. Then the zero-one integer linear programming problem is equivalent to the following concave minimization problem:

$$\begin{aligned} \min \quad & f(x) = c^T x + \mu x^T (e - x) \\ \text{s.t.} \quad & Ax \leq b, \quad 0 \leq x \leq e \end{aligned}$$

where  $\mu$  is a sufficiently large positive integer. We know that the function  $f(x)$  is concave because  $-x^T x$  is concave.

The equivalence of the two problems is based on the facts that a concave function attains its minimum at a vertex and that  $x^T(x - e) = 0$ ,  $0 \leq x \leq e$ , implies  $x_i = 0$  or  $1$  for  $i = 1, \dots, n$ . We note that a vertex of the feasible domain is not necessarily a vertex of the unit hypercube  $0 \leq x \leq e$ , but the global minimum is attained only when  $x^T(e - x) = 0$ , provided that  $\mu$  is a sufficiently large number.

These transformation techniques can be applied to reduce quadratic zero-one problems to equivalent concave minimization problems. For instance, consider a quadratic zero-one problem of the following form:

$$\begin{aligned} \min \quad & f(x) = c^T x + x^T Q x \\ \text{s.t.} \quad & x \in \{0, 1\} \end{aligned}$$

where  $Q$  is a real symmetric  $(n \times n)$  matrix. Given any real number  $\mu$ , let  $\tilde{Q} = Q + \mu I$  where  $I$  is the  $(n \times n)$  unit matrix, and  $\tilde{c} = c - \mu e$ . Because of  $\tilde{f}(x) = f(x)$ , the above quadratic zero-one problem is equivalent to the problem:

$$\begin{aligned} \min \quad & f(x) = \tilde{c}^T x + x^T \tilde{Q} x \\ \text{s.t.} \quad & x_i \in \{0, 1\}, \quad (i = 1, \dots, n) \end{aligned}$$

In this case, if we choose  $\mu$  such that  $\bar{Q} = Q + \mu I$  becomes a negative semidefinite matrix (e. g.,  $\mu = -\lambda$ , where  $\lambda$  is the largest eigenvalue of  $Q$ ), then the objective function  $\bar{f}(x)$  becomes concave and the constraints can be replaced by  $0 \leq x \leq e$ . Thus, this problem is equivalent to the minimization of a quadratic concave function over the unit hypercube [4].

### Various Equivalent Forms of Quadratic Zero-One Programming Problems

The problem considered here is a quadratic zero-one program, which has the form

$$\begin{aligned} \min f(x) &= x^T Q x, \\ \text{s.t.} \quad x_i &\in \{0, 1\}, \quad i = 1, \dots, n, \end{aligned} \tag{16}$$

where  $Q$  is an  $n \times n$  matrix [6,7]. Throughout this section the following notation will be used.

- $\{0, 1\}^n$ : set of  $n$  dimensional 0–1 vectors.
- $R^{n \times n}$ : set of  $n \times n$  dimensional real matrices.
- $R^n$ : set of  $n$  dimensional real vectors.

In order to formalize the notion of equivalence we need some definitions.

**Definition 1** The problem  $P$  is “polynomially reducible” to problem  $P_0$  if given an instance  $I(P)$  of problem  $P$ , an instance  $I(P_0)$  of problem  $P_0$  can be obtained in polynomial time such that solving  $I(P)$  will solve  $I(P_0)$ .

**Definition 2** Two problems  $P_1$  and  $P_2$  are called “equivalent” if  $P_1$  is “polynomially reducible” to  $P_2$  and  $P_2$  is “polynomially reducible” to  $P_1$ .

Consider the following three problems:

$$\begin{aligned} P: \quad \min f(x) &= x^T Q x, \quad x \in \{0, 1\}^n, \\ & \quad Q \in R^{n \times n}, \\ P_1: \quad \min f(x) &= x^T Q x + c^T x, \quad x \in \{0, 1\}^n, \\ & \quad Q \in R^{n \times n}, c \in R^n. \\ P_2: \quad \min f(x) &= x^T Q x, \quad x \in \{0, 1\}^n, \\ & \quad Q \in R^{n \times n}, \\ & \quad \sum_{i=1}^n x_i = k \text{ for some } k \\ \text{s.t.} \quad & 0 \leq k \leq n, \\ & \text{where } x = (x_1, x_2, \dots, x_n). \end{aligned}$$

Next we show that problems  $P, P_1$ , and  $P_2$  are all “equivalent”. Then, formulation  $P_2$  will be used in the rest of the sections.

**Lemma 1**  $P$  is “polynomially reducible” to  $P_1$ .

*Proof 2* It is very easy to see that  $P$  is a special case of  $P_1$ . □

**Lemma 2**  $P_1$  is “polynomially reducible” to  $P$ .

*Proof 3* Problem  $P_1$  is defined as follows:  $\min f(x) = x^T Q x + c^T x, x \in \{0, 1\}^n, Q \in R^{n \times n}, c \in R^n$ . If  $Q = (q_{ij})$  then let  $B = (b_{ij})$  where

$$b_{ij} = \begin{cases} q_{ij} & \text{if } i \neq j \\ q_{ij} + c_i & \text{if } i = j. \end{cases}$$

Since  $x_i^2 = x_i$  (because  $x_i \in \{0, 1\}$ ), we have  $g(x) = x^T B x = x^T Q x + c^T x$ . So the following problem is equivalent to problem  $P_1$  :  $\min g(x) = x^T B x, x \in \{0, 1\}^n, B \in R^{n \times n}$ . □

Using Lemma 1 and Lemma 2, it is evident that  $P$  and  $P_1$  are “equivalent”.

**Lemma 3**  $P_2$  is “polynomially reducible” to  $P$ .

*Proof 4* Problem  $P_2$  is as follows:  $\min f(x) = x^T Q x, x \in \{0, 1\}^n, Q \in R^{n \times n}, \sum_{i=1}^n x_i = k$  for some  $k$  s.t.  $0 \leq k \leq n$ . If  $Q = (q_{ij})$  then let  $M = 2[\sum_{j=1}^n \sum_{i=1}^n |q_{ij}|] + 1$ . Now, define the following problem  $P$ :  $\min g(x) = x^T Q x + M(\sum_{i=1}^n x_i - k)^2$  s.t.  $x \in \{0, 1\}^n, Q \in R^{n \times n}$ . Let  $x_b = (x_1^b, \dots, x_n^b)$  and  $x_0 = (x_1^0, \dots, x_n^0)$  such that  $\sum_{i=1}^n x_i^b \neq k$  and  $\sum_{i=1}^n x_i^0 = k$ , then  $g(x_0) \leq \frac{M-1}{2}$  as  $\sum_{i=1}^n x_i^0 = k, g(x_b) \geq \frac{-(M-1)}{2} + M$  or  $g(x_b) \geq \frac{M+1}{2}$  as  $|\sum_{i=1}^n x_i^b - k| \geq 1$ . Therefore,  $g(x_0) < g(x_b)$  if  $\sum_{i=1}^n x_i^b \neq k$  and  $\sum_{i=1}^n x_i^0 = k$ . Hence, if  $\min g(x) = g(x_0)$  where  $x_0 = (x_1^0, \dots, x_n^0)$  then  $\sum_{i=1}^n x_i^0 = k$ . So  $\min f(x) = \min g(x)$ . From the above discussion, it can be easily seen that  $P_2$  is “polynomially reducible” to  $P$ . □

The proof of Lemma 3 also illustrates how equality (knapsack) constraints in a quadratic zero-one program can be eliminated.

**Lemma 4**  $P$  is “polynomially reducible” to  $P_2$ .

*Proof 5* Let problem  $P$  be defined as follows:  $\min f(x) = x^T Q x, x \in \{0, 1\}^n, Q \in R^{n \times n}$ . Define a series of  $(n + 1)$  problems:  $P_2(0), P_2(1), P_2(2), \dots,$

$P_2(n)$ , where  $P_2(j)$  is the following problem  $\min f(x) = x^T Q x$ ,  $x \in \{0, 1\}^n$ ,  $Q \in R^{n \times n}$ ,  $\sum_{i=1}^n x_i = j$ . Let the minimum of the problem  $P_2(j)$  be  $y_j$ , then the minimum of problem  $P$  is easily seen to be the  $\min \{y_0, y_1, \dots, y_n\}$ .  $\square$

Lemma 3 and Lemma 4 imply that  $P$  and  $P_2$  are “equivalent”. Since “equivalent” is a transitive relative,  $P$ ,  $P_1$ ,  $P_2$  are all “equivalent”.

### Complexity of Quadratic Zero-One Programming Problems

Quadratic zero-one programming is a difficult problem. We next will show that the quadratic knapsack zero-one problem in ( $P_2$ ) is a NP hard problem by proving that it is equivalent to the  $k$ -clique problem. A  $k$ -clique is a complete graph with  $k$  vertices.

#### $k$ -clique Problem

Given a graph  $G=(V, E)$  ( $V$  is the set of vertices and  $E$  is the set of edges), does the graph  $G$  have a  $k$ -clique as one of its subgraphs?

$k$ -clique problem is known to be NP-complete. We will show that the  $k$ -clique problem is “polynomially reducible” to problem  $P_2$  defined in the previous subsection.

**Theorem 4** *The  $k$ -clique problem is “polynomially reducible” to  $P_2$ .*

*Proof* Problem  $P_2$  was defined as  $\min f(x) = x^T Q x$ , s.t.  $x_i \in \{0, 1\}$ ,  $i = 1, \dots, n$ ,  $\sum_{i=1}^n x_i = m$  for some  $0 \leq m \leq n$ . Given the graph  $G = (V, E)$ , define  $Q = (q_{ij})$  such that

$$q_{ij} = \begin{cases} 0 & \text{if } (v_i, v_j) \in E \\ -1 & \text{if } (v_i, v_j) \notin E, \end{cases}$$

where  $n = |V|$ ,  $m = k$  (we are trying to find a  $k$ -clique). The meaning attached to the vector  $x \in \{0, 1\}^n$  in problem  $P_2$  is as follows

$$x_i = \begin{cases} 1 & \text{means that } v_i \text{ is in the clique,} \\ 0 & \text{means that } v_i \text{ is not in the clique.} \end{cases}$$

We can easily prove that the graph  $G$  has a  $k$ -clique if and only if  $\min f(x) = -k(k-1)$ . So the  $k$ -clique problem is “polynomially reducible” to  $P_2$ .  $\square$

Problem  $P_2$  is “equivalent” to  $P$ , so problem  $P$  is also NP-hard. Therefore, as the dimension of the problem increases, the necessary CPU time to solve the problem increases exponentially.

### Quadratic Zero-One Programming and Mixed Integer Programming

In this section, we consider a quadratic zero-one programming problem in the following form:

$$\begin{aligned} \min f(x) &= x^T Q x, \\ \text{s.t.} & \sum_{i=1}^n x_i = k, \quad x \in \{0, 1\}^n. \end{aligned} \quad (17)$$

Let  $Q$  be  $n \times n$  matrix, whose each element  $q_{i,j} \geq 0$ . Define  $x = (x_1, \dots, x_n)$ , where each  $x_i$  represents binary decision variables. We will show that the problem in (17) can be linearized as the following mixed integer programming problems. The first linearization technique is trivial and can be found elsewhere. Recently, more efficient linearization technique was introduced in [1]. In addition, the linearization technique for more general case (where  $q_{i,j} \in \text{real}$ ) and multi-quadratic programming was also proposed in [1].

#### Conventional Linearization Approach

For each product  $x_i x_j$  in the objective function of the problem (17) we introduce a new continuous variable,  $x_{ij} = x_i x_j$  ( $i \neq j$ ). Note that  $x_{ii} = x_i^2 = x_i$  for  $x_i \in \{0, 1\}$ . The equivalent mixed integer programming problem (MIP) is given by:

$$\begin{aligned} \min & \sum_i \sum_j q_{ij} x_{ij} \\ \text{s.t.} & \sum_{i=1}^n x_i = k, \\ & x_{ij} \leq x_i, & \text{for } i, j = 1, \dots, n (i \neq j) \\ & x_{ij} \leq x_j, & \text{for } i, j = 1, \dots, n (i \neq j) \\ & x_i + x_j - 1 \leq x_{ij}, & \text{for } i, j = 1, \dots, n (i \neq j) \\ & 0 \leq x_{ij} \leq 1, & \text{for } i, j = 1, \dots, n (i \neq j) \end{aligned} \quad (18)$$

where  $x_i \in \{0, 1\}$ ,  $i, j = 1, \dots, n$ .

The main disadvantage of this approach is that the number of additional variables we need to introduce is

$O(n^2)$ , and the number of new constraints is also  $O(n^2)$ . The number of 0–1 variables remains the same.

### A New Linearization Approach

Consider the following mixed integer programming problem:

$$\begin{aligned}
 \min_{x,y,s} g(s) &= \sum_{i=1}^n s_i = e^T s \\
 \text{s.t.} \quad &\sum_{i=1}^n x_i = k, \\
 &Qx - y - s = 0, \\
 &y \leq \mu(e - x), \\
 &x_i \in \{0, 1\}, \quad \text{for } i = 1, \dots, n \\
 &y_i, s_i \geq 0, \quad \text{for } i = 1, \dots, n.
 \end{aligned} \tag{19}$$

where  $Q$  is an  $n \times n$  matrix, whose each element  $q_{i,j} \geq 0$ .

In [1], the mixed integer 0–1 programming problem in (19) was proved equivalent to the quadratic zero-one programming in (17). The main advantage of this approach is that we only need to introduce  $O(n)$  additional variables and  $O(n)$  new constraints, where the number of 0–1 variables remains the same. This linearization technique proved more robust and more efficiently solving quadratic zero-one and multi-quadratic zero-one programming problems [1].

### Article Outline

[Keywords](#)

[See also](#)

[References](#)

### Keywords

Quadratic programming; Knapsack constraint

The quadratic knapsack problem is one of the simplest quadratic programming problems as defined below (cf. also ► [Quadratic programming with bound constraints](#)):

$$(P) \begin{cases} \min & f(x) = \frac{1}{2}x^T Qx + c^T x \\ \text{s.t.} & \sum_{i=1}^n a_i x_i = M, \\ & 0 \leq x_i \leq 1, \quad i = 1, \dots, n, \end{cases}$$

where  $x \in \mathbf{R}^n$  is a variable vector,  $Q \in \mathbf{R}^{n \times n}$ ,  $c \in \mathbf{R}^n$  and  $M$  is a scalar.

The problems are mainly classified by the nature of matrix  $Q$ . When the matrix  $Q$  is *positive semidefinite*, i.e., the objective function  $f(x)$  is convex, problem (P) can be solved in polynomial time by the *ellipsoid algorithm* [8], and several kinds of interior point algorithms (e.g. [5,7,11], which solve general convex quadratic problems including (P) as a special case). Also, P.M. Pardalos, Y. Ye and C.G. Han [15] show a potential reduction algorithm for the special case of (P) defined below:

$$\begin{cases} \min & \frac{1}{2}x^T Qx \\ \text{s.t.} & \sum_{i=1}^n x_i = 1, \\ & x_i \geq 0, \quad i = 1, \dots, n. \end{cases}$$

In particular, when (P) has a diagonal matrix  $Q$  with positive elements, an  $O(n)$  algorithm has been proposed by P. Brucker [3]. The algorithm generates the corresponding KKT condition using binary search. Pardalos and N. Kuvorov [13] also propose an  $O(n)$  randomized method.

The convex case is important because of its frequent appearance as a subproblem in many application areas. Among those are general convex quadratic programming [9], multicommodity network flow problems [1], resource management [2], and portfolio selection problems [10].

The problem becomes extremely difficult if  $f(x)$  is not convex. S. Sahni [16] shows that the problems with the negative diagonal matrix  $Q$  are *NP-hard* (cf. also ► **Computational complexity theory**; ► **Complexity theory**), which implies that the general indefinite case is also *NP-hard*.

Let  $a_1, \dots, a_n$  and  $b$  be positive integers, and let us consider the *subset sum problem*, which finds a feasible solution of the set defined below:

$$\left\{ x: \sum_{i=1}^n a_i x_i = b, \quad x_i \in \{0, 1\}, \quad i = 1, \dots, n \right\}.$$

The feasibility is determined by the the following concave quadratic knapsack problem:

$$\begin{cases} \min & \sum_{i=1}^n x_i(1 - x_i) \\ \text{s.t.} & \sum_{i=1}^n a_i x_i = M, \quad 0 \leq x_i \leq 1, \quad i = 1, \dots, n. \end{cases}$$

The subset sum problem is feasible if and only if the global optimum value of the corresponding quadratic knapsack problem is zero.

As we see in the above, the indefinite case arises in several combinatorial optimization problems. For example, given a graph  $G(V, E)$  where  $V = \{1, \dots, n\}$  is a set of vertices and  $E \subseteq V^2$  is a set of edges, find the *maximum clique* of  $G$ . This problem can be formulated in the following way:

$$\begin{cases} \min & \sum_{(i,j) \in E} -x_i x_j \\ \text{s.t.} & \sum_{i=1}^n x_i = 1, \\ & x_i \geq 0, \quad i = 1, \dots, n. \end{cases}$$

If  $G$  has a maximum clique of size  $k$ , then the global maximum is  $(1/k - 1)/2$ . We can also formulate the *maximum independent set problem* and the *node covering problem* in a similar fashion.

One can also formulate any quadratic minimization problem over a convex hull by the quadratic knapsack problem. Consider the problem of the form:

$$\begin{cases} \min & q(z) = z^T Mz + r^T z \\ \text{s.t.} & z \in P, \end{cases} \quad (1)$$

where  $z, r \in \mathbf{R}^m$ ,  $M \in \mathbf{R}^{m \times m}$  and  $P \subseteq \mathbf{R}^m$  is the polytope described as the convex hull of a given set of points  $\{v_1, \dots, v_n\}$ . It can be verified easily that the above general quadratic problem has the following equivalent formulation

$$\begin{cases} \min & f(x) = x^T (V^T M V)x + r^T Vx \\ \text{s.t.} & \sum_{i=1}^n x_i = 1, \\ & x_i \geq 0, \quad i = 1, \dots, n, \end{cases} \quad (2)$$

where  $V = [v_1, \dots, v_n]$ . Let  $z^*$  and  $x^*$  be optimum solutions of (1) and (2), respectively. Then we have

$$q(z^*) = f(x^*),$$

and moreover  $z^* = Vx^*$ .

There exist only a few algorithms for obtaining a global optimum solution for the case of the general indefinite  $Q$ . See [15] for a partitioning approach as well as an interior point method, while [4] surveys algorithms for general nonconvex quadratic problems.

The case when the objective function is separable has also been well investigated by several authors. Some practical algorithms to obtain an exact solution are reported in [6,14]. S.A. Vavasis [18] shows an  $O(n(\log n)^2)$  algorithm for finding a local minimum of the problem, while K.G. Murty and S.N. Kabadi [12] show that verifying a local minimum for an indefinite quadratic problem with general constraints is NP-hard. Also, [17] gives an  $\epsilon$ -approximation algorithm which is weakly polynomial in the problem size if the number of negative diagonal elements is fixed.

### Keywords

Quadratic programming; Bounds constraints; Global optimization; Indefinite quadratic problems; Optimality conditions

### Synonyms

QPwBC

### Problem Statement

The *bound constrained quadratic problem* has the following form:

$$\begin{aligned} \min_{x \in \Omega} f(x) &= \min_{x \in \Omega} \frac{1}{2} x^T Q x + c^T x, \\ \Omega &= \{x \in \mathbf{R}^n : l \leq x \leq u\}, \end{aligned} \quad (1)$$

where  $Q = (q_{ij}) \in \mathbf{R}^{n \times n}$  is an indefinite symmetric matrix and  $x, c, l, u \in \mathbf{R}^n$ . Here (as always in the sequel), all inequalities involving vectors are interpreted componentwise, and  $\nabla f(x) = Qx + c$  is the gradient of  $f$ . The region  $\Omega$  is assumed to be nonempty (i. e.  $l_i \leq u_i$  for each  $i \in \{1, \dots, n\}$ ) and may be unbounded (i. e.  $l_i = -\infty$  and/or  $u_i = +\infty$  for some  $i \in \{1, \dots, n\}$ ). The function  $f(x)$  is assumed to be bounded below on  $\Omega$ . For each  $x \in \Omega$ , the *active set*  $A(x)$  is defined as:

$$A(x) = \{i : x_i \in \{l_i, u_i\}\}.$$

Problems of the form (1) naturally arise in a number of different applications. Moreover, QPwBC is a basic subroutine for many nonlinear programming codes, and the monotone *linear complementarity* problem can be written in the above form. For the convex case (i. e.  $Q$  positive semidefinite), which is known to be polynomially solvable [16], many efficient algorithms exist [4,5,7,9,10,12,18,36]. However, not many algorithms exist for the efficient solution of the general nonconvex problem [8,17,22,24,25,26].

From the complexity point of view, problem (1) is NP-hard [32], and even checking local optimality for a feasible point is NP-hard [20,27]. The complexity of finding a stationary point for (1) is an open question (in

the concave case this problem is PLS-complete [15]). Algorithms to construct approximate solutions [33] in polynomial time exist.

### Optimality Conditions

For problem (1) the classical local optimality conditions can be stated in a very special form. Moreover, there exist interesting results about global optimality which lead to efficient numerical procedures.

### Local Optimality Conditions

**Proposition 1** *If  $x^* \in \Omega$  is a local minimum for problem (1) then:*

- A) *if  $q_{ii} \geq 0$ , then*
- i)  $[\nabla f(x^*)]_i = 0$ ; or
  - ii)  $[\nabla f(x^*)]_i > 0$  and  $x_i^* = l_i$ ; or
  - iii)  $[\nabla f(x^*)]_i < 0$  and  $x_i^* = u_i$ .
- B) *if  $q_{ii} < 0$ , then*
- i)  $[\nabla f(x^*)]_i > 0$  and  $x_i^* = l_i$ ; or
  - ii)  $[\nabla f(x^*)]_i < 0$  and  $x_i^* = u_i$ .

Proposition 1 specializes the classical *KKT stationarity conditions*, which only involve first order information, to problem (1) by taking into the account the sign of the second order pure derivatives. If  $x^*$  is *nondegenerate*, i. e.

$$(x_i^* - l_i)(x_i^* - u_i) + |[\nabla f(x^*)]_i| \neq 0$$

for each  $i \in A(x^*)$ , then the conditions A)–B) are sufficient for local minimization.

The following proposition states a relationship between the number of negative eigenvalues of the matrix  $Q$  and the cardinality of the active set at a stationarity point  $x^*$ .

**Proposition 2** *If the matrix  $Q$  has  $k$  negative eigenvalues counting multiplicities, then at least  $k$  constraints are active at a local solution  $x^*$  of problem (1).*

Because of Proposition 2, if  $f$  is concave, the problem is bounded if and only if all upper and lower bounds are finite, and the solution can be found by checking all the vertices of  $\Omega$ . Therefore the concave QPwBC problem is equivalent to a *quadratic zero-one problem* [1,22].

### Global Optimality Conditions

Global optimality conditions for problem (1) can be stated in terms of copositivity [14] of the Hessian matrix.

**Definition 3** An  $n \times n$  matrix  $Q$  is *copositive* with respect to a polyhedral cone  $\Gamma \subset \mathbf{R}^n$  (denoted by  $\Gamma$ -copositive) if and only if

$$v^T Q v \geq 0 \text{ for all } v \in \Gamma \setminus \{0\}$$

(for *strict copositivity*,  $\geq$  has to be replaced by  $>$ ).

**Definition 4** Given  $\bar{x} \in \Omega$ , the *tangent cone*  $\Gamma(\bar{x})$  of  $\Omega$  in  $\bar{x}$  is defined as

$$\Gamma(\bar{x}) = \{v \in \mathbf{R}^n : \bar{x} + \alpha v \in \Omega \text{ for some } \alpha > 0\}.$$

**Definition 5** Given  $\bar{x} \in \Omega$  and  $v \in \mathbf{R}^n$ , we define  $\lambda(\bar{x}, v)$  as follows:

$$\lambda(\bar{x}, v) = \max \{ \lambda \geq 0 : \bar{x} + \lambda v \in \Omega \}.$$

Let us consider the following decomposition for the cone  $\Gamma(x)$ :

$$\Gamma(x) = \left( \bigcup_{i=1}^n \Gamma_i^+(x) \right) \cup \left( \bigcup_{i=1}^n \Gamma_i^-(x) \right),$$

where

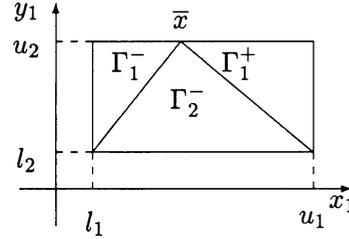

$$\begin{aligned} \Gamma_i^+(x) &= \{v \in \Gamma : [x + \lambda(x, v) \cdot v]_i = u_i\}, \\ \Gamma_i^-(x) &= \{v \in \Gamma : [x + \lambda(x, v) \cdot v]_i = l_i\}, \\ & i = 1, \dots, n, \end{aligned}$$

i. e. if  $v \in \Gamma_i^+(x) \setminus \{0\}$  (or  $v \in \Gamma_i^-(x) \setminus \{0\}$ ), then  $v_i \neq 0$  and the maximum stepsize along  $v$  moving from  $x$  saturates the  $i$ th upper (lower) constraint (see Fig. 1).

**Proposition 6** A KKT point  $\bar{x}$  yields a global minimum if and only if  $\bar{x}$  is stationary point and the  $Q_i^+$  (or  $Q_i^-$ ) are  $\Gamma_i^+$ -copositive (respectively,  $\Gamma_i^-$ -copositive), where

$$\begin{aligned} Q_i^+ &= ((u_i - \bar{x}_i)Q + 2\nabla f(\bar{x})e_i^T), \\ Q_i^- &= ((\bar{x}_i - l_i)Q - 2\nabla f(\bar{x})e_i^T). \end{aligned}$$

Finally, the following Proposition [21] gives a sufficient condition for a KKT point to be a global minimum, in terms of convexity of some augmented function  $L(x)$ .

**Quadratic Programming with Bound Constraints, Figure 1**  
Partitioning of the set  $\Gamma(\bar{x})$  for the two-dimensional case

**Proposition 7** Let  $\bar{x}$  be a KKT point for problem (1). Let  $l_i$  and  $u_i$  be finite for each  $i \in \{1, \dots, n\}$ . Let

$$D = \text{diag} \left( \frac{|\nabla f(\bar{x})_1|}{u_1 - l_1}, \dots, \frac{|\nabla f(\bar{x})_n|}{u_n - l_n} \right).$$

If  $L(x) = f(x) + (x - \bar{x})^T D(x - \bar{x})$  is convex in  $\Omega$ , then  $\bar{x}$  is a global solution of (1). Moreover, if  $L(x)$  is strictly convex in  $\Omega$ , then this solution is unique.

This kind of result can be a useful tool for branch and bound algorithms for global optimization. Moreover, Proposition 7 allows one to construct test problems in quadratic programming with known global minimum.

More results on the global optimization criteria for (1) exist in the literature (see, for example, [21] and references therein).

### Algorithms for Local Minimization

Most of the algorithms to locally solve problem (1) can be classified in the so-called *active set strategies*, which reduce the solution of the problem to a sequence of auxiliary unconstrained subproblems on affine subspaces of  $\mathbf{R}^n$  (faces). They generate a sequence of feasible points  $x^{(k)}$ , each  $x^{(k)}$  associated with a working set  $W^{(k)} \subseteq A(x^{(k)})$ . The *active set algorithms* can be described according to the very general framework in Table 1.

These methods differentiate on the way they solve the subproblems  $P(x^{(k)}, W^{(k)})$  and on the definition of a new face. One of the first of such algorithms, due to B.T. Polyak [29], uses a conjugate gradient algorithm to solve  $P(x^{(k)}, W^{(k)})$ . Since then, many modifications have been proposed for the solution of the auxiliary problem. In particular, the approximate solution of such problems is suitable to deal with large scale problems. With

Initialization:
take a first point  $x^{(0)} \in \Omega$ ;
 $W^{(0)} = A(x^{(0)}); k = 0$ ;
REPEAT
  Solve the quadratic unconstrained problem:
 $P(x^{(k)}, W^{(k)}) = \min f(x^{(k)} + v)$ ,
 $v_i = 0, \forall i \in W^{(k)}$ ;
  IF  $P(x^{(k)}, W^{(k)})$  is unbounded below THEN
    ACT1) choose  $x^{(k+1)} \in \Omega$ :
 $A(x^{(k+1)}) = A(x^{(k)})$  and  $f(x^{(k+1)}) < f(x^{(k)})$ ;
    choose  $W^{(k+1)} \supset W^{(k)}$ ;
  ELSE
    ACT2)  $\alpha^{(k)} = \max\{\alpha \in [0, 1] : x^{(k)} + \alpha v^{(k)} \in \Omega\}$ ;
 $x^{(k+1)} = x^{(k)} + \alpha^{(k)} v^{(k)}$ ;
    choose  $W^{(k+1)}$ 
    such that  $A(x^{(k+1)}) \supseteq W^{(k+1)} \neq W^{(k)}$ ;
  ENDIF
   $k = k + 1$ ;
UNTIL(stop condition holds)

```

regard to the definition of a new working set, in ACT2) a projected gradient step can be taken in order to add more than a new variable to the new working set [18]. Arguments of combinatorial nature show that, in non-degeneracy assumptions, an active set strategy terminates in a finite number of steps at a stationary point, provided that the exact minimization of the subproblems is performed (at least once every  $j$  steps, for some prefixed  $j$ ). In case of degeneracy, the finite termination still holds for some active set algorithms. Specialized versions of active set strategies have been successfully proposed for solving large sparse problems [4,5,19].

On a completely different approach are based the algorithms that belong to the family of the interior point methods (cf. also ► **Linear programming: Interior point methods**); after Karmarkar's polynomial algorithm for linear programming, many interior point algorithms have been developed for the convex linear complementary problem (and therefore for the convex QPwBC). They include the primal-dual potential reduction algorithm and the path following algorithms [34]. For more detail see ► **Linear complementarity problem**. Finally, *penalty techniques* have been successfully proposed for the convex QPwBC [6].

**Algorithms for Global Minimization**

The global optimality conditions expressed in Proposition 6, suggest a very simple algorithmic framework for solving (1), whose main ingredient is the procedure COPOS( $Q, \Gamma, d$ ). Such a procedure [2], given an  $n \times n$  matrix  $Q$  and a polyhedral cone  $\Gamma$ , detects either the  $\Gamma$ -copositivity of  $Q$  or a direction  $d \in \Gamma$  such that  $d^T Q d < 0$ . In the sequel all  $Q_i$  matrices and the cones  $\Gamma_i$  are relative to the stationary point  $\bar{x}$ .

In the algorithm in Table 2, COPOS is used to escape from local solution which are not global.

In [3] the basic algorithm escape has been improved using pseudoconvexity and a preprocessing procedure. However, because of complexity reasons (the problem of exactly checking copositivity is itself NP complete!) algorithms based on copositivity are suitable only for very small size problems.

A different approach [23], originally proposed for concave quadratic problems [30], uses a *separable formulation* based on the eigenstructure of the quadratic form. Using the linear variable transformation  $x = Py$ , where  $P$  is an orthogonal matrix whose columns are the eigenvectors of  $Q$ , the original problem is transformed into the separable form

$$\min_{y \in M} \phi_1(y) + \phi_2(y),$$

**Quadratic Programming with Bound Constraints, Table 2**  
**Global QPwBC algorithm**

