In what follows, the big oh notation ( $\mathcal{O}$ ) introduced in [3] will be used when expressing the time complexity function. We say that, for two real-valued functions  $f$  and  $g$ , ‘ $f(n)$  is  $\mathcal{O}(g(n))$ ’, or ‘ $f(n)$  is of the same order as  $g(n)$ ’, if  $|f(n)| \leq k \cdot |g(n)|$  for all  $n \geq 0$  and some  $k > 0$ .

### Polynomial Versus Exponential Algorithms

An *efficient, polynomially bounded, polynomial time algorithm*, or simply a *polynomial algorithm*, is one which solves a problem instance in time bounded by a power of the instance size. Formally:

**Definition 3** An algorithm  $A$  is *polynomial time* if there exists a polynomial  $p$  such that

$$T_A(n) \leq p(n), \quad \forall n \in \mathbb{Z}^+ \equiv \{1, 2, \dots\}.$$

More specifically, an algorithm is *polynomial of degree  $c$* , or *has complexity  $\mathcal{O}(n^c)$* , or *runs in  $\mathcal{O}(n^c)$  time* if, for some  $k > 0$ , the algorithm never takes longer than  $kn^c$  (the TCF) to solve an instance of size  $n$ .

**Definition 4** The collection  $P$  comprises all problems for which a polynomial time algorithm exists.

Problems which belong to  $P$  are the ones we referred to earlier as ‘easy’. All other algorithms are called *exponential time* or just *exponential*, and problems for which nothing quicker exists are ‘hard’. Although not all algorithms in this class have TCF’s that are technically exponential functions, we may think of a typical one as running in  $\mathcal{O}(c^{p(n)})$  for some polynomial  $p(n)$ . Other examples of exponential rates of growth are  $n^n$  and  $n!$ .

The terms ‘hard’ and ‘easy’ are somewhat misleading, even though exponential TCFs clearly lead to far more rapid growth in solution times. Suppose an ‘easy’ problem has an algorithm with running time bounded by, say  $kn^5$ . Such a TCF may not be exponential, but it may well be considered pretty rapidly growing. Furthermore, some algorithms take a long time to solve even small problems (large  $k$ ), and hence are unsatisfactory in practice even if the time grows slowly. On the other hand, an algorithm for which the TCF is exponential is not always useless in practice. Recall, the concept of the TCF is a worst case estimate, so complexity is only an upper bound on the amount of time required by an algorithm. This is a conservative measure and usually useful, but it is too pessimistic for some popular algorithms. The simplex algorithm for linear programming, for example, has a TCF that is  $\mathcal{O}(2^n)$ , but it has been shown that for the average case the complexity is only  $\mathcal{O}(n)$ . Thus, the algorithm is actually very fast for most problems encountered.

Despite these caveats, exponential algorithms generally have running times that tend to increase at an exponential rate and often seem to ‘explode’ when a certain problem size is exceeded. Polynomial time algorithms usually turn out to be of low degree ( $\mathcal{O}(n^3)$  or better), run pretty efficiently, and are considered desirable.

## Reducibility

A problem can be placed in  $P$  as soon as a polynomial time algorithm is found for it. Sometimes, rather than finding such an algorithm, we may place it in  $P$  by showing that it is ‘equivalent’ to another problem which is already known to be in  $P$ . We explain what we mean by equivalence between problems with the following definitions.

**Definition 5** A problem  $\Pi'$  is *reducible* or *transformable* to a problem  $\Pi$  ( $\Pi' \propto \Pi$ ) if, for any instance  $I'$  of  $\Pi'$ , an instance  $I$  of  $\Pi$  can be constructed in polynomially bounded time, such that the solution to  $I$  is sufficient to find the solution to  $I'$  in polynomial time.

We call the construction of the  $I$  that corresponds to  $I'$  a *polynomial transformation* of  $I'$  into  $I$ .

**Definition 6** Two problems are *equivalent* if each is reducible (or simply *reduces*) to the other.

Since reduction, and hence equivalence, are clearly transitive properties, we can define *equivalence classes of problems*, where all problems in the same equivalence class are reducible (or equivalent) to each other. Consider polynomial problems. Clearly, for two equivalent problems, if one is known to be polynomial, the other must be, too. Also, if two problems are each known to be polynomial, they are equivalent. This is because any problem  $\Pi' \in P$  is reducible to any other problem  $\Pi \in P$ , or indeed to any  $\Pi \notin P$ , in the following trivial sense. For any instance  $I'$  of  $\Pi'$ , we can pick any instance of  $\Pi$ , ignore its solution, and find the solution to  $I'$  directly. We conclude that  $P$  is an equivalence class.

We state a third simple result for polynomial problems as a theorem.

**Theorem 7** *If  $\Pi \in P$ , then  $\Pi' \propto \Pi \Rightarrow \Pi' \in P$ .*

Given any instance  $I'$  of  $\Pi'$ , one can find an instance  $I$  of  $\Pi$  by applying a polynomial time transformation to  $I'$ . Since  $\Pi \in P$ , there is a polynomial time algorithm that solves  $I$ . Hence, using the transformation followed by the algorithm,  $I'$  can be solved in polynomial time.

## Classification of Hard Problems

In practice, we do not usually use reduction to show a problem is polynomial. We are more likely to start

optimistically looking for an *efficient algorithm* directly, which may be easier than seeking another problem known to be polynomial, for which we can find an appropriate transformation. But suppose we cannot find either an efficient algorithm or a suitable transformation. We begin to suspect that our problem is not ‘easy’ (i. e., is not a member of  $P$ ). How can we establish that it is in fact ‘hard’? We start by defining a larger class of problems, which includes  $P$  and also all the difficult problems we ever encounter. To describe it, consider any combinatorial decision problem. For a typical instance, there may be a very large number of possible solutions which may have to be searched. Picture a candidate solution as a set of values assigned to the variables  $\mathbf{x} = (x_1, \dots, x_n)$ . The question may be ‘for a given vector  $\mathbf{c}$  is there a solution  $\mathbf{x}$  such that  $\mathbf{c}\mathbf{x} \leq B$ ?’ and the algorithm may search the solutions until it finds one satisfying the inequality (whereupon it stops with the answer YES) or exhausts all solutions (and stops at NO).

This may well be a big job. But suppose we are told ‘the answer is YES, and here is a solution  $\mathbf{x}$  that satisfies the inequality’. We feel we must at least *verify* this, but that is trivial. Intuitively, even for the hardest problems, the amount of work to check that a given candidate solution confirms the answer YES should be small, even for very large instances. We will now define our ‘hard’ problems as those which, though hard to solve, are easy to verify, where as usual ‘easy’ means taking a time which grows only polynomially with instance size. To formalize this, let:

$$V_A(n) = \begin{cases} \text{maximal time for } A \\ \text{to verify that a given solution} \\ \text{establishes the answer YES} \\ \text{for any instance of length } n. \end{cases}$$

**Definition 8** An algorithm  $\bar{A}$  is *nondeterministic polynomial time* if there exists a polynomial  $p$  such that for every input of length  $n$  with answer YES,  $V_{\bar{A}}(n) \leq p(n)$

**Definition 9** The collection  $NP$  comprises all problems for which a nondeterministic polynomial algorithm exists.

It may be noted that a problem in  $NP$  is solvable by searching a decision tree of polynomially bounded depth, since verifying a solution is equivalent to trac-

ing one path through the tree. From this, it is easy to see that  $P \subseteq NP$ . Strangely, complexity theorists have been unable to show that  $P \subset NP$ ; it remains possible that all the problems in  $NP$  could actually be solved by polynomial algorithms, so that  $P = NP$ . However, since so many brilliant researchers have worked on so many difficult problems in  $NP$  for so many years without success, this is regarded as being very unlikely. Assuming  $P \neq NP$ , as we shall hereafter, it can be shown that the problems in  $NP$  include an infinite number of equivalence classes, which can be ranked in order of increasing difficulty; where an equivalence class  $C$  is ‘more difficult’ than another class  $C'$  if, for every problem  $\Pi \in C$  and every  $\Pi' \in C'$ ,  $\Pi' \propto \Pi$  but  $\Pi \not\propto \Pi'$ . There also exist problems that cannot be compared: neither  $\Pi \propto \Pi'$  nor  $\Pi' \propto \Pi$ .

Fortunately, however, all problems that arise naturally have always been found to lie in one of two equivalence classes: the ‘easy’ problems in  $P$ , and the ‘hard’ ones, which we now define.

The class of *NP-hard problem* ( $NPH$ ) is a collection of problems with the property that every problem in  $NP$  can be reduced to the problems in this class. More formally,

**Definition 10**

$$NPH = \{ \Pi : \forall \Pi' \in NP : \Pi' \propto \Pi \}.$$

Thus each problem in  $NPH$  is at least as hard as any problem in  $NP$ . We know that some problems in  $NPH$  are themselves in  $NP$ , though some are not. Those that are include the toughest problems in  $NP$ , and form the class of *NP-complete problem* ( $NPC$ ). That is,

**Definition 11**

$$NPC = \left\{ \Pi : \begin{array}{c} (\Pi \in NP) \\ \text{and} \\ (\forall \Pi' \in NP : \Pi' \propto \Pi) \end{array} \right\}.$$

The problems in  $NPC$  form an equivalence class. This is so because all problems in  $NP$  reduce to them, hence, since they are all in  $NP$ , they reduce to each other. The class  $NPC$  includes the most difficult problems in  $NP$ . As we mentioned earlier, by a surprising but happy chance, all the problems we ever encounter outside the

most abstract mathematics turn out to belong to either  $P$  or  $NPC$ .

**Using Reduction to Establish Complexity**

When tackling a new problem  $\Pi$ , we naturally wonder whether it belongs to  $P$  or  $NPC$ . As we said above, to show that the problem belongs to  $P$ , we usually try to find a polynomial time algorithm, though we could seek to reduce it to a problem known to be polynomial. If we are unable to show that the problem is in  $P$ , the next step generally is to attempt to show that it lies in  $NPC$ ; if we can do so, we are justified in not developing an efficient algorithm. To do this, clearly no direct algorithmic development is possible, and only a reduction argument will do. This is based on the following theorem, which should be clear enough to require no proof.

**Theorem 12**  $\forall \Pi \Pi' \in NP : (\Pi' \in NPC) \text{ and } (\Pi' \propto \Pi) \text{ imply } \Pi \in NPC.$

Thus, we need to find a problem  $\Pi' \in NPC$  and show  $\Pi' \propto \Pi$ , thereby demonstrating that  $\Pi$  is at least as hard as any problem in  $NPC$ . To facilitate this, we need a list of problems known to be in  $NPC$ . Several hundred are listed in [2] in a dozen categories such as graph theory, mathematical programming, sequencing and scheduling, number theory, etc., and more are being added all the time. Even given an ample selection, a good deal of tenacity and ingenuity are needed to pick one with appropriate similarities to ours and to fill in the precise details of the transformation.

Of course, to build up the membership in  $NPC$  using Theorem 12, we need other problems that have already been show to belong to that class. To begin this process, at least one problem needs to be in  $NPC$ . It was S.A. Cook [1] who showed that the satisfiability problem is  $NP$ -complete, using direct arguments that did not involve reduction. This very important result is called *Cook’s theorem*. For a proof, see [2].

As a simple illustration of reduction, we show that the traveling salesperson decision problem (TSP) is in  $NPC$ . To do so, we first select a closely related problem, the Hamiltonian circuit problem (HCP), which we assume has already been shown to be  $NP$ -complete. We then find a reduction of HCP to TSP. The problems are defined as follows.

**Definition 13** (*TSP, traveling salesperson problem*).

Instance:

- a positive integer  $n$ ;
- a finite set  $C = \{c_1, \dots, c_n\}$  of ‘cities’;
- ‘distances’,  $d_{ij} \in \mathbf{Z}^+$ .  $\forall i, j : c_i, c_j \in C$ ;
- a bound  $B \in \mathbf{Z}^+$ .

Question: Does there exist a *tour* (i. e., a closed path that visits every city exactly once), of length no greater than  $B$ ?

**Definition 14** (*HCP, Hamiltonian circuit problem*)

Instance: A graph  $G = (V, E)$ , where  $V$  is the set of  $m$  vertices, and  $E$  the set of edges.

Question: Does  $G$  contain a *Hamiltonian circuit*, i. e., a tour that traverses all vertices exactly once?

*Example 15* To show:  $HCP \propto TSP$ .

In TSP, we have a complete graph and seek the shortest tour, whereas in HCP, given an arbitrary graph we require any tour. Thus, given the challenge of showing that the traveling salesperson problem (or the decision version of it) is *NP*-complete, we have found a similar problem whose membership in *NPC* is already established. We may still be unable to find a polynomial transformation from HCP, in which case another problem must be sought. A transformation of  $\Pi'$  to  $\Pi$  is a way of computing each parameter of  $\Pi$  in terms of the parameters of  $\Pi'$ . In this case, the reduction is relatively simple. The parameters of HCP are:

- $m = \text{cardinality } V$ ;
- $E = \left\{ (i, j) : \begin{array}{l} G \text{ contains an arc} \\ \text{between vertices } i, j \end{array} \right\}$ .

The parameters of TSP are computed as follows:

- $n = m$ ;
- $d_{ij} = \begin{cases} 1 & (i, j) \in E, \\ N & \text{otherwise;} \end{cases}$
- $B = m$ .

Here,  $N$  can be any number larger than 1; say, 2. Clearly, the shortest possible tour in TSP has length  $m$ , and this only occurs when arcs in  $E$  are used exclusively; that is, when a tour in HCP exists.

To complete the reduction, we need to show that the transformation can be performed in polynomial time. For that, given a pair of nodes in TSP, we need to check if an arc exists in HC, and this requires time

$$\mathcal{O} \left[ \frac{m(m-1)}{2} \right] = \mathcal{O}(m^2).$$

## Keywords

Concave programming; Multi-extremal global optimization

Concave programming constitutes one of the most fundamental and intensely-studied problem classes in deterministic nonconvex optimization. There are at least three reasons for this. First, many of the mathematical properties of concave programming are intriguingly attractive. Some are even identical to properties of linear programming. Second, concave programming has a remarkably broad range of direct and indirect applications. Third, the algorithmic ideas used in concave programming have played and continue to play an active and often fundamental role in the development of solution procedures for other types of nonconvex programming problems.

The *concave programming*, or *concave minimization*, problem (CMP) can be written

$$\begin{cases} \text{globmin} & f(x), \\ \text{s.t.} & x \in D, \end{cases}$$

where  $D$  is a nonempty, closed convex set in  $\mathbf{R}^n$  and  $f$  is a real-valued, concave function defined on some open convex set  $A$  in  $\mathbf{R}^n$  that contains  $D$ . The goal in CMP is to find the global minimum value that  $f$  achieves over  $D$ , and, if this value is not equal to  $-\infty$ , to find, if it exists, at least one point in  $D$  that achieves this value. In many applications,  $D$  is compact and  $A$  equals all of  $\mathbf{R}^n$ . CMP invariably contains many points in  $D$  that are local, but not global, minimizers of  $f$  over  $D$ . For this reason, CMP is an example of a (*multi-extremal*) *global optimization* problem [7].

The application of standard algorithms designed for solving constrained convex programming problems generally will fail to solve CMP. Even instances of CMP with relatively simple components can apparently present very significant solution challenges. For example, B. Kalantari [8] has shown that in problems involving the minimization of concave quadratic functions over rectangles in  $\mathbf{R}^n$ , an exponential number of extreme point local minima can exist. Additionally, P.M. Pardalos and G. Schnitger [13] have shown that minimizing a concave quadratic function over a hypercube is an *NP-hard* problem.

Although CMP is more difficult to solve than a convex programming problem, it possesses some highly interesting, special mathematical properties. A number of these properties have been exploited by researchers to create successful algorithms for solving the problem.

For instance, if  $D$  contains at least one extreme point, and CMP has at least one global optimal solution, then there must exist a global optimal solution which is an extreme point of  $D$  [14]. This is perhaps the most important and striking property of concave minimization problems. As a result of this property, just as in linear programming, if CMP has a global optimal solution, then one can confine the search for such a solution to the set of extreme points of  $D$ , provided that this set is nonempty. This property holds, as in linear programming, even when  $D$  is unbounded. A number of algorithms for CMP are based upon this property.

Another highly important property for CMP is that if  $D$  is a compact set, then CMP must have a global optimal solution which is an extreme point of  $D$ . This is perhaps the most widely-known theoretical result in concave minimization [1]. Like the property stated in the previous paragraph, it forms the basis for a number of important concave minimization algorithms.

For cases where  $D$  is a polyhedron, possibly unbounded, that contains at least one extreme point, it has been shown that either CMP has a global optimal solution which is an extreme point of  $D$ , or CMP must be unbounded and  $f$  must be unbounded from below over some extreme direction of  $D$ . Notice that the same property, remarkably, holds in the case of linear programming. This property is used by a large number of the algorithms designed to solve CMP when  $D$  is a nonempty polyhedron.

CMP displays a remarkable diversity of applications. Each application is either direct or indirect. By direct, we mean that the original model formulation takes the form of CMP immediately or, if not, with only relatively simple algebraic manipulations. The indirect applications involve problems whose direct formulations do not take the form of CMP, but existing theory can be used to reformulate these problems in the form of CMP.

Some of the oldest and most diverse direct applications of CMP belong to a class of problems called *fixed charge* problems. In these problems, the objective func-

tion  $f$  is *separable*, i. e., it is of the form

$$f(x) = \sum_{i=1}^n f_i(x_i).$$

For each  $i = 1, \dots, n$ , in these problems  $f_i$  is a concave function on  $\{x_i \in \mathbf{R}: x_i \geq 0\}$  of the form

$$f_i(x_i) = \begin{cases} 0 & \text{if } x_i = 0, \\ c_i + w_i(x_i) & \text{if } x_i > 0, \end{cases}$$

where  $c_i > 0$  is the fixed *setup cost* of undertaking activity  $i$  at a positive level, and  $w_i(x_i)$  is a continuous concave function on  $\{x_i \in \mathbf{R}: x_i > 0\}$  that represents the *variable cost* of undertaking the activity at level  $x_i$ .

When the functions  $w_i(x_i)$ ,  $i = 1, \dots, n$ , are linear, the classical *linear fixed charge* problem is obtained. Some of the oldest applications of concave minimization involve solving problems of this type. Among these are applications to transportation planning, site selection, production lot sizing and network design. For cases where at least one of the functions  $w_i(x_i)$ ,  $i = 1, \dots, n$ , is piecewise linear, several types of applications have been reported. Included among these are problems involving price breaks, such as bid evaluation problems, certain inventory planning problems and various plant location problems. When  $w_i(x_i)$  is a general concave function for some  $i = 1, \dots, n$ , applications involving *economies of scale*, for instance, can be solved.

More recently, CMP has been directly applied to a class of problems called *multiplicative programming* problems. These are problems of the form CMP where

$$f(x) = \prod_{j=1}^p f_j(x) \quad (1)$$

for some set of  $p \geq 2$  functions  $f_j$ ,  $j = 1, \dots, p$ , that are each nonnegative over  $D$ . Notice that if  $f_k(\bar{x}) = 0$  for some  $k \in \{1, \dots, p\}$  and some  $\bar{x} \in D$ , then it is easy to see that the global minimum value for CMP is 0, and  $\bar{x}$  is a global optimal solution. Therefore, it is generally assumed in multiplicative programming problems that each function  $f_j$  is positive over  $D$ . Let us make this assumption henceforth.

The objective function (1) of a multiplicative program is generally not a concave function. But, when each function  $f_j$ ,  $j = 1, \dots, p$ , is a concave function on

$\mathbf{R}^n$ , some simple transformations of (1) yield concave functions over  $D$ . For instance, if, for each  $x \in D$ , we define  $w_1$  and  $w_2$  by

$$w_1(x) = \ln f(x) = \sum_{j=1}^p \ln f_j(x),$$

$$w_2(x) = [f(x)]^{\frac{1}{p}},$$

respectively, then, whenever each  $f_j$ ,  $j = 1, \dots, p$ , is a concave function on  $\mathbf{R}^n$ , both  $w_1$  and  $w_2$  are concave functions on  $D$  [3,10]. Thus, by using  $w_1$  or  $w_2$ , multiplicative programming problems in which  $f_j$ ,  $j = 1, \dots, p$ , are concave functions can be easily transformed to concave minimization problems.

Various applications of multiplicative programming problems with concave or linear functions  $f_j$ ,  $j = 1, \dots, p$ , in (1) have arisen, especially since the 1960s. For example, the linear case has been applied to the problem of optimizing value functions for multiple objective programming problems subject to linear or nonlinear constraints. For  $p = 2$ , the linear case has been used to help solve the modular design problem, to design integrated circuit chips and to select bond portfolios. The concave case has been used to analyze and solve a number of problems in microeconomics.

Subject to occasional restrictions, large classes of integer programming problems can be converted by various means into the form of CMP and solved as concave minimization problems. As a result, these integer programming problems, indirectly, are applications of concave minimization. The transformation processes used to accomplish the conversion, however, can be rather involved. They may also increase the size of the original problem [4], and they may call for choosing values for parameters that are difficult to determine [5,9].

In particular, by using a certain general transformation process, any feasible linear integer or quadratic integer programming problem over a polyhedron with nonnegative, bounded variables can be converted into the form of CMP and solved as a concave minimization problem. By using more customized conversion processes, linear zero-one programs, quadratic assignment problems, and other special integer programming problems can also be transformed to the form of CMP and solved as concave minimization problems. The specialized transformations generally take advantage of

some aspect of the original integer programming problem that the general processes ignore.

There are many other indirect applications of CMP, including *d.c. optimization*, *indefinite quadratic programming*, and *bilinear programming*, for instance. For further details and additional direct and indirect applications, see [1,2,6,7,11,12].

To solve CMP, a large number of algorithms have been developed. Many of these rely on one or more of the following four approaches.

In the *cutting plane approach*, a local minimum for  $f$  over  $D$  is found. Subsequently, a hyperplane is constructed and used to cut off all points of  $D$  whose objective function values are not less than that of the local minimum. This yields a new closed convex set  $D^1 \subset D$ . This process is then repeated with  $D^1$  in the role of  $D$ . By iterating this process, the portion of  $D$  remaining to be explored is progressively reduced. Termination occurs when it can be shown that  $f(y) \geq f(x^k)$  for all  $y \in D^k$ , where  $D^k$  is the portion of  $D$  remaining at iteration  $k$ , and  $x^k$  is the local minimum found through iteration  $k$  with the smallest objective function value.

In a typical *outer approximation* approach,  $D$  is assumed to be compact. To initiate the approach, a simple bounded polyhedron  $P^1$  containing  $D$  whose vertices can be enumerated is constructed. A vertex  $v^1$  of  $P^1$  of minimum objective function value among all of the vertices of  $P^1$  is found. This gives a lower bound  $f(v^1)$  for the optimal value of CMP. If  $v^1 \in D$ ,  $v^1$  is a global optimal solution for CMP and termination occurs. Otherwise, a new bounded polyhedron  $P^2 \subset P^1$  is constructed that contains  $D$ , and its vertices are enumerated. With  $P^2$  in the role of  $P^1$ , the process is repeated. By repeating this process, a sequence of telescoping bounded polyhedra containing  $D$  is obtained. Termination occurs in the first iteration  $k$  where the vertex  $v^k$  found that minimizes  $f$  over all of the vertices of  $P^k$  lies in  $D$ .

In *inner approximation (polyhedral annexation)* approaches for CMP,  $D$  is assumed to be a bounded polyhedron. Typically, at each major iteration of an inner approximation algorithm, a local minimum extreme point solution  $\bar{x}$  for CMP is available. A sequence of expanding inner approximating compact polyhedra for  $(D \cap G)$  is constructed via a series of subiterations, where  $G = \{x \in \mathbb{R}^n : f(x) \geq f(\bar{x})\}$ . During this process, either an improved local minimum extreme point  $\bar{\bar{x}}$  is found, or, after  $k$  subiterations, the algorithm de-

terminates that  $D \subseteq P^k$ , where  $P^k$  is the current inner approximation of  $(D \cap G)$ . In the former case,  $\bar{\bar{x}}$  replaces  $\bar{x}$  and a new major iteration begins. In the latter case, since  $P^k \subseteq (D \cap G)$ , it follows that  $D \subseteq G$ , and the algorithm therefore terminates with the global optimal solution  $\bar{x}$ .

In the *branch and bound* approaches for CMP,  $D$  is repeatedly subdivided into finer and finer partitions. A lower bound for  $f$  over each partition element is calculated. The lowest of these lower bounds at any step  $k$  of the process gives a global lower bound  $LB_k$  for  $f$  over  $D$ . At any stage, typically some feasible solutions for CMP have been detected. A feasible solution  $\bar{y}$  with the smallest  $f$  value among all feasible solutions detected through any point in the algorithm is always available. This solution is called the *incumbent solution*. When, at some step  $k$ , the inequality  $LB_k \geq f(\bar{y})$  holds for the first time, the algorithm stops and returns the global optimal solution  $\bar{y}$ .

Details concerning these and other solution approaches can be found in [1,2,6,7].

### Introduction

Conjugate-gradient methods (CG methods) are used to solve large-dimensional problems that arise in computational linear algebra and computational nonlinear optimization. These two subjects share a broad common frontier, and one of the most easily traversed crossing points is via the following simple observation: the problem of solving a system of linear equations  $\mathbf{Ax} = \mathbf{b}$  for the unknown vector  $\mathbf{x} \in \mathbf{R}^n$ , where  $\mathbf{A}$  is a positive definite, symmetric matrix and  $\mathbf{b}$  is a given vector, is mathematically equivalent to finding the minimizing point of the strictly convex quadratic function

$$q(\mathbf{x}) = -\mathbf{b}^\top \mathbf{x} + \frac{1}{2} \mathbf{x}^\top \mathbf{A} \mathbf{x}.$$

The *linear CG method* for solving the system of linear equations is able to capitalize on this equivalent optimization formulation. It was developed in the pioneering 1952 paper of M.R. Hestenes and E.L. Stiefel [11] who, in turn, cite antecedents in the contributions of several other authors (see [9]). The method fell out of favor with numerical analysts during the 1960s because it did not compete with direct methods, in particular, Gaussian elimination, but it continued to be widely used in real-world applications by specialists in other areas. Interest in CG as an iterative method, downplaying its finite-termination properties, revived in the 1970s when the solution of *large scale linear systems* was coming to the forefront of academic research.

The *nonlinear CG method* extends the linear CG approach to the problem of minimizing a smooth, nonlinear function  $f(\mathbf{x})$ ,  $\mathbf{x} \in \mathbf{R}^n$ , where  $n$  can be large. It was developed in another landmark article published in 1964 by R. Fletcher and C. Reeves [8]. Optimization techniques for this class of problems, which are inherently iterative in nature, form a direction of descent at an approximation to the solution (the current iterate), and search along this direction to obtain a new iterate with an improved function value. The *Fletcher-Reeves algorithm* combined a search direction derived from the *Hestenes-Stiefel approach* with an efficient line search procedure along this direction vector adapted from the 1959 variable-metric breakthrough algorithm of W.C. Davidon [6]. The resulting CG algorithm was a marked enhancement of the classical steepest descent method of A.-L. Cauchy.

Like steepest descent, the nonlinear CG method is storage-efficient and requires only a few  $n$ -vectors of computer storage beyond that needed to specify the problem itself. During the three decades after its discovery, a large number of storage-efficient *nonlinear CG-related algorithms* were proposed. In particular, a structural connection between conjugate-gradient and variable-metric techniques for defining search direction vectors provided the springboard for effective new families of variable-storage/limited-memory algorithms and affine-reduced-Hessian algorithms that occupy a middle ground.

These three classes of algorithms, namely, linear CG, nonlinear CG and nonlinear CG-related, will be discussed in the respective Sections below.

### Notation and Preliminaries

Lowercase boldface letters, e. g.,  $\mathbf{x}$ , denote vectors, and uppercase boldface letters, e. g.,  $\mathbf{A}$ , denote symmetric, positive definite matrices. The *residual* at  $\mathbf{x}$  of the linear system  $\mathbf{Ax} = \mathbf{b}$  is  $\mathbf{r} = \mathbf{Ax} - \mathbf{b}$ . It equals the gradient vector  $\mathbf{g} = -\mathbf{b} + \mathbf{Ax}$  of the strictly convex, quadratic form

$$q(\mathbf{x}) = -\mathbf{b}^\top \mathbf{x} + \frac{1}{2} \mathbf{x}^\top \mathbf{Ax}$$

at  $\mathbf{x}$ . The gradient vector of  $q$  vanishes only at the unique solution  $\mathbf{A}^{-1}\mathbf{b}$  of the linear system.

### Linear CG Algorithms

A basic CG algorithm for solving the system of linear equations  $\mathbf{Ax} = \mathbf{b}$ , where  $\mathbf{A}$  is a positive definite, symmetric matrix, is as follows:

```

(Initialization)
0   $\mathbf{x}_1 =$  arbitrary;
    $\mathbf{r}_1 =$  residual of linear system at  $\mathbf{x}_1$ ;
    $\mathbf{d}_1 = -\mathbf{r}_1$ ;
(Iteration  $i$ )
1   $\mathbf{x}_{i+1} =$  unique minimizing point of  $q$  on
   halfline through  $\mathbf{x}_i$  along direction  $\mathbf{d}_i$ ;
2   $\mathbf{r}_{i+1} =$  residual of linear system at  $\mathbf{x}_{i+1}$ ;
3   $\beta_i = \|\mathbf{r}_{i+1}\|^2 / \|\mathbf{r}_i\|^2$ ;
4   $\mathbf{d}_{i+1} = -\mathbf{r}_{i+1} + \beta_i \mathbf{d}_i$ .
    
```

In the computational linear algebra setting, the matrix  $\mathbf{A}$  is provided exogenously. The residual  $\mathbf{r}_{i+1}$ , at step 2, is computed as  $\mathbf{Ax}_{i+1} - \mathbf{b}$  or else obtained by updating  $\mathbf{r}_i$ .

The direction  $\mathbf{d}_i$  is always a descent direction for  $q$  at  $\mathbf{x}_i$ . At step 1, the minimizing point is computed as follows:

$$\alpha_i = -\frac{\mathbf{r}_i^\top \mathbf{d}_i}{\mathbf{d}_i^\top \mathbf{A} \mathbf{d}_i}; \quad \mathbf{x}_{i+1} = \mathbf{x}_i + \alpha_i \mathbf{d}_i.$$

There are numerous variants on this basic algorithm that seek to enhance convergence through problem preconditioning (transformation of variables), to improve algorithm stability and to solve related computational linear algebra problems. A contextual overview and further references can be found in [2].

Here our focus is optimization. In this setting, the residual at  $\mathbf{x}_{i+1}$  is given its alternative interpretation and representation as the gradient vector  $\mathbf{g}_{i+1}$  of  $q$  at  $\mathbf{x}_{i+1}$ , and this gradient is assumed to be provided exogenously. The minimizing point at step 1 is computed, alternatively, as follows:

$$\alpha_i = -\frac{\mathbf{g}_i^\top (\bar{\mathbf{x}}_i - \mathbf{x}_i)}{\mathbf{d}_i^\top (\bar{\mathbf{g}}_i - \mathbf{g}_i)},$$

where  $\bar{\mathbf{x}}_i$  is any point on the ray through  $\mathbf{x}_i$  in the direction  $\mathbf{d}_i$  and  $\bar{\mathbf{g}}_i$  is its corresponding gradient vector;  $\mathbf{x}_{i+1} = \mathbf{x}_i + \alpha_i \mathbf{d}_i$ . The expression for  $\alpha_i$  is derived from the previous linear systems version and the relation  $\mathbf{A}(\bar{\mathbf{x}}_i - \mathbf{x}_i) = \bar{\mathbf{g}}_i - \mathbf{g}_i$ .

We will call the resulting optimization algorithm the *CG-standard for minimizing  $q$* . It will provide an important guideline for defining CG algorithms in the subsequent discussion.

### Nonlinear CG Algorithms

A nonlinear CG algorithm is used to find a minimizing point of the nonlinear function  $f(\mathbf{x})$ ,  $\mathbf{x} \in \mathbf{R}^n$ , when  $n$  is large and/or computer storage is at a premium. A basic algorithm can be stated as follows:

```

(Initialization)
0   $\mathbf{x}_1 =$  arbitrary;
    $\mathbf{g}_1 =$  gradient of  $f$  at  $\mathbf{x}_1$ ;
    $\mathbf{d}_1 = -\mathbf{g}_1$ ;
(Iteration  $i$ )
1   $\mathbf{x}_{i+1} =$  an improved iterate on halfline
   through  $\mathbf{x}_i$  along direction  $\mathbf{d}_i$ ;
2   $\mathbf{g}_{i+1} =$  gradient of  $f$  at  $\mathbf{x}_{i+1}$ ;
3   $\beta_i = \|\mathbf{g}_{i+1}\|^2 / \|\mathbf{g}_i\|^2$ ;
4   $\mathbf{d}_{i+1} = -\mathbf{g}_{i+1} + \beta_i \mathbf{d}_i$ .
    
```

Note that this algorithm is closely patterned after the *CG-standard*. The improved iterate at step 1 is obtained by a *line search* procedure, which is normally based on quadratic or cubic polynomial fitting (suitably safeguarded). When  $f = q$ , such a line search procedure can immediately locate the minimizing point along the line of search, once it has gathered the requisite information to make an exact fit. In other words, when applied to the minimization of  $q$ , the foregoing nonlinear CG algorithm is able to replicate the CG-standard precisely. This property characterizes a nonlinear CG algorithm.

Considerable research has gone into alternative expressions for the quantity  $\beta_i$ . The four leading contenders are the *Fletcher-Reeves* (FR), *Hestenes-Stiefel* (HS), *Polyak-Polak-Ribière* (PPR) and *Dai-Yuan* (DY) choices (see [5,8,11,20,22]). These define  $\beta_i$  as follows:

$$\begin{aligned} \text{FR: } \beta_i &= \frac{\mathbf{g}_{i+1}^\top \mathbf{g}_{i+1}}{\mathbf{g}_i^\top \mathbf{g}_i}; \\ \text{HS: } \beta_i &= \frac{\mathbf{g}_{i+1}^\top \mathbf{y}_i}{\mathbf{d}_i^\top \mathbf{y}_i}; \\ \text{PPR: } \beta_i &= \frac{\mathbf{g}_{i+1}^\top \mathbf{y}_i}{\mathbf{g}_i^\top \mathbf{g}_i}; \\ \text{DY: } \beta_i &= \frac{\mathbf{g}_{i+1}^\top \mathbf{g}_{i+1}}{\mathbf{d}_i^\top \mathbf{y}_i}, \end{aligned} \quad (1)$$

where  $\mathbf{y}_i = \mathbf{g}_{i+1} - \mathbf{g}_i$  is the gradient change that corresponds to the step  $\mathbf{s}_i = \mathbf{x}_{i+1} - \mathbf{x}_i$ .

When line searches are exact and the function is quadratic, the following relations hold:

$$\mathbf{g}_{i+1}^\top \mathbf{g}_{i+1} = \mathbf{g}_{i+1}^\top \mathbf{y}_i, \quad \mathbf{g}_i^\top \mathbf{g}_i = \mathbf{d}_i^\top \mathbf{y}_i. \quad (3)$$

Thus, the values of the scalar  $\beta_i$  are identical for all four choices, and each of the associated algorithms becomes the CG-standard. In general, however, they are applied to nonquadratics and use inexact line searches, resulting in four distinct, nonlinear CG algorithms that can exhibit behavior very different from one another.

The following generalization yields a *two-parameter family*:

$$\beta_i = \frac{\lambda_i (\mathbf{g}_{i+1}^\top \mathbf{g}_{i+1}) + (1 - \lambda_i) (\mathbf{g}_{i+1}^\top \mathbf{y}_i)}{\mu_i (\mathbf{g}_i^\top \mathbf{g}_i) + (1 - \mu_i) (\mathbf{d}_i^\top \mathbf{y}_i)}, \quad (4)$$

where  $\lambda_i \in [0, 1]$  and  $\mu_i \in [0, 1]$ . For any choice of  $\lambda_i$  and  $\mu_i$  in these ranges, the associated algorithm re-

duces to the CG-standard when  $f$  is quadratic and line searches are exact, which follows from (3). If the scalars  $\lambda_i$  and  $\mu_i$  take only their extreme values, 0 or 1, then one obtains four possible combinations corresponding to (1)–(2). The above two-parameter family of nonlinear CG algorithms, which subsumes FR, HS, PPR and DY, and its subfamilies (defined, for example, by taking  $\lambda_i \equiv 1$ ) are currently a topic of active research.

When the line search is sufficiently accurate, a nonlinear CG algorithm always produces a direction of descent at step 4. Suitable inexact line search termination conditions, in conjunction with different choices of  $\beta_i$ , have been extensively studied, both theoretically and computationally. A good overview of the theory and convergence analysis of nonlinear CG algorithms can be found in [19]. The nonlinear CG algorithm based on the PPR choice for  $\beta_i$  [20,22] and a suitable restarting strategy [23] has emerged as the most efficient in practice. However, it is well known that no single nonlinear CG algorithm works well all the time. There is enormous variability in performance on different problems or even within different regions of the same problem.

### Nonlinear CG-Related Algorithms

We informally characterize a *nonlinear CG-related algorithm* as follows:

- its computer storage requirements are ‘similar’ to those of an implemented nonlinear CG algorithm, for example, [23];
- its path traverses the iterates of the CG-standard when the function is a strictly convex quadratic, line searches are exact, and the same initialization is used.

In other words, it may use a few more  $n$ -vectors of computer storage than, say, the PPR nonlinear CG algorithm, and it is permitted to generate additional intermediate iterates and form search vectors in novel ways. A nonlinear CG-related algorithm does not have to imitate the ‘structure’ of the basic nonlinear CG algorithm of the previous Section. But the above requirement that its path must cover the iterates of the CG-standard of the first Section implies the following: if the candidate algorithm does not exhibit finite termination when applied to a quadratic  $q$  then it is not a CG-related algorithm.

Let us now briefly categorize the main lines of development.

### Classical Alternatives to CG

These seek to enhance or accelerate the steepest descent algorithm of Cauchy more directly, without explicitly introducing notions of conjugacy. The year of publication of [8] was indeed a banner year for such developments. Two particularly noteworthy contributions, which coincidentally also appeared in 1964, were the *parallel-tangents* or *PARTAN* algorithm of B.V. Shah, R.J. Buehler and O. Kempthorne [24] and the *heavy ball algorithm* of B.T. Polyak [21]. For a modern description of the former, and its subsequently discovered CG-related properties, see [14]. The basic iteration of the latter algorithm is as follows:

$$\mathbf{x}_{i+1} = \mathbf{x}_i - \alpha \mathbf{g}_i + \beta(\mathbf{x}_i - \mathbf{x}_{i-1}),$$

where  $\alpha$  is a constant positive stepsize and  $\beta$  is a scalar with  $0 < \beta < 1$ . Although, strictly speaking, it is not CG-related in this form, the algorithm has CG-like rate of convergence properties on a quadratic under optimal choices of the algorithm parameters  $\alpha$  and  $\beta$  (see [3]). The algorithms in [24] and [21] both used very simple steplength techniques to move from one iterate to the next, in contrast to the nonlinear CG implementation of [8]. The introduction of the line-search technique of Davidon [6] into either of these 1964 algorithms, as in [8], could have propelled them much more into the limelight at the time. More recently, the important contribution of Yu.E. Nesterov [17] on global rate of convergence is based on an algorithm akin to PARTAN [24]. However, in general, classical alternatives to CG remain on the sidelines.

### Nonlinear CG Variants

These are premised on retaining the algorithmic structure, and the conjugacy properties on quadratics, of the basic nonlinear CG algorithm of the above Section when the initial direction is not along the negative gradient and/or line searches are inexact. For instance, the *three-term-recurrence algorithm* (TTR) is able to simultaneously relax both CG-standard requirements. The overall iteration follows the basic algorithm of the previous Section, but with the computation of the search

direction at steps 3 and 4 replaced as follows:

$$\beta_i = \frac{\mathbf{y}_i^\top \mathbf{y}_i}{\mathbf{y}_i^\top \mathbf{d}_i}, \quad \gamma_i = \frac{\mathbf{y}_{i-1}^\top \mathbf{y}_i}{\mathbf{y}_{i-1}^\top \mathbf{d}_{i-1}},$$

and

$$\mathbf{d}_{i+1} = -\mathbf{y}_i + \beta_i \mathbf{d}_i + \gamma_i \mathbf{d}_{i-1}.$$

Conjugacy of search directions is retained when the initial search direction is chosen to be an arbitrary direction of descent. If this initial direction is along the negative gradient and line searches are exact, then the TTR generates the same search directions and iterates as the CG-standard on a positive definite quadratic. A drawback of the TTR algorithm is that it does not guarantee a descent direction on more general functions even if line searches are exact. But, in practice, the direction almost always satisfies the condition  $\mathbf{g}_{i+1}^\top \mathbf{d}_{i+1} < 0$ .

For references to other nonlinear CG variants, see [10] and the survey articles in [1]. Despite theoretical advantages on quadratics, algorithms in this category, in practice, have not proved to be significantly superior to the PPR nonlinear CG algorithm of the above Section.

### Variable-Storage/Limited-Memory Algorithms

These are premised on a key structural relationship between the nonlinear CG algorithm and the BFGS variable-metric algorithm, and its properties on quadratics, see [4,12,15]. The most effective CG-related algorithm, to date, is the L-BFGS algorithm of J. Nocedal [18]. This is described in more detail in ► **Unconstrained nonlinear optimization: Newton-Cauchy framework** and is not repeated here. The algorithm has the property that it produces a descent direction under weak termination conditions on the line search. It has proved to be an efficient and versatile algorithm (it can exploit additional computer storage when available) that generally outperforms the PPR algorithm in practice.

For an overview of other variable-storage algorithms that draw on the *BFGS-CG relationship*, see the survey articles in [1].

### Affine-Reduced-Hessian Algorithms

These make estimates of curvature, i.e., approximations to the Hessian or its inverse, in an affine sub-

space usually of low dimension and defined by the most recent gradient and one or more prior steps and/or gradients. For algorithms of this type and their CG-related properties, see [7,13,16] and references cited therein.

The foregoing principle, on which such algorithms are premised, has the conceptual advantage that it provides a *true continuum* between the nonlinear CG and full-storage variable-metric (and Newton) algorithms. But, practical affine-reduced-Hessian implementations are not yet widespread.

## Conclusion

CG algorithms are among the simplest and most elegant algorithms of computational nonlinear optimization. They can be surprisingly effective in practice, and thus will always have an honored place in the repertoire. Nevertheless, the subject still lacks a comprehensive underlying theory, and many interesting algorithmic issues remain to be explored.

Some references cited in the present discussion are listed below, and other key references can be traced, in turn, through their bibliographies.

### Introduction

Contact map overlap maximization is a problem that arises in computational biology as an important approach to compare structural similarity of proteins. Contact map overlap was proposed in [6] as a measure for protein structural similarity, and is employed in the Critical Assessment of Techniques for Protein Structure Prediction (CASP).

Proteins consist of amino acid residues and assume specific 3-dimensional structures. Proteins of similar structures often have similar function and properties. Therefore, structure alignment provides critical insights into the relation of existing proteins, and has important applications in designing knowledge-based potential functions that are useful for protein folding prediction.

### Definition

Given two proteins A and B with  $m$  and  $n$  residues, respectively, we denote the residues of A with indices  $i, i'$ , and  $i''$ , and the residues of B with indices  $j, j'$  and  $j''$ . If two residues in the same protein are close in space, we say that they are *in contact*. A list of residue pairs is known as the *contact map* of a given protein. In this article, the contact map for protein A (resp. B) is denoted as  $E^A$  (resp.  $E^B$ ) so that  $E_{ii'}^A = 1$  (resp.  $E_{jj'}^B = 1$ ) if residues  $i$  and  $i'$  in protein A (resp.  $j$  and  $j'$  in protein B) are in contact, and  $E_{ii'}^A = 0$  (resp.  $E_{jj'}^B = 0$ ) otherwise.

From a graph-theoretic perspective, a contact map is a node-node incident graph where nodes represent residues and edges represent contacts. The *contact map overlap* maximization problem aims at identifying an ordered residue correspondence between two contact maps so as to result in a maximum common subgraph. To solve this problem, a correspondence (alignment) must be established between the node sets (residues) of the contact maps so that the number of common contacts (edges) can be maximized. If residue  $i$  in protein A aligns with residue  $j$  in protein B, they form a *pair*  $(i, j)$ . If pairs  $(i, j)$  and  $(i', j')$  result in common contacts, i. e.,  $E_{ii'}^A = 1$  and  $E_{jj'}^B = 1$ , then they form an *overlap*. If two pairs  $(i, j)$  and  $(i', j')$  form an overlap, we set  $h(i, j, i', j') = 1$ . Otherwise,  $h(i, j, i', j')$  is set to zero.

An important requirement for structure alignment is that the relative orders of residues in the original sequences agree – a property that is known as the *non-crossing* property in the CMO literature. For two pairs  $(i, j)$  and  $(i', j')$  to be non-crossing, either  $i < i'$  and  $j < j'$  or  $i > i'$  and  $j > j'$  must hold. In this paper, non-crossing pairs are also referred to as *parallel* pairs.

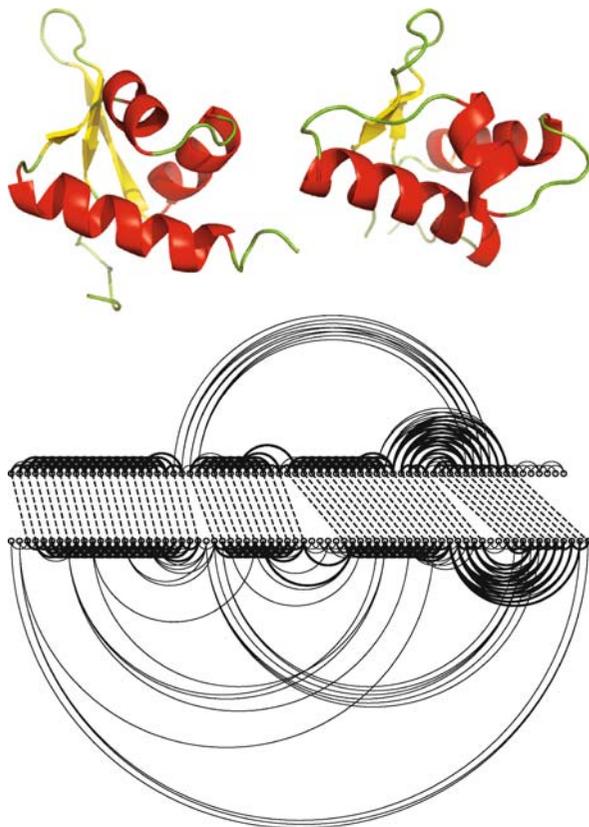

For convenience of the presentation,  $[i, i']$  (resp.  $[j, j']$ ) will denote the set of residues  $\{i'' : i \leq i'' \leq i'\}$  (resp.  $\{j'' : j \leq j'' \leq j'\}$ ). The interval product  $[i, i'] \times [j, j']$  therefore denotes the set of pairs  $\{(i'', j'') : i \leq i'' \leq i', j \leq j'' \leq j'\}$ . For any given set of residue pairs  $S$ , we will use  $\mathbb{Q}(S)$  to denote the set of subsets of  $S$  that contain only parallel pairs. The objective of CMO is to identify a set of parallel pairs that maximize the resultant number of overlaps. For proteins A and B, the problem can be stated as follows:

$$\max_{Q \in \mathbb{Q}([1, m] \times [1, n])} \frac{1}{2} \sum_{(i, j) \in Q} \sum_{(i', j') \in Q} h(i, j, i', j').$$

An optimal alignment of the contact maps of the human Rap30 DNA-binding domain (1BBY) and the DNA binding domain of Escherichia coli LexA repressor (1LEA) is shown in Fig. 1 together with their 3-dimensional structures.

### Methods

Goldman et al. [7] proved that CMO is APX-hard, which practically defies the existence of a polynomial time exact algorithm or even a polynomial time approximation scheme. In the remainder of this section, we

**Contact Map Overlap Maximization Problem, CMO, Figure 1**  
An instance of CMO involving 1BBY and 1LEA

will survey both exact and approximate algorithms for this problem.

### Exact algorithms

Four exact algorithms have been proposed for the CMO problem so far. All embrace the branch-and-bound framework to ensure global optimality. The branch-and-reduce algorithm [12,13] currently has an edge against all other exact algorithms both in terms of computational speed as well as its ability to solve challenging instances.

**Integer Linear Program** Carr et al. [5] proposed an integer linear programming formulation for the problem. This formulation was further developed in [9] and involves two sets of binary variables:  $x_{ij}$  and  $y_{iji'j'}$ . Variable  $x_{ij}$  equals one if pair  $(i, j)$  is chosen in the optimal alignment and zero otherwise. Variable  $y_{iji'j'}$  equals

one if both pairs  $(i, j)$  and  $(i', j')$  are chosen in the final solution. Otherwise, variable  $y_{iji'j'}$  is set to zero. The model is as follows:

$$(M1) \quad \max \sum_{(i,j,i',j'): E^A(i,i')=1, E^B(j,j')=1, i < i', j < j'} y_{iji'j'} \quad (1)$$

$$\text{s.t.} \quad \sum_{i': E^A(i,i')=1, i' > i} y_{iji'j'} \leq x_{ij} \quad (2)$$

$$\sum_{j': E^B(j,j')=1, j' > j} y_{iji'j'} \leq x_{ij} \quad (3)$$

$$\sum_{i: E^A(i,i')=1, i < i'} y_{iji'j'} \leq x_{i'j'} \quad (4)$$

$$\sum_{j: E^B(j,j')=1, j < j'} y_{iji'j'} \leq x_{i'j'} \quad (5)$$

$$x_{ij} + x_{i'j'} \leq 1 \quad \forall \text{ crossing pairs } (i, j) \text{ and } (i', j') \quad (6)$$

$$x_{ij} \in \{0, 1\}, y_{iji'j'} \in \{0, 1\}$$

The sum of common contacts in Eq. (1) constitutes the number of overlaps by definition since Eq. (6) prohibits the existence of crossing pairs in the final solution. Equations (2)–(5) ensure that the optimal solution contains at most one pair from each residue that does not cross a chosen pair. In addition to these necessary constraints, two classes of cuts, *clique-cuts* and *odd-hole-cuts*, can be optionally generated in polynomial time and append to (M1) as was shown in [9].

**Lagrangian Relaxation** In [3], Caprara and Lancia proposed a Lagrangian relaxation approach for the CMO problem. Their approach begins with an integer linear program formulation of CMO as is shown in model (M2) below. In this model,  $x_{ij}$  and  $y_{iji'j'}$  bear same definitions as their counterparts in (M1), and  $\mathcal{I}$  is the set of maximal set of crossing pairs.

$$(M2) \quad \max \sum_{(i,j,i',j')} \frac{1}{2} h_{iji'j'} y_{iji'j'} \quad (7)$$

$$\text{s.t.} \quad \sum_{(i,j):(i,j) \in \mathcal{I}} x_{ij} \leq 1, \quad \forall \mathcal{I} \in \mathcal{I} \quad (8)$$

$$\sum_{(i,j)} y_{ijj'j'} \leq x_{i'j'}, \quad \forall I \in \mathcal{I}, (i', j') \quad (9)$$

$$y_{ijj'j'} = y_{i'j'ij}, \quad \forall i < i', j < j' \quad (10)$$

$$x_{ij}, y_{ijj'j'} \in \{0, 1\} \quad (11)$$

It is easy to verify that Eq. (7) yields the number of overlaps given the validity of Eq. (10). Since any two pairs in a maximal set of crossing pairs would cross, constraint (8) enforces the non-crossing property by prohibiting any such two pairs to co-exist in the final alignment. Constraint (9) ensures that, if an arbitrary pair  $(i', j')$  is chosen, the final solution should contain no more than one pair  $(i, j)$  from any maximal crossing pair set that could form an overlap with pair  $(i', j')$ .

By introducing multipliers  $\lambda_{ijj'j'}$  for Eq. (9), Caprara and Lancia obtained the following Lagrangian relaxation of (M2):

$$\begin{aligned} (LM2) \\ \min_{\lambda} \max_{i,j} \sum_{(i,j,i',j')} \frac{1}{2} h_{ijj'j'} y_{ijj'j'} \\ + \sum_{(i,j,i',j'):i < i', j < j'} \lambda_{ijj'j'} (y_{ijj'j'} - y_{i'j'ij}) \end{aligned}$$

s.t. Constraints (8), (9), and (11).

A subgradient method was used to iteratively improve the multipliers, while an  $\mathcal{O}(|E^A||E^B|)$  algorithm was employed to solve (LM2) for the set of multipliers at each iteration.

**Reformulation as Maximum Clique** Strickland et al. [11] showed that CMO can be cast into a maximum clique problem. To this end, they considered a two-dimensional lattice whose rows correspond to the contacts in  $E^A$  and columns correspond to the contacts in  $E^B$ . Each vertex of the lattice, if chosen, contributes a unit overlap to the objective value. In addition, an edge is drawn between two vertices if the corresponding pair of overlaps are admissible to some feasible alignments. It is not difficult to see that a maximum clique in the resultant graph indeed corresponds to an optimal solution for the CMO problem. This algorithm involves a number of preprocessing routines

to reduce the problem size before calling a maximum clique solver. In a more recent work [10], the authors proposed improved data structures to enhance the algorithm performance.

**Combinatorial Branch-and-Reduce** Xie and Sahinidis [12,13] developed a branch-and-reduce algorithm, which combines the generic branch-and-bound framework with problem-specific reduction schemes. The algorithm initializes a branch-and-bound tree with a root node where all pairs are allowed. Reduction schemes, both based on domination and the current best solution value, are used to remove inferior pairs. Lower and upper bounds on the overlaps for the current node are then computed using dynamic programming. If the lower and upper bounds agree, the search is terminated with a global optimal alignment. Otherwise, the algorithm chooses a branching pair and creates two children nodes. The branching pair is enforced in one of the node, while it is disallowed in the other node.

A key step in their algorithm is the computation of the contribution to the overlaps by a given pair on a set of pairs. Define  $\mathbb{Q}(S)$  to be the set of all subsets of  $S$  that contain only parallel pairs. Then, the contribution of pair  $(i, j)$  to the objective value on the set  $S$  is defined as

$$p(i, j, S) := \max_{Q \in \mathbb{Q}(S)} \sum_{(i',j') \in Q} h(i, j, i', j').$$

In particular, let  $p^+(i, j, i', j')$  and  $p^-(i, j, i', j')$  denote  $p(i, j, S)$  when  $S = [i', m] \times [j', n]$  and when  $S = [1, i'] \times [1, j']$ , respectively. They proved that computing a single term of  $p^+(\cdot)$  or  $p^-(\cdot)$  can be accomplished in  $\mathcal{O}(mn)$  time with preprocessing time and space complexity of  $\mathcal{O}(m + n)$ .

The upper bounding scheme is summarized in Proposition 1, where, for a node  $V$  of the search tree,  $\mathbb{C}(V)$  is the set of pairs that must be included and  $\mathbb{F}(V)$  is the set of pairs that have the freedom to be in the solution or not. In addition, define

$$g(i, j) := \sum_{(i',j') \in \mathbb{C}(V)} h(i, j, i', j'). \forall (i, j) \in \mathbb{F}(V)$$

Then:

**Proposition 1** Define

$$t(i, j) := \begin{cases} g(i, j), & \text{if } (i, j) \in \mathbb{F}(V); \quad i = 1 \text{ or } j = 1, \\ \max \{g(i, j), g(i, j) + w(i, j)\}, & \text{if } (i, j) \in \mathbb{F}(V); \quad i > 1 \text{ and } j > 1, \\ -\infty, & \text{otherwise,} \end{cases}$$

where

$$\bar{h}(i, j, i', j') := \begin{cases} h(i, j, i', j'), & \text{if } (i, j), (i', j') \in \mathbb{F}(V) \\ 0, & \text{otherwise,} \end{cases}$$

$$w(i, j) := \begin{cases} -\infty, & \text{if } [1, i-1] \times [1, j-1] \cap \mathbb{F}(V) = \emptyset, \\ \max_{(i', j') \in [1, i-1] \times [1, j-1] \cap \mathbb{F}(V)} \{t(i', j') + \bar{h}(i', j', i, j) + \frac{1}{2}u(i', j', i, j)\}, & \text{otherwise,} \end{cases}$$

and

$$u(i', j', i, j) := p^+(i', j', i+1, j+1) + p^-(i, j, i'-1, j'-1).$$

Then

$$\frac{1}{2} \sum_{(i, j) \in \mathbb{C}(V)} \sum_{(i', j') \in \mathbb{C}(V)} h(i, j, i', j') + \left\lfloor \max_{(i, j) \in \mathbb{F}(V)} t(i, j) \right\rfloor$$

is an upper bound for the current node  $V$ .

Proposition 1 suggests an  $\mathcal{O}(m^2 n^2)$  algorithm to compute the upper bound. In addition, the upper bounding scheme also provides a natural lower bound as was shown in [13].

### Approximate Algorithms

This subsection outlines both approximation algorithms (i.e., with performance guarantee) and heuristics (i.e., without performance guarantee) that have been proposed in the literature for the CMO problem.

Goldman et al. [7] considered a special class of CMO instances from 2-dimensional self-avoiding walk, and proposed a 3-approximation algorithm that runs in  $\mathcal{O}(n^6)$  time. Agarwal et al. [1] proposed a 6-approximation algorithm for the same class of problems, with

however a better complexity of  $\mathcal{O}(n^3 \log n)$ . In addition, they proved the special class of CMO from 3-dimensional self-avoiding walk is MAXSNP-hard, and proposed a  $\mathcal{O}(\sqrt{n})$ -approximation algorithm for this class of CMO instances.

Carr et al. [4] proposed to use a memetic algorithm, which combines global search and local search, to solve general instances of CMO. In [2], Caprara et al. proposed several heuristics, including a genetic algorithm, local search, and greedy algorithms based on Lagrangian relaxation. Existing computational studies [8,13] suggest that Lagrangian-relaxation-based greedy algorithms perform the best among existing heuristics for a large set of test instances.

### Conclusions

The contact map overlap maximization problem is a very important problem in computational biology. Efficient algorithms, both exact and approximate, for this problem are of great interest. Despite the inherent difficulty of this problem, many large-scale practical instances have been solved within reasonable amounts of time. Many challenging instances of the problem currently remain unsolved [13].

### Introduction

In this paper we use the following notation:  $\mathbb{R}^n$  is an  $n$ -dimensional space, where the scalar product will be denoted by  $\langle x, y \rangle$ :

$$\langle x, y \rangle = \sum_{i=1}^n x_i y_i,$$

and  $\|\cdot\|$  will denote the associated norm. The gradient of a function  $f: \mathbb{R}^n \rightarrow \mathbb{R}^1$  will be denoted by  $\nabla f$ .

A function  $f$  is differentiable at a point  $x \in \mathbb{R}^n$  with respect to a direction  $g \in \mathbb{R}^n$  if the limit

$$f'(x, g) = \lim_{\alpha \downarrow 0} \frac{f(x + \alpha g) - f(x)}{\alpha}$$

exists. The closed unit ball will be denoted by  $B: B = \{x \in \mathbb{R}^n: \|x\| \leq 1\}$ .

Consider a function  $f$  defined on  $\mathbb{R}^n$ . This function is called locally Lipschitz continuous if for any bounded subset  $X \subset \mathbb{R}^n$  there exists an  $L > 0$  such that

$$|f(x) - f(y)| \leq L\|x - y\| \quad \forall x, y \in X.$$

If  $f$  is convex then one can define a subdifferential  $\partial f(x)$  of this function at a point  $x \in \mathbb{R}^n$  as follows [13]:

$$\partial f(x) = \{v \in \mathbb{R}^n: f(y) - f(x) \geq \langle v, y - x \rangle, y \in \mathbb{R}^n\}.$$

Elements  $v \in \partial f(x)$  of the subdifferential  $\partial f(x)$  are called subgradients of  $f$  at the point  $x$ . For a convex function  $f$  defined on  $\mathbb{R}^n$  the subdifferential  $\partial f(x)$  is nonempty, convex and compact at any  $x \in \mathbb{R}^n$ . A set-valued mapping  $x \mapsto \partial f(x)$  is upper semicontinuous.

An  $\varepsilon$ -subdifferential  $\partial_\varepsilon f(x)$ ,  $\varepsilon > 0$  of the convex function  $f$  at a point  $x \in \mathbb{R}^n$  is defined as [13]

$$\partial_\varepsilon f(x) = \{v \in \mathbb{R}^n: f(y) - f(x) \geq \langle v, y - x \rangle - \varepsilon, y \in \mathbb{R}^n\}.$$

Elements  $v \in \partial_\varepsilon f(x)$  of the subdifferential  $\partial_\varepsilon f(x)$  are called  $\varepsilon$ -subgradients of  $f$  at the point  $x$ . For a convex function  $f$  defined on  $\mathbb{R}^n$  the  $\varepsilon$ -subdifferential  $\partial_\varepsilon f(x)$  is nonempty, convex and compact at any  $x \in \mathbb{R}^n$  and a set-valued mapping  $x \mapsto \partial_\varepsilon f(x)$  is continuous in Hausdorff metric at any  $x$ .

Most efficient methods in nonsmooth optimization such as the bundle method and its variations are based

on  $\varepsilon$ -subgradients of convex functions (see, for example, [10,11]).

The analysis of nonsmooth, nonconvex functions has been area of intensive research for more than three decades. Clarke [4,5] introduced the notion of generalized gradient. We define a Clarke subdifferential for locally Lipschitz continuous functions defined on  $\mathbb{R}^n$ . A locally Lipschitz function  $f$  is differentiable almost everywhere and one can define for it a Clarke subdifferential [5] by

$$\partial f(x) = \text{co} \left\{ v \in \mathbb{R}^n : \exists (x^k \in D(f), x^k \rightarrow x, k \rightarrow +\infty) : v = \lim_{k \rightarrow +\infty} \nabla f(x^k) \right\},$$

where  $D(f)$  denotes the set where  $f$  is differentiable, and  $\text{co}$  denotes the convex hull of a set. It is shown in [5] that the mapping  $\partial f(x)$  is upper semicontinuous and bounded on bounded sets. The generalized directional derivative of  $f$  at  $x$  in the direction  $g$  is defined to be

$$f^0(x, g) = \limsup_{y \rightarrow x, \alpha \downarrow 0} \alpha^{-1} [f(y + \alpha g) - f(y)].$$

The generalized directional derivative always exists and

$$f^0(x, g) = \max \{ \langle v, g \rangle : v \in \partial f(x) \}.$$

$f$  is called a Clarke regular function on  $\mathbb{R}^n$  if it is differentiable with respect to any direction  $g \in \mathbb{R}^n$  and  $f'(x, g) = f^0(x, g)$  for all  $x, g \in \mathbb{R}^n$ . For nonregular functions the Clarke subdifferential has calculus only by means of inclusions, which makes very difficult the computation of subgradients of some complex nonsmooth, nonconvex functions. The cluster function from the cluster analysis is one such example [2,3].

Demyanov and Rubinov [6,7] introduced the notion of quasidifferential. Let  $f$  be a locally Lipschitz continuous function defined on  $\mathbb{R}^n$ . This function is called quasidifferentiable at a point  $x \in \mathbb{R}^n$  if it is directionally differentiable and there exist compact, convex sets  $\underline{\partial}f(x)$  and  $\overline{\partial}f(x)$  such that

$$f'(x, g) = \max \{ \langle v, g \rangle, \sim v \in \underline{\partial}f(x) \} + \min \{ \langle w, g \rangle, \sim w \in \overline{\partial}f(x) \}.$$

The pair

$$Df(x) = [\underline{\partial}f(x), \overline{\partial}f(x)]$$

is called a quasidifferential of the function  $f$  at a point  $x$ . The set  $\underline{\partial}f(x)$  is said to be a subdifferential and the set  $\overline{\partial}f(x)$  a superdifferential of the function  $f$  at  $x$ .

Unlike the Clarke subdifferential, the quasidifferential enjoys a full-scale calculus; however, set-valued mappings  $x \mapsto \underline{\partial}f(x)$  and  $x \mapsto \overline{\partial}f(x)$  need not be even upper semicontinuous.

Unfortunately, the notion of an  $\varepsilon$ -subdifferential cannot be extended for nonsmooth, nonconvex functions. Instead one can define the Goldstein  $\varepsilon$ -subdifferential [9]. However, in general the Goldstein  $\varepsilon$ -subdifferential is only upper semicontinuous.

In this paper, we consider continuous approximations to subdifferentials and quasidifferentials. We will also describe an algorithm for computation of elements of such approximations.

**Definitions**

**Continuous Approximations**

Let  $X$  be a compact subset of the space  $\mathbb{R}^n$ . We consider a family  $C(x, \varepsilon) = C_\varepsilon(x)$  of set-valued mappings depending on a parameter  $\varepsilon > 0$ . For each  $\varepsilon > 0$

$$C(\cdot, \varepsilon): X \rightarrow 2^{\mathbb{R}^n}.$$

We suppose that  $C(x, \varepsilon)$  is a compact convex set for all  $x \in X$  and  $\varepsilon > 0$ . It is assumed that there exists a number  $K > 0$  such that

$$\sup \{ \|v\| : v \in C(x, \varepsilon), x \in X, \varepsilon > 0 \} \leq K. \tag{1}$$

**Definition 1** The limit  $C_L(x)$  of the family  $\{C(x, \varepsilon)\}, \varepsilon > 0$  at a point  $x$  is defined as follows:

$$C_L(x) = \left\{ v \in \mathbb{R}^n : \exists (x^k \rightarrow x, \varepsilon_k \rightarrow +0, k \rightarrow +\infty, v^k \in C(x^k, \varepsilon_k)) : v = \lim_{k \rightarrow +\infty} v^k \right\}.$$

It is possible that the limit  $C_L(x)$  is not convex even if all the sets  $C(x, \varepsilon)$  are convex. We consider  $\text{co}C_L(x)$  the convex hull of  $C_L(x)$ . It follows from Definition 1 and the inequality (1) that the mapping  $\text{co}C_L$  has compact convex images.

**Definition 2** A family  $\{C(x, \varepsilon)\}, \varepsilon > 0$  is called a continuous approximation to a subdifferential  $\partial f$  on  $X$  if the following holds:

1.  $C(x, \varepsilon)$  is a Hausdorff continuous mapping with respect to  $x$  on  $X$  for all  $\varepsilon > 0$ .
2. The subdifferential  $\partial f(x)$  is the convex hull of the limit of the family  $\{C(x, \varepsilon)\}, \varepsilon > 0$  on  $X$ , i.e. for all  $x \in X$

$$\partial f(x) = \text{co}C_L(x).$$

Some properties of the continuous approximations were studied in [1].

Such continuous approximations need not be monotonically decreasing as  $\varepsilon \rightarrow +0$ . Uniform and strongly continuous approximations to the subdifferential studied in [14] have such a property. Let  $f$  be a locally Lipschitz continuous function defined on an open set which contains a compact set  $X$ . We consider a family of set-valued mappings  $A_\varepsilon f: \mathbb{R}^n \rightarrow 2^{\mathbb{R}^n}, \varepsilon > 0$ . Assume that the sets  $A_\varepsilon f(x)$  are nonempty and compact for all  $\varepsilon > 0$  and  $x \in X$ . We will denote by  $\partial f(x + B_\delta)$  the set  $\bigcup\{\partial f(y): y \in B_\delta(x)\}$ , where  $B_\delta(x) = \{y \in \mathbb{R}^n : \|x - y\| \leq \delta\}$ .

**Definition 3 ([14])** We say that the family  $\{A_\varepsilon f(\cdot)\}_{\varepsilon>0}$  is a uniform continuous approximation to the subdifferential  $\partial f$  on  $X$ , if the following conditions are satisfied:

1. For each given  $\varepsilon > 0, \mu > 0$  there exists  $\tau > 0$ , such that for all  $x \in X$

$$\partial f(x + B_\tau) \subset A_\varepsilon f(x) + B_\mu.$$

2. For each  $x \in X$  and for all  $0 < \varepsilon_1 < \varepsilon_2$ :

$$A_{\varepsilon_1} f(x) \subset A_{\varepsilon_2} f(x).$$

3.  $A_\varepsilon f(x)$  is Hausdorff continuous with respect to  $x$  on  $X$ .
4. For each  $x \in X$

$$\bigcap_{\varepsilon>0} A_\varepsilon f(x) = \partial f(x).$$

**Definition 4 ([14])** We say that the family  $\{A_\varepsilon f(\cdot)\}_{\varepsilon>0}$  is a strong continuous approximation to the subdifferential  $\partial f$  on  $X$ , if  $\{A_\varepsilon f(\cdot)\}_{\varepsilon>0}$  satisfies properties 1–3 above and instead of property 4 the following is valid:

- 4'. For every  $\gamma, \mu > 0$  there exists  $\varepsilon > 0$  such that for all  $x \in X$

$$\partial f(x) \subset A_\varepsilon f(x) \subset \partial f(x + B_\gamma) + B_\mu.$$

For the set-valued mapping  $C(x, \varepsilon)$  we set

$$C_0(x) = \left\{ v \in \mathbb{R}^n : \exists(\varepsilon_k \rightarrow +0, k \rightarrow +\infty, v^k \in C(x, \varepsilon_k)) : v = \lim_{k \rightarrow +\infty} v^k \right\}$$

and let

$$C(x, 0) = C_0(x).$$

**Theorem 1 ([1])** Let the family  $\{A_\varepsilon f(\cdot)\}_{\varepsilon>0}$  be a uniform continuous approximation to the subdifferential  $\partial f$  on a compact set  $X$ . Then  $C(x, \varepsilon) = A_\varepsilon f(x)$  is a continuous approximation to the subdifferential  $\partial f$  in the sense of Definition 2.

**Corollary 1** It was shown in [14] that a strong continuous approximation is a uniform continuous approximation. So a strong continuous approximation is a continuous approximation in the sense of Definition 2.

**Theorem 2 ([1])** Let the family  $C(x, \varepsilon)$  be a continuous approximation to the subdifferential  $\partial f$  on a compact set  $X$  and the mapping  $C(x, \varepsilon)$  be continuous with respect to  $(x, \varepsilon), x \in X, \varepsilon > 0$ . Assume  $\text{co}C_L(x) = C_0(x)$  for all  $x \in X$ . Then the mapping

$$Q(x, \varepsilon) = \text{co} \bigcup \{C(x, t) : 0 \leq t \leq \varepsilon\}$$

is a uniform continuous approximation to  $\partial f$  on  $X$ .

**Corollary 2** Let the family  $C(x, \varepsilon)$  be a continuous approximation to the subdifferential  $\partial f$  on a compact set  $X$  and the mapping  $C(x, \varepsilon)$  be a continuous with respect to  $(x, \varepsilon), x \in X, \varepsilon > 0$ . Assume  $\text{co}C_L(x) = C_0(x)$  for all  $x \in X$ . Then the mapping  $Q$  is upper semicontinuous with respect to  $(x, \varepsilon)$  at the point  $(x, 0)$ .

One can get a chain rule for continuous approximations [1,14]. However it is not always applicable to compute elements of continuous approximations. In the next section we propose an algorithm to compute those elements.

## Methods

### Computation of the Continuous Approximations

We consider a locally Lipschitz continuous function  $f$  defined on  $\mathbb{R}^n$  and assume that this function is semismooth and quasidifferentiable (for the definition of semismooth functions see [12]). We also assume that

both sets  $\underline{\partial}f(x)$  and  $\overline{\partial}f(x)$  are represented as a convex hull of a finite number of points at any  $x \in \mathbb{R}^n$ , that is at a point  $x \in \mathbb{R}^n$  there exist sets

$$A = \{a^1, \dots, a^m\}, \quad a^i \in \mathbb{R}^n, \quad i = 1, \dots, m, \quad m \geq 1$$

and

$$B = \{b^1, \dots, b^p\}, \quad b^j \in \mathbb{R}^n, \quad j = 1, \dots, p, \quad p \geq 1$$

such that

$$\underline{\partial}f(x) = \text{co}A, \quad \overline{\partial}f(x) = \text{co}B.$$

In other words we assume that the subdifferential and the superdifferential of the function  $f$  are polytopes at any  $x \in \mathbb{R}^n$ . This assumption is true, for example, for functions represented as a maximum, minimum or max–min of a finite number of smooth functions.

We take a direction  $g \in \mathbb{R}^n$  such that

$$g = (g_1, \dots, g_n), \quad |g_i| = 1, \quad i = 1, \dots, n$$

and consider the sequence of  $n$  vectors  $e^j = e^j(\alpha)$ ,  $j = 1, \dots, n$  with  $\alpha \in (0, 1]$ :

$$\begin{aligned} e^1 &= (\alpha g_1, 0, \dots, 0), \\ e^2 &= (\alpha g_1, \alpha^2 g_2, 0, \dots, 0), \\ &\dots = \dots \dots \dots, \\ e^n &= (\alpha g_1, \alpha^2 g_2, \dots, \alpha^n g_n). \end{aligned}$$

We introduce the following sets:

$$\begin{aligned} \underline{R}_0 &= A, \quad \overline{R}_0 = B, \\ \underline{R}_j &= \left\{ v \in \underline{R}_{j-1} : v_j g_j = \max\{w_j g_j : w \in \underline{R}_{j-1}\} \right\}, \\ \overline{R}_j &= \left\{ v \in \overline{R}_{j-1} : v_j g_j = \min\{w_j g_j : w \in \overline{R}_{j-1}\} \right\}. \end{aligned}$$

It is clear that

$$\begin{aligned} \underline{R}_j \neq \emptyset, \quad \forall j \in \{0, \dots, n\}, \quad \underline{R}_j \subseteq \underline{R}_{j-1}, \\ \forall j \in \{1, \dots, n\} \end{aligned}$$

and

$$\begin{aligned} \overline{R}_j \neq \emptyset, \quad \forall j \in \{0, \dots, n\}, \quad \overline{R}_j \subseteq \overline{R}_{j-1}, \\ \forall j \in \{1, \dots, n\}. \end{aligned}$$

Moreover

$$v_r = w_r \quad \forall v, w \in \underline{R}_j, \quad r = 1, \dots, j \quad (2)$$

and

$$v_r = w_r \quad \forall v, w \in \overline{R}_j, \quad r = 1, \dots, j. \quad (3)$$

Consider the following two sets:

$$\begin{aligned} \underline{R}(x, e^j(\alpha)) &= \left\{ v \in A : \langle v, e^j \rangle = \max_{u \in A} \langle u, e^j \rangle \right\}, \\ \overline{R}(x, e^j(\alpha)) &= \left\{ w \in B : \langle w, e^j \rangle = \min_{u \in B} \langle u, e^j \rangle \right\}. \end{aligned}$$

**Proposition 1** Assume that the function  $f$  is quasidifferentiable and its subdifferential and superdifferential are polytopes at a point  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$\underline{R}(x, e^j(\alpha)) \subset \underline{R}_j, \quad \overline{R}(x, e^j(\alpha)) \subset \overline{R}_j, \quad j = 1, \dots, n$$

for all  $\alpha \in (0, \alpha_0)$ .

**Corollary 3** Assume that the function  $f$  is quasidifferentiable and its subdifferential and superdifferential are polytopes at a point  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$\begin{aligned} f'(x, e^j(\alpha)) &= f'(x, e^{j-1}(\alpha)) + v_j \alpha^j g_j + w_j \alpha^j g_j, \\ \forall v &\in \underline{R}_j, \quad w \in \overline{R}_j, \quad j = 1, \dots, n \end{aligned}$$

for all  $\alpha \in (0, \alpha_0)$ .

**Proposition 2** Assume that the function  $f$  is quasidifferentiable and its subdifferential and superdifferential are polytopes at a point  $x$ . Then the sets  $\underline{R}_n$  and  $\overline{R}_n$  are singletons.

In the next subsection we propose an algorithm to approximate subgradients. This algorithm finds a subgradient which can be represented as a sum of elements of the sets  $\underline{R}_n$  and  $\overline{R}_n$ .

### Computation of Subgradients

Let  $g \in \mathbb{R}^n$ ,  $|g_i| = 1$ ,  $i = 1, \dots, n$  be a given vector and  $\lambda > 0$ ,  $\alpha > 0$  be given numbers. We define the following points

$$x^0 = x, \quad x^j = x^0 + \lambda e^j(\alpha), \quad j = 1, \dots, n.$$

It is clear that

$$x^j = x^{j-1} + (0, \dots, 0, \lambda \alpha^j g_j, 0, \dots, 0), \quad j = 1, \dots, n.$$

Let  $v = v(\alpha, \lambda) \in \mathbb{R}^n$  be a vector with the following coordinates:

$$v_j = (\lambda \alpha^j g_j)^{-1} [f(x^j) - f(x^{j-1})], \quad j = 1, \dots, n. \quad (4)$$

For any fixed  $g \in \mathbb{R}^n$ ,  $|g_i| = 1, i = 1, \dots, n$  and  $\alpha > 0$  we introduce the following set:

$$V(g, \alpha) = \left\{ w \in \mathbb{R}^n : \exists (\lambda_k \rightarrow +0, k \rightarrow +\infty), \right. \\ \left. w = \lim_{k \rightarrow +\infty} v(\alpha, \lambda_k) \right\}.$$

**Proposition 3** Assume that  $f$  is a quasidifferentiable function and its subdifferential and superdifferential are polytopes at  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$V(g, \alpha) \subset \partial f(x)$$

for all  $\alpha \in (0, \alpha_0]$ .

*Remark 1* It follows from Proposition 3 that in order to approximate subgradients of quasidifferentiable functions one can choose a vector  $g \in \mathbb{R}^n$  such that  $|g_i| = 1, i = 1, \dots, n$ , sufficiently small  $\alpha > 0, \lambda > 0$  and apply (4) to compute a vector  $v(\alpha, \lambda)$ . This vector is an approximation to a certain subgradient.

*Remark 2* A class of quasidifferentiable functions presents a broad class of nonsmooth functions, including many interesting nonregular functions. Thus, the scheme proposed in this section allows one to approximate subgradients of a broad class of nonsmooth functions.

### Discrete Gradients

In the previous subsection we demonstrated an algorithm for the computation of subgradients. In this subsection we consider an algorithm for the computation of subdifferentials. This algorithm is based on the notion of a discrete gradient. We start with its definition [1].

Let  $f$  be a locally Lipschitz continuous function defined on  $\mathbb{R}^n$ . Let

$$S_1 = \{g \in \mathbb{R}^n : \|g\| = 1\}, \\ G = \{e \in \mathbb{R}^n : e = (e_1, \dots, e_n), |e_j| = 1, \\ j = 1, \dots, n\}, \\ P = \{z(\lambda) : z(\lambda) \in \mathbb{R}^1, z(\lambda) > 0, \lambda > 0, \\ \lambda^{-1}z(\lambda) \rightarrow 0, \lambda \rightarrow 0\}.$$

Here  $S_1$  is the unit sphere,  $G$  is the set of vertices of the unit hypercube in  $\mathbb{R}^n$  and  $P$  is the set of univariate positive infinitesimal functions.

We take any  $g \in S_1$  and define  $|g_i| = \max\{|g_k|, k = 1, \dots, n\}$ . We also take any  $e = (e_1, \dots, e_n) \in G$ , a positive number  $\alpha \in (0, 1]$  and define the sequence of  $n$  vectors  $e^j(\alpha), j = 1, \dots, n$ . Then for given  $x \in \mathbb{R}^n$  and  $z \in P$  we define a sequence of  $n + 1$  points as follows:

$$x^0 = x + \lambda g, \\ x^1 = x^0 + z(\lambda)e^1(\alpha), \\ x^2 = x^0 + z(\lambda)e^2(\alpha), \\ \dots = \dots \dots, \\ x^n = x^0 + z(\lambda)e^n(\alpha).$$

**Definition 5** The discrete gradient of the function  $f$  at the point  $x \in \mathbb{R}^n$  is the vector  $\Gamma^i(x, g, e, z, \lambda, \alpha) = (\Gamma_1^i, \dots, \Gamma_n^i) \in \mathbb{R}^n, g \in S_1$  with the following coordinates:

$$\Gamma_j^i = [z(\lambda)\alpha^j e_j]^{-1} [f(x^j) - f(x^{j-1})], \\ j = 1, \dots, n, j \neq i, \\ \Gamma_i^i = (\lambda g_i)^{-1} \left[ f(x + \lambda g) - f(x) - \lambda \sum_{j=1, j \neq i}^n \Gamma_j^i g_j \right].$$

It follows from the definition that

$$f(x + \lambda g) - f(x) = \lambda \langle \Gamma^i(x, g, e, z, \lambda, \alpha), g \rangle \quad (5)$$

for all  $g \in S_1, e \in G, z \in P, \lambda > 0, \alpha > 0$ .

*Remark 3* One can see that the discrete gradient is defined with respect to a given direction  $g \in S_1$  and in order to compute the discrete gradient  $\Gamma^i(x, g, e, z, \lambda, \alpha)$  first we define a sequence of points  $x^0, \dots, x^n$  and compute the values of the function  $f$  at these points, that is we compute  $n + 2$  values of this function including the point  $x$ .  $n - 1$  coordinates of the discrete gradient are defined similar to those of the vector  $v(\alpha, \lambda)$  from (4) and  $i$ th coordinate is defined so as to satisfy the equality (5), which can be considered as some version of the mean value theorem.

**Proposition 4** Let  $f$  be a locally Lipschitz continuous function defined on  $\mathbb{R}^n$  and  $L > 0$  be its Lipschitz constant. Then for any  $x \in \mathbb{R}^n, g \in S_1, e \in G, \lambda > 0, z \in P, \alpha > 0$

$$\|\Gamma^i\| \leq C(n)L, C(n) = (n^2 + 2n^{3/2} - 2n^{1/2})^{1/2}.$$

For a given  $\alpha > 0$  we define the following set:

$$B(x, \alpha) = \{v \in \mathbb{R}^n : \exists(g \in S_1, e \in G, z_k \in P, \\ z_k \rightarrow +0, \lambda_k \rightarrow +0, k \rightarrow +\infty),$$

$$v = \lim_{k \rightarrow +\infty} \Gamma^i(x, g, e, z_k, \lambda_k, \alpha)\}. \quad (6)$$

**Proposition 5** *Let the function  $f$  be a differentiable with respect to any direction  $g \in \mathbb{R}^n$ . Then for any  $g \in \mathbb{R}^n$  there exists  $v \in B(x, \alpha)$ ,  $\alpha > 0$  such that*

$$f'(x, g) = \langle v, g \rangle.$$

**Proposition 6** *Let the function  $f$  be a locally Lipschitz continuous, differentiable with respect to any direction  $g \in \mathbb{R}^n$  and  $x \in D(f)$ . Then  $\nabla f(x) \in B(x, \alpha)$ ,  $\alpha > 0$ .*

**Proposition 7** *Assume that  $f$  is a semismooth, quasidifferentiable function and its subdifferential and superdifferential are polytopes at a point  $x$ . Then there exists  $\alpha_0 > 0$  such that*

$$\text{co}B(x, \alpha) \subset \partial f(x)$$

for all  $\alpha \in (0, \alpha_0]$ .

*Remark 4* Proposition 7 implies that discrete gradients can be applied to approximate subdifferentials of a broad class of semismooth, quasidifferentiable functions.

*Remark 5* The discrete gradient contains three parameters:  $\lambda > 0$ ,  $z \in P$  and  $\alpha > 0$ .  $z \in P$  is used to exploit semismoothness of the function  $f$  and it can be chosen sufficiently small. In general  $\alpha$  depends on  $x$ . However if  $f$  is a semismooth quasidifferentiable function and its subdifferential and superdifferential are polytopes at any  $x \in \mathbb{R}^n$  then there exist  $\delta > 0$  and  $\alpha_0 > 0$  such that  $\alpha(x) \in (0, \alpha_0]$  for all  $y \in B_\delta(x)$ . The most important parameter is  $\lambda > 0$ . In the sequel we assume that  $z \in P$  and  $\alpha > 0$  are sufficiently small.

Consider the following set at a point  $x \in \mathbb{R}^n$ :

$$D_0(x, \lambda, z) = \text{cl co}\left\{v \in \mathbb{R}^n : \exists(g \in S_1, e \in G) : v \\ = \Gamma^i(x, g, e, \lambda, z, \alpha)\right\}.$$

Proposition 4 implies that the set  $D_0(x, \lambda, z)$  is compact and convex for any  $x \in \mathbb{R}^n$ .

**Corollary 4** *Let  $f$  be a quasidifferentiable semismooth function. Assume that its subdifferential and superdifferential are polytopes and that in the equality*

$$f(x + \lambda g) - f(x) = \lambda f'(x, g) + o(\lambda, g), \quad g \in S_1$$

*$\lambda^{-1} o(\lambda, g) \rightarrow 0$  as  $\lambda \rightarrow +0$  uniformly with respect to  $g \in S_1$ . Then for any  $\delta > 0$  there exist  $\lambda_0 > 0$  and  $z_0 \in P$  such that*

$$D_0(x, \lambda, z) \subset \partial f(x) + B_\delta$$

for all  $\lambda \in (0, \lambda_0)$  and  $z \in (0, z_0)$ .

Consider the continuous approximation  $C(x, \varepsilon)$  to the subdifferential  $\partial f(x)$ . Then Corollary 4 implies that for any  $\delta > 0$  there exist  $\varepsilon_0 > 0$ ,  $\lambda_0 > 0$  and  $z_0 \in P$  such that

$$D_0(x, \lambda, z) \subset C(x, \varepsilon) + B_\delta$$

for all  $\varepsilon \in (0, \varepsilon_0)$ ,  $\lambda \in (0, \lambda_0)$  and  $z \in (0, z_0)$ . Thus, discrete gradients can be used to compute subsets of continuous approximations to the subdifferential in the sense of Definition 2. Consequently they can also be used to compute subsets of uniform and strongly uniform continuous approximations.