```

Initialization:
take a first stationary point  $\bar{x}$ ;
 $i = 1$ ;
REPEAT
  IF  $\Gamma_i^+ \neq \{0\}$  THEN call COPOS( $Q_i^+, \Gamma_i^+, d$ );
  IF  $\Gamma_i^- \neq \{0\}$  THEN call COPOS( $Q_i^-, \Gamma_i^-, d$ );
  IF a direction  $d$  is found such that  $d^T Q^+ d < 0$ 
  or  $d^T Q^- d < 0$ ;
  THEN
 $x^* = \bar{x} + \lambda_{max}(d)d$ ;
    use  $x^*$  as starting point for a procedure that
    generates a new stationary point  $\bar{x}$ ;
 $i = 0$ ;
  ENDIF
   $i = i + 1$ ;
UNTIL( $i = n + 1$ ).

```

where  $M$  is a rectangle of minimum volume that contains  $\widehat{\Omega} = \{y \in \mathbf{R}^n: l \leq Py \leq u\}$ . The functions  $\Phi_1(y)$  and  $\Phi_2(y)$  are, respectively, the concave part and the convex part of the objective function.

The function  $\Phi_2(y)$  can be underestimated by using a piecewise linear approximation and this gives a convex problem which approximates the original problem and for which an error bound can be given, depending both on the size of the negative eigenvalues of  $Q$  and on the size of the range of allowed displacements along the respective eigenvectors. This technique can be incorporated within a branch and bound framework. A way to improve the approximation is to make a partitioning of the domain along the eigendirections, based on the error estimate, and bounding techniques can be devised. An efficient parallel implementation is described in [28].

The *reformulation-linearization/convexification techniques* [31] are based on a suitable *linearized reformulation* of the problem (1). The goal of RLT is to try to approximate the convex envelope of the objective function over the feasible region in deriving tighter and tighter lower bounding linear programs.

Based on the combinatorial nature of the problem some *branch and bound enumerative techniques* have been proposed [13], that can be very expensive from a computational point of view, and therefore only suitable for small size problems or problems whose sparsity allows only a low number of subproblems to be explored.

More attracting from the computational point of view are algorithms based on *interior point methods*, whose main drawback is unfortunately that no guarantee exist about the convergence to the global solution of problem (1) [11].

### Keywords

Quadratic programming; Bisection method; Newton method; Trust region model; Complexity

*Quadratic programming* (QP) plays an important role in optimization theory. In one sense it is a continuous optimization and a fundamental subroutine for general nonlinear programming, but it is also considered one of the most challenging combinatorial optimization problems.

One of QP problems is to minimize a *quadratic function* over an *ellipsoid constraint*. Since any ellipsoid can be transformed to a *ball* by an affine transformation, without loss of generality, we consider the following ball-constrained QP problem BQP ( $r$ ):

$$\begin{cases} \min & \frac{1}{2}x^T Qx + c^T x \\ \text{s.t.} & x \in \mathcal{B}(r) = \{x \in \mathbf{R}^n : \|x\| \leq r\}, \end{cases} \quad (1)$$

where  $Q \in \mathbf{R}^{n \times n}$ ,  $c \in \mathbf{R}^n$ , and superscript  $\top$  denotes the transpose operation. Here,  $\|\cdot\|$  denotes  $L_2$  norm and  $r > 0$  is the radius of the ball. A main recent result is that this problem is an 'easy' problem, even when the objective function is nonconvex.

We begin with a brief history of this problem. There is a class of nonlinear programming algorithms called *model trust region methods*. In these algorithms, a quadratic function is used as an approximate model of the true objective function around the current iterate. Then the main step is to minimize the model function. In general, however, the model is expected to be accurate or trusted only in a neighborhood of the current

iterate. Accordingly, the quadratic model is minimized in a  $L_2$ -norm neighborhood, which is a ball, around the current iterate. Recently (1996), it was demonstrated [5] that a class of combinatorial optimization problems can be solved by solving a sequence of ball-constrained QP problem.

The model-trust region method is due to K. Levenberg [7] and D.W. Marquardt [8]. These authors considered only the case where  $Q$  is positive definite. J.J. Moré [10] proposed an algorithm with a convergence proof for this case. D.M. Gay [4] and D.C. Sorenson [15] proposed algorithms for the general case, see also [2]. These algorithms work very well in practice, but no theoretical complexity result was established for this problem then.

It is well known [4,15] that the solution  $x$  of problem BQP ( $r$ ) satisfies the following necessary and sufficient conditions:

$$\begin{aligned} (Q + \mu I)x &= -c, \\ \mu &\geq \max\{0, -\underline{\lambda}\}, \\ \|x\| &= r, \end{aligned} \tag{2}$$

where  $\underline{\lambda}$  denotes the least eigenvalue of matrix  $Q$ . Since  $Q$  is not positive semidefinite, we must have  $\underline{\lambda} < 0$ .

Let  $\mu^*$  and  $x^*$  satisfy conditions (2). It has been shown that  $\mu^*$  is unique and

$$\mu^* \leq |\underline{\lambda}| + \frac{\|c\|}{r}. \tag{3}$$

It is also known that

$$|\underline{\lambda}| \leq n \max\{|q_{ij}|\},$$

where  $q_{ij}$  is the  $(i, j)$ th component of matrix  $Q$ . Thus, we have

$$0 \leq \mu^* \leq \mu^0 := n \max\{|q_{ij}|\} + \frac{\|c\|}{r}, \tag{4}$$

where  $\mu^0$  is a computable upper bound. It is further proved that ([19])

$$\frac{1}{2}r^2 |\underline{\lambda}| \leq \frac{1}{2}r^2 \mu^* \leq q(0) - q(x^*) \leq \frac{1}{2}r^2 |\underline{\lambda}| + r \|c\|. \tag{5}$$

This inequality can be used to develop an *approximation algorithm* for general quadratic optimization, see [3].

We now analyze the complexity of solving BQP ( $r$ ). A simple *bisection method* was proposed in [18] and in

[19]. For any given  $\mu$ , denote solutions of the top linear equations by  $x_\mu$  in conditions (2), i. e.,

$$x_\mu := -(Q + \mu I)^{-1}c, \quad \forall \mu > |\underline{\lambda}|. \tag{6}$$

For any given  $\mu$  we can check to see if  $\mu \geq |\underline{\lambda}|$  by checking the positive definiteness of matrix  $Q + \mu I$ , which can be solved as a  $LDL^T$  decomposition. These facts lead to a bisection method to search for the root of  $\|x_\mu\| = r$  over the interval  $\mu \in [|\underline{\lambda}|, \mu^0] \subset [0, \mu^0]$ . Obviously, for a given  $\epsilon'' \in (0, 1)$ , a  $\mu$  such that, say  $0 \leq \mu - \mu^* \leq \epsilon' \mu^*/8$ , can be obtained in  $O(\log(\mu^0/\mu^*) + \log(1/\epsilon'))$  bisection steps, and the cost of each step is  $O(n^3)$  arithmetic operations (for performing  $LDL^T$  decomposition).

The remaining question is what  $\epsilon'$  would be sufficient to generate an  $\epsilon$ -minimizer of  $q(x)$  over the ball  $\mathcal{B}(r)$ , that is, an  $x$  satisfying

$$\frac{q(x) - q(x^*)}{q(0) - q(x^*)} \leq \epsilon.$$

Let  $\mu$  denote the right endpoint of the interval generated by the bisection search. Then,  $\mu \geq \mu^*$ . If  $\mu = \mu^*$ , then we get an exact solution  $x^* = x_{\mu^*}$ . Thus, we assume  $\mu > \mu^* \geq \underline{\lambda}$ . By the positive semidefiniteness of  $Q + \mu^* I$ , we have

$$\|x_\mu\| < \|x^*\| = r.$$

We consider two cases.

*Case I.* In the first case we assume

$$\left(1 - \frac{\epsilon}{8\sqrt{n}}\right) \mu^* \geq |\underline{\lambda}|$$

or

$$\mu^* \geq |\underline{\lambda}| + \frac{\epsilon}{8\sqrt{n}} \mu^*.$$

Using the relation (6) and simplifying, we obtain

$$\begin{aligned} \|x^*\|^2 - \|x_\mu\|^2 &= (x^*)^\top \\ &\quad \times (I - (Q + \mu^* I)(Q + \mu I)^{-2}(Q + \mu^* I))x^* \\ &= (x^*)^\top (2(\mu - \mu^*)(Q + \mu I)^{-1} \\ &\quad - (\mu - \mu^*)^2(Q + \mu I)^{-2})x^*. \end{aligned}$$

Next we bound the above expression by using the smallest *eigenvalue*  $\underline{\lambda}$  of  $Q$ . This gives

$$\begin{aligned} \|x^*\|^2 - \|x_\mu\|^2 &\leq \left( \frac{2(\mu - \mu^*)}{(\mu - |\underline{\lambda}|)} - \frac{(\mu - \mu^*)^2}{((\mu - |\underline{\lambda}|))^2} \right) \|x^*\|^2 \\ &= \left( \frac{2(\mu - \mu^*)}{(\mu - \mu^*) + (\mu^* - |\underline{\lambda}|)} \right. \\ &\quad \left. - \frac{(\mu - \mu^*)^2}{((\mu - \mu^*) + (\mu^* - |\underline{\lambda}|))^2} \right) \|x^*\|^2 \\ &= \frac{(\mu - \mu^*)^2 + 2(\mu - \mu^*)(\mu^* - |\underline{\lambda}|)}{((\mu - \mu^*) + (\mu^* - |\underline{\lambda}|))^2} r^2 \\ &= \left( 1 - \frac{(\mu^* - |\underline{\lambda}|)^2}{((\mu - \mu^*) + (\mu^* - |\underline{\lambda}|))^2} \right) r^2 \\ &\leq \left( 1 - \frac{(\frac{\epsilon \mu^*}{8\sqrt{n}})^2}{((\mu - \mu^*) + \frac{\epsilon \mu^*}{8\sqrt{n}})^2} \right) r^2, \end{aligned}$$

where in the last step we used the assumption

$$\mu^* \geq |\underline{\lambda}| + \frac{\epsilon}{8\sqrt{n}} \mu^*.$$

Therefore, if we have  $\mu - \mu^* \leq \epsilon' \mu^*/8$ , then

$$\|x^*\|^2 - \|x_\mu\|^2 \leq \frac{\left(\frac{2\sqrt{n}\epsilon'}{\epsilon}\right) + \left(\frac{\sqrt{n}\epsilon'}{\epsilon}\right)^2}{\left(1 + \left(\frac{\sqrt{n}\epsilon'}{\epsilon}\right)\right)^2} r^2 \leq \frac{2\sqrt{n}\epsilon'}{\epsilon} r^2. \quad (7)$$

On the other hand, note that

$$\begin{aligned} q(x_\mu) - q(x^*) &= \frac{1}{2} x_\mu^\top Q x_\mu + c^\top x_\mu - \frac{1}{2} (x^*)^\top Q x^* - c^\top x^* \\ &= \frac{1}{2} (Q x_\mu + c)^\top (x_\mu - x^*) \\ &\quad + \frac{1}{2} (Q x^* + c)^\top (x_\mu - x^*) \\ &= -\frac{1}{2} \mu x_\mu^\top (x_\mu - x^*) - \frac{1}{2} \mu^* (x^*)^\top (x_\mu - x^*) \\ &= -\frac{1}{2} (\mu - \mu^*) x_\mu^\top (x_\mu - x^*) \\ &\quad - \frac{1}{2} \mu^* (\|x_\mu\|^2 - \|x^*\|^2). \end{aligned}$$

Now we use the bound (7), the assumption  $\mu - \mu^* \leq \epsilon' \mu^*/8$  and the fact  $\|x_\mu\| \leq \|x^*\| = r$  to obtain:

$$\begin{aligned} q(x_\mu) - q(x^*) &\leq \frac{\mu^* r^2 \epsilon'}{8} + r^2 \mu^* \frac{\sqrt{n}\epsilon'}{\epsilon} \\ &= \left( \frac{\epsilon'}{4} + \frac{2\sqrt{n}\epsilon'}{\epsilon} \right) \frac{\mu^* r^2}{2} \\ &\leq \left( \frac{\epsilon'}{4} + \frac{2\sqrt{n}\epsilon'}{\epsilon} \right) (q(0) - q(x^*)), \end{aligned}$$

where the last step is due to (5). Thus, if we select

$$\epsilon' \leq \frac{\epsilon^2}{2\sqrt{n} + \frac{1}{4}},$$

then  $x_\mu$  is feasible for BQP( $r$ ) and

$$q(x_\mu) - q(x^*) \leq \epsilon (q(0) - q(x^*)),$$

i. e.,  $x_\mu$  is an  $\epsilon$ -minimizer to  $x^*$ .

Case II. In this case, we have

$$\left( 1 - \frac{\epsilon}{8\sqrt{n}} \right) \mu^* < |\underline{\lambda}|$$

or

$$\mu^* < |\underline{\lambda}| + \mu^* \frac{\epsilon}{8\sqrt{n}}.$$

Again, if we have  $\mu - \mu^* < \epsilon' \mu^*/8$ , then  $\mu - |\underline{\lambda}| < \frac{\epsilon' \mu^*}{8} + \frac{\mu^* \epsilon}{8\sqrt{n}}$ . However, unlike Case I, we find that  $\|x_\mu\|$  is not sufficiently close to  $r$ . When we observe this fact, we do the following computation, essentially due to S.A. Vavasis and R. Zippel [18], to enhance  $x_\mu$ .

Let  $\underline{q}$ ,  $\|\underline{q}\| = 1$ , be an *eigenvector* associated with the eigenvalue  $\underline{\lambda}$ . Then, one of the unit vectors  $e_j$ ,  $j = 1, \dots, n - m$ , must have  $|e_j^\top \underline{q}| \geq \frac{1}{\sqrt{n}}$ . (In fact, we can use any unit vector  $q$  to replace  $e_j$  as long as  $q^\top \underline{q} \geq \frac{1}{\sqrt{n}}$ . A randomly generated  $q$  will do it with high probability.) Now we solve for  $y$  from

$$(Q + \mu I)y = e_j$$

and let

$$x = x_\mu + \alpha y,$$

where  $\alpha$  is chosen such that  $\|x\| = r$ . Note we have

$$(8) \quad (Q + \mu I)x = -c + \alpha e_j,$$

and in the computation of  $x_\mu$  and  $y$ , matrix  $Q + \mu I$  needs to be factorized only once.

It is easy to show that

$$\|y\| \geq \frac{1}{\sqrt{n}(\mu - |\underline{\lambda}|)}$$

and

$$|\alpha| \leq 2r(\mu - |\underline{\lambda}|)\sqrt{n} \leq 2r \left( \frac{\epsilon'\mu^*}{8} + \frac{\epsilon\mu^*}{8\sqrt{n}} \right) \sqrt{n}.$$

Then, we have from (8)

$$\begin{aligned} q(x) - q(x^*) &= \frac{1}{2}(Qx + c)^\top(x - x^*) \\ &\quad + \frac{1}{2}(Qx^* + c)^\top(x - x^*) \\ &= \frac{1}{2}(Qx + c - \alpha e_j)^\top(x - x^*) \\ &\quad + \frac{1}{2}\alpha e_j^\top(x - x^*) - \frac{1}{2}\mu^*(x^*)^\top(x - x^*) \\ &= -\frac{1}{2}\mu x^\top(x - x^*) \\ &\quad + \frac{1}{2}\alpha e_j^\top(x - x^*) - \frac{1}{2}\mu^*(x^*)^\top(x - x^*) \\ &= -\frac{1}{2}(\mu x + \mu^* x^*)^\top(x - x^*) \\ &\quad + \frac{1}{2}\alpha e_j^\top(x - x^*) \\ &= -\frac{1}{2}(\mu - \mu^*)x^\top(x - x^*) + \frac{1}{2}\alpha e_j^\top(x - x^*), \end{aligned}$$

where the last step follows from  $\|x\| = \|x^*\| = r$ . Now we use  $\mu - \mu^* < \epsilon'\mu^*/8$  and the preceding upper bound on  $\alpha$  to estimate the right-hand side:

$$\begin{aligned} q(x) - q(x^*) &\leq \frac{r^2\mu^*\epsilon'}{8} + 2 \left( \frac{\epsilon'\mu^*}{8} + \frac{\epsilon\mu^*}{8\sqrt{n}} \right) r^2\sqrt{n} \\ &= \left( \frac{\epsilon'}{4} + \frac{\sqrt{n}\epsilon'}{2} + \frac{\epsilon}{2} \right) \frac{\mu^*r^2}{2} \\ &\leq \left( \frac{\epsilon'}{4} + \frac{\sqrt{n}\epsilon'}{2} + \frac{\epsilon}{2} \right) (q(0) - q(x^*)), \end{aligned}$$

where the last step is due to (5). Thus, if we choose

$$\epsilon' \leq \frac{\epsilon}{\sqrt{n} + \frac{1}{2}},$$

then  $x$  is feasible for BQP( $r$ ) and

$$q(x) - q(x^*) \leq \epsilon(q(0) - q(x^*)) \leq \epsilon(\bar{z} - \underline{z}),$$

i. e.,  $x$  is an  $\epsilon$ -minimizer of  $q(x)$  over  $\mathcal{B}(r)$ .

Hence, the bisection method will terminate with an  $\epsilon$ -minimizer of BQP( $r$ ) in at most

$$O \left( \log \left( \frac{\mu^0}{\mu^*} \right) + \log \left( \frac{1}{\epsilon} \right) + \log n \right)$$

steps, or in a total of  $O(n^3(\log(\mu^0/\mu^*) + \log(1/\epsilon) + \log n))$  arithmetic operations.

**Theorem** *The total running time of the bisection algorithm for generating an  $\epsilon$ -minimal solution to the ball-constrained QP is bounded by  $O(n^3(\log(\mu^0/\mu^*) + \log(1/\epsilon) + \log n))$  arithmetic operations.*

Recently, F. Rendl and H. Wolkowicz [14] showed that BQP( $r$ ) can be reformulated as a positive semidefinite problem, which is a convex nonlinear problem. There are polynomial *interior point algorithms* (see [11]) to compute an  $d_{x'}$  such that  $q'(d_{x'}) - q(d_{x'}(\mu^k)) \leq \epsilon'$  in  $O(n^3 \log(M^k/\epsilon'))$  arithmetic operations. This will also establish an

$$O \left( \left( \frac{n^6}{\epsilon} \log \frac{1}{\epsilon} + n^4 \log n \right) \left( \log \frac{1}{\epsilon} + \log n \right) \right)$$

arithmetic operation bound for the algorithm.

The polynomial complexity in Theorem 1 can be further improved. In particular, see [20] for a mixed bisection and *Newton method* for solving BQP( $r$ ) and for an arithmetic operation bound  $O(n^3 \log(\log(\mu^0/\mu^*) + \log(1/\epsilon')))$  to yield a  $\mu$  such that  $0 \leq \mu - \mu^* \leq \epsilon'$ . The brief idea of the method is to first find an approximate  $\underline{\mu}$  to the absolute value of the least eigenvalue  $|\underline{\lambda}|$  and an approximate eigenvector  $q$  to the true  $q$ , such that  $0 \leq \underline{\mu} - \underline{\lambda} \leq \epsilon'$  and  $q^\top q^k \geq 1 - \epsilon'$ . This approximation can be done in  $O(n^3 \log(\log(1/\epsilon')))$  arithmetic operations. Then, we will use  $q$  to replace  $e_j$  in Case II (i. e.,  $\|x_{\underline{\mu}} < r$ ) to enhance  $x(\underline{\mu})$  and generate a desired approximation. Otherwise, we know  $\mu^* > \underline{\mu}$  and, using the mixed method in [20], we will generate a  $\mu \in (\underline{\mu}, \mu^0)$  such that  $|\mu - \mu^*| \leq \epsilon'\mu^*/8$  in  $O(n^3 \log(\log(\mu^0/\mu^*) + \log(1/\epsilon')))$  arithmetic operations.

Finally, let  $Q$  and  $c$  have integer data. Consider the decision problem: Is there an  $x \in \mathbf{R}^n$  satisfying  $\|x\| \leq 1$ , and  $q(x) < 0$ ? Under the *Turing machine* computational model, this problem can be answered in polynomial time (see [18]).

## Quadratic Semi-assignment Problem QSAP

LEONIDAS PITSOULIS

Princeton University, Princeton, USA

MSC2000: 90C27, 90C11, 90C08

**Article Outline**

Optimization

Consider that we have  $n$  ‘objects’ and  $m$  ‘locations’,  $n > m$ , and we want to assign all objects to locations with at least one object to each location, so as to minimize the overall distance covered by the flow of materials moving between different objects. Given a flow matrix  $F =$

$(f_{ij})$  and a distance matrix  $D = (d_{ij})$ , we can formulate the *quadratic semi-assignment problem* as follows:

$$\left\{ \begin{array}{l} \min \quad \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^{m-1} \sum_{l=k+1}^m f_{ij} d_{kl} x_{ki} x_{lj} \\ \quad + \sum_{i=1}^m \sum_{j=1}^n b_{ij} x_{ij} \\ \text{s.t.} \quad \sum_{j=1}^n x_{ij} = 1, \quad i = 1, \dots, m, \\ \quad x_{ij} \in \{0, 1\}, \\ \quad i = 1, \dots, m, \quad j = 1, \dots, n. \end{array} \right.$$

Comparing the above formulation with that of the quadratic assignment problem (cf. [► Quadratic assignment problem](#)), we can see that the QSAP is a relaxed version of the QAP, where instead of assignment constraints we have semi-assignment constraints. SQAP unifies some interesting combinatorial optimization problems like clustering and  $m$ -coloring. In a *clustering problem* we are given  $n$  objects and a dissimilarity matrix  $F = (f_{ij})$ . The goal is to find a partition of these objects into  $m$  classes so as to minimize the sum of dissimilarities of objects belonging to the same class. Obviously this problem is a QSAP with coefficient matrices  $F$  and  $D$ , where  $D$  is an  $m \times m$  identity matrix. In the  *$m$ -coloring problem* we are given a graph with  $n$  vertices and want to check whether its vertices can be colored by  $m$  different colors such that each two vertices which are joined by an edge receive different colors. This problem can be modeled as a SQAP with  $F$  equal to the adjacency matrix of the given graph and  $D$  the  $m \times m$  identity matrix. The  $m$ -coloring has an answer ‘yes’ if and only if the above SQAP has optimal value equal to 0. Practical applications of the SQAP include distributed computing [5] and scheduling [1].

SQAP was originally introduced by D.E. Greenberg [2]. As pointed out in [3], this problem is NP-hard. I.Z. Milis and V.F. Magirou [5] propose a Lagrangian relaxation algorithm for this problem, and show that similarly as for the QAP, it is very hard to provide optimal solutions even for SQAPs of small size. Lower bounds for the SQAP have been provided in [4], and polynomially solvable special cases have been discussed in [3].

Mathematical programming

Smoothness, or the existence of the classical derivative information for a function plays a significant role in the theory and the tools used today for modeling, approximation, optimization and for their applications. Nevertheless, nature seems to be more rich than the assumptions done within current mathematical or physical theories. Nonsmoothness arises in a very large number of applications. The arising phenomena, including complex dynamics, pattern formation and chaos, are appealing for both theoretical investigations and practical applications. Most of them have not yet been studied. Abandoning smoothness assumptions one arrives at the area of *nonsmooth analysis*.

Within nonsmooth approximation the classical notion of the derivative is replaced by some set-valued generalized derivative. This is required for the construction of qualitative and quantitative first order approximations of a function with points of nondifferentiability (kinks) or, respectively of a set with corners. In fact, the linearization (i. e., the linear or affine approximation) of a function at a given point which is based on the familiar Taylor expansion formula is based on the assumption that the derivative of the function (or its gradient) exists at the considered point.

Historically, for convex nondifferentiable functions, a suitable set-valued extension of the derivative has been provided by the *subdifferential* of *convex analysis*, in the sense of J.-J. Moreau and R.T. Rockafellar [8,12]. For the general case of nonconvex, nondifferentiable functions, a direct extension of the convex analysis subdifferential has been provided by the *generalized subdifferential* in the sense of F.H. Clarke and Rockafellar [1,2,13]. This notion has been used in a variety of applications, although it does not possess the above mentioned first order approximation property. One should note that a large number of notions have been proposed for the approximation of nonconvex and nonsmooth functions (or sets) or of the solution of affiliated opti-

mization problems. A complete list would go beyond the limits of this short article. This activity demonstrates the large practical interest of this area.

The *quasidifferential* in the sense of V.F. Demyanov and A.M. Rubinov is an appropriate tool for the construction of first order approximations of functions and sets and, subsequently, for the solution of nonsmooth and nonconvex optimization problems. By treating separately convex and concave contributions of the function the quasidifferential introduces an ordered pair of convex sets. Intuitively speaking, the convex analysis subdifferential is present, for the convex contribution, while the superdifferential takes into account the concave parts (which, in turn, can also be studied by means of convex analysis arguments, since a concave function becomes convex if one changes its sign). The links of the quasidifferential with other notions of nonsmooth analysis have been discussed in ► [Quasidifferentiable optimization: Dini derivatives, Clarke derivatives](#) and [4]. More important is that certain calculus rules have been developed for the calculation of the quasidifferential of sums, differences, products, quotients and, more general, of every function that can be constructed by using finite number times the minimum and maximum operators over a finite number of classical, smooth constituent functions (see ► [Quasidifferentiable optimization: Calculus of quasidifferentials](#) and [7]). Finally, based on the notion of the quasidifferential, certain new variational formulations can be constructed which generalize the notion of *variational inequalities* of convex analysis. These variational formulations have the form of sets of variational inequalities, are valid for the general nonsmooth and nonconvex case (see also ► [Quasidifferentiable optimization: Variational formulations](#) [6,11]) and give a computationally advantageous form to the *hemivariational inequalities* in the sense of P.D. Panagiotopoulos (see, among others, ► [Nonconvex energy functions: Hemivariational inequalities](#); ► [Hemivariational inequalities: Applications in mechanics](#) and [6,9,10,11]).

Here, the definition of the quasidifferential for one-dimensional and finite-dimensional functions is given and hints for its extension into functionals are discussed. Finally, some information on the related, and more convenient for the numerical applications notion of the codifferential and on the construction of optimization algorithms is provided.

### One-Dimensional Nonsmooth Functions

Let  $f$  be a real-valued finite function defined on the real line  $\mathbf{R}$ . The most powerful and widely used tool to study the properties of  $f$  is the notion of derivative. Function  $f$  is called *differentiable* at  $x \in \mathbf{R}$  if there exists its derivative  $f'(x)$  at  $x$ , which is defined by

$$f'(x) = \lim_{\alpha \rightarrow 0} \frac{1}{\alpha} [f(x + \alpha) - f(x)] . \quad (1)$$

If this limit exists for every point of some open set  $S \in \mathbf{R}$ , the function  $f$  is called differentiable on  $S$ .

Among the variety of applications of the derivative one recalls here the first order approximation (linearization) of  $f$  in the neighborhood of a point  $x$ :

$$f(x + \Delta) = f(x) + f'(x)\Delta + o_x(\Delta) \quad (2)$$

with

$$\frac{o_x(\Delta)}{\Delta} \rightarrow 0 \quad \text{as } \Delta \rightarrow 0 . \quad (3)$$

Moreover,  $x^*$  is a minimum of the function  $f$  if

$$f'(x^*) = 0 . \quad (4)$$

Relation (4) defines a stationary point of  $f$ , since it also holds true for a maximum and for a saddle point of  $f$ . As is usual, higher order derivatives are checked in order to specify the nature of the stationary point.

### One-Sided Differentials

Assume now that the limit (1) does not exist, but at the same time the following directional derivatives exist: the right-hand side derivative  $f'_+(x)$  and the left-hand side derivative  $f'_-(x)$  of  $f$  at  $x$ . The right-hand side derivative is defined by:

$$f'_+(x) = \lim_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha) - f(x)] . \quad (5)$$

Analogously, the left-hand side derivative is defined by the limit:

$$f'_-(x) = \lim_{\alpha \uparrow 0} \frac{1}{\alpha} [f(x + \alpha) - f(x)] . \quad (6)$$

Here  $\alpha \downarrow 0$  means that  $\alpha \rightarrow 0$ , by taking positive values  $\alpha > 0$  and  $\alpha \uparrow 0$  means that  $\alpha \rightarrow 0$ , with negative values  $\alpha < 0$ .

It is clear that for a function  $f$  to be differentiable at  $x$  it is necessary and sufficient that  $f'_+(x) = f'_-(x)$ .

The *directional derivative* of a function  $f$  at point  $x$  and in the direction  $x \in \mathbf{R}$  is defined by the limit:

$$f'(x, g) = \lim_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha g) - f(x)] , \quad (7)$$

if this limit exists.

The notion of directional derivative is a proper extension of the notion of the derivative. For example, it can be used to linearize a given function (cf. (2)) along a direction  $g$ . In this case relation (2) holds along a given direction, a different value holds for the opposite direction, etc, so that it provides the basis for a quasilinearization of the function  $f$ .

From the definition one may easily see that a necessary condition for a directionally differentiable function  $f$  to attain a minimum at point  $x^*$  is that:

$$f'(x^*, g) \geq 0 , \quad \forall g \in \mathbf{R} . \quad (8)$$

If strict inequality holds in (8) for every direction  $g$  not equal to zero, the condition becomes also sufficient for  $x^*$  to be a strict local minimum of  $f$ . On the other hand, a necessary condition for a directionally differentiable function  $f$  to attain a maximum at point  $x^*$  is that:

$$f'(x^{**}, g) \leq 0 , \quad \forall g \in \mathbf{R} , \quad (9)$$

with analogous implications for a strict local maximum.

A point  $x^*$  which satisfies relation (8) is called an inf-stationary point of  $f$ , while a point  $x^{**}$  satisfying (9) is called a sup-stationary point. It is interesting to observe that for a nonsmooth function first order optimality conditions may, in some cases, become sufficient for a minimum or a maximum.

### Quasidifferential

A function  $f: \mathbf{R} \rightarrow \mathbf{R}$  is called *quasidifferentiable* (q.d) at a point  $x$  if it is directionally differentiable at  $x$  and there exists a pair of closed intervals  $\underline{\partial}f(x) = [v_1, v_2]$  and  $\bar{\partial}f(x) = [w_1, w_2]$  such that

$$f'(x, g) = \max_{v \in \underline{\partial}f(x)} vg + \min_{w \in \bar{\partial}f(x)} wg , \quad \forall g \in \mathbf{R} . \quad (10)$$

The pair of intervals  $Df(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$  is called a *quasidifferential* of  $f$  at  $x$ . The set  $\underline{\partial}f(x)$  is called the

subdifferential and the set  $\bar{\partial}f(x)$  the superdifferential of  $f$  at  $x$ .

It is clear that a quasidifferential is not uniquely defined. In fact, if a function  $f$  is quasidifferentiable at  $x$  and  $Df(x)$  is its quasidifferential at this point, i. e.,  $Df(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$ , then every pair of the form  $[\underline{\partial}f(x) + C\bar{\partial}f(x) - C]$ , where  $C$  is an interval  $C = [c_1, c_2] \in \mathbf{R}$ , with  $c_1 \leq c_2$  is also a quasidifferential of  $f$  at  $x$ . In fact, the quasidifferential is a class of equivalent ordered pairs of convex sets.

### Necessary and Sufficient Optimality Conditions

For a quasidifferentiable function the necessary and sufficient optimality conditions (see (8)–(9)) can be written as follows. Let  $Df(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$  be a quasidifferential of  $f$  at  $x$ . A necessary condition for function  $f$  to attain a minimum at point  $x^*$  is that:

$$-\bar{\partial}f(x^*) \subset \underline{\partial}f(x^*). \quad (11)$$

The condition

$$-\bar{\partial}f(x^*) \subset \text{int } \underline{\partial}f(x^*) \quad (12)$$

is sufficient for  $x^*$  to be a strict local minimum of  $f$ . Analogously, a necessary condition for a maximum of  $f$  at  $x^{**}$  is that:

$$-\underline{\partial}f(x^{**}) \subset \bar{\partial}f(x^{**}), \quad (13)$$

with an analogous result for a sufficient condition for a strict local maximum:

$$-\underline{\partial}f(x^{**}) \subset \text{int } \bar{\partial}f(x^{**}). \quad (14)$$

## Finite-Dimensional Nonsmooth Functions

### Subdifferentiable Functions

Let a function  $f$  defined on an open set  $X \subset \mathbf{R}^n$  be directionally differentiable at a point  $x \in X$ . The function  $f$  is *subdifferentiable* at  $x$  if its directional derivative is a superlinear function, i. e. there exists a convex compact set  $U$  such that

$$f'(x, g) = \max_{h \in U} (h, g), \quad \forall g \in \mathbf{R}^n. \quad (15)$$

### Superdifferentiable Functions

A function is *superdifferentiable* at  $x$  if its directional derivative can be written by means of a convex compact set  $V$  as

$$f'(x, g) = f'_x(g) = \min_{h \in V} (h, g), \quad \forall g \in \mathbf{R}^n. \quad (16)$$

### Quasidifferentiable Functions

A directionally differentiable function  $f$  defined on an open set  $X \subset \mathbf{R}^n$  is called *quasidifferentiable* at a point  $x \in X$ , if there exists an ordered pair of convex compact sets  $[U, V]$  in  $\mathbf{R}^n \times \mathbf{R}^n$  which produces the directional derivative of the function by:

$$f'(x, g) = f'_x(g) = \max_{h \in U} (h, g) + \min_{h \in V} (h, g), \quad \forall g \in \mathbf{R}^n. \quad (17)$$

Clearly, the first term on the right of (17) is a sublinear function while the second term is a superlinear function. Thus, the directional derivative of a quasidifferentiable function belongs to the space  $L$  of functions which can be written as the sum of a sublinear function and a superlinear function. Moreover with an element  $[U, V]$  of the space of compact sets it is associated the class of equivalent ordered pairs of compact convex sets.

Thus, the class of equivalent ordered pairs of convex compact sets  $[U, V]$  of (17) (the quasidifferential  $Df(x)$  of  $f$  at  $x$ ) fully describes the first order derivative of the directionally differentiable function  $f$  and gives rise to the quasilinearization (17) and, subsequently, to a qualitative and quantitative first order approximation of  $f$  in the sense of (2).

As an example, let us mention that for a differentiable function  $f$  either  $Df = [\nabla f, \{0\}]$  or  $Df = [\{0\}, \nabla f]$  can be used as the quasidifferential of  $f$ . For a convex, nondifferentiable function  $f$ ,  $Df = [\partial f, \{0\}]$ , where  $\partial f$  denotes the classical subdifferential of convex analysis [12] can be used. Analogously, for a concave function  $f$ , one may use  $Df = [\{0\}, \partial f]$ , where  $\partial f$  denotes the superdifferential of the concave function  $f$ . A *difference convex function* (d.c. function) is a function  $f$  which can be expressed as the difference of two appropriately determined convex constituents, i. e.,  $f(x) = f_1(x) - f_2(x)$ ,  $\forall x \in X$ , where  $f_1(x)$  and  $f_2(x)$  are convex functions. In this case one constructs a quasidifferential simply by

$Df(x) = [\partial f_1(x), \partial f_2(x)]$ , where the convex subdifferentials of the functions  $f_1(x)$  and  $f_2(x)$  are used.

### Further Related Topics

Extension of the theory of quasidifferentiability to infinite-dimensional function spaces has not been studied till now (1999) in details. First hints can be found in [3,6].

The notion of the quasidifferential has been extended by Demyanov to the notion of the *codifferential*, which has certain advantages for numerical applications (see ► [Quasidifferentiable optimization: Codifferentiable functions](#) and [4]). Several applications of the quasidifferentiability concept and related references are given in ► [Quasidifferentiable optimization: Applications](#) and in [5].

Nonsmooth optimization; Codifferentiability

Quasidifferentiability and codifferentiability extend the notion of the subdifferential of convex analysis for a quite general class of nonconvex and nonsmooth functions. If for a directionally differentiable function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  there exists an ordered pair of convex compact sets  $[U, V]$  in  $\mathbf{R}^n \times \mathbf{R}^n$  which produces the directional derivative of  $f$  at  $x$  in the direction  $g$  by the expression:

$$f'(x, g) = \max_{h \in U} (h, g) + \min_{h \in V} (h, g), \quad (1)$$

this function is called *quasidifferentiable* in the sense of V.F. Demyanov and A.M. Rubinov.

If moreover the quasidifferential of the above function is of the form  $[U, 0]$  (where 0 is considered as an element of the space  $\mathbf{R}^n$ ), then function  $f$  is called *subdifferentiable*.

More details on this notion, the calculus rules for computing quasidifferentials, its connection to other notions of nonsmooth analysis and its applications can be found in ► [Quasidifferentiable optimization](#); ► [Quasidifferentiable optimization: Calculus of quasidifferentials](#); ► [Quasidifferentiable optimization: Dini derivatives, Clarke derivatives](#); ► [Quasidifferentiable optimization: Applications](#); as well as in [1,2,3].

The quasidifferential, as well as the subdifferential of *convex analysis*, are set-valued quantities which include discontinuities at the points of nondifferentiability. In numerical algorithms this may cause problems. A notion that takes into account neighboring information would be more appropriate. This led Demyanov to extend the notion of the quasidifferential and to define the notion of the codifferential.

Let  $X$  be an open subset of  $\mathbf{R}^n$  and let a function  $f$  be defined and finite for every  $x \in X$ . A function  $f$  is called *codifferentiable* at  $x$  if there exist convex, compact sets  $\underline{d}f(x) \subset \mathbf{R}^{n+1}$  and  $\bar{d}f(x) \subset \mathbf{R}^{n+1}$  such that the function admits a first order approximation in a neighborhood of  $x$  of the form

$$f(x + \Delta) = f(x) + \max_{[\alpha, v] \in \underline{d}f(x)} [\alpha + (v, \Delta)] + \min_{[b, w] \in \bar{d}f(x)} [b + (w, \Delta)] + o_x(\Delta), \quad (2)$$

where  $o_x(\alpha\Delta)/\alpha \rightarrow 0$ , as  $\alpha \downarrow 0, \forall \Delta \in \mathbf{R}^n$ . The ordered pair of convex, compact sets  $Df(x) = [\underline{d}f(x), \bar{d}f(x)]$  is called a *codifferential* of  $f$  at  $x$ , where  $\underline{d}f(x)$  is a *hypodifferential* and  $\bar{d}f(x)$  is a *hyperdifferential*.

If there exists a codifferential of the form  $Df(x) = [\bar{d}f(x), 0]$ , where 0 is considered as an element of space  $\mathbf{R}^{n+1}$ , the function  $f$  is called *hypodifferentiable*.

One recalls that classical convex nondifferentiable functions are subdifferentiable (resp. hypodifferentiable) in the above outlined framework, since one may use the classical convex analysis subdifferential in the above definitions for the construction of the subdifferential (resp. the hypodifferential) at a given point.

More details about codifferentiability (including extensions to higher order codifferentials) can be found in ► [Quasidifferentiable optimization: Codifferentiable functions](#).

### Hypodifferentiable Optimization

Efficient nonsmooth optimization algorithms can be constructed for hypodifferentiable functions. In fact, the technique of replacing a nondifferentiable optimization problem by an enlarged, classical, inequality constrained optimization problem has been successfully used for convex or for composite optimization problems [4,13]. For hypodifferentiable functions a direction of descent at each given point can be determined and used in an iterative optimization procedure.

Let us consider a conceptual iterative steepest descent optimization algorithm and the form it takes for nondifferentiable (hypodifferentiable) functions. First, recall that a nondifferentiable function does not possess derivatives in the classical sense. One uses set-valued approximations of the derivative (cf., the subdifferential or the hypodifferential) at the points of the nondifferentiability instead.

Accordingly optimality conditions (which will also provide the stopping rules for an optimization algorithm) and the calculation of the steepest descent direction must appropriately be modified.

The first order necessary condition for a hypodifferentiable function  $f$  to attain a minimum at point  $x_0$  reads:

$$0 \in \underline{d}f(x_0). \quad (3)$$

Points  $x_0$  for which relation (3) is satisfied are called *infstationary points*. Note that the previous relation hold in the space  $\mathbf{R}^{n+1}$ .

If at a given point  $x_k$ , at the  $k$ th iteration of an iterative optimization scheme, relation (3) is not satisfied, then one may always find the point  $\bar{z}$  with minimum norm in the closed convex set  $\underline{d}f(x_k)$ , such that:

$$\bar{z}^*(x_k) = (\eta^*(x_k), z^*(x_k)) = \arg \min_{\bar{z} \in \underline{d}f(x_k)} \|\bar{z}\|. \quad (4)$$

Since (3) is not satisfied, one has  $\|\bar{z}^*(x_k)\| > 0$ . The direction

$$g_k(x_k) = -\frac{z^*(x_k)}{\|z^*(x_k)\|} \quad (5)$$

can be used as a descent direction within an optimization algorithm.

In the conceptual manner used in this note, the next step of the iterative algorithm will have the form:

$$x_{k+1} = x_k + \alpha_k g_k,$$

where steplength  $\alpha_k$  will be determined from the solution of the one-dimensional optimization problem (along the direction  $g_k$ ):

$$\alpha_k = \arg \min_{\alpha \geq 0} \{f(x_k + \alpha g_k)\}.$$

For more general quasidifferentiable and codifferentiable functions one may construct appropriate solution algorithms, see ► [Quasidifferentiable optimization: Algorithms for QD functions](#) and in the original literature (see, e. g., [1]).

## Comments

Nondifferentiable optimization procedures have attracted the attention of several researchers and practitioners in the last decade. The lost of information which is connected with smoothing approaches is, for several applications, critical for the quality of the results. Beyond the quasidifferentiable optimization literature, previously mentioned in this note, general methods and theory for descent type methods for nonsmooth functions can be found in [7,12]. In this respect, the bundle concept has been found useful (see, among others, [6,8,9,11]). An application of this method for the solution of hemivariational inequality problems arising in mechanics can be found in [10] and [5].

Closing one would like to mention again the additional requirements of nonsmooth optimization with respect to classical, smooth one. First, stopping criteria must take into account the set-valued nature of the nonsmooth optimality conditions. Otherwise cycling in an iterative scheme or premature exit at a noncritical point may occur. This is the more critical point. Moreover, the line search must take into account the nondifferentiability of the involved function. This requirement is, usually, easily taken into account (for instance, by means of a derivative-free technique).

### Codifferentiable (c.d.) Functions

$f: \mathbf{R}^n \rightarrow \mathbf{R}$  is called *quasidifferentiable* at  $x \in \mathbf{R}^n$  if it is directionally differentiable (in the sense of Dini or Hadamard) and there exists a pair  $\mathcal{D}f(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$  of compact convex sets of  $\mathbf{R}^n$  such that

$$f'(x, g) = \max_{v \in \underline{\partial}f(x)} (v, g) + \min_{w \in \bar{\partial}f(x)} (w, g). \quad (1)$$

Here  $f'(x, g)$  is either the Dini or Hadamard derivative of  $f$  at  $x$  in a direction  $g \in \mathbf{R}^n$ . (See ▶ [Quasidifferentiable optimization: Optimality conditions](#)).

In the sequel we discuss only the problem of minimizing the function  $f$ . In ► **Quasidifferentiable optimization: Optimality conditions**, necessary conditions for a minimum of  $f$  were formulated in terms of quasidifferentials (q.d.) and a formula for computing steepest descent directions was derived. However, it is difficult to apply steepest descent directions for constructing numerical methods for minimizing the function  $f$  since the quasidifferential mapping  $\mathcal{D}f$  is, in general, discontinuous in the Hausdorff metric. This is why we need some other tool to overcome the discontinuity of  $\mathcal{D}f$ .

A function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  is called *Dini codifferentiable* (D.c.d.) at  $x \in \mathbf{R}^n$  if there exists a pair  $Df(x) = [\underline{d}f(x), \overline{d}f(x)]$  of compact convex sets of  $\mathbf{R}^{n+1}$  such that

$$f(x + \Delta) = f(x) + \max_{[a,v] \in \underline{d}f(x)} [a + (v, \Delta)] + \min_{[b,w] \in \overline{d}f(x)} [b + (w, \Delta)] + o_x(\Delta). \quad (2)$$

$$\frac{o_x(\alpha\Delta)}{\alpha} \rightarrow 0, \quad \forall \Delta \in \mathbf{R}^n. \quad (3)$$

Here  $a, b \in \mathbf{R}; v, w \in \mathbf{R}^n$ . If in (2)

$$\frac{o_x(\Delta)}{\|\Delta\|} \xrightarrow{\|\Delta\| \rightarrow 0} 0, \quad \forall \Delta \in \mathbf{R}^n, \quad (4)$$

then  $f$  is called *Hadamard codifferentiable* (H.c.d.) at  $x$ .

Without loss of generality it may be assumed that

$$\max_{[a,v] \in \underline{d}f(x)} a = \min_{[b,w] \in \overline{d}f(x)} b = 0. \quad (5)$$

If it causes no misunderstanding, we shall use the term codifferentiable (c.d.) for both Dini and Hadamard codifferentiable functions.

The pair  $Df(x) = [\underline{d}f(x), \overline{d}f(x)]$  is called a *codifferential* of  $f$  at  $x$ ,  $\underline{d}f(x)$  is a *hypodifferential*,  $\overline{d}f(x)$  is a *hyperdifferential*. A codifferential (like quasidifferential) is not uniquely defined. If there exists a codifferential of the form  $Df(x) = [\underline{d}f(x), \{0_{n+1}\}]$ , the function  $f$  is called *hypodifferentiable* at  $x$ . If there exists a codifferential of the form  $Df(x) = [\{0_{n+1}\}, \overline{d}f(x)]$ , the function  $f$  is called *hyperdifferentiable* at  $x$ .

It is easy to see that the class of Dini (Hadamard) codifferentiable functions coincides with the class of Dini (Hadamard) quasidifferentiable functions.

For example, if  $Df(x) = [\underline{d}f(x), \overline{d}f(x)]$  is a codifferential of  $f$  at  $x$  such that (5) holds, then the pair  $\mathcal{D}f(x) = [\underline{\partial}f(x), \overline{\partial}f(x)]$ , where

$$\begin{aligned} \underline{\partial}f(x) &= \{v \in \mathbf{R}^n : [0, v] \in \underline{d}f(x)\}, \\ \overline{\partial}f(x) &= \{w \in \mathbf{R}^n : [0, w] \in \overline{d}f(x)\}, \end{aligned}$$

is a quasidifferential of  $f$  at  $x$ .

A function  $f$  is called *continuously codifferentiable* at  $x$  if it is codifferentiable in some neighborhood of  $x$  and there exists a codifferential mapping  $\mathcal{D}f$  which is Hausdorff continuous at  $x$ .

*Remark 1* Of course, it is possible to introduce the notion of continuously quasidifferentiable function; however, if  $f$  is continuously q.d. at  $x$  then it is just differentiable at  $x$ .

For a fixed  $\Delta$  the functions (see (1) and (2))

$$\Phi_{1x}(\Delta) = f(x) + \max_{v \in \underline{\partial}f(x)} (v, \Delta) + \min_{w \in \overline{\partial}f(x)} (w, \Delta)$$

and

$$\begin{aligned} \Phi_{2x}(\Delta) &= f(x) + \max_{[a,v] \in \underline{d}f(x)} [a + (v, \Delta)] \\ &+ \min_{[b,w] \in \overline{d}f(x)} [b + (w, \Delta)] \end{aligned}$$

are both first order approximations of  $f$  in a neighborhood of  $x$ . The function  $F_1(\Delta) = \Phi_{1x}(\Delta) - f(x)$  is positively homogeneous (of degree one) in  $\Delta$  while the function  $F_2(\Delta) = \Phi_{2x}(\Delta) - f(x)$  is, in general, not positively homogeneous. The loss of homogeneity is the price to be paid for the continuity (if any) of the codifferential mapping.

Note again that the ‘value’ of the mapping  $\mathcal{D}f$  at any  $x$  is a pair of convex compact sets in  $\mathbf{R}^{n+1}$ .

It turns out that most of the known functions are continuously codifferentiable (see [3,4]). For example, all smooth, convex, concave and concavo-convex functions are continuously codifferentiable. The class of c.d. functions enjoys a very rich calculus similar to that for q.d. functions (see ► **Quasidifferentiable optimization: Optimality conditions**) which is a generalization of the classical differential calculus. The class of c.d. functions was introduced in [3].

First we discuss the problem of minimizing a c.d. function on the entire space (in the absence of constraints).

For a c.d. function the following necessary condition holds:

**Proposition 2** For a point  $x^* \in \mathbf{R}^n$  to be a minimizer of  $f$  on  $\mathbf{R}^n$  it is necessary that

$$\begin{aligned} 0_{n+1} &\in \{\underline{df}(x^*) + [0, w]\}, \\ \forall [0, w] &\in \bar{df}(x^*) \end{aligned} \quad (6)$$

(it is assumed that condition (5) holds).

A point  $x^*$  satisfying (6) is called *inf-stationary*. Let  $x$  be not inf-stationary. Then there exists  $\bar{w} = [0, w] \in \bar{df}(x)$  such that

$$0_{n+1} \notin \{\underline{df}(x^*) + \bar{w}\} = L_{\bar{w}}(x). \quad (7)$$

Find

$$\min_{\bar{z} \in L_{\bar{w}}(x)} \|\bar{z}\| = \|\bar{z}_{\bar{w}}(x)\|.$$

(7) implies that

$$\begin{aligned} \bar{z}_{\bar{w}}(x) &= [\eta_{\bar{w}}(x), z_{\bar{w}}(x)] \neq 0_{n+1} \\ (\eta_{\bar{w}}(x) &\in \mathbf{R}, \quad z_{\bar{w}}(x) \in \mathbf{R}^n). \end{aligned}$$

It is also possible to show that  $z_{\bar{w}}(x) \neq 0_n$  and that for the direction

$$g_{\bar{w}}(x) = -\frac{z_{\bar{w}}(x)}{\|z_{\bar{w}}(x)\|}$$

the inequality  $f'(x, g_{\bar{w}}(x)) \leq -\|\bar{z}_{\bar{w}}(x)\|$  holds.

### Method of Codifferential Descent (MCD)

Let a function  $f$  be defined, Lipschitz and continuously codifferentiable on  $\mathbf{R}^n$ . Fix any  $\mu > 0$ . Choose an arbitrary  $x_0 \in \mathbf{R}^n$ . Let  $x_k$  have already been found. If condition (6) holds at  $x_k$ , then  $x_k$  is inf-stationary and the process terminates. Otherwise, for every  $\bar{w} \in \bar{d}_\mu f(x_k)$  where

$$\bar{d}_\mu(x) = \left\{ \bar{w} \in \bar{df}(x) : \bar{w} = (\omega, w), 0 \leq \omega \leq \mu \right\} \quad (8)$$

we find

$$\min_{\bar{z} \in L_{\bar{w}}(x_k)} \|\bar{z}\| = \|\bar{z}_{k\bar{w}}\|$$

with

$$\bar{z}_{k\bar{w}} = [\eta_{k\bar{w}}, z_{k\bar{w}}], \quad L_{\bar{w}}(x_k) = [\underline{df}(x_k) + \bar{w}].$$

Now, for every  $\bar{w} \in \bar{d}_\mu f(x_k)$  we find

$$\min_{\alpha \geq 0} f(x_k - \alpha z_{k\bar{w}}) = f(x_k - \alpha_{k\bar{w}} z_{k\bar{w}}) \quad (9)$$

and then

$$\min_{\bar{w} \in \bar{d}_\mu f(x_k)} f(x_k - \alpha_{k\bar{w}} z_{k\bar{w}}) = f(x_k - \alpha_{k\bar{w}_k} z_{k\bar{w}_k}).$$

Put  $x_{k+1} = x_k - \alpha_{k\bar{w}_k} z_{k\bar{w}_k}$ . Continuing in the same manner we construct a sequence  $\{x_k\}$  such that  $f(x_{k+1}) < f(x_k)$ .

**Proposition 3** (See [4, Thm. V.5.1].) Let the set  $\{x \in \mathbf{R}^n : f(x) \leq f(x_0)\}$  be bounded,  $x^*$  be a limit point of the sequence  $\{x_k\}$  and let relation (4) hold uniformly in  $x$  from some neighborhood of  $x^*$  and in  $\Delta$  from  $S = \{\Delta \in \mathbf{R}^n : \|\Delta\| = 1\}$ .

Then the point  $x^*$  is an inf-stationary point of  $f$  (i. e. condition (6) holds).

*Remark 4* The above described MCD is a conceptual method (according to the terminology of E. Polak). It should be adjusted to a specific class of functions. The MCD is a generalization of the classical steepest descent method.

For example, if for every  $x \in \mathbf{R}^n$  the set  $\bar{df}(x)$  is the convex hull of a finite number of points then in (8) one can take only points  $\bar{w} = (w, \omega)$  which are 'vertices' of  $\bar{df}$  such that  $0 \leq \omega \leq \mu$ .

In this case at each step it is required to solve only a finite number of one-dimensional optimization problems (9).

### Method of Hypodifferential Descent (MHD)

Let  $f$  be defined, Lipschitz and continuously hypodifferentiable on  $\mathbf{R}^n$ , i. e. there exists a codifferential mapping of the form  $Df(x) = [\underline{df}(x), \{0_{n+1}\}]$  which is Hausdorff continuous. Then the necessary condition for a minimum (6) takes the form

$$0_{n+1} \in \underline{df}(x^*). \quad (10)$$

If  $x \in \mathbf{R}^n$  is not an inf-stationary point (i. e., (10) does not hold) then let us find

$$\min_{\bar{z} \in \underline{df}(x)} \|\bar{z}\| = \|(\eta(x), z(x))\| = \rho(x) = \|\bar{z}(x)\|.$$

Since  $\rho(x) > 0$  then  $\bar{z}(x) \neq 0_{n+1}$ . It is possible to show that  $z(x) \neq 0_n$ . The direction  $g(x) = -z(x) / \|z(x)\|$

is a descent direction (not necessarily the steepest descent direction). The vector function  $g(x)$  is continuous at any point which is not inf-stationary.

Take any  $x_0 \in \mathbf{R}^n$ . Let  $x_k$  have already been constructed. Let us find  $\rho(x_k) = \|\bar{z}(x_k)\|$ . If  $\rho(x_k) = 0$  then  $x_k$  is inf-stationary and the process terminates. Otherwise, take  $g_k = -z(x_k)/\|z(x_k)\|$  and find

$$\min_{\alpha \geq 0} f(x_k + \alpha g_k) = f(x_k + \alpha_k g_k).$$

Put  $x_{k+1} = x_k + \alpha_k g_k$ . Continuing analogously we construct a sequence  $\{x_k\}$  such that  $f(x_{k+1}) < f(x_k)$ .

**Proposition 5** *Let  $x^*$  be a limit point of the sequence  $\{x_k\}$  and the hypotheses of Proposition 3 hold. Then  $0_{n+1} \in \text{df}(x^*)$  i. e.  $x^*$  is an inf-stationary point of  $f$ .*

**Difference of Convex (d.c.) Functions**

Let  $f(x) = f_1(x) - f_2(x)$  where  $f_1, f_2: \mathbf{R}^n \rightarrow \mathbf{R}$  are convex. A d.c. function is quasidifferentiable with the quasidifferential  $\mathcal{D}f(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$  where  $\underline{\partial}f(x) = \partial f_1(x)$ ,  $\bar{\partial}f(x) = -\partial f_2(x)$ ,  $\partial f_1(x)$  and  $\partial f_2(x)$  are *subdifferentials* (in the sense of convex analysis) of the functions  $f_1$  and  $f_2$  respectively:

$$\partial f_i(x) = \left\{ v \in \mathbf{R}^n : \begin{array}{l} f_i(z) - f_i(x) \geq (v, z - x), \\ \forall z \in \mathbf{R}^n \end{array} \right\}.$$

The sets  $\partial f_i$  are convex and compact. The necessary condition for a minimum (6) takes the form

$$\partial f_2(x^*) \subset \partial f_1(x^*). \tag{11}$$

If  $f_2$  is a polyhedral function (i. e.  $f_2(x) = \max_{i \in I} \{a_i + (v_i, x)\}$  where  $a_i \in \mathbf{R}$ ,  $v_i \in \mathbf{R}^n$ ,  $I = 1, \dots, N$ ) then condition (11) is sufficient for the point  $x^*$  to be a local minimizer of  $f$ .

Since the mappings  $\partial f_1$  and  $\partial f_2$  are discontinuous then  $\mathcal{D}f$  is also discontinuous.

If  $F$  is a convex function,  $\varepsilon \geq 0$  then the set

$$\partial_\varepsilon F(x) = \left\{ v \in \mathbf{R}^n : \begin{array}{l} F(z) - F(x) \\ \geq (v, z - x) - \varepsilon, \\ \forall z \in \mathbf{R}^n \end{array} \right\}$$

is called the  $\varepsilon$ -subdifferential of  $F$  at  $x$ .

We shall use the following properties of a convex function (see, e. g., [7]):

1)  $\partial_\varepsilon F(x)$  is a closed compact set.

2) The mapping  $\partial_\varepsilon F$  is Hausdorff continuous jointly in  $\varepsilon$  and  $x$  on  $(0, \infty) \times \mathbf{R}^n$ .  
3)

$$\begin{aligned} \max_{v \in \partial_\varepsilon F(x)} (v, g) &= \inf_{\alpha \geq 0} \frac{1}{\alpha} [F(x + \alpha g) - F(x) + \varepsilon] \\ &:= F'_\varepsilon(x, g). \end{aligned}$$

In [6] the following necessary and sufficient condition for a global minimum is stated:

For a point  $x^*$  to be a global minimizer of a d.c. function  $f(x) = f_1(x) - f_2(x)$  it is necessary and sufficient that

$$\partial_\varepsilon f_2(x^*) \subset \partial_\varepsilon f_1(x^*), \quad \forall \varepsilon \geq 0. \tag{12}$$

Note that if  $\varepsilon_1 > \varepsilon_2$  and

$$f'_{\varepsilon_1 \varepsilon_2}(x, g) := f'_{\varepsilon_1}(x, g) - f'_{\varepsilon_2}(x, g) \leq 0 \tag{13}$$

then

$$\inf_{\alpha \geq 0} f(x + \alpha g) \leq f(x) + \varepsilon_2 - \varepsilon_1. \tag{14}$$

Let us construct the following method for finding an inf-stationary point of  $f$  (i. e. a point satisfying (11)).

Fix  $\varepsilon_0, \mu_0 = \varepsilon_0/2$ . Take an arbitrary  $x_{00} \in \mathbf{R}^n$ . Assume that the set

$$C = \{x \in \mathbf{R}^n : f(x) \leq f(x_{00})\}$$

is bounded (then it is closed since  $f$  is continuous). If

$$B_{00} := \partial_{\mu_0} f_2(x_{00}) \subset A_{00} := \partial_{\varepsilon_0} f_1(x_{00})$$

then we put  $x_0 = x_{00}$ . If

$$\partial_{\mu_0} f_2(x_{00}) \not\subset \partial_{\varepsilon_0} f_1(x_{00})$$

then let us find

$$\max_{w \in B_{00}} \min_{v \in A_{00}} \|v - w\| = \|v_{00} - w_{00}\| = \rho_{00}$$

and put  $g_{00} = (w_{00} - v_{00})/\|w_{00} - v_{00}\|$ . Since  $\rho_{00} > 0$  then

$$f'_{\varepsilon_0 \mu_0}(x_{00}, g_{00}) < 0$$

and, by (13) and (14), we conclude that

$$\inf_{\alpha \geq 0} f(x_{00} + \alpha g_{00}) = f(x_{00} + \alpha_{00} g_{00}) \leq f(x_{00}) - \frac{\varepsilon_0}{2}. \tag{15}$$

Now take  $x_{01} = x_{00} + \alpha_{00} g_{00}$  and check the condition

$$B_{01} := \partial_{\mu_0} f_2(x_{01}) \subset A_{01} := \partial_{\varepsilon_0} f_1(x_{01}).$$

Continuing in the same manner, in a finite number of steps we shall find a point  $x_{0s_0}$  such that

$$B_{0s_0} := \partial_{\mu_0} f_2(x_{0s_0}) \subset A_{0s_0} := \partial_{\varepsilon_0} f_1(x_{0s_0}) \tag{16}$$

(it is due to (15) and the boundedness of  $C$ ).

Put  $x_0 = x_{0s_0}$ . By (16)

$$B_0 := \partial_{\mu_0} f_2(x_0) \subset A_0 := \partial_{\varepsilon_0} f_1(x_0).$$

Let  $x_k$  be constructed such that

$$\partial_{\mu_i} f_2(x_k) \subset \partial_{\varepsilon_i} f_1(x_k), \quad \forall i \in 0, \dots, k, \tag{17}$$

where  $\mu_i = \mu_0/2^i, \varepsilon_i = \varepsilon_0/2^i$ .

Put  $x_{k+1,0} = x_k$ . If

$$\partial_{\mu_{k+1}} f_2(x_{k+1,0}) \subset \partial_{\varepsilon_{k+1}} f_1(x_{k+1,0}) \tag{18}$$

then we take  $x_{k+1} = x_{k+1,0}$ . If (18) does not hold, we continue as above and in a finite number of steps a point  $x_{k+1,s_{k+1}}$  will be found such that

$$\partial_{\mu_{k+1}} f_2(x_{k+1,s_{k+1}}) \subset \partial_{\varepsilon_{k+1}} f_1(x_{k+1,s_{k+1}})$$

and we put  $x_{k+1} = x_{k+1,s_{k+1}}$ .

As a result we construct a bounded sequence  $\{x_k\}$  satisfying (17).

**Proposition 6** Any limit point of the sequence  $\{x_k\}$  is an inf-stationary point of  $f$ .

### Difference of Max-Type (d.m.) Functions

Let

$$f(x) = f_1(x) - f_2(x)$$

where  $f_1, f_2: \mathbf{R}^n \rightarrow \mathbf{R}$  are max-type functions:

$$f_1(x) = \max_{y \in G_1} \varphi_1(x, y),$$

$$f_2(x) = \max_{y \in G_2} \varphi_2(x, y)$$

where  $\varphi_1$  and  $\varphi_2$  are continuous on  $\mathbf{R}^n \times G_1$  and  $\mathbf{R}^n \times G_2$ , respectively, and there exist derivatives  $\varphi_{1x'}$  and  $\varphi_{2x'}$  which are continuous. The function  $f$  (called a *d.m. function*) is quasidifferentiable. It is also continuously codifferentiable:

$$f(x + \Delta) = f(x) + \max_{[a,v] \in \underline{d}f(x)} [a + (v, \Delta)] + \min_{[b,w] \in \overline{d}f(x)} [b + (w, \Delta)] + o_x(\Delta),$$

where

$$\underline{d}f(x) = \text{co} \left\{ \begin{array}{l} a = \varphi_1(x, y) - f_1(x), \\ v = \varphi'_{1x}(x, y), \\ y \in G_1 \end{array} \right\} \subset \mathbf{R} \times \mathbf{R}^n,$$

$$\overline{d}f(x) = \text{co} \left\{ \begin{array}{l} b = f_2(x) - \varphi_2(x, y), \\ w = -\varphi'_{2x}(x, y), \\ y \in G_2 \end{array} \right\} \subset \mathbf{R} \times \mathbf{R}^n.$$

Here  $a, b \in \mathbf{R}; v, w \in \mathbf{R}^n$ .

Now it is possible to employ the MCD for finding inf-stationary points.

### Twice Codifferentiable Functions

A function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  is called *twice codifferentiable* at  $x \in \mathbf{R}^n$  if there exist convex compact sets  $d^2f(x)$  and  $\overline{d}^2f(x) \subset \mathbf{R} \times \mathbf{R}^n \times \mathbf{R}^{n \times n}$  such that

$$f(x + \Delta) = f(x) + \max_{[a,v,A] \in \underline{d}^2f(x)} \left[ a + (v, \Delta) + \frac{1}{2}(A\Delta, \Delta) \right] + \min_{[b,w,B] \in \overline{d}^2f(x)} \left[ b + (w, \Delta) + \frac{1}{2}(B\Delta, \Delta) \right] + o(\Delta^2)$$

where

$$\frac{o((\alpha\Delta)^2)}{\alpha^2} \xrightarrow{\alpha \rightarrow 0} 0, \quad \forall \Delta \in \mathbf{R}^n.$$

Here  $\mathbf{R}^{n \times n}$  is the space of real  $(n \times n)$ -matrices.

The pair of sets  $D^2f(x) = [d^2f(x), \overline{d}^2f(x)]$  is called a *second order codifferential* of  $f$  at  $x$ . If  $f$  is twice c.d. in some neighborhood of  $x$  and the mapping  $D^2f$  is Hausdorff continuous at  $x$ , then the function is called *twice continuously codifferentiable* at  $x$ .

The class of twice c.d. functions is quite rich and enjoys a well-developed calculus (see [4]).

Let  $f$  be twice continuously c.d. on  $\mathbf{R}^n$ . Then the following second order Newton-type method can be employed to find inf-stationary points of  $f$ .

Take any  $x_0 \in \mathbf{R}^n$ . Let  $x_k$  have already been constructed. Put

$$F_k(\Delta) = \max_{[a,v,A] \in \vec{d}^2 f(x_k)} \left[ a + (v, \Delta) + \frac{1}{2}(A\Delta, \Delta) \right] + \min_{[b,w,B] \in \vec{d}^2 f(x_k)} \left[ b + (w, \Delta) + \frac{1}{2}(B\Delta, \Delta) \right],$$

find

$$\min_{\Delta \in \mathbf{R}^n} F_k(\Delta) = F_k(\Delta_k)$$

and take  $x_{k+1} = x_k + \Delta_k$ .

The sequence  $\{x_k\}$  thus constructed converges (under some additional assumptions) to an inf-stationary point of  $f$  (see [1]).

### Quasidifferentiable Programming Problems

Let functions  $f$  and  $h_i: \mathbf{R}^n \rightarrow \mathbf{R}$  ( $i \in I = 1, \dots, N$ ) be quasidifferentiable on  $\mathbf{R}^n$  and let

$$\Omega = \{x \in \mathbf{R}^n: h_i(x) \leq 0, \forall i \in I\}.$$

Assume that  $\Omega \neq \emptyset$ .

It is required to find

$$(P) \min_{x \in \Omega} f(x) = f^*.$$

The set  $\Omega$  is called *quasidifferentiable*, problem (P) is a quasidifferentiable (q.d.) programming problem. Necessary conditions for a minimum of  $f$  on  $\Omega$  are stated in ► **Quasidifferentiable optimization: Optimality conditions**. If all the functions  $f$  and  $f_i'$  are, in addition, continuously codifferentiable then it is possible to extend the MCD to problem (P) (see [4]).

Another approach to problem (P) is based on the penalization technique.

We say that problem (P) is *calm* if

$$\limsup_{\varepsilon \downarrow 0} \frac{f^* - f_\varepsilon}{\varepsilon} \leq B < \infty \tag{19}$$

where

$$f_\varepsilon = \inf_{x \in \Omega_\varepsilon} f(x),$$

$$\Omega_\varepsilon = \{x \in \mathbf{R}^n: h_i(x) \leq \varepsilon, \forall i \in I\}, \varepsilon > 0.$$

**Proposition 7** *If the calmness condition (19) holds then there exists  $A^* < \infty$  such that, for any  $A > A^*$ , the set of minimizers of the function  $f$  on  $\Omega$  coincides with the set of minimizers of the function*

$$F(x, A) = f(x) + A \sum_{i \in I} h_i^+(x) \tag{20}$$

on  $\mathbf{R}^n$ . Here  $h_i^+(x) = \max\{0, h_i(x)\}$ .

**Remark 8** Thus, the constrained optimization problem (P) is reduced to the unconstrained one. Since the function  $F(x, A)$  is again quasidifferentiable, one can use methods for unconstrained optimization. Another condition (different from (19)) under which Proposition 7 is valid was stated in [2].

**Remark 9** Problem (P) is called a *d.c. programming problem* if all the functions  $f$  and  $h_i'$  ( $i \in I$ ) are d.c., i. e.  $f = f_1 - f_2, h_i = h_{1i} - h_{2i}$  where  $f_1, f_2, h_{1i}, h_{2i}$  are convex. If the calmness condition (19) holds then, by Proposition 7, problem (P) is reduced to that of minimizing the function  $F(x, A)$  (see (20)) (if  $A$  is sufficiently large). We have

$$h_i^+(x) = \max\{0, h_i(x)\} = \max\{0, h_{1i}(x) - h_{2i}(x)\} = \bar{h}_{1i}(x) - \bar{h}_{2i}(x),$$

where

$$\bar{h}_{1i}(x) = \max\{h_{1i}(x), h_{2i}(x)\}, \bar{h}_{2i}(x) = h_{1i}(x) + h_{2i}(x).$$

The functions  $\bar{h}_{1i}$  and  $\bar{h}_{2i}$  are convex, therefore  $h_i^+$  is d.c. and, hence, the function  $F(x, A)$  is also d.c. and one may use the method described above for d.c. functions.

Nonsmooth optimization; Quasidifferentiability; Nonsmooth modeling

Quasidifferentiability and the notion of the quasidifferential extend the subdifferential of convex analysis for a quite general class of nonconvex and nonsmooth, but directionally differentiable functions. By using an ordered pair of convex sets, the quasidifferential copes in a nice way with both nonsmoothness and nonconvexity issues. Since its introduction by V.F. Demyanov, a number of quasidifferential optimization problems have been studied. Moreover calculus rules have been developed and applications, among others in mechanics and engineering [5] have been considered. In addition, the related, more appropriate for numerical purposes notion of the codifferential has been introduced.

Let us consider a classical optimization algorithm, the (anti)gradient optimization, and how it is modified for quasidifferentiable functions. First, recall that a nondifferentiable function does not has derivatives in

the classical sense. One should use set-valued approximations at the points of the nondifferentiability instead. This replacement introduces the following two problems in a gradient optimization algorithm. First, one has to calculate an appropriate direction of descent, which should be followed at a given iteration step. Moreover, the optimality conditions for a nondifferentiable function have a form dictated by the set-valued approximation of the derivative (i. e., one should check, at a given point, if zero is element of a set, or if some relation between sets is satisfied). Several applications of the quasidifferentiability concept are briefly reviewed in this short article.

### Nonsmooth Modeling

Let us recall first the notion of quasidifferentiability in the sense of Demyanov. A function  $f$  which is defined on an open set  $X \subset \mathbf{R}^n$  and which is directionally differentiable at a point  $x \in X$  is called *quasidifferentiable* if there exists an ordered pair of convex compact sets  $[\underline{\partial}f(x), \bar{\partial}f(x)]$  in  $\mathbf{R}^n \times \mathbf{R}^n$  which produces the directional derivative of the function by the following formula

$$f'(x, g) = \max_{w \in \underline{\partial}f(x)} \langle w, g \rangle + \min_{v \in \bar{\partial}f(x)} \langle v, g \rangle, \quad (1)$$

for all directions  $g \in \mathbf{R}^n$ . More details are given in ► [Quasidifferentiable optimization](#).

Relation (1) gives rise to a qualitative and quantitative nonsmooth approximation (quasilinearization) of a nonsmooth and nonconvex function  $f$  at point  $x$ . Theoretical results on nonsmooth modeling can be found, among others, in [8,9,14].

The notion of the quasidifferential gives rise to nonsmooth models, with applications in mechanics [5,11]. In particular, interesting nonconvex variational formulations can be written, as it is discussed in more detail in ► [Quasidifferentiable optimization: Variational formulations](#). They extend the *variational inequalities*, which are valid for the convex, nondifferentiable case, and constitute a parallel development to the *hemivariational inequalities* in the sense of P.D. Panagiotopoulos (see also ► [Nonconvex energy functions: Hemivariational inequalities](#); ► [Hemivariational inequalities: Applications in mechanics](#) as well as [12]). Furthermore, quasidifferential and codifferential optimization techniques can be used for the construction of numerical

algorithms for problems of nonsmooth computational mechanics [5].

### Nonsmooth and Nonconvex Optimization

The notion of the quasidifferential allows one to calculate one steepest descent direction of a quasidifferentiable function  $f(x)$  at a given point  $x_0$ . Assume that at point  $x_0$  one has the subdifferential  $\underline{\partial}f(x_0)$  and the superdifferential  $\bar{\partial}f(x_0)$ . Then, a steepest descent direction  $h$  can be calculated by:

$$h = \frac{w_1^* + w_2^*}{\|w_1^* + w_2^*\|}, \quad (2)$$

for  $w_1^* \in \underline{\partial}f(x_0)$ ,  $w_2^* \in \bar{\partial}f(x_0)$ , such that

$$\|w_1^* + w_2^*\| = \max_{w_1 \in \underline{\partial}f(x_0)} \left\{ \min_{w_2 \in \bar{\partial}f(x_0)} \|w_1 + w_2\| \right\}.$$

Moreover, there exists necessary (and in some cases sufficient) set-valued optimality conditions for quasidifferentiable optimization problems (see ► [Quasidifferentiable optimization](#)). Thus one has whatever is needed for the construction of a numerical algorithm. Calculus rules exist for the construction of the quasidifferential (see ► [Quasidifferentiable optimization: Calculus of quasidifferentials](#)), if this is not obvious from the definition of the optimization problem. Stopping rules for an optimization algorithm can also be extracted. In fact, if the optimality criteria are satisfied, then (at least local) minimum point has been calculated. Otherwise, one can calculate a steepest descent direction by (2) and proceed with a (steepest descent like) numerical optimization scheme. In this respect the affiliated notion of the codifferentiability has certain advantages for the numerical implementation. More details can be found in ► [Quasidifferentiable optimization: Codifferentiable functions](#) and in [3,6].

It is worth noting to observe here that formula (2) may admit multiple solutions. This should be expected since one deals with nonconvex (global) optimization problems. This is actually one of the advantages of the quasidifferentiability concept since, theoretically, if one follows all possible directions of descent which may arise along an iterative algorithm one should be able to calculate multiple solutions (i. e., local minima).

More information on smooth (convex and nonconvex) optimization and appropriate algorithms devel-

oped for these problems can be found, among others, in [2,7]. Note also the multi-objective programming approach for the solution of systems of quasidifferentiable equations which has been developed in [13].

### Multilevel and Marginal Function Optimization

Interesting results on the application of the quasidifferentiability concept for the sensitivity analysis and algorithms for multilevel optimization problems have been presented in [1,10].

### Applications in nonsmooth mechanics

Quasidifferential modeling and optimization have been used for nonsmooth mechanics applications. As it is already mentioned these results can be found in [5,11]. A number of recent (2000) applications of quasidifferentiability can be found in [4].

Certain *semipermeability* or *temperature control* problems in *thermoelasticity*, which may be combined with analogous mechanical unilateral contact effects, can be formulated and studied in a unified framework by nonsmooth modeling techniques [7]. The theory of quasidifferentiable optimization, in the sense of V.F. Dem'yanov and A.M. Rubinov, provides a general framework for the treatment of both convex and nonconvex, nonsmooth modeling problems [1,2,3,4]. Coupled thermal and kinematical nonconvex unilateral effects will be modeled in the sequel by using the quasidifferentiable optimization approach. Analogous formulations which have been based on the notion of *hemivariational inequalities* have been proposed and studied for semipermeability and thermal problems by P.D.

Panagiotopoulos et al. [6,7]. An extension to thermo-viscoelasticity has recently been published in [5].

This short article is mainly based on the results presented in [4,7], where more details can be found.

### Classical Thermoelastic Model

Let us consider a thermoelastic medium in the Euclidean space  $\mathbf{R}^3$ . A point is denoted by  $x$  and its coordinates with respect to a fixed Cartesian coordinate system  $0x_1x_2x_3$  by  $x_i, i = 1, 2, 3$ . The time variable  $t$  takes values in the interval  $[0, T] \subset \mathbf{R}$ . Moreover, let  $u = u(x, t)$  be the displacement of the material point  $x$  at time  $t$  with reference to the natural state of the body, which is characterized by zero stresses and a constant absolute temperature  $\theta_0 > 0$ . The density at point  $x$  of the natural state is denoted by  $\rho = \rho(x)$  and the open, bounded, connected subset of  $\mathbf{R}^3$  occupied by the body is denoted by  $\Omega$ . As usual, the boundary  $\Gamma$  of  $\Omega$  is assumed to be regular.

The behavior of a linear thermoelastic body is governed by the following constitutive equations for the stress tensor  $\sigma = \{\sigma_{ij}\}, i = 1, 2, 3$ , and the specific entropy deviation  $\eta - \eta_0$  (where  $\eta_0$  is the specific entropy of the natural state)

$$\begin{aligned} \sigma_{ij} &= t_{ij} - m_{ij}(\theta - \theta_0) \\ &= C_{ijhk}\varepsilon_{hk} - m_{ij}(\theta - \theta_0), \end{aligned} \tag{1}$$

$$\eta - \eta_0 = \frac{1}{\theta_0}c_D(\theta - \theta_0) + \frac{1}{\rho}m_{ij}\varepsilon_{ij}. \tag{2}$$

Here  $\theta = \theta(x, t)$  is the absolute temperature, and  $\varepsilon = \{\varepsilon_{ij}\}$  the strain tensor, which is related to the displacements by the small deformation elasticity relation

$$\varepsilon_{ij}(u) = \frac{1}{2}(u_{i,j} + u_{j,i}).$$

Here  $C = \{C_{ijhk}\}, i, j, h, k = 1, 2, 3$ , is the elasticity tensor, which satisfies the well-known symmetry and ellipticity conditions,  $m = \{m_{ij}\}$  is the symmetry tensor of thermal expansion, and  $c_D = c_D(x) > 0$  is the specific heat at zero strain of the body.  $C(x), m(x)$  and  $c_D(x)$  are referred to the natural state of the body. The equations of motion are:

$$\rho u_i'' = \sigma_{ij,j} + f_i, \tag{3}$$

and the law of conservation of energy has the form

$$\rho\theta_0\eta' = -q_{i,i} + Q. \tag{4}$$

Here  $f = \{f_i\}$ ,  $f_i = f_i(x, t)$ , is the volume force vector,  $q = \{q_i\}$ ,  $q_i = q_i(x, t)$ , is the heat flux vector and  $Q = Q(x, t)$  is the radiant heating per unit volume. *Fourier's law of heat conduction* reads:

$$q_i = -k_{ij}\theta_{,j}. \quad (5)$$

The symmetric tensor of thermal conductivity  $k = \{k_{ij}\}$ ,  $k_{ij} = k_{ij}(x)$ , refers to the natural state of the body and satisfies the condition

$$k_{ij}a_i a_j \geq ca_i a_i, \quad \forall a = \{a_i\} \in \mathbb{R}^3,$$

where  $c$  is a positive constant. These relations lead to the following system of differential equations, which describe the *linear thermoelastic behavior of a generally nonhomogeneous and nonisotropic body*:

$$\rho u_i'' = f_i + (C_{ijhk}\varepsilon_{hk})_{,j} - (m_{ij}(\theta - \theta_0))_{,j}, \quad \text{in } \Omega \times (0, T), \quad (6)$$

$$\rho c_D \theta' - (k_{ij}\theta_{,j})_{,i} + m_{ij}\theta_0 \varepsilon'_{ij} = Q, \quad \text{in } \Omega \times (0, T). \quad (7)$$

In the sequel the following initial conditions at  $t = 0$  are assumed:

$$u_i = u_{0i}(x), \quad u_i' = u_{1i}(x) \quad \text{in } \Omega, \quad (8)$$

and

$$\theta = \bar{\theta}(x) \quad \text{in } \Omega. \quad (9)$$

Let the following bilinear forms be introduced:

$$\begin{aligned} a(u, v) &= \int_{\Omega} C_{ijhk}\varepsilon_{ij}(u)\varepsilon_{hk}(v) d\Omega, \\ (u, v) &= \int_{\Omega} u_i v_i d\Omega, \\ M_1(\theta, v) &= \int_{\Omega} (m_{ij}\theta)_{,j} v_i d\Omega, \\ M_2(u, \varphi) &= \int_{\Omega} m_{ij} u_{i,j} \varphi d\Omega, \\ K(\theta, \varphi) &= \int_{\Omega} k_{ij} \theta_{,j} \varphi_{,i} d\Omega, \\ (\theta, \varphi) &= \int_{\Omega} \theta \varphi d\Omega. \end{aligned} \quad (10)$$

### Quasidifferential Thermal Boundary Conditions

In order to complete the description of the previous boundary value problem one needs to specify boundary conditions for the thermal and for the elasticity problem. First, let us assume that between the boundary temperature and the heat flux the following quasidifferential (QD) superpotential relation holds:

$$\begin{aligned} q_i n_i &= -k_{ij}\theta_{,j} n_i = w_1(\theta, t) + w_2(\theta, t), \\ \text{with } \{w_1(\theta, t), w_2(\theta, t)\} &\in Dj(\theta, t), \\ \text{on } \Gamma_1 \times (0, T), \end{aligned} \quad (11)$$

where  $\Gamma_1 \subset \Gamma$  and on the remaining part of the boundary one assumes, for simplicity, that:

$$\theta = 0 \quad \text{on } \Gamma - \Gamma_1. \quad (12)$$

For the displacements, a simple boundary condition is considered:

$$u_i = 0 \quad \text{on } \Gamma \times (0, T). \quad (13)$$

Here  $n = \{n_i\}$  denotes, as usual, the unit normal to  $\Gamma$  directed towards the exterior of  $\Omega$ .

### Variational Formulation

One follows here the usual way for the construction of the variational or weak formulation of the previous boundary value problem (see also ► **quasidifferentiable optimization: variational formulations**; ► **hemivariational inequalities: applications in mechanics**). Let the virtual variations  $v - u'$  and  $\varphi - \theta$  are sufficiently smooth. Then, by multiplying (6) and (7) by  $v - u'$  and  $\varphi - \theta$  respectively, integrating over  $\Omega$ , and using the Green—Gauss theorem, one obtains the variational equalities

$$\begin{aligned} (\rho u'', v - u') + a(u, v - u') + M_1(\theta - \theta_0, v - u') \\ = (f, v - u') + \int_{\Gamma} t_{ij} n_j (v_i - u'_i) d\Gamma \\ \text{in } \Omega \times (0, T) \end{aligned} \quad (14)$$

and

$$\begin{aligned} (\rho c_D \theta', \varphi - \theta) + K(\theta, \varphi - \theta) + M_2(\theta_0 u', \varphi - \theta) \\ = (Q, \varphi - \theta) + \int_{\Gamma} k_{ij} \theta_{,j} n_i (\varphi - \theta) d\Gamma \\ \text{in } \Omega \times (0, T). \end{aligned} \quad (15)$$

Now let us assume that  $C_{ijkl}, k_{ij}, m_{ij}, \rho > 0$  and  $c_D > 0$  are elements of  $L^\infty(\Omega)$ , and that  $f(t) \in [L^2(\Omega)]^3$  and  $Q(t) \in L^2(\Omega)$ . Moreover, the spaces  $[H^1(\Omega)]^3$  for  $v, u'$  and  $H^1(\Omega)$  for  $\varphi, \theta$  are introduced.

Let us recall that a QD boundary condition (for instance, the relation (11)), gives rise, due to the definition of the quasidifferential, to a min-max relation. This relation, is used for the formulation of nonconvex variational problems, as it is discussed in more details in **► quasidifferentiable optimization: variational formulations**.

Thus, the variational equalities (14) and (15) are combined with the boundary conditions (11)–(13), and lead to the following variational problem: find functions  $u: [0, T] \rightarrow [H^1(\Omega)]^3$  and  $\theta: [0, T] \rightarrow \Phi = H^1(\Omega): \theta = 0$  on  $\Gamma - \Gamma_1$ , with  $u'(t) \in [H^1(\Omega)]^3$ ,  $u''(t) \in [L^2(\Omega)]^3$ ,  $\theta'(t) \in L^2(\Omega)$ , which satisfy the initial conditions and the variational expression

$$\begin{aligned} & (\rho u'', v - u') + a(u, v - u') + M_1(\theta - \theta_0, v - u') \\ & = (f, v - u'), \quad \forall v \in [H^1(\Omega)]^3, \end{aligned} \quad (16)$$

and

$$\begin{aligned} & (\rho c_D \theta', \varphi - \theta) + K(\theta, \varphi - \theta) \\ & + M_2(\theta_0 u', \varphi - \theta) \\ & + \max \{ \langle w_1^*, \varphi - \theta \rangle : w_1^* \in \underline{\partial} J(\theta, t) \} \\ & + \min \{ \langle w_2^*, \varphi - \theta \rangle : w_2^* \in \bar{\partial} J(\theta, t) \} \\ & = (Q, \varphi - \theta), \quad \forall \varphi \in \Phi. \end{aligned} \quad (17)$$

### Quasidifferential Elastic Boundary Conditions

Assume now simple thermal boundary conditions, i. e.,

$$\theta = \theta_0 \quad \text{on } \Gamma \times (0, T). \quad (18)$$

For the elasticity problem let a nonmonotone, possibly multivalued quasidifferential (QD) boundary law holds on a part  $\Gamma_S$  of the boundary  $\Gamma$ :

$$\begin{aligned} & -S = \{-S_i\} = \{-\sigma_{ij} n_j\} \\ & = S_1(u', x, t) + S_2(u', x, t), \\ & \{S_1(u', x, t), S_2(u', x, t)\} \in D\psi(u', x, t) \\ & \text{on } \Gamma_S \times (0, T). \end{aligned} \quad (19)$$

On the remaining part of the boundary one assumes simply that:

$$u_i = U_i \quad \text{on } \Gamma_U \times (0, T). \quad (20)$$

Here  $\Gamma = \bar{\Gamma}_U \cup \bar{\Gamma}_S$ , where  $\Gamma_U$  and  $\Gamma_S$  are nonempty, disjoint, open sets,  $U_i = U_i(x, t)$  is a prescribed displacement vector on  $\Gamma_U$  (which should be compatible with the initial conditions (8)–(9)).

In an analogous way one proceeds with the boundary value problem which is defined by the relations (6)–(9) and (18)–(19). Let  $v, u' \in [H^1(\Omega)]^3$  be such that  $v = u' = U'(t)$  on  $\Gamma_U$  and  $\varphi, \theta \in H^1(\Omega)$  with  $\varphi = \theta = \theta_0$  on  $\Gamma$ . In this case one gets the variational problem: find  $u: [0, T] \rightarrow [H^1(\Omega)]^3$  with  $u' = U$  on  $\Gamma_U$  and  $\theta \in H^1(\Omega)$  with  $\theta = \theta_0$  on  $\Gamma$  with  $u'(t) \in [H^1(\Omega)]^3$ ,  $u''(t) \in [L^2(\Omega)]^3$ ,  $\theta'(t) \in L^2(\Omega)$ , which satisfy the initial conditions and the variational expression

$$\begin{aligned} & (\rho u'', v - u') + a(u, v - u') \\ & + M_1(\theta - \theta_0, v - u') \\ & + \max \{ \langle S_1^*, v - u' \rangle : S_1^* \in \underline{\partial} \Psi(u', t) \} \\ & + \min \{ \langle S_2^*, v - u' \rangle : S_2^* \in \bar{\partial} \Psi(u', t) \} \\ & = (f, v - u'), \\ & \forall v \in [H^1(\Omega)]^3 \quad \text{with } v = U'(t) \text{ on } \Gamma_U \end{aligned} \quad (21)$$

and

$$\begin{aligned} & (\rho c_D \theta', \varphi - \theta) + K(\theta, \varphi - \theta) \\ & + M_2(\theta_0 u', \varphi - \theta) \\ & = (Q, \varphi - \theta), \\ & \forall \varphi \in H^1(\Omega) \quad \text{with } \varphi = \theta_0 \text{ on } \Gamma. \end{aligned} \quad (22)$$

More general thermoelastic problems may be considered by considering QD laws for both the elasticity and the thermal part of the problem, or even mixed laws.

A function  $f$  defined on an open set  $X \subset \mathbf{R}^n$  and directionally differentiable at a point  $x \in X$  is called *quasidifferentiable* (in the sense of V.F. Demyanov) if there exists an ordered pair of convex compact sets  $[U, V]$  in  $\mathbf{R}^n \times \mathbf{R}^n$  which produces the directional derivative of the function by the following formula

$$f'(x, g) = \max_{h \in U} (h, g) + \min_{h \in V} (h, g), \quad (1)$$

for all directions  $g \in \mathbf{R}^n$ .

Quasidifferentiability is a genuine generalization of the classical differentiability concept which is valid for smooth differentiable functions, and of the convex analysis subdifferential, which, in turn, is a set-valued differential valid for convex, nondifferentiable functions. An ordered pair of convex sets is used for the approximation of the directional derivative in (1). More

details can be found in the companion article ► **Quasidifferentiable optimization**, the links with other notions of nonsmooth analysis are discussed in ► **Quasidifferentiable optimization: Dini derivatives, Clarke derivatives** and applications are briefly presented in ► **Quasidifferentiable optimization: Applications**. One may also consult the original publications [2,3,4,5,6].

Using classical differential calculus and on the assumption of smooth (differentiable) functions the derivative of sums, of differences or of composite functions etc may easily be calculated. To this end one uses calculus rules and the derivatives of the involved functions (cf., the chain rule of differentiation). For quasidifferentiable functions there exist appropriate calculus rules [2]. The situation is more complicated here, since one manipulates ordered pairs of convex sets. Furthermore, calculus rules have been developed for composite functions which can be produced from a finite number of smooth constituents and from the application of a finite number of minimum or maximum operators. Moreover, as the quasidifferential of a given function is not uniquely determined (it is actually a class of equivalent ordered pairs of convex sets) one may wish to simplify the results of such a calculus operation.

It is clear that, since quasidifferentials have found a number of applications, among others in optimization, in mechanics, in control theory and in economy, the need for refining the quasidifferential calculus and for incorporating it into automatic computational procedures (e.g. in computer algebra systems, in analogy to classical systems [1]) is obvious. For the latter task, which at the present remains open for future research efforts, use of results developed within the theory of interval analysis may be advantageous.

Calculus rules for one-dimensional functions (defined on  $\mathbf{R}$ ) and for functions defined on  $\mathbf{R}^n$  are given without proofs here. See [2,3] for more details.

**One-Dimensional Case**

A function in  $\mathbf{R}^1$  and sets which are intervals of the real line  $\mathbf{R}^1$  are considered first. Let  $D_1$  and  $D_2$  be two pairs of closed intervals:  $D_1 = [A_1, B_1]$ ,  $D_2 = [A_2, B_2]$ , where  $A_1 = [v_{11}, v_{12}]$ ,  $B_1 = [w_{11}, w_{12}]$ ,  $A_2 = [v_{21}, v_{22}]$ ,  $B_2 = [w_{21}, w_{22}]$ , with  $v_{i1} \leq v_{i2}$ ,  $w_{i1} \leq w_{i2}$ ,  $\forall i \in \{1, 2\}$ . Addition of intervals is defined as follows:  $D = D_1 + D_2 = [A_1 + B_1, A_2 + B_2] = [A, B]$ , where  $A = [v_{11} + v_{21}, v_{12} + v_{22}]$  and  $B$

$= [w_{11} + w_{21}, w_{12} + w_{22}]$ . Moreover, for  $D = [A, B]$ ,  $A = [v_1, v_2]$ ,  $B = [w_1, w_2]$ ,  $v_1 \leq v_2$ ,  $w_1 \leq w_2$ , multiplication by a scalar quantity  $\lambda$  is defined by:

$$\lambda D = \begin{cases} \lambda[A, B], & \lambda \geq 0, \\ \lambda[B, A], & \lambda < 0, \end{cases}$$

where, on the right-hand side one has  $\lambda [A, B] = [[\lambda v_1, \lambda v_2], [\lambda w_1, \lambda w_2]]$ , etc.

Based on these results concerning calculus of closed intervals one derives calculus rules for quasidifferentials in the one-dimensional case.

Let  $f_1$  be a directionally differentiable function at a point  $x$  and let  $Df_1(x) = [\underline{\partial}f_1(x), \bar{\partial}f_1(x)]$  be its quasidifferential at a point  $x \in \mathbf{R}^1$ :  $\underline{\partial}f_1(x) = [v_{11}, v_{12}]$ ,  $\bar{\partial}f_1(x) = [w_{11}, w_{12}]$ ,  $v_{11} \leq v_{12}$ ,  $w_{11} \leq w_{12}$ . Then the function  $f = \lambda f_1$  is also directionally differentiable at  $x$  and admits a quasidifferential of the form  $Df(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$ , where

$$\begin{aligned} \underline{\partial}f(x) &= \begin{cases} [\lambda v_{11}, \lambda v_{12}], & \lambda \geq 0, \\ [\lambda w_{12}, \lambda w_{11}], & \lambda < 0, \end{cases} \\ \bar{\partial}f(x) &= \begin{cases} [\lambda w_{11}, \lambda w_{12}], & \lambda \geq 0, \\ [\lambda v_{12}, \lambda v_{11}], & \lambda < 0. \end{cases} \end{aligned}$$

If in addition,  $f_1(x) \neq 0$  then the function  $f = 1/f_1$  is also directionally differentiable at  $x$  and

$$Df(x) = -\frac{1}{f_1^2} Df_1(x) = [\underline{\partial}f(x), \bar{\partial}f(x)],$$

where

$$\begin{aligned} \underline{\partial}f(x) &= \left[ -\frac{1}{f_1^2} w_{12}, -\frac{1}{f_1^2} w_{11} \right], \\ \bar{\partial}f(x) &= \left[ -\frac{1}{f_1^2} v_{12}, -\frac{1}{f_1^2} v_{11} \right]. \end{aligned}$$

Let us consider two directionally differentiable functions  $f_1, f_2$  at a point  $x$  and let  $Df_1(x), Df_2(x)$  be their quasidifferentials

$$\begin{aligned} Df_1(x) &= [\underline{\partial}f_1(x), \bar{\partial}f_1(x)], \\ Df_2(x) &= [\underline{\partial}f_2(x), \bar{\partial}f_2(x)], \end{aligned}$$

with the corresponding intervals denoted by:

$$\begin{aligned} \underline{\partial}f_1(x) &= [v_{11}, v_{12}], & \bar{\partial}f_1(x) &= [w_{11}, w_{12}], \\ \underline{\partial}f_2(x) &= [v_{21}, v_{22}], & \bar{\partial}f_2(x) &= [w_{21}, w_{22}], \\ v_{i1} &\leq v_{i2}, & w_{i1} &\leq w_{i2}, & \forall i \in \{1, 2\}. \end{aligned}$$

Then the function  $f = f_1 + f_2$  is also directionally differentiable at  $x$  and one can take  $Df(x) = [\underline{\partial}f(x), \overline{\partial}f(x)]$ , where

$$\begin{aligned}\underline{\partial}f(x) &= \underline{\partial}f_1(x) + \underline{\partial}f_2(x) = [v_1, v_2] \\ \overline{\partial}f(x) &= \overline{\partial}f_1(x) + \overline{\partial}f_2(x) = [w_1, w_2],\end{aligned}$$

with  $v_1 = v_{11} + v_{21}$ ,  $v_2 = v_{12} + v_{22}$ ,  $w_1 = w_{11} + w_{21}$  and  $w_2 = w_{12} + w_{22}$ .

Analogously one proceeds with the product of two functions  $f = f_1 f_2$ , where

$$\begin{aligned}Df(x) &= f_1(x)Df_2(x) + f_2(x)Df_1(x) \\ &= [\underline{\partial}f(x), \overline{\partial}f(x)].\end{aligned}$$

Furthermore, let  $\varphi_i(x)$  ( $i \in I = \{1, \dots, N\}$ ) be directionally differentiable functions at a point  $x$ . The functions

$$f_1(x) = \max_{i \in I} \varphi_i(x), \quad f_2(x) = \min_{i \in I} \varphi_i(x)$$

are also quasidifferentiable.

Finally, let  $f(z_1, \dots, z_m)$  be a smooth function and let  $y_1, \dots, y_m$  be quasidifferentiable functions at a point  $x_0$ . Then the function  $F(x) = f(y_1(x), \dots, y_m(x))$  is also quasidifferentiable at  $x_0$ .

One concludes that the family of quasidifferentiable functions is a linear space, closed with respect to all smooth operations, as well as the operations of taking the pointwise maximum and minimum over a finite number of functions.

### Finite-Dimensional Case

In this case one needs calculus rules for pairs of convex sets of  $\mathbf{R}^n$  (see, e. g. [4,6]).

Let the functions  $f, f_1, f_2$  be quasidifferentiable at  $x$  and  $\lambda$  be a real number. Then the sum, the product, the function  $\lambda f$  and the function  $1/f(x)$  (or every point  $x$  such that  $f(x) \neq 0$ ) are also quasidifferentiable and an element of their quasidifferential can be calculated as follows:

$$\begin{aligned}D(f_1 + f_2)(x) &= Df_1(x) + Df_2(x), \\ D(f_1 \cdot f_2)(x) &= f_1(x)Df_2(x) + f_2(x)Df_1(x), \\ D(\lambda f)(x) &= \lambda Df(x), \\ D\left(\frac{1}{f}\right)(x) &= -\frac{1}{f^2(x)}Df(x).\end{aligned}$$

Let moreover the functions  $f_1, \dots, f_m$  be defined on an open set  $X \subset \mathbf{R}^n$  and be quasidifferentiable at  $x \in X$ . Then, the functions

$$\phi_1(x) = \max_{i \in \{1, \dots, m\}} f_i(x), \quad \phi_2(x) = \min_{i \in \{1, \dots, m\}} f_i(x)$$

are quasidifferentiable at  $x$  as well. The following relations hold:

$$D\phi_j(x) = \left[ \underline{\partial}\phi_j(x), \overline{\partial}\phi_j(x) \right], \quad j = 1, 2,$$

with

$$\begin{aligned}\underline{\partial}\phi_1(x) &= \text{co} \bigcup_{k \in R(x)} \left( \underline{\partial}f_k(x) - \sum_{\substack{i \in R(x), \\ i \neq k}} \overline{\partial}f_i(x) \right), \\ \overline{\partial}\phi_1(x) &= \sum_{k \in R(x)} \overline{\partial}f_k(x), \quad \underline{\partial}\phi_2(x) = \sum_{k \in Q(x)} \underline{\partial}f_k(x), \\ \overline{\partial}\phi_2(x) &= \text{co} \bigcup_{k \in Q(x)} \left( \overline{\partial}f_k(x) - \sum_{\substack{i \in Q(x), \\ i \neq k}} \underline{\partial}f_i(x) \right).\end{aligned}$$

Here,  $[\underline{\partial}f_k(x), \overline{\partial}f_k(x)]$  is a quasidifferential of  $f_k$  at  $x$  and the following activity sets have been used:

$$\begin{aligned}R(x) &= \{i \in I: f_i(x) = \phi_1(x)\}, \\ Q(x) &= \{i \in I: f_i(x) = \phi_2(x)\},\end{aligned}$$

where  $I = \{1, \dots, n\}$ .

Finally, consider the case of a composite function. Let a mapping  $H(x) = (h_1(x), \dots, h_m(x))$  be defined such that  $H(x): X \rightarrow Y$ , where  $X$  is an open set in  $\mathbf{R}^n$  and  $Y$  is an open set in  $\mathbf{R}^m$  and every function  $h_i$  is quasidifferentiable at  $x_0 \in X$ . Let us assume that a function  $f$  is defined on  $Y$  and is Hadamard differentiable and quasidifferentiable at  $y_0 = H(x_0)$ . Then the composite function

$$\phi(x) = f(H(x))$$

is quasidifferentiable at  $x_0$  and its quasidifferential  $D\phi(x_0) = [\underline{\partial}\phi(x_0), \overline{\partial}\phi(x_0)]$  is expressed by the formulas:

$$\underline{\partial}\phi(x_0) = \left\{ p: \begin{array}{l} p = \sum_{i=1}^m (v^{(i)}(\lambda_i + \mu_i) - \underline{v}^{(i)}\lambda_i - \overline{v}^{(i)}\mu_i), \\ v = (v^{(1)}, \dots, v^{(m)}) \in \underline{\partial}f(y_0), \\ \lambda_i \in \underline{\partial}h_i(x_0), \mu_i \in \overline{\partial}h_i(x_0) \end{array} \right\}$$

$$\overline{\partial}\phi(x_0) = \left\{ l: \begin{array}{l} l = \sum_{i=1}^m (v^{(i)}(\lambda_i + \mu_i) + \underline{v}^{(i)}\lambda_i + \overline{v}^{(i)}\mu_i), \\ v = (v^{(1)}, \dots, v^{(m)}) \in \overline{\partial}f(y_0), \\ \lambda_i \in \underline{\partial}h_i(x_0), \mu_i \in \overline{\partial}h_i(x_0) \end{array} \right\},$$

where  $\underline{v}$  and  $\overline{v}$  are arbitrary vectors such that

$$\underline{v} \leq v \leq \overline{v}, \quad \forall v \in \underline{\partial}f(y_0) \cup (-\overline{\partial}f(y_0)).$$

Concrete examples and the derivation of the above rules can be found in the above given literature. One should only mention that if some of the involved sets (i. e., the subdifferential or the superdifferential) happens to be polyhedral, then certain of the previous rules can be simplified significantly (see, e. g., [7]). The latter case appears, among others, in the applications of quasidifferential calculus within a finite element method environment for applications in mechanics (see also ► [Quasidifferentiable optimization: Variational formulations](#); ► [Quasidifferentiable optimization: Applications to thermoelasticity](#), and [5]).

### Keywords

Nonsmooth optimization; Quasidifferentiability;  
Codifferentiability; Nonconvex optimization

If for a directionally differentiable function there exists an ordered pair of convex compact sets  $[U, V]$  in  $\mathbf{R}^n \times \mathbf{R}^n$  which produces the directional derivative of  $f$  at  $x$  in the direction  $g$  by the expression:

$$f'(x, g) = \max_{h \in U} (h, g) + \min_{h \in V} (h, g); \quad (1)$$

this function is called *quasidifferentiable* in the sense of V.F. Demyanov and A.M. Rubinov. This notion covers a large number of structured nonconvex and nonsmooth functions, which can be used for the solution of nonconvex and global optimization problems. For instance, the class of difference convex functions is included.

More details on this notion, the calculus rules for computing quasidifferentials, its connection to other notions of nonsmooth analysis and its applications can be found in ► [Quasidifferentiable optimization](#); ► [Quasidifferentiable optimization: Calculus of quasidifferentials](#); ► [Quasidifferentiable optimization: Dini derivatives, Clarke derivatives](#); ► [Quasidifferentiable optimization: Applications](#), as well as in [1,2,3].

The quasidifferential, as well as the subdifferential of *convex analysis*, are set-valued quantities which include discontinuities at the points of nondifferentiability. In numerical algorithms this may cause problems.

A notion that takes into account neighboring information would be more appropriate. This led Demyanov to extend the notion of the quasidifferential by introducing the *codifferential*. Accordingly, the notions of *subdifferential* and *superdifferential* are extended to the notions of *hypodifferential* and *hyperdifferential*. One should mention that all quasidifferentiable functions are codifferentiable as well. Moreover, calculus rules exist, in analogy to the quasidifferential calculus rules.

These notions, which are useful for the construction of numerical algorithms in nonsmooth optimization [1] and nonsmooth computational mechanics [2] are introduced in this short paper. More details are given in the cited literature and in the previously mentioned lemmas.

### Codifferentiable Functions

Let  $X$  be an open subset of  $\mathbf{R}^n$  and let a function  $f$  be defined and finite for every  $x \in X$ . A function  $f$  is called *codifferentiable* at  $x$  if there exist convex compact sets  $\underline{d}f(x) \subset \mathbf{R}^{n+1}$  and  $\bar{d}f(x) \subset \mathbf{R}^{n+1}$  such that the function admits a first order approximation in a neighborhood of  $x$  of the form

$$f(x + \Delta) = f(x) + \max_{[\alpha, v] \in \underline{d}f(x)} [\alpha + (v, \Delta)] + \min_{[b, w] \in \bar{d}f(x)} [b + (w, \Delta)] + o_x(\Delta), \quad (2)$$

where  $o_x(\alpha, \Delta)/\alpha \rightarrow 0$  as  $\alpha \downarrow 0, \forall \Delta \in \mathbf{R}^n$ . The ordered pair of convex compact sets  $Df(x) = [\underline{d}f(x), \bar{d}f(x)]$  is called a *codifferential* of  $f$  at  $x$ , where  $\underline{d}f(x)$  is a *hypodifferential* and  $\bar{d}f(x)$  is a *hyperdifferential*.

If moreover there exists a codifferential  $Df$  which is Hausdorff continuous in a neighborhood of  $x$ , the function  $f$  is called *continuously codifferentiable* at  $x$ .

If there exists a codifferential of the form  $Df(x) = [\underline{d}f(x), \{0\}]$ , the function  $f$  is called *hypodifferentiable*, while if there exists a codifferential of the form  $Df(x) = [\{0\}, \bar{d}f(x)]$  the function is called *hyperdifferentiable*.

Note here that for a continuously codifferentiable function the first order approximation which is based on (2) is a continuous function in both  $x$  and  $\Delta$  (recall that the analogous approximation based on the quasidifferential is a continuous function of only  $\Delta$ ).

### Twice Codifferentiable Functions

Twice codifferentiable functions present a suitable tool for constructing higher order approximations of non-differentiable functions. They extend the notion of second order derivatives of classical smooth analysis.

Let a function  $f$  be defined on an open set  $X \subset \mathbf{R}^n$  and let it be finite there. The function  $f$  is *twice codifferentiable* at  $x \in X$  if there exist convex compact sets  $\underline{d}^2 f(x)$ , and  $\overline{d}^2 f(x)$ , both subsets of  $\mathbf{R} \times \mathbf{R}^n \times \mathbf{R}^{n \times n}$  such that

$$f(x+\Delta) = f(x) + \max_{[\alpha, v, A] \in \underline{d}^2 f(x)} \left[ \alpha + (v, \Delta) + \frac{1}{2}(A\Delta, \Delta) \right] + \min_{[b, w, B] \in \overline{d}^2 f(x)} \left[ b + (w, \Delta) + \frac{1}{2}(B\Delta, \Delta) \right] + o(\Delta^2),$$

with  $o((\alpha \Delta)^2)/\alpha^2 \rightarrow 0$  as  $\alpha \downarrow 0$  and  $\forall \Delta \in \mathbf{R}^n$ . Here  $\mathbf{R}^{n \times n}$  is the space of real  $(n \times n)$ -matrices.

The ordered pair of convex sets  $D^2 f(x) = [\underline{d}^2 f(x), \overline{d}^2 f(x)]$  is called a *second order codifferential* of  $f$  at  $x$ , the set  $\underline{d}^2 f(x)$  is a *second order hypodifferential* and the set  $\overline{d}^2 f(x)$  is a *second order hyperdifferential* of  $f$  at  $x$ . Moreover, if  $f$  is twice codifferentiable in some neighborhood of a point  $x$  and the mapping  $D^2 f$  is Hausdorff continuous at  $x$ , then the function  $f$  is called *twice continuously codifferentiable* at  $x$ .

Analogously to the quasidifferentiable and codifferentiable functions, twice hypodifferentiable functions and twice hyperdifferentiable functions may be defined. Calculus rules do also exist for twice codifferentiable functions (see [1, p. 216]).

For example, let  $f$  be convex and finite on a convex set  $X \subset \mathbf{R}^n$ ,  $x \in X$ , and let  $X_0$  be an arbitrary closed convex and bounded subset of  $X$  with  $x \in \text{int } X_0$ . In this case one may consider the second order codifferential  $D^2 f(x) = [d^2 f(x), 0]$ , with

$$\underline{d}^2 f(x) = \text{co} \left\{ [\alpha, v, A] : \begin{array}{l} \alpha = f(z) - f(x) \\ + (v(z), x - z), \\ v(z) \in \partial f(z), \\ A = 0 \in \mathbf{R}^{n \times n}, \\ z \in X_0 \end{array} \right\}.$$

Here  $v(z) \in \partial f(z)$  is an arbitrary element of the set valued mapping, which is kept fixed for every  $z \in X_0$  and

$\partial f(z)$  is equal to the classical convex analysis subdifferential.

Moreover, for a twice continuously differentiable function  $f$  it is well-known that

$$f(x+\Delta) = f(x) + (f'(x), \Delta) + \frac{1}{2}(f''(x)\Delta, \Delta) + o(\Delta^2),$$

where  $f''(x)$  is the matrix of second order derivatives (Hessian) of  $f$  at  $x$ . The function  $f$  is twice continuously codifferentiable and one may consider (among other choices) one of the following second order codifferentials of  $f$ :

$$\underline{d}^2 f(x) = \{[0, f'(x), f''(x)]\},$$

$$\overline{d}^2 f(x) = \{0, 0, 0\},$$

or

$$\underline{d}^2 f(x) = \{0, 0, 0\},$$

$$\overline{d}^2 f(x) = \{[0, f'(x), f''(x)]\}.$$

### Applications

Efficient nonsmooth optimization algorithms can be constructed based on the notion of the codifferential, or, for hypodifferentiable functions, on the notion of the hypodifferential. In fact, the technique of replacing a nondifferentiable optimization problem by an enlarged, classical, inequality constrained optimization problem has been successfully used for convex or for composite optimization problems [4,15]. For hypodifferentiable functions a direction of descent at each given point can be determined and used in an iterative optimization procedure. For general, codifferentiable functions, several directions of descent can be determined. This can be expected, given that one deals with nonconvex, global optimization problems. Some details in this direction are given in ► **Quasidifferentiable optimization: Applications** and in the original publications [3,11].

Furthermore, twice (or higher order) quasidifferentials and codifferentials provide set-valued approximations of the higher order derivatives of a function. For numerical optimization tasks this information may lead to more efficient algorithms, in analogy to the use of Hessian matrices in classical, smooth optimization. Other attempts for generalized second order derivatives can be found, for convex functions in [5] and

for nonconvex functions in [10,12]. For more information in the area of nonsmooth optimization see, e. g., [6,7,8,9,13].

Another area of interest for practical applications will be the use of this information for the construction of necessary and sufficient (local) optimality conditions. Applications of these results include stability and sensitivity analysis for quasidifferentiable and codifferentiable optimization problems. In mechanics, this information can be used for the study of the stability of structures governed by quasidifferentiable superpotentials (cf. e. g., [14] and ► [Quasidifferentiable optimization: Stability of dynamic systems](#)). Applications in economics will be of interest as well. Much work remains to be done in this area, which is open for further investigations (as of 1999).

Nonsmooth analysis; Clarke generalized gradient; Quasidifferentiability; Dini derivative

The notion of the *quasidifferential* in the sense of V.F. Demyanov and A.M. Rubinov [5] constitutes a set-valued extension of the classical differential, which is appropriate for nonsmooth and generally nonconvex but directionally differentiable functions. This class of functions covers a large number of applications in nonsmooth analysis and, among others, includes the popular in *global optimization* class of difference convex functions. The quasidifferential approximates the directional derivative of a function by using an ordered pair of convex sets, the subdifferential and the superdifferential. Definitions are given in ► [Quasidifferentiable](#)

**optimization.** Information on the corresponding calculus can be found in ► [Quasidifferentiable optimization: Calculus of quasidifferentials.](#)

Here, the relation between quasidifferentials and more classical notions in nonsmooth analysis is briefly addressed. In particular, the Dini directional derivatives and the F.H. Clarke [2,3] derivatives are considered. Other notions of nonsmooth analysis may be found, among others, in the recent publications [1,3,11].

### Dini Derivatives

The *Dini upper derivative* of a function  $f: \mathbf{R}^n \rightarrow \overline{\mathbf{R}}$  at a point  $x \in \text{dom } f$  in a direction  $g \in \mathbf{R}^n$  is defined by:

$$f_D^\uparrow = \limsup_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x, \alpha g) - f(x)]. \quad (1)$$

Note that the upper limit in (1) is not necessarily finite. Analogously, the *Dini lower derivative* of  $f$  at  $x$  is defined by the relation

$$f_D^\downarrow = \liminf_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x, \alpha g) - f(x)].$$

Recall that if the limit

$$f'(x, g) = \lim_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha g) - f(x)]$$

exists it is called the *derivative* of a function  $f$  at a point  $x$  in a direction  $g$ , or the *Dini derivative* and it is denoted by  $f_D'(x, g)$ .

Since the Dini derivative (resp. the Dini upper or lower derivative) is just the one-sided (resp. the one-sided upper or lower) derivative of an ordinary real-valued function, one can use the methods developed to study functions of one variable. Thus, for instance, calculus rules for directional derivatives can be constructed.

A function  $f$  defined on an open set  $\Omega$  is called *Dini uniformly directionally differentiable* at a point  $x \in \Omega$  if it is directionally differentiable at  $x$  and there exists a real number  $\alpha_0$  such that

$$\frac{1}{\alpha} [f(x + \alpha g) - f(x) - \alpha f'(x, g)] < \epsilon, \quad (2)$$

$$\forall \alpha \in (0, \alpha_0), \quad \forall g \in S,$$

where  $S = \{g \mid |g| = 1\}$  is the unit sphere. By setting  $\alpha g = v$  in (2) one gets:

$$|f(x + v) - f(x) - f'_x(v)| < \epsilon \|v\|,$$

$$\forall v \text{ such that } \|v\| \leq \alpha_0.$$

Thus the uniform directional differentiability means that  $\frac{1}{\|v\|} |f(x+v) - f(x) - f'_x(v)|$  tends to zero, as  $\|v\| \rightarrow 0$ .

More details on Dini derivatives and their use in optimization can be found in [9].

### Clarke Derivatives

Let us consider the upper and lower Dini derivatives of a function  $f$  for a fixed direction  $g$ , i. e. the functions  $x \rightarrow f_D^\uparrow(x, g)$  and  $x \rightarrow f_D^\downarrow(x, g)$ . Let us also consider the upper (resp. the lower) regularizations of these functions:

$$\bar{f}_D^\uparrow(x, g) = \max \left\{ f_D^\uparrow(x, g), \limsup_{x' \rightarrow x} f_D^\uparrow(x', g) \right\},$$

respectively

$$\bar{f}_D^\downarrow(x, g) = \min \left\{ f_D^\downarrow(x, g), \liminf_{x' \rightarrow x} f_D^\downarrow(x', g) \right\}.$$

For a Lipschitz function  $f$ , the upper and lower Dini derivatives are bounded in some neighborhood of  $x$ , hence both previous limits are finite.

The Clarke upper and lower derivatives are defined as upper and lower regularizations of the Dini upper and lower derivatives, i. e.

$$\begin{aligned} f_{CL}^\uparrow(x, g) &= \bar{f}_D^\uparrow(x, g), \\ f_{CL}^\downarrow(x, g) &= \bar{f}_D^\downarrow(x, g). \end{aligned}$$

For the initial, equivalent definition of these quantities, see [2,6 p. 69]. Here the approach of [8] has been followed. For every fixed direction  $g$ , the function  $x \rightarrow f_{CL}^\uparrow(x, g)$  is upper semicontinuous and the function  $x \rightarrow f_{CL}^\downarrow(x, g)$  is lower semicontinuous.

It is appropriate to recall here some properties of the Clarke derivatives. For every fixed point  $x$ , the function  $g \rightarrow f_{CL}^\uparrow(x, g)$  is sublinear and the function  $g \rightarrow f_{CL}^\downarrow(x, g)$  is superlinear, thus the subdifferential  $\partial f_{CL}^\uparrow(x, g)$  and the superdifferential  $\bar{\partial} f_{CL}^\downarrow(x, g)$  can be determined, such that

$$\begin{aligned} f_{CL}^\uparrow(x, g) &= \max_{l \in \partial f_{CL}^\uparrow(x, g)} (l, g), \\ f_{CL}^\downarrow(x, g) &= \min_{w \in \bar{\partial} f_{CL}^\downarrow(x, g)} (w, g). \end{aligned}$$

Moreover, the following relations hold

$$\begin{aligned} f_{CL}^\uparrow(x, -g) &= (-f)_{CL}^\uparrow(x, -g), \\ f_{CL}^\uparrow(x, g) &= -f_{CL}^\uparrow(x, -g). \end{aligned}$$

From the above properties it results that

$$\max_{l \in \partial f_{CL}^\uparrow(x, g)} (l, g) = \max_{w \in \bar{\partial} f_{CL}^\downarrow(x, g)} (w, g);$$

thus the two compact convex sets coincide. The Clarke subdifferential is thus defined as

$$\partial_{CL} f(x) = \partial f_{CL}^\uparrow(x, g) = \bar{\partial} f_{CL}^\downarrow(x, g).$$

The mapping  $x \rightarrow \partial_{CL} f(x)$  is upper semicontinuous. An element of the Clarke subdifferential is called a *generalized gradient* of  $f$  at  $x$ .

Concerning the relation between the directional derivative of the function (if it is directionally differentiable) and the Clarke upper and lower derivatives one has, in general,

$$f_{CL}^\downarrow(x, g) \leq f'(x, g) \leq f_{CL}^\uparrow(x, g). \quad (3)$$

Thus Clarke upper and lower derivatives are a sublinear majorant and a superlinear minorant of  $f'(x, g)$  respectively. Only in the case of an u.s.c. (resp. l.s.c.) directional derivative  $f'(x, g)$  the second (resp. the first) inequality in (3) holds as an equality. The latter property is considered to be the major drawback of the Clarke subdifferential in nonsmooth analysis applications, because it does not always give rise to an approximation of the directional derivative at the points of nondifferentiability.

For further reference we recall here the necessary optimality conditions for a locally Lipschitz function  $f$  at a point  $x$ :

$$0 \in \partial_{CL} f(x).$$

Note also that since approximations of sets and functions are linked, the notion of Clarke subdifferential gives rise to a notion for the generalized tangent cone (and respectively a generalized normal cone). The reader is referred to [2,3] [6, p. 83], [10] for more details.

### Quasidifferential and Clarke Subdifferential

Before giving some information on the links between the quasidifferential and the Clarke subdifferential, some elements on the several definitions of the difference of convex compact sets are in order.

### Differences of Convex Sets

Before stating the definition, some introductory material must be given. The max-face of a compact set  $U$  generated by  $x \in \mathbf{R}^n$  is defined by

$$G_x(U) = \left\{ h \in U : (h, x) = \max_{g \in U} (x, g) \right\}.$$

Recall that the max-face set coincides with the subdifferential of the *support function* of  $U$ , i. e.  $G_x(U) = \underline{\partial} p_U(x)$ . Recall also that for a convex function defined on  $\mathbf{R}^n$  the set of points of  $T \subset \mathbf{R}^n$  where max-face is a singleton is of measure zero is a set of full measure (with respect to  $\mathbf{R}^n$ , i. e.  $\mathbf{R}^n \setminus T$  is a set of measure zero).

The difference of two sets  $U$  and  $V$ ,  $U \dot{-} V$  is defined on the set of full measure  $T$  where both  $G_x(U)$  and  $G_x(V)$  are singletons by:

$$U \dot{-} V = \text{clco} \{ \nabla p_U(x) - \nabla p_V(x) : x \in T \},$$

where  $\nabla g$  denotes the gradient of function  $g$ . One may observe here that if  $U = V + W$  then  $U \dot{-} V = W$ .

An equivalent definition of  $U \dot{-} V$  is given by

$$U \dot{-} V = \text{clco} \left( \bigcup_{x \in T_{U,V}} [G_x(U) - G_x(V)] \right), \quad (4)$$

where the dependence of  $T$  on both  $U$  and  $V$  is explicitly indicated.

An extension of (4) leads to the quasidifference operation  $\ddot{-}$ , defined by

$$U \ddot{-} V = \text{clco} \left( \bigcup_{x \neq 0} [G_x(U) - G_x(V)] \right). \quad (5)$$

Unfortunately  $\ddot{-}$  is not invariant with respect to the equivalence relation  $\approx$ . Nevertheless an estimate of the form  $U \ddot{-} V \supset U \dot{-} V$ , for every sets  $U$  and  $V$  always holds and in some cases there exist conditions under which the inclusion holds as an equality (see e. g. [6, p. 117]).

### Estimation Results

The Clarke subdifferential can also be generated, in some cases, by the set operators difference  $\dot{-}$  and quasidifference  $\ddot{-}$  applied on the subdifferential  $\underline{\partial} f(x)$  and the superdifferential  $\overline{\partial} f(x)$  of a quasidifferentiable function  $f(x)$ .

Under appropriate assumptions on  $f$ , and for appropriate choice of the elements of the subdifferential and the subdifferential of  $f$  at  $x$ , an estimate of the following form can be extracted:

$$A \subset \partial_{\text{CL}} f(x) \subset B.$$

with set  $A = \underline{\partial} f(x) \dot{-} (-\overline{\partial} f(x))$  and set  $B = \underline{\partial} f(x) \ddot{-} (-\overline{\partial} f(x))$ , as it is discussed in [6, pp. 143–155]. A different approach to the study of the relationship between the Clarke subdifferential and the quasidifferential is followed in [7] (see also [6, pp. 156–159]). More details in this direction can also be found in [4].

### Keywords

Quasidifferential functions; Quasidifferential; Exact penalty function; Exact penalty parameter; Regularity

Penalty function methods are used for solving many constrained optimization problems of the form: Find

$$\inf_{x \in X} f(x) = f^*, \quad (1)$$

where  $f$  is a locally Lipschitz quasidifferentiable function defined on  $\mathbf{R}^n$ ,  $\mathcal{D}f(x) = [\bar{\partial}f(x), \underline{\partial}f(x)]$  is its quasidifferential at a point  $x \in \mathbf{R}^n$ ,  $X \subset \mathbf{R}^n$  is a closed set.

It is always possible to define  $X$  in the form (see [2])

$$X = \{x \in \mathbf{R}^n : \varphi(x) = 0\}, \quad (2)$$

where  $\varphi$  is also a locally Lipschitz quasidifferentiable function defined on  $\mathbf{R}^n$ , the pair of sets  $\mathcal{D}\varphi(x) = [\bar{\partial}\varphi(x), \underline{\partial}\varphi(x)]$  is a quasidifferential of  $\varphi$  at  $x \in \mathbf{R}^n$  and

$$\varphi(x) > 0, \quad \forall x \notin X.$$

Thus the set  $X$  is the set of global minimum points of the function  $\varphi$  on  $\mathbf{R}^n$ . Hence, it is closed. We shall assume that the set  $X \subset \mathbf{R}^n$  is not empty and bounded.

As the function  $\varphi$  is quasidifferentiable then the following expansion holds:

$$\varphi(x + \alpha g) = \varphi(x) + \alpha \varphi'(x, g) + o(\alpha, x, g),$$

where

$$\frac{o(\alpha, x, g)}{\alpha} \xrightarrow{\alpha \downarrow 0} 0.$$

We shall assume that in this expansion at each point  $x \in \mathbf{R}^n$  the convergence to 0 is uniform with respect to  $g \in \mathbf{R}^n$ ,  $\|g\| = 1$ .

The idea of penalty function methods consists in reducing the problem (1) to a problem of the unconstrained optimization. Among the different approaches existing for such reduction we shall consider the method of exact penalty functions.

For solving the problem (1) a penalty function

$$F(c, x) = f(x) + c\varphi(x)$$

is introduced, where  $c$  is a nonnegative number, and then the problem

$$\inf_{x \in \mathbf{R}^n} F(c, x) \tag{3}$$

is considered.

We assume that  $\inf_x \in \mathbf{R}^n F(c, x)$  is attained for every  $c \geq 0$ . In practice it would be useful to find conditions which guarantee that there exists an exact penalty parameter  $c^* \geq 0$  such that the set

$$\left\{ x \in \mathbf{R}^n : x = \arg \min_{x \in \mathbf{R}^n} F(c^*, x) \right\}$$

coincides with the set

$$\left\{ x \in \mathbf{R}^n : x = \arg \min_{x \in X} f(x) \right\}.$$

At first such a problem was investigated in [5,10] for the problem of convex programming. Now there are many works in this field of mathematics. (See, for example, [1,4,6,8,9]).

The implementation of exact penalty function methods first of all depends on the properties of the function  $\varphi$ . Therefore various conditions are imposed on  $\varphi$  to make it possible to solve our problem. We shall consider some of them.

### Regularity Condition 1

(See [3].)

We say that a *regularity condition* is satisfied for the function  $\varphi$  if for any boundary point  $x^* \in \text{bd}X$  there exist positive real numbers  $\varepsilon(x^*)$  and  $\beta(x^*)$ , such that

$$\begin{aligned} \frac{o(\alpha, x, g)}{\alpha} &> -\varphi'(x, g) + \beta(x^*) \\ &= - \left[ \max_{v \in \partial\varphi(x)} \langle v, g \rangle + \min_{w \in \partial\varphi(x)} \langle w, g \rangle \right] + \beta(x^*), \end{aligned}$$

$$\forall x \in \mathcal{A}(X) \cap S_{\varepsilon(x^*)}(x^*),$$

$$\forall \alpha \in (0, \varepsilon(x^*)],$$

$$\forall g \in N(X, x) : \|g\| = 1,$$

where  $\text{bd} X$  is the set of boundary points of  $X$ ,

$$S_{\varepsilon(x^*)}(x^*) = \{x \in \mathbf{R}^n : \|x - x^*\| \leq \varepsilon(x^*)\},$$

$$\mathcal{A}(X) = \left\{ x \in \text{bd} X : \begin{array}{l} \exists z \notin X : \\ x \text{ is a projection of } z \end{array} \right\},$$

$N(X, x)$  is the *normal cone* to the set  $X$  at the point  $x \in X$ :

$$N(X, x) = \left\{ g \in \mathbf{R}^n : \begin{array}{l} \langle g_1, g \rangle \leq 0, \\ \forall g_1 \in \Gamma(X, x) \end{array} \right\}$$

and

$$\Gamma(X, x) = \left\{ g \in \mathbf{R}^n : \begin{array}{l} \exists g_k \in \mathbf{R}^n, \alpha_k \geq 0, \\ g_k \rightarrow g, \alpha_k \downarrow 0, \\ x + \alpha_k g_k \in X \end{array} \right\}.$$

The regularity condition 1 is a condition about the behavior of the function  $\varphi$  only at the boundary points of the set  $X$ .

If for the function  $\varphi$  the regularity condition 1 holds, then there exists an exact penalty parameter  $c^*$ .

Since in practice the exact penalty parameter is a priori unknown, a sequence of real values  $c_k$  is constructed, satisfying the conditions

$$0 = c_0 < \dots < c_k < \dots,$$

$$\lim_{k \rightarrow +\infty} c_k = +\infty.$$

Let us find

$$x(\cdot_k) = \arg \min_{x \in \mathbf{R}^n} F(\cdot_k, x).$$

As a result, a decreasing sequence of real values  $\{\varphi(x(c_k))\}$  is constructed. There exists an integer  $K > 0$  such that  $x(c_k) \in X, \forall k > K$ . Thus, for  $k > K$ , the points  $x(c_k)$  will be global minimum points of a function  $F(c_k, x)$  on  $\mathbf{R}^n$ , i. e. will be solutions of problem (1). The value of the penalty parameter  $c^*$  is directly proportional to the Lipschitz constant of the function  $f$  on the set

$$\mathcal{L}(x^{**}) = \{x \in \mathbf{R}^n : \varphi(x) \leq \varphi(x^{**})\},$$

where

$$x^{**} = \min_{x \in \mathbf{R}^n} f(x),$$

and inversely proportional to the number  $\beta(x^*)$ , where the point  $x^*$  is a limit point of the sequence  $\{x(c_k)\}$ . In this method the regularity condition 1 is used only in a neighborhood of the point  $x^*$ .

Note that the function  $\varphi$  is essentially nondifferentiable at the boundary points of the set  $X$ .

For differentiable functions at the boundary points of the set  $X$ , the regularity condition 1 does not hold. For this reason, if the function  $\varphi$  at the boundary points of the set  $X$  is superdifferentiable, then it cannot be used for constructing a sequence of exact penalty functions  $F(c, x)$ .

An example of a function, which can be used for constructing a family of exact penalty functions (even not requiring the set  $X$  to be bounded) is the Euclidean distance function. For it as an exact penalty parameter it is possible to take the Lipschitz constant of the function  $f$  on the set  $\mathcal{L}(x^{**})$ . However this function is not suitable for practical use due to computational problems.

We shall notice, that the regularity condition 1 is not constructive. Sometimes instead of it one uses another regularity condition.

### Regularity Condition 2

(See [3].)

We shall assume that there exists a real number  $\beta > 0$ , such that the following inequality holds

$$\inf_{x \in \mathcal{A}(X)} \min_{\substack{\|g\|=1, \\ g \in N(X, x)}} \varphi'(x, g) = \inf_{x \in \mathcal{A}(X)} \min_{\|g\|=1} \left[ \max_{v \in \partial\varphi(x)} \langle v, g \rangle + \min_{w \in \bar{\partial}\varphi(x)} \langle w, g \rangle \right] \geq \beta. \quad (4)$$

If the set  $X$  is bounded and does not consist of isolated points, and the regularity condition 2 is fulfilled for the family of penalty functions  $\{F(c_k, x)\}$  then there exists an exact penalty parameter.

Under some assumptions on the set  $X$  it is possible to get an analytical representation of the normal cone for this set at each boundary point and then, having calculated the constant  $\beta$ , it is possible to evaluate the exact penalty parameter  $c^*$ .

We shall assume, that for the function  $\varphi$  at each point  $x \in \text{bd } X$  the regularity condition 2 holds. Then the representation of the normal cone  $N(X, x)$  to the given set  $X$  at the point  $x \in \text{bd } X$ ,

$$N(X, x) = \bigcap_{w \in \bar{\partial}\varphi(x)} \text{cl cone}(\partial\varphi(x) + w),$$

holds. Here,  $\text{cl } A$  is the closure of  $A$ ,  $\text{cone } A$  is the conical hull of  $A$ .

For example, if the function  $\varphi$  is subdifferentiable at each boundary point of the set  $X$ , then

$$N(X, x) = \text{cl cone}(\partial\varphi(x)),$$

and (4) can be rewritten as

$$\inf_{x \in \mathcal{A}(X)} \min_{\|g\|=1, g \in \text{cl cone}(\partial\varphi(x))} \max_{v \in \partial\varphi(x)} \langle v, g \rangle \geq \beta > 0. \quad (5)$$

*Example 1* Let

$$\begin{aligned} f_0(x) &= \frac{1}{2} \langle A_0 x, x \rangle + \langle b_0, x \rangle, \quad x, b_0 \in \mathbf{R}^n, \\ f_i(x) &= \frac{1}{2} \langle A_i x, x \rangle + \langle b_i, x \rangle + c_i, \\ x, b_i &\in \mathbf{R}^n, \quad c_i \in \mathbf{R}^1, \quad i \in I = 1, \dots, p, \end{aligned}$$

where  $f_i, i \in (0, \dots, p)$  are strongly convex functions. All the matrices  $A_i, i = 0, \dots, p$ , are positive definite.

Consider the problem

$$\min_{x \in X} f_0(x), \quad (6)$$

where

$$X = \{x \in \mathbf{R}^n : f_i(x) \leq 0, i \in I\}.$$

Let

$$\begin{aligned} \varphi(x) &= \max\{0, \varphi_1(x)\}, \\ \varphi_1(x) &= \max_{i \in I} f_i(x), \\ x &\in \mathbf{R}^n. \end{aligned}$$

Then

$$X = \{x \in \mathbf{R}^n : \varphi(x) = 0\}.$$

Let

$$\bar{x} = \arg \min_{x \in \mathbf{R}^n} \varphi_1(x).$$

We shall assume that  $\varphi_1(\bar{x}) < 0$ .

Problem (6) is a convex programming problem. For this problem the regularity condition 1 is valid.

Let  $d$  be the radius of the maximal ball centered at the point  $\bar{x}$  and inscribed into the set  $X$ . Then the number  $c^* = L/2 \cdot md$  is an exact penalty parameter for the

problem (6). In this equality  $L$  is a Lipschitz constant of the function  $f_0$  on the set

$$X_1 = \{x \in \mathbf{R}^n : \varphi(x) \leq \varphi(x^{**})\},$$

$$x^{**} = \arg \min_{x \in \mathbf{R}^n} f_0(x),$$

i. e. the number

$$L = \max_{x \in X_1} \|A_0 x + b_0\|$$

can be taken as a Lipschitz constant of  $f$  on  $X_1$ ,  $m$  is a strong convexity constant of the function  $\varphi_1$   $m = \min_{i \in I} \bar{m}_i$ , where  $\bar{m}_i$  is constant of strong convexity of the function  $f_i$ ,  $i \in I$ .

*Example 2* Consider the optimization problem

$$\min_{x \in X} f(x), \tag{7}$$

where

$$f(x) = f_1(x) - f_2(x),$$

$$X = \{x \in \mathbf{R}^n : \varphi_1(x) - \varphi_2(x) \leq 0\},$$

$f_1, f_2, \varphi_1, \varphi_2$  are convex functions defined on  $\mathbf{R}^n$ .

Let the set  $X$  be bounded. It can be defined in the form

$$X = \{x \in \mathbf{R}^n : \varphi(x) = 0\},$$

where  $\varphi(x) = \max\{0, \varphi_1(x) - \varphi_2(x)\}$ .

The function  $\varphi$  can be represented as the difference of convex (d.c.) functions

$$\varphi(x) = \max\{\varphi_1(x), \varphi_2(x)\} - \varphi_2(x).$$

We shall consider only points  $x \in X$  where  $\varphi_1(x) = \varphi_2(x)$ . Then the pair of convex sets

$$\mathcal{D}\varphi(x) = [\text{co}\{\partial\varphi_1(x), \partial\varphi_2(x)\}, -\partial\varphi_2(x)]$$

is a quasidifferential of the function  $\varphi$  at a point  $x$ , where  $\partial\varphi_i(x)$ ,  $i = 1, 2$ , is the subdifferential of the convex function  $\varphi_i$  at  $x$  in the sense of convex analysis. Here  $\text{co} A$  is the convex hull of  $A$ .

If the regularity condition 2 is valid for the function  $\varphi$ , i. e. there exists a real value  $\beta > 0$  such that

$$\inf_{x \in \mathcal{A}(X)} \min_{g \in N(X, x)} \|g\| = 1$$

$$\left\{ \max_{v \in \text{co}\{\partial\varphi_1(x), \partial\varphi_2(x)\}} \langle v, g \rangle - \max_{w \in \partial\varphi_2(x)} \langle w, g \rangle \right\} \geq \beta,$$

then there exists an exact penalty parameter  $c^*$  for the sequence of penalty functions

$$F(c_k, x) = f(x) + c_k \varphi(x)$$

$$= (f_1(x) + c_k \max\{\varphi_1(x), \varphi_2(x)\}) - (f_2(x) + c_k \varphi_2(x)).$$

Let the set  $X$  be defined as

$$X = \{x \in \mathbf{R}^n : \varphi_1(x) - \varphi_2(x) = 0\};$$

then it can be rewritten as

$$X = \{x \in \mathbf{R}^n : \varphi(x) = 0\},$$

where  $\varphi(x) = \max\{0, |\varphi_1(x) - \varphi_2(x)|\}$ .

In this case the function  $\varphi$  can be represented as the difference of convex functions, namely

$$\varphi(x) = \max\{2\varphi_1(x), 2\varphi_2(x), \varphi_1(x) + \varphi_2(x)\} - (\varphi_1(x) + \varphi_2(x)).$$

If the regularity condition 2 is valid for the function  $\varphi$ , i. e. there exists a real value  $\beta > 0$  such that

$$\inf_{x \in \mathcal{A}(X)} \min_{g \in N(X, x)} \|g\| = 1$$

$$\left\{ \max_{v \in \text{co}\{2\partial\varphi_1(x), 2\partial\varphi_2(x), \partial\varphi_1(x) + \partial\varphi_2(x)\}} \langle v, g \rangle - \max_{w \in \partial(\varphi_1(x) + \varphi_2(x))} \langle w, g \rangle \right\} \geq \beta,$$

then there exists an exact penalty parameter  $c^*$  for the sequence of penalty functions

$$F(c_k, x) = f(x) + c_k \varphi(x)$$

$$= f_1(x) + c_k \max\{2\varphi_1(x), 2\varphi_2(x), \varphi_1(x) + \varphi_2(x)\} - (f_2(x) + c_k \varphi_1(x) + c_k \varphi_2(x)).$$

Thus the solution of the problem (7) can be obtained as the result of unconstrained optimization of d.c.functions.

V.F. Demyanov [2] considers the following condition for constructing a family of exact penalty functions. Put

$$d(x) = \min_{\|g\|=1} \varphi'(x, g)$$

$$= \min_{\|g\|=1} \left[ \max_{v \in \underline{\partial}\varphi(x)} \langle v, g \rangle + \min_{w \in \bar{\partial}\varphi(x)} \langle w, g \rangle \right],$$

$$\Psi_X(x) = \limsup_{x' \rightarrow x, x' \notin X} d(x').$$

### Regularity Condition 3

If for some  $\varepsilon > 0$  the set

$$X_\varepsilon = \{x \in \mathbf{R}^n : \varphi(x) \leq \varepsilon\}$$

is bounded and

$$\Psi_X(x) < 0, \quad \forall x \in \text{bd } X,$$

then for the family of penalty functions  $F(c_k, x)$  there exists an exact penalty parameter  $c^* < \infty$ .

To use the regularity condition 3 it is necessary to know the behavior of the function  $\varphi$  in the neighborhood of the set  $X$ .

Sometimes the following regularity condition is used (see [7]).

### Regularity Condition 4

(Condition of  $\rho$ -regularity). We say that the problem (1) with the set  $X$  is  $\rho$ -regular if there exists a positive number  $\beta$  such that the inequality

$$\varphi(x) \geq \beta \rho_X(x), \quad \forall x \in \mathbf{R}^n \setminus X,$$

holds, where  $\rho_X$  is the Euclidean distance function.

It is not difficult to observe that the regularity condition 4 is not constructive. In [7] the existence of an exact penalty parameter for a family of penalty functions is proved for problems of nonlinear programming if the condition of  $\rho$ -regularity is satisfied.

### Directionally Differentiable Functions

Let  $f$  be a real-valued function defined on an open set  $X \subset \mathbf{R}^n$ ,  $x \in X$ . The function  $f$  is called *Dini differentiable* at the point  $x$  in a direction  $g \in \mathbf{R}^n$  if there exists the finite limit

$$f'_D(x, g) = \lim_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha g) - f(x)]. \quad (1)$$

Here  $\alpha \downarrow 0$  means that  $\alpha \rightarrow 0$ ,  $\alpha > 0$ . The quantity  $f'_D(x, g)$  is called the *Dini derivative* of  $f$  at  $x$  in a direction  $g$ .

The function  $f$  is called *Hadamard differentiable* at the point  $x$  in a direction  $g \in \mathbf{R}^n$  if there exists the finite

limit

$$f'_H(x, g) = \lim_{[\alpha, g'] \rightarrow [0, g]} \frac{1}{\alpha} [f(x + \alpha g') - f(x)]. \quad (2)$$

Clearly, if  $f$  is Hadamard differentiable at  $x$  in a direction  $g$  then it is Dini differentiable as well and

$$f'_H(x, g) = f'_D(x, g). \quad (3)$$

If the limit in (1) exists and is finite for every  $g \in \mathbf{R}^n$  then the function  $f$  is called *Dini directionally differentiable* (D-d.d) at  $x$ . The quantity  $f'_D(x, g)$  is called the *Hadamard derivative* of  $f$  at  $x$  in a direction  $g$ .

If the limit in (2) exists and is finite for every  $g \in \mathbf{R}^n$  then the function  $f$  is called the *Hadamard directionally differentiable* (H-d.d) at  $x$ . Of course, every H-d.d. function at  $x$  is D-d.d., the converse is not necessarily true.

The directional (and generalized directional) derivatives may be used to describe optimality conditions (see ► **Dini and Hadamard derivatives in optimization**). However, using properties of special classes of functions one can expect to get more ‘constructive’ conditions. One of such classes is the family of quasidifferentiable functions.

### Quasidifferentiable Functions

Let  $f$  be a real-valued function defined on an open set  $X \subset \mathbf{R}^n$ ,  $x \in X$ . The function  $f$  is called *Dini (Hadamard) quasidifferentiable* (q.d) at  $x$  if it is Dini (Hadamard) directionally differentiable at  $x$  and if its directional derivative  $f'_D(x, g)$  ( $f'_H(x, g)$ ) can be represented in the form

$$f'_D(x, g) = \max_{v \in \underline{\partial}f_D(x)} (v, g) + \min_{w \in \bar{\partial}f_D(x)} (w, g),$$

$$\left( f'_H(x, g) = \max_{v \in \underline{\partial}f_H(x)} (v, g) + \min_{w \in \bar{\partial}f_H(x)} (w, g) \right),$$

where the sets  $\underline{\partial}f_D(x)$ ,  $\bar{\partial}f_D(x)$ ,  $\underline{\partial}f_H(x)$ ,  $\bar{\partial}f_H(x)$  are convex compact sets of  $\mathbf{R}^n$ . The pair

$$Df_D(x) = [\underline{\partial}f_D(x), \bar{\partial}f_D(x)],$$

$$(Df_H(x) = [\underline{\partial}f_H(x), \bar{\partial}f_H(x)])$$

is called a *Dini (Hadamard) quasidifferential* of  $f$  at  $x$ . Most of the results stated below are valid for both Dini

and Hadamard q.d. functions, therefore we shall use the notation  $Df(x) = [\underline{\partial}f(x), \overline{\partial}f(x)]$  for both  $D_Df(x)$  and  $D_Hf(x)$  and the pair  $Df(x)$  will just be called a *quasidifferential* of  $f$  at  $x$ . Analogously, the notation  $f'(x, g)$  is used for both  $f'_D(x, g)$  and  $f'_H(x, g)$ .

The directional derivative  $f'(x, g)$  is positively homogeneous (in  $g$ ) of degree one:

$$f'(x, \lambda g) = \lambda f'(x, g), \quad \forall \lambda > 0. \quad (4)$$

Note that Hadamard quasidifferentiability implies Dini quasidifferentiability, the converse not necessarily being true.

Thus for a quasidifferentiable (q.d) function

$$f'(x, g) = \max_{v \in \underline{\partial}f(x)} (v, g) + \min_{w \in \overline{\partial}f(x)} (w, g), \quad (5)$$

$$\forall g \in \mathbf{R}^n.$$

The set  $\underline{\partial}f(x)$  is called a *subdifferential* of  $f$  at  $x$ , and the set  $\overline{\partial}f(x)$  is called a *superdifferential* of  $f$  at  $x$ . Note that a quasidifferential is not uniquely defined: If a pair  $D = [A, B]$  is a quasidifferential of  $f$  at  $x$  then, e. g., for any convex compact set  $C \subset \mathbf{R}^n$  the pair  $D_1 = [A + C, B - C]$  is a quasidifferential of  $f$  at  $x$  (since, by (5), both these pairs produce the same function  $f'(x, g)$ ). The equivalence class of pairs of convex compact sets  $Df(x) = [\underline{\partial}f(x), \overline{\partial}f(x)]$  producing the function  $f'(x, g)$  by formula (5) is called the *quasidifferential* of  $f$  at  $x$  (we shall use the same notation  $Df(x)$  for the quasidifferential of  $f$  at  $x$ ).

If there exists a quasidifferential  $Df(x)$  of the form  $Df(x) = [\underline{\partial}f(x), \{0_n\}]$  then  $f$  is called *subdifferentiable* at  $x$ . If there exists a quasidifferential  $Df(x)$  of the form  $Df(x) = [\{0_n\}, \overline{\partial}f(x)]$  then  $f$  is called *superdifferentiable* at  $x$ . Here  $0_n = (0, \dots, 0) \in \mathbf{R}^n$ .

### Examples of q.d. Functions

1) If  $f$  is a smooth function on  $X$  then

$$f'(x, g) = (f'(x), g), \quad (6)$$

where  $f'(x)$  is the gradient of  $f$  at  $x$ . It is clear that

$$f'(x, g) = \max_{v \in \underline{\partial}f(x)} (v, g) + \min_{w \in \overline{\partial}f(x)} (w, g), \quad (7)$$

with

$$\underline{\partial}f(x) = \{f'(x)\}, \quad \overline{\partial}f(x) = \{0_n\}.$$

Hence,  $f$  is Hadamard quasidifferentiable and even subdifferentiable. Since in (7) one can also take

$$\underline{\partial}f(x) = \{0_n\}, \quad \overline{\partial}f(x) = \{f'(x)\},$$

then  $f$  is superdifferentiable as well.

2) If  $f$  is a convex function on a convex open set  $X \subset \mathbf{R}^n$  then (as it is known from convex analysis)  $f$  is H-d.d. on  $X$  and

$$f'(x, g) = \max_{v \in \underline{\partial}f(x)} (v, g),$$

where  $\underline{\partial}f(x)$  is the subdifferential of  $f$  (in the sense of convex analysis):

$$\underline{\partial}f(x) = \left\{ v \in \mathbf{R}^n : \begin{array}{l} f(z) - f(x) \geq (v, z - x) \\ \forall z \in X \end{array} \right\}.$$

Therefore  $f$  is Hadamard quasidifferentiable and one can take the pair  $Df(x) = [\underline{\partial}f(x), \{0_n\}]$  as its quasidifferential. Thus,  $f$  is even subdifferentiable.

3) If  $f$  is concave on a convex set  $X$  then  $f$  is H-d.d. and

$$f'(x, g) = \min_{w \in \overline{\partial}f(x)} (w, g),$$

where

$$\overline{\partial}f(x) = \left\{ w \in \mathbf{R}^n : \begin{array}{l} f(z) - f(x) \leq (w, z - x) \\ \forall z \in X \end{array} \right\}.$$

Hence,  $f$  is Hadamard quasidifferentiable and one can take the pair

$$Df(x) = [\{0_n\}, \overline{\partial}f(x)]$$

as its quasidifferential. Thus,  $f$  is even superdifferentiable.

### Calculus of Quasidifferentials

The family of q.d. functions enjoys a well-developed calculus: First let us define the operation of addition of two pairs of compact convex sets and the operation of multiplication of a pair by a real number.

If  $D_1 = [A_1, B_1]$ ,  $D_2 = [A_2, B_2]$  are pairs of convex compact sets in  $\mathbf{R}^n$  then

$$D_1 + D_2 = [A, B]$$

with

$$A = A_1 + A_2, \quad B = B_1 + B_2.$$

If  $D = [A, B]$  where  $A$  and  $B$  are convex compact sets,  $\lambda \in \mathbf{R}$  then

$$\lambda D = \begin{cases} [\lambda A, \lambda B], & \lambda \geq 0, \\ [\lambda B, \lambda A], & \lambda < 0. \end{cases}$$

Let  $X \subset \mathbf{R}^n$  be an open set.

**Proposition 1 ([1, Chap. III])**

1) If functions  $f_1, \dots, f_N$  are quasidifferentiable at a point  $x \in X$ , and  $\lambda_1, \dots, \lambda_N$  are real numbers then the function

$$f = \sum_{i=1}^N \lambda_i f_i$$

is also quasidifferentiable at  $x$  with a quasidifferential  $Df(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$  where

$$Df(x) = \sum_{i=1}^N \lambda_i Df_i(x), \tag{8}$$

$Df_i(x)$  being a quasidifferential of  $f_i$  at  $x$ .

2) If  $f_1$  and  $f_2$  are quasidifferentiable at a point  $x \in X$  then the function  $f = f_1 \cdot f_2$  is also q.d. at  $x$  and

$$Df(x) = f_1(x)Df_2(x) + f_2(x)Df_1(x). \tag{9}$$

3) If  $f_1$  and  $f_2$  are quasidifferentiable at a point  $x \in X$  and  $f_2(x) \neq 0$  then the function  $f = \{f_1/f_2\}$  is also q.d. at  $x$  and

$$Df(x) = \frac{1}{f_2^2(x)} [f_2(x)Df_1(x) - f_1(x)Df_2(x)]. \tag{10}$$

4) Let functions  $f_1, \dots, f_N$  be quasidifferentiable at a point  $x \in X$ . Construct the functions

$$\begin{aligned} \varphi_1(x) &= \max_{i \in \{1, \dots, N\}} f_i(x), \\ \varphi_2(x) &= \min_{i \in \{1, \dots, N\}} f_i(x). \end{aligned}$$

Then the functions  $\varphi_1$  and  $\varphi_2$  are q.d. at  $x$  and

$$\begin{aligned} D\varphi_1(x) &= [\underline{\partial}\varphi_1(x), \bar{\partial}\varphi_1(x)], \\ D\varphi_2(x) &= [\underline{\partial}\varphi_2(x), \bar{\partial}\varphi_2(x)], \end{aligned} \tag{11}$$

where

$$\underline{\partial}\varphi_1(x) = \text{co} \left\{ \underline{\partial}f_k(x) - \sum_{\substack{i \in R(x) \\ i \neq k}} \bar{\partial}f_i(x) : k \in R(x) \right\},$$

$$\bar{\partial}\varphi_1(x) = \sum_{k \in R(x)} \bar{\partial}f_k,$$

$$\underline{\partial}\varphi_2(x) = \sum_{k \in Q(x)} \underline{\partial}f_k,$$

$$\bar{\partial}\varphi_2(x) = \text{co} \left\{ \bar{\partial}f_k(x) - \sum_{\substack{i \in Q(x) \\ i \neq k}} \underline{\partial}f_i(x) : k \in Q(x) \right\}.$$

Here  $[\underline{\partial}f_k(x), \bar{\partial}f_k(x)]$  is a quasidifferential of the function  $f_k$  at the point  $x$ ,

$$R(x) = \{i \in \{1, \dots, N\} : f_i(x) = \varphi_1(x)\},$$

$$Q(x) = \{i \in \{1, \dots, N\} : f_i(x) = \varphi_2(x)\}.$$

The following composition theorem holds.

**Proposition 2 [1, Chap. III])** Let  $X$  be an open set in  $\mathbf{R}^n$ ,  $Y$  be an open set in  $\mathbf{R}^m$  and let a mapping  $H(x) = (h_1(x), \dots, h_m(x))$  be defined on  $X$ , take its values in  $Y$  and its coordinate functions  $h_i$  be quasidifferentiable at a point  $x_0 \in X$ . Assume also that a function  $f$  is defined on  $Y$  and is Hadamard quasidifferentiable at the point  $y_0 = H(x_0)$ . Then the function

$$\varphi(x) = f(H(x))$$

is quasidifferentiable at the point  $x_0$ .

The corresponding formula for the quasidifferential of  $\varphi$  at  $x_0$  is presented in [Thm. III.2.3]

*Remark 3* Thus, the family of quasidifferentiable functions is a linear space closed with respect to all ‘smooth’ operations and, what is most important, the operations of taking the pointwise maximum and minimum. Formulas (8)–(10) are just generalizations of the rules of classical differential calculus. Most problems and results of classical differential calculus may be formulated for nonsmooth functions in terms of quasidifferentials (see, e. g., [1,3]). For example, a mean value theorem is valid [5].

### Necessary and Sufficient Conditions for an Unconstrained Optimum

The following results hold due to the properties of directionally differentiable functions.

Let  $X \subset \mathbf{R}^n$  be an open set,  $f$  be a real-valued function defined and directionally differentiable on  $X$ .

**Proposition 4** For a point  $x^* \in X$  to be a local or global minimizer of  $f$  on  $X$  it is necessary that

$$f'(x^*, g) \geq 0, \quad \forall g \in \mathbf{R}^n. \quad (12)$$

If  $f$  is Hadamard d.d. at  $x^*$  and

$$f'_H(x^*, g) > 0, \quad \forall g \in \mathbf{R}^n, g \neq 0_n, \quad (13)$$

then  $x^*$  is a strict local minimizer of  $f$ .

For a point  $x^{**} \in X$  to be a local or global maximizer of  $f$  on  $X$  it is necessary that

$$f'(x^{**}, g) \leq 0, \quad \forall g \in \mathbf{R}^n. \quad (14)$$

If  $f$  is Hadamard d.d. at  $x^{**}$  and

$$f'_H(x^{**}, g) < 0, \quad \forall g \in \mathbf{R}^n, g \neq 0_n, \quad (15)$$

then  $x^{**}$  is a strict local maximizer of  $f$ .

These conditions may be restated in terms of quasidifferentials. Let  $f$  be quasidifferentiable on an open set  $X \subset \mathbf{R}^n$ .

**Proposition 5** (see [1,3,5]) For a point  $x^* \in X$  to be a local or global minimizer of  $f$  on  $X$  it is necessary that

$$-\bar{\partial}f(x^*) \subset \underline{\partial}f(x^*). \quad (16)$$

If  $f$  is Hadamard quasidifferentiable at  $x^*$  and

$$-\bar{\partial}f(x^*) \subset \text{int } \underline{\partial}f(x^*), \quad (17)$$

then  $x^*$  is a strict local minimizer of  $f$ .

For a point  $x^{**} \in X$  to be a local or global maximizer of  $f$  on  $X$  it is necessary that

$$-\underline{\partial}f(x^{**}) \subset \bar{\partial}f(x^{**}). \quad (18)$$

If  $f$  is Hadamard quasidifferentiable at  $x^{**}$  and

$$-\underline{\partial}f(x^{**}) \subset \text{int } \bar{\partial}f(x^{**}), \quad (19)$$

then  $x^{**}$  is a strict local maximizer of  $f$ .

*Remark 6* The quasidifferential represents a generalization of the notion of gradient to the nonsmooth case and therefore conditions (16)–(19) are first order optimality conditions.

In the smooth case one can take  $Df(x) = [\underline{\partial}f(x), \bar{\partial}f(x)]$  where  $\underline{\partial}f(x) = \{f'(x)\}$ ,  $\bar{\partial}f(x) = \{0_n\}$ ; therefore condition (16) is equivalent to

$$f'(x^*) = 0_n, \quad (20)$$

condition (18) is equivalent to

$$f'(x^{**}) = 0_n, \quad (21)$$

and, since both sets  $\underline{\partial}f$  and  $\bar{\partial}f$  are singletons, the conditions (17) and (19) are impossible. Thus, conditions (17) and (19) are essentially 'nonsmooth'.

A point  $x^* \in X$  satisfying (16) is called an inf-stationary point, a point  $x^{**} \in X$  satisfying (18) is called a sup-stationary point of  $f$ . In the smooth case the necessary condition for a minimum (20) is the same as the necessary condition for a maximum (21).

### Directions of Steepest Descent and Ascent

Let  $x \in X$  be not an inf-stationary point of  $f$  (i. e. condition (16) is not satisfied). Take  $w \in \bar{\partial}f(x)$  and find

$$\min_{v \in \underline{\partial}f(x)} \|v + w\| = \|v(w) + w\| = \rho_1(w).$$

Since  $\underline{\partial}f(x)$  is a convex compact set, the point  $v(w)$  is unique. Find now

$$\max_{w \in \bar{\partial}f(x)} \rho_1(w) = \rho_1(w(x)).$$

The point  $w(x)$  is not necessarily unique. As  $x$  is not an inf-stationary point, then  $\rho_1(w(x)) > 0$ . The direction

$$g_1(x) = -\frac{v(w(x)) + w(x)}{\|v(w(x)) + w(x)\|} = -\frac{v(w(x)) + w(x)}{\rho_1(w(x))} \quad (22)$$

is a *steepest descent direction* of the function  $f$  at the point  $x$ , i. e.

$$f'(x, g_1(x)) = \min_{\|g\|=1} f'(x, g).$$

Here  $\|\cdot\|$  is the Euclidean norm. The quantity  $f'(x, g_1(x)) = -\rho_1(w(x))$  is the *rate of steepest descent* of

at  $x$ . It may happen that the set of steepest descent directions is not a singleton (and it need not be convex too). Recall that in the smooth case the steepest descent direction is always unique (if  $x$  is not a stationary point).

Similarly, if  $x \in X$  is not a sup-stationary point of  $f$  (i. e. condition (18) does not hold) then let us take  $v \in \partial f(x)$  and find

$$\min_{w \in \bar{\partial} f(x)} \|v + w\| = \|v + w(v)\| = \rho_2(v)$$

and

$$\max_{v \in \underline{\partial} f(x)} \rho_2(v) = \rho_2(v(x)).$$

The direction

$$g_2(x) = \frac{v(x) + w(v(x))}{\|v(x) + w(v(x))\|} = \frac{v(x) + w(v(x))}{\rho_2(v(x))} \quad (23)$$

is a *steepest ascent direction* of the function  $f$  at  $x$ , i. e.

$$f'(x, g_2(x)) = \max_{\|g\|=1} f'(x, g).$$

The quantity  $f'(x, g_2(x)) = \rho_2(v(x))$  is the *rate of steepest ascent* of  $f$  at  $x$ . As above it may happen that there exist many steepest ascent directions.

*Remark 7* Thus, the necessary conditions (16) and (18) are ‘constructive’: in the case where one of these conditions is violated we are able to find steepest descent or ascent directions.

The condition for a minimum (16) can be rewritten in the equivalent form

$$0_n \in \bigcap_{w \in \bar{\partial} f(x^*)} [\partial f(x^*) + w] := L_1(x^*), \quad (24)$$

and the condition for a maximum (18) can also be represented in the equivalent form

$$0_n \in \bigcap_{v \in \underline{\partial} f(x^{**})} [\bar{\partial} f(x^{**}) + v] := L_2(x^{**}). \quad (25)$$

However, if, for example, (24) is violated at a point  $x$ , we are unable to recover steepest descent directions, it may even happen that the set  $L_1(x)$  is empty (see [1, Sects. V.2 and V.3]).

Therefore, condition (24) is not ‘constructive’: if a point  $x$  is not inf-stationary then condition (24) supplies no information about the behavior of the function

in a neighborhood of  $x$  and we are unable to get a ‘better’ point (e. g., to decrease the value of the function). The same is true for the condition for a maximum (25). Nevertheless conditions (25) and (25) may be useful for some other purposes.

*Example 8* Let  $x = (x^{(1)}, x^{(2)}) \in \mathbf{R}^2$ ,  $x_0 = (0, 0)$ ,  $f(x) = |x^{(1)}| - |x^{(2)}|$ . We have  $f(x) = f_1(x) - f_2(x)$ , where  $f_1(x) = \max\{f_3(x), f_4(x)\}$ ,  $f_2(x) = \{f_5(x), f_6(x)\}$ ,  $f_3(x) = x^{(1)}$ ,  $f_4(x) = -x^{(1)}$ ,  $f_5(x) = x^{(2)}$ ,  $f_6(x) = -x^{(2)}$ . The functions  $f_3$ - $f_6$  are smooth therefore (see (7))

$$Df_3(x) = [\underline{\partial} f_3(x), \bar{\partial} f_3(x)],$$

$$\text{with } \underline{\partial} f_3(x) = \{(1, 0)\}, \bar{\partial} f_3(x) = \{(0, 0)\},$$

$$Df_4(x) = [\underline{\partial} f_4(x), \bar{\partial} f_4(x)],$$

$$\text{with } \underline{\partial} f_4(x) = \{(-1, 0)\}, \bar{\partial} f_4(x) = \{(0, 0)\},$$

$$Df_5(x) = [\underline{\partial} f_5(x), \bar{\partial} f_5(x)],$$

$$\text{with } \underline{\partial} f_5(x) = \{(0, 1)\}, \bar{\partial} f_5(x) = \{(0, 0)\},$$

$$Df_6(x) = [\underline{\partial} f_6(x), \bar{\partial} f_6(x)],$$

$$\text{with } \underline{\partial} f_6(x) = \{(0, -1)\}, \bar{\partial} f_6(x) = \{(0, 0)\},$$

Applying (11) one gets  $Df_1(x_0) = [\underline{\partial} f_1(x_0), \bar{\partial} f_1(x_0)]$ , where

$$\underline{\partial} f_1(x_0) = \text{eratornameco}\{\underline{\partial} f_3(x_0) - \bar{\partial} f_4(x_0)$$

$$\underline{\partial} f_4(x_0) - \bar{\partial} f_3(x_0)\} = \text{co}\{(1, 0), (-1, 0)\},$$

$$\bar{\partial} f_1(x_0) = \{(0, 0)\},$$

$$Df_2(x_0) = [\underline{\partial} f_2(x_0), \bar{\partial} f_2(x_0)],$$

where

$$\underline{\partial} f_2(x_0) = \text{co}\{\underline{\partial} f_5(x_0) - \bar{\partial} f_6(x_0), \underline{\partial} f_6(x_0) - \bar{\partial} f_5(x_0)\} \\ = \text{co}\{(0, 1), (0, -1)\},$$

$$\bar{\partial} f_2(x_0) = \{(0, 0)\}.$$

Finally, formula (8) yields

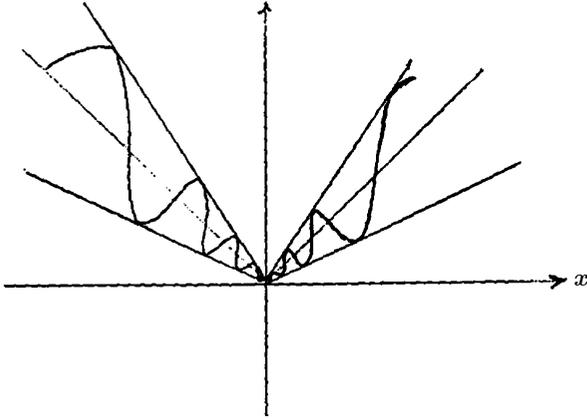

$$Df(x_0) = [\underline{\partial} f(x_0), \bar{\partial} f(x_0)],$$

where

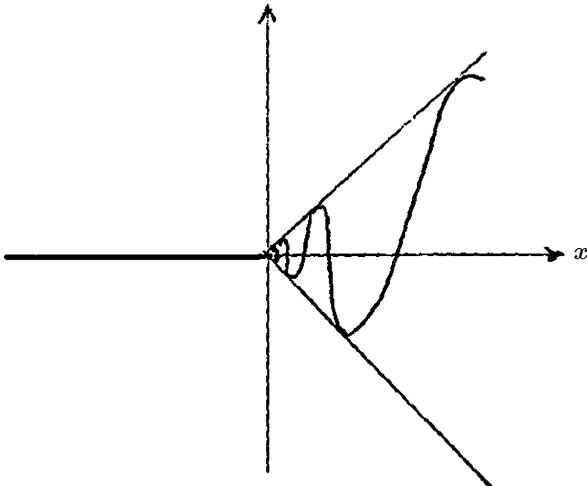

$$\underline{\partial} f(x_0) = \text{co}\{(1, 0), (-1, 0)\},$$

$$\bar{\partial} f(x_0) = \text{co}\{(0, 1), (0, -1)\}.$$

Since (see Fig. 1) conditions (16) and (18) are not satisfied, the point  $x_0$  is neither inf-stationary nor sup-stationary.

Quasidifferentiable Optimization: Optimality Conditions, Figure 1

Quasidifferentiable Optimization: Optimality Conditions, Figure 2

Applying (22) and (23) we conclude that there exist two directions of steepest descent:  $g_1 = (0, 1)$ ,  $g_1' = (0, -1)$  and two directions of steepest ascent:  $g_2 = (1, 0)$ ,  $g_2' = (-1, 0)$ .

It is also clear that the sets (see (24), (25))

$$L_1(x_0) = \bigcap_{w \in \partial f(x_0)} [\partial f(x_0) + w]$$

and

$$L_2(x_0) = \bigcap_{v \in \bar{\partial} f(x_0)} [\bar{\partial} f(x_0) + v]$$

are both empty.

*Remark 9* If a function  $f$  is directionally differentiable but not quasidifferentiable, and if its directional derivative  $f'(x, g)$  is continuous as a function of direction (this is the case, e. g., if  $f$  is directionally differentiable and Lipschitz) then (by the Stone–Weierstrass theorem) its directional derivative may be approximated (to within any given accuracy) by the difference of two positively homogeneous convex functions, i. e.

$$f'(x, g) \approx \max_{v \in A} (v, g) + \min_{w \in B} (w, g), \tag{26}$$

where  $A$  and  $B$  are convex compact sets in  $\mathbf{R}^n$ . Relation (26) shows that  $f'$  can be studied by means of quasidifferential calculus (e. g., one is able to find an approximation of a steepest descent direction etc.). Corresponding results can be found in [1,4].

*Remark 10* In many cases of practical importance the quasidifferential of a function  $f$  is a pair of sets each of them being the convex hull of a finite number of points or/and balls. If this happens it is easy to store and operate with the quasidifferential, to check necessary conditions, to find directions of descent or ascent, to construct numerical methods.

**Necessary and Sufficient Conditions for a Constrained Optimum**

Let a function  $f$  be defined and finite on some open set  $X \subset \mathbf{R}^n$  and let  $\Omega \subset X$ . Consider the problem of finding a minimum or a maximum of  $f$  on  $\Omega$ . For the definiteness in the sequel we shall consider only the problem of minimizing  $f$  on  $\Omega$  since the problem of maximizing  $f$  is the problem of minimizing the function  $f_1 = -f$ .

Let  $x \in \Omega$ . The set

$$\Gamma(x, \Omega) = \left\{ g \in \mathbf{R}^n : \begin{array}{l} \exists \{[\alpha_k, g_k]\} : \\ [\alpha_k, g_k] \rightarrow [+0, g] \\ x + \alpha_k g_k \in \Omega \\ \forall k \end{array} \right\} \tag{27}$$

is called the *Bouligand cone* to the set  $\Omega$  at the point  $x$  (or the *cone of feasible directions*). It is nonempty and closed. If  $x \in \text{int } \Omega$  then  $\Gamma(x, \Omega) = \mathbf{R}^n$ .

**Proposition 11** Let  $f$  be Hadamard directionally differentiable at a point  $x^* \in \Omega$ . For the point  $x^*$  to be a local or global minimizer of  $f$  on  $\Omega$  it is necessary that

$$f'_H(x^*, g) \geq 0, \quad \forall g \in \Gamma(x^*, \Omega). \tag{28}$$

If

$$f'_H(x^*, g) > 0, \quad \forall g \in \Gamma(x^*, \Omega), g \neq 0_n, \quad (29)$$

then  $x^*$  is a strict local minimizer of  $f$  on  $\Omega$ , i. e. there exists  $\delta > 0$  such that

$$\begin{aligned} f(x) &> f(x^*), \\ \forall x \in \Omega, \|x - x^*\| < \delta, x &\neq x^*. \end{aligned}$$

The set  $\Omega \subset \mathbf{R}^n$  is called *quasidifferentiable* if it can be represented in the form

$$\Omega = \{x \in \mathbf{R}^n : h(x) \leq 0\}, \quad (30)$$

where  $h$  is a quasidifferentiable function.

Take  $x \in \Omega$  and consider the cones

$$\begin{aligned} \gamma_1(x) &= \{g \in \mathbf{R}^n : h'(x, g) < 0\}, \\ \Gamma_1(x) &= \{g \in \mathbf{R}^n : h'(x, g) \leq 0\}. \end{aligned}$$

Let  $h(x) = 0$ . We say that the ‘regularity condition is satisfied at  $x$ ’ if

$$\text{cl } \gamma_1(x) = \Gamma_1(x). \quad (31)$$

If  $h(x) = 0$  (i. e., by (30),  $x \in \Omega$ ) and the regularity condition (31) holds then

$$\Gamma(x, \Omega) = \Gamma_1(x). \quad (32)$$

Now we are able to express condition (28) and (29) in terms of quasidifferentials of the functions  $f$  and  $h$ .

If  $h(x) < 0$  then  $x \in \text{int } \Omega$ ,  $\Gamma(x, \Omega) = \mathbf{R}^n$  and, by Proposition 5, conditions (16) and (17) hold. Therefore let us consider the case  $h(x) = 0$ .

**Proposition 12** *Let functions  $f$  and  $h$  be Hadamard quasidifferentiable at a point  $x^* \in \Omega$  and  $h(x^*) = 0$ . Assume also that the regularity condition (31) is satisfied at  $x^*$ . For the point  $x^*$  to be a local or global minimizer of  $f$  on  $\Omega$  it is necessary that*

$$(\partial f(x^*) + w) \cap [-\text{cl}(\text{cone}(\partial h(x^*) + w'))] \neq \emptyset \quad (33)$$

for all  $w \in \bar{\partial}f(x^*)$ ,  $w' \in \bar{\partial}h(x^*)$ .

Condition (33) is equivalent to the condition

$$-\bar{\partial}f(x^*) \subset L(x^*), \quad (34)$$

where

$$L(x) = \bigcap_{w \in \bar{\partial}h(x)} [\partial f(x) + \text{cl}(\text{cone}(\partial h(x) + w))].$$

The set  $L(x)$  is nonempty and convex.

If  $h(x^*) = 0$  and

$$-\bar{\partial}f(x^*) \subset \text{int } L(x^*), \quad (35)$$

then  $x^*$  is a strict local minimizer of  $f$  on  $\Omega$ .

A point  $x^* \in \Omega$  is called an *inf-stationary point* of  $f$  on  $\Omega$  if condition (28) holds.

Let  $x \in \Omega$ ,  $h(x) = 0$ . Assume that  $x$  is not an inf-stationary point and find

$$\begin{aligned} \min_{z \in [\partial f(x) + w]} \|z + z'\| &= \|z(w, w') + z'(w, w')\| \\ &= \|v(w, w') + w + v'(w, w') + w'\| \\ &= \|q(w, w')\| = d(w, w') \end{aligned}$$

and

$$\begin{aligned} \rho(x) &= \max_{\substack{w \in \bar{\partial}f(x) \\ w' \in \bar{\partial}h(x)}} d(w, w') \\ &= d(w_0, w'_0) = \|q(w_0, w'_0)\|. \end{aligned} \quad (36)$$

Since  $x$  is not inf-stationary then  $\rho(x) > 0$ .

**Proposition 13** *If  $h(x) = 0$  and the regularity condition (31) holds then the direction*

$$g_0 = -\frac{q(w_0, w'_0)}{\rho(x)} \quad (37)$$

is a steepest descent direction of  $f$  on  $\Omega$  at  $x$  and  $g_0 \in \Gamma(x, \Omega)$ ,

$$\begin{aligned} f'(x, g_0) &= \min_{\|g\|=1, g \in \Gamma(x)} f'(x, g) \\ &= -\|q(w_0, w'_0)\| = -\rho(x) \end{aligned}$$

i. e.  $-\rho(x)$  is the rate of steepest descent.

**Remark 14** If there exist several pairs  $[w_0, w'_0]$  ( $w_0 \in \bar{\partial}f(x)$ ,  $w'_0 \in \bar{\partial}h(x)$ ) satisfying (36), then (by (37)) there are several steepest descent directions.

**Remark 15** Condition (33) is also equivalent to

$$\begin{aligned} 0_n &\in \bigcap_{\substack{w \in \bar{\partial}f(x^*) \\ w' \in \bar{\partial}h(x^*)}} [\partial f(x^*) + w + \text{cl}(\text{cone}(\partial h(x^*) + w'))] \\ &= L'(x^*). \end{aligned} \quad (38)$$

However, condition (38) is not ‘constructive’ since the set  $L'(x)$  may happen to be empty if  $x$  is not a stationary point (we consider the case  $h(x) = 0$ ).

**Proposition 16** *Let  $x^* \in \Omega$  and  $h(x^*) = 0$ . Assume that the functions  $f$  and  $h$  are quasidifferentiable at  $x^*$ . For the point  $x^*$  to be a local or global minimizer of  $f$  on  $\Omega$  it is necessary that*

$$L_1(x^*) \subset L_2(x^*), \quad (39)$$

where

$$\begin{aligned} L_1(x) &= -[\bar{\partial}f(x) + \bar{\partial}h(x)], \\ L_2(x) &= \text{co}\{\underline{\partial}f(x) - \bar{\partial}h(x), \underline{\partial}h(x) - \bar{\partial}f(x)\}. \end{aligned}$$

If, in addition,  $f$  and  $h$  are Hadamard q.d. at  $x^*$ ,  $h(x^*) = 0$  and  $L_1(x^*) \subset \text{int } L_2(x^*)$  then  $x^*$  is a strict local minimizer of  $f$  on  $\Omega$ .

**Proposition 17** *Let  $h(x^*) = 0$ ,  $f$  and  $h$  be Hadamard q.d. at  $x^*$ . If the regularity condition (31) holds at  $x^*$  then condition (39) is equivalent to condition (28).*

Let  $x \in \Omega$ ,  $h(x) = 0$ . Assume that (39) does not hold. Find

$$d(x) = \max_{v \in L_1(x)} \rho(v) = \rho(v(x)),$$

where

$$\rho(v) = \min_{w \in L_2(x)} \|v - w\| = \|v - w(v)\|.$$

Since (39) is not satisfied then  $\rho(v(x)) > 0$ .

**Proposition 18** *The direction*

$$g'_0 = \frac{v(x) - w(v(x))}{\rho(v(x))} \quad (40)$$

is a descent direction of  $f$  on  $\Omega$  at  $x$ .

**Remark 19** While the steepest descent direction  $g_0$  (see (37)) may be not admissible, the direction  $g'_0$  (see (40)) is always admissible, i. e. for sufficiently small  $\alpha > 0$  we have  $x + \alpha g'_0 \in \Omega$ .

Recent results and the state-of-the-art in quasidifferentiable calculus can be found in [2].

Quasidifferentiability; Nonsmooth mechanics; Elastic stability

Problems in mechanics whose governing relations can be obtained from a generally nondifferentiable and nonconvex, but quasidifferentiable (in the sense of V.F. Demyanov and A.M. Rubinov) potential function are considered. They consider a fairly general form for the modeling and the study of nonsmooth problems in mechanics [4] and they cover certain classes of variational and hemivariational inequality problems of mechanics [14,15]. The notion of hemivariational inequalities has been introduced and thoroughly studied in mechanics by P.D. Panagiotopoulos (see also ► **Nonconvex energy functions: Hemivariational inequalities;**

► **Hemivariational inequalities: Applications in mechanics**). Moreover, there exists extensive theoretical support for the use of quasidifferentiable calculus and optimization techniques, see, e.g., [3,4]. For methods and heuristic algorithms of nonconvex optimization in computational mechanics, see [12]. In this short note some techniques for treating stability problems for nonsmooth structures are outlined. This way results for classical, smooth structures (e.g., [1,10,11]) can be extended to cover nonsmooth ones (cf., also [8,9]). This work and the preliminary results outlined here are based on [18,19].

All previously mentioned potentials are piecewise-differentiable and may be described, in general, as continuous selections of differentiable functions. In turn, the structural analysis problem results from minimality or in general critical point conditions of the potential (see examples in [2,6,7,14,15]).

Results from stability analysis of parametric optimization problems for nondifferentiable functions are used for the study of a stepwise holonomic, incremental structural analysis problem. In particular the systematic first and second order linearizations proposed in respectively, and the arising normal forms are adopted for the potential energy function.

The techniques outlined here may be useful both for the analysis of the stability of structures which involve nonmonotone and possibly multivalued nonlinearities (in a holonomic or a stepwise holonomic setting) and for the design of incremental-iterative algorithms for structural analysis purposes.

### Smooth Potentials and Stability in Mechanics

Let a discretized elastostatic analysis problem be formulated as a potential energy minimization problem:

$$\min_{u \in U_{\text{ad}}} \{ \bar{\Pi}(u, \lambda) = \Pi(e(u)) - p(u, \lambda) \} . \quad (1)$$

Here  $u$  is the  $n$ -vector of displacement degrees of freedom,  $e$  is the  $m$ -vector of discrete element deformations,  $\Pi(e) \in \mathbf{R}$  is the internal energy density,  $p(u, \lambda) \in \mathbf{R}$  is the external loading potential, parametrized by a loading scalar  $\lambda \in \mathbf{R}^1$  and  $U_{\text{ad}} \subseteq \mathbf{R}^n$  is the space of admissible displacements. Displacement  $u$  and deformation  $e$  vectors are connected by the geometric compatibility operator  $A(u): \mathbf{R}^n \rightarrow \mathbf{R}^m$  such that  $e(u) = A(u)$  holds.

On the assumption that  $\bar{\Pi}(u, \lambda)$  is smooth, the equilibrium configurations for the structural system are critical points of this potential, i. e. for fixed  $\lambda = \bar{\lambda}$  one has:

$$\Sigma_{\text{crit}} = \left\{ u \in \mathbf{R}^n : \nabla_u \bar{\Pi}(u, \bar{\lambda}) = 0 \right\}. \quad (2)$$

Moreover, inspection of the second order derivatives (the Hessian matrix of  $\bar{\Pi}(u, \bar{\lambda})$ ) gives us stability information [1]. If  $u$  is a nondegenerate critical point, i. e.  $u \in \Sigma_{\text{crit}}$  and  $\nabla_u^2 \bar{\Pi}(u, \bar{\lambda})$  is regular, then a positive or negative definite Hessian  $\nabla_u^2 \bar{\Pi}(u, \bar{\lambda})$  indicates that the point  $u$  is a local minimum or maximum, respectively. Only local minima correspond to stable equilibrium configurations. If  $\nabla_u^2 \bar{\Pi}(u, \bar{\lambda})$  is singular in  $u \in \Sigma_{\text{crit}}$ , then higher order derivatives of  $\bar{\Pi}(u, \bar{\lambda})$  must be examined for stability [1].

If  $u_0$  is either a noncritical or a nondegenerate critical point of  $\bar{\Pi}(u, \bar{\lambda})$ , which is assumed here to be at least a  $C^2$ -function, i. e. two times continuously differentiable, then  $\bar{\Pi}(u, \bar{\lambda})$  is  $C^1$ -equivalent to its second order approximation around  $u_0$ , i. e.

$$\begin{aligned} (\bar{\Pi} \circ \Phi)(u) &= \bar{\Pi}(u_0, \bar{\lambda}) + \nabla_u \bar{\Pi}(u_0, \bar{\lambda})^\top (u - u_0) \\ &\quad + \frac{1}{2} (u - u_0)^\top \nabla_u^2 \bar{\Pi}(u_0, \bar{\lambda}) (u - u_0), \end{aligned} \quad (3)$$

where  $\Phi$  is a  $C^1$ -coordinate transformation (diffeomorphism). In the vicinity of a nondegenerate critical point the behavior of  $\bar{\Pi}(u, \bar{\lambda})$  is characterized by the number of negative eigenvalues of  $\nabla_u^2 \bar{\Pi}(u, \bar{\lambda})$  (the *quadratic index*).

In the coordinates  $\Delta u = u - u_0$  and the notation  $\Delta \bar{\Pi}(\Delta u, \bar{\lambda}) = \bar{\Pi}(u, \bar{\lambda}) - \bar{\Pi}(u_0, \bar{\lambda})$  we can determine (cf. [5, p. 21]) a local  $C^1$ -coordinate transformation  $\Phi: U \rightarrow V$ , where  $U, V$  are neighborhoods of the origin, such that:

$$\begin{aligned} \Delta \bar{\Pi} \circ \Phi^{-1}(y) &= -y_1^2 - \dots - y_k^2 + y_{k+1}^2 + \dots + y_n^2, \\ \forall y \in V. \end{aligned} \quad (4)$$

Qualitative stability results for fixed load  $\lambda = \bar{\lambda}$  are recognized in the normal form (4).

### Incremental Algorithm

Incremental-iterative solution algorithms are based on appropriate approximations of (1). Let us consider the

one-parametric load incrementation on the following case of (1) (cf. [10]):

$$\min_{u \in \mathbf{R}^n} \{ \bar{\Pi}(u, \lambda) = \Pi(u) - \lambda p^\top u \}. \quad (5)$$

For equilibrium we have

$$\nabla_u \bar{\Pi}(u, \lambda) = 0 \quad \Rightarrow \quad \nabla_u \Pi(u) - \lambda p = 0 \quad (6)$$

For the examination of the stability of a solution we study the following relation in terms of  $\lambda - \lambda_0 = \Delta \lambda$ , (defining  $\Delta u$  as a function of  $\Delta \lambda$ , if  $\nabla_u^2 \Pi(u_0)$  is regular)

$$\nabla_u^2 \Pi(u_0) \Delta u + \Delta \lambda p = 0, \quad (7)$$

which connects the incremental displacement  $\Delta u$  for a change of loading equal to  $\Delta \lambda p$ . Relation (7) can be produced by subtraction of the Taylor expansions of the equilibrium equation (6) in  $(u_0 + \Delta u, \lambda_0 + \Delta \lambda)$  and  $(u_0, \lambda_0)$ , respectively, and by using the approximation (up to higher order terms)

$$\nabla_u \Pi(u_0 + \Delta u) = \nabla_u \Pi(u_0) + \nabla_u^2 \Pi(u_0) \Delta u. \quad (8)$$

Consider the coordinate transformation:  $\Delta u = \Phi^{-1}(y) = \phi_i y_i = F y$  where  $\phi_i$  are the eigenvectors of  $\nabla^2 \Pi(u_0)$  and the summation convention over repeated indices is used. Then equation (7) is written in the new coordinate system as:

$$\begin{aligned} \nabla^2 \Pi(u_0) F y - p \Delta \lambda &= 0 \\ \Rightarrow F^\top \nabla^2 \Pi(u_0) F y - F^\top p \Delta \lambda &= 0 \quad (9) \\ \Rightarrow [\omega_i y_i] - F^\top p \Delta \lambda &= 0. \end{aligned}$$

Here  $\omega_i$  are the eigenvalues of the local tangential stiffness matrix  $K(u_0) = \nabla^2 \Pi(u_0)$ , which act as stability coefficients for the linearized equation of equilibrium (7) [10,11].

### Nonsmooth Superpotentials

Let us assume problem (1) with a nonsmooth potential energy function. For simplicity let only the internal energy function  $\Pi(u)$  be nonsmooth and  $U_{\text{ad}} = \mathbf{R}^n$  in (1).

Let  $V$  denote an open subset of  $\mathbf{R}^n$ . We call a function  $f: V \rightarrow \mathbf{R}$  a *continuous selection* of the  $C^r$ -functions  $g_i: V \rightarrow \mathbf{R}$ ,  $1 \leq i \leq k$ , (briefly,  $f \in \text{CS}\{g_1, \dots, g_k\}$ ), if  $f$  is continuous and  $\forall u \in V \exists i \in \{1, \dots, k\}: f(u) = g_i(u)$ . Let

$\Pi(u)$  in (1) be a piecewise differentiable  $PC^r$  function of appropriate order  $r > 1$ , defined on an open set  $U \subseteq \mathbf{R}^n$ . This means that (cf. [7]) at every point  $u_0 \in U$  there exists an open neighborhood  $V \subseteq U$  and a finite collection of  $C^r$ -functions  $\{\Pi_1, \dots, \Pi_k\}$  defined on  $V$  such that  $\Pi|_V \in CS\{\Pi_1, \dots, \Pi_k\}$ .

Let  $I(u)$  be the active index set  $\text{set}\{i: \Pi(u) = \Pi_k(u)\}$ . One considers a smooth external loading potential  $p(u, \lambda)$ , which depends on the one-dimensional loading parameter  $\lambda$  (cf. (1)).

The assumption of a  $PC^r$ -potential energy function is very general and covers a large number of nonsmooth mechanics applications (see, also, [13, Chap. 8]). More detailed analysis of the requirements which are necessary in order for a  $PC^r$ -function to be the potential of a certain structural analysis problem must be investigated on a case-by-case basis.

Any  $PC^r$ -potential is locally Lipschitz continuous and Bouligand differentiable with the  $B$ -derivative at a point  $u_0 \in \mathbf{R}^n$  in the direction  $d \in \mathbf{R}^n$  being a continuous selection of the functions  $\nabla \Pi_i(u_0)^T d, i \in \widehat{I}(u_0)$ . Here  $\widehat{I}(u_0)$  denotes the essentially active index set  $\widehat{I}(u_0) = \{i \in I(u_0): u_0 \in \text{cl}(\text{int}(\{u \in U: \Pi(u) = \Pi_i(u)\}))\}$ , with  $\text{cl}$  (resp.  $\text{int}$ ) abbreviating the closure (resp. the interior) of a set. For completeness, recall that Clarke's generalized subdifferential is given by [7]  $\partial_{\text{Cl}} \Pi(u_0) = \text{conv} \{ \nabla \Pi_i(u_0): i \in \widehat{I}(u_0) \}$  where  $\text{conv}$  stands for the convex hull.

### Nonsmooth Local Approximations

For the needs of the applications in mechanics the first and the second order differentiation, or the appropriate analogous nonsmooth notions, and suitable local nonsmooth approximations which generalize the (second order) Taylor expansion of a smooth function are used. A local coordinate transformation will provide us with a simple formulation of the energy minimization problem, cf. (4), which, in turn, will be used for the extraction of stability information analogous to (9).

Following [6], a critical point  $u_0$  of a  $PC^2$ -potential function  $\overline{\Pi}(u)$  is called a *nondegenerate critical point* if  $\overline{\Pi}$  is locally representable as a continuous selection of functions  $\overline{\Pi}_1, \dots, \overline{\Pi}_k$  such that the following properties are true:

ND1) the vectors  $\nabla \overline{\Pi}_j(u_0), j \in I(u_0) \setminus \{i\}$  are linearly independent  $\forall i \in I(u_0)$ ,

ND2) the restricted Hessian of the Lagrangian, the matrix  $\nabla^2 L(u_0)|_{V(u_0)}$ , is invertible.

Here  $V(u_0)$  denotes the space

$$\left\{ y \in \mathbf{R}^n: \begin{matrix} [\nabla \overline{\Pi}_i(u_0) - \nabla \overline{\Pi}_j(u_0)]^T y = 0, \\ i, j \in I(u_0) \end{matrix} \right\}.$$

For the Lagrangian

$$L(u) = \sum_{i \in I(u_0)} \lambda_i \overline{\Pi}_i(u)$$

holds

$$\begin{aligned} \sum_{i \in I(u_0)} \lambda_i \nabla \overline{\Pi}_i(u_0) &= 0, \\ \sum_{i \in I(u_0)} \lambda_i &= 1, \quad \lambda_i \geq 0. \end{aligned} \tag{10}$$

The qualitative behavior of the potential energy function, the link to the stability of the described mechanical system, can be shown if one considers the normal form (cf. (4)). In this context, the following result of [6] is of importance.

Let  $\overline{\Pi} \in CS(\overline{\Pi}_i, i \in I)$  and let  $u_0 \in \mathbf{R}^n$  be a nondegenerate critical point for  $\overline{\Pi}$  with quadratic index equal to  $q$ . Suppose moreover that  $|I_0(u_0)| = k + 1$ . Then at  $u_0$ , the potential is topologically equivalent to  $g(y)$ , where

$$\begin{aligned} g(y_1, \dots, y_n) &= \overline{\Pi}(u_0) + CS \left( y_1, \dots, y_k, - \sum_{i=1}^k y_i \right) \\ &\quad - \sum_{j=k+1}^{k+q} y_j^2 + \sum_{r=k+q+1}^n y_r^2. \end{aligned} \tag{11}$$

One observes that the second term in the right-hand side of (11) is sufficiently rich to describe locally every type of nonsmooth, finite-dimensional functions.

Furthermore, following [7] one notes that a  $PC^2$ -function can always be transformed into the min-max normal form:

$$\overline{\Pi}(u) = \max_{1 \leq i \leq k} \min_{j \in M_i} \overline{\Pi}_j(u), \tag{12}$$

where (12) is considered as a local representation of the potential in a neighborhood of  $u_0, M_i \subseteq \{1, \dots, m\}$  and the functions  $\overline{\Pi}_j: U \rightarrow \mathbf{R}, j \in \{1, \dots, m\}$ , are  $C^2$ -functions.

In this case a consistent nonsmooth second order approximation of the  $PC^2$ -potential, expressed by the normal form (12), is given by:

$$\max_{1 \leq i \leq k} \min_{j \in M_i} \left\{ \begin{array}{l} \overline{\Pi}_j(u_0) + \nabla \overline{\Pi}_j(u_0)^\top (u - u_0) \\ + \frac{1}{2} (u - u_0)^\top \nabla^2 \overline{\Pi}_j(u_0) (u - u_0) \end{array} \right\}. \quad (13)$$

Note here that the previously denoted min-max form is not defined in an unique way.

### Stability Results. Discussion

For a structural analysis system with a structured nonsmooth  $PC^2$ -potential with (11) and for a nondegenerate critical point  $u_0 \in \mathbf{R}^n$ , the local approximation (11) is available. Let us assume a potential of the external loading equal to  $\lambda p^\top u$ , as in (5) and let for the present the load parameter  $\lambda$  be fixed to a given value. From (11) the following complete subdivision of the coordinate space  $\mathbf{R}^n$  arises:

$$\mathbf{R}^n = \mathbf{R}^k \oplus \mathbf{R}^q \oplus \mathbf{R}^{n-k-q} = \mathbf{R}^{\text{non}} \oplus \mathbf{R}^{\text{un}} \oplus \mathbf{R}^{\text{st}}, \quad (14)$$

where  $\mathbf{R}^{\text{non}}$  stands for the essentially nondifferentiable subspace,  $\mathbf{R}^{\text{un}}$  for the unstable subspace and  $\mathbf{R}^{\text{st}}$  for the stable subspace. Let, moreover, the local coordinate transformation that leads to (11) be traced for the components of the vector  $\lambda p$  (cf. (6)–(9)). Let the components of the last vector in the three subspaces of ((14)) be  $\tilde{p}^{\text{non}}$ ,  $\tilde{p}^{\text{un}}$  and  $\tilde{p}^{\text{st}}$ , respectively.

Further one considers the type of the CS in the linear term of the right-hand side in (11) in comparison with the three above defined components of the loading vector. This information can be used for stability analysis. Smooth and nonsmooth contributions should be treated separately. For the nonsmooth part, for example, if one has a max-type function and  $q = 0$ , then only stable local minima of the potential energy function arise.

The above outlined scheme can be followed for the derivation of stability considerations for a structure at a given point and for a given loading level ( $\lambda$  is constant). For the examination of the stability question along a given loading path (one-parametric change of  $\lambda$ ) one should take into account that the local representation (11) may change as  $\lambda$  changes. The results are qualitative of the same nature, but, for practical ap-

plications, a combinatorial problem arises, which concerns the way of possible changes of the subdivision (14) as loading changes. Further work in this direction will generalize the computational mechanics techniques for the tracing of post-buckling equilibria in nonsmooth mechanics' applications. Theoretical support will be provided by the theory of parametric optimization (cf., e. g., [5] and the applications in contact mechanics [16,17]).

Quasidifferentiability

In science and, especially in engineering, the variational or weak formulation of a given boundary value problem has certain advantages. Instead of writing pointwise relations (for example, partial differential equations) which hold for each point of the considered system, one multiplies the governing relation with an arbitrary virtual variation, integrates over the entire area and requires that the latter integral be equal to zero. This is a weak or a variational formulation of the problem. Since the considered virtual variation is arbitrary

one gets back, on the assumption of sufficient regularity, the initial pointwise relations.

Variational formulations provide the basis for the development of numerical approximation methods (for example, by the *finite element method*). One of the advantages is that by performing partial integration one transfers differentiability requirements from the actual variables of the problem to the virtual ones, which, in turn, results in less demanding requirements on the complexity of the required finite element basis approximation functions. The literature on variational problems is very large, so that every selection of references would be incomplete. In this sense, let us mention here the publications [1,3,7,8,14].

In the language of smooth optimization, instead of considering the first order optimality condition that the derivative of a function at a given point is equal to zero, one proceeds as follows. The latter equation is multiplied by a virtual change of the variables along an arbitrary direction. Then, one considers the equivalent relation that the directional derivative of the function is equal to zero for all directions emanating from the assumed point.

In mechanics the arising quantities have a physical meaning (for instance, they correspond to the virtual work of a system). For historical reasons one speaks about *variational principles*. Moreover, on adequate smoothness assumptions one writes variational equalities. Finally, for engineering applications, and depending on the nature of the studied problem, one has to solve, after numerical discretization, systems of linear or nonlinear equations.

In connection with convex, nondifferentiable potentials or for convex problems with inequality constraints it is intuitively conceivable that not all virtual variations are allowed for. The theory of variational inequalities has been developed for the study of this class of problems. It is connected with the subdifferential of convex analysis and it is appropriate for the study of monotone operators [5,9]. In simple cases, or after appropriate reformulations one gets linear or nonlinear complementarity problems (see, e. g. [6] for a recent review).

For general nonconvex and nonsmooth problems a nonconvex extension of the notion of the variational inequality is required. For potential operators and by using the generalized subdifferential in the sense of F.H.

Clarke, this class of variational problems have been developed and studied by P.D. Panagiotopoulos, who called them *hemivariational inequalities*. See ► **Nonconvex energy functions: Hemivariational inequalities;** ► **Hemivariational inequalities: Applications in mechanics** or [9,11] for more details.

The notion of quasidifferentiability, in the sense of V.F. Demyanov and A.M. Rubinov, provides an elegant way for the formulation and study of nonconvex variational inequality problems. By taking advantage of the ability of the quasidifferentials to provide a qualitative and quantitative nonsmooth approximation of a nonsmooth function one arrives at a very powerful variational description of the problem. This link has been studied for several applications in mechanics in [4,10,12]. One should mention that the author's understanding of this theory and their first attempts have been based on previous theoretical results of C.A. Stuart and J.F. Toland [13] and G. Auchmuty [2] concerning difference convex energy functions. Of course, the class of *difference convex functions* is included in the class of quasidifferentiable functions, so that the here presented approach is sufficiently general.

### Variational Formulation of Subdifferential Laws

Let us assume a monotone possibly multivalued (i. e., with complete vertical branches) relation (a law) between the quantities  $u$  and  $-f$ . To be more precise, one may think about a nonlinear boundary law which connects boundary reactions  $-f$  with boundary displacements  $u$  in mechanics. Let a convex l.s.c. and proper function  $\Phi$  exists, the convex superpotential in the sense of J.-J. Moreau, and that the previously mentioned law is written in the subdifferential form:

$$-f \in \partial\Phi(u). \quad (1)$$

Here  $\partial$  denotes the subdifferential of convex analysis. Function  $\Phi(u)$  can be considered as the potential energy corresponding to the mechanical law (1).

By definition, (1) is equivalent to the following variational inequality:

$$\Phi(u^*) - \Phi(u) \geq -\langle f, u^* - u \rangle, \quad \forall u^* \in \mathbf{R}. \quad (2)$$

For example, if  $\Phi$  is the indicator  $I_K$  of a convex closed interval  $K$  of  $\mathbf{R}$ , then one has

$$-f \in \partial I_K(u). \quad (3)$$

This is a unilateral constraint as one easily recognizes by considering the equivalent variational inequality (for  $u \in K$ ):

$$\langle f, u^* - u \rangle \geq 0, \quad \forall u^* \in K. \quad (4)$$

Indeed, if  $u_* - u$  is an admissible variation of  $u$  (in the sense that it satisfies (4)), then the same does not hold for the variation  $u - u_*$ . Of course in the one-dimensional case  $\langle \cdot, \cdot \rangle$  is a simple multiplication. For multidimensional problems it will be an inner product.

Analogous subdifferential relations can be written for multidimensional laws (for example, for constitutive laws in elastoplasticity [9]).

### Variational Formulation of Quasidifferential Laws

Let us assume now a nonmonotone possibly multivalued relation. By means of a real-valued, *quasidifferentiable superpotential* energy function  $\Phi$ , one may express this relation in the form:

$$-f = w_1 + w_2, \quad (5)$$

with  $\{w_1, w_2\} \in D\Phi(u) = [\underline{\partial}\Phi(u), \bar{\partial}\Phi(u)]$ .

By definition, (5) is equivalent to the relation:

$$\begin{aligned} \langle -f, u^* - u \rangle &= \max_{w_1^* \in \underline{\partial}\Phi(u)} \langle w_1^*, u^* - u \rangle \\ &\quad + \min_{w_2^* \in \bar{\partial}\Phi(u)} \langle w_2^*, u^* - u \rangle, \quad (6) \\ \forall u^* &\in U, \end{aligned}$$

for  $u \in U$ , or with the *system of variational inequalities*

$$\begin{aligned} \langle -f, u^* - u \rangle - \langle w_2^*, u^* - u \rangle &\leq \max_{w_1^* \in \underline{\partial}\Phi(u)} \langle w_1^*, u^* - u \rangle, \\ \forall u^* \in U, \quad \forall w_2^* \in \bar{\partial}\Phi(u), \quad (7) \end{aligned}$$

and

$$\begin{aligned} \langle -f, u^* - u \rangle - \langle w_1^*, u^* - u \rangle &\geq \min_{w_2^* \in \bar{\partial}\Phi(u)} \langle w_2^*, u^* - u \rangle, \\ \forall u^* \in U, \quad \forall w_1^* \in \underline{\partial}\Phi(u). \quad (8) \end{aligned}$$

Space  $U$  is in general a subspace of  $\mathbf{R}^n$  and depends on the considered application.

Analogously one treats multidimensional relations (for example, boundary adhesive layers) or constitutive laws (e. g., materials with softening effects). A number of concrete examples have been given in [4, Chap. 3].

### Example: an Elastostatic Problem Involving QD-Superpotentials

Let  $\Omega \subset \mathbf{R}^3$  be an open bounded subset occupied by a deformable body in its undeformed state. On the assumption of small deformations one writes the virtual work relation

$$\begin{aligned} &\int_{\Omega} \sigma_{ij}(u) \varepsilon_{ij}(v - u) \, d\Omega \\ &= \int_{\Omega} f_i (v_i - u_i) \, d\Omega + \int_{\Gamma} \sigma_{ij} n_j (v_i - u_i) \, d\Gamma, \quad (9) \\ \forall v &\in V, \end{aligned}$$

for  $u \in V$ . Here  $V$  denotes the function space of the displacements which will be defined further. As it has been outlined previously, for the derivation of (9) one multiplies the equilibrium equation:

$$\sigma_{ij,j} + f_i = 0, \quad (10)$$

where  $f_i$  is the volume force vector, by a virtual displacement  $v_i - u_i$  and then we have integrated over  $\Omega$ . On the assumption of appropriately regular functions, one applies the Green–Gauss theorem by taking into account the strain-displacement relation

$$\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}). \quad (11)$$

Let us assume further that the body is linearly elastic, i. e. that

$$\sigma_{ij} = C_{ijkl} \varepsilon_{kl}, \quad (12)$$

where  $C = \{C_{ijkl}\}$ ,  $i, j, h, k = 1, 2, 3$ , is the elasticity tensor which obeys to the well-known symmetry and ellipticity conditions. The energy bilinear form of linear elasticity is further denoted by  $\alpha(u, v) = \int_{\Omega} C_{ijkl} \varepsilon_{ij}(u) \varepsilon_{kl}(v) \, d\Omega$ .

### Variational Equality

For example, let us assume first that on the boundary  $\Gamma$  of the structure the classical boundary conditions  $S_N = 0$  and  $u_{T_i} = 0$ ,  $i = 1, 2, 3$ , hold. Then one gets the classical

variational equality: Find  $u \in V_0 = \{v: v \in V, v_{T_i} = 0 \text{ on } \Gamma\}$  such that

$$\alpha(u, v) = \int_{\Omega} f_i v_i \, d\Omega, \quad \forall v \in V_0.$$

### Convex Variational Inequality

Furthermore, let us assume now that on  $\Gamma$  the general monotone multivalued subdifferential boundary condition (1) holds. Using (2) and (9) one obtains the following variational inequality: find  $u \in V$  with  $\Phi(u) < \infty$ , such that

$$\begin{aligned} \alpha(u, v - u) + \int_{\Gamma} (\Phi(v) - \Phi(u)) \, d\Gamma \\ \geq \int_{\Omega} f_i (v_i - u_i) \, d\Omega, \\ \forall v \in V: j(v) < \infty. \end{aligned}$$

### QD Laws and Systems of Variational Inequalities

Let us assume that on  $\Gamma$  the nonmonotone, possibly multivalued boundary condition (5) holds, where  $\Phi$  is a quasidifferentiable functional. It has the form

$$-S = w_1 + w_2,$$

with  $\{w_1, w_2\} \in Dj(u) = \{\underline{\partial}\Phi(u), \bar{\partial}\Phi(u)\}$ .

Then one has, by definition, the relation (6), where  $\Phi'(u, v) = \langle -S, v \rangle$ . Finally, by an analogous way, one has the variational problem: find  $u \in V$ ,  $w_1, w_2 \in W$  such as to satisfy the relation

$$\begin{aligned} \alpha(u, v - u) - \int_{\Omega} f_i (v_i - u_i) \, d\Omega \\ + \max_{\substack{w_1^*(x) \in \underline{\partial}\Phi(u(x)) \\ \text{a.e. on } \Gamma}} \langle w_1^*, v - u \rangle \\ + \min_{\substack{w_2^*(x) \in \bar{\partial}\Phi(u(x)) \\ \text{a.e. on } \Gamma}} \langle w_2^*, v - u \rangle = 0, \end{aligned} \quad (13)$$

$$\forall v \in V.$$

The function spaces  $V$  and  $W$  depend on the studied application. For instance, for three-dimensional elastostatics the following choice has been proposed in [4]:  $V = [H^1(\Omega)]^3$ ,  $W = [L^2(\Gamma)]^3$ . A more general formulation, also proposed in the previously given original publication, would be to assume that  $w_1, w_2 \in [H^{-1/2}(\Gamma)]^3$ .

Then in the left-hand side of (13) one should replace  $w_1(x) \in \bar{\partial}\Phi(u(x))$  a.e. on  $\Gamma$  by  $w_1 \in \bar{\partial}F(u)$  and  $w_2(x) \in \underline{\partial}\Phi(u(x))$  a.e. on  $\Gamma$  by  $w_2 \in \underline{\partial}F(u)$ , where one assumes that

$$F(u) = \begin{cases} \int_{\Gamma} \Phi(u(x)) \, d\Gamma & \text{if } \Phi(\cdot) \in L^2(\Gamma), \\ \infty & \text{otherwise.} \end{cases}$$

Then instead of (13) one has the following problem: find  $u \in [H^1(\Omega)]^3$ ,  $w_1, w_2 \in [H^{-1/2}(\Gamma)]^3$  such that

$$\begin{aligned} \alpha(u, v - u) - \int_{\Omega} f_i (v_i - u_i) \, d\Omega \\ + \max_{w_1^*} \{\langle w_1^* + w_2^*, v - u \rangle : w_1^* \in \underline{\partial}F(u)\} \\ + \min_{w_2^*} \{\langle w_1^* + w_2^*, v - u \rangle : w_1^* \in \underline{\partial}F(u)\} = 0, \\ \forall v \in [H^1(\Omega)]^3. \end{aligned}$$

One should mention that the related questions concerning the extension of QD-superpotentials to function spaces remain still open.

Moreover we can write the min-max form which reads: find  $u \in [H^1(\Omega)]^3$  such as to satisfy the relation:

$$\begin{aligned} \alpha(u, v - u) - \int_{\Omega} f_i (v_i - u_i) \, d\Omega \\ + \min_{w_2^* \in \underline{\partial}F(u)} \max_{w_1^* \in \bar{\partial}F(u)} \{\langle w_1^* + w_2^*, v - u \rangle = 0, \\ \forall v \in [H^1(\Omega)]^3. \end{aligned}$$

If in particular the superpotential  $F$  can be expressed as the difference of two convex functions, i. e. if  $F = \Phi_1 - \Phi_2$ , with  $\Phi_1$  and  $\Phi_2$  convex, then one has

$$\underline{\partial}F = \partial\Phi_1, \quad \bar{\partial}F = -\partial\Phi_2,$$

where  $\partial$  is the subdifferential of the convex analysis. In this case the following system of variational inequalities results, as it can easily be shown by using the definition of the subdifferential: find  $u \in [H^1(\Omega)]^3$ , such as to satisfy

$$\begin{aligned} \alpha(u, v - u) - \int_{\Omega} f_i (v_i - u_i) \, d\Omega \\ - \langle w_2^*, v - u \rangle + \Phi_1(v) - \Phi_1(u) \geq 0, \\ \forall v \in [H^1(\Omega)]^3 \end{aligned}$$

for all  $w_2^* \in [H^{-1/2}(\Gamma)]^3$  such that

$$\langle w_2^*, v - u \rangle \leq \Phi_2(v) - \Phi_2(u), \quad \forall v \in [H^1(\Omega)]^3.$$

Further information on variational formulations in elastostatics can be found in ► [Hemivariational inequalities: Applications in mechanics](#).

Variational inequalities; Nonsmooth mechanics;  
Implicit variational problems

Variational or weak formulations of boundary value problems in science and, in particular, in engineering are integral, energetic expressions of all involved quantities (involving differential equations and boundary conditions). Usually, under differentiability (smoothness) assumptions of the involved variables and equalities throughout the considered model one gets variational equality problems. The strong formulation of the initial problem (i. e., constitutive relations, boundary conditions, etc) can be reconstructed if one considers certain values for the (otherwise arbitrary) variations in the weak form, i. e., in the variational equality. Variational formulations provide the basis for modern computational mechanics techniques (e. g., the *finite element method*) and for this reason they have been extensively studied in the affiliated literature (see, among others, [22]). In terms of optimization they can be considered as stationary point statements for the total differential of an appropriately constructed (convex or nonconvex) potential energy function, provided that the studied problem admits a potential. Namely, the weak formulation expresses the fact that the variation of a function for every small variation of the involved independent variables is equal to zero, which, due to the arbitrariness of the variations, is equivalent to the more classical requirement that the first derivative of the function vanishes at a critical point.

Due to inequality-type constraints or due to lack of differentiability in the involved functions one is some-

times obliged to consider one-sided (unilateral) variations of the problem's variables. A systematic way of doing so is provided by the theory of *variational inequalities* [13]. They are related to monotone operators, to convex, nondifferentiable optimization problems and to complementarity problems. Variational inequalities have been applied for the study of problems in engineering [17,20], economics, transportation planning and flow in networks (see also [6,8,10]).

Extensions for nonconvex variational inequalities, which are based on the generalized gradient approach in the sense of F.H. Clarke, have been proposed and studied by P.D. Panagiotopoulos who named them *hemivariational inequalities*. Details are given in ► **Nonconvex energy functions: Hemivariational inequalities** and ► **Hemivariational inequalities: Applications in mechanics**. Parallel developments which are based on the notion of the quasidifferentiability in the sense of V.F. Demyanov and A.M. Rubinov are described in ► **Quasidifferentiable optimization: Variational formulations**.

Furthermore, there exist problems where the admissible space (for the variables and their variations) or the involved potentials depend on the solution of the problem. This class of implicit variational inequality problems are called quasivariational inequalities. They have been used for the modeling of stochastic impulsive control problems, in free boundary problems, in mechanics and in economy. The interested reader may find more information in the references [1,2,7,9,15]. Here a short outline of quasivariational inequality problems is given. A model application arising in unilateral contact problems with Coulomb friction in engineering mechanics demonstrates the discussed ideas. This approach is based on early theoretical and numerical studies of [19] (see also numerical applications in [11,12]) and, among others, have recently been tested for several convex and nonconvex problems of mechanics in [14].

## Variational Inequalities

Let us first consider abstract variational formulations of a boundary value problem which is defined in a subset  $\Omega$  of  $\mathbf{R}^n$ ,  $n = 1, \dots, n$ , with boundary  $\Gamma$ . Let  $V$  be a real Hilbert space and  $V'$  be its dual space. Let  $a(\cdot, \cdot): V \times V \rightarrow \mathbf{R}$  be a symmetric, continuous and coercive bilinear form and  $(l, \cdot)$  be a continuous linear form on  $V$ . An

abstract variational problem reads: find  $u \in V$  such that

$$a(u, v - u) = (l, v - u), \quad \forall v \in V. \tag{1}$$

Let moreover  $K$  be a closed convex subset of  $V$  and assume that a solution of the boundary value problem within the set  $K$  is sought. It can be shown that this solution is characterized by the following abstract variational inequality (of the G. Fichera type, see [20, p. 188]):

$$\begin{cases} \text{Find } u \in K \subset V \\ \text{s.t. } a(u, v - u) \geq (l, v - u), \\ \quad \forall v \in K. \end{cases} \tag{2}$$

For a convex, l.s.c. proper functional  $\Phi$  on  $V$  one may define the more general (nonlinear) variational inequality ([14]):

$$\begin{cases} \text{Find } u \in V \\ \text{s.t. } \alpha(u, v) + \Phi(v) - \Phi(u) \geq (l, v - u), \\ \quad \forall v \in V. \end{cases} \tag{3}$$

It is obvious that (2) is a special case of (3), with  $\Phi = I_K$ , where the *indicator function* of the set  $K$  is defined by  $I_K(v) = 0$  if  $v \in K$ ,  $+\infty$  otherwise.

Let moreover  $j: \mathbf{R} \rightarrow \mathbf{R}$  denotes a locally Lipschitz function and let  $j^0(u, v - u)$  denotes the generalized gradient of the nonconvex and nonsmooth function  $j$ . By definition, one has the following connection with the generalized gradient, in the sense of Clarke:

$$j^0(u, v) = \{ \max \langle w, v \rangle : w \in \partial_{\text{CL}} j(u) \}. \tag{4}$$

A hemivariational inequality problem reads:

$$\begin{cases} \text{find } u \in V \\ \text{s.t. } a(u, v - u) + \int_{\Omega} j^0(u, v - u) \, d\Omega \geq (l, v - u), \\ \quad \forall v \in V. \end{cases} \tag{5}$$

**Implicit Variational Inequalities and Quasivariational Inequalities**

If one assumes for instance that the linear form  $(l, \cdot)$  or the set  $K$  in the previous relations depend on the so-

lution  $u$ , one gets various types of implicit variational inequalities or quasivariational inequalities.

Let the set  $K$  be a variable of the solution  $u$ . Then from (2) one gets the quasivariational inequality:

$$\begin{cases} \text{find } u \in K(u) \subset V \\ \text{s.t. } \alpha(u, v) \geq (l, v - u), \\ \quad \forall v \in K(u). \end{cases}$$

Along the same lines one formulates from (3) the implicit variational inequality:

$$\begin{cases} \text{find } u \in V \\ \text{s.t. } \alpha(u, v) + \Phi(u; v) - \Phi(u; u) \geq (l, v - u), \\ \quad \forall v \in V. \end{cases}$$

Here the first argument in  $\Phi(\cdot, \cdot)$  is tackled as a parameter. A concrete application of this method will be demonstrated by the mechanical problem in the next section.

Finally, in analogy to the previous extensions, for a continuous mapping  $h(u)$  the following quasihemivariational inequality (which may also be characterized as implicit hemivariational inequality) problem can be written (see [16, p. 128]):

$$\begin{cases} \text{find } u \in V \\ \text{s.t. } a(u, v - u) + h(u)j^0(u, v - u) \geq l(v - u), \\ \quad \forall v \in V. \end{cases} \tag{6}$$

**Mechanical Example: Coupled Unilateral Contact Problem with Friction**

Let  $\Omega \in \mathbf{R}^3$  be an open bounded subset occupied by a deformable body in its undeformed state. On the assumption of small deformations one writes the virtual work relation (for  $u \in V$ )

$$\begin{aligned} \int_{\Omega} \sigma_{ij} \varepsilon_{ij}(v - u) \, d\Omega &= \int_{\Omega} f_i (v_i - u_i) \, d\Omega \\ &+ \int_{\Gamma} S_N (v_N - u_N) \, d\Gamma \\ &+ \int_{\Gamma} S_{T_i} (v_{T_i} - u_{T_i}) \, d\Gamma, \end{aligned} \tag{7}$$

$\forall v \in V.$

Here  $V$  denotes the function space of the displacements, which in general is an appropriate subset of  $H^1(\Omega)$  and  $f_i, S_N, S_{T_i} \in L_2(\Gamma)$ . Recall here that the abstract bilinear form  $\alpha(\cdot, \cdot)$  reads in this case of linear elasticity

$$\alpha(u, v) = \int_{\Omega} C_{ijhk} \varepsilon_{ij}(u) \varepsilon_{hk}(v) \, d\Omega. \tag{8}$$

Moreover the underlying elastostatic equilibrium equation boundary value problem has the form:

$$\sigma_{ij,j} + f_i = 0, \tag{9}$$

where the  $f_i$  is the volume force vector. One recalls here the strain-displacement relation (small deformation theory):

$$\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}). \tag{10}$$

Let a linearly elastic body be assumed, i. e., the constitutive material relation reads:

$$\sigma_{ij} = C_{ijhk} \varepsilon_{hk},$$

where  $C = \{C_{ijhk}\}$ ,  $i, j, h, k = 1, 2, 3$ , is the elasticity tensor which satisfies the well-known symmetry and ellipticity properties.

Recall here that on the assumption that classical support conditions hold on  $\Gamma$  (i. e., say  $u_N = 0$  and  $u_{T_i} = 0$ ,  $i = 1, 2, 3$ ) one gets the following variational equality:

$$\left\{ \begin{array}{l} \text{Find } u \in V_0 = \left\{ v \in V : \begin{array}{l} v_N = 0, \\ v_{T_i} = 0 \\ \text{on } \Gamma \end{array} \right\} \\ \text{s.t. } \alpha(u, v) = \int_{\Omega} f_i v_i \, d\Omega, \\ \forall v \in V_0. \end{array} \right. \tag{11}$$

### Signorini–Coulomb Unilateral Frictional Contact

Let us assume the pointwise unilateral contact relations (known as *Signorini condition*, for the frictionless unilateral contact case):

$$\begin{aligned} -S_N &\geq 0, \quad u_N - g \leq 0, \\ -S_N(u_N - g) &= 0 \quad \text{on } \Gamma. \end{aligned} \tag{12}$$

Here, the inequalities on the boundary tractions correspond to the mechanical restriction that no tensile trac-

tions are permitted. Moreover, the normal boundary displacements should not be greater than a given initial distance  $g$ , because no penetration is allowed. Finally, the complementarity relation expresses the physical fact that either contact is realized or a separation takes place.

A simplified static version of the Coulomb’s friction law connects the tangential (frictional) forces  $S_{T_i}$  with the normal (contact) forces  $S_N$  by the relation

$$\gamma = \mu |S_N| - |S_T| \geq 0. \tag{13}$$

Here  $|*|$  denotes the norm in  $\mathbf{R}^3$  and  $\mu$  is the friction coefficient. The friction mechanism is considered to work in the following way: If  $|S_T| < \mu |S_N|$  (i. e.  $\gamma > 0$ ) the slipping value  $\gamma$  must be equal to zero and if  $|S_T| = \mu |S_N|$  (i. e.  $\gamma = 0$ ) then we have slipping in the opposite direction of  $S_T$ . Explicitly we have:

$$\left\{ \begin{array}{ll} \text{if } \gamma > 0 & \text{then } y_T = 0, \\ \text{if } \gamma = 0 & \text{then there exists } \sigma > 0 \\ & \text{s.t. } y_{T_i} = -\sigma S_{T_i}, \end{array} \right. \tag{14}$$

where  $i = 1, 2, 3$  refers to the components of vector  $S_T$  with respect to a reference Cartesian coordinate system.

Contact law (12) can be written in the superpotential form:

$$-S_N \in \partial \mathbf{I}_{U_{ad}}(u_N) = \partial \Phi_N(u) = \mathcal{N}_{U_{ad}}(u_N). \tag{15}$$

Here the set of admissible displacements is introduced:

$$U_{ad} = \{u \in V : u_N - g \leq 0\} \tag{16}$$

and the notions of the convex analysis subdifferential and of the normal cone to a set have been used. The corresponding variational inequality reads

$$-S_N(u_N)(v_N - u_N) \leq 0, \quad \forall v_N \in U_{ad}. \tag{17}$$

For the friction law one writes, analogously:

$$-S_T \in \partial_{u_N} (\mu |S_N| |u_N|) = \partial \Phi_T(S_N; u_T), \tag{18}$$

where the involved potential is nondifferentiable (due to the absolute value nonlinearity of  $|u_N|$ ) and depends on the normal contact traction  $S_N$ , thus, implicitly, on the solution of the problem  $u$ , i. e. one considers the parametrized potential  $\Phi_T(u; u_T) = \Phi_T(S_N; u_T)$

$= \mu|S_N||u_N|$ . The corresponding variational inequality reads

$$-S_T(u_T)(v_T - u_T) \leq \Phi_T(u; v_T) - \Phi_T(u; u_T), \quad (19)$$

$$\forall v_T \in U_{ad}.$$

Combining relations (7), (9) and (15) one gets the implicit variational inequality: find  $u \in U_{ad}$  such that

$$\int_{\Omega} \sigma_{ij} \varepsilon_{ij}(v - u) d\Omega + \Phi_T(u; v_T) - \Phi_T(u; u_T)$$

$$\geq \int_{\Omega} f_i(v_i - u_i) d\Omega, \quad (20)$$

$$\forall v \in U_{ad}.$$

A dual problem in terms of stresses provides us a corresponding quasivariational inequality problem. For simplicity, a two-dimensional problem is considered further. Moreover, the following set of admissible boundary tractions for the Signorini–Coulomb unilateral contact problem is assumed:

$$S_{ad} = \{(S_N, S_T): g_j(S_N, S_T) \leq 0, j = 1, 2\},$$

where the constraint functions have the form:

$$g_1(S_N, S_T) = \mu S_N - S_T,$$

$$g_2(S_N, S_T) = \mu S_N + S_T.$$

Moreover one needs the set of admissible stresses (which include the boundary tractions):  $\Sigma(\sigma) = \{\sigma: \sigma_{ij,j} + f_i = 0\} \cap S_{ad}$ . It may be shown that in this case the previous problem is expressed in the form of the quasivariational inequality:

$$\begin{cases} \text{find } \sigma \in \Sigma(\sigma) \\ \text{s.t. } \int_{\Omega} \varepsilon_{ij}(\tau_{ij} - \sigma_{ij}) d\Omega \geq 0, \\ \forall \tau \in \Sigma(\sigma) \end{cases}$$

### Numerical Algorithms: Applications

Theoretical results and numerical algorithms can be found in several books dealing with variational inequalities, convex analysis and their applications. For the numerical solution, usually one solves, iteratively, a number of variational inequality problems. The resulting series approximates the solution of the initial quasivariational inequality. Further information and references, mainly connected with the mechanical problems used

as model applications in this paper and their generalizations, can be found in [3,5,14,18,21]. Finally iterative solution methods can be based on multilevel optimization techniques, as it is discussed in ► **Multilevel optimization in mechanics.**

### Introduction

Crew scheduling problems (CSPs) consist of assigning crews to trains and creating rosters for each crew,

while satisfying several Federal Railway Administration (FRA) regulations and trade-union work rules. The objectives are to minimize the cost of operating trains on one hand and to improve the quality of life for crew on the other hand. This chapter gives a comprehensive description of the existing literature related to crew scheduling, an overview of CSP for the North American Railroads and describes an application of space-time network flow based multi-commodity methods [13] to solve this problem. Network flow models have found successful applications in a large number of diverse fields which include applied mathematics, computer science, engineering, management, and operations research [1].

Crew scheduling has been historically associated with airlines and mass-transit companies. Several papers on crew schedule management have appeared in the past literature; most notable among these are due to [4,6,8,15,16]. All these articles explore a set covering based approach to solve the crew scheduling problem. Crew scheduling is conventionally divided into two stages: (1) *Crew pairing*: A crew pairing is a sequence of connected segments that start and end at the same crew base and satisfy all legality constraints. The objective is to find the minimum-cost set of crew pairings such that each flight or train segment is covered. (2) *Crew rostering*: The objective here is to assign individual crew members to trips or sequences of crew pairings. This pairing and rostering approach uses a set covering formulation and is usually solved using column generation embedded in a branch-and-bound framework (also called branch-and-price [10]). This approach has gained wide acceptance and application in both the airline industry [2,3,11] and in European [5], Asian [7], and Australian railroads [9,14].

While there have been several papers devoted to the study of railroad crew scheduling problems in Europe, Asia, and Australia, North American railroad problems are yet to be addressed satisfactorily. One application of optimization methods to North American railroad crew scheduling is due to [12]. They studied crew balancing in the context of a major North American Railroad, BNSF Railway and developed a dynamic programming approach to solve this problem. The major short-coming of their approach is that they did not consider the possibility of different crew types; each governed by a different set of rules. Another drawback is that their approach could handle only a particular crew district configuration (*single-ended* crew district). While most crew districts in North America are *single-ended*, there are several which are *double-ended* or even more complex (these configurations are described in the next section). The multi-commodity network flow approach described here models all the rules considered by [12] and also handles the case where different crew pools have different sets of rules. It is also applicable to all the crew district configurations encountered in North America.

Crew pairing and rostering approaches which use column generation have been the predominantly successful methods to solve crew scheduling problems. However, this approach is not suited for North American railroads due to the following reasons:

1. The rail network of North American railroad is divided into several *crew districts*. As a train follows its route, it goes from one crew district to another, picking up and dropping off crew at crew change terminals. Almost all crew districts consist of two or three terminals. Hence, a pairing and rostering approach is needlessly complex and not required since most pairings would consist of two trains, a train from home to away and a train from away to home. In addition, rail networks typically consist of 200–300 crew districts and the emphasis is on an approach which is simple and fast, and column generation techniques which are computationally intensive are not appropriate.
2. The FRA regulations governing North American railroads are extremely complex. The most complicating of these rules is *First-In-First-Out* (FIFO) requirement. FIFO constraints require that crews should be called on duty in the order in which they

become qualified for assignment at a location. The success of all approaches using column generation or branch-and-price algorithms is contingent on the ease of solving the sub-problem. It should be noted that the addition of the FIFO side constraints to the problem would spoil the special structure of the sub-problem and blow up the computational times.

Henceforth, whenever CSP is mentioned, it is mentioned in the context of the North American railroad CSP.

### Definitions

This section gives an overview of the CSP and defines some of the essential terminology needed to understand the problem. It also gives an overview of some of the typical regulations which govern crew management and lists the set of inputs required to properly define and formulate the crew scheduling problem.

### Terminology

**Crew District:** The rail network of a railroad is divided into *crew districts* that constitute a subset of terminals (nodes). Each crew district is typically a geographic corridor over which trains can travel with one crew. A typical railroad network for a major railroad in the U.S. may be divided into as many as 200 to 300 crew districts. As a train follows its route, it goes from one crew district to another, picking up and dropping off crew at crew change terminals.

**Crew Pools:** Within a crew district, there are several types of crews called *crew pools* or *crew types*, which may be governed by different trade-union rules and regulations. For example, a crew pool may have preference for the trains operated in a pre-specified time window. Similarly, a crew pool consisting of senior crew personnel is assigned only to pre-designated trains so that crews in that pool know their working hours ahead of time.

**Home and Away Terminals:** The terminals where crews from a crew pool change trains are designated either as *home terminals* or *away terminals*. The railroad does not incur any lodging cost when a crew is at its home terminal. However, the railroad has to make arrangements for crew accommodation at their away ter-

minals. A crew district with one home terminal and one away terminal is called a *single-ended crew district*. The other type of crew district is a *double-ended crew district*, in which more than one terminal is a home terminal for different crew pools. Some of the other crew district configurations are crew districts with one home terminal and several away terminals, and crew districts with several home terminals and corresponding sets of away terminals.

**Crew Detention:** Once a crew reaches its away terminal and rests for the prescribed hours, the crew is ready to head back to its home terminal. However, if there is no train scheduled to depart, then the crew may have to wait in a hotel. According to the trade-union rules, once a crew is at the away terminal for more than a pre-specified number of hours (generally 16 hours), the crew earns wages (called *detention costs*) without being on duty.

**Crew Deadheading:** *Crew deadheading* refers to the repositioning of crew between terminals. A crew normally operates a train from its home terminal to an away terminal, rests for a designated time, and then operates another train back to its home terminal. Sometimes, at the away terminal, there is no return train projected for some time, or there is a shortage of crews at another terminal. Thus, instead of waiting for train assignment at its current terminal, the crew can take a taxicab or a train (as a passenger) and deadhead to the home terminal. Similarly, the crew may also deadhead from a home terminal to an away terminal in order to rebalance and better match the train demand patterns and avoid train delays.

**On-duty and Tie-up Time:** Whenever a crew is assigned to a train, it performs some tasks to prepare the train for departure, and hence crews are called on-duty before train departure time. The time at which the crew has to report for duty is called the *on-duty time*. Similarly, a crew performs some tasks after the arrival of the train at its destination, and hence crews are released from duty after the train arrival. The time at which the crew is released from duty is called *tie-up time*. The duty duration before train departure is referred to as *duty-before-departure* and the duty duration after train arrival as *duty-after-arrival*. Hence, the total duty time

(or *duty-period*) of a crew assigned to a train is the sum of the *duty-before-departure*, the *duty-after-arrival*, and the travel time of the train.

**Duty Period:** In most cases, duty-period of a crew assigned to a train is the total duration between the *on-duty time* and the *tie-up time*. In some cases when a crew rests for a very short time at an away location before getting assigned to a train, the rest time and the duration of the second train may also included in the duty period of the crew.

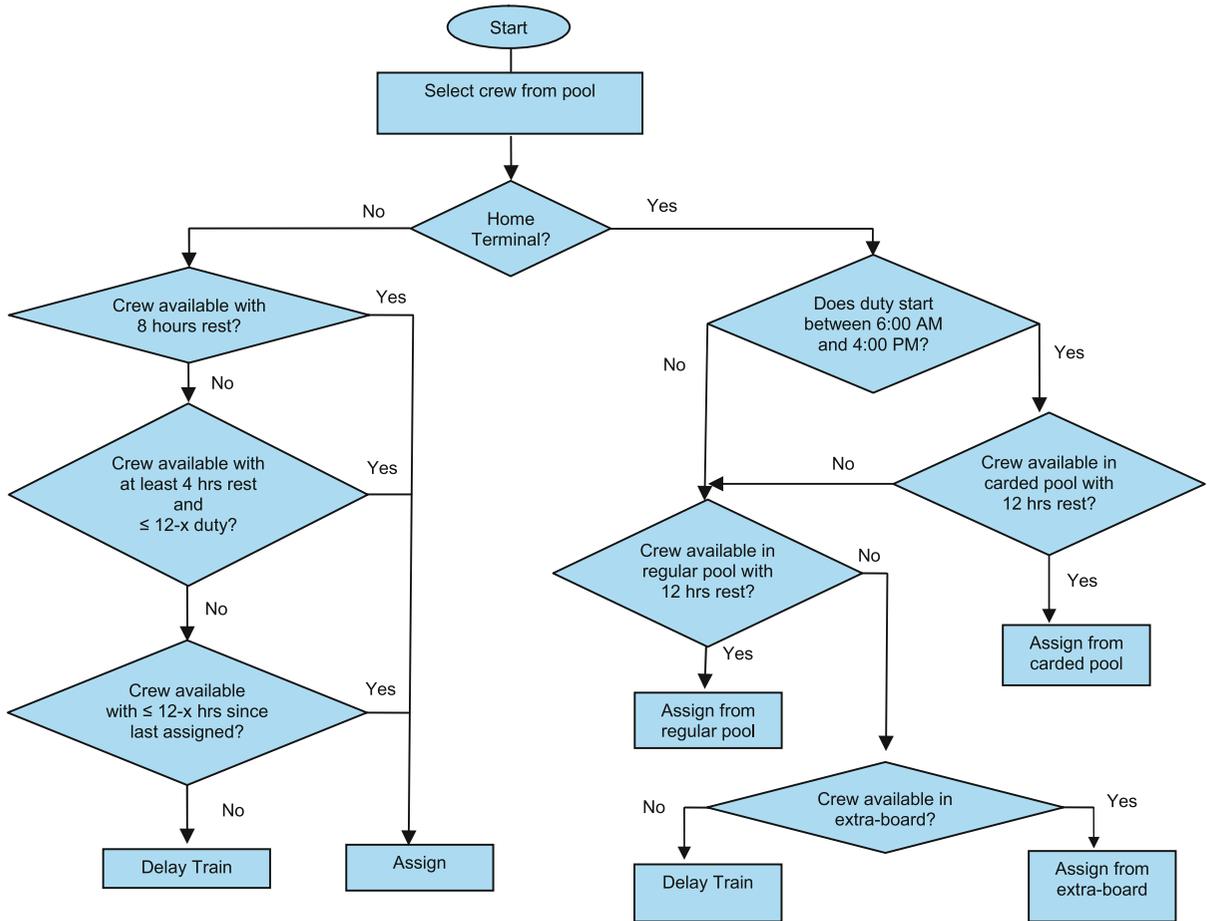

**Dead Crews:** By federal law, a train crew can only be on duty for a maximum of 12 consecutive hours, at which time the crew must cease all work and it becomes *dead or dog-lawed*.

**Train Delays:** When a train reaches a crew-change location and there is no available crew qualified to operate this train, the train must be delayed. Train delays due to crew unavailability are quite common among railroads. These delays are very expensive (some estimate \$1000 per hour) and can be reduced significantly through better crew scheduling and train scheduling.

### Regulatory and Contractual Requirements

Assignment of crews to trains is governed by a variety of Federal Railway Administration (FRA) regulations and trade-union rules. These regulations range from the simple to the complex. The regulations also vary from district to district and from crew pool to crew pool. Some examples of these kinds of constraints and their typical parameter values:

- Duty-period of a crew cannot exceed 12 hours. Duty-period of a crew on a train is usually calculated as the time interval between the on-duty time and tie-up time of the train.
- When a crew is released from duty at the home terminal or has been deadheaded to the home terminal, they can resume duty only after 12 hours (10 hours rest followed by 2 hours call period) if duty-period is greater than 10 hours, and after 10 hours (8 hours rest followed by 2 hours call period) if duty-period is less than or equal to 10 hours.
- Whenever a crew is released from duty at the away

**Railroad Crew Scheduling, Figure 1**  
An example of crew assignment decision tree

terminal, they usually must go for a minimum 8 hours rest, except for a few exceptions.

- Crews belonging to certain pools must be assigned to trains in a FIFO order.
- A train can only be operated by crews belonging to pre-specified pools.
- Every train must be operated by a single crew.
- Crews are guaranteed a certain minimum pay per month regardless of whether or not they work.

Figure 1 gives an example of the kind of decision process that needs to be followed by crew planners.

### Problem Inputs

The inputs for the mathematical formulation of the crew scheduling problem are:

- **Train Schedule:** The train schedule contains information about the departure time, arrival time, on-duty time, tie-up time, departure location, and arrival location for every train in each crew district it passes through.
- **Crew Pool Attributes:** This includes attributes of various crew types, namely their home locations, their away locations, minimum rest time, train preferences, etc.
- **Crew Initial Position:** This provides the position of crew at the beginning of the planning horizon. This includes information of the terminal at which a crew is released from duty, the time of release, the number of hours on duty in the previous assignment, and the crew pool the crew belongs to.
- **Train-Pool Preferences:** The train-pool prefer-

ences, if any, contain information about the set of trains that can be operated by a crew pool.

- **Away Terminal Attributes:** This consists of information about the away terminals for each crew pool. It includes the rest rules and the detention rules for each crew pool at each corresponding away terminal.
- **Deadhead Attributes:** This consists of the time taken to travel by taxi between two terminals in a crew district.
- **Cost parameters:** Cost parameters are used to set up the objective function for the crew scheduling problem. They consist of crew wage per hour, deadhead cost per hour, detention cost per hour, and train delay cost per hour.

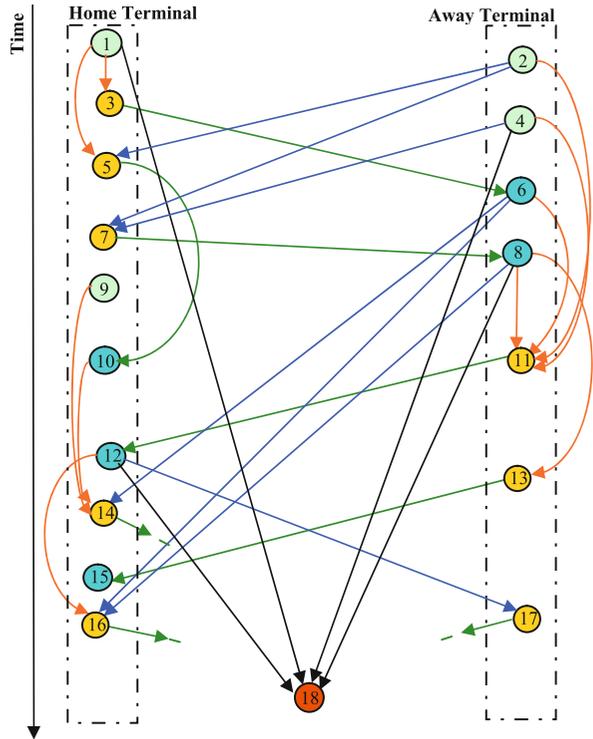

**Formulation**

The CSP is formulated as a multi-commodity network flow problem on a space-time network. The construction of the space-time network is described first and then the formulation of the CSP as an integer programming problem is given.

**Space-Time Network**

The CSP is decomposed into a separate problem for each crew district. In the space-time network, each node corresponds to a crew event and has two defining attributes: location and time. The events that are modeled while constructing the space-time network are departure of trains, arrival of trains, departure of deadheads, arrival of deadheads, supply of crew, and termination of crew duty to mark the end of the planning horizon. Figure 2 presents an example of the space-time network in a crew district. Note that for the sake of clarity, this network only represents a subset of all the arcs.

For each crew, a supply node whose time corresponds to the time at which this crew is available for assignment, and whose location corresponds to the terminal from which the crew is released for duty is created. Each supply node is assigned a supply of one unit and corresponds to a crew member. The network also has a common sink node for all crews at the end of the planning horizon. This sink has no location attribute and has the time attribute equal to the end of the planning horizon. The sink node has a demand equal to the total number of crew supplied.

**Railroad Crew Scheduling, Figure 2**  
 Space-time network for a single-ended district with a single crew type. Node legend: green (supply), blue (arrival), yellow (departure), red (demand) Arc legend: green (train), orange (rest), blue (deadhead), black (demand)

For each train (say  $l$ ) passing through a crew district, a *departure node* (say  $l'$ ) is created at the first departing station of the train in the crew district and an *arrival node* (say  $l''$ ) at the last arriving station of the train in the crew district. Each arrival or departure node has two attributes: place and time. For example,  $place(l') = \text{departure-station}(l)$  and  $time(l') = \text{on-duty-time}(l)$ ; and similarly,  $place(l'') = \text{arrival-station}(l)$  and  $time(l'') = \text{tie-up-time}(l)$ .

*Train arc* ( $l', l''$ ) is created for each train  $l$  connecting the departure node and arrival node of train  $l$ . *Deadhead arcs* are constructed to model the travel of crew by taxi. A deadhead arc is constructed between a train arrival or crew supply node at a location and a train departure node at another location. All the deadhead arcs which satisfy the contractual rules and regulations are created. *Rest arcs* are constructed to model resting of a crew at a location. A rest arc is constructed between a train arrival node or a crew supply node at a loca-

tion and a train departure node at the same location. Rest arcs are created in conformance to the contractual rules and regulations. Since the contractual regulations are often crew pool specific, deadhead arcs and rest arcs are created specific to a crew pool. Finally, *demand arcs* are created from all train arrival nodes and crew supply nodes to the sink node. Each arc has an associated cost equivalent to the crew wages, deadhead costs, or detention costs, depending on the type of the arc. It can be noted that all contractual requirements other than the FIFO constraint are easily handled in the network construction.

The space-time network does not model the case when qualified crews are not available for assignment to a train causing train delays. Train delays are modeled by the construction of additional arcs. To do this, rest arcs and deadhead arcs which do not honor the rest regulations are constructed and flows on these arcs are penalized to ensure that flows on these arcs occur only when qualified crews are not available for assignment. The flows on these arcs denote that the train will be delayed until crew becomes qualified for train operation. However, as the delay of a train may have propagating effect in the availability of crews in subsequent assignments, it is assumed that the crew assigned to a delayed train has sufficient slack in the rest time at the train arrival node to make it qualified for subsequent assignments.

### Integer Programming Formulation

The CSP is formulated as an integer multi-commodity flow problem on the space-time network described in the previous section. Each crew pool represents a commodity. Crew enters the system at crew supply nodes, takes a sequence of connected train, rest, and deadhead arcs before finally reaching the sink.

### Decision Variables

$x_l^c$  : Flow of crew pool  $c \in C$  on each train arc  $l \in L$

$x_d$  : Flow on deadhead arc  $d \in D$

$x_r$  : Flow on rest arc  $r \in R$

### Objective function

$$\text{Min } \sum_{l \in L} \sum_{c \in C} c_l^c x_l^c + \sum_{d \in D} c_d x_d + \sum_{r \in R} c_r x_r$$

### Constraints

$$\sum_{c \in C} x_l^c = 1, \text{ for all } l \in L \quad (1)$$

$$\sum_{a \in i^+} x_a = 1, \text{ for all } i \in N_s \quad (2)$$

$$\sum_{a \in N_d^-} x_a = f \quad (3)$$

$$x_l^c = \sum_{a \in \text{tail}(l)_c^-} x_a, \text{ for all } l \in L, c \in C \quad (4)$$

$$x_l^c = \sum_{a \in \text{head}(l)_c^+} x_a, \text{ for all } l \in L, c \in C \quad (5)$$

$$\sum_{r' \in A_r} x_{r'} - M(1 - x_r) \leq 0, \text{ for all } r \in R \quad (6)$$

$$x_l^c \in \{0, 1\} \text{ and integer, for all } l \in L, c \in C \quad (7)$$

$$x_d \in \{0, 1\} \text{ and integer, for all } d \in D \quad (8)$$

$$x_r \in \{0, 1\} \text{ and integer, for all } r \in R \quad (9)$$

Constraint (1) is the train cover constraint which ensures that every train is assigned a qualified crew to operate it. Constraint (2) ensures flow balance at a crew supply node. Constraint (3) ensures the flow balance at the sink node. Constraints (4) and (5) ensure flow balance at train departure and arrival nodes respectively. Constraint (6) ensures that the crew assignment honors the FIFO constraint. Constraints (7), (8), and (9) specify that all the decision variables in the model are binary. The objective function is constructed to minimize the total cost of crew wages, deadheading, detentions and train delays. Note that the detention and delay costs are taken into account while calculating the cost of rest arcs.

**Theorem 1** *There is a one to one correspondence between a feasible flow on the space-time network satisfying constraints (1)–(9) and a feasible solution to the crew scheduling problem.*

Most crew districts have two terminals, and a typical train schedule has around 500 trains running in

Railroad Crew Scheduling, Table 1

Notation

$N$	Set of nodes in the space time network	$i_c^+$	Set of outgoing arcs specific to crew pool $c$ at node $i$
$L$	Set of train arcs in the network, indexed by $l$	$i_c^-$	Set of incoming arcs specific to crew pool $c$ at node $i$
$D$	Set of deadhead arcs in the network, indexed by $d$	$A_r$	Set of arcs on which flow will violate FIFO constraint if there is flow on rest arc $r$
$R$	Set of rest arcs in the network, indexed by $r$	$f$	Total number of available crew
$A$	Set of arcs in the space-time network, indexed by $a$	$M$	A very large number
$G(N, A)$	Space-time network	$c_l^c$	Cost of crew wages for crew pool $c \in C$ on train arc $l \in L$
$N_s$	Set of crew supply nodes	$c_d$	Cost of deadhead arc $d \in D$
$N_d$	Sink node	$c_r$	Cost of rest arc $r \in R$
$C$	Set of crew pools in the system, indexed by $c$	$tail(l)$	The node from which arc $l$ originates
$i^+$	Set of outgoing arcs at node $i$	$head(l)$	The node at which arc $l$ terminates
$i^-$	Set of incoming arcs at node $i$		

a couple of weeks in a crew district. Each crew district could have two to four crew types and around 50 crews. Therefore, the space-time network could have around  $50 + 2 \times 500 = 1,050$  nodes. The number of deadhead arcs is typically around 25,000, and the number of rest arcs is around 100,000.

Since the number of rest arcs for a typical problem is of the order of 100,000, and as each rest arc has one FIFO constraint, the number of FIFO constraints in the model would be 100,000, which makes the problem very large. In addition, these constraints spoil the special structure of the problem and a direct approach to solve the CSP suffers from intractability and does not converge to a feasible solution in several hours of computational time. However, the integer programming problem with FIFO constraints relaxed (*Relaxed Problem*) can be solved to optimality within minutes. Efficient methods to solve the CSP are described in the next section.

**Methods and Applications**

**Successive Constraint Generation (SCG)**

The SCG algorithm works by iteratively pruning out crew assignments which violate the FIFO constraints from the current solution of a more relaxed problem. The SCG algorithm starts with the optimal solution of the Relaxed Problem. The algorithm scans the rest arcs in the current solution with positive flow, and for each rest arc assignment which violates FIFO constraints, it adds the corresponding FIFO constraints. The problem

is then re-solved and the solution re-checked for FIFO infeasibilities. This process is repeated until all FIFO infeasibilities are pruned.

**Algorithm-SCG**

1. Solve the Relaxed Problem. If a feasible solution exists, then proceed to Step 2. Otherwise STOP as the instance is infeasible.
2. Examine all the rest arcs with positive flow in the solution of Step 1. Add FIFO constraints to the integer program on those rest arcs assignments which violate FIFO requirements.
3. If FIFO constraints are added in Step 2, re-optimize the modified integer program and go to Step 2. Otherwise, STOP. The current solution is optimal.

The SCG algorithm is an exact algorithm guaranteeing optimal solution to the original problem. However, in the worst case, SCG could add all the FIFO constraints to the integer program and would hence become an intractable approach. Fortunately, this seldom happens in practice. Computational results show that the number of constraints added is usually much less than the total number of rest arcs in the network.

While SCG is an exact algorithm and produces provably optimal solutions, the running time of this algorithm could be quite high. Some instances had running times in the order of minutes while others had much higher running times. While these running times are acceptable in the planning environment, they restrict the applicability of this algorithm in the real-time environment.

### Quadratic Cost-Perturbation (QCP) Algorithm

The QCP algorithm penalizes FIFO violations. This method guarantees zero FIFO violations in the case where there is no priority in assigning crews to trains and serves as a heuristic method for the other case when there are priority restrictions. The basic intuition behind this approach is that the costs of arcs while solving the Relaxed Problem is perturbed in a way that it guarantees FIFO compliance.

The cost perturbation strategy is presented through the illustration shown in Fig. 3 for the case when there is only one crew pool type. In case (I), crew assignments are made in a non-FIFO manner, and in case (II), the assignments are made in a FIFO manner. Consider the case when crews are detained at the Terminal 2. Then, due to the nature of detention costs, the cost of the assignment (II) would definitely be less than or equal to the cost of assignment (I), and hence the solution to the Relaxed Problem would honor FIFO constraints. On the other hand, suppose all the rest arcs had a cost of zero; then both the assignments would have the same cost, and the Relaxed Problem would have no cost incentive to choose assignment (II) over assignment (I). Thus, a solution to the Relaxed Problem may violate the FIFO constraints. In order to provide an incentive to the Relaxed Problem to choose case (II) over case (I),

the cost assignments on rest arcs are perturbed so that the solution of the Relaxed Problem has assignments of type (II) and not assignments of type (I).

The cost perturbation scheme that is used is a function of the duration of rest arcs. Suppose that the time duration between events corresponding to nodes 2 and 4, 4 and 5, and 5 and 7 are  $a$ ,  $b$ , and  $c$ , respectively. Consider a cost assignment which is proportional to the square of the duration of rest arcs. The constant of proportionality is represented by  $k$  ( $k$  is set to a very small value).

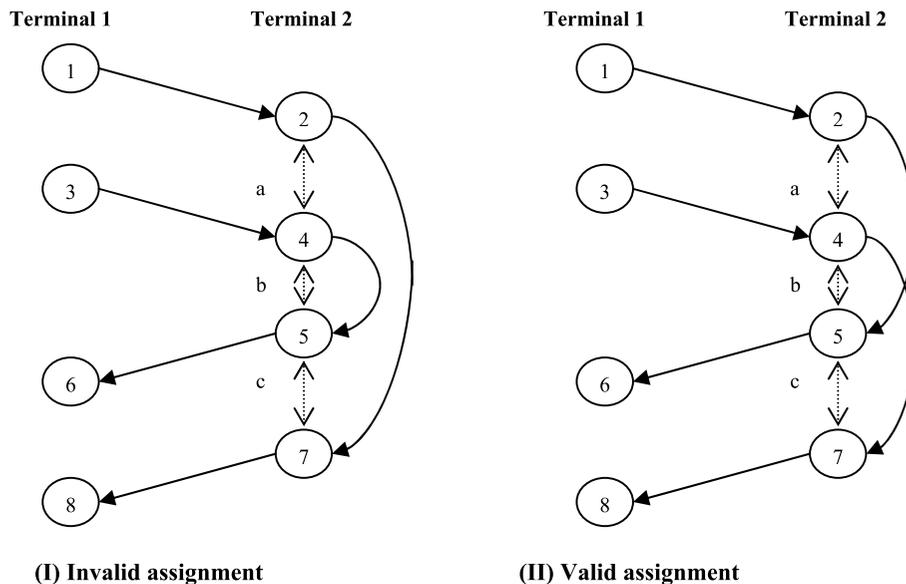

Then,

Cost of assignment (I)

$$\begin{aligned} &= k(\text{duration of arc } (2, 7))^2 \\ &\quad + k(\text{duration of arc } (4, 5))^2 \\ &= k(a + b + c)^2 + kb^2 \\ &= k(a^2 + 2b^2 + c^2 + 2ab + 2bc + 2ca) \end{aligned}$$

Cost of assignment (II)

$$\begin{aligned} &= k(\text{duration of arc } (2, 5))^2 \\ &\quad + k(\text{duration of arc } (4, 7))^2 \\ &= k(a + b)^2 + k(b + c)^2 \\ &= k(a^2 + 2b^2 + c^2 + 2ab + 2bc) \end{aligned}$$

Railroad Crew Scheduling, Figure 3  
Illustrating the FIFO assignments

It can be observed that the cost of assignments in case (II) is less than that in case (I). Hence, when the rest arcs have zero costs, the QCP scheme applied to the Relaxed Problem gives FIFO compliant assignments unless there is priority in assigning crew pools to trains. These observations are stated as the following theorem.

**Theorem 2** *Quadratic Cost Perturbation applied to the Relaxed Problem guarantees FIFO compliant crew assignments if there is no priority in assigning crews to the trains.*

The solution time of QCP is very short and is comparable to that of the Relaxed Problem. Note that in the case where there are priorities, this approach could be used to obtain a solution with a small number of violations and the SCG algorithm can be then used to prune out these violations. An interesting observation was that for most of the instances tested, this method produced solutions with objective function values same as those for the Relaxed Problem. This implies that FIFO constraints can be satisfied with little or no impact on the solution cost. Hence, QCP can be used to obtain excellent quality solutions using much less computational time. Due to its attractive running times and high solution quality, this method has the potential to be used in both the planning and the real-time environment.

## Applications

The crew scheduling model has applications in the tactical, planning and strategic environments. Some specific examples of how the model can be used as an effective tool for decision making are provided in this section.

**Tactical Crew Scheduling:** Tactical scheduling refers to the decisions that need to be taken in the real-time planning environment on daily basis. The model for the CSP has several potential applications in the tactical scheduling environment. Some of the applications are: (i) Assign crews to trains, (ii) Recommend which crews to place in hotels and which crews to deadhead home, (iii) Minimize trains delayed due to shortage of crew, and (iv) Disruption management.

**Crew Planning:** The essence of the crew planning problem for operations or planning is to determine

how many crews should be deployed in each crew pool. A planning problem is solved every month as the train pattern changes with seasonal traffic demand fluctuations. Currently, railroads solve the pool sizing problem based on historical precedent and rules-of-thumb, through negotiation with the union, and by trial and error. The network flow model can satisfy the need for a structured approach that captures all of the considerations, quantifies the various costs, and recommends the best way to define and staff crew pools. Some of the applications of the model in the planning environment are: (i) Develop and evaluate crew schedules, and (ii) Analyze robustness of the plan with respect to availability of the crew in the pool.

**Crew Strategic Analysis:** Strategic management involves development of policies and plans and allocating resources to implement these plans. The timeframe of strategic management extends over several months or even years. Strategic crew problems include forecasting future head-count needs and evaluating major policy changes such as negotiating changes to trade-union rules or changing the number and location of crew change points on a network. The model can be used to quickly calibrate efficient frontiers for each crew district and show what number of crews minimizes the sum of train delay costs and crew costs. Some of the applications of the network flow model in the strategic environment are: (i) Determining the number of crew districts and territory of crew districts, (ii) Effect of changing crew trade-union rules, and (iii) Forecasting crew requirement.

## Conclusions

The crew scheduling problem for North American railroads is governed by several Federal Railway Administration (FRA) regulations and trade-union work rules. In addition to satisfying these regulations, the objective is to minimize the total wage costs, train delay costs, deadhead costs, and detention costs. The railroads divide their network into a number of crew districts, and each crew district has several crew pools. Each crew pool in a district could have a different set of operating rules. These factors make this a complex problem to model and solve.

The network flow formulation for the crew scheduling problem described in this article is both flexible and robust and can be easily manipulated to represent each of the possibilities encountered in real-life. The crew scheduling problem is formulated as an integer program on a space-time network. The network is constructed in such a way that all FRA regulations and trade-union work rules other than FIFO constraints are enforced during the network construction phase itself. The operational constraints are handled in the integer programming formulation. Two efficient approaches to solve the problem are described.

The crew scheduling model has applications in a wide range of settings. The broad spectrum of applications varies from the short-term problem of assigning crews to trains over the next few days to the long-term problem of forecasting crew requirements based on future demand patterns. The model gives railroad executives a method to calibrate and quantify the impact of current decisions on future operations by running several “what-if” scenarios. It has the potential to make a significant impact on the railroad’s on-time performance, crew utilization, and productivity, while also improving the quality-of-life for crew and improving railroad safety.

## Introduction

Everyday railroad managers need to assign hundreds of locomotives to hundreds of different trains. Locomotive scheduling entails optimally assigning a set of locomotives to each train so that the assignment satisfies a variety of business constraints and minimizes the total scheduling cost. Major US railroad companies have several billions of dollars of capital investment in locomotives. Thus, solving this problem effectively is of critical importance for railroads. This chapter gives a description of the existing literature related to locomotive scheduling, an overview of the North American railroad locomotive scheduling problem (LSP) and summary of the key features of two comprehensive models for locomotive scheduling developed by [1] and [15].

The set of locomotives assigned to a train is called *consist*. When a train arrives at its destination, its consist is either assigned to an outbound train in its entirety, or its consist goes to the pool of locomotives where new consists are formed. The former case is referred to as a *train-to-train connection* between the inbound and outbound trains, and the latter case is referred to as a *consist-busting*. The cost of assembling and disassembling consists must be controlled by developing plans that minimize *consist-busting*.

Locomotives which provide power to the train are referred to as *active* locomotives. Due to difference in power demand at different stations, locomotives are also *repositioned* from one station to another. The locomotives can be repositioned by simply *deadheading* on an existing train, or by dispatching a set of locomotives which travel independently from one station to another, also referred to as *light travel*.

LSPs are notoriously hard combinatorial optimization problems. The paper [7] presents an excellent survey of existing locomotive scheduling models and algorithms for this problem. The models described in existing literature can broadly be classified in two categories: *Single locomotive type* and *Multiple locomotive type models*. *Single locomotive scheduling models* assume that there is only one type of locomotive available for assignment. These models can be viewed as minimum cost flow problems with side constraints; some papers on single locomotive scheduling models are due to [3,4,8,10,16]. *Single locomotive assignment models* are appropriate for some European railroad companies but are not suited for US railroad companies since most trains are assigned multiple types of locomotives. *Multiple locomotive assignment models* have been studied by [5,6,9,12,13,14,17,18]. The most recent and comprehensive multiple locomotive assignment model is due to [1] which has been further refined by [15]. While [1] develop the initial framework to solve this problem; [15] improve the initial effort on several dimensions leading to the development of a practical locomotive scheduling approach.

## Definitions

This section lists the set of inputs required to define and formulate the LSP. It also describes the constraints that govern the problem and the objective function.

## Problem Inputs

**Locomotive Data:** A railroad typically has several different types of locomotives with different pulling and cost characteristics and different number of axles (often ranging from four to nine). The set of all the locomotive types is denoted by  $K$  and the index  $k$  represents a particular locomotive type. The following data is associated with each locomotive type  $k \in K$ : (i)  $h^k$ : the horsepower provided by a locomotive of type  $k$ ; (ii)  $\lambda^k$ : the number of axles in a locomotive of type  $k$ ; (iii)  $G^k$ : the weekly ownership cost for a locomotive of type  $k$ ; and (iv)  $B^k$ : fleet size of locomotives of type  $k$ , that is, the number of locomotives available for assignment.

**Train Data:** Locomotives pull a set of trains  $L$  from their origins to their destinations. Trains have different weekly frequencies; some trains run every day, while others run less frequently. The same train running on

different days is considered as different train entities; that is, if a train runs five days a week, it is considered as five different trains. The index  $l$  is used to denote a specific train. Each train has the following associated information: (i)  $dep-time(l)$ : the departure time for the train  $l$ ; (ii)  $arr-time(l)$ : the arrival time for train  $l$ ; (iii)  $dep-station(l)$ : the departure station for train  $l$ ; (iv)  $arr-station(l)$ : the arrival station for train  $l$ ; (v)  $T_l$ : tonnage requirement of train  $l$ ; (vi)  $\beta_l$ : horsepower per tonnage needed for train  $l$ ; (vii)  $H_l$ : horsepower requirement of train  $l$ , which is defined as  $H_l = \beta_l T_l$ ; and (viii)  $E_l$ : the penalty for using a single locomotive consist for train  $l$ .

**Locomotive-Train Combinations:** The following information is specified for each train-locomotive type combination: (i)  $c_l^k$ : the cost incurred in assigning an active locomotive of type  $k$  to train  $l$ ; (ii)  $d_l^k$ : the cost incurred in assigning a deadheaded locomotive of type  $k$  to train  $l$ ; and (iii)  $t_l^k$ : the tonnage pulling capability provided by an active locomotive of type  $k$  to train  $l$ . Also specified for each train  $l$  are three disjoint sets of locomotive types: (i)  $MostPreferred[l]$ , the preferred classes of locomotives; (ii)  $LessPreferred[l]$ : the acceptable (but not preferred) classes of locomotives; and (iii)  $Prohibited[l]$ , the prohibited classes of locomotives. When assigning locomotives to a train, locomotives from the classes listed as  $MostPreferred[l]$  and  $LessPreferred[l]$  can be assigned (a penalty is associated for using  $LessPreferred[l]$ ).

### Hard Constraints

Hard constraints are mandatory constraints which have to be satisfied for a locomotive assignment plan to be feasible.

**Power Requirement for Trains:** Each train must be assigned locomotives with at least the required tonnage and horsepower.

**Locomotive Class to Train Type:** Each train type (e. g., auto train, or merchandise train, or intermodal train) is targeted to use specific classes of locomotive types.

**Geographic:** Each geographic region permits the travel of only specific locomotive types. For example, it may be specified that Atlanta can only use: CW40, AC44, and AC60 locomotives.

**Locomotive Balance Constraints:** The number of incoming locomotives of each type into a station must

be equal to the number of outgoing locomotives of that type at that station.

**Active Axle Constraints:** Each train must be assigned locomotives with at most 24 active axles. Exceeding 24 powered axles may overstress the couplers and cause a train separation.

**Consist Size Constraints:** Each train can be assigned at most 12 locomotives including both the active and deadheading locomotives. This business policy reduces risk exposure if the train were to suffer a catastrophic derailment.

**Fleet Size Constraints:** The number of assigned locomotives of each type is at most the number of available locomotives of that type.

**Repeatability of the Schedule:** The routing of locomotives should be such that the number of locomotives of each type at each station at the end of the week should be equal to the number of locomotives of each type at each station at the beginning of the next week (so that the plan is repeatable every week).

### Soft Constraints

These constraints are flexible constraints and they define characteristics of a solution which are preferred but not mandatory.

**Consistency in Locomotive Assignment:** A train should be assigned the same consist each day that it runs. Railroads believe that crews will perform more efficiently and more safely if they operate the same equipment on a particular route and train.

**Consistency in Train Connections:** If locomotives traveling on a train to its destination station connect to another train originating at that station, then they should preferably make the same connection on each day that both of the trains run.

**Avoid Consist Busting:** Since consist busting involves the use of more resources, it is preferable to avoid consist busting.

**Avoid Single Locomotive Consists:** If a single locomotive is assigned to a train and this locomotive breaks down, then the train will get stranded.

### Objective Function

The objective function for the LSP is to minimize the sum of: (i) Cost of ownership, maintenance, and fueling of locomotives; (ii) Cost of active and deadheaded

locomotives; (iii) Cost of light traveling locomotives; (iv) Penalty for consist-busting; (v) Penalty for inconsistency in locomotive assignment; and (vi) Penalty for using single locomotive consists.

**Formulation**

The LSP is formulated as a multi-commodity flow problem with side constraints on a network called the *weekly space-time network*. Each locomotive type defines a commodity in the network.

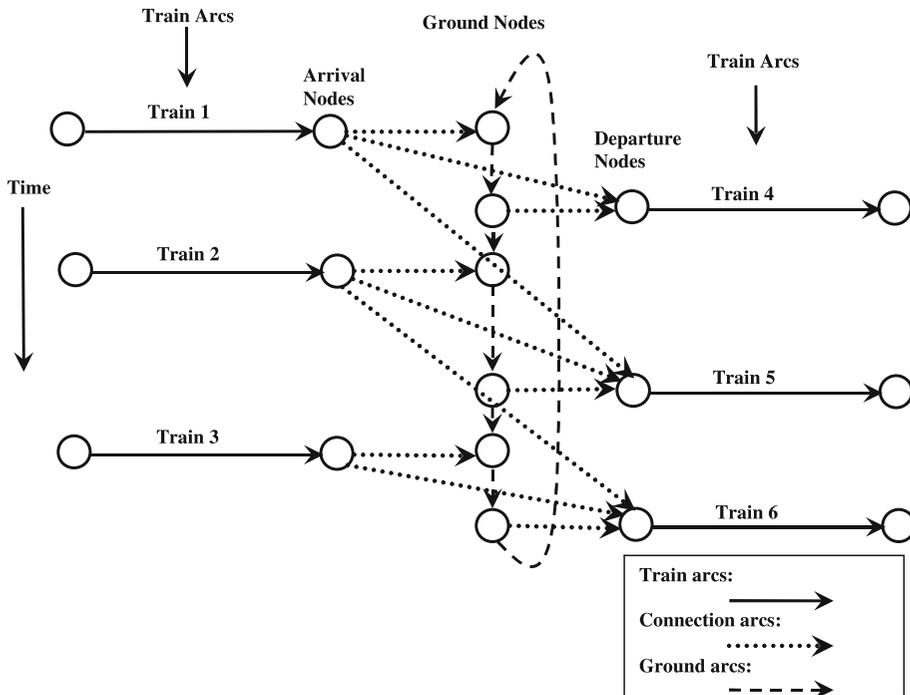

**Space-Time Network**

The weekly space-time network is denoted as  $G^7 = (N^7, A^7)$ , where  $N^7$  denotes the node set and  $A^7$  denotes the arc set. Figure 1 displays a part of the weekly space-time network at one location. The network is constructed as follows:

**Nodes in the Weekly Space-Time Network:** The network contains a *train arc*  $(i_l, j_l)$  for each train  $l$ . The tail node  $i_l$  of the arc denotes the event for the departure of train  $l$  at  $dep-station(l)$  and is called a *departure node*. The head node  $j_l$  denotes the arrival

event of train  $l$  at  $arr-station(l)$  and is called an *arrival node*. For each arrival event, an *arrival-ground node* is created, and for each departure event, a *departure-ground node* is created. Each node in the network is associated with two attributes: time and place.  $Time(i)$  denotes the time attribute of node  $i$  in the weekly space-time network. The sets of departure, arrival, and ground nodes are denoted by the sets  $DepNodes$ ,  $ArrNodes$ , and  $GrNodes$ , respectively. Let the set  $AllNodes = DepNodes \cup ArrNodes \cup GrNodes$ .

**Arcs in the Weekly Space-Time Network:** The network contains four types of arcs. The first is the set of train arcs, denoted by the set  $TrArcs$ , and contains an arc for every train. Each arrival node is connected to the associated arrival-ground node by a directed arc called the *arrival-ground connection arc*. Each departure-ground node is connected to the associated departure node through a directed arc called the *ground-departure connection arc*. All the ground nodes at each station are sorted in the chronological order of their time attributes and each ground node is connected to the next ground node through directed arcs called *ground arcs*. The ground arcs allow inbound locomo-

Railroad Locomotive Scheduling, Figure 1  
A part of the weekly space-time network

tives to stay in an inventory pool as they wait to be connected to the outbound trains. The last ground node in the week at a station is connected to the first ground node of the week at that station through the ground arc; this ground arc models the ending inventory of locomotives for a week, which becomes the starting inventory for the following week. The possibility of an inbound train sending its entire consist to an outbound train is modeled by creating *train-train connection arcs* from train arrival nodes to train departure nodes whenever such a connection can be feasibly made. Therefore, the four kinds of arcs are: train arcs (*TrArcs*), connection arcs (*CoArcs*), and ground arcs (*GrArcs*). Let  $AllArcs = TrArcs \cup CoArcs \cup GrArcs$ .

The LSP can be formulated as a flow of different types of locomotives in the weekly space-time network. Locomotives flowing on train arcs are either active or deadheading; and those flowing on connection and ground arcs are idling (that is, waiting between two consecutive assignments). The following additional notation for the weekly space-time networks is used in the MIP formulations: (i)  $I[i]$ : the set of incoming arcs into node  $i \in AllNodes$ ; (ii)  $O[i]$ : the set of arcs emanating from node  $i \in AllNodes$ ; (iii)  $d_l^k$ : defined for every arc  $l \in AllArcs$  (for a train arc  $l$ ,  $d_l^k$  denotes the cost of deadheading of locomotive type  $k$  on train arc  $l$ , and for every other arc it denotes the cost of traveling for a non-active locomotive of locomotive type  $k$  on arc  $l$ ); (iv)  $CB$ : the set of all connection arcs from arrival nodes to ground nodes; alternatively,  $CB = \{(i, j) \in AllArcs: i \in ArrNodes \text{ and } j \in GrNodes\}$ ; (v)  $CheckTime$ : a time instant of the week when no event takes place (that is, no train arrives or departs at any station); and (vi)  $S$ : the set of arcs that cross the *CheckTime* [that is,  $S = \{(i, j) \in AllArcs: time(i) < CheckTime < time(j)\}$ ].

### Problem Size and Computational Issues

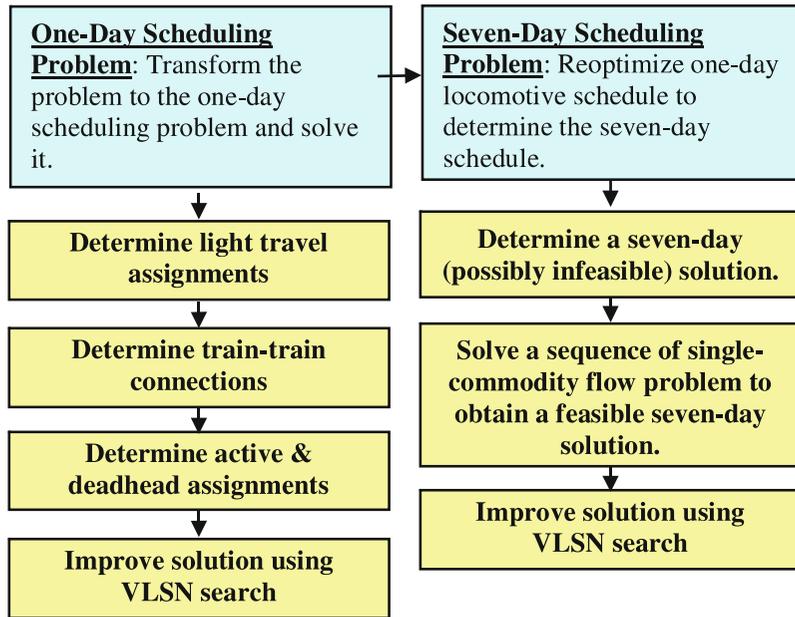

The integer programming formulation of the LSP contains around 200,000 variables and 100,000 constraints and cannot be solved to optimality or near optimality using commercial state-of-the-art software. Even the linear programming relaxation of this problem cannot be solved in a reasonable amount of time. Additionally, the formulation given above cannot capture the consistency constraints effectively. The main contribution made in [1] was to develop a two-stage solution

approach to solve this problem. In the first stage, the daily locomotive scheduling problem which is a simplified problem is solved, and in the second stage the daily locomotive schedule is modified to obtain the feasible weekly locomotive schedule.

This approximate two stage approach was motivated by the observation that in a typical problem more than 90% of the train arcs in the space-time network correspond to the trains that run 5, 6, or 7 days. Based on this observation, the daily locomotive scheduling model that is a simplification of the weekly locomotive scheduling model is created in the following manner. (i) all trains that run  $p$  days or more per week run every day of the week; and (ii) all trains that run fewer than  $p$  days do not run at all. (Note: This assumption results in an approximation in the sense that locomotives are provided to some trains that do not exist, and locomotives are not provided to some trains that exist.)

To transform the solution of the daily locomotive scheduling solution into a feasible solution to the weekly scheduling problem, locomotives are taken from the trains that exist in the daily problem but do not exist in the weekly problem (Type 1 trains) and assigned to the trains that do not exist in the daily problem but exist in the weekly problem (Type 2 trains). This may lead to the model using additional locomotives to meet the constraints. The solution of the daily problem can be translated into the solution of the weekly problem more effectively if the number of Type 1 trains is less than the number of Type 2 trains but still as close as possible.

Another contribution made in [1] is determination of good train-train connections and good light arcs. Railroads often specify some “candidate” train-train connections and “candidate light arcs” out of which a certain number are fixed in the final solution. In the basic formulation, each “candidate” train connection or light arc has a fixed charge variable associated with it and these fixed charge variables make the MIP very hard to solve. This issue is handled in the following manner. The space-time network that contains all the candidate train-train connection arcs and candidate light arcs is constructed. The linear programming relaxation of the LSP has no fixed charge variables, and has large costs for all the train-to-ground and ground-to-train arc flows to discourage the flow on such arcs (or,

Railroad Locomotive Scheduling, Figure 2  
Overview of the multi-stage locomotive scheduling algorithm

alternatively, to discourage consist-busting), is solved. Let  $\varphi(l)$  denote the total flow of locomotives (of all types) on any arc  $l$  in the daily space-time network. The candidate train-train connection arc  $h$  with the largest value of  $\varphi(h)$  is selected. This arc indicates a successful potential train-train connection. Connection arc  $h$  is made the unique connection arc for the two corresponding trains and the linear programming relaxation is resolved. If this linear programming relaxation is infeasible or if it increases the cost of the new solution by an amount greater than  $\theta$ , then the train-train connection is not made; otherwise, it is fixed as a good connection. This iterative procedure is repeated until either the desired number of train-train connections is reached (as specified by some parameter  $\gamma$ ), or until the set of candidate train-train connections becomes empty. Using a similar greedy iterative approach, the set of good light moves is also determined. Figure 2 gives an overview of the overall approach in [1].

### Consist Flow Formulation for the LSP

Consist busting is such an anathema to real world railroad managers that most managers stipulate that a high quality locomotive plan is one designed such that no

consist busting is required. Consist busting affects crew requirements, station fluidity, locomotive productivity, and mechanical maintenance processes. Consist busting consumes between two and six additional hours per locomotive within the station, asset time that could be productively used to pull trains on the mainline. Upon reassembly, each consist must undergo extensive operational testing as well. In addition, consist-busting often results in outbound trains getting their locomotives from several inbound trains. If any of these inbound trains is delayed, the outbound train is also delayed, which potentially propagates to further delays down the line. Consequently, railroad managers seek to streamline and simplify processes in order to eliminate fragility in the operating plan. In reality, consists will be tactically busted as part of real-time operations to compensate for unplanned events.

In order to minimize consist busting, [15] extended the locomotive flow formulation described in [1]. Most features of the model are kept identical but consists are routed over the network instead of individual locomotives. In this formulation, referred to as *consist flow formulation*, each consist type (that is, a group of locomotives) is defined to be a commodity that flows on the network. Thus, the consist flow formulation differs

from the locomotive flow formulation in the sense that locomotive types are replaced by the consist types. Observe that each feasible solution of the consist flow formulation has a corresponding feasible solution to the locomotive flow formulation with the same cost, but the converse is not true. Thus, the reader might be led to believe that consist formulation is quite restrictive and may produce significantly inferior optimal solution compared to the flow formulation. However, computational results revealed that if the number and types of consists are judiciously chosen, then both formulations produce solutions with comparable quality.

The consist flow formulation is a multi-commodity integer program. The network is constructed in a similar way to that described in Sect. “**Space-Time Network**”

### Additional Notation

- $C$ : Denotes the set of consist types available for assignment and  $c \in C$  represent a particular consist.
- $c_l^c$ : Cost of assigning an active consist of type  $c \in C$  to train  $l$ .
- $d_l^c$ : Defined for every arc  $l \in AllArcs$ . For a train arc  $l \in TrArcs$ ,  $d_l^c$  captures the cost of deadheading a consist of type  $c \in Con$  arc  $l$ . For an arc  $l \in CoArcs \cup GrArcs$ ,  $d_l^c$  captures the cost of idling for a consist type  $c \in Con$  arc  $l$ .
- $\alpha^{ck}$ : Number of locomotives of type  $k \in K$  in consist type  $c \in C$ .
- $I[i]$ : Set of arcs entering node  $i$ .
- $O[i]$ : Set of arcs leaving node  $i$ .
- $S$ : Set of overnight arcs or arcs that cross the Sunday midnight timeline. (This time is chosen as the time for counting the number of locomotives used in the solution.)

### Decision Variables

- $x_l^c$ : Binary variable representing the number of active consists of type  $c \in C$  on arc  $l \in TrArcs$ .
- $y_l^c$ : Integer variable representing the number of non-active consists (deadheading, light-traveling or idling) of type  $c \in C$  on arc  $l \in AllArcs$ .
- $z_l$ : Binary variable which takes value 1 if at least one consist flows on arc  $l \in LiArcs$  and 0 otherwise.
- $s^k$ : Integer variable indicating the number of unused locomotives of type  $k \in K$ .

### Objective Function

$$\min z = \sum_{l \in TrArcs} \sum_{c \in C} c_l^c x_l^c + \sum_{l \in AllArcs} \sum_{c \in C} d_l^c y_l^c + \sum_{l \in LiArcs} F_l z_l - \sum_{k \in K} G^k s^k \quad (1)$$

### Constraints

$$\sum_{c \in C} x_l^c = 1, \quad \text{for all } l \in TrArcs, \quad (2)$$

$$\sum_{c \in C} \sum_{k \in K} \alpha^{ck} (x_l^c + y_l^c) \leq 12, \quad \text{for all } l \in TrArcs, \quad (3)$$

$$\sum_{l \in I[i]} (x_l^c + y_l^c) = \sum_{l \in O[i]} (x_l^c + y_l^c), \quad \text{for all } i \in AllNodes, \quad c \in C, \quad (4)$$

$$\sum_{k \in K} \sum_{c \in C} \alpha^{ck} y_l^c \leq 12 z_l, \quad \text{for all } l \in LiArcs, \quad (5)$$

$$\sum_{l \in S} \sum_{c \in C} \alpha^{ck} (x_l^c + y_l^c) \text{day}(l) + s^k = B^k, \quad \text{for all } k \in K, \quad (6)$$

$$x_l^c \in \{0,1\}, \quad \text{for all } l \in TrArcs, \quad c \in C, \quad (7)$$

$$y_l^c \geq 0 \text{ and integer}, \quad \text{for all } l \in AllArcs, \quad c \in C, \quad (8)$$

$$z_l \in \{0,1\}, \quad \text{for all } l \in LiArcs. \quad (9)$$

$$s^k \geq 0, \quad \text{for all } k \in K \quad (10)$$

Constraint (2) ensures that every train  $l$  is assigned exactly one active consist. Constraint (3) ensures that the locomotive flow upper-bound on each train arc is satisfied. Constraint (4) ensures that flow is balanced at every node for every consist type. Constraint (5) ensures that the locomotive flow upper-bound on each light arc is satisfied. Constraint (6) ensures that the number of locomotives used for each fleet type is no more than the fleet size.

Note that in this formulation, it is not required to explicitly specify the constraints that each train gets the required tonnage, horsepower and does not exceed the 24-active axle requirement. These constraints are implicitly handled in the formulation. The active axle constraints are handled by not creating consists which have more than 24 active axles. The tonnage and horsepower

constraints are handled implicitly in the following way; if assigning consist  $c \in C$  as an active consist to train  $l \in TrArcs$  violates the tonnage or horse power constraints, then the corresponding variable is set to zero ( $x_l^c = 0$ ); thus disallowing the assignment of consist  $c$  to train  $l$ . The consist flow formulation has significantly less side constraints compared to the locomotive flow formulation, resulting in faster solution time. Another speed-up in the consist flow formulation comes from the fact that each active consist assignment variable,  $x_l^c$ , is a binary variable, whereas in the locomotive flow formulation, it is an integer variable and can take values 0, 1, 2, 3, ... etc. The MIP optimization engine, which is typically a branch and bound algorithm, is likely to explore lesser branches for a binary integer program compared to a general integer program as there are lesser options to pursue. There are instances where the locomotive flow formulation could not give a feasible integral solution in 10 hours, but the consist flow formulation gave an optimal solution within a few minutes of computational time.

Railroads often impose complex rules on what locomotive types may be combined into ideal consists. Some locomotives do not work well together. Some railroads segregate AC powered locomotives and DC powered locomotives. These requirements are often very hard or impossible to honor in the locomotive flow formulation but are rather trivial in the consist flow formulation. Further, in the locomotive flow formulation, an outbound train often obtains its planned consist from locomotives coming from multiple trains and if any of these inbound trains is delayed, the outbound train is delayed as well. But in the consist flow formulation, all outbound trains derive their active consist only from one inbound train (but may derive their deadhead consists from other trains) thus reducing the impact of train delays. In summary, the benefits of using the consist formulation are (1) solution speed and robustness greatly improved, (2) consist busting is reduced to zero, and (3) constraints are more easily incorporated, resulting in more practical solutions.

Computational tests show that the consist flow formulation may have its optimal objective function value as much as 5% higher than that of the locomotive flow formulation. However, the solution is far superior in terms of consistency, simplicity, and robustness. Thus, it may be easier to comply with and may need overall

fewer locomotives in practice (considering train delays, for example).

## Methods and Applications

In [15], the authors describe methods to use the consist-based formulation to incorporate several practical requirements to generate an implementable plan. These include incremental locomotive planning, satisfying cab-signal requirements, incorporating foreign power requirements, and accounting for shop power requirements. The interested reader may refer to [15] for further details.

In this section, the result of two case studies to illustrate the uses of the model to assist decision making, are presented. The aspects of the problem observed are: (1) Effect of varying minimum connection time on solution cost, and (2) Effect of varying transport volumes on key transport performance characteristics.

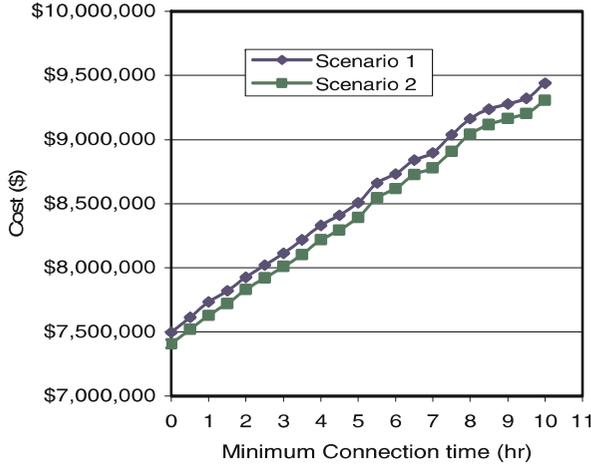

### Effect of Varying Minimum Connection Time on Solution Cost

Freight trains do not run on time and often arrive later than their planned arrival time, which makes it difficult for locomotive dispatchers to adhere to the locomotive plan. One method commonly recommended to improve plan compliance is to increase the train-train minimum connection times. Although increasing the minimum connection time may improve plan adherence, it also increases locomotive costs as more locomotives will be held in inventory at terminals. This study quantifies the impact of increasing the minimum connection times.

The following conclusions can be drawn from the study (see Fig. 3):

- The minimum connection time could have a significant impact on the solution cost.
- The solution cost increases linearly with the increase in connection times at the rate of around \$200,000 per hour.

Depending upon the lateness of trains and the willingness of railroad planners to improve locomotive plan compliance, appropriate connection times can be used. As shown in this study, railroads can use the model to estimate the benefit of reducing locomotive connection times at terminals; this reduction may involve the investment of resources to improve efficiency of termi-

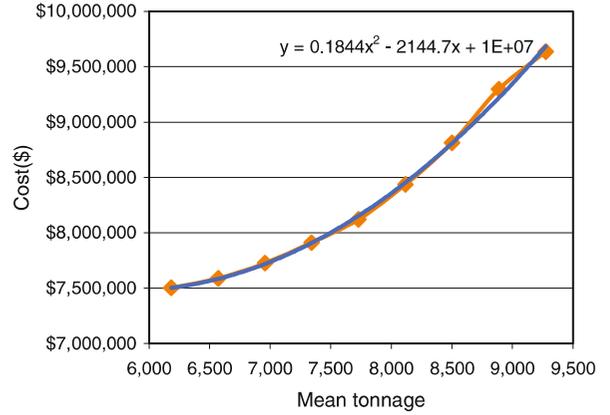

**Railroad Locomotive Scheduling, Figure 3**  
Solution cost vs. minimum connection time

nal activities like fueling and servicing locomotives, and consist-busting overheads.

**Effect of Varying Transport Volume on Key Performance Characteristics**

In this study, the impact of varying transport volumes (or train tonnages) on the following key transport characteristics: number of locomotives used, solution cost, mean pulling power of a consist, and mean miles traveled per consist, is measured. The results of these tests are presented in Table 1 and Fig. 4.

The following conclusions can be drawn from this study:

**Railroad Locomotive Scheduling, Figure 4**  
Impact of transport volumes on solution cost

- As the transport volume (mean tonnage) increases, the solution cost increases as a quadratic function as shown in Fig. 4. The nature of the variation indicates that the rate of change of cost with respect to tonnage (slope) is a linear increasing function.
- The mean pulling power of each consist and the number of locomotives used increase as expected but the surprising observation is that the average number of miles traveled by each consist remains roughly the same.

As demonstrated in this study, railroads can use the model as a generic approach for modeling the optimal number of locomotives needed or the cost as a function of the rail freight transport volume over the entire network.

**Railroad Locomotive Scheduling, Table 1**  
Effect of varying transport volumes

% increase in tonnage	Mean tonnage of trains	Locos Used	Solution Cost (\$)	Mean pulling power/consist	Mean miles/ consist
-20	6,183	1,026	7,502,802	10,099	405.05
-15	6,570	1,026	7,588,421	10,373	405.04

## Conclusions

The LSP creates a blueprint for use by managers to assist them in making tactical, day-to-day decisions regarding locomotive assignments. This article provides an overview of some of the recent work done in this area. The locomotive planning tools presented in this article have the potential to serve as a core component in a strategic fleet sizing model. Each year, railroads develop five year outlooks and forecast the demand for freight transportation and the associated train schedules to handle that demand. Railroads also must project locomotive fleet supply, as units reach their economic limit of repair and are retired from the fleet. The gap between the future supply of locomotives and the future demand for locomotives must be closed with a combination of improved productivity and new purchases. This planning tool will go a long way towards helping railroad financial executives and strategic planners set asset goals and negotiate the purchase of new locomotives. The planning tool can also be used to perform “*what-if*” kind of analysis and allow railroad managers to take informed decisions after analyzing their global impacts.

## Keywords

Global optimization; Nonsmooth optimization; Unbounded optimization; Interval methods

A general *global optimization problem* is a problem of the form

$$\begin{cases} \max & f(x) \\ \text{s.t.} & x \in S, \end{cases}$$

where  $f$  is a continuous function on  $S$ , and  $S \subset \mathbf{R}^d$  is a compact body, and the goal is to find a point in the set

$$S^* \equiv \{x \in S: f(x) = f^*\}$$

where

$$f^* \equiv \max_{x \in S} f(x).$$

It is well-known that, without additional assumptions, this problem is inherently unsolvable in a finite number of steps. Therefore, the global optimization problem is usually considered solved if a point is found in

$$B_\epsilon^* \equiv \{x \in S: \|x - x^*\| \leq \epsilon \text{ for some } x^* \in S^*\}$$

or in the level set

$$S_\epsilon \equiv \{x \in S: f(x) \geq f^* - \epsilon\}$$

for some  $\epsilon > 0$  [17].

Stochastic methods are methods that contain some stochastic elements. This means that either the outcome of the method is a random variable, or the objective function itself is considered to be a realization of a stochastic process. Therefore, the possibility of an absolute guarantee of success is sacrificed. Instead, it is usually possible to prove that, as the effort increases to infinity, an element of  $B_\epsilon^*$  or  $S_\epsilon$  will be found with probability one. Surveys on the topic of stochastic methods for global optimization can be found in [10,29,38] and [33].

*Random search methods* are those stochastic methods that rely solely on the random sampling of a sequence of points in the feasible region of the problem, according to some prespecified probability distribution, or sequence of probability distributions. These methods are applicable to, and enjoy an asymptotic performance guarantee for, a very wide class of problems. Therefore, these methods have, during the last decade, enjoyed increasing interest for its ability to handle prob-

lems whose mathematical structure is difficult (or undesirable, or even impossible) to analyze.

## Conceptual Methods

The methods discussed here are of a conceptual nature, in the sense that at this point there does not exist an efficient implementation of these methods. However, the theoretical results that can be obtained for these methods are interesting in itself. Moreover, they have shown potential for inspiring (or theoretically supporting) practical algorithms for global optimization.

### (Pure) Random Search

The simplest stochastic method for global optimization is *pure random search* (PRS) ([12] and [5]). This method consists of generating a sequence of independent and identically distributed uniform points in the feasible region  $S$ , while keeping track of the best point that is found. In pseudocode, the method is given below.

The sequence of points generated by this method converges to a global optimum with probability one. In particular, the probability that a point in  $S_\epsilon$  is reached within the first  $N$  iterations is equal to

$$1 - (1 - \varphi(S_\epsilon))^N,$$

where  $\varphi$  denotes the uniform distribution on  $S$ . In other words, this method offers a probabilistic asymptotic guarantee.