### Continuous Approximations to the Quasidifferential

In this subsection we will consider continuous approximations to the Demyanov–Rubinov quasidifferential. We consider a function of the form

$$f(x) = F(x, y_1(x), \dots, y_m(x)), \quad (7)$$

where  $x \in \mathbb{R}^n$ , the function  $F$  is continuously differentiable in  $\mathbb{R}^{n+m}$ ,  $y_i(x)$ ,  $i \in I = \{1, \dots, m\}$ , are semismooth, regular functions and their subdifferentials are polytopes. It is easy to see that the function  $f$  is differentiable with respect to any direction and

$$f'(x, g) = \left\langle \frac{\partial F(x, y(x))}{\partial x}, g \right\rangle \\ + \sum_{i \in I} \frac{\partial F(x, y(x))}{\partial y_i} y'_i(x, g),$$

where  $y(x) = (y_1(x), \dots, y_m(x))$ ,  $\partial F(x, y(x))/\partial x$  is the gradient of the function  $F$  with respect to  $x$ , and  $\partial F(x, y(x))/\partial y_i$  is the partial derivative of the function  $F$  with respect to  $y_i$ ,  $i \in I$ .

Let

$$I_1(x) = \left\{ i \in I: \frac{\partial F(x, y(x))}{\partial y_i} > 0 \right\},$$

$$I_2(x) = \left\{ i \in I: \frac{\partial F(x, y(x))}{\partial y_i} < 0 \right\}.$$

Consider the mappings  $B_i(x, \alpha)$  corresponding to the functions  $y_i(x), i \in I$ . We introduce the following two sets:

$$\underline{Z}(x, \alpha) = \text{co} \left\{ v \in \mathbb{R}^n: v = \frac{\partial F(x, y(x))}{\partial x} + \sum_{i \in I_1(x)} \frac{\partial F(x, y(x))}{\partial y_i} v^i, v^i \in B_i(x, \alpha), i \in I_1(x) \right\},$$

$$\overline{Z}(x, \alpha) = \text{co} \left\{ w \in \mathbb{R}^n: w = \sum_{i \in I_2(x)} \frac{\partial F(x, y(x))}{\partial y_i} w^i, w^i \in B_i(x, \alpha), i \in I_2(x) \right\}.$$

**Proposition 8** Assume that the function  $F$  is continuously differentiable in  $\mathbb{R}^{n+m}$ , functions  $y_i(x), i \in I$ , are semismooth and regular and their subdifferentials are polytopes. Then the function  $f$  is quasidifferentiable and there exists  $\alpha_0 > 0$  such that

$$\underline{Z}(x, \alpha) \subset \underline{\partial}f(x)$$

and

$$\overline{Z}(x, \alpha) \subset \overline{\partial}f(x)$$

for all  $\alpha \in (0, \alpha_0)$ .

**Corollary 5** Suppose we are given the function  $f(x) = f_1(x) - f_2(x)$ , where  $f_1$  and  $f_2$  are semismooth, regular functions and their subdifferentials are polytopes, and  $B_1(x, \alpha)$  and  $B_2(x, \alpha)$  are mappings corresponding to the functions  $f_1$  and  $f_2$ , respectively. Then the function  $f$  is quasidifferentiable and there exists  $\alpha_0 > 0$  such that

$$B_1(x, \alpha) \subset \partial f_1(x), B_2(x, \alpha) \subset \partial f_2(x)$$

for all  $\alpha \in (0, \alpha_0)$ .

Let  $D_{0i}(x, \lambda, z)$  be mappings corresponding to the functions  $y_i(x), i \in I$ . We set

$$D_1(x, \lambda, z) = \text{co} \left\{ v \in \mathbb{R}^n: v = \frac{\partial F(x, y(x))}{\partial x} + \sum_{i \in I_1(x)} \frac{\partial F(x, y(x))}{\partial y_i} v^i, v^i \in D_{0i}(x, z, \lambda), i \in I_1(x) \right\},$$

$$D_2(x, z, \lambda, \beta) = \text{co} \left\{ w \in \mathbb{R}^n: w = \sum_{i \in I_2(x)} \frac{\partial F(x, y(x))}{\partial y_i} w^i, w^i \in D_{0i}(x, z, \lambda), i \in I_2(x) \right\}.$$

Note that the mappings  $D_1(x, \lambda, z), D_2(x, \lambda, z)$  are Hausdorff continuous with respect to  $x$  for any fixed  $\lambda > 0, z \in P$ .

It follows from Corollary 4 that the sets  $D_1(x, \lambda, z), D_2(x, \lambda, z)$  can be used to compute subsets of continuous approximations to the subdifferential and superdifferential of the function (7).

### Conclusions

In this paper we introduced continuous approximations to the subdifferential and the quasidifferential of the nonsmooth, nonconvex functions. We proposed the algorithm for their computation. This algorithm allows one to approximate subgradients a broad class of nonsmooth functions.

### Nonlinear Systems and Global Optimization

Man-made systems and processes can often be modeled to reasonable accuracy by postulating the exclusive use

of continuous linear functions. For instance, one may think of the simplest production and distribution models known from the OR literature. (Models with integer variables will not be discussed here, even though they can be equivalently reformulated, to fit into the present framework.) If we attempt, however, the analysis of natural — physical, chemical, biological, environmental, or even economic, financial and societal — systems and their governing processes, then nonlinear functions start to play a significant role in the quantitative description. To illustrate this point, one may think of the most prominent (basic) function forms in physics: probably polynomials, power functions, the exponential-logarithmic pair and trigonometric functions come to mind first. Clouds, water flows, rugged terrains, plants and animals — as well as many other natural objects — all possess visible nonlinearities. For sophisticated examples and general principles, one may think of discussions of nonlinear dynamics, chaos, self-organizing systems and the fractal nature of the Universe: consult, e. g., [3,5,14,19,25].

Prescriptive (control, management, optimization) models which attempt to describe and optimize the behavior of inherently nonlinear systems — as a rule — lead to nonlinear decision problems. Since nonlinear decision models frequently possess multiple local optima, the general relevance of global optimization (GO) becomes obvious. In this brief article we present a list of important and challenging GO applications. We also provide several illustrative references: these describe numerous further application areas.

### The Continuous Global Optimization Model

We shall consider problems in the general form

$$\left\{ \begin{array}{l} \min_{x \in D} f(x) \\ \text{s.t. } D := \left\{ x : \begin{array}{l} l \leq x \leq u; \\ g(x) \leq 0, \\ j = 1, \dots, J \end{array} \right\} \end{array} \right. \quad (1)$$

In (1) we use the following notation:

- $x$  is a vector which represents decision alternatives in  $\mathbf{R}^n$ ;
- $f(x)$  is a continuous objective function;

- $D$  is a nonempty set of feasible decisions, defined by
  - $g(x)$ , an  $m$ -vector of continuous constraint functions; and
  - $l, u$ , explicit (finite, componentwise)  $n$ -vector bounds.

Explicit bounds on the constraint function values can also be imposed; however, such more specialized models are directly amenable to the form (1).

First of all, note that if all functions are continuous, then – by the classical theorem of Weierstrass – the optimal solution set to (1) is nonempty. At the same time, without further structural assumptions, (1) can be a very difficult global optimization problem. In other words – unless additional information is provided – there may well exist multiple (local) solutions of various quality to (1). Naturally, in most cases one would like to find the ‘very best’ (global) solution to the underlying decision problem, avoiding the ‘traps’ offered by local optima. To attain this objective, a considerable variety of GO models and solution approaches have been suggested: consult, e. g., [12].

### Test Problems

Although our primary topic is real-world GO applications, one should at least mention several standardized test problem suites, since these often originate from real-world applications. For collections of (both convex and nonconvex) nonlinear programming test problems, consult, e. g., [11,18]. See [6,7,13,22] for collections of GO test problems. On the WWW, see [1,8] and [21]; especially [21] provides numerous further links and pointers, including discussions of test and real-world problems.

### Illustrative Applications

Since GO problems are literally ubiquitous in scientific, engineering and economic decision making, we shall only list a number of illustrative applications. All application areas will be listed simply in alphabetical order, by information source. (The reader will notice overlaps among the problems studied in different works.)

The test problem collection [6] presents application models from the following fields:

- chemical reactor networks;
- distillation column sequencing;
- heat exchanger network synthesis;

- indefinite quadratic programming;
- mechanical design;
- general nonlinear programming;
- phase and chemical reaction equilibrium;
- pooling and blending;
- quadratically constrained problems;
- reactor-separator-recycling systems;
- VLSI design.

The volume [7] significantly expands upon the above material, adding more specific classes of nonlinear programming models, combinatorial optimization problems, and dynamic models, as well as further practical examples (see later on).

The MINPACK-2 collection presented at [1] includes models related to the following types of problems:

- brain activity;
- Chebychev quadrature;
- chemical and phase equilibria;
- coating thickness standardization;
- combustion of propane;
- control systems (analysis and design);
- database optimization;
- design with composites;
- elastic-plastic torsion;
- enzyme reaction analysis;
- exponential data fitting;
- flow in a channel;
- flow in a driven cavity;
- Gaussian data fitting;
- Ginzburg–Landau problem;
- human heart dipole;
- hydrodynamic modeling;
- incompressible elastic rods;
- isomerization of alpha-pinene;
- Lennard–Jones clusters;
- minimal surfaces;
- pressure distribution;
- Ramsey graphs;
- solid fuel ignition;
- steady-state combustion;
- swirling flow between disks;
- thermistor resistance analysis;
- thin film design;
- VLSI design.

A detailed discussion of several GO case studies and applications is presented in [22]. These problems were

analyzed by using LGO, an integrated model development environment to formulate and solve GO problems; consult also [23]. The current list of LGO applications includes, for instance, the following areas:

- bio-mechanical design;
- ‘black box’ (closed, confidential, etc.) system design and operation;
- combination of negotiated expert opinions (forecasts, votes, assessments, etc.);
- data classification, pattern recognition;
- dynamic population and resource management;
- extremal energy (point arrangement) problems, free and surface-constrained forms;
- inverse model fitting to observation data (calibration);
- multifacility location-allocation problems;
- nonlinear approximation, nonlinear regression, and other curve/surface fitting problems;
- optimized tuning of equipment and instruments in medical research and other areas;
- reactor maintenance policy analysis;
- resource allocation (in cutting, loading, scheduling, sequencing, etc. problems);
- risk analysis and control in various environmental management contexts;
- robotics design issues;
- robust product/mixture design;
- satisfiability problems;
- statistical modeling;
- systems of nonlinear equations and inequalities;
- therapy (dosage and schedule) optimization.

The WWW site [21] discusses, inter alia, the following application areas:

- bases for finite elements;
- boundary value problems;
- chemical engineering problems;
- chemical phase equilibria;
- complete pivoting example;
- distance geometry models;
- extreme forms;
- identification of dynamical systems with matrices depending linearly on parameters;
- indefinite quadratic programming models;
- minimax problems;
- nonlinear circuits;
- optimal control problems;
- optimal design;

- parameter identification with data of bounded error;
- PDE defect bounds;
- PDE solution by least squares;
- pole assignment;
- production planning;
- propagation of discrete dynamical systems;
- protein-folding problem;
- pseudospectrum;
- quadrature formulas;
- Runge–Kutta formulas;
- spherical designs (point configurations);
- stability of parameter matrices.

The collection of test problems [7] includes models from the following application areas:

- batch plant design under uncertainty;
- chemical reactor network synthesis;
- conformational problems in clusters of atoms and molecules;
- dynamic optimization problems in parameter estimation;
- homogeneous azeotropic separation system;
- network synthesis;
- optimal control problems;
- parameter estimation and data reconcillation;
- phase and chemical reaction equilibrium;
- pooling/blending operations;
- pump network synthesis;
- robust stability analysis;
- trim loss minimization.

The article [4] reviews several significant applications of rigorous global optimization (based on the interval branch and bound approach). These applications include:

- currency trading;
- finite element analysis (in a high-tech engineering design context);
- gene prediction in genome therapeutics;
- magnetic resonance imaging (in a medical application);
- numerical mathematics (search for an approximate greatest common divisor of given polynomials);
- parameter estimation in signal processing;
- portfolio management;

One can immediately add here the application of interval techniques to an issue of paramount significance in numerical modeling:

- solving systems of nonlinear (and linear) equations; consult, e. g., [20]

The volume [24] also covers a broad range of applications from the following areas:

- agro-ecosystem management;
- analysis of nucleid acid sequences;
- assembly line design;
- cellular mobile network design;
- chemical process optimization;
- chemical product design;
- computational modeling of atomic and molecular structures;
- controller design for motors;
- electrical engineering design;
- feeding strategies in animal husbandry;
- financial modeling;
- laser equipment design;
- mechanical engineering design;
- radiotherapy equipment calibration;
- robotics design;
- satellite data analysis (interferometry problem);
- virus structure reconstruction;
- water resource distribution systems.

As the above lists illustrate, the application potentials of global optimization are indeed most diverse.

For additional literature on real-world applications, see, e. g., the following references:

### The Continuous Global Optimization Model

We shall consider the continuous global optimization problem (GOP) in the general form

$$\left\{ \begin{array}{l} \min_{x \in D} f(x) \\ \text{s.t. } D := \left\{ x : \begin{array}{l} l \leq x \leq u; \\ g(x) \leq 0, \\ j = 1, \dots, J \end{array} \right\} \end{array} \right\}. \quad (1)$$

In (1) the following assumptions are used:

- $x$  is a vector representing decision alternatives in  $\mathbf{R}^n$ ;
- $D$  is a nonempty set of feasible decisions, defined by
  - $l, u$ : explicit (finite, componentwise)  $n$ -vector bounds of  $x$ , and
  - $g(x)$  is an  $m$ -vector of continuous constraint functions defined on  $[l, u]$ ;

**Continuous Global Optimization: Models, Algorithms and Software, Figure 1**

**A two-variable multi-extremal function**

- $f(x)$  is a continuous objective function defined on  $D$ .

Explicit bounds on the constraint function values can also be imposed; however, such more specialized models are also directly amenable to the form (1).

Since the functions  $f$  and  $g$  are all continuous in  $D$ , the GOP (1) evidently has a nonempty globally optimal solution set  $X^*$ . At the same time, one can immediately realize that — in its full generality — instances of model (1) can pose a very significant numerical challenge. Since the usual convexity assumptions are absent,  $D$  may be disconnected and/or nonconvex, and the objective function  $f$  may also be multi-extremal. That is, the number of local (pseudo) solutions to (1) is typically unknown and it can be large; the quality of the various local and global solutions may differ significantly. To illustrate this point, see Fig. 1, which depicts a ‘hilly landscape’ (in fact, the surface plot of a relatively simple composition of trigonometric functions with embedded polynomial arguments, in just two variables). For instance, this function could be the objective in (1) defined on the corresponding interval feasible region  $[l, u]$ .

To solve the GOP (1) — in a strict mathematical sense — means to find the complete set of globally optimal solutions  $X^*$ , and the associated global optimum value  $f^* = f(x^*)$ ,  $x^* \in X^*$ . In most cases, at least in the realm of continuous GO, we need to replace this ‘ambitious’ objective by finding a verified estimate — upper and lower bounds — of  $f^*$ , and corresponding approximation(s) of points from the set  $X^*$ . Naturally,

such estimates are to be determined on the basis of a finite number of algorithmically generated sample points from  $D$ , or from the embedding interval  $[l, u]$ .

For reasons of better analytical and numerical tractability, usually the following additional assumptions are made:

- $D$  is a full-dimensional subset (a ‘body’) in  $\mathbf{R}^n$ ;
- $X^*$  is at most countable;
- $g$  (i. e., each of its component functions) and  $f$  are Lipschitz-continuous on  $[l, u]$ .

Observe that the first assumption makes algorithmic search possible within the set  $D$ . With respect to the second assumption, note that — in most practical contexts — the set of global optimizers consists only of a single point, or of several points. Finally, the Lipschitz assumption — i. e., that changes in function values are uniformly controlled by changes in their argument — is a sufficient condition for estimating  $f^*$  on the basis of a finite set of search points. We emphasize that the factual knowledge of the smallest suitable Lipschitz constant is not required — and in practice it is typically unknown indeed. The Lipschitz criterion is evidently met, e. g., by all continuously differentiable functions defined on  $[l, u]$ ; however, their class is even broader.

Due to the very general model structure postulated above, classical (convexity-based) numerical approaches are, generally speaking, not directly applicable to solve GOPs: instead, truly global scope methodology is needed. In the past decades, a considerable variety of GO models and solution approaches have been proposed and analyzed. Below we shall provide a concise review, with a view towards software development. For detailed discussions, consult, e. g., the illustrative list of references.

### Model Types

The most important GO model classes that have been extensively studied include the following. (Note that postulated properties of  $g$  — such as e. g., convexity — are required componentwise.)

- Bilinear and biconvex programming ( $f$  is bilinear or biconvex,  $D$  is convex).
- Combinatorial optimization (problems that have discrete decision variables in  $f$  and/or in  $g$  can be equivalently reformulated as GO problems in continuous variables).

- Concave minimization ( $f$  is concave,  $D$  is convex).
- Continuous global optimization ( $f$  and  $g$  are arbitrary continuous functions).
- Differential convex (DC) optimization ( $f$  and the components in  $g$  can all be explicitly represented, as the difference of two corresponding convex functions).
- Fractional programming ( $f$  is the ratio of two real functions, and  $g$  is convex).
- Linear and nonlinear complementarity problems ( $f$  is the scalar product of two vector functions,  $D$  is typically assumed to be convex).
- Lipschitz optimization ( $f$  and  $g$  are arbitrary Lipschitz-continuous functions).
- Minimax problems ( $f$  is some minimax objective, the maximum is considered over a discrete set or a convex set,  $D$  is convex).
- Multilevel optimization (e. g., models of noncooperative games, involving hierarchies of decision makers, the conflicting criteria are aggregated by  $f$ ;  $D$  is usually assumed to be convex).
- Multi-objective programming (e. g., determination of the efficient set, when several conflicting objectives are to be optimized over the region  $D$ ).
- Multiplicative programming ( $f$  is the product of several convex functions, and  $g$  is convex, or – more generally – also multiplicative).
- Network problems ( $f$  can be taken from several nonconvex function classes, and  $g$  is typically linear or convex).
- Parametric nonconvex programming (in these the feasible region  $D$  and/or the objective  $f$  may also depend also on a parameter vector).
- Quadratic optimization ( $f$  is an arbitrary – indefinite – quadratic function;  $g$  is linear or, in the more general case, is also made up by arbitrary quadratic functions).
- Reverse convex programming (at least one of the functions in  $g$  expresses a reverse convex constraint).
- Separable global optimization ( $f$  is an arbitrary nonlinear – in general, nonconvex – separable function,  $D$  is typically convex).
- Stochastic (nonconvex) models in which the functions  $f, g$  depend on random factors.
- Various other nonlinear programming problems, in absence of a verified convex structure: this broad

category includes, e. g., models in which some of the functions  $f, g$  are defined by complex ‘black box’ computational procedures.

Note that the problem classes listed are not necessarily distinct; in fact, several of them are hierarchically contained in the more general problem types listed. For detailed descriptions of most of these model types and their connections consult, e. g., [13], with numerous further references.

Observe also that in the list presented, there are specifically structured models (such as e. g., a concave minimization problem under linear or convex constraints), as well as far more general ones (such as e. g., differential convex, Lipschitz or continuous problems). Hence, one can reasonably expect that the most suitably tailored solution approaches will also vary to a considerable extent. Very general search strategies should work for most models – albeit their efficiency might be low for specialized problems. At the same time, strictly specialized solvers may not work at all for problem classes outside of their scope.

Several of the most important GO strategies are listed below, together with additional remarks and references. Again, the items of the list are not necessarily exclusive. Most GO software implementations are based upon one of these approaches, possibly combining ideas from several strategies.

## Exact Methods

### Naive Approaches

These include the most well known passive (simultaneous) or direct (not fully adaptive) sequential GO strategies: uniform grid, space covering, and pure random searches. Note that such methods are obviously convergent under mild assumptions, but are – as a rule – impracticable in higher-dimensional problems. Consult corresponding chapters in [13,24,30].

### Complete (Enumerative) Search Strategies

These are based upon an exhaustive (and typically streamlined) enumeration of all possible solutions. Applicable to combinatorial problems, as well as to certain ‘well-structured’ continuous GO problems such as, e. g., concave programming. See, e. g., [14].

### Homotopy (Parameter Continuation), Trajectory Methods, and Related Approaches

These methods have the ‘ambitious’ objective of visiting all stationary points of the objective function: this, in turn, leads to the list of all – global as well as local – optima. This general approach includes differential equation model based, path following search strategies, as well as fixed-point methods and pivoting algorithms. See, for instance, [5] and [8].

### Successive Approximation (Relaxation) Methods

The initial optimization problem is replaced by a sequence of relaxed subproblems that are easier to solve. Successive refinement of subproblems to approximate the initial problem; cutting planes and more general cuts, diverse minorant function constructions, nested optimization and decomposition strategies are also possible. Applicable to structured GO problems such as, e.g., concave minimization and DC problems [14].

### Branch and Bound Algorithms

A variety of partition strategies have been proposed to solve GOPs. These are based upon adaptive partition, sampling, and subsequent lower and upper bounding procedures: these operations are applied iteratively to the collection of active (remaining ‘candidate’) subsets within the feasible set  $D$ . Their exhaustive search feature is similar in spirit to analogous integer programming methodology. Branch and bound subsumes many specific approaches, and allows for a range of implementations.

Branch and bound methods typically rely on some a priori structural knowledge about the problem. This information may relate, for instance to how rapidly each function can vary (e.g. the knowledge of a suitable ‘overall’ Lipschitz constant, for each function  $f$  and  $g$ ); or to the availability of an analytic formulation – and guaranteed smoothness – of all functions (for instance, in interval arithmetic based methods).

The branch and bound methodology is applicable to broad classes of GO problems: e.g., in combinatorial optimization, concave minimization, reverse convex programs, DC programming, and Lipschitz optimization. For details, consult [12,14,15,20,24,26].

### Bayesian Search (Partition) Algorithms

These methods are based upon some postulated statistical information, to enable a prior stochastic description of the function class modeled. During optimization, the problem instance characteristics are adaptively estimated and updated. Note that, typically only the corresponding one-dimensional model development is exact; furthermore, that in most practical cases ‘myopic’ approximate decisions govern the search procedure.

This general approach is applicable also to (merely) continuous GO problems. Theoretically, convergence to the optimal solution set is guaranteed only by generating an everywhere dense set of search points. One of the obvious challenges of using statistical methods is the choice and verification of an ‘appropriate’ statistical model, for the class of problems to which they are applied. Additionally, it seems to be difficult to implement rigorous and computationally efficient versions of these algorithms for higher-dimensional optimization problems. Note, however, that if one ‘skips’ the underlying Bayesian paradigm, then these methods can also be pragmatically viewed as adaptive partition algorithms, and – as such – they can be directly extended to higher dimensions: see [24]. For detailed expositions on Bayesian approaches, consult, e.g., [18,19,27].

### Adaptive Stochastic Search Algorithms

This is another broad class of methods, based upon random sampling in the feasible set. In its basic form, it includes various random search strategies that are convergent, with probability one. Search strategy adjustments, clustering and deterministic solution refinement options, statistical stopping rules, etc. can also be added as enhancements.

The methodology is applicable to both discrete and continuous GO problems under very mild conditions. Consult, for instance, [2,24,30].

### Heuristic Strategies

#### ‘Globalized’ Extensions of Local Search Methods

These are partially heuristic algorithms, yet often successful in practice. The essential idea is to apply a preliminary grid search or random search based global phase, followed by applying a local (convex program-

ming) method. For instance, random multistart performs a local search from several points selected randomly from the search domain  $D$ . Note that even such sampling is not trivial, when  $D$  has a complicated shape, as being defined, e. g., by (merely) continuous nonlinear functions.

Frequently, sophisticated algorithm enhancements are added to this basic strategy. For instance, the clustering of sample points is aimed at selecting only a single point from each sampled ‘basin’ of  $f$  from which then a local search method is initiated. For more details, consult, for instance, [27].

### Genetic Algorithms, Evolution Strategies

These methods ‘mimic’ biological evolution: namely, the process of natural selection and the ‘survival of the fittest’ principle. An adaptive search procedure based on a ‘population’ of candidate solution points is used. Iterations involve a competitive selection that drops the poorer solutions. The remaining pool of candidates with higher ‘fitness value’ are then ‘recombined’ with other solutions by swapping components with another; they can also be ‘mutated’ by making some smaller-scale change to a candidate. The recombination and mutation moves are applied sequentially; their aim is to generate new solutions that are biased towards subsets of  $D$  in which good – although not necessarily globally optimized – solutions have already been found.

Numerous variants of this general strategy, based on diverse evolution ‘game rules’, can be constructed. The different types of evolutionary search methods include approaches that are aimed at continuous GOPs, and also others that are targeted towards solving combinatorial problems. The latter group is often called genetic algorithms. For details, consult, e. g., [10,17,22,29].

### Simulated Annealing

These techniques are based upon the physical analogy of cooling crystal structures that spontaneously attempt to arrive at some stable (globally or locally minimal potential energy) equilibrium. This general principle is applicable to both discrete and continuous GO problems under mild structural requirements: consult, e. g., [1,22,28].

### Tabu Search

In this general category of metaheuristics, the essential idea during search is to ‘forbid’ moves to points already visited in the (usually discrete) search neighborhood, at least for a number of upcoming steps. This way, one can temporarily accept new inferior solutions, in order to avoid (sub)paths already investigated. This approach can lead to exploring new regions of  $D$ , with the goal of finding a solution by ‘globalized’ search.

Tabu search has traditionally been applied to combinatorial optimization (e. g., scheduling, routing, traveling salesman) problems. The technique can be made – at least, in principle – directly applicable to continuous GOPs by a discrete approximation (encoding) of the problem, but other extensions are also possible. See [9,22,29].

### Approximate Convex Global Underestimation

This heuristically attractive strategy attempts to estimate the (postulated) large scale, ‘overall’ convexity characteristics of the objective function  $f$  based on directed sampling in  $D$ . Applicable to smooth problems. See, e. g., [6].

### Continuation Methods

These first transform the potential function into a more smooth (‘simpler’) function which has fewer local minimizers, and then attempt to trace the minimizers back to the original function. Again, this methodology is applicable to smooth problems. For theoretical background, see, for instance, [8].

### Sequential Improvement of Local Optima

These methods usually operate on adaptively constructed auxiliary functions, to assist the search for gradually better optima. The general heuristic principle is realized by so-called tunneling, deflation, and filled function approaches; consult, for example, [16].

### Global Optimization Software

In spite of significant theoretical advances in GO, software development and ‘standardized’ use lag behind. This can be expected due to the potential numerical difficulty of GOPs; recall Fig. 1. Even ‘much simpler’ problem instances – such as e. g., concave minimization, or

indefinite quadratic programming – belong to the hardest ( $NP$ ) class of mathematical programming problems.

As summarized above, there exist several broad classes of algorithmic GO approaches that possess strong theoretical convergence properties, and – at least in principle – are straightforward to implement. However, all such rigorous approaches involve a computational demand that increases exponentially as a function of problem size, even in case of the simplest GO problem instances. (Consult, for example, [13] for related discussions.) Therefore many practical GO strategies are completed by a ‘traditional’ local optimization phase. Global convergence, however, needs to be guaranteed by the global scope algorithm component: the latter – at least in theory – should be used in a complete, ‘exhaustive’ fashion. The above remarks indicate the basic inherent theoretical (and practical) difficulty of developing robust, yet efficient GO software.

Since the computational demand of rigorous strategies can be expected to be some exponential function of the problem dimensionality, GO problems in  $\mathbf{R}^n$  ( $n$  being just 5, 10, 20, 50, 100, ...) may have rapidly increasing – possibly straight enormous – numerical complexity. This is (and will remain) true, in spite of the fact that computational power seems to grow at an unbelievable pace: the so-called ‘curse of dimensionality’ is here to stay.

In 1996, a survey on continuous GO software was prepared for the newsletter of the Mathematical Programming Society [23]. Additional information has been collected from the Internet, from several GO books, and from the *Journal of Global Optimization*. Drawing on the responses of software developers and the additional information available, over 50 software products were annotated in that review. (In order to assist in obtaining further information, contact person(s), their e-mail addresses, ftp and/or WWW sites have also been listed.)

Most probably, by now the number of solvers aimed at GOPs is around one hundred (or even more). The general impression is, however, that many of these software products are still at an experimental development stage, and of dominantly ‘academic’ character, as opposed to ‘industrial strength’ tools. (Of course, it is not impossible that proprietary software products used by industry and private companies are not announced publicly.)

Below we shall list some key aspects that should be addressed by professional quality GO software development:

- well-specified hardware and software environments (supported development platforms);
- quality user guidance: clearly outlined model development procedure, sensible modeling and troubleshooting tips, user file templates, and (also) non-trivial numerical examples;
- fully functional, ‘friendly’ user interface;
- ‘fool-proof’ solver selection and execution procedures;
- good runtime communication and documentation: clear system output for all foreseeable program execution versions and situations, including proper error messages, and result file(s);
- visualization features which are especially desirable in nonlinear systems modeling, to avoid problem misrepresentation, and to assist in finding alternative models and solution procedures;
- reliable, high-quality user support;
- continuous product maintenance and development (since not only science progresses, but hardware devices, operating systems, as well as development platforms are in permanent change).

This tentative ‘wish-list’ of requirements indicates that although the task is not impossible, it is a challenge. As for an example, we refer to LGO – an integrated model development and solver system – that has been developed with a view towards the desiderata listed above. Details regarding LGO are described, e. g., in [24,25].

## Software Evaluation

In order to obtain information regarding the scope and usability of GO software, it needs to be thoroughly tested. This is a demanding task, when done properly. Consideration needs to be given to the selection of appropriate – nontrivial and practically meaningful – examples. Computational experiments should be carefully designed; and the results should be reported in sufficient details, to assure a fair and accurate assessment. For corresponding discussions and GO (or other) test problems, consult, e. g., [3,4,7,21].

A GO software evaluation framework can be proposed, for instance, along the following guidelines.

### Software Applicability Range (Solvable Model Types)

- objective function: concave, DC, Lipschitz, continuous, or some other (general or more special) function form;
- constraints: unconstrained problems, bound constrained problems, linear constraints, general nonlinear smooth constraints;
- additional information related to solvable model types and sizes, with corresponding expected runtimes (within given hardware and software environments).

### GO Methodology Applied

- summary (or more detailed) description of basic principles;
- adequate list of references;

### Hardware and Software Requirements

- supported hardware platforms;
- minimal hardware configuration needed;
- operating systems;
- programming languages and environments;
- compiler(s) needed;
- connectivity to other development environments;
- portability to other hardware and software platforms.

### Test Results

- test problem description, mathematical and/or coded form;
- real world background information (when applicable);
- best known results, with references;
- accuracy requirements, stopping criteria;
- hardware and software environment used in testing;
- standard timing (to facilitate comparisons among different platforms);
- time and computational demand, in order to find the (estimated) global optimum;
- comparative success rate;
- information regarding the reproducibility of results.

### Additional Software Information

- installation procedure;
- user interface features;

- academic and/or professional licenses; conditions of use;
- user support (manual, on-line help, example files, input and result handling, etc.);
- other points of interest.

Of course – at least from a practical point of view – the most meaningful test is to apply GO methods to problems that are of interest in the real world. For numerous existing and prospective GO applications, please consult the related articles ► [Global Optimization in the Analysis and Management of Environmental Systems](#) and ► [Continuous Global Optimization: Applications](#).

## Introduction

Nonlinear optimization problems involving discrete decision variables, also known as generalized disjunctive programming (GDP) or mixed-integer nonlinear programming (MINLP) problems, arise frequently in applications. Examples from process engineering include the synthesis of heat exchanger or reactor networks, the optimization of separation processes, such as sequencing and tray optimization problems of distillation columns, and the optimization of entire process flowsheets [3]. The discrete decisions in these problems are usually related to the structure of the process whereas typical continuous variables are process states such as temperatures, concentrations or flows.

Connections between continuous and discrete optimization problems have been studied for several decades (see, e.g., [4]). In particular, in [9] it was observed that discrete variables can be modeled by complementarity constraints, that is, the discrete model is replaced by a continuous model. A broad survey on other approaches to model discrete decisions by continuous formulations is given in [10], including concave optimization problems and relaxation by semi-definite programming, with applications to the maximum clique problem, satisfiability, the Steiner tree problem, and minimax problems.

Extensive work has been addressed to discrete-continuous problems with linear objective function and constraints, known as mixed-integer linear programming (MILP) problems. In fact, a number of powerful algorithms have been developed which are ready to solve practically relevant, large-scale problems of this type. As soon as the objective function and the constraints comprise nonlinear terms in the continuous variables, as it is usually the case, for example, for problems in process engineering, the optimization problem is referred to as a mixed-integer nonlinear programming (MINLP) problem. Algorithms for MINLP problems are either based on branch and bound with nonlinear programming (NLP) subproblems or on decomposition methods that alternately solve NLP and MILP subproblems. These algorithms are guaranteed to locate the global optimum if the nonlinearities are *convex*.

Optimization problems involving *nonconvex* objective function and constraints are by far more difficult to solve. In [11] it is proposed to reformulate discrete-

continuous optimization problems by the idea from [9], as purely continuous optimization problems with complementarity constraints. In this approach, the discrete variable set of an MINLP problem is replaced by continuous variables which are restricted to take discrete values by enforcing a special type of either non-differentiable or degenerate continuous constraints.

[15] complements this approach by purely continuous reformulations of MINLP problems with better theoretical properties, as will be explained below. As all continuous reformulation approaches inevitably lead to nonconvex optimization problems, searching for a global solution may be numerically challenging. On the other hand, these continuous reformulations yield efficient ways to locally solve MINLP problems on the basis of NLP solution methods.

## Definitions

Consider a generalized disjunctive representation [12] of nonlinear optimization problems, where an objective function is minimized subject to two different types of constraints, namely global constraints that hold irrespectively of any discrete decision, and constraints contained in disjunctions that are only enforced if a corresponding Boolean variable  $Y_{i,k}$  is True. The optimization problem is then formulated as follows:

$$(GDP) \min_{x,Y} \Phi(x) + \sum_{k \in K} b_k$$

$$\text{s.t. } f(x) = 0, \quad (1)$$

$$g(x) \leq 0, \quad (2)$$

$$\bigvee_{i \in D_k} \begin{bmatrix} Y_{i,k} \\ h_{i,k}(x) = 0, \\ r_{i,k}(x) \leq 0, \\ b_k = \gamma_{i,k}, \end{bmatrix}, k \in K, \quad (3)$$

$$D_k = \{1, 2, \dots, n_k\},$$

$$\Omega(Y) = \text{True}, Y_{i,k} \in \{\text{True}, \text{False}\}. \quad (4)$$

In *GDP*,  $x$  represents a vector of continuous decision variables and  $Y_{i,k}$  are Boolean variables.  $b_k$  is a scalar and  $\gamma_{i,k}$  represents a fixed charge. The objective function comprises the sum of all fixed charges and a nonlinear term  $\Phi(x)$ . Whereas the model equations (1) and inequality constraints (2) hold irrespectively

of discrete choices, there are further equations and inequality constraints (3) that are contained in  $n_k, k \in K$ , disjunctions. Each disjunction  $k$  may consist of several terms  $i \in D_k$ , where the index set  $D_k$  defines the number of terms for each disjunction. Note that exactly one term  $i \in D_k$  holds per disjunction, that is,  $\bigvee_{i \in D_k}$  is understood as an ‘exclusive or’ operator. The disjunctive constraints are only enforced if the Boolean variable value  $Y_{i,k}$  is True. Otherwise, if  $Y_{i,k}$  is False, the corresponding constraints are removed from the optimization problem.

The Boolean variables themselves are related to each other by so called propositional logic constraints (4). These logic constraints are used to model interrelationships between disjunctive constraints. For example, assume that the first disjunctive term from disjunction  $k = 1$  has to be selected ( $Y_{1,1} = \text{True}$ ) if another term from disjunction  $k = 2$  is removed from the constraint set ( $Y_{1,2} = \text{False}$ ). This situation can be expressed by the implication  $\neg Y_{1,2} \Rightarrow Y_{1,1}$ , which can be transformed into a constraint of type (4):

$$Y_{1,2} \vee Y_{1,1} = \text{True}. \quad (5)$$

Any optimization problem in disjunctive form  $GDP$  can be posed as an equivalent MINLP problem [5] by, for example, transforming the disjunctive constraints into big-M or binary multiplication constraints and by replacing the Boolean variables  $Y_{i,k}$  by binary variables  $y_{i,k} \in \{0, 1\}$ .

A problem reformulation based on binary multiplication is:

$$(BM) \quad \min_{x,y} \quad \Phi(x) + \sum_{k \in K} b_k$$

$$\text{s.t.} \quad f(x) = 0,$$

$$g(x) \leq 0,$$

$$y_{i,k} \cdot h_{i,k}(x) = 0, \quad (6)$$

$$y_{i,k} \cdot r_{i,k}(x) \leq 0, \quad (7)$$

$$y_{i,k} \cdot (b_k - \gamma_{i,k}) = 0, \quad (8)$$

$$Ay \leq a, \quad (9)$$

$$\sum_{i \in D_k} y_{i,k} = 1, \quad (10)$$

$$y_{i,k} \in \{0, 1\}, \quad i \in D_k, k \in K, \quad (11)$$

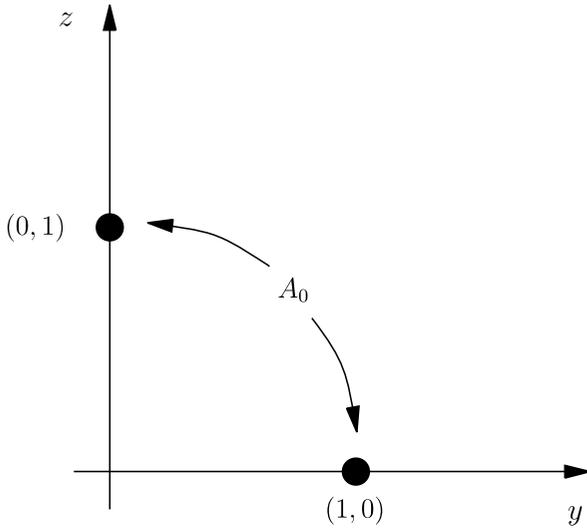

where each disjunctive constraint is multiplied by a variable  $y_{i,k}$ . If  $y_{i,k} = 0$ , the corresponding constraint becomes redundant. On the other hand, a constraint contained in a disjunction is enforced with  $y_{i,k} = 1$ . The propositional logic constraints (4) can be modeled by the linear constraints (9) on the binary variables. Note that with these inequalities not only exclusive but also inclusive ‘or’-relations can be modeled, although a binary variable itself takes only *exclusively* the values 0 or 1. In fact, for two binary variables  $y_1$  and  $y_2$  the inclusive relation  $y_1 + y_2 \geq 1$ , modeling (5), becomes exclusive under the additional relation  $y_1 + y_2 \leq 1$ .

It is important to note that the problem formulation  $BM$  has the drawback of being nonconvex even if the nonlinear, disjunctive constraints of the original optimization problem are convex. Thus, a problem reformulation based on binary multiplication would be employed only if the disjunctive optimization problem was nonconvex itself, as it is the case, for example, in a large portion of process engineering applications. Hence, this drawback should not be regarded as a strong limitation. Also note that the nonconvex expressions in (7) can be convexified if  $r_{i,k}$  is a convex function [16]. However, in the following this assumption will not be made.

## Formulations

Instead of applying an MINLP algorithm for solving the discrete-continuous optimization problem  $BM$  introduced in the previous section directly, one can reformulate the problem such that no discrete variables are present anymore. In particular, the discrete set defined in (10),(11) can be replaced by a set of restrictions involving continuous variables only, which can be used as constraints to form a purely continuous NLP. Since NLP solvers are usually designed to work with continuous variables, that is, variables from at least one-dimensional sets, the basic idea here is to increase the dimension of the constraint sets for  $y_{i,k}$ . Note that the discrete variables  $y_{i,k}$  as defined in (11) are contained in a set of dimension zero.

For the explanation of the main ideas consider a single disjunction with  $n_k = 2$  as it appears in (3). Put  $y_k := y_{1,k}$  as well as  $z_k := y_{2,k}$  and drop the fixed index  $k$ . This leads to a single binary decision variable

**Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 1**  
 Values of the discrete variable  $(y, z)$

$y \in \{0, 1\}$  and its negation  $z$ , where the pair  $(y, z)$  can then attain exactly one of the values  $(1, 0)$  and  $(0, 1)$ , that is,

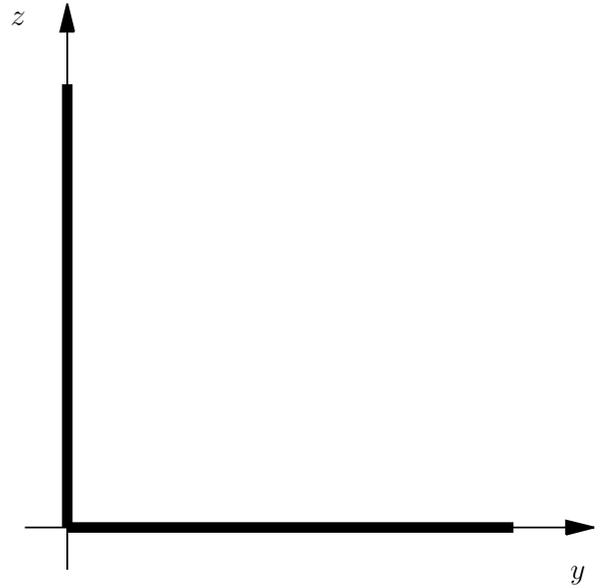

$$(y, z) \in A_0 = \{(1, 0), (0, 1)\}, \tag{12}$$

(cf. Fig. 1). Hence, in this case the conditions (10),(11) are replaced equivalently by (12). In the general case  $n_k \geq 2$  there are several ways to use the set  $A_0$  to reformulate (10),(11) equivalently. A first possibility is to introduce additional variables  $z_{i,k} = 1 - y_{i,k}$  and replace only (11) by the conditions  $(y_{i,k}, z_{i,k}) \in A_0, i \in D_k$ .

Note that the constraint (10) guarantees that exactly one of the variables  $y_{i,k}, i \in D_k$ , is equal to 1, since these variables *can only take* the values 0 and 1. This restriction can be relaxed in conjunction with an alternative approach for modeling binary decision variables explained below. Having these later developments in mind, note that an alternative reformulation of (10), (11) using  $A_0$  is

$$\left( y_{i,k}, \sum_{j \in D_k \setminus \{i\}} y_{j,k} \right) \in A_0, \quad i \in D_k, k \in K. \tag{13}$$

An advantage of the latter reformulation is that it does not increase the problem dimension by auxiliary variables  $z_{i,k}$ .

**Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 2**  
 The points which satisfy the complementarity condition (14),(15)

**Representing the Discrete Decisions by Approximate Continuous Variables**

There are a number of ways to describe  $A_0$  with continuous constraints. A suggestion of [9,11] is to replace (12) with the equivalent set of constraints

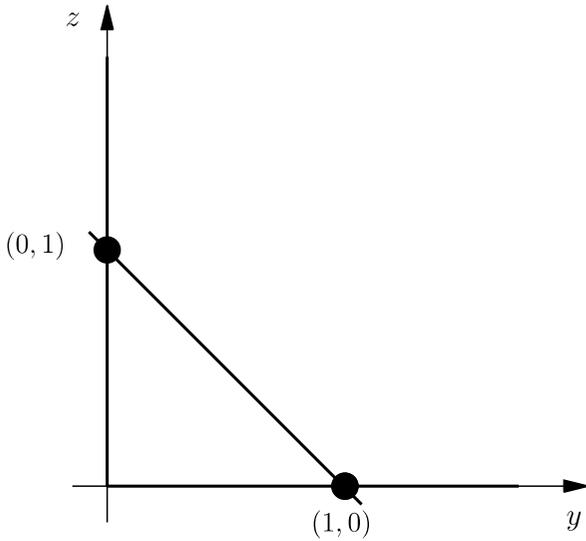

$$y \cdot z = 0, \tag{14}$$

$$y \geq 0, z \geq 0, \tag{15}$$

$$y + z = 1. \tag{16}$$

In fact, the constraints (14),(15) are known as a *complementarity* condition. They model a piecewise linear set with one kink at the origin in  $\mathbb{R}^2$ , as depicted in Fig. 2. Together with the constraint (16) one obtains exactly the set  $A_0$  (cf. Fig. 3).

It is well-known that sets whose description contains complementarity conditions are not easy to treat numerically. In fact, the so-called Mangasarian-Fromovitz constraint qualification is violated everywhere in the feasible set as soon as a complementarity condition appears [14]. This constraint qualification, however, is known to characterize the (numerical) stability of the described set [6,13].

**Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 3**  
**Modeling discrete variables with a complementarity condition**

There are many suggestions on how a complementarity condition can be treated numerically, in particular in the literature on so-called mathematical programs with equilibrium constraints (MPECs) which are optimization problems with complementarity conditions in the constraints [7,8].

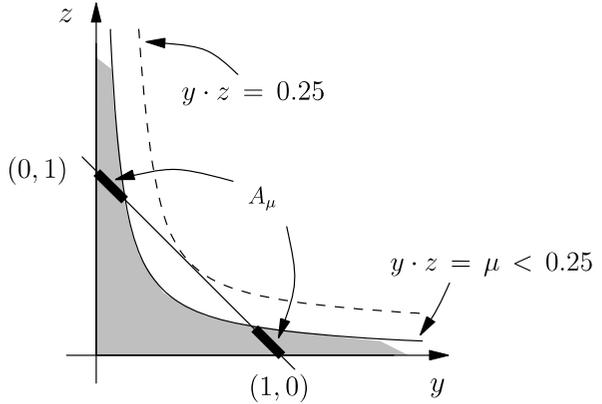

One approach is to use regularization techniques, for example to replace the condition (14) by its relaxation  $y \cdot z \leq \mu$  with some positive parameter  $\mu$ . The idea is to trace the solutions of the corresponding auxiliary problems to a solution of the original problem while driving  $\mu$  to zero.

For the reformulation of binary variables this approach means that the discrete set  $A_0$  is replaced by the one-dimensional set

$$A_\mu = \{(0, 1) + t \cdot (1, -1) \mid t \in [0, 0.5 - \sqrt{0.25 - \mu}]\} \cup [0.5 + \sqrt{0.25 - \mu}, 1],$$

which is disconnected for  $\mu < 0.25$  as illustrated in Fig. 4.

Hence, this approach replaces discrete by continuous variables, at least via an approximation. [15] refers to the variables from the set  $A_\mu$  as *approximate continuous*. In view of (13), a possible approximation of binary

**Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 4**  
**Continuous variables for the relaxed complementarity condition**

variables from a general disjunction is

$$\left( y_{i,k}, \sum_{j \in D_k \setminus \{i\}} y_{j,k} \right) \in A_\mu, \quad i \in D_k, k \in K$$

with  $\mu > 0$ .

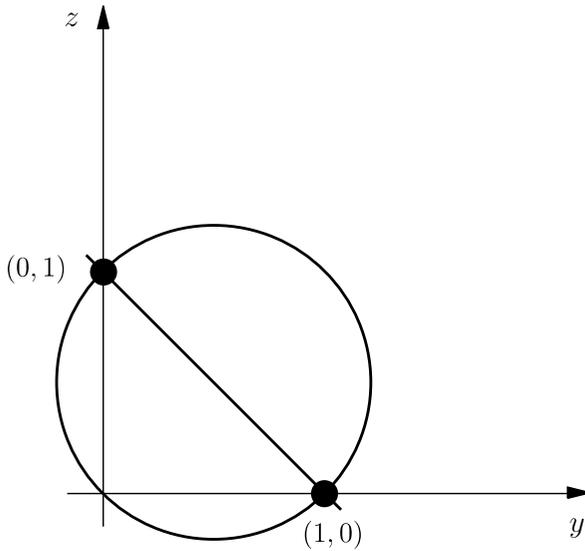

Note that there are two serious drawbacks of the reformulation by a complementarity condition. First, a look at Fig. 3 shows that the kink at the origin is irrelevant for the description of  $A_0$  because of the additional constraint (16). Thus, there is no need to use the numerically demanding complementarity condition together with (16), but any function with a smooth zero set and the correct intersection points would do. For example, one can use the constraint

$$\left( y - \frac{1}{2} \right)^2 + \left( z - \frac{1}{2} \right)^2 = \frac{1}{2},$$

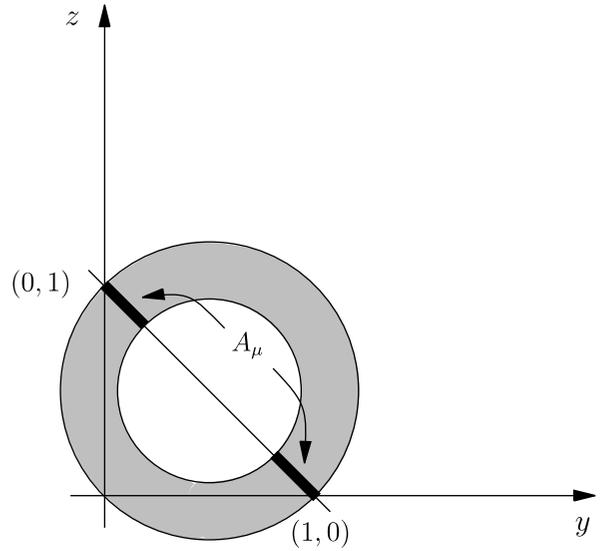

which is illustrated in Fig. 5.

Here, the Mangasarian–Fromovitz constraint qualification and even the stronger linear independence constraint qualification are satisfied everywhere in the set  $A_0$  (for background information on constraint qualifications see [1]). This can be seen as an important advantage when compared to the properties of  $A_0$  represented by the complementarity condition.

A second drawback which the circle condition shares with the reformulation by a complementarity condition is that the variables are still contained in the

Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 5  
The circle condition

Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 6  
The circle relaxation

discrete set  $A_0$ . In order to obtain a one-dimensional set one can again relax the conditions that describe  $A_0$  to obtain a set  $A_\nu$  corresponding to  $A_\mu$  from the MPEC relaxation above. In fact, the constraints

$$\begin{aligned} \left(y - \frac{1}{2}\right)^2 + \left(z - \frac{1}{2}\right)^2 &\leq \frac{1}{2} \\ \left(y - \frac{1}{2}\right)^2 + \left(z - \frac{1}{2}\right)^2 &\geq \left(\frac{1}{\sqrt{2}} - \nu\right)^2 \\ y + z &= 1, \end{aligned}$$

with  $\nu > 0$  describe sets  $A_\nu$  (cf. Fig. 6), which correspond to the sets  $A_\mu$  ( $\mu > 0$ ) via a reparametrization, that is, one arrives at the same set of approximate continuous variables.

Unfortunately, for the limiting case  $\nu = 0$  the circle is not described by one equality constraint but by two inequalities with gradients pointing in opposite directions, so that the Mangasarian–Fromovitz constraint qualification is then again violated in  $A_0$ .

### Representing the Discrete Decisions by Exact Continuous Variables

Although both the reformulation by a complementarity condition and the reformulation by a circle condition lead to well performing numerical methods for small

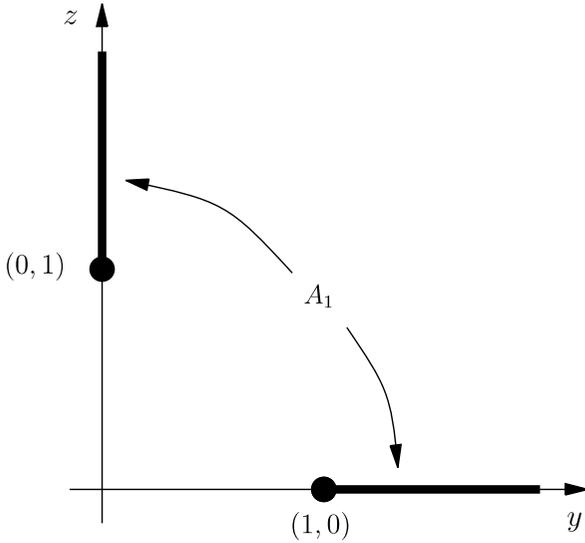

examples [11,15] they share two intrinsic drawbacks:

- the replacement for  $A_0$  is one-dimensional, but only approximate,
- in the (limiting) case of an exact description for  $A_0$ , the Mangasarian–Fromovitz constraint qualification is violated,
- the one-dimensional set becomes discrete if equality constraints are inconsistent (see below).

Since these properties may affect the numerical solution of large problems, [15] proposes a different continuous reformulation of the integrality constraints with better theoretical features.

The subsequent considerations are based on an alternative model reformulation that allows to replace the discrete decision variables defined in (10) by variables  $y_{i,k}$ , which are *not* defined on a discrete set as, for example,  $A_0$ . In fact, this model reformulation has the property of being equivalent to the corresponding disjunctive optimization problem in conjunction with one-dimensional rather than discrete variables  $y_{i,k}$ . Before describing the model reformulation in detail, we focus on the variables  $y_{i,k}$  and show how a continuous, one-dimensional set  $A_1$  can be defined using appropriate constraints.

In fact, since in *BM* any disjunctive constraint is not only enforced by  $y_{i,k} = 1$ , but alternatively also by

**Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 7**  
**A one-dimensional feasible set for  $(y, z)$ .**

$y_{i,k} \geq 1$ , one may define  $y_{i,k}$  as continuous variables of dimension one according to:

$$y_{i,k} \in \{0\} \cup [1, \infty).$$

Of course, now the negation of  $y_{i,k}$  in general does not coincide with  $1 - y_{i,k}$ , as the value of  $y_{i,k}$  might exceed 1. On the other hand, for the case  $n_k = 2$  as above we obtain

$$(y, z) \in A_1 = ([1, \infty) \times \{0\}) \cup (\{0\} \times [1, \infty)) \quad (17)$$

(cf. Fig. 7). Hence, the negation of  $y_{i,k}$  is coded by the variable  $z_{i,k}$ . Moreover, one can now describe the binary decisions via

$$\left( y_{i,k}, \sum_{j \in D_k \setminus \{i\}} y_{j,k} \right) \in A_1, \quad i \in D_k, k \in K. \quad (18)$$

The set  $A_1$  is obviously one-dimensional and is an *exact* rather than approximate model of a discrete decision. Therefore, the variables defined by the set  $A_1$  are referred to as *exact continuous*.

To be able to apply an NLP solution algorithm, one has to describe  $A_1$  by continuous constraints. One possibility, of course, is to use the (degenerate) complementarity condition (14),(15) with the additional constraint  $y + z \geq 1$ . However, it is also possible to choose

a function with an appropriate zero set, such that the linear independence constraint qualification holds everywhere in the feasible set. A function with these properties is the so-called *Fischer–Burmeister* function  $\varphi_{FB}(y, z) = y + z - \sqrt{y^2 + z^2}$ . This means that one can write

$$A_1 = \{ (y, z) \in \mathbb{R}^2 \mid \varphi_{FB}(y, z) = 0, y + z \geq 1 \}. \quad (19)$$

Equivalently, one could use a multitude of other so-called NCP-functions (for a survey see [2]). NCP-functions are used for the description of nonlinear complementarity problems. They are designed such that their zero set coincides with the set defined by (14),(15) (cf. Fig. 2). A description like (19) reveals better numerical properties than the original description via (14),(15). For example, whereas the Mangasarian–Fromovitz constraint qualification is violated everywhere in the set under a description via (14),(15), the description as the zero set of the Fischer–Burmeister function even leads to the validity of the linear independence constraint qualification everywhere in the set, except for the origin (which does not play a role here). In terms of the Fischer–Burmeister function, and using (19), the condition (18) is equivalent to

$$\varphi_{FB} \left( y_{i,k}, \sum_{j \in D_k \setminus \{i\}} y_{j,k} \right) = 0, \quad i \in D_k, k \in K, \\ \sum_{i \in D_k} y_{i,k} \geq 1, \quad k \in K.$$

**Modeling Propositional Logic Constraints with Exact Continuous Variables**

The question remains how logical conditions on two logical variables  $Y_1$  and  $Y_2$  should be modeled when  $(y_1, z_1)$  and  $(y_2, z_2)$  are not discrete but continuous as proposed in (17). This can easily be done by adding inequality constraints. In fact,  $Y_1 \wedge Y_2$  is true if and only if  $y_1 \geq 1$  and  $y_2 \geq 1$ . Moreover,  $Y_1 \vee Y_2$  is true if and only if  $y_1 + y_2 \geq 1$ . For the negation of  $Y_1$  one may *not* use  $1 - y_1$ , as  $y_1$  might take a value strictly larger than one. On the other hand, for  $n_k = 2$  the negation of  $Y_1$  is already coded in the variable  $z_1$ . Moreover, for  $n_k > 2$  the negation of  $y_{i,k}$  is coded in  $\sum_{j \in D_k \setminus \{i\}} y_{j,k}$ , and one can proceed as above. Just like in the discrete case, inclusive as well as exclusive ‘or’-relations can be modeled with exact continuous variables.

To circumvent the introduction of nonconvexity into the model by binary multiplication in *BM*, [15] presents an alternative, convex reformulation approach on the basis of tailored big-*M* constraints which can also be used in conjunction with exact continuous variables as defined in equation (17). A distinctive property of the binary multiplication-based model formulation *BM*, however, is the treatment of inconsistent equality constraints.

### The Case of Inconsistent Equalities

In many applications, the constraints (6)–(8) in *BM* lead to implicit restrictions on the exact continuous variables. In particular, (6) and (8) have to hold simultaneously for  $i \in D_k, k \in K$ . In process engineering applications, the underlying equations (i. e.  $h_{i,k}(x) = 0, i \in D_k$  as well as  $b_k - \gamma_{i,k} = 0, i \in D_k$ ) are often inconsistent for fixed  $k \in K$ , that is, they do not admit a common solution or, put geometrically, the sets described by these equations are disjoint. Note that this is an inherent property of a GDP problem with so-called disjoint disjunctions which have non-empty intersecting feasible regions [17].

This is particularly the case, if for fixed  $k \in K$  the values  $\gamma_{i,k}$  are pairwise distinct for  $i \in D_k$ . It implies that *at most* one of the variables  $y_{i,k}, i \in D_k$ , is non-vanishing. In the case  $n_k = 2$  with  $y = y_1$  and  $z = y_2$  this means that the equation  $y \cdot z = 0$  holds automatically. As a consequence, the only constraint needed for the description of  $A_1$  (cf. Fig. 7) is  $y + z \geq 1$ , that is, the set

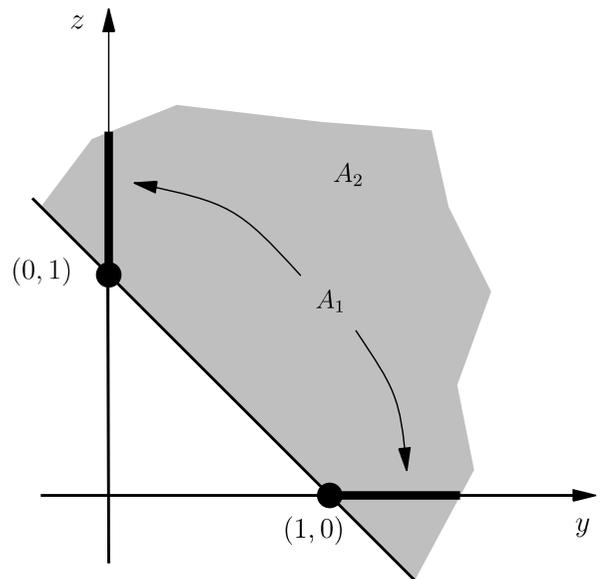

$$A_2 = \{ (y, z) \in \mathbb{R}^2 \mid y + z \geq 1 \}$$

coincides with  $A_1$  in the case of inconsistent equalities (cf. Fig. 8).

Although the pair  $(y, z)$  does not vary in the complete two-dimensional set  $A_2$  from Fig. 8, in the restrictions one does not code the same information twice. This can be expected to lead to better numerical performance when NLP solvers are applied.

### Conclusions

In [15] several example problems involving discrete and continuous decision variables from process engi-

Continuous Reformulations of Discrete-Continuous Optimization Problems, Figure 8

A two-dimensional feasible set for  $(y, z)$

neering are treated numerically, with approximate as well as exact continuous variables representing the discrete decisions. It is shown that, using these reformulations, an efficient numerical treatment of disjunctive optimization problems is possible, but one can only expect to find local solutions when using standard NLP solvers. This is due to the fact that any continuous reformulation of a disjunctive optimization problem leads to a nonconvex optimization problem. Consequently, the reformulation approaches may be combined with global optimization algorithms whenever the problem size admits to do so.

Continuous review inventory models; (Q, R) models

### Introduction

Inventory control is an important issue in supply chain management. Today, many different approaches are used to solve the complicated inventory control problems. While some of the approaches use a periodic review cycle, others use methods based on continuous review of inventory. In this survey, stochastic inventory theory that is based on continuous review is analyzed.

One of the challenging tasks in continuous review inventory problems is finding the order quantity (Q) and the reorder point (R) such that the total cost is minimized and fill rate constraints are satisfied. The total cost includes ordering cost, backorder cost, and inventory holding cost. The fill rate is defined as the fraction of demand satisfied from inventory on hand. Under the continuous inventory control methodology, when the inventory position (on-hand inventory plus outstanding orders minus backorders) drops down to or below a reorder point, R, an order of size Q is placed.

Although they are all the same, there are many different representations of this inventory model such as

$(Q, r)$  (Boyaci and Gallego [5]),  $(Q, R)$  (Hing et al. [14]),  $(R, Q)$  (Axsater [2,3] and Marklund [16]). In addition, for some of the problems it is assumed that the order quantity ( $nQ$ ) is a multiple of minimum batch size,  $Q$ . Here,  $n$  is the minimum integer required to increase the inventory position to above  $R$  (Chen and Zheng[8]). In this case, the problem is formulated as a  $(R, nQ)$  type model.

## Models

When the literature of  $(Q, R)$  models is investigated, some similarities and differences among the publications can easily be identified. Thus, the publications can be classified according to those similarities and differences. Two of the most distinctive attributes of  $(Q, R)$  models are as follows:

1. Type of supply chain: While some articles only consider one entity that uses a  $(Q, R)$  policy [1,5,14], others consider a multi echelon inventory system [2,3,8,16].
2. Exact evaluation or near-optimal evaluation: The  $(Q, R)$  inventory problems are not easy to solve; thus, many of the research papers give approximate solution approaches or try to find bounds on the solutions [1,2,4,5,20], only a small number of articles give the exact evaluation of the  $(Q, R)$  inventory system [3,9,21].

In the next section, the literature based on type of supply chain considered and the evaluation methods used is reviewed. First, heuristic methods are analyzed. Second, publications providing optimal methods are reviewed. In the last section, we give some concluding remarks.

## Single-Echelon Models

Hing et al. [14] focus on average inventory level approximation in a  $(Q, R)$  system with backorders. They compare different approaches proposed in the literature. Their numerical analysis shows that the approximation developed by Hadley and Whitin [13],  $1/2Q + \text{safety stock}$ , is more robust than other approximations that have been proposed so far. Then, the authors propose a new methodology based on spreadsheet optimization. Using numerical examples they show that spreadsheet optimization based approach is better than those methods proposed in the literature.

Agrawal and Seshadri [1] provide upper and lower bounds for optimal  $R$  and  $Q$  subject to fill rate constraints. Although the authors consider backorder cost, the algorithm that was developed to find bounds can be used when backorder costs are zero. Another important application of the algorithm is that it can be applied when there are no service level constraints.

Like Agrawal and Seshadri [1], Platt et al. [19] also consider fill rate constraints and propose two heuristics that can be used for  $(Q, R)$  policy models. While the first heuristic is suitable for deterministic lead time demand models, the second one assumes that demand during the lead time follows a normal distribution. Both heuristics are used to find  $R$  and  $Q$  values. The authors compare the proposed heuristics with others that have been proposed in the literature. Their analysis shows that their heuristics do not necessarily outperform the other heuristics in each problem instance.

Boyaci and Gallego [5] propose a new  $(Q, R)$  model that minimizes average holding and ordering costs subject to upper bounds on the expected and maximum waiting times for the backordered items. They provide optimality conditions and an exact algorithm for the problem. Boyaci and Gallego [5] conclude their study by performing a numerical analysis.

Gallego [12] proposes heuristics to find distribution-free bounds on the optimal cost and optimal batch size when a  $(Q, R)$  policy is used. He also shows that the heuristics work well when the demand distribution is Poisson or compound Poisson.

Bookbinder and Cakanyildirim [4] consider a  $(Q, R)$  policy where lead time is not constant. They treat lead time as a random variable and develop two probabilistic models. While in the first model the lead time is fixed, in the second model the lead time can be reduced by using an expediting factor ( $\tau$ ). The order quantity, reorder point, and expediting factor are the three decision variables in the second model. The authors show that for both models the expected cost per unit time is jointly convex. They also make a sensitivity analysis with respect to cost parameters.

Ryu and Lee [20] consider the lead time as a decision variable. However, in this study the demand is constant. In their model, Ryu and Lee [20] assume that there are two suppliers for the items to be procured. They mainly consider two cases. In the first case, lead time cannot be decreased but in the second case, or-

ders can be expedited. The authors also assume that lead-time distributions are non-identical exponential. For the first case, their objective is to determine a  $Q$ , an  $R$ , and an order-splitting proportion. In the second case, they find new values for the lead times using the order-splitting proportion. Their sensitivity analysis shows that the order-splitting proportion tends to be a half, and it is biased by the coefficient of the expediting function.

Cakanyildirim et al. [6] develop a model that considers lead-time variability. The authors assume that lead time is effected by both the lot size and the reserved capacity. The authors come up with a closed-form solution for the situation where lead time is proportional to the lot size. Cakanyildirim et al. [6] also present the effect of linear and concave lead times on the value of cost function. In the model, in addition to the order quantity and the reorder point, the reserved capacity is also a decision variable. Finally, the authors consider a case in which fixed proportion of capacity is allocated at the manufacturing facility.

Most of the articles in the literature consider lead time as a constant and focus on demand during the lead time. However, Wu and Ouyang [21] assume that lead time is a decision variable and that lead-time demand follows a normal distribution. They also assume that an arrival order may contain some defective parts and that those parts will be kept in inventory until next delivery. Moreover, they include an inspection cost for defective parts to the model. Their model is defined as  $(Q, R, L)$  inventory model where order quantity ( $Q$ ), reorder point ( $R$ ), and lead time ( $L$ ) are decision variables. The objective is to minimize the total cost which includes ordering costs, inventory holding costs (defective and non-defective), lost sales costs, backorder costs, and inspection costs. The authors present an algorithm to find the optimal solutions for the given problem.

Duran et al. [9] present a  $(Q, R)$  policy where orders can be expedited. At the time of order release, if inventory position is less than or equal to a critical value  $r_e$ , the order is expedited at an additional cost. If the inventory level is higher than  $r_e$  and lower than or equal to the reorder point  $R$ , then order is not expedited. The aim is to find the order quantity ( $Q$ ), the reorder point ( $R$ ), and the expediting point  $r_e$  which minimize average cost (note that this does not include backorder

costs). The authors present an optimal algorithm to obtain the  $Q$ ,  $R$ , and  $r_e$  values if they are restricted to be integers.

The model proposed by Kao and Hsu [15] is different from other models reviewed in this paper because the authors discuss the order quantity and reorder point with fuzzy demand. Kao and Hsu [15] use this fuzzy demand to construct the fuzzy total inventory cost. The authors derive five pairs of simultaneous nonlinear equations to find the optimal order quantity  $Q$  and the reorder point  $R$ . The authors show that when the demand is a trapezoid fuzzy number, the equations can be reduced to a set of closed-form equations. Then, they prove that the solution to these equations give an optimal solution. Kao and Hsu [15] also present a numerical example to show that the solution methodology developed in the paper is easy to apply in practice.

### Multi-Echelon Models

Moinzadeh and Lee [18] present a model to determine the batch size in a multi-echelon system with one central depot and  $M$  sites. In their problem, when the number of failed items is equal to the order quantity  $Q$  at any site, then those items are sent to the depot. If the depot has sufficient inventory on hand, it delivers the items immediately; otherwise, the items are backlogged. Although all sites use a  $(Q, R)$  policy, the depot uses a  $(S-I, S)$  policy. In other words, whenever the depot receives an order of size  $Q$ , it places an order simultaneously to replenish its stock. After determining the  $Q$  and  $R$  values for each site, the authors use an approximation to estimate the total system stock and the backorder levels. The numerical results show that the  $(Q, R)$  policy is better than the  $(S-I, S)$  policy for such systems.

Forsberg [10] deals with a multi-echelon inventory system with one warehouse and multiple non-identical retailers. The author assumes that the retailers face independent Poisson demand and both the warehouse and the retailers use  $(Q, R)$  policies. Forsberg [10] evaluates inventory holding and shortage costs using an exact solution approach.

Chen and Zheng [8] study a  $(nQ, R)$  policy in a multi-stage serial inventory system where *stage 1* orders from *stage 2*, *stage 2* from *stage 3*, etc., and *stage N* places orders to an outside supplier with unlimited capacity. The demand seen by *stage 1* is compound Pois-

son and excess demand is backlogged at every stage. The transportation lead times among stages are constant. By using a two-step approach, Chen and Zheng [8] provide near-optimal solution. In the first step, they find the lower and upper bounds on the cost function by changing the penalty cost of being short on inventory. In the second step, the authors minimize the bounds by using three different heuristic approaches. Chen and Zheng [8] also propose an optimal algorithm that requires additional computational effort.

Axsater [2] considers a two-stage inventory system with one warehouse and  $N$  non-identical retailers. He presents an exact method to evaluate inventory holding and shortage costs when there are only two retailers. He focuses on the timing of the warehouse orders for the sub-batches of  $Q$ . He identifies three possibilities and evaluates the cost for each case separately. At the end, total cost is calculated by summing the costs for the three cases. When there are more than two retailers, he extends his evaluation technique by combining the retailers into two groups, and then uses the same approach he developed for the two retailer case. The author also presents a model where the lead times are constant and all facilities use  $(Q, R)$  policies with different  $Q$  and  $R$  values. In this model, all stockouts are backordered, delayed orders are delivered on a first-come-first-served basis, and partial shipments are also allowed. In order to simplify the problem, Axsater [2] assumes that all batch sizes are multiples of the smallest batch size. In the objective function, the author only considers expected inventory holding cost and back-order cost.

Like Axsater [2], Marklund [16] also considers a two-stage supply chain with one central warehouse and an arbitrary number of non-identical retailers. Customer demands occur only at the retailers. The retailers use  $(Q, R)$  policies with different parameters, and they request products from the central warehouse whenever their inventory positions reach  $R$  or fall below  $R$ . The author proposes a new policy  $(Q_0, a_0)$  that is motivated by relating the traditional echelon stock model to the installation stock  $(Q, R)$  model where the order quantity  $Q$  is a multiple of a minimum batch size. In the article, Marklund [16] gives the detailed derivation of the exact cost function when the retailers use  $(Q, R)$  policies and the warehouse uses the new  $(Q_0, a_0)$  policy. The performance of the new policy is compared to traditional ech-

elon stock policy and  $(Q, R)$  policy through numerical examples. Although the results show that the proposed policy outperforms the other policies in all numerical examples, the author does not guarantee that the policy will always give the best result.

Fujiwara and Sedarage [11] apply a  $(Q, R)$  policy for a multi-part assembly system under stochastic lead times. The objective of the article is to simultaneously determine the order quantity and the assembly lot size so that the average total cost per unit time is minimized. The total cost includes setup costs, inventory holding costs of parts and assembled items, and shortage costs of assembled items. The authors try to find separate reorder points,  $r_i$ , for each part and a global order quantity,  $Q$ , which will be used for all parts. Although the authors propose a global order quantity  $Q$ , they also mention that this kind of policy may not be optimal. They suggest that instead of a global  $Q$ , a common  $Q$  where all order quantities are multiples of  $Q$  might be more sensible.

Chen and Zheng [7] consider a distribution system with one warehouse and multiple retailers. The retailers' demands follow an independent compound Poisson process. It is assumed that the order quantity is a multiple of the smallest batch size. The order quantity and the reorder point are calculated by using a heuristic. The authors present an exact procedure for evaluating the performance (average cost) of the  $(nQ, R)$  policy when the demand is a Poisson process. Chen and Zheng [7] also give two approximation procedures for the case with compound Poisson processes. The approximations are based on exact formulations of the case with Poisson processes.

Axsater [3] presents an exact analysis of a two-stage inventory system with one warehouse and multiple retailers. The demand for each retailer follows an independent compound Poisson process. The retailers replenish their stock from the warehouse, and the warehouse replenishes its stock from an outside supplier. The transportation times from the warehouse to the retailers and from the outside supplier to the warehouse are constant. In addition, if there is a shortage, then additional delay may also occur since shortages and stockouts are backordered. The author emphasizes that the approach developed is not directly applicable for items with large demand. Instead, it is suitable mostly for slow-moving parts such as spare parts.

Moinzadeh [17] also considers a supply chain with one warehouse and multiple identical retailers. The author assumes that demand at the retailers is random but stationary and that each retailer places its order according to a  $(Q, R)$  policy. In addition, Moinzadeh [17] assumes that the warehouse receives online information about the demand. The author shows the effect of information sharing on order replenishment decisions of the supplier. In the article, the author first proposes a possible replenishment policy for the supplier and then provides an exact analysis for the operating measures of such systems. The author concludes the article by giving information about when information sharing is most beneficial.

## Conclusions

We provide a literature review on continuous review  $(Q, R)$  inventory policies. Although we review most of the well known papers that deal with  $(Q, R)$  policy, this is not an exhaustive review of the literature. Our aim is to present the importance of the  $(Q, R)$  policy and show possible extensions of the simple  $(Q, R)$  model.

Nonlinear equations; Linear equations; Integral equations; Iterative method; Contraction mapping

### Statement of the Result

The method of *successive substitution*, *Richardson iteration*, or *direct iteration* seeks to find a *fixed point* of a map  $K$ , that is a point  $u^*$  such that

$$u^* = K(u^*).$$

Given an initial iterate  $u_0$ , the iteration is

$$u_{k+1} = K(u_k), \quad \text{for } k \geq 0. \quad (1)$$

Let  $X$  be a Banach space and let  $D \subset X$  be closed. A map  $K : D \rightarrow D$  is a *contraction* if

$$\|K(u) - K(v)\| \leq \alpha \|u - v\| \quad (2)$$

for some  $\alpha \in (0, 1)$  and all  $u, v \in D$ . The contraction mapping theorem, [3,7,13,14], states that if  $K$  is a contraction on  $D$  then

- $K$  has a unique fixed point  $u^*$  in  $D$ , and
- for any  $u_0 \in D$  the sequence  $\{u_k\}$  given by (1) converges to  $u^*$ .

The message of the contraction mapping theorem is that if one wishes to use direct iteration to solve a fixed point problem, then the fixed point map  $K$  must satisfy (2) for some  $D$  and relative to some choice of norm. The choice of norm need not be made explicitly, it is determined implicitly by the  $K$  itself. However, if there is no norm for which (2) holds, then another, more robust, method, such as Newton's method with a line search, must be used, or the problem must be reformulated.

One may wonder why a Newton-like method is not always better than a direct iteration. The answer is that the cost for a single iteration is very low for Richardson iteration. So, if the equation can be set up to make the contraction constant  $\alpha$  in (2) small, successive substitution, while taking more iterations, can be more efficient than a Newton-like iteration, which has costs in linear algebra and derivative evaluation that are not incurred by successive substitution.

### Affine Problems

An affine fixed point map has the form

$$K(u) = Mu + b$$

where  $M$  is a linear operator on the space  $X$ . The fixed point equation is

$$(I - M)u = b, \quad (3)$$

where  $I$  is the identity operator. The classical stationary iterative methods in numerical linear algebra, [8,13], are typically analyzed in terms of affine fixed point problems, where  $M$  is called the iteration matrix. Multigrid methods, [2,4,5,9], are also stationary iterative methods. We give an example of how multigrid methods are used later in this article.

The contraction condition (2) holds if

$$\|M\| \leq \alpha < 1. \quad (4)$$

In (4) the norm is the operator norm on  $X$ .  $M$  may be a well defined operator on more than one space and (4) may not hold in all of them. Similarly, if  $X$  is finite dimensional and all norms are equivalent, (4) may hold in one norm and not in another. It is known, [10], that (4) holds for some norm if and only if the spectral radius of  $M$  is  $< 1$ .

When (4) does not hold it is sometimes possible to form an approximate inverse *preconditioner*  $P$  so that direct iteration can be applied to the equivalent problem

$$u = (I - P(I - M))u - Pb. \quad (5)$$

In order to apply the contraction mapping theorem and direct iteration to (5) we require that

$$\|I - P(I - M)\| \leq \alpha < 1$$

in some norm. In this case we say that  $P$  is an *approximate inverse* for  $I - M$ . In the final section of this article we give an example of how approximate inverses can be built for discretizations of integral operators.

### Nonlinear Problems

If the nonlinear fixed point map  $K$  is sufficiently smooth, then a Newton-like method may be used to solve

$$F(u) = u - K(u) = 0.$$

The transition from a current approximation  $u_c$  of  $u^*$  to an update  $u_+$  is

$$u_+ = u_c - P(u_c - K(u_c)), \tag{6}$$

where

$$P \approx F'(u^*)^{-1} = (I - K'(u^*))^{-1}.$$

$P = F(u_c)^{-1}$  is Newton's method and  $P = F'(u_0)^{-1}$  is the chord method.

It is easy to show [7,13,14] that if  $u$  is near  $u^*$  and  $P$  is an approximate inverse for  $F'(u^*)$  then the preconditioned fixed point problem

$$u = u - P(u - K(u))$$

is a contraction on a neighborhood  $D$  of  $u^*$ . This is, in fact, one way to analyze the convergence of Newton's method. In this article our focus is on preconditioners that remain constant for several iterations and do not require computation of the derivative of  $K$ .

The point to remember is that, if the goal is to transform a given fixed point map into a contraction, preconditioning of nonlinear problems can be done by the same process (formation of an approximate inverse) as for linear problems.

### Integral Equations Example

We close this article with the *Atkinson-Brakhage preconditioner* for integral operators [2,4]. We will begin with the linear case, from which the nonlinear algorithm is a simple step. Let  $\Omega \in \mathbf{R}^N$  be compact and let  $k(x, y)$  be a continuous function on  $\Omega \times \Omega$ . We consider the affine fixed point problem

$$u(x) = f(x) + (\mathbf{K}u)(x) = f(x) + \int_{\Omega} k(x, y)u(y) dy,$$

where  $f \in X = C(\Omega)$  is given and a solution  $u^* \in X$  is sought. In this example  $D = X$ . We will assume that the linear operator  $I - \mathbf{K}$  is nonsingular on  $X$ .

We consider a family of increasingly accurate quadrature rules, indexed with a level  $l$ , with weights  $\{w_i^l\}_{i=1}^{N_l}$  and nodes  $\{x_i^l\}_{i=1}^{N_l}$  that satisfy

$$\lim_{l \rightarrow \infty} \sum_{j=1}^{N_l} f(x_j^l)w_j^l = \int_{\Omega} f(x) dx$$

for all  $f \in X$ . The family of operators  $\{\mathbf{K}_l\}$  defined by

$$\mathbf{K}_l u(x) = \sum_{j=1}^{N_l} k(x, x_j^l)u(y)w_j^l$$

converges strongly to  $\mathbf{K}$ , that is

$$\lim_{l \rightarrow \infty} \mathbf{K}_l u = \mathbf{K}u$$

for all  $u \in X$ . The family  $\{\mathbf{K}_l\}$  is also *collectively compact*, [1]. This means that if  $\mathbf{B}$  is a bounded subset of  $X$ , then

$$\cup_l \mathbf{K}_l(\mathbf{B})$$

is precompact in  $X$ . The direct consequences of the strong convergence and collective compactness are that  $I - \mathbf{K}_l$  are nonsingular for  $l$  sufficiently large and

$$(I - \mathbf{K}_l)^{-1} \rightarrow (I - \mathbf{K})^{-1} \tag{7}$$

strongly in  $X$ . The Atkinson-Brakhage preconditioner is based on these results.

For  $g \in X$  one can compute

$$v = (I - \mathbf{K}_l)^{-1}g$$

by solving the finite-dimensional linear system

$$v_i = g(x_i^l) + \sum_{j=1}^{N_l} k(x_i^l, x_j^l)v_j w_j^l \tag{8}$$

for the values  $v(x_i^l) = v_i$  of  $v$  at the nodal points and then applying the *Nyström interpolation*

$$v(x) = g(x) + \sum_{j=1}^{N_l} k(x, x_j^l)v_j w_j^l = g(x) + (\mathbf{K}_l v)(x)$$

to recover  $v(x)$  for all  $x \in \Omega$ . (8) can be solved at a cost of  $O(N_l^3)$  floating point operations if direct methods for linear equations are used and for much less if iterative methods such as GMRES [15] are used. In that case, only  $O(1)$  matrix-vector products are need to obtain a solution that is accurate to truncation error [6]. This is, up to a multiplicative factor, optimal. The Atkinson-Brakhage preconditioner can dramatically reduce this factor, however.

The results in [1] imply that

$$M_l = I + (I - \mathbf{K}_l)^{-1}\mathbf{K},$$

the Atkinson–Brakhage preconditioner, converges to  $(I - K)^{-1}$  in the operator norm. Hence, for  $l$  sufficiently large (coarse mesh sufficiently fine) Richardson iteration can be applied to the system

$$u = u - M_l(I - K_l)u - M_l f,$$

where  $L \gg l$ . Applying this idea for a sequence of grids or levels leads to the optimal form of the Atkinson–Brakhage iteration [11]. The algorithm uses a coarse mesh, which we index with  $l = 0$ , to build the preconditioner and then cycles through the grids sequentially until the solution at a desired fine ( $l = L$ ) mesh is obtained. One example of this is a sequence of composite midpoint rule quadratures in which  $N_{l+1} = 2N_l$ . Then, [2,11], if the coarse mesh is sufficiently fine, only one Richardson iteration at each level will be needed. The cost at each level is two matrix vector products at level  $l$  and a solve at level 0.

- 1) Solve  $u_0 - K_0 u_0 = f$ ; set  $u = u_0$ .
- 2) For  $l = 1, \dots, L$ :
  - a) Compute  $r = u - K_l u - f$ ;
  - b)  $u = u - M_l r$ .

Nonlinear problems can be solved with exactly the same idea. We will consider the special case of *Hammerstein equations*

$$u(x) = K(u)(x) = \int_{\Omega} k(x, y, u(y)) dy.$$

If we use a sequence of quadrature rules as in the linear case we can define

$$K_l(u)(x) = \sum_{j=1}^{N_l} k(x, x_j^l, u(x_j^l)) w_j^l.$$

The nonlinear form of the Atkinson–Brakhage algorithm for Hammerstein equations simply uses the approximation

$$I + (I - K'_0(u_0))^{-1} K'(u) \approx (I - K'_l(u))^{-1}$$

in a Newton-like iteration. One can see from the formal description below that little has changed from the linear case.

- 1) Solve  $u_0 - K_0(u_0) = 0$ ; set  $u = u_0$ .
- 2) For  $l = 1, \dots, L$ :
  - a) Compute  $r = u - K_l(u)$ ;
  - b)  $u = u - (I + (I - K'_l(u_0))^{-1} K'(u))r$ .

The Atkinson–Brakhage algorithm can, under some conditions, be further improved, [12] and the number of fine mesh operator-function products per level reduced to one. There is also no need to explicitly represent the operator as an integral operator with a kernel.

### Keywords and Phrases

Optimal control; Control vector iteration; Variation method; Pontryagin's maximum principle

In solving optimal control problems involving nonlinear differential equations, some iterative procedure must be used to obtain the optimal control policy. As is true with any iterative procedure, one is concerned about the convergence rate and also about the reliability of obtaining the optimal control policy. Although from Pontryagin's maximum principle it is known that the minimum of the performance index corresponds to the minimum of the Hamiltonian, to obtain the minimum value for the Hamiltonian is not always straightforward. Here we outline a procedure that changes the control policy from iteration to iteration, improving the value of the performance index at each iteration, until the improvement is less than certain amount. Then the iteration procedure is stopped and the results are analyzed. Such a procedure is called control vector iteration method (CVI), or iteration in the policy space.

### Optimal Control Problem

To illustrate the procedure, let us consider the optimal control problem, where the system is described by the differential equation

$$\frac{dx}{dt} = f(x, u), \quad \text{with } x(0) \text{ given,} \quad (1)$$

where  $x$  is an  $n$ -dimensional state vector and  $u$  is an  $r$ -dimensional control vector. The optimal control problem is to determine the control  $u$  in the time interval  $0 \leq t < t_f$ , so that the performance index

$$I = \int_0^{t_f} \phi(x, u) dt \quad (2)$$

is minimized. We consider the case where the final time  $t_f$  is given. To carry out the minimization of the performance index in (2) subject to the constraints in (1), we consider the augmented performance index

$$J = \int_0^{t_f} \left[ \phi + z^T \left( f - \frac{dx}{dt} \right) \right] dt, \quad (3)$$

where the  $n$ -dimensional vector of Lagrange multipliers  $z$  is called the adjoint vector. The last term in (3) can be thought of as a penalty function to ensure that the state equation is satisfied throughout the given time interval. We introduce the Hamiltonian

$$H = \phi + z^T f \quad (4)$$

and use integration by parts to simplify (3) to

$$J = \int_0^{t_f} \left( H + \frac{dz^T}{dt} x \right) dt - z(t_f)x(t_f) + z^T(0)x(0). \quad (5)$$

The optimal control problem now reduces to the minimization of  $J$ .

To minimize  $J$  numerically, we assume that we have evaluated  $J$  at iteration  $j$  by using control policy denoted by  $u^{(j)}$ . Now the problem is to determine the control policy  $u^{(j+1)}$  at the next iteration. Since the goal is to minimize  $J$ , obviously we want to make the change in  $J$  negative and numerically as large as possible. If we let  $\delta u = u^{(j+1)} - u^{(j)}$ , the corresponding change in  $J$  is obtained by using Taylor series expansion up to the

quadratic terms:

$$\begin{aligned} \delta J = & \int_0^{t_f} \left[ \left( \left( \frac{\partial H}{\partial \mathbf{x}} \right)^T + \frac{d\mathbf{z}^T}{dt} \right) \delta \mathbf{x} + \left( \frac{\partial H}{\partial \mathbf{u}} \right)^T \delta \mathbf{u} \right] dt \\ & + \frac{1}{2} \int_0^{t_f} \left[ \delta \mathbf{x}^T \frac{\partial^2 H}{\partial \mathbf{x}^2} \delta \mathbf{x} + 2\delta \mathbf{x}^T \frac{\partial^2 H}{\partial \mathbf{x} \partial \mathbf{u}} \delta \mathbf{u} \right. \\ & \left. + \delta \mathbf{u}^T \frac{\partial^2 H}{\partial \mathbf{u}^2} \delta \mathbf{u} \right] dt - \mathbf{z}^T(t_f) \delta \mathbf{x}(t_f). \end{aligned} \quad (6)$$

The necessary condition for minimum of  $J$  is that the first integral in (6) should be zero; i. e.,

$$\frac{d\mathbf{z}}{dt} = -\frac{\partial H}{\partial \mathbf{x}}, \quad \text{with } \mathbf{z}(t_f) = \mathbf{0}. \quad (7)$$

and

$$\frac{\partial H}{\partial \mathbf{u}} = \mathbf{0}. \quad (8)$$

In control vector iteration, we relax the necessary condition in (8) and choose  $\delta \mathbf{u}$  to make  $\delta J$  negative and in the limit (8) is satisfied. One approach is to choose

$$\delta \mathbf{u} = -\epsilon \frac{\partial H}{\partial \mathbf{u}}, \quad (9)$$

where  $\epsilon$  is a positive parameter which may vary from iteration to iteration. This method is sometimes called first variation method, since the driving force for the change in the control policy is based only on the first term of the Taylor series expansion. The negative sign in (9) is required to minimize the Hamiltonian, as is required by Pontryagin's maximum principle. Numerous papers have been written on the determination of the stepping parameter  $\epsilon$  [7].

### Second Variation Method

Instead of arbitrarily determining the stepping parameter  $\epsilon$ , one may solve the accessory minimization problem, where  $\delta \mathbf{u}$  is chosen to minimize  $\delta J$  given by (6) after the requirements for the adjoint are satisfied; i. e., it is required to find  $\delta \mathbf{u}$  to minimize  $\delta J$  given by

$$\begin{aligned} \delta J = & \int_0^{t_f} \left[ \left( \frac{\partial H}{\partial \mathbf{u}} \right)^T \delta \mathbf{u} + \frac{1}{2} \delta \mathbf{x}^T \frac{\partial^2 H}{\partial \mathbf{x}^2} \delta \mathbf{x} \right. \\ & \left. + \delta \mathbf{x}^T \frac{\partial^2 H}{\partial \mathbf{x} \partial \mathbf{u}} \delta \mathbf{u} + \frac{1}{2} \delta \mathbf{u}^T \frac{\partial^2 H}{\partial \mathbf{u}^2} \delta \mathbf{u} \right] dt, \end{aligned} \quad (10)$$

subject to the differential equation

$$\frac{d\delta \mathbf{x}}{dt} = \left( \frac{\partial \mathbf{f}^T}{\partial \mathbf{x}} \right)^T \delta \mathbf{x} + \left( \frac{\partial \mathbf{f}^T}{\partial \mathbf{u}} \right)^T \delta \mathbf{u}, \quad \text{with } \delta \mathbf{x}(0) = \mathbf{0}. \quad (11)$$

The solution to this accessory minimization problem is straightforward, since (11) is linear and the performance index in (10) is almost quadratic, and can be easily done, as shown in ([1], pp. 259–266) and [7]. The resulting equations, to be integrated backwards from  $t = t_f$  to  $t = 0$  with zero starting conditions, are

$$\begin{aligned} \frac{d\mathbf{J}}{dt} + \mathbf{J} \left( \frac{\partial \mathbf{f}^T}{\partial \mathbf{x}} \right)^T + \frac{\partial \mathbf{f}^T}{\partial \mathbf{x}} \mathbf{J} + \frac{\partial^2 H}{\partial \mathbf{x}^2} \\ - \mathbf{S}^T \left( \frac{\partial^2 H}{\partial \mathbf{u}^2} \right)^{-1} \mathbf{S} = \mathbf{0}, \end{aligned} \quad (12)$$

where the  $(r \times n)$ -matrix  $\mathbf{S} = \partial^2 H / \partial \mathbf{u} \partial \mathbf{x} + \partial \mathbf{f}^T / \partial \mathbf{x} \mathbf{J}$ , and

$$\frac{d\mathbf{g}}{dt} - \mathbf{S}^T \left( \frac{\partial^2 H}{\partial \mathbf{u}^2} \right)^{-1} \left( \frac{\partial H}{\partial \mathbf{u}} + \frac{\partial \mathbf{f}^T}{\partial \mathbf{x}} \mathbf{g} \right) + \left( \frac{\partial \mathbf{f}^T}{\partial \mathbf{x}} \right) \mathbf{g} = \mathbf{0}. \quad (13)$$

The control policy is then updated through the equation

$$\begin{aligned} \mathbf{u}^{(j+1)} = & \mathbf{u}^{(j)} - \left( \frac{\partial^2 H}{\partial \mathbf{u}^2} \right)^{-1} \left( \frac{\partial H}{\partial \mathbf{u}} + \frac{\partial \mathbf{f}^T}{\partial \mathbf{x}} \mathbf{g} \right) \\ & - \left( \frac{\partial^2 H}{\partial \mathbf{u}^2} \right)^{-1} \mathbf{S} \left( \mathbf{x}^{(j+1)} - \mathbf{x}^{(j)} \right). \end{aligned} \quad (14)$$

This method of updating the control policy is called the second variation method. In (12) the  $(n \times n)$ -matrix  $\mathbf{J}$  is symmetric, so the total number of differential equations to be integrated backwards is  $n(n+1)/2 + 2n$ . However, the convergence is quadratic if the initial control policy is close to the optimum.

To obtain good starting conditions, Luus and Lapidus [6] suggested the use of first variation method for the first few iterations and then to switch over to the second variation method.

One additional feature of the second variation method is that the control policy given in (14) is a function of the present state, so that the control policy is treated as being continuous and is not restricted to be

ing piecewise constant over an integration time step, as is the case with the first variation method. As was shown in ([1], pp. 316–317), for the linear six-plate gas absorber example, when the system equation is linear and the performance index is quadratic, the second variation method yields the optimal control policy in a single step.

### Determination of Stepping Parameter

However, the large number and complexity of equations required for obtaining the control policy and the instability of the method for very complex systems led to investigating different means of obtaining faster convergence with the first variation method. The effort was directed on the best means of obtaining the stepping parameter  $\epsilon$  in (9). When  $\epsilon$  is too large, overstepping occurs, and if  $\epsilon$  is too small, the convergence rate is very small.

Numerous papers have been written on the determination of  $\epsilon$ . Several methods were compared by Rao and Luus [8] in solving typical optimal control problems. Although they suggested a means of determining the ‘best’ method for performance indices that are almost quadratic, it is found that a very simple scheme is quite effective for a wide variety of optimal control problems. Instead of trying to get very fast convergence and risk instability, the emphasis is placed on the robustness. The strategy is to obtain the initial value for  $\epsilon$  from the magnitude of  $\partial H/\partial \mathbf{u}$ , and then increasing  $\epsilon$  when the iteration has been successful, and reducing its value if overstepping occurs. This type of approach was used in [2] in solving the optimal control of a pyrolysis problem. When the iteration was successful, the stepping parameter was increased by 10 percent, and when overstepping resulted, the stepping parameter was reduced to half its value. The algorithm for first variation method may be presented as follows:

- Choose an initial control policy  $\mathbf{u}^{(0)}$  and a value for  $\epsilon$ ; set the iteration index  $j$  to 0.
- Integrate (1) from  $t = 0$  to  $t = t_f$  and evaluate the performance index in (2). Store the values of the state vector at the end of each integration time step.
- Integrate the adjoint equation (7) from  $t = t_f$  to  $t = 0$ , using for  $\mathbf{x}$  the stored values of the state vector in Step 2. At each integration time step evaluate the gradient  $\partial H/\partial \mathbf{u}$ .

- Choose a new control policy

$$\mathbf{u}^{(j+1)} = \mathbf{u}^{(j)} - \epsilon \frac{\partial H}{\partial \mathbf{u}} . \quad (15)$$

- Integrate (1) from  $t = 0$  to  $t = t_f$  and evaluate the performance index in (2). Store the values of the state vector at the end of each integration time step. If the performance index is worse (i. e., overstepping has occurred), reduce  $\epsilon$  to half its value and go to Step 4. If the performance index has been improved increase  $\epsilon$  by a small factor, such as 1.10 and go to Step 3, and continue for a number of iterations, or terminate the iterations when the change in the performance index in an iteration is less than some criterion, and interpret the results.

### Illustration of the First Variation Method

Let us consider the nonlinear continuous stirred tank reactor that has been used for optimal control studies in ([1], pp. 308–318) and [6], and which was shown in [4] to exhibit multiplicity of solutions. The system is described by the two equations

$$\begin{aligned} \frac{dx_1}{dt} = & -2(x_1 + 0.25) \\ & + (x_2 + 0.5) \exp\left(\frac{25x_1}{x_1 + 2}\right) - u(x_1 + 0.25) , \end{aligned} \quad (16)$$

$$\frac{dx_2}{dt} = 0.5 - x_2 - (x_2 + 0.5) \exp\left(\frac{25x_1}{x_1 + 2}\right) , \quad (17)$$

with the initial state  $x_1(0) = 0.09$  and  $x_2(0) = 0.09$ . The control  $u$  is a scalar quantity related to the valve opening of the coolant. The state variables  $x_1$  and  $x_2$  represent deviations from the steady state of dimensionless temperature and concentration, respectively. The performance index to be minimized is

$$I = \int_0^{t_f} (x_1^2 + x_2^2 + 0.1u^2) dt , \quad (18)$$

where the final time  $t_f = 0.78$ . The Hamiltonian is

$$\begin{aligned} H = & z_1(-2(x_1 + 0.25) + R - u(x_1 + 0.25)) \\ & + z_2(0.5 - x_2 - R) + x_1^2 + x_2^2 + 0.1u^2 , \end{aligned} \quad (19)$$

where  $R = (x_2 + 0.5) \exp(25x_1/(x_1 + 2))$ . The adjoint equations are

$$\frac{dz_1}{dt} = (u + 2)z_1 - 2x_1 + 50R \frac{(z_2 - z_1)}{(x_1 + 2)^2}, \quad (20)$$

$$\frac{dz_2}{dt} = -2x_2 + \frac{(z_2 - z_1)}{(x_2 + 0.5)}R + z_2, \quad (21)$$

and the gradient of the Hamiltonian is

$$\frac{\partial H}{\partial u} = 0.2u - (x_1 + 0.25)z_1. \quad (22)$$

To illustrate the computational aspects of CVI, the above algorithm was used with a Pentium-120 personal computer using WATCOM Fortran compiler version 9.5. The calculations were done in double precision. As found in [4], convergence to the local optimum was obtained when small values for the initial control policy were used, and the global optimum was obtained when large values were used as initial policy. As is seen in Table 1, when an integration time step of 0.0065 was used (allowing 120 piecewise constant steps), in spite of the large number of iterations, the optimal control policy can be obtained in less than 2 s of computer time. The iterations were stopped when the change in the performance index from iteration to iteration was less than  $10^{-6}$ .

The total computation time for making this run with 11 different initial control policies was 9.6 s on the Pentium-120 digital computer. When an integra-

3.0	0.133130	136	1.38

**Control Vector Iteration CVI, Table 2**  
Effect of the number of time stages P on the optimal performance index

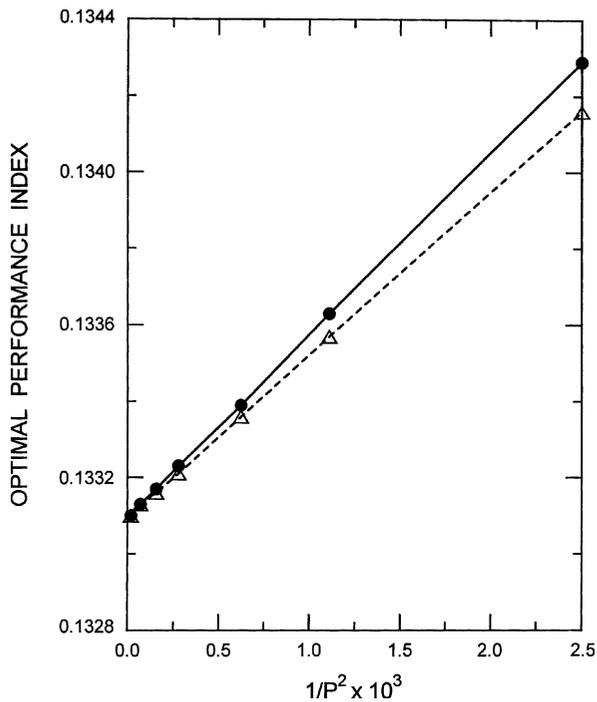

Number of time stages P	Optimal I by CVI	Optimal I by IDP
20	0.13429	0.13416
30	0.13363	0.13357
40	0.13339	0.13336
60	0.13323	0.13321
80	0.13317	0.13316
120	0.13313	0.13313
240	0.13310	0.13310

tion time step of 0.00312 was used, the value of the performance index at the global optimum was improved to 0.133104. When a time step of 0.001 was used, giving 780 time steps, the optimal control policy yielded  $I = 0.133097$ . Even here the computation time for the 11 different initial conditions was only 31 s. With the use of piecewise linear control and only 20 time stages, a performance index of  $I = 0.133101$  was obtained in [3] with iterative dynamic programming (IDP). To obtain this result with IDP, by using 5 randomly chosen points and 10 passes, each consisting of 20 iterations, took 13.4 s on a Pentium-120. The use of 15 time stages yielded  $I = 0.133112$  and required 7.8 s. Therefore, computationally CVI is faster than IDP for this problem, but the present formulation does not allow piecewise linear control to be used in CVI.

The effect of the number of time stages for piecewise constant control is shown in Table 2, where CVI results are compared to those obtained by IDP in [5].

As can be seen, the given algorithm gives results very close to those obtained by IDP, and the deviations decrease as the number of time stages increases, because the approximations introduced during the backward integration when the stored values for the state vector are used, and in the calculation of the gradient of the Hamiltonian in CVI become negligible as the time stages become very small. As is shown in Fig. 1, when the optimal value of the performance index is plotted against  $1/P^2$ , the extrapolated value, as  $1/P^2$  approaches zero, gives the value obtained with the second variation method.

The first variation method is easy to program and will continue to be a very useful method of determining the optimal control of nonlinear systems.

We develop an algorithmic theory of convex optimization over discrete sets. Using a combination of algebraic and geometric tools we are able to provide polynomial time algorithms for solving broad classes of convex combinatorial optimization problems and convex integer programming problems in variable dimension. We discuss some of the many applications of this theory including to quadratic programming, matroids, bin packing and cutting-stock problems, vector partitioning and clustering, multiway transportation problems, and privacy and confidential statistical data disclosure. Highlights of our work include a strongly polynomial time algorithm for convex and linear combinatorial optimization over any family presented by a membership oracle when the underlying polytope has few edge-directions; a new theory of so-termed  $n$ -fold integer programming, yielding polynomial time solution of important and natural classes of convex and linear integer programming problems in variable dimension; and a complete complexity classification of high dimen-

sional transportation problems, with practical applications to fundamental problems in privacy and confidential statistical data disclosure.

**Introduction**

The general linear discrete optimization problem can be posed as follows.

LINEAR DISCRETE OPTIMIZATION. Given a set  $S \subseteq \mathbb{Z}^n$  of integer points and an integer vector  $w \in \mathbb{Z}^n$ , find an  $x \in S$  maximizing the standard inner product  $wx := \sum_{i=1}^n w_i x_i$ .

The algorithmic complexity of this problem, which includes *integer programming* and *combinatorial optimization* as special cases, depends on the presentation of the set  $S$  of feasible points. In integer programming, this set is presented as the set of integer points satisfying a given system of linear inequalities, which in standard form is given by

$$S = \{x \in \mathbb{N}^n : Ax = b\},$$

where  $\mathbb{N}$  stands for the nonnegative integers,  $A \in \mathbb{Z}^{m \times n}$  is an  $m \times n$  integer matrix, and  $b \in \mathbb{Z}^m$  is an integer vector. The input for the problem then consists of  $A, b, w$ . In combinatorial optimization,  $S \subseteq \{0, 1\}^n$  is a set of  $\{0, 1\}$ -vectors, often interpreted as a family of subsets of a ground set  $N := \{1, \dots, n\}$ , where each  $x \in S$  is the indicator of its support  $\text{supp}(x) \subseteq N$ . The set  $S$  is presented implicitly and compactly, say as the set of indicators of subsets of edges in a graph  $G$  satisfying a given combinatorial property (such as being a matching, a forest, and so on), in which case the input is  $G, w$ . Alternatively,  $S$  is given by an oracle, such as a *membership oracle* which, queried on  $x \in \{0, 1\}^n$ , asserts whether or not  $x \in S$ , in which case the algorithmic complexity also includes a count of the number of oracle queries needed to solve the problem.

Here we study the following broad generalization of linear discrete optimization.

CONVEX DISCRETE OPTIMIZATION. Given a set  $S \subseteq \mathbb{Z}^n$ , vectors  $w_1, \dots, w_d \in \mathbb{Z}^n$ , and a convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$ , find an  $x \in S$  maximizing  $c(w_1 x, \dots, w_d x)$ .

This problem can be interpreted as *multi-objective* linear discrete optimization: given  $d$  linear functionals  $w_1 x, \dots, w_d x$  representing the values of points  $x \in S$  under  $d$  criteria, the goal is to maximize their “con-

vex balancing” defined by  $c(w_1x, \dots, w_dx)$ . In fact, we have a hierarchy of problems of increasing generality and complexity, parameterized by the number  $d$  of linear functionals: at the bottom lies the linear discrete optimization problem, recovered as the special case of  $d = 1$  and  $c$  the identity on  $\mathbb{R}$ ; and at the top lies the problem of maximizing an arbitrary convex functional over the feasible set  $S$ , arising with  $d = n$  and with  $w_i = \mathbf{1}_i$  the  $i$ th standard unit vector in  $\mathbb{R}^n$  for all  $i$ .

The algorithmic complexity of the convex discrete optimization problem depends on the presentation of the set  $S$  of feasible points as in the linear case, as well as on the presentation of the convex functional  $c$ . When  $S$  is presented as the set of integer points satisfying a given system of linear inequalities we also refer to the problem as *convex integer programming*, and when  $S \subseteq \{0, 1\}^n$  and is presented implicitly or by an oracle we also refer to the problem as *convex combinatorial optimization*. As for the convex functional  $c$ , we will assume throughout that it is presented by a *comparison oracle* that, queried on  $x, y \in \mathbb{R}^d$ , asserts whether or not  $c(x) \leq c(y)$ . This is a very broad presentation that reveals little information on the function, making the problem, on the one hand, very expressive and applicable, but on the other hand, very hard to solve.

There is a massive body of knowledge on the complexity of linear discrete optimization – in particular (linear) integer programming [55] and (linear) combinatorial optimization [31]. The purpose of this monograph is to provide the first comprehensive unified treatment of the extended convex discrete optimization problem. The monograph follows the outline of five lectures given by the author in the Séminaire de Mathématiques Supérieures Series, Université de Montréal, during June 2006. Colorful slides of these lectures are available online at [46] and can be used as a visual supplement to this monograph. The monograph has been written under the support of the ISF – Israel Science Foundation. The theory developed here is based on and is a culmination of several recent papers including [5,12,13,14,15,16,17,25,39,47,48,49,50,51] written in collaboration with several colleagues – Eric Babson, Jesus De Loera, Komei Fukuda, Raymond Hemmecke, Frank Hwang, Vera Rosta, Uriel Rothblum, Leonard Schulman, Bernd Sturmfels, Rekha Thomas, and Robert Weismantel. By developing and using a combination of geometric and algebraic tools,

we are able to provide polynomial time algorithms for several broad classes of convex discrete optimization problems. We also discuss in detail some of the many applications of our theory, including to quadratic programming, matroids, bin packing and cutting-stock problems, vector partitioning and clustering, multiway transportation problems, and privacy and confidential statistical data disclosure.

We hope that this monograph will, on the one hand, allow users of discrete optimization to enjoy the new powerful modelling and expressive capability of convex discrete optimization along with its broad polynomial time solvability, and on the other hand, stimulate more research on this new and fascinating class of problems, their complexity, and the study of various relaxations, bounds, and approximations for such problems.

### Limitations

Convex discrete optimization is generally intractable even for small fixed  $d$ , since already for  $d = 1$  it includes linear integer programming which is NP-hard. When  $d$  is a variable part of the input, even very simple special cases are NP-hard, such as the following problem, so-called *positive semi-definite quadratic binary programming*,

$$\max \{ (w_1x)^2 + \dots + (w_nx)^2 : x \in \mathbb{N}^n, \\ x_i \leq 1, \quad i = 1, \dots, n \}.$$

Therefore, throughout this monograph we will assume that  $d$  is fixed (but arbitrary).

As explained above, we also assume throughout that the convex functional  $c$  which constitutes part of the data for the convex discrete optimization problem is presented by a comparison oracle. Under such broad presentation, the problem is generally very hard. In particular, if the feasible set is  $S := \{x \in \mathbb{N}^n : Ax = b\}$  and the underlying polyhedron  $P := \{x \in \mathbb{R}_+^n : Ax = b\}$  is *unbounded*, then the problem is inaccessible even in one variable with no equation constraints. Indeed, consider the following family of univariate convex integer programs with convex functions parameterized by  $-\infty < u \leq \infty$ ,

$$\max \{ c_u(x) : x \in \mathbb{N} \}, \\ c_u(x) := \begin{cases} -x, & \text{if } x < u; \\ x - 2u, & \text{if } x \geq u. \end{cases}$$

Consider any algorithm attempting to solve the problem and let  $u$  be the maximum value of  $x$  in all queries to the oracle of  $c$ . Then the algorithm can not distinguish between the problem with  $c_u$ , whose objective function is unbounded, and the problem with  $c_\infty$ , whose optimal objective value is 0. Thus, convex discrete optimization (with an oracle presented functional) over an *infinite* set  $S \subset \mathbb{Z}^n$  is quite hopeless. Therefore, an algorithm that solves the convex discrete optimization problem will either return an optimal solution, or assert that the problem is infeasible, or assert that the underlying polyhedron is unbounded. In fact, in most applications, such as in combinatorial optimization with  $S \subseteq \{0, 1\}^n$  or integer programming with  $S := \{x \in \mathbb{Z}^n : Ax = b, l \leq x \leq u\}$  and  $l, u \in \mathbb{Z}^n$ , the set  $S$  is finite and the problem of unboundedness does not arise.

### Outline and Overview of Main Results and Applications

We now outline the structure of this monograph and provide a brief overview of what we consider to be our main results and main applications. The precise relevant definitions and statements of the theorems and corollaries mentioned here are provided in the relevant sections in the monograph body. As mentioned above, most of these results are adaptations or extensions of results from one of the papers [5,12,13,14,15,16,17,25,39,47,48,49,50,51]. The monograph gives many more applications and results that may turn out to be useful in future development of the theory of convex discrete optimization.

The rest of the monograph consists of five sections. While the results evolve from one section to the next, it is quite easy to read the sections independently of each other (while just browsing now and then for relevant definitions and results). Specifically, Sect. “**Convex Combinatorial Optimization and More**” uses definitions and the main result of Sect. “**Reducing Convex to Linear Discrete Optimization**”; Sect. “**Convex Integer Programming**” uses definitions and results from Sections “**Reducing Convex to Linear Discrete Optimization**” and “**Linear N-fold Integer Programming**”; and Sect. “**Multway Transportation Problems and Privacy in Statistical Databases**” uses the main results of Sections “**Linear N-fold Integer Programming**” and “**Convex Integer Programming**”.

In Sect. “**Reducing Convex to Linear Discrete Optimization**” we show how to reduce the convex discrete optimization problem over  $S \subset \mathbb{Z}^n$  to strongly polynomially many linear discrete optimization counterparts over  $S$ , provided that the convex hull  $\text{conv}(S)$  satisfies a suitable geometric condition, as follows.

**Theorem 1** *For every fixed  $d$ , the convex discrete optimization problem over any finite  $S \subset \mathbb{Z}^n$  presented by a linear discrete optimization oracle and endowed with a set covering all edge-directions of  $\text{conv}(S)$ , can be solved in strongly polynomial time.*

This result will be incorporated in the polynomial time algorithms for convex combinatorial optimization and convex integer programming to be developed in Sect. “**Convex Combinatorial Optimization and More**” and Sect. “**Convex Integer Programming**”.

In Sect. “**Convex Combinatorial Optimization and More**” we discuss convex combinatorial optimization. The main result is that convex combinatorial optimization over a set  $S \subseteq \{0, 1\}^n$  presented by a membership oracle can be solved in strongly polynomial time provided it is endowed with a set covering all edge-directions of  $\text{conv}(S)$ . In particular, the standard linear combinatorial optimization problem over  $S$  can be solved in strongly polynomial time as well.

**Theorem 2** *For every fixed  $d$ , the convex combinatorial optimization problem over any  $S \subseteq \{0, 1\}^n$  presented by a membership oracle and endowed with a set covering all edge-directions of the polytope  $\text{conv}(S)$ , can be solved in strongly polynomial time.*

An important application of Theorem 2 concerns convex matroid optimization.

**Corollary 1** *For every fixed  $d$ , convex combinatorial optimization over the family of bases of a matroid presented by membership oracle is strongly polynomial time solvable.*

In Sect. “**Linear N-fold Integer Programming**” we develop the theory of linear  $n$ -fold integer programming. As a consequence of this theory we are able to solve a broad class of linear integer programming problems in variable dimension in polynomial time, in contrast with the general intractability of linear integer programming. The main theorem here may seem a bit technical at a first glance, but is

really very natural and has many applications discussed in detail in Sect. “[Linear N-fold Integer Programming](#)”, Sect. “[Convex Integer Programming](#)” and Sect. “[Multiway Transportation Problems and Privacy in Statistical Databases](#)”. To state it we need a definition. Given an  $(r + s) \times t$  matrix  $A$ , let  $A_1$  be its  $r \times t$  sub-matrix consisting of the first  $r$  rows and let  $A_2$  be its  $s \times t$  sub-matrix consisting of the last  $s$  rows. We refer to  $A$  explicitly as  $(r + s) \times t$  matrix, since the definition below depends also on  $r$  and  $s$  and not only on the entries of  $A$ . The  $n$ -fold matrix of an  $(r + s) \times t$  matrix  $A$  is then defined to be the following  $(r + ns) \times nt$  matrix,

$$A^{(n)} := (\mathbf{1}_n \otimes A_1) \oplus (I_n \otimes A_2)$$

$$= \begin{pmatrix} A_1 & A_1 & A_1 & \cdots & A_1 \\ A_2 & 0 & 0 & \cdots & 0 \\ 0 & A_2 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & A_2 \end{pmatrix}.$$

Given now any  $n \in \mathbb{N}$ , lower and upper bounds  $l, u \in \mathbb{Z}_{\infty}^{nt}$  with  $\mathbb{Z}_{\infty} := \mathbb{Z} \cup \{\pm\infty\}$ , right-hand side  $b \in \mathbb{Z}^{r+ns}$ , and linear functional  $wx$  with  $w \in \mathbb{Z}^{nt}$ , the corresponding linear  $n$ -fold integer programming problem is the following program in variable dimension  $nt$ ,

$$\max \{wx : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\}.$$

The main theorem of Sect. “[Linear N-fold Integer Programming](#)” asserts that such integer programs are polynomial time solvable.

**Theorem 3** *For every fixed  $(r + s) \times t$  integer matrix  $A$ , the linear  $n$ -fold integer programming problem with any  $n, l, u, b$ , and  $w$  can be solved in polynomial time.*

Theorem 3 has very important applications to high-dimensional transportation problems which are discussed in Sect. “[Three-Way Line-Sum Transportation Problems](#)” and in more detail in Sect. “[Multiway Transportation Problems and Privacy in Statistical Databases](#)”. Another major application concerns bin packing problems, where items of several types are to be packed into bins so as to maximize packing utility subject to weight constraints. This includes as a special case the classical cutting-stock problem of [27]. These are

discussed in detail in Sect. “[Packing Problems and Cutting-Stock](#)”.

**Corollary 2** *For every fixed number  $t$  of types and type weights  $v_1, \dots, v_t$ , the corresponding integer bin packing and cutting-stock problems are polynomial time solvable.*

In Sect. “[Convex Integer Programming](#)” we discuss convex integer programming, where the feasible set  $S$  is presented as the set of integer points satisfying a given system of linear inequalities. In particular, we consider convex integer programming over  $n$ -fold systems for any fixed (but arbitrary)  $(r + s) \times t$  matrix  $A$ , where, given  $n \in \mathbb{N}$ , vectors  $l, u \in \mathbb{Z}_{\infty}^{nt}$ ,  $b \in \mathbb{Z}^{r+ns}$  and  $w_1, \dots, w_d \in \mathbb{Z}^{nt}$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$ , the problem is

$$\max \{c(w_1x, \dots, w_dx) : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\}.$$

The main theorem of Sect. “[Convex Integer Programming](#)” is the following extension of Theorem 3, asserting that convex integer programming over  $n$ -fold systems is polynomial time solvable as well.

**Theorem 4** *For every fixed  $d$  and  $(r + s) \times t$  integer matrix  $A$ , convex  $n$ -fold integer programming with any  $n, l, u, b, w_1, \dots, w_d$ , and  $c$  can be solved in polynomial time.*

Theorem 4 broadly extends the class of objective functions that can be efficiently maximized over  $n$ -fold systems. Thus, all applications discussed in Sect. “[Some Applications](#)” automatically extend accordingly. These include convex high-dimensional transportation problems and convex bin packing and cutting-stock problems, which are discussed in detail in Sect. “[Transportation Problems and Packing Problems](#)” and Sect. “[Multiway Transportation Problems and Privacy in Statistical Databases](#)”.

Another important application of Theorem 4 concerns vector partitioning problems which have applications in many areas including load balancing, circuit layout, ranking, cluster analysis, inventory, and reliability, see e. g. [7,9,25,39,50] and the references therein. The problem is to partition  $n$  items among  $p$  players so as to maximize social utility. With each item is associated a  $k$ -dimensional vector representing its utility under  $k$  criteria. The social utility of a partition is a convex function of the sums of vectors of items that each

player receives. In the constrained version of the problem, there are also restrictions on the number of items each player can receive. We have the following consequence of Theorem 4; more details on this application are in Sect. “[Vector Partitioning and Clustering](#)”.

**Corollary 3** *For every fixed number  $p$  of players and number  $k$  of criteria, the constrained and unconstrained vector partition problems with any item vectors, convex utility, and constraints on the number of item per player, are polynomial time solvable.*

In the last Sect. “[Multiway Transportation Problems and Privacy in Statistical Databases](#)” we discuss multiway (high-dimensional) transportation problems and secure statistical data disclosure. Multiway transportation problems form a very important class of discrete optimization problems and have been used and studied extensively in the operations research and mathematical programming literature, as well as in the statistics literature in the context of secure statistical data disclosure and management by public agencies, see e. g. [4,6,11,18,19,42,43,53,60,62] and the references therein. The feasible points in a transportation problem are the multiway tables (“contingency tables” in statistics) such that the sums of entries over some of their lower dimensional sub-tables such as lines or planes (“margins” in statistics) are specified. We completely settle the algorithmic complexity of treating multiway tables and discuss the applications to transportation problems and secure statistical data disclosure, as follows.

In Sect. “[The Universality Theorem](#)” we show that “short” 3-way transportation problems, over  $r \times c \times 3$  tables with variable number  $r$  of rows and variable number  $c$  of columns but fixed small number 3 of layers (hence “short”), are *universal* in that every integer programming problem is such a problem (see Sect. “[The Universality Theorem](#)” for the precise stronger statement and for more details).

**Theorem 5** *Every linear integer programming problem  $\max\{cy : y \in \mathbb{N}^n : Ay = b\}$  is polynomial time representable as a short 3-way line-sum transportation problem*

$$\max \left\{ wx : x \in \mathbb{N}^{r \times c \times 3} : \sum_i x_{i,j,k} = z_{j,k}, \right. \\ \left. \sum_j x_{i,j,k} = v_{i,k}, \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

In Sect. “[The Complexity of the Multiway Transportation Problem](#)” we discuss  $k$ -way transportation problems of any dimension  $k$ . We provide the first polynomial time algorithm for convex and linear “long” ( $k + 1$ )-way transportation problems, over  $m_1 \times \cdots \times m_k \times n$  tables, with  $k$  and  $m_1, \dots, m_k$  fixed (but arbitrary), and variable number  $n$  of layers (hence “long”). This is best possible in view of Theorem 21. Our algorithm works for any *hierarchical collection of margins*: this captures common margin collections such as all line-sums, all plane-sums, and more generally all  $h$ -flat sums for any  $0 \leq h \leq k$  (see Sect. “[Tables and Margins](#)” for more details). We point out that even for the very special case of linear integer transportation over  $3 \times 3 \times n$  tables with specified line-sums, our polynomial time algorithm is the only one known. We prove the following statement.

**Corollary 4** *For every fixed  $d, k, m_1, \dots, m_k$  and family  $\mathcal{F}$  of subsets of  $\{1, \dots, k+1\}$  specifying a hierarchical collection of margins, the convex (and in particular linear) long transportation problem over  $m_1 \times \cdots \times m_k \times n$  tables is polynomial time solvable.*

In our last subsection Sect. “[Privacy and Entry-Uniqueness](#)” we discuss an important application concerning privacy in statistical databases. It is a common practice in the disclosure of a multiway table containing sensitive data to release some table margins rather than the table itself. Once the margins are released, the security of any specific entry of the table is related to the set of possible values that can occur in that entry in any table having the same margins as those of the source table in the data base. In particular, if this set consists of a unique value, that of the source table, then this entry can be exposed and security can be violated. We show that for multiway tables where one category is significantly richer than the others, that is, when each sample point can take many values in one category and only few values in the other categories, it is possible to check entry-uniqueness in polynomial time, allowing disclosing agencies to make learned decisions on secure disclosure.

**Corollary 5** *For every fixed  $k, m_1, \dots, m_k$  and family  $\mathcal{F}$  of subsets of  $\{1, \dots, k+1\}$  specifying a hierarchical collection of margins to be disclosed, it can be decided in polynomial time whether any specified entry  $x_{i_1, \dots, i_{k+1}}$  is the same in all long  $m_1 \times \cdots \times m_k \times n$  tables with the disclosed margins, and hence at risk of exposure.*

## Terminology and Complexity

We use  $\mathbb{R}$  for the reals,  $\mathbb{R}_+$  for the nonnegative reals,  $\mathbb{Z}$  for the integers, and  $\mathbb{N}$  for the nonnegative integers. The sign of a real number  $r$  is denoted by  $\text{sign}(r) \in \{0, -1, 1\}$  and its absolute value is denoted by  $|r|$ . The  $i$ th standard unit vector in  $\mathbb{R}^n$  is denoted by  $\mathbf{1}_i$ . The *support* of  $x \in \mathbb{R}^n$  is the index set  $\text{supp}(x) := \{i : x_i \neq 0\}$  of nonzero entries of  $x$ . The *indicator* of a subset  $I \subseteq \{1, \dots, n\}$  is the vector  $\mathbf{1}_I := \sum_{i \in I} \mathbf{1}_i$  so that  $\text{supp}(\mathbf{1}_I) = I$ . When several vectors are indexed by subscripts,  $w_1, \dots, w_d \in \mathbb{R}^n$ , their entries are indicated by pairs of subscripts,  $w_i = (w_{i,1}, \dots, w_{i,n})$ . When vectors are indexed by superscripts,  $x^1, \dots, x^k \in \mathbb{R}^n$ , their entries are indicated by subscripts,  $x^i = (x_{i,1}^i, \dots, x_{i,n}^i)$ . The integer lattice  $\mathbb{Z}^n$  is naturally embedded in  $\mathbb{R}^n$ . The space  $\mathbb{R}^n$  is endowed with the standard inner product which, for  $w, x \in \mathbb{R}^n$ , is given by  $wx := \sum_{i=1}^n w_i x_i$ . Vectors  $w$  in  $\mathbb{R}^n$  will also be regarded as linear functionals on  $\mathbb{R}^n$  via the inner product  $wx$ . Thus, we refer to elements of  $\mathbb{R}^n$  as points, vectors, or linear functionals, as will be appropriate from the context. The *convex hull* of a set  $S \subseteq \mathbb{R}^n$  is denoted by  $\text{conv}(S)$  and the set of *vertices* of a polyhedron  $P \subseteq \mathbb{R}^n$  is denoted by  $\text{vert}(P)$ . In linear discrete optimization over  $S \subseteq \mathbb{Z}^n$ , the *facets* of  $\text{conv}(S)$  play an important role, see Chvátal [10] and the references therein for earlier work, and Grötschel, Lovász and Schrijver [31,45] for the later culmination in the equivalence of separation and linear optimization via the ellipsoid method of Yudin and Nemirovskii [63]. As will turn out in Sect. “Reducing Convex to Linear Discrete Optimization”, in convex discrete optimization over  $S$ , the *edges* of  $\text{conv}(S)$  play an important role (most significantly in a way which is *not* related to the Hirsch conjecture discussed in [41]). We therefore use extensively convex polytopes, for which we follow the terminology of [32,65].

We often assume that the feasible set  $S \subseteq \mathbb{Z}^n$  is finite. We then define its *radius* to be its  $l_\infty$  radius  $\rho(S) := \max\{\|x\|_\infty : x \in S\}$  where, as usual,  $\|x\|_\infty := \max_{i=1}^n |x_i|$ . In other words,  $\rho(S)$  is the smallest  $\rho \in \mathbb{N}$  such that  $S$  is contained in the cube  $[-\rho, \rho]^n$ .

Our algorithms are applied to rational data only, and the time complexity is as in the standard Turing machine model, see e.g. [1,26,55]. The input typically consists of rational (usually integer) numbers, vectors, matrices, and finite sets of such objects. The *bi-*

*nary length* of an integer number  $z \in \mathbb{Z}$  is defined to be the number of bits in its binary representation,  $\langle z \rangle := 1 + \lceil \log_2(|z| + 1) \rceil$  (with the extra bit for the sign). The length of a rational number presented as a fraction  $r = \frac{p}{q}$  with  $p, q \in \mathbb{Z}$  is  $\langle r \rangle := \langle p \rangle + \langle q \rangle$ . The length of an  $m \times n$  matrix  $A$  (and in particular of a vector) is the sum  $\langle A \rangle := \sum_{i,j} \langle a_{i,j} \rangle$  of the lengths of its entries. Note that the length of  $A$  is no smaller than the number of entries,  $\langle A \rangle \geq mn$ . Therefore, when  $A$  is, say, part of an input to an algorithm, with  $m, n$  variable, the length  $\langle A \rangle$  already incorporates  $mn$ , and so we will typically not account additionally for  $m, n$  directly. But sometimes, especially in results related to  $n$ -fold integer programming, we will also emphasize  $n$  as part of the input length. Similarly, the length of a finite set  $E$  of numbers, vectors or matrices is the sum of lengths of its elements and hence, since  $\langle E \rangle \geq |E|$ , automatically accounts for its cardinality.

Some input numbers affect the running time of some algorithms through their unary presentation, resulting in so-called “pseudo polynomial” running time. The *unary length* of an integer number  $z \in \mathbb{Z}$  is the number  $|z| + 1$  of bits in its unary representation (again, an extra bit for the sign). The unary length of a rational number, vector, matrix, or finite set of such objects are defined again as the sums of lengths of their numerical constituents, and is again no smaller than the number of such numerical constituents.

When studying convex and linear integer programming in Sect. “Linear  $N$ -fold Integer Programming” and Sect. “Convex Integer Programming” we sometimes have lower and upper bound vectors  $l, u$  with entries in  $\mathbb{Z}_\infty := \mathbb{Z} \uplus \{\pm\infty\}$ . Both binary and unary lengths of a  $\pm\infty$  entry are constant, say 3 by encoding  $\pm\infty := \pm“00”$ .

To make the input encoding precise, we introduce the following notation. In every algorithmic statement we describe explicitly the input encoding, by listing in square brackets all input objects affecting the running time. Unary encoded objects are listed directly whereas binary encoded objects are listed in terms of their length. For example, as is often the case, if the input of an algorithm consists of binary encoded vectors (linear functionals)  $w_1, \dots, w_d \in \mathbb{Z}^n$  and unary encoded integer  $\rho \in \mathbb{N}$  (bounding the radius  $\rho(S)$  of the feasible set) then we will indicate that the input is *encoded as*  $[\rho, \langle w_1, \dots, w_d \rangle]$ .

Some of our algorithms are strongly polynomial time in the sense of [59]. For this, part of the input is regarded as “special”. An algorithm is then *strongly polynomial time* if it is polynomial time in the usual Turing sense with respect to all input, and in addition, the number of arithmetic operations (additions, subtractions, multiplications, divisions, and comparisons) it performs is polynomial in the special part of the input. To make this precise, we extend our input encoding notation above by splitting the square bracketed expression indicating the input encoding into a “left” side and a “right” side, separated by semicolon, where the entire input is described on the right and the special part of the input on the left. For example, Theorem 1, asserting that the algorithm underlying it is strongly polynomial with data *encoded as*  $[n, |E|; \langle \rho(S), w_1, \dots, w_d, E \rangle]$ , where  $\rho(S) \in \mathbb{N}$ ,  $w_1, \dots, w_d \in \mathbb{Z}^n$  and  $E \subset \mathbb{Z}^n$ , means that the running time is polynomial in the binary length of  $\rho(S)$ ,  $w_1, \dots, w_d$ , and  $E$ , and the number of arithmetic operations is polynomial in  $n$  and the cardinality  $|E|$ , which constitute the special part of the input.

Often, as in [31], part of the input is presented by oracles. Then the running time and the number of arithmetic operations count also the number of oracle queries. An oracle algorithm is *polynomial time* if its running time, including the number of oracle queries, and the manipulations of numbers, some of which are answers to oracle queries, is polynomial in the length of the input encoding. An oracle algorithm is *strongly polynomial time* (with specified input encoding as above), if it is polynomial time in the entire input (on the “right”), and in addition, the number of arithmetic operations it performs (including oracle queries) is polynomial in the special part of the input (on the “left”).

### Reducing Convex to Linear Discrete Optimization

In this section we show that when suitable auxiliary geometric information about the convex hull  $\text{conv}(S)$  of a finite set  $S \subseteq \mathbb{Z}^n$  is available, the convex discrete optimization problem over  $S$  can be reduced to the solution of strongly polynomially many linear discrete optimization counterparts over  $S$ . This result will be incorporated into the polynomial time algorithms developed in Sect. “[Convex Combinatorial Optimization and More](#)”

and Sect. “[Convex Integer Programming](#)” for convex combinatorial optimization and convex integer programming respectively. In Sect. “[Edge-Directions and Zonotopes](#)” we provide some preliminaries on edge-directions and zonotopes. In Sect. “[Strongly Polynomial Reduction of Convex to Linear Discrete Optimization](#)” we prove the reduction which is the main result of this section. In Sect. “[Pseudo Polynomial Reduction when Edge-Directions are not Available](#)” we prove a pseudo polynomial reduction for any finite set.

### Edge-Directions and Zonotopes

We begin with some terminology and facts that play an important role in the sequel. A *direction* of an edge (1-dimensional face)  $e = [u, v]$  of a polytope  $P$  is any nonzero scalar multiple of  $u - v$ . A set of vectors  $E$  *covers all edge-directions* of  $P$  if it contains a direction of each edge of  $P$ . The *normal cone* of a polytope  $P \subset \mathbb{R}^n$  at its face  $F$  is the (relatively open) cone  $C_P^F$  of those linear functionals  $h \in \mathbb{R}^n$  which are maximized over  $P$  precisely at points of  $F$ . A polytope  $Z$  is a *refinement* of a polytope  $P$  if the normal cone of every vertex of  $Z$  is contained in the normal cone of some vertex of  $P$ . If  $Z$  refines  $P$  then, moreover, the closure of each normal cone of  $P$  is the union of closures of normal cones of  $Z$ . The *zonotope* generated by a set of vectors  $E = \{e_1, \dots, e_m\}$  in  $\mathbb{R}^d$  is the following polytope, which is the projection by  $E$  of the cube  $[-1, 1]^m$  into  $\mathbb{R}^d$ ,

$$\begin{aligned} Z &:= \text{zone}(E) \\ &:= \text{conv} \left\{ \sum_{i=1}^m \lambda_i e_i : \lambda_i = \pm 1 \right\} \subset \mathbb{R}^d. \end{aligned}$$

The following fact goes back to Minkowski, see [32].

**Lemma 1** *Let  $P$  be a polytope and let  $E$  be a finite set that covers all edge-directions of  $P$ . Then the zonotope  $Z := \text{zone}(E)$  generated by  $E$  is a refinement of  $P$ .*

*Proof* Consider any vertex  $u$  of  $Z$ . Then  $u = \sum_{e \in E} \lambda_e e$  for suitable  $\lambda_e = \pm 1$ . Thus, the normal cone  $C_Z^u$  consists of those  $h$  satisfying  $h \lambda_e e > 0$  for all  $e$ . Pick any  $\hat{h} \in C_Z^u$  and let  $v$  be a vertex of  $P$  at which  $\hat{h}$  is maximized over  $P$ . Consider any edge  $[v, w]$  of  $P$ . Then  $v - w = \alpha_e e$  for some scalar  $\alpha_e \neq 0$  and some  $e \in E$ , and  $0 \leq \hat{h}(v - w) = \hat{h} \alpha_e e$ , implying  $\alpha_e \lambda_e > 0$ .

It follows that every  $h \in C_Z^u$  satisfies  $h(v - w) > 0$  for every edge of  $P$  containing  $v$ . Therefore  $h$  is maximized over  $P$  uniquely at  $v$  and hence is in the cone  $C_P^v$  of  $P$  at  $v$ . This shows  $C_Z^u \subseteq C_P^v$ . Since  $u$  was arbitrary, it follows that the normal cone of every vertex of  $Z$  is contained in the normal cone of some vertex of  $P$ .  $\square$

The next lemma provides bounds on the number of vertices of any zonotope and on the algorithmic complexity of constructing its vertices, each vertex along with a linear functional maximized over the zonotope uniquely at that vertex. The bound on the number of vertices has been rediscovered many times over the years. An early reference is [33], stated in the dual form of 2-partitions. A more general treatment is [64]. Recent extensions to  $p$ -partitions for any  $p$  are in [3,39], and to Minkowski sums of arbitrary polytopes are in [29]. Interestingly, already in [33], back in 1967, the question was raised about the algorithmic complexity of the problem; this is now settled in [20,21] (the latter reference correcting the former). We state the precise bounds on the number of vertices and arithmetic complexity, but will need later only that for any fixed  $d$  the bounds are polynomial in the number of generators. Therefore, below we only outline a proof that the bounds are polynomial. Complete details are in the above references.

**Lemma 2** *The number of vertices of any zonotope  $Z := \text{zone}(E)$  generated by a set  $E$  of  $m$  vectors in  $\mathbb{R}^d$  is at most  $2 \sum_{k=0}^{d-1} \binom{m-1}{k}$ . For every fixed  $d$ , there is a strongly polynomial time algorithm that, given  $E \subset \mathbb{Z}^d$ , encoded as  $[m := |E|; \langle E \rangle]$ , outputs every vertex  $v$  of  $Z := \text{zone}(E)$  along with a linear functional  $h_v \in \mathbb{Z}^d$  maximized over  $Z$  uniquely at  $v$ , using  $O(m^{d-1})$  arithmetics operations for  $d \geq 3$  and  $O(m^d)$  for  $d \leq 2$ .*

*Proof* We only outline a proof that, for every fixed  $d$ , the polynomial bounds  $O(m^{d-1})$  on the number of vertices and  $O(m^d)$  on the arithmetic complexity hold. We assume that  $E$  linearly spans  $\mathbb{R}^d$  (else the dimension can be reduced) and is generic, that is, no  $d$  points of  $E$  lie on a linear hyperplane (one containing the origin). In particular,  $0 \notin E$ . The same bound for arbitrary  $E$  then follows using a perturbation argument (cf. [39]).

Each oriented linear hyperplane  $H = \{x \in \mathbb{R}^d : hx = 0\}$  with  $h \in \mathbb{R}^d$  nonzero induces a partition

of  $E$  by  $E = H^- \uplus H^0 \uplus H^+$ , with  $H^- := \{e \in E : he < 0\}$ ,  $E^0 := E \cap H$ , and  $H^+ := \{e \in E : he > 0\}$ . The vertices of  $Z = \text{zone}(E)$  are in bijection with ordered 2-partitions of  $E$  induced by such hyperplanes that avoid  $E$ . Indeed, if  $E = H^- \uplus H^+$  then the linear functional  $h_v := h$  defining  $H$  is maximized over  $Z$  uniquely at the vertex  $v := \sum\{e : e \in H^+\} - \sum\{e : e \in H^-\}$  of  $Z$ .

We now show how to enumerate all such 2-partitions and hence vertices of  $Z$ . Let  $M$  be any of the  $\binom{m}{d-1}$  subsets of  $E$  of size  $d - 1$ . Since  $E$  is generic,  $M$  is linearly independent and spans a unique linear hyperplane  $\text{lin}(M)$ . Let  $\hat{H} = \{x \in \mathbb{R}^d : \hat{h}x = 0\}$  be one of the two orientations of the hyperplane  $\text{lin}(M)$ . Note that  $\hat{H}^0 = M$ . Finally, let  $L$  be any of the  $2^{d-1}$  subsets of  $M$ . Since  $M$  is linearly independent, there is a  $g \in \mathbb{R}^d$  which linearly separates  $L$  from  $M \setminus L$ , namely, satisfies  $gx < 0$  for all  $x \in L$  and  $gx > 0$  for all  $x \in M \setminus L$ . Furthermore, there is a sufficiently small  $\epsilon > 0$  such that the oriented hyperplane  $H := \{x \in \mathbb{R}^d : hx = 0\}$  defined by  $h := \hat{h} + \epsilon g$  avoids  $E$  and the 2-partition induced by  $H$  satisfies  $H^- = \hat{H}^- \uplus L$  and  $H^+ = \hat{H}^+ \uplus (M \setminus L)$ . The corresponding vertex of  $Z$  is  $v := \sum\{e : e \in H^+\} - \sum\{e : e \in H^-\}$  and the corresponding linear functional which is maximized over  $Z$  uniquely at  $v$  is  $h_v := h = \hat{h} + \epsilon g$ .

We claim that any ordered 2-partition arises that way from some  $M$ , some orientation  $\hat{H}$  of  $\text{lin}(M)$ , and some  $L$ . Indeed, consider any oriented linear hyperplane  $\hat{H}$  avoiding  $E$ . It can be perturbed to a suitable oriented  $\hat{H}$  that touches precisely  $d - 1$  points of  $E$ . Put  $M := \hat{H}^0$  so that  $\hat{H}$  coincides with one of the two orientations of the hyperplane  $\text{lin}(M)$  spanned by  $M$ , and put  $L := \hat{H}^- \cap M$ . Let  $H$  be an oriented hyperplane obtained from  $M$ ,  $\hat{H}$  and  $L$  by the above procedure. Then the ordered 2-partition  $E = H^- \uplus H^+$  induced by  $H$  coincides with the ordered 2-partition  $E = \hat{H}^- \uplus \hat{H}^+$  induced by  $\hat{H}$ .

Since there are  $\binom{m}{d-1}$  many  $(d - 1)$ -subsets  $M \subseteq E$ , two orientations  $\hat{H}$  of  $\text{lin}(M)$ , and  $2^{d-1}$  subsets  $L \subseteq M$ , and  $d$  is fixed, the total number of 2-partitions and hence also the total number of vertices of  $Z$  obey the upper bound  $2^d \binom{m}{d-1} = O(m^{d-1})$ . Furthermore, for each choice of  $M$ ,  $\hat{H}$  and  $L$ , the linear functional  $\hat{h}$  defining  $\hat{H}$ , as well as  $g$ ,  $\epsilon$ ,  $h_v = h = \hat{h} + \epsilon g$ , and the vertex  $v = \sum\{e : e \in H^+\} - \sum\{e : e \in H^-\}$  of  $Z$  at which  $h_v$  is uniquely maximized over  $Z$ , can all be com-

puted using  $O(m)$  arithmetic operations. This shows the claimed bound  $O(m^d)$  on the arithmetic complexity.  $\square$

We conclude with a simple fact about edge-directions of projections of polytopes.

**Lemma 3** *If  $E$  covers all edge-directions of a polytope  $P$ , and  $Q := \omega(P)$  is the image of  $P$  under a linear map  $\omega: \mathbb{R}^n \rightarrow \mathbb{R}^d$ , then  $\omega(E)$  covers all edge-directions of  $Q$ .*

*Proof* Let  $f$  be a direction of an edge  $[x, y]$  of  $Q$ . Consider the face  $F := \omega^{-1}([x, y])$  of  $P$ . Let  $V$  be the set of vertices of  $F$  and let  $U = \{u \in V : \omega(u) = x\}$ . Then for some  $u \in U$  and  $v \in V \setminus U$ , there must be an edge  $[u, v]$  of  $F$ , and hence of  $P$ . Then  $\omega(v) \in (x, y]$  hence  $\omega(v) = x + \alpha f$  for some  $\alpha \neq 0$ . Therefore, with  $e := \frac{1}{\alpha}(v - u)$ , a direction of the edge  $[u, v]$  of  $P$ , we find that  $f = \frac{1}{\alpha}(\omega(v) - \omega(u)) = \omega(e) \in \omega(E)$ .  $\square$

### Strongly Polynomial Reduction of Convex to Linear Discrete Optimization

A linear discrete optimization oracle for a set  $S \subseteq \mathbb{Z}^n$  is one that, queried on  $w \in \mathbb{Z}^n$ , either returns an optimal solution to the linear discrete optimization problem over  $S$ , that is, an  $x^* \in S$  satisfying  $wx^* = \max\{wx : x \in S\}$ , or asserts that none exists, that is, either the problem is infeasible or the objective function is unbounded. We now show that a set  $E$  covering all edge-directions of the polytope  $\text{conv}(S)$  underlying a convex discrete optimization problem over a finite set  $S \subset \mathbb{Z}^n$  allows to solve it by solving polynomially many linear discrete optimization counterparts over  $S$ . The following theorem extends and unifies the corresponding reductions in [49] and [12] for convex combinatorial optimization and convex integer programming respectively. Recall from Sect. “Terminology and Complexity” that the *radius* of a finite set  $S \subset \mathbb{Z}^n$  is defined to be  $\rho(S) := \max\{|x_i| : x \in S, i = 1, \dots, n\}$ .

**Theorem 6** *For every fixed  $d$  there is a strongly polynomial time algorithm that, given finite set  $S \subset \mathbb{Z}^n$  presented by a linear discrete optimization oracle, integer vectors  $w_1, \dots, w_d \in \mathbb{Z}^n$ , set  $E \subset \mathbb{Z}^n$  covering all edge-directions of  $\text{conv}(S)$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[n, |E|; \{\rho(S), w_1, \dots, w_d, E\}]$ , solves the convex dis-*

*crete optimization problem*

$$\max \{c(w_1x, \dots, w_dx) : x \in S\}.$$

*Proof* First, query the linear discrete optimization oracle presenting  $S$  on the trivial linear functional  $w = 0$ . If the oracle asserts that there is no optimal solution then  $S$  is empty so terminate the algorithm asserting that no optimal solution exists to the convex discrete optimization problem either. So assume the problem is feasible. Let  $P := \text{conv}(S) \subset \mathbb{R}^n$  and  $Q := \{(w_1x, \dots, w_dx) : x \in P\} \subset \mathbb{R}^d$ . Then  $Q$  is a projection of  $P$ , and hence by Lemma 3 the projection  $D := \{(w_1e, \dots, w_de) : e \in E\}$  of the set  $E$  is a set covering all edge-directions of  $Q$ . Let  $Z := \text{zone}(D) \subset \mathbb{R}^d$  be the zonotope generated by  $D$ . Since  $d$  is fixed, by Lemma 2 we can produce in strongly polynomial time all vertices of  $Z$ , every vertex  $v$  along with a linear functional  $h_v \in \mathbb{Z}^d$  maximized over  $Z$  uniquely at  $v$ . For each of these polynomially many  $h_v$ , repeat the following procedure. Define a vector  $g_v \in \mathbb{Z}^n$  by  $g_{v,j} := \sum_{i=1}^d w_{i,j} h_{v,i}$  for  $j = 1, \dots, n$ . Now query the linear discrete optimization oracle presenting  $S$  on the linear functional  $w := g_v \in \mathbb{Z}^n$ . Let  $x_v \in S$  be the optimal solution obtained from the oracle, and let  $z_v := (w_1x_v, \dots, w_dx_v) \in Q$  be its projection. Since  $P = \text{conv}(S)$ , we have that  $x_v$  is also a maximizer of  $g_v$  over  $P$ . Since for every  $x \in P$  and its projection  $z := (w_1x, \dots, w_dx) \in Q$  we have  $h_v z = g_v x$ , we conclude that  $z_v$  is a maximizer of  $h_v$  over  $Q$ . Now we claim that each vertex  $u$  of  $Q$  equals some  $z_v$ . Indeed, since  $Z$  is a refinement of  $Q$  by Lemma 1, it follows that there is some vertex  $v$  of  $Z$  such that  $h_v$  is maximized over  $Q$  uniquely at  $u$ , and therefore  $u = z_v$ . Since  $c(w_1x, \dots, w_dx)$  is convex on  $\mathbb{R}^n$  and  $c$  is convex on  $\mathbb{R}^d$ , we find that

$$\begin{aligned} & \max_{x \in S} c(w_1x, \dots, w_dx) \\ &= \max_{x \in P} c(w_1x, \dots, w_dx) \\ &= \max_{z \in Q} c(z) \\ &= \max\{c(u) : u \text{ vertex of } Q\} \\ &= \max\{c(z_v) : v \text{ vertex of } Z\}. \end{aligned}$$

Using the comparison oracle of  $c$ , find a vertex  $v$  of  $Z$  attaining maximum value  $c(z_v)$ , and output  $x_v \in S$ , an optimal solution to the convex discrete optimization problem.  $\square$

### Pseudo Polynomial Reduction when Edge-Directions Are not Available

Theorem 6 reduces convex discrete optimization to polynomially many linear discrete optimization counterparts when a set covering all edge-directions of the underlying polytope is available. However, often such a set is not available (see e.g. [8] for the important case of bipartite matching). We now show how to reduce convex discrete optimization to many linear discrete optimization counterparts when a set covering all edge-directions is not offhand available. In the absence of such a set, the problem is much harder, and the algorithm below is polynomially bounded only in the unary length of the radius  $\rho(S)$  and of the linear functionals  $w_1, \dots, w_d$ , rather than in their binary length  $\langle \rho(S), w_1, \dots, w_d \rangle$  as in the algorithm of Theorem 6. Moreover, an upper bound  $\rho \geq \rho(S)$  on the radius of  $S$  is required to be given explicitly in advance as part of the input.

**Theorem 7** *For every fixed  $d$  there is a polynomial time algorithm that, given finite set  $S \subseteq \mathbb{Z}^n$  presented by a linear discrete optimization oracle, integer  $\rho \geq \rho(S)$ , vectors  $w_1, \dots, w_d \in \mathbb{Z}^n$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[\rho, w_1, \dots, w_d]$ , solves the convex discrete optimization problem*

$$\max \{c(w_1x, \dots, w_dx) : x \in S\}.$$

*Proof* Let  $P := \text{conv}(S) \subset \mathbb{R}^n$ , let  $T := \{(w_1x, \dots, w_dx) : x \in S\}$  be the projection of  $S$  by  $w_1, \dots, w_d$ , and let  $Q := \text{conv}(T) \subset \mathbb{R}^d$  be the corresponding projection of  $P$ . Let  $r := n\rho \max_{i=1}^d \|w_i\|_\infty$  and let  $G := \{-r, \dots, -1, 0, 1, \dots, r\}^d$ . Then  $T \subseteq G$  and the number  $(2r+1)^d$  of points of  $G$  is polynomially bounded in the input as encoded.

Let  $D := \{u - v : u, v \in G, u \neq v\}$  be the set of differences of pairs of distinct point of  $G$ . It covers all edge-directions of  $Q$  since  $\text{vert}(Q) \subseteq T \subseteq G$ . Moreover, the number of points of  $D$  is less than  $(2r+1)^{2d}$  and hence polynomial in the input. Now invoke the algorithm of Theorem 6: while the algorithm requires a set  $E$  covering all edge-directions of  $P$ , it needs  $E$  only to compute a set  $D$  covering all edge-directions of the projection  $Q$  (see proof of Theorem 6, which here is computed directly).  $\square$

### Convex Combinatorial Optimization and More

In this section we discuss convex combinatorial optimization. The main result is that convex combinatorial optimization over a set  $S \subseteq \{0, 1\}^n$  presented by a membership oracle can be solved in strongly polynomial time provided it is endowed with a set covering all edge-directions of  $\text{conv}(S)$ . In particular, the standard linear combinatorial optimization problem over  $S$  can be solved in strongly polynomial time as well. In Sect. “**From Membership to Linear Optimization**” we provide some preparatory statements involving various oracle presentation of the feasible set  $S$ . In Sect. “**Linear and Convex Combinatorial Optimization in Strongly Polynomial Time**” we combine these preparatory statements with Theorem 6 and prove the main result of this section. An extension to arbitrary finite sets  $S \subset \mathbb{Z}^n$  endowed with edge-directions is established in Sect. “**Linear and Convex Discrete Optimization over any Set in Pseudo Polynomial Time**”. We conclude with some applications in Sect. “**Some Applications**”.

As noted in the introduction, when  $S$  is contained in  $\{0, 1\}^n$  we refer to discrete optimization over  $S$  also as *combinatorial optimization* over  $S$ , to emphasize that  $S$  typically represents a family  $\mathcal{F} \subseteq 2^N$  of subsets of a ground set  $N := \{1, \dots, n\}$  possessing some combinatorial property of interest (for instance, the family of bases of a matroid over  $N$ , see Sect. “**Matroids and Maximum Norm Spanning Trees**”). The convex combinatorial optimization problem then also has the following interpretation (taken in [47,49]). We are given a weighting  $\omega : N \rightarrow \mathbb{Z}^d$  of elements of the ground set by  $d$ -dimensional integer vectors. We interpret the weight vector  $\omega(j) \in \mathbb{Z}^d$  of element  $j$  as representing its value under  $d$  criteria (e.g., if  $N$  is the set of edges in a network then such criteria may include profit, reliability, flow velocity, etc.). The weight of a subset  $F \subseteq N$  is the sum  $\omega(F) := \sum_{j \in F} \omega(j)$  of weights of its elements, representing the total value of  $F$  under the  $d$  criteria. Now, given a convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$ , the objective function value of  $F \subseteq N$  is the “convex balancing”  $c(\omega(F))$  of the values of the weight vector of  $F$ . The convex combinatorial optimization problem is to find a family member  $F \in \mathcal{F}$  maximizing  $c(\omega(F))$ . The usual linear combinatorial optimization problem over  $\mathcal{F}$  is the special case of  $d = 1$  and  $c$  the identity on

$\mathbb{R}$ . To cast a problem of that form in our usual setup just let  $S := \{\mathbf{1}_F : F \in \mathcal{F}\} \subseteq \{0, 1\}^n$  be the set of indicators of members of  $\mathcal{F}$  and define weight vectors  $w_1, \dots, w_d \in \mathbb{Z}^n$  by  $w_{i,j} := \omega(j)_i$  for  $i = 1, \dots, d$  and  $j = 1, \dots, n$ .

### From Membership to Linear Optimization

A *membership oracle* for a set  $S \subseteq \mathbb{Z}^n$  is one that, queried on  $x \in \mathbb{Z}^n$ , asserts whether or not  $x \in S$ . An *augmentation oracle* for  $S$  is one that, queried on  $x \in S$  and  $w \in \mathbb{Z}^n$ , either returns an  $\hat{x} \in S$  with  $w\hat{x} > wx$ , i. e. a better point of  $S$ , or asserts that none exists, i. e.  $x$  is optimal for the linear discrete optimization problem over  $S$ .

A membership oracle presentation of  $S$  is very broad and available in all reasonable applications, but reveals little information on  $S$ , making it hard to use. However, as we now show, the edge-directions of  $\text{conv}(S)$  allow to convert membership to augmentation.

**Lemma 4** *There is a strongly polynomial time algorithm that, given set  $S \subseteq \{0, 1\}^n$  presented by a membership oracle,  $x \in S$ ,  $w \in \mathbb{Z}^n$ , and set  $E \subset \mathbb{Z}^n$  covering all edge-directions of the polytope  $\text{conv}(S)$ , encoded as  $[n, |E|; \langle x, w, E \rangle]$ , either returns a better point  $\hat{x} \in S$ , that is, one satisfying  $w\hat{x} > wx$ , or asserts that none exists.*

*Proof* Each edge of  $P := \text{conv}(S)$  is the difference of two  $\{0, 1\}$ -vectors. Therefore, each edge direction of  $P$  is, up to scaling, a  $\{-1, 0, 1\}$ -vector. Thus, scaling  $e := \frac{1}{\|e\|_\infty} e$  and  $e := -e$  if necessary, we may and will assume that  $e \in \{-1, 0, 1\}^n$  and  $we \geq 0$  for all  $e \in E$ . Now, using the membership oracle, check if there is an  $e \in E$  such that  $x + e \in S$  and  $we > 0$ . If there is such an  $e$  then output  $\hat{x} := x + e$  which is a better point, whereas if there is no such  $e$  then terminate asserting that no better point exists.

Clearly, if the algorithm outputs an  $\hat{x}$  then it is indeed a better point. Conversely, suppose  $x$  is not a maximizer of  $w$  over  $S$ . Since  $S \subseteq \{0, 1\}^n$ , the point  $x$  is a vertex of  $P$ . Since  $x$  is not a maximizer of  $w$ , there is an edge  $[x, \hat{x}]$  of  $P$  with  $\hat{x}$  a vertex satisfying  $w\hat{x} > wx$ . But then  $e := \hat{x} - x$  is the one  $\{-1, 0, 1\}$  edge-direction of  $[x, \hat{x}]$  with  $we \geq 0$  and hence  $e \in E$ . Thus, the algorithm will find and output  $\hat{x} = x + e$  as it should.  $\square$

An augmentation oracle presentation of a finite  $S$  allows to solve the linear discrete optimization problem  $\max\{wx : x \in S\}$  over  $S$  by starting from any feasible  $x \in S$  and repeatedly augmenting it until an optimal solution  $x^* \in S$  is reached. The next lemma bounds the running time needed to reach optimality using this procedure. While the running time is polynomial in the binary length of the linear functional  $w$  and the initial point  $x$ , it is more sensitive to the radius  $\rho(S)$  of the feasible set  $S$ , and is polynomial only in its unary length. The lemma is an adaptation of a result of [30,57] (stated therein for  $\{0, 1\}$ -sets), which makes use of bit-scaling ideas going back to [23].

**Lemma 5** *There is a polynomial time algorithm that, given finite set  $S \subset \mathbb{Z}^n$  presented by an augmentation oracle,  $x \in S$ , and  $w \in \mathbb{Z}^n$ , encoded as  $[\rho(S), \langle x, w \rangle]$ , provides an optimal solution  $x^* \in S$  to the linear discrete optimization problem  $\max\{wz : z \in S\}$ .*

*Proof* Let  $k := \max_{j=1}^n \lceil \log_2(|w_j| + 1) \rceil$  and note that  $k \leq \langle w \rangle$ . For  $i = 0, \dots, k$  define a linear functional  $u_i = (u_{i,1}, \dots, u_{i,n}) \in \mathbb{Z}^n$  by  $u_{i,j} := \text{sign}(w_j) \lfloor 2^{i-k} |w_j| \rfloor$  for  $j = 1, \dots, n$ . Then  $u_0 = 0$ ,  $u_k = w$ , and  $u_i - 2u_{i-1} \in \{-1, 0, 1\}^n$  for all  $i = 1, \dots, k$ .

We now describe how to construct a sequence of points  $y_0, y_1, \dots, y_k \in S$  such that  $y_i$  is an optimal solution to  $\max\{u_i y : y \in S\}$  for all  $i$ . First note that all points of  $S$  are optimal for  $u_0 = 0$  and hence we can take  $y_0 := x$  to be the point of  $S$  given as part of the input. We now explain how to determine  $y_i$  from  $y_{i-1}$  for  $i = 1, \dots, k$ . Suppose  $y_{i-1}$  has been determined. Set  $\tilde{y} := y_{i-1}$ . Query the augmentation oracle on  $\tilde{y} \in S$  and  $u_i$ ; if the oracle returns a better point  $\hat{y}$  then set  $\tilde{y} := \hat{y}$  and repeat, whereas if it asserts that there is no better point then the optimal solution for  $u_i$  is read off to be  $y_i := \tilde{y}$ . We now bound the number of calls to the oracle. Each time the oracle is queried on  $\tilde{y}$  and  $u_i$  and returns a better point  $\hat{y}$ , the improvement is by at least one, i. e.  $u_i(\hat{y} - \tilde{y}) \geq 1$ ; this is so because  $u_i, \tilde{y}$  and  $\hat{y}$  are integer. Thus, the number of necessary augmentations from  $y_{i-1}$  to  $y_i$  is at most the total improvement, which we claim satisfies

$$\begin{aligned} u_i(y_i - y_{i-1}) &= (u_i - 2u_{i-1})(y_i - y_{i-1}) \\ &\quad + 2u_{i-1}(y_i - y_{i-1}) \leq 2n\rho + 0 = 2n\rho, \end{aligned}$$

where  $\rho := \rho(S)$ . Indeed,  $u_i - 2u_{i-1} \in \{-1, 0, 1\}^n$  and  $y_i, y_{i-1} \in S \subset [-\rho, \rho]^n$  imply  $(u_i - 2u_{i-1})(y_i -$

$y_{i-1} \leq 2n\rho$ ; and  $y_{i-1}$  optimal for  $u_{i-1}$  gives  $u_{i-1}(y_i - y_{i-1}) \leq 0$ .

Thus, after a total number of at most  $2n\rho k$  calls to the oracle we obtain  $y_k$  which is optimal for  $u_k$ . Since  $w = u_k$  we can output  $x^* := y_k$  as the desired optimal solution to the linear discrete optimization problem. Clearly the number  $2n\rho k$  of calls to the oracle, as well as the number of arithmetic operations and binary length of numbers occurring during the algorithm, are polynomial in  $\rho(S)$ ,  $\langle x, w \rangle$ . This completes the proof.  $\square$

We conclude this preparatory subsection by recording the following result of [24] which incorporates the heavy simultaneous Diophantine approximation of [44].

**Proposition 1** *There is a strongly polynomial time algorithm that, given  $w \in \mathbb{Z}^n$ , encoded as  $[n; \langle w \rangle]$ , produces  $\hat{w} \in \mathbb{Z}^n$ , whose binary length  $\langle \hat{w} \rangle$  is polynomially bounded in  $n$  and independent of  $w$ , and with  $\text{sign}(\hat{w}z) = \text{sign}(wz)$  for every  $z \in \{-1, 0, 1\}^n$ .*

### Linear and Convex Combinatorial Optimization in Strongly Polynomial Time

Combining the preparatory statements of Sect. “**From Membership to Linear Optimization**” with Theorem 6, we can now solve the convex combinatorial optimization over a set  $S \subseteq \{0, 1\}^n$  presented by a membership oracle and endowed with a set covering all edge-directions of  $\text{conv}(S)$  in strongly polynomial time. We start with the special case of linear combinatorial optimization.

**Theorem 8** *There is a strongly polynomial time algorithm that, given set  $S \subseteq \{0, 1\}^n$  presented by a membership oracle,  $x \in S$ ,  $w \in \mathbb{Z}^n$ , and set  $E \subset \mathbb{Z}^n$  covering all edge-directions of the polytope  $\text{conv}(S)$ , encoded as  $[n, |E|; \langle x, w, E \rangle]$ , provides an optimal solution  $x^* \in S$  to the linear combinatorial optimization problem  $\max\{wz : z \in S\}$ .*

*Proof* First, an augmentation oracle for  $S$  can be simulated using the membership oracle, in strongly polynomial time, by applying the algorithm of Lemma 4.

Next, using the simulated augmentation oracle for  $S$ , we can now do linear optimization over  $S$  in strongly polynomial time as follows. First, apply to  $w$  the algorithm of Proposition 1 and obtain  $\hat{w} \in \mathbb{Z}^n$  whose binary length  $\langle \hat{w} \rangle$  is polynomially bounded in

$n$ , which satisfies  $\text{sign}(\hat{w}z) = \text{sign}(wz)$  for every  $z \in \{-1, 0, 1\}^n$ . Since  $S \subseteq \{0, 1\}^n$ , it is finite and has radius  $\rho(S) = 1$ . Now apply the algorithm of Lemma 5 to  $S$ ,  $x$  and  $\hat{w}$ , and obtain a maximizer  $x^*$  of  $\hat{w}$  over  $S$ . For every  $y \in \{0, 1\}^n$  we then have  $x^* - y \in \{-1, 0, 1\}^n$  and hence  $\text{sign}(w(x^* - y)) = \text{sign}(\hat{w}(x^* - y))$ . So  $x^*$  is also a maximizer of  $w$  over  $S$  and hence an optimal solution to the given linear combinatorial optimization problem. Now,  $\rho(S) = 1$ ,  $\langle \hat{w} \rangle$  is polynomial in  $n$ , and  $x \in \{0, 1\}^n$  and hence  $\langle x \rangle$  is linear in  $n$ . Thus, the entire length of the input  $[\rho(S), \langle x, \hat{w} \rangle]$  to the polynomial-time algorithm of Lemma 5 is polynomial in  $n$ , and so its running time is in fact strongly polynomial on that input.  $\square$

Combining Theorems 6 and 8 we recover at once the following result of [49].

**Theorem 9** *For every fixed  $d$  there is a strongly polynomial time algorithm that, given set  $S \subseteq \{0, 1\}^n$  presented by a membership oracle,  $x \in S$ , vectors  $w_1, \dots, w_d \in \mathbb{Z}^n$ , set  $E \subset \mathbb{Z}^n$  covering all edge-directions of the polytope  $\text{conv}(S)$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[n, |E|; \langle x, w_1, \dots, w_d, E \rangle]$ , provides an optimal solution  $x^* \in S$  to the convex combinatorial optimization problem*

$$\max \{c(w_1z, \dots, w_dz) : z \in S\}.$$

*Proof* Since  $S$  is nonempty, a linear discrete optimization oracle for  $S$  can be simulated in strongly polynomial time by the algorithm of Theorem 8. Using this simulated oracle, we can apply the algorithm of Theorem 6 and solve the given convex combinatorial optimization problem in strongly polynomial time.  $\square$

### Linear and Convex Discrete Optimization over any Set in Pseudo Polynomial Time

In Sect. “**Linear and Convex Combinatorial Optimization in Strongly Polynomial Time**” above we developed strongly polynomial time algorithms for linear and convex discrete optimization over  $\{0, 1\}$ -sets. We now provide extensions of these algorithms to arbitrary finite sets  $S \subset \mathbb{Z}^n$ . As can be expected, the algorithms become slower.

We start by recording the following fundamental result of Khachiyan [40] asserting that linear programming is polynomial time solvable via the ellipsoid

method [63]. This result will be used below as well as several more times later in the monograph.

**Proposition 2** *There is a polynomial time algorithm that, given  $A \in \mathbb{Z}^{m \times n}$ ,  $b \in \mathbb{Z}^m$ , and  $w \in \mathbb{Z}^n$ , encoded as  $[(A, b, w)]$ , either asserts that  $P := \{x \in \mathbb{R}^n : Ax \leq b\}$  is empty, or asserts that the linear functional  $wx$  is unbounded over  $P$ , or provides a vertex  $v \in \text{vert}(P)$  which is an optimal solution to the linear program  $\max\{wx : x \in P\}$ .*

The following analog of Lemma 4 shows how to convert membership to augmentation in polynomial time, albeit, no longer in strongly polynomial time. Here, both the given initial point  $x$  and the returned better point  $\hat{x}$  if any, are vertices of  $\text{conv}(S)$ .

**Lemma 6** *There is a polynomial time algorithm that, given finite set  $S \subset \mathbb{Z}^n$  presented by a membership oracle, vertex  $x$  of the polytope  $\text{conv}(S)$ ,  $w \in \mathbb{Z}^n$ , and set  $E \subset \mathbb{Z}^n$  covering all edge-directions of  $\text{conv}(S)$ , encoded as  $[\rho(S), (x, w, E)]$ , either returns a better vertex  $\hat{x}$  of  $\text{conv}(S)$ , that is, one satisfying  $w\hat{x} > wx$ , or asserts that none exists.*

*Proof* Dividing each vector  $e \in E$  by the greatest common divisor of its entries and setting  $e := -e$  if necessary, we can and will assume that each  $e$  is primitive, that is, its entries are relatively prime integers, and  $we \geq 0$ . Using the membership oracle, construct the subset  $F \subseteq E$  of those  $e \in E$  for which  $x + re \in S$  for some  $r \in \{1, \dots, 2\rho(S)\}$ . Let  $G \subseteq F$  be the subset of those  $f \in F$  for which  $wf > 0$ . If  $G$  is empty then terminate asserting that there is no better vertex. Otherwise, consider the convex cone  $\text{cone}(F)$  generated by  $F$ . It is clear that  $x$  is incident on an edge of  $\text{conv}(S)$  in direction  $f$  if and only if  $f$  is an extreme ray of  $\text{cone}(F)$ . Moreover, since  $G = \{f \in F : wf > 0\}$  is nonempty, there must be an extreme ray of  $\text{cone}(F)$  which lies in  $G$ . Now  $f \in F$  is an extreme ray of  $\text{cone}(F)$  if and only if there do not exist nonnegative  $\lambda_e, e \in F \setminus \{f\}$ , such that  $f = \sum_{e \neq f} \lambda_e e$ ; this can be checked in polynomial time using linear programming. Applying this procedure to each  $f \in G$ , identify an extreme ray  $g \in G$ . Now, using the membership oracle, determine the largest  $r \in \{1, \dots, 2\rho(S)\}$  for which  $x + rg \in S$ . Output  $\hat{x} := x + rg$  which is a better vertex of  $\text{conv}(S)$ .  $\square$

We now prove the extensions of Theorems 8 and 9 to arbitrary, not necessarily  $\{0, 1\}$ -valued, finite sets.

While the running time remains polynomial in the binary length of the weights  $w_1, \dots, w_d$  and the set of edge-directions  $E$ , it is more sensitive to the radius  $\rho(S)$  of the feasible set  $S$ , and is polynomial only in its unary length. Here, the initial feasible point and the optimal solution output by the algorithms are vertices of  $\text{conv}(S)$ . Again, we start with the special case of linear combinatorial optimization.

**Theorem 10** *There is a polynomial time algorithm that, given finite  $S \subset \mathbb{Z}^n$  presented by a membership oracle, vertex  $x$  of the polytope  $\text{conv}(S)$ ,  $w \in \mathbb{Z}^n$ , and set  $E \subset \mathbb{Z}^n$  covering all edge-directions of  $\text{conv}(S)$ , encoded as  $[\rho(S), (x, w, E)]$ , provides an optimal solution  $x^* \in S$  to the linear discrete optimization problem  $\max\{wz : z \in S\}$ .*

*Proof* Apply the algorithm of Lemma 5 to the given data. Consider any query  $x' \in S, w' \in \mathbb{Z}^n$  made by that algorithm to an augmentation oracle for  $S$ . To answer it, apply the algorithm of Lemma 6 to  $x'$  and  $w'$ . Since the first query made by the algorithm of Lemma 5 is on the given input vertex  $x' := x$ , and any consequent query is on a point  $x' := \hat{x}$  which was the reply of the augmentation oracle to the previous query (see proof of Lemma 5), we see that the algorithm of Lemma 6 will always be asked on a vertex of  $S$  and reply with another. Thus, the algorithm of Lemma 6 can answer all augmentation queries and enables the polynomial time solution of the given problem.  $\square$

**Theorem 11** *For every fixed  $d$  there is a polynomial time algorithm that, given finite set  $S \subseteq \mathbb{Z}^n$  presented by membership oracle, vertex  $x$  of  $\text{conv}(S)$ , vectors  $w_1, \dots, w_d \in \mathbb{Z}^n$ , set  $E \subset \mathbb{Z}^n$  covering all edge-directions of the polytope  $\text{conv}(S)$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[\rho(S), (x, w_1, \dots, w_d, E)]$ , provides an optimal solution  $x^* \in S$  to the convex combinatorial optimization problem*

$$\max \{c(w_1 z, \dots, w_d z) : z \in S\}.$$

*Proof* Since  $S$  is nonempty, a linear discrete optimization oracle for  $S$  can be simulated in polynomial time by the algorithm of Theorem 10. Using this simulated oracle, we can apply the algorithm of Theorem 6 and solve the given problem in polynomial time.  $\square$

## Some Applications

**Positive Semidefinite Quadratic Binary Programming** The quadratic binary programming problem is the following: given an  $n \times n$  matrix  $M$ , find a vector  $x \in \{0, 1\}^n$  maximizing the quadratic form  $x^T M x$  induced by  $M$ . We consider here the instance where  $M$  is positive semidefinite, in which case it can be assumed to be presented as  $M = W^T W$  with  $W$  a given  $d \times n$  matrix. Already this restricted version is very broad: if the rank  $d$  of  $W$  and  $M$  is variable then, as mentioned in the introduction, the problem is NP-hard. We now show that, for fixed  $d$ , Theorem 9 implies at once that the problem is strongly polynomial time solvable (see also [2]).

**Corollary 6** *For every fixed  $d$  there is a strongly polynomial time algorithm that given  $W \in \mathbb{Z}^{d \times n}$ , encoded as  $[n; \langle W \rangle]$ , finds  $x^* \in \{0, 1\}^n$  maximizing the form  $x^T W^T W x$ .*

*Proof* Let  $S := \{0, 1\}^n$  and let  $E := \{\mathbf{1}_1, \dots, \mathbf{1}_n\}$  be the set of unit vectors in  $\mathbb{R}^n$ . Then  $P := \text{conv}(S)$  is just the  $n$ -cube  $[0, 1]^n$  and hence  $E$  covers all edge-directions of  $P$ . A membership oracle for  $S$  is easily and efficiently realizable and  $x := 0 \in S$  is an initial point. Also,  $|E|$  and  $\langle E \rangle$  are polynomial in  $n$ , and  $E$  is easily and efficiently computable.

Now, for  $i = 1, \dots, d$  define  $w_i \in \mathbb{Z}^n$  to be the  $i$ th row of the matrix  $W$ , that is,  $w_{i,j} := W_{i,j}$  for all  $i, j$ . Finally, let  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  be the squared  $l_2$  norm given by  $c(y) := \|y\|_2^2 := \sum_{i=1}^d y_i^2$ , and note that the comparison of  $c(y)$  and  $c(z)$  can be done for  $y, z \in \mathbb{Z}^d$  in time polynomial in  $\langle y, z \rangle$  using a constant number of arithmetic operations, providing a strongly polynomial time realization of a comparison oracle for  $c$ .

This translates the given quadratic programming problem into a convex combinatorial optimization problem over  $S$ , which can be solved in strongly polynomial time by applying the algorithm of Theorem 9 to  $S$ ,  $x = 0$ ,  $w_1, \dots, w_d$ ,  $E$ , and  $c$ .  $\square$

## Matroids and Maximum Norm Spanning Trees

Optimization problems over matroids form a fundamental class of combinatorial optimization problems. Here we discuss matroid bases, but everything works for independent sets as well. Recall that a family  $\mathcal{B}$  of subsets of  $\{1, \dots, n\}$  is the family of *bases* of a *matroid* if all members of  $\mathcal{B}$  have the same cardinality, called

the *rank* of the matroid, and for every  $B, B' \in \mathcal{B}$  and  $i \in B \setminus B'$  there is a  $j \in B'$  such that  $B \setminus \{i\} \cup \{j\} \in \mathcal{B}$ . Useful models include the *graphic matroid* of a graph  $G$  with edge set  $\{1, \dots, n\}$  and  $\mathcal{B}$  the family of spanning forests of  $G$ , and the *linear matroid* of an  $m \times n$  matrix  $A$  with  $\mathcal{B}$  the family of sets of indices of maximal linearly independent subsets of columns of  $A$ .

It is well known that linear combinatorial optimization over matroids can be solved by the fast greedy algorithm [22]. We now show that, as a consequence of Theorem 9, convex combinatorial optimization over a matroid presented by a membership oracle can be solved in strongly polynomial time as well (see also [34,47]). We state the result for bases, but the analogous statement for independent sets hold as well. We say that  $S \subseteq \{0, 1\}^n$  is the *set of bases* of a matroid if it is the set of indicators of the family  $\mathcal{B}$  of bases of some matroid, in which case we call  $\text{conv}(S)$  the *matroid base polytope*.