```

PROCEDURE pure random search()
  InputInstance();
  Set  $y = -\infty$ ;
  DO
    Generate a point  $x$  from the uniform distribution over  $S$ ;
    Set  $y = \max(y, f(x))$ ;
  OD;
  RETURN( $y$ );
END pure random search;

```

### A pseudocode for PRS

In [37], F.J. Solis and R.J.-B. Wets introduce a class of random search methods whose most important feature, as compared to pure random search, is that disimprove-

ments are disallowed through a generalization of the acceptance-rejection approach. Moreover, sampling is not limited to the uniform distribution, but to a (pre-specified) sequence of (absolutely continuous) probability distributions on  $S$ . Asymptotic convergence with probability one can again be shown.

If the random search method is *adaptive*, i. e. if we allow the distributions to be sampled from to depend on the values of previously found solutions, then convergence cannot be assured in general.

### Pure Adaptive Search

*Pure adaptive search* (PAS) differs from PRS, and resembles the random search methods of Solis and Wets, in that it forces improvement in each iteration. However, the improving force is much stronger in that the algorithm is truly adaptive, without using any form of acceptance-rejection. In particular, an iteration point is generated from the uniform distribution on the subset of points that are improving with respect to the previous iteration point. More formally, the method reads:

```

PROCEDURE pure adaptive search()
  InputInstance();
  Set  $y = -\infty$ ;
  DO
    Generate a point  $x$  from the uniform distribution over  $\{x \in S : f(x) > y\}$ ;
    Set  $y = f(x)$ ;
  OD;
  RETURN( $y$ );
END pure adaptive search;

```

#### A pseudocode for PAS

This method has been introduced and analyzed in [27] for convex programming problems, and by Z.B. Zabinsky and R.L. Smith [42] for more general global optimization problems. For Lipschitz continuous problems with convex feasible regions, the expected number of iterations to achieve a solution with a given precision increases at most linearly in the dimension  $d$  of the problem. This result suggests there is hope for an efficient random search method for global optimization. In fact, several random search methods have reported empirical linearity in dimension for optimizing quadratic functions ([34,35] and [37]). PAS has been extended to

the case of a finite domain in [44], with analogous performance results.

### Adaptive Search

It is generally very difficult to generate a point uniformly distributed in a *level set* of the global optimization problem. A method that avoids this issue, at the cost of having to generate from other distributions than the uniform, is *adaptive search* (AS). In this method, a sequence of improving points is generated by generating points according to a sequence of distributions in the feasible region  $S$ , while using an acceptance-rejection approach to attain improvement. The sequence of generating distributions should be chosen in such a way that, as the method progresses, these distributions concentrate more and more around the global optimum of the problem. An example of a family of distributions having this property is the family of *Boltzmann distributions*. This family of distributions, parameterized by a positive parameter  $T$ , are absolutely continuous on  $S$  with densities

$$g_T(x) \propto e^{f(x)/T}.$$

Note that, as the parameter  $T$  approaches infinity, the sequence of distributions approaches the uniform distribution on  $S$ . On the other hand, it can be shown that, as the parameter  $T$  approaches zero, the sequence of distributions converges to a distribution that concentrates on the set of points where the global optimum is attained. Using this family of distributions, the adaptive search method reads:

```

PROCEDURE adaptive search()
  InputInstance();
  Set  $y = -\infty$ ;
  Set  $T = \infty$ ;
  DO
    Generate points  $x$  from the Boltzmann distribution with parameter  $T$  until a point is found with  $f(x) > y$ ;
    Set  $y = f(x)$ ;
    Decrease  $T$ ;
  OD;
  RETURN( $y$ );
END adaptive search;

```

#### A pseudocode for AS

This method was introduced by H.E. Romeijn and Smith [30] with the objective of studying the behavior of *simulated annealing* (see below). They generalized the key result for pure adaptive search as follows. If the value of the parameter  $T$  depends, in a monotonically decreasing way, on the current record value, then the expected number of improving points to achieve a solution with a given precision increases at most linearly in the dimension  $d$  of the problem for a wide class of global optimization problems. The parameter  $T$  can be used to limit the total number of iterations (including the nonrecord values generated in the acceptance-rejection phase). Ideally, one should choose the value of the parameter  $T$  in such a way that, during the next iteration, the probability of obtaining an improving point is at least equal to some fixed value.

### Hesitant Adaptive Search

One way of implementing PAS would be to use an acceptance-rejection approach for generating points in level sets of  $S$  (assuming the problem of generating a uniformly distributed point in  $S$  itself is relatively easy). In terms of total number of iterations, this approach would be equivalent to PAS, with the following modification. At each iteration, either a new PAS iterate is generated (with some probability  $b$ ) or the previous iteration point is repeated (with probability  $1 - b$ ), where  $b$  depends on the current record value. More precisely,  $b$  is the relative measure of the level set corresponding to the current record value. *hesitant adaptive search* (HAS), introduced by D.W. Bulger and G.R. Wood [13] with the objective of studying *localization search* algorithms (see below), generalizes this way of viewing PAS by relaxing the specific choice of  $b$  mentioned above. An explicit expression for the expected number of iterations required to obtain a point with a given objective function value (or better), and even the full distribution of this random variable, can be derived (see also [40]).

## Algorithms

### Simulated Annealing

Simulated annealing (SA) is a random search method that avoids getting trapped in local maxima by accepting, in addition to transitions corresponding to an increase in function value, also transitions correspond-

ing to a *decrease* in function value. The latter is done in a limited way by means of a probabilistic acceptance criterion. In the course of the maximization process, the probability of accepting deteriorations descends slowly towards zero. These ‘deteriorations’ make it possible to move away from local optima and explore the feasible region  $S$  in its entirety.

SA originated from an analogy with the physical annealing process of finding low energy states of a solid in a heat bath [26]. M. Pincus [28] developed an algorithm based on this analogy for solving discretizations of continuous global optimization problems. Many applications to date have been to discrete (combinatorial) optimization problems (see e. g. [1,23] and [2]).

All SA algorithms for global optimizations can be viewed as approximative versions of AS. The main problem with directly implementing AS is that, in general, it will be extremely difficult to generate points exactly from the Boltzmann distribution on  $S$ . The approximative character of SA lies in the fact that SA algorithms use a *Markov chain sampling* approach instead. This means that a Markov chain is defined on  $S$  having the property that the limiting distribution of this Markov chain is the desired Boltzmann distribution. One way of achieving this is the following. First, create a Markov chain on  $S$  that has the uniform distribution as its limiting distribution. Examples of such Markov chains are the *hit and run* generator (see [8,9,36] and [32]), and the random ball walk (see [25]). This Markov chain can then be filtered as follows to change the limiting distribution to the Boltzmann distribution. If the current iteration point is  $x$ , and the current value of the *temperature parameter* is  $T$ , then the candidate point (say  $z$ ) that is generated by the Markov chain is accepted with probability

$$\min\{1, e^{(f(z)-f(x))/T}\}$$

(the *Metropolis criterion*). Otherwise, we discard the candidate point and remain at the current iteration point.

C.J.P. Bélisle [7] showed that, although successive iterations of SA may experience deteriorations in objective function value, these effects are, under mild conditions, transient if the Markov chain reaches globally, i. e., if each feasible point can be reached from any other feasible point in one iteration. In particular, if the sequence of temperature parameters  $T$  decreases to zero

```

PROCEDURE simulated annealing()
  InputInstance();
  Set  $y = -\infty$ ;
  Set  $T = \infty$ ;
  Choose  $x \in S$ ;
  DO
    Generate a point  $z$  according to some
    Markov chain transition distribution;
    With probability  $\min\{1, e^{(f(z)-f(x))/T}\}$ ,
    set  $x = z$ ;
    If  $f(x) > y$  set  $y = f(x)$ ;
    Adjust  $T$ ;
  OD;
  RETURN( $y$ );
END simulated annealing;

```

#### A pseudocode for SA

in probability, SA will eventually be absorbed in arbitrarily small neighborhoods of the global maximum. The *cooling schedule* controlling the way the parameter  $T$  is decreased should be chosen in accordance with AS. In practice, this means that the temperature parameter should be proportional to (an estimation of) the value error corresponding to the current record value. If the temperature value is held constant at 0 (which means that no deteriorations are ever accepted), we obtain the *improving hit and run* algorithm (see [43]). In [24], M. Locatelli derives convergence results for simulated annealing algorithms with nonglobally reaching Markov chains.

Examples of specific SA algorithms can be found in [3,11,15,16,21,31,39] and [32]. In [22], the first polynomial time implementation of an SA algorithm is presented, albeit for the unimodal problem of minimizing a linear function over an up-monotone convex set in the positive orthant. The authors derive an SA algorithm using the rapidly mixing Markov chains developed in [18].

Finally, a class of algorithms closely related to the SA algorithms discussed above are algorithms based on the *Langevin stochastic differential equation*

$$dx(t) = \nabla f(x(t)) dt + \epsilon(t) dw(t), \quad (1)$$

where  $\nabla f$  is the gradient of  $f$  and  $w(t)$  is a standard  $d$ -dimensional Wiener process. If  $\epsilon(t)$  is constant, then the limiting distribution of the sequence of points thus

generated is precisely the Boltzmann distribution at temperature  $\epsilon^2/2$ . In other words, algorithms based on this result can be viewed as SA algorithms, but using continuous time instead of discrete time Markov chains. See e.g. [19] and [14] for theoretical results, and [4] for a practical implementation.

```

PROCEDURE pure localization search()
  InputInstance();
  Set  $y = -\infty$ ;
  Set  $L = S$ ;
  DO
    Generate a point  $x$  uniformly in  $L$ ;
    IF  $f(x) > y$ , set  $y = f(x)$ ;
    Shrink  $L$  (while remaining a superset of the
    current record level set);
  OD;
  RETURN( $y$ );
END pure localization search;

```

#### A pseudocode for PLS

#### Pure Localization Search

The aim of *pure localization search* (PLS) is to approximate PAS. The approximation consists of the following. Instead of generating a point uniformly from a level set, a point is generated uniformly from a superset of the level set, called a *localization*. Note that PRS is an instance of PLS, where the superset of each level set is the entire feasible region  $S$ .

This class of algorithms was introduced in [6] where, in addition, an example of a particular PLS algorithm for one-dimensional Lipschitz optimization is provided.

#### Conclusions

The main advantage of random search methods for solving global optimization problems is that they are applicable to a very wide class of optimization problems, and nevertheless provide a convergence guarantee, albeit an asymptotic one. Therefore, random search methods have been applied most successfully to problems that are black-box and/or unstructured, so that approaches that make use of a particular mathematical structure cannot be used. Examples include industrial

design problems and the design of composite laminates [20,41]. Moreover, these methods are usually very easily implemented. As such, they are also often used as a first approach towards solving a problem, until insight into the structural properties of the problem warrant the development of new, or application of existing, special purpose optimization methods.

Reactive Scheduling: New or Modified Orders

Extensions of Reactive Scheduling Formulation

### Cases

Nominal Production Schedule

Case 1: Reactive Scheduling with Unit Shutdown

### Conclusions

### References

## Introduction

The purpose of reactive scheduling is to adjust a production schedule upon the occurrence of unexpected or unforeseen events. The original schedule is usually obtained a priori and then reactive scheduling is performed upon the breakdown of a piece of equipment, when new customer orders are received, or when existing orders are modified or deleted. Thus, in order to be effective, reactive scheduling systems must be able to generate updated production schedules relatively quickly. It is not desirable to do full-scale rescheduling for every unexpected event and usually heuristic approaches are developed to achieve the desired schedule modifications. Recent reviews on scheduling approaches that include reactive scheduling issues can be found in Floudas and Lin [3,4].

The proposed scheduling formulation uses the continuous-time scheduling formulation for short-term scheduling proposed by Floudas and coworkers [5,8,9] and the medium-term scheduling framework developed by Lin et al. [10] and Janak [6]. Full-scale rescheduling of each production schedule is avoided by fixing binary variables for a subset of tasks from the original production schedule. The subset of tasks to fix is determined using a detailed set of rules that reflect the production needs and can be modified for different production facilities. The fixing of tasks results in a reduced computational effort required to solve the resulting MILP problem and thus a suitable, updated production schedule can be determined in a shorter amount of CPU time.

### Problem Statement

In the batch plant investigated, there are several different types of operations (or tasks) possible and the plant has many different types of units where over 80 are modeled explicitly. Also, there are hundreds of different products that can be produced through a variety of processing recipes resulting in hundreds of different tasks. Each product is made using one of the processing recipes shown in Fig. 1 or a slight variation. The recipes are represented in the form of State-Task Network (STN), in which the *state* node is denoted by a circle and the *task* node by a rectangle.

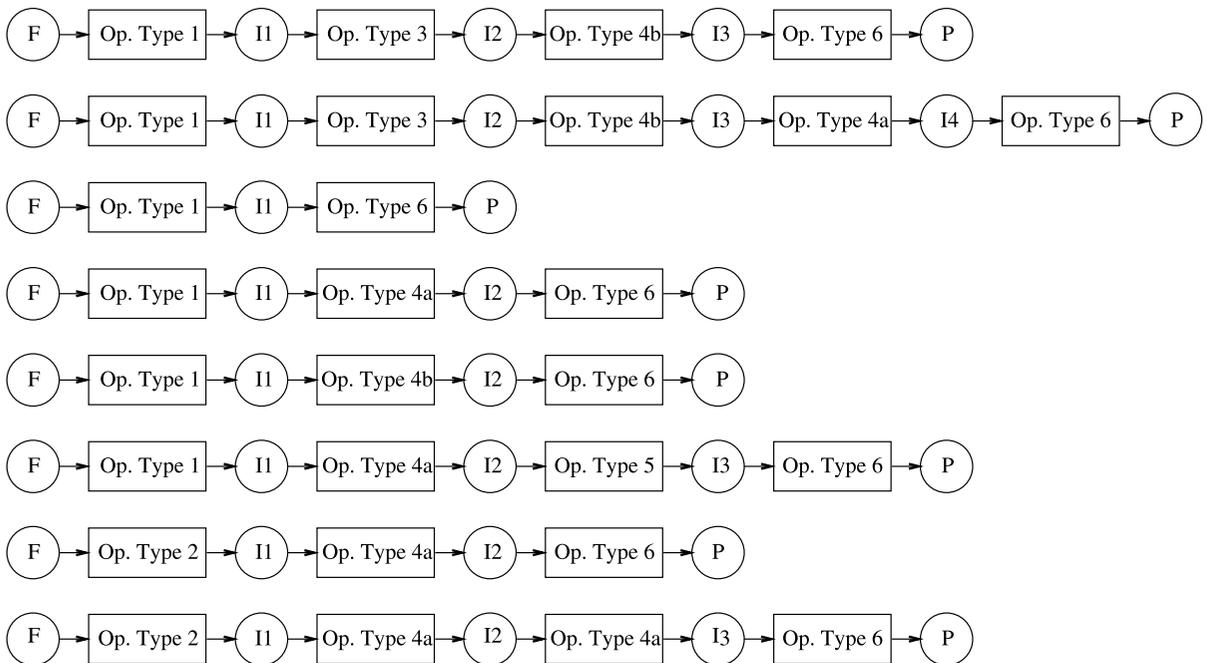

The information on which units are suitable for each product is given. All the units are utilized in a batch mode with the exception of the type 5 and 6 units, which operate in a continuous mode. The capacity limits of the type 1, 2, and 3 units vary from one product to another, while the capacity limits of the type 4a, 4b, 5, and 6 units are the same for all suitable products. The processing time or processing rate of each task in the suitable units is also specified. Additional information for the plant under investigation can be found in Janak et al. [6].

The time horizon considered for production scheduling is a few weeks or longer and customer orders are fixed throughout the time horizon with specified amounts and due dates. There is no limitation on external raw materials and we apply the zero-wait storage condition or limited intermediate storage capacity for all materials based on actual plant data. There are two different types of products produced, category 1 and 2. The solution of this medium-term scheduling problem, even for only a few days, results in a large-scale scheduling problem that can be very computationally complex. New techniques need to be developed in order to both efficiently and accurately carry out reactive scheduling.

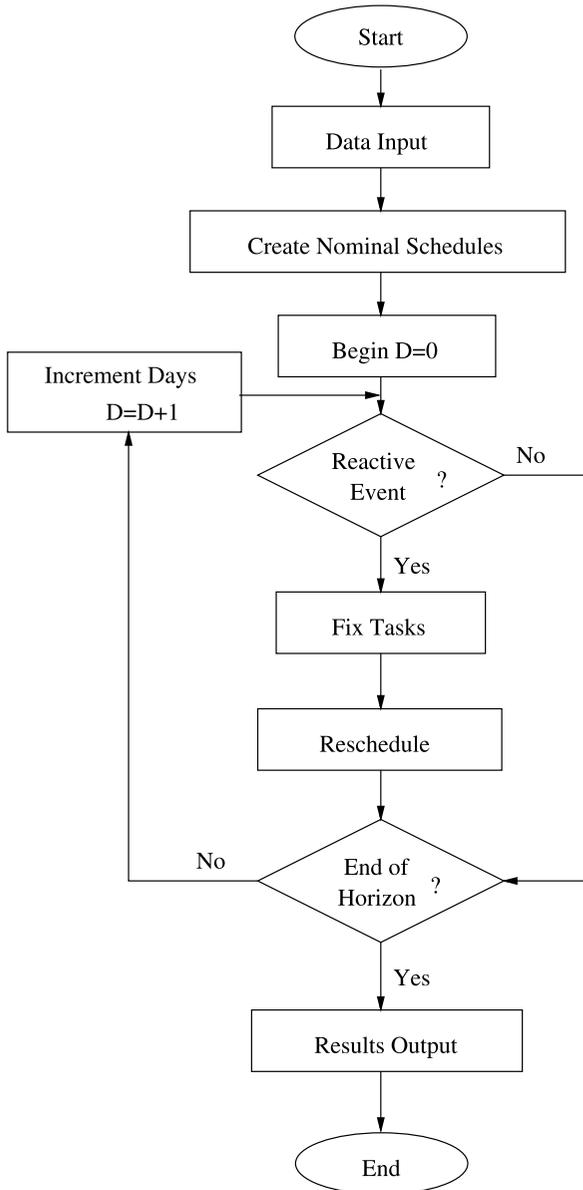

### Formulation

The overall methodology for solving the reactive scheduling problem in a medium-term production scheduling framework can be summarized in the following steps. The flowchart for the overall reactive scheduling framework is shown in Fig. 2.

**Step 1.** Obtain a nominal production schedule for the full scheduling horizon using the medium-term

Reactive Scheduling of Batch Processes, Figure 1  
State-task network (STN) representation of plant

**Reactive Scheduling of Batch Processes, Figure 2**  
Flowchart of the reactive scheduling framework

scheduling framework proposed in Janak et al. [6] by decomposing the full scheduling horizon into smaller short-term scheduling subproblems in successive time horizons.

**Step 2.** Upon the realization of an unexpected event, perform the following steps.

- a. Fix all the tasks in the short-term scheduling subhorizons which have already taken place using the nominal schedule.

- b. For the subhorizon that is currently in production, there are two cases of unexpected events which are considered: breakdown of a unit or the addition/modification of orders. If a unit breaks down, then fix the appropriate tasks for the current subhorizon using the rules outlined in Sect. “**Reactive Scheduling: Unit Shutdowns**”. For the case when orders are added or modified, then fix the appropriate tasks for the current subhorizon using the rules outlined in Sect. “**Reactive Scheduling: New or Modified Orders**”. Note that a combination of both can also be performed.

- c. Once the tasks have been fixed, then the overall short-term scheduling model presented in Janak et al. [6] with some modifications can be used to perform rescheduling. First, the formulation is enhanced so that the results of the level 1 decomposition model are fixed to match the results from the nominal schedules. Thus, the days in each subhorizon are fixed so that the horizons match the nominal schedules. Next, modifications need to be made to reflect changes from the unexpected events. Each of the two cases of unexpected events that can occur in a particular subhorizon requires a different modification to the model. Complete information on these modifications can be found in Sect. “**Reactive Scheduling: Unit Shutdowns**” and “**Reactive Scheduling: New or Modified Orders**”

**Step 3.** Once the items in Step 2 have been completed, then the horizon with the current reactive events is ready to be rescheduled. This is done in the same manner as the nominal schedule, however, a smaller time limit or integer solution limit may be employed, if desired. Next, the remaining overall time horizon is rescheduled from scratch. This is necessary since changes in the reactive time horizon can cause changes in the inventory, demand satisfaction, and unit availability which can make the nominal solution for the remaining time horizons infeasible or severely suboptimal.

### Reactive Scheduling: Unit Shutdowns

For the case when a piece of equipment breaks or is shut down during a subhorizon, then, for Step 2b in the overall framework, the following tasks need to be performed. For the current subhorizon, tasks are fixed

in a particular unit at a specific event point by setting the associated binary variable to one. For the case of unit shutdown, we also fix the starting time and batch size of all tasks that are fixed. Tasks are fixed for the unit shutdown case if they start processing before the unit shutdown in all unaffected units or if they start and finish processing before the shutdown time in the unit that is shut down. For Step 2c in the overall framework, some additional information needs to be included in the model before rescheduling is performed. For the case of unit shutdown, the starting and finishing times of all tasks in the particular unit that shuts down need to be appropriately bounded so that the unit becomes unavailable during the shutdown period. Also, for the subsequent scheduling horizon, the starting time of the unit that was shut down needs to be set to either the end of the last task or to the time the unit became available again, depending on which is later. This ensures that no task will be scheduled during the blocked off time if it overlaps into the next horizon.

The mathematical formulation for reactive scheduling with unit shutdowns uses the same sets of constraints developed for short-term scheduling in Janak et al. [6] including constraints (22)–(52), (56)–(58), and the overall objective function given in constraint (66). In addition, the above additional requirements can be described mathematically as follows:

$$wv(i, j, n) = 1, \forall i \in I^{\text{fix}}, j \in J_i, n \in N \quad (1)$$

$$T^s(i, j, n) = T^s(i, j, n)^{\text{const}}, \quad \forall i \in I^{\text{fix}}, j \in J_i, n \in N \quad (2)$$

$$B(i, j, n) = B(i, j, n)^{\text{const}}, \quad \forall i \in I^{\text{fix}}, j \in J_i, n \in N \quad (3)$$

$$T^s(i, j, n), T^f(i, j, n) \leq \text{Shutdown}_j^{\text{start}}, \quad \forall i \in I, j \in J^{\text{sd}}, n \in N, n \leq N^{\text{int}} \quad (4)$$

$$T^s(i, j, n), T^f(i, j, n) \geq \text{Shutdown}_j^{\text{end}}, \quad \forall i \in I, j \in J^{\text{sd}}, n \in N, n > N^{\text{int}} \quad (5)$$

where  $I^{\text{fix}}$  is the set of tasks ( $i$ ) to be fixed,  $J^{\text{sd}}$  is the set of units ( $j$ ) which experience a shutdown,  $N^{\text{int}}$  is an intermediate event point,  $T^s(i, j, n)^{\text{const}}$  is the value of the

starting time of the task from the nominal scheduling run,  $B(i, j, n)^{\text{const}}$  is the batch size of the task from the nominal scheduling run,  $\text{Shutdown}_j^{\text{start}}$  is the beginning of the shutdown in unit ( $j$ ), and  $\text{Shutdown}_j^{\text{end}}$  is the end of the shutdown in unit ( $j$ ).

### Reactive Scheduling: New or Modified Orders

For the case when new orders are added to a scheduling horizon, then, for Step 2b in the overall framework, the following actions need to be performed. For the current subhorizon, tasks can be fixed in a particular unit at a specific event point for a variety of reasons. Some of the possible cases for fixing tasks from the nominal schedule considered in this work are as follows.

1. If the task takes place in a unit that is not suitable for any products which have new or changed orders. This is done so that production is free in any unit which may need to accommodate a new order or remove an old order.
2. If the task takes place in a unit that is heavily utilized (e. g., more than a specified percentage). This is done because well utilized units should not be rescheduled, if possible. Note that in this case, a task is only fixed in a unit that is heavily utilized if the unit does not have any tasks taking place in it which correspond to new or modified orders.
3. If the task corresponds to a product with one of the top four largest demands in the current subhorizon. This is done to help ensure that the larger demands in the horizon can be met.
4. If the task is suitable in three or less processing units. These tasks are fixed because they most likely cannot be processed anywhere else.
5. If the task occurs in a special processing unit, specific to the problem at hand. For instance, if the task occurs in a unit which has very tight production or predetermined production.
6. If the task occurs in one of the larger processing units, such as the large type 1 units, and corresponds to a product with demand that is greater than or equal to some amount. These tasks are fixed because they represent a good utilization of resources. Larger demands should be assigned to the larger processing units.

Thus, if a task satisfies one or more than one of the items above, then it is fixed in the reactive scheduling

formulation using the data from the nominal schedule. Note that a task which corresponds to a reduced or deleted order cannot be fixed, regardless of whether or not it satisfies any of the above items. For Step 2c in the overall framework, some additional information needs to be included in the model before rescheduling is performed. For the case of new orders, the demands used in the mathematical framework need to be updated to reflect any changes.

The mathematical formulation for reactive scheduling with new or modified orders also uses the same sets of constraints developed for short-term scheduling in Janak et al. [6] including constraints (22)–(52), (56)–(58), and the overall objective function given in constraint (66). In addition, the above additional requirements can be described mathematically using Eq. (1) given for reactive scheduling with unit shutdowns.

### Extensions of Reactive Scheduling Formulation

As mentioned previously, it is also possible to consider a combination of reactive events. For instance, multiple units could become unavailable and multiple orders could be added or modified in a single horizon. This case can be addressed using the same methodology described in the previous section. In order to fix a task, we would need to check that the task does not correspond to a modified order and that it does not occur during a blocked time in any of the unavailable units. Then, if both of these conditions are met and if the task satisfies one or more of the above criteria, it can be fixed. Note that as more reactive events take place, most likely fewer tasks will be able to be fixed in the reactive scheduling formulation, making the resulting problem more computationally complex.

### Cases

In this section, an example problem is presented to demonstrate the effectiveness of the proposed approach. Additional examples can be found in Janak et al. [7]. The example considers the production scheduling of an industrial batch plant including campaign mode production. We use the nominal schedule obtained in Janak et al. [6] and we consider reactive scheduling in the event of unit shutdowns. The example is implemented with GAMS 2.50 [1] and solved using CPLEX 9.0 [2] with a 3.20 GHz Linux workstation. The

dual simplex method is used with best-bound search and strong branching. The short-term scheduling horizon where reactive scheduling is performed is run with a relative optimality tolerance equal to 0.001% along with a 30 minute time limit. The subsequent short-term scheduling horizons are fully rescheduled and are run with a relative optimality tolerance equal to 0.001% along with a three hour time limit and an integer solution limit of 40.

### Nominal Production Schedule

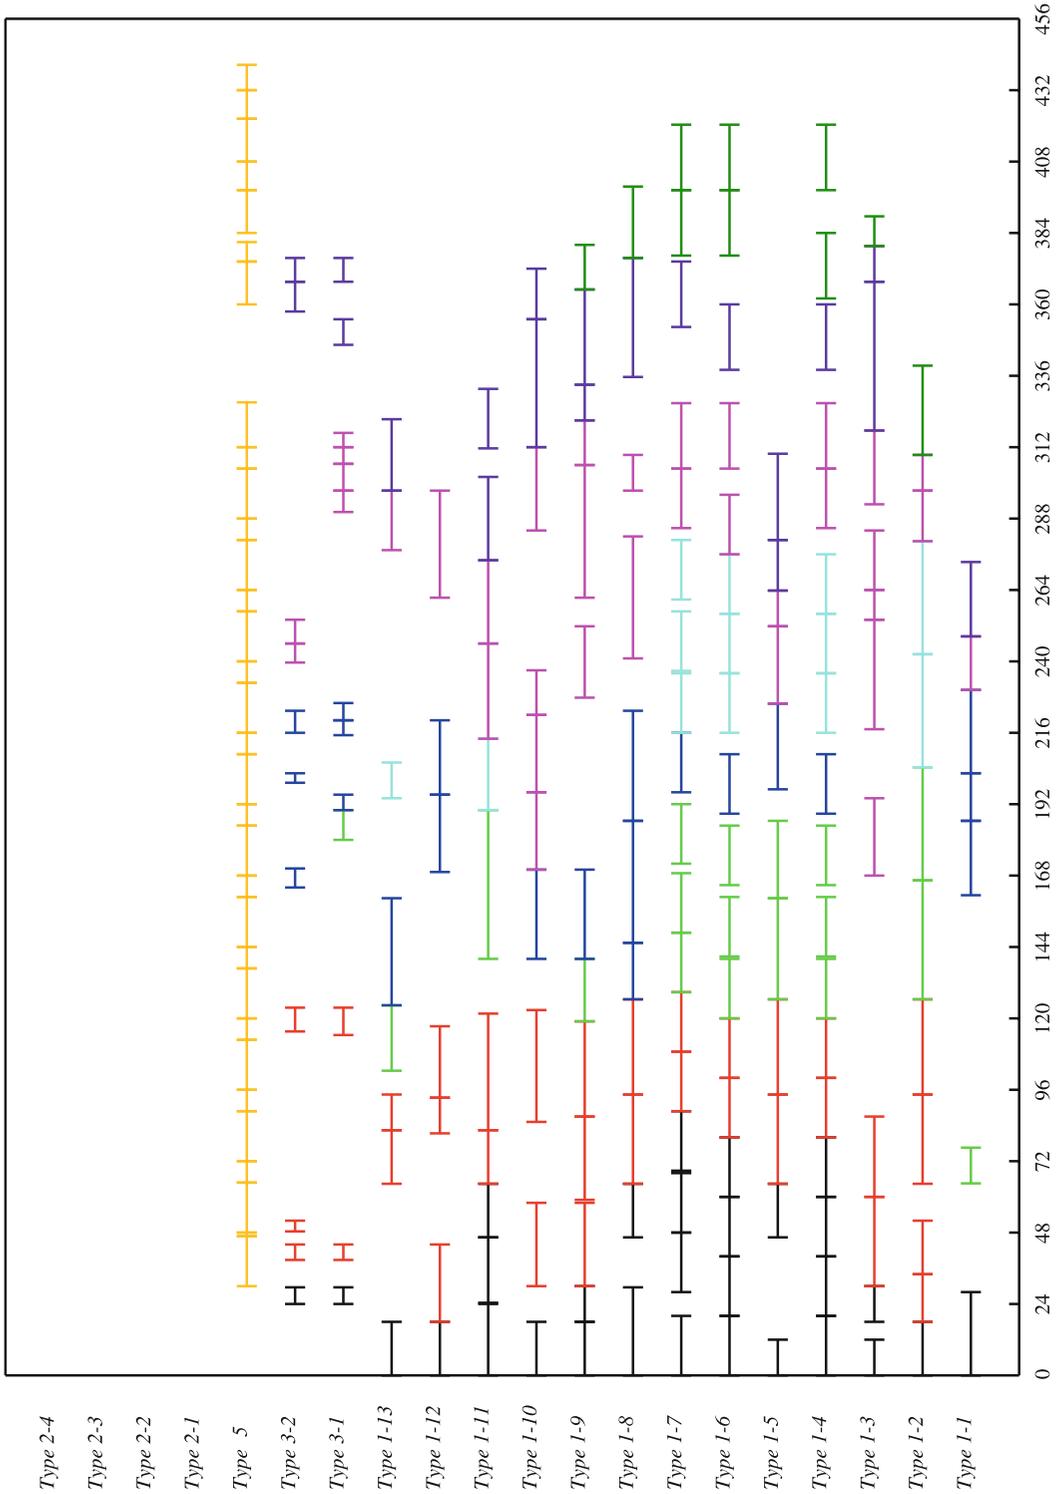

The nominal production schedule was determined in Janak et al. [6] where the total time period is 19 days, from D0 to D18. The nominal problem is solved including campaign mode production so that production in the type 5 unit is fixed to yield campaigns of predetermined length. The rolling horizon framework decomposes the time horizon into 8 individual subhorizons, each with its own products and demands. The results of the decomposition for each time horizon can be seen in Table 1.

The final production schedule for the entire time period can be seen in Fig. 3 and 4 where the processing units (operation type 1, 2, 3, and 5) are shown in the first figure and the other units (operation type 4a, 4b, and 6) are shown in the second. Each short-term scheduling horizon is represented with a different color.

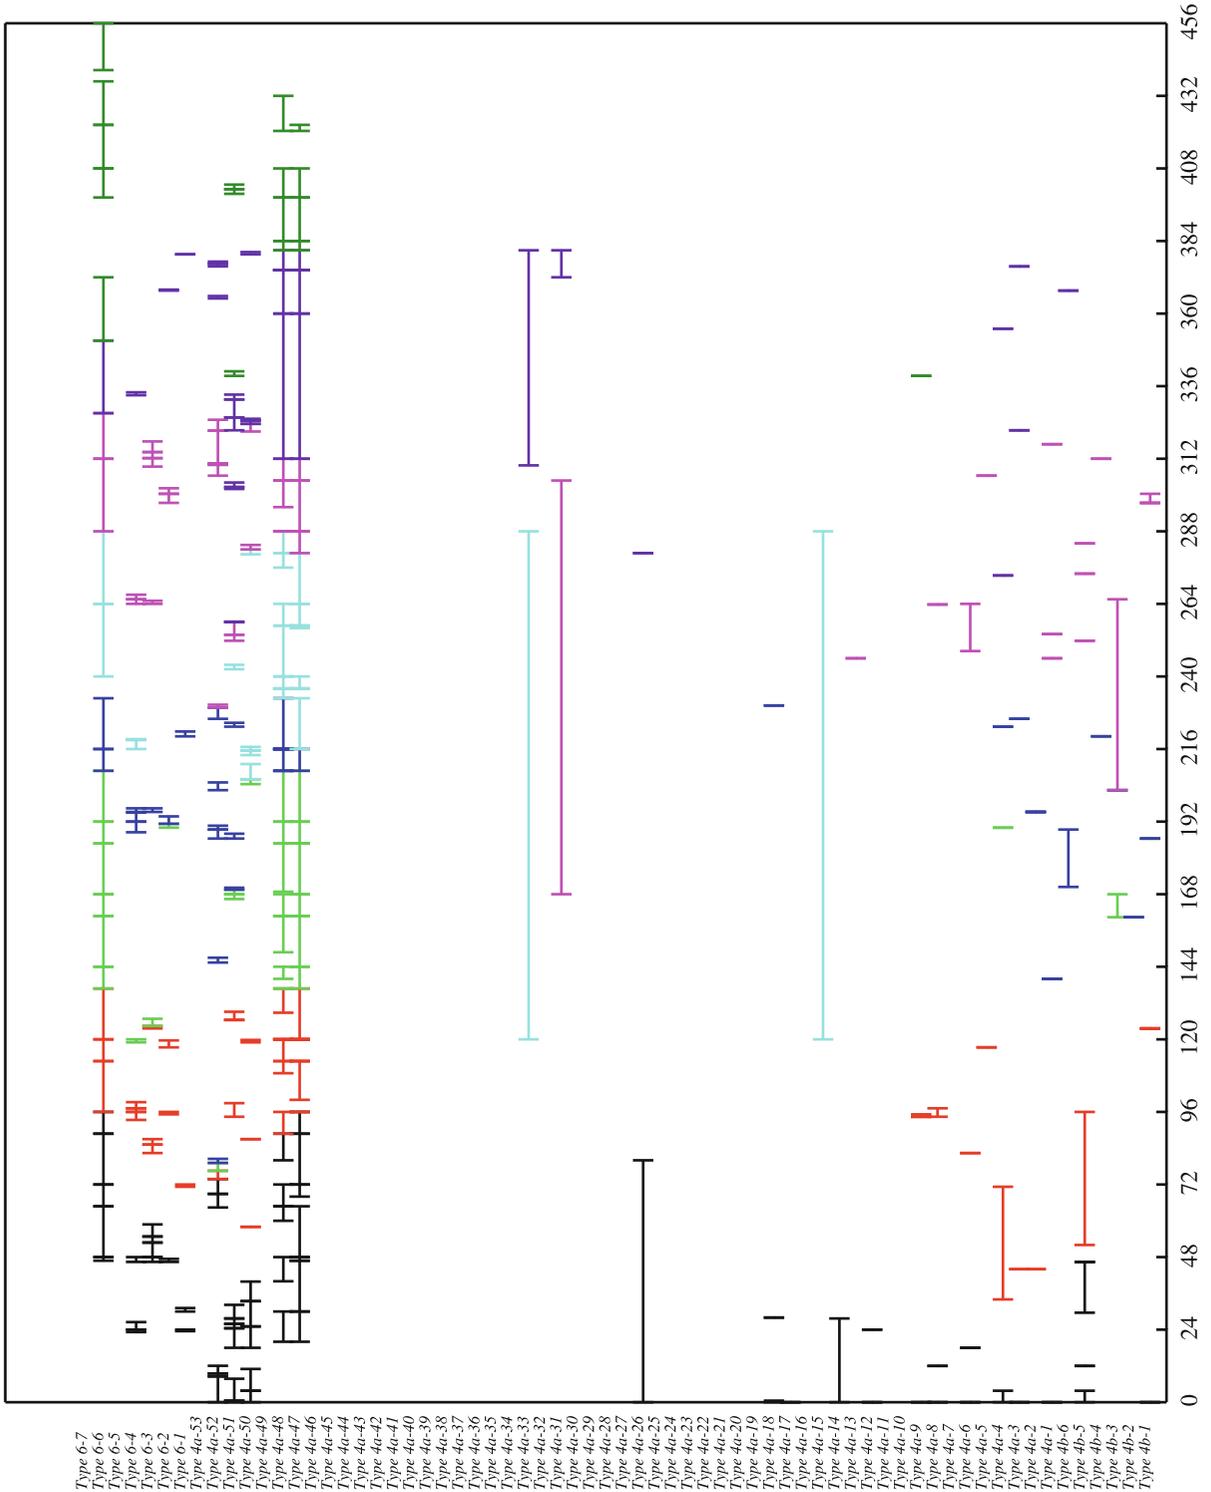

The total demand for the entire 14-day period is 2323.545 and the total production is 2719.859, where 15.00 of the demands are not met. The production schedules obtained satisfy demands for all but one product, though some due dates are relaxed, and also

produce 17.06% more material than the demands require. Note that many of the processing units are not fully utilized, as shown in Table 2, indicating the potential for even more production in the given time period which may be incorporated using reactive scheduling.

### Case 1: Reactive Scheduling with Unit Shutdown

In the example, we consider reactive scheduling for the first time horizon where several units are unavailable for a period of time. We will use the nominal production schedule as our base schedule where the first time horizon covers three days (i. e., D0 to D2) and utilizes nine event points. The three different unit shutdowns considered can be seen in Table 3.

The reactive scheduling framework for unit shutdowns fixes tasks that start before the latest shutdown start time in units which are unaffected and fixes tasks that start and end before the shutdown time in units which experience a shutdown. Thus, for this example,

**Reactive Scheduling of Batch Processes, Table 3**  
Unit shutdowns for case 1

Unit	Unavailable Start Time (h)	Unavailable End Time (h)
Type 1-3	24	48
Type 1-5	36	72
Type 1-11	48	72

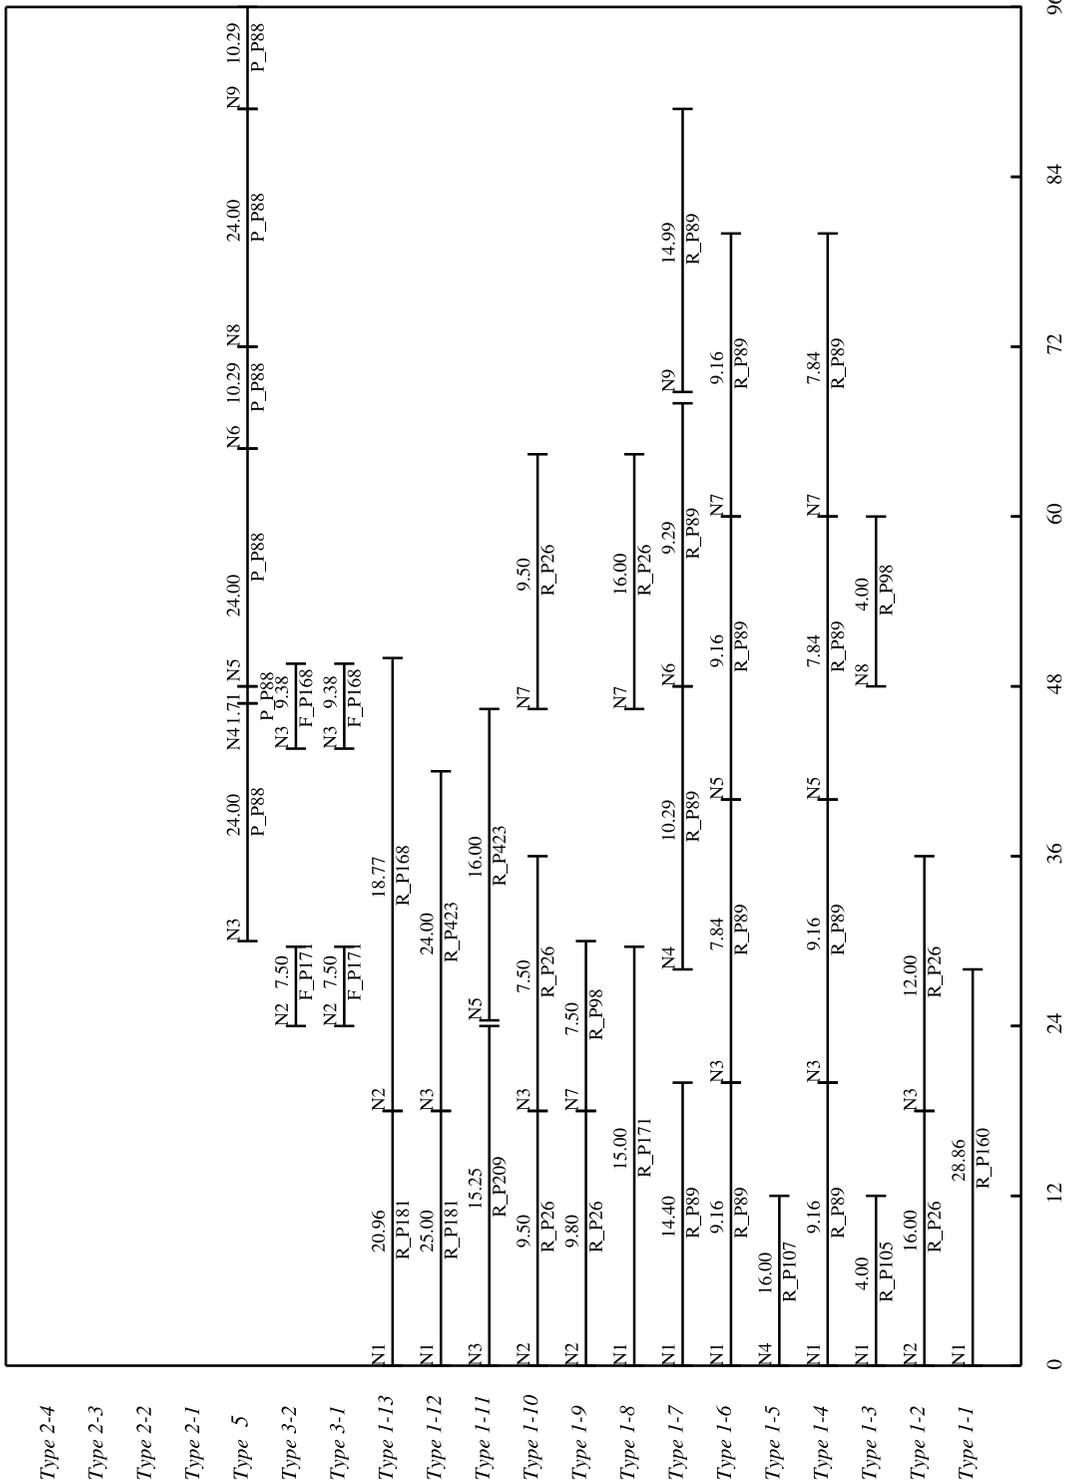

all the tasks starting before time 48 hours in all the units except Type 1-3, Type 1-5, and Type 1-11 are fixed. This means that both the binary variable ( $wv(i, j, n)$ ), starting time ( $ts(i, j, n)$ ), and batch size ( $b(i, j, n)$ ) of the task need to be fixed for each task ( $i$ ) in those units ( $j$ ) at the event point ( $n$ ) they occurred in the nominal production schedule. Thus, if we consider the nominal production schedule for the first time horizon shown in Fig. 5, then the tasks shown in Table 4 are fixed in each unit.

In addition, in each of the units which experience a shutdown, bounds need to be placed on the starting and finishing times for all tasks at event points which do not already have tasks fixed to them. An intermediate event point is chosen and all of the event points before and including the intermediate event point have an upper bound placed on the starting and finishing times of tasks to be less than or equal to the start of the shutdown. Similarly, all of the event points after the intermediate event point have a lower bound placed on the starting and finishing times of tasks to be greater than or equal to the end of the shutdown. Note that the intermediate event point is unit specific and is determined so that there are approximately the same number of event points before and after the shutdown while excluding event points that already have tasks assigned to them.

**Reactive Scheduling of Batch Processes, Table 4**  
Tasks to fix in case 1

Unit	Task	Event Point
Type 1-1	R_P160	N1
Type 1-2	R_P26	N2
Type 1-3	R_P105	N1
Type 1-4	R_P89	N1, N3, N5
Type 1-5	R_P107	N4
Type 1-6	R_P89	N1, N3, N5
Type 1-7	R_P89	N1, N4, N7
Type 1-8	R_P171	N1
	R_P26	N7
Type 1-9	R_P26	N2
	R_P98	N7
Type 1-10	R_P26	N2
Type 1-11	R_P209	N3
	R_P423	N5
Type 1-12	R_P181	N1
Type 1-13	R_P181	N1

Reactive Scheduling of Batch Processes, Figure 6

Reactive production schedule for the processing units in the first horizon from case 1

**Reactive Scheduling of Batch Processes, Table 5**  
**Bounds on timing in units in case 1**

Unit	Fixed Event Points	Bounds
Type 1-3	N1	$ts(i, j, n), tf(i, j, n) \leq 24$ for N2, N3, N4, N5 $ts(i, j, n), tf(i, j, n) \geq 48$ for N6, N7, N8, N9
Type 1-5	N4	$ts(i, j, n), tf(i, j, n) \leq 36$ for N1, N2, N3, N5 $ts(i, j, n), tf(i, j, n) \geq 72$ for N6, N7, N8, N9
Type 1-11	N3, N5	$ts(i, j, n), tf(i, j, n) \leq 48$ for N1, N2, N4, N6 $ts(i, j, n), tf(i, j, n) \geq 72$ for N7, N8, N9

Thus, considering the nominal production schedule for the first time horizon, the bounds shown in Table 5 are placed for each of the units which experience a shutdown.

Then, fixing the above sets of tasks from Table 4 and imposing the bounds defined in Table 5, we obtain a reactive production schedule which excludes production in the affected units during the shutdown periods and maintains all of the production that has already taken place. The reactive schedule for this example can be seen in Fig. 6. Note that once a reactive schedule is obtained for the first time horizon which incorporates the unit shutdown information, the subsequent horizons must each rescheduled from scratch due to the changes in inventory, demand satisfaction, and unit availability.

## Conclusions

In this chapter, we presented a reactive scheduling framework which provides an immediate response to unexpected events such as equipment breakdown or the addition or modification of orders. The reactive scheduling formulation takes into account the schedule currently in progress as well as planned productions that are not affected by the unexpected event. The proposed mathematical framework utilizes an efficient MILP mathematical framework developed for short-term scheduling problems with modifications introduced to reflect the effects of the unforeseen event. To avoid full rescheduling of the current production schedule, the formulation determines tasks which are not affected by the unforeseen event, either directly or indirectly, and can be carried out as scheduled. The resulting tasks along with additional subsets of tasks are then fixed in the MILP problem and the rest of

the horizon is rescheduled. We considered two types of unexpected events: unit shutdown and the addition or modification of orders, as well as their combination. All the cases of unexpected events utilize the nominal production schedule, the original MILP formulation for short-term scheduling with modifications, and a program to determine which tasks may be fixed before rescheduling. The formulation is then able to determine an updated production schedule for the remaining time horizon in a reasonable amount of CPU time. Reactive scheduling of a large-scale industrial batch plant was performed to demonstrate the effectiveness of the proposed approach. Results indicate that the reactive scheduling framework is capable of determining updated production schedules to account for unexpected events and can also be used to improve existing production schedules.

Redundancy; Minimal representation

A typical *nonlinear program* is to find a point in a *feasible region* that will minimize an *objective function*. The feasible region is often represented by a finite set of algebraic inequalities called *constraints*. If a constraint can be removed from the set without causing a change to the feasible region it is said to be *redundant* with respect to the remaining constraints. A constraint that is not redundant is said to be *nonredundant*, *irredundant*, or *necessary*.

A more formal definition requires some notation. Let  $R \subseteq \mathbf{R}^n$  denote a nonempty feasible region. The set of constraints indexed by  $I = \{1, \dots, m\}$  is given by  $G(I) = \{g_i \leq 0 : i \in I\}$ , where  $g_i(x) : \mathbf{R}^n \rightarrow \mathbf{R}$ , and the region determined by  $G(I)$  is  $R(I) = \{x : g_i(x) \leq 0, i \in I\}$ . Suppose that  $R = R(I)$ . We then call  $G(I)$  a *representation* of  $R$ . The  $k$ th inequality constraint ' $g_k(x) \leq 0$ ' is redundant with respect to  $G(I_k)$  if  $R(I_k) = R(I)$ , where  $I_k = I - \{k\}$ . Further definitions, such as those for *relatively redundant constraints*, *weakly necessary constraints*, etc., can be found in [3,5].

Of course, there can be more than one redundant constraint. If  $\hat{I}$  is a proper subset of  $I$ , and if  $R(\hat{I}) = R(I)$ , the constraint set  $G(\hat{I})$  is called a *reduction* of  $G(I)$ . Further,  $G(\hat{I})$  is called a *common dependency set* for the set of redundant constraints  $G(I - \hat{I})$  [8]. If all the constraints in  $G(\hat{I})$  are nonredundant, then  $G(\hat{I})$  is called a *prime representation* of the feasible region. A related concept is that of a *minimal representation*.

For linear constraints, i. e., when  $g_i(x) = a_i^\top x - b_i$ , where  $a_i \in \mathbf{R}^n$  and  $b_i \in \mathbf{R}$ , a minimal representation is one having the fewest constraints. In [11] it is proved that a representation is minimal if and only if it con-

tains no redundant constraints and no *implicit equality constraints*. The constraint ' $g_k(x) \leq 0$ ' is an implicit equality in  $G(I)$  if  $g_k(x) = 0$  for all  $x \in R(I)$ . In order to obtain a minimal representation the implicit equalities must first be replaced with explicit equalities, and then the redundant constraints must be removed one at a time. (The definition of redundancy is easily modified to include equality constraints.)

For the quadratic case, i. e., when  $g_i(x) = a_i^\top x + (1/2) x^\top H_i x - b_i$ , where the  $H_i$  are symmetric, positive definite matrices, a minimal representation is defined as one having the least number of quadratic constraints, and, among those with the same number of quadratic constraints, the least number of linear constraints. It was proved in [10] that a representation was minimal if and only if it contained no redundant constraints, no implicit equality constraints, and no pseudoquadratic constraints. A *pseudoquadratic constraint* is one that can be replaced by a finite number of linear constraints without causing a change to the feasible region. For example, since  $\{x \in \mathbf{R}^2 : x_2 = 0, x_1^2 + x_2^2 \leq 1\}$  equals  $\{x \in \mathbf{R}^2 : x_2 = 0, -1 \leq x_1 \leq 1\}$ , the constraint ' $x_1^2 + x_2^2 \leq 1$ ' was pseudoquadratic.

Algorithms used to detect redundant constraints can usually be classified as either deterministic methods or probabilistic methods. The *deterministic methods* are optimization based. Consider the nonlinear program  $\max \{g_k(x) : x \in R(I_k)\}$ . If there is no solution; that is, if the program is either *unbounded* or *infeasible* ( $R(I_k) = \emptyset$ ), then it follows from the definition of redundancy that the  $k$ th constraint is necessary. Otherwise the program has a solution  $x^*$ . If  $g_k(x^*) > 0$ , then again the  $k$ th constraint is necessary, and if  $g_k(x^*) \leq 0$ , the constraint is redundant. This method can work quite well in the linear case [6,9] as each of the constraints can be classified by solving a *linear program*. Consequently, for the linear case, the redundancy problem is polynomial. The importance of redundancy detection to the solution of large sparse linear programs is discussed in [1]; and the importance of redundancy detection for model analysis is discussed in [7]. For the nonlinear case, this approach has the drawback that it requires the solution of nonconvex programs. For example, if all the constraint functions are convex, then  $\max \{g_k(x) : x \in R(I_k)\}$  is a nonconvex program.

An alternative to the deterministic, optimization based methods are the *probabilistic methods*. The first

such method, which became known as the *hyperspheres direction hit and run* method was introduced in [4]. (A description of the method can be found in [9].) This technique generates a sequence of random lines that pass through the feasible region. The lines are generated as follows. A given feasible point  $x \in R$  and a direction  $s$ , sampled from a uniform distribution over the surface of the unit hypersphere, determines the line  $\{x + \sigma s : \sigma \in \mathbf{R}\}$ . The next feasible point is sampled uniformly from the feasible segment of the line. Note that in order to determine the feasible line segment the intersection points of the line with all the constraint boundaries must be calculated. Under appropriate assumptions, the constraints hit by the feasible line segment are nonredundant. This technique requires a *stopping rule* after which all constraints that have not been hit are classified, possibly with error, as redundant. The main advantages of hit and run methods are that they can very quickly identify most of the necessary constraints, and that they can be applied to a large class of nonlinearly constrained regions. The main disadvantages are the need for an initial feasible point, and the need to calculate the intersection points.

For general nonlinear programs it may well be that neither the deterministic nor the hit and run methods are applicable. For these problems, there is an algorithm [2] based on a connection between the redundancy problem and the constraints in a *set covering problem*. This method only requires that for any  $x \in \mathbf{R}^n$  it can be determined if  $g_i(x)$  is negative or nonnegative. In fact, the method does not even require a nonempty feasible region. This technique is probabilistic in that it samples points from  $\mathbf{R}^n$ . Each point that is sampled is used to generate an  $m$ -bit binary word whose  $k$ th bit is unity if and only if the  $k$ th constraint is violated at that point. Upon termination of the sampling process, the collection of all the generated binary words form the rows of a set covering matrix  $E$  having  $m$  columns, one corresponding to each constraint. Let  $y$  be a nontrivial feasible solution to the set-covering problem, i. e.,  $Ey \geq e$ , where  $e$  is a vector of 'ones', and where  $y$  has at least one zero component. Then  $G(\hat{I})$  is a reduction of  $G(I)$ , where  $i \in \hat{I}$  if and only if  $y_i = 1$ . An objective function can be introduced to the set-covering problem so that any set covering heuristic can be used to find an approximately minimal representation. Here the definition of minimal will depend on the choice of objec-

tive. The main disadvantage to the approach is the need to generate the set covering rows. The main advantage is its general applicability.

relaxations

Discrete and continuous nonconvex programming problems arise in a host of practical applications in the context of production planning and control, location-allocation, distribution, economics and game theory, quantum chemistry, and process and engineering design situations. Several recent advances have been made in the development of branch-and-cut type algorithms for mixed-integer linear and nonlinear programming problems, as well as polyhedral outer-approximation methods for continuous nonconvex programming problems. At the heart of these approaches is a sequence of linear (or convex) programming relaxations that drive the solution process, and the success of such algorithms is strongly tied in with the strength or tightness of these relaxations.

The *Reformulation-Linearization-Technique* (RLT) is a method that generates such tight linear programming relaxations for not only constructing exact solution algorithms, but also to design powerful heuristic procedures for large classes of discrete combinatorial and continuous nonconvex programming problems. Its development originated in [4,5,6], initially focusing on 0-1 and mixed 0-1 linear and polynomial programs [21,22], and later branching into the more general family of continuous, nonconvex polynomial programming problems [18,45,49]. For the family of mixed 0-1 linear (and polynomial) programs in  $n$  0-1 variables, the RLT generates an  $n$ -level hierarchy, with the  $n$ -th level providing an explicit algebraic characterization of the convex hull of feasible solutions [21,22]. The RLT essentially consists of two steps—a reformulation step in which certain additional nonlinear valid inequalities are automatically generated, and a linearization step in which each product term is re-

placed by a single continuous variable. The level of the hierarchy directly corresponds to the degree of the polynomial terms produced during the reformulation stage. Hence, in the reformulation phase, given a value of the level  $d \in \{1, \dots, n\}$ , the RLT constructs various polynomial factors of degree  $d$  comprised of the product of some  $d$  binary variables  $x_j$  or their complements  $(1 - x_j)$ . These factors are then used to multiply each of the defining constraints in the problem (including the variable bounding restrictions), to create a (nonlinear) polynomial mixed-integer zero-one programming problem. Suitable additional constraint-factor products can be used to further enhance the procedure. In general, for a variable restricted to lie in the interval  $[l_j, u_j]$ , the nonnegative expressions  $(x_j - l_j)$  and  $(u_j - x_j)$  are referred to as *bound-factors*, and for a structural inequality  $\alpha x \geq \beta$ , for example, the expression  $(\alpha x - \beta)$  is referred to as a *constraint-factor*; implied product constraints can be generated using either bound-factors or constraint-factors. After using the relationship  $x_j^2 = x_j$  for each binary variable  $x_j$ ,  $j \in \{1, \dots, n\}$ , which in effect accounts for the tightening of the relaxation, the linearization phase substitutes a single variable  $w_j$  (respectively,  $v_{jk}$ ), in place of each nonlinear term of the type  $\prod_{j \in J} x_j$  (respectively,  $y_k \prod_{j \in J} x_j$ ), where  $y$  represents the set of continuous variables. Hence, relaxing integrality, the nonlinear polynomial problem is linearized into a higher dimensional polyhedral set  $X_d$  defined in terms of the original variables  $(x, y)$  and the new variables  $(w, v)$ . Denoting the projection of  $X_d$  onto the space of the original  $(x, y)$ -variables as  $X_{P_d}$ , it is shown that as  $d$  varies from 1 to  $n$ , we get,

$$X_{P_0} \supseteq X_{P_1} \supseteq X_{P_2} \supseteq \dots \supseteq X_{P_n} = \text{conv}(X),$$

where  $X_{P_0}$  is the ordinary linear programming relaxation, and  $\text{conv}(X)$  represents the convex hull of the original feasible region  $X$ . An extension of this development to the case of general integer/discrete variables is presented in [7,25], where the bound-factors are replaced by suitable Lagrange interpolating polynomials, and a further extension to 0-1 mixed-integer as well as general mixed-discrete semi-infinite and bounded convex programming problems is presented in [26] (see also [50]). Lovasz and Shrijver [16] and Boros et al. [9] have also independently developed various concepts related to the RLT process. This RLT

process has also been extended and enhanced in [27] through the use of more generalized constraint-factors that imply the bounding restrictions  $0 \leq x_j \leq 1$  for  $j \in \{1, \dots, n\}$ . A similar hierarchy of relaxations leading to the convex hull representation is obtained based on the use of these generalized factors in the reformulation phase, in lieu of simply the bound-factors  $x_j$  and  $(1 - x_j)$ , for  $j \in \{1, \dots, n\}$ . In addition, this hierarchy embeds within its construction stronger logical implications than only  $x_j^2 = x_j$ ,  $\forall j \in \{1, \dots, n\}$ . For example, consider an RLT constraint that has been generated by taking the product of some nonnegative polynomial factor  $F$  with a defining constraint  $\gamma^\top x \geq \delta$  to yield  $[F(\gamma^\top x - \delta)]_L \geq 0$ , where  $[\cdot]_L$  denotes the linearization of the polynomial expression  $[\cdot]$  under the RLT substitution process. Then, this constraint can be tightened by deriving a stronger valid inequality of the type  $\hat{\gamma}^\top x \geq \hat{\delta}$  under the condition that  $F > 0$ , and then imposing the RLT constraint  $[F(\hat{\gamma}^\top x - \hat{\delta})]_L \geq 0$ , which is valid whenever  $F = 0$  or  $F > 0$ . The resulting overall RLT process is shown in [27] to not only subsume the previous development, but also provide the opportunity to exploit frequently-arising special structures such as generalized/variable upper bounds, covering, partitioning, and packing constraints, as well as sparsity.

The hierarchy of higher-dimensional representations produced in this manner markedly strengthens the usual continuous relaxation, as is evidenced not only by the fact that the convex hull representation is obtained at the highest level, but that in computational studies on many classes of problems, even the first level representation helps design algorithms that significantly dominate existing procedures in the literature [4,6,20,27,30,41]. Based on a special case of the RLT process that employs the bound-factors for only a single variable at a time, Balas et al. [8] describe a *lift-and-project* cutting plane algorithm that is shown to produce encouraging results. The theoretical implications of this hierarchy are noteworthy; the resulting representations subsume and unify many published linearization methods for nonlinear 0-1 programs, and the algebraic representation available at level  $n$  promotes new methods for identifying and characterizing facets and valid linear inequalities in the original variable space, as well as for providing information that directly bridges the gap between discrete and contin-

uous sets [3,38,40]. Indeed, since the level- $n$  formulation characterizes the convex hull, all valid inequalities in the original variable space must be obtainable via a suitable projection; thus such a projection operation serves as an all-encompassing tool for generating valid inequalities. References [38,40] provide discussions on generating facets and tight valid inequalities for several classes of problems. Reference [3] discusses persistency issues for certain constrained and unconstrained pseudo-Boolean programming problems whereby variables that take on 0-1 values at an optimum to an RLT relaxation would persist to take on these same values at an optimum to the original problem. References [1,2,13,34,39,42], respectively discuss the use of RLT to generate improved model representations for the set partitioning, quadratic assignment, traveling salesman problems, and to 0-1 mixed-integer programs subject to various assignment constraints.

Although the Reformulation-Linearization Technique was originally designed to employ factors involving 0-1 variables in order to generate 0-1 (mixed-integer) polynomial programming problems that are subsequently re-linearized, the approach has also been extended to solve continuous, bounded variable polynomial programming problems. Problems of this type involve the optimization of a polynomial objective function subject to polynomial constraints in a set of continuous, bounded variables, and arise in numerous applications in engineering design, production, location, and distribution problems. Reference [45] prescribes an RLT process that employs suitable polynomial-factors (bound-factors based on bounding restrictions  $l_j \leq x_j \leq u_j$ ,  $j \in \{1, \dots, n\}$ , as well as constraint factors) to generate additional polynomial constraints through a multiplication process, which upon linearization through variable redefinitions as above, produces a linear programming relaxation. The resulting relaxation is used in concert with a suitable designed partitioning technique that attempts to reduce the error between the original nonlinear and their resulting linearized terms, in order to develop an algorithm that is proven to converge to a global optimum for this problem. Special classes of polynomial constraints based on grid factors, Lagrange interpolating polynomials, and mean value theorem constraints can be generated to further tighten these RLT relaxations [48]. In some cases (e.g., see [47]), it is benefi-

cial to retain certain simple convex constraints in the relaxation, resulting in a more general *Reformulation-Linearization/Convexification Technique*. Additionally, Serali and Fraticelli [35] have proposed a class of semidefinite cuts based on semidefinite relaxation enhancements that can be used to significantly tighten RLT representations. While RLT essentially operates on polynomial functions having integral exponents, many engineering design applications lead to polynomial programs having general rational exponents. For such problems, a global optimization technique has been designed [18] by introducing a new level of approximation at the reformulation step, and accordingly, redesigning the partitioning scheme in order to induce the overall sequence of relaxations generated to become exact in the limit. Further extensions for solving nonlinear factorable programs for which the objective and constraint functions involve sums of products of univariate functions have also been developed [49]. Here, suitable under/over-approximating nonconvex polynomial functions are derived for the defining univariate functions in the problem, and then an appropriate partitioning scheme is devised that drives the errors from these approximations and those for the RLT process applied to the resulting polynomial program simultaneously to zero in the limit, in order to obtain a global optimum for the given factorable program. For nonconvex programs that are defined in terms of black-box functions, a new concept of a pseudo-global RLT approach has been developed by Serali and Ganesan [36], which has been successfully applied to the design of containerships.

A special application of the RLT to mixed-integer quadratic problems subject to linear equality constraints that yields exact reformulations having fewer quadratic terms and some additional supporting RLT constraints has been developed to produce tighter convex relaxations [10,11,12,14,15]. More precisely, we multiply a subset of equality constraints  $Ax = b$  by an appropriate subset of problem variables  $\{x_k \mid k \in K\}$ , to obtain a *reduced RLT system*  $\forall k \in K(Aw_k = bx_k)$ , where  $w_k \equiv (x_k x_1, \dots, x_k x_n)$  for all  $k \in K$ . This is equivalent to the homogeneous linear system  $\forall k \in K(Az_k = 0)$  where  $z_k = (w_{k1} - x_k x_1, \dots, w_{kn} - x_k x_n)$ , which may be written in a more compact way as  $A'z = 0$ . If we partition  $A'$  into basic and non-basic submatrices  $B, N$ , and accordingly partition  $z$  into

$z_B$  and  $z_N$ , we have  $(B|N)z = 0$ , whence  $Nz_N = 0$  implies that  $Bz_B = 0$ . We therefore conclude that enforcing the reduced RLT system and the subset of quadratic relations  $w_{ki} = x_k x_i$  for  $(k, i)$  corresponding to nonbasic columns of  $N$  is enough to infer  $w_{ki} = x_k x_i$  for all  $(k, i)$ . In other words, by letting the RLT process ensure that  $z_N = 0$ , we automatically obtain as an implication of the RLT linearized constraints that the quadratic relation  $z_B = 0$  will hold true as well.

For the continuous case, there exist special instances where RLT can produce convex hull or convex envelope representations [17,28]. Various classes of applications have been studied for which specialized RLT designs have been used to develop enhanced effective algorithms. This list, which is ever expanding, includes bilinear programming problems [15,28], general indefinite quadratic programming problems [12,13,47], location-allocation problems employing different distance metrics [20,29,41,46], water distribution network design problems [43,44], the solution of Hartree-Fock equations in quantum chemistry [14], the linear complementarity problem [37], and hard and fuzzy clustering problems [31,32]. References [11,19,23,24,25,33] provide expository discussions and a survey of RLT theory and applications.

Regression; Best fit; Estimate; Isotonic regression; Quasiconvex regression; Umbrella regression; Convex regression; Concave regression; Least squares distance function; Mean absolute deviation; Maximum absolute deviation; Algorithms; Computational complexity; Pool adjacent violators algorithm; Greatest convex minorant; Greatest quasiconvex minorant; Isotone functions; Monotone function

Consider the following general problem of regression. Given  $n$  measurements or observations  $f = (f_1, \dots, f_n) \in \mathbf{R}^n$  with  $f_i = \mu_i + \eta_i$ , where  $\mu = (\mu_1, \dots, \mu_n)$  is unknown but is in some predefined subset  $K$  of  $\mathbf{R}^n$ , and  $\eta_i$  is the noise generated by sampling, it is required to find a *best fit* or an *estimate*  $g$  of  $\mu$ . The set  $K$  is dictated by the underlying system which generates  $f$ . A best fit or an optimal solution  $g$  is obtained by minimizing a suitable distance function  $d(f, g)$  subject to  $g \in K$ . If  $w = (w_1, \dots, w_n) > 0$  is a given weight function, we use the following distance functions in our analysis:

$$d_\infty(f, g) = \max \{w_i |f_i - g_i| : 1 \leq i \leq n\},$$

$$d_1(f, g) = \sum \{w_i |f_i - g_i| : 1 \leq i \leq n\},$$

$$d_2(f, g) = \sum \{w_i (f_i - g_i)^2 : 1 \leq i \leq n\}.$$

Note that  $(d_2(f, g))^{1/2}$  and not  $d_2(f, g)$  is a distance function in that it satisfies the well known triangle inequality. Let the primed entries  $d_\infty'(f, g)$ ,  $d_1'(f, g)$  and  $d_2'(f, g)$  denote the corresponding distances when  $w_i = 1$  for all  $i$ . As will be seen later that the results for the two sets of distances are different. We call  $f, g, w$  etc. ‘functions’ because they may be considered as such on some underlying set  $S = \{x_1, \dots, x_n\}$ , where  $f_i = f(x_i)$ ,  $g_i = g(x_i)$ ,  $w_i = w(x_i)$  etc. The best known example of a *regression* problem is the linear regression where  $K$  consists of linear functions given by  $g_i = a x_i + b$  with  $x_1 < \dots < x_n$ , and the numbers  $a$  and  $b$  are unknowns to be determined by minimizing  $d_2(f, g)$ . In this article we are concerned with the following three cases:  $K$  formed by

- isotone or monotone functions,
- quasiconvex and umbrella functions, and, finally
- convex and concave functions.

We develop algorithms to compute best fits and obtain their *computational complexity*. In most cases the algorithms are of *polynomial complexity*. Wherever possible we derive explicit expressions for best fits. Applications can be cited to problems in reliability engineering, economics, social sciences, *order restricted statistical inference* etc. [10,13,14,15,18,24]. For example, the failure rate of a system increases with the age of the system (isotonicity), the human mortality rate (or the number of auto accidents) first decreases and then increases with age (quasiconvexity), the efficiency of an organization first increases and then decreases with its size (quasiconcavity). Similarly, in economics assumptions of convexity/concavity are made about functions representing utility, marginal utility, productivity, supply, demand etc.

We briefly discuss the significance of different distance functions used in regression. In the classical approach to optimization and regression, the *least squares distance function*  $d_2(f, g)$  was extensively used. Its differentiability properties led to certain simplification of mathematical analysis. For some time now, both  $d_1(f, g)$  (*mean absolute deviation*) and  $d_\infty(f, g)$  (*maximum absolute deviation*) distance functions are being used. For example, see MINMAD and MINMADAX regression in [2] and the least absolute value (LAV) or  $L_1$ -norm estimation and  $L_\infty$ -norm estimation in [11]. See also [6]. If we write  $d_p(f, g) = \sum \{w_i |f_i - g_i|^p: 1 \leq i \leq n\}$ ,  $1 \leq p < \infty$ , then  $(d_p(f, g))^{1/p}$  is a distance function, and  $\|f\|_p = d_p(f, 0)^{1/p}$ ,  $1 \leq p < \infty$ , and  $\|f\|_\infty = d_\infty(f, 0)$  are, respectively, the  $L_p$  and  $L_\infty$  norms on  $\mathbf{R}^n$ . Both  $d_1$  and  $d_\infty$  distances have the strong advantage that their form allows transformation of the regression problem to a linear program which facilitates computation of its solution [2,19]. The nature of the problem essentially determines the choice of the distance function. Then the algorithms developed for the solution, their computational complexities and the properties of the best fits obtained, all in turn, depend on the distance function used.

### Isotonic Regression

A function  $g = (g_1, \dots, g_n) \in \mathbf{R}^n$  is called *isotonic* or *monotonic (nondecreasing)* if  $g_1 \leq \dots \leq g_n$ . We let  $K$  be the set of all isotonic functions and consider the *isotonic regression problem* of minimizing  $d_2(f, g)$  subject to  $g \in$

$K$ . Since  $d_2(f, g)$  is strictly convex in  $g$  and  $K$  is a closed convex cone, the solution of this problem is unique. ( $K$  is a cone if  $\lambda h \in K$  whenever  $h \in K$  and  $\lambda \geq 0$ .)

We describe the *pool adjacent violators algorithm* (PAV) for computing the solution. See [24] and other references given there. The form presented below appears in [5]. Let  $N = \{1, \dots, n\}$ . A *partition*  $J$  of  $N$  is a decomposition of  $N$  into disjoint sets of consecutive integers such that their union is  $N$ . Each member of  $J$  is called a *block* and is denoted by  $B$ . We let  $\Delta_B(c) = \sum \{w_i (f_i - c)^2: i \in B\}$ . We let  $g_i(J)$  be any  $n$ -vector whose  $i$ th coordinate  $g_i(J)$ ,  $i \in N$ , is given by  $g_i(J) = \mu_B$ , where  $B$  is the unique block of  $J$  containing  $i$  and  $\mu_B$  is the minimizer of  $\Delta_B$ . Clearly,  $g_i(J)$  has identical values for all  $i$  in a block. Also  $\mu_B$  equals the 'block average'  $\sum \{w_i f_i: i \in B\} / \sum \{w_i: i \in B\}$ . The PAV algorithm starts with the finest partition whose blocks are single integers in  $N$  and an initial infeasible solution  $g$  violating the constraint  $g_1 \leq \dots \leq g_n$ . It successively merges blocks to reduce infeasibility and obtains a new coarser partition  $J$  and an infeasible solution  $g(J)$ . It terminates when  $g(J)$  becomes feasible obtaining the optimal solution and the final optimal partition. Let  $B = \{p, \dots, q\}$ ,  $1 \leq p \leq q \leq n$ , denote a block of a partition  $J$  during any iteration of the algorithm. The predecessor and successor blocks of  $B$ , denoted respectively by  $B^-$  and  $B^+$ , of the same partition  $J$ , are defined as follows: If  $p > 1$ , then  $B^-$  is the block containing  $p - 1$ , otherwise  $B^- = \emptyset$ . Similarly, if  $q < n$ , then  $B^+$  is the block containing  $q + 1$ , otherwise  $B^+ = \emptyset$ .

It can be shown that [4,21] the algorithm is of linear time complexity ( $O(n)$ ) in the usual unit cost RAM model [1]. We now describe an interesting implementing of the algorithm [21]. Let  $W_i = \sum \{w_j: 1 \leq j \leq i\}$  and  $F_i = \sum \{w_j f_j: 1 \leq j \leq i\}$  with  $W_0 = F_0 = 0$ . Clearly,  $W_{i-1} < W_i$ . By plotting the  $n + 1$  points  $P_i = (W_i, F_i)$ ,  $0 \leq i \leq n$ , in the plane we obtain the *cumulative sum diagram* (csd). Note that the slope of the line segment joining  $P_{i-1}$  and  $P_i$  is  $f_i$ . Let  $Q_i = (W_i, G_i)$ , be the *greatest convex minorant* (gcm) or the *lower convex hull* of the csd. This is the largest convex function which does not exceed the csd at any point. It is easy to see that  $P_0 = Q_0$  and  $P_n = Q_n$ . Also since the gcm is convex, the slopes  $(G_i - G_{i-1})/(W_i - W_{i-1})$  are nondecreasing. It has been shown that  $g_i = (G_i - G_{i-1})/(W_i - W_{i-1})$ ,  $1 \leq i \leq n$ , give an optimal solution to the *isotonic regression* problem. Graham's scan [12] can be easily modi-