**Corollary 7** *For every fixed  $d$  there is a strongly polynomial time algorithm that, given set  $S \subseteq \{0, 1\}^n$  of bases of a matroid presented by a membership oracle,  $x \in S$ ,  $w_1, \dots, w_d \in \mathbb{Z}^n$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[n; \langle x, w_1, \dots, w_d \rangle]$ , solves the convex matroid optimization problem*

$$\max \{c(w_1 z, \dots, w_d z) : z \in S\}.$$

*Proof* Let  $E := \{\mathbf{1}_i - \mathbf{1}_j : 1 \leq i < j \leq n\}$  be the set of differences of pairs of unit vectors in  $\mathbb{R}^n$ . We claim that  $E$  covers all edge-directions of the matroid base polytope  $P := \text{conv}(S)$ . Consider any edge  $e = [y, y']$  of  $P$  with  $y, y' \in S$  and let  $B := \text{supp}(y)$  and  $B' := \text{supp}(y')$  be the corresponding bases. Let  $h \in \mathbb{R}^n$  be a linear functional uniquely maximized over  $P$  at  $e$ . If  $B \setminus B' = \{i\}$  is a singleton then  $B' \setminus B = \{j\}$  is a singleton as well in which case  $y - y' = \mathbf{1}_i - \mathbf{1}_j$  and we are done. Suppose then, indirectly, that it is not, and pick an element  $i$  in the symmetric difference  $B \Delta B' := (B \setminus B') \cup (B' \setminus B)$  of minimum value  $h_i$ . Without loss of generality assume  $i \in B \setminus B'$ . Then there is a  $j \in B' \setminus B$  such that  $B'' := B \setminus \{i\} \cup \{j\}$  is also a basis. Let  $y'' \in S$  be the indicator of  $B''$ . Now  $|B \Delta B' q| > 2$  implies that  $B''$  is neither  $B$  nor  $B'$ . By the choice of  $i$  we have  $h y'' = h y - h_i + h_j \geq h y$ . So  $y''$  is also a max-

imizer of  $h$  over  $P$  and hence  $y'' \in e$ . But no  $\{0, 1\}$ -vector is a convex combination of others, a contradiction.

Now,  $|E| = \binom{n}{2}$  and  $E \subset \{-1, 0, 1\}^n$  imply that  $|E|$  and  $\langle E \rangle$  are polynomial in  $n$ . Moreover,  $E$  can be easily computed in strongly polynomial time. Therefore, applying the algorithm of Theorem 9 to the given data and the set  $E$ , the convex discrete optimization problem over  $S$  can be solved in strongly polynomial time.  $\square$

One important application of Corollary 7 is a polynomial time algorithm for computing the *universal Gröbner basis* of any system of polynomials having a finite set of common zeros in fixed (but arbitrary) number of variables, as well as the construction of the *state polyhedron* of any member of the *Hilbert scheme*, see [5,51]. Other important applications are in the field of *algebraic statistics* [52], in particular for *optimal experimental design*. These applications are beyond our scope here and will be discussed elsewhere.

Here is another concrete example of a convex matroid optimization application.

*Example 1* (MAXIMUM NORM SPANNING TREE). Fix any positive integer  $d$ . Let  $\|\cdot\|_p: \mathbb{R}^d \rightarrow \mathbb{R}$  be the  $l_p$  norm given by  $\|x\|_p := (\sum_{i=1}^d |x_i|^p)^{\frac{1}{p}}$  for  $1 \leq p < \infty$  and  $\|x\|_\infty := \max_{i=1}^d |x_i|$ . Let  $G$  be a connected graph with edge set  $N := \{1, \dots, n\}$ . For  $j = 1, \dots, n$  let  $u_j \in \mathbb{Z}^d$  be a weight vector representing the values of edge  $j$  under some  $d$  criteria. The weight of a subset  $T \subseteq N$  is the sum  $\sum_{j \in T} u_j$  representing the total values of  $T$  under the  $d$  criteria. The problem is to find a spanning tree  $T$  of  $G$  whose weight has maximum  $l_p$  norm, that is, a spanning tree  $T$  maximizing  $\|\sum_{j \in T} u_j\|_p$ .

Define  $w_1, \dots, w_d \in \mathbb{Z}^n$  by  $w_{i,j} := u_{j,i}$  for  $i = 1, \dots, d$ ,  $j = 1, \dots, n$ . Let  $S \subseteq \{0, 1\}^n$  be the set of indicators of spanning trees of  $G$ . Then, in time polynomial in  $n$ , a membership oracle for  $S$  is realizable, and an initial  $x \in S$  is obtainable as the indicator of any greedily constructible spanning tree  $T$ . Finally, define the convex functional  $c := \|\cdot\|_p$ . Then for most common values  $p = 1, 2, \infty$ , and in fact for any  $p \in \mathbb{N}$ , the comparison of  $c(y)$  and  $c(z)$  can be done for  $y, z \in \mathbb{Z}^d$  in time polynomial in  $\langle y, z, p \rangle$  by computing and comparing the integer valued  $p$ th powers  $\|y\|_p^p$  and  $\|z\|_p^p$ . Thus, by Corollary 7, this problem is solvable in time polynomial in  $\langle u_1, \dots, u_n, p \rangle$ .

## Linear N-fold Integer Programming

In this section we develop a theory of linear  $n$ -fold integer programming, which leads to the polynomial time solution of broad classes of linear integer programming problems in variable dimension. This will be extended to convex  $n$ -fold integer programming in Sect. “Convex Integer Programming”.

In Sect. “Oriented Augmentation and Linear Optimization” we describe an adaptation of a result of [56] involving an oriented version of the augmentation oracle of Sect. “From Membership to Linear Optimization”. In Sect. “Graver Bases and Linear Integer Programming” we discuss Graver bases and their application to linear integer programming. In Sect. “Graver Bases of N-fold Matrices” we show that Graver bases of  $n$ -fold matrices can be computed efficiently. In Sect. “Linear N-fold Integer Programming in Polynomial Time” we combine the preparatory statements from Sect. “Oriented Augmentation and Linear Optimization”, Sect. “Graver Bases and Linear Integer Programming”, and Sect. “Graver Bases of N-fold Matrices”, and prove the main result of this section, asserting that linear  $n$ -fold integer programming is polynomial time solvable. We conclude with some applications in Sect. “Some Applications”.

Here and in Sect. “Convex Integer Programming” we concentrate on discrete optimization problems over a set  $S$  presented as the set of integer points satisfying an explicitly given system of linear inequalities. Without loss of generality we may and will assume that  $S$  is given either in standard form  $S := \{x \in \mathbb{N}^n : Ax = b\}$  where  $A \in \mathbb{Z}^{m \times n}$  and  $b \in \mathbb{Z}^m$ , or in the form

$$S := \{x \in \mathbb{Z}^n : Ax = b, l \leq x \leq u\}$$

where  $l, u \in \mathbb{Z}_\infty^n$  and  $\mathbb{Z}_\infty = \mathbb{Z} \uplus \{\pm\infty\}$ , where some of the variables are bounded below or above and some are unbounded. Thus,  $S$  is no longer presented by an oracle, but by the explicit data  $A, b$  and possibly  $l, u$ . In this setup we refer to discrete optimization over  $S$  also as *integer programming* over  $S$ . As usual, an algorithm solving the problem must either provide an  $x \in S$  maximizing  $wx$  over  $S$ , or assert that none exists (either because  $S$  is empty or because the objective function is unbounded over the underlying polyhedron). We will sometimes assume that an initial point  $x \in S$  is given,

in which case  $b$  will be computed as  $b := Ax$  and not be part of the input.

### Oriented Augmentation and Linear Optimization

We have seen in Sect. “From Membership to Linear Optimization” that an augmentation oracle presentation of a finite set  $S \subset \mathbb{Z}^n$  enables to solve the linear discrete optimization problem over  $S$ . However, the running time of the algorithm of Lemma 5 which demonstrated this, was polynomial in the unary length of the radius  $\rho(S)$  of the feasible set rather than in its binary length.

In this subsection we discuss a recent result of [56] and show that, when  $S$  is presented by a suitable stronger oriented version of the augmentation oracle, the linear optimization problem can be solved by a much faster algorithm, whose running time is in fact polynomial in the binary length  $\langle \rho(S) \rangle$ . The key idea behind this algorithm is that it gives preference to augmentations along interior points of  $\text{conv}(S)$  staying far off its boundary. It is inspired by and extends the combinatorial interior point algorithm of [61].

For any vector  $g \in \mathbb{R}^n$ , let  $g^+, g^- \in \mathbb{R}_+^n$  denote its *positive* and *negative* parts, defined by  $g_j^+ := \max\{g_j, 0\}$  and  $g_j^- := -\min\{g_j, 0\}$  for  $j = 1, \dots, n$ . Note that both  $g^+, g^-$  are nonnegative,  $\text{supp}(g) = \text{supp}(g^+) \uplus \text{supp}(g^-)$ , and  $g = g^+ - g^-$ .

An *oriented augmentation oracle* for a set  $S \subset \mathbb{Z}^n$  is one that, queried on  $x \in S$  and  $w_+, w_- \in \mathbb{Z}^n$ , either returns an *augmenting vector*  $g \in \mathbb{Z}^n$ , defined to be one satisfying  $x + g \in S$  and  $w_+g^+ - w_-g^- > 0$ , or asserts that none exists.

Note that this oracle involves *two* linear functionals  $w_+, w_- \in \mathbb{Z}^n$  rather than one ( $w_+, w_-$  are two distinct independent vectors and *not* the positive and negative parts of one vector). The conditions on an augmenting vector  $g$  indicate that it is a feasible direction and has positive value under the nonlinear objective function determined by  $w_+, w_-$ . Note that this oracle is indeed stronger than the augmentation oracle of Sect. “From Membership to Linear Optimization”: to answer a query  $x \in S, w \in \mathbb{Z}^n$  to the latter, set  $w_+ := w_- := w$ , thereby obtaining  $w_+g^+ - w_-g^- = wg$  for all  $g$ , and query the former on  $x, w_+, w_-$ ; if it replies with an augmenting vector  $g$  then reply with the better point  $\hat{x} := x + g$ , whereas if it asserts that no  $g$  exists then assert that no better point exists.

The following lemma is an adaptation of the result of [56] concerning sets of the form  $S := \{x \in \mathbb{Z}^n : Ax = b, 0 \leq x \leq u\}$  of nonnegative integer points satisfying equations and upper bounds. However, the pair  $A, b$  is neither explicitly needed nor does it affect the running time of the algorithm underlying the lemma. It suffices that  $S$  is of that form. Moreover, an arbitrary lower bound vector  $l$  rather than 0 can be included. So it suffices to assume that  $S$  coincides with the intersection of its affine hull and the set of integer points in a box, that is,  $S = \text{aff}(S) \cap \{x \in \mathbb{Z}^n : l \leq x \leq u\}$  where  $l, u \in \mathbb{Z}^n$ . We now describe and prove the algorithm of [56] adjusted to any lower and upper bounds  $l, u$ .

**Lemma 7** *There is a polynomial time algorithm that, given vectors  $l, u \in \mathbb{Z}^n$ , set  $S \subset \mathbb{Z}^n$  satisfying  $S = \text{aff}(S) \cap \{z \in \mathbb{Z}^n : l \leq z \leq u\}$  and presented by an oriented augmentation oracle,  $x \in S$ , and  $w \in \mathbb{Z}^n$ , encoded as  $[(l, u, x, w)]$ , provides an optimal solution  $x^* \in S$  to the linear discrete optimization problem  $\max\{wz : z \in S\}$ .*

*Proof* We start with some strengthening adjustments to the oriented augmentation oracle. Let  $\rho := \max\{\|l\|_\infty, \|u\|_\infty\}$  be an upper bound on the radius of  $S$ . Then any augmenting vector  $g$  obtained from the oriented augmentation oracle when queried on  $y \in S$  and  $w_+, w_- \in \mathbb{Z}^n$ , can be made in polynomial time to be *exhaustive*, that is, to satisfy  $y + 2g \notin S$  (which means that no longer augmenting step in direction  $g$  can be taken). Indeed, using binary search, find the largest  $r \in \{1, \dots, 2\rho\}$  for which  $l \leq y + rg \leq u$ ; then  $S = \text{aff}(S) \cap \{z \in \mathbb{Z}^n : l \leq z \leq u\}$  implies  $y + rg \in S$  and hence we can replace  $g := rg$ . So from here on we will assume that if there is an augmenting vector then the oracle returns an exhaustive one. Second, let  $\mathbb{R}_\infty := \mathbb{R} \uplus \{\pm\infty\}$  and for any vector  $v \in \mathbb{R}^n$  let  $v^{-1} \in \mathbb{R}_\infty^n$  denote its entry-wise reciprocal defined by  $v_i^{-1} := \frac{1}{v_i}$  if  $v_i \neq 0$  and  $v_i^{-1} := \infty$  if  $v_i = 0$ . For any  $y \in S$ , the vectors  $(y - l)^{-1}$  and  $(u - y)^{-1}$  are the reciprocals of the “entry-wise distance” of  $y$  from the given lower and upper bounds. The algorithm will query the oracle on triples  $y, w_+, w_-$  with  $w_+ := w - \mu(u - y)^{-1}$  and  $w_- := w + \mu(y - l)^{-1}$  where  $\mu$  is a suitable positive scalar and  $w$  is the input linear functional. The fact that such  $w_+, w_-$  may have infinite entries does not cause any problem: indeed, if  $g$  is an augmenting vector then  $y + g \in S$  implies that  $g_i^+ = 0$  whenever  $y_i = u_i$

and  $g_i^- = 0$  whenever  $l_i = y_i$ , so each infinite entry in  $w_+$  or  $w_-$  occurring in the expression  $w_+g^+ - w_-g^-$  is multiplied by 0 and hence zeroed out.

The algorithm proceeds in phases. Each phase  $i$  starts with a feasible point  $y_{i-1} \in S$  and performs repeated augmentations using the oriented augmentation oracle, terminating with a new feasible point  $y_i \in S$  when no further augmentations are possible. The queries to the oracle make use of a positive scalar parameters  $\mu_i$  fixed throughout the phase. The first phase ( $i=1$ ) starts with the input point  $y_0 := x$  and sets  $\mu_1 := \rho \|w\|_\infty$ . Each further phase  $i \geq 2$  starts with the point  $y_{i-1}$  obtained from the previous phase and sets the parameter value  $\mu_i := \frac{1}{2}\mu_{i-1}$  to be half its value in the previous phase. The algorithm terminates at the end of the first phase  $i$  for which  $\mu_i < \frac{1}{n}$ , and outputs  $x^* := y_i$ . Thus, the number of phases is at most  $\lceil \log_2(2n\rho\|w\|_\infty) \rceil$  and hence polynomial in  $\langle l, u, w \rangle$ .

We now describe the  $i$ th phase which determines  $y_i$  from  $y_{i-1}$ . Set  $\mu_i := \frac{1}{2}\mu_{i-1}$  and  $\hat{y} := y_{i-1}$ . Iterate the following: query the strengthened oriented augmentation oracle on  $\hat{y}$ ,  $w_+ := w - \mu_i(u - \hat{y})^{-1}$ , and  $w_- := w + \mu_i(\hat{y} - l)^{-1}$ ; if the oracle returns an exhaustive augmenting vector  $g$  then set  $\hat{y} := \hat{y} + g$  and repeat, whereas if it asserts that there is no augmenting vector then set  $y_i := \hat{y}$  and complete the phase. If  $\mu_i \geq \frac{1}{n}$  then proceed to the  $(i+1)$ th phase, else output  $x^* := y_i$  and terminate the algorithm.

It remains to show that the output of the algorithm is indeed an optimal solution and that the number of iterations (and hence calls to the oracle) in each phase is polynomial in the input. For this we need the following facts, the easy proofs of which are omitted:

1. For every feasible  $y \in S$  and direction  $g$  with  $y + g \in S$  also feasible, we have

$$(u - y)^{-1}g^+ + (y - l)^{-1}g^- \leq n .$$

2. For every  $y \in S$  and direction  $g$  with  $y + g \in S$  but  $y + 2g \notin S$ , we have

$$(u - y)^{-1}g^+ + (y - l)^{-1}g^- > \frac{1}{2} .$$

3. For every feasible  $y \in S$ , direction  $g$  with  $y + g \in S$  also feasible, and  $\mu > 0$ , setting  $w_+ := w - \mu(u -$

$y)^{-1}$  and  $w_- := w + \mu(y - l)^{-1}$  we have

$$w_+g^+ - w_-g^- = wg - \mu \left( (u - y)^{-1}g^+ + (y - l)^{-1}g^- \right) .$$

Now, consider the last phase  $i$  with  $\mu_i < \frac{1}{n}$ , let  $x^* := y_i := \hat{y}$  be the output of the algorithm at the end of this phase, and let  $\hat{x} \in S$  be any optimal solution. Now, the phase is completed when the oracle, queried on the triple  $\hat{y}$ ,  $w_+ = w - \mu_i(u - \hat{y})^{-1}$ , and  $w_- = w + \mu_i(\hat{y} - l)^{-1}$ , asserts that there is no augmenting vector. In particular, setting  $g := \hat{x} - \hat{y}$ , we find  $w_+g^+ - w_-g^- \leq 0$  and hence, by facts 1 and 3 above,

$$w\hat{x} - wx^* = wg \leq \mu_i \left( (u - \hat{y})^{-1}g^+ + (\hat{y} - l)^{-1}g^- \right) < \frac{1}{n} n = 1 .$$

Since  $w\hat{x}$  and  $wx^*$  are integer, this implies that in fact  $w\hat{x} - wx^* \leq 0$  and hence the output  $x^*$  of the algorithm is indeed an optimal solution to the given optimization problem.

Next we bound the number of iterations in each phase  $i$  starting from  $y_{i-1} \in S$ . Let again  $\hat{x} \in S$  be any optimal solution. Consider any iteration in that phase, where the oracle is queried on  $\hat{y}$ ,  $w_+ = w - \mu_i(u - \hat{y})^{-1}$ , and  $w_- = w + \mu_i(\hat{y} - l)^{-1}$ , and returns an exhaustive augmenting vector  $g$ . We will now show that

$$w(\hat{y} + g) - w\hat{y} \geq \frac{1}{4n}(w\hat{x} - wy_{i-1}) , \quad (1)$$

that is, the increment in the objective value from  $\hat{y}$  to the augmented point  $\hat{y} + g$  is at least  $\frac{1}{4n}$  times the difference between the optimal objective value  $w\hat{x}$  and the objective value  $wy_{i-1}$  of the point  $y_{i-1}$  at the beginning of phase  $i$ . This shows that at most  $4n$  such increments (and hence iterations) can occur in the phase before it is completed.

To establish (1), we show that  $wg \geq \frac{1}{2}\mu_i$  and  $w\hat{x} - wy_{i-1} \leq 2n\mu_i$ . For the first inequality, note that  $g$  is an exhaustive augmenting vector and so  $w_+g^+ - w_-g^- > 0$  and  $\hat{y} + 2g \notin S$  and hence, by facts 2 and 3,  $wg > \mu_i((u - \hat{y})^{-1}g^+ + (\hat{y} - l)^{-1}g^-) > \frac{1}{2}\mu_i$ . We proceed with the second inequality. If  $i = 1$  (first phase) then this indeed holds since  $w\hat{x} - wy_0 \leq 2n\rho\|w\|_\infty = 2n\mu_1$ . If  $i \geq 2$ , let  $\tilde{w}_+ := w - \mu_{i-1}(u - y_{i-1})^{-1}$  and  $\tilde{w}_- :=$

$w + \mu_{i-1}(y_{i-1} - l)^{-1}$ . The  $(i - 1)$ th phase was completed when the oracle, queried on the triple  $y_{i-1}, \tilde{w}_+,$  and  $\tilde{w}_-,$  asserted that there is no augmenting vector. In particular, for  $\tilde{g} := \hat{x} - y_{i-1}$ , we find  $\tilde{w}_+ \tilde{g}^+ - \tilde{w}_- \tilde{g}^- \leq 0$  and so, by facts 1 and 3,

$$\begin{aligned} & w\hat{x} - wy_{i-1} \\ &= w\tilde{g} \leq \mu_{i-1} \left( (u - y_{i-1})^{-1} \tilde{g}^+ + (y_{i-1} - l)^{-1} \tilde{g}^- \right) \\ &\leq \mu_{i-1} n = 2n\mu_i. \quad \square \end{aligned}$$

### Graver Bases and Linear Integer Programming

We now come to the definition of a fundamental object introduced by Graver in [28]. The *Graver basis* of an integer matrix  $A$  is a canonical finite set  $\mathcal{G}(A)$  that can be defined as follows. Define a partial order  $\sqsubseteq$  on  $\mathbb{Z}^n$  which extends the coordinate-wise order  $\leq$  on  $\mathbb{N}^n$  as follows: for two vectors  $u, v \in \mathbb{Z}^n$  put  $u \sqsubseteq v$  and say that  $u$  is *conformal* to  $v$  if  $|u_i| \leq |v_i|$  and  $u_i v_i \geq 0$  for  $i = 1, \dots, n$ , that is,  $u$  and  $v$  lie in the same orthant of  $\mathbb{R}^n$  and each component of  $u$  is bounded by the corresponding component of  $v$  in absolute value. It is not hard to see that  $\sqsubseteq$  is a well partial ordering (this is basically Dickson’s lemma) and hence every subset of  $\mathbb{Z}^n$  has finitely-many  $\sqsubseteq$ -minimal elements. Let  $\mathcal{L}(A) := \{x \in \mathbb{Z}^n : Ax = 0\}$  be the lattice of linear integer dependencies on  $A$ . The *Graver basis* of  $A$  is defined to be the set  $\mathcal{G}(A)$  of all  $\sqsubseteq$ -minimal vectors in  $\mathcal{L}(A) \setminus \{0\}$ .

Note that if  $A$  is an  $m \times n$  matrix then its Graver basis consist of vectors in  $\mathbb{Z}^n$ . We sometimes write  $\mathcal{G}(A)$  as a suitable  $|\mathcal{G}(A)| \times n$  matrix whose rows are the Graver basis elements. The Graver basis is centrally symmetric ( $g \in \mathcal{G}(A)$  implies  $-g \in \mathcal{G}(A)$ ); thus, when listing a Graver basis we will typically give one of each antipodal pair and prefix the set (or matrix) by  $\pm$ . Any element of the Graver basis is primitive (its entries are relatively prime integers). Every circuit of  $A$  (nonzero primitive minimal support element of  $\mathcal{L}(A)$ ) is in  $\mathcal{G}(A)$ ; in fact, if  $A$  is totally unimodular then  $\mathcal{G}(A)$  coincides with the set of circuits (see Sect. “Convex Integer Programming over Totally Unimodular Systems” in the sequel for more details on this). However, in general  $\mathcal{G}(A)$  is much larger. For more details on Graver bases and their connection to Gröbner bases see Sturmfels [58] and for the currently fastest procedure for computing them see [35,36].

Here is a quick simple example; we will see more structured and complex examples later on. Consider the  $1 \times 3$  matrix  $A := (1, 2, 1)$ . Then its Graver basis can be shown to be the set  $\mathcal{G}(A) = \pm\{(2, -1, 0), (0, -1, 2), (1, 0, -1), (1, -1, 1)\}$ . The first three elements (and their antipodes) are the circuits of  $A$ ; already in this small example non-circuits appear as well: the fourth element (and its antipode) is a primitive linear integer dependency whose support is not minimal.

We now show that when we do have access to the Graver basis, it can be used to solve linear integer programming. We will extend this in Sect. “Convex Integer Programming”, where we show that the Graver basis enables to solve convex integer programming as well. In Sect. “Graver Bases of N-fold Matrices” we will show that there are important classes of matrices for which the Graver basis is indeed accessible.

First, we need a simple property of Graver bases. A finite sum  $u := \sum_i v_i$  of vectors  $v_i \in \mathbb{R}^n$  is *conformal* if each summand is conformal to the sum, that is,  $v_i \sqsubseteq u$  for all  $i$ .

**Lemma 8** *Let  $A$  be any integer matrix. Then any  $h \in \mathcal{L}(A) \setminus \{0\}$  can be written as a conformal sum  $h := \sum g_i$  of (not necessarily distinct) Graver basis elements  $g_i \in \mathcal{G}(A)$ .*

*Proof* By induction on the well partial order  $\sqsubseteq$ . Recall that  $\mathcal{G}(A)$  is the set of  $\sqsubseteq$ -minimal elements in  $\mathcal{L}(A) \setminus \{0\}$ . Consider any  $h \in \mathcal{L}(A) \setminus \{0\}$ . If it is  $\sqsubseteq$ -minimal then  $h \in \mathcal{G}(A)$  and we are done. Otherwise, there is a  $h' \in \mathcal{G}(A)$  such that  $h' \sqsubset h$ . Set  $h'' := h - h'$ . Then  $h'' \in \mathcal{L}(A) \setminus \{0\}$  and  $h'' \sqsubset h$ , so by induction there is a conformal sum  $h'' = \sum_i g_i$  with  $g_i \in \mathcal{G}(A)$  for all  $i$ . Now  $h = h' + \sum_i g_i$  is the desired conformal sum of  $h$ .  $\square$

The next lemma shows the usefulness of Graver bases for oriented augmentation.

**Lemma 9** *Let  $A$  be an  $m \times n$  integer matrix with Graver basis  $\mathcal{G}(A)$  and let  $l, u \in \mathbb{Z}_\infty^n, w_+, w_- \in \mathbb{Z}^n,$  and  $b \in \mathbb{Z}^m$ . Suppose  $x \in T := \{y \in \mathbb{Z}^n : Ay = b, l \leq y \leq u\}$ . Then for every  $g \in \mathbb{Z}^n$  which satisfies  $x + g \in T$  and  $w_+ g^+ - w_- g^- > 0$  there exists an element  $\hat{g} \in \mathcal{G}(A)$  with  $\hat{g} \sqsubseteq g$  which also satisfies  $x + \hat{g} \in T$  and  $w_+ \hat{g}^+ - w_- \hat{g}^- > 0$ .*

*Proof* Suppose  $g \in \mathbb{Z}^n$  satisfies the requirements. Then  $Ag = A(x + g) - Ax = b - b = 0$  since  $x, x + g \in$

$T$ . Thus,  $g \in \mathcal{L}(A) \setminus \{0\}$  and hence, by Lemma 8, there is a conformal sum  $g = \sum_i h_i$  with  $h_i \in \mathcal{G}(A)$  for all  $i$ . Now,  $h_i \sqsubseteq g$  is equivalent to  $h_i^+ \leq g^+$  and  $h_i^- \leq g^-$ , so the conformal sum  $g = \sum_i h_i$  gives corresponding sums of the positive and negative parts  $g^+ = \sum_i h_i^+$  and  $g^- = \sum_i h_i^-$ . Therefore we obtain

$$\begin{aligned} 0 < w_+g^+ - w_-g^- &= w_+ \sum_i h_i^+ - w_- \sum_i h_i^- \\ &= \sum_i (w_+h_i^+ - w_-h_i^-) \end{aligned}$$

which implies that there is some  $h_i$  in this sum with  $w_+h_i^+ - w_-h_i^- > 0$ . Now,  $h_i \in \mathcal{G}(A)$  implies  $A(x + h_i) = Ax = b$ . Also,  $l \leq x, x + g \leq u$  and  $h_i \sqsubseteq g$  imply that  $l \leq x + h_i \leq u$ . So  $x + h_i \in T$ . Therefore the vector  $\hat{g} := h_i$  satisfies the claim.  $\square$

We can now show that the Graver basis enables to solve linear integer programming in polynomial time provided an initial feasible point is available.

**Theorem 12** *There is a polynomial time algorithm that, given  $A \in \mathbb{Z}^{m \times n}$ , its Graver basis  $\mathcal{G}(A)$ ,  $l, u \in \mathbb{Z}_\infty^n$ ,  $x, w \in \mathbb{Z}^n$  with  $l \leq x \leq u$ , encoded as  $[\langle A, \mathcal{G}(A), l, u, x, w \rangle]$ , solves the linear integer program  $\max\{wz : z \in \mathbb{Z}^n, Az = b, l \leq z \leq u\}$  with  $b := Ax$ .*

*Proof* First, note that the objective function of the integer program is unbounded if and only if the objective function of its relaxation  $\max\{wy : y \in \mathbb{R}^n, Ay = b, l \leq y \leq u\}$  is unbounded, which can be checked in polynomial time using linear programming. If it is unbounded then assert that there is no optimal solution and terminate the algorithm.

Assume then that the objective is bounded. Then, since the program is feasible, it has an optimal solution. Furthermore, (as basically follows from Cramer's rule, see e. g. [13, Theorem 17.1]) it has an optimal  $x^*$  satisfying  $|x_j^*| \leq \rho$  for all  $j$ , where  $\rho$  is an easily computable integer upper bound whose binary length  $\langle \rho \rangle$  is polynomially bounded in  $\langle A, l, u, x \rangle$ . For instance,  $\rho := (n+1)(n+1)!r^{n+1}$  will do, with  $r$  the maximum among  $\max_i |\sum_j A_{i,j}x_j|$ ,  $\max_{i,j} |A_{i,j}|$ ,  $\max\{|l_j| : |l_j| < \infty\}$ , and  $\max\{|u_j| : |u_j| < \infty\}$ .

Let  $T := \{y \in \mathbb{Z}^n : Ay = b, l \leq y \leq u\}$  and  $S := T \cap [-\rho, \rho]^n$ . Then our linear integer programming problem now reduces to linear discrete optimization over  $S$ . Now, an oriented augmentation oracle for  $S$  can be simulated in polynomial time using the

given Graver basis  $\mathcal{G}(A)$  as follows: given a query  $y \in S$  and  $w_+, w_- \in \mathbb{Z}^n$ , search for  $g \in \mathcal{G}(A)$  which satisfies  $w_+g^+ - w_-g^- > 0$  and  $y + g \in S$ ; if there is such a  $g$  then return it as an augmenting vector, whereas if there is no such  $g$  then assert that no augmenting vector exists. Clearly, if this simulated oracle returns a vector  $g$  then it is an augmenting vector. On the other hand, if there exists an augmenting vector  $g$  then  $y + g \in S \subseteq T$  and  $w_+g^+ - w_-g^- > 0$  imply by Lemma 9 that there is also a  $\hat{g} \in \mathcal{G}(A)$  with  $\hat{g} \sqsubseteq g$  such that  $w_+\hat{g}^+ - w_-\hat{g}^- > 0$  and  $y + \hat{g} \in T$ . Since  $y, y + g \in S$  and  $\hat{g} \sqsubseteq g$ , we find that  $y + \hat{g} \in S$  as well. Therefore the Graver basis contains an augmenting vector and hence the simulated oracle will find and output one.

Define  $\hat{l}, \hat{u} \in \mathbb{Z}^n$  by  $\hat{l}_j := \max(l_j, -\rho)$ ,  $\hat{u}_j := \min(u_j, \rho)$ ,  $j = 1, \dots, n$ . Then it is easy to see that  $S = \text{aff}(S) \cap \{y \in \mathbb{Z}^n : \hat{l} \leq y \leq \hat{u}\}$ . Now apply the algorithm of Lemma 7 to  $\hat{l}, \hat{u}, S, x$ , and  $w$ , using the above simulated oriented augmentation oracle for  $S$ , and obtain in polynomial time a vector  $x^* \in S$  which is optimal to the linear discrete optimization problem over  $S$  and hence to the given linear integer program.  $\square$

As a special case of Theorem 12 we recover the following result of [55] concerning linear integer programming in standard form when the Graver basis is available.

**Theorem 13** *There is a polynomial time algorithm that, given matrix  $A \in \mathbb{Z}^{m \times n}$ , its Graver basis  $\mathcal{G}(A)$ ,  $x \in \mathbb{N}^n$ , and  $w \in \mathbb{Z}^n$ , encoded as  $[\langle A, \mathcal{G}(A), x, w \rangle]$ , solves the linear integer programming problem  $\max\{wz : z \in \mathbb{N}^n, Az = b\}$  where  $b := Ax$ .*

### Graver Bases of N-fold Matrices

As mentioned above, the Graver basis  $\mathcal{G}(A)$  of an integer matrix  $A$  contains all circuits of  $A$  and typically many more elements. While the number of circuits is already typically exponential and can be as large as  $\binom{n}{m+1}$ , the number of Graver basis elements is usually even larger and depends also on the entries of  $A$  and not only on its dimensions  $m, n$ . So unfortunately it is typically very hard to compute  $\mathcal{G}(A)$ . However, we now show that for the important and useful broad class of  $n$ -fold matrices, the Graver basis is better behaved and can be computed in polynomial time. Recall the following definition from the introduction. Given an  $(r + s) \times t$

matrix  $A$ , let  $A_1$  be its  $r \times t$  sub-matrix consisting of the first  $r$  rows and let  $A_2$  be its  $s \times t$  sub-matrix consisting of the last  $s$  rows. We refer to  $A$  explicitly as  $(r + s) \times t$  matrix, since the definition below depends also on  $r$  and  $s$  and not only on the entries of  $A$ . The  $n$ -fold matrix of an  $(r + s) \times t$  matrix  $A$  is then defined to be the following  $(r + ns) \times nt$  matrix,

$$A^{(n)} := (\mathbf{1}_n \otimes A_1) \oplus (I_n \otimes A_2)$$

$$= \begin{pmatrix} A_1 & A_1 & A_1 & \cdots & A_1 \\ A_2 & 0 & 0 & \cdots & 0 \\ 0 & A_2 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & A_2 \end{pmatrix}.$$

We now discuss a recent result of [54], which originates in [4], and its extension in [38], on the stabilization of Graver bases of  $n$ -fold matrices. Consider vectors  $x = (x^1, \dots, x^n)$  with  $x^k \in \mathbb{Z}^t$  for  $k = 1, \dots, n$ . The type of  $x$  is the number  $|\{k : x^k \neq 0\}|$  of nonzero components  $x^k \in \mathbb{Z}^t$  of  $x$ . The Graver complexity of an  $(r + s) \times t$  matrix, denoted  $c(A)$ , is defined to be the smallest  $c \in \mathbb{N} \cup \{\infty\}$  such that for all  $n$ , the Graver basis of  $A^{(n)}$  consists of vectors of type at most  $c(A)$ . We provide the proof of the following result of [38,54] stating that the Graver complexity is always finite.

**Lemma 10** *The Graver complexity  $c(A)$  of any  $(r+s) \times t$  integer matrix  $A$  is finite.*

*Proof* Call an element  $x = (x^1, \dots, x^n)$  in the Graver basis of some  $A^{(n)}$  pure if  $x^i \in \mathcal{G}(A_2)$  for all  $i$ . Note that the type of a pure  $x \in \mathcal{G}(A^{(n)})$  is  $n$ . First, we claim that if there is an element of type  $m$  in some  $\mathcal{G}(A^{(l)})$  then for some  $n \geq m$  there is a pure element in  $\mathcal{G}(A^{(n)})$ , and so it will suffice to bound the type of pure elements. Suppose there is an element of type  $m$  in some  $\mathcal{G}(A^{(l)})$ . Then its restriction to its  $m$  nonzero components is an element  $x = (x^1, \dots, x^m)$  in  $\mathcal{G}(A^{(m)})$ . Let  $x^i = \sum_{j=1}^{k_i} g_{i,j}$  be a conormal decomposition of  $x^i$  with  $g_{i,j} \in \mathcal{G}(A_2)$  for all  $i, j$ , and let  $n := k_1 + \dots + k_m \geq m$ . Then  $g := (g_{1,1}, \dots, g_{m,k_m})$  is in  $\mathcal{G}(A^{(n)})$ , else there would be  $\hat{g} \sqsubset g$  in  $\mathcal{G}(A^{(n)})$  in which case the nonzero  $\hat{x}$  with  $\hat{x}^i := \sum_{j=1}^{k_i} \hat{g}_{i,j}$  for all  $i$  would satisfy  $\hat{x} \sqsubset x$  and  $\hat{x} \in \mathcal{L}(A^{(m)})$ , contradicting  $x \in \mathcal{G}(A^{(m)})$ . Thus  $g$  is a pure element of type  $n \geq m$ , proving the claim.

We proceed to bound the type of pure elements. Let  $\mathcal{G}(A_2) = \{g_1, \dots, g_m\}$  be the Graver basis of  $A_2$  and

let  $G_2$  be the  $t \times m$  matrix whose columns are the  $g_i$ . Suppose  $x = (x^1, \dots, x^n) \in \mathcal{G}(A^{(n)})$  is pure for some  $n$ . Let  $v \in \mathbb{N}^m$  be the vector with  $v_i := |\{k : x^k = g_i\}|$  counting the number of  $g_i$  components of  $x$  for each  $i$ . Then  $\sum_{i=1}^m v_i$  is equal to the type  $n$  of  $x$ . Next, note that  $A_1 G_2 v = A_1 (\sum_{k=1}^n x^k) = 0$  and hence  $v \in \mathcal{L}(A_1 G_2)$ . We claim that, moreover,  $v \in \mathcal{G}(A_1 G_2)$ . Suppose indirectly not. Then there is  $\hat{v} \in \mathcal{G}(A_1 G_2)$  with  $\hat{v} \sqsubset v$ , and it is easy to obtain a nonzero  $\hat{x} \sqsubset x$  from  $x$  by zeroing out some components so that  $\hat{v}_i = |\{k : \hat{x}^k = g_i\}|$  for all  $i$ . Then  $A_1 (\sum_{k=1}^n \hat{x}^k) = A_1 G_2 \hat{v} = 0$  and hence  $\hat{x} \in \mathcal{L}(A^{(n)})$ , contradicting  $x \in \mathcal{G}(A^{(n)})$ .

So the type of any pure element, and hence the Graver complexity of  $A$ , is at most the largest value  $\sum_{i=1}^m v_i$  of any nonnegative element  $v$  of the Graver basis  $\mathcal{G}(A_1 G_2)$ .  $\square$

Using Lemma 10 we now show how to compute  $\mathcal{G}(A^{(n)})$  in polynomial time.

**Theorem 14** *For every fixed  $(r + s) \times t$  integer matrix  $A$  there is a strongly polynomial time algorithm that, given  $n \in \mathbb{N}$ , encoded as  $[n; n]$ , computes the Graver basis  $\mathcal{G}(A^{(n)})$  of the  $n$ -fold matrix  $A^{(n)}$ . In particular, the cardinality  $|\mathcal{G}(A^{(n)})|$  and binary length  $\langle \mathcal{G}(A^{(n)}) \rangle$  of the Graver basis of the  $n$ -fold matrix are polynomially bounded in  $n$ .*

*Proof* Let  $c := c(A)$  be the Graver complexity of  $A$  and consider any  $n \geq c$ . We show that the Graver basis of  $A^{(n)}$  is the union of  $\binom{n}{c}$  suitably embedded copies of the Graver basis of  $A^{(c)}$ . For every  $c$  indices  $1 \leq k_1 < \dots < k_c \leq n$  define a map  $\phi_{k_1, \dots, k_c}$  from  $\mathbb{Z}^{ct}$  to  $\mathbb{Z}^{nt}$  sending  $x = (x^1, \dots, x^c)$  to  $y = (y^1, \dots, y^n)$  with  $y^{k_i} := x^i$  for  $i = 1, \dots, c$  and  $y^k := 0$  for  $k \notin \{k_1, \dots, k_c\}$ . We claim that  $\mathcal{G}(A^{(n)})$  is the union of the images of  $\mathcal{G}(A^{(c)})$  under the  $\binom{n}{c}$  maps  $\phi_{k_1, \dots, k_c}$  for all  $1 \leq k_1 < \dots < k_c \leq n$ , that is,

$$\mathcal{G}(A^{(n)}) = \bigcup_{1 \leq k_1 < \dots < k_c \leq n} \phi_{k_1, \dots, k_c}(\mathcal{G}(A^{(c)})). \quad (2)$$

If  $x = (x^1, \dots, x^c) \in \mathcal{G}(A^{(c)})$  then  $x$  is a  $\sqsubseteq$ -minimal nonzero element of  $\mathcal{L}(A^{(c)})$ , implying that  $\phi_{k_1, \dots, k_c}(x)$  is a  $\sqsubseteq$ -minimal nonzero element of  $\mathcal{L}(A^{(n)})$  and therefore we have  $\phi_{k_1, \dots, k_c}(x) \in \mathcal{G}(A^{(n)})$ . So the right-hand side of (2) is contained in the left-hand side. Conversely, consider any  $y \in \mathcal{G}(A^{(n)})$ . Then, by Lemma 10, the type of  $y$  is at most  $c$ , so there are indices  $1 \leq k_1 < \dots < k_c \leq n$

such that all nonzero components of  $y$  are among those of the reduced vector  $x := (y^{k_1}, \dots, y^{k_c})$  and therefore  $y = \phi_{k_1, \dots, k_c}(x)$ . Now,  $y \in \mathcal{G}(A^{(n)})$  implies that  $y$  is a  $\sqsubseteq$ -minimal nonzero element of  $\mathcal{L}(A^{(n)})$  and hence  $x$  is a  $\sqsubseteq$ -minimal nonzero element of  $\mathcal{L}(A^{(c)})$ . Therefore  $x \in \mathcal{G}(A^{(c)})$  and  $y \in \phi_{k_1, \dots, k_g}(\mathcal{G}(A^{(c)}))$ . So the left-hand side of (2) is contained in the right-hand side.

Since  $A$  is fixed we have that  $c = c(A)$  and  $\mathcal{G}(A^{(c)})$  are constant. Then (2) implies that  $|\mathcal{G}(A^{(n)})| \leq \binom{n}{c} |\mathcal{G}(A^{(c)})| = O(n^c)$ . Moreover, every element of  $\mathcal{G}(A^{(n)})$  is an  $nt$ -dimensional vector  $\phi_{k_1, \dots, k_c}(x)$  obtained by appending zero components to some  $x \in \mathcal{G}(A^{(c)})$  and hence has linear binary length  $O(n)$ . So the binary length of the entire Graver basis  $\mathcal{G}(A^{(n)})$  is  $O(n^{c+1})$ . Thus, the  $\binom{n}{c} = O(n^c)$  images  $\phi_{k_1, \dots, k_c}(\mathcal{G}(A^{(c)}))$  and their union  $\mathcal{G}(A^{(n)})$  can be computed in strongly polynomial time, as claimed.  $\square$

*Example 2* Consider the  $(2 + 1) \times 2$  matrix  $A$  with  $A_1 := I_2$  the  $2 \times 2$  identity and  $A_2 := (1, 1)$ . Then  $\mathcal{G}(A_2) = \pm(1, -1)$  and  $\mathcal{G}(A_1 \mathcal{G}_2) = \pm(1, 1)$  from which the Graver complexity of  $A$  can be concluded to be  $c(A) = 2$  (see the proof of Lemma 10). The 2-fold matrix of  $A$  and its Graver basis, consisting of two antipodal vectors only, are

$$A^{(2)} = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix},$$

$$\mathcal{G}(A^{(2)}) = \pm \begin{pmatrix} 1 & -1 & -1 & 1 \end{pmatrix}.$$

By Theorem 14, the Graver basis of the 4-fold matrix  $A^{(4)}$  is computed to be the union of the images of the  $6 = \binom{4}{2}$  maps  $\phi_{k_1, k_2}: \mathbb{Z}^{2 \cdot 2} \rightarrow \mathbb{Z}^{4 \cdot 2}$  for  $1 \leq k_1 < k_2 \leq 4$ , getting

$$A^{(4)} = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix},$$

$$\mathcal{G}(A^{(4)}) = \pm \begin{pmatrix} 1 & -1 & -1 & 1 & 0 & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & -1 & 1 & 0 & 0 \\ 1 & -1 & 0 & 0 & 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & -1 & -1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & -1 & 1 \\ 0 & 0 & 0 & 0 & 1 & -1 & -1 & 1 \end{pmatrix}.$$

### Linear N-fold Integer Programming in Polynomial Time

We now proceed to provide a polynomial time algorithm for linear integer programming over  $n$ -fold matrices. First, combining the results of Sect. “Graver Bases and Linear Integer Programming” and Sect. “Graver Bases of N-fold Matrices”, we get at once the following polynomial time algorithm for converting any feasible point to an optimal one.

**Lemma 11** *For every fixed  $(r + s) \times t$  integer matrix  $A$  there is a polynomial time algorithm that, given  $n \in \mathbb{N}$ ,  $l, u \in \mathbb{Z}_\infty^{nt}$ ,  $x, w \in \mathbb{Z}^{nt}$  satisfying  $l \leq x \leq u$ , encoded as  $[(l, u, x, w)]$ , solves the linear  $n$ -fold integer programming problem with  $b := A^{(n)}x$ ,*

$$\max \{wz : z \in \mathbb{Z}^{nt}, A^{(n)}z = b, l \leq z \leq u\}.$$

*Proof* First, apply the polynomial time algorithm of Theorem 14 and compute the Graver basis  $\mathcal{G}(A^{(n)})$  of the  $n$ -fold matrix  $A^{(n)}$ . Then apply the polynomial time algorithm of Theorem 12 to the data  $A^{(n)}, \mathcal{G}(A^{(n)})$ ,  $l, u, x$  and  $w$ .  $\square$

Next we show that an initial feasible point can also be found in polynomial time.

**Lemma 12** *For every fixed  $(r + s) \times t$  integer matrix  $A$  there is a polynomial time algorithm that, given  $n \in \mathbb{N}$ ,  $l, u \in \mathbb{Z}_\infty^{nt}$ , and  $b \in \mathbb{Z}^{r+ns}$ , encoded as  $[(l, u, b)]$ , either finds an  $x \in \mathbb{Z}^{nt}$  satisfying  $l \leq x \leq u$  and  $A^{(n)}x = b$  or asserts that none exists.*

*Proof* If  $l \not\leq u$  then assert that there is no feasible point and terminate the algorithm. Assume then that  $l \leq u$  and determine some  $x \in \mathbb{Z}^{nt}$  with  $l \leq x \leq u$  and  $\langle x \rangle \leq \langle l, u \rangle$ . Now, introduce  $n(2r + 2s)$  auxiliary variables to the given  $n$ -fold integer program and denote by  $\hat{x}$  the resulting vector of  $n(t + 2r + 2s)$  variables. Suitably extend the lower and upper bound vectors to  $\hat{l}, \hat{u}$  by setting  $\hat{l}_j := 0$  and  $\hat{u}_j := \infty$  for each auxiliary variable  $\hat{x}_j$ . Consider the auxiliary integer program of finding an integer vector  $\hat{x}$  that minimizes the sum of auxiliary variables subject to the lower and upper bounds  $\hat{l} \leq \hat{x} \leq \hat{u}$  and the following system of equations, with  $I_r$  and  $I_s$  the

$r \times r$  and  $s \times s$  identity matrices,

$$\begin{pmatrix} A_1 & I_r & -I_r & 0 & 0 & A_1 & I_r & -I_r & 0 \\ A_2 & 0 & 0 & I_s & -I_s & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & A_2 & 0 & 0 & I_s \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \\ 0 & \cdots & A_1 & I_r & -I_r & 0 & 0 & 0 & \\ 0 & \cdots & 0 & 0 & 0 & 0 & 0 & 0 & \\ -I_s & \cdots & 0 & 0 & 0 & 0 & 0 & 0 & \\ \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \\ 0 & \cdots & A_2 & 0 & 0 & I_s & -I_s & 0 & \end{pmatrix} \hat{x} = b.$$

This is again an  $n$ -fold integer program, with an  $(r+s) \times (t + 2r + 2s)$  matrix  $\hat{A}$ , where  $\hat{A}_1 = (A_1, I_r, -I_r, 0, 0)$  and  $\hat{A}_2 = (A_2, 0, 0, I_s, -I_s)$ . Since  $A$  is fixed, so is  $\hat{A}$ . It is now easy to extend the vector  $x \in \mathbb{Z}^{nt}$  determined above to a feasible point  $\hat{x}$  of the auxiliary program. Indeed, put  $\hat{b} := b - A^{(n)}x \in \mathbb{Z}^{r+ns}$ ; now, for  $i = 1, \dots, r + ns$ , simply choose an auxiliary variable  $\hat{x}_j$  appearing only in the  $i$ th equation, whose coefficient equals the sign  $\text{sign}(\hat{b}_i)$  of the corresponding entry of  $\hat{b}$ , and set  $\hat{x}_j := |\hat{b}_i|$ . Define  $\hat{w} \in \mathbb{Z}^{n(t+2r+2s)}$  by setting  $\hat{w} := 0$  for each original variable and  $\hat{w} := -1$  for each auxiliary variable, so that maximizing  $\hat{w}\hat{x}$  is equivalent to minimizing the sum of auxiliary variables. Now solve the auxiliary linear integer program in polynomial time by applying the algorithm of Lemma 11 corresponding to  $\hat{A}$  to the data  $n, \hat{l}, \hat{u}, \hat{x}$ , and  $\hat{w}$ . Since the auxiliary objective  $\hat{w}\hat{x}$  is bounded above by zero, the algorithm will output an optimal solution  $\hat{x}^*$ . If the optimal objective value is negative, then the original  $n$ -fold program is infeasible, whereas if the optimal value is zero, then the restriction of  $\hat{x}^*$  to the original variables is a feasible point  $x^*$  of the original integer program.  $\square$

Combining Lemmas 11 and 12 we get at once the main result of this section.

**Theorem 15** *For every fixed  $(r+s) \times t$  integer matrix  $A$  there is a polynomial time algorithm that, given  $n$ , lower and upper bounds  $l, u \in \mathbb{Z}_{\infty}^{nt}$ ,  $w \in \mathbb{Z}^{nt}$ , and  $b \in \mathbb{Z}^{r+ns}$ , encoded as  $[(l, u, w, b)]$ , solves the following linear  $n$ -fold integer programming problem,*

$$\max \{wx : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\}.$$

Again, as a special case of Theorem 15 we recover the following result of [13] concerning linear integer programming in standard form over  $n$ -fold matrices.

**Theorem 16** *For every fixed  $(r+s) \times t$  integer matrix  $A$  there is a polynomial time algorithm that, given  $n$ , linear functional  $w \in \mathbb{Z}^{nt}$ , and right-hand side  $b \in \mathbb{Z}^{r+ns}$ , encoded as  $[(w, b)]$ , solves the following linear  $n$ -fold integer program in standard form,*

$$\max \{wx : x \in \mathbb{N}^{nt}, A^{(n)}x = b\}.$$

**Some Applications**

**Three-Way Line-Sum Transportation Problems**

Transportation problems form a very important class of discrete optimization problems studied extensively in the operations research and mathematical programming literature, see e. g. [6,42,43,53,60,62] and the references therein. We will discuss this class of problem and its applications to secure statistical data disclosure in more detail in Sect. “**Multiway Transportation Problems and Privacy in Statistical Databases**”.

It is well known that 2-way transportation problems are polynomial time solvable, since they can be encoded as linear integer programs over totally unimodular systems. However, already 3-way transportation problem are much more complicated. Consider the following 3-way transportation problem over  $p \times q \times n$  tables with all line-sums fixed,

$$\max \left\{ wx : x \in \mathbb{N}^{p \times q \times n}, \sum_i x_{i,j,k} = z_{j,k}, \sum_j x_{i,j,k} = v_{i,k}, \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

The data for the problem consist of given integer numbers (lines-sums)  $u_{i,j}, v_{i,k}, z_{j,k}$  for  $i = 1, \dots, p, j = 1, \dots, q, k = 1, \dots, n$ , and a linear functional given by a  $p \times q \times n$  integer array  $w$  representing the transportation profit per unit on each cell. The problem is to find a transportation, that is, a  $p \times q \times n$  nonnegative integer table  $x$  satisfying the line sum constraints, which attains maximum profit  $wx = \sum_{i=1}^p \sum_{j=1}^q \sum_{k=1}^n w_{i,j,k} x_{i,j,k}$ .

When at least two of the table sides, say  $p, q$ , are variable part of the input, and even when the third side is fixed and as small as  $n = 3$ , this problem is already *universal* for integer programming in a very

strong sense [14,16], and in particular is NP-hard [15]; this will be discussed in detail and proved in Sect. “Multiway Transportation Problems and Privacy in Statistical Databases”. We now show that in contrast, when two sides, say  $p, q$ , are fixed (but arbitrary), and one side  $n$  is variable, then the 3-way transportation problem over such long tables is an  $n$ -fold integer programming problem and therefore, as a consequence of Theorem 16, can be solved in polynomial time.

**Corollary 8** *For every fixed  $p$  and  $q$  there is a polynomial time algorithm that, given  $n$ , integer profit array  $w \in \mathbb{Z}^{p \times q \times n}$ , and line-sums  $u \in \mathbb{Z}^{p \times q}$ ,  $v \in \mathbb{Z}^{p \times n}$  and  $z \in \mathbb{Z}^{q \times n}$ , encoded as  $\{w, u, v, z\}$ , solves the integer 3-way line-sum transportation problem*

$$\max \left\{ wx : x \in \mathbb{N}^{p \times q \times n}, \sum_i x_{i,j,k} = z_{j,k}, \right. \\ \left. \sum_j x_{i,j,k} = v_{i,k}, \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

*Proof* Re-index  $p \times q \times n$  arrays as  $x = (x^1, \dots, x^n)$  with each component indexed as  $x^k := (x_{i,j}^k) := (x_{1,1,k}, \dots, x_{p,q,k})$  suitably indexed as a  $pq$  vector representing the  $k$ th layer of  $x$ . Put  $r := t := pq$  and  $s := p + q$ , and let  $A$  be the  $(r + s) \times t$  matrix with  $A_1 := I_{pq}$  the  $pq \times pq$  identity and with  $A_2$  the  $(p + q) \times pq$  matrix of equations of the usual 2-way transportation problem for  $p \times q$  arrays. Re-arrange the given line-sums in a vector  $b := (b^0, b^1, \dots, b^n) \in \mathbb{Z}^{r+ns}$  with  $b^0 := (u_{i,j})$  and  $b^k := ((v_{i,k}), (z_{j,k}))$  for  $k = 1, \dots, n$ .

This translates the given 3-way transportation problem into an  $n$ -fold integer programming problem in standard form,

$$\max \{ wx : x \in \mathbb{N}^{nt}, A^{(n)}x = b \},$$

where the equations  $A_1(\sum_{k=1}^n x^k) = b^0$  represent the constraints  $\sum_k x_{i,j,k} = u_{i,j}$  of all line-sums where summation over layers occurs, and the equations  $A_2 x^k = b^k$  for  $k = 1, \dots, n$  represent the constraints  $\sum_i x_{i,j,k} = z_{j,k}$  and  $\sum_j x_{i,j,k} = v_{i,k}$  of all line-sums where summations are within a single layer at a time.

Using the algorithm of Theorem 16, this  $n$ -fold integer program, and hence the given 3-way transportation problem, can be solved in polynomial time.  $\square$

*Example 3* We demonstrate the encoding of the  $p \times q \times n$  transportation problem as an  $n$ -fold integer program

as in the proof of Corollary 8 for  $p = q = 3$  (smallest case where the problem is genuinely 3-dimensional). Here we put  $r := t := 9$ ,  $s := 6$ , write

$$x^k := (x_{1,1,k}, x_{1,2,k}, x_{1,3,k}, x_{2,1,k}, x_{2,2,k}, x_{2,3,k}, \\ x_{3,1,k}, x_{3,2,k}, x_{3,3,k}), \quad k = 1, \dots, n,$$

and let the  $(9 + 6) \times 9$  matrix  $A$  consist of  $A_1 = I_9$  the  $9 \times 9$  identity matrix and

$$A_2 := \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \end{pmatrix}.$$

Then the corresponding  $n$ -fold integer program encodes the  $3 \times 3 \times n$  transportation problem as desired. Already for this case, of  $3 \times 3 \times n$  tables, the only known polynomial time algorithm for the transportation problem is the one underlying Corollary 8.

Corollary 8 has a very broad generalization to multiway transportation problems over long  $k$ -way tables of any dimension  $k$ ; this will be discussed in detail in Sect. “Multiway Transportation Problems and Privacy in Statistical Databases”.

**Packing Problems and Cutting-Stock** We consider the following rather general class of packing problems which concern maximum utility packing of many items of several types in various bins subject to weight constraints. More precisely, the data is as follows. There are  $t$  types of items. Each item of type  $j$  has integer weight  $v_j$ . There are  $n_j$  items of type  $j$  to be packed. There are  $n$  bins. The weight capacity of bin  $k$  is an integer  $u_k$ . Finally, there is a utility matrix  $w \in \mathbb{Z}^{t \times n}$  where  $w_{j,k}$  is the utility of packing one item of type  $j$  in bin  $k$ . The problem is to find a feasible packing of maximum total utility. By incrementing the number  $t$  of types by 1 and suitably augmenting the data, we may assume that the last type  $t$  represents “slack items” which occupy the unused capacity in each bin, where the weight of each slack item is 1, the utility of packing any slack item in any bin is 0, and the number of slack items is the total residual weight capacity  $n_t := \sum_{k=1}^n u_k - \sum_{j=1}^{t-1} n_j v_j$ . Let  $x \in \mathbb{N}^{t \times n}$  be a variable matrix where  $x_{j,k}$  represents

the number of items of type  $j$  to be packed in bin  $k$ . Then the packing problem becomes the following linear integer program,

$$\max \left\{ wx : x \in \mathbb{N}^{t \times n}, \sum_j v_j x_{j,k} = u_k, \sum_k x_{j,k} = n_j \right\}.$$

We now show that this is in fact an  $n$ -fold integer programming problem and therefore, as a consequence of Theorem 16, can be solved in polynomial time. While the number  $t$  of types and type weights  $v_j$  are fixed, which is natural in many bin packing applications, the numbers  $n_j$  of items of each type and the bin capacities  $u_k$  may be very large.

**Corollary 9** *For every fixed number  $t$  of types and integer type weights  $v_1, \dots, v_t$ , there is a polynomial time algorithm that, given  $n$  bins, integer item numbers  $n_1, \dots, n_t$ , integer bin capacities  $u_1, \dots, u_n$ , and  $t \times n$  integer utility matrix  $w$ , encoded as  $[(n_1, \dots, n_t, u_1, \dots, u_n, w)]$ , solves the following integer bin packing problem,*

$$\max \left\{ wx : x \in \mathbb{N}^{t \times n}, \sum_j v_j x_{j,k} = u_k, \sum_k x_{j,k} = n_j \right\}.$$

*Proof* Re-index the variable matrix as  $x = (x^1, \dots, x^n)$  with  $x^k := (x_1^k, \dots, x_t^k)$  where  $x_j^k$  represents the number of items of type  $j$  to be packed in bin  $k$  for all  $j$  and  $k$ . Let  $A$  be the  $(t+1) \times t$  matrix with  $A_1 := I_t$  the  $t \times t$  identity and with  $A_2 := (v_1, \dots, v_t)$  a single row. Re-arrange the given item numbers and bin capacities in a vector  $b := (b^0, b^1, \dots, b^n) \in \mathbb{Z}^{t+n}$  with  $b^0 := (n_1, \dots, n_t)$  and  $b^k := u_k$  for all  $k$ . This translates the bin packing problem into an  $n$ -fold integer programming problem in standard form,

$$\max \{ wx : x \in \mathbb{N}^{nt}, A^{(n)}x = b \},$$

where the equations  $A_1(\sum_{k=1}^n x^k) = b^0$  represent the constraints  $\sum_k x_{j,k} = n_j$  assuring that all items of each type are packed, and the equations  $A_2 x^k = b^k$  for  $k = 1, \dots, n$  represent the constraints  $\sum_j v_j x_{j,k} = u_k$

assuring that the weight capacity of each bin is not exceeded (in fact, the slack items make sure each bin is perfectly packed).

Using the algorithm of Theorem 16, this  $n$ -fold integer program, and hence the given integer bin packing problem, can be solved in polynomial time.  $\square$

*Example 5 (cutting-stock problem).* This is a classical manufacturing problem [27], where the usual setup is as follows: a manufacturer produces rolls of material (such as scotch-tape or band-aid) in one of  $t$  different widths  $v_1, \dots, v_t$ . The rolls are cut out from standard rolls of common large width  $u$ . Given orders by customers for  $n_j$  rolls of width  $v_j$ , the problem facing the manufacturer is to meet the orders using the smallest possible number of standard rolls. This can be cast as a bin packing problem as follows. Rolls of width  $v_j$  become items of type  $j$  to be packed. Standard rolls become identical bins, of capacity  $u_k := u$  each, where the number of bins is set to be  $n := \sum_{j=1}^t \lceil n_j / \lfloor u/v_j \rfloor \rceil$  which is sufficient to accommodate all orders. The utility of each roll of width  $v_j$  is set to be its width negated  $w_{j,k} := -v_j$  regardless of the standard roll  $k$  from which it is cut (paying for the width it takes). Introduce a new roll width  $v_0 := 1$ , where rolls of that width represent “slack rolls” which occupy the unused width of each standard roll, with utility  $w_{0,k} := -1$  regardless of the standard roll  $k$  from which it is cut (paying for the unused width it represents), with the number of slack rolls set to be the total residual width  $n_0 := nu - \sum_{j=1}^t n_j v_j$ . Then the cutting-stock problem becomes a bin packing problem and therefore, by Corollary 9, for every fixed  $t$  and fixed roll widths  $v_1, \dots, v_t$ , it is solvable in time polynomial in  $\sum_{j=1}^t \lceil n_j / \lfloor u/v_j \rfloor \rceil$  and  $(n_1, \dots, n_t, u)$ .

One common approach to the cutting-stock problem uses so-called *cutting patterns*, which are feasible solutions of the knapsack problem  $\{y \in \mathbb{N}^t : \sum_{j=1}^t v_j y_j \leq u\}$ . This is useful when the common width  $u$  of the standard rolls is of the same order of magnitude as the demand roll widths  $v_j$ . However, when  $u$  is much larger than the  $v_j$ , the number of cutting patterns becomes prohibitively large to handle. But then the values  $\lfloor u/v_j \rfloor$  are large and hence  $n := \sum_{j=1}^t \lceil n_j / \lfloor u/v_j \rfloor \rceil$  is small, in which case the solution through the algorithm of Corollary 9 becomes particularly appealing.

## Convex Integer Programming

In this section we discuss convex integer programming. In particular, we extend the theory of Sect. “**Linear N-fold Integer Programming**” and show that convex  $n$ -fold integer programming is polynomial time solvable as well. In Sect. “**Convex Integer Programming over Totally Unimodular Systems**” we discuss convex integer programming over totally unimodular matrices. In Sect. “**Graver Bases and Convex Integer Programming**” we show the applicability of Graver bases to convex integer programming. In Sect. “**Convex N-fold Integer Programming in Polynomial Time**” we combine Theorem 6, the results of Sect. “**Linear N-fold Integer Programming**”, and the preparatory facts from Sect. “**Graver Bases and Convex Integer Programming**”, and prove the main result of this section, asserting that convex  $n$ -fold integer programming is polynomial time solvable. We conclude with some applications in Sect. “**Some Applications**”.

As in Sect. “**Linear N-fold Integer Programming**”, the feasible set  $S$  is presented as the set of integer points satisfying an explicitly given system of linear inequalities, given in one of the forms

$$S := \{x \in \mathbb{N}^n : Ax = b\} \quad \text{or} \\ S := \{x \in \mathbb{Z}^n : Ax = b, l \leq x \leq u\},$$

with matrix  $A \in \mathbb{Z}^{m \times n}$ , right-hand side  $b \in \mathbb{Z}^m$ , and lower and upper bounds  $l, u \in \mathbb{Z}_\infty^n$ .

As demonstrated in Sect. “**Limitations**”, if the polyhedron  $P := \{x \in \mathbb{R}^n : Ax = b, l \leq x \leq u\}$  is unbounded then the convex integer programming problem with an oracle presented convex functional is rather hopeless. Therefore, an algorithm that solves the convex integer programming problem should either return an optimal solution, or assert that the program is infeasible, or assert that the underlying polyhedron is unbounded.

Nonetheless, we do allow the lower and upper bounds  $l, u$  to lie in  $\mathbb{Z}_\infty^n$  rather than  $\mathbb{Z}^n$ , since often the polyhedron is bounded even though the variables are not bounded explicitly (for instance, if each variable is bounded below only, and appears in some equation all of whose coefficients are positive). This results in broader formulation flexibility. Furthermore, in the next subsections we prove auxiliary lemmas asserting that certain sets cover all edge-directions of rele-

vant polyhedra, which do hold also in the unbounded case. So we now extend the notion of edge-directions, defined in Sect. “**Edge-Directions and Zonotopes**” for polytopes, to polyhedra. A *direction* of an edge (1-dimensional face)  $e$  of a polyhedron  $P$  is any nonzero scalar multiple of  $y - x$  where  $x, y$  are any two distinct points in  $e$ . As before, a set *covers all edge-directions* of  $P$  if it contains a direction of each edge of  $P$ .

## Convex Integer Programming over Totally Unimodular Systems

A matrix  $A$  is *totally unimodular* if the determinant of every square submatrix of  $A$  lies in  $\{-1, 0, 1\}$ . Such matrices arise naturally in network flows, ordinary (2-way) transportation problems, and many other situations. A fundamental result in integer programming [37] asserts that polyhedra defined by totally unimodular matrices are integer. More precisely, if  $A$  is an  $m \times n$  totally unimodular matrix,  $l, u \in \mathbb{Z}_\infty^n$ , and  $b \in \mathbb{Z}^m$ , then

$$P_I := \text{conv}\{x \in \mathbb{Z}^n : Ax = b, l \leq x \leq u\} \\ = \{x \in \mathbb{R}^n : Ax = b, l \leq x \leq u\} := P,$$

that is, the underlying polyhedron  $P$  coincides with its integer hull  $P_I$ . This has two consequences useful in facilitating the solution of the corresponding convex integer programming problem via the algorithm of Theorem 6. First, the corresponding linear integer programming problem can be solved by linear programming over  $P$  in polynomial time. Second, a set covering all edge-directions of the implicitly given integer hull  $P_I$ , which is typically very hard to determine, is obtained here as a set covering all edge-directions of  $P$  which is explicitly given and hence easier to determine.

We now describe a well known property of polyhedra of the above form. A *circuit* of a matrix  $A \in \mathbb{Z}^{m \times n}$  is a nonzero primitive minimal support element of  $\mathcal{L}(A)$ . So a circuit is a nonzero  $c \in \mathbb{Z}^n$  satisfying  $Ac = 0$ , whose entries are relatively prime integers, such that no nonzero  $c'$  with  $Ac' = 0$  has support strictly contained in the support of  $c$ .

**Lemma 13** *For every  $A \in \mathbb{Z}^{m \times n}$ ,  $l, u \in \mathbb{Z}_\infty^n$ , and  $b \in \mathbb{Z}^m$ , the set of circuits of  $A$  covers all edge-directions of the polyhedron  $P := \{x \in \mathbb{R}^n : Ax = b, l \leq x \leq u\}$ .*

*Proof* Consider any edge  $e$  of  $P$ . Pick two distinct points  $x, y \in e$  and set  $g := y - x$ . Then  $Ag = 0$

and therefore, as can be easily proved by induction on  $|\text{supp}(g)|$ , there is a finite decomposition  $g = \sum_i \alpha_i c_i$  with  $\alpha_i$  positive real number and  $c_i$  circuit of  $A$  such that  $\alpha_i c_i \sqsubseteq g$  for all  $i$ , where  $\sqsubseteq$  is the natural extension from  $\mathbb{Z}^n$  to  $\mathbb{R}^n$  of the partial order defined in Sect. “Graver Bases and Linear Integer Programming”. We claim that  $x + \alpha_i c_i \in P$  for all  $i$ . Indeed,  $c_i$  being a circuit implies  $A(x + \alpha_i c_i) = Ax = b$ ; and  $l \leq x, x + g \leq u$  and  $\alpha_i c_i \sqsubseteq g$  imply  $l \leq x + \alpha_i c_i \leq u$ .

Now let  $w \in \mathbb{R}^n$  be a linear functional uniquely maximized over  $P$  at the edge  $e$ . Then  $w\alpha_i c_i = w(x + \alpha_i c_i) - wx \leq 0$  for all  $i$ . But  $\sum(w\alpha_i c_i) = wg = wy - wx = 0$ , implying that in fact  $w\alpha_i c_i = 0$  and hence  $x + \alpha_i c_i \in e$  for all  $i$ . This implies that each  $c_i$  is a direction of  $e$  (in fact, all  $c_i$  are the same and  $g$  is a multiple of some circuit).  $\square$

Combining Theorem 6 and Lemma 13 we obtain the following statement.

**Theorem 17** *For every fixed  $d$  there is a polynomial time algorithm that, given  $m \times n$  totally unimodular matrix  $A$ , set  $C \subset \mathbb{Z}^n$  containing all circuits of  $A$ , vectors  $l, u \in \mathbb{Z}_\infty^n, b \in \mathbb{Z}^m$ , and  $w_1, \dots, w_d \in \mathbb{Z}^n$ , and convex  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[\langle A, C, l, u, b, w_1, \dots, w_d \rangle]$ , solves the convex integer program*

$$\max \{c(w_1 x, \dots, w_d x) : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}.$$

*Proof* First, check in polynomial time using linear programming whether the objective function of any of the following  $2n$  linear programs is unbounded,

$$\max \{\pm y_i : y \in P\}, \quad i = 1, \dots, n, \\ P := \{y \in \mathbb{R}^n : Ay = b, l \leq y \leq u\}.$$

If any is unbounded then terminate, asserting that  $P$  is unbounded. Otherwise, let  $\rho$  be the least integer upper bound on the absolute value of all optimal objective values. Then  $P \subseteq [-\rho, \rho]^n$  and  $S := \{y \in \mathbb{Z}^n : Ay = b, l \leq y \leq u\} \subset P$  is finite of radius  $\rho(S) \leq \rho$ . In fact, since  $A$  is totally unimodular,  $P_I = P = \text{conv}(S)$  and hence  $\rho(S) = \rho$ . Moreover, by Cramer’s rule,  $\langle \rho \rangle$  is polynomially bounded in  $\langle A, l, u, x \rangle$ .

Now, since  $A$  is totally unimodular, using linear programming over  $P_I = P$  we can simulate in poly-

nomial time a linear discrete optimization oracle for  $S$ . By Lemma 13, the given set  $C$ , which contains all circuits of  $A$ , also covers all edge-directions of  $\text{conv}(S) = P_I = P$ . Therefore we can apply the algorithm of Theorem 6 and solve the given convex  $n$ -fold integer programming problem in polynomial time.  $\square$

While the number of circuits of an  $m \times n$  matrix  $A$  can be as large as  $2^{\binom{n}{m+1}}$  and hence exponential in general, it is nonetheless relatively small in that it is bounded in terms of  $m$  and  $n$  only and is independent of the matrix  $A$  itself. Furthermore, it may happen that the number of circuits is much smaller than the upper bound  $2^{\binom{n}{m+1}}$ . Also, if in a class of matrices,  $m$  grows slowly in terms of  $n$ , say  $m = O(\log n)$ , then this bound is subexponential. In such situations, the above theorem may provide a good strategy for solving convex integer programming over totally unimodular systems.

### Graver Bases and Convex Integer Programming

We now extend the statements of Sect. “Convex Integer Programming over Totally Unimodular Systems” about totally unimodular matrices to arbitrary integer matrices. The next lemma shows that the Graver basis of any integer matrix covers all edge-directions of the integer hulls of polyhedra defined by that matrix.

**Lemma 14** *For every  $A \in \mathbb{Z}^{m \times n}, l, u \in \mathbb{Z}_\infty^n$ , and  $b \in \mathbb{Z}^m$ , the Graver basis  $\mathcal{G}(A)$  of  $A$  covers all edge-directions of the polyhedron  $P_I := \text{conv}\{x \in \mathbb{Z}^n : Ax = b, l \leq x \leq u\}$ .*

*Proof* Consider any edge  $e$  of  $P_I$  and pick two distinct points  $x, y \in e \cap \mathbb{Z}^n$ . Then  $g := y - x$  is in  $\mathcal{L}(A) \setminus \{0\}$ . Therefore, by Lemma 8, there is a conformal sum  $g = \sum_i h_i$  with  $h_i \in \mathcal{G}(A)$  for all  $i$ . We claim that  $x + h_i \in P_I$  for all  $i$ . Indeed, first note that  $h_i \in \mathcal{G}(A) \subset \mathcal{L}(A)$  implies  $Ah_i = 0$  and hence  $A(x + h_i) = Ax = b$ ; and second note that  $l \leq x, x + g \leq u$  and  $h_i \sqsubseteq g$  imply that  $l \leq x + h_i \leq u$ .

Now let  $w \in \mathbb{Z}^n$  be a linear functional uniquely maximized over  $P_I$  at the edge  $e$ . Then  $wh_i = w(x + h_i) - wx \leq 0$  for all  $i$ . But  $\sum(wh_i) = wg = wy - wx = 0$ , implying that in fact  $wh_i = 0$  and hence  $x + h_i \in e$  for all  $i$ . Therefore each  $h_i$  is a direction of  $e$  (in fact, all  $h_i$  are the same and  $g$  is a multiple of some Graver basis element).  $\square$

Combining Theorems 6 and 12 and Lemma 14 we obtain the following statement.

**Theorem 18** *For every fixed  $d$  there is a polynomial time algorithm that, given integer  $m \times n$  matrix  $A$ , its Graver basis  $G(A)$ ,  $l, u \in \mathbb{Z}_\infty^n$ ,  $x \in \mathbb{Z}^n$  with  $l \leq x \leq u$ ,  $w_1, \dots, w_d \in \mathbb{Z}^n$ , and convex  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(A, G(A), l, u, x, w_1, \dots, w_d)]$ , solves the convex integer program with  $b := Ax$ ,*

$$\max \{c(w_1 z, \dots, w_d z) : z \in \mathbb{Z}^n, \\ Az = b, l \leq z \leq u\}.$$

*Proof* First, check in polynomial time using linear programming whether the objective function of any of the following  $2n$  linear programs is unbounded,

$$\max \{\pm y_i : y \in P\}, i = 1, \dots, n, \\ P := \{y \in \mathbb{R}^n : Ay = b, l \leq y \leq u\}.$$

If any is unbounded then terminate, asserting that  $P$  is unbounded. Otherwise, let  $\rho$  be the least integer upper bound on the absolute value of all optimal objective values. Then  $P \subseteq [-\rho, \rho]^n$  and  $S := \{y \in \mathbb{Z}^n : Ay = b, l \leq y \leq u\} \subset P$  is finite of radius  $\rho(S) \leq \rho$ . Moreover, by Cramer's rule,  $\langle \rho \rangle$  is polynomially bounded in  $\langle A, l, u, x \rangle$ .

Using the given Graver basis and applying the algorithm of Theorem 12 we can simulate in polynomial time a linear discrete optimization oracle for  $S$ . Furthermore, by Lemma 14, the given Graver basis covers all edge-directions of the integer hull  $P_I := \text{conv}\{y \in \mathbb{Z}^n : Ay = b, l \leq y \leq u\} = \text{conv}(S)$ . Therefore we can apply the algorithm of Theorem 6 and solve the given convex program in polynomial time.  $\square$

### Convex N-fold Integer Programming in Polynomial Time

We now extend the result of Theorem 15 and show that convex integer programming problems over  $n$ -fold systems can be solved in polynomial time as well. As explained in the beginning of this section, the algorithm either returns an optimal solution, or asserts that the program is infeasible, or asserts that the underlying polyhedron is unbounded.

**Theorem 19** *For every fixed  $d$  and fixed  $(r + s) \times t$  integer matrix  $A$  there is a polynomial time algorithm that, given  $n$ , lower and upper bounds  $l, u \in \mathbb{Z}_\infty^{nt}$ ,  $w_1, \dots, w_d \in \mathbb{Z}^{nt}$ ,  $b \in \mathbb{Z}^{r+ns}$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(l, u, w_1, \dots, w_d, b)]$ , solves the convex  $n$ -fold integer programming problem*

$$\max \{c(w_1 x, \dots, w_d x) : x \in \mathbb{Z}^{nt}, \\ A^{(n)} x = b, l \leq x \leq u\}.$$

*Proof* First, check in polynomial time using linear programming whether the objective function of any of the following  $2nt$  linear programs is unbounded,

$$\max \{\pm y_i : y \in P\}, i = 1, \dots, nt, \\ P := \{y \in \mathbb{R}^{nt} : A^{(n)} y = b, l \leq y \leq u\}.$$

If any is unbounded then terminate, asserting that  $P$  is unbounded. Otherwise, let  $\rho$  be the least integer upper bound on the absolute value of all optimal objective values. Then  $P \subseteq [-\rho, \rho]^{nt}$  and  $S := \{y \in \mathbb{Z}^{nt} : A^{(n)} y = b, l \leq y \leq u\} \subset P$  is finite of radius  $\rho(S) \leq \rho$ . Moreover, by Cramer's rule,  $\langle \rho \rangle$  is polynomially bounded in  $n$  and  $\langle l, u, b \rangle$ .

Using the algorithm of Theorem 15 we can simulate in polynomial time a linear discrete optimization oracle for  $S$ . Also, using the algorithm of Theorem 14 we can compute in polynomial time the Graver basis  $G(A^{(n)})$  which, by Lemma 14, covers all edge-directions of  $P_I := \text{conv}\{y \in \mathbb{Z}^{nt} : A^{(n)} y = b, l \leq y \leq u\} = \text{conv}(S)$ . Therefore we can apply the algorithm of Theorem 6 and solve the given convex  $n$ -fold integer programming problem in polynomial time.  $\square$

Again, as a special case of Theorem 19 we recover the following result of [12] concerning convex integer programming in standard form over  $n$ -fold matrices.

**Theorem 20** *For every fixed  $d$  and fixed  $(r + s) \times t$  integer matrix  $A$  there is a polynomial time algorithm that, given  $n$ , linear functionals  $w_1, \dots, w_d \in \mathbb{Z}^{nt}$ , right-hand side  $b \in \mathbb{Z}^{r+ns}$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(w_1, \dots, w_d, b)]$ , solves the convex  $n$ -fold integer program in standard form*

$$\max \{c(w_1 x, \dots, w_d x) : x \in \mathbb{N}^{nt}, A^{(n)} x = b\}.$$

## Some Applications

### Transportation Problems and Packing Problems

Theorems 19 and 20 generalize Theorems 15 and 16 by broadly extending the class of objective functions that can be maximized in polynomial time over  $n$ -fold systems. Therefore all applications discussed in Sect. “Some Applications” automatically extend accordingly.

First, we have the following analog of Corollary 8 for the *convex integer transportation problem* over long 3-way tables. This has a very broad further generalization to multiway transportation problems over long  $k$ -way tables of any dimension  $k$ , see Sect. “Multiway Transportation Problems and Privacy in Statistical Databases”.

**Corollary 10** *For every fixed  $d, p, q$  there is a polynomial time algorithm that, given  $n$ , arrays  $w_1, \dots, w_d \in \mathbb{Z}^{p \times q \times n}$ , line-sums  $u \in \mathbb{Z}^{p \times q}$ ,  $v \in \mathbb{Z}^{p \times n}$  and  $z \in \mathbb{Z}^{q \times n}$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(w_1, \dots, w_d, u, v, z)]$ , solves the convex integer 3-way line-sum transportation problem*

$$\max \left\{ c(w_1 x, \dots, w_d x) : x \in \mathbb{N}^{p \times q \times n}, \right. \\ \left. \sum_i x_{i,j,k} = z_{j,k}, \quad \sum_j x_{i,j,k} = v_{i,k}, \right. \\ \left. \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

Second, we have the following analog of Corollary 9 for convex bin packing.

**Corollary 11** *For every fixed  $d$ , number of types  $t$ , and type weights  $v_1, \dots, v_t \in \mathbb{Z}$ , there is a polynomial time algorithm that, given  $n$  bins, item numbers  $n_1, \dots, n_t \in \mathbb{Z}$ , bin capacities  $u_1, \dots, u_n \in \mathbb{Z}$ , utility matrices  $w_1, \dots, w_d \in \mathbb{Z}^{t \times n}$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(n_1, \dots, n_t, u_1, \dots, u_n, w_1, \dots, w_d)]$ , solves the convex integer bin packing problem,*

$$\max \left\{ c(w_1 x, \dots, w_d x) : x \in \mathbb{N}^{t \times n}, \right. \\ \left. \sum_j v_j x_{j,k} = u_k, \quad \sum_k x_{j,k} = n_j \right\}.$$

**Vector Partitioning and Clustering** The vector partition problem concerns the partitioning of  $n$  items among  $p$  players to maximize social value subject to constraints on the number of items each player can receive. More precisely, the data is as follows. With each item  $i$  is associated a vector  $v_i \in \mathbb{Z}^k$  representing its utility under  $k$  criteria. The utility of player  $h$  under ordered partition  $\pi = (\pi_1, \dots, \pi_p)$  of the set of items  $\{1, \dots, n\}$  is the sum  $v_h^\pi := \sum_{i \in \pi_h} v_i$  of utility vectors of items assigned to  $h$  under  $\pi$ . The social value of  $\pi$  is the balancing  $c(v_{1,1}^\pi, \dots, v_{1,k}^\pi, \dots, v_{p,1}^\pi, \dots, v_{p,k}^\pi)$  of the player utilities, where  $c$  is a convex functional on  $\mathbb{R}^{pk}$ . In the constrained version, the partition must be of a given *shape*, i. e. the number  $|\pi_h|$  of items that player  $h$  gets is required to be a given number  $\lambda_h$  (with  $\sum \lambda_h = n$ ). In the unconstrained version, there is no restriction on the number of items per player.

Vector partition problems have applications in diverse areas such as load balancing, circuit layout, ranking, cluster analysis, inventory, and reliability, see e. g. [7,9,25,39,50] and the references therein. Here is a typical example.

*Example 6 (minimal variance clustering).* This problem has numerous applications in the analysis of statistical data: given  $n$  observed points  $v_1, \dots, v_n$  in  $k$ -space, group them into  $p$  clusters  $\pi_1, \dots, \pi_p$  that minimize the sum of cluster variances given by

$$\sum_{h=1}^p \frac{1}{|\pi_h|} \sum_{i \in \pi_h} \left\| v_i - \left( \frac{1}{|\pi_h|} \sum_{i \in \pi_h} v_i \right) \right\|^2.$$

Consider instances where there are  $n = pm$  points and the desired clustering is balanced, that is, the clusters should have equal size  $m$ . Suitable manipulation of the sum of variances expression above shows that the problem is equivalent to a constrained vector partition problem, where  $\lambda_h = m$  for all  $h$ , and where the convex functional  $c: \mathbb{R}^{pk} \rightarrow \mathbb{R}$  (to be maximized) is the Euclidean norm squared, given by

$$c(z) = \|z\|^2 = \sum_{h=1}^p \sum_{i=1}^k |z_{h,i}|^2.$$

If either the number of criteria  $k$  or the number of players  $p$  is variable, the partition problem is intractable since it instantly captures NP-hard problems [39].

When both  $k, p$  are fixed, both the constrained and unconstrained versions of the vector partition problem are polynomial time solvable [39,50]. We now show that vector partition problems (either constrained or unconstrained) are in fact convex  $n$ -fold integer programming problems and therefore, as a consequence of Theorem 20, can be solved in polynomial time.

**Corollary 12** *For every fixed number  $p$  of players and number  $k$  of criteria, there is a polynomial time algorithm that, given  $n$ , item vectors  $v_1, \dots, v_n \in \mathbb{Z}^k$ ,  $\lambda_1, \dots, \lambda_p \in \mathbb{N}$ , and convex functional  $c: \mathbb{R}^{pk} \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(v_1, \dots, v_n, \lambda_1, \dots, \lambda_p)]$ , solves the constrained and unconstrained partitioning problems.*

*Proof* There is an obvious one-to-one correspondence between partitions and matrices  $x \in \{0, 1\}^{p \times n}$  with all column-sums equal to one, where partition  $\pi$  corresponds to the matrix  $x$  with  $x_{h,i} = 1$  if  $i \in \pi_h$  and  $x_{h,i} = 0$  otherwise. Let  $d := pk$  and define  $d$  matrices  $w_{h,j} \in \mathbb{Z}^{p \times n}$  by setting  $(w_{h,j})_{h,i} := v_{i,j}$  for all  $h = 1, \dots, p$ ,  $i = 1, \dots, n$  and  $j = 1, \dots, k$ , and setting all other entries to zero. Then for any partition  $\pi$  and its corresponding matrix  $x$  we have  $v_{h,j}^\pi = w_{h,j}x$  for all  $h = 1, \dots, p$  and  $j = 1, \dots, k$ . Therefore, the unconstrained vector partition problem is the convex integer program

$$\max \left\{ c(w_{1,1}x, \dots, w_{p,k}x) : x \in \mathbb{N}^{p \times n}, \sum_h x_{h,i} = 1 \right\}.$$

Suitably arranging the variables in a vector, this becomes a convex  $n$ -fold integer program with a  $(0 + 1) \times p$  defining matrix  $A$ , where  $A_1$  is empty and  $A_2 := (1, \dots, 1)$ .

Similarly, the constrained vector partition problem is the convex integer program

$$\max \left\{ c(w_{1,1}x, \dots, w_{p,k}x) : x \in \mathbb{N}^{p \times n}, \sum_h x_{h,i} = 1, \sum_i x_{h,i} = \lambda_h \right\}.$$

This again is a convex  $n$ -fold integer program, now with a  $(p + 1) \times p$  defining matrix  $A$ , where now  $A_1 := I_p$  is the  $p \times p$  identity matrix and  $A_2 := (1, \dots, 1)$  as before.

Using the algorithm of Theorem 20, this convex  $n$ -fold integer program, and hence the given vector partition problem, can be solved in polynomial time.  $\square$

## Multiway Transportation Problems and Privacy in Statistical Databases

Transportation problems form a very important class of discrete optimization problems. The feasible points in a transportation problem are the multiway tables (“contingency tables” in statistics) such that the sums of entries over some of their lower dimensional subtables such as lines or planes (“margins” in statistics) are specified. Transportation problems and their corresponding transportation polytopes have been used and studied extensively in the operations research and mathematical programming literature, as well as in the statistics literature in the context of secure statistical data disclosure and management by public agencies, see [4,6,11,18,19,42,43,53,60,62] and references therein.

In this section we completely settle the algorithmic complexity of treating multiway tables and discuss the applications to transportation problems and secure statistical data disclosure, as follows. After introducing some terminology in Sect. “Tables and Margins”, we go on to describe, in Sect. “The Universality Theorem”, a universality result that shows that “short” 3-way  $r \times c \times 3$  tables, with variable number  $r$  of rows and variable number  $c$  of columns but fixed small number 3 of layers (hence “short”), are *universal* in a very strong sense. In Sect. “The Complexity of the Multiway Transportation Problem” we discuss the general multiway transportation problem. Using the results of Sect. “The Universality Theorem” and the results on linear and convex  $n$ -fold integer programming from Sect. “Linear  $N$ -fold Integer Programming” and Sect. “Convex Integer Programming”, we show that the transportation problem is intractable for short 3-way  $r \times c \times 3$  tables but polynomial time treatable for “long”  $(k + 1)$ -way  $m_1 \times \dots \times m_k \times n$  tables, with  $k$  and the sides  $m_1, \dots, m_k$  fixed (but arbitrary), and the number  $n$  of layers variable (hence “long”). In Sect. “Privacy and Entry-Uniqueness” we turn to discuss data privacy and security and consider the central problem of detecting entry uniqueness in tables with disclosed margins. We show that as a consequence of the results of Sect. “The Universality Theorem” and Sect. “The Complexity of

the **Multiway Transportation Problem**”, and in analogy to the complexity of the transportation problem established in Sect. “**The Complexity of the Multiway Transportation Problem**”, the entry uniqueness problem is intractable for short 3-way  $r \times c \times 3$  tables but polynomial time decidable for long  $(k + 1)$ -way  $m_1 \times \dots \times m_k \times n$  tables.

**Tables and Margins**

We start with some terminology on tables, margins and transportation polytopes. A  $k$ -way table is an  $m_1 \times \dots \times m_k$  array  $x = (x_{i_1, \dots, i_k})$  of nonnegative integers. A  $k$ -way transportation polytope (or simply  $k$ -way polytope for brevity) is the set of all  $m_1 \times \dots \times m_k$  nonnegative arrays  $x = (x_{i_1, \dots, i_k})$  such that the sums of the entries over some of their lower dimensional sub-arrays (margins) are specified. More precisely, for any tuple  $(i_1, \dots, i_k)$  with  $i_j \in \{1, \dots, m_j\} \cup \{+\}$ , the corresponding margin  $x_{i_1, \dots, i_k}$  is the sum of entries of  $x$  over all coordinates  $j$  with  $i_j = +$ . The support of  $(i_1, \dots, i_k)$  and of  $x_{i_1, \dots, i_k}$  is the set  $\text{supp}(i_1, \dots, i_k) := \{j : i_j \neq +\}$  of non-summed coordinates. For instance, if  $x$  is a  $4 \times 5 \times 3 \times 2$  array then it has 12 margins with support  $F = \{1, 3\}$  such as  $x_{3,+,2,+} = \sum_{i_2=1}^5 \sum_{i_4=1}^2 x_{3,i_2,2,i_4}$ . A collection of margins is hierarchical if, for some family  $\mathcal{F}$  of subsets of  $\{1, \dots, k\}$ , it consists of all margins  $u_{i_1, \dots, i_k}$  with support in  $\mathcal{F}$ . In particular, for any  $0 \leq h \leq k$ , the collection of all  $h$ -margins of  $k$ -tables is the hierarchical collection with  $\mathcal{F}$  the family of all  $h$ -subsets of  $\{1, \dots, k\}$ . Given a hierarchical collection of margins  $u_{i_1, \dots, i_k}$  supported on a family  $\mathcal{F}$  of subsets of  $\{1, \dots, k\}$ , the corresponding  $k$ -way polytope is the set of nonnegative arrays with these margins,

$$T_{\mathcal{F}} := \left\{ x \in \mathbb{R}_+^{m_1 \times \dots \times m_k} : x_{i_1, \dots, i_k} = u_{i_1, \dots, i_k}, \text{supp}(i_1, \dots, i_k) \in \mathcal{F} \right\}.$$

The integer points in this polytope are precisely the  $k$ -way tables with the given margins.

**The Universality Theorem**

We now describe the following *universality* result of [14,16] which shows that, quite remarkably, any rational polytope is a short 3-way  $r \times c \times 3$  polytope with all line-sums specified. (In the terminology of

Sect. “**Tables and Margins**” this is the  $r \times c \times 3$  polytope  $T_{\mathcal{F}}$  of all 2-margins fixed, supported on the family  $\mathcal{F} = \{\{1, 2\}, \{1, 3\}, \{2, 3\}\}$ .) By saying that a polytope  $P \subset \mathbb{R}^p$  is *representable* as a polytope  $Q \subset \mathbb{R}^q$  we mean in the strong sense that there is an injection  $\sigma : \{1, \dots, p\} \rightarrow \{1, \dots, q\}$  such that the coordinate-erasing projection

$$\begin{aligned} \pi : \mathbb{R}^q &\rightarrow \mathbb{R}^p : x = (x_1, \dots, x_q) \\ &\mapsto \pi(x) = (x_{\sigma(1)}, \dots, x_{\sigma(p)}) \end{aligned}$$

provides a bijection between  $Q$  and  $P$  and between the sets of integer points  $Q \cap \mathbb{Z}^q$  and  $P \cap \mathbb{Z}^p$ . In particular, if  $P$  is representable as  $Q$  then  $P$  and  $Q$  are isomorphic in any reasonable sense: they are linearly equivalent and hence all linear programming related problems over the two are polynomial time equivalent; they are combinatorially equivalent and hence they have the same face numbers and facial structure; and they are integer equivalent and therefore all integer programming and integer counting related problems over the two are polynomial time equivalent as well.

We provide only an outline of the proof of the following statement; complete details and more consequences of this theorem can be found in [14,16].

**Theorem 21** *There is a polynomial time algorithm that, given  $A \in \mathbb{Z}^{m \times n}$  and  $b \in \mathbb{Z}^m$ , encoded as  $\{[A, b]\}$ , produces  $r, c$  and line-sums  $u \in \mathbb{Z}^{r \times c}$ ,  $v \in \mathbb{Z}^{r \times 3}$  and  $z \in \mathbb{Z}^{c \times 3}$  such that the polytope  $P := \{y \in \mathbb{R}_+^n : Ay = b\}$  is representable as the 3-way polytope*

$$T := \left\{ x \in \mathbb{R}_+^{r \times c \times 3} : \sum_i x_{i,j,k} = z_{j,k}, \sum_j x_{i,j,k} = v_{i,k}, \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

*Proof* The construction proving the theorem consists of three polynomial time steps, each representing a polytope of a given format as a polytope of another given format.

First, we show that any  $P := \{y \geq 0 : Ay = b\}$  with  $A, b$  integer can be represented in polynomial time as  $Q := \{x \geq 0 : Cx = d\}$  with  $C$  matrix all entries of which are in  $\{-1, 0, 1, 2\}$ . This reduction of coefficients will enable the rest of the steps to run in polynomial time. For each variable  $y_j$  let  $k_j := \max\{\lfloor \log_2 |a_{i,j}| \rfloor :$

$i = 1, \dots, m\}$  be the maximum number of bits in the binary representation of the absolute value of any entry  $a_{i,j}$  of  $A$ . Introduce variables  $x_{j,0}, \dots, x_{j,k_j}$ , and relate them by the equations  $2x_{j,i} - x_{j,i+1} = 0$ . The representing injection  $\sigma$  is defined by  $\sigma(j) := (j, 0)$ , embedding  $y_j$  as  $x_{j,0}$ . Consider any term  $a_{i,j} y_j$  of the original system. Using the binary expansion  $|a_{i,j}| = \sum_{s=0}^{k_j} t_s 2^s$  with all  $t_s \in \{0, 1\}$ , we rewrite this term as  $\pm \sum_{s=0}^{k_j} t_s x_{j,s}$ . It is not hard to verify that this represents  $P$  as  $Q$  with defining  $\{-1, 0, 1, 2\}$ -matrix.

Second, we show that any  $Q := \{y \geq 0 : Ay = b\}$  with  $A, b$  integer can be represented as a face  $F$  of a 3-way polytope with all plane-sums fixed, that is, a face of a 3-way polytope  $T_{\mathcal{F}}$  of all 1-margins fixed, supported on the family  $\mathcal{F} = \{\{1\}, \{2\}, \{3\}\}$ .

Since  $Q$  is a polytope and hence bounded, we can compute (using Cramer's rule) an integer upper bound  $U$  on the value of any coordinate  $y_j$  of any  $y \in Q$ . Note also that a face of a 3-way polytope  $T_{\mathcal{F}}$  is the set of all  $x = (x_{i,j,k})$  with some entries forced to zero; these entries are termed "forbidden", and the other entries are termed "enabled".

For each variable  $y_j$ , let  $r_j$  be the largest between the sum of positive coefficients of  $y_j$  and the sum of absolute values of negative coefficients of  $y_j$  over all equations,

$$r_j := \max \left( \sum_k \{a_{k,j} : a_{k,j} > 0\}, \sum_k \{|a_{k,j}| : a_{k,j} < 0\} \right).$$

Assume that  $A$  is of size  $m \times n$ . Let  $r := \sum_{j=1}^n r_j$ ,  $R := \{1, \dots, r\}$ ,  $h := m + 1$  and  $H := \{1, \dots, h\}$ . We now describe how to construct vectors  $u, v \in \mathbb{Z}^r$ ,  $z \in \mathbb{Z}^h$ , and a set  $E \subset R \times R \times H$  of triples – the enabled, non-forbidden, entries – such that the polytope  $Q$  is represented as the face  $F$  of the corresponding 3-way polytope of  $r \times r \times h$  arrays with plane-sums  $u, v, z$  and only entries indexed by  $E$  enabled,

$$F := \left\{ x \in \mathbb{R}_+^{r \times r \times h} : x_{i,j,k} = 0 \text{ for all } (i, j, k) \notin E, \text{ and } \sum_{i,j} x_{i,j,k} = z_k, \sum_{i,k} x_{i,j,k} = v_j, \sum_{j,k} x_{i,j,k} = u_i \right\}.$$

We also indicate the injection  $\sigma : \{1, \dots, n\} \rightarrow R \times R \times H$  giving the desired embedding of coordinates  $y_j$  as coordinates  $x_{i,j,k}$  and the representation of  $Q$  as  $F$ .

Roughly, each equation  $k = 1, \dots, m$  is encoded in a "horizontal plane"  $R \times R \times \{k\}$  (the last plane  $R \times R \times \{h\}$  is included for consistency with its entries being "slacks"); and each variable  $y_j$ ,  $j = 1, \dots, n$  is encoded in a "vertical box"  $R_j \times R_j \times H$ , where  $R = \bigsqcup_{j=1}^n R_j$  is the natural partition of  $R$  with  $|R_j| = r_j$  for all  $j = 1, \dots, n$ , that is, with  $R_j := \{1 + \sum_{l < j} r_l, \dots, \sum_{l \leq j} r_l\}$ .

Now, all "vertical" plane-sums are set to the same value  $U$ , that is,  $u_j := v_j := U$  for  $j = 1, \dots, r$ . All entries not in the union  $\bigsqcup_{j=1}^n R_j \times R_j \times H$  of the variable boxes will be forbidden. We now describe the enabled entries in the boxes; for simplicity we discuss the box  $R_1 \times R_1 \times H$ , the others being similar. We distinguish between the two cases  $r_1 = 1$  and  $r_1 \geq 2$ . In the first case,  $R_1 = \{1\}$ ; the box, which is just the single line  $\{1\} \times \{1\} \times H$ , will have exactly two enabled entries  $(1, 1, k^+)$ ,  $(1, 1, k^-)$  for suitable  $k^+, k^-$  to be defined later. We set  $\sigma(1) := (1, 1, k^+)$ , namely embed  $y_1 = x_{1,1,k^+}$ . We define the *complement* of the variable  $y_1$  to be  $\bar{y}_1 := U - y_1$  (and likewise for the other variables). The vertical sums  $u, v$  then force  $\bar{y}_1 = U - y_1 = U - x_{1,1,k^+} = x_{1,1,k^-}$ , so the complement of  $y_1$  is also embedded. Next, consider the case  $r_1 \geq 2$ . For each  $s = 1, \dots, r_1$ , the line  $\{s\} \times \{s\} \times H$  (respectively,  $\{s\} \times \{1 + (s \bmod r_1)\} \times H$ ) will contain one enabled entry  $(s, s, k^+(s))$  (respectively,  $(s, 1 + (s \bmod r_1), k^-(s))$ ). All other entries of  $R_1 \times R_1 \times H$  will be forbidden. Again, we set  $\sigma(1) := (1, 1, k^+(1))$ , namely embed  $y_1 = x_{1,1,k^+(1)}$ ; it is then not hard to see that, again, the vertical sums  $u, v$  force  $x_{s,s,k^+(s)} = x_{1,1,k^+(1)} = y_1$  and  $x_{s,1+(s \bmod r_1),k^-(s)} = U - x_{1,1,k^+(1)} = \bar{y}_1$  for each  $s = 1, \dots, r_1$ . Therefore, both  $y_1$  and  $\bar{y}_1$  are each embedded in  $r_1$  distinct entries.

We now encode the equations by defining the horizontal plane-sums  $z$  and the indices  $k^+(s), k^-(s)$  above as follows. For  $k = 1, \dots, m$ , consider the  $k$ th equation  $\sum_j a_{k,j} y_j = b_k$ . Define the index sets  $J^+ := \{j : a_{k,j} > 0\}$  and  $J^- := \{j : a_{k,j} < 0\}$ , and set  $z_k := b_k + U \cdot \sum_{j \in J^-} |a_{k,j}|$ . The last coordinate of  $z$  is set for consistency with  $u, v$  to be  $z_h = z_{m+1} := r \cdot U - \sum_{k=1}^m z_k$ . Now, with  $\bar{y}_j := U - y_j$  the complement of variable  $y_j$  as above, the  $k$ th equation can be

rewritten as

$$\begin{aligned} & \sum_{j \in J^+} a_{k,j} y_j + \sum_{j \in J^-} |a_{k,j}| \bar{y}_j \\ &= \sum_{j=1}^n a_{k,j} y_j + U \cdot \sum_{j \in J^-} |a_{k,j}| \\ &= b_k + U \cdot \sum_{j \in J^-} |a_{k,j}| = z_k . \end{aligned}$$

To encode this equation, we simply “pull down” to the corresponding  $k$ th horizontal plane as many copies of each variable  $y_j$  or  $\bar{y}_j$  by suitably setting  $k^+(s) := k$  or  $k^-(s) := k$ . By the choice of  $r_j$  there are sufficiently many, possibly with a few redundant copies which are absorbed in the last hyperplane by setting  $k^+(s) := m+1$  or  $k^-(s) := m+1$ . This completes the encoding and provides the desired representation.

Third, we show that any 3-way polytope with plane-sums fixed and entry bounds,

$$F := \left\{ y \in \mathbb{R}_+^{l \times m \times n} : \begin{aligned} \sum_{i,j} y_{i,j,k} &= c_k , \\ \sum_{i,k} y_{i,j,k} &= b_j , \\ \sum_{j,k} y_{i,j,k} &= a_i , \\ y_{i,j,k} &\leq e_{i,j,k} \end{aligned} \right\} ,$$

can be represented as a 3-way polytope with line-sums fixed (and no entry bounds),

$$T := \left\{ x \in \mathbb{R}_+^{r \times c \times 3} : \begin{aligned} \sum_I x_{I,J,K} &= z_{J,K} , \\ \sum_J x_{I,J,K} &= v_{I,K} , \sum_K x_{I,J,K} &= u_{I,J} \end{aligned} \right\} .$$

In particular, this implies that any face  $F$  of a 3-way polytope with plane-sums fixed can be represented as a 3-way polytope  $T$  with line-sums fixed: forbidden entries are encoded by setting a “forbidding” upper-bound  $e_{i,j,k} := 0$  on all forbidden entries  $(i, j, k) \notin E$  and an “enabling” upper-bound  $e_{i,j,k} := U$  on all enabled entries  $(i, j, k) \in E$ . We describe the presentation, but omit the proof that it is indeed valid; further details on this step can be found in [14,15,16]. We give

explicit formulas for  $u_{I,J}, v_{I,K}, z_{J,K}$  in terms of  $a_i, b_j, c_k$  and  $e_{i,j,k}$  as follows. Put  $r := l \cdot m$  and  $c := n + l + m$ . The first index  $I$  of each entry  $x_{I,J,K}$  will be a pair  $I = (i, j)$  in the  $r$ -set

$$\{(1, 1), \dots, (1, m), (2, 1), \dots, (2, m), \dots, (l, 1), \dots, (l, m)\} .$$

The second index  $J$  of each entry  $x_{I,J,K}$  will be a pair  $J = (s, t)$  in the  $c$ -set

$$\{(1, 1), \dots, (1, n), (2, 1), \dots, (2, l), (3, 1), \dots, (3, m)\} .$$

The last index  $K$  will simply range in the 3-set  $\{1, 2, 3\}$ . We represent  $F$  as  $T$  via the injection  $\sigma$  given explicitly by  $\sigma(i, j, k) := ((i, j), (1, k), 1)$ , embedding each variable  $y_{i,j,k}$  as the entry  $x_{(i,j),(1,k),1}$ . Let  $U$  now denote the minimal between the two values  $\max\{a_1, \dots, a_l\}$  and  $\max\{b_1, \dots, b_m\}$ . The line-sums (2-margins) are set to be

$$\begin{aligned} u_{(i,j),(1,t)} &= e_{i,j,t} , \\ u_{(i,j),(2,t)} &= \begin{cases} U & \text{if } t = i, \\ 0 & \text{otherwise.} \end{cases} , \\ u_{(i,j),(3,t)} &= \begin{cases} U & \text{if } t = j, \\ 0 & \text{otherwise.} \end{cases} \end{aligned}$$

$$v_{(i,j),t} = \begin{cases} U & \text{if } t = 1, \\ e_{i,j,+} & \text{if } t = 2, \\ U & \text{if } t = 3. \end{cases} ,$$

$$z_{(i,j),1} = \begin{cases} c_j & \text{if } i = 1, \\ m \cdot U - a_j & \text{if } i = 2, \\ 0 & \text{if } i = 3. \end{cases}$$

$$z_{(i,j),2} = \begin{cases} e_{+,+,j} - c_j & \text{if } i = 1, \\ 0 & \text{if } i = 2, \\ b_j & \text{if } i = 3. \end{cases} ,$$

$$z_{(i,j),3} = \begin{cases} 0 & \text{if } i = 1, \\ a_j & \text{if } i = 2, \\ l \cdot U - b_j & \text{if } i = 3. \end{cases} .$$

Applying the first step to the given rational polytope  $P$ , applying the second step to the resulting  $Q$ , and applying the third step to the resulting  $F$ , we get in polynomial time a 3-way  $r \times c \times 3$  polytope  $T$  of all line-sums fixed representing  $P$  as claimed.  $\square$

### The Complexity of the Multiway Transportation Problem

We are now finally in position to settle the complexity of the general multiway transportation problem. The data for the problem consists of: positive integers  $k$  (table dimension) and  $m_1, \dots, m_k$  (table sides); family  $\mathcal{F}$  of subsets of  $\{1, \dots, k\}$  (supporting the hierarchical collection of margins to be fixed); integer values  $u_{i_1, \dots, i_k}$  for all margins supported on  $\mathcal{F}$ ; and integer “profit”  $m_1 \times \dots \times m_k$  array  $w$ . The transportation problem is to find an  $m_1 \times \dots \times m_k$  table having the given margins and attaining maximum profit, or assert that none exists. Equivalently, it is the linear integer programming problem of maximizing the linear functional defined by  $w$  over the transportation polytope  $T_{\mathcal{F}}$ ,

$$\max \{ wx : x \in \mathbb{N}^{m_1 \times \dots \times m_k} : x_{i_1, \dots, i_k} = u_{i_1, \dots, i_k}, \text{supp}(i_1, \dots, i_k) \in \mathcal{F} \}.$$

The following result of [15] is an immediate consequence of Theorem 21. It asserts that if two sides of the table are variable part of the input then the transportation problem is intractable already for short 3-way tables with  $\mathcal{F} = \{\{1, 2\}, \{1, 3\}, \{2, 3\}\}$  supporting all 2-margins (line-sums). This result can be easily extended to  $k$ -way tables of any dimension  $k \geq 3$  and  $\mathcal{F}$  the collection of all  $h$ -subsets of  $\{1, \dots, k\}$  for any  $1 < h < k$  as long as two sides of the table are variable; we omit the proof of this extended result.

**Corollary 13** *It is NP-complete to decide, given  $r, c$ , and line-sums  $u \in \mathbb{Z}^{r \times c}$ ,  $v \in \mathbb{Z}^{r \times 3}$ , and  $z \in \mathbb{Z}^{c \times 3}$ , encoded as  $[(u, v, z)]$ , if the following set of tables is nonempty,*

$$S := \left\{ x \in \mathbb{N}^{r \times c \times 3} : \sum_i x_{i,j,k} = z_{j,k}, \sum_j x_{i,j,k} = v_{i,k}, \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

*Proof* The integer programming feasibility problem is to decide, given  $A \in \mathbb{Z}^{m \times n}$  and  $b \in \mathbb{Z}^m$ , if  $\{y \in \mathbb{N}^n : Ay = b\}$  is nonempty. Given such  $A$  and  $b$ , the polynomial time algorithm of Theorem 21 produces  $r, c$  and  $u \in \mathbb{Z}^{r \times c}$ ,  $v \in \mathbb{Z}^{r \times 3}$ , and  $z \in \mathbb{Z}^{c \times 3}$ , such that  $\{y \in \mathbb{N}^n : Ay = b\}$  is nonempty if and only if the set  $S$  above is nonempty. This reduces integer programming

feasibility to short 3-way line-sum transportation feasibility. Since the former is NP-complete (see e.g. [55]), so turns out to be the latter.  $\square$

We now show that in contrast, when all sides but one are fixed (but arbitrary), and one side  $n$  is variable, then the corresponding long  $k$ -way transportation problem for any hierarchical collection of margins is an  $n$ -fold integer programming problem and therefore, as a consequence of Theorem 16, can be solved in polynomial time. This extends Corollary 8 established in Sect. “**Three-Way Line-Sum Transportation Problems**” for 3-way line-sum transportation.

**Corollary 14** *For every fixed  $k$ , table sides  $m_1, \dots, m_k$ , and family  $\mathcal{F}$  of subsets of  $\{1, \dots, k+1\}$ , there is a polynomial time algorithm that, given  $n$ , integer values  $u = (u_{i_1, \dots, i_{k+1}})$  for all margins supported on  $\mathcal{F}$ , and integer  $m_1 \times \dots \times m_k \times n$  array  $w$ , encoded as  $[(u, w)]$ , solves the linear integer multiway transportation problem*

$$\max \{ wx : x \in \mathbb{N}^{m_1 \times \dots \times m_k \times n}, x_{i_1, \dots, i_{k+1}} = u_{i_1, \dots, i_{k+1}}, \text{supp}(i_1, \dots, i_{k+1}) \in \mathcal{F} \}.$$

*Proof* Re-index the arrays as  $x = (x^1, \dots, x^n)$  with each  $x^j = (x_{i_1, \dots, i_{k,j}})$  a suitably indexed  $m_1 m_2 \dots m_k$  vector representing the  $j$ th layer of  $x$ . Then the transportation problem can be encoded as an  $n$ -fold integer programming problem in standard form,

$$\max \{ wx : x \in \mathbb{N}^{nt}, A^{(n)}x = b \},$$

with an  $(r+s) \times t$  defining matrix  $A$  where  $t := m_1 m_2 \dots m_k$  and  $r, s, A_1$  and  $A_2$  are determined from  $\mathcal{F}$ , and with right-hand side  $b := (b^0, b^1, \dots, b^n) \in \mathbb{Z}^{r+ns}$  determined from the margins  $u = (u_{i_1, \dots, i_{k+1}})$ , in such a way that the equations  $A_1(\sum_{j=1}^n x^j) = b^0$  represent the constraints of all margins  $x_{i_1, \dots, i_{k,+}}$  (where summation over layers occurs), whereas the equations  $A_2 x^j = b^j$  for  $j = 1, \dots, n$  represent the constraints of all margins  $x_{i_1, \dots, i_{k,j}}$  with  $j \neq +$  (where summations are within a single layer at a time).

Using the algorithm of Theorem 16, this  $n$ -fold integer program, and hence the given multiway transportation problem, can be solved in polynomial time.  $\square$

The proof of Corollary 14 shows that the set of feasible points of any long  $k$ -way transportation problem, with all sides but one fixed and one side  $n$  variable,

for any hierarchical collection of margins, is an  $n$ -fold integer programming problem. Therefore, as a consequence of Theorem 20, we also have the following extension of Corollary 14 for the convex integer multiway transportation problem over long  $k$ -way tables.

**Corollary 15** *For every fixed  $d, k$ , table sides  $m_1, \dots, m_k$ , and family  $\mathcal{F}$  of subsets of  $\{1, \dots, k + 1\}$ , there is a polynomial time algorithm that, given  $n$ , integer values  $u = (u_{i_1, \dots, i_{k+1}})$  for all margins supported on  $\mathcal{F}$ , integer  $m_1 \times \dots \times m_k \times n$  arrays  $w_1, \dots, w_d$ , and convex functional  $c: \mathbb{R}^d \rightarrow \mathbb{R}$  presented by a comparison oracle, encoded as  $[(u, w_1, \dots, w_d)]$ , solves the convex integer multiway transportation problem*

$$\max \{ c(w_1 x, \dots, w_d x) : x \in \mathbb{N}^{m_1 \times \dots \times m_k \times n}, \\ x_{i_1, \dots, i_{k+1}} = u_{i_1, \dots, i_{k+1}}, \text{supp}(i_1, \dots, i_{k+1}) \in \mathcal{F} \}.$$

**Privacy and Entry-Uniqueness**

A common practice in the disclosure of a multiway table containing sensitive data is to release some of the table margins rather than the table itself, see e.g. [11,18,19] and the references therein. Once the margins are released, the security of any specific entry of the table is related to the set of possible values that can occur in that entry in any table having the same margins as those of the source table in the data base. In particular, if this set consists of a unique value, that of the source table, then this entry can be exposed and privacy can be violated. This raises the following fundamental *entry-uniqueness problem*: given a consistent disclosed (hierarchical) collection of margin values, and a specific entry index, is the value that can occur in that entry in any table having these margins unique? We now describe the results of [48] that settle the complexity of this problem, and interpret the consequences for secure statistical data disclosure.

First, we show that if two sides of the table are variable part of the input then the entry-uniqueness problem is intractable already for short 3-way tables with all 2-margins (line-sums) disclosed (corresponding to  $\mathcal{F} = \{\{1, 2\}, \{1, 3\}, \{2, 3\}\}$ ). This can be easily extended to  $k$ -way tables of any dimension  $k \geq 3$  and  $\mathcal{F}$  the collection of all  $h$ -subsets of  $\{1, \dots, k\}$  for any  $1 < h < k$  as long as two sides of the table are variable; we omit the proof of this extended result. While this result indicates

that the disclosing agency may not be able to check for uniqueness, in this situation, some consolation is in that an adversary will be computationally unable to identify and retrieve a unique entry either.

**Corollary 16** *It is coNP-complete to decide, given  $r, c$ , and line-sums  $u \in \mathbb{Z}^{r \times c}$ ,  $v \in \mathbb{Z}^{r \times 3}$ ,  $z \in \mathbb{Z}^{c \times 3}$ , encoded as  $[(u, v, z)]$ , if the entry  $x_{1,1,1}$  is the same in all tables in*

$$\left\{ x \in \mathbb{N}^{r \times c \times 3} : \sum_i x_{i,j,k} = z_{j,k}, \right. \\ \left. \sum_j x_{i,j,k} = v_{i,k}, \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

*Proof* The *subset-sum problem*, well known to be NP-complete, is the following: given positive integers  $a_0, a_1, \dots, a_m$ , decide if there is an  $I \subseteq \{1, \dots, m\}$  with  $a_0 = \sum_{i \in I} a_i$ . We reduce the complement of subset-sum to entry-uniqueness. Given  $a_0, a_1, \dots, a_m$ , consider the polytope in  $2(m + 1)$  variables  $y_0, y_1, \dots, y_m, z_0, z_1, \dots, z_m$ ,

$$P := \left\{ (y, z) \in \mathbb{R}_+^{2(m+1)} : a_0 y_0 - \sum_{i=1}^m a_i y_i = 0, \right. \\ \left. y_i + z_i = 1, i = 0, 1, \dots, m \right\}.$$

First, note that it always has one integer point with  $y_0 = 0$ , given by  $y_i = 0$  and  $z_i = 1$  for all  $i$ . Second, note that it has an integer point with  $y_0 \neq 0$  if and only if there is an  $I \subseteq \{1, \dots, m\}$  with  $a_0 = \sum_{i \in I} a_i$ , given by  $y_0 = 1$ ,  $y_i = 1$  for  $i \in I$ ,  $y_i = 0$  for  $i \in \{1, \dots, m\} \setminus I$ , and  $z_i = 1 - y_i$  for all  $i$ . Lifting  $P$  to a suitable  $r \times c \times 3$  line-sum polytope  $T$  with the coordinate  $y_0$  embedded in the entry  $x_{1,1,1}$  using Theorem 21, we find that  $T$  has a table with  $x_{1,1,1} = 0$ , and this value is unique among the tables in  $T$  if and only if there is *no* solution to the subset-sum problem with  $a_0, a_1, \dots, a_m$ .  $\square$

Next we show that, in contrast, when all table sides but one are fixed (but arbitrary), and one side  $n$  is variable, then, as a consequence of Corollary 14, the corresponding long  $k$ -way entry-uniqueness problem for any hierarchical collection of margins can be solved in polynomial time. In this situation, the algorithm of Corollary 17 below allows disclosing agencies to efficiently check possible collections of margins before disclosure: if an entry value is not unique then disclosure

may be assumed secure, whereas if the value is unique then disclosure may be risky and fewer margins should be released. Note that this situation, of long multiway tables, where one category is significantly richer than the others, that is, when each sample point can take many values in one category and only few values in the other categories, occurs often in practical applications, e. g., when one category is the individuals age and the other categories are binary (“yes-no”). In such situations, our polynomial time algorithm below allows disclosing agencies to check entry-uniqueness and make learned decisions on secure disclosure.

**Corollary 17** *For every fixed  $k$ , table sides  $m_1, \dots, m_k$ , and family  $\mathcal{F}$  of subsets of  $\{1, \dots, k+1\}$ , there is a polynomial time algorithm that, given  $n$ , integer values  $u = (u_{j_1, \dots, j_{k+1}})$  for all margins supported on  $\mathcal{F}$ , and entry index  $(i_1, \dots, i_{k+1})$ , encoded as  $[n, \langle u \rangle]$ , decides if the entry  $x_{i_1, \dots, i_{k+1}}$  is the same in all tables in the set*

$$\{x \in \mathbb{N}^{m_1 \times \dots \times m_k \times n} : x_{j_1, \dots, j_{k+1}} = u_{j_1, \dots, j_{k+1}}, \text{supp}(j_1, \dots, j_{k+1}) \in \mathcal{F}\}.$$

*Proof* By Corollary 14 we can solve in polynomial time both transportation problems

$$l := \min \{x_{i_1, \dots, i_{k+1}} : x \in \mathbb{N}^{m_1 \times \dots \times m_k \times n}, x \in T_{\mathcal{F}}\},$$

$$u := \max \{x_{i_1, \dots, i_{k+1}} : x \in \mathbb{N}^{m_1 \times \dots \times m_k \times n}, x \in T_{\mathcal{F}}\},$$

over the corresponding  $k$ -way transportation polytope

$$T_{\mathcal{F}} := \{x \in \mathbb{R}_+^{m_1 \times \dots \times m_k \times n} : x_{j_1, \dots, j_{k+1}} = u_{j_1, \dots, j_{k+1}}, \text{supp}(j_1, \dots, j_{k+1}) \in \mathcal{F}\}.$$

Clearly, entry  $x_{i_1, \dots, i_{k+1}}$  has the same value in all tables with the given (disclosed) margins if and only if  $l = u$ , completing the description of the algorithm and the proof.  $\square$

### Keywords

Convex underestimator; Nonconvex optimization

Let  $f: S \rightarrow \mathbf{R}$  be a *lower semicontinuous function*, where  $S \subseteq \mathbf{R}^n$  is a nonempty convex subset. The convex envelope taken over  $S$  is a function  $f_S: S \rightarrow \mathbf{R}$  such that

- $f_S$  is a convex function defined over the set  $S$ ;
- $f_S(x) \leq f(x)$  for all  $x \in S$ ;
- if  $h$  is any other convex function such that  $h(x) \leq f(x)$  for all  $x \in S$ , then  $h(x) \leq f_S(x)$  for all  $x \in S$ .

In other words,  $f_S$  is the pointwise supremum among any *convex underestimators* of  $f$  over  $S$ , and is uniquely determined. The following demonstrates the most fundamental properties shown by [3,6]. Suppose that the minimum of  $f$  over  $S$  exists. Then,

$$\min \{f(x) : x \in S\} = \min \{f_S(x) : x \in S\}$$

and

$$\begin{aligned} \{x^* : f(x^*) \leq f(x), \forall x \in S\} \\ \subseteq \{x^* : f_S(x^*) \leq f_S(x), \forall x \in S\}. \end{aligned}$$

The properties indicate that an optimal solution of a nonconvex minimization problem could be obtained by minimizing the associated convex envelope. In general, however, finding the convex envelope is at least as difficult as solving the original one.

Several practical results have been proposed for special classes of objective functions and constraints. Suppose that the function  $f$  is concave and  $S$  is a polytope with vertices  $v^0, \dots, v^K$ . Then, the convex envelope  $f_S$  over  $S$  can be expressed as:

$$\left\{ \begin{array}{l} f_S(x) = \min \sum_{i=0}^K \alpha_i f(v^i) \\ \text{s.t.} \quad \sum_{i=0}^K \alpha_i v^i = x, \\ \sum_{i=0}^K \alpha_i = 1, \\ \alpha_i \geq 0, \quad i = 0, \dots, K. \end{array} \right.$$

Especially, if  $S$  is an  $n$ -simplex with vertices  $v^0, \dots, v^n$ ,  $f_S$  is the affine function

$$f_S(x) = a^\top x + b,$$

which is uniquely determined by solving the following linear system

$$a^\top v^i + b = f(v^i), \quad i = 0, \dots, n.$$

The properties above have been used to solve concave minimization problems with linear constraints [4,6].

The following property shown in [1,5] is frequently used in the literature. For each  $i = 1, \dots, p$ , let  $f^i: S_i \rightarrow \mathbf{R}$  be a continuous function, where  $S_i \subseteq \mathbf{R}^{n_i}$ , and let  $n = n_1 + \dots + n_p$ . If

$$f(x) = \sum_{i=1}^p f^i(x^i)$$

and

$$S = S_1 \times \dots \times S_p,$$

where  $x^i \in \mathbf{R}^{n_i}$ ,  $i = 1, \dots, p$ , and  $x = (x^1, \dots, x^p) \in \mathbf{R}^n$ , then the convex envelope  $f_S(x)$  can be expressed as:

$$f_S(x) = \sum_{i=1}^p f_S^i(x^i).$$

In particular, let  $f(x) = \sum_{i=1}^n f_i(x_i)$  be a separable function, where  $x = (x_1, \dots, x_n) \in \mathbf{R}^n$ , and let  $f_i(x_i)$  be concave for each  $i = 1, \dots, n$ . Then the convex envelope of  $f(x)$  over the rectangle  $R = \{x \in \mathbf{R}^n: a_i \leq x_i \leq b_i, i = 1, \dots, n\}$  can be the affine function, which is given by the sum of the linear functions below:

$$f_R(x) = \sum_{i=1}^n l_i(x_i),$$

where  $l_i(x_i)$  meets  $f_i(x_i)$  at both ends of the interval  $a_i \leq x_i \leq b_i$  for each  $i = 1, \dots, n$ . B. Kalantari and J.B. Rosen [7] show an algorithm for the global minimization of a quadratic concave function over a polytope. They exploit convex envelopes of separable functions over rectangles to generate lower bounds in a *branch and bound scheme*.

Also, convex envelopes of *bilinear functions* over rectangles have been proposed in [2]. Consider the following rectangles:

$$\Omega_i = \left\{ (x_i, y_i) : \begin{array}{l} l_i \leq x_i \leq L_i, \\ m_i \leq y_i \leq M_i \end{array} \right\},$$

$i = 1, \dots, n,$

and let

$$f^i(x_i, y_i) = x_i y_i, \quad i = 1, \dots, n,$$

be bilinear functions with two variables. It has been shown that for each  $i = 1, \dots, n$ , the convex envelope of  $f^i(x_i, y_i)$  over  $\Omega_i$  is expressed as:

$$f_{\Omega_i}^i(x_i, y_i) = \max\{m_i x_i + l_i y_i - l_i m_i, M_i x_i + L_i y_i - L_i M_i\}.$$

Moreover, it can be verified that  $f_{\Omega_i}^i(x_i, y_i)$  agrees with  $f^i(x_i, y_i)$  at the four extreme points of  $\Omega_i$ . Thus, the convex envelope of the general bilinear function

$$f(x, y) = x^\top y = \sum_{i=1}^n f^i(x_i, y_i),$$

where  $x^\top = (x_1, \dots, x_n)$  and  $y^\top = (y_1, \dots, y_n)$  over  $\Omega = \Omega_1 \times \dots \times \Omega_n$  can be expressed as

$$f_\Omega(x, y) = \sum_{i=1}^n f_{\Omega_i}^i(x_i, y_i).$$

Another characterization of convex envelopes of bilinear functions over a special type of polytope, which includes a rectangle as a special case, is derived in [8].

**Introduction**

A twice continuously differentiable function in several variables, when considered on a compact convex set  $C$ , becomes convex if an appropriate convex quadratic is added to it, e.g. [2]. Equivalently, a twice continuously differentiable function is the difference of a convex function and a convex quadratic on  $C$ . This decomposition is valid also for smooth functions with Lipschitz derivatives [8]. Here we recall three conditions that are both necessary and sufficient for the decomposition [9,10]. We also list several implications of the convexification in optimization and applied mathematics [10,11]. A different notion of convexification is studied in, e.g. [6]; see also [3,5].

**Definitions**

**Definition 1.** ([7,10]) Given a continuous function  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  on a compact convex set  $C$  of the Euclidean space  $\mathbb{R}^n$ , consider  $\phi: \mathbb{R}^{n+1} \rightarrow \mathbb{R}$  defined by  $\phi(x, \alpha) = f(x) - 1/2\alpha x^T x$  where  $x^T$  is the transpose of  $x$ . If  $\phi(x, \alpha)$  is convex on  $C$  for some  $\alpha = \alpha^*$ , then  $\phi(x, \alpha)$  is said to be a *convexification* of  $f$  and  $\alpha^*$  is its *convexifier* on  $C$ . Function  $f$  is *convexifiable* if it has a convexification.

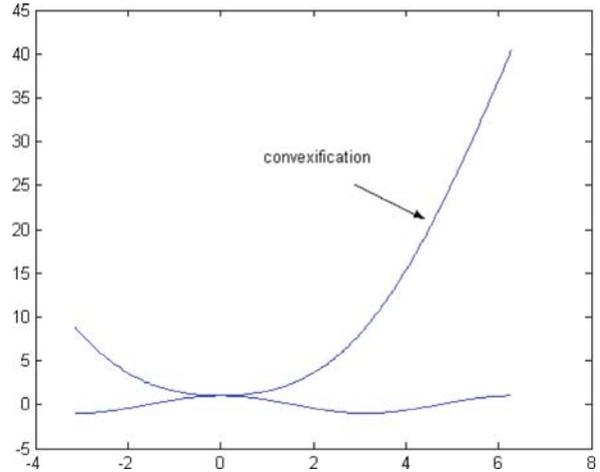

**Observation.** If  $\alpha^*$  is a convexifier of  $f$  on a compact convex set  $C$ , then so is every  $\alpha < \alpha^*$ .

**Illustration 1.** Consider  $f(t) = \cos t$  on, say,  $-\pi \leq t \leq 2\pi$ . This function is convexifiable, its convexifier is any  $\alpha \leq -1$ . For, e.g.,  $\alpha^* = -2$ , its convexification is  $\phi(t, -2) = \cos t + t^2$ . Note that  $f(t)$  is the difference of (strictly) convex  $\phi(t, \alpha) = \cos t - 1/2\alpha t^2$  and (strictly) convex quadratic  $-1/2\alpha x^T x$  for every sufficiently small  $\alpha$ . The graphs of  $f(t)$  and its convexification  $\phi(t, -2)$  are depicted in Fig. 1.

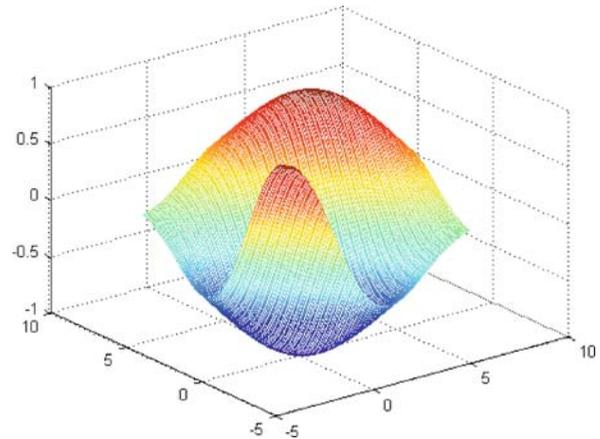

**Characterizations of a Convexifiable Function**

One can characterize convexifiable functions using the fact that a continuous  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  is convex if, and only if,  $f$  is mid-point convex, i.e.,  $f((x+y)/2) \leq 1/2(f(x) + f(y))$ ,  $x, y \in C$ , e.g. [4]. Denote the norm of  $u \in \mathbb{R}^n$  by  $\|u\| = (u^T u)^{1/2}$ . With a continuous  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  one can associate  $\Psi: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$ :

**Definition 2.** ([10]) Consider a continuous  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  on a compact convex set  $C$  in  $\mathbb{R}^n$ . The mid-point ac-

**Convexifiable Functions, Characterization of, Figure 1**  
Function  $f(t) = \cos t$  and its convexification

**Convexifiable Functions, Characterization of, Figure 2**  
Mid-point acceleration function of  $f(t) = \cos t$

celeration function of  $f$  on  $C$  is the function

$$\Psi(x, y) = (4 / \|x - y\|^2)[f(x) + f(y) - 2f((x + y) / 2)], \quad x, y \in C, x \neq y.$$

Function  $\Psi$  describes a mid-point “displacement of the displacement” (i.e., the “acceleration”) of  $f$  at  $x$  between  $x$  and  $y$  along the direction  $y - x$ . The graph of  $\Psi$  for the scalar function  $f(t) = \cos t$  is depicted in Fig. 2.

Using  $\Psi$  one can characterize a convexifiable function:

**Theorem 1.** ([10]) Consider a continuous  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  on a compact convex set  $C$  in  $\mathbb{R}^n$ . Function  $f$  is convexifi-

able on  $C$  if, and only if, its mid-point acceleration function  $\Psi$  is bounded from below on  $C$ .

For scalar functions one can also use a determinant:

**Theorem 2. ([9] Determinant Characterization of Scalar Convexifiable Function)** A continuous scalar function  $f: \mathbb{R} \rightarrow \mathbb{R}$  is convexifiable on a compact convex interval  $I$  if, and only if, there exists a number  $\alpha$  such that for every three points  $s < t < \xi$  in  $I$

$$\det \begin{pmatrix} 1 & 1 & 1 \\ s & t & \xi \\ f(s) & f(t) & f(\xi) \end{pmatrix} \geq \frac{1}{2} \alpha (s-t)(t-\xi)(\xi-s).$$

**Illustration 2.** Function  $f(t) = -|t|^{3/2}$  on  $C = [-1, 1]$  is continuously differentiable but it is not convexifiable. Indeed, for  $s = 0, \Psi(0, t) = 2^{5/2}(1 - 2^{1/2})/t^{-1/2} \rightarrow -\infty$  as  $t > 0, t \rightarrow 0$ . Also, using Theorem 2 at  $s = -\epsilon, t = 0, \xi = \epsilon > 0$ , we find that there is no  $\alpha$  such that  $\alpha \leq -2/\epsilon$  as  $\epsilon \rightarrow 0$ . Function  $g(t) = -|t|$  is not convexifiable around the origin.

Scalar convexifiable functions can be represented explicitly on a compact interval  $I$ :

**Theorem 3. ([9] Explicit Representation of Scalar Convexifiable Functions)** A continuous scalar function  $f: I \rightarrow \mathbb{R}$  is convexifiable if, and only if, there exists a number  $\alpha$  such that

$$f(t) = f(c) + \frac{1}{2} \alpha (t^2 - c^2) + \int_c^t g(\xi, \alpha) d\xi.$$

Here  $c, t \in I, c < t$ , and  $g = g(\cdot, \alpha): I \rightarrow \mathbb{R}$  is a non-decreasing right-continuous function.

An implication of this result is that every smooth function with a Lipschitz derivative, in particular every analytic function and every trajectory of an object governed by Newton's Second Law, is of this form.

Two important classes of functions are convexifiable and a convexifier  $\alpha$  can be given explicitly. First, if  $f$  is twice continuously differentiable, then the second derivative of  $f$  at  $x$  is represented by the Hessian matrix  $H(x) = (\partial^2 f(x)/\partial x_i \partial x_j), i, j = 1, \dots, n$ . This is a symmetric matrix with real eigenvalues. Denote its smallest eigenvalue at  $x$  by  $\lambda(x)$  and its "globally" smallest eigenvalue over a compact convex set  $C$  by

$$\lambda^* = \min_{x \in C} \lambda(x).$$

**Corollary 1. ([7])** A twice continuously differentiable function  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  is convexifiable on a compact convex set  $C$  in  $\mathbb{R}^n$  and  $\alpha = \lambda^*$  is a convexifier.

Suppose that  $f$  is a continuously differentiable (smooth) function with the derivative satisfying the Lipschitz property, i. e.,  $\|\nabla f(x) - \nabla f(y)\| \leq L\|x - y\|$  for every  $x, y \in C$  and some constant  $L$ . Here  $\nabla f(u)$  is the (Frechet) derivative of  $f$  at  $u$ . We represent the derivative of  $f$  at  $x$  by a column  $n$ -tuple gradient  $\nabla f(x) = (\partial f(x)/\partial x_i)$ .

**Corollary 2. ([8])** A continuously differentiable function  $f: \mathbb{R}^n \rightarrow \mathbb{R}$ , with the derivative having the Lipschitz property with a constant  $L$  on a compact convex set  $C$  in  $\mathbb{R}^n$ , is convexifiable on  $C$  and  $\alpha = -L$  is a convexifier.

A Lipschitz function may not be convexifiable. For example,  $f(t) = t^2 \sin(1/t)$  for  $t \neq 0$  and  $f(0) = 0$  is a Lipschitz function and it is also differentiable (not continuously differentiable). Its derivative is uniformly bounded, but the function is not convexifiable, e. g. [7,11].

### Canonical Form of Smooth Programs

Every mathematical program (NP)

$$\text{Min} f(x), f^i(x) \leq 0, \quad i \in P = \{1, \dots, m\}, x \in C,$$

where the functions  $f, f^i: \mathbb{R}^n \rightarrow \mathbb{R}, i \in P$  are continuous and convexifiable on a compact convex set  $C$  can be reduced to a canonical form. First one considers some convexifications of these functions:  $\phi(x, \alpha) = f(x) - 1/2 \alpha x^T x$  and  $\phi^i(x, \alpha_i) = f^i(x) - 1/2 \alpha_i x^T x$ , where  $\alpha, \alpha_i$  are, respectively, arbitrary convexifiers of  $f, f^i, i \in P$ . Then one associates with (NP) the following program with partly linear convexifications

$$\begin{aligned} & \text{(LF; } \theta, \varepsilon) : \\ & \text{Min}_{(x, \theta)} \phi(x, \alpha) + \frac{1}{2} \alpha x^T \theta, \\ & \phi^i(x, \alpha_i) + \frac{1}{2} \alpha_i x^T \theta \leq 0, \quad i \in P, \\ & x \in C, \|x - \theta\| \leq \varepsilon. \end{aligned}$$

Here  $\varepsilon \geq 0$  is a scalar parameter. This parameter was fixed at zero value in [2]. For the sake of "numerical stability" it was extended to  $\varepsilon \geq 0$  in [7]. If the norm is chosen to be uniform, i. e.,  $\|u\|_\infty = \max_{i=1, \dots, n} |u_i|$

then  $(LF; \theta, \varepsilon)$  is a convex program in  $x$  for every fixed  $(\theta, \varepsilon)$  and linear in  $(\theta, \varepsilon)$  for every  $x$ . Such programs are called partly linear-convex. Theory of optimality and stability for such programs and related models is well studied, e. g. [1,8].

*Remark* Since one can construct the program  $(LF; \theta, \varepsilon)$  for every (NP) with convexifiable functions, we refer to  $(LF; \theta, \varepsilon)$  as the *parametric Liu–Floudas canonical form* of (NP).

Let us relate an optimal solution of (NP) to optimal solutions  $x^0(\varepsilon), \theta^0(\varepsilon)$  of  $(LF; \theta, \varepsilon)$ .

**Theorem 4.** ([8,9]) *Consider (NP) with a unique optimal solution, where all functions are assumed to be convexifiable, and its partly linear-convex program  $(LF; \theta, \varepsilon)$ . Then a feasible  $x^*$  is an optimal solution of (NP) if and only if,  $x^* = \lim_{\varepsilon \rightarrow 0} x^0(\varepsilon)$  and  $\theta^* = \lim_{\varepsilon \rightarrow 0} \theta^0(\varepsilon)$ , with  $x^* = \theta^*$ . Moreover, the feasible set mapping of  $(LF; \theta, \varepsilon)$  is lower semi-continuous at  $\theta^*$  and  $\varepsilon^* = 0$ , relative to all feasible perturbations of  $(\theta, \varepsilon)$ .*

## Other Applications

There are many other areas of applications of convexifiable functions:

(i) Every convexifiable function  $f$  is the difference of a convex function  $\phi(x, \alpha)$  and a convex quadratic  $1/2\alpha x^T x$  for every sufficiently small  $\alpha$  on a compact convex set. Hence it follows that the results for convex functions can be applied to  $\phi(x, \alpha)$ . With minor adjustments, pertaining to the quadratic term, such results can be extended to convexifiable (generally non-convex) functions. Here is an illustration of how this works for the mean value. The result is well known for convex functions (the case  $\alpha = 0$ ).

**Theorem 5.** ([9]) *Consider a continuous scalar convexifiable function  $f: \mathbb{R} \rightarrow \mathbb{R}$  on an open interval  $(a, b)$  with a convexifier  $\alpha$ . Then*

$$\begin{aligned} 1/(d-c) \int_c^d f(\xi) d\xi &\leq \frac{1}{2}[f(c) + f(d)] \\ &- \frac{1}{12}\alpha(d-c)^2, \quad \text{for every } a < c < d < b. \end{aligned}$$

A composite version of this result follows.

**Theorem 6.** ([9]) *Integral Mean-Value for Composite Convexifiable Function) Let  $f: (a, b) \rightarrow \mathbb{R}$  be continuous and convexifiable with a convexifier  $\alpha$  and let  $g: [c, d] \rightarrow (a, b)$  be continuous. Then*

$$\begin{aligned} f\left(1/(d-c) \cdot \int_c^d g(t) dt\right) &\leq 1/(d-c) \\ &\cdot \int_c^d (f \circ g)(t) dt + \frac{1}{2}\alpha \cdot R(c, d; g) \end{aligned}$$

where

$$\begin{aligned} R(c, d; g) &= [1/(d-c) \cdot \int_c^d g(t) dt]^2 - 1/(d-c) \\ &\cdot \int_c^d [g(t)]^2 dt. \end{aligned}$$

*Remarks* If  $f: (a, b) \rightarrow \mathbb{R}$  and  $g: [c, d] \rightarrow (a, b)$  are continuous on  $(a, b)$ , then, in Theorem 5 and 6, one can specify  $\alpha = 0$ , if  $f$  is convex on  $(a, b)$ . Also  $\alpha = \lambda^* = \min_{t \in I} f''(t)$ , if  $f$  is twice continuously differentiable or analytic on  $(a, b)$ , and  $\alpha = -L$  a negative Lipschitz constant of the derivative of  $f$  on  $(a, b)$ , if  $f$  is continuously differentiable.

(ii) Convexification of differential equations: A solution  $y(t)$  of an ordinary differential equation of second or higher order, over a compact interval, is continuously differentiable with a Lipschitz derivative. Such  $y$  is convexifiable. Using  $y(t) = \phi(t, \alpha) + 1/2\alpha t^2$ , the problems in differential equations can be “convexified”, i. e., transformed to equivalent differential equations with convex solutions  $\phi(t, \alpha)$ . After back-substitution, the true solution  $y(t)$  is recovered. In particular, the problems of theoretical mechanics based on the Second Newton Law, can be “convexified”, e. g. [9,11].

(iii) Convexification in linear algebra: Some of the basic eigenvalue inequalities for symmetric matrices follow from inequalities for convex functions, e. g. [4]. Using a convexification, one can extend these results to non-convexity. For example, after finding a convexifier of the product function  $f(x) = x_1 x_2 \cdots x_n$ , the following follows:

**Corollary 3. (Bounds for the Determinant of an Arbitrary Symmetric Matrix [11])** *Let  $A = (a_{ij})$  be an*

$n \times n$  real symmetric matrix where  $n \geq 2$  and let  $\rho$  be its spectral radius. Then

$$\begin{aligned} \prod_{i=1,\dots,n} a_{ii} - (n-1)\rho^{n-2} \sum_{i,j=1,\dots,n;i < j} a_{ij}^2 &\leq \det A \\ &\leq \prod_{i=1,\dots,n} a_{ii} + (n-1)\rho^{n-2} \sum_{i,j=1,\dots,n;i < j} a_{ij}^2. \end{aligned}$$

If the left hand-side in Corollary 3 is positive, then the matrix  $A$  is non-singular.

From the two-sided Jensen inequalities, obtained by convexification, new estimates follow for the absolute value of the inner product function in arbitrary inner product spaces. In some situations the new estimates are sharper than the Cauchy–Schwarz inequality. Many results for convexifiable functions, including the canonical form (LF;  $\theta$ ,  $\varepsilon$ ), can be extended to non-smooth Lipschitz functions. This can be done using the fact that every Lipschitz function, when considered on a compact convex set, is only a linear function away from the set of all coordinate-wise monotone functions [11].

## Conclusions

A necessary and sufficient condition for convexifiability on a compact convex set is given using the mid-point acceleration function. For scalar functions there are also characterizations given in terms of determinants and integrals. In particular, every smooth function with a Lipschitz derivative is convexifiable. Such function is only a convex quadratic away from the set of all convex functions. Using this “closeness”, many results for convex functions can be extended to smooth (generally non-convex) functions with Lipschitz derivatives. On the other hand, mathematical programs with convexifiable functions can be reduced to the parametric Liu-Floudas partly linear-convex canonical form.

### Keywords

Minimax problem; Convex optimization;  
 Max-function

### Synonyms

Minimax

### Examples of the Problem

In a classic nonlinear program (NLP) a smooth objective function is minimized on a feasible set defined by finitely many smooth constraints. However, many optimization problems have an objective function that is

not smooth but is of the max type, that is, defined as

$$f(x) := \max \{f_\ell(x) : \ell \in \mathcal{L}\}, \quad (1)$$

where the functions  $f_\ell: \mathbf{R}^n \rightarrow \mathbf{R}$  are themselves smooth.

When  $\mathcal{L}$  is finite, the minimization of  $f$  is called a *finite minimax problem*. In a general *minimax problem*, the indices  $\ell$  can range over an infinite compact set  $\mathcal{L}$ , see [6]. Those  $f_\ell$ 's realizing the maximum in (1) are called *active functions*. The corresponding indices form the *active index set*, defined as  $\mathcal{L}_a(x) := \{\ell \in \mathcal{L} : f_\ell(x) = f(x)\}$ .

There are numerous examples of optimization problems dealing with the minimization of convex max-functions:

- When processing empirical data  $\{(t_\ell, p_\ell) : \ell = 1, \dots, m\}$ , consider the problem of selecting the coefficients  $x$  of a polynomial  $p_x(t) = \sum_{j=0}^n x_j t^j$  that fits well the data. The quality of the approximation can be measured through the deviation  $f_\ell(x) := |p_\ell - p_x(t_\ell)|$ , defined for all  $\ell$ . Depending on the nature of the problem, it can be interesting to minimize either the sum of squared deviations or the maximum deviation. The first case is a *least squares problem*, while the second is known as *Chebyshev best approximation*, and is a particular instance of (1), with index set  $\ell = \{\ell : \ell = 1, \dots, m\}$ .
- A more general case is finding the best approximation of a continuous function  $\varphi_0$  on a compact interval  $\mathcal{L}$ . Instead of  $n$  powers  $t^j$ ,  $n$  linearly independent functions  $\varphi_j: \mathcal{L} \rightarrow \mathbf{R}$  are given. To find the linear combination  $\sum_j x_j \varphi_j$  which best approximates  $\varphi_0$  in the max-norm comes to solve (1), with  $f_\ell(x) = |\sum_j x_j \varphi_j(\ell) - \varphi_0(\ell)|$ . Because the problem has infinitely many constraints, it is also an example of semi-infinite programming.
- A basic problem in structural optimization, see [2], is to find the stiffest structure of a given volume that is able to carry loads varying on a given set. Optimization can be performed through the variation of sizing variables, like the thickness of bars in a truss; shape variables, as the splines defining the boundary of the body; or even the distribution and properties of the composite material used to make the structure itself. After discretization by finite elements, the design problem has an objective function as in (1). The  $f_\ell$ 's therein have usually the form  $f_\ell(x) = (1/2)x^\top A_\ell$

$x - b^\top x$ , with  $A_\ell$  denoting the stiffness matrix of the  $\ell$ th element of the grid.

- Some large scale mixed integer problems can be solved by *decomposition techniques* using Lagrangian relaxation. The idea is to coordinate, by means of a master program, the iterative resolution of problems of smaller dimension or complexity, called local problems. When applying price decomposition, the master is led to maximize a dual function, say  $\theta(\lambda)$ , on the space of multipliers  $\Lambda$ , using some iterative method. In production planning problems, the iterate  $\lambda^k$  sent to the local solvers can be interpreted as prices paid by the master. Let  $\ell = \prod_i \mathcal{L}^i$  denote the (decomposed) primal space and let  $L(x, \lambda) = \sum_i L^i(x^i, \lambda)$  be the (decomposed) Lagrangian of the original problem. Each local unit  $i$  decides its corresponding optimal level of production by solving  $\min_{x^i \in \mathcal{L}^i} L^i(x^i, \lambda^k)$ . Having those local optimal levels, the master adjusts prices by updating  $\lambda^k$  in order to maximize the dual function  $\theta$ , defined as the pointwise minimum of the Lagrangian:  $\theta(\lambda) = \min_{x \in \mathcal{L}} L(x, \lambda) = \sum_i \min_{x^i \in \mathcal{L}^i} L^i(x^i, \lambda)$ . An equivalent problem for the master is to minimize  $f(\lambda) := -\theta(\lambda)$ . This last formulation has an objective  $f$  that is a max-function as in (1), letting  $f_\ell(\lambda) = -\sum_i L^i(x_\ell^i, \lambda)$ , for each  $x_\ell \in \mathcal{L}$ .
- Solving a nonlinear program using *exact penalties* leads to the iterative minimization of penalized objective which are max-functions, with the max-operation involving the constraints.
- In game theory, consider a zero sum game, with two players whose strategy is to optimize their individual choice against the worst possible selection by the other player. The first player can choose his action over  $n$  possible moves, with probability distribution  $x = (x_1, \dots, x_n)$ . To every possible move  $j = 1, \dots, m$  of the second player, corresponds a loss  $a_{i,j}$  player I pays to player II. Let  $\ell$  be a continuous index counting elements in the set of probability distributions of the second player:  $\mathcal{L} = \{z \in \mathbf{R}^m : \sum_{j=1}^m z_j = 1, z_j \geq 0\}$ . Calling  $A = [a_{i,j}]$  the  $n \times m$  loss-matrix, the average amount to be paid by player I is  $f_\ell(x) = x^\top A z_\ell$ . It follows that the first player needs to solve a problem like (1). The mini-maximization of the bivariate function  $F(x, z) = x^\top A z$  is also called a *saddle-point problem*.

## Continuity and Optimality Conditions

When taking the pointwise maximum in (1), some properties of the functions  $f_\ell$  are transmitted to  $f$ . Such is the case of continuity and convexity, but not of differentiability.

More precisely,  $f$  is continuous when both the  $f_\ell$ -s and its gradients  $\nabla f_\ell$  are continuous. When the underlying functions  $f_\ell$  are convex, so is  $f$ .

Convexity implies that the max-function  $f$  is differentiable almost everywhere. Nevertheless, at those points where more than one underlying function  $f_i$  realizes the maximum, the gradient fails to exist. Typically, such is the case at  $\bar{x}$ , a minimizer of  $f$ . For instance, suppose that  $\mathcal{L}_a(\bar{x}) = \{1, 2\}$ , i. e., there are two active functions at  $\bar{x}$ :  $f(\bar{x}) = f_1(\bar{x}) = f_2(\bar{x})$ . Clearly, for  $\nabla f(\bar{x})$  to exist, the unlikely equality  $\nabla f(\bar{x}) = \nabla f_1(\bar{x}) = \nabla f_2(\bar{x})$  needs to hold. Moreover, the optimality condition for minimizing  $f$  on  $\mathbf{R}^n$  would require all the involved gradients to be null.

Rather than a single gradient, it is possible to define a whole set of *subgradients* by making convex combinations of  $\nabla f_1(\bar{x})$  and  $\nabla f_2(\bar{x})$ . For an arbitrary convex max-function  $f$ , at any given  $x$ , the set of subgradients is the so-called *subdifferential* of  $f$  at  $x$ . Its expression is given by the formula

$$\partial f(x) = \left\{ \sum_{l \in \mathcal{L}_a(x)} \alpha_l \nabla f_l(x) : \alpha \in \Delta \right\}, \quad (2)$$

where  $\Delta$  is the unit simplex

$$\Delta := \left\{ \alpha \in \mathbb{R}^{|\mathcal{L}_a(x)|} : \sum_{l \in \mathcal{L}_a(x)} \alpha_l = 1, \alpha_l \geq 0 \right\}. \quad (3)$$

When  $\mathcal{L}$  in (1) is an infinite compact set, (2) still holds, provided the application  $\ell \mapsto f_\ell(x)$  is upper semicontinuous for each  $x$ , see [8, Chap. VI, §4.4].

Consider the constrained problem

$$\min_{x \in \Omega} f(x), \quad (4)$$

where  $\Omega \subset \mathbf{R}^n$  is a closed convex set and  $f$  is the function defined in (1). Assume the index set  $\mathcal{L}$  is infinite and suppose (4) has a solution  $\bar{x}$  such that  $f(\bar{x}) = \max \{f_\ell(\bar{x}) : \ell \in \mathcal{L}\}$ . Then it can be proved (see [6, Chap. VI, Thm. 3.3]) that (4) is equivalent to the finite

minimax

$$\min_{x \in \Omega} \max_{i=1, \dots, r} \{f_{\ell_i}(x) : \ell_i \in \mathcal{L}\}, \quad (5)$$

with  $r \leq n + 1$ . The set  $\{\ell_1, \dots, \ell_r\}$  is called an *extremal basis* of (4).

When  $\Omega$  satisfies a constraint qualification condition of Slater type, see, for instance, [7, Chap. III], a necessary optimality condition (OC) characterizing a minimizer  $\bar{x}$  of (4) is

$$0 \in \partial f(\bar{x}) + N_\Omega(\bar{x}), \quad (6)$$

where  $N$  is the normal cone of convex analysis. Because  $f$  is convex, the optimality condition is also sufficient.

The optimality condition (6) can be further specified when  $\Omega$  is represented by a set of convex inequalities:

$$\Omega := \{x \in \mathbf{R}^n : c_j(x) \leq 0, j \in \mathcal{J}\}. \quad (7)$$

Observe that  $\Omega$  may contain an infinite number of constraints  $c_j$ , assumed to be smooth and convex. Using (1) together with (7), the following characterization of  $\bar{x}$  results:

**Lemma 1** *There exist  $r \leq n + 1$  and  $s \leq n$  such that for the index sets  $\mathcal{L}_a(\bar{x}) := \{\ell_1, \dots, \ell_r\} \subset \mathcal{L}$  and  $\{j_1, \dots, j_s\} \subset \mathcal{J}$  it holds*

$$\sum_{i=1}^r \alpha_i \nabla f_{\ell_i}(\bar{x}) + \sum_{i=1}^s \mu_i \nabla c_{j_i}(\bar{x}) = 0, \quad (8)$$

where the multipliers  $\alpha$  and  $\mu$  are positive and  $\alpha$  is an element of the simplex  $\Delta$  in  $\mathbb{R}^{|\mathcal{L}_a(\bar{x})|}$  from (3).

This characterization ensures the existence of an extremal basis of (4) near  $\bar{x}$ .

## Algorithms of Minimization

Depending on the nature of the problem, several approaches have been proposed to solve (4):

- Reformulation as a NLP.
- Minimization of the nonsmooth max-function.
- Determination of a saddle point.
- Search of an extremal basis.

For example, the amount of available information can determine the method of resolution: if for any given  $x$ , all the active indices in (1) are known, then the full subdifferential (2) is available and a nonlinear programming technique can be applied.

### Nonlinear Programming

An important feature of this approach is that smooth NLP techniques have a superlinear rate of convergence. The essential idea is first to write (4) as an NLP with an additional variable:

$$\begin{cases} \min_{\substack{r \in \mathbb{R} \\ x \in \Omega}} r \\ \text{s.t.} \quad r \geq f_\ell(x), \quad \ell \in \mathcal{L}, \end{cases} \quad (9)$$

and then solve the associated optimality conditions by using a Newton-like method, such as sequential quadratic programming (cf. also ► **Successive quadratic programming**) or interior point schemes, see [4, Parts III–IV] and [3, §§4.3–4.4].

### Nonsmooth Optimization

Sometimes the explicit knowledge of all the active constraints in (9) can be difficult, if not impossible, to obtain; such is the case for structural optimization problems.

On the other hand, it is often possible to obtain a single subgradient almost for free when computing  $f(x)$ . Indeed, suppose that just one active index  $l$  in  $\ell_a(x)$  is known:  $f(x) = f_l(x)$ . Then, because of (2),  $\nabla f_l(x) \in \partial f(x)$ .

Algorithms from nonsmooth optimization, such as bundle methods [8, Chaps. XIV–XV], are designed to minimize a general convex function, possibly nondifferentiable, with the information furnished by an oracle that gives  $f(x)$  and only one subgradient at  $x$ . Nonsmooth optimization techniques, specialized to a max-function like  $f$  in (1), have been successfully used in [12] and [9] to solve general minimax problems.

Although bundle methods are essentially first order methods, in recent years some proposals have been given that aim at obtaining better than linear convergence. They consist of a combination of bundle, proximal and quasi-Newton techniques [5,10,11].

### Other Methods of Resolution

V.F. Demyanov and V.N. Malozemov treat (4) in an indirect way, by solving an infinite sequence of finite minimax problems. Keeping (5) in mind, the idea is to asymptotically identify an extremal basis by making successive approximations on a finite grid of the index set  $\mathcal{L}$ .

In game theory, rather than solving (4) by some ‘mini-maximization’ procedure, it can be more convenient to find a *saddle point*. That is, an equilibrium point satisfying  $\min_x \max_{z_\ell} F(x, z_\ell) = \max_{z_\ell} \min_x F(x, z_\ell)$ , with  $F(x, z_\ell) := f_\ell(x)$ . The determination of saddle points of  $F$  can be performed taking advantage of the extra structure of the problem. Some popular methods are Arrow–Hurwicz’s and Uzawa’s, see [1].

W.I. Zangwill [9] first proposed the *convex-simplex algorithm* (CSA) for the following problem:

$$\min_{x \in S} f(x), \quad (1)$$

where  $f(x)$  is a *pseudoconvex function* on  $\mathbf{R}^n$ . The set  $S$  is a nonempty *polyhedron*, i. e.,  $S = \{x \in \mathbf{R}^n: Ax = b, x \geq 0\}$ ,  $A$  is a  $m \times n$  matrix, and  $b$  is a vector in  $\mathbf{R}^m$ . For simplicity,  $S$  is assumed to be bounded also.

CSA belongs to a class of algorithms called *feasible direction methods*. Given an initial feasible solution, algorithms in this class solve problem (1) by iteratively generating an improving feasible direction that leads to another feasible solution with an improved objective value. The name ‘convex-simplex’ is to indicate that the algorithm generates improving feasible directions in manner similar to the simplex algorithm for linear programs. When  $f(x)$  is linear, the algorithm is identical to the simplex algorithm. In general, a vector  $d$  is an *improving feasible direction* at a point,  $x$ , feasible to problem (1) if the following (sufficient) conditions hold

- $\nabla f(x)^\top d < 0$ ,
- $Ad = 0$ , and
- $d_j \geq 0$  if  $x_j = 0$ .

It follows from the first order Taylor series expansion of  $f(x)$  that

$$f(x + \lambda d) = f(x) + \lambda \nabla f(x)^\top d + \lambda \|d\| \alpha(x; \lambda d),$$

where  $\lim_{\lambda \rightarrow 0} \alpha(x; \lambda d) = 0$ . Via the above expansion, condition a) implies that  $f(x + \lambda d) < f(x)$  for a sufficiently small  $\lambda > 0$ , i. e.,  $d$  leads to an improvement in the objective function. The remaining two conditions guarantee that  $d$  can produce a point in  $S$ . In particular, condition b) yields the following:

$$A(x + \lambda d) = Ax + \lambda Ad = Ax = b.$$

This shows that  $x + \lambda d$  is always feasible with respect to the equality constraint. Next, each component of  $x + \lambda d$  can be written as

$$x_i + \lambda d_i = \begin{cases} x_i + \lambda d_i & \text{if } x_i > 0, \\ \lambda d_i & \text{if } x_i = 0. \end{cases}$$

When  $\lambda$  is a sufficiently small positive number,  $x_i + \lambda d_i$  remains nonnegative in the first case. For the second case, it follows directly from condition c) that  $\lambda d_i \geq 0$  for all  $\lambda > 0$ . Thus,  $x + \lambda d \in S$  when  $\lambda$  is sufficiently small.

To describe how CSA generates an improving feasible direction, let  $a_j$  denote the  $j$ th column of  $A$ . Also, assume that every  $m$  columns of  $A$  are linearly independent and every extreme point of  $S$  has  $m$  strictly positive components. Under these assumptions, every feasible solution has at least  $m$  positive components and at most  $(n - m)$  zero components. Given a feasible solution  $x$ , let  $I(x)$  be the set of indices for the  $m$  largest components of  $x$ . Then,  $A$  can be partitioned into  $[B, N]$ , where  $B = [a_j : j \in I(x)]$  and  $N = [a_j : j \notin I(x)]$ . Similarly,  $x^\top$  can be partitioned into  $[x_B^\top, x_N^\top]$  where  $x_B^\top$ , the *basic component*, corresponds to components of  $x$  belonging to  $I(x)$ , and  $x_N^\top$ , the *nonbasic component*, corresponds to components not in  $I(x)$ . By the above assumptions,  $x_B^\top > 0$  and  $B$  is nonsingular.

Partitioning the direction vector,  $d^\top$ , into its basic and nonbasic components, i. e.,  $[d_B^\top, d_N^\top]$ , produces the following sequence of relationships:

$$\begin{aligned} Ad &= 0, \\ Bd_B + Nd_N &= 0, \\ d_B &= -B^{-1}Nd_N. \end{aligned}$$

The last equality yields the following:

$$\begin{aligned} \nabla f(x)^\top d &= \nabla_B f(x)^\top d_B + \nabla_N f(x)^\top d_N \\ &= [\nabla_N f(x)^\top - \nabla_B f(x)^\top B^{-1}N] d_N \\ &= r_N^\top d_N = \sum_{j \notin I(x)} r_j d_j, \end{aligned}$$

where  $r_N^\top \equiv \nabla_N f(x)^\top - \nabla_B f(x)^\top B^{-1} N$ . In order for  $d$  to be an improving direction,  $\nabla f(x)^\top d < 0$ . There are several approaches to make this inner product negative. Each approach generates a different algorithm and all of which can be viewed as an extension or variant of the *reduced gradient algorithm* first proposed by P. Wolfe [8].

Like the simplex algorithm, CSA allows only one nonbasic component of  $d$  to be nonzero. In particular, let

$$j^+ = \operatorname{argmax}_{j \notin I(x)} \{-r_j : r_j < 0\}$$

and

$$j^- = \operatorname{argmax}_{j \notin I(x)} \{x_j r_j : x_j > 0, r_j > 0\}.$$

Then, CSA chooses  $d_N$  as follows. If  $-r_{j^+} \geq x_{j^-} r_{j^-}$ , then  $d_{j^+} = 1$  and  $d_j = 0$  for the remaining nonbasic components. This makes  $\nabla f(x)^\top d = r_{j^+} < 0$ . Otherwise,  $d_{j^-} = -1$  instead and  $\nabla f(x)^\top d = -r_{j^-} < 0$ . Given  $d_N$ , the basic component can be computed using the relationship  $d_B = -B^{-1} N d_N$ .

When  $r_N \geq 0$  and  $r_N^\top x_N = 0$ , the indices  $j^+$  and  $j^-$  are undefined in the above construction. When this occurs,  $x$  is globally optimal and  $d_N$  is usually set to zero to indicate that there is no improving feasible direction. To demonstrate, it is sufficient to show that there exist vectors  $\mu^\top = [\mu_B^\top, \mu_N^\top] \geq 0$  and  $v$  (unrestricted) satisfying the following equations:

$$\begin{aligned} \nabla_B f(x) + B^\top v - \mu_B &= 0, \\ \nabla_N f(x) + N^\top v - \mu_N &= 0, \\ \mu_B^\top x_B &= 0, \\ \mu_N^\top x_N &= 0. \end{aligned}$$

These equations are known as the *Karush-Kuhn-Tucker conditions* (see, e. g., [2]) and they are sufficient optimality conditions for problem (1). Letting  $\mu_B = 0$ ,  $\mu_N = \nabla_N f(x) - N(B^\top)^{-1} \nabla_N f(x)$ , and  $v = -(B^\top)^{-1} \nabla_B f(x)$  satisfies the first three conditions. Since  $\mu_N = r_N$ , the above assumptions concerning  $r_N$  imply that  $\mu_N \geq 0$  and  $\mu_N^\top x_N = 0$ . Thus, the Karush-Kuhn-Tucker conditions hold and  $x$  must be globally optimal.

When  $d_N \neq 0$ , a better feasible point can be obtained from a solution to the following problem, typically called the *line search problem*:

$$\min_{0 \leq \lambda \leq \lambda_{\max}} f(x + \lambda d),$$

where  $\lambda_{\max} = \min_j \{-x_j/d_j : d_j < 0\}$ . This prevents components of  $x + \lambda d$  from being negative. (If  $S$  is unbounded, then every component of  $d$  may be nonnegative and  $\lambda_{\max} = \infty$ .) Algorithms such as the bisection search, the golden section method, and an inexact line search technique (e. g., the *Armijo rule*, [1]) can efficiently solve the line search problem.

To summarize, CSA can be stated as follows:

0	Select $x^1 \in S$ and set $k = 1$ .
1	Identify $I(x^k)$ and form the submatrices $B$ and $N$ . Compute $r_N^\top = \nabla_N f(x^k)^\top - \nabla_B f(x^k)^\top B^{-1} N.$
2	IF $r_N \geq 0$ and $r_N^\top x_N^\top = 0$ , THEN stop and $x^k$ is an optimal solution. ELSE, let $j^+ = \operatorname{argmax}_{j \notin I(x^k)} \{-r_j : r_j < 0\},$ $j^- = \operatorname{argmax}_{j \notin I(x^k)} \{x_j^k r_j : x_j^k > 0, r_j > 0\}.$ Set $d_N^k = 0$ . IF $-r_{j^+} \geq x_{j^-}^k r_{j^-}$ , THEN set $d_{j^+}^k = 1$ . ELSE, set $d_{j^-}^k = -1$ instead. Set $d_B^k = B^{-1} N d_N^k$ . Go to Step 3.
3	Set $\lambda_{\max} = \min_j \{-x_j^k/d_j^k : d_j^k < 0\}$ and compute $\lambda^k = \operatorname{argmin}_{0 \leq \lambda \leq \lambda_{\max}} f(x^k + \lambda d^k).$ Then, set $x^{k+1} = x^k + \lambda^k d^k$ and $k = k + 1$ . Return to Step 1.

### The convex-simplex algorithm (CSA)

The convergence proof for CSA is the same as that of the reduced gradient algorithm and follows standard arguments in nonlinear programming. Although CSA behaves like the simplex algorithm, CSA converges slowly when compared to other algorithms. This is due in part to the restriction that only one nonbasic component of the improving feasible direction can be nonzero. To accelerate CSA, B.A. Murtagh and M.A.

Saunders [5] used a second order approximation for the objective function and allowed several nonbasic components to be nonzero. The latter is often referred to as *superbasic variables*.

For other developments, S. Nguyen [6] and R.V. Helgason and J.L. Kennington [4] specialized CSA to nonlinear network flow problems. D.P. Rutenberg [7] (see also [3]) demonstrated that special techniques for solving linear programs with generalized network and generalized upper bounding structure also extend to CSA.

## Copositive Optimization

IMMANUEL M. BOMZE

### Article Outline

#### References

Copositive optimization (or copositive programming, coined in [4]) is a special case of conic optimization that consists in extremizing a linear function over a (convex) cone subject to additional (inhomogeneous) linear (inequality or equality) constraints.

It is well known that the simplest class of hard problems in continuous optimization is that of quadratic optimization problems [20] – to extremize a (possibly indefinite) quadratic form  $x^T Q x$  over a polyhedron  $\{x \in \mathbb{R}_+^n : Ax = b\}$ . Note that a linear term in the objective function can be removed by an affine transformation of the polyhedron. The number of local, non-global solutions to this problem may be exponential in the number of variables and/or constraints.

This class has a close connection to copositive optimization. The idea here is to linearize the quadratic form

$$x^T Q x = \text{trace}(x^T Q x) = \text{trace}(Q, x x^T) = \langle Q, x x^T \rangle$$

by introducing the new symmetric matrix variable  $X = x x^T$  and Frobenius duality  $\langle X, Y \rangle = \text{trace}(X, Y)$ . If  $Ax \in \mathbb{R}_+^m$  for all  $x \in \mathbb{R}_+^n$  and  $b \in \mathbb{R}_+^m$ , then the linear constraints can be squared, to arrive in a similar way at constraints of the form  $\langle A_i, X \rangle = b_i^2$ .

Now the set of all these  $X$  generated by feasible  $x$  is nonconvex since  $\text{rank}(x x^T) = 1$ . The convex hull

$$\mathcal{K} = \text{conv} \{x x^T : x \in \mathbb{R}_+^n\},$$

results in a convex matrix cone known as the cone of completely positive matrices since [14]; see [1]. Note that a similar construction dropping nonnegativity constraints leads to

$$\mathcal{P} = \text{conv} \{x x^T : x \in \mathbb{R}^n\},$$

the cone of positive-semidefinite matrices, the basic set in semidefinite optimization (or semidefinite programming, SDP).

The first account of copositive optimization goes back to [4], who established a copositive representation of a subclass of particular interest, namely, in standard quadratic optimization (StQP). Here the feasible polyhedron is the standard simplex  $\Delta = \{x \in \mathbb{R}_+^n :$

$\sum_i x_i = 1$ ): this subclass is also NP-hard from the worst-case complexity but allows for a polynomial-time approximation scheme [3]. There can be up to  $\approx 2^n / (1.25\sqrt{n})$  local nonglobal solutions. Now, with  $J$  the  $n \times n$  all-ones matrix, we have

$$\begin{aligned} \min \{x^\top Qx : x \in \Delta\} \\ = \min \{\langle Q, X \rangle : \langle J, X \rangle = 1, X \in \mathcal{K}\}. \end{aligned}$$

Note that the right-hand problem is convex, so there are no more local, nonglobal solutions. In addition, the objective function is now linear, and there is just one linear equality constraint. The complexity has been completely pushed into the feasibility condition  $X \in \mathcal{K}$ , which also shows that there are indeed convex minimization problems that cannot be solved easily.

The duality theory for conic optimization problems requires the dual cone  $\mathcal{K}^*$  of  $\mathcal{K}$  w.r.t. the Frobenius inner product  $\langle \dots, \rangle$ , which is

$$\begin{aligned} \mathcal{K}^* = \{S \text{ symmetric } n \times n : \langle S, X \rangle \geq 0 \\ \text{for all } X \in \mathcal{K}\}. \end{aligned}$$

Here it can easily be shown that  $\mathcal{K}^*$  coincides with the cone of copositive matrices, which justifies the terminology:

$$\mathcal{K}^* = \{S \text{ symmetric } n \times n : x^\top Sx \geq 0 \text{ if } x \in \mathbb{R}_+^n\},$$

i. e., a matrix  $S$  is copositive [18] (most probably abbreviating “conditionally positive-semidefinite”), if  $S$  generates a quadratic form  $x^\top Sx$  taking no negative values over the positive orthant. The dual of the special program over  $\mathcal{K}$  above is then

$$\max \{y : S = Q - yJ \in \mathcal{K}^*\},$$

a linear objective in just one variable  $y$  with the innocent-looking feasibility constraint  $S \in \mathcal{K}^*$ . This shows that checking membership of  $\mathcal{K}^*$  (and, similarly, of  $\mathcal{K}$ ) is already NP-hard, and there are many approaches to algorithmic copositivity detection; for recent developments see, e. g., [7] and references therein.

More generally, a typical primal-dual pair in copositive optimization (COP) is of the following form:

$$\begin{aligned} \inf \{\langle C, X \rangle : \langle A_i, X \rangle = b_i, \quad i = 1: m, X \in \mathcal{K}\} \\ \geq \sup \left\{ \sum_i b_i y_i : y \in \mathbb{R}^m, S = C - y_i A_i \in \mathcal{K}^* \right\}. \end{aligned}$$

The inequality above is just standard weak duality, but observe we have to use inf and sup since – as in general conic optimization – there may be problems with the attainability of either or both problems above, and likewise there could be a (finite or infinite) positive duality gap without any further conditions such as strict feasibility (Slater’s condition). For the above representation of standard quadratic optimization problems, this is not the case:

$$\begin{aligned} \min \{\langle Q, X \rangle : \langle J, X \rangle = 1, X \in \mathcal{K}\} \\ = \max \{y : S = Q - yJ \in \mathcal{K}^*\}. \end{aligned}$$

But for a similar class arising in many applications, the multi-standard quadratic optimization problems [6], dual attainability is not guaranteed while the duality gap is zero – an intermediate form between weak and strong duality [25].

Recently Burer [8] showed a more general result: any mixed-binary quadratic optimization problem

$$\min \left\{ \frac{1}{2} x^\top Qx + c^\top x : Ax = b, x \in \mathbb{R}_+^n, \right. \\ \left. x_j \in \{0, 1\}, \text{ all } j \in B \right\}$$

can (under mild conditions) be represented as COP:

$$\min \left\{ \frac{1}{2} \langle \hat{Q}, \hat{X} \rangle : \mathcal{A}(\hat{X}) = \hat{b}, X \in \mathcal{K} \right\},$$

where  $\hat{X}$  and  $\hat{Q}$  are  $(n+1) \times (n+1)$  matrices, and the size of  $(\mathcal{A}, \hat{b})$  is polynomial in the size of  $(A, b)$ .

Denote by  $\mathcal{N} = \{N \text{ symmetric } n \times n : N_{ij} \geq 0 \text{ for all } i, j = 1: n\}$  the cone of nonnegative matrices. Then evidently

$$\mathcal{K} \subseteq \mathcal{P} \cap \mathcal{N} \subset \mathcal{P} + \mathcal{N} \subseteq \mathcal{K}^*,$$

which also shows that  $\mathcal{K}$  never can be self-dual (note  $(\mathcal{P} \cap \mathcal{N})^* = \mathcal{P}^* + \mathcal{N}^* = \mathcal{P} + \mathcal{N}$ ), unlike  $\mathcal{P} = \mathcal{P}^*$  and  $\mathcal{N} = \mathcal{N}^*$ . For  $n \geq 5$ , A. Horn noted that the leftmost and the rightmost inclusion above is strict [10,14], so the middle sets  $\mathcal{P} \cap \mathcal{N}$  and  $\mathcal{P} + \mathcal{N}$  can only be used as tractable approximations for the intractable cones  $\mathcal{K}$  and  $\mathcal{K}^*$ , respectively.

Copositive approximation hierarchies [3,15,21,22] start with  $\mathcal{K}^{(0)} = \mathcal{P} + \mathcal{N}$  and consist of an increasing sequence  $\mathcal{K}^{(r)}$  of cones satisfying  $\bigcup_{r \geq 0} \mathcal{K}^{(r)} = \text{int } \mathcal{K}^*$ , the cone of strictly copositive matrices, i. e., those that

generate quadratic forms strictly positive over  $\Delta$ . For instance, a higher-order approximation due to [21] squares the variables to get rid of sign constraints:  $S \in \mathcal{K}^*$  if and only if  $y^\top S y \geq 0$  for all  $y$  s.t.  $y_i = x_i^2$ , some  $x \in \mathbb{R}^n$ , and this is guaranteed if the  $n$ -variable polynomial of degree  $2(r+2)$  in  $x$ ,

$$p_S^{(r)}(x) = \left(\sum x_i^2\right)^r y^\top S y = \left(\sum x_i^2\right)^r \sum_{j,k} S_{jk} x_j^2 x_k^2,$$

is nonnegative for all  $x \in \mathbb{R}^n$ . But this holds in particular if

- (a)  $p_S^{(r)}$  has no negative coefficients; or if
- (b)  $p_S^{(r)}$  is a sum-of-squares (s.o.s.):

$$p_S^{(r)}(x) = \sum_i [f_i(x)]^2, \quad f_i \text{ some polynomials.}$$

This gives the approximation cones

$$C^{(r)} = \{S \text{ symmetric } n \times n: S \text{ satisfies (a)}\}$$

and

$$\mathcal{K}^{(r)} = \{S \text{ symmetric } n \times n: S \text{ satisfies (b)}\}.$$

While  $C^{(r)}$  can be described by linear constraints on the entries of  $S$ , leading to LP formulations, the cones  $\mathcal{K}^{(r)}$  need for their description linear matrix inequalities (LMIs), leading to SDP formulations. However, for large  $r$  both are also intractable as they generate problems on matrices of order  $\mathcal{O}(n^{r+1} \times n^{r+1})$ , see [3].