```

Initialization: Set  $J = \{\{i\} : i \in N\}$ ;
compute the minimizer  $\mu_B$  of  $\Delta_B$ ,  $B \in J$ 
(if  $B = \{i\}$ , then  $\mu_B = f_i$ ).
Set  $B = \{1\}$ ,  $B+ = \{2\}$ ,  $B- = \emptyset$ ;
WHILE  $B+ \neq \emptyset$ 
  IF  $\mu_B > \mu_{B+}$  THEN
    merge  $B$  and  $B+$ 
    (i.e. set  $J = J \setminus \{B, B+\} \cup \{B \cup B+\}$  and
     $B = B \cup B+$ );
    compute the new  $\mu_B$ ;
    set  $B+$  appropriately
    ( $B-$  remains unchanged);
  WHILE  $B- \neq \emptyset$  and  $\mu_{B-} > \mu_B$ 
    merge  $B$  and  $B-$ 
    (i.e. set  $J = J \setminus \{B, B-\} \cup \{B \cup B-\}$ 
    and  $B = B \cup B-$ );
    compute the new  $\mu_B$ ;
    set  $B-$  appropriately
    ( $B+$  remains unchanged);
  END WHILE
ELSE set  $B = B+$ ;
  set  $B-$  and  $B+$  appropriately;
END IF
END WHILE
 $x_i(J) = \mu_B$ ,  $i \in B \in J$ , is an optimal solution

```

### Regression by Special Functions: Algorithms and Complexity, Algorithm 1

#### Algorithm PAV (pool adjacent violators)

fied to obtain the gcm in  $O(n)$  time. See e. g. [28]. Thus the overall algorithm is again  $O(n)$ . The treatment and the results for  $d_2'$  are identical to those of  $d_2$ .

Now consider the problem of *isotonic medium regression* which is the problem of minimizing  $d_1'$  ( $f, g$ ) subject to  $g \in K$  [7,23]. The PAV algorithm can be applied to this problem with  $\Delta_B(c) = \sum \{|f_i - c| : i \in B\}$ . A minimizer  $\mu_B$  of  $\Delta_B$  can be easily shown to be a median of the set  $\{f_i : i \in B\}$ . We choose  $\mu_B$  to be the central medium of the set  $\{f_i : i \in B\}$  defined as follows. For an ordered (ascending)  $\{c_1, \dots, c_r\}$ , it is  $c_{(r+1)/2}$  if  $r$  is odd, and

$$\frac{c_{\frac{r}{2}} + c_{\frac{r}{2}+1}}{2}$$

if  $r$  is even. (If  $r$  is even, then both the lower and upper mediums,  $c_{r/2}$  and  $c_{r/2+1}$ , or any point in be-

tween the two, minimize  $\Delta_B(c)$ . The nonuniqueness of the medium is addressed later.) The PAV algorithm with this choice of the central medium is of complexity  $O(n^2)$ , since the median of an unordered set of cardinality  $r$  can be computed in linear time  $O(r)$  ([1, Algorithm 3.6]). Now consider minimizing  $d_1(f, g)$ . In this case, let  $\Delta_B(c) = \sum \{w_i |f_i - c| : i \in B\}$ , whose minimizer  $\mu_B$  is a weighted median of the set  $\{f_i : i \in B\}$ . Again it is not unique. We use the unique weighted central medium of an ordered (ascending) set  $\{c_1, \dots, c_r\}$  with weight  $w_i$  for  $c_i$  defined as follows. Let  $\lambda = \sum \{w_i : 1 \leq i \leq n\}$ . The central median is  $c_q$  if  $\sum \{w_i : 1 \leq i \leq q-1\} < \lambda/2 < \sum \{w_i : q \leq i \leq r\}$  for some  $q$ . It is  $(c_{q-1} + c_q)/2$  if  $\sum \{w_i : 1 \leq i \leq q-1\} = \lambda/2$  (As before both the lower and upper mediums,  $c_{q-1}$  and  $c_q$ , or any point in between the two, minimize  $\Delta_B(c)$ ). Again it can be computed in linear time by extending ([1, Algorithm 3.6]) to the weighted case. It will be seen that the ratio  $\max \{w_i\} / \min \{w_i\}$  plays an important role in analysis. The PAV algorithm for this case is of complexity  $O(n^2)$ . Now consider the nonuniqueness of the medium. We may use the lower or upper medium for  $\mu_B$  in the PAV algorithm since both minimize  $\Delta_B(c)$ . When we consistently use the lower (resp. upper) medium in the algorithm for  $d_1$  or  $d_1'$ , we get the minimal (resp. maximal) optimal solution to the problem. This has been established in [5] for a general case of minimizing a separable convex function subject to the monotonicity constraint. This problem includes, as special cases, the isotonic regression with distances  $d_1$  and  $d_2$ , and other situations such as in [25,26]. Now consider the problem of *isotone optimization*, i. e., minimizing  $d_\infty$  and  $d_\infty'$  [27]. Define  $t_{ij} = w_i w_j / (w_i + w_j)$  and  $\theta = \max \{t_{ij} (f_i - f_j) : 1 \leq i < j \leq n\}$ . Define two isotonic functions  $\underline{g}$  and  $\bar{g}$  by  $\underline{g}_i = \max \{f_j - \frac{\theta}{w_j} : 1 \leq j \leq i\}$ ,  $\bar{g}_i = \min \{f_j + \frac{\theta}{w_j} : i \leq j \leq n\}$ ,  $1 \leq i \leq n$ . Then both  $\underline{g}$  and  $\bar{g}$  are optimal solutions to isotone optimization with distance function  $d_\infty$  and  $\theta = d_\infty(f, \underline{g}) = d_\infty(f, \bar{g})$ . Furthermore, a monotonic  $g$  is an optimal solution if and only if  $\underline{g} \leq g \leq \bar{g}$ . The computation of the solution clearly takes  $O(n^2)$  time. The above results are also valid for  $d_\infty'$ , but in this case the results can be simplified and an  $O(n)$  algorithm for the computation can be obtained (28, [Sect. 6]). Define  $\underline{k}_1 = f_1$ ,  $\underline{k}_i = \max\{\underline{k}_{i-1}, f_i\}$ ,  $i = 2, \dots, n$ , and  $\bar{k}_n = f_n$ ,  $\bar{k}_i = \min\{\bar{k}_{i+1}, f_i\}$ ,  $i = n-1, n-2, \dots, 1$ . Let  $\theta = \frac{d'_\infty(f, \underline{k})}{2} = \frac{d'_\infty(f, \bar{k})}{2}$ . Then

$g_i = \underline{k}_i - \theta$  and  $\bar{g}_i = \bar{k}_i + \theta$ . Clearly, the algorithm is  $O(n)$ . For isotonic regression problems with integer constraints see [10] and [18].

### Quasiconvex and Umbrella Regression

A function  $g = (g_1, \dots, g_n) \in \mathbf{R}^n$  is called *quasiconvex* if  $g_i \leq \max\{g_p, g_q\}$  holds for all  $i$  with  $p \leq i \leq q$  for all  $1 \leq p \leq q \leq n$  [22]. A  $g$  is called *quasiconcave* or *umbrella* if  $-g$  is quasiconvex. It can be shown that  $g \in \mathbf{R}^n$  is quasiconvex if and only if there exists an index  $r$ ,  $1 \leq r \leq n$ , such that  $g_1 \geq \dots \geq g_r \leq g_{r+1} \leq \dots \leq g_n$ . (Thus  $g_r = \min\{g_i: 1 \leq i \leq n\}$ .) [8,29]. If  $r = 1$  (resp.  $n$ ), then  $g$  is nondecreasing (resp. nonincreasing). Similar results may be stated for a quasiconcave function. In what follows we discuss regression by quasiconvex functions, the results for quasiconcave functions are symmetric. The quasiconvex problem can be transformed into  $2n$  isotonic subproblems by the observation made above. Let  $K$  denote the set of all quasiconvex  $g$ , and let  $K_r$  denote all  $g = (g_1, \dots, g_n)$  with  $g_1 \geq \dots \geq g_r$  and  $g_{r+1} \leq \dots \leq g_n$ , where  $1 \leq r \leq n$ . Note that  $K_r$  is the set of all quasiconvex  $g$  such that  $g_r$  or  $g_{r+1}$  equals  $\min\{g_i: 1 \leq i \leq n\}$ . Clearly,  $K = \cup\{K_r: 1 \leq r \leq n\}$ . It is easy to see that  $K$  is a closed cone which is not convex, although  $K_r$ , for each fixed  $r$ , is a closed convex cone. Hence optimal solutions obtained in this section are not necessarily unique. To solve the quasiconvex Regression problem of minimizing  $d_2(f, g)$  subject to  $g \in K$ , we consider the following two subproblems for each  $r$ :

- $P1_r$ : Find  $g_i$ ,  $1 \leq i \leq r$ , and  $\Delta 1_r$  so that  $\Delta 1_r = \min \sum \{w_i (f_i - g_i)^2: 1 \leq i \leq r\}$  subject to  $g_1 \geq \dots \geq g_r$ ; and
- $P2_r$ : Find  $g_i$ ,  $r+1 \leq i \leq n$ , and  $\Delta 2_r$  so that  $\Delta 2_r = \min \sum \{w_i (f_i - g_i)^2: r+1 \leq i \leq n\}$  subject to  $g_{r+1} \leq \dots \leq g_n$ .

We then minimize  $\Delta 1_r + \Delta 2_r$  subject to  $1 \leq r \leq n$ . Note that both  $P1_r$  and  $P2_r$  are isotonic regression problems. They can be solved in  $O(r)$  and  $O(n-r)$  time respectively, using the PAV algorithm of the previous section. Thus, the quasiconvex regression problem can be solved in  $O(n^2)$  time. We have shown in [31] that the complexity can be improved to  $O(n)$  by using special mathematical results and suitable data structures. Our algorithm uses one forward and one backward pass on indexes  $1, \dots, n$  to obtain the unique optimal solutions of both  $P1_r$  and  $P2_r$  and the values of  $\Delta_r = \Delta 1_r$  and

$\Delta 2_r$  for all  $r$ . Although we use Graham's scan and the gcm discussed in the previous section to compute the solutions of the isotonic regression subproblems  $P1_r$  and  $P2_r$ , alternative schemes without using the gcm can be easily devised. Another algorithm of unknown complexity appears in a later article [9]. Now consider the *quasiconvex medium regression* problem of minimizing  $d_1(f, g)$  subject to  $g \in K$ . We may consider problems  $P1_r$  and  $P2_r$ , as above where  $\sum w_i (f_i - g_i)^2$  is replaced by  $\sum w_i |f_i - g_i|$ . These isotonic medium regression problems can be solved in quadratic time giving an overall complexity of  $O(n^3)$ . Whether this complexity can be improved or not is an open issue at this time.

The strategy of transforming the quasiconvex problem into  $2n$  isotonic subproblems can also be used for  $d_\infty$ . Since each isotonic subproblem can be solved in  $O(n^2)$  time as for isotonic regression (see above), it may seem that the complexity of the quasiconvex problem is  $O(n^3)$ . A little reflection will show that the computations can be organized in  $O(n^2)$  time. Indeed, using the notation for isotonic regression above, the constants  $t_{ij}(f_i - f_j)$ ,  $1 \leq i \leq j \leq n$ , can be computed in  $O(n^2)$  time. Then the  $\theta$ 's needed for the subproblems can be computed recursively in  $O(n^2)$  time. The rest of the computations are  $O(n)$ . If  $d_\infty'$  is used, then the complexity can be improved to  $O(n)$ . Let  $f_m = \min\{f_i: 1 \leq i \leq n\}$ ,  $m$  is not unique. Define  $\underline{k}_m = f_m$ ,  $\underline{k}_i = \max\{\underline{k}_{i-1}, f_i\}$ ,  $i = m+1, m+2, \dots, n$ ,  $\underline{k}_i = \max\{\underline{k}_{i+1}, f_i\}$ ,  $i = m-1, m-2, \dots, 1$ ,  $\theta = \frac{d_\infty'(f, \underline{k})}{2}$  and  $\underline{g}_i = \underline{k}_i - \theta$ ,  $1 \leq i \leq n$ . Then  $\underline{g}$  is an optimal solution to the problem. Also, define  $\bar{k}_1 = f_1$ ,  $\bar{k}_i = \min\{\bar{k}_{i-1}, f_i\}$ ,  $i = 2, \dots, m-1$ ,  $\bar{k}_n = f_n$ ,  $\bar{k}_i = \min\{\bar{k}_{i+1}, f_i\}$ ,  $i = n-1, n-2, \dots, m+1$ ,  $\bar{k}_m = f_m$ ,  $\theta = \frac{d_\infty'(f, \bar{k})}{2}$  and  $\bar{g}_i = \bar{k}_i + \theta$ ,  $1 \leq i \leq n$ . Then  $\bar{k}$  is the *greatest quasiconvex minorant* of  $f$ , i. e., the largest quasiconvex function such that  $\bar{k}_i \leq f_i$  for all  $i$ , and  $\bar{g}$  is the maximal optimal solution to the problem. Clearly, the computations are  $O(n)$  [29]. This problem on an interval is considered in [30].

### Convex and Concave Regression

We consider functions  $f, g$  etc. on a set  $S = \{x_1, \dots, x_n\}$  so that  $f_i = f(x_i)$ ,  $g_i = g(x_i)$  etc. Then  $g$  is convex if  $(g_i - g_{i-1})/\delta_{i-1} \leq (g_{i+1} - g_i)/\delta_i$ ,  $2 \leq i \leq n-1$ , where  $\delta_i = x_{i+1} - x_i$ ,  $1 \leq i \leq n-1$ . These constraints are linear. If the points  $x_i$  are equally spaced, i. e., all  $\delta_i$  have identical values, then the convexity condition be-

comes  $g_{i+1} - 2g_i + g_{i-1} \geq 0$ ,  $2 \leq i \leq n-1$ . Let  $K$  be the set of all convex functions. Then  $K$  is a closed convex cone. We first consider the *convex regression problem* of minimizing  $d_2(f, g)(d_2'(f, g))$  subject to  $g \in K$ . Clearly, this is a quadratic programming problem where  $d_2$  ( $d_2'$ ) is a strictly convex function of  $g$ . Its solution is unique. The problem may be formulated as a linear complementarity problem and solved [3,20]. Special methods as in [16,17] and other references given there, may be applied. Some earlier work appears in [13,14]. Results on complexity analysis of algorithms for these problems, in general, are lacking. The problem with  $d_1$ ,  $d_1'$  or  $d_\infty$  distance function can be formulated as a linear programming problem [2,19] and solved. Now consider  $d_\infty'$ . Let  $\bar{k}$  be the greatest convex minorant of  $f$ , i. e., the largest convex function such that  $\bar{k}_i \leq f_i$  for all  $i$ . It may be easily computed in  $O(n)$  time using Graham's scan as for isotonic regression. Let  $\theta = \frac{d_\infty'(f, \bar{k})}{2}$  and  $\bar{g}_i = \bar{k}_i + \theta$ ,  $1 \leq i \leq n$ . Then  $\bar{g}$  is a solution to the problem computed in  $O(n)$  time. Indeed, it is the maximal optimal solution to the problem [28,32].

Since regression problems are indeed approximation problems, some of the results of [33] are applicable to our problems. In particular, note the significance of the dual cone of the cone  $K$  of isotone functions as stated in the last paragraph there.

### Projections

Projection methods have become a useful technique for solving the *convex feasibility problem*

$$(CFP) \quad \text{Find } x \in C,$$

where  $C$  is a closed, convex nonempty set defined in a Hilbert space  $H$  endowed with an inner product  $\langle \cdot, \cdot \rangle : H^2 \rightarrow \mathbf{R}$ , and the induced norm  $\|x\|^2 = \langle x, x \rangle$ .

Projection methods are iterative. Given  $x_i \notin C$ , the standard iterative scheme is

$$x_{i+1} = x_i + \omega_i(P_{S_i}(x_i) - x_i), \tag{1}$$

where  $S_i \supseteq C$  is a closed convex set,  $P_{S_i}(x_i)$  is the projection of  $x_i$  on the set  $S_i$ , and  $\omega_i \in \mathbf{R}$  is the relaxation parameter. If  $\omega_i < 1$  we call it an *underprojection*, and if

$\omega_i > 1$  we call it an *overprojection*. In general,  $0 < \eta \leq \omega_i \leq 2 - \eta$  is required to ensure convergence.

We attempt to present an overview of projection techniques. This section will cover the choice of the supersets  $\{S_i\}_1^\infty$ . Next section will study the relaxation parameter and a third section offers additional material on the subject, including pertinent references. We use a standard notation with minor peculiarities that should cause no difficulty to the reader.

Let us start by recalling that  $P_S(x)$ , the projection of  $x$  on a closed convex nonempty set  $S$ , is the point in  $S$  closest to  $x$ , namely,

$$P_S(x) \stackrel{\text{def}}{=} \underset{z \in S}{\operatorname{argmin}} \|z - x\|^2. \tag{2}$$

By the minimum principle, (2) holds if and only if  $P_S(x) \in S$  and

$$[z \in S] \Rightarrow [\langle z - P_S(x), x - P_S(x) \rangle \leq 0]. \tag{3}$$

Since

$$\begin{aligned} &\langle P_S(x) - x, x - z \rangle \\ &= \langle P_S(x) - x, x - P_S(x) + P_S(x) - z \rangle, \end{aligned}$$

we immediately obtain that (3) is equivalent to

$$[z \in S] \Rightarrow \langle P_S(x) - x, x - z \rangle \leq -\|P_S(x) - x\|^2. \tag{4}$$

In general, the projection problem (2) is difficult, but sometimes it is a straightforward computation. If  $S$  is a halfspace given by  $S \stackrel{\text{def}}{=} \{z \in H : \langle a, z \rangle \leq \beta\}$ , where  $a \in H$ ,  $\beta \in \mathbf{R}$ , the projection of  $x$  onto  $S$  is given by:

$$P_S(x) := \begin{cases} x & x \in S, \\ x - \frac{\langle a, x \rangle - \beta}{\langle a, a \rangle} a & \text{otherwise.} \end{cases} \tag{5}$$

We can easily verify that (3) holds.

In most techniques based on (1)  $S_i$  is a halfspace, a hyperplane, or an appropriate set that renders (2) an easy problem. For instance, if  $C$  is the solution set of a linear system of equations in the Euclidean space  $\mathbf{R}^n$ , i. e.,  $C = \{z \in \mathbf{R}^n : Az = b\}$ , block action methods split the system in  $p$  subsystems, i. e.,

$$[Az = b] := \begin{pmatrix} A_1 z = b_1 \\ \vdots \\ A_p z = b_p \end{pmatrix}.$$

Let  $C_k = \{z \in \mathbf{R}^n: A_k z = b_k\}$ , for  $k = 1, \dots, p$ . If  $A_k$  is full rank, and  $A_k'$  its transpose, then

$$P_{C_k}(x_i) = x_i - A_k'(A_k A_k')^{-1}(A_k x_i - b_k).$$

Observe that (3) and (4) hold as equalities. A standard method chooses

$$S_i = C_k, \quad k = (i \bmod p) + 1$$

Convergence will be apparent in the next section.

An important CFP is to find  $x \in C$ , where  $C$  is defined by convex inequalities, i. e.,

$$C = \{z \in H: f_j(z) \leq b^j, j = 1, \dots, m\}, \quad (6)$$

where  $f_j(\cdot): H \rightarrow \mathbf{R}$  are convex subdifferentiable functions and  $b^j$  are scalars, for  $j = 1, \dots, m$ . Convexity of  $C$  can be shown by well known properties of convex functions that we state for completeness

**Lemma 1** Let  $f(\cdot): H \rightarrow \mathbf{R}$ . Let  $v_1, \dots, v_p$  be vectors in  $H$ , and  $\mu_1, \dots, \mu_p$  be nonnegative scalars such that  $\sum_{k=1}^p \mu_k = 1$ . Then  $f(\cdot)$  is convex if and only if

$$f\left(\sum_{k=1}^p \mu_k v_k\right) \leq \sum_{k=1}^p \mu_k f(v_k). \quad (7)$$

**Lemma 2**  $f_1(\cdot), \dots, f_m(\cdot): H \rightarrow \mathbf{R}$  are convex functions, and  $v_1, \dots, v_m$  are nonnegative scalars. Then  $\sum_{j=1}^m v_j f_j(\cdot)$  is also convex.

**Lemma 3** If  $f(\cdot): H \rightarrow \mathbf{R}$  is convex and subdifferentiable, with subgradient  $\partial f(\cdot): H \rightarrow H$ , then

$$[y, x \in H] \Rightarrow f(y) \geq f(x) + \langle \partial f(x), y - x \rangle$$

and (obviously)

$$[\beta \geq f(y)] \Rightarrow [\beta \geq f(x) + \langle \partial f(x), y - x \rangle].$$

We turn our attention to the choice of  $\{S_i\}_1^\infty$  for solving  $z \in C$  defined by (6). Given  $x_i$  define the halfspace

$$C_j(x_i) = \{z \in H: f_j(x_i) + \langle \partial f_j(x_i), z - x_i \rangle \leq b^j\}. \quad (8)$$

As  $[z \in C] \Rightarrow [b^j \geq f_j(z)]$  we assert by Lemma 3 that  $C_j(x_i) \supseteq C$ . In the next section it will be evident that convergence of (1) is ensured if  $j = (i \bmod m) + 1$  and  $S_i = C_j(x_i)$ .

Let  $f^+(\cdot) \stackrel{\text{def}}{=} \max(0, f_j(\cdot))$ . Another possible choice for  $S_i$  is

$$S_i = \left\{ z \in H: \begin{array}{l} \sum_{j=1}^m f_j^+(x_i)(f_j(x_i) \\ + \langle \partial f_j(x_i), z - x_i \rangle \leq b^j) \end{array} \right\}. \quad (9)$$

By Lemma 3,  $S_i$  contains the convex set  $C_i$  given next. It is obvious that  $C_i \supseteq C$ :

$$C_i = \left\{ z \in H: \sum_{j=1}^m f_j^+(x_i)(f_j(z) \leq b^j) \right\}.$$

### Relaxation

Both  $\{S_i\}_1^\infty$ , and  $\{\omega_i\}_1^\infty$  influence the quality of convergence of projection methods significantly. This section is concerned with the relaxation parameter. We would like to choose  $\{\omega_i\}_1^\infty$ , such that  $z \in C$  is obtained with the fewest number of iterations possible. Using the iterative scheme (1) we have for all  $z \in S_i$  that

$$\begin{aligned} \|x_{i+1} - z\|^2 &= \|x_i - z + \omega_i(P_{S_i}(x_i) - x_i)\|^2 \\ &= \|x_i - z\|^2 + 2\omega_i \langle x_i - z, P_{S_i}(x_i) - x_i \rangle \\ &\quad + \omega_i^2 \|P_{S_i}(x_i) - x_i\|^2. \end{aligned}$$

Since  $S_i \supseteq C$ , we conclude by (4) that

$$\begin{aligned} [z \in C] &\Rightarrow \|x_{i+1} - z\|^2 \\ &\leq \|x_i - z\|^2 - \omega_i(2 - \omega_i) \|P_{S_i}(x_i) - x_i\|^2. \end{aligned} \quad (10)$$

We may reasonably expect that  $\omega_i = 1$  is the 'best' choice because  $\omega(2 - \omega)$  achieves its maximum value at  $\omega = 1$  and therefore  $x_{i+1}$  is the 'closest' to the set  $C$ ; however,  $\omega_i = 1$  for all  $i$  can be a very poor choice. Let us illustrate this fact with the following example in the Euclidean space  $\mathbf{R}^2$ ,  $z = (z^1, z^2)$ :

*Example 4* Let

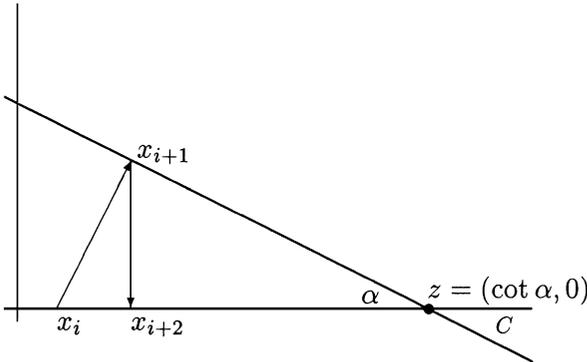

$$\begin{aligned} C &= \{z^2 \leq 0, (\sin \alpha)z^1 + (\cos \alpha)z^2 \geq \cos \alpha\}, \\ S_i &= \begin{cases} (\sin \alpha)z^1 + (\cos \alpha)z^2 \geq \cos \alpha & i \text{ even,} \\ z^2 \leq 0 & i \text{ odd.} \end{cases} \end{aligned}$$

Now the problem is: Starting at  $x = 0$ , estimate the number of iterations needed to generate  $z \in C$ .

- (Scheme 1) Assume exact projections, i. e.  $\forall i: x_{i+1} = P_{S_i}(x_i)$ .

We deduce from Fig. 1 that for all  $i$ :

$$\|x_{i+1} - z\| = \|x_i - z\| \cos \alpha. \quad (11)$$

Relaxation in Projection Methods, Figure 1  
Successive projections

Consequently:

$$\|x_i - z\| = \|x_0 - z\| \cos^i \alpha, \quad \text{for all } i, \quad (12)$$

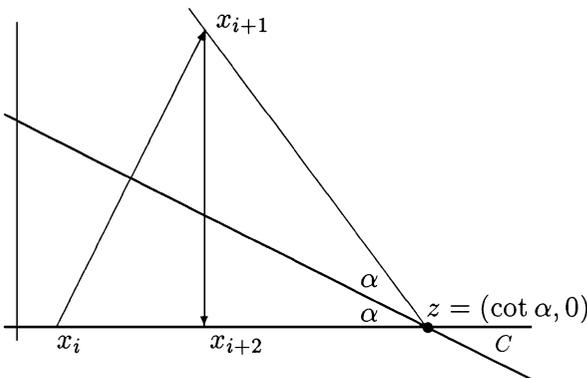

which means that the smaller  $\alpha$ , the bigger the number of iterations. Indeed, if  $\alpha = 10^\circ$  and  $x_0$  is the origin we need more than 700 iterations ( $i > 700$ ) to ensure that  $\|x_i - z\| \leq 10^{-4}$ .

- (Scheme 2) Assume

$$x_{i+1} = \begin{cases} x_i + 2(P_{S_i}(x_i) - x_i) & i \text{ even,} \\ P_{S_i}(x_i) & i \text{ odd.} \end{cases}$$

We deduce from Fig. 2 for  $i$  even that

$$\begin{aligned} \|x_{i+1} - z\| &= \|x_i - z\|, \\ \|x_{i+2} - z\| &= \|x_{i+1} - z\| \cos(2\alpha) \\ &= \|x_i - z\| \cos(2\alpha). \end{aligned}$$

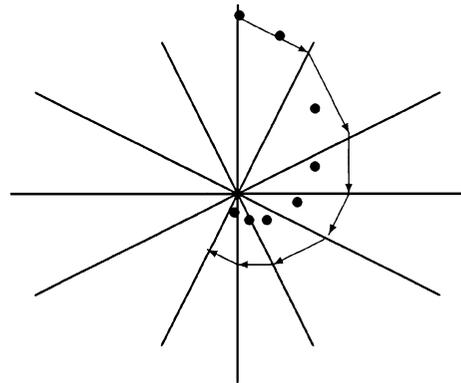

Relaxation in Projection Methods, Figure 2  
Overprojections

Consequently:

$$\|x_{2i} - z\| = \|x_0 - z\| \cos^i(2\alpha). \quad (13)$$

If  $\alpha = 10^\circ$  and  $x_0$  is the origin then  $\|x_i - z\| \leq 10^{-4}$  for all  $i \geq 350$ , a significant reduction in the number of iterations.

A small angle  $\alpha$  means a small rate of convergence, and overprojection ( $\omega > 1$ ) has the desirable practical effect of opening up this angle. Convergence of projection methods may significantly improve if an optimum value of the relaxation parameter is chosen; however this choice is often difficult. We argue that, in general, it is beneficial to overproject ( $\omega > 1$ ), despite some rare examples require underprojection ( $\omega < 1$ ) to achieve a better (linear) rate of convergence. Figure 3 illustrates this latter possibility. The convex set  $C$  is the unique point intersection of a bundle of straight lines passing through it.

Relaxation in Projection Methods, Figure 3  
Under projection •, ..., •; Projection →

### Fejér Property

Most convergence analysis of projection methods are derived from the so called Fejér property, namely, the monotonicity of the sequence  $\{\|x_i - z\|\}_1^\infty$ . Note from (10) that

$$\left( \begin{array}{l} z \in C \\ 0 \leq \omega_i \leq 2 \end{array} \right) \Rightarrow [\|x_{i+1} - z\| \leq \|x_i - z\|]. \quad (14)$$

Hence, a sufficient condition to preserve the Fejér property is that the value of the relaxation parameter  $\omega_i$  belongs to the interval  $[0, 2]$ . To ensure convergence a stronger condition is usually imposed.  $\{\omega_i\}_1^\infty$

must stay uniformly bounded away from 0, and 2. We will show below that this condition is not necessary. We will obtain a relaxation parameter  $\omega > 2$ , preserving the Fejér property, and not impairing convergence. Even more, numerical results reveal that the quality of convergence improves significantly. In order to present the key facts without obscuring our presentation, we focus our attention on parallel algorithms for solving the *convex intersection problem* (CIP), namely: Find  $z \in C$ , where  $C$  is a nonempty intersection of a finite collection of  $p$  convex sets, that is,

$$C = C_1 \cap \dots \cap C_p.$$

We assume (again for the sake of clarity) that the projection problem

$$y_{ik} = \operatorname{argmin}_{x \in C_k} \|x - x_i\|^2 \tag{15}$$

is easily solved.

```

Problem  CIP
Data     x0, an estimate to z ∈ C,
        η: 0 < η ≤ 1,
        δ: 0 < δ ≤ 1/p,
        i = 0, the iteration number
REPEAT
  FOR k = 1, . . . , p DO
  IN parallel
  Let yik be defined by (15)
  dik = yik - xi
  END parallel
  Choose ωik : η ≤ ωik ≤ (2 - η),
  Choose μik ≥ δ: ∑k=1p μik = 1,
  END FOR
  xi+1 = xi + ∑k=1p μikωikdik, i = i + 1
UNTIL   Convergence
    