Copositive optimization has been receiving increasing attention also because many NP-hard combinatorial problems have a representation in this domain; we start with the historically first such representation, the maximum (weight) clique problem, which amounts to finding a largest (or heaviest) clique in an undirected graph  $G$  (with weights on the vertices). Using an StQP formulation going back to [19] and applying some regularization [2], the following copositive formulation was introduced in [4]:

$$\begin{aligned} 1/\omega(G) &= \min \{x^\top Q_G x: x \in \Delta\} \\ &= \min \{\langle Q_G, X \rangle: \langle J, X \rangle = 1, X \in \mathcal{K}\}, \end{aligned}$$

where  $Q_G$  is a matrix derived from the adjacency matrix of  $G$  (and the weights). Taking the inverse  $t = 1/y$  in the dual of the last problem above, we also arrive at the formulation of [9] (for the complementary graph):

$$\omega(G) = \min \{t: tQ_G - J \in \mathcal{K}^*\}.$$

Here  $\omega(G)$  is the clique number of  $G$ , i.e., the size (weight) of a maximum (weight) clique in  $G$ . Replacing  $\mathcal{K}^*$  with its zero-order approximation, we get a strengthening  $\theta'(G)$  of the well-known Lovász bound  $\theta(G)$  [16,17,26]:

$$\theta'(G) = \min \{t: tQ_G - J \in \mathcal{P} + \mathcal{N}\} \geq \omega(G),$$

while shrinking further the feasible set to  $\mathcal{P}$ , we finally arrive at the Lovász number  $\theta(G)$  which – as  $\theta'(G)$  – can be computed in polynomial time:

$$\theta(G) = \min \{t: tQ_G - J \in \mathcal{P}\} \geq \omega(G).$$

Strong duality yields, as above,

$$1/\theta'(G) = \min \{\langle Q_G, X \rangle: \langle J, X \rangle = 1, X \in \mathcal{P} \cap \mathcal{N}\},$$

and a recent improvement over  $\theta'(G)$  adding a single valid linear cut motivated by the COP representation is

$$\begin{aligned} 1/\theta^C(G) &= \min \{\langle Q_G, X \rangle: \langle J, X \rangle = 1, \\ &\quad \langle C, X \rangle \geq 0, X \in \mathcal{P} \cap \mathcal{N}\} \geq 1/\theta'(G), \end{aligned}$$

where  $C \in \mathcal{K}^*$  is arbitrary: indeed, for any  $X \in \mathcal{K}$  we then have  $\langle C, X \rangle \geq 0$ . See [5] for appropriate choices of  $C$  and results, and [9,13,15,22] for higher-order approximation alternatives, with a particular emphasis on SDP-based bounds on the clique number. Similar copositivity optimization approaches, among many others, were employed to obtain bounds on the (fractional) chromatic number of a graph [11,12], and graph partitioning and quadratic assignment problems [23,24].

### Introduction

Let us denote the set of  $n \times n$  real symmetric matrices by

$$S_n = \{X \in \mathbb{R}^{n \times n}, X = X^T\}.$$

We will be considering the following subsets of  $S_n$ :

- The  $n \times n$  symmetric *positive semidefinite* matrices

$$S_n^+ = \{X \in S_n, y^T X y \geq 0 \forall y \in \mathbb{R}^n\};$$

- The  $n \times n$  symmetric *copositive* matrices

$$C_n = \{X \in S_n, y^T X y \geq 0 \forall y \in \mathbb{R}^n, y \geq 0\};$$

we can conclude that its extreme rays are of the form  $xx^T$ , where the nonnegative  $x \in \mathbb{R}^n$  supports an independent set (i. e., the set  $\{i : x_i > 0\}$  is independent). Therefore, the extreme points of the set defined by (4) are given by the intersection of the extreme rays of  $C_G$  with the hyperplane  $O_n \bullet X = 1$ .

Since the optimum value of a linear function over a convex set is attained at an extreme point, there is an optimum solution of the form

$$X^* = x^*x^{*T}, \quad x^* \in \mathbb{R}^n, \quad x^* \geq 0, \quad \|x^*\| = 1,$$

and where  $x^*$  supports an independent set. Therefore, we can reformulate the program (3) as

$$\begin{aligned} \max_x \left( \sum_{i=1}^n x_i \right)^2, \quad \|x\| = 1, \\ x \geq 0, \quad x_i x_j > 0 \Rightarrow (i, j) \notin E. \end{aligned}$$

Then, it is easy to see that the maximum is attained when  $x$  supports a maximum independent set and all  $x_i > 0$  are equal to  $1/\alpha(G)$ . This provides the optimum value to the program (3) equal to  $\alpha(G)$ . QED.

Since  $X \in C_n^*$  is always nonnegative, we can reduce the set of constraints  $x_{ij} = 0, (i, j) \in E$  in (4) to a single constraint  $A \bullet X = 0$ . Thus, the following copositive program is dual to (3), (4):

$$\alpha(G) = \min_{\lambda, y \in \mathbb{R}} \{ \lambda I + yA - O_n = Q, \quad Q \in C_n \}.$$

Therefore, the maximum independent set problem is reducible to copositive programming. See also [1,2] for reduction of the standard quadratic optimization problem to copositive programming.

Furthermore, it can be shown that checking if a given matrix is not copositive is  $NP$ -complete [5] and, hence, checking matrix copositivity is  $co$ - $NP$ -complete.

### Models

#### Approximating $C_n$ with Linear Matrix Inequalities

While, in general, there is no polynomial-time verifiable certificate of copositivity, unless  $co$ - $NP = NP$ , in many cases it is still possible to show by a short argument that a matrix is copositive. For instance, if the matrix  $M$  can be represented as sum of a positive semidefinite matrix  $S \in S_n^+$  and a nonnegative matrix

$N \in \mathcal{N}_n$ , then it follows that  $M \in C_n$ . Hence, we can obtain a semidefinite relaxation of a copositive program over  $M$  introducing the linear matrix constraints:

$$\begin{cases} M = S + N \\ N \geq 0, \quad S \in S_n^+ \end{cases}$$

Parrilo showed in [6] that using sufficiently large systems of linear matrix inequalities, one can approximate the copositive cone  $C_n$  to any desired accuracy.

Obviously, copositivity of the matrix  $M$  is equivalent to (global) nonnegativity of the fourth-degree form:

$$\begin{aligned} P(x) &= (x \circ x)^T M (x \circ x) \\ &= \sum_{i=1}^n \sum_{j=1}^n M_{ij} x_i^2 x_j^2 \geq 0, \quad x \in \mathbb{R}^n, \end{aligned} \quad (5)$$

where “ $\circ$ ” denotes the componentwise (Hadamard) product. It is shown in [6] that the mentioned decomposition into positive semidefinite and nonnegative matrices exists if and only if  $P(x)$  can be represented as sum of squares. Higher-order sufficient conditions for copositivity proposed by Parrilo in [6] correspond to checking whether the polynomial

$$P^{(r)}(x) = \left( \sum_{i=1}^n x_i^2 \right) P(x) \quad (6)$$

has a sum-of-squares decomposition (or – a weaker condition – whether  $P^{(r)}(x)$  has only nonnegative coefficients). These conditions can be expressed via linear matrix inequalities over  $n^r \times n^r$  symmetric matrices. In particular, for  $r = 1$ , Parrilo showed that the existence of a sum-of-squares decomposition of  $P^{(1)}(x)$  is equivalent to feasibility of the following system (see also [3]):

$$\begin{cases} M - M^{(i)} \in S_n^+, \quad i = 1, \dots, n, \\ M_{ii}^{(i)} = 0, \quad i = 1, \dots, n, \\ M_{jj}^{(i)} + 2M_{ij}^{(j)} = 0, \quad i \neq j, \\ M_{jk}^{(i)} + M_{ik}^{(j)} + M_{ij}^{(k)} \geq 0, \quad i < j < k, \end{cases}$$

where  $M^{(i)}$  ( $i = 1, \dots, n$ ) are symmetric matrices.

With sufficiently large  $r$ , the convergence to the copositivity constraint on  $M$  is guaranteed by the famous theorem of Pólya [7]:

**Theorem 3 (Pólya)** *Let  $f$  be a homogeneous polynomial which is positive on the simplex*

$$\Delta = \left\{ x \in \mathbb{R}^n : \sum_{i=1}^n x_i = 1, x \geq 0 \right\}.$$

*Then, for a sufficiently large  $N$ , all the coefficients of the polynomial*

$$\left( \sum_{i=1}^n x_i \right)^N f(x)$$

*are positive.*

The notion of cost approximation (CA) was created in the thesis [39], to describe the construction of the subproblem of a class of iterative methods in mathematical programming. In order to explain the notion of CA, we will consider the following conceptual problem (the full generality of the algorithm is explained in detail in [45] and in [37,38,40,42,43,44,46]):

$$\begin{cases} \min & T(x) := f(x) + u(x), \\ \text{s.t.} & x \in X, \end{cases} \quad (1)$$

where  $X \subseteq \mathbb{R}^n$  is nonempty, closed and convex,  $u: \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$  is lower semicontinuous (l.s.c.), proper and convex, and  $f: \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$  is continuously differentiable (for short, in  $C^1$ ) on  $\text{dom } u \cap X$ , where  $\text{dom}$  denotes ‘effective domain’. This problem is general enough to cover convex optimization ( $f = 0$ ), unconstrained optimization ( $f = 0$  and  $X = \mathbb{R}^n$ ), and differentiable constrained optimization ( $u = 0$ ). We note

that if  $\text{int}(\text{dom } u) \cap X$  is nonempty, then any locally optimal solution  $x^*$  satisfies the inclusion

$$-\nabla f(x^*) \in \partial u(x^*) + N_X(x^*), \quad (2)$$

where  $N_X$  is the normal cone operator for  $X$  and  $\partial u$  is the subdifferential mapping for  $u$ . Equivalently, by the definitions of these two operators,

$$\nabla f(x^*)^\top (x - x^*) + u(x) - u(x^*) \geq 0, \quad x \in X.$$

The CA algorithm was devised in order to place a number of existing algorithms for (1) in a common framework, thereby facilitating comparisons, for example, between their convergence properties. In short, the method works iteratively as follows. Note that, from (2), we seek a zero of the mapping  $[\nabla f + \partial u + N_X]$ . Given an iterate,  $x^t \in \text{dom } u \cap X$ , this mapping is approximated by a monotone mapping, constructed so that a zero of which is easier to find. Such a point,  $y^t$ , is then utilized in the search for a new iterate,  $x^{t+1}$ , having the property that the value of some merit function for (1) is reduced sufficiently, for example through a line search in  $T$  along the direction of  $d^t := y^t - x^t$ .

### Instances of the CA Algorithm

To obtain a monotone approximating mapping, we introduce a monotone mapping  $\Phi^t: \text{dom } u \cap X \rightarrow \mathbf{R}^n$ , which replaces the (possibly nonmonotone) mapping  $\nabla f$ ; by subtracting off the error at  $x^t$ ,  $[\Phi^t - \nabla f](x^t)$ , from  $\Phi^t$ , so that the resulting mapping becomes  $[\Phi^t + \partial u + N_X] + [\nabla f - \Phi^t](x^t)$ , the CA subproblem becomes the inclusion

$$[\Phi^t + \partial u + N_X](y^t) + [\nabla f - \Phi^t](x^t) \ni 0^n. \quad (3)$$

We immediately reach an interesting fixed-point characterization of the solutions to (2):

**Theorem 1** (Fixed-point, [45]) *The point  $x^t$  solves (2) if and only if  $y^t = x^t$  solves (3).*

This result is a natural starting point for devising stopping criteria for an algorithm.

Assume now that  $\Phi^t \equiv \nabla \varphi^t$  for a convex function  $\varphi^t$ . We may then derive the inclusion equivalently as follows. At  $x^t$ , we replace  $f$  with the function  $\varphi^t$ , and subtract off the linearization of the error at  $x^t$ ; the subproblem objective function then becomes

$$T_{\varphi^t}(y) := \varphi^t(y) + u(y) + [\nabla f(x^t) - \nabla \varphi^t(x^t)]^\top y.$$

It is straightforward to establish that (3) is the optimality conditions for the convex problem of minimizing  $T_{\varphi^t}$  over  $X$ .

### Linearization Methods

Our first example instances utilize Taylor expansions of  $f$  to construct the approximations.

Let  $u = 0$  and  $X = \mathbf{R}^n$ . Let  $\Phi^t(y) := (1/\gamma_t) Q^t y$ , where  $\gamma_t > 0$  and  $Q^t$  is a symmetric and positive definite mapping in  $\mathbf{R}^n \times \mathbf{R}^n$ . The inclusion (3) reduces to

$$\nabla f(x^t) + \frac{1}{\gamma_t} Q^t (y^t - x^t) = 0^n,$$

that is,  $y^t = x^t - \gamma_t (Q^t)^{-1} \nabla f(x^t)$ . The direction of  $y^t - x^t$ ,  $d^t := -\gamma_t (Q^t)^{-1} \nabla f(x^t)$ , is the search direction of the class of *deflected gradient methods*, which includes the *steepest descent method* ( $Q^t := I^n$ , the identity matrix) and *quasi-Newton methods* ( $Q^t$  equals (an approximation of)  $\nabla^2 f(x^t)$ , if positive definite). (See further [5,35,47,50].)

In the presence of constraints, this choice of  $\Phi^t$  leads to  $y^t = P_X^{Q^t} [x^t - \gamma_t (Q^t)^{-1} \nabla f(x^t)]$ , where  $P_X^{Q^t}[\cdot]$  denotes the projection onto  $X$  with respect to the norm  $\|z\|_{Q^t} := \sqrt{z^\top Q^t z}$ . Among the algorithms in this class we find the *gradient projection algorithm* ( $Q^t := I^n$ ) and *Newton's method* ( $Q^t := \nabla^2 f(x^t)$ ,  $\gamma_t := 1$ ). (See [5,19,27,50].)

A first order Taylor expansion of  $f$  is obtained from choosing  $\varphi^t(y) := 0$ ; this results in  $T_{\varphi^t}(y) = \nabla f(x^t)^\top y$  (if  $u = 0$  is still assumed), which is the subproblem objective in the Frank–Wolfe algorithm ([5,17]; cf. also ▶ **Frank–Wolfe algorithm**).

We next provide the first example of the very useful fact that the result of the cost approximation (in the above examples a linearization), leads to different approximations of the original problem, and ultimately to different algorithms, depending on which *representation* of the problem to one applies the cost approximation.

Consider the problem

$$\begin{cases} \min & f(x) \\ \text{s.t.} & g_i(x) = 0, \quad i = 1, \dots, \ell, \end{cases} \quad (4)$$

where  $f$  and  $g_i$ ,  $i = 1, \dots, \ell$ , are functions in  $C^2$ . We may associate this problem with its first order optimal-

ity conditions, which in this special case is

$$F(x^*, \lambda^*) := \begin{pmatrix} \nabla_x L(x^*, \lambda^*) \\ -\nabla_\lambda L(x^*, \lambda^*) \end{pmatrix} = \begin{pmatrix} 0^n \\ 0^\ell \end{pmatrix}, \quad (5)$$

where  $\lambda \in \mathbf{R}^\ell$  is the vector of Lagrange multipliers for the constraints in (4), and  $L(x, \lambda) := f(x) + \lambda^\top g(x)$  is the associated Lagrangian function. We consider using Newton’s method for this system, and therefore introduce a (primal-dual) mapping  $\Phi: \mathbf{R}^{2(n+\ell)} \rightarrow \mathbf{R}^{n+\ell}$  of the form

$$\begin{aligned} \Phi((y, p), (x, \lambda)) &:= \nabla F(x, \lambda) \begin{pmatrix} y \\ p \end{pmatrix} \\ &= \begin{pmatrix} \nabla_x^2 L(x, \lambda) & \nabla g(x)^\top \\ -\nabla g(x) & 0 \end{pmatrix} \begin{pmatrix} y \\ p \end{pmatrix}. \end{aligned}$$

The resulting CA subproblem in  $(y, p)$  can be written as the following linear system:

$$\begin{aligned} \nabla_x^2 L(x, \lambda)(y - x) + \nabla g(x)^\top p &= 0^n, \\ \nabla g(x)(y - x) &= -g(x); \end{aligned}$$

this system constitutes the first order optimality conditions for (e. g., [4, Sec. 10.4])

$$\begin{cases} \min & f(x) + \nabla f(x)^\top (y - x) \\ & + \frac{1}{2} (y - x)^\top \nabla_x^2 L(x, \lambda) (y - x) \\ \text{s.t.} & g(x) + \nabla g(x)^\top (y - x) = 0^\ell, \end{cases}$$

where we have added some fixed terms in the objective function for clarity. This is the generic subproblem of *sequential quadratic programming* (SQP) methods for the solution of (4); see, for example, [5,16].

**Regularization, Splitting and Proximal Point Methods**

We assume now that  $f := f_1 + f_2$ , where  $f_1$  is convex on  $\text{dom } u \cap X$ , and rewrite the cost mapping as

$$\begin{aligned} [\nabla f + \partial u + N_X] &= [\nabla \varphi^t + \nabla f_1 + \partial u + N_X] \\ &\quad - [\nabla \varphi^t - \nabla f_2]. \end{aligned}$$

The CA subproblem is, as usual, derived by fixing the second term at  $x^t$ ; the difference to the original setup is that we have here performed an *operator splitting* in the mapping  $\nabla f$  to keep an additive part from being approximated. (Note that such a splitting can always be

found by first choosing  $f_1$  as a convex function, and then define  $f_2 := f - f_1$ . Note also that we can derive this subproblem from the original derivation by simply redefining  $\varphi^t := \varphi^t + f_1$ .) We shall proceed to derive a few algorithms from the literature.

Consider choosing  $\varphi^t(y) = 1/(2\gamma_t) \|y - x^t\|^2$ ,  $\gamma_t > 0$ . If  $f_2 = 0$ , then we obtain the subproblem objective  $T_{\varphi^t}(y) = T(y) + 1/(2\gamma_t) \|y - x^t\|^2$ , which is the subproblem in the *proximal point algorithm* (e. g., [32,33,34,51,52]). This is the most classical algorithm among the regularization methods. More general choices of strictly convex functions  $\varphi^t$  are of course possible, leading for example to the class of regularization methods based on Bregman functions ([9,14,22]) and  $\psi$ -divergence functions ([23,54]). If, on the other hand,  $f_1 = 0$ , then we obtain the gradient projection algorithm if also  $u = 0$ .

We can also construct algorithms in between these two extremes, yielding a true operator splitting. If both  $f_1$  and  $f_2$  are nonzero, choosing  $\varphi^t = 0$  defines a *partial linearization* ([25]) of the original objective, wherein only  $f_2$  is linearized. Letting  $x = (x_1^\top, x_2^\top)^\top$ , the choice  $\varphi^t(y) = 1/(2\gamma_t) \|y_1 - x_1^t\|^2$  leads to the *partial proximal point algorithm* ([7,20]); choosing  $\varphi^t(y) = f(y_1, x_2^t)$  leads to a linearization of  $f$  in the variables  $x_2$ .

Several well-known methods can be derived either directly as CA algorithms, or as *inexact proximal point algorithms*. For example, the *Levenberg–Marquardt algorithm* ([5,49]), which is a Newton-like algorithm wherein a scaled diagonal matrix is added to the Hessian matrix in order to make the resulting matrix positive definite, is the result of solving the proximal point subproblem with one iteration of a Newton algorithm. Further, the *extra-gradient algorithm* of [24] is the result of instead applying one iteration of the gradient projection algorithm to the proximal point subproblem.

The perhaps most well-known splitting algorithm is otherwise the class of *matrix splitting methods in quadratic programming* (e. g., [28,29,35,36]). In a quadratic programming problem, we have

$$f(x) = \frac{1}{2} x^\top A x + q^\top x,$$

where  $A \in \mathbf{R}^{n \times n}$ . A splitting  $(A_1^t, A_2^t)$  of this matrix is one for which  $A = A_1^t + A_2^t$ , and it is further termed regular if  $A_1^t - A_2^t$  is positive definite. Matrix splitting

methods correspond to choosing

$$f_1(x) = \frac{1}{2}x^\top A_1^t x,$$

and results in the CA subproblem mapping  $y \mapsto A_1^t y + [A_2^t x^t + q]$ , which obviously is monotone whenever  $A_1^t$  was chosen positive semidefinite.

Due to the fact that proximal point and splitting methods have dual interpretations as augmented Lagrangian algorithms ([51]), a large class of multiplier methods is included among the CA algorithms. See [45, Chapt. 3.2–3.3] for more details.

### Perturbation Methods

All the above algorithms assume that

- i) the mappings  $\partial u$  and  $N_X$  are left intact; and
- ii) the CA subproblem has the fixed-point property of Theorem 1.

We here relax these assumptions, and are then able to derive subgradient algorithms as well as perturbed CA algorithms which include both regularization algorithms and exterior penalty algorithms.

Let  $[\Phi^t + N_X] + [\nabla f + \partial u + \Phi^t]$  represent the original mapping, having moved  $\partial u$  to the second term. Then by letting any element  $\xi_u(x^t) \in \partial u(x^t)$  represent this point-to-set mapping at  $x^t$ , we reach the subproblem mapping of the *auxiliary problem principle* of [12]. Further letting  $\Phi^t(y) = (1/\gamma_t)[y - x^t]$  yields the subproblem in the classical *subgradient optimization* scheme ([48,53]), where, assuming further that  $f = 0$ ,  $y^t := P_X[x^t - \gamma_t \xi_u(x^t)]$ . (Typically,  $\ell_t := 1$  is taken.)

Let again  $[\Phi^t + \partial u + N_X] + [\nabla f + \Phi^t]$  represent the original problem mapping, but further let  $u$  be replaced by an *epiconvergent sequence*  $\{u^t\}$  of l.s.c., proper and convex functions. An example of an epiconvergent sequence of convex functions is provided by convex exterior penalty functions. In this way, we can construct CA algorithm that approximate the objective function and simultaneously replace some of the constraints of the problem with exterior penalties. See [3,13] for example methods of this type.

One important class of regularization methods takes as the subproblem mapping  $[\Phi^t + \nabla f + \partial u + N_X]$ , where  $\Phi^t$  is usually taken to be strongly monotone (cf. (12)). This subproblem mapping evidently does not have the fixed-point property, as it is not identical to the original one at  $x^t$  unless  $\Phi^t(x^t) = 0^n$  holds. In order

to ensure convergence, we must therefore force the sequence  $\{\Phi^t\}$  of mappings to tend to zero; this is typically done by constructing the sequence as  $\Phi^t := (1/\gamma_t)\Phi$  for a fixed mapping  $\Phi$  and for a sequence of  $\gamma_t > 0$  constructed so that  $\{\gamma_t\} \rightarrow \infty$  holds. For this class of algorithms, F. Browder [10] has established convergence to a unique limit point  $x^*$  which satisfies  $-\Phi(x^*) \in N_{X^*}(x^*)$ , where  $X^*$  is the solution set of (2). The origin of this class of methods is the work of A.N. Tikhonov [55] for *ill-posed problems*, that is, problems with multiple solutions. The classical regularization mapping is the scaled identity mapping,  $\Phi^t(y) := (1/\gamma_t)[y]$ , which leads to least squares (least norm) solutions. See further [49,56].

### Variational Inequality Problems

Consider the following extension of (2):

$$-F(x^*) \in \partial u(x^*) + N_X(x^*), \quad (6)$$

where  $F: X \rightarrow \mathbf{R}^n$  is a continuous mapping on  $X$ . When  $F = \nabla f$  we have the situation in (2), and also in the case when  $F(x, y) = (\nabla_x \Pi(x, y)^\top, -\nabla_y \Pi(x, y)^\top)^\top$  holds for some saddle function  $\Pi$  on some convex product set  $X \times Y$  (cf. (5)), the *variational inequality problem* (6) has a direct interpretation as the necessary optimality conditions for an optimization problem. In other cases, however, a merit function (or, objective function), for the problem (6) is not immediately available. We will derive a class of suitable merit functions below.

Given the convex function  $\varphi: \text{dom } u \cap X \rightarrow \mathbf{R}$  in  $C^1$  on  $\text{dom } u \cap X$ , we introduce the function

$$\psi(x) := \sup_{y \in X} L(y, x), \quad x \in \text{dom } u \cap X, \quad (7)$$

where

$$L(y, x) := u(x) - u(y) + \varphi(x) - \varphi(y) + [F(x) - \nabla \varphi(x)]^\top (x - y). \quad (8)$$

We introduce the optimization problem

$$\min_{x \in X} \psi(x). \quad (9)$$

**Theorem 2** (*Gap function, [45]*) *For any  $x \in X$ ,  $\psi(x) \geq 0$  holds. Further,  $\psi(x) = 0$  if and only if  $x$  solves (6). Hence, the solution set of (6) (if nonempty) is identical*

to that of the optimization problem (9), and the optimal value is zero.

The Theorem shows that the CA subproblem defines an auxiliary function  $\psi$  which measures the violation of (6), and which can be used (directly or indirectly) as a merit function in an algorithm.

To immediately illustrate the possible use of this result, let us consider the extension of Newton’s method to the solution of (6). Let  $x \in \text{dom } u \cap X$ , and consider the following cost approximating mapping:  $y \mapsto \Phi(y, x) := \nabla F(x)(y - x)$ . The CA subproblem then is the linearized variational inequality problem of finding  $y \in \text{dom } u \cap X$  such that

$$[F(x) + \nabla F(x)^\top(y - x)]^\top(z - y) + u(z), -u(y) \geq 0, \quad \forall z \in X. \quad (10)$$

Assuming that  $x$  is not a solution to (6), we are interested in utilizing the direction  $d := y - x$  in a line search based on a merit function. We will utilize the *primal gap function* ([2,62]) for this purpose, which corresponds to the choice  $\varphi := 0$  in the definition of  $\psi$ . We denote the primal gap function by  $\psi_p$ . Let  $w$  be an arbitrary solution to its inner problem, that is,  $\psi_p(x) = u(x) - u(w) + F(x)^\top(x - w)$ . The steplength is chosen such that the value of  $\psi_p$  decreases sufficiently; to show that this is possible, we use Danskin’s theorem and the variational inequality (10) with  $z = w$  to obtain (the maximum is taken over all  $w$  defining  $\psi_p(x)$ )

$$\begin{aligned} \psi'_p(x; d) &:= \max_w \left\{ [F(x) + \nabla F(x)^\top(x - w)]^\top d + u'(x; d) \right\} \\ &\leq -\psi_p(x) - d^\top \nabla F(x)^\top d, \end{aligned}$$

which shows that  $d$  defines a direction of descent with respect to the merit function  $\psi_p$  at all points outside the solution set, whenever  $F$  is monotone and in  $C^1$  on  $\text{dom } u \cap X$ . (See also [30] for convergence rate results.) So, if Newton’s method is supplied with a line search with respect to the primal gap function, it is globally convergent for the solution of variational inequality problems.

The merit function  $\psi$  and the optimization problem (9) cover several examples previously considered for the solution of (6).

The primal gap function, as typically all other gap functions, is nonconvex, and further also nondifferentiable in general. In order to utilize methods from

differentiable optimization, we consider letting  $\varphi$  be strictly convex, whence the solution  $y^t$  to the inner problem (7) is unique. Under the additional assumption that  $\text{dom } u \cap X$  is bounded and that  $u$  is in  $C^1$  on this set,  $\psi$  is in  $C^1$  on  $\text{dom } u \cap X$ . Among the known differentiable gap functions that are covered by this class of merit functions we find those of [1,18,26,40], and [31,59,60,61].

## Descent Properties

### Optimization

Assume that  $x^t$  is not a solution to (2). We are interested in the conditions under which the direction of  $d^t := y^t - x^t$  provides a descent direction for the merit function  $T$ . Let  $d^t := \bar{y}^t - x^t$ , where  $\bar{y}^t$  is a possibly inexact solution to (3). Then, if  $\Phi^t = \nabla \varphi^t$ , the requirement is that

$$T_{\varphi^t}(\bar{y}^t) < T_{\varphi^t}(x^t), \quad (11)$$

that is, any improvement in the value of the subproblem objective over that at the current iterate is enough to provide a descent direction. To establish this result, one simply utilizes the convexity of  $\varphi^t$  and  $u$  and the formula for the directional derivative of  $T$  in the direction of  $d^t$  (see [45, Prop. 2.14.b]). We further note that (11) is possible to satisfy if and only if  $x^t$  is not a solution to (2); this result is in fact a special case of Theorem 1.

If  $\Phi^t$  has stronger monotonicity properties, descent is also obtained when  $\Phi^t$  is not necessarily a gradient mapping, and, further, if it is Lipschitz continuous then we can establish measures of the steepness of the search directions, extending the gradient relatedness conditions of unconstrained optimization. Let  $\Phi^t$  be *strongly monotone* on  $\text{dom } u \cap X$ , that is, for  $x, y \in \text{dom } u \cap X$ ,

$$[\Phi^t(x) - \Phi^t(y)]^\top(x - y) \geq m_{\Phi^t} \|x - y\|^2, \quad (12)$$

for some  $m_{\Phi^t} > 0$ . This can be used to establish that

$$T'(x^t; d^t) \leq -m_{\Phi^t} \|d^t\|^2.$$

If  $y^t$  is not an exact solution to (3), in the sense that for a vector  $\bar{y}^t$ , we satisfy a perturbation of (3) where its right-hand side  $0^n$  is replaced by  $r^t \neq 0^n$ , then  $d^t := \bar{y}^t - x^t$  is a descent direction for  $T$  at  $x^t$  if  $\|r^t\| < m_{\Phi^t} \|d^t\|$ .

### Variational Inequality Problems

The requirements for obtaining a descent direction in the problem (6) are necessarily much stronger than in the problem (2), the reason being the much more complex form that the merit functions for (6) takes. (For example, the directional derivative of  $T$  at  $x$  in any direction  $d$  depends only on those quantities, while the directional derivative of  $\psi$  depends also on the argument  $y$  which defines its value at  $x$ .) Typically, monotonicity of the mapping  $F$  is required, as is evidenced in the above example of the Newton method. If further a differentiable merit function is used, the requirements are slightly strengthened, as the following example result shows.

**Theorem 3** (Descent properties, [45,60]) *Assume that  $X$  is bounded,  $u$  is finite on  $X$  and  $F$  is monotone and in  $C^1$  on  $X$ . Let  $\varphi: X \times X \rightarrow \mathbf{R}$  be a continuously differentiable function on  $X \times X$  of the form  $\varphi(y, x)$ , strictly convex in  $y$  for each  $x \in X$ . Let  $\alpha > 0$ . Let  $x \in X$ ,  $y$  be the unique vector in  $X$  satisfying*

$$\psi_\alpha(x) := \max_{y \in X} L_\alpha(y, x),$$

where

$$\begin{aligned} L_\alpha(y, x) &:= u(x) - u(y) \\ &+ \frac{1}{\alpha} [\varphi(x, x) - \varphi(y, x)] \\ &+ \left[ F(x) - \frac{1}{\alpha} \nabla_y \varphi(x, x) \right]^\top (x - y). \end{aligned}$$

Then, with  $d := y - x$ , either  $d$  satisfies

$$\psi'_\alpha(x; d) \leq -\gamma \psi_\alpha(x), \quad \gamma \in (0, 1),$$

or

$$\psi_\alpha(x) \leq -\frac{1}{\alpha(1-\gamma)} (\varphi(y, x) + \nabla_x \varphi(y, x)^\top d).$$

A descent algorithm is devised from this result as follows. For a given  $x \in X$  and choice of  $\alpha > 0$ , the CA subproblem is solved with the scaled cost approximating, continuous and iteration-dependent function  $\varphi$ . If the resulting direction does not have the descent property, then the value of  $\alpha$  is increased and the CA subproblem rescaled and resolved. Theorem 3 shows that a sufficient increase in the value of  $\alpha$  will produce a descent direction unless  $x$  solves (6).

### Steplength Rules

In order to establish convergence of the algorithm, the steplength taken in the direction of  $d^t$  must be such that the value of the merit function decreases sufficiently. An exact line search obviously works, but we will introduce simpler steplength rules that do not require a one-dimensional minimization to be performed.

The first is the *Armijo rule*. We assume temporarily that  $u = 0$ . Let  $\alpha, \beta \in (0, 1)$ , and  $\ell := \beta^{\bar{i}}$ , where  $\bar{i}$  is the smallest nonnegative integer  $i$  such that

$$f(x^t + \beta^i d^t) - f(x^t) \leq \alpha \beta^i \nabla f(x^t)^\top d^t. \quad (13)$$

There exists a finite integer such that (13) is satisfied for any search direction  $\bar{d}^t := \bar{y}^t - x^t$  satisfying (11), by the descent property and Taylor's formula (see [45, Lemma 2.24.b]).

In the case where  $u \neq 0$ , however, the situation becomes quite different, since  $T := f + u$  is nondifferentiable. Simply replacing  $\nabla f(x^t)^\top d^t$  with  $T'(x^t; d^t)$  does not work. We can however use an overestimate of the predicted decrease  $T'(x^t; d^t)$ . Let  $\alpha, \beta \in (0, 1)$ , and  $\ell := \beta^{\bar{i}}$ , where  $\bar{i}$  is the smallest nonnegative integer  $i$  such that

$$\begin{aligned} T(x^t + \beta^i d^t) - T(x^t) \\ \leq \alpha \beta^i [\nabla \varphi^t(x^t) - \nabla \varphi^t(y^t)]^\top d^t, \end{aligned}$$

where now  $y^t$  necessarily is an exact solution to (3), and  $\varphi^t$  must further be strictly convex. We note that  $T'(x^t; d^t) \leq [\nabla \varphi^t(x^t) - \nabla \varphi^t(y^t)]^\top d^t$  indeed holds, with equality in the case where  $u = 0$  and  $X = \mathbf{R}^n$  (see [45, Remark 2.28]).

To develop still simpler steplength rules, we further assume that  $\nabla f$  is Lipschitz continuous, that is, that for  $x, y \in \text{dom } u \cap X$ ,

$$\|\nabla f(x) - \nabla f(y)\| \leq M_{\nabla f} \|x - y\|,$$

for some  $M_{\nabla f} > 0$ . The Lipschitz continuity assumption implies that for every  $\ell \in [0, 1]$ ,

$$\begin{aligned} T(x^t + \ell d^t) - T(x^t) \\ \leq \ell [\nabla \varphi^t(x^t) - \nabla \varphi^t(y^t)]^\top d^t \\ + \frac{M_{\nabla f}}{2} \ell^2 \|d^t\|^2; \end{aligned}$$

adding a strong convexity assumption on  $\varphi^t$  yields that

$$T(x^t + \ell d^t) - T(x^t) \leq \ell \left( -m_{\varphi^t} + \frac{M_{\nabla f} \ell}{2} \right) \|d^t\|^2.$$

This inequality can be used to validate the *relaxation step*, which takes

$$\ell_t \in \left(0, \frac{2m_{\varphi^t}}{M_{\nabla f}}\right) \cap [0, 1], \quad (14)$$

and the *divergent series steplength rule*,

$$[0, 1] \supset \{\ell_t\} \rightarrow 0, \quad \sum_{t=0}^{\infty} \ell_t = \infty. \quad (15)$$

In the case of (14), descent is guaranteed in each step, while in the case of (15), descent is guaranteed after a finite number of iterations.

### Convergence Properties

Convergence of the CA algorithm can be established under many combinations of

- i) the properties of the original problem mappings;
- ii) the choice of forms and convexity properties of the cost approximating mappings;
- iii) the choice of accuracy in the computations of the CA subproblem solutions;
- iv) the choice of merit function; and
- v) the choice of steplength rule.

A subset of the possible results is found in [45, Chapt. 5–9]. Evident from these results is that convergence relies on reaching a critical mass in the properties of the problem and algorithm, and that, given that this critical mass is reached, there is a very large freedom-of-choice how this mass is distributed. So, for example, weaker properties in the monotonicity of the subproblem must be compensated both by stronger coercivity conditions on the merit function and by the use of more accurate subproblem solutions and steplength rules.

### Decomposition CA Algorithms

Assume that  $\text{dom } u \cap X$  is a *Cartesian product set*, that is, for some finite index set  $\mathcal{C}$  and positive integers  $n_i$  with  $\sum_{i \in \mathcal{C}} n_i = n$ ,

$$X = \prod_{i \in \mathcal{C}} X_i, \quad X_i \subseteq \mathbb{R}^{n_i};$$

$$u(x) = \sum_{i \in \mathcal{C}} u_i(x_i), \quad u_i: \mathbb{R}^{n_i} \rightarrow \mathbb{R} \cup \{+\infty\}.$$

Such problems arise in applications of equilibrium programming, for example in traffic ([41]) and Nash equi-

librium problems ([21]); of course, box constrained and unconstrained problems fit into this framework as well.

The main advantage of this problem structure is that one can devise several decomposition versions of the CA algorithm, wherein components of the original problem are updated upon in parallel or sequentially, independently of each other. With the right computer environment at hand, this can mean a dramatic increase in computing efficiency. We will look at three computing models for decomposition CA algorithm, and compare their convergence characteristics. In all three cases, decomposition is achieved by choosing the cost approximating mapping separable with respect to the partition of  $\mathbf{R}^n$  defined by  $\mathcal{C}$ :

$$\Phi(x)^\top = [\Phi_1(x_1)^\top, \dots, \Phi_{|\mathcal{C}|}(x_{|\mathcal{C}|})^\top]. \quad (16)$$

The individual subproblems, given  $x$ , then are to find  $y_i$ ,  $i \in \mathcal{C}$ , such that

$$\begin{aligned} \Phi_i(y_i) + \partial u_i(y_i) + N_{X_i}(y_i) + F_i(x) - \Phi_i(x_i) \\ \geq 0^{n_i}; \end{aligned}$$

if  $\Phi_i \equiv \nabla \varphi_i$  for some convex function  $\varphi_i: \text{dom } u_i \cap X_i \rightarrow \mathbf{R}$  in  $C^1$  on  $\text{dom } u_i \cap X_i$ , then this is the optimality conditions for

$$\begin{aligned} \min_{y_i \in X_i} T_{\varphi_i}(y_i) \\ := \varphi_i(y_i) + u_i(y_i) + [F_i(x) - \nabla \varphi_i(x_i)]^\top y_i. \end{aligned}$$

### Sequential Decomposition

The *sequential CA algorithm* proceeds as follows. Given an iterate  $x^t \in \text{dom } u \cap X$  at iteration  $t$ , choose an index  $i_t \in \mathcal{C}$  and a cost approximating mapping  $\Phi_{i_t}^t$ , and solve the problem of finding  $y_{i_t}^t \in \mathbf{R}^{n_{i_t}}$  such that ( $i = i_t$ )

$$\begin{aligned} \Phi_{i_t}^t(y_{i_t}^t) + \partial u_{i_t}(y_{i_t}^t) + N_{X_{i_t}}(y_{i_t}^t) + F_{i_t}(x^t) - \Phi_{i_t}^t(x_{i_t}^t) \\ \geq 0^{n_{i_t}}. \end{aligned}$$

Let  $y_j^t := x_j^t$  for all  $j \in \mathcal{C} \setminus \{i_t\}$  and  $d^t := y^t - x^t$ . The next iterate,  $x^{t+1}$ , is then defined by  $x^{t+1} := x^t + \ell_t d^t$ , that is,

$$x_j^{t+1} := \begin{cases} x_j^t + \ell_t (y_j^t - x_j^t), & j = i_t, \\ x_j^t, & j \neq i_t, \end{cases}$$

for some value of  $\ell_t$  such that  $x_{i_t}^t + \ell_t (y_{i_t}^t - x_{i_t}^t) \in \text{dom } u_{i_t} \cap X_{i_t}$ , and the value of a merit function  $\psi$  is reduced sufficiently.

Assume that  $F$  is the gradient of a function  $f: \text{dom } u \cap X \rightarrow \mathbf{R}$ . Let the sequence  $\{i_t\}$  be chosen according to the *cyclic rule*, that is, in iteration  $t$ ,

$$i_t := t \pmod{|\mathcal{C}|} + 1.$$

Choose the cost approximating mapping ( $i = i_t$ )

$$y_i \mapsto \Phi_i^t(y_i) := \nabla_i f(x_{\neq i}^t, y_i),$$

$$y_i \in \text{dom } u_i \cap X_i.$$

Note that this mapping is monotone whenever  $f$  is convex in  $x_i$ . Since  $\Phi_i^t(x_i^t) = \nabla_i f(x^t)$ , the CA subproblem is equivalent (under this convexity assumption) to finding

$$y_i^t \in \arg \min_{y_i \in X_i} \{f(x_{\neq i}^t, y_i) + u_i(y_i)\}.$$

An exact line search would produce  $\ell_t := 1$ , since  $y_i^t$  minimizes  $f(x_{\neq i}, \cdot) + u_i$  over  $\text{dom } u_i \cap X_i$  (the remaining components of  $x$  kept fixed), and so  $x_i^{t+1} := y_i^t$ . The iteration described is that of the classic *Gauss–Seidel algorithm* ([35]) (also known as the *relaxation algorithm*, the *coordinate descent method*, and the *method of successive displacements*), originally proposed for the solution of unconstrained problems. The Gauss–Seidel algorithm is hence a special case of the sequential CA algorithm.

In order to compare the three decomposition approaches, we last provide the steplength requirement in the relaxation steplength rule (cf. (14)). The following interval is valid under the assumptions that for each  $i \in \mathcal{C}$ ,  $\nabla_i f$  is Lipschitz continuous on  $\text{dom } u_i \cap X_i$  and each mapping  $\Phi_i^t$  is strongly monotone:

$$\ell_{i,t} \in \left(0, \frac{2m_{\Phi_i^t}}{M_{\nabla_i f}}\right) \cap [0, 1]. \quad (17)$$

### Synchronized Parallel Decomposition

The synchronized parallel CA algorithm is identical to the original scheme, where the CA subproblems are constructed to match the separability structure in the constraints.

We presume the existence of a multiprocessor powerful enough to solve the  $|\mathcal{C}|$  CA subproblems in parallel. (If fewer than  $|\mathcal{C}|$  processors are available, then either some of the subproblems are solved in sequence or, if possible, the number of components is decreased; in

either case, the convergence analysis will be the same, with the exception that the value of  $|\mathcal{C}|$  may change.)

In the sequential decomposition CA algorithm, the steplengths are chosen individually for the different variable components, whereas the original CA algorithm uses a uniform steplength,  $\ell_t$ . If the relative scaling of the variable components is poor, in the sense that  $F$  or  $u$  changes disproportionately to unit changes in the different variables  $x_i$ ,  $i \in \mathcal{C}$ , then this ill-conditioning may result in a poor performance of the parallel algorithm. Being forced to use the same steplength in all the components can also have an unwanted effect due to the fact that the values of some variable components are close to their optimal ones while others may be far from optimal, in which case one might for example wish to use longer steps for the latter components. These two factors lead us to introduce the possibility to scale the component directions in the synchronized parallel CA algorithm. We stress that such effects cannot in general be accommodated into the original algorithm through a scaling of the mappings  $\Phi_i^t$ . The scaling factors  $s_{i,t}$  introduced are assumed to satisfy

$$0 < \underline{s}_i \leq s_{i,t} \leq 1, \quad i \in \mathcal{C}.$$

Note that the upper bound of one is without any loss of generality.

Assume that  $F$  is the gradient of a function  $f: \text{dom } u \cap X \rightarrow \mathbf{R}$ . In the parallel algorithm, choose the cost approximating mapping of the form (16), where for each  $i \in \mathcal{C}$ ,

$$y_i \mapsto \Phi_i^t(y_i) := \nabla_i f(x_{\neq i}^t, y_i),$$

$$y_i \in \text{dom } u_i \cap X_i.$$

This mapping is monotone on  $\text{dom } u \cap X$  whenever  $f$  is convex in each component  $x_i$ . Since  $\Phi_i^t(x_i^t) = \nabla_i f(x^t)$ ,  $i \in \mathcal{C}$ , it follows that the CA subproblem is equivalent (under the above convexity assumption on  $f$ ) to finding

$$y_i^t \in \arg \min_{y_i \in X_i} \{f(x_{\neq i}^t, y_i) + u_i(y_i)\}.$$

Choosing  $\ell_t := 1$  and  $s_{i,t} := 1$ ,  $i \in \mathcal{C}$ , yields  $x^{t+1} := y^t$ , and the resulting iteration is that of the *Jacobi algorithm* [8,35] (also known as the *method of simultaneous displacements*). The Jacobi algorithm, which was originally proposed for the solution of systems of equations,

is therefore a parallel CA algorithm where the cost approximating mapping is (18) and unit steps are taken.

The admissible step in component  $i$  is  $\ell s_{i,t} \in [0, 1]$ , where

$$\ell \in \left( 0, \min_{i \in \mathcal{C}} \left\{ \frac{2m_{\Phi_i}}{s_{i,t} M_{\nabla f}} \right\} \right). \quad (18)$$

The maximal step is clearly smaller than in the sequential approach. To this conclusion contributes both the minimum operation and that  $M_{\nabla_i f} \leq M_{\nabla f}$ ; both of these requirements are introduced here because the update is made over all variable components simultaneously. (An intuitive explanation is that the sequential algorithm utilizes more recent information when it constructs the subproblems.) One may therefore expect the sequential algorithm to converge to a solution with a given accuracy in less iterations, although the parallel algorithm may be more efficient in terms of solution time; the scaling introduced by  $s_{i,t}$  may also improve the performance of the parallel algorithm to some extent.

Although the parallel version of the algorithm may speed-up the practical convergence rate compared to the sequential one, the need for synchronization in carrying out the updating step will generally deteriorate performance, since faster processors must wait for slower ones. In the next section, we therefore introduce an asynchronous version of the parallel algorithm, in which processors do not wait to receive the latest information available.

### Asynchronous Parallel Decomposition

In the algorithms considered in this Section, the synchronization step among the processors is removed. Because the speed of computations and communications can vary among the processors, and communication delays can be substantial, processors will perform the calculations out of phase with each other. Thus, the advantage of reduced synchronization is paid for by an increase in interprocessor communications, the use of outdated information, and a more difficult convergence detection (see [8]). (Certainly, the convergence analysis also becomes more complicated.) Recent numerical experiments indicate, however, that the introduction of such *asynchronous computations* can substantially enhance the efficiency of parallel iterative methods (e. g., [6,11,15]).

The model of partial asynchronism that we use is as follows. For each processor (or, variable component)  $i \in \mathcal{C}$ , we introduce

- a) initial conditions,  $x_i(t) := x_i^0 \in X_i$ , for all  $t \leq 0$ ;
- b) a set  $\mathcal{T}^i$  of times at which  $x_i$  is updated; and
- c) a variable  $\tau_j^i(t)$  for each  $j \in \mathcal{C}$  and  $t \in \mathcal{T}^i$ , denoting the time at which the value of  $x_j$  used by processor  $i$  at time  $t$  is generated by processor  $j$ , satisfying  $0 \leq \tau_j^i(t) \leq t$  for all  $j \in \mathcal{C}$  and  $t \geq 0$ .

We note that the sequential CA algorithm and the synchronized parallel CA algorithm can both be expressed as asynchronous algorithms: the cyclic sequential algorithm model is obtained from the choices  $\mathcal{T}^i := \cup_{k \geq 0} \{|\mathcal{C}| k + i - 1\}$  and  $\tau_j^i(t) := t$ , while the synchronous parallel model is obtained by choosing  $\mathcal{T}^i := \{1, 2, \dots\}$  and  $\tau_j^i(t) := t$ , for all  $i, j$  and  $t$ .

The communication delay from processor  $j$  to processor  $i$  at time  $t$  is  $t - \tau_j^i(t)$ . The convergence of the *partially asynchronous parallel decomposition CA algorithm* is based on the assumption that this delay is upper bounded: there exists a positive integer  $P$  such that

- i) for every  $i \in \mathcal{C}$  and  $t \geq 0$ , at least one element of  $\{t, \dots, t + P - 1\}$  belongs to  $\mathcal{T}^i$ ;
- ii)  $0 \leq t - \tau_j^i(t) \leq P - 1$  holds for all  $i, j \in \mathcal{C}$  and all  $t \geq 0$ ; and
- iii)  $\tau_j^i(t) = t$  holds for all  $i \in \mathcal{C}$  and all  $t \geq 0$ .

In short, parts i) and ii) of the assumption state that no processor waits for an arbitrarily long time to compute a subproblem solution or to receive a message from another processor. (Note that a synchronized model satisfies  $P = 1$ .) Part iii) of the assumption states that processor  $i$  always uses the most recent value of its own component  $x_i$  of  $x$ , and is in [58] referred to as a *computational nonredundancy condition*. This condition holds in general when no variable component is updated simultaneously by more than one processor, as, for example, in message passing systems. For further discussions on the assumptions, we refer the reader to [8,57]; we only remark that they are easily enforced in practical implementations.

The iterate  $x(t)$  is defined by the vector of  $x_i(t)$ ,  $i \in \mathcal{C}$ . At a given time  $t$ , processor  $i$  has knowledge of a possibly outdated version of  $x(t)$ ; we let

$$x^i(t)^\top := \left[ x_1(\tau_1^i(t))^\top, \dots, x_{|\mathcal{C}|}(\tau_{|\mathcal{C}|}^i(t))^\top \right]$$

denote this vector. (Note that iii) above implies the relation  $x_i^i(t) := x_i(\tau_i^i(t)) = x_i(t)$ .)

To describe the (partially) asynchronous parallel CA algorithm, processor  $i$  updates  $x_i(t)$  according to

$$x_i(t+1) := x_i(t) + \ell s_i(y_i(t) - x_i^i(t)), \quad t \in \mathcal{T}^i,$$

where  $y_i(t)$  solves the CA subproblem defined at  $x^i(t)$ , and  $s_i \in (0, 1]$  is a scaling parameter. (We define  $d_i(t) := y_i(t) - x_i^i(t)$  to be zero at each  $t \notin \mathcal{T}^i$ .)

The admissible steplength for  $i \in \mathcal{C}$  is  $\ell s_i \in [0, 1]$ , where

$$\ell \in \left( 0, \frac{2 \min_{i \in \mathcal{C}} \left\{ \frac{m\phi_i}{s_i} \right\}}{M_{\nabla f} [1 + (|\mathcal{C}| + 1)P]} \right). \quad (19)$$

If further for some  $M \geq 0$  and every  $i \in \mathcal{C}$ , all vectors  $x, y$  in  $\text{dom } u \cap X$  with  $x_i = y_i$  satisfy

$$\|\nabla_i f(x) - \nabla_i f(y)\| \leq M \|x - y\|, \quad (20)$$

then, in the above result, the steplength restrictions are adjusted to

$$\ell \in \left( 0, \frac{2 \min_{i \in \mathcal{C}} \left\{ \frac{m\phi_i}{s_i} \right\}}{M_{\nabla f} + (|\mathcal{C}| + 1)MP} \right).$$

(We interpret the property (20) as a quantitative measure of the coupling between the variables.)

Most important to note is that the upper bound on  $\ell$  is (essentially) inversely proportional to the maximal allowed asynchronism  $P$ ; this is very intuitive, since if processors take longer steps then they should exchange information more often. Conversely, the more outdated the information is, the less reliable it is, hence the shorter step.

The relations among the steplengths in the three approaches (cf. (17), (18), and (19)) quantify the intuitive result that utilizing an increasing degree of parallelism and asynchronism results in a decreasing quality of the step directions, due to the usage of more outdated information; subsequently, smaller steplengths must be used. More detailed discussions about this topic is found in [45, Sect. 8.7.2].

### Introduction/Background

Financial risk management has evolved over the past two decades in terms of both its theory and its practices. Economic uncertainties, changes in the business environment and the introduction of new complex financial products (e. g., financial derivatives) led financial institutions and regulatory authorities to the development of a new framework for financial risk management, focusing mainly on the capital adequacy of banks and credit institutions.

Banks and other financial institutions are exposed to many different forms of financial risks. Usually these are categorized as [14]:

- Market risk that arises from the changes in the prices of financial securities and currencies.
- Credit risk originating from the inability of firms and individuals to meet their debt obligations to their creditors.
- Liquidity risk that arises when a transaction cannot be conducted at the existing market prices or when early liquidation is required in order to meet payments obligations.
- Operational risk that originate from human and technical errors or accidents.
- Legal risk which is due to legislative restrictions on financial transactions.

Among these types of risk, credit risk is considered as the primary financial risk in the banking system and exists in virtually all income-producing activities [7]. How a bank selects and manages its credit risk is critically important to its performance over time.

In this context credit risk management defines the whole range of activities that are implemented in order to measure, monitor and minimize credit risk. Credit risk management has evolved dramatically over the last 20 years. Among others, some factors that have increased the importance of credit risk management include [2]: (i) the worldwide increase in the number of bankruptcies, (ii) the trend towards disintermediation by the highest quality and largest borrowers, (iii) the increased competition among credit institutions, (iv) the declining value of real assets and collateral in many markets, and (v) the growth of new financial instruments with inherent default risk exposure, such as credit derivatives.

Early credit risk management was primarily based on empirical evaluation systems of the creditworthiness of a client. CAMEL has been the most widely used system in this context, which is based on the empirical combination of several factors related to capital, assets, management, earnings and liquidity.

It was soon realized, however, that such empirical systems cannot provide a solid and objective basis for credit risk management. This led to an outgrowth of studies from academics and practitioners on the development of new credit risk assessment systems. These efforts were also motivated by the changing regulatory framework that now requires banks to implement specific methodologies for managing and monitoring their credit portfolios [4].

The existing practices are based on sophisticated statistical and optimization methods, which are used to develop a complete framework for measuring and monitoring credit risk. Credit rating models are in the core of this framework and are used to assess the credit-worthiness of firms and individuals. The following sections describe the functionality of credit rating systems and the type of optimization methods that are used in some popular techniques for developing rating systems.

### Definitions

As already noted, credit risk is defined as the likelihood that an obligor (firm or individual) will be unable or unwilling to fulfill debt obligations towards the creditors. In such a case, the creditors will suffer losses that have to be measured as accurately as possible.

The expected loss  $L_{it}$  over a period  $t$  from granting credit to a given obligor  $i$  can be measured as follows:

$$L_{it} = PD_{it}LGD_iEAD_i$$

where  $PD_{it}$  is the probability of default for the obligor  $i$  in the time period  $t$ ,  $LGD_i$  is the percentage of exposure the bank might lose in case the borrower defaults and  $EAD_i$  is the amount outstanding in case the borrower defaults. The time period  $t$  is usually taken equal to one year.

In the new regulatory framework default is considered to have occurred with regard to a particular obligor when one or more of the following events has taken place [4,11]:

- it is determined that the obligor is unlikely to pay its debt obligations in full;
- a credit loss event associated with any obligation of the obligor;
- the obligor is past due more than 90 days on any credit obligation; or
- the obligor has filed for bankruptcy or similar protection from creditors.

The aim of credit rating models is to assess the probability of default for an obligor, whereas other models are used to estimate  $LGD$  and  $EAD$ . Rating systems measure credit risk and differentiate individual credits and groups of credits by the risk they pose. This allows bank management and examiners to monitor changes and trends in risk levels thus promoting safety

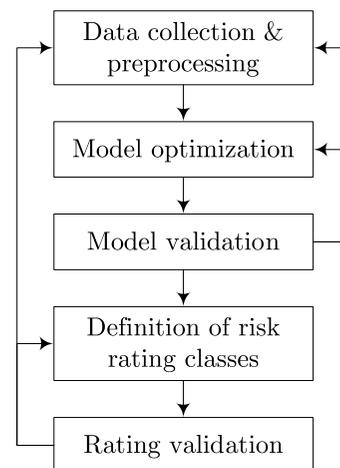

and soundness in the credit granting process. Credit rating systems are also used for credit approval and underwriting, loan pricing, relationship management and credit administration, allowance for loan and lease losses and capital adequacy, credit portfolio management and reporting [7].

### Formulation

Generally, a credit rating model can be considered as a mapping function  $f : \mathbb{R}^n \rightarrow G$  that estimates the probability of default of an obligor described by a vector  $\mathbf{x} \in \mathbb{R}^n$  of input features and maps the result to a set  $G$  of risk categories. The feature vector  $\mathbf{x}$  represents all the relevant information that describes the obligor, including financial and nonfinancial data.

The development of a rating model is based on the process of Fig. 1.

The process begins with the collection of appropriate data regarding known cases in default and nondefault cases. These data can be taken from the historical database of a bank, or from external resources. At this data selection stage, some preprocessing of the data is necessary in order to transform the obtained data into useful features, to clean out the data from possible outliers and to select the appropriate set of features for the analysis. These steps lead to the final data  $\{\mathbf{x}_i, y_i\}_{i=1}^m$ , where  $\mathbf{x}_i$  is the input feature vector for obligor  $i$ ,  $y_i$  in the known status of the obligor (e. g.  $y_i = -1$  for cases

**Credit Rating and Optimization Methods, Figure 1**  
The process for developing credit rating models

in default and  $y_i = 1$  for nondefault cases), and  $m$  in the number of observations in the data set. These data, which are used for model development, are usually referred to as *training data*.

The second stage involves the optimization process, which refers to the identification of the model's parameters that best fit the training data. In the simplest case, the model can be expressed as a linear function of the form:

$$f(\mathbf{x}) = \mathbf{x}\boldsymbol{\beta} + \beta_0$$

where  $\boldsymbol{\beta} \in \mathbb{R}^n$  is the vector with the coefficients of the selected features in the model and  $\beta_0$  is a constant term. Other types of nonlinear models are also applicable.

In the above linear case, the objective of the optimization process is to identify the optimal parameter vector  $\boldsymbol{\alpha} = (\boldsymbol{\beta}, \beta_0)$  that best fit the training data. This can be expressed as an optimization problem of the following general form:

$$\min_{\boldsymbol{\alpha} \in S} \mathcal{L}(\boldsymbol{\alpha}, \mathbf{X}) \quad (1)$$

where  $S$  is a set of constraints that define the feasible (acceptable) values for the parameter vector  $\boldsymbol{\alpha}$ ,  $\mathbf{X}$  is the training data set and  $\mathcal{L}$  is a loss function measuring the differences between the model's output and the given classification of the training observations.

The result of the model optimization process are validated using another sample of obligors with known status. This is referred to as the *validation sample*. Typically it consists of cases different than the ones of the training sample and for a future time period. The optimal model is applied to these new observations and its predictive ability is measured. If this is acceptable, then the model's outputs are used to define a set of risk rating classes (usually 10 classes are used). Each rating class is associated with a probability of default and it includes borrowers with similar credit risk levels. The defined rating needs also to be validated in terms of its stability over time, the distribution of the borrowers in the rating groups, and the consistency between the estimated probabilities of default in each group and the empirical ones which are taken from the population of rated borrowers.

## Methods/Applications

The optimization problem (1) is expressed in different forms depending on the method used to develop the rating model. The characteristics of some popular methods are outlined below.

### Logistic Regression

Logistic regression is the most widely used method in financial decision-making problems, with numerous applications in credit risk rating. Logistic regression assumes that the log of the probability odds is a linear function:

$$\log \frac{p}{1-p} = \beta_0 + \mathbf{x}\boldsymbol{\beta}$$

where  $p = \Pr(1 | \mathbf{x})$  is the probability that an obligor  $\mathbf{x}$  is a member of class 1, which is then expressed as

$$p = \left[ 1 + \exp^{-(\beta_0 + \mathbf{x}\boldsymbol{\beta})} \right]^{-1}$$

The parameters of the model (constant term  $\beta_0$  and coefficient vector  $\boldsymbol{\beta}$ ) are estimated to maximize the conditional likelihood of the classification given the training data. This is expressed as

$$\max_{\beta_0, \boldsymbol{\beta} \in \mathbb{R}} \prod_{i=1}^m \Pr(y_i | \mathbf{x}_i)$$

which can be equivalently written as

$$\max_{\beta_0, \boldsymbol{\beta} \in \mathbb{R}} \sum_{i=1}^m \left[ \frac{y_i + 1}{2} \ln(p_i) + \frac{1 - y_i}{2} \ln(1 - p_i) \right]$$

where  $y_i = 1$  if obligor  $i$  is in the nondefault group and  $y_i = -1$  otherwise.

Nonlinear optimization techniques such as the Newton algorithm are used to perform this optimization.

Logistic regression has been widely applied in credit risk rating both by academics and by practitioners [1]. Its advantages are mainly related to its simplicity and transparency: it provides direct estimates of the probabilities of default as well as estimates for the significance of the predictor variables and it is computationally feasible even for large data sets.

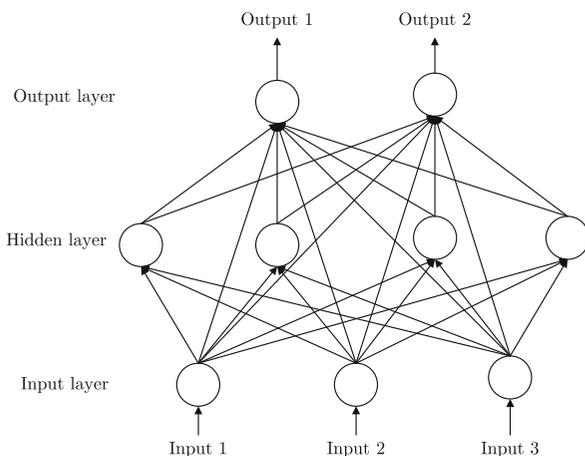

## Neural Networks

Neural networks is a popular methodology for developing decision-making models in complex domains. A neural network is a network of parallel processing units (neurons) organized into layers. A typical structure of a neural network (Fig. 2) includes the following structural elements:

1. An input layer consisting of a set of nodes (processing units – neurons); one for each input to the network.
2. An output layer consisting of one or more nodes depending on the form of the desired output of the network. In classification problems, the number of nodes of the output layer is determined in accordance with the number of groups.
3. A series of intermediate layers referred to as hidden layers. The nodes of each hidden layer are fully connected with the nodes of the subsequent and the preceding layer.

Each connection between two nodes of the network is assigned a weight representing the strength of the connection. On the basis of the connections' weights, the input to each node is determined as the weighted average of the outputs from all the incoming connections. Thus, the input  $in_{ir}$  to node  $i$  of the hidden layer  $r$  is defined as follows:

$$in_{ir} = \sum_{j=0}^{r-1} \sum_{k=1}^{n_j} w_{ik}^j o_{ik} + \phi_{ir}$$

**Credit Rating and Optimization Methods, Figure 2**  
A typical architecture of a neural network

where  $n_j$  is the number of nodes at the hidden layer  $j$ ,  $w_{ik}$  is the weight of the connection between node  $i$  at layer  $r$  and node  $k$  at layer  $j$ ,  $o_{kj}$  is the output of node  $k$  at layer  $j$  and  $\phi_{ir}$  an bias term.

The output of each node is specified through a transformation function. The most common form of this function is the logistic function:

$$o_{ir} = (1 + \exp^{-in_{ir}})^{-1}$$

The determination of the optimal neural network model requires the estimation of the connection weights and the bias terms of the nodes. The most widely used network training methodology is the backpropagation approach [18]. Nonlinear optimization techniques are used for this purpose [10,13,16].

Neural networks have become increasingly popular in recent years for the development of credit rating models [3]. Their main advantages include their ability to model complex nonlinear relationships in credit data, but they have also been criticized for their lack of transparency, the difficulty of specifying a proper architecture and the increased computational resources that are needed for large data sets.

## Support Vector Machines

Support vector machines (SVMs) have become an increasingly popular nonparametric methodology for developing classification models. In a dichotomous classification setting, SVMs can be used to develop a linear decision function  $f(\mathbf{x}) = \text{sgn}(\mathbf{x}\boldsymbol{\beta} + \beta_0)$ .

The optimal decision function  $f$  should maximize the margin induced in the separation of the classes [24], which is defined as  $2/\|\boldsymbol{\beta}\|$ . Thus, the estimation of the optimal model is expressed as a quadratic programming problem of the following from:

$$\begin{aligned} \min \quad & \frac{1}{2} \boldsymbol{\beta}^T \boldsymbol{\beta} + C \mathbf{e}^T \mathbf{d} \\ \text{subject to} \quad & \mathbf{Y}(\mathbf{X}\boldsymbol{\beta} + \mathbf{e}\beta_0) + \mathbf{d} \geq \mathbf{e} \\ & \boldsymbol{\beta}, \beta_0 \in \mathbb{R}, \mathbf{d} \geq \mathbf{0} \end{aligned} \quad (2)$$

where  $\mathbf{X}$  is an  $m \times n$  matrix with the training data,  $\mathbf{Y}$  is an  $m \times m$  matrix such that  $Y_{ii} = y_i$  and  $Y_{ij} = 0$  for all  $i \neq j$ ,  $\mathbf{d}$  is  $m \times 1$  vector with nonnegative error (slack) variables defined such that  $d_i > 0$  iff  $y_i(\mathbf{x}_i\boldsymbol{\beta} + \beta_0) < 1$ ,  $\mathbf{e}$  is a  $m \times 1$  vector of ones, and  $C > 0$  is a user-defined constant representing the trade-off between the two con-

flicting objectives (maximization of the separating margin and minimization of the training errors).

SVMs can also be used to develop nonlinear models. This is achieved by mapping the problem data to a higher-dimensional space  $H$  (feature space) through a transformation of the form  $\mathbf{x}_i \mathbf{x}_j^\top = \phi(\mathbf{x}_i) \phi^\top(\mathbf{x}_j)$ . The mapping function  $\phi$  is implicitly defined through a symmetric positive definite kernel function  $K(\mathbf{x}_i, \mathbf{x}_j) = \phi(\mathbf{x}_i) \phi^\top(\mathbf{x}_j)$  [22]. The representation of the data using the kernel function enables the development of a linear model in the feature space  $H$ .

For large training sets several computational procedures have been proposed to enable the fast training of SVM models. Most of these procedures are based on a decomposition scheme. The optimization problem (2) is decomposed into smaller subproblems taking advantage of the sparse nature of SVM models, since only a small part of the data (the support vectors), contribute to the final form of the model. A review of the algorithms for training SVMs can be found in [6].

SVMs seem to be a promising methodology for developing credit rating models. The algorithmic optimization advances enable their application to large credit data sets and they provide a unified framework for developing both linear and nonlinear models. Recent application of SVMs in credit rating can be found in [9,12,21].

### Multicriteria Value Models and Linear Programming Techniques

The aforementioned classification methods assume that the groups are defined in a nominal way (i.e., the grouping provides a simple description of the cases). However, in credit risk modeling the groups are defined in an ordinal way, in the sense that an obligor classified in a low risk group is preferred to an obligor classified in a high risk group (in terms of its probability of default). Multicriteria methods are well-suited to the study of ordinal classification problems [26].

A typical multicriteria method that is well-suited for the development of credit rating models is the UTADIS method. The method leads to the development of an multiattribute additive value function:

$$V(\mathbf{x}) = \sum_{j=1}^n w_j v_j(x_j)$$

where  $w_j$  is the weight of attribute  $j$ , and  $v_j(x_j)$  is the corresponding marginal value function. Each marginal value function provides a monotone mapping of the performance of the obligors on the corresponding attribute in a scale between 0 (high risk) and 1 (low risk). According to [15], such an additive value function model is well-suited for credit scoring and is widely used by banks in their internal rating systems.

Using a piece-wise linear modeling approach, the estimation of the value function is performed based on a set of training data using linear programming techniques. For a two-class problem, the general form of the linear programming formulation is as follows [8]:

$$\begin{aligned} & \min d_1 + d_2 + \dots + d_m \\ & \text{subject to: } y_i [V(\mathbf{x}_i) - \beta] + d_i \geq \delta, \quad 1, 2, \dots, m \\ & \quad w_1 + w_2 + \dots + w_n = 1 \\ & \quad w_j, d_i, \beta \geq 0 \end{aligned}$$

where  $\beta$  is a value threshold that distinguishes the two classes,  $\delta$  is a small positive user-defined constant and  $d_i = \max\{0, \delta - y_i [V(\mathbf{x}_i) - \beta]\}$  denotes the classification error for obligor  $i$ .

Extensions of this framework and alternative linear programming formulations with applications to credit risk rating have been presented by [5,17,19]. The main advantages of these methodologies involve their computational efficiency and the simplicity and transparency of the resulting models.

### Evolutionary Optimization

Evolutionary algorithms (EA) are stochastic search and optimization heuristics inspired from the theory of natural evolution. In an EA, different possible solutions of an optimization problem constitute the individuals of a population. The quality of each individual is assessed with a fitness (objective) function. Better solutions are assigned higher fitness values than worse performing solutions. The key idea of EAs is that the optimal solution can be found if an initial population is evolved using a set of stochastic genetic operators, similar to the "survival of the fittest" mechanism of natural evolution. The fitness values of the individuals in a population are used to define how they will be propagated to subsequent generations of populations. Most EAs include operators that select individuals for reproduction, pro-

duce new individuals based on those selected, and determine the composition of the population at the subsequent generation.

Well-known EAs and similar metaheuristic techniques include, among others, genetic algorithms, genetic programming, tabu search, simulated annealing, ant colony optimization and particle swarm optimization. EAs have been used to facilitate the development of credit rating systems addressing some important issues such as feature selection, rule extraction, neural network development, etc. Some recent applications can be found in the works of Varetto [20], Salcedo-Sanza et al. [25] and Tsakonas et al. [23].

## Conclusions

Credit rating systems are in the core of the new regulatory framework for the supervision of financial institutions. Such systems support the credit granting process and enable the measurement and monitoring of credit risk exposure.

The increasing volume of credit data which are available for developing rating systems highlight the importance of implementing efficient optimization techniques for the construction of rating models. The existing optimization methods used in this field, are mainly based on nonlinear optimization, linear programming and evolutionary algorithms.

Future research is expected to take advantage of the advances in computer science, algorithmic developments regarding new forms of decision models, the analysis of the combination of different models, the comparative investigation on the performance of the existing methods and the implementation into decision support system that can be used by credit analysts in their daily practice.

Criss-cross

### Introduction

From the early days of linear optimization (LO) (or linear programming), many people have been looking for a *pivot algorithm* that avoids the *two-phase procedure* needed in the simplex method when solving the general LO problem in standard primal form

$$\min \{c^\top x : Ax = b, x \geq 0\},$$

and its dual

$$\max \{b^\top y : A^\top y \leq c\}.$$

Such a method was assumed to rely on the intrinsic symmetry behind the *primal and dual problems* (i. e. it hoped to be *selfdual*), and it should be able to start with any *basic solution*.

There were several attempts made to relax the feasibility requirement in the simplex method. It is important to mention Dantzig's [7] parametric selfdual simplex algorithm. This algorithm can be interpreted as *Lemke's algorithm* [22] for the corresponding linear complementarity problem (cf. ► [Linear complementarity problem](#)) [23]. In the 1960s people realized that pivot sequences through possibly infeasible basic solutions might result in significantly shorter paths to the optimum. Moreover a selfdual one phase procedure was expected to make linear programming more easily accessible for broader public. Probably these advantages stimulated the introduction of the *criss-cross method* by S. Ziont [39,40].

### Ziont's Criss-Cross Method

Assuming that the reader is familiar with both the primal and dual simplex methods, Ziont's criss-cross method can easily be explained.

- It can be initialized by any, possibly both primal and dual infeasible *basis*.

If the basis is optimal, we are done.

If the basis is not *optimal*, then there are some primal or dual infeasible variables. One might choose any of these.

It is advised to choose once a primal and then a dual infeasible variable, if possible.

- If the selected variable is dual infeasible, then it enters the basis and the leaving variable is chosen among the primal feasible variables in such a way that primal feasibility of the currently primal feasible variables is preserved.

If no such basis exchange is possible another infeasible variable is selected.

- If the selected variable is primal infeasible, then it leaves the basis and the entering variable is chosen among the dual feasible variables in such a way that dual feasibility of the currently dual feasible variables is preserved.

If no such basis exchange is possible another infeasible variable is selected.

If the current basis is infeasible, but none of the infeasible variables allows a pivot fulfilling the above requirements then it is proved that the LO problem has no optimal solution.

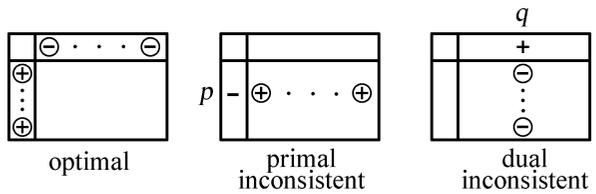

Once a primal or dual feasible solution is reached then Ziont’s method reduces to the primal or dual simplex method, respectively.

One attractive character of Ziont’s criss-cross method is primal-dual symmetry (selfduality), and this alone differentiates itself from the simplex method. However it is not clear how one can design a finite version (i. e. a finite pivot rule) of this method. Both lexicographic perturbation and minimal index resolution seem not to be sufficient to prove finiteness in the general case when the initial basis is both primal and dual infeasible. Nevertheless, although not finite, this is the first published criss-cross method in the literature.

The other thread, that lead to finite criss-cross methods, was the intellectual effort to find finite, other than the lexicographic rule [4,8], variants of the simplex method. These efforts were also stimulated by studying the combinatorial structures behind linear programming. From the early 1970s in several branches of the optimization theory, finitely convergent algorithms were published. In particular A.W. Tucker [32] introduced the *consistent labeling* technique in the Ford–Fulkerson maximal flow algorithm; pivot selection rules based on least-index ordering, such as the Bard-type scheme for the  $P$ -matrix linear complementarity problem (K.G. Murty, [24]) and the celebrated least-index rule in linear and oriented matroid programming (R.G. Bland, [2]). A thorough survey of pivot algorithms can be found in [29].

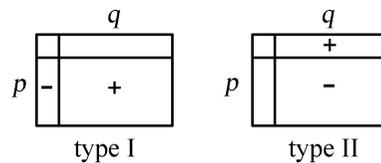

It is remarkable that almost at the same time, in different parts of the world (China, Hungary, USA) essentially the same result was obtained independently by approaching the problem from quite different directions.

Below we will refer to the standard simplex (basis) tableau. A tableau is called *terminal* if it gives a primal and dual optimal solution or evidence of primal or dual infeasibility/inconsistency of the problem. Terminal tableaus have the following sign structure.

Terminal tableaus

The pivot operations at all known pivot methods, including all variants of the primal and dual simplex method and Ziont’s criss-cross method have the following properties. When a primal infeasible variable is selected to leave the basis, the entering variable is selected so that after the pivot both variables involved in the pivot will be primal feasible. Analogously, when a dual infeasible variable is selected to enter the basis, then the leaving variable is selected in such a way that after the pivot both variables involved in the pivot will be dual feasible. Such pivots are called *admissible*. The sign structure of tableaus at an admissible pivot of ‘type I’ and ‘type II’ are demonstrated by the following figure.

Admissible pivot situations

Observe that, while dual(primal) simplex pivots preserve dual(primal) feasibility of the basic solution, admissible pivots do not in general. Admissible pivots extract the greedy nature of pivot selection, i. e. ‘repair primal/dual infeasibility’ of the pivot variables.

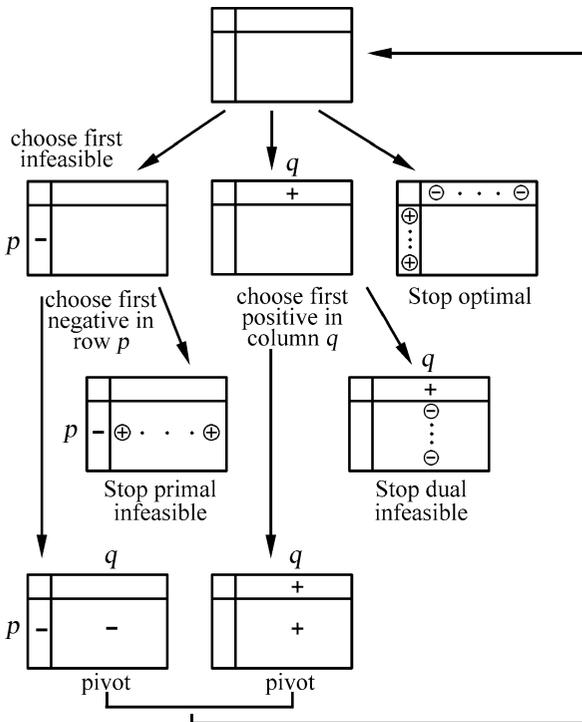

### The Least-Index Criss-Cross Method

The first finite criss-cross algorithm, which we call the *least-index criss-cross method*, was discovered independently by Y.Y. Chang [26], T. Terlaky [26,27,28] and Zh. Wang [34]; further, a strongly related general recursion by D. Jensen [18]. Chang presented the algorithm for positive semidefinite linear complementarity problems, Terlaky for linear optimization, for oriented matroids and with coauthors for QP, LCP and for oriented matroid LCP [9,16,19], while Wang primarily for the case of oriented matroids.

The least-index criss-cross method is perhaps the simplest finite pivoting method to LO problems. This criss-cross method is a purely combinatorial pivoting method, it uses admissible pivots and traverses through different (possibly both primal and dual infeasible) bases until the associated basic solution is optimal, or an evidence of primal or dual infeasibility is found.

To ease the understanding a figure is included that shows the scheme of the least-index criss-cross method.

Scheme of the least-index criss-cross method

Observe the simplicity of the algorithm:

- It can be initiated with any basis.
- No two phases are needed.
- No ratio test is used to preserve feasibility, only the signs of components in a basis tableau and a prefixed ordering of variables determine the pivot selection.

Several finiteness proofs for the least-index criss-cross method can be found in the literature. The proofs are quite elementary, they are based on the orthogonality of the primal and dual spaces [14,26,28,29,34]; on recursive argumentation [11,18,33] or on lexicographically increasing lists [11,14].

- 0 | Let an ordering of the variables be fixed.  
Let  $T(B)$  be an arbitrary basis tableau (it can be neither primal nor dual feasible);
- 1 | Let  $r$  be the minimal  $i$  such that either  $x_i$  is primal infeasible or  $x_i$  has a negative reduced cost. IF there is no  $r$ , THEN stop; the first terminal tableau is obtained, thus  $T(B)$  is optimal.
- 2 | IF  $x_r$  is primal infeasible THEN let  $p := r$ ;  $q := \min\{\ell : t_{p\ell} < 0\}$ .  
IF there is no  $q$ , THEN stop; the second terminal tableau is obtained, thus the primal problem is infeasible.  
Go to Step 3.  
IF  $x_r$  is dual infeasible, THEN let  $q := r$  ;  $p := \min\{\ell : t_{lq} > 0\}$ .  
IF there is no  $q$ , THEN stop: the third terminal tableau is obtained, thus the dual problem is infeasible.  
Go to Step 3.
- 3 | Pivot on  $(p, q)$ . Go to Step 1.

#### The least-index criss-cross rule

One of the most important consequences of the finiteness of the least-index criss-cross method is the *strong duality theorem* of linear optimization. This gives probably the simplest algorithmic proof of this fundamental result:

**Theorem 1 (Strong duality theorem)** Exactly one of the following two cases occurs.

- At least one of the primal problem and the dual problem is infeasible.
- Both problems have an optimal solution and the optimal objective values are equal.

### Other Interpretations

The least-index criss-cross method can be interpreted as a *recursive algorithm*. This recursive interpretation and the finiteness proof based on it can be derived from the results in [2,3,18] and can be found in [33].

### Recursive Interpretation

As performing the least-index criss-cross method at each pivot one can make a note of the larger of the two indices  $r = \max\{p, q\}$  that entered or left the basis. In this list, an index must be followed by another larger one before the same index occurs anew.

The recursive interpretation is becoming apparent when one notes that it is based on the observation that the size of the solved subproblem (the subproblem for which a terminal tableau is obtained) is monotonically increasing.

The third interpretation is based on the proof technique developed by J. Edmonds and K. Fukuda [9] and adapted by Fukuda and T. Matsui [11] to the case of the least-index criss-cross method.

### Lexicographically Increasing List

Let  $u$  be a binary vector with appropriate dimension, set initially to be the zero vector. In applying the algorithm let  $r = \max\{p, q\}$  be the larger of the two indices  $p$  that entered or  $q$  that left the basis.

At each pivot update  $u$  as follows: let  $u_r = 1$  and  $u_i = 0, \forall i < r$ . The remaining components of  $u$  stay unchanged. Then at each step of the least-index criss-cross method the vector  $u$  strictly increases lexicographically, thus the method terminates in a finite number of steps.

### Other Finite Criss-Cross Methods

Both the recursive interpretation and the hidden flexibility of pivot selection in the least-index criss-cross method make it possible to develop other finite variants. Such finite criss-cross methods, which do not rely on a fixed minimal index ordering, were developed on the basis of the finite simplex rules presented by S. Zhang [37]. These finite criss-cross rules [38] are as follows.

### First-in Last-out Rule (FILO)

First, choose a primal or dual infeasible variable that has changed its basis-nonbasis status most recently.

Then choose a variable in the selected row or column so that the pivot entry fulfills the sign requirement of the admissible pivot selection and which has changed its basis/nonbasis status most recently.

When more than one candidates occur with the same pivot age then one break tie as you like (e. g. randomly).

This rule can easily be realized by assigning an ‘age’ vector  $u$  to the vector of the variables and using a pivot counter  $k$ . Initially we set  $k = 0$  and  $u = 0$ . Increase  $k$  by one at each pivot and we set the pivot coordinates of  $u$  equal to  $k$ . Then the pivot selections are made by choosing the variable with the highest possible  $u_i$  value satisfying the sign requirements.

### Most Often Selected Variable Rule

First, choose a primal or dual infeasible variable that has changed its basis-nonbasis status most frequently.

Then choose a variable in the selected row or column so that the pivot entry fulfills the sign requirement of the admissible pivot selection and which has changed its basis/nonbasis status most frequently.

When more than one candidates occur with the same pivot age then one break tie as you like (e. g. randomly).

The most often selected rule can also be realized by assigning another ‘age’ vector  $u$  to the vector of the variables. Initially we set  $u = 0$ . At each pivot we increase the pivot-variable components of  $u$  by one. Then the pivot selections are made by choosing the variable with the highest possible  $u_i$  value satisfying the sign requirement.

### Exponential and Average Behavior

The worst-case exponential behavior of the least-index criss-cross method was studied by C. Roos [25]. Roos’

exponential example is a variant of the cube of V. Klee and G.J. Minty [21]. In this example the starting solution is the origin defined by a feasible basis, the variables are ordered so that the least-index criss-cross method follows a simplex path, i. e. without making any ratio test feasibility of the starting basis is preserved. Another exponential example was presented by Fukuda and Namiki [12] for linear complementarity problems.

Contrary to the clear result on the worst-case behavior, to date not much is known about the expected or average number of pivot steps required by finite criss-cross methods.

### Best-Case Analysis of Admissible Pivot Methods

As it was discussed above, and it is the case for many simplex algorithms, the least-index criss-cross method is not a polynomial time algorithm. A question naturally arises: whether there exists a polynomial criss-cross method? Unfortunately no answer to this question is available at this moment. However some weaker variants of this question can be answered positively. The problem is stated as follows: An arbitrary basis is given. What is the shortest admissible pivot path from this given basis to an optimal basis?

For *nondegenerate problems*, [10] shows the existence of such an admissible pivot sequence of length at most  $m$ . The nondegeneracy assumption is removed in [15]. This result solves a relaxation of the  $d$ -step conjecture.

Observe, that we do not know of any such result for feasibility preserving, i. e. simplex algorithms. In fact, the maximum length of feasibility-preserving pivot sequences between two feasible bases is not known to be bounded by a polynomial in the size of the given LO problem.

### Generalizations

Finite criss-cross methods were generalized to solve fractional linear optimization problems, to large classes of linear complementarity problems (LCPs; cf. ► **Linear complementarity problem**) and to oriented matroid programming problems (OMPs).

### Fractional Linear Optimization

Fractional linear or, as it is frequently referred to, *hyperbolic programming*, can be reformulated as a linear op-

timization problem. Thus it goes without surprise that the least-index criss-cross method is generalized to this class of optimization problems as well [17].

### Linear Complementarity Problems

The largest solvable class of LCPs is the class of LCPs with a *sufficient matrix* [5,6]. The LCP least-index criss-cross method is a proper generalization of the LO criss-cross method. When the LCP arises from a LO problem, the LO criss-cross method is obtained.

### Convex Quadratic Optimization

Convex quadratic optimization problems give an LCP with a bisymmetric coefficient matrix. Because a bisymmetric matrix is semidefinite and semidefinite matrices form a subclass of sufficient matrices, one obtain a finite criss-cross algorithm for convex quadratic optimization problems as well. Such criss-cross algorithms were published e. g. in [20]. The least-index criss-cross method is extremely simple for the *P-matrix* LCP. Starting from an arbitrary complementary basis, here the least-indexed infeasible variable leaves the basis and it is replaced by its complementary pair. This algorithm was originally proposed in [24], and studied in [12]. The general case of sufficient LCPs was treated in [4,13,16].

### Oriented Matroids

The intense research in the 1970s on *oriented matroids* and oriented matroid programming [2,9] gave a new insight in pivot algorithms. It became clear that although the simplex method has rich combinatorial structures, some essential results like the finiteness of Bland's least-index simplex rule [2] does not hold in the oriented matroid context. Edmonds and Fukuda [9] showed that it might cycle in the oriented matroid case due to the possibility of nondegenerate cycling which is impossible in the linear case.

The predecessors of finite criss-cross rules are: Bland's recursive algorithm [2,3], the Edmonds-Fukuda algorithm [9], its variants and generalizations [1,35,36,37]. All these are variants of the simplex method in the linear case, i. e. they preserve the feasibility of the basis, but not in the oriented matroid case. In the case of oriented matroid programming only Todd's finite lexicographic method [30,31] preserves feasibility

of the basis and therefore yields a finite simplex algorithm for oriented matroids.

The least-index criss-cross method is a finite criss-cross method for oriented matroids [28,34]. A general recursive scheme of finite criss-cross methods is given in [18]. Finite criss-cross rules are also presented for oriented matroid quadratic programming and for oriented matroid linear complementarity problems [13,19].

In solving global and combinatorial optimization problems cuts are used as a device to discard portions of the feasible set where it is known that no optimal solution can be found. Specifically, given the optimization problem

$$\min \{f(x): x \in D \subset \mathbb{R}^n\}, \quad (1)$$

if  $x^0$  is an unfit solution and there exists a function  $l(x)$  satisfying  $l(x^0) > 0$ , while  $l(x) \leq 0$  for every optimal solution  $x$ , then by adding the inequality  $l(x) \leq 0$  to the constraint set we exclude  $x^0$  without excluding any optimal solution. The inequality  $l(x) \leq 0$  is called a *valid cut*, or briefly, a *cut*. Most often the function  $l(x)$  is affine: the cut is then said to be linear, and the hyperplane  $l(x) = 0$  is called a cutting plane. However, nonlinear cuts have proved to be useful, too, for a wide class of problems.

Cuts may be employed in different contexts: outer and inner approximation (conjunctive cuts), branch and bound (disjunctive cuts), or in combined form.

### Outer Approximation

Let  $\Omega \subset \mathbb{R}^n$  be the set of optimal solutions of problem (2). Suppose there exists a family  $\mathcal{P}$  of polytopes  $P \supset \Omega$  such that for each  $P \in \mathcal{P}$  a *distinguished point*  $z(P) \in P$  (conceived of as some approximate solution) can be defined satisfying the following conditions:

- A1)  $z(P)$  always exists (unless  $\Omega = \emptyset$ ) and can be computed by an efficient procedure;
- A2) given any  $P \in \mathcal{P}$  and the associated distinguished point  $z = z(P)$ , we can recognize when  $z \in \Omega$  and if  $z \notin \Omega$ , we can construct an affine function  $l(x)$  such that  $P' = P \cap \{x: l(x) \leq 0\} \in \mathcal{P}$ , and  $l(z) > 0$ , while  $l(x) \leq 0, \forall x \in \Omega$ , i. e.  $\Omega \subset P' \subset P \setminus \{z\}$ .

Under these conditions, one can attempt to solve problem (2) by the following *outer approximation method* (OA method) [8]:

### Prototype OA (outer approximation) procedure

0	Start with an initial polytope $P_1 \in \mathcal{P}$ . Set $k = 1$ .
1	Compute the distinguished point $z^k = z(P_k)$ (by A1)). If $z(P_k)$ does not exist, terminate: the problem is infeasible. If $z(P_k) \in \Omega$ , terminate. Otherwise, continue.
2	Using A2), construct an affine function $l_k(x)$ such that $P_{k+1} = P_k \cap \{x: l_k(x) \leq 0\} \in \mathcal{P}$ and $l_k(x)$ strictly separates $z^k$ from $\Omega$ , i. e. satisfies $l_k(z^k) > 0, \quad l_k(x) \leq 0 \quad \forall x \in \Omega. \quad (2)$ Set $k \leftarrow k + 1$ and return to Step 1.

The algorithm is said to be *convergent* if it is either finite or generates an infinite sequence  $\{z^k\}$  every cluster point of which is an optimal solution of problem (2).

Usually the distinguished point  $z^k$  is defined as a vertex of the polytope  $P_k$  satisfying some criterion (e. g., minimizing a given concave function). In these cases, the implementation of the above algorithm requires a procedure for computing, at iteration  $k$ , the vertex set  $V_k$  of the current polytope  $P_k$ . At the beginning,  $V_1$  is supposed to be known, while  $P_{k+1}$  is obtained from  $P_k$  simply by adding one more linear constraint  $l_k(x) \leq 0$ . Using this information  $V_{k+1}$  can be derived from  $V_k$  by an on-line vertex enumeration procedure [1].

*Example 1 (Concave minimization.)* Consider the problem (1) where  $f(x)$  is concave and  $D$  is a convex compact set with  $\text{int } D \neq \emptyset$ .

Assume that  $D$  is defined by a convex inequality  $g(x) \leq 0$  and let  $w \in \text{int } D$ . Take  $\mathcal{P}$  to be the collection of all polytopes containing  $D$ . For every  $P \in \mathcal{P}$  define  $z := z(P)$  to be a minimizer of  $f(x)$  over the vertex set  $V$  of  $P$  (hence, by concavity of  $f(x)$ , a minimizer of  $f(x)$  over  $P$ ). Clearly, if  $z \in D$ , it solves the problem. Otherwise, the line segment joining  $z$  to  $w$  meets the boundary of  $D$  at a unique point  $y$  and the affine function  $l(x) = \langle p, x - y \rangle + g(y)$  with  $p \in \partial g(y)$  strictly separates  $D$  from  $z$  (indeed,  $l(z) = g(z) > 0$  while  $l(x) \leq g(x) - \langle g(x) - g(z), x - z \rangle + g(z) \leq 0$  for all  $x \in D$ ). Obviously  $P' = P \cap \{x : l(x) \leq 0\} \in \mathcal{P}$ , so Assumptions A1) and A2) are fulfilled and the OA algorithm can be applied. The convergence of the algorithm is easy to establish.

*Example 2 (Reverse convex programming.)* Consider the problem (1) where  $f(x) = \langle c, x \rangle$ , while  $D = \{x \in \mathbf{R}^n : h(x) \leq 0 \leq g(x)\}$  with  $g(x), h(x)$  continuous convex functions. Assume that the problem is *stable*, i. e. that  $D = \text{cl}(\text{int } D)$ , so a feasible solution  $\bar{x} \in D$  is optimal if and only if

$$\{x \in D : \langle c, x - \bar{x} \rangle \leq 0\} \subset \{x : g(x) \leq 0\}. \quad (3)$$

Also for simplicity assume a point  $w$  is available satisfying  $\max\{h(w), g(w)\} < 0$  and  $\langle c, w \rangle < \min\{\langle c, x \rangle : h(x) \leq 0 \leq g(x)\}$  (the latter assumption amounts to assuming that the constraint  $g(x) \geq 0$  is essential).

Let  $\Omega$  be the set of optimal solutions,  $\mathcal{P}$  the collection of all polytopes containing  $\Omega$ . For every  $P \in \mathcal{P}$  let  $z = z(P)$  be a maximizer of  $g(x)$  over the vertex set  $V$

of the polyhedron  $P \cap \{x : \langle c, x \rangle \leq \gamma\}$ , where  $\gamma$  is the value of the objective function at the best feasible solution currently available (set  $\gamma = +\infty$  if no feasible solution is known yet). By (3), if  $g(z) \leq 0$ , then  $\gamma$  is the optimal value (for  $\gamma < +\infty$ ), or the problem is infeasible (for  $\gamma = +\infty$ ). Otherwise,  $g(z) > 0$ , and we can construct an affine function  $l(x)$  strictly separating  $z$  from  $\Omega$  as follows. Since  $\max\{h(w), g(w)\} < 0$  while  $\max\{h(z), g(z)\} > 0$  the line segment joining  $z, w$  meets the surface  $\max\{h(x), g(x)\} = 0$  at a unique point  $y$ .

- 1) If  $g(y) = 0$  (while  $h(y) \leq 0$ ), then  $y$  is a feasible solution and since  $y = \lambda w + (1 - \lambda)z$  for some  $\lambda \in (0, 1)$  we must have  $\langle c, y \rangle = \lambda \langle c, w \rangle + (1 - \lambda)\langle c, z \rangle < \gamma$ , so the cut  $l(x) = \langle c, x - y \rangle \leq 0$  strictly separates  $z$  from  $\Omega$ .
- 2) If  $h(y) = 0$ , then the cut  $l(x) = \langle p, x - y + h(y) \rangle \leq 0$ , where  $p \in \partial h(y)$ , strictly separates  $z$  from  $\Omega$  (indeed,  $l(x) \leq h(x) - h(y) + h(y) = h(x) \leq 0$  for all  $x \in \Omega$  while  $l(z) > 0$  because  $l(w) < 0, l(y) = 0$ ).

Thus assumptions A1), A2) are satisfied, and again the OA algorithm can be applied. The convergence of the OA algorithm for this problem is established by a more elaborate argument than for the concave minimization problem (see [3,8]).

Various variants of OA method have been developed for a wide class of optimization problems, since any optimization problem described by means of differences of convex functions can be reduced to a reverse convex program of the above form [3]. However, a difficulty with this method when solving large scale problems is that the size of the vertex set  $V_k$  of  $P_k$  may grow exponentially with  $k$ , creating serious storage problems and making the computation of  $V_k$  almost impracticable.

### Inner Approximation

Consider the concave minimization problem under linear constraints, i. e. the problem (2) when  $f(x)$  is a concave function and  $D$  is a polytope in  $\mathbf{R}^n$ .

Without loss of generality we may assume that  $0$  is a vertex of  $D$ . For any real number  $\gamma \leq f(0)$ , the set  $C_\gamma = \{x \in \mathbf{R}^n : f(x) \geq \gamma\}$  is convex and  $0 \in D \cap C_\gamma$ . Of course,  $D \subset C_\gamma$  if and only if  $f(x) \geq \gamma$  for all  $x \in D$ .

The idea of the *inner approximation* method (IA method), also called the *polyhedral annexation* method (or PA method)[3], is to construct a sequence of expanding polytopes  $P_1 \subset P_2 \subset \dots$  together with a nonin-

creasing sequence of real numbers  $\gamma_1 \geq \gamma_2 \geq \dots$ , such that  $\gamma_k \in f(D)$ ,  $P_k \subset C_{\gamma_k}$ ,  $k = 1, 2, \dots$ , and eventually  $D \subset P_h$  for some  $h$ : then  $\gamma_h \leq f(x)$  for all  $x \in D$ , i. e.  $\gamma_h$  will be the optimal value.

For every set  $P \subset \mathbf{R}^n$  let  $P^\circ$  be the polar of  $P$ , i. e.  $P^\circ = \{y \in \mathbf{R}^n : \langle y, x \rangle \leq 1, \forall x \in P\}$ . As is well known  $P^\circ$  is a closed convex set containing 0 (in fact a polyhedron if  $P$  is a polyhedron), and  $P \subset Q$  only if  $P^\circ \supset Q^\circ$ ; moreover, if  $C$  is a closed convex set containing 0, then  $(C^\circ)^\circ = C$ . Therefore, setting  $S_k = (P^k)^\circ$ , the IA method amounts to constructing a sequence of nested polyhedra  $S_1 \supset \dots \supset S_h$  satisfying  $S_k \subset C_{\gamma_k}$ ,  $k = 1, \dots, h$  and  $S_h \subset D^\circ$ . The key point in this scheme is: Given  $\gamma_k \in f(D)$  and a polyhedron  $S_k$  such that  $S_k^\circ \subset C_{\gamma_k}$ , check whether  $S_k \subset D^\circ$  and if there is  $y^k \in S_k \setminus D^\circ$ , then construct a cut  $l_k(y) \leq 1$  to exclude  $y^k$  and to form a smaller polyhedron  $S_{k+1}$  such that  $S_{k+1}^\circ \subset C_{\gamma_{k+1}}$  for some  $\gamma_{k+1} \in f(D)$  satisfying  $\gamma_{k+1} \leq \gamma_k$ .

To deal with this point, define  $s(y) = \max\{\langle y, x \rangle : x \in D\}$ . Since  $y \in D^\circ$  whenever  $s(y) \leq 1$  we will have  $S_k \subset D^\circ$  whenever

$$\max\{s(y) : y \in S_k\} \leq 1. \tag{4}$$

But clearly the function  $s(y)$  is convex as the pointwise maximum of a family of linear functions. Therefore, denoting the vertex set and the extreme direction set of  $S_k$  by  $V_k, U_k$ , respectively, we will have (4) (i. e.  $S_k \subset D^\circ$ ) whenever

$$\begin{cases} \max\{s(y) : y \in V_k\} \leq 1, \\ \max\{s(y) : y \in U_k\} \leq 0. \end{cases} \tag{5}$$

Thus, checking the inclusion  $S_k \subset D^\circ$  amounts to checking (5), a condition that fails to hold in either of the following cases:

$$s(y^k) > 1 \quad \text{for some } y^k \in V_k \tag{6}$$

$$s(y^k) > 0 \quad \text{for some } y^k \in U_k. \tag{7}$$

In each case, it can be verified that if  $x^k$  maximizes  $\langle y^k, x \rangle$  over  $D$ , and  $\gamma_{k+1} = \min\{\gamma_k, f(x^k)\}$  while

$$\theta_k = \sup\{\theta : f(\theta x^k) \geq \gamma_{k+1}\},$$

then  $S_{k+1} = S_k \cap \{y : \langle x^k, y \rangle \leq 1/\theta_k\}$  satisfies

$$P_{k+1} := S_{k+1}^\circ = \text{conv}(P_k \cup \{\theta_k x^k\}) \subset C_{\gamma_{k+1}}.$$

In the case (6),  $S_{k+1}$  no longer contains  $y^k$  while in the case (7),  $y^k$  is no longer an extreme direction of  $S_{k+1}$ . In this sense, the cut  $\langle x^k, y \rangle \leq 1/\theta_k$  excludes  $y^k$ . We can thus state the following algorithm.

**IA Algorithm (for concave minimization)**

0	By translating if necessary, make sure that 0 is a vertex of $D$ . Let $\bar{x}^1$ be the best basic feasible solution available, $\gamma_1 = f(\bar{x}^1)$ . Take a simplex $P_1 \subset C_{\gamma_1}$ and let $S_1 = P_1^\circ$ , $V_1 =$ vertex set of $S_1$ , $U_1 =$ extreme direction set of $S_1$ . Set $k = 1$ .
1	Compute $s(y)$ for every new $y \in (V_k \cup U_k) \setminus \{0\}$ . If (5) holds, then terminate: $S_k \subset D^\circ$ so $\bar{x}^k$ is a global optimal solution.
2	If (6) or (7) holds, then let $x^k \in \arg \max\{\langle y^k, x \rangle : x \in D\}.$ Update the current best feasible solution by comparing $x^k$ and $\bar{x}^k$ . Set $\gamma_{k+1} = f(\bar{x}^{k+1})$ .
3	Compute $\theta_k = \max\{\theta \geq 1 : f(\theta x^k) \geq \gamma_{k+1}\}$ and let $S_{k+1} = S_k \cap \left\{y : \langle x^k, y \rangle \leq \frac{1}{\theta_k}\right\}.$ From $V_k$ and $U_k$ derive the vertex set $V_{k+1}$ and the extreme direction set $U_{k+1}$ of $S_{k+1}$ . Set $k \leftarrow k+1$ and go to Step 1.

It can be shown that the IA algorithm is finite [3]. Though this algorithm can be interpreted as dual to the OA algorithm, its advantage over the OA method is that it can be started at any vertex of  $D$ , so that each time the set  $V_k$  has reached a certain critical size, it can be stopped and ‘restarted’ at a new vertex of  $D$ , using the last obtained best value of  $f(x)$  as the initial  $\gamma_1$ . In that way the set  $V_k$  can be kept within manageable size.

Note that if  $D$  is contained in a cone  $M$  and  $P_1 = \{x \in M : \langle v^1, x \rangle \leq 1\} \subset C_{\gamma_1}$ , then it can be shown that (7) automatically holds, and only (6) must be checked [6].

**Concavity Cut**

The cuts mentioned above are used to separate an unfit solution from some convex set containing at least one optimal solution. They were first introduced in convex programming [2,4]. Another type of cuts originally devised for concave minimization [7] is the following.

Suppose that a feasible solution  $\bar{x}$  has already been known with  $f(\bar{x}) = \gamma$  and we would like to check whether there exists a better feasible solution. One way to do that is to take a vertex  $x^0$  of  $D$  with  $f(x^0) > \gamma$  and to construct a cone  $M$ , as small as possible, vertexed at  $x^0$ , containing  $D$  and having exactly  $n$  edges. Since  $x^0$  is interior to the convex set  $C_\gamma = \{x : f(x) \geq \gamma\}$ , each

$i$ th edge of  $M$ , for  $i = 1, \dots, n$ , meets the boundary of  $C_\gamma$  at a uniquely defined point  $y^i$  (assuming that  $C_\gamma$  is bounded). Through these  $n$  points  $y^1, \dots, y^n$  (which are affinely independent) one can draw a unique hyperplane, of equation  $\pi(x - x^0) = 1$  such that  $\pi(y^i - x^0) = 1$  ( $i = 1, \dots, n$ ), hence  $\pi = e^\top U^{-1}$ , where  $U$  is the matrix of columns  $y^1 - x^0, \dots, y^n - x^0$  and  $e$  denotes a vector of  $n$  ones. Since the linear inequality

$$e^\top U^{-1}(x - x^0) \geq 1 \quad (8)$$

excludes  $x^0$  without excluding any feasible solution  $x$  better than  $\bar{x}$ , this inequality defines a valid cut. In particular, if it so happens that the whole polytope  $D$  is cut off, i. e. if

$$D \subset \{x: e^\top U^{-1}(x - x^0) \leq 1\}, \quad (9)$$

then  $\bar{x}$  is a global optimal solution.

This cut is often referred to as a  $\gamma$ -valid *concavity cut* for  $(f, D)$  at  $x^0$  [3]. Its construction requires the availability of a cone  $M \supset S$  vertexed at  $x^0$  and having exactly  $n$  edges. In particular, if the vertex  $x^0$  of  $D$  has exactly  $n$  neighboring vertices then  $M$  can be taken to be the cone generated by the  $n$  halflines from  $x^0$  through each of these neighbors of  $x^0$ . Note, however, that the definition of the concavity cut can be extended so that its construction is possible even when the cone  $M$  has more than  $n$  edges (as e. g., when  $x^0$  is a degenerated vertex of  $D$ ).

Condition (9), sufficient for optimality, suggests a cutting method for solving the linearly constrained concave minimization problem by using concavity cuts to iteratively reduce the feasible polyhedron. Unfortunately, experience has shown that concavity cuts, when applied repeatedly, tend to become shallower and shallower. Though these cuts can be significantly strengthened by exploiting additional structure of the problem (e. g., in concave quadratic minimization, bilinear programming [5] and also in low rank nonconvex problems [6]), pure cutting methods are often outperformed by *branch and cut* methods where cutting is combined with successive partition of the space [8].

Concavity cuts have also been used in combinatorial optimization ('intersection cuts', or in a slightly extended form, 'convexity cuts').

## Nonlinear Cuts

In many problems, *nonlinear cuts* arise in a quite natural way.

For example, consider the following problem of *monotonic optimization* [10]:

$$\max \{f(x): g(x) \leq 1, h(x) \geq 1, x \in \mathbb{R}_+^n\}, \quad (10)$$

where  $f, g, h$  are continuous increasing functions on  $\mathbb{R}_+^n$  (a function  $f(x)$  is said to be *increasing* on  $\mathbb{R}_+^n$  if  $0 \leq x \leq x' \Rightarrow f(x) \leq f(x')$ ; the notation  $x \leq x'$  means  $x_i \leq x'_i$  for all  $i$  while  $x < x'$  means  $x_i < x'_i$  for all  $i$ ). As argued in [10], a very broad class of optimization problems can be cast in the form (10). Define  $G = \{x \in \mathbb{R}_+^n: g(x) \leq 1\}$ ,  $H = \{x \in \mathbb{R}_+^n: h(x) \geq 1\}$ , so that the problem is to maximize  $f(x)$  over the feasible set  $G \cap H$ . Clearly

$$0 \leq x \leq x' \in G \Rightarrow x \in G, \quad (11)$$

$$0 \leq x \leq x' \notin H \Rightarrow x \notin H. \quad (12)$$

Assume that  $g(0) < 1$  and  $0 < a \leq x \leq b$  for all  $x \in G \cap H$  (so  $0 \in \text{int } G$ ,  $b \in H$ ). From (11) it follows that if  $z \in \mathbb{R}_+^n \setminus G$  and  $\pi(z)$  is the last point of  $G$  on the halfline from  $0$  through  $z$ , then the cone  $K_\pi(z) = \{x \in \mathbb{R}_+^n: x > \pi(z)\}$  separates  $z$  from  $G$ , i. e.  $G \cap K_\pi(z) = \emptyset$ , while  $z \in K_\pi(z)$ .

A set of the form  $P = \cup_{y \in V} \{x: 0 \leq y\}$ , where  $V$  is a finite subset of  $\mathbb{R}_+^n$ , is called a *polyblock* of vertex set  $V$  [9]. A vertex  $v$  is said to be *improper* if  $v \leq v'$  for some  $v' \in V \setminus \{v\}$ . Of course, improper vertices can be dropped without changing  $P$ . Also if  $P \supset G \cap H$  then the polyblock of vertex set  $V' = V \cap H$  still contains  $G \cap H$  because  $v \notin H$  implies that  $[0, v] \cap H = \emptyset$ . With these properties in mind we can now describe the *polyblock approximation* procedure for solving (10).

Start with the polyblock  $P_1 = [0, b] \supset G \cap H$  and its vertex set  $V_1 = \{b\} \subset H$ . At iteration  $k$  we have a polyblock  $P_k \supset G \cap H$  with vertex set  $V_k \subset H$ . Let  $y^k \in \arg \max \{f(x): x \in V_k\}$ . Clearly  $y^k$  maximizes  $f(x)$  over  $P_k$ , and  $y^k \in H$ , so if  $y^k \in G$  then  $y^k$  is an optimal solution. If  $y^k \notin G$  then the point  $x^k = \pi(y^k)$  determines a cone  $K_{x^k}$  such that the set  $P_{k+1} = P_k \setminus K_{x^k}$  excludes  $y^k$  but still contains  $G \cap H$ . It turns out that  $P_{k+1}$  is a polyblock whose vertex set  $V_{k+1}$  is obtained from  $V_k$  by adding  $n$  points  $v^{k,1}, \dots, v^{k,n}$  (which are the  $n$  vertices of the hyperrectangle  $[x^k, y^k]$  adjacent to  $y^k$ ) and then dropping

all those which do not belong to  $H$ . With this polyblock  $P_{k+1}$ , we pass to iteration  $k+1$ .

In that way we generate a nested sequence of polyblocks  $P_1 \supset P_2 \supset \dots \supset G \cap H$ . It can be proved that either  $y^k$  is an optimal solution at some iteration  $k$  or  $f(y^k) \searrow \gamma := \max\{f(x) : x \in G \cap H\}$ .

A similar method can be developed for solving the problem

$$\min \{f(x) : g(x) \leq 1, h(x) \geq 1, x \in \mathbb{R}_+^n\}$$

by interchanging the roles of  $g, h$  and  $a, b$ . In contrast with what happens in OA methods, the vertex set  $V_k$  of the polyblock  $P_k$  in the polyblock approximation algorithm is extremely easy to determine. Furthermore this method admits restarts, which provide a way to prevent stall and overcome storage difficulties when solving large scale problems [10].

Cutting-stock problem; Cutting pattern; Column generation; Knapsack problem

A company that produces large rolls of paper, textile, steel, etc., usually faces the problem of how to cut the large rolls into smaller rolls, called finished rolls, in such a way that the demands for all finished rolls be satisfied. Any large roll is cut according to some cutting pattern and the problem is to find the cutting patterns to be used and to how many large rolls they should be applied. We assume, for the sake of simplicity, that each large roll has width  $W$ , an integer multiple of some unit and the finished roll widths are also specified by some integers  $w_1, \dots, w_m$ . Let  $a_{ij}$  designate the number of rolls of width  $w_i$  produced by the use of the  $j$ th pattern,  $i = 1, \dots, m, j = 1, \dots, n$ . Let further  $b_i$  designate the demand for roll  $i, i = 1, \dots, m$ , and  $c_j = 1, j = 1, \dots, n$ . If  $A = (a_{ij})$ ,  $\mathbf{b} = (b_1, \dots, b_m)^T$ ,  $\mathbf{c} = (c_1, \dots, c_n)^T$ , then the problem is:

$$\begin{cases} \min & \mathbf{c}^T \mathbf{x} \\ \text{s.t.} & A\mathbf{x} = \mathbf{b} \\ & \mathbf{x} \geq \mathbf{0}. \end{cases}$$

Here  $x_j$  means the number of  $j$ th cutting patterns to be used and as such, an all integer solution would be required to the problem. However, one is usually satisfied with an optimal solution of the above problem without the integrality restriction and, having that, a simple round-off procedure provides us with the solution to the problem.

In the above problem, however, the matrix  $A$  is huge, therefore we do not, and in most cases cannot, create it, by enumerating the cutting patterns. P.C. Gilmore and R.E. Gomory [3,4] resolved this difficulty by an ingenious column generation technique. It works in such a way that we generate column  $j$ , in the course of the simplex algorithm, whenever needed. Assume

## Cutting-Stock Problem

that  $B$  is the current basis and designate by  $\boldsymbol{\pi}$  the corresponding dual vector, i. e., the solution of the linear equation:  $\boldsymbol{\pi}^\top B = \mathbf{c}_B^\top$ . Now, if  $\mathbf{a} = (a_1, \dots, a_m)^\top \in \mathbb{Z}_+^m$  satisfies the inequality  $\mathbf{w}^\top \mathbf{a} \leq W$ , then, by definition,  $\mathbf{a}$  represents a cutting pattern, a column of the matrix  $A$ . Since the cutting-stock problem is a minimization problem, the basis  $B$  is optimal if  $\boldsymbol{\pi}^\top \mathbf{a} \leq 1$  for any  $\mathbf{a}$  that satisfies  $\mathbf{w}^\top \mathbf{a} \leq W$ . We can check it by solving the linear program:

$$\begin{cases} \min & \boldsymbol{\pi}^\top \mathbf{a} \\ \text{s.t.} & \mathbf{w}^\top \mathbf{a} \leq W \\ & \mathbf{a} \in \mathbb{Z}_+^m. \end{cases}$$

If the optimum value is greater than 1, then the optimal  $\mathbf{a}$  vector may enter the basis, otherwise  $B$  is an optimal basis and  $\mathbf{x}_B$  is an optimal solution to the problem. The problem to find the vector  $\mathbf{a}$  is a knapsack problem for which efficient solution methods exist.

In practice, however, frequently more complicated cutting-stock problems come up, due to special customer requirements depending on quality and other characteristics. In addition, we frequently need to include set up costs, capacity constraints and costs due to delay in manufacturing. These lead to the development of special algorithms as described in [1,4,5,6,7]. Recently Cs.I. Fábíán [2] formulated stochastic variants of the cutting-stock problem, for use in fiber manufacturing.

Cyclic coordinate search; Line search methods; Pattern search; Aitken double sweep method; Gauss–Southwell method; Nondifferentiable optimization

Often the solution of multivariable optimization problems it is desired to be done with a *gradient-free algorithm*. This may be the case when gradient evaluations are difficult, or in fact gradients of the underlying optimization method do not exist. Such a method that offers this feature is the method of the cyclic coordinate search and its variants.

The minimization problem considered is:

$$\min_{\mathbf{x}} f(\mathbf{x}).$$

The method in its basic form uses the coordinate axes as the search directions. In particular, the search directions  $\mathbf{d}^{(1)}, \dots, \mathbf{d}^{(n)}$ , where the  $\mathbf{d}^{(i)}$  are vectors of zeros, except for a 1 in the  $i$ th position. Therefore along each search direction  $\mathbf{d}^{(i)}$  the corresponding variable  $x_i$  is changed only, with all remaining variables being kept constant to their previous values.

It is assumed here that the minimization is carried out in order over all variables with indices  $1, \dots, n$  at each iteration of the algorithm. However there are

variants. The first of these is the *Aitken double sweep method*, which processes first the variables in the order mentioned above, and then in the second sweep returns in reverse order, that is  $n-1, \dots, 1$ . The second variant is termed the *Gauss–Southwell method* [2], according to which the component (variable) with largest partial derivative magnitude in the gradient vector is selected for line searching. The latter requires the availability of first derivatives of the objective function.

The algorithm of the cyclic coordinate method can be summarized as follows:

### 1. Initialization

Select a tolerance  $\epsilon > 0$ , to be used in the termination criterion of the algorithm. Select an initial point  $\mathbf{x}^{(0)}$  and initialize by setting  $\mathbf{z}^{(1)} = \mathbf{x}^{(0)}$ . Set  $k = 0$  and  $i = 1$ .

### 2. Main iteration

Let  $\alpha_i^*$  (scalar variable) be the optional solution to the line search problem of minimizing  $f(\mathbf{z}^{(i)} + \alpha \mathbf{d}_i)$ . Set  $\mathbf{z}^{(i+1)} = \mathbf{z}^{(i)} + \alpha_i^* \mathbf{d}^{(i)}$ . If  $j < n$ , then increase  $i$  to  $i+1$  and repeat step 2. Otherwise, if  $j = n$ , then go to step 3.

### 3. Termination check

Set  $\mathbf{x}^{k+1} = \mathbf{z}^{(n)}$ . If the termination criterion is satisfied, for example  $\|\mathbf{x}^{(k+1)} - \mathbf{x}^{(k)}\| \leq \epsilon$ , then stop. Else, set  $\mathbf{z}^{(1)} = \mathbf{x}^{(k+1)}$ . Increase  $k$  to  $k+1$ , set  $i = 1$  and repeat step 2.

The steps above outline the basic cyclic coordinate method, the Aitken and Gauss–Southwell variants can be easily included by modifying the main algorithm.

In terms of convergence rate comparisons, D.G. Luenberger [3] remarks that such comparisons are not easy. However, an interesting analysis presented there indicates that roughly  $n-1$  coordinate searches can be as effective as a single gradient search. Unless the variables are practically uncoupled from one another then coordinate search seems to require approximately  $n$  line searches to bring about the same effect as one step of steepest descent.

It can generally be proved that the cyclic coordinate method, when applied to a differentiable function, will converge to a stationary point [1,3]. However, when differentiability is not present then the method can stall at a suboptimal point. Interestingly there are ways to overcome such difficulties, such as by applying at every  $p$ th iteration (a heuristic number, user specified) the search direction  $\mathbf{x}^{(k+1)} - \mathbf{x}^{(k)}$ . This is even applied in practice for differentiable functions, as it is found to be helpful in accelerating convergence. These modifications are referred to as *acceleration steps* or *pattern searches*.

DEA; Comparative efficiency assessment; Linear programming

Data envelopment analysis (DEA) is a novel technique based on linear programming for evaluating the relative performance of similar units, referred to as decision making units (DMUs). The system under evaluation consists of  $n$  DMUs: each DMU consumes varying amount of  $m_1$  different inputs (resources) to produce  $m_2$  different outputs (products). Specifically, the  $j$ th DMU is characterized by the input vector  $x^j > 0$  and the output vector  $y^j > 0$ . The aim of DEA is to discern, for each DMU, whether or not is operating in an efficient way, given its inputs and outputs, relative to all remaining DMUs under consideration. The measure of efficiency is the ratio of a weighted sum of the outputs to a weighted sum of the inputs. For each DMU, the weights are different and obtained by solving a linear programming problem with the objective of showing the DMU in the best possible light.

The ability to deal directly with incommensurable inputs and outputs, the possibility of each DMU of adopting a different set of weights and the focus on individual observation in contrast to averages are among the most appealing features of model based on DEA.

A process is defined *output-efficient* if there is no other process that, using the same or smaller amount of inputs, produces higher level of outputs. A process is defined *input-efficient* if there is no other process that produces the same or higher level of outputs, using smaller amount of inputs. For each orientation there are four possible models:

- 1) the ‘constant returns’ model;
- 2) the ‘variable returns’ model;
- 3) the ‘increasing returns’ model;
- 4) the ‘decreasing returns’ model.

Each model is defined by a specific set of economic assumptions regarding the relation between inputs and outputs [10,11]. Associated with each of the four DEA models, independent of the orientation, there is a *production possibility set*, that is, the set of all possible inputs and outputs for the entire system. This set consists of the  $n$  DMUs and of ‘virtual’ DMUs obtained as linear combination of the original data. The efficient frontier is a subset of the boundary points of this production set. The objective of DEA is to determine if the DMU under evaluation lies on the efficient frontier and to assign a score based on the distance from this frontier [6].

The production set for the ‘constant returns’ model is

$$T_1 = \left\{ (x, y) \geq 0 : \begin{array}{l} x \geq \mu \sum_{j=1}^n x^j \lambda_j, \\ y \leq \mu \sum_{j=1}^n y^j \lambda_j, \\ \forall \lambda_j \geq 0, \quad \sum_{j=1}^n \lambda_j = 1, \\ \mu > 0 \end{array} \right\},$$

while for the ‘variable returns’ model we have

$$T_2 = \left\{ \begin{array}{l} x \geq \mu \sum_{j=1}^n x^j \lambda_j, \\ (x, y) \geq 0: \quad y \leq \mu \sum_{j=1}^n y^j \lambda_j, \\ \forall \lambda_j \geq 0, \quad \sum_{j=1}^n \lambda_j = 1 \end{array} \right\}.$$

The production sets for the ‘increasing’ (resp. ‘decreasing’) returns models are similar to the set  $T_2$  above with the equality constraint  $\sum_{j=1}^n \lambda_j = 1$  replaced by the inequality  $\sum_{j=1}^n \lambda_j \leq 1$  (resp.  $\sum_{j=1}^n \lambda_j \geq 1$ ).

The ‘constant returns, input oriented’ envelopment LP is given next:

$$\left\{ \begin{array}{l} \min_{\theta, \lambda \geq 0} \quad \theta \\ \text{s.t.} \quad \sum_{j=1}^n x^j \lambda_j - x^{j*} \theta \leq 0 \\ \sum_{j=1}^n y^j \lambda_j \geq y^{j*}. \end{array} \right. \quad (1)$$

For the ‘constant returns, output oriented’ case we have, instead, the following LP problem [4]:

$$\left\{ \begin{array}{l} \max_{\psi, \lambda \geq 0} \quad \psi \\ \text{s.t.} \quad \sum_{j=1}^n x^j \lambda_j \leq x^{j*} \\ \sum_{j=1}^n y^j \lambda_j - y^{j*} \psi \geq 0. \end{array} \right. \quad (2)$$

In both cases the additional constraint

$$\sum_{j=1}^n \lambda_j \begin{pmatrix} (=) \\ (\leq) \\ (\geq) \end{pmatrix} 1$$

defines the LP for the variable, increasing and decreasing returns DEA models, respectively.

The corresponding dual problem for the input-oriented case is

$$\left\{ \begin{array}{l} \max_{\pi, \sigma, \beta} \quad \sigma^\top y^{j*} + \beta \\ \text{s.t.} \quad -\pi^\top x^j + \sigma^\top y^j + \beta \leq 0 \\ j = 1, \dots, n \\ \pi^\top x^{j*} \leq 1 \\ \pi \geq 0, \quad \sigma \geq 0, \end{array} \right. \quad (3)$$

where  $\beta = 0$ ,  $\beta$  unrestricted,  $\beta \leq 0$  and  $\beta \geq 0$  for the constant, variable, increasing and decreasing return DEA models.

For the output-oriented case the dual is:

$$\left\{ \begin{array}{l} \min_{\pi, \sigma, \beta} \quad \pi^\top x^{j*} + \beta \\ \text{s.t.} \quad \pi^\top x^j - \sigma^\top y^j + \beta \geq 0 \\ j = 1, \dots, n \\ \sigma^\top y^{j*} \geq 1 \\ \pi \geq 0, \quad \sigma \geq 0 \end{array} \right. \quad (4)$$

with  $\beta = 0$ ,  $\beta$  unrestricted  $\beta \geq 0$  and  $\beta \leq 0$  for the constant, variable, increasing and decreasing returns DEA models.

For the ‘input-oriented, constant returns’ case, the reference DMU  $j^*$  is

- *inefficient* if
  - the optimal value of problem (1) is different from 1, or
  - the optimal value of Problem (1) is equal to 1 but there exists an optimal solution with at least one slack variable strictly positive;
- *efficient* in the remaining cases.

Moreover the efficient DMU  $j^*$  can be

- *extreme-efficient* if Problem (1) has the unique solution  $\lambda_{j^*}^* = 1, \lambda_j^* = 0, j = 1, \dots, n, j \neq j^*$ ;
- *nonextreme efficient* when Problem (1) has alternate optimal solutions.

The efficiency for the other models is defined in a similar manner.

The conditions  $\theta \geq 0$  and  $\psi \geq 0$  can be introduced without loss of generality in (1) and (2) since only non-negative values for these variables are possible given our assumption on the data. Since  $\lambda_{j^*} = 1, \lambda_j = 0$  for  $j \neq j^*$ ,  $\theta^* = 1$ , and  $\lambda_{j^*} = 1, \lambda_j = 0$  for  $j \neq j^*$ ,  $\psi^* = 1$  are always feasible for (1) and (2), respectively, the optimal objective function value lies in the interval (0, 1] for the input orientation case and [1,  $\infty$ ) for the output orientation case.

The linear programs (1) and (3) above can be interpreted in the following way. In the input-oriented case, we compare the reference DMU  $j^*$  with a ‘virtual’ DMU obtained as linear combination of the original DMUs. Each input and output of this virtual DMU is a linear combination of the corresponding component of the inputs and outputs of all the DMUs. The optimal value is, in this case, always less than or equal to 1. If the optimal value is strictly less than 1, then it is possible to construct a virtual DMU that produces at least the

same amount of outputs as the reference DMU using an amount of inputs that is strictly smaller than amount used by the  $j^*$ th DMU. When this happens we declare the DMU  $j^*$  inefficient. Instead, when the optimal value is equal to 1 there are three possible cases:

- there exists an optimal solution with at least one slack variable strictly positive;
- the optimal solution is unique;
- there exists multiple optimal solutions.

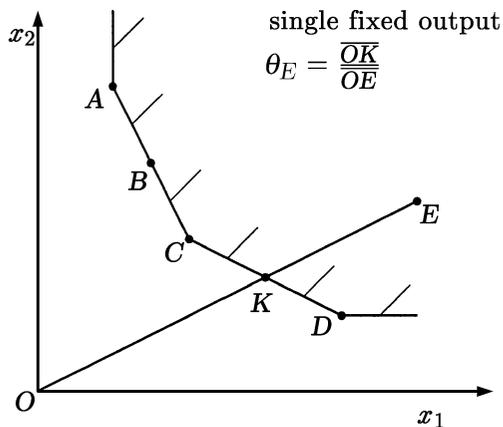

In the first case we declare the reference DMU inefficient. In the last two cases the  $j^*$ th DMU is efficient (extreme-efficient, respectively nonextreme efficient).

For Problem (3), the optimal solution  $\pi^*$  and  $\sigma^*$  represent the weights that are the most favorable for the reference DMU, i. e., the weights that produce the highest efficiency score under the hypothesis that, using the same weights for the other DMUs, the efficiency remains always below 1.

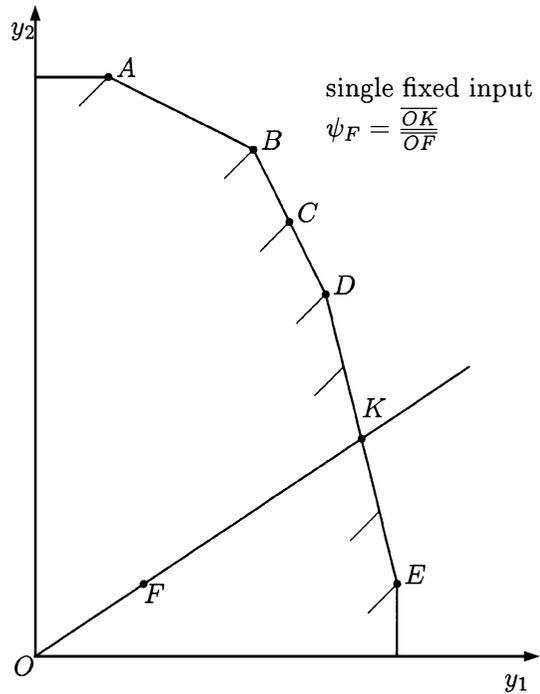

Similar interpretations can be given for the output-oriented case for Problems (2) and (4).

In Fig. 1 it is represented the production possibility set and the efficient frontier for the five DMUs ‘A’ to ‘E’. These DMUs are characterized by two different inputs and a single output value set to some fixed value.

All the DMUs are efficient but the DMU ‘E’. The DMU ‘B’ is efficient but nonextreme. The virtual DMU ‘K’, obtained as convex combination of the DMUs ‘C’ and ‘D’, is more efficient than the DMU ‘E’. The optimal value  $\theta^*$  for the linear programming problem (1) for the DMU ‘E’ is exactly the ratio of the lengths of the segments OE and OK.

Data Envelopment Analysis, Figure 1  
Two-input, single output DMUs

Data Envelopment Analysis, Figure 2  
Two-output, single input DMUs

Figure 2 shows the case of DMUs characterized by two distinct outputs and a single input set to a fixed value. All the DMUs are efficient except the DMU ‘F’ that is dominated by the virtual DMU ‘K’. The optimal value  $\psi^*$  for the linear programming problem (2) for the DMU ‘F’ is the ratio of the lengths of the segments OE and OK.

The original ‘constant returns’ model was proposed in [4]. In [2] the *variable returns* model was proposed with the objective of discriminating between technical efficiency and scale efficiency. The bibliography published in [7] (part of [3]) contains more than 500 references to published article in the period 1978–1992 and many more articles appeared since.

In all the DEA models discussed above, all efficient DMUs receive an equal score of 1. An important modification proposed in [1] allows to rank efficient units. The main idea is to exclude the column being scored from the DEA envelopment LP technology matrix. The efficiency score is now a value between  $(0, +\infty]$  in both orientations. In [5] are discussed in detail the issues (infeasibility, relationship between modified and standard formulation, degeneracy, interpretation of the optimal solutions) related to these DEA models.

In [8] and [9] the properties of ‘unit invariance’ (independence of the units in which inputs and outputs are measured) and ‘translation invariance’ (independence of an affine translation of the inputs and the outputs) of an efficiency DEA measure are discussed. The translation invariance property is particularly important when data contain zero or negative values. Standard DEA models are not unit invariant and translation invariant. In [8] it is proposed a weighted additive DEA model that satisfies these properties:

$$\left\{ \begin{array}{l} \min_{\lambda, s^+, s^-} \quad \sum_{i=1}^{m_1} w_i^+ s_i^+ + \sum_{r=1}^{m_2} w_r^- s_r^- \\ \text{s.t.} \quad \sum_{j=1}^n x_i^j \lambda_j + s_i^+ = x_i^{j*} \\ \quad \quad \quad i = 1, \dots, m_1 \\ \quad \quad \quad \sum_{j=1}^n y_r^j \lambda_j - s_r^- = y_r^{j*} \\ \quad \quad \quad r = 1, \dots, m_2 \\ \quad \quad \quad \sum_{j=1}^n \lambda_j = 1 \\ \quad \quad \quad \lambda_j \geq 0, \quad j = 1, \dots, n, \\ \quad \quad \quad s_i^+ \geq 0, \quad i = 1, \dots, m_1, \\ \quad \quad \quad s_r^- \geq 0, \quad r = 1, \dots, m_2. \end{array} \right. \quad (5)$$

where  $w_i^+$  and  $w_r^-$  are the sample standard deviation of the inputs and outputs variables respectively.

Models based on data envelopment analysis have been widely used in order to evaluate efficiency in both public and private sectors. [3, Part II] contains 15 application of DEA showing the ‘range, power, elegance and insight obtainable via DEA analysis’. Banks, hospitals, and universities are among the most challenging sectors where models based on DEA have been able to assess efficiency and determine strength and weakness of the various units.

## Introduction

Data mining has proven valuable in almost every aspect of life involving large data sets. Data mining is made possible by the generation of masses of data from computer information systems. In engineering, satellites stream masses of data down to storage systems, yielding a mountain of data that needs some sort of data mining to enable humans to gain knowledge. Data mining has been applied in engineering applications such as quality [4], manufacturing and service [13], labor scheduling [17], and many other places. Medicine has been an extensive user of data mining, both in the technical area [21] and in health policy [6]. Pardalos [16] provide recent research in this area. Governmental operations have received support from data mining, primarily in the form of fraud detection [9].

In business, data mining has been instrumental in customer relationship management [5,8], financial analysis [3,12], credit card management [1], health service debt management [22], banking [19], insurance [18], and many other areas of business involving services. Kusiak [13] reviewed data mining applications to include service applications of operations. Recent reports of data mining applications in web service and technology include Tseng and Lin [20] and Hou and Yang [11]. In addition to Tseng and Lin, Lee et al. [14] discuss issues involving mobile technology and data mining. Data mining support is required to make sense of the masses of business data generated by computer technology. Understanding this information-generation system and tools available leading to analysis is fundamental for business in the 21st century. The major applications have been in customer segmentation (by banks and retail establishments wishing to focus on profitable customers) and in fraud and rare event detection (especially by insurance and government, as well as by banks for credit scoring). Data mining has been used by casinos in customer management, and by organizations evaluating personnel.

We will discuss data mining functions, data mining process, data systems often used in conjunction with data mining, and provide a quick review of software tools. Four prototypical applications are given to demonstrate data mining use in business. Ethical issues will also be discussed.

## Definitions

There are a few basic functions that have been applied in business. Bose and Mahapatra [2] provided an extensive list of applications by area, technique, and problem type.

- **Classification** uses a training data set to identify classes or clusters, which then are used to categorize data. Typical applications include categorizing risk and return characteristics of investments, and credit risk of loan applicants. The Adams [1] case, for example, involved classification of loan applications into groups of expected repayment and expected problems.
- **Prediction** identifies key attributes from data to develop a formula for prediction of future cases, as in regression models. The Sung et al. [19] case predicted bankruptcy while the Drew et al. [5] case and the customer retention part of the Smith et al. [18] case predicted churn.
- **Association** identifies rules that determine the relationships among entities, such as in market basket analysis, or the association of symptoms with diseases. IF-THEN rules were shown in the Sung et al. [19] case.
- **Detection** determines anomalies and irregularities, valuable in fraud detection. This was used in claims analysis by Smith et al. [18].

To provide analysis, data mining relies on some fundamental analytic approaches. Regression and neural network approaches are alternative ways to identify the best fit in a given set of data. Regression tends to have advantages with linear data, while neural network models do very well with irregular data. Software usually allows the user to apply variants of each, and lets the analyst select the model that fits best. Cluster analysis, discriminant analysis, and case-based reasoning seek to assign new cases to the closest cluster of past observations. Rule induction is the basis of decision tree methods of data mining. Genetic algorithms apply to special forms of data, and are often used to boost or improve the operation of other techniques.

In order to conduct data mining analyzes, a **data mining process** is useful. The Cross-Industry Standard Process for Data Mining (CRISP-DM) is widely used by industry members [15]. This model consists of six phases intended as a cyclical process:

- **Business understanding:** Business understanding includes determining business objectives, assessing the current situation, establishing data mining goals, and developing a project plan.
  - **Data understanding:** Once business objectives and the project plan are established, data understanding considers data requirements. This step can include initial data collection, data description, data exploration, and the verification of data quality. Data exploration such as viewing summary statistics (which includes the visual display of categorical variables) can occur at the end of this phase. Models such as cluster analysis can also be applied during this phase, with the intent of identifying patterns in the data.
  - **Data preparation:** Once the data resources available are identified, they need to be selected, cleaned, built into the form desired, and formatted. Data cleaning and data transformation in preparation for data modeling needs to occur in this phase. Data exploration at a greater depth can be applied during this phase, and additional models utilized, again providing the opportunity to see patterns based on business understanding.
  - **Modeling:** Data mining software tools such as visualization (plotting data and establishing relationships) and cluster analysis (to identify which variables go well together) are useful for initial analysis. Tools such as generalized rule induction can develop initial association rules. Once greater data understanding is gained (often through pattern recognition triggered by viewing model output), more detailed models appropriate to the data type can be applied. The division of data into training and test sets is also needed for modeling (sometimes even more sets are needed for model refinement).
  - **Evaluation:** Model results should be evaluated in the context of the business objectives established in the first phase (business understanding). This will lead to the identification of other needs (often through pattern recognition), frequently reverting to prior phases of CRISP-DM. Gaining business understanding is an iterative procedure in data mining, where the results of various visualization, statistical, and artificial intelligence tools show the user new relationships that provide a deeper understanding of organizational operations.
  - **Deployment:** Data mining can be used both to verify previously held hypotheses, and for knowledge discovery (identification of unexpected and useful relationships). Through the knowledge discovered in the earlier phases of the CRISP-DM process, sound models can be obtained that may then be applied to business operations for many purposes, including prediction or identification of key situations. These models need to be monitored for changes in operating conditions, because what might be true today may not be true a year from now. If significant changes do occur, the model should be redone. It is also wise to record the results of data mining projects so documented evidence is available for future studies.
- This six-phase process is not a rigid, by-the-numbers procedure. There is usually a great deal of backtracking. Additionally, experienced analysts may not need to apply each phase for every study. But CRISP-DM provides a useful framework for data mining.
- There are many **database systems** that provide content needed for data mining. Database software is available to support individuals, allowing them to record information that they consider personally important. They can extract information provided by repetitive organizational reports, such as sales by region within their area of responsibility, and regularly add external data such as industry-wide sales, as well as keep records of detailed information such as sales representative expense account expenditure.
- **Data warehousing** is an orderly and accessible repository of known facts and related data that is used as a basis for making better management decisions. Data warehouses provide ready access to information about a company's business, products, and customers. This data can be from both internal and external sources. Data warehouses are used to store massive quantities of data in a manner that can be easily updated and allow quick retrieval of specific types of data. Data warehouses often integrate information from a variety of sources. Data needs to be identified and obtained, cleaned, catalogued, and stored in a fashion that expedites organizational decision making. Three general data warehouse processes exist. (1) Warehouse generation is the process of designing the warehouse and loading data. (2) Data management is the process of storing the

data. (3) Information analysis is the process of using the data to support organizational decision making.

- **Data marts** are sometimes used to extract specific items of information for data mining analysis. Terminology in this field is dynamic, and definitions have evolved as new products have entered the market. Originally, many data marts were marketed as preliminary data warehouses. Currently, many data marts are used in conjunction with data warehouses rather than as competitive products. But also many data marts are being used independently in order to take advantage of lower-priced software and hardware. Data marts are usually used as repositories of data gathered to serve a particular set of users, providing data extracted from data warehouses and/or other sources. Designing a data mart tends to begin with the analysis of user needs. The information that pertains to the issue at hand is relevant. This may involve a specific time-frame and specific products, people, and locations. Data marts are available for data miners to transform information to create new variables (such as ratios, or coded data suitable for a specific application). In addition, only that information expected to be pertinent to the specific data mining analysis is extracted. This vastly reduces the computer time required to process the data, as data marts are expected to contain small subsets of the data warehouse's contents. Data marts are also expected to have ample space available to generate additional data by transformation.
- **Online analytical processing (OLAP)** is a multidimensional spreadsheet approach to shared data storage designed to allow users to extract data and generate reports on the dimensions important to them. Data is segregated into different dimensions and organized in a hierarchical manner. Many variants and extensions are generated by the OLAP vendor industry. A typical procedure is for OLAP products to take data from relational databases and store them in multidimensional form, often called a **hypercube**, to reflect the OLAP ability to access data on these multiple dimensions. Data can be analyzed locally within this structure. One function of OLAP is standard report generation, including financial performance analysis on selected dimensions (such as by department, geographical region, product, salesperson, time, or other dimensions desired by the

analyst). Planning and forecasting are supported through spreadsheet analytic tools. Budgeting calculations can also be included through spreadsheet tools. Usually, pattern analysis tools are available.

There are many statistical and analytic **software tools** marketed to provide data mining. Many good data mining software products are being used, including the well-established (and expensive) Enterprise Miner by SAS and Intelligent Miner by IBM, CLEMENTINE by SPSS (a little more accessible by students), PolyAnalyst by Megaputer, and many others in a growing and dynamic industry. For instance, SQL Server 2005 has recently been vastly improved by Microsoft, making a more usable system focused on the database perspective.

These products use one or more of a number of analytic approaches, often as complementary tools that might involve initial cluster analysis to identify relationships and visual analysis to try to understand why data clustered as it did, followed by various prediction models. The major categories of methods applied are regression, decision trees, neural networks, cluster detection, and market basket analysis. The Web site [www.KDnuggets.com](http://www.KDnuggets.com) gives information on many products, classified by function. In the category of overall data mining suites, they list 56 products in addition to 16 free or shareware products. Specialized software products were those using multiple approaches (15 commercial plus 3 free), decision tree (15 plus 10 free), rule-based (7 plus 4 free), neural network (12 plus 3 free), Bayesian (13 plus 11 free), support vector machines (3 plus 8 free), cluster analysis (8 plus 10 free), text mining (50 plus 4 free), and other software for functions such as statistical analysis, visualization, and Web usage analysis.

### Example Applications

There are many applications of data mining. Here we present four short examples in the business world.

#### Customer Relationship Management (CRM)

The idea of customer relationship management is to target customers for special treatment based on their anticipated future value to the firm. This requires estimation of where in the customer life-cycle each subject is, as well as lifetime customer value, based on expected

tenure with the company, monthly transactions by that customer, and the cost of providing service. Lifetime value of a customer is the discounted expected stream of cash flow generated by the customer.

Many companies applying CRM score each individual customer by their estimated lifetime value (LTV), stored in the firm's customer database [5]. This concept has been widely used in catalog marketing, newspaper publishing, retailing, insurance, and credit cards. LTV has been the basis for many marketing programs offering special treatment such as favorable pricing, better customer service, and equipment upgrades.

While CRM is very promising, it has often been found to be less effective than hoped [10]. CRM systems can cost up to \$70 million to develop, with additional expenses incurred during implementation. Many of the problems in CRM expectations have been blamed on over-zealous sales pitches. CRM offers a lot of opportunities to operate more efficiently. However, they are not silver bullets, and benefits are not unlimited. As with any system, prior evaluation of benefits is very difficult, and investments in CRM systems need to be based on sound analysis and judgment.

### Credit Scoring

Data mining can involve model building (extension of conventional statistical model building to very large data sets) and pattern recognition. Pattern recognition aims to identify groups of interesting observations. Interesting is defined as discovery of knowledge that is important and unexpected. Often experts are used to assist in pattern recognition. Adams et al. [1] compared data mining used for model building and pattern recognition on the behavior of customers over a one-year period. The data set involved bank accounts at a large British credit card company observed monthly. These accounts were revolving loans with credit limits. Borrowers were required to repay at least some minimum amount each month. Account holders who paid in full were charged no interest, and thus not attractive to the lender.

We have seen that clustering and pattern search are typically the first activities in data analysis. Then appropriate models are built. Credit scoring is a means to use the results of data mining modeling for two purposes. Application scoring was applied in the Adams

et al. example to new cases, continuing an activity that had been done manually for half a century in this organization. Behavioral scoring monitors revolving credit accounts with the intent of gaining early warnings of accounts facing difficulties.

### Bankruptcy Prediction

Corporate bankruptcy prediction is very important to management, stockholders, employees, customers, and other stakeholders. A number of data mining techniques have been applied to this problem, including multivariate discriminant analysis, logistical regression, probit, genetic algorithms, neural networks, and decision trees.

Sung et al. [19] applied decision analysis and decision tree models to a bankruptcy prediction case. Decision tree models provide a series of IF-THEN rules to predict bankruptcy. Pruning (raising the proportion of accurate fit required to keep a specific IF-THEN relationship) significantly increased overall prediction accuracy in the crisis period, indicating that data collected in the crisis period was more influenced by noise than data from the period with normal conditions. Example rules obtained were as shown in Table 1, giving an idea of how decision tree rules work.

For instance, in normal conditions, if the variable Productivity of capital (E6) was greater than 19.65, the model would predict firm survival with 86 percent confidence. Conversely, if Productivity of capital (E6) was less than or equal to 19.65, and if the Ratio of cash flow to total assets (C9) was less than or equal to 5.64, the model would predict bankruptcy with 84 percent confidence. These IF-THEN rules are stated in ways that are easy for management to see and use. Here the rules are quite simple, a desirable feature. With large data sets, it is common to generate hundreds of clauses in decision tree rules, making it difficult to implement (although gaining greater accuracy). The number of rules can be controlled through pruning rates within the software.

### Fraud Detection

Data mining has successfully supported many aspects of the insurance business, to include fraud detection, underwriting, insolvency prediction, and customer segmentation. An insurance firm had a large data warehouse system recording details on every transac-

**Data Mining, Table 1**  
**Bankruptcy Prediction Rules**

Condition	Rule	Prediction	Confidence level
Normal	$E6 > 19.65$	Nonbankrupt	0.86
Normal	$C9 > 5.64$	Nonbankrupt	0.95
Normal	$C9 \leq 5.64$ & $E6 \leq 19.65$	Bankrupt	0.84
Crisis	$E6 > 20.61$	Nonbankrupt	0.91
Crisis	$C8 > 2.64$	Nonbankrupt	0.85
Crisis	$C3 > 87.23$	Nonbankrupt	0.86
Crisis	$C8 \leq 2.64$ , $E6 \leq 20.61$ , & $C3 \leq 87.23$	Bankrupt	0.82

Where C3 = Ratio of fixed assets to equity & long-term liabilities. C8 = Ratio of cash flow to liabilities. C9 = Ratio of cash flow to total assets. E6 = Productivity of capital. Based on Sung et al. [19]

tion and claim [18]. An aim of the analysis was to accurately predict average claim costs and frequency, and to examine the impact of pricing on profitability.

In evaluating claims, data analysis for hidden trends and patterns is needed. In this case, recent growth in the number of policy holders led to lower profitability for the company. Understanding the relationships between cause and effect is fundamental to understanding what business decisions would be appropriate.

Policy rates are based on statistical analysis assuming various distributions for claims and claim size. In this case, clustering was used to better model the performance of specific groups of insured.

Profitability in insurance is often expressed by the cost ratio, or sum of claim costs divided by sum of premiums. Claim frequency ratio is the number of claims divided by the number of policy units of risk (possible claims). Profitability would be improved by lowering

the frequency of claims, or the costs of claims relative to premiums.

Data was extracted from the data warehouse for policies for which premiums were paid in the first quarter over a three-year period. This meant that policies were followed over the period, augmented by new policies, and diminished by terminations. Data on each policy holder was available as well as claim behavior over the preceding year. The key variables of cost ratio and claim frequency ratio were calculated for each observation. Sample sizes for each quarter were well above 100,000.

Descriptive statistics found exceptional growth in policies over the past two years for young people (under 22), and with cars insured for over \$40,000. Clustering analysis led to the conclusion that the claim cost of each individual policy holder would be pointless, as the vast majority of claims could not be predicted. Af-

Ease of integration	Good	Good	Good	Very good
Ease of operation	Easy	Difficult	Easy	Difficult

Extracted from Bose and Mahapatra [2]

ter experimentation, the study was based on 50 clusters. A basic k-means algorithm was used. This identified several clusters as having abnormal cost ratios or frequency sizes. By testing over a two-year gap, stability for each group was determined. Table 2 compares data mining techniques.

### Ethical Issues in Data Mining

Data mining is a potentially useful tool, capable of doing a lot of good, not only for business but also for the medical field and for government. It does, however, bring with it some dangers. So, how can we best protect ourselves, especially in the area of business data mining?

A number of options exist. Strict control of data usage through governmental regulation was proposed by Garfinkel [7]. A number of large database projects that made a great deal of practical sense have ultimately been stopped. Those involving government agencies were successfully stopped due to public exposure, the negative outcry leading to cancellation of the National Data Center and the Social Security Administration projects. A system with closely held information by credit bureaus in the 1960s was only stopped after governmental intervention, which included the passage of new laws. Times have changed, with business adopting a more responsive attitude toward consumers. Innovative data mining efforts by Lotus/Equifax and by Lexis-Nexis were quickly stopped by public pressure alone.

Public pressure seems to be quite effective in providing some control over potential data mining abuses. If that fails, litigation is available (although slow in effect). It is necessary for us to realize what businesses can do with data. There will never be a perfect system to protect us, and we need to be vigilant. However, too much control can also be dangerous, inhibiting the ability of business to provide better products and services through data mining. Garfinkel prefers more governmental intervention, while we would prefer less governmental intervention and more reliance on publicity and, if necessary, the legal system.

Control would be best accomplished if it were naturally encouraged by systemic relationships. The first systemic means of control is publicity. Should those adopting questionable practices persist, litigation is a slow, costly, but ultimately effective means of sys-

tem correction. However, before taking drastic action, a good rule is that if the system works, it is best not to fix it. The best measure that electronic retailers can take is to not do anything that will cause customers to suspect that their rights are being violated.

### Conclusions

Data mining has evolved into a useful analytic tool in all aspects of human study, to include medicine, engineering, and science. It is a necessary means to cope with the masses of data that are produced in contemporary society. Within business, data mining has been especially useful in applications such as fraud detection, loan analysis, and customer segmentation. Such applications heavily impact the service industry. Data mining provides a way to quickly gain new understanding based upon large-scale data analysis.

This paper reviewed some of the applications that have been applied in services. It also briefly reviewed the data mining process, some of the analytic tools available, and some of the major software vendors of general data mining products. Specific tools for particular applications are appearing with astonishing rapidity.

As optimization techniques become widely used in engineering, economics, and other sciences, an increasing number of nonconvex optimization problems are encountered that can be described in terms of *dc functions* (differences of convex functions). These problems are called dc optimization problems, and the theory dealing with these problems is referred to as dc programming, or dc optimization ([3,4,5,6,13]; see also [1,8]).

Historically, the first dc optimization problem that was seriously studied is the concave minimization problem [11]. Subsequently, reverse convex programming and some other special dc optimization problems such as quadratic and, more generally, polynomial programming problems appeared before a unified theory was developed and the term dc optimization was introduced [12]. In fact, most global optimization problems of interest that have been studied so far can be identified as dc optimization problems, despite the diversity of the approaches used.

### DC Structure in Optimization

Let  $\Omega$  be a convex set in  $\mathbb{R}^n$ . A function  $f: \Omega \rightarrow \mathbb{R}$  is said to be *dc on  $\Omega$*  if it can be expressed as the difference of two convex functions on  $\Omega$ :  $f(x) = p(x) - q(x)$ , where  $p(x), q(x): \Omega \rightarrow \mathbb{R}$  are convex. Denote the set of dc functions on  $\Omega$  by  $DC(\Omega)$ .

**Proposition 1**  *$DC(\Omega)$  is a vector lattice with respect to the two operations of pointwise maximum and pointwise minimum.*

In other words, if  $f_i(x) \in DC(\Omega)$ ,  $i = 1, \dots, m$ , then:

1.  $\sum_{i=1}^m \alpha_i f_i(x) \in DC(\Omega)$ , for any real numbers  $\alpha_i$ ;
2.  $g(x) = \max\{f_1(x), \dots, f_m(x)\} \in DC(\Omega)$ ;
3.  $h(x) = \min\{f_1(x), \dots, f_m(x)\} \in DC(\Omega)$ .

From this property it follows in particular that if  $f \in DC(\Omega)$ , then  $|f| \in DC(\Omega)$ , and if  $g, h \in DC(\Omega)$ , then  $gh \in DC(\Omega)$ . But for the purpose of optimization

the most important consequence is that

$$\begin{aligned} g_i(x) &\leq 0, \quad \forall i = 1, \dots, m \\ \Leftrightarrow g(x) &:= \max\{g_1(x), \dots, g_m(x)\} \leq 0, \\ g_i(x) &\leq 0 \text{ for at least one } i = 1, \dots, m \\ \Leftrightarrow g(x) &:= \min\{g_1(x), \dots, g_m(x)\} \leq 0. \end{aligned}$$

Therefore, any finite system of dc inequalities, whether conjunctive or disjunctive, can be rewritten as a single dc inequality.

By easy manipulations it is then possible to reduce any dc optimization problem to the following *canonical form*:

$$\begin{aligned} &\text{minimize } f(x) \\ &\text{subject to } g(x) \leq 0 \leq h(x), \end{aligned} \quad (\text{CDC})$$

where all functions  $f, g, h$  are convex.

Thus dc functions allow a very compact description of a wide class of nonconvex optimization problems.

### Recognizing dc Functions

To exploit the dc structure in optimization problems, it is essential to be able to recognize dc functions that are still in hidden form (i. e., not yet presented as differences of convex functions). The next proposition addresses this question.

**Proposition 2** *Every function  $f \in C^2$  is dc on any compact convex set  $\Omega$ .*

It follows that any polynomial function is dc, and hence, by the Weierstrass theorem,  $DC(\Omega)$  is dense in the Banach space  $C(\Omega)$  of continuous functions on  $\Omega$  with the supnorm topology. In other words, any continuous function can be approximated as closely as desired by a dc function.

More surprisingly, any closed set  $S$  in  $\mathbb{R}^n$  can be shown to be a *dc set*, i. e., a set that is the solution set of a dc inequality. Namely, given any closed set  $S \subset \mathbb{R}^n$  and any strictly convex function  $h: \mathbb{R}^n \rightarrow \mathbb{R}$ , there exists a continuous convex function  $g_S: \mathbb{R}^n \rightarrow \mathbb{R}$  such that  $S = \{x \in \mathbb{R}^n: g_S(x) - h(x) \leq 0\}$  [10].

In many situations we not only need to recognize a dc function but also to know how to represent it effectively as a difference of two convex functions. While several classes of functions have been recognized as dc functions [2], there are still few results about effective

dc representations of these functions. For composite functions a useful result about dc representation is the following [13].

**Proposition 3** *Let  $h(x) = u(x) - v(x)$ , where  $u, v: \Omega \rightarrow \mathbb{R}_+$  are convex functions on a compact convex set  $\Omega \subset \mathbb{R}^m$  such that  $0 \leq h(x) \leq a \forall x \in \Omega$ . If  $q: [0, a] \rightarrow \mathbb{R}$  is a convex nondecreasing function such that  $q'_-(a) < \infty$  ( $q'_-(a)$  being the left derivative of  $q(t)$  at  $a$ ), then  $q(h(x))$  is a dc function on  $\Omega$ :*

$$q(h(x)) = g(x) - K[a + v(x) - u(x)],$$

where  $g(x) = q(h(x)) + K[a + v(x) - u(x)]$  is a convex function and  $K$  is any constant satisfying  $K \geq q'_-(a)$ .

For example, by writing  $x^\alpha = e^{h(x)}$  with  $h(x) = \sum_{i=1, \dots, n} \alpha_i \log x_i$  and applying the above proposition, it is easy to see that  $x^\alpha = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$ , with  $\alpha \in \mathbb{R}_+^n$ , is dc on any box  $\Omega = [r, s] \subset \mathbb{R}_{++}^n$ . Hence, any synomial function  $f(x) = \sum_{\alpha} c_{\alpha} x^{\alpha}$ , with  $c_{\alpha} \in \mathbb{R}$ ,  $\alpha \in \mathbb{R}_+^n$ , is also dc on  $\Omega$ .

### Global Optimality Criterion

A key question in the theoretical as well as computational study of a global optimization problem is how to test a given feasible solution for global optimality.

Consider a pair of problems in some sense mutually obverse:

$$\inf\{f(x): x \in \Omega, h(x) \geq \alpha\}, \quad (\text{P}_{\alpha})$$

$$\sup\{h(x): x \in \Omega, f(x) \leq \gamma\}, \quad (\text{Q}_{\gamma})$$

where  $\alpha, \gamma \in \mathbb{R}$ ,  $\Omega$  is a closed set in  $\mathbb{R}^n$ , and  $f, g: \mathbb{R}^n \rightarrow \mathbb{R}$  are two arbitrary functions.

We say that problem  $(\text{P}_{\alpha})$  is *regular* if

$$\inf \text{P}_{\alpha} = \inf\{f(x): x \in \Omega, h(x) > \alpha\}. \quad (1)$$

Analogously, problem  $(\text{Q}_{\gamma})$  is regular if  $\sup \text{Q}_{\gamma} = \sup\{h(x): x \in \Omega, f(x) < \gamma\}$ .

**Proposition 4** *Let  $\bar{x}$  be a feasible solution of problem  $(\text{P}_{\alpha})$ . If  $\bar{x}$  is optimal to problem  $(\text{P}_{\alpha})$  and if problem  $(\text{Q}_{\gamma})$  is regular for  $\gamma = f(\bar{x})$ , then*

$$\sup\{h(x): x \in \Omega, f(x) \leq \gamma\} = \alpha. \quad (2)$$

*Conversely, if (2) holds and if problem  $(\text{P}_{\alpha})$  is regular, then  $\bar{x}$  is optimal to  $(\text{P}_{\alpha})$ .*

Turning now to the canonical dc optimization problem (CDC), let us set  $\Omega = \{x: g(x) \leq 0\}$  and without losing generality assume that the reverse convex constraint  $h(x) \geq 0$  is essential, i. e.,

$$\inf\{f(x): x \in \Omega\} < \inf\{f(x): x \in \Omega, h(x) \geq 0\}. \quad (3)$$

Since CDC is a problem  $(P_\alpha)$  with  $\alpha = 0$ , if  $\bar{x}$  is a feasible solution to CDC, then condition (3) ensures the regularity of the associated problem  $(Q_\gamma)$  for  $\gamma = f(\bar{x})$ . Define

$$C = \{x: h(x) \leq 0\}, \quad D(\gamma) = \{x \in \Omega: f(x) \leq \gamma\}, \quad (4)$$

and for any set  $E$  denote its polar by  $E^*$ . As specialized for CDC, Proposition 4 yields:

**Proposition 5** *In order that a feasible solution  $\bar{x}$  of CDC may be a global minimizer, it is necessary that the following equivalent conditions hold for  $\gamma = f(\bar{x})$ :*

$$D(\gamma) \subset C, \quad (5)$$

$$0 = \max\{h(x): x \in D(\gamma)\}, \quad (6)$$

$$C^* \subset [D(\gamma)]^*. \quad (7)$$

*If the problem is regular, then any one of the above conditions is also sufficient.*

An important special dc program is the following problem:

$$\text{minimize } g(x) - h(x) \quad \text{subject to } x \in \mathbb{R}^n, \quad (\text{DC})$$

where  $g, h: \mathbb{R}^n \rightarrow \bar{\mathbb{R}}$  are convex functions ( $\bar{\mathbb{R}}$  denotes the set of extended real numbers). Writing this problem as  $\min\{g(x) - t: x \in D, h(x) \geq t\}$  with  $D = \text{dom}g \cap \text{dom}h$  and using (7), one can derive the following:

**Proposition 6** *Let  $g, h: \mathbb{R}^n \rightarrow \bar{\mathbb{R}}$  be two convex functions such that  $h(x)$  is proper and lsc. Let  $\bar{x}$  be a point where  $g(\bar{x})$  and  $h(\bar{x})$  are finite. In order for  $\bar{x}$  to be a global minimizer of  $g(x) - h(x)$  over  $\mathbb{R}^n$ , it is necessary and sufficient that*

$$\partial_\varepsilon h(\bar{x}) \subset \partial_\varepsilon g(\bar{x}) \quad \forall \varepsilon > 0, \quad (8)$$

where  $\partial_\varepsilon f(a) = \{p \in \mathbb{R}^n: \langle p, x - a \rangle - \varepsilon \leq f(x) - f(a) \quad \forall x \in \mathbb{R}^n\}$  is the  $\varepsilon$ -subdifferential of  $f(x)$  at point  $a$ .

## Solution Methods

Numerous solution methods have been proposed for different classes of dc optimization. Each of them proceeds either by outer approximation (OA) of the feasible set or by branch and bound (BB) or is of a hybrid type, combining OA with BB. Following are some typical dc algorithms.

### An OA Method for (CDC)

Without losing generality, assume (3), i. e.,

$$\exists w \quad \text{s.t. } g(w) \leq 0, \quad f(w) < \min\{f(x): x \in \Omega, h(x) \geq 0\}. \quad (9)$$

where, as was defined above,  $\Omega = \{x: g(x) \leq 0\}$ . In most cases checking the regularity of a problem is not easy while regularity is needed for the sufficiency of the optimality criteria in Proposition 5. Therefore the method to be presented below only makes use of the necessity part of this proposition and is independent of any regularity assumption.

In practice, what we usually need is not an exact solution but just an approximate solution of the problem. Given tolerances  $\varepsilon > 0, \eta > 0$ , we are interested in  $\varepsilon$ -approximate solutions, i. e., solutions  $x \in \Omega$  satisfying  $h(x) \geq -\varepsilon$ . An  $\varepsilon$ -approximate solution  $x^*$  is then said to be  $\eta$ -optimal if  $f(x^*) - \eta \leq \min\{f(x): x \in \Omega, h(x) \geq 0\}$ .

With  $\bar{x}$  now being a given  $\varepsilon$ -approximate solution and  $\gamma = f(\bar{x}) - \eta$ , consider the subproblem

$$\max\{h(x): x \in \Omega, f(x) \leq \gamma\}. \quad (Q_\gamma)$$

For simplicity assume that the set  $D(\gamma) = \{x \in \Omega, f(x) \leq \gamma\}$  is bounded. Then  $(Q_\gamma)$  is a convex maximization problem over a compact convex set and can be solved by an OA algorithm (see [13] or [3]) generating a sequence  $\{x^k, y^k\}$  such that

$$x^k \in \Omega, f(x^k) \leq \gamma, h(x^k) \leq \max(Q_\gamma) \leq h(y^k) \quad (10)$$

and, furthermore,  $\|x^k - y^k\| \rightarrow 0$  as  $k \rightarrow +\infty$ . These relations imply that we must either have  $h(y^k) < 0$  for some  $k$  (which implies that  $\max(Q_\gamma) < 0$ ), or else  $h(x^k) \geq -\varepsilon$  for some  $k$ . In the former case,

this means there is no  $x \in \Omega$  with  $h(x) \geq 0$  and  $f(x) \leq f(\bar{x}) - \eta$ , i. e.,  $\bar{x}$  is  $\eta$ -optimal to CDC, and we are done. In the latter case,  $x^k$  is an  $\varepsilon$ -approximate solution with  $f(x^k) \leq f(\bar{x}) - \eta$ . Using then a local search (or any inexpensive way available) one can improve  $x^k$  to  $x' \in \Omega \cap \{x: h(x) = -\varepsilon\}$ , and, after resetting  $\gamma \leftarrow f(x') - \eta$  in  $(Q_\gamma)$ , one can repeat the procedure with the new  $(Q_\gamma)$ . And so on.

As is easily seen, the method consists essentially of a number of consecutive cycles in each of which, say the  $l$ th cycle, a convex maximization subproblem  $(Q_\gamma)$  is solved with  $\gamma = f(x^l) - \eta$  for some  $\varepsilon$ -approximate solution  $x^l$ . This sequence of cycles can be organized into a unified procedure. For this, it suffices to start each new cycle from the result of the previous cycle: after resetting  $\gamma \leftarrow \gamma' := f(x') - \eta$  in  $(Q_\gamma)$ , we have  $D(\gamma') \subset D(\gamma)$ , with a point  $x' \notin D(\gamma')$ , so the algorithm can be continued by using a hyperplane separating  $x'$  from  $D(\gamma')$  to form with the current polytope outer approximating  $D(\gamma)$  a smaller polytope outer approximating  $D(\gamma')$ . Since each cycle decreases the objective function value by at least a quantity  $\eta > 0$ , and the objective function is bounded from below, the whole procedure must terminate after finitely many cycles, yielding an  $\varepsilon$ -approximate solution that is  $\eta$ -optimal to (CDC).

It is also possible to use a BB algorithm for solving the subproblem  $(Q_\gamma)$  in each cycle. The method then proceeds exactly as in the BB method for GDC to be presented next.

### A BB Method for General DC Optimization

A general dc optimization problem can be formulated as

$$\min\{f(x): g_i(x) \geq 0, \\ i = 1, \dots, m, x \in \Omega\}, \quad (\text{GDC})$$

where  $\Omega$  is a compact convex subset of  $\mathbb{R}^n$ , and  $f, g_1, \dots, g_m$  are dc functions on  $\Omega$ . Although in principle GDC can be reduced to the canonical form and solved as a CDC problem, this may not be an efficient method as it does not take account of specific features of GDC. For instance, if the feasible set of GDC is highly nonconvex, computing a single feasible solution may be as hard as solving the problem itself. Under these conditions, a direct application of the OA or the BB strate-

gies to GDC is fraught with pitfalls. Without adequate precautions, such approaches may lead to grossly incorrect results or to an unstable solution that may change drastically upon a small change of the data or the tolerances [15,16].

A safer approach is to reduce GDC to a sequence of problems with a convex feasible set in the following way. By simple manipulations it is always possible to arrange that the objective function  $f(x)$  is convex. Let  $g(x) = \min_{i=1, \dots, m} g_i(x)$ , and for every  $\gamma \in \mathbb{R} \cup \{+\infty\}$  consider the subproblem

$$\max\{g(x): x \in \Omega, f(x) \leq \gamma\}. \quad (\text{R}_\gamma)$$

Assuming the set  $D(\gamma) := \{x \in \Omega, f(x) \leq \gamma\}$  to be bounded, we have in  $(\text{R}_\gamma)$  a dc optimization over a compact convex set. Using a *BB procedure* to solve  $(\text{R}_\gamma)$  we generate a nested sequence of partition sets  $M_k$  (boxes, e.g., using a rectangular subdivision), together with a sequence  $\alpha(M_k) \in \mathbb{R} \cup \{-\infty\}$ , and  $x^k \in \mathbb{R}^n$ ,  $k = 1, 2, \dots$ , such that

$$\text{diam } M_k \rightarrow 0 \text{ as } k \rightarrow +\infty, \quad (11)$$

$$\alpha(M_k) \searrow \max\{g(x): x \in M_k \cap D(\gamma)\} (k \rightarrow +\infty), \quad (12)$$

$$\alpha(M_k) \geq \max(\text{R}_\gamma), x^k \in M_k \cap D(\gamma), \quad (13)$$

where  $\max(P)$  denotes, as usual, the optimal value of problem  $P$ . Condition (11) means that the subdivision rule used must be exhaustive, while (12) indicates that  $\alpha(M_k)$  is an upper bound over the feasible solutions in  $M_k$ , and (13) follows from the fact that  $M_k$  is the partition set with the largest upper bound among all partition sets currently of interest.

As before, we say that  $x$  is an  $\varepsilon$ -approximate solution of GDC if  $x \in \Omega$ ,  $g(x) \geq -\varepsilon$  and  $x^*$  is  $\eta$ -optimal if  $f(x^*) - \eta \leq \min\{f(x): g(x) \geq 0, x \in \Omega\}$ . From (11)–(13) it follows that  $\alpha(M_k) - g(x^k) \rightarrow 0$  as  $k \rightarrow +\infty$ , and hence, for any given  $\varepsilon > 0$ , either  $\alpha(M_k) < 0$  for some  $k$  or  $g(x^k) \geq -\varepsilon$  for some  $k$ . In the former case,  $\max(\text{R}_\gamma) < 0$ , hence  $\max(\text{GDC}) > \gamma$ ; in the latter case,  $x^k$  is an  $\varepsilon$ -approximate solution of GDC with  $f(x^k) \leq \gamma$ . So, given any  $\varepsilon$ -approximate solution  $\bar{x}$  with  $\gamma = f(\bar{x}) - \eta$ , a finite number of iterations of this BB

procedure will help to determine whether there is no feasible solution  $x$  to GDC with  $f(x) \leq f(\bar{x}) - \eta$ , i. e.,  $\bar{x}$  is  $\eta$ -optimal to GDC, or else there exists an  $\varepsilon$ -approximate solution  $x'$  to GDC with  $f(x') \leq f(\bar{x}) - \eta$ . In the latter case, we can reset  $f(x') - \eta \leftarrow \gamma$  and repeat the procedure with the new  $\gamma$ , and so on. In this way the whole solution process consists of a number of cycles, each involving a finite BB procedure and giving a decrease in the incumbent value of  $f(x)$  by at least  $\eta > 0$ . By starting each cycle right from the result of the previous one, the sequence of cycles forms a unified procedure. Since  $\eta$  is a positive constant, the number of cycles is finite and the procedure terminates with an  $\varepsilon$ -approximate solution that is  $\eta$ -optimal to GDC.

The efficiency of such a BB procedure depends on two basic operations: branching and bounding. Usually, branching is performed by means of an exhaustive subdivision rule, so as to satisfy condition (11). For rectangular partition, this condition can be achieved by the standard bisection rule: bisect the current box  $M$  into two equal subboxes by means of a hyperplane perpendicular to a longest edge of  $M$  at its midpoint. However, it has been observed that the convergence guaranteed by an exhaustive subdivision rule is rather slow, especially in high dimensions. To improve the situation, the idea is to use, instead of the standard bisection, an *adaptive subdivision rule* defined as follows. Let the upper bound  $\alpha(M_k)$  in (12) be obtained as  $\alpha(M_k) = \max\{\Gamma(x) : x \in M_k \cap D(\gamma)\}$ , where  $\Gamma(x)$  is some concave overestimator of  $g(x)$  over  $M_k$  that is tight at some point  $y^k \in M_k$ , i. e., satisfies  $\Gamma(y^k) = g(y^k)$ . If  $x^k \in \operatorname{argmax}\{\Gamma(x) | x \in M_k \cap D(\gamma)\}$ , then the subdivision rule is to bisect  $M_k$  by means of the hyperplane  $x_s = x_s^k + y_s^k/2$ , where  $s \in \operatorname{argmax}_{i=1, \dots, n} |y_i^k - x_i^k|$ . As has been proved in [13], such an adaptive bisection rule ensures the existence of an infinite subsequence  $\{k_\nu\}$  such that  $y^{k_\nu} - x^{k_\nu} \rightarrow 0$  as  $\nu \rightarrow +\infty$ . The common limit  $x^*$  of  $x^{k_\nu}$  and  $y^{k_\nu}$  then yields an optimal solution of the problem (R $_\gamma$ ). Computational experience has effectively confirmed that convergence achieved with an adaptive subdivision rule is usually much faster than with the standard bisection. For such an adaptive subdivision to be possible, the constraint set  $D(\gamma)$  of (12) must be convex, so that for each partition set  $M_k$  two points  $x^k \in M_k \cap D(\gamma)$  and  $y^k \in M_k$  can be defined such that  $\alpha(M_k) - g(y^k) = o(\|x^k - y^k\|)$ .

### DCA—A Local Optimization Approach to (DC)

By rewriting DC as a canonical dc optimization problem

$$\min\{t - h(x) : x \in \mathbb{R}^n, t \in \mathbb{R}, g(x) - t \leq 0\},$$

we see that DC can be solved by the same method as CDC. Since, however, for some large-scale problems we are not so much interested in a global optimal solution as in a sufficiently good feasible solution, a local optimization approach to DC has been developed [9] that seems to perform quite satisfactorily in a number of applications. This method, referred to as DCA, is based on the well-known Toland equality:

$$\inf_{x \in \operatorname{dom}g} \{g(x) - h(x)\} = \inf_{y \in \operatorname{dom}h^*} \{g^*(y) - g^*(y)\}, \quad (14)$$

where  $g, h : \mathbb{R}^n \rightarrow \mathbb{R}$  are lower semicontinuous proper convex functions, and the star denotes the conjugate, e. g.,  $g^*(y) = \sup\{x, y\} - g(x) : x \in \operatorname{dom}g\}$ . Taking account of this equality, DCA starts with  $x^0 \in \operatorname{dom}g$  and for  $k = 1, 2, \dots$ , computes  $y^k \in \partial h(x^k)$ ;  $x^{k+1} \in \partial g^*(y^k)$ . As has been proved in [9], the thus generated sequence  $x^k, y^k$  satisfies the following conditions:

1. The sequences  $g(x^k) - h(x^k)$  and  $h^*(x^k) - g^*(x^k)$  are decreasing.
2. Every accumulation point  $x^*$  (resp.  $y^*$ ) of the sequence  $\{x^k\}$  (resp.  $\{y^k\}$ ) is a critical point of the function  $g(x) - h(x)$  (resp.  $h^*(y) - g^*(y)$ ).

Though global optimality cannot be guaranteed by this method, it has been observed that in many cases of interest it yields a local minimizer that is also global.

### Applications and Extensions

The above described dc methods are of a general-purpose type. For many special dc problems more efficient algorithms are needed to take full advantage of additional structures. Along this line, dc methods have been adapted to solve problems with separated nonconvexity, bilinear programming, multilevel programming, multiobjective programming, optimization problems over efficient sets, polynomial and symomial programming, fractional programming, continuous location problems, clustering and datamining problems, etc. [4]. In particular, quite efficient methods have been developed for a class of dc optimization problems important for applications called multiplicative program-

ming [4,5]. Also, techniques for bounding, branching, and decomposition have been refined that have very much widened the range of applicability of dc methods. Most recently, *monotonic optimization*, also called *DM optimization*, has emerged as a new promising field of research dealing with a class of optimization problems important for applications whose structure, though different from the dc structure, shares many common features with the latter. To be specific, let  $C$  be a family of real valued functions on  $\mathbb{R}^n$  such that (i)  $g_1, g_2 \in C, \alpha_1, \alpha_2 \in \mathbb{R}_+ \Rightarrow \alpha_1 g_1 + \alpha_2 g_2 \in C$ ; (ii)  $g_1, g_2 \in C \Rightarrow g(x) := \max\{g_1(x), g_2(x)\} \in C$ . Then the family  $\mathcal{D}(C) = C - C$  is a vector lattice with respect to the two operations of pointwise maximum and pointwise minimum. When  $C$  is the set of convex functions,  $\mathcal{D}(C)$  is nothing but the vector lattice of dc functions. When  $C$  is the set of increasing functions on  $\mathbb{R}^n$ , i. e., the set of functions  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  such that  $x' \geq x \Rightarrow f(x') \geq f(x)$ , the vector lattice  $\mathcal{D}(C)$  consists of *DM functions*, i. e., functions representable as the difference of two increasing functions. For the theory, methods, and algorithms of DM optimization, we refer the reader to [7,14,18].