```

**Parallel projection algorithm (PPA)**

Above we have presented a parallel projection algorithm (PPA); we will now sketch its proof of convergence under suitable standard conditions. Then we introduce a  $\lambda$  factor to modify the relaxation parameters and argue that the solution of a quadratic programming problem will lead to *optimal relaxation*. Finally we present the accelerated projection algorithm (APA) that subsumes our work.

**Convergence of PPA**

By using (10), (7) on the convex function  $f(\cdot) = \|\cdot\|^2$ , and the definitions of  $\omega_{ik}$  and  $\mu_{ik}$  we obtain for  $z \in C$  that

$$\begin{aligned} \|x_{i+1} - z\|^2 &= \left\| x_i + \sum_{k=1}^p \mu_{ik} \omega_{ik} d_{ik} - z \right\|^2 \\ &= \left\| \sum_{k=1}^p \mu_{ik} (x_i + \omega_{ik} d_{ik} - z) \right\|^2 \\ &\leq \sum_{k=1}^p \mu_{ik} \|x_i + \omega_{ik} d_{ik} - z\|^2 \\ &\leq \sum_{k=1}^p \mu_{ik} [\|x_i - z\|^2 - \omega_{ik}(2 - \omega_{ik}) \|d_{ik}\|^2] \\ &\leq \|x_i - z\|^2 - \eta^2 \sum_{k=1}^p \mu_{ik} \|d_{ik}\|^2 \\ &\leq \|x_i - z\|^2 - p\delta\eta^2 \sum_{k=1}^p \|d_{ik}\|^2. \end{aligned}$$

From the last inequality we observe that the Fejér property is maintained. Hence,  $\{x_i\}_1^\infty$  is a bounded sequence. Moreover,  $\{\|x_i - z\|\}_1^\infty$  decreases monotonically and is bounded below, therefore it has a limit. This forces  $\{\sum_{k=1}^p \|d_{ik}\|^2\}_1^\infty \rightarrow 0$ . Hence,  $\{d_{ik}\}_1^\infty \rightarrow 0, k = 1, \dots, p$ , which happens to be a convenient convergence test.

So far the relaxation parameters  $\mu_{ik} \omega_{ik}$  belong to  $(0, 2)$ , as required by standard convergence analysis for projection methods. We now show the existence of a  $\lambda$  factor that, in general, takes the relaxation parameters out of the interval  $(0, 2)$ , but the Fejér property of the sequence  $\{\|x_i - z\|\}_1^\infty$  and the desired convergence condition are preserved.

Let us put

$$x(\lambda) \stackrel{\text{def}}{=} x_i + \lambda \sum_{k=1}^p \mu_{ik} \omega_{ik} d_{ik}. \tag{16}$$

We then obtain for  $\lambda \geq 0$  that

$$[z \in C] \Rightarrow [\|x(\lambda) - z\|^2 \leq \|x_i - z\|^2 + \varphi(\lambda)], \tag{17}$$

where by (4)

$$\varphi(\lambda) = -2\lambda \sum_{k=1}^p \mu_{ik} \omega_{ik} \|d_{ik}\|^2 + \lambda^2 \left\| \sum_{k=1}^p \mu_{ik} \omega_{ik} d_{ik} \right\|^2. \tag{18}$$

The minimum of  $\varphi(\lambda)$  occurs at

$$\lambda_i = \frac{\sum_{k=1}^p \mu_{ik} \omega_{ik} \|d_{ik}\|^2}{\left\| \sum_{k=1}^p \mu_{ik} \omega_{ik} d_{ik} \right\|^2} > 0 \tag{19}$$

and for any  $\alpha \geq 0$  we obtain that

$$\varphi(\alpha \lambda_i) = -\alpha(2 - \alpha) \frac{\left[ \sum_{k=1}^p \mu_{ik} \omega_{ik} \|d_{ik}\|^2 \right]^2}{\left\| \sum_{k=1}^p \mu_{ik} \omega_{ik} d_{ik} \right\|^2}. \tag{20}$$

If we choose  $\alpha_i: \eta \leq \alpha_i \leq 2 - \eta$  and let  $x_{i+1} \stackrel{\text{def}}{=} x(\alpha_i \lambda_i)$ , we ensure by (17) and (20) that the Fejér property is preserved. Consequently  $\{\varphi(\alpha_i \lambda_i)\}_1^\infty \rightarrow 0$  and we can assert that  $\{d_{ik}\}_1^\infty \rightarrow 0, k = 1, \dots, p$ , as long as the sequences  $\{\mu_{ik} \omega_{ik}\}_1^\infty, k = 1, \dots, p$ , remain uniformly positive. Note that no upper bounds and no other conditions whatsoever are imposed on the latter sequences.

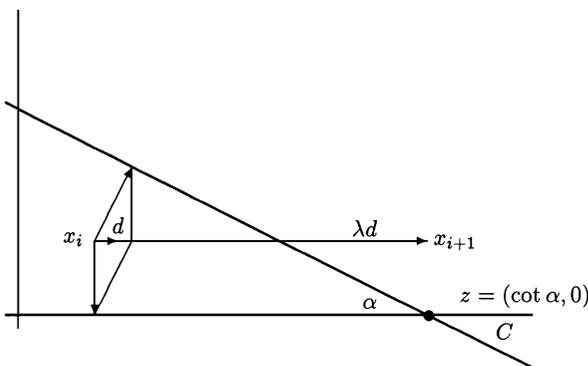

To observe that  $\lambda_i$  may cause an overprojection, assume that  $\omega_{ik} = 1, k = 1, \dots, p$ , at all iterations; then  $x_{i+1} := x(\alpha_i \lambda_i)$  becomes

$$x_{i+1} := x_i + \underbrace{\frac{\sum_{k=1}^p \mu_{ik} \|d_{ik}\|^2}{\left\| \sum_{k=1}^p \mu_{ik} d_{ik} \right\|^2}}_{\lambda_i} \underbrace{\sum_{k=1}^p \mu_{ik} d_{ik}}_{d_i}, \tag{21}$$

where  $\lambda_i \geq 1$  by (7).

Figure 4 shows one iteration on Example 4 with  $\alpha_i = 1$ , and  $\mu_{ik} = 0.5$ .

The net effect of the  $\lambda$  factor is to pull the sequence  $\{x_i\}_1^\infty$  out of a wedge of small angle. In the optimization jargon we look for the minimum of a given upper bound of the distance from  $x(\lambda)$  to  $C$  along the

Relaxation in Projection Methods, Figure 4  
 $\lambda$  factor

direction  $d_i := \sum_{k=1}^p \mu_{ik} \omega_{ik} d_{ik}$  starting from  $x_i$ . It is worth noticing that sometimes inequality (17) becomes an equality; for instance, when  $C$  is a linear system of equations. In this case  $x(\lambda_i)$  is indeed the closest point to  $C$  along  $d_i$ .

Let us proceed one step further with our analysis. Denote the vector  $w$  in the Euclidean space  $\mathbf{R}^p$  with components  $w^k = \mu_k \omega_k, k = 1, \dots, p$ . We then write

$$x(w) = x_i + \sum_{k=1}^p w^k d_{ik} \tag{22}$$

and obtain (almost verbatim as argued for  $\varphi(\lambda)$ )

$$\|x(w) - z\|^2 \leq \|x_i - z\|^2 + \varphi(w),$$

$$\varphi(w) = -2 \sum_{k=1}^p w^k \|d_{ik}\|^2 + \left\| \sum_{k=1}^p w^k d_{ik} \right\|^2.$$

Hence we argue that

$$w_i = \underset{w^k \geq \delta}{\operatorname{argmin}} \varphi(w) \tag{23}$$

should yield ‘good’ (over)relaxation parameters. But the parallel algorithm can degrade severely, unless we have at hand an efficient algorithm for solving the quadratic program (23). Otherwise, any acceptable value for  $w_i$  combined with the  $\lambda$  factor can be advantageous.

The net effect of  $w_i$  is to obtain ‘locally’ the best direction of search to locate some  $z \in C$ . Thus,  $w_i$  can be considered as the optimum relaxation parameter. In Example 4,  $z$  is obtained in one step.

Table 1 summarizes the accelerated parallel algorithm (APA) that subsumes our work. We dropped the iteration number  $i$  for convenience.

**Discussion**

The literature on projection methods is rather vast and rapidly growing. Reviews on projection methods and/or their applications in mathematics, physics and social sciences published in the 1990s include [1,4,5,7,10,13,21,23], and others.

Projection methods have a long history. In their early inceptions [6,20,22] no relaxation parameters were introduced, but soon it was noticed that overrelaxation (or overprojection) could speed convergence. Successive over relaxation techniques were introduced

**Relaxation in Projection Methods, Table 1**  
**Accelerated parallel algorithm**

Problem	Find $z \in C = C_1 \cap \dots \cap C_p$

in the solution of large linear system of equations. Significant work on determining and computing the optimum relaxation was performed in the 1950s ([19] gives a good list of references on the subject). R. Bramley and A. Sameh [2] found that underprojection could improve convergence, at least theoretically, in the solution of a nonsymmetric linear system of equations.

Convergence rate of projection methods is linear under mild conditions, i. e.,  $\|x_{i+1} - z\| \leq \gamma_i \|x_i - z\|$ , where  $\{\gamma_i \in \mathbf{R}\}_1^\infty$  is uniformly positive and strictly less than one. The value of  $\gamma_i$  depends strongly on the angle  $\alpha_i$  between supporting hyperplanes of  $S_i$  and  $S_{i+1}$  [11,18,24]. Overprojection and most techniques used to improve the quality of convergence of projection methods merely attempt to reduce  $\gamma_i$ . For the convex inequality problem, see [12,14]. In [12] projection aggregation methods were developed and the choice of (9) was justified. In [14] a projection algorithm with a superlinear rate of convergence is presented, where  $\{\omega_i\}_1^\infty \rightarrow 1$  is needed.

We proved that the sequence  $\{x_i\}_1^\infty$  generated by the parallel algorithms (PPA and APA) satisfies the Fejér property. Strong convergence in Hilbert spaces for a countable number of sets can be proved under mild additional conditions [1,9, Thm. 2.16]. It is straightforward to show that convergence is preserved if we

project on closed supersets  $S_{ik} \supseteq C_k, k = 1, \dots, p$ . We only need

$$\|P_{S_{ik}}(x) - x\| \geq \delta \|P_{C_k}(x) - x\|$$

for some  $\delta > 0$ .

The  $\lambda$  factor has been suggested in [8,12], and [15]. Numerical results reported in the latter paper, in [9,25] and [17] are impressive. However, the actual theoretical improvement of the quality of convergence is an open question. See [16] for theoretical results when  $C$  is the intersection of affine sets (hyperplanes). In [12,15] the use of the  $\lambda$  factor is analysed for sequential versions of the projection method.

We suggest the solution of the quadratic problem (23) to obtain 'optimal' relaxation parameters. K.C. Kiwiel recommends the solution of the nonlinear programming problem (20) [21]. To the author's knowledge, there exists no evidence of the superiority of either approach. We do not believe that the exact solution of either problem is a good strategy, because this can degrade the performance of a parallel algorithm. Our recommendation is to obtain some acceptable initial values for the relaxation parameters, and then use the  $\lambda$  factor.

Throughout the paper we have assumed that  $C \neq \emptyset$ . The inconsistency case, i. e.,  $C = \emptyset$ , has attracted a lot of attention lately. See [3] and references therein.

Quadratic programming; Graph; Clique; Evolutionary game theory; Heuristics; Dynamical system

*Replicator equations* are a class of *dynamical systems* developed and studied in the context of *evolutionary game theory*, a discipline pioneered by J. Maynard Smith [36] which aims to model the evolution of animal behavior using the principles and tools of game theory. Because of their dynamical properties, they have been recently applied with significant success to a number of *combinatorial optimization* problems. It is the purpose of this article to provide a summary and an up-to-date bibliography of these applications.

## The Model and its Properties

In this Section we discuss the basic intuition behind replicator equations and present a few theoretical properties that are instrumental for their application to optimization problems. For a more systematic treatment see [23,55].

Consider a large, ideally infinite population of individuals belonging to the same species which compete for a particular limited resource, such as food, territory, etc. This kind of conflict is modeled as a game, the players being pairs of randomly selected population members. In contrast to traditional application fields of game theory, such as economics or sociology [33], players here do not behave ‘rationally,’ but act instead according to a pre-programmed behavior pattern, or *pure strategy*. Reproduction is assumed to be asexual, which means that, apart from mutation, offspring will inherit the same genetic material, and hence behavioral phenotype, as its parent. Let  $J = \{1, \dots, n\}$  be the set of pure strategies and, for all  $i \in J$ , let  $x_i(t)$  be the relative frequency of population members playing strategy  $i$ , at time  $t$ . The *state* of the system at time  $t$  is simply the vector  $\mathbf{x}(t) = (x_1(t), \dots, x_n(t))^T$ . Clearly, the states are constrained to lie in the standard simplex of the  $n$ -dimensional Euclidean space  $\mathbf{R}^n$ :

$$S_n = \{\mathbf{x} \in \mathbf{R}^n : x_i \geq 0, \forall i \in J, \mathbf{e}^T \mathbf{x} = 1\}.$$

Here and in the sequel, the letter  $\mathbf{e}$  is reserved for a vector of appropriate length, consisting of unit entries (hence  $\mathbf{e}^T \mathbf{x} = \sum_i x_i$ ).

One advantage of applying game theory to biology is that the notion of ‘utility’ is much simpler and clearer than in human contexts. Here, a player’s utility can simply be measured in terms of Darwinian fitness or reproductive success, i. e., the player’s expected number of offspring. Let  $W = (w_{ij})$  be the  $n \times n$  ‘payoff’ (or fitness) matrix. Specifically, for each pair of strategies  $i, j \in J$ ,  $w_{ij}$  represents the payoff of an individual playing strategy  $i$  against an opponent playing strategy  $j$ . Without loss of generality, we shall assume that the payoff matrix is nonnegative, i. e.,  $w_{ij} \geq 0$  for all  $i, j \in J$ . At time  $t$ , the average payoff of strategy  $i$  is given by:

$$\pi_i(t) = \sum_{j=1}^n w_{ij} x_j(t), \quad (1)$$

while the mean payoff over the entire population is  $\sum_{i=1}^n x_i(t) \pi_i(t)$ .

In evolutionary game theory the assumption is made that the game is played over and over, generation after generation, and that the action of natural selection will result in the evolution of the fittest strategies. If successive generations blend into each other, the evolution of behavioral phenotypes can be described by the following set of differential equations [53]:

$$\dot{x}_i(t) = x_i(t) \left( \pi_i(t) - \sum_{j=1}^n x_j(t) \pi_j(t) \right) \quad (2)$$

for  $i = 1, \dots, n$ , where a dot signifies derivative with respect to time. The basic idea behind this model is that the average rate of increase  $\dot{x}_i(t)/x_i(t)$  equals the difference between the average fitness of strategy  $i$  and the mean fitness over the entire population. It is straightforward to show that the simplex  $S_n$  is invariant under equation (2) or, in other words, any trajectory starting in  $S_n$  will remain in  $S_n$ . To see this, simply note that  $(d/dt) \sum_i x_i(t) = \sum_i \dot{x}_i(t) = 0$ , which means that the (relative) interior of  $S_n$  (i. e., the set defined by  $x_i > 0$ , for all  $i = 1, \dots, n$ ) is invariant. The additional observation that the boundary too is invariant, completes the proof.

Similar arguments provide a rationale for the following discrete-time version of the replicator dynamics, assuming nonoverlapping generations, which can be obtained from (2) by setting  $1/\Delta t = \sum_{j=1}^n x_j(t) \pi_j(t)$ :

$$x_i(t + \Delta t) = \frac{x_i(t) \pi_i(t)}{\sum_{j=1}^n x_j(t) \pi_j(t)} \quad (3)$$

for  $i = 1, \dots, n$ . Because of the nonnegativity of the fitness matrix  $W$  and the normalization factor, this system too makes the simplex  $S_n$  invariant as its continuous counterpart.

A point  $\mathbf{x} = \mathbf{x}(t)$  is said to be a *stationary* (or equilibrium) point for the dynamical systems under consideration if  $\dot{x}_i(t) = 0$  in the continuous-time case, and  $x_i(t + \Delta t) = x_i(t)$  in the discrete-time case ( $i = 1, \dots, n$ ). Moreover, a stationary point is said to be *asymptotically stable* if any trajectory starting in its vicinity will converge to it as  $t \rightarrow \infty$ . It turns out that both the continuous-time and discrete-time replicator dynamics have the same set of stationary points, namely all the

points in  $S_n$  satisfying, for all  $i = 1, \dots, n$ , the condition

$$x_i(t) \left( \pi_i(t) - \sum_{j=1}^n x_j(t) \pi_j(t) \right) = 0,$$

or, equivalently,  $\pi_i(t) = \sum_{j=1}^n x_j(t) \pi_j(t)$  whenever  $x_i > 0$ .

Equations (2) and (3) arise independently in different branches of theoretical biology [23]. In population ecology, for example, the famous Lotka–Volterra equations for predator–prey systems turn out to be equivalent to the continuous-time dynamics (2), under a simple barycentric transformation and a change in velocity. In population genetics they are known as *selection equations* [17]. In this case, each  $x_i$  represents the frequency of the  $i$ th allele  $A_i$  and the payoff  $w_{ij}$  is the fitness of genotype  $A_i A_j$ . Here the fitness matrix  $W$  is always symmetric. The discrete-time dynamical equations turn out to be a special case of a general class of dynamical systems introduced in [2] and studied in [3] in the context of Markov chain theory. They also represent an instance of the so-called *relaxation labeling processes*, a class of parallel, distributed algorithms developed in computer vision to solve (continuous) constraint satisfaction problems [25,44,50]. An independent connection between relaxation labeling processes and game theory has recently been described in [37].

The following theorem states that under replicator dynamics the population’s average fitness always increases, provided that the payoff matrix is symmetric (in game theory terminology, this situation is referred to as a doubly symmetric game).

**Theorem 1** *Suppose that the (nonnegative) payoff matrix  $W$  is symmetric. Then, the quadratic polynomial  $F$  defined as*

$$F(\mathbf{x}) = \mathbf{x}^T W \mathbf{x} \quad (4)$$

*is strictly increasing along any nonconstant trajectory of both continuous-time (2) and discrete-time (3) replicator equations. In other words, for all  $t \geq 0$  we have*

$$\frac{d}{dt} F(\mathbf{x}(t)) > 0$$

*for system (2), and  $F(\mathbf{x}(t + \Delta t)) > F(\mathbf{x}(t))$  for system (3), unless  $\mathbf{x}(t)$  is a stationary point. Furthermore, any such trajectory converges to a (unique) stationary point.*

The previous result is known in mathematical biology as the *fundamental theorem of natural selection* [17,23,55] and, in its original form, traces back to [18]. As far as the discrete-time model is concerned, it can be regarded as a straightforward implication of the Baum–Eagon theorem [2,3] which is valid for general polynomial functions over product of simplices. F.R. Waugh and R.M. Westervelt [54] also proved a similar result for a related class of continuous- and discrete-time dynamical systems. In the discrete-time case, however, they put bounds on the eigenvalues of  $W$  in order to achieve convergence to fixed points.

The fact that all trajectories of the replicator dynamics converge to a stationary point has been proved in [32,34]. However, in general, not all stationary points are local maximizers of  $F$  on  $S_n$ . The vertices of  $S_n$ , for example, are all stationary points for (2) and (3) whatever the landscape of  $F$ . Moreover, there may exist trajectories which, starting from the interior of  $S_n$ , eventually approach a saddle point of  $F$ . However, a result proved by I. Bomze [5] asserts that all asymptotically stable stationary points of replicator dynamics correspond to (strict) local maximizers of  $F$  on  $S_n$ , and vice versa (see [10] for additional results relating the fields of optimization theory, evolutionary game theory and the qualitative behavior of dynamical systems).

Under continuous-time replicator dynamics, the trajectories approach their limits most efficiently in the sense that (2) is a gradient system if one uses the (non-Euclidean) *Shahshahani metric* [23] which, for any point  $\mathbf{u} \in S_n$ , is defined as

$$d_{\mathbf{u}}(\mathbf{x}, \mathbf{y}) = \sum_{\{i: u_i > 0\}} \frac{1}{u_i} x_i y_i.$$

This efficiency result is called *Kimura’s maximum principle*.

## Maximum Clique Problems

Let  $G = (V, E)$  be an undirected graph, where  $V = \{1, \dots, n\}$  is the set of vertices and  $E \subseteq V \times V$  is the set of edges. The *order* of  $G$  is the number of its vertices, and its *size* is the number of edges. Two vertices  $i, j \in V$  are said to be *adjacent* if  $(i, j) \in E$ . The *adjacency matrix* of  $G$  is the  $n \times n$  symmetric matrix  $A_G = (a_{ij})$  defined as

follows:

$$a_{ij} = \begin{cases} 1 & \text{if } (i, j) \in E, \\ 0 & \text{otherwise.} \end{cases}$$

A subset  $C$  of vertices in  $G$  is called a *clique* if all its vertices are mutually adjacent, i. e., for all  $i, j \in C$ , with  $i \neq j$ , we have  $(i, j) \in E$ . A clique is said to be *maximal* if it is not contained in any larger clique, and *maximum* if it is the largest clique in the graph. The *clique number*, denoted by  $\omega(G)$ , is defined as the cardinality of the maximum clique. The *maximum clique problem* is to find a clique whose cardinality equals the clique number.

The maximum clique problem is a well-known example of combinatorial optimization problem, not only because it was one of the first problems shown to be *NP*-complete [19], but also for its theoretical as well as practical implications. Due to the inherent computational complexity of the problem, exact algorithms are guaranteed to return a solution only in a time which increases exponentially with the number of vertices in the graph, and this makes them inapplicable even to moderately large problem instances. Moreover, a series of recent theoretical results show that the problem is in fact difficult to solve even in terms of approximation. Because of these negative results, much effort has recently been directed towards devising efficient heuristics for finding large cliques, for which no formal guarantee of performance may be provided, but are anyway of interest in practical applications. We refer to [8] for a recent survey of results concerning algorithms, complexity and applications of this problem.

In 1965, T.S. Motzkin and E.G. Straus [38] established a remarkable connection between the maximum clique problem and a certain *quadratic programming* problem. Consider the following quadratic function, sometimes called the *Lagrangian* of  $G$ :

$$f_G(\mathbf{x}) = \mathbf{x}^\top A_G \mathbf{x} \quad (5)$$

and let  $\mathbf{x}^*$  be a global maximizer of  $f_G$  on  $S_n$ ,  $n$  being the order of  $G$ . In [38] it is proved that the clique number of  $G$  is related to  $f_G(\mathbf{x}^*)$  by the following formula:

$$\omega(G) = \frac{1}{1 - f_G(\mathbf{x}^*)}. \quad (6)$$

Additionally, it is shown that a subset of vertices  $C$  is a maximum clique of  $G$  if and only if its *characteristic*

vector  $\mathbf{x}^C$ , which is the vector of  $S_n$  defined as

$$x_i^C = \begin{cases} \frac{1}{|C|} & \text{if } i \in C, \\ 0 & \text{otherwise,} \end{cases}$$

is a global maximizer of  $f_G$  on  $S_n$ . In [21,47], the Motzkin–Straus theorem has been extended by providing a characterization of maximal cliques in terms of local maximizers of  $f_G$  on  $S_n$ .

Once that the maximum clique problem is formulated in terms of maximizing a quadratic polynomial over the standard simplex, the use of replicator dynamics naturally suggests itself [42]. In fact, consider a replicator system with payoff matrix defined as:

$$W = A_G.$$

From the fundamental theorem of natural selection, we know that the replicator dynamical systems, starting from an arbitrary initial state, will iteratively maximize the Lagrangian  $f_G$  in  $S_n$ , and will eventually converge to a local maximizer which, by virtue of the Motzkin–Straus formula provides an estimate of the clique number of  $G$ . Additionally, if the converged solution happens to be a characteristic vector of some subset of vertices of  $G$ , then we are also able to extract the vertices comprising the clique from its nonzero components. Clearly, in theory there is no formal guarantee that the converged solution will be a global maximizer of  $f_G$ . However, experimental work suggests that the basins of attraction of global maximizers are quite large, and frequently the algorithm converges to one of them.

In [42], M. Pelillo presents extensive experimental results with the previous approach over thousands of randomly generated graphs. The discrete-time dynamics (3) was used, and the system was started from the vector  $(1/n, \dots, 1/n)^\top$  which corresponds to the simplex barycenter. Two series of experiments were conducted. In the first one, graphs with a relatively small number of vertices were considered, i. e. with up to 500 vertices and densities ranging from 0.10 to 0.90. The solutions found by the algorithm were always very close to the optimal ones, as found by standard exact algorithms. In the second part of the study, graphs with up to 2000 vertices and about one million edges were used (in this case all graphs had density 0.50). Here to gauge the quality of the solutions found the *Matula estimate* was employed,

which accurately predicts the clique number in a random graph, when the number of vertices is sufficiently large [35]. Specifically, let

$$M(n, \delta) = 2 \log_{1/\delta} n - 2 \log_{1/\delta} \log_{1/\delta} + 2 \log_{1/\delta} \frac{e}{2} + 1.$$

D.W. Matula proved that, as  $n \rightarrow \infty$ , the order of the maximum clique in an  $n$ -vertex  $\delta$ -density random graph is either  $\lfloor M(n, \delta) \rfloor$  or  $\lceil M(n, \delta) \rceil$  with probability tending to 1, where  $\lfloor x \rfloor$  denotes the largest integer less than or equal to  $x$ , and  $\lceil x \rceil$  denotes the smallest integer greater than or equal to  $x$ . Interestingly, it was also shown that the smallest maximal clique is expected to have  $M(n, \delta)/2$  vertices [4]. Experimentally, in [42] it was found that the cardinality of the cliques found by the replicator dynamical system turned out to be significantly larger than the estimated minimum, thereby contradicting what is known as the *Jerrum conjecture* [27], which states that in a large 0.5-density random graph it may be hard to find a clique whose order is even a bit larger than that of the smallest maximal clique. A similar conclusion was also drawn in [26]. Overall, the results presented in [42] were competitive with those obtained using more sophisticated neural network heuristics, both in terms of quality of solutions and speed.

One drawback associated with the original Motzkin–Straus formulation, however, relates to the existence of spurious solutions, i. e., maximizers of  $f_G$  which are not in the form of characteristic vectors. This was first observed in [40]. To illustrate, consider the path  $P^3$ , i. e. the graph with three vertices  $\{1, 2, 3\}$  and two edges, one between 1 and 2, and the other between 2 and 3. Clearly,  $C = \{1, 2\}$  and  $D = \{2, 3\}$  are maximum cliques, and from the Motzkin–Straus theorem it follows that their characteristic vectors  $\mathbf{x}^C$  and  $\mathbf{x}^D$  are global maximizers of the Lagrangian of  $P^3$  in  $S_3$ . However, it can easily be proved that all the points lying on the segment connecting  $\mathbf{x}^C$  and  $\mathbf{x}^D$ , which is a subset of  $S_3$  since the simplex is convex, are also global solutions of the Motzkin–Straus program. See [47] for general characterizations of such spurious solutions. In principle, spurious solutions represent a problem since, while providing information about the cardinality of the maximum clique, they do not allow us to easily extract its vertices.

The spurious solution problem has been solved in [5]. Consider the following regularized version of  $f_G$ :

$$\widehat{f}_G(\mathbf{x}) = \mathbf{x}^\top A_G \mathbf{x} + \frac{1}{2} \mathbf{x}^\top \mathbf{x}, \quad (7)$$

which is obtained from (5) by substituting the adjacency matrix  $A_G$  of  $G$  with

$$\widehat{A}_G = A_G + \frac{1}{2} I_n,$$

where  $I_n$  is the  $n \times n$  identity matrix. Unlike the Motzkin–Straus formulation, it can be proved that all maximizers of  $\widehat{f}_G$  on  $S_n$  are strict, and are characteristic vectors of maximal/maximum cliques in the graph [5].

**Theorem 2** *Let  $C$  be a subset of vertices of a graph  $G$ , and let  $\mathbf{x}^C$  be its characteristic vector. Then,  $C$  is a maximum (maximal) clique of  $G$  if and only if  $\mathbf{x}^C$  is a global (local) maximizer of  $\widehat{f}_G$  in  $S_n$ . Moreover, all local (and hence global) maximizers of  $\widehat{f}_G$  over  $S_n$  are strict.*

In an exact sense, therefore, a one-to-one correspondence exists between maximal cliques and local maximizers of  $\widehat{f}_G$  in  $S_n$  on the one hand and maximum cliques and global maximizers on the other hand.

Preliminary experiments with this regularized formulation (7) on random graphs are reported in [5], and a more extensive empirical study on DIMACS benchmark graphs is presented in [10]. The emerging picture is the following. The solutions produced by the replicator models are typically very close to the ones obtained using more sophisticated continuous-based heuristics. Moreover, the original version of the Motzkin–Straus problem performs slightly better than its regularized counterpart, but the former often returns spurious solutions. This may be intuitively explained by observing that, since all local maxima of  $\widehat{f}_G$  are strict, its landscape is certainly less smoothed than the one associated to the nonregularized version. This therefore enhances the tendency of local optimization procedures to get stuck into local maxima. This is the price to pay for the algorithm to return nonspurious, ‘informative’ solutions.

In order to study the effects of varying the starting point of clique finding replicator dynamics, Bomze and F. Rendl [12] implemented various sophisticated heuristics and compared them with the usual (less expensive) strategy of starting from the simplex barycenter. Surprisingly, they concluded that the amount of

sophistication seems to have no significant impact on the quality of the solutions obtained. Additionally, they showed that using (Runge–Kutta discretizations of) the continuous-time dynamics (2) instead of (3) does not improve efficiency. This analysis indicates that to improve the performance of replicator dynamics on the maximum clique problem one has necessarily to resort to some escape strategies. Various attempts along this direction can be found in [5,6,9,13].

The Motzkin–Straus theorem has been generalized to the weighted case in [21]. Let  $G = (V, E, \mathbf{w})$  be a weighted graph, where  $V = \{1, \dots, n\}$  is the vertex set,  $E \subseteq V \times V$  is the edge set and  $\mathbf{w} \in \mathbb{R}^n$  is the *weight vector*, the  $i$ th component of which corresponds to the weight assigned to vertex  $i$ . It is assumed that  $w_i > 0$  for all  $i \in V$ . Given a subset of vertices  $C$ , the weight assigned to  $C$  is defined as

$$W(C) = \sum_{i \in C} w_i.$$

A maximal weight clique  $C$  is one that is not contained in any other clique having weight larger than  $W(C)$ . Since we are assuming that all weights are positive, it is clear that the concepts of maximal clique and maximal weight clique coincide. A maximum weight clique is one having largest total weight, and the *weighted clique number* of  $G$ , denoted  $\omega(G, \mathbf{w})$ , is its weight. The *maximum weight clique problem* is to find a clique  $C$  such that  $W(C) = \omega(G, \mathbf{w})$  (see [8] for a recent review). The classical (unweighted) version of the maximum clique problem arises as a special case when all vertices have the same weight. For this reason the maximum weight clique problem has at least the same computational complexity as its unweighted counterpart.

Note that the original Motzkin–Straus program for unweighted graphs can be reformulated as a minimization problem by considering the function

$$g(\mathbf{x}) = \mathbf{x}^\top (I + A_{\bar{G}})\mathbf{x},$$

where  $A_{\bar{G}}$  is the adjacency matrix of the complement graph  $\bar{G}$ , which is the graph having the same vertex set as  $G$  and  $\bar{E} = \{(i, j) \in V \times V : i \neq j \text{ and } (i, j) \notin E\}$  as its edge set. It is straightforward to see that if  $\mathbf{x}^*$  is a global minimizer of  $g$  in  $S_n$ , then  $\omega(G) = 1/g(\mathbf{x}^*)$ . This is simply a different formulation of the Motzkin–Straus formula (6). Now, consider a weighted graph  $G = (V,$

$E, \mathbf{w})$ , and let  $\mathcal{M}(G, \mathbf{w})$  be the class of symmetric  $n \times n$  matrices  $M = (m_{ij})_{i, j \in V}$  defined as  $2m_{ij} \geq m_{ii} + m_{jj}$  if  $(i, j) \notin E$  and  $m_{ij} = 0$  otherwise, and  $m_{ii} = 1/w_i$  for all  $i \in V$ . Given a global solution  $\mathbf{x}^*$  of the following quadratic program, which is in general indefinite,

$$\begin{cases} \min & g(\mathbf{x}) = \mathbf{x}^\top M\mathbf{x} \\ \text{s.t.} & \mathbf{x} \in S_n, \end{cases} \tag{8}$$

we have [21]:

$$\omega(G, \mathbf{w}) = \frac{1}{g(\mathbf{x}^*)}$$

for any matrix  $M \in \mathcal{M}(G, \mathbf{w})$ . Furthermore, denote by  $\mathbf{x}^C(\mathbf{w})$  the *weighted characteristic vector* of  $C$ , which is the vector in  $S_n$  with coordinates

$$x_i^C(\mathbf{w}) = \begin{cases} \frac{w_i}{W(C)} & \text{if } i \in C, \\ 0 & \text{otherwise.} \end{cases}$$

It turns out that a subset  $C$  of vertices is a maximum weight clique if and only if its characteristic vector  $\mathbf{x}^C(\mathbf{w})$  is a global minimizer of (8). Notice that the matrix  $I + A_{\bar{C}}$  belongs to  $\mathcal{M}(G, \mathbf{e})$ . In other words, the original Motzkin–Straus theorem turns out to be a special case of the preceding result.

As in the unweighted case, this formulation suffers from the existence of spurious solutions, and this entails the lack of a one-to-one correspondence between the solutions of the continuous optimization problem and those of the original, discrete one. In [11] these spurious solutions are characterized and a regularized version which avoids this kind of problems is introduced (see also [7]). Specifically, let  $\mathcal{N}(G, \mathbf{w})$  be the the class of  $n \times n$  symmetric matrices  $M = (m_{ij})_{i, j \in V}$  defined as  $m_{ij} \geq m_{ii} + m_{jj}$  if  $(i, j) \notin E$  and  $m_{ij} = 0$  otherwise, and  $m_{ii} = 1/2w_i$  for all  $i \in V$ . The following theorem is the weighted counterpart of Theorem 2.

**Theorem 3** *Let  $C$  be a subset of vertices of a weighted graph  $G = (V, E, \mathbf{w})$ , and let  $\mathbf{x}^C(\mathbf{w})$  be its characteristic vector. Then, for any matrix  $M \in \mathcal{N}(G, \mathbf{w})$ ,  $C$  is a maximum (maximal) weight clique of  $G$  if and only if  $\mathbf{x}^C(\mathbf{w})$  is a global (local) solution of program (8). Moreover, all local (and hence global) solutions of (8) are strict.*

Note that  $\mathcal{N}(G, \mathbf{w})$  is isomorphic to the positive orthant in  $\binom{[n]}{2} - |E|$  dimensions. This class is a polyhedral

pointed cone with its apex given by the matrix  $M(\mathbf{w}) = (m_{ij}(\mathbf{w}))_{i,j \in V}$  with entries

$$m_{ij}(\mathbf{w}) = \begin{cases} \frac{1}{2w_i} & \text{if } i = j, \\ \frac{1}{2w_i} + \frac{1}{2w_j} & \text{if } i \neq j, (i, j) \notin E, \\ 0 & \text{if } i \neq j, (i, j) \in E. \end{cases}$$

Observe that in the unweighted case,  $M(\mathbf{e}) = \mathbf{e}\mathbf{e}^\top - \widehat{A}_G = \widehat{A}_{\overline{G}}$ , the regularized adjacency matrix of the complement graph  $\overline{G}$ . This reflects the elementary property that an independent set of  $G$ , i. e. a subset of pairwise nonadjacent vertices, is a clique of  $\overline{G}$ . Hence, while the local maximizers of  $\mathbf{x}^\top \widehat{A}_G \mathbf{x}$  over  $S_n$  correspond to maximal cliques of  $G$ , the local minimizers of  $\mathbf{x}^\top \widehat{A}_G \mathbf{x}$  over  $S_n$  correspond to maximal independent sets.

Theorem 3 suggests using replicator equations to approximately solve the maximum weight clique problem. Indeed, note that replicator equations are maximization procedures, while ours is a minimization problem. However, it is a straightforward exercise to see that the problem of minimizing a quadratic form  $\mathbf{x}^\top M \mathbf{x}$  on  $S_n$  is equivalent to maximizing  $\gamma \mathbf{e}\mathbf{e}^\top - M$ , where  $\gamma$  is an arbitrary constant. Therefore, the payoff matrix for replicator dynamics to be used in this case is:

$$W = \gamma \mathbf{e}\mathbf{e}^\top - M$$

where  $M = (m_{ij})$  is any matrix in  $\mathcal{N}(G, \mathbf{w})$ , and

$$\gamma = \max_{i,j \in V} m_{ij}.$$

Experiments with this approach on both random graphs and DIMACS benchmark graphs are reported in [11]. Weights were generated randomly in both cases. The results obtained with replicator dynamics (3) were compared with those produced by a very efficient maximum weight clique algorithm of the branch and bound variety. The algorithm performed remarkably well especially on large and dense graphs, and it was typically an order of magnitude more efficient than its competitor.

### Graph Isomorphism

Given two graphs  $G' = (V', E')$  and  $G'' = (V'', E'')$ , an isomorphism between them is any bijection  $\phi: V' \rightarrow V''$  such that  $(i, j) \in E' \Leftrightarrow (\phi(i), \phi(j)) \in E''$ , for all  $i, j \in$

$V'$ . Two graphs are said to be *isomorphic* if there exists an isomorphism between them. The *graph isomorphism problem* is therefore to decide whether two graphs are isomorphic and, in the affirmative, to find an isomorphism.

The graph isomorphism problem is one of those few combinatorial optimization problems which still resist any computational complexity characterization [19,28]. Despite decades of active research, no polynomial time algorithm for it has yet been found. At the same time, while clearly belonging to *NP*, no proof has been provided that it is *NP*-complete. Indeed, there is strong evidence that this cannot be the case, for otherwise the polynomial hierarchy would collapse [14,52]. The current belief is that the problem lies strictly between the *P* and *NP*-complete classes.

The subgraph isomorphism problem is more general and in fact more difficult, being *NP*-complete [19]. Given two graphs, it is the problem of determining whether one is isomorphic to a subgraph of the other. At the highest level of generality we find the maximum common subgraph problem, which consists of finding the largest isomorphic subgraphs of two graphs. A simpler version of this problem is to find a maximal common subgraph, i. e., an isomorphism between subgraphs which is not included in any larger subgraph isomorphism.

H.G. Barrow and R.M. Burstall [1], and also D. Kozen [30], introduced the notion of an *association graph* as a useful auxiliary graph structure for solving general graph/subgraph isomorphism problems. Specifically, the association graph derived from graphs  $G' = (V', E')$  and  $G'' = (V'', E'')$  is the undirected graph  $G = (V, E)$  where

$$V = V' \times V''$$

and

$$E = \{((i, h), (j, k)) \in V \times V : i \neq j, h \neq k, (i, j) \in E' \Leftrightarrow (h, k) \in E''\}.$$

The following straightforward result establishes an equivalence between the graph isomorphism problem and the maximum clique problem [46].

**Theorem 4** *Let  $G' = (V', E')$  and  $G'' = (V'', E'')$  be two graphs of order  $n$ , and let  $G$  be the corresponding association graph. Then,  $G'$  and  $G''$  are isomorphic if and only if*

$\omega(G) = n$ . In this case, any maximum clique of  $G$  induces an isomorphism between  $G'$  and  $G''$ , and vice versa. In general, maximum (maximal) cliques in  $G$  are in one-to-one correspondence with maximum (maximal) common subgraph isomorphisms between  $G'$  and  $G''$ .

By virtue of Theorem 2, it is a straightforward exercise to formulate the graph isomorphism problem in terms of a quadratic programming problem. Let  $G'$  and  $G''$  be two arbitrary graphs of order  $n$ , and let  $A_G$  denote the adjacency matrix of the corresponding association graph  $G$ , whose order is  $n^2$ . The graph isomorphism problem is equivalent to the following program:

$$\begin{cases} \max & \widehat{f}_G(\mathbf{x}) = \mathbf{x}^\top (A + \frac{1}{2}I_{n^2})\mathbf{x} \\ \text{s.t.} & \mathbf{x} \in S_{n^2}. \end{cases} \quad (9)$$

More precisely,  $G'$  and  $G''$  are isomorphic if and only if  $\widehat{f}_G(\mathbf{x}^*) = 1 - 1/2n$ . In this case, any global solution to (9) induces an isomorphism between  $G'$  and  $G''$ , and vice versa. In general, local (global) solutions to (9) are in one-to-one correspondence with maximal (maximum) common subgraph isomorphisms between  $G'$  and  $G''$ .

The previous result allows one to use replicator dynamics with payoff matrix

$$W = A_G + \frac{1}{2}I_{n^2}$$

as a heuristic for graph isomorphism problems. Starting from an arbitrary initial state, the dynamical system will converge to a local solution of (9). This will correspond to a characteristic vector of a maximal clique in the association graph  $G$  which, in turn, will induce an isomorphism between two subgraphs of  $G'$  and  $G''$  which is maximal, in the sense that there is no other isomorphism between subgraphs of  $G'$  and  $G''$  that includes the one found.

The algorithm outlined above has been tested over hundreds of random 100-vertex graphs with expected densities ranging from 1% to 99%. Except for very sparse and very dense instances, the algorithm was always able to obtain a correct isomorphism very efficiently. In terms of quality of solutions, the result compare favorably with those obtained using more sophisticated state-of-the-art deterministic annealing heuristics which, in contrast to replicator dynamics, are explicitly designed to escape from poor local solutions. As far as

computational time is concerned, replicator dynamics turned out to be significantly faster.

In [46] experiments were also done using the following exponential version of replicator equations, which arises as a model of evolution guided by imitation [22,23,24,55]:

$$\dot{x}_i(t) = x_i(t) \left( \frac{e^{\kappa\pi_i(t)}}{\sum_{j=1}^n x_j(t)e^{\kappa\pi_j(t)}} - 1 \right), \quad (10)$$

$i = 1, \dots, n$ , where  $\kappa$  is a positive constant. As  $\kappa$  tends to 0, the orbits of this dynamics approach those of the standard, 'first order' replicator model (2), slowed down by the factor  $\kappa$ ; moreover, for large values of  $\kappa$  the model approximates the so-called 'best-reply' dynamics [24]. As it turns out [22], these models behave essentially in the same way as the standard replicator equations (2), the only difference being the size of the basins of attraction around stable equilibria.

A customary way of discretizing equation (10) is given by the following difference equations [15,20]:

$$x_i(t+1) = \frac{x_i(t)e^{\kappa\pi_i(t)}}{\sum_{j=1}^n x_j(t)e^{\kappa\pi_j(t)}}, \quad (11)$$

$i = 1, \dots, n$ . The extensive results reported in [46] with this dynamics show that exponential replicator dynamics may be considerably faster and even more accurate than the standard, first order model.

The approach just described is general and can clearly be extended to deal with subgraph isomorphism or relational structure matching problems [45]. Preliminary experiments, however, seem to indicate that local optima may represent a problem here, especially in matching sparse and dense graphs. In these cases escape procedures like those presented in [5,6,9,13] would be helpful.

### Subtree Isomorphism

Given a graph  $G = (V, E)$ , a *path* is any sequence of distinct vertices  $i_0 \cdots i_n$  such that for all  $k = 1, \dots, n$ ,  $(i_{k-1}, i_k) \in E$ ; in this case, the *length* of the path is  $n$ . If  $i_0 = i_n$  the path is called a *cycle*. A graph is said to be *connected* if any pair of vertices is joined by a path. The *distance* between two vertices  $i$  and  $j$ , denoted by  $d(i, j)$ , is the length of the shortest path joining them (by convention  $d(i, j) = \infty$ , if there is no such path). Given a subset of

vertices  $C \subseteq V$ , the *induced subgraph*  $G[C]$  is the graph having  $C$  as its vertex set, and two vertices are adjacent in  $G[C]$  if and only if they are adjacent in  $G$ .

A connected graph with no cycles is called a *tree*. A *rooted tree* is one which has a distinguished vertex, called the *root*. The *level* of a vertex  $i$  in a rooted tree, denoted by  $\text{lev}(i)$ , is the length of the path connecting the root to  $i$ . Note that there is an obvious equivalence between rooted trees and directed trees, where the edges are assumed to be oriented. We shall therefore use the same terminology typically used for directed trees to define the relation between two adjacent vertices. In particular, if  $(i, j) \in E$  and  $\text{lev}(j) - \text{lev}(i) = +1$ , we say that  $i$  is the *parent* of  $j$  and, conversely,  $j$  is a *child* of  $i$ . Trees have a number of interesting properties. One which turns out to be very useful for our characterization is that in a tree any two vertices are connected by a *unique path*.

Let  $T_1 = (V_1, E_1)$  and  $T_2 = (V_2, E_2)$  be two rooted trees. Any bijection  $\phi: H_1 \rightarrow H_2$ , with  $H_1 \subseteq V_1$  and  $H_2 \subseteq V_2$ , is called a *subtree isomorphism* if it preserves the adjacency and hierarchical relationships between the vertices and, in addition, the subgraphs obtained when we restrict ourselves to  $H_1$  and  $H_2$ , i. e.,  $T_1[H_1]$  and  $T_2[H_2]$ , are trees. The former condition amounts to stating that, given  $i, j \in H_1$ , we have  $(i, j) \in E_1$  if and only if  $(\phi(i), \phi(j)) \in E_2$ , and  $i$  is the parent of  $j$  if and only if  $\phi(i)$  is the parent of  $\phi(j)$ . A subtree isomorphism is *maximal* if there is no other subtree isomorphism  $\phi': H_1' \rightarrow H_2'$  with  $H_1$  a strict subset of  $H_1'$ , and *maximum* if  $H_1$  has largest cardinality. The maximal (maximum) subtree isomorphism problem is to find a maximal (maximum) subtree isomorphism between two rooted trees. This is a problem solvable in polynomial time [19].

Let  $i$  and  $j$  be two distinct vertices of a rooted tree  $T$ , and let  $i = x_0 \cdots x_n = j$  be the (unique) path joining them. The *path-string* of  $i$  and  $j$ , denoted by  $\text{str}(i, j)$ , is the string  $s_1 \cdots s_n$  on the alphabet  $\{-1, +1\}$  where, for all  $k = 1, \dots, n$ ,  $s_k = \text{lev}(x_k) - \text{lev}(x_{k-1})$ . By convention, when  $i = j$  we define  $\text{str}(i, j) = \varepsilon$ , where  $\varepsilon$  is the null string (i. e., the string having zero length). The path-string concept has a very intuitive meaning. Because of the orientation induced by the root, only two types of elementary moves can be done from any given vertex, i. e., going down to one of the children (if one exists) or going up to the parent (if the vertex is not the root).

Assigning to the first move the label  $+1$ , and to the second the label  $-1$ , the path-string of  $i$  and  $j$  is simply the string of elementary moves required to move from  $i$  to  $j$ , following the unique path joining them.

The *tree association graph* (TAG) of two rooted trees  $T_1 = (V_1, E_1)$  and  $T_2 = (V_2, E_2)$  is the graph  $G = (V, E)$  where

$$V = V_1 \times V_2 \quad (12)$$

and, for any two vertices  $(i, h)$  and  $(j, k)$  in  $V$ , we have

$$((i, h), (j, k)) \in E \Leftrightarrow \text{str}(i, j) = \text{str}(h, k). \quad (13)$$

The following theorem establishes a one-to-one correspondence between the maximum subtree isomorphism problem and the maximum clique problem [48].

**Theorem 5** *Any maximal (maximum) subtree isomorphism between two rooted trees induces a maximal (maximum) clique in the corresponding TAG, and vice versa.*

In many practical applications the trees being matched have vertices with an associated vector of symbolic and/or numeric attributes. The framework just described can naturally be extended for solving attributed tree matching problems [48].

Formally, an *attributed tree* is a triple  $T = (V, E, \alpha)$ , where  $(V, E)$  is the ‘underlying’ rooted tree and  $\alpha$  is a function which assigns an attribute vector  $\alpha(i)$  to each vertex  $i \in V$ . It is clear that in matching two attributed trees, the objective is to find an isomorphism which pairs vertices having ‘similar’ attributes. To this end, let  $\sigma$  be any similarity measure on the attribute space, i. e., any (symmetric) function which assigns a positive number to any pair of attribute vectors. If  $\phi: H_1 \rightarrow H_2$  is a subtree isomorphism between two attributed trees  $T_1 = (V_1, E_1, \alpha_1)$  and  $T_2 = (V_2, E_2, \alpha_2)$ , the overall similarity between the induced subtrees  $T_1[H_1]$  and  $T_2[H_2]$  can be defined as follows:

$$S(\phi) = \sum_{i \in H_1} \sigma(\alpha_1(i), \alpha_2(\phi(i))).$$

The isomorphism  $\phi$  is called a *maximal similarity subtree isomorphism* if there is no other subtree isomorphism  $\phi': H_1' \rightarrow H_2'$  such that  $H_1$  is a strict subset of  $H_1'$  and  $S(\phi) < S(\phi')$ . It is called a *maximum similarity subtree isomorphism* if  $S(\phi)$  is largest among all subtree isomorphisms between  $T_1$  and  $T_2$ .

The *weighted TAG* of two attributed trees  $T_1$  and  $T_2$  is the weighted graph  $G = (V, E, \mathbf{w})$ , where  $V$  and  $E$  are defined as in (12) and (13), and  $\mathbf{w}$  is a vector which assigns a positive weight to each vertex  $(i, h) \in V = V_1 \times V_2$  as follows:

$$w_{ih} = \sigma(\alpha_1(i), \alpha_2(h)).$$

The following result is the weighted counterpart of Theorem 5 [48].

**Theorem 6** *Any maximal (maximum) similarity subtree isomorphism between two attributed trees induces a maximal (maximum) weight clique in the corresponding weighted TAG, and vice versa.*

Theorems 5 and 6 provide a formal justification for applying replicator dynamics to find maximal subtree isomorphisms. In [48] this approach has been applied in computer vision to the problem of matching articulated and deformed visual shapes described by ‘shock’ trees, an abstract representation of shape based on the singularities arising during a curve evolution process. The experiments, conducted on a number of shapes representing various object classes, yielded very good results, both in the weighted and in the unweighted case. The system typically converged towards the globally optimal solutions in only a few seconds, and compared favorably with another powerful tree matching algorithm.

## A Geometric Problem

Let  $G = \{\mathbf{x}_1, \dots, \mathbf{x}_m\}$  be a finite set of points in  $\mathbf{R}^n$ . The *convex hull* of  $G$ , denoted by  $\text{conv}(G)$ , is defined as the smallest convex set containing  $G$ . A basic problem in computational geometry is to determine whether a given query point  $\mathbf{y}$  is inside or outside  $\text{conv}(G)$  [49]. This task can easily be accomplished by a replicator dynamical system [43]. Such an algorithm can be used as a subroutine for solving more general geometric problems, such as the polygon inclusion and the convex hull problems.

Consider the  $n \times m$  real matrix defined as  $X = [\mathbf{x}_1 \dots \mathbf{x}_m]$ . It is well known that  $\text{conv}(G)$  can be written as

$$\text{conv}(G) = \{\mathbf{u} \in \mathbf{R}^n : \mathbf{u} = X\mathbf{v}, \mathbf{v} \in S_m\}.$$

Given an arbitrary point  $\mathbf{y} \in \mathbf{R}^n$  the measure

$$E(\mathbf{y}, G) = \min_{\mathbf{v} \in S_m} \|X\mathbf{v} - \mathbf{y}\|_2,$$

sometimes called the *exteriority* of  $\mathbf{y}$  to  $\text{conv}(G)$ , is just the Euclidean distance between  $\mathbf{y}$  and its closest point in  $\text{conv}(G)$ . The exteriority measure can provide useful information about the ability of neural networks to generalize well [16]. Clearly,  $\mathbf{y} \in \text{conv}(G)$  if and only if  $E(\mathbf{y}, G) = 0$ , in which case the closest point to  $\mathbf{y}$  is  $\mathbf{y}$  itself.

For convenience, the problem of evaluating  $E(\mathbf{y}, G)$  is translated into the equivalent (but more manageable) quadratic program:

$$\begin{cases} \min & C(\mathbf{v}) = \frac{1}{2} \|X\mathbf{v} - \mathbf{y}\|_2^2 \\ \text{s.t.} & \mathbf{v} \in S_m. \end{cases} \quad (14)$$

It is a well-known fact that  $C$  is convex (strictly convex indeed if the vectors  $\mathbf{x}_1, \dots, \mathbf{x}_m$  happen to be linearly independent), and this implies that all local minima of  $C$  are also global minima. Any descent procedure is therefore guaranteed to approach the global optimal solution in this case, without the risk of getting trapped into poor local minima.

It is interesting to note that a similar optimization problem, known as the problem of ‘optimal stability’, also arises in the context of learning in perceptron neural networks, where the goal is to derive the parameters of the network so as to ensure larger basins of attraction [31,51]. Moreover, our problem turns out to be closely related to that of determining whether a given set of prototype vectors can be stored in a neural network associative memory [29].

Note that the quadratic objective function in (14) is explicitly written as follows:

$$C(\mathbf{v}) = \frac{1}{2} \mathbf{v}^T X^T X \mathbf{v} - \mathbf{y}^T X \mathbf{v} + \frac{1}{2} \mathbf{y}^T \mathbf{y},$$

which is a nonhomogeneous quadratic polynomial. In order for replicator equations to find a solution of problem (14), we need to construct the payoff matrix as

$$W = X^T X$$

and to replace the  $\pi$  function defined in (1) with:

$$\pi_i(t) = \sum_{j=1}^n w_{ij} x_j(t) + s_i,$$

where  $s_i$  equals the  $i$ th component of  $-X^T \mathbf{y}$ . After a proper rescaling of  $W$  and the  $s_i$ 's, it is readily seen that  $C$  is a Liapunov function for both continuous-time

(2) and discrete-time (3) dynamics. The algorithms will converge to a local solution of (14), say  $\mathbf{v}^*$ , starting from any interior point. Owing to the convexity of  $C$ ,  $\mathbf{v}^*$  will be also a global minimizer of  $C$ , so that the exteriority can be calculated as:

$$E(\mathbf{y}, G) = \sqrt{2C(\mathbf{v}^*)}.$$

In [43], experiments with a simple toy problem demonstrate the validity of the approach.

### Multipopulation Models

The single-population replicator equations discussed so far can easily be generalized to the case where interactions take place among  $n \geq 2$  individuals randomly drawn from  $n$  distinct populations [23,55]. In this case, the continuous-time dynamics (2) becomes

$$\dot{x}_i^\mu(t) = x_i^\mu(t) \left( \pi_i^\mu(t) - \sum_v x_i^v(t) \pi_i^v(t) \right), \quad (15)$$

and its discrete-time counterpart is

$$x_i^\mu(t + \Delta t) = \frac{x_i^\mu(t) \pi_i^\mu(t)}{\sum_v x_i^v(t) \pi_i^v(t)}. \quad (16)$$

The function  $\pi$  can either be linear, as in (1), or can take a more general form. If there exists a polynomial  $F$  such that

$$\pi_i^\mu = \frac{\partial F}{\partial x_i^\mu},$$

then it can be proved that  $F$  strictly increases along any trajectory of both dynamics [2,3,23]. Note that these dynamics work in a product of standard simplices.

H. Mühlenbein et al. [39] used multipopulation replicator equations to approximately solve the *graph partitioning problem*, which is NP-complete [19]. Given a graph  $G = (V, E)$  with edge weights  $w_{ij}$ , their goal was to partition the vertices of  $G$  into a predefined number of clusters in such a way as to maximize the overall intrapartition traffic

$$F = \prod_{\mu} K^{\mu},$$

where

$$K^{\mu} = \sum_i \sum_j w_{ij} x_i^{\mu} x_j^{\mu}$$

is the intrapartition traffic for cluster  $\mu$ . Here,  $x_i^{\mu}$  can be interpreted as the probability that vertex  $i$  belongs to cluster  $\mu$ .

By putting

$$\pi_i^{\mu} = \frac{2F \sum_j w_{ij} x_j^{\mu}}{K^{\mu}},$$

the replicator equations seen above will indeed converge toward a maximizer of  $F$ . However, in so doing the system typically converges towards an interior attractor, thereby giving an infeasible solution. To avoid this problem, Mühlenbein et al. [39] put a ‘selection pressure’ parameter  $S$  on the main diagonal of the weight matrix, and altered it during the evolution of the process. Intuitively,  $S = 0$  has no influence on the system. Negative values of  $S$  prevent the vertices to decide for a partition, whereas positive values force the vertices to take a decision. The proposed algorithm starts with a negative value of  $S$ , and makes the discrete-time dynamics (16) evolve. After convergence, if an infeasible solution has been found,  $S$  is increased and the algorithm is started again. The entire procedure is iterated until convergence to a feasible solution. A similar, but more principled, strategy for the maximum clique problem can be found in [9]. The results presented in [39] on a particular problem instance are fairly encouraging. However, more experiments on larger and diverse graphs are needed to fully assess the potential of the approach.

Multipopulation replicator models have also been used in [39,41] to solve the traveling salesman problem, which asks for the shortest closed tour connecting a given set of cities, subject to the constraint that each city be visited only once. The results presented on small problem instances, i. e., up to 30 cities, are encouraging but it seems that the results do not scale well with the size of the problem.

### Conclusions

Despite their simplicity and inherent inability to escape from local solutions, replicator dynamics have proved to be a useful heuristic for attacking a variety of combinatorial optimization problems. They are completely devoid of operational parameters, which typically require a lengthy, problem-dependent tuning phase, and are especially suited for parallel hardware implementation.

Optimal control; Markov process; Ordinary differential equations; Resource allocation; Epidemiology; Systems theory and control

This article describes *resource allocation* for control of epidemics of infectious diseases in humans, particularly diseases that are spread directly between individuals, such as sexually-transmitted diseases and influenza. In its most general form, the problem is to determine the optimal amount to spend over time and in different populations on programs for controlling the spread of an infectious disease. Restricted versions of the problem include that of determining the level of investment over time in a single program targeted to a single population; determination of the appropriate investment in competing interventions targeted to the same population; and determination of the appropriate allocation of resources for a single intervention targeted to different populations.

While resource allocation problems have been studied by economists and operations researchers for many years (see, for example, [4,10,26]), resource allocation

for *epidemic control* poses special challenges. Epidemics of infectious diseases are dynamic and are inherently nonlinear: while an epidemic is growing, saving one person today from getting infected could translate into scores of people being saved from infection over time. In addition, an epidemic may progress differently in different populations, and different programs for the control of an infectious disease can have very different costs and effectiveness.

Approaches to the problem of resource allocation for epidemic control include analytical derivations for simple epidemic models, numerical analysis of more sophisticated epidemic models, and heuristic approaches for decision makers. Before these approaches are described, a simple *epidemic model* is presented. Understanding this type of model is key to understanding the resource allocation problem.

### Epidemic Models

One of the simplest types of epidemic models assumes transmission of an infectious disease within a closed population that is divided into three subgroups: uninfected individuals, infected individuals, and those removed from the infection-transmission process [12,13]. To specify the model, let  $x(t)$  represent the number of uninfected individuals in the population at time  $t$ ,  $y(t)$  the number of infected individuals in the population at time  $t$  (these individuals are assumed to be infectious), and  $z(t)$  the number of individuals removed from the infection-transmission process at time  $t$ . Let  $\beta(t)$  be the rate of infection-transmitting contacts at time  $t$ ,  $u(t)$  the rate at which susceptibles are immunized at time  $t$ , and  $\gamma(t)$  the rate of removal from the population at time  $t$ . The model can be written as

$$\frac{dx(t)}{dt} = -\beta(t)x(t)y(t) - u(t), \quad (1)$$

$$\frac{dy(t)}{dt} = \beta(t)x(t)y(t) - \gamma(t)y(t), \quad (2)$$

$$\frac{dz(t)}{dt} = \gamma(t)y(t) + u(t) \quad (3)$$

This model and similar models provide the foundation for much of the work that has been done on optimal resource allocation for epidemic control.

A key feature of this and other models of infectious disease is a nonlinear growth rate that is a function of the size of the uninfected group multiplied by the size of the infected group. More sophisticated models may include features such as entry into and exit from the population, further subdivision of the population by risk group and disease stage, different types of infectious contacts, variable infectivity rates, and stochastic parameters. Comprehensive expositions of mathematical epidemic models can be found in [2] and [3].

### Analytical Results

A number of researchers have considered the application of *control theory* to simple epidemic models similar to that outlined above with the goal of obtaining analytical results characterizing the form of the optimal solution. The parameters of the model may be assumed to be deterministic or stochastic. Examples of controls typically considered include vaccination of susceptibles (which increases the rate  $u(t)$ ), treatment or removal of infectious persons (which increases the rate  $\gamma(t)$ ), and reduction in the sufficient contact rate ( $\beta(t)$ ) between susceptibles and infectious persons. A finite or infinite time horizon may be considered. The goal is to determine the optimal control over time: for example, the optimal rate of immunization  $u(t)$  for  $0 \leq t \leq T$ . For analytical tractability, most analyses assume that only one type of control is applied (and thus only one parameter is affected by the control).

A typical objective in the application of such control might be to minimize the cost of control (e. g., immunization cost plus the fixed cost of establishing the immunization program) plus the cost associated with the number of individuals who become infected. With the exception of the fixed cost of establishing a control program, costs are usually assumed to be linear: the cost of control is a constant multiplied by the affected parameter, and the cost of disease is a constant multiplied by the number of individuals who become infected.

Use of simple epidemic models and linear cost functions allows for characterization of the form of the optimal solution: for example, immunization of all individuals until the epidemic is reduced to a certain level (a 'bang-bang' solution with a single switching point). A survey up to 1977 of the application of control theory to infectious diseases can be found in K. Wickwire

[27]. More recent work of this type can be found in D. Greenhalgh [6], S.P. Sethi [23], and Sethi and P.W. Staats [24].

A related type of analysis considers the optimal timing of interventions for epidemic control. For example, H.L. Lee and W.P. Pierskalla [15] considered mass screening for a contagious disease with no latent period. The goal is to minimize the average number of infected individuals in the population over a fixed time horizon. The authors showed that under certain assumptions, an optimal strategy is mass screening at equal time intervals.

Another type of analysis considers allocation of resources among different population subgroups with the goal of disease eradication (reducing the disease equilibrium in each population to zero). Use of an equilibrium condition allows for analytical tractability. For example, R.M. May and R.M. Anderson [17] considered the distribution of vaccine among several heterogeneously mixing populations. The goal is to eradicate the disease with as little vaccine as possible. They characterized the optimal fraction of each population that should be immunized. As another example, J. Abounadi and L.M. Wein [1] analyzed resource allocation for control of human immunodeficiency virus (HIV) among homogeneously mixing and heterogeneously mixing population groups. Expenditure of resources on a given population group reduces that group's contact rates. The goal is to eradicate the disease while minimizing the total cost of control (which is a monotonically increasing function of the reduction in the contact rates). The authors developed analytical results characterizing the amount of resource that should be spent on each population.

More recent analytical work by A. Richter, M.L. Brandeau and G.S. Zaric [22] considers allocation of resources across nonmixing populations with the goal of minimizing the total number of new infections that occur over a fixed time horizon. Resources for transmission reduction are to be allocated among the population groups subject to a constraint on total available resources (cost of control is a monotonically increasing function of the reduction in the transmission rate) and subject to limits on attainable transmission rates in each population. The authors establish conditions under which the resource allocation problem is convex or concave, as well as other analytical results. Zaric [28]

extended such analyses to more sophisticated epidemic models.

### Numerical Analyses

Another approach to the problem of resource allocation for epidemic control uses numerical analysis of more sophisticated epidemic models, often tailored for specific diseases. Several notable examples are mentioned here.

Using a model of tuberculosis epidemiology, policies for the control of tuberculosis in developing countries were analyzed by C. ReVelle and colleagues in [18] and [19]. Numerical analysis was used to determine the set of interventions that minimizes the cost of control required to achieve a specified number of active cases at the end of a given time horizon. I.M. Longini, E. Ackerman and L.R. Elveback [16] used numerical analysis to determine the optimal distribution of a fixed amount of vaccine among different age groups during an Influenza A epidemic. H.W. Hethcote and J.A. Yorke [8] and Hethcote, Yorke and A. Nold [9] used numerical analysis of an epidemic model to evaluate the equilibrium epidemic state for policies aimed at controlling the spread of gonorrhea. Although the results were not compared explicitly with program cost, the authors suggested that such comparison must be made before the appropriate allocation of resources can be determined.

A framework similar to that of [22] was used by Richter, Brandeau and D.K. Owens [21] to evaluate allocation of HIV prevention resources among different programs targeted to different risk groups in the patient population of a large health care system. The authors estimated the cost-effect function associated with each intervention as applied to each population (defined as the reduction in transmission that could be achieved as a function of expenditure), and used numerical analysis to determine the optimal allocation of a fixed budget across the prevention programs and the populations.

In [5], C.M. Friedrich and Brandeau investigated the optimal level of funding for a single HIV prevention program targeted to a single population using a simple epidemic model. Via simulation, the authors developed qualitative insights into the nature of the optimal investment (e.g., spend no money, spend some of the money, or spend as much money as possible) for different types of cost-effect functions.

Another approach to the resource allocation problem uses ideas from artificial intelligence. W.Y. Tan and S. Yakowitz [25] proposed the application of a *machine-learning algorithm* for a *Markov decision process* (e.g., see T.L. Lai and Yakowitz [14]) to determine the optimal policy for control of an epidemic. The approach was illustrated using numerical analysis of a stochastic model of the HIV epidemic in a single population. The goal is to minimize the number of new infections by continuously allocating a fixed amount of resources between programs that either lower the contact rate or lower the infectivity per contact. As the learning algorithm progresses, the resource allocation progresses to an equilibrium; [25] showed that this equilibrium is the optimal allocation.

### Practical Tools for Decision Makers

Existing analytical work on resource allocation for epidemic control has limited applicability due to the simple epidemic models and simple control policies that are assumed. Numerical approaches can provide applicable results, but require the development of realistic epidemic models and the collection of a significant amount of data. As an alternative, E.H. Kaplan [11] has proposed a heuristic approach for community planners who must allocate HIV prevention resources. He also suggests that decision makers subjectively construct *production functions* that estimate the number of new HIV infections that would occur in a particular population group if  $x$  incremental dollars were spent on a given HIV prevention program targeted to that group. Then the problem of allocating a fixed prevention budget among prevention programs and populations so as to minimize new HIV cases reduces to a knapsack problem.

#### Keywords

Reverse convex programming; Nonconvex programming; Global optimization

The purpose of this article is to introduce the complex reverse convex programming problem. As such, this article is not a complete survey of the research into solution methods for *reverse convex programs*. This article

will provide several examples that demonstrate the importance or relevance of the problem class, and will introduce the reader to some typical solution strategies that illustrate the combinatorial nature of the problem. Much of the early work in reverse convex programming deals with finding local minima [1,2,15,17]. The discussion of this article is directed toward the *global optimization* of reverse convex programs.

#### Definitions

Let  $X$  and  $C$  denote two convex subsets of  $\mathbf{R}^n$ , where  $X$  is closed. Let  $G = \text{cl}(C^c)$ ; that is,  $G$  is the closure of the complement of a convex subset of  $\mathbf{R}^n$ . We call such a set a *reverse convex set*. The corresponding reverse convex feasible region is defined as

$$F = X \cap G. \quad (1)$$

Let  $f: O \rightarrow \mathbf{R}^1$ , where  $O$  is an open subset of  $\mathbf{R}^n$  such that  $O \supset F$ . The general reverse convex programming problem (RCP) is defined as

$$\min \{f(x): x \in X \cap G\}. \quad (2)$$

Clearly,  $F$  is generally a nonconvex set and, moreover,  $F$  is often disconnected. As a result, (2) is a member of a class of difficult optimization problems, whether or not  $f$  is a convex function.

#### Examples

The first two examples below are well-known difficult examples in their own right; each can be rewritten as an equivalent reverse convex optimization problem. There is no computational significance of this conversion; however, the conversion is included so the reader may better understand the general complexity of the reverse convex class of optimization problems.

*Example 1* Let

$$XI = \left\{ x \in \mathbb{R}^n: \begin{array}{l} Ax \geq b, x_j \in \{0, 1\}, \\ j = 1, \dots, n \end{array} \right\},$$

where  $A$  is  $(m \times n)$ -matrix and  $b$  is an  $m$ -vector. Then

$$\min \{c^\top x: x \in XI\}. \quad (3)$$

is the well-known 0–1 linear integer programming problem. Define the two sets  $X = \{x \in \mathbf{R}^n: Ax \geq b, 0$

$\leq x_j \leq 1, j = 1, \dots, n\}$  and  $G = \{x \in \mathbf{R}^n: \sum_j x_j(1 - x_j) \leq 0\}$ . We see that  $G$  is a reverse convex set and that (3) is equivalent to the reverse convex optimization problem

$$\min \{c^\top x: x \in X \cap G\}. \tag{4}$$

*Example 2* Let  $X_A = \{x \in \mathbf{R}^n: Ax \geq b, x \geq 0\}$  and let  $f$  be a concave function on  $\mathbf{R}^n$ . The problem

$$\min \{f(x): x \in X_A\} \tag{5}$$

is the well-known, and difficult, concave minimization problem ( $f$  is continuous since we assume it is defined on  $\mathbf{R}^n$ ). Introduce an additional variable,  $\eta$ , and the inequality constraint  $\eta - f(x) \geq 0$ . Let  $X = \{(x, \eta) \in \mathbf{R}^{n+1}: Ax + \eta 0 \geq b, x \geq 0\}$ , where  $0$  is a column  $m$ -vector of zeros and let  $G = \{(x, \eta): \eta - f(x) \geq 0\}$ , a reverse convex set. Then (5) is equivalent to the reverse convex optimization problem

$$\min_{x, \eta} \{\eta: (x, \eta) \in X \cap G\}. \tag{6}$$

*Example 3* Let  $E$  denote the node-arc incidence matrix of a connected, directed graph (assume there are  $m$  nodes and  $n$  arcs). Let  $f_{i,j}$  denote the nonnegative flow on arc  $(i, j)$  and let  $k_{i,j} \geq 0$  denote the capacity of arc  $(i, j)$ . Assume the capacity of arc  $(i, j)$  can be increased by an amount  $x_{i,j} \geq 0$  at a corresponding cost of  $c_{i,j}(x_{i,j}) \geq 0$ . Also assume, for each arc  $(i, j)$ , we have  $c_{i,j}(x_{i,j}) < c_{i,j}(\bar{x}_{i,j})$  if  $x_{i,j} < \bar{x}_{i,j}$ ,  $c_{i,j}(x_{i,j}) \rightarrow \infty$ , as  $x_{i,j} \rightarrow \infty$ , and  $c_{i,j}$  is continuous. Let  $B > 0$  denote the capacity expansion budget; it is desired to increase the flow capacity (from the source to the sink, respectively represented by the first and last rows of  $E$ ) as much as possible. We assume the network at hand has the property that there are *economies of scale* present. That is, the average cost of capacity expansion, for each arc, is a decreasing function. That is, each incremental capacity cost function,  $c_{i,j}$ , is concave. Let  $v$  denote the value of a feasible flow vector  $f$ . Let  $q = (-1, 0, \dots, 0, 1)'$ . The optimization problem may be written as

$$\left\{ \begin{array}{l} \max_{f, x, v} \quad v \\ \text{s.t.} \quad Ef - vq = 0 \\ \quad \quad f - x \leq k \\ \quad \quad \sum_{i,j} c_{i,j}(x_{i,j}) \leq B \\ \quad \quad f \geq 0, \quad x \geq 0. \end{array} \right. \tag{7}$$

Since each  $c_{i,j}$  is concave and continuous, the set  $G = \{x \geq 0: \sum_{i,j} c_{i,j}(x_{i,j}) \leq B\}$  is a reverse convex set.

*Example 4* Consider the following problem, an example of the linear bilevel optimization problem [5],

$$\left\{ \begin{array}{l} \min_{x,y} \quad c^\top x + d^\top y \\ \text{s.t.} \quad A_1 x + D_1 y \geq b^1, \end{array} \right. \tag{8}$$

where  $y$  solves

$$\left\{ \begin{array}{l} \min_z \quad f^\top z \\ \text{s.t.} \quad A_2 x + D_2 z \geq b^2. \end{array} \right.$$

The interpretation of this problem is that a ‘king’ decides upon a vector pair,  $(x^*, y^*)$ . He imposes his choice of  $x^*$  upon his subjects; however, this benevolent king will allow his subjects to choose the vector  $y$  (since the king is optimistic and, he assumes, omniscient as well, he assumes his subjects’ optimal choice of  $y$ , when faced with  $x^*$ , will be the same as his choice,  $y^*$ ). Let

$$\sigma(b^2 - A_2 x) = \left\{ \begin{array}{l} \min_z \quad f^\top z \\ \text{s.t.} \quad A_2 x + D_2 z \geq b^2, \end{array} \right. \tag{9}$$

denote the so-called optimal value function for the king’s subjects, as a function of the king’s choice of  $x$ . The king’s problem (8) is equivalent to

$$\left\{ \begin{array}{l} \min_{x,y} \quad c^\top x + d^\top y \\ \text{s.t.} \quad A_1 x + D_1 y \geq b^1 \\ \quad \quad A_2 x + D_2 y \geq b^2 \\ \quad \quad \sigma(b^2 - A_2 x) - f^\top y \geq 0. \end{array} \right. \tag{10}$$

Since  $\sigma$  is a convex polyhedral function of  $x$ , we see that the last constraint of (10) is a reverse convex constraint. That is, the set  $G = \{(x, y): \sigma(b^2 - A_2 x) - f^\top y \geq 0\}$  is a reverse convex set. Of course this problem is quite difficult in that, unlike the previous examples, the reverse convex constraint is not explicitly known.

*Example 5* Consider the reverse convex optimization problem with several reverse convex constraints:

$$\min \{f(x): x \in X, g_i(x) \geq 0, i = 1, \dots, m\} \tag{11}$$

where each  $g_i$  is a convex function. By the addition of a variable, (11) can be converted to a reverse convex optimization problem with one reverse convex constraint [21]. Let

$$g(x) = \min \{g_i(x): i = 1, \dots, m\} \tag{12}$$

and let

$$\begin{aligned} p(x) &= \sum_i g_i(x), \\ q(x) &= \max \left\{ \sum_{j \neq i} g_j(x) : i = 1, \dots, m \right\}. \end{aligned} \quad (13)$$

Then  $0 \leq g(x) = p(x) - q(x)$  is equivalent to the two constraints, in  $(x, t)$ ,

$$\begin{cases} q(x) - t \leq 0, \\ p(x) - t \geq 0, \end{cases} \quad (14)$$

where, of course, the last constraint is a reverse convex constraint. See U. Ueung [22] for an early branch and bound approach to the global optimization of (11).

*Example 6* Consider the separable optimization problem

$$\begin{cases} \min_{\substack{x \in X \\ y \in Y}} f_1(x) + f_2(y) \\ \text{s.t.} & g^1(x) + g^2(y) \geq 0, \end{cases} \quad (15)$$

where  $X, Y$  are convex sets of, perhaps, different dimensions;  $f_1$  is convex,  $f_2$  is concave,  $g^1$  is a vector of concave functions, and  $g^2$  is a vector of convex functions. Assume for each  $y \in Y$ , that the problem

$$(P_y) \quad \begin{cases} \min_{x \in X} f_1(x) \\ \text{s.t.} & g^1(x) \geq -g^2(y) \end{cases}$$

has a saddle point. Let  $y^i, i = 1, \dots, k$ , be points of  $Y$  and let  $(x^i, \lambda^i)$  denote a saddle point for  $(P_{y^i}), i = 1, \dots, k$ . The  $k$ th relaxed master of Benders' decomposition procedure [6,8] is

$$\begin{cases} \min_{\substack{y \in Y \\ \eta}} \eta \\ \text{s.t.} & \eta - (f_2(y) - \lambda^{i\top} g^2(y)) \\ & \geq f_1(x^i) - \lambda^{i\top} g^1(x^i), \\ & i = 1, \dots, k. \end{cases} \quad (16)$$

This is a problem with several reverse convex constraints. Note that a simple change of variable,  $\gamma = \eta - f_2(y)$ , leads to the equivalent problem

$$\begin{cases} \min_{\substack{y \in Y \\ \gamma}} \gamma + f_2(y) \\ \text{s.t.} & \gamma + \lambda^{i\top} g^2(y) \\ & \geq f_1(x^i) - \lambda^{i\top} g^1(x^i), \\ & i = 1, \dots, k. \end{cases} \quad (17)$$

This problem involves the minimization of a concave function subject to several reverse convex constraints, a very difficult formulation of the relaxed master.

### Some Basic Concepts for Solution Methods

Let  $f: \mathbf{R}^n \rightarrow \mathbf{R}^1$  and  $g: \mathbf{R}^n \rightarrow \mathbf{R}^1$  be convex functions and let  $G = \{x \in \mathbf{R}^n: g(x) \geq 0\}$ , a reverse convex set. Also assume

$$\exists w \in X \cap G^c \ni f(w) < f^*, \quad (18)$$

where  $f^*$  is the optimal value of the reverse convex problem (2). Then any optimal solution  $\bar{x}$  has the property that  $g(\bar{x}) = 0$ ; it then follows that

$$0 = \max \{g(x) : x \in X, f(x) \leq f(\bar{x})\} \quad (19)$$

and, therefore,  $\bar{x}$  is optimal for (19). Under certain additional 'stability' [21] conditions, it is also the case that if  $\bar{x}$  satisfies (19) then  $\bar{x}$  is optimal for (2).

### X a Convex Polytope, f Linear

In order to develop an understanding of the combinatorial nature of the problem, it is useful to consider the following. If, in addition to the above assumptions,  $X$  is a convex polytope then the feasible region (1) is also a convex polytope (see [11,12]). This, in turn, implies that there is an optimal solution for (2) on an edge of the feasible region (1) if  $f$  is a linear function (or, of course, if  $f$  is a concave function). In this case we refer to the reverse convex programming problem as *LRCP* to denote that we are dealing with *linear programs with an additional reverse convex constraint*. Assume a vertex,  $\bar{x}$  of  $X$ , can be found with the property that  $g(\bar{x}) \geq 0$ . Then pivot via the simplex algorithm, so as to decrease  $f(x) = c^\top x$ , until a neighboring pair of vertices,  $u$  and  $v$ , is found with the property  $g(u) \geq 0$  and  $g(v) < 0$ . Let  $z \in [u, v]$  be the last point on the edge  $[u, v]$  with the property  $g(z) = 0$ . Consider the convex polytope  $X \cap \{x: c^\top x = c^\top z\}$  and generate the  $n - 1$  neighbors (we assume nondegeneracy for this discussion) of  $z$  on the hyperplane  $\{x: c^\top x = c^\top z\}$ . If one of those neighbors, say  $\eta$ , is such that  $g(\eta) \geq 0$  then we consider the edge,  $[\eta_1, \eta_2]$  of  $X$ , that contains  $\eta$  and continuing pivoting, via the simplex algorithm, from that edge's endpoint which is feasible. On the other hand, if no neighbor of  $z$  is feasible, we solve (19) with  $\bar{x} = z$ . If  $\bar{x}$  is

optimal for (19) then, under ‘stability’,  $\bar{x}$  is optimal for (2). If  $\bar{x}$  is not optimal for (19), let  $x'$  be optimal; then  $x'$  is a vertex of  $X$  (if  $c^\top x' < c^\top \bar{x}$ ) or  $x'$  is on an edge of  $X$  (if  $c^\top x' = c^\top \bar{x}$ ) and, of course,  $g(x') > 0$ . Note that we have made an implicit assumption that (19) is an easier problem to solve than the original problem (2). There is no theoretical justification for this assumption; often however, in practice, the assumption appears to hold. Also, all that is needed is an  $x'$  with the aforementioned properties; an optimal  $x'$  is not necessarily required.

See [3,4] for an early usage of the concave minimization problem (19) in the context of the application of Benders’ decomposition [6,8] to an economies-of-scale network capacity expansion problem of the form of (7). Also see [11] for a full discussion of the above pivoting method.

Since an edge optimal solution exists, a branch and bound edge search strategy may be in order. The first is due to R.J. Hillestad [10]; also, see [14]. We will not discuss this approach.

There is also a large literature, employing cutting planes based on the seminal paper of H. Tuy [20], which discusses the usefulness and difficulties of cutting planes for reverse convex optimization (e.g., see [7,9,12,13,18]). This literature will not be discussed in this article.

### X Convex, F Convex

Under assumption (18), and following Tuy [21], define the mapping  $\pi: X \cap G \rightarrow \mathbf{R}^n$  by

$$\alpha = \min \{ \delta \in [0, 1] : g(x + \delta(w - x)) = 0 \} ,$$

$$\pi(x) = x + \alpha(w - x) .$$
(20)

If  $z$  solves (19) but  $g(z) > 0$ , then  $f(\pi(z)) < f(\bar{x})$ . This suggests the following:

```

Select   $\bar{x} \in X \cap \partial G(\partial G = \{x : g(x) = 0\})$ 
Repeat  Let  $z$  solve (19)
        If  $g(z) > 0$ ,  $\bar{x} \leftarrow \pi(z)$ 
Until    $\{g(z) = 0\}$ 

```

Under a few technical assumptions, this method will, in the limit, produce an optimal solution. However, the major step in the algorithm involves a convex

maximization problem over a convex set and, in some sense, illustrates the relationship between convex maximization (concave minimization) and reverse convex programs. Of course, the convex maximization problem is often as difficult to solve as the original reverse convex program (2) and, therefore, solving the latter by a sequence of convex maximization problems may not be effective. However, there are excellent concave minimization methods (cf. e.g., ► **Concave Programming**).

There are various algorithmic strategies that attempt to overcome the inherent difficulties for solving (19) directly. Let  $\delta_x$  denote a support for  $g$  at the point  $x$ . Let  $\bar{x} \in X \cap G$  and let  $z$  solve the convex optimization problem, with a linear objective,

$$\max \{ \delta_{\bar{x}}^\top (x - \bar{x}) : x \in X, f(x) \leq f(\bar{x}) \} .$$
(21)

If  $\delta_{\bar{x}}^\top (z - \bar{x}) > 0$ , then  $g(z) > 0$  and  $f(\pi(z)) < f(\bar{x})$ . To see the latter, observe

$$f(\pi(z)) \leq f(z) + \alpha(f(w) - f(z))$$

$$< f(z) + \alpha(f(w) - f^*) < f(z) \leq f(\bar{x}) ,$$

where the strict inequalities hold since (18) implies that  $\alpha > 0$  and that  $z$  cannot be optimal for (2). This suggests the following:

```

Select   $\bar{x} \in X \cap G$ 
DO      Repeat
        Let  $z$  solve (21)
        If  $\delta_{\bar{x}}^\top (z - \bar{x}) > 0$ ,  $\bar{x} \leftarrow \pi(z)$ 
        Until  $\{ \delta_{\bar{x}}^\top (z - \bar{x}) = 0 \}$ 
         $\bar{x} \leftarrow \pi(z)$ 
        let  $z$  solve (19)
        If  $g(z) > 0$ ,  $\bar{x} \leftarrow \pi(z)$ 
WHILE   $\{g(z) > 0\}$ 

```

Of course, the point of solving (21) is to avoid, as long as possible, addressing problem (19). Nevertheless, (19) must be dealt with eventually. Another approach is to use an outer approximation method for problem (19). For instance, see Tuy [21] for a method which generates a sequence of convex polytopes,  $\{S_k\}$ , with the properties  $S_k \subset S_{k-1}$  and each  $S_k \supset X \cap G$ . Other methods, and combinations of methods, have been developed for problem (2) and the reader is referred to [13] as well as to the ‘Journal of Global Optimization’.

## Test Problem Construction

At this point in time, as one might imagine, there are no generally applicable and efficient methods for solving (2), the general RCP. Therefore, in order to test new procedures, it is important to have at hand a method for generating problems for which we know the optimal vector. There are several such methods; we will develop one, the first, due to Y. Sung and J.B. Rosen [19] (also, see [16]), for constructing a concave minimization problem, over a convex polytope, whose answer is known. A slight modification of that method leads to the construction of an LRCP whose answer is known. We proceed as follows.

Let  $X = \{x \in \mathbf{R}^n: Ax \leq b\}$ , where  $A$  is  $m \times n$ ,  $m > n$  (e.g., nonnegativity constraints are included), and it is assumed that  $X$  is bounded. Let  $f(x) = c^\top x$  and let  $\bar{x}$  be any edge point of  $X$  that is not a vertex of  $X$ . Then  $\bar{x}$  is a vertex of  $X \cap \{x: c^\top x \leq c^\top \bar{x}\}$ . Without loss of generality, assume the first  $n - 1$  rows of  $(A, b)$  define the edge of  $X$  of which  $\bar{x}$  is an element. That is,  $\bar{x}$  is the unique solution of the system of equations

$$\begin{aligned} a_i^\top x &= b_i, & i &= 1, \dots, n - 1, \\ c^\top x &= c^\top \bar{x} \end{aligned} \quad (22)$$

(we assume  $c^\top$  is not a linear combination of the rows  $a_i^\top$ ,  $i = 1, \dots, n - 1$ ). Let  $Dx = d$  denote the matrix representation of (22). Let

$$\begin{aligned} v_i &= \min \{a_i^\top x: Ax \leq b, c^\top x \leq c^\top \bar{x}\}, \\ i &= 1, \dots, n - 1, \\ v_n &= \min \{c^\top x: Ax \leq b\} \end{aligned} \quad (23)$$

and, for arbitrarily small  $\varepsilon > 0$ , define  $v^\top(\varepsilon) = (v_1 - \varepsilon, \dots, v_n - \varepsilon)$ . Let the  $j$ th component of the vector  $r$  be defined by  $r_j = (d_j + v_j(\varepsilon))/2$ . Then  $\bar{x}$  is the unique optimal solution for the LRCP

$$\min \left\{ c^\top x: \begin{array}{l} Ax \leq b, \\ \|Dx - r\|^2 - \|d - v(\varepsilon)\|^2 / 4 \geq 0 \end{array} \right\},$$

where  $\|\cdot\|$  denotes the Euclidean norm.

bility margin analysis problem. On an abstract level, M.G. Safonov [25] showed the analysis problem to be equivalent to testing for the *topological separation* of the graphs of the operators  $T$  and  $\Delta$  – this is so even in very general cases where  $T$  and  $\Delta$  are nonlinear operators.

The *multivariable stability margin*  $K_m(T)$  associated with a given controller  $K$  is [26,27]

$$K_m(T) \triangleq \begin{cases} \inf_{\gamma \geq 0} \gamma \\ \text{s.t.} & \text{system (S) is unstable} \\ & \Delta \in \gamma \Delta. \end{cases}$$

Thus, the quantity  $K_m$  is the smallest nonnegative real number  $\gamma$  for which the ‘scaled’ set  $\gamma \Delta$  contains a destabilizing  $\Delta$ . In cases where there is no  $\gamma \geq 0$  for which there is a destabilizing  $\Delta \in \gamma \Delta$ , one defines  $K_m = \infty$ . Clearly, a controller  $K(s)$  solves the robust control synthesis problem if and only if the nominal closed-loop transfer function  $T(s)$  satisfies

$$K_m(T) > 1.$$

It may be assumed without loss of generality that  $\dim(u_1) = \dim(y_1)$ .

### Linear Time-Invariant Robustness

If, as is often assumed by control engineers, both  $\Delta$  and  $T$  are linear time-invariant with stable rational Laplace transforms, then robustness analysis may be related to the *characteristic equation* of system (S)

$$\det(I - \Delta(s)T(s)) = 0. \quad (1)$$

The system (S) is said to be stable for a given  $\Delta(s)$  if and only if (1) has no solution  $\bar{\mathbb{C}}_+$  where  $\bar{\mathbb{C}}_+$  denotes the closed right-half of the complex plane.

Suppose, additionally, that the set  $\Delta$  is specified in the frequency-domain as simply the set of stable  $\Delta$ 's for which  $\Delta(j\omega) \in \Delta(j\omega)$  where, for each  $\omega$ ,  $\Delta(j\omega)$  is a given set of matrices. Then, the multivariable stability margin can be evaluated as

$$K_m = \inf_{\omega} k_m(j\omega)$$

where

$$k_m(T(j\omega)) \triangleq \begin{cases} \inf_{\gamma \geq 0} \gamma \\ \text{s.t.} & \det(I - \gamma \Delta(j\omega)T(j\omega)) = 0, \\ & \Delta(j\omega) \in \Delta(j\omega). \end{cases} \quad (2)$$

Closely related to the multivariable stability margin  $k_m(j\omega)$  is the *structured singular value* [9]

$$\mu(T(j\omega)) \triangleq \frac{1}{k_m(T(j\omega))}.$$

Thus, an ‘optimal’ solution to the robust control synthesis problem is obtained if one can solve the so-called  $\mu$ -*synthesis control* problem

$$\min_{K(s)} \sup_{\omega} \mu(T(j\omega)).$$

The exact computation of  $\mu(T(j\omega))$  is in general impractical, except for very simply structured uncertainty sets  $\Delta$ . Indeed, the optimization problem (2) is in general *NP-hard*, meaning that it cannot be computed in polynomial time in the worst cases [6]. Still, easy to compute conservative upper-bounds on  $\mu$  abound, but even for these it is usually necessary to first reformulate the robustness analysis problem.

### Topological Separation, Sectors and IQCs

The robustness analysis problem (2) can be interpreted in terms of a ‘topological separation’ of the graphs of  $\Delta(j\omega)$  and  $T(j\omega)$  (e.g., [15,16,25]):

$$\text{graph}(\Delta) \triangleq \left\{ z = \begin{pmatrix} u_1 \\ y_1 \end{pmatrix} \in \text{range} \begin{pmatrix} \Delta \\ I \end{pmatrix} \right\} \quad (3)$$

$$\text{graph}(\gamma T) \triangleq \left\{ z = \begin{pmatrix} u_1 \\ y_1 \end{pmatrix} \in \text{range} \begin{pmatrix} I \\ \gamma T \end{pmatrix} \right\}. \quad (4)$$

In particular, the robustness condition  $k_m(T) > 1$  is equivalent to the existence of a complex matrix  $Q$  such that the quadratic functional  $z^*Qz$  topologically separates  $\text{graph}(\Delta)$  and  $\text{graph}(\gamma T)$  in the sense that [15,25]

$$\text{Re}(z^*Qz) \geq 0 \quad \text{for all } z \in \text{graph}(\Delta), z \neq 0, \quad (5)$$

$$\text{Re}(z^*Qz) < 0 \quad \text{for all } z \in \text{graph}(\gamma T), z \neq 0. \quad (6)$$

Indeed, for  $\epsilon > 0$  sufficiently small one such matrix is [16]

$$Q(j\omega) = \begin{pmatrix} \gamma T^*(j\omega) \\ -I \end{pmatrix} (\gamma T(j\omega) \quad -I) - \epsilon I.$$

Safonov [25], building on the 1960s nonlinear stability work of I.W. Sandberg [32,33] and G. Zames [37], called this quadratic form of the topological separation condition the *sector stability criterion*. Later, A.

Megretski and A. Rantzer [19] have dubbed it the *integral quadratic constraint (IQC)* approach and linked it to the *S-procedure* nonlinear stability concept of V.A. Yakubovich.

In formulating robustness analysis as an optimization problem, the conditions (3)–(4) are usually rewritten as matrix definiteness conditions

$$\text{herm} \left( \begin{pmatrix} \Delta(j\omega) \\ I \end{pmatrix}^* Q(j\omega) \begin{pmatrix} \Delta(j\omega) \\ I \end{pmatrix} \right) \geq 0 \quad \text{for all } \Delta \in \Delta \quad (7)$$

$$\text{herm} \left( \begin{pmatrix} I \\ \gamma T(j\omega) \end{pmatrix}^* Q(j\omega) \begin{pmatrix} I \\ \gamma T(j\omega) \end{pmatrix} \right) < 0, \quad (8)$$

where

$$\text{herm}(X) \triangleq \frac{1}{2}(X + X^*).$$

Consequently, the problem (2) can be reformulated as the optimization  $k_m(T(j\omega)) \triangleq \inf_{\gamma \geq 0} \gamma$  subject to the LMI constraints (7)–(8). Unfortunately, verifying that there exists a  $Q$  satisfying (7)–(8) is not in general easier than the original problem. The problem remains inherently *NP-hard* [6].

As is apparent from (7)–(8), the problem in this form is an instance *linear matrix inequality (LMI)* problem, but with possibly infinitely many LMI constraints: (7) has one LMI for each element of the set  $\Delta$  which in general may be infinite – for example, even the unit interval  $\Delta = [0, 1] \subset \mathbf{R}$  has infinitely many points.

### Restrictions on $Q$

The class of matrices  $Q$  which may potentially solve the optimization (7)–(8) is inherently restricted. K.C. Goh and Safonov [15] established that every IQC topological separating functional is isomorphic to the *positivity* and *small gain* stability criteria of Zames [37]. More precisely, for some invertible matrix  $\tilde{F}$ , the change of variables

$$\begin{pmatrix} \tilde{u}_1 \\ \tilde{y}_1 \end{pmatrix} \triangleq \tilde{F} \begin{pmatrix} u_1 \\ y_1 \end{pmatrix} = \tilde{F}z$$

causes the topological separation conditions (5)–(6) to simplify to the so-called ‘small gain’ form

$$\begin{aligned} \|\tilde{y}_1\|^2 - \|\tilde{u}_1\|^2 &\geq 0 \text{ for all } z \in \text{graph}(\Delta), z \neq 0, \\ \|\tilde{y}_1\|^2 - \|\tilde{u}_1\|^2 &< 0 \text{ for all } z \in \text{graph}(\gamma T), z \neq 0, \end{aligned}$$

which corresponds to  $Q = \tilde{F}^* \begin{pmatrix} -I & 0 \\ 0 & I \end{pmatrix} \tilde{F}$ . Similarly, if one defines

$$\hat{F} \triangleq \begin{pmatrix} -I & I \\ I & I \end{pmatrix} \tilde{F},$$

then under the invertible change of variables

$$\begin{pmatrix} \hat{u}_1 \\ \hat{y}_1 \end{pmatrix} \triangleq \hat{F} \begin{pmatrix} u_1 \\ y_1 \end{pmatrix} = \hat{F}z$$

conditions (5)–(6) assume the ‘positivity’ form

$$\begin{aligned} \text{Re}(\hat{y}_1^* \hat{u}) &\geq 0 \quad \text{for all } z \in \text{graph}(\Delta), z \neq 0, \\ \text{Re}(\hat{y}_1^* \hat{u}) &< 0 \quad \text{for all } z \in \text{graph}(\gamma T), z \neq 0, \end{aligned}$$

which corresponds to  $Q = \hat{F}^* \begin{pmatrix} 0 & 0 \\ I & 0 \end{pmatrix} \hat{F}$ . One implication of these results is that, without loss of generality, one may restrict the  $Q$  matrices to those for which  $\text{rank}(Q) = \dim(Q)/2$  without introducing any conservativeness in solving the optimization. Another implication is that any  $Q$  that solves (7)–(8) must have a Hermitian part whose sign matrix has exactly as many 1’s as  $-1$ ’s. But, despite these freedoms to further restrict  $Q$  as above, the problem of exact computation of  $k_m$  remains inherently *NP-hard*.

### Linear Matrix Inequalities

Since exact computation of the multivariable stability margin is inherently *NP-hard*, one must settle for computing upper and/or lower bounds on  $k_m$ . In particular, ‘conservative’ lower-bounds are preferred by control engineers, since these give conservative sufficient conditions for stability of the uncertain system.

Many practical algorithms for computing a lower-bound  $\underline{k}_m$  on the multivariable stability margin involve the solution of finite-dimensional linear matrix inequalities of the form

$$\begin{aligned} k_m(T(j\omega)) &\geq \underline{k}_m(T(j\omega)) \\ &\triangleq \begin{cases} \inf_{\gamma \geq 0} & \gamma \\ \text{s.t.} & \\ \text{herm} & \left( \begin{pmatrix} I \\ \gamma T(j\omega) \end{pmatrix}^* Q(M) \begin{pmatrix} I \\ \gamma T(j\omega) \end{pmatrix} \right) < 0, \\ & \text{herm}(M(\theta)) > 0. \end{cases} \quad (9) \end{aligned}$$

Casting the  $k_m$  lower-bounding problem in this framework typically involves assuming additional ‘structural’ characteristics for the uncertainty set  $\Delta$  and exploiting these characteristics to identify linearly parametrized subsets of matrices  $Q(\theta)$  and  $M(\theta)$  for which (7) is known to hold a priori. Then, having eliminated the constraint (7), the problem assumes the form of the *semidefinite programming* problem (9), which is practical to solve. Indeed, for each fixed  $\gamma \geq 0$  it is a convex *linear matrix inequality* (LMI) optimization problem. The key to success here is identify which classes of linearly parametrized matrices  $Q(\theta)$  and  $M(\theta)$  go with which sorts of uncertainty structure.

### Uncertainty Structure

Several commonly encountered uncertainty structures (cf. [13]) are listed in the table below along with linearly parametrized  $M(\theta)$  and  $Q(M)$  such that

$$\begin{pmatrix} \Delta \\ I \end{pmatrix}^* Q(M) \begin{pmatrix} \Delta \\ I \end{pmatrix} \geq 0$$

for all  $\begin{cases} \Delta \in \mathbf{\Delta}, \\ M(\theta) \text{ with } \text{herm}(M(\theta)) > 0. \end{cases}$

Uncertainty $\Delta$	$M(\theta)$ and $Q(\theta)$
Small gain $\Delta \in \mathbf{C}^{m \times m}$ $\ \Delta\  \leq 1,$	$M = \theta I, \theta \in \mathbf{R},$ $Q = \theta \begin{pmatrix} -M & 0 \\ 0 & M \end{pmatrix}$
Positive $\Delta \in \mathbf{C}^{m \times m}$ $\text{herm}(\Delta) \geq 0,$	$M(\theta) = \theta I, \theta \in \mathbf{R},$ $Q = \begin{pmatrix} 0 & 0 \\ M & 0 \end{pmatrix}$
Repeated small gain $\delta \in \mathbf{R}$ $\Delta = \delta I_{m \times m},  \delta  \leq 1,$	$M(\theta) = \theta \in \mathbf{C}^{m \times m},$ $Q = \begin{pmatrix} -M & M \\ -M & M \end{pmatrix}$
Repeated positive $\delta \in \mathbf{R}$ $\Delta = \delta I_{m \times m}, \delta \geq 0,$	$M(\theta) = \theta \in \mathbf{C}^{m \times m},$ $Q = \begin{pmatrix} 0 & 0 \\ M & 0 \end{pmatrix}$
Repeated positive $\delta \in \mathbf{C}$ $\Delta = \delta I_{m \times m},$ $\text{Re}(\delta) \geq 0,$	$M(\theta) = \theta \in \mathbf{C}^{m \times m},$ $M(\theta) = M^*(\theta),$ $Q = \begin{pmatrix} 0 & 0 \\ M & 0 \end{pmatrix}$

When it is known that each of the individual uncertainties  $\Delta_i$  satisfies such a condition for a  $Q_i$  ( $i = 1, \dots, m$ ) partitioned evenly as

$$Q_i \triangleq \begin{pmatrix} Q_i^{(11)} & Q_i^{(12)} \\ Q_i^{(21)} & Q_i^{(22)} \end{pmatrix},$$

then it follows that inequality (7) holds for a likewise partitioned  $Q$  having (for  $j, k = 1, 2$ )

$$Q^{(jk)} = \begin{pmatrix} Q_1^{(jk)}(M_1) & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & Q_n^{(jk)}(M_n) \end{pmatrix}.$$

### State-Space Robustness Analysis

Insofar as stability analysis is concerned, the ‘state-integrator’ operator  $(1/s)I$  may be regarded as a repeated positive uncertainty  $\delta I, \delta \in \overline{\mathbf{C}}_+, [34]$ . This leads to a rearrangement of the block diagram of the system (S) so that the state-integrator is relocated from inside the nominal plant  $T(s) = C(Is - A)^{-1}B + D$  into the  $\Delta$  block as an additional *fictitious uncertainty*. Thus,  $\Delta$  and  $T$  become

$$\Delta \leftarrow \begin{pmatrix} \frac{1}{s}I & 0 & \dots & 0 \\ 0 & \Delta_1 & \dots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \dots & \Delta_n \end{pmatrix}, \quad T \leftarrow \begin{pmatrix} A & B \\ C & D \end{pmatrix},$$

whence  $T$  becomes a constant matrix.

### History and Further Reading

The origins of robust control theory can be traced to 1970s research work headed by M. Athans at the MIT Electronic Systems Laboratory. Up to this time, most mathematical control theorists generally assumed that untried 1960s optimal control theories would produce superior feedback designs. In 1971, researchers Athans [1] and H.H. Rosenbrock [24] began to voice cautious doubts about the this popular view. By 1975 the worst expectations had been confirmed when early attempts to apply *linear-quadratic Gaussian* (LQG) optimal control theory to practical feedback designs produced unacceptable results, see [2,21,30]. The problem was quickly identified to be a lack of attention to the *multivariable stability margin* problem [36]. Athans

and Safonov [25,29] introduced the use of the term *robustness* to describe this problem and laid the foundation for its solution based on quadratic separating functionals. The idea of computing lower-bounds on  $k_m$  via LMI optimization is due to M.K.H. Fan and A.L. Tits [12].

The evolution robust control theory during its infancy and up to 1982 is accurately described in [30]. Bibliographies focusing on more recent developments in the theory of multivariable stability margin may be found in references [8,22]. The article [27] provides an elementary introduction to robust control theory including motivating examples and a sampling of nonoptimization techniques for estimating conservative bounds on multivariable stability margin. Books on robust control design methods include J.M. Maciejowski [18], S. Skogestad and I. Postlethwaite [35], and B.R. Barmish [4]. Linear matrix inequality (LMI) optimization methods in control theory are emphasized in books of S.P. Boyd, L. ElGhaoui, E. Feron and V. Balakrishnan [5] and of ElGhaoui and S. Niculescu [11]. References [17,17,23] describe classes of optimal  $H_\infty$  robust control synthesis problems can be reduced to LMI optimizations using embeddings based on *Parrott's theorem* and *Finsler's theorem*. Bilinear matrix inequality (BMI) formulations of the robust control synthesis problems are described in [20,31]. Commercial software packages for robust control include [3,7,14].

### Keywords

Robust stability; Discrete-time systems

Consider the robust stability analysis of linear, time-invariant, discrete-time control systems with uncertain real parameters  $q_i$ ,  $i = 1, \dots, \ell$ , with given lower and upper bounds  $q_i^- \leq q_i \leq q_i^+$ . The scalars  $q_i$  form a vector  $\mathbf{q} = [q_1, \dots, q_\ell]^T$  that is bounded by a hyperrectangle  $Q = \{\mathbf{q}: q_i^- \leq q_i \leq q_i^+, i = 1, \dots, \ell\}$ . The characteristic polynomial is

$$P(z, \mathbf{q}) = \sum_{k=0}^n a_k(\mathbf{q})z^k, \quad \mathbf{q} \in Q.$$

For simplicity we assume  $a_n(\mathbf{q}) > 0$  for all  $\mathbf{q} \in Q$ . Suppose the coefficients  $a_k(q_1, \dots, q_\ell)$  depend (affine) linearly on the uncertain parameters, i. e.

$$a_k(\mathbf{q}) = a_{k0} + a_{k1}q_1 + \dots + a_{k\ell}q_\ell.$$

Then  $P(z, Q) = \{P(z, \mathbf{q}): \mathbf{q} \in Q\}$  is a *polytope of polynomials*. The question of robust *Schur stability* of the polytope is now: Are all roots of  $P(z, Q)$  located inside the unit circle of the complex  $z$ -plane?

### Solution

Define the vertex polynomials  $P_i(z)$ ,  $i = 1, \dots, 2^\ell$ , for which all  $q_i$  take on their maximum or minimum value. An obvious necessary condition for robust Schur stability is that all vertex polynomials  $P_i$  are Schur stable.

The following derivation of a necessary and sufficient condition was given in [1]. In the first step the edge theorem [2] is used. For the present problem it says, that the polytope of polynomials is Schur stable if and only if all exposed edges are Schur stable. The notion of 'exposed' edge is illustrated by the case  $\ell = 2$ . The admissible region is a rectangle in the  $(q_1, q_2)$ -plane. The four edges of the rectangle are exposed, the two diagonals are, however, not exposed. In the  $\ell$ -dimensional hyperrectangle each vertex is connected to  $\ell$  neighboring vertices by exposed edges. Counting each edge only once there are  $\ell 2^\ell - 1$  edges. The edge theorem reduces the test of an  $\ell$ -dimensional continuum to a finite number of one-dimensional stability tests for the edges.

The second step is now the Schur stability test for an edge between vertices  $\mathbf{q}_B$  and  $\mathbf{q}_C$  with corresponding polynomials  $P_B(z)$  and  $P_C(z)$ . A point on the edge is described by

$$P_A(z, \alpha) = \alpha P_B(z) + (1 - \alpha)P_C(z), \alpha \in (0, 1).$$

Starting from a stable polynomial  $P_A(z, 0) = P_C(z)$  there are three possibilities how  $P_A(z, \alpha)$  can become unstable with increasing  $\alpha$ :

- i) a real root crosses the point  $z = +1$ ;
- ii) a real root crosses the point  $z = -1$ ; and
- iii) a complex conjugate pair of roots crosses the unit circle.

By stability of the vertices  $P_B(1) > 0$ ,  $P_C(1) > 0$  and therefore  $P_A(1, \alpha) > 0$  for  $\alpha \in (0, 1)$ . A similar argument holds for  $P_B(-1)$  and  $P_C(-1)$ .

Condition iii) is checked by the following test. For a polynomial

$$P(z) = \sum_{k=0}^n a_k z^k = a_n \prod_{i=1}^n (z - z_i),$$

define the  $(n - 1) \times (n - 1)$  matrices

$$X = \begin{pmatrix} a_n & a_{n-1} & \cdots & \cdots & a_2 \\ 0 & a_n & & & \vdots \\ \vdots & & & & \vdots \\ \vdots & & & a_n & a_{n-1} \\ 0 & \cdots & \cdots & 0 & a_n \end{pmatrix},$$

$$Y = \begin{pmatrix} 0 & \cdots & \cdots & 0 & a_0 \\ \vdots & & & a_0 & a_1 \\ \vdots & & & \vdots & \vdots \\ 0 & a_0 & & \vdots & \vdots \\ a_0 & a_1 & \cdots & \cdots & a_{n-2} \end{pmatrix},$$

$$S(P) = X - Y.$$

It is shown in [4] that

$$\det S(P) = a_n^{n-1} \times \prod_{\substack{k=1 \\ i < k}}^n (1 - z_i z_k).$$

Notice that  $S(P) = 0$  for  $z_i = 1/z_k$ , which is true for complex conjugate roots on the unit circle (and for pairs  $z_i, z_k$  for which  $|z_i| > 1$  or  $|z_k| > 1$ , i. e. the stability boundary has been crossed already). The following arguments from [1] follow closely a corresponding argument in [3] for Hurwitz stability.  $P_A(z, \alpha)$ ,  $\alpha \in (0, 1)$ , has no complex conjugate roots on the unit circle if and only if

$$S(P_A) = S[\alpha P_B + (1 - \alpha)P_C] = \alpha S(P_B) + (1 - \alpha)S(P_C)$$

is nonsingular for all  $\alpha \in (0, 1)$ . Equivalently,

$$\frac{S(P_A)}{\alpha} = S(P_B) - \lambda S(P_C)$$

(with  $\lambda = (\alpha - 1)/\alpha$ ) is nonsingular for all  $\lambda \in (-\infty, 0)$  and equivalently

$$\frac{S(P_A)S(P_C)^{-1}}{\alpha} = S(P_B)S(P_C)^{-1} - \lambda I$$

is nonsingular for all  $\lambda \in (-\infty, 0)$ . That is  $S(P_B)S(P_C)^{-1}$  has no negative real eigenvalues.

### Summary

A polytope of polynomials of degree  $n$  with  $\ell$  interval parameters is Schur stable if and only if

- i) all  $2^\ell$  vertices are Schur stable;
- ii) for all  $2^\ell - 1$  edges a testing matrix has no negative real eigenvalues. The computation of the testing matrix involves forming two  $(n - 1) \times (n - 1)$  matrices from the coefficients of the corresponding vertex polynomials, one inversion and one multiplication. Since the sequence of vertices is arbitrary, the total number of inversions is  $\ell 2^{\ell-2}$ .

### Introduction

In engineering applications, optimization problems often arise in which an optimal steady state of a dynamical system is sought. Chemical production plants, for example, can often be described by ordinary differential equations and algebraic equations, and an optimal continuous operation corresponds to an optimal steady state of the differential algebraic (DAE) model.

Because an optimal steady state is sought, the dynamical optimization problem reduces to an algebraic optimization problem. This point of view, however, neglects the stability properties of the dynamical system. While a steady state of a dynamical system is the solution of a nonlinear set of algebraic equations, these algebraic equations do not reveal anything about the stability of the resulting steady state. In fact, a steady state that is optimal with respect to a profit function may be found, but this steady state may turn out to be unstable. This problem has been addressed with the use of matrix measures before [2,14,17]. Unfortunately, matrix measures overestimate the region of instability in the process design space and therefore lead to suboptimal results.

The present contribution summarizes recent progress on a new approach to take stability boundaries into account in steady state optimization. The new methodology, which is based on ideas from nonlinear dynamics, permits to consider the stability of nonlinear dynamical systems without having to introduce approximations. The approach is based on the notion of the distance to critical manifolds in the parameter space [16]. This idea proves to be very generally applicable. As a result, the approach cannot only be used to consider stability boundaries in steady state optimization, but other boundaries that are critical for the systems' dynamics as well as feasibility boundaries.

In engineering models, some or all parameters are often *uncertain*, i. e., they are only known up to a considerable error. In a chemical production plant, for example, a precise value of some or all kinetic constants of the chemical reactions may not be known. In fact, uncertainty of this kind arises systematically in engineering models, because precise measurements of system parameters create cost themselves. Therefore, a trade-off usually exists between measuring unknown system parameters to desirable precision on the one hand, and affordable precision on the other hand.

## Definitions

In this section the problem is introduced. For a more detailed introduction we refer to [24].

A large class of dynamical systems can be modeled by differential-algebraic (DAE) systems of the form

$$\begin{aligned} \dot{x}^d(t) &= f^d(x^d(t), x^a(t), u(t), d(t), \vartheta, t), \quad x^d(0) = x_0^d, \\ 0 &= f^a(x^d(t), x^a(t), u(t), d(t), \vartheta, t), \\ y(t) &= h(x^d(t), x^a(t), u(t), d(t), \vartheta, t), \end{aligned} \quad (1)$$

where  $x = (x^{dT}, x^{aT})^T \in \mathbb{R}^{n_x}$ ,  $u \in \mathbb{R}^{n_u}$ ,  $d \in \mathbb{R}^{n_d}$ ,  $\vartheta \in \mathbb{R}^{n_\vartheta}$ ,  $y \in \mathbb{R}^{n_y}$  are state variables, inputs, disturbances, parameters, and outputs of the system. In (1),  $t$  denotes time, and  $f := (f^{dT}, f^{aT})^T$  and  $h$  are smooth functions which map from some subset  $U \subset \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_d} \times \mathbb{R}^{n_\vartheta} \times \mathbb{R}$  onto  $\mathbb{R}^{n_x}$  and  $\mathbb{R}^{n_y}$ , respectively. The state variables  $x$  and the corresponding equations have been partitioned into dynamic state variables  $x^d$  and differential equations  $f^d$ , and algebraic variables  $x^a$  and equations  $f^a$ . In the se-

quel we assume that inputs  $u$ , and disturbances  $d$  vary only quasi-statically compared to the system dynamics. Mönnigmann and Marquardt [24] show that the system (1) can be simplified considerably under this assumption. The simplified system reads

$$\begin{aligned} \dot{x} &= f(x, \alpha, p), \quad x(0) = x_0, \\ y &= h(x, \alpha, p), \end{aligned} \quad (2)$$

where  $p$  denotes all inputs, references, and parameters that can be assumed to be known precisely, while  $\alpha$  denotes inputs, references, disturbances, and parameters that can be modeled in terms of an average value and an uncertainty. The parameters  $\alpha$  therefore have the form

$$\alpha_i \in [\alpha] := [\alpha_i^{(0)} - \Delta\alpha_i, \alpha_i^{(0)} + \Delta\alpha_i], \quad (3)$$

$$i = 1, \dots, n_\alpha.$$

By a slight abuse of notation, we use the same symbols  $f$  and  $h$  in (1) and (2).

The steady state optimization problem for the uncertain dynamical system (2) with stability constraints can now be stated:

$$\begin{aligned} \min_{x^{(0)}, \alpha^{(0)}, p^{(0)}} \quad & \phi(x^{(0)}, \alpha^{(0)}, p^{(0)}) & (a) \\ \text{subject to} \quad & 0 = f(x^{(0)}, \alpha^{(0)}, p^{(0)}), & (b) \\ & \left. \begin{aligned} 0 &= f(\tilde{x}, \tilde{\alpha}, p^{(0)}) \\ \operatorname{Re}(\lambda) &< 0 \quad \forall \lambda \in \sigma(J(\tilde{x}, \tilde{\alpha}, p^{(0)})) \end{aligned} \right\} \forall \tilde{\alpha} \in [\alpha], & (c) \\ & 0 \leq g(\hat{x}, \hat{\alpha}, p^{(0)}) \quad \forall \hat{\alpha} \in [\alpha], & (d) \\ & x \in X, \alpha \in A, p \in P. & (e) \end{aligned} \quad (4)$$

where  $\phi$  is the merit function and (4b) ensures that the optimal point of operation is a steady state of the dynamical system. Equations (4c) constitute a semi-infinite constraint that guarantees all eigenvalues in the spectrum  $\sigma(J)$  of the Jacobian  $J(x, \alpha, p)$  of  $f$  with respect to  $x$  to be in the open left half of the complex plane. This constraint ensures stability of the nonlinear system. Since constraint (4c) enforces this condition for all  $\alpha$  within the uncertainty region (3), the resulting optimal steady state will be robust with respect to the uncertainty in  $\alpha$ . In (4d),  $g$  is a twice continuously differentiable function that maps into  $\mathbb{R}^{n_g}$ ,  $n_g \geq 1$ . Equation (4d) is a semi-infinite constraint that ensures the inequality constraints to hold for all  $\alpha$ . Finally, (4e) denotes bounds on  $x$ ,  $\alpha$ , and  $p$ . In a typical application

there exist box constraints on some or all of the state variables and parameters. We note that some or all of the nominal values of the uncertain parameters  $\alpha^{(0)}$  may be degrees of freedom in the optimization.

**Method**

Mönnigmann et al. [19] introduced an algorithm for solving the semi-infinite problem (4). This algorithm is based on detecting and backing-off critical manifolds. We first introduce the notion of a critical manifold and a normal vector, and then present the algorithm for solving (4).

**Critical Manifolds and Normal Vectors**

In order to introduce the notion of a critical manifold, consider a single feasibility constraint

$$0 \leq g_i(x, \alpha, p) \tag{5}$$

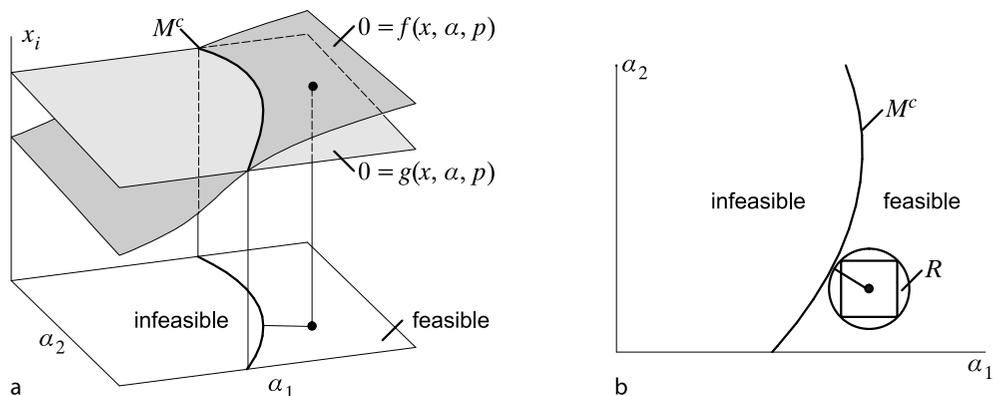

from among the feasibility constraints in (4d). In this simple case, the critical manifold, denoted by  $M^c$ , is defined by the set of points at which the constraint (5) is active,

$$M^c = \{(x, \alpha, p) \mid 0 = f(x, \alpha, p), 0 = g_i(x, \alpha, p)\} . \tag{6}$$

This critical manifold  $M_i^c$  separates the part of the space of uncertain parameters  $\alpha$  in which the constraint holds from the part in which the constraint is violated, cf. Fig. 1.

In Fig. 1 the dot marks a candidate steady state of operation in the feasible regime. The shortest distance in the space of the uncertain parameters  $(\alpha_1, \alpha_2)$  between this candidate point of operation and the critical manifold occurs along the marked direction that is normal to the critical manifold. By imposing a minimum distance from the candidate point of operation to the critical boundary, we can ensure that the critical boundary is not crossed, regardless of the actual values of the uncertain parameters in the uncertainty region (3). This amounts to overestimating the uncertainty region by a circle and forcing the circle to at most touch the critical boundary tangentially, or to stay at a larger distance from the critical boundary, cf. Fig. 1. In the situation sketched in Fig. 1 we assume that the uncertain parameters have been scaled appropriately. This can be done, for example, by measuring them in units of their uncertainties  $\Delta\alpha_i$  [18]. In the general case, the uncertainty region (3) defines a hyperrectangle and the circle shown in Fig. 1b becomes a hyperellipsoid. Regardless of the number  $n_\alpha$  and scaling of the uncertain parameters, the distance between the candidate point of operation and the critical manifold, or the distance between the uncertainty region and the critical manifold can be measured with the aid of the normal vector. We refer to [18] for details.

The concepts of a critical manifold and of measuring the distance to a critical manifold along a normal vector have been introduced for feasibility constraints. The most important application of the normal vector approach, however, is the use of normal vectors to en-

Robust Design of Dynamic Systems by Constructive Nonlinear Dynamics, Figure 1  
 Critical manifold  $M^c$  and robustness region  $R$ . This figure is reproduced from [16]. We note that the overestimation introduced by the circle in (b) can be mitigated by other descriptions [9].

sure a parametric distance from stability boundaries in order to guarantee robust stability. Critical points for stability of ODE and DAE systems have been investigated in bifurcation theory. A thorough discussion of the use of normal vectors to manifolds of bifurcation points is beyond the scope of this paper and we refer the reader to textbooks in applied bifurcation theory (see, for example, [15]) and previous papers on the use of normal vectors in steady state optimization [18,21]. We give a sketch of the idea, however.

A simple result of nonlinear systems theory states that a steady state  $(x^{(0)}, \alpha^{(0)}, p^{(0)})$  of a nonlinear system (2) is stable if all eigenvalues of the Jacobian  $A(x, \alpha, p)$  defined by

$$A_{ij} = \frac{\partial f_i}{\partial x_j}(x, \alpha, p),$$

evaluated at this steady state, lie in the left half of the complex plane. Since  $A$  is non-symmetric in general, stability may be lost due to either a real eigenvalue or a complex conjugate pair of eigenvalues in the open right half of the complex plane. In bifurcation theory, these two cases are known as saddle-node or Hopf bifurcation [15]. Under genericity conditions [15], a manifold of saddle-node (Hopf) bifurcations exists in the vicinity of a saddle-node (Hopf) bifurcation point. Saddle-node bifurcations are usually characterized by the necessary conditions

$$\begin{aligned} 0 &= f(x^*, \alpha^*, p^*) & (a) \\ 0 &= A(x^*, \alpha^*, p^*)v & (b) \\ 0 &= v^T v - 1 & (c) \end{aligned} \quad (7)$$

where  $(x^*, \alpha^*, p^*)$  is the bifurcation point. Equations (7a) ensure that the bifurcation point is a steady state. Equations (7b) are eigenequations with a real eigenvalue zero, the critical eigenvalue. Finally, (7c) is a regularization that is necessary because (7b) determines the eigenvector  $v$  up to its length only. Based on these necessary conditions the manifold

$$M^c := \{(x^*, \alpha^*, p^*) \mid \exists v \in \mathbb{R}^n \text{ such that (7) holds}\} \quad (8)$$

can be stated. Similar necessary conditions can be stated for Hopf bifurcation points. Note that the determinant of  $A$  is zero if and only if a real zero eigenvalue exists.

The determinant therefore can be used as a test function for checking if a steady state may be a saddle-node bifurcation (numerically more robust test functions exist, see [15], for example). Test functions of this type will be used in the algorithm to detect the crossing of critical manifolds.

Mönnigmann and Marquardt [18] presented a scheme for the derivation of systems of equations for the calculation of normal vectors. This scheme can be applied to defining equations for manifolds of the form (5) or (6). Mönnigmann and Marquardt [18] applied this scheme to a number of bifurcation point types. The saddle-node normal vector system, for example, comprises of

Equation (7) and

$$0 = \sum_{i=1}^{n_x} v_j \frac{\partial f_j}{\partial \alpha_i}(x^*, \alpha^*, p^*) - r_i, \quad i = 1, \dots, n_\alpha, \quad (9)$$

where  $r \in \mathbb{R}^{n_\alpha}$  is the desired normal vector. This system has first been stated and used by Dobson [4]. Similar systems for the calculation of normal vector can be derived for the feasibility constraints, Hopf bifurcations, and other critical dynamical points [18]. In general, these systems have the form

$$0 = G^{(\tau)}(x, \bar{x}^\tau, \alpha, p, r), \quad (10)$$

where  $\bar{x}$  denote auxiliary variables such as the eigenvector  $v$  in (7). The upper index  $\tau$  is introduced to distinguish between the various types of critical points and manifolds such as  $\tau = \text{saddle-node}$ ,  $\tau = \text{Hopf}$ , or  $\tau = \text{feasibility}$ .

### Algorithm

Based on the normal vector systems (10) an algorithm for solving (4) can be stated. Before proceeding to the algorithm a few remarks are necessary. For brevity, these remarks are given in an informal fashion. For a more detailed and precise discussion we refer to [20,21].

Loosely speaking, the optimization algorithm will move the robustness region (3) (or an approximation thereof such as the circle in Fig. 1) in the parameter space while seeking a minimum for the profit function (4a). In this process, critical manifolds may be crossed. Test functions, like the determinant introduced in Sect.

“Critical Manifolds and Normal Vectors”, can be used to signal the crossing of critical manifolds. Whenever a critical point is detected, this point is added to a set of known critical points denoted by  $\mathcal{J}$ . Later in the algorithm these points are used to initialize normal vector constraints. Critical points that have been used to initialize normal vector constraints are collected in a set  $\mathcal{I}$ . Points in  $\mathcal{J}$  can be processed to  $\mathcal{I}$  by solving an optimization problem that is not discussed here for brevity. We refer to [20] for details.

Given the index set  $\mathcal{I}$ , the following optimization problem is solved:

$$\min_{x^{(0)}, \alpha^{(0)}, p^{(0)}} \phi(x^{(0)}, \alpha^{(0)}, p^{(0)}) \quad (a)$$

$$\text{subject to } 0 = f(x^{(0)}, \alpha^{(0)}, p^{(0)}) \quad (b)$$

$$0 = G^{(\tau_i, i)}(x^{(i)}, \bar{x}^{(\tau_i, i)}, \alpha^{(i)}, p^{(0)}, r^{(i)}), \quad \forall i \in \mathcal{I}, \quad (c)$$

$$0 = \alpha^{(0)} - \alpha^{(i)} + l \frac{r^{(i)}}{\|r^{(i)}\|_2}, \quad \forall i \in \mathcal{I}, \quad (d)$$

$$0 \leq l^{(i)} - \sqrt{n_\alpha}, \quad \forall i \in \mathcal{I} \quad (e)$$

$$x \in X, \quad \alpha \in A, \quad p \in P. \quad (f)$$

(11)

Because the crossing of critical manifolds is only detected at the nominal point of operation, critical manifolds may enter the robustness region without being detected [20]. For this reason, a rigorous numerical test for critical points in the robustness region is necessary. Interval arithmetics can be used to carry out this test [21] for problems of moderate complexity.

Finally, an adjustable parameter  $\hat{l}, \hat{l} > \sqrt{n_\alpha}$ , has to be chosen. This parameter is used to switch off normal vector constraints.

The algorithm can now be stated as follows.

1. (Initialization) Choose a steady state of (2) that is stable in the sense of (4c) and feasible with respect to the constraints (4d). Choose a value for  $\hat{l}$ . If critical point in the vicinity of the steady state are known a priori, put them into  $\mathcal{J}$ . Set  $\mathcal{I} = \emptyset$ .
2. (Update of  $\mathcal{I}$ ) Process points in  $\mathcal{J}$  to  $\mathcal{I}$  [21]. Remove critical points from  $\mathcal{I}$  for which  $l^{(i)} > \hat{l}$ .
3. (Optimization) Solve problem (11) using the current index set  $\mathcal{I}$ .
4. (Detection of critical manifolds) Analyze the path between the starting and end point of step 3. If a critical manifold has been crossed along this path, put

this point into  $\mathcal{J}$  and return to step 2. Otherwise proceed to step 5.

5. (Rigorous search for critical points) Check for critical points in the robustness region (3). If a critical point exists that has not been detected in step 4, put it into  $\mathcal{J}$  and return to step 2. Otherwise stop.

For several details on the practical implementation we refer to [20]. For details on step 5 we refer to [21].

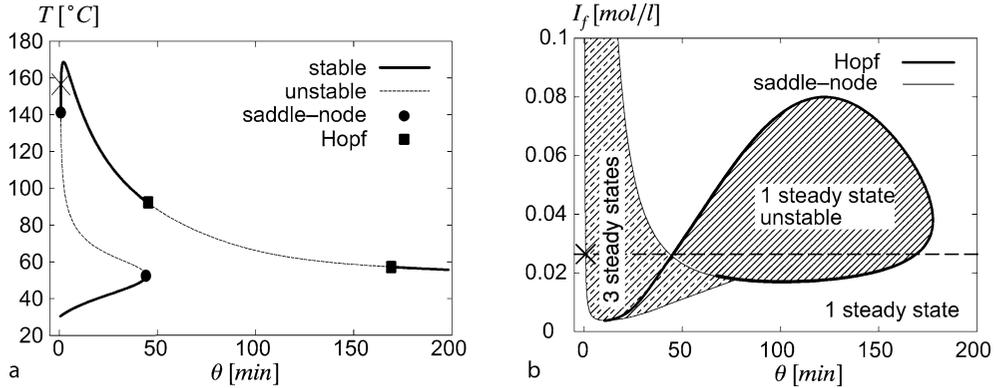

## Cases

The normal vector based optimization approach has successfully been applied to different types of problems and a number of cases. The treated models range from a few to a few hundred model equations in size:

- Steady state optimization of parametrically uncertain dynamical systems with constraints for stability [1,9,21,22,24];
- Steady state optimization of parametrically uncertain systems with constraints on the location of higher codimension critical points. Normal vector constraints on the location of these points can be used to guarantee parametric robustness with respect to hysteresis, for example [7,18].
- Steady state optimization with parametrically robust pole placement. In applications of this type, the algorithm is applied to simultaneously seek an optimal plant design and to tune controller parameters [5,8,10,11,12,13,16,19,23].
- Optimization of parametrically uncertain transient processes [3,6].

Here the use of the normal vector based methodology is demonstrated with a small example. Because only two uncertain parameters exist in this example, the results can be visualized. The result for this example have first been published in [24].

The system treated here is a simple model for the solution free radical homopolymerisation of vinyl acetate. The model has been analyzed thoroughly with respect to its nonlinear dynamic behavior by numerical bifurcation analysis. We refer to [25] for details on the model and its analysis. The process is optimized with respect to an economic cost function that takes the cost of monomer, the cost of an initiator of the polymerization, and the cost of the solvent into account [24]. Two parameters are assumed to be uncertain. These are the residence time in the reactor  $\theta$  and the concentration of

Robust Design of Dynamic Systems by Constructive Nonlinear Dynamics, Figure 2

Optimum which results in the first sweep through the algorithm with  $J = \emptyset$ ,  $\mathcal{I} = \emptyset$ . The optimum that results in step three is marked by the cross. These results were first reported in [24]

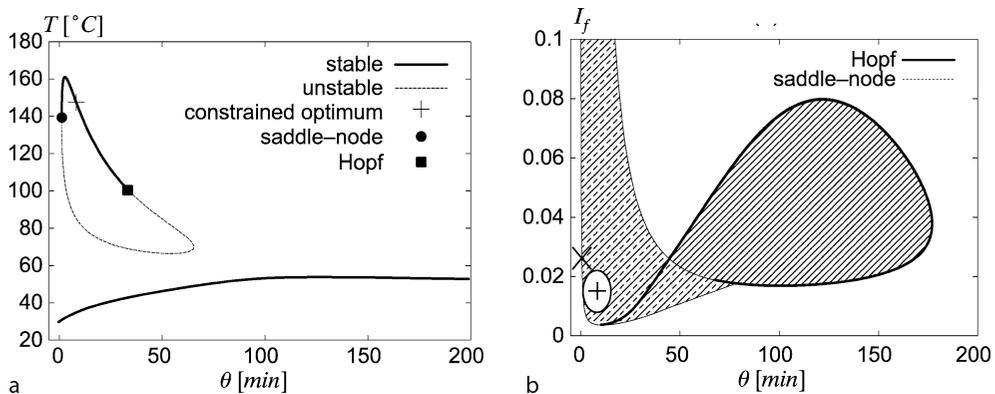

initiator  $I_f$ :

$$\begin{aligned} \Delta\theta &= \Delta\alpha_1 = 5 \text{ min}, \\ \Delta I_f &= \Delta\alpha_2 = 0.005 \text{ mol/l}. \end{aligned} \quad (12)$$

Assuming that nothing is known about the location of critical boundaries, the algorithm proceeds with  $J = \mathcal{I} = \emptyset$ . The parameter  $\hat{l}$  is set to  $\hat{l} = 2$ . The value of  $\hat{l}$  is not important, since normal vector constraints are never switched off in step two in this particular example. The result of the optimization solved in step three is shown in Fig. 2a. Figure 2b shows the location of the stability boundaries which result from saddle-node and Hopf bifurcations as a function of  $\theta$  and  $I_f$ . The particular value of  $I_f$ , at which Fig. 2a was obtained

by the horizontal dashed line in Fig. 2b. While the optimal point of operation lies on a stable branch of steady states, the optimal point is obviously not robust with respect to variations in  $\theta$ . The analysis in step 4 or 5 will therefore reveal that a loss of stability is likely due to the saddle-node bifurcations in the vicinity of the candidate optimal point.

In the next step a close saddle-node bifurcation is therefore added to  $J$ , and the optimization (11) is repeated with a single normal vector constraint. The result is shown in Fig. 3. Since the robustness region marked by the ellipse contains no critical points, the algorithm terminates. An optimal point of operation that is stable despite the parametric uncertainty (12) has therefore been found.

Robust Design of Dynamic Systems by Constructive Nonlinear Dynamics, Figure 3

Optimum which results from the optimization with constraint on the minimal distance to the saddle-node bifurcation manifold. The optimum from Fig. 2 is marked for reference. These results were first reported in [24]

## Conclusions

This contribution summarizes recent progress in the development of methods for the optimization of nonlinear dynamical systems with parametric uncertainties. The approach has successfully been applied to various problems in plant design and integrated plant design and controller tuning. Cases discussed here are restricted to steady state optimization. The extension to the robust optimization of transient processes is subject to current investigations [3,9].

### Introduction

Many deficiencies in global optimization methods for problems with nonconvex constraints require the necessity to reexamine certain concepts of approximate optimal solutions and to develop a robust approach to these problems.

### Difficulties of Problems with Nonconvex Constraints

A wide class of global optimization problems have the form

$$\min\{f(x) \mid g_i(x) \geq 0 (i = 1, \dots, m), x \in [a, b]\}, \quad (\text{P})$$

where  $f, g_1, \dots, g_m$  are nonconvex continuous real-valued functions on  $\mathbb{R}^n$ ,  $a, b \in \mathbb{R}^n$ , and  $[a, b] := \{x \in \mathbb{R}^n \mid a \leq x \leq b\}$ . When the feasible set

$$D := \{x \in [a, b] \mid g_i(x) \geq 0, i = 1, \dots, m\}$$

is highly nonconvex, computing just one feasible solution may be almost as hard as solving the problem itself. Therefore, most current methods for solving these problems are confined to finding only an approximate optimal value rather than an approximate optimal solution. Even within these limitations, many methods are deficient in one way or another, providing approximate optimal solutions which are not guaranteed to be close enough to the true optimum, or in other cases that very

unstable with respect to perturbations of the data or refinements of the tolerances.

Typically, the given problem is relaxed to

$$\min\{f(x) \mid g_i(x) + \varepsilon \geq 0 (i = 1, \dots, m), x \in [a, b]\}, \quad (\text{R})$$

where  $\varepsilon > 0$  is the tolerance. Although this problem is a bit easier than (P) because it satisfies the regularity assumption, an optimal solution of it can rarely be computed exactly in finitely many iterations. So the best that one can expect to compute in finitely many iterations is an  $\eta$ -optimal solution of (R), i. e., a feasible solution  $x^*$  of (R) such that  $f(x^*) \leq f(x) + \eta$  for every other feasible solution  $x$ . Such an  $x^*$  is sometimes referred to as an  $(\varepsilon, \eta)$ -approximate optimal solution of the original problem. Unfortunately, the inadequacy of this concept has been shown on simple examples where an  $(\varepsilon, \eta)$ -approximate optimal solution lies so far away from the true optimum that it can hardly be accepted as an approximation of the latter in some reasonable sense.

In view of these limitations and deficiencies, a robust approach to nonconvex global optimization problems is desirable which could provide the user with reliable good feasible solutions, stable under small perturbations of the data and easily implementable, though not necessarily the best among all possible feasible solutions.

### $\mathcal{D}(C)$ -Optimization Problems

The basic idea of this robust approach is to transform an optimization problem with a complicated nonconvex constraint set into a sequence of problems with nice constraint sets. Such a transformation is possible if the functions describing the problem belong to certain classes we are going to define.

For any two functions  $g_1, g_2: \mathbb{R}^n \rightarrow \mathbb{R}$  write  $g = g_1 \vee g_2$ ,  $h = g_1 \wedge g_2$  if  $g(x) = \max\{g_1(x), g_2(x)\}$ ,  $h(x) = \min\{g_1(x), g_2(x)\}$ .

Let  $C$  be a family of real-valued functions on  $\mathbb{R}^n$  such that

- (i)  $f_1, f_2 \in C, \alpha_1, \alpha_2 \in \mathbb{R}_+ \Rightarrow \alpha_1 f_1 + \alpha_2 f_2 \in C$ ;
- (ii)  $g_1, g_2 \in C \Rightarrow g_1 \vee g_2 \in C$ .

**Proposition 1** Under assumptions i and ii the family  $\mathcal{D}(C) = C - C$  is a vector lattice with respect to the two operations  $\vee$  and  $\wedge$ .

Also note that if  $f \in \mathcal{D}(C)$  then  $|f| \in \mathcal{D}(C)$  because  $|f| = \max\{f, -f\}$ .

An optimization problem of the form (P) where  $f, g_i \in \mathcal{D}(C), i = 1, \dots, m$ , is called a  $\mathcal{D}(C)$ -optimization problem.

**Proposition 2** Assume  $C$  satisfies assumptions i and ii and also that:

(iii) Every function  $x \mapsto x_i$ , with  $i \in \{1, \dots, n\}$ , belongs to  $C$ .

Then by simple manipulations any  $\mathcal{D}(C)$ -optimization problem can be rewritten in the form (called “standard”)

$$\min\{f(x)|g(x) \geq 0, x \in [a, b]\},$$

where  $f \in C, g \in \mathcal{D}(C)$ . (1)

Two most important cases when  $C$  satisfies assumptions i, ii, and iii are:

1)  $C$  is the family of convex functions. Any  $f \in \mathcal{D}(C)$  is then called a *dc function* and a  $\mathcal{D}(C)$ -optimization problem is called a *dc optimization problem*. Until recently most problems studied in global optimization could be shown to belong to this class [1].

2)  $C$  is the family of increasing functions, i.e., functions  $f(x)$  such that  $x' \leq x \Rightarrow f(x') \leq f(x)$ . Any  $f \in \mathcal{F}$  is then called a *dm function* and a  $\mathcal{D}(C)$ -optimization problem is called a *dm optimization*, or else a *monotonic optimization problem*. A theory of monotonic optimization has emerged in recent years that has been shown to parallel dc optimization in several respects [2,5,6].

As a result, any dc (dm, respectively) optimization problem can be written in the form (1) where  $f, g_1$ , and  $g_2$  are convex (increasing, respectively) functions.

Since any polynomial can be viewed either as a dc or as a dm function, the set of dc functions or dm functions on a box  $[a, b]$  is dense in the space  $C[a, b]$  of continuous functions on  $[a, b]$  with the supnorm topology. Virtually every global optimization of interest belongs to either of the basic classes described above.

### A Robust Approach

In a continuous nonconvex optimization problem, an isolated optimal solution is usually very difficult to compute and very difficult to implement when it is computable. To avoid these difficulties most global optimization methods assume that the feasible set  $D$  satisfies

fies

$$D = cl(int)D,$$

where  $clA, intA$  denote the closure and the interior, respectively, of the set  $A$ . However, this condition is generally very hard to check. Practically we often have to consider feasible sets which are not known a priori to contain isolated points or not.

Therefore, from a practical point of view it is desirable to know how to discard isolated feasible solutions without having to check for their presence.

A nonisolated feasible solution  $x^*$  of (P) is called an *essential optimal solution* if

$$f(x^*) \leq f(x) \quad \forall x \in D^*,$$

where  $D^*$  denotes the set of nonisolated points (accumulation points) of  $D := \{x \in [a, b]|g(x) \geq 0\}$ . In other words, an essential optimal solution is an optimal solution of the problem

$$\min\{f(x)|x \in D^*\}.$$

For a given tolerance  $\varepsilon \geq 0$  a point  $x \in [a, b]$  satisfying  $g(x) \geq \varepsilon$  is said to be  $\varepsilon$ -feasible, and an  $\varepsilon$ -feasible point which is nonisolated is called an *essential  $\varepsilon$ -feasible solution*. In other words, an essential  $\varepsilon$ -feasible solution is a nonisolated point of the set  $D_\varepsilon := \{x \in [a, b]|g(x) \geq \varepsilon\}$ . For given tolerances  $\varepsilon > 0, \eta > 0$ , an essential  $\varepsilon$ -feasible solution  $x^*$  is called an *essential  $(\varepsilon, \eta)$ -optimal solution* if

$$f(x^*) \leq f(x) + \eta \quad \forall x \in D_\varepsilon^*,$$

where  $D_\varepsilon^*$  is the set of all essential  $\varepsilon$ -feasible solutions. An essential  $(\varepsilon, \eta)$ -optimal solution for  $\varepsilon = 0, \eta = 0$  is obviously essential optimal.

The above discussion suggests that instead of trying to find an optimal solution to (P), it would be more practical and reasonable to look for an essential  $(\varepsilon, \eta)$ -optimal solution.

The robust approach embodies this point of view for  $\mathcal{D}(C)$ -optimization, i.e., for a class of problems that includes virtually every nonconvex global optimization problem of interest.

### Interchangeability Between Objective and Constraint

From now on we consider problem (P) where  $g_1$ ,

... ,  $g_m \in \mathcal{D}(C)$ . Setting  $g(x) = \min_{i=1,\dots,m} g_i(x)$ , we rewrite (P) as

$$\min\{f(x)|g(x) \geq 0, \quad x \in [a, b]\}, \tag{P}$$

where  $f, g \in \mathcal{D}(C)$ . Further, by Proposition 2, without loss of generality we can assume  $f \in C$ . Given  $\varepsilon, \gamma \in \mathbb{R}$ , let us consider the pair of optimization problems

$$\min\{f(x)|g(x) \geq \varepsilon, x \in [a, b]\}, \tag{P_\varepsilon}$$

$$\max\{g(x)|f(x) \leq \gamma, x \in [a, b]\}, \tag{Q_\gamma}$$

where the objective and constraint functions are interchanged. Owing to the fact  $f \in C$ , a key feature of problem (Q<sub>γ</sub>) for our purpose is that its feasible set is a *convex* set (if  $C$  is the set of convex functions) or a *normal* set (if  $C$  is the set of increasing functions), so in either case problem (Q<sub>γ</sub>) has no isolated feasible solution and computing a feasible solution to (Q<sub>γ</sub>) can be done at cheap cost.

**Proposition 3** *If  $\max(Q_\gamma) < \varepsilon$  then  $\min(P_\varepsilon) > \gamma$ .*

On the basis of this property, the robust approach to  $\mathcal{D}(C)$ -optimization consists in replacing the original problem (P), possibly very difficult, by a sequence of easier, stable, problems (Q<sub>γ</sub>), where the parameter  $\gamma$  can be iteratively adjusted until a stable (robust) solution to (P) is obtained.

**Successive Incumbent Transcending**

A key step towards finding a global optimal solution of a problem (P) is to deal with the following question of incumbent transcending.

(\*, γ) *Given a real number γ, check whether problem (P) has an essential ε-feasible solution x satisfying  $f(x) \leq \gamma$ , and find one such solution if it exists.*

Using Proposition 3, consider a convergent branch-and-bound (BB) algorithm for solving problem (Q<sub>γ</sub>) generating a sequence of partition sets  $M_k$  together with numbers  $\alpha(M_k) \in \mathbb{R} \cup \{-\infty\}$ , and points  $x^k, y^k$  such that

$$x^k \in M_k, f(x^k) \leq \gamma, \tag{2}$$

$$\alpha(M_k) \geq \max(7), \tag{3}$$

$$\alpha(M_k) - g(x^k) \rightarrow 0 \quad (k \rightarrow +\infty). \tag{4}$$

$\alpha(M)$  is an upper bound over  $M$  and (3) holds because  $M_k$  is the partition set with largest  $\alpha(M)$  among all partition sets currently of interest, while (4) is the convergence condition.

From (4) we have  $g(x^k) \rightarrow \max(Q_\gamma)$  and hence, for  $\varepsilon > 0$  given, either  $g(x^k) > 0$  for some  $k$  or  $\alpha(M_{kk}) < \varepsilon$  for some  $k$ . In the former case,  $x^k$  is an essential  $\varepsilon$ -feasible solution of (P) satisfying  $f(x^k) \leq \gamma$ . In the latter case,  $\max(Q_\gamma) < \varepsilon$ ; hence by Proposition 3,  $\min(P_\varepsilon) > \gamma$ , so no feasible solution  $x$  of (P) exists such that  $f(x) \leq \gamma$  (hence, if  $\gamma = f(\bar{x}) - \eta$  and  $\bar{x}$  is an essential  $\varepsilon$ -feasible solution, then  $\bar{x}$  is an  $\eta$ -optimal solution of (P)).

Thus, with the stopping criterium “ $g(x^k) > 0$  or  $\alpha(M_k) < \varepsilon$ ” a convergent BB procedure for solving (Q<sub>γ</sub>) will help to transcend a given incumbent value  $\gamma$ , i. e., to solve the subproblem (\*, γ).

For brevity a convergent BB procedure for solving (Q<sub>γ</sub>) with stopping criterion “ $\alpha(M) < \varepsilon$  or  $g(x^k) > 0$ ” will be referred to as *procedure (\*, γ)*.

Using this finite procedure, one can solve problem (P) according to the following successive incumbent transcending (SIT) scheme, where  $\gamma_0$  denotes an arbitrary real number larger than  $\max\{f(x)|x \in [a, b]\}$ .

**SIT (Successive Incumbent Transcending) Scheme**

Start with  $\gamma = \gamma_0$ .

Call procedure (\*, γ). If an essential  $\varepsilon$ -feasible solution  $\bar{x}$  of (P) is obtained with  $f(\bar{x}) \leq \gamma$ , reset  $\gamma \leftarrow f(\bar{x}) - \eta$  and repeat. Otherwise, stop:  $\bar{x}$  is an  $\eta$ -optimal solution if  $\gamma = f(\bar{x}) - \eta$ ; problem (P) has no  $\varepsilon$ -feasible solution if  $\gamma = \gamma_0$ .

Since  $f(D)$  is compact and  $\eta > 0$  this scheme is necessarily finite.

**The SIT Algorithm for  $\mathcal{D}(C)$  Optimization**

Incorporating procedure (\*, γ) into the SIT scheme, we obtain the following SIT algorithm for (P).

Let  $\gamma_0$  be any real number such that  $\gamma > \max\{f(x)|x \in [a, b]\}$ .

**SIT algorithm for (P)**

Select tolerances  $\varepsilon > 0, \eta > 0$ .

*Step 0.* Let  $\mathcal{P}_1 = \{M_1\}, M_1 = [a, b], \mathcal{R}_1 = \emptyset$ .

Let  $\gamma = \gamma_0$ . Set  $k = 1$ .

*Step 1.* For each box (hyperrectangle)  $M \in \mathcal{P}_k$  compute an upper bound  $\alpha(M)$  for  $\max\{g(x)|x \in M \cap \Omega, f(x) \leq \gamma\}$ . Delete every  $M$  such that  $\alpha(M) < \varepsilon$ .

*Step 2.* Let  $\mathcal{P}'_k$  be the collection of boxes resulting from  $\mathcal{P}_k$  after completion of step 1. Let  $\mathcal{R}'_k = \mathcal{R}_k \cup \mathcal{P}'_k$ .

*Step 3.* If  $\mathcal{R}'_k = \emptyset$  then *terminate*. If  $\gamma = \gamma_0$  the problem (P) is essentially  $\varepsilon$ -infeasible; otherwise, the essential feasible solution  $\bar{x}$  such that  $\gamma = f(\bar{x}) - \eta$  is an essential  $\eta$ -optimal solution of (P).

*Step 4.* If  $\mathcal{R}'_k \neq \emptyset$ , let  $M_k \in \operatorname{argmax}\{\alpha(M)|M \in \mathcal{R}'_k\}$ . Divide  $M_k$  into two subboxes using the standard bisection. Let  $\mathcal{P}_{k+1}$  be the collection of these two subboxes of  $M_k$ ,  $\mathcal{R}_{k+1} = \mathcal{R}'_k \setminus \{M_k\}$ . Increment  $k$ , and return to step 1.

**Proposition 4** *The SIT algorithm terminates after finitely many steps, yielding an  $(\varepsilon, \eta)$ -optimal solution or evidence that the problem has no essential  $\varepsilon$ -feasible solution.*

### Extensions

So far all constraints have been assumed to be of inequality type:  $g_i(x) \geq 0, i = 1, \dots, m$ . In the case when there are equality constraints such as

$$h_j(x) = 0, \quad j = 1, \dots, s,$$

one can use linear equalities to eliminate certain variables, so without loss of generality it can always be assumed that all equality constraints are nonlinear. Since an exact solution to a nonlinear system of equations cannot be expected to be computable in finitely many steps, one should be content with replacing every given equality constraint  $h_j(x) = 0$  by an approximate one:

$$-\delta \leq h_j(x) \leq \delta, \quad j = 1, \dots, s,$$

where  $\delta > 0$  is the tolerance. A mixed system with both inequality and equality constraints can thus be replaced with an approximate system involving only inequality constraints to which the above approach can be applied.

### Abstract

The various robust linear programming models investigated so far in the literature essentially appear to be based either on what is referred to as *rowwise* uncertainty models or on *columnwise* uncertainty models (these basically assume that the rows, or the columns, of the constraint matrix are subject to changes within

a well-specified *uncertainty set*). In this chapter, we discuss a special case of columnwise uncertainty, namely the subclass of robust linear programming (LP) models with uncertainty limited to the right hand side (RHS) only (this subclass does not appear to have been significantly investigated so far). In this context we introduce the concept of a ‘two-stage robust LP model’ as opposed to the standard case (which might be referred to as a ‘single-stage robust LP model’) and we address the question of whether LP duality can be used to convert a LP problem with RHS uncertainty into a robust LP problem with uncertainty on the objective function. We show how to derive both statements of (a) the dual to the robust model and (b) the robust version of the dual. The resulting expressions of the objective function to be optimized in both cases, appear to be clearly distinct. Moreover, from a complexity point of view, one appears to be efficiently solvable (it reduces to a convex optimization problem), whereas the other, as a nonconvex optimization problem, is expected to be computationally difficult in the general case. As an application of the two-stage robust LP model introduced here, we next investigate the *PERT (program evaluation and review technique) scheduling problem*, considering two possible natural ways of specifying the uncertainty set for the task durations: the case where the uncertainty set is a scaled ball with respect to the  $L_\infty$  norm; the case where the uncertainty set is a scaled Hamming ball of bounded radius (which, though leading to a quite different model, bears some resemblance to the well-known Bertsimas–Sim approach to robustness). We show that in both cases the resulting robust optimization problem can be efficiently solved in polynomial time.

Robust linear programming; Duality; PERT scheduling

### Introduction

Various models for handling robustness objectives with respect to uncertainties on some specified coefficients in linear programming (LP) models have been proposed in the literature. We can mention Soyster [9], Ben-Tal and Nemirovski [1,2] and Bertsimas and Sim [3,4].

The various approaches proposed can roughly be divided into two distinct categories, depending on whether the underlying uncertainty model refers to possible fluctuations on the row vectors of the constraint matrix (we call this ‘*rowwise uncertainty*’), or on the column vectors (we call this ‘*columnwise uncertainty*’).

Columnwise uncertainty was first considered by Soyster [9]. In this model each column  $A_j$  of the  $m \times n$  constraint matrix is either supposed to be exactly known, or is only known to belong to a given subset  $K_j \subset \mathbb{R}^m$  (‘uncertainty set’). The cost vector and the right hand side (RHS) are supposed to be certain. A robust solution is a solution which is feasible for all possible choices of the uncertain column vectors in their respective uncertainty sets. With this definition, assuming nonnegativity constraints on all variables of the LP, it can easily be shown that the problem of finding an optimal robust solution reduces to solving an ordinary LP with constraint matrix  $A = (a_{i,j})$ , where  $\forall i, j$ , and the coefficient  $a_{i,j}$  is defined as

- $a_{i,j} = \max_{v \in K_j} \{v_i\}$  in case of a  $i$ th constraint of the form  $\leq$
- $a_{i,j} = \min_{v \in K_j} \{v_i\}$  in case of a  $i$ th constraint of the form  $\geq$ .

Note that the above maximization (or minimization) can easily be carried out if we assume the uncertainty sets are either of finite cardinality (and not too big!) or closed convex.

As observed by many authors, a drawback of Soyster’s model is that it usually leads to rather conservative solutions, in other words the price to pay for robustness in the above sense is often too high.

Contrasting with the above, rowwise uncertainty has attracted more interest and has been studied by, among others, Ben-Tal and Nemirovski [1,2], and more recently by Bertsimas and Sim [3,4].

Ben-Tal and Nemirovski start with the assumption that each row  $A_i$  of the constraint matrix belongs to a known uncertainty set consisting of an ellipsoid  $E_i \subset \mathbb{R}^n$ , and a solution  $x \in \mathbb{R}^n$ ,  $x \geq 0$  is said to be robust in this context if and only if it satisfies

$$\text{for all } i : A_i x \leq b_i, \forall A_i \in E_i.$$

Ben-Tal and Nemirovski then show that finding an optimal robust solution reduces to solving a conic

quadratic problem, which can be done in polynomial time.

A way to obviate nonlinearity, while retaining the idea of rowwise uncertainty, was proposed by Bertsimas and Sim [3,4], considering a slightly different model of uncertainty. More precisely, they assume that each uncertain coefficient  $a_{ij}$  can take values in a given interval  $[a_{i,j} - \alpha_{i,j}, a_{i,j} + \alpha_{i,j}]$  and, for each row  $i$ , a positive parameter  $\Gamma_i > 0$  (not larger than the total number of uncertain coefficients in row  $i$ ) is considered. A solution  $x$  is then qualified as  $\Gamma$ -robust (in the sense of Bertsimas and Sim) if and only if for all  $i = 1, \dots, m$  this solution satisfies the  $i$ th constraint for all possible choices of the coefficients in row  $i$  such that at most  $\Gamma_i$  of the uncertain coefficients in the row are allowed to deviate from the nominal values  $a_{i,j}$  (note that the above statement implicitly assumes the  $\Gamma_i$  parameters to be integers, but Bertsimas and Sim show that a slightly more general definition, allowing for nonintegral values of the  $\Gamma_i$ 's can be handled in the same way). With this model of uncertainty, Bertsimas and Sim show that finding an optimal  $\Gamma$ -robust solution can be reduced to solving an ordinary linear program only moderately increased in size, thus opening the way to large-scale applications. Moreover the approach readily extends to optimization problems including integrality constraints on all or part of the variables; in that case the robust version of the problem is a mixed-integer program, but, again, the resulting robust model is only moderately increased in size compared with the original model.

In the present chapter we investigate a specific subclass of robust LP decision problems with columnwise uncertainty, namely LP problems with uncertainty on the RHS coefficients only. To handle such problems, a first natural idea would be to use duality to reformulate them as robust LPs with uncertainty on the objective. This is the subject of Sect. “**Duality and Robustness for LPs with Uncertainty on the RHS**”.

### **Duality and Robustness for LPs with Uncertainty on the RHS**

We first address in this section the question of whether duality can prove in any way useful to convert a columnwise uncertain linear program into a rowwise uncertain linear program, assuming of course the same uncertainty model for the columns of the given linear

program and for the corresponding rows in the dual.

Intuitively, no nice (i. e. strong) duality result is to be expected when taking into account robustness constraints since, in both the primal and the dual, there is a price to pay for uncertainty; therefore, if we maximize in the primal, the robust primal optimal solution value will be (in general strictly) less than the optimal solution value of the ‘nominal’ primal LP, and minimizing in the dual will lead to a robust dual optimal solution value (in general) strictly larger than the same value.

Let us illustrate the phenomenon for a small typical example. Consider the following LP (a continuous knapsack problem actually) with two uncertain coefficients  $a_1$  and  $a_2$  in the constraint matrix

$$\begin{aligned} \text{(P)} \quad & \text{Maximize} && 4x_1 + 3x_2 \\ & \text{subject to} && \\ & && a_1x_1 + a_2x_2 \leq 4 \\ & && x_1 \geq 0, x_2 \geq 0, \end{aligned}$$

the standard LP dual of which reads

$$\begin{aligned} \text{(D)} \quad & \text{Minimize} && 4u \\ & \text{subject to} && \\ & && a_1u \geq 4 \\ & && a_2u \geq 3 \\ & && u \geq 0. \end{aligned}$$

Let us assume that the uncertainty set for  $a_1$  is the real interval  $[2, 3]$ , the uncertainty set for  $a_2$  is the real interval  $[1, 2]$ , and let us take as the definition of a robust solution in both (P) and (D) a solution which is feasible for any possible values of  $a_1$  and  $a_2$  in their respective uncertainty sets. Then it is easily seen that the optimal robust primal solution is  $x^0 = [0, 2]$  with corresponding primal objective function value 6; and the optimal robust dual solution is  $u^0 = 3$  with corresponding dual objective function value 12. This example thus clearly shows that no natural extension of the usual properties related to LP duality is to be expected in the context of robust LP.

A special case of columnwise uncertainty in LP is when uncertainty only concerns the coefficients of the RHS. Such problems frequently arise in practical applications. As a typical example, we mention the robust program evaluation and review technique (PERT) scheduling problem with uncertainty on the durations

of (some of) the tasks, assuming that a robust earliest termination date has to be determined. More precisely, we want to determine the minimum total duration of the project under any possible assignment of task durations, taken in a given uncertainty set. The two-stage robust model discussed in Sect. “**Two-Stage Robust (LP) Decision Model**” will appear to be relevant to such applications.

Consider the following LP

$$\begin{aligned} \max \quad & c^T x \\ & Ax \leq b \\ & x \geq 0 \end{aligned}$$

and assume that the RHS  $b$  is not known exactly, but is only known to belong to some uncertainty set  $B \subset \mathbb{R}^m$ . The set  $B$  may be finite or infinite (we will introduce additional assumptions for this set when necessary).

Two distinct robustness models for LPs with uncertain RHS will be successively discussed in the following sections, namely single-stage robust decision models (Sect. “**Single-Stage Robust (LP) Decision Model**”) and two-stage robust decision models (Sect. “**Two-Stage Robust (LP) Decision Model**”). For both cases it will be shown that, even in the restricted situation addressed here (uncertainty on the RHS only), one cannot use standard duality theory to convert a columnwise uncertain linear program into a rowwise uncertain linear program while preserving equivalence. Also, examples will be provided to show that the two-stage robust LP decision model is capable of producing less conservative solutions than the single-stage robust LP model.

### Single-Stage Robust (LP) Decision Model

We first consider the simplest case where the values of all the decision variables  $x$  have to be fixed (taking into account uncertainty) before we get any kind of information on the actual realization of the uncertain parameters. In such a simple model (indeed a special case of Soyster’s model) feasibility has to be ensured for any  $b \in B$ , and the problem to be solved simply reduces to

$$\begin{aligned} \max \quad & c^T x \\ & Ax \leq \underline{b} \\ & x \geq 0, \end{aligned}$$

where  $\forall i, \underline{b}_i = \min_{b \in B} \{b_i\}$ .

The (standard) LP dual to the above problem reads

$$\begin{aligned} \text{(D1)} \quad \min \quad & u^T \underline{b} \\ & u^T A \geq c \\ & u \geq 0. \end{aligned}$$

On the other hand, if we consider the dual to

$$\begin{aligned} \max \quad & c^T x \\ & Ax \leq b \\ & x \geq 0 \end{aligned}$$

we get

$$\begin{aligned} \min \quad & u^T b \\ & u^T A \geq c \\ & u \geq 0. \end{aligned}$$

Now consider the robust version of this dual problem where the cost vector  $b$  is uncertain and can take any value in  $B$ . A simple and natural objective in this context is to find  $u$  achieving a minimum value of  $\max u^T b$  over all possible  $b \in B$ , thus leading to

$$\begin{aligned} \text{(D2)} \quad \min \max_{u, b \in B} \quad & \{u^T b\} \\ \text{subject to} \quad & u^T A \geq c \\ & u \geq 0. \end{aligned}$$

It is clearly realized that (D1) and (D2) are completely different optimization problems for the same solution sets since

$$\forall u \geq 0, u^T \underline{b} \leq \max_{b \in B} \{u^T b\},$$

with strict inequality holding in the general case.

If the set  $B$  is either finite or closed convex, it is observed that (D2) can be efficiently solved via standard convex optimization techniques since the function

$$u \rightarrow \max_{b \in B} \{u^T b\}$$

is convex. Also, in this case,  $\underline{b}$  can be efficiently computed since  $\min_{b \in B} \{b_i\}$  too is a convex optimization problem; therefore problem (D1), too, can be efficiently solved.

## Two-Stage Robust (LP) Decision Model

It frequently arises in applications that the process of decision making under uncertainty can be decomposed into two successive steps (two-stage decision making) or more (multistage decision making). For simplicity of presentation, we restrict ourselves here to the case of two-stage decision making. In this case, the set of decision variables  $x$  is decomposed (partitioned) into two distinct sets of variables which we denote  $y$  and  $z$ . The  $y$  variables concern the decisions to be taken in the first stage (before knowing anything about which realization of uncertainty will arise) and the  $z$  variables concern the decisions to be taken in the second stage (after realization of uncertainty).

Limiting ourselves, to make the discussion easier to follow, to the case where the objective function only depends on the decision variables of the first stage, our decision problem can thus be rewritten

$$(I) \quad \begin{aligned} & \max \quad \gamma^T y \\ & \text{subject to} \quad Fy + Gz \geq b \\ & \quad \quad \quad y \geq 0, z \geq 0, \end{aligned}$$

where  $\gamma$  and  $b$  are vectors and  $F$  and  $G$  are matrices of appropriate dimensions. (Observe that the reason for restricting ourselves to the case of an objective not depending on the  $z$  variables is only for the sake of simplicity in the presentation; our two-stage robust decision model would readily handle the general case of an objective depending on both the  $y$  and the  $z$  variables). Now, since the RHS  $b$  in (I) is uncertain, we have to make our robustness objectives precise. In the sequel, we consider robustness for a solution  $y$  by requiring that feasibility can be ensured for any possible RHS  $b \in B$  by using the second-stage decision variables  $z$  (by analogy with the terminology used in stochastic programming, the  $z$  variables might be referred to as ‘recourse’ variables). So, if we define  $Y = \{y/y \geq 0 \text{ and } \forall b \in B, \exists z \geq 0 : Gz \leq b - Fy\}$ , we want to solve

$$\max_{y \in Y} \{\gamma^T y\}.$$

Note that in the above, for any given robust solution  $y$ , the value taken by the  $z$  variables depends on which  $b \in B$  is actually realized. This is an important feature of our model which explains why it can produce less

conservative solutions than Soyster’s model (see the example given in Remark 1 below).

According to Farkas’ lemma, we know that, for fixed  $b \in B$ , a necessary and sufficient condition for the existence of  $z \geq 0$  verifying  $Gz \leq b - Fy$  is that

$$\begin{aligned} & u^T(b - Fy) \geq 0 \quad \forall u \text{ in the polyhedral cone:} \\ & C = \{u/u^T G \geq 0 \text{ and } u \geq 0\}. \end{aligned}$$

Denoting  $u^1, u^2, \dots, u^p$ , the extreme rays of the above cone, we can equivalently represent the set  $Y$  as the system of linear inequalities

$$(u^j)^T Fy \leq (u^j)^T b, \forall b \in B, \forall j = 1, \dots, p,$$

which is equivalent to

$$(u^j)^T Fy \leq w^j = \min_{b \in B} (u^j)^T b.$$

The robust two-stage decision problem is then reformulated as

$$(I)' \quad \begin{aligned} & \max \quad \gamma^T y \\ & \text{subject to} \quad (u^j)^T Fy \leq w^j, \forall j = 1, \dots, p \\ & \quad \quad \quad y \geq 0. \end{aligned}$$

Since we are interested in investigating duality in the context of robustness, let us state the (standard) dual to (I)'. So, introducing dual variables  $\lambda_j$ , ( $j = 1, \dots, p$ ), the dual to (I)' can be written as

$$\begin{aligned} & \min \quad \sum_j \lambda_j w^j = \sum_j \lambda_j \min_{b \in B} (u^j)^T b \\ & \text{subject to} \quad \sum_j \lambda_j F^T u^j \geq \gamma \\ & \quad \quad \quad \lambda_j \geq 0, \forall j = 1, \dots, p \end{aligned}$$

and since:  $\{u/u = \sum \lambda_j u^j, \lambda_j \geq 0\} = \{u/G^T u \geq 0, u \geq 0\}$ , this can be rewritten as

$$(DI)' \quad \begin{aligned} & \min \min_{u \geq 0} \quad u^T b \\ & \text{subject to} \quad F^T u \geq \gamma \\ & \quad \quad \quad G^T u \geq 0 \\ & \quad \quad \quad u \geq 0 \end{aligned}$$

or, equivalently if we denote  $W$  as the set of solutions to (DI)',

$$\min_{u \in W} \min_{b \in B} \{u^T b\}. \quad (1)$$

An a priori different way of using duality in our context would be to take the (standard) LP dual to (I) for fixed  $b$ , and then to carry out robustness analysis with respect to the coefficients  $b$  of the objective in the dual, allowing  $b$  to take all possible values in  $B$ . The LP dual to (I) reads

$$(DI) \quad \min \quad u^T b \\ \text{subject to} \quad F^T u \geq \gamma \\ G^T u \geq 0 \\ u \geq 0.$$

A natural robust version of (DI) consists in finding the dual solution  $u$  minimizing the value of  $u^T b$  produced by the worst possible  $b$ :

$$\min_{u \in W} \max_{b \in B} \{u^T b\}, \quad (2)$$

which is to be contrasted with (1): indeed, it is seen that the robust version of the dual significantly differs from the dual of the robust version of the initial (primal) problem (I) because the function of  $u$  to be minimized is  $\min_{b \in B} \{u^T b\}$  in one case, and  $\max_{b \in B} \{u^T b\}$  in the other case.

It is worth observing that this structural difference between the two functions also implies a difference with respect to the practical solvability of the corresponding problems. The objective function in (2) is convex in  $u$ , making the robust version of (DI) efficiently solvable, whereas the objective in (1) is concave in  $u$ , making (DI)' and thus (by standard LP duality) (I)' also difficult problems in the general case.

*Remark 1* As already suggested, the two-stage robust decision model proposed here is capable of producing less conservative solutions than Soyster's model. The reason for this is that if, for a given uncertainty set  $B$ , we consider Soyster's model for problem (I), the problem to be solved is

$$\max_{y \in Y_S} \{\gamma^T y\},$$

where the set  $Y_S$  is defined as  $\{y/y \geq 0 \text{ and } \exists z \geq 0 : Gz \leq \underline{b} - Fy\}$  with  $\underline{b}$  defined as

$$\forall i, \underline{b}_i = \min_{b \in B} \{b_i\}.$$

It is easily seen that  $Y_S \subseteq Y = \{y/y \geq 0 \text{ and } \forall b \in B, \exists z \geq 0 : Gz \leq b - Fy\}$  and cases where strict inclusion holds (leading to an improved robust optimal solution value over the optimal value of Soyster's model)

can easily be found, as illustrated by the following example.

In this example we consider three variables,  $y \geq 0$ ,  $z_1 \geq 0$  and  $z_2 \geq 0$ , and three constraints,

$$y - z_1 \leq b_1 \\ y - z_2 \leq b_2 \\ z_1 + z_2 \leq b_3,$$

and the uncertainty set  $B$  is taken as the set containing the two vectors  $(1, 0, 1)^T$  and  $(0, 1, 1)^T$ . The objective function is to maximize  $y$ . It is easily checked that the set  $Y_S$  corresponding to Soyster's model is in this case the real interval  $[0, 1/2]$  leading to an optimal robust solution value 0.5. On the other hand, the set  $Y$  corresponding to our two-stage model is the real interval  $[0, 1]$  leading to the (less conservative) optimal robust solution value 1. Indeed, the value  $y = 1$  is feasible in our model because, in the case where  $b = (1, 0, 1)^T$  occurs, we can take  $z_1 = 0$  and  $z_2 = 1$ , and in the case where  $b = (0, 1, 1)^T$  occurs, we can take  $z_1 = 1$  and  $z_2 = 0$ . (Observe, as already pointed out, that the value taken by the  $z$  variables indeed depends on which  $b \in B$  is actually realized.) Of course, this example does not rule out the possibility of having  $Y = Y_S$  for some special instances. As will be seen in the next section, this possibility will arise in connection with the robust PERT scheduling problem, in the special case (referred to there as Case 1) where the uncertainty set on the task durations is the Cartesian product of a family of real intervals.

### An Application of the Two-Stage Robust LP Model with RHS Uncertainty: Robust PERT Scheduling

In this section we specialize the general two-stage robust LP decision model investigated earlier to robust PERT scheduling, with an uncertainty set  $D$  on the durations of the tasks, supposed to be given as a (finite or infinite) list of 'scenarios'. More precisely, we want to determine an earliest termination date which can be achieved for any realization of the task durations  $d$  in a given uncertainty set  $D$ .

#### Formulation as a Two-Stage Robust LP Model

Consider a PERT network represented as a directed circuitless graph  $N$  in which the nodes correspond to tasks

(the tasks are numbered  $i = 1, 2, \dots, n$ ; the set of tasks is denoted  $I$ ), and there is an arc  $(i, j)$  with length (duration)  $d_i$  whenever there is a precedence constraint stating that processing of task  $j$  should not start before completion of task  $i$ . The set of arcs is denoted  $U$ . We assume that node 1 has no immediate predecessor (it thus represents the initial task) and node  $n$  has no direct successor (it thus represents the terminal task of the project). Denoting  $y_j$  ( $j = 1, \dots, n$ ) the starting date for each task  $j$ , and assuming first that the task durations  $d_i$  are exactly known, we want to minimize the total duration of the project while satisfying all precedence constraints; in other words

$$\begin{aligned} &\text{Maximize} && -y_n \\ &\text{subject to} && \\ &&& y_1 = 0 \\ &&& y_i - y_j \leq -d_i, \forall (i, j) \in U. \end{aligned}$$

Indeed, it is easy to check that in the above,  $y_1 = 0$  can be replaced by  $y_1 \geq 0$ , or equivalently  $-y_1 \leq 0$ ; thus, the problem can be rewritten

$$\begin{aligned} &\text{Maximize} && -y_n \\ &\text{subject to} && \\ &&& -y_1 \leq 0 \\ &&& y_i - y_j \leq -d_i, \forall (i, j) \in U. \end{aligned}$$