Intelligent multicriteria decision support systems

In practical real-world situations the available time for making decisions is often limited, while the cost of investigation is increasing with time. Therefore, it would

be enviable to exploit the increasing processing power provided by the modern computer technology, to save significant amounts of time and cost in decision making problems. Computationally intensive, but routine tasks, such as data management and calculations can be performed with remarkable speed by a common personal computer, compared to the time that a human would need to perform the same tasks. On the other hand, computers are unable to perform cognitive tasks, while their inference and reasoning capabilities are still very limited compared to the capabilities of the human brain. Thus, in decision making problems, computers can support decision makers by managing the data of the problem and performing computationally intensive calculations, based on a selected decision model, which could help in the analysis, while the decision makers themselves have to examine the obtained results of the models and conclude to the most appropriate decision.

This merging of human judgment and intuition together with computer systems constitutes the underlying philosophy, methodological framework and basic goal of *decision support systems* [17]. The term 'decision support system' (DSS) is already consolidated and it is used to describe any computer system that provides information on a specific decision problem using analytical decision models and access to databases, in order to support a decision maker in making decisions effectively in complex and ill-structured problems where no straightforward, algorithmic procedure can be employed [28].

The development of DSSs kept pace with the advances in computer and information technologies, and since the 1970s numerous DSSs have been designed by academic researchers and practitioners for the examination and analysis of several decision problems including finance and accounting, production management, marketing, transportation, human resources management, agriculture, education, etc. [17,19].

Except for the specific decision problems that DSSs address, these systems are also characterized by the type of decision models and techniques that they incorporate (i. e. statistical analysis tools, mathematical programming and optimization techniques, multicriteria decision aid methods, etc.). Some of these methodologies (optimization, statistical analysis, etc.) which have already been implemented in several DSSs, are based on the classical monocriterion approach. How-

ever, real world decision problems can be hardly considered through the examination of a single criterion, attribute or point of view that will lead to the 'optimum' decision. In fact such a monocriterion approach is merely an oversimplification of the actual nature of the problem at hand, that can lead into unrealistic decisions.

On the other hand, a more realistic and flexible approach would be the simultaneous consideration of all pertinent factors that may affect a decision. However, through this appealing approach a very essential issue emerges: how can several and often conflicting factors can be aggregated to make rational decisions? This issue constitutes the focal point of interest for all the *multicriteria decision aid* methods. The incorporation of multicriteria decision aid methods in DSSs provides the decision makers with a highly efficient tool to study complex real world decision problems where multiple criteria of conflicting nature are involved. Therefore, the subsequent sections of this paper will concentrate on this specific category of DSSs (*multicriteria DSSs*, MCDSSs).

The article is organized as follows. In section 2 some basic concepts, notions and principles of multicriteria decision aid are discussed. Section 3 presents the main features and characteristics of MCDSSs, along with a review of the research that has been conducted in this field, while some extensions of the classical MCDSSs framework in group decision making and intelligent decision support are also discussed. Finally, section 4 concludes the paper and outlines some possible future research directions in the design, development and implementation of MCDSSs.

### **Multicriteria Decision Aid**

Multicriteria decision aid (MCDA, the European School) or multicriteria decision making (MCDM, the American School) [49,64] constitutes an advanced field of operations research which is devoted to the development and implementation of decision support methodologies to confront complex decision problems involving multiple criteria, goals or objectives of conflicting nature. The foundations of MCDA can be traced back in the works of J. von Neumann and O. Morgenstern [43], and P.C. Fishburn [20] on utility theory, A. Charnes and W.W. Cooper [10] on goal program-

ming, and B. Roy [47] on the concept of outranking relations and the foundations of the ELECTRE methods. These pioneering works have affected the subsequent research in the field of MCDA that can be distinguished in two major groups: discrete and continuous MCDA. The former is involved with decision problems where there is a finite set of alternatives which should be considered in order to select the most appropriate one, to rank them from the best to the worst, or to classify them in predefined homogeneous classes. On the contrary in continuous MCDA problems the alternatives are not defined a priori, but instead one seeks to construct an alternative that meets his/her goals or objectives (for instance the construction of a portfolio of stocks).

There are different ways to address these two classes of problems in MCDA. Usually, a continuous MCDA problem is addressed through *multi-objective* or *goal programming* approaches. In the former case, the objectives of the decision maker are expressed as a set of linear or non linear functions which have to be 'optimized', whereas in the latter case the decision maker expresses his/her goals in the form of a reference or ideal point which should be achieved as close as possible. These two approaches extend the classical single-objective optimization framework, through the simultaneous consideration of more than one objectives or goals. Of course in this new context it seems illusory to speak of optimality, but instead the aim is initially to determine the set of efficient solutions (solutions which are not dominated by any other solution) and then to identify interactively a specific solution which is consistent with the preference structure of the decision maker. The books [54,57] and [63] provide an excellent and extensive discussion of both multi-objective and goal programming.

On the other hand, discrete MCDA problems are usually addressed through the *multi-attribute utility theory* (MAUT) [26], the *outranking relations approach* [48] or the *preference disaggregation approach* ([23,44]). These three approaches are mainly focused on the determination and modeling of the decision makers' preferences, in order to develop a global preference model which can be used in decision making. Their differences concern mainly the form of the global preference model that is developed, as well as the procedure that is used to estimate the parameters of the model. The developed

preference model in both MAUT and preference disaggregation is a utility or value function either additive or multiplicative, whereas the outranking relations approach is based on pairwise comparisons of the form 'alternative  $a$  is at least as good as alternative  $b$ '. Concerning the procedure that is used to estimate the parameters of the global preference model, both in MAUT and outranking relations there is a direct interrogation of the decision maker. More precisely, in MAUT the decision maker is asked to determine the trade-offs among the several attributes or criteria, while in outranking relations the decision maker has to determine several parameters, such as the weights of the evaluation criteria, indifference, strict preference and veto thresholds for each criterion. On the contrary, in preference disaggregation, an ordinal regression procedure is used to estimate the global preference model. Based on a reference set of alternatives, which may consist either of past decisions or by a small subset of the alternatives under consideration, the decision maker is asked to provide a ranking or a classification of the alternatives according to his/her decision policy (global preferences). Then, using an ordinal regression procedure the global preference model is estimated so that the original ranking or classification (and consequently the global preference system of the decision maker) can be reproduced as consistently as possible.

### Multicriteria Decision Support Systems

From the above brief discussion of the basic concepts and approaches of MCDA, it is clear that in any case the decision maker and his/her preferences constitute the focal point of the methodological framework of MCDA. This special characteristic of MCDA implies that a comprehensive model of a decision situation cannot be developed, but instead the model should be developed to meet the requirements of the decision maker [46]. The development of such a model can be only achieved through an iterative and interactive process, until the decision maker's preferences are consistently represented in the model. Both interactivity and iterative operation are two of the key characteristics of DSSs. Consequently, a DSS incorporating MCDA methods could provide essential support in structuring the decision problem, analyzing the preferences of the decision maker, and supporting the model building process.

The support provided by multicriteria DSSs (MCDSSs) is essential for the decision maker as well as for the decision analyst.

- The decision maker through the use of MCDSSs becomes familiar with sophisticated operations research techniques, he is supported in structuring the decision problem considering all possible points of view, attributes or criteria, and furthermore, he is able to analyze the conflicts between these points of view and consider the existing trade-offs. All these capabilities provided by MCDSSs serve the learning process of decision makers in resolving complex decision problems in a realistic context, and constitute a solid scientific basis for arguing upon the decisions taken.
- On the other hand, from the decision analyst point of view, MCDSSs provide a supportive tool which is necessary throughout the decision making process, enabling the decision analyst who usually acts as an intermediate between the system and the decision maker, to highlight the essential features of the problem to the decision maker, to introduce the preferences of the decision maker in the system, and to develop the corresponding model. Furthermore, through sensitivity and robustness analyses the decision analyst is able to examine several scenarios, concerning both the significance of the evaluation criteria as well as the changes in the decision environment.

The supportive operation of MCDSSs in making decisions in ill-structured complex decision problems was the basic motivation for computer scientists, management scientists and operations researchers in the development of such systems. Actually, MCDSSs are one of the major areas of DSSs research since the 1970s [19] and significant progress has been made both on the theoretical and the practical/implementation viewpoints.

The first MCDSSs to be developed in the 1970s where mainly oriented towards the study of multi-objective mathematical programming problems ([16,61]). These early pioneer systems, mainly due to the limited capabilities of computer technology during that period, were primarily developed for academic purposes, they were implemented in mainframe computers, with no documentation available, while they had no visual representation capabilities [31]. Today, after more than twenty years of research and advances

in MCDA, DSSs, and computer science, most MCDSSs provide many advanced capabilities to decision makers including among others [46]:

- 1) Enhanced data management capabilities including interactive addition, deletion or modification of criteria.
- 2) Assessment and management of weights.
- 3) User-friendly interfaces based on visual representations of both alternatives and criteria to assist the interaction between the system and the decision maker.
- 4) Sensitivity analysis (what-if analysis) to determine how the changes in the weights of the evaluation criteria can affect the actual decision.

These capabilities are in accordance with the general characteristics of DSSs, that is interactivity, flexibility and adaptability to the changes of the decision environment, user oriented design and development, and combination of data base management with decision models. Although the aforementioned capabilities are common to most of the existing MCDSSs, one could provide a distinction of the MCDSSs according to the MCDA approaches that they employ:

- MCDSSs based on the multi-objective programming approach:
  - the TOMMIX system [2],
  - the TRIMAP system [11],
  - the VIG system ([29,32]),
  - the VIDMA system [30],
  - the DIDAS system [36],
  - the AIM system [37],
  - the ADBASE system [58], and
  - the STRANGE system [59].
- MCDSSs based on the MAUT approach:
  - the MACBETH system [5],
  - the VISA system [6], and
  - the EXPERT CHOICE system [21].
- MCDSSs based on the outranking relations approach:
  - the PROMCALC and GAIA systems [7],
  - the ELECCALC system [27],
  - the PRIAM system [34], and
  - the ELECTRE TRI system [62].
- MCDSSs based on the preference disaggregation approach:
  - the PEFCALC system [22],
  - the MINORA system [51],

- the MIIDAS system [52], and
- the PREFDIS system [66].

Most of the existing MCDSSs are designed for the study of general multicriteria decision problems. Although they provide advanced capabilities for modeling the decision makers' preferences in order to make a specific decision regarding the choice of an alternative and the ranking or the classification of the alternatives, MCDSSs do not consider the specific characteristics, as well as the nature of the decision that should be taken according to the specific decision problem that is considered.

To address the unique nature of some significant decision problems, where except for the application of MCDA methodology, some other type of analyses are necessary to consider the environment in which the decision is taken, several authors proposed domain specific MCDSSs. Some decision problems for which specific MCDSSs have been developed include the assessment of corporate performance and viability (the BANKADVISER system [39], the FINCLAS system [65], the FINEVA system [68], and the system proposed in [53]), bank evaluation (the BANKS system [40]), bank asset liability management [33], financial planning [18], portfolio selection [67], new product design (the MARKEX system [42]), urban planning (the system proposed in [1]), strategic planning [9], and computer system design [15].

### Multicriteria Group Decision Support Systems

A common characteristic of all the aforementioned MCDSSs is that they refer to decisions that are taken by individual decision makers. However, in many cases the actual decision is not the responsibility of an individual, but instead there is a team of negotiating or cooperative participants who must conclude to a consensus decision. In this case, although the decision process and consequently the required decision support, remains the same, as far as each individual decision maker is concerned, the process that will lead the cooperative team or the negotiating parties to a consensus decision is completely different from the individual decision making process. Therefore, the type of support needed also differs.

Group DSSs (GDSSs) aim at supporting such decision processes, and since the tools provided by MCDA

can be extended to generalized group decision process, several attempts have been made to design and develop such multicriteria systems. Some examples of *multicriteria GDSSs* include the Co-oP system [8], the JUDGES system [12], the WINGDSS system [13], the MEDIATOR system [24], and the SCDAS system [35].

### Intelligent Multicriteria Decision Support Systems

Except for the extension of the MCDSSs framework in supporting group decision making, recently researchers have also investigated the extension of MCDSSs through the exploitation of the advances in the field of artificial intelligence. Scientific fields such as those of neural networks, expert systems, fuzzy sets, genetic algorithms, etc., provide promising features and new capabilities regarding the representation of expert knowledge, the development of intelligent and more friendly user interfaces, the reasoning and explanation abilities, as well as the handling of incomplete, uncertain and imprecise information.

These appealing new capabilities provided by artificial intelligence techniques can be incorporated in the existing MCDSSs framework to provide expert advice on the problem under consideration, assistance to the use of the several modules of the system, explanations concerning the results MCDA, models, support on structuring the decision making process, as well as recommendations and further guidance for the future actions that the decision maker should take in order to implement successfully his/her decisions. The terms '*intelligent multicriteria decision support systems*' or '*knowledge-based multicriteria decision support systems*' have been used by several authors to describe MCDSSs which take advantage of artificial intelligence techniques in combination with MCDA methods.

Some representative examples of intelligent MCDSSs are, the system proposed in [3] for multi-objective linear programming, the MARKEX system for new product design [42], the CREDEX system [45] and the CGX system [55] for credit granting problems, the MIIDAS system for estimating additive utility functions based on the preference disaggregation approach [52], the INVEX system for investment analysis [60] based on the PROMETHEE method, as well as the FINEVA system [68] for the assessment of corporate performance and viability. All these systems incor-

porate in their structure one or more expert system components either to derive estimations regarding the problem under consideration (FINEVA, MARKEX, CREDEX, CGX, INVEX systems) or to support the use of the MCDA models which are incorporated in the system and generally support and improve the communication between the user and the system (MIIDAS and MARKEX systems). Furthermore, the INVEX system incorporates fuzzy sets to provide an initial distinction between good and bad investment projects, so that the number of alternatives to be considered latter on in the multicriteria analysis module is reduced.

The ongoing research on the integration of artificial intelligence with MCDA regarding the theoretical foundations of this integration and the related implementation issues ([4,25]), the construction of fuzzy outranking relations ([14,41,50]), and the applications of neural networks in preference modeling and utility assessment ([38,56]) constitutes a significant basis for the design and development of intelligent MCDSSs implementing the theoretical findings of this research.

## Conclusions

This article investigated the potentials provided by MCDSSs in the decision making process. MCDSSs during the last two decades have consolidated their position within the operations research, information systems and management science communities as an efficient tool for supporting the whole decision making process beginning from problem structuring until the implementation of the final decision, in complex ill-structured problems.

The review which was presented in this paper reveals that recent advances in MCDSSs include systems for general use to solve both discrete and continuous MCDA problems, systems designed to study some specific real world decisions, as well as systems designed to support negotiation and group decision making.

As the computer science and technology progresses rapidly, new areas of applications of MCDSSs can be explored including their operation over the Internet to provide computer support to co-operative work of dispersed and asynchronous decision units. The incorporation of artificial intelligence techniques in the existing framework of MCDSSs also constitutes another significant area of future research. Although, as its has been

illustrated in this paper, researchers have already tried to integrate these two approach in an integrated intelligent system, there is a lot of work to be done in order to take the most out of the capabilities of neural networks, fuzzy sets and expert systems to provide user-friendly support in decision problems where multiple criteria are involved.

## Abstract

Stochastic multistage mean-variance optimization problems represent one of the most frequently used modeling tools for planning problems, especially financial. Decomposition algorithms represent a powerful tool for the solution of problems belonging to this class. The first aim of this article is to introduce multi-stage mean-variance models, explain their applications and structure. The second aim is the discussion of efficient solution methods of such problems using decomposition algorithms.

## Background

Stochastic programming (SP) is becoming an increasingly popular tool for modeling decisions under uncertainty because of the flexible way uncertain events can be modeled, and real-world constraints can be imposed with relative ease. SP also injects robustness to the optimization process. Consider the following standard “deterministic” quadratic program:

$$\begin{aligned} \min_x \quad & \frac{1}{2}x'Hx + c'x \\ \text{s.t.} \quad & Ax = b \\ & x^l \leq x \leq x^u. \end{aligned} \quad (1)$$

It is not always possible to know the exact values of the problem data of (1) given by  $H$ ,  $A$ ,  $c$ , and  $b$ . Instead, we may have some estimations in the form of data gathered either empirically or known to be approximated well by a probability distribution. The SP framework allows us to solve problems where the data of the problem are represented as functions of the randomness, yielding results that are more robust to deviations.

The power and flexibility of SP does, however, come at a cost. Realistic models include many possible events distributed across several periods, and the end result is a large-scale optimization problem with hundreds of thousands of variables and constraints. Models of this scale cannot be handled by general-purpose optimization algorithms, so special-purpose algorithms at-

tempt to take advantage of the specific structure of SP models. We examine two decomposition algorithms that had encouraging results reported in linear SP; the first is based on the regularized version of Benders decomposition developed by [21], and the second on an augmented-lagrangian-based scheme developed by [4].

Others [9,24,27] formulated multistage SP as a problem in optimal control, where the current stage variables depend on the parent node variables, and used techniques from optimal control theory to solve the resulting problem. Another related method is the approximation algorithm by [11] where a sequence of scenario trees is generated whose solution produces lower and upper bounds on the solution of the true problem. Decomposition algorithms are not, however, the only approach to tackle the state explosion from which SPs suffer; approximation algorithms and stochastic methods are just two examples of other methods where research is very active [5]. In this study, we are concerned only with decomposition methods.

## Problem Statement

We consider a quadratic multistage SP. In the linear case, SP was first proposed independently by [10] and [1]; for a more recent description see [7] and [13]. For two stages, the problem is:

$$\min_x \quad \frac{1}{2}x'Hx + c'x + Q(x) \quad (2a)$$

$$\text{s.t.} \quad Ax = b \quad (2b)$$

$$x^l \leq x \leq x^u. \quad (2c)$$

We use  $'$  to denote the transpose of a vector or a matrix.  $c$  and  $x^{u,l}$  are known vectors in  $\mathfrak{R}^{n_1}$ . Let  $A$  and  $H$  be known matrices in  $\mathfrak{R}^{m_1 \times n_1}$  and  $\mathfrak{R}^{n_1 \times n_1}$ . These quantities represent the state of the world that is known. We assume that  $H$  is positive semidefinite. The first two terms in the objective function (2a) model the goals of the decision maker that do not depend on uncertain events.  $Q(x)$  represents the expected value of the second-stage objective function:

$$Q(x) = E_{\xi}[Q(x, \xi(\omega))],$$

where

$$Q(x, \xi(\omega)) = \min_y \frac{1}{2}\alpha y'(\omega)H(\omega)y(\omega) - (1 - \alpha)c'(\omega)y(\omega) \quad (3)$$

$$s.t \quad W(\omega)y(\omega) = h(\omega) - T(\omega)x \tag{4}$$

$$y(\omega)^l \leq y(\omega) \leq y(\omega)^u. \tag{5}$$

Let  $\Omega$  be the set of all random events, and  $\omega \in \Omega$  be the particular realization of an event so that when  $\omega$  is known the random events are aggregated in the vector  $\xi(\omega) = [y(\omega), H(\omega), W(\omega), h(\omega), T(\omega), y^{u,l}(\omega)]$ , and let  $\mathcal{E}$  be the support of  $\xi$ . The uncertainty of the second stage is represented by the random data  $H(\omega), W(\omega)$ , and  $T(\omega)$ , which are matrices in  $\Re^{n_2 \times n_2}, \Re^{m_2 \times n_2}$ , and  $\Re^{m_2 \times n_1}$  respectively. The vectors  $c(\omega), h(\omega)$ , and  $y^{l,u}(\omega)$  are random vectors in  $\Re^{n_2}, \Re^{m_2}$ , and  $\Re^{n_2}$  respectively. We assume that the number of possible realizations of  $\omega$  is finite. Under this assumption,  $\xi(\omega)$  is taken to mean that for different  $\omega$ 's the data of the problem change. The dependence of  $y$  on uncertainty is depicted as  $y(\omega) \in \Re^{n_2}$ . The vector  $y(\omega)$  is still the decision variable but this notation is used to stress the point that for different realizations of  $\omega$  we must have a different  $y$ . In the objective function (3), the quadratic term represents the risk of the decision measured by variance, while the linear term represents the expected outcome. The scalar  $\alpha \in [0, 1]$  is used in (3) to describe the trade-off between risk expectation.

Deriving the multi-stage problem from the two-stage formulation is just a matter of applying the ideas described above recursively to attain the required number of stages. For the multistage problem with  $T_s$  periods, the first-stage decision remains the same but for  $t = 2 \dots T_s$  we have

$$Q_t(x_{t-1}) = E_{\xi_t} \left[ Q_t(x_{t-1}, \xi_t(\omega)) \right], \tag{6}$$

where

$$\begin{aligned} Q_t(x_{t-1}, \xi_t(\omega)) = \min_y & \alpha \frac{1}{2} y_t'(\omega) H_t(\omega) y_t(\omega) \\ & - (1 - \alpha) c_t' y_t(\omega) + Q_{t+1}(y_t(\omega)) \\ s.t \quad & W_t(\omega) y_t(\omega) = h_t(\omega) - T_{t-1}(\omega) x_{t-1} \\ & y_t(\omega)^l \leq y_t(\omega) \leq y_t(\omega)^u. \end{aligned} \tag{7}$$

For the last time period  $t = T_s$ , the recourse function  $Q_{T_s+1}$  is zero.

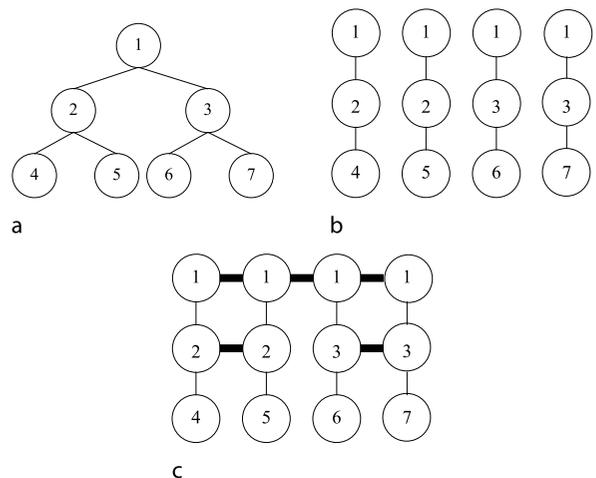

Our principal concern involves decomposition algorithms for (7). For more insight into the properties of stochastic quadratic problems the reader is referred

to [14], and [15]. Before we delve into decomposition algorithms, we introduce some terminology that will be used in the next section.

The dynamic programming model (7) is usually referred to as *non-anticipative*. This property means that decisions are based on the past and not the future. There are two ways this concept can be represented, namely compact and split-view formulations [20].

The compact variable formulation can be mapped directly onto a tree structure known as the *scenario tree*; see Fig. 1a. The root of the tree represents the state of the world that is deterministic. As we move down the scenario tree, different events represent different realizations of  $\omega$ , each level of the tree represents a different time period, and the path from the root to a leaf node is known as a *scenario*. We use  $v = (t, k)$  to denote the  $k$ th node in period  $t$ ,  $a(v)$  the ancestor node, and  $d(v)$  the descendant nodes. Benders decomposition, to be introduced in the next section, assumes such a structure and the result is a decomposition of the large scale problem into several subproblems, each representing a node in the tree.

In a split-variable formulation for each scenario, from the set of possible scenarios, new decision variables are introduced so that the large-scale problem is decomposed into  $n$  subproblems, where  $n$  is the number of scenarios. Conceptually, using this approach, the non-anticipative constraints are completely relaxed; see

**Decomposition Algorithms for the Solution of Multistage Mean-Variance Optimization Problems, Figure 1**  
**Different views on non-anticipativity**

Fig. 1b. To enforce these constraints, new constraints are introduced that “rebuild” the links between sub-problems, usually through some penalty function (see Fig. 1c).

## Methods

The importance of decomposition algorithms in SP was recognized early on, as results in the theory of stochastic programs are closely linked with their solution algorithms. The two algorithms described in this section represent two very promising approaches in decomposition of SPs.

### Nested Benders Decomposition (NBD)

Benders decomposition was first proposed in [2], and it has been applied to SP by [26]; it is usually referred to as the *L-shaped method* due to the structure of the constraint matrix. The extension to the non-linear convex case has been done in [12], and the extension to the general convex SP appears in [8]. The algorithm has also been widely studied for multistage problems in a parallel environment [6]. More recent studies appear in [18]. In [15] the quadratic case is also studied.

It can easily be seen that (2a) is equivalent to:

$$\begin{aligned} \min_{x, \theta} \quad & \frac{1}{2}x'Hx + c'x + e'\theta \\ \text{s.t.} \quad & Ax = b \\ & \theta \leq p_\omega Q(x, \xi(\omega)) \\ & x^l \leq x \leq x^u \end{aligned} \quad (8)$$

where  $e$  is a vector of ones. The dimension of the latter vector is equal to the number of nodes in the next period. The expression  $p_\omega Q(x, \xi(\omega))$  represents the value of the next stage decision if event  $\omega$  occurs (with probability  $p_\omega$ ). The dimensions of the rest of the data are the same as in (2a). Even though it is possible to aggregate the  $\theta$  vector to a single variable, computational studies [5,6] have shown that the reduction of variables did not enhance performance, possibly due to loss of information.

To represent the recourse function in (8), we construct an approximation using outer linearizations. This is achieved by computing cuts (cutting planes). There are two types of cuts: optimality and feasibility. Instead of solving the large-scale problem (8) we solve

the relaxed version

$$\begin{aligned} \min_x \quad & \frac{1}{2}x'Hx + c'x + e'\theta \\ \text{s.t.} \quad & Ax = b \\ & Dx \geq d \end{aligned} \quad (9a)$$

$$\theta \geq Gx + g \quad (9b)$$

$$x^l \leq x \leq x^u$$

where (9a) and (9b) represent feasibility and optimality cuts, respectively. The aim of these constraints is to approximate the feasible region of (8). Feasibility cuts are constructed as follows: Assuming that  $t = T$  and for a fixed  $\hat{\omega}$  the  $\nu$ th problem in (7) takes the following form:

$$\begin{aligned} Q(x) = \min_y \quad & \frac{\alpha}{2}y'Hy - (1 - \alpha)c'y \\ \text{s.t.} \quad & Wy = h - Tx_{a(\nu)} \\ & y^l \leq y \leq y^u \end{aligned} \quad (10)$$

Assume that this problem is infeasible due to the vector  $x_{a(\nu)}$  generated in a subproblem of a previous stage. Consider the following problem:

$$\begin{aligned} P(y, x_{a(\nu)}) = \min_y \quad & e'y^+ + e'y^- \\ \text{s.t.} \quad & Wy + y^+ - y^- = h - Tx_{a(\nu)} \end{aligned} \quad (11)$$

$$y^l \leq y \leq y^u \quad (12)$$

$$y^{+, -} \geq 0$$

Then since the original problem was infeasible due to  $x_{a(\nu)}$  we must have that  $P(\cdot, x_{a(\nu)}) > 0$ . Let  $\lambda$  be the Lagrange multiplier of the constraint in (11), then by duality we must also have that  $\lambda'(h - Tx_{a(\nu)}) \leq 0$ . Set  $D = \lambda'T$  and  $d = \lambda'h$  to obtain (9a), a supporting hyperplane to  $Q(x)$ . To apply this result when  $t \neq T$  just note that the same procedure is recursively applied by taking under consideration the additional constraints from cuts of other subproblems.

For optimality cuts, one proceeds as follows: again we start with the problem in (10) and let  $x_k$  be the solution vector of a subproblem in the previous stage. By the gradient inequality we must have that ( $\omega$  is dropped since it is clear from context):

$$Q(x) \geq Q(x_k) + \nabla Q(x_k)(x - x_k)$$

$$Q(x_k) = \frac{\alpha}{2}y'H y - (1 - \alpha)c'y + \lambda'(Wy - h + Tx_k)$$

$$\nabla Q(x_k) = \lambda'T$$

Thus

$$Q(x) \geq \lambda' T x + \frac{a}{2} y' H y - (1 - \alpha) c' y + \lambda' (W y - h)$$

Set

$$\theta = Q(x)$$

$$G = \lambda' T$$

$$g = \frac{\alpha}{2} y' H y - (1 - \alpha) c' y + \lambda (W y - h)$$

to obtain (9b). Since we require a lower support for the expected value, we then multiply  $G$  and  $g$  by the probability of  $\omega$  taking the particular realization of  $\hat{\omega}$  for two-stage problems and the conditional probability for multistage problems. The application of optimality cuts when  $t \neq T$  is again developed recursively just by taking into account the additional variables and constraints.

The algorithm proceeds by solving the relaxed problem (7) to obtain a solution vector, known as the *proposal vector*. The latter is then used to solve the subproblems in (10). If a subproblem is feasible then an optimality cut is appended to the constraint set of the ancestor problem (also called the *master problem*). Otherwise, only a feasibility cut is appended.

In the linear case, there are some well known drawbacks to the algorithmic framework developed above [5,21]. We expect issues similar to the following to manifest themselves in the quadratic case:

- The algorithm tends to be inefficient in early iterations due to the poor description of the original objective function provided by the cuts. Moreover, if a good warm-start is used, the algorithm may deviate significantly from this point, so any efficiency achieved by a good starting point is lost.
- The number of cuts for master problems may increase substantially, adding considerable computational burden to their solution.

For these reasons a regularized version of the algorithm was proposed in [21]; see also [22,23] for the multistage version. Ruszczyński's results, as well as a study performed in [28], indicate that the regularized version outperforms the original algorithm.

The basic idea is to add a quadratic term  $\rho \|x - \hat{x}\|_2^2$  in the objective function, where  $\hat{x}$  is chosen as the "best" current point, in a way to be made precise, and  $\rho$  is a penalty parameter. For a high value of  $\rho$

the algorithm is penalized from deviating from the current point. In [21], the convergence of the algorithm for  $\rho = \frac{1}{2}$  was established for the convex case. The regularizing term stabilizes the behavior of the algorithm between iterations, enables valid deletion schemes of the cuts, and avoids degenerate iterations that would otherwise be possible.

The original problem is now decomposed into three types of subproblems. The first type is for the root node. The following problem is solved at each iteration:

$$\begin{aligned} \min_{x, \theta} \quad & \frac{1}{2} \alpha x' H x - (1 - \alpha) c' x + e' \theta + \frac{\rho}{2} \|x - \hat{x}\|_2^2 \\ \text{s.t.} \quad & A x = b \\ & G x \geq \theta + g \\ & D x \geq d \\ & x^l \leq x \leq x^u. \end{aligned}$$

The second type is for non-terminal nodes. The following subproblem needs to be considered:

$$\begin{aligned} \min_{y_v, \theta_v} \quad & \frac{a}{2} y_v' H_v y_v - (1 - \alpha) c_v' y_v \\ & + e' \theta_v + \frac{\rho_v}{2} \|y_v - \hat{y}_v\|_2^2 \\ \text{s.t.} \quad & W y_v = h_v - T_{a(v)} x_{a(v)} \\ & G_v y_v \geq \theta_v + g_v \\ & D_v y_v \geq d_v \\ & y_v^l \leq y_v \leq y_v^u. \end{aligned} \tag{13}$$

The third type is for terminal nodes. This type of subproblem is identical to (13) without, of course, the cuts in the constraint set and the regularizing term in the objective function.

The way cuts are recursively defined and the way subproblems are nested in each other has led this to be referred to as *nested Benders decomposition* (NBD). The algorithm can now be stated as follows:

**Step 1:** Set the iteration counter  $i = 0$  and  $t = k = 0$ , and let  $\hat{x}$  be a feasible point.

**Step 2:** Construct and solve  $v(t, k)$  to find the solution vector  $x_v^i$ .

**Step 2.1:** If the problem is infeasible and  $t = 0$  then STOP: the problem is infeasible.

**Step 2.2:** If the problem is infeasible and  $t > 0$ , generate an optimality cut (9a) and append it to the constraint set of  $a(v)$ .

**Step 2.3:** If the problem was optimal and  $t > 0$ , generate an optimality cut (9b) and append it to the constraint set of  $a(v)$ .

**Step 3:** Compute

$$\hat{F}(x_v^i) = \frac{1}{2}x'Hx + c'x + \sum_{j=d(v)} \theta_j$$

$$F(\hat{x}_v^i) = \frac{1}{2}x'Hx + c'x + \sum_{j=d(v)} Q_j(x).$$

If  $\hat{F} = F$  and  $t = k = 0$  then STOP:  $\hat{x}$  is optimal; Else go to step 4

**Step 4:** Update the regularizing term:

- 4.1 If a subproblem returned a feasibility cut then  $\hat{x}_v^{i+1} = \hat{x}_v^i$ .
- 4.2 If  $F(x_v^i) > F(\hat{x}_v^i)$  or  $F(x_v^i) > \tau F(\hat{x}_v^i) + (1-\tau)\hat{F}$ , then set  $\hat{x}_v^{i+1} = \hat{x}_v^i$ , and increase  $\rho$ .
- 4.3 If  $F(x_v^i) < F(\hat{x}_v^i)$  or  $F(x_v^i) < \tau F(\hat{x}_v^i) + (1-\tau)\hat{F}$ , then set  $\hat{x}_v^{i+1} = x_v^i$  and decrease  $\rho$ .
- 4.4 If  $F(x_v^i) = \hat{F}$ , then set  $\hat{x}_v^{i+1} = x_v^i$ , and decrease  $\rho$ .

**Step 5:** Set  $i = i + 1$ , find the next subproblem to solve (see below), and go to step 2.

### Augmented Lagrangian Decomposition (ALD)

An alternative algorithm to Benders decomposition described in the previous section is based on the augmented lagrangian and the method of multipliers [3]. The fundamental difference between NBD and ALD is the way the two algorithms attack non-anticipativity constraints. NBD handles these constraints by having a master problem generating proposals to the subproblems further down the event tree; proposal vectors are affected by “future” nodes by feasibility and optimality cuts. In ALD a different approach is taken: non-anticipativity constraints are relaxed by expressing the large-scale problem in terms of smaller subproblems that are discouraged from violating the original constraints. The algorithm we use was developed in [4], so here we only sketch the main idea. ALD was developed and applied to the stochastic quadratic programming setting in [25] with encouraging results. Similar algorithms to ALD have been developed for linear stochastic programs [16,17].

The expectation in (6) for a given time period can also be written as

$$\min_y \sum_{i=1}^m p_i \left( \frac{\alpha}{2} y_i' H_i y_i - (1-\alpha) c_i' y_i \right)$$

$$s.t. W_j y_i = h_j - T_j x_{a(i)} \quad j = 1 \dots r$$

$$y_i^l \leq y_i \leq y_i^u.$$
(14)

The problem in (14) is to be interpreted as follows: at the current time period there are  $m$  scenarios, each having different realizations for  $H$ ,  $W$ ,  $c$ , etc. There are  $r$  linking constraints (14) that are linked by the vector  $x_{a(i)}$ . In [4] the problem is decomposed by introducing a new variable  $z$  as follows

$$\min_{y,z} \sum_{i=1}^m p_i \left( \frac{\alpha}{2} y_i' H_i y_i - (1-\alpha) c_i' y_i \right)$$

$$s.t. W_{ji} y_i = z_{ij} \quad j = 1 \dots r; i \in I(j)$$

$$z_{ij} = h_j - T_j x_{a(i)} \quad j = 1 \dots r; i \in I(j)$$

$$y_i^l \leq y_i \leq y_i^u,$$
(15)

where  $I(j)$  contains the indices of the subproblems that the  $j$ th constraint “crosses”, i.e.,  $I(j) = \{i | w_{ji} \neq 0\}$ . “Crosses” means that a constraint contains data from more than one subproblem. It is obvious that (14) and (15) are exactly the same problem, but the structure of (15) facilitates a decomposition algorithm via the relaxation of the constraints of (15). In [4] the method of multipliers is used for the general problem  $\min\{f(x) | Ax = b\}$ . Let  $L_c(x, \lambda)$  denote the associated augmented lagrangian defined by  $L_c(x, \lambda) = f(x) + \lambda'(Ax - b) + \frac{\epsilon}{2} \|Ax - b\|_2^2$ , where  $\lambda$  is the vector of multipliers. The general algorithmic framework of the method of multipliers can be described as follows:

**Step 1:** Initialization: Set the iteration counter  $k = 0$ , and set  $c(0) > 0$ . Set  $x(0)$ , and  $\lambda(0)$  as the starting point for the decision variables, and lagrange multipliers, respectively.

**Step 2:** Compute the next point  $x(k+1) = \arg \min L_c(x, \lambda(k))$ .

**Step 3:** Update the Lagrange multiplier vector  $\lambda(k+1) = \lambda(k) + c(k)(Ax(k+1) - b)$ .

**Step 4:** Update the penalty parameter  $c(k)$ , and set  $k = k + 1$ . If some convergence criterion is not satisfied go to step 2.

Applying this general algorithmic framework to (15), the problem is decomposed into  $m$  subproblems and the non-anticipativity constraints are enforced through the penalty term in the augmented lagrangian.

The computation for the solution of (15) involves keeping  $z$  fixed in order to compute the next incumbent for  $y$ , and then keeping  $y$  fixed in order to compute the next incumbent for  $z$ . Thus, at the  $k$ th iteration the following subproblems are solved:

$$\begin{aligned}
 y_i(k+1) &= \arg \min_{\xi} \left\{ p_i \left( \frac{\alpha}{2} \xi_i' H_i \xi_i - (1-\alpha) c_i' \xi_i \right) \right. \\
 &\quad \left. + \sum_{\{j|i \in I(j)\}} (\lambda'_{ji}(k) W_{ji} \xi_i) \right. \\
 &\quad \left. + \frac{c(k)}{2} (W_{ji} \xi_i - z_{ji})^2 \right\} \\
 &\quad \forall i = 1, \dots, n \\
 z_{ji}(k+1) &= \arg \min_{\zeta_{ji}} \left\{ - \sum_{i \in I(j)} \lambda'_{ji}(k) \zeta_{ji} + \frac{c(k)}{2} \right. \\
 &\quad \left. \cdot \sum_{i \in I(j)} (W_{ji} \xi_i - \zeta_{ji})^2 \right\} \quad \forall j = 1, \dots, r \\
 &\quad \text{s.t } \zeta_{ji} = h_j - T_j x_{a(i)} \quad i \in I(j)
 \end{aligned}$$

followed by an update of the lagrange-multiplier vector  $\lambda_{ji}(k+1) = \lambda_{ji}(k) + c(k)(W_{ji} y_i(k+1) - z_{ji}(k+1))$ . From a computational point of view the above iterative framework is inefficient because of the alternate minimizations required, making this algorithm unsuitable for a parallel environment. In our implementation we used the more efficient iteration proposed in [4]:

$$\begin{aligned}
 y_i(k+1) &= \arg \min_{\xi} \left\{ p_i \left( \frac{\alpha}{2} \xi_i' H_i \xi_i - (1-\alpha) c_i' \xi_i \right) \right. \\
 &\quad \left. + \sum_{\{j|i \in I(j)\}} (\lambda'_j(k) W_{ji} \xi_i) \right. \\
 &\quad \left. + \frac{c(k)}{2} (W_{ji} (\xi_i - y_i(k)) + w_j)^2 \right\} \quad (16)
 \end{aligned}$$

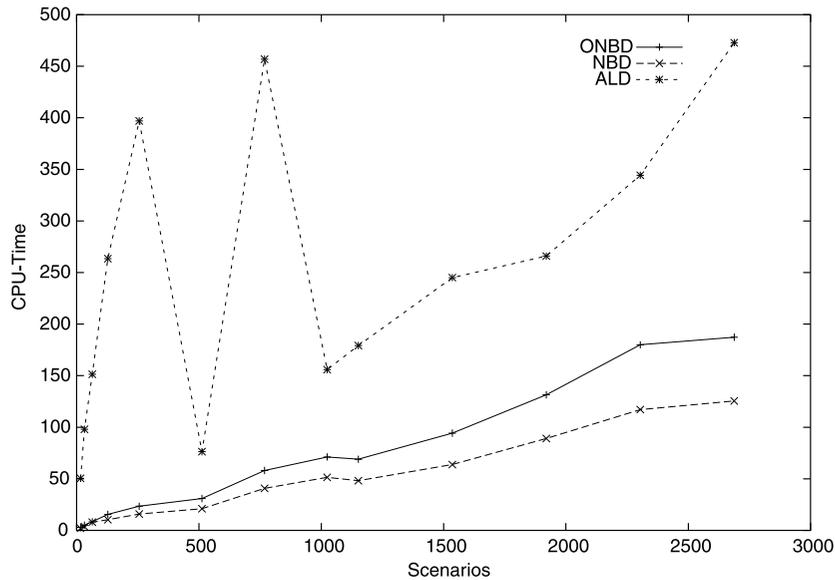

where  $w_j = \frac{1}{m_j} (W_j y_i - h_j + T_j x_{a(i)})$ ,  $\lambda_j(k+1) = \lambda_j(k) + \frac{c(k)}{m_j} (W_j y_i - h_j + T_j x_{a(i)})$ , and  $m_j$  denotes the cardinality of  $I(j)$ . The derivation of this iteration is discussed in Bertsekas and Tsitsiklis ([4], p. 249). The expression in (16) forms the main iteration of the ALD

algorithm. In order to have a complete description of the algorithm we need to specify how one can perform the updates of the penalty parameter  $c(k)$  and how we tested for convergence.

The obvious convergence criteria for ALD are a test for feasibility and small changes in the objective function. However, it is possible, due to a poor selection of updates for  $c(k)$ , to reach a suboptimal solution. For this reason, it is vital to check the KKT conditions of the problem in addition to any other stopping criteria. If the KKT conditions are not satisfied while the change in the objective function is small ( $10^{-6}$  in our implementation), the update strategy for the penalty parameter appears to have been inappropriate. We performed various experiments with different update strategies for this penalty parameter and found that the strategy that works best on most problems is to start with a small value (0.001) and increase it at every iteration by another small factor (1.05); being more aggressive with the update of this parameter caused the algorithm to terminate prematurely. Note that an arbitrary starting point can be used to start the algorithm. If a feasible solution or the solution from a previous run is available it may be beneficial to start with a higher penalty term.

## Numerical Experiments

The two algorithms were implemented and tested on a multistage financial planning problem. The detailed results can be found in [19]. Figure 2 summarizes the numerical performance (in terms of CPU time) as the number of scenario increases. ALD, and NBD stand for Augmented Lagrangian Decomposition, and Nested Benders Decomposition respectively. ONBD refers to Ordinary Nested Benders Decomposition, i.e. NBD without the regularizing term. From Fig. 2 it is clear that the regularized version of Benders decomposition is the most efficient of the algorithms we considered in this article. This result is in line with similar studies performed in the linear setting. One possible explanation is that the NBD algorithm takes advantage of the constraint structure of multistage stochastic programming problems more effectively. Note that the ALD algorithm can be applied to separable convex problems with more general constraint structure while NBD will need to be modified in order to be applicable to other types of separable problems. SP problems are one of the

**Decomposition Algorithms for the Solution of Multistage Mean-Variance Optimization Problems, Figure 2**  
Solution times vs. number of scenarios

most frequently occurring class of large scale problems, so it is important to know whether cutting plane type algorithms or Lagrangian based algorithms take advantage of this structure more effectively. Based on the results of our experiments it seems that the NBD algorithm appears to be substantially better. Furthermore, we found that the penalty parameter often caused notable changes to the convergence times of both NBD and ALD. Finding an update scheme that works for all problems is a difficult task. In ALD the penalty parameter has two goals, one is forcing feasibility and the other of keeping iterations close to each other, thus a 'suboptimal' penalty update scheme may be more damaging than in NBD, this may give some insight to the difference in performance of the two algorithms. More detailed numerical experiments can be found in [19].

### References

In many nonconvex optimization problems the set of variables is partitioned into two groups such that the problem becomes much easier to solve when the variables in one group are held temporarily fixed. To exploit this structure, a method which has proved to be efficient is to *decompose* the problem into a sequence of easier subproblems involving only variables of the other group. The basic tool for this decomposition is the branch and bound (BB) concept.

## BB Procedure for Decomposition

Consider the nonconvex global optimization problem

$$\min \{F(x, y) : G(x, y) \preceq_K 0, x \in X, y \in Y\}, \quad (\text{P})$$

where  $X$  is a compact convex subset of  $\mathbb{R}^n$ ,  $Y$  is a closed convex subset of  $\mathbb{R}^p$ ,  $F: X \times Y \rightarrow \mathbb{R}$ ,  $G: X \times Y \rightarrow \mathbb{R}^m$ ,  $K$  is a closed convex cone in  $\mathbb{R}^m$  and  $\preceq_K$  is the partial ordering in  $\mathbb{R}^m$  induced by the cone  $K$ , i. e., such that  $y \preceq_K y' \Leftrightarrow y' - y \in K$ .

Problems of this form abound in applications such as pooling and blending in oil refining, optimal design of water distribution, structural design, signal processing, robust stability analysis and design of chips.

Suppose that by fixing  $x \in X$  problem (P) becomes an easier problem in  $y \in Y$ . Then, to take advantage of this property one can solve (P) by a BB algorithm with branching performed in the  $x$ -space.

Specifically, at iteration  $k$  of the BB procedure a collection  $S_k$  of partition sets in the  $x$ -space is considered, where for each partition set  $M \in S_k$  a number (lower bound)  $\beta(M) \in \mathbb{R} \cup \{+\infty\}$  has been computed such that

$$\beta(M) \leq \inf \{F(x, y) : G(x, y) \preceq_K 0, x \in M \cap X, y \in Y\}. \quad (1)$$

A partition set  $M_k \in \operatorname{argmin}\{\beta(M): M \in S_k\}$  is then further subdivided according to an exhaustive subdivision rule (e. g., the standard bisection rule, if rectangular subdivision is used), while the best feasible solution available  $(\bar{x}^k, \bar{y}^k)$  is recorded. By removing every  $M$  such that  $\beta(M) \geq F(\bar{x}^k, \bar{y}^k)$  the new collection  $S_{k+1}$  is formed. If  $S_{k+1} = \emptyset$ , the procedure terminates, concluding that the problem is infeasible if no feasible solution is available, or else that the current best feasible solution is actually an optimal one. Otherwise, the next iteration is started.

A key operation in this procedure is bounding:  $M \mapsto \beta(M)$ . It is assumed that this operation satisfies the following natural conditions:

- (a)  $M' \subset M \Rightarrow \beta(M') \geq \beta(M)$ ;
- (b)  $\beta(M) < +\infty \Rightarrow M \cap X \neq \emptyset$ .

When the BB procedure is infinite it generates a filter (an infinite nested sequence of partition sets)  $M_{k_\nu}, \nu = 1, 2, \dots$ , such that

$$\begin{aligned} \beta(M_{k_\nu}) &\leq \min(P) \quad \forall \nu, \\ M_{k_\nu} \cap X &\neq \emptyset \quad \forall \nu, \\ \bigcap_{\nu=1}^{+\infty} M_{k_\nu} &= \{x^*\}. \end{aligned} \quad (3)$$

The algorithm is said to be *convergent* if  $x^* \in X$  and

$$\min(P) = \min\{F(x^*, y): G(x^*, y) \leq_K 0, y \in Y\}, \quad (4)$$

so any optimal solution  $y^*$  of this problem yields an optimal solution  $(x^*, y^*)$  of (P).

The basic issue of this decomposition scheme is under which conditions the BB procedure described above is guaranteed to converge in sense (4).

First observe that, since  $M_{k_{\nu+1}} \subset M_{k_\nu}$  and hence,  $\beta(M_{k_{\nu+1}}) \geq \beta(M_{k_\nu})$ , we have from (3)

$$\beta(M_{k_\nu}) \nearrow \beta^* \leq \min(P). \quad (5)$$

**Theorem 1** *If  $\beta(M_k) = +\infty$  for some  $k$  then (P) is infeasible and the algorithm terminates. If  $\beta(M_k) < +\infty \forall k$ , then there is an infinite subsequence  $M_{k_\nu}, \nu = 1, 2, \dots$ , satisfying (3) and such that  $x^* \in X$ . If in ad-*

*dition*

$$\begin{aligned} \lim_{\nu \rightarrow +\infty} \beta(M_{k_\nu}) \\ = \min\{F(x^*, y): G(x^*, y) \leq_K 0, y \in Y\}, \end{aligned} \quad (6)$$

*then the BB decomposition algorithm is convergent.*

Condition (6) simply says that the lower bound must be *eventually exact* as  $k \rightarrow +\infty$ . Also note that for ensuring that  $x^* \in X$  the condition  $x \in M \cap X$  in (1) is essential and cannot be omitted.

### Convergence Achieved with Lagrangian Bounds

In many important cases *Lagrangian bounds* can be used throughout the decomposition algorithm, so that for every partition set  $M$ :

$$\begin{aligned} \beta(M) = \sup_{\lambda \in K^*} \inf\{F(x, y) + \langle \lambda, G(x, y) \rangle: \\ x \in M \cap X, y \in Y\}, \end{aligned} \quad (7)$$

where  $K^* = \{\lambda \in \mathbb{R}^m: \langle \lambda, u \rangle \geq 0 \forall u \in K\}$  is the dual cone of  $K$ .

For every  $t \geq 0$  define

$$v(t) = \sup_{\lambda \in K^*} \inf_{\substack{y \in Y \\ \|x - x^*\| \leq t, x \in X}} \{F(x, y) + \langle \lambda, G(x, y) \rangle\}, \quad (8)$$

where, as throughout in what follows,  $x^*$  denotes the limit point of an exhaustive filter of partition sets generated by the BB algorithm, i. e., an infinite nested sequence  $\{M_{k_\nu}\}$  such that  $\bigcap_{\nu=1}^{+\infty} M_{k_\nu} = \{x^*\}$ .

**Theorem 2** *Assume Lagrangian bounds are used throughout the BB decomposition algorithm, and:*

(A1)  $v(t) \rightarrow v(0)$  as  $t \searrow 0$ .

(A2)  $\sup_{\lambda \in K^*} \inf_{y \in Y} \{F(x^*, y) + \langle \lambda, G(x^*, y) \rangle\} = \min_{y \in Y} \sup_{\lambda \in K^*} \{F(x^*, y) + \langle \lambda, G(x^*, y) \rangle\}$ .

*Then the BB decomposition algorithm is convergent.*

Condition A1 expresses the continuity of  $v(t)$  at  $t = 0$ . Condition A2 requires that the duality gap be zero for the subproblem  $\min_{y \in Y} \{F(x^*, y): G(x^*, y) \leq_K 0\}$ .

**Theorem 3** *Assume that  $F(x, y), G_i(x, y), i = 1, \dots, m$ , are lower semi-continuous and:*

(i) *There exists a compact set  $Y^0 \subset Y$  such that*

$$\begin{aligned} (\forall x \in X)(\forall \lambda \in K^*) \\ Y^0 \cap \operatorname{argmin}_{y \in Y} \{F(x, y) + \langle \lambda, G(x, y) \rangle\} \neq \emptyset; \end{aligned} \quad (9)$$

$$(ii) \sup_{\lambda \in K^*} \inf_{y \in Y} \{F(x^*, y) + \langle \lambda, G(x^*, y) \rangle\} = \min_{y \in Y} \sup_{\lambda \in K^*} \{F(x^*, y) + \langle \lambda, G(x^*, y) \rangle\}.$$

Then the BB decomposition algorithm using Lagrangian bounds is convergent. Furthermore, the function  $x \mapsto \sigma(x) := \min\{F(x, y) : G(x, y) \leq_K 0, y \in Y\}$  is lower semicontinuous at  $x^*$  and satisfies

$$\lim_{\substack{x \in X \\ x \rightarrow x^*}} \sigma(x) = \min(P). \quad (10)$$

**Remark 1** Condition (i) cannot be replaced by the following weaker one

(\*) There exists a compact set  $Y^0 \subset Y$  such that for each  $\lambda \in \mathbb{R}_+^m$  and for each  $x \in X$  either the set of optimal solutions of the problem

$$\min\{F(x, y) + \sum_{i=1}^m \lambda_i G_i(x, y) : y \in Y\} \quad (11)$$

is empty or it has a nonempty intersection with  $Y^0$ .

### Partly Convex Optimization Problems

An important class of problems (P) is constituted by *partly convex problems*, i. e., problems (P) with the following assumption:

(PCA) For every fixed  $x \in X$  the function  $y \mapsto F(x, y)$  is convex, while the mapping  $y \mapsto G(x, y)$  is  $K$ -convex. The latter means that  $G(x, \alpha y^1 + (1 - \alpha)y^2) \leq_K \alpha G(x, y^1) + (1 - \alpha)G(x, y^2)$  whenever  $y^1, y^2 \in \mathbb{R}^p, 0 \leq \alpha \leq 1$ .

Owing to (PCA), for every  $\lambda \in K^*$  and fixed  $x \in X$  the function  $\langle \lambda, G(x, y) \rangle$  is convex and the problem  $\min\{F(x, y) + \langle \lambda, G(x, y) \rangle : y \in Y\}$  is a convex optimization problem. Specific decomposition methods for this class of problems were developed earlier in [3,4], and more recently in [1]. Within the present framework, the convergence conditions can be specialized as follows.

A function  $f : Y \rightarrow \mathbb{R}$  is said to be *coercive* on  $Y$  if  $\lim_{y \in Y, y \rightarrow +\infty} f(y) = +\infty$ . Clearly this is equivalent to saying that for any  $\eta \in \mathbb{R}$  the set  $\{y \in Y : f(y) \leq \eta\}$  is bounded.

**Theorem 4** Assume (PCA) with  $F(x, y), G_i(x, y), i = 1, \dots, m$ , is lower semi-continuous on  $X \times Y$  and continuous in  $x$  for fixed  $y \in Y$ . Assume further that:

(S) For some  $\lambda^* \in K^*$  the function  $y \mapsto F(x^*, y) + \langle \lambda^*, G(x^*, y) \rangle$  is coercive on  $Y$ .

Then the BB decomposition algorithm using Lagrangian bounds is convergent and the function  $\sigma(x) := \min\{F(x, y) : G(x, y) \leq_K 0, y \in Y\}$  is lower semicontinuous at  $x^*$  and satisfies

$$\lim_{\substack{x \in X \\ x \rightarrow x^*}} \sigma(x) = \min(P).$$

**Remark 2** Condition A2, sometimes referred to as *dual properness* at  $x^*$ , means that the subproblem  $\min\{F(x^*, y) : G(x^*, y) \leq_K 0, y \in Y\}$  has zero duality gap. When  $Y$  is bounded, condition (S) obviously holds, so by Theorem 4, both conditions A1 and A2 follow from (PCA) and the lower semicontinuity of  $F(x, y), G_i(x, y), i = 1, \dots, m$ . On the other hand, when  $Y$  is unbounded, dual properness (i. e., condition A2), even coupled with continuity of the functions involved, is not sufficient to guarantee condition A1. These results suggest that several methods developed in the literature for problems of the form (P) should be revised for validity.

### Partly Linear Optimization

A subclass of the class of partly convex optimization problems is formed by partly linear optimization problems which have the general formulation

$$\min\{\langle c(x), y \rangle + \langle c^0, x \rangle : A(x)y + B(x) \leq b, r \leq x \leq s, y \geq 0\}, \quad (\text{GPL})$$

where  $x \in \mathbb{R}^n, y \in \mathbb{R}^p, c : \mathbb{R}^n \rightarrow \mathbb{R}^p, c^0 \in \mathbb{R}^n, A : \mathbb{R}^n \rightarrow \mathbb{R}^{m \times p}, B \in \mathbb{R}^{m \times n}, b \in \mathbb{R}^m, r, s \in \mathbb{R}_+^n$ .

A special case of interest is the “pooling and blending problem” from the petrochemical industry which can be stated as

$$\min\{c^T y : A(x)y \leq b, y \geq 0, x \in X\},$$

where  $X$  is a box in  $\mathbb{R}^n$  and  $A(x)$  is an  $m \times p$  matrix whose elements  $a_{ij}(x)$  are continuous functions of  $x$ . Condition (S) in Theorem 4 now reads

$$\begin{aligned} &\text{For some } \lambda^* \in \mathbb{R}_+^m \\ &\text{we have } c^T y + \lambda^*, A(x^*)y - b \rightarrow +\infty \\ &\text{as } y \rightarrow +\infty, \end{aligned}$$

which clearly holds if and only if  $\langle A(x^*), \lambda^* \rangle + c > 0$ . For example this condition is fulfilled by the partly linear problems considered in [1], and also by the bilinear matrix inequalities problem studied in [5].

## Extensions

The above decomposition method can be extended to a number of important nonconvex global optimization problems.

## Partly Monotonic Optimization

A function  $f(x): \mathbb{R}^n \rightarrow \mathbb{R}$  is said to be increasing (decreasing, respectively) if  $f(x) \leq f(x')$  ( $f(x) \geq f(x')$ , respectively) whenever  $x \leq x'$  [7].

**Theorem 5** In problem (P) assume that  $X = [a, b] \subset \mathbb{R}_+^m$ ,  $F(x, y)$ ,  $G(x, y)$  are continuous, and

(PMA)  $F(x, y)$ ,  $G_i(x, y)$ ,  $i = 1, \dots, m$ ,  
are increasing in  $x \in [a, b]$  for every fixed  $y \in Y$ .

Assume further that the set  $\{y \in Y: G(b, y) \leq_K 0\}$  is contained in some box  $Y^0$ . Then, with lower bounds defined as

$$M = [r, s] \subset [a, b] \mapsto \beta(M) = \min\{F(r, y): G(s, y) \leq_K 0, y \in Y\}, \quad (12)$$

the BB decomposition algorithm is convergent.

If  $F(x, y)$ ,  $G_i(x, y)$ ,  $i = 1, \dots, m$ , are monotonic in  $y \in Y^0$  (or more generally, dm functions in  $y \in Y^0$  [7]) then the subproblems in (12) are standard monotonic (or dm) optimization problems and can be solved by currently available algorithms [7,10].

*Remark 3* Theorem 5 still holds if  $F(x, y)$ ,  $G_i(x, y)$ ,  $i = 1 \dots, m$  are decreasing in  $x \in [a, b]$  for fixed  $y \in Y$  and we define

$$\beta(M) = \min\{F(s, y): G(r, y) \leq_K 0\}.$$

## Monotonic/Convex Optimization

**Theorem 6** In problem (P) assume  $X \subset [a, b]$ ,  $F(x, y)$ ,  $G_i(x, y)$ ,  $i = 1, \dots, m$ , are continuous in  $(x, y)$ , increasing in  $x \in [a, b]$  for fixed  $y \in Y$ , and convex (affine, respectively) in  $y$  for fixed  $x \in [a, b]$ . Assume, in addition, that

(ST) For some  $\lambda^* \in K^*$   
the function  $F(a, y) + \langle \lambda^*, G(a, y) \rangle$  is coercive on  $Y$ .

Then for every  $M = [r, s] \subset [a, b]$ , the Lagrangian bound problem

$$\sup_{\lambda \in K^*} \inf_{\substack{x \in M \cap X \\ y \in Y}} F(x, y) + \langle \lambda, G(x, y) \rangle \quad (13)$$

is a convex (linear, respectively) program and the associated BB decomposition algorithm is convergent.

Optimization; Decomposition

A frequently applied approach in the history of optimization is that of decomposition, by which a large problem is decomposed into smaller problems. The principle of decomposition goes back to the seminal paper by G.B. Dantzig and P. Wolfe [2].

The basic model is a linear programming problem with two sets of constraints to be stated as follows:

$$\begin{cases} \max & cx \\ \text{s.t.} & A_1x \leq b_1 \\ & A_2x \leq b_2 \\ & x \geq 0. \end{cases} \quad (1)$$

where  $c \in \mathbf{R}^n$ ,  $A_1 \in \mathbf{R}^{m \times n}$ ,  $b_1 \in \mathbf{R}^m$ ,  $A_2 \in \mathbf{R}^{q \times n}$  and  $b_2 \in \mathbf{R}^q$  are given constants and  $x \in \mathbf{R}^n$  is a vector of variables.

The fundamental idea is to solve (1) by interaction between two optimization problems, one of which is subject to the first set of constraints and the other subject to the second set of constraints. Denote the second set by

$$X = \{x \geq 0: A_2x \leq b_2\}.$$

For simplicity we assume that  $X$  is bounded and nonempty. Hence  $X$  is a polytope. Let  $x^i$  denote an extreme point of  $X$  for  $i \in P$  where  $P$  is the index set of all extreme points. According to the Minkowski representation theorem (see [1]), the polytope  $X$  can alternatively be represented as the convex hull of the extreme points, i. e.

$$X = \left\{ x = \sum_{i \in P} \lambda_i x^i : \sum_{i \in P} \lambda_i = 1, \lambda_i \geq 0 \text{ for } i \in P \right\}.$$

If  $X$  is unbounded extreme rays are introduced in the representation of  $X$  leading to a straightforward extension of the subsequent considerations.

Hence (1) is equivalent to

$$\begin{cases} \max & \sum_{i \in P} cx^i \lambda_i \\ \text{s.t.} & \sum_{i \in P} A_1 x^i \lambda_i \leq b_1 \\ & \sum_{i \in P} \lambda_i = 1 \\ & \lambda_i \geq 0. \end{cases} \quad (2)$$

Problem (2) operates with fewer rows than the original formulation (1). The variable  $x$  has been substituted by the variables  $\lambda_i$ . However, since the number of extreme points is usually very large in comparison with the dimension  $n$  of the problem, the number of  $\lambda$ -variables may also be very large, and it requires a big effort to enumerate and calculate all extreme points. Fortunately, this is unnecessary. In fact, by the Caratheodory theorem, at most  $n + 1$  extreme points need to be considered, see for example [1]. The trouble is to find the correct ones.

Problem (2) is called the *full master problem* since all extreme points are introduced in the formulation. As already indicated we shall consider formulations dealing with only a subset of extreme points. For this purpose let  $\bar{P}$  denote a subset of the index set  $P$  leading to a tightening of (2), called the *restricted master problem*.

$$\begin{cases} \max & \sum_{i \in \bar{P}} cx^i \lambda_i \\ \text{s.t.} & \sum_{i \in \bar{P}} A_1 x^i \lambda_i \leq b_1 \\ & \sum_{i \in \bar{P}} \lambda_i = 1 \\ & \lambda_i \geq 0 \text{ for } i \in \bar{P}. \end{cases} \quad (3)$$

Assume here for simplicity that (3) is feasible. If not, additional techniques exist and may be applied to make the problem feasible. So an optimal basic solution exists together with optimal dual variables to be denoted by  $y \in \mathbf{R}^m$  and  $v \in \mathbf{R}$  according to the  $m + 1$  rows of (3). By linear programming duality there exists a dual linear programming problem of the full master problem (2) with the variables  $(y, v)$  and with constraints

$$yA_1x^i + v \geq cx^i \quad \text{for all } i \in P. \quad (4)$$

Also by linear programming we know that an optimal solution has been found for the full master problem (2) if and only if the dual solution  $(y, v)$  satisfies (4). This may of course be checked through examination of all extreme points  $x^i$ . Fortunately, this is not necessary and here comes the major idea behind the decomposition principle. Instead we consider the following linear programming problem, the so-called *subproblem*.

$$\begin{cases} u = \max & (c - yA_1)x \\ \text{s.t.} & A_2x \leq b_2 \\ & x \geq 0. \end{cases} \quad (5)$$

**Decomposition Principle of Linear Programming, Table 1**

Step 1	Calculate an optimal dual solution $(y, v)$ of the restricted master problem (3).
Step 2	Determine an extreme point by solving the subproblem (5). If (6) is violated expand the index set $\bar{P}$ by including the extreme point and go to Step 1.
Step 3	An optimal solution has been obtained by the solution of the last master problem as $x = \sum_{i \in \bar{P}} x^i \lambda_i$

By assumption an optimal solution exists among the extreme points of  $X$ . Let  $i^* \in P$  denote the index of an optimal extreme point. Observe that the objective function calculates the maximal value  $u$  of  $cx^i - yA_1x^i$  among all extreme points  $x^i$  in  $X$ . Hence by (4) it remains to check if

$$u \leq v. \quad (6)$$

If so, then all constraints of (4) are satisfied and we may stop. Otherwise introduce the elements  $(cx^{i^*}, A_1x^{i^*})$  as a new column in the restricted masterproblem (3) and continue by solving it.

The above discussion can be summarized into the *algorithm* in Table 1.

The number of extreme points in  $X$  is finite. Hence only a finite number of mutually different columns may be introduced in the restricted master problem. This implies that the algorithm must terminate in a finite number of steps.

The decomposition principle is suited to solve large scale problems. Moreover it has a nice economic interpretation. Consider a central level and a sublevel of a decentralized organization. The central level operates on the first set of constraints  $A_1x \leq b_1$  and the sublevel on the second set of constraints  $A_2x \leq b_2$ . The right hand sides  $b_1, b_2$  may be interpreted as resources for the central level and sublevel, respectively. During the course of the algorithm information is communicated from one level to the other. The central level solves the restricted master problem and as a result marginal prices  $y$  on central resources are communicated to the sublevel. The sublevel solves the subproblem in which the objective function incorporates the costs for utilization of the central resources. The sublevel then suggests activities  $x^i$  to be incorporated at central level. During

the iterations no direct information about the coefficients in the constraints is communicated between the central level and the sublevel. Instead price information is communicated from the central level to the sublevel and the algorithm is the fundamental method among the so-called price-directive procedures.

In most applications the last set of constraints,  $A_2x \leq b_2$  have a so-called *block-angular structure*, in which the variables are grouped into independent blocks. This implies that the subproblem separates into multiple independent problems. In an economic context the block-angular structure reflects a division of the sublevel into multiple independent sublevels, each of which communicates directly with the central level.

A counterpart of the present Dantzig–Wolfe decomposition procedure exists in the form of Benders decomposition. In linear programming they are dual in the sense that application of Benders decomposition on the dual program of the original problem (1) is equivalent to the direct application of the present procedure on (1).

Decomposition; Lagrangian relaxation; Lagrangian decomposition

A large number of combinatorial optimization problems can be viewed as potentially ‘easy’ problems to solve that are complicated by a set of side constraints. If the complicating constraints were removed, the resulting problem would have constraints possessing a high degree of structure, for which many efficient algorithms exist. One of the most attractive methods to exploit this property is the Lagrangian relaxation technique, in which the complicating constraints are dualized and then removed from the constraint set. This class of methods, originally proposed by various authors for a variety of problems, and later generalized in [3], has proven highly successful in solving otherwise difficult combinatorial problems. For an excellent introduction to the approach and its applications, see [1,2].

Consider the following problem (P):

$$\max f^\top x \quad (1)$$

such that

$$Ax \leq b \quad (2)$$

$$Cx \leq d \quad (3)$$

$$x \in X, \quad (4)$$

where  $x$  is an  $n$ -vector,  $b$  is an  $m$ -vector and  $d$  is a  $k$ -vector, and  $f$ ,  $A$  and  $C$  have conformable dimensions. Some or all of the  $x$  variables can be integers (i. e.  $X \subseteq Z^n$ ). It is assumed that there is a finite and nonempty set of solutions to the constraints in the problem (2)–

(4). Let (LP) represent problem (P) with any integrality constraints in  $X$  removed.

The following notation is used in the sequel. For any problem  $(\cdot)$ ,  $OS(\cdot)$  is its optimal set, and  $V(\cdot)$  represents its optimal value. For any set  $S$ ,  $Co(S)$  represents the convex hull of the set.

The *Lagrangian relaxation*  $(LR_u)$  of (P) relative to the constraint set (2) and a conformable nonnegative vector  $u$  is defined as

$$\begin{cases} \max_x & f^\top x + u(b - Ax) \\ \text{s.t.} & Cx \leq d \\ & x \in X. \end{cases}$$

The problem

$$(LR) = \min_{u \geq 0} (LR_u)$$

is called the *Lagrangian dual* relative to (2). The constraints (2) are referred to as the ‘dualized constraints’, and  $u$  is the corresponding multiplier or dual vector. The constraints should be chosen so that the remaining set  $Cx \leq d$  possesses desirable structure. For example, (3) might only specify upper bounds on the variable, or might be a single ‘knapsack’ constraint of the form  $\sum_{i=1}^n x_i \leq 1$ .

The first point to note about  $(LR_u)$  is that it always provides an upper bound for (P), i. e.

$$V(LR_u) \geq V(P).$$

This can easily be seen from the fact that  $u \geq 0$  and  $Ax \leq b$  for any solution  $x$  which is optimal for (P). In practice, it is desirable to have  $V(LR_u)$  as close to  $V(P)$  as possible. Moreover, there is already an LP relaxation of (P), obtained by dropping the integrality requirement on  $x$ . How does  $V(LR_u)$  relate to  $V(LP)$ ? To answer this question, consider the following relaxation of (P), denoted by  $(P^*)$ :

$$\begin{cases} \max & f^\top x \\ \text{s.t.} & Ax \leq b \\ & x \in Co\{Cx \leq d: x \in X\}. \end{cases}$$

It can be shown ([3]) that

$$V(P) \leq V(P^*) = V(LR) \leq V(LP).$$

The equality for the optimal values of problems  $(P^*)$  and (LR) follows from the fact that they are duals of each other. Moreover, it can be shown that if the multipliers for the constraints obtained from solving the LP relaxation were used, the resulting Lagrangian relaxation provides a bound at least as tight as the bound from (LP). Also, if  $\bar{u}$  is an optimal solution for (LR), with  $A\bar{x} \leq b$  and  $u(A\bar{x} - b) = 0$ , then  $\bar{x}$  is optimal for  $(P)$ .

When are the inequalities above strict? This can be shown through the following *integrality property*, again due to [3]: The optimal value of  $(LR_u)$  is not changed by dropping the integrality condition on the  $x$  variables.

If the integrality property (also referred to as the *complementary slackness property*) holds, then

$$V(P) = V(P^*) = V(LR) = V(LP).$$

In this case, therefore, Lagrangian relaxation can do no better than the standard LP relaxation for  $(P)$ . For a large number of practical problems, however, this property does not hold. This fact allows  $(LR_u)$  to be used in place of (LP) to provide lower bounds in a branch and bound algorithm.

### Lagrangian decomposition

A drawback of the Lagrangian relaxation (LR) described above is that only one of the possibly many special structured constraint sets embedded in the problem can be exploited. This results in the loss of structure of all the dualized constraints. One way to avoid this is to use Lagrangian decomposition ([4,5,6,7]).

Introducing a new set of ‘copy’ constraints  $y = x$ , problem  $(P)$  is equivalent to

$$\max_{x,y} f^T x$$

such that

$$Ay \leq b \quad (5)$$

$$Cx \leq d \quad (6)$$

$$y = x \quad (7)$$

$$x \in X, \quad y \in Y, \quad (8)$$

where  $X \subseteq Y$ . Dualizing the ‘copy’ constraints (7) results in

$$\max f^T x + v(y - x)$$

such that

$$Ay \leq b \quad (9)$$

$$Cx \leq d \quad (10)$$

$$x \in X, y \in Y, \quad (11)$$

which can be decomposed to the following problem  $(LD_v)$ :

$$\left\{ \begin{array}{ll} \max_x & F_1(x) \\ \text{s.t.} & Cx \leq d \\ & x \in X \end{array} \right\} + \left\{ \begin{array}{ll} \max_y & F_2(y) \\ \text{s.t.} & Ay \leq b \\ & y \in Y \end{array} \right\},$$

where  $F_1(x) = (f - v)^T x$  and  $F_2(y) = v^T y$ . The Lagrangian decomposition dual (LD) can then be defined to be

$$\min_{v \geq 0} V(LD_v)$$

If  $\bar{u}$  is an optimal solution to (LR), then, with  $\bar{v} = \bar{u} \cdot A$ , it can be shown that

$$V(LD_{\bar{v}}) = V(LR_{\bar{u}}) - \bar{u}(b - A\bar{y})$$

and therefore

$$V(LD) \leq V(LR).$$

It is possible to define an integrality property ([5]) such that if either the  $x$ - or the  $y$ -problem has the property, then  $V(LD)$  will be equal to the stronger of the bounds obtained from the two Lagrangian relaxations corresponding to each set of constraints.

Lagrangian decomposition (LD) has several advantages over (LR). Every constraint in the original problem appears in one of the subproblems. It thus avoids having to choose between the various sets of structured constraints. Secondly, as shown above, the bounds from (LD) can be tighter than those from (LR). Furthermore, the bound can be tightened by adding surrogate constraints (for example, a surrogate constraint from  $Ax \leq b$  can be added to the  $x$ -problem in (LD)). Thirdly, analogous to (LR), it can be shown that (LD) is really the

dual of a primal problem involving the optimization of the original objective function over the intersection of the convex hulls of the two constraint sets. Finally, empirical results suggest that when using heuristics based on Lagrangian decomposition, any intermediate solutions found in the solution of (LD) lead to better solutions for problem (P) as compared to solutions found by Lagrangian relaxation.

### Aggregation Schemes

The main drawback of the Lagrangian decomposition method is that a large number of multipliers ( $\nu$ ) are introduced, one for each of the copy variables. The calculation of  $\nu$  can be time consuming at each step. Moreover, the convergence of the scheme can be slowed significantly by the larger number of directions (for the multipliers) to search. In order to avoid this, an alternate approach that has been suggested [8] is to aggregate some or all of the variables using a simplified linear function, and then to dualize the resulting copy constraints. The purpose of the aggregation is to substantially reduce the number of dual variables, while still maintaining the constraint structure as in the standard decomposition.

Let  $A \equiv [A_1 \mid A_2]$ , and  $x \equiv \begin{pmatrix} x^1 \\ x^2 \end{pmatrix}$ , with  $x^1 \in \mathbf{R}^{n_1}$  and  $x^2 \in \mathbf{R}^{n-n_1}$ . Introduce the copy variables  $y \equiv \begin{pmatrix} y^1 \\ y^2 \end{pmatrix} = x$  and the constraints

$$x^1 = y^1 \quad \text{and} \quad A_2 x^2 = g(y^2),$$

where  $g(\cdot)$  is the *aggregation function* (for example,  $g(y^2) = A_2 y^2$ , or  $g(y^2) = y^2$ ). Then, the problem (P) can be written as

$$\max f^\top x$$

such that

$$A_1 y^1 + g(y^2) \leq b \quad (12)$$

$$Cx \leq d \quad (13)$$

$$x^1 = y^1 \quad (14)$$

$$A_2 x^2 = g(y^2) \quad (15)$$

$$x \in X, \quad y \in Y, \quad (16)$$

where  $X \subseteq Y$ . Dualizing the constraints (14) and (15) leads to

$$\begin{cases} \max & f^\top x + w^1(y^1 - x^1) + w^2(g(y^2) - A_2 x^2) \\ \text{s.t.} & A_1 y^1 + g(y^2) \leq b \\ & Cx \leq d \\ & x \in X, \quad y \in Y, \end{cases}$$

which can be decomposed to the problem (LDA<sub>w</sub>), given by

$$\begin{cases} \max_x & F_1(x) \\ & Cx \leq d \\ & x \in X \end{cases} + \begin{cases} \max_y & F_2(y) \\ & A_1 y^1 + g(y^2) \leq b \\ & y \in Y, \end{cases}$$

where  $F_1(x) = f^\top x - w^1 x^1 - w^2 A_2 x^2$  and  $F_2(y) = w^1 y^1 + w^2 g(y^2)$ . The corresponding dual problem (LDA) is then defined by

$$\min_{w \geq 0} \text{LDA}_w$$

It can then be proved that for any optimal solution of (LR) defined by  $\bar{u} \in \text{OS}(\text{LR})$ , with  $\bar{w}_1 = \bar{u} A_1$  and  $\bar{w}_2 = \bar{u}$ ,

$$V(\text{LDA}_{\bar{w}}) \leq V(\text{LR}_{\bar{u}})$$

and therefore

$$V(\text{LDA}) \leq V(\text{LR}).$$

This inequality is strict only if the second subproblem in (LDA<sub>w</sub>) (i. e. the problem of maximizing  $F_2(y)$ ) does not satisfy the integrality (*complementary slackness*) property. Moreover, this inequality holds only for the Lagrangian relaxation with those constraints that have been aggregated. Any other Lagrangian relaxation defined for problem (P) by dualizing other sets of constraints will not necessarily satisfy this inequality.

Similarly, defining  $\bar{v} \equiv (\bar{w}^1, \bar{w}^2)^\top$ , it can also be easily shown that

$$V(\text{LD}_{\bar{v}}) \leq V(\text{LDA}_{\bar{w}})$$

and therefore

$$V(\text{LD}) \leq V(\text{LDA}).$$

In general, therefore, the bound obtained by aggregating some or all of the variables is stronger than the

bound obtained from Lagrangian relaxation but weaker than the bounds from standard Lagrangian decomposition. However, while the standard (LD) introduces  $n$  multipliers, (LDA) has  $n_1 + m$ , which can be considerably less depending on the number of dualized constraints. Moreover, any inherent problem structure is still maintained in (LDA). The aggregate formulation can thus be viewed as a reasonable compromise between tightness of the bounds and speed of solution. As in the case of standard decomposition, (LDA) can be defined by aggregating different subsets of variables. Unfortunately, it is not always apparent a priori which is the best choice for obtaining the tightest bound, and various alternatives may have to be tried in practice.

One possible method of exploiting the potential inequalities in these various bounds is as follows:

- 1) solve (LR) to obtain  $\bar{u}$ ;
- 2) if the integrality property does not hold, set  $\bar{w}^1 = \bar{u}A_1$  and  $\bar{w}^2 = \bar{u}$ , and solve (LDA $_{\bar{u}}$ ); this problem is guaranteed to give a tighter bound than (LR);
- 3) set  $\bar{v} \equiv \left(\frac{\bar{w}^1}{\bar{w}^2}\right)$ , and solve (LD $_{\bar{v}}$ ). Note that if the aggregate function  $g(y^2)$  is of the form  $A_2y$ , this step will not yield any improvement.

### Practical Issues

Because (LR), (LD) and (LDA) can all provide tighter bounds than (LP), any one of the relaxations can be used in place of (LP) to provide upper bounds in a classical branch and bound algorithm to solve (P). Consequently, the choice of the relaxation scheme used, as well as the quality of the bounds obtained, is of considerable importance. These are discussed in some detail below.

### Choosing Among Alternate Relaxations

Often, there are several choices for the constraints to be dualized. For example, consider the generalized assignment problem

$$\min \sum_{i=1}^m \sum_{j=1}^n c_{ij}x_{ij}$$

such that

$$\sum_{i=1}^m x_{ij} = 1, \quad j = 1, \dots, n, \quad (17)$$

$$\sum_{j=1}^n a_{ij}x_{ij} \leq b_i, \quad i = 1, \dots, m, x_{ij} = 0 \text{ or } 1 \quad \forall i, j. \quad (18)$$

By dualizing the first set of constraints (17), this problem reduces to  $m$  knapsack problems. Conversely, dualizing (18) results in a generalized upper bound (GUB) problem in 0–1 variables. Which of the two relaxations should be used? There are two conflicting factors involved here, namely the tightness of the bounds and the ease of solution of the problem. It would be wise to select a relaxation that yields a problem that is fairly easy to solve, but not so easy that the bounds are very loose. In general, it is difficult to know this a priori. In some instances, however, the test of the integrality property can be useful. For example, in the generalized assignment problem, the integrality property holds for the second relaxation but not the first, suggesting that the second relaxation will yield a tighter bound.

For the case of the Lagrangian decomposition, this issue is not important since all constraints are maintained in one of the subproblems. However, if aggregation is being used, then again, it is in general hard to know a priori which variables to aggregate and which ones to copy. Often, the best solution is to try various alternatives and use the computational results to guide the choice.

### Choice of Multipliers

It is clear that for (LR), the best choice for  $u$  is an optimal solution to the problem

$$\min_{u \geq 0} V(\text{LR}_u)$$

since this will yield the tightest bound  $V(\text{LR})$ . Similarly, the best dual vectors  $v$  and  $w$  for (LD) and (LDA) are those from the optimal solutions to the respective dual problems. Unfortunately, these optimal values for the dual variables cannot be determined a priori, and therefore, an interactive procedure is the only viable approach to improving the value of  $u$ ,  $v$  or  $w$ . Below, a couple of techniques for updating  $u$  for (LR) are discussed, but the methods are just as relevant for updating  $v$  and  $w$  for (LD) and (LDA).

In general, the function  $V(\text{LR}_u)$  is piecewise linear, convex and differentiable at all points except where

the Lagrangian problem has multiple optimal solutions. This observation has led to the development of *subgradient techniques* for the determining the  $u$  that minimizes  $V(LR_u)$ . This method is similar to traditional gradient methods, except that at the nondifferentiable points, it chooses randomly from the set of optimal Lagrange solutions. Given an initial value  $u^0$  (typically  $u^0 = 0$ ), a sequence  $\{u^k\}$  is generated by the formula

$$u^{k+1} = \max\{u^k + t^k(Ax^k - b), 0\},$$

where  $x^k$  is an optimal solution to  $(LR_{u^k})$  and  $t^k$  is a scalar stepsize, generally designed to be a decreasing sequence converging to zero. It is not possible to prove optimality in this method, so usually it is terminated upon reaching a specified number of iterations. Because of its simplicity, the subgradient technique is generally the method of first choice when solving (LR).

An alternate way to update  $u$  is to use *dual descent* algorithms, also referred to as *multiplier adjustment* methods. In these methods, the sequence  $u^k$  is generated by

$$u^{k+1} = u^k + t^k d^k,$$

where  $d^k$  is an *descent direction*, determined from the directional derivative of  $V(LR_{u^k})$  using a finite set of directions. Typically, the direction of steepest descent is chosen, and the stepsize  $t^k$  is the one that minimizes  $V(LR_{u^k + t^k d^k})$ . Unlike subgradient optimization, this procedure guarantees monotonic bound improvement. Moreover, it may only adjust a few multipliers at each iteration, resulting in improved computational performance. However, for general problems, the set of directions to choose from can be very large, resulting in very poor descent. It is therefore essential to tailor these methods to particular problems to exploit their structure in determining the set of directions.

## Applications

Lagrangian relaxation and decomposition have been successfully applied to solve a large number of practical combinatorial problems. These include the generalized assignment problem, capacitated facility location problem, the traveling salesman problem and instances of the general mixed integer programming problem. For each of these problems, the constraints contain well-understood structures such as knapsack, spanning tree

and generalized upper bound constraints, thus facilitating the dualization of the other complicating constraints. For a number of problems, these techniques represent the best available solution method. Computational results for these and other problems indicate that the bounds provided by (LR) and (LD) can be extremely sharp. These results have led to (LD) and (LDA) being considered among the best available solution methods for solving these problems.

### Introduction

The assumption of a fixed template for de novo peptide and protein design is highly questionable [41], as protein is commonly known to exhibit backbone flexibility, as illustrated by the superposition of NMR structures in Fig. 1. De novo design templates were observed to allow

residues that would not have been permissible had the backbone been fixed [34]. The Mayo group claimed that their ORBIT protein design program was robust against 15% change in the backbone. Nevertheless, they found in a later case study on T4 lysozyme that core repacking to stabilize the fold was difficult to achieve without considering a flexible template [37]. The secondary structures of  $\alpha$ -helices and  $\beta$ -sheets actually display twisting and bending in the fold, and Emberly et al. [6,7] applied principal component analysis of database protein structures to quantify the degree and modes of their flexibilities.

In this chapter we classify the various methods of incorporating backbone flexibility into the design template into three main types according to their treatment of the backbone and side-chain conformations. The first type involves considering a set of multiple discrete templates and performing de novo design with discrete rotamers on each of the templates under the fixed-backbone assumption. The second type considers a continuum template by means of algebraic parameterization of the backbone and variation of the parameters to allow for backbone movement during sequence selection. However, it still employs rotamer libraries to simplify the side-chain conformations. Through novel sequence selection formulations [14] and pairwise contact potentials which are discretized over distance bins [35,44,45], the third type considers a continuum design template in which the  $C\alpha$ – $C\alpha$  distances and dihedral angles assume

continuous values between upper and lower bounds observed from the template structures [9], and confirms sequence specificity to the target fold based on these bounded continuous distances and angles via NMR structure refinement methods [16,17] rather than the discrete rotamer approach. For each category we will quote some examples of successes of de novo peptide and protein design.

### Flexible Template via Multiple Discrete Templates and Discrete Rotamers

By incorporating protein backbone flexibility via discrete templates and discrete rotamers, de novo protein design frameworks either separate sequence selection and backbone movement explicitly or iterate between sequence space and structure space [3]. Notice that in both cases, the sequence search methods outlined in the previous section are all applicable, as fixed backbones and discrete rotamers are still assumed.

### Approaches Which Separate Sequence Selection and Backbone Movement

These approaches consider an ensemble of fixed backbones, searches for sequences for each of them assuming a fixed template, and finally identify the best solutions from all the results. Successes using different kinds of search algorithms include the ones described next.

**Successes Using Dead-End Elimination** By varying the supersecondary structure parameters, Ross et al. [46] and Su and Mayo [48] generated several sets of perturbed backbones from the native structure and redesigned the core of the  $\beta$ 1 domain of the streptococcal protein using the DEE algorithm under the fixed-template assumption for each backbone. Confirmed by NMR experiments, six of the seven sequences tested folded into nativelike structure.

**Successes Using the Self-Consistent Mean Field Method** Kono and Saven [29] applied their self-consistent mean field based protein combinatorial library design strategy to a set of similar backbone structures to obtain new sequences that are robust to distance changes in the template for the immunoglobulin light chain-binding domain of protein L.

**Successes of Monte Carlo Methods/Genetic Algorithms** The Pande group generated families of 100 fixed templates within 1 Å root-mean-square deviation (rmsd) from the initial backbone using a Monte Carlo method. With these fixed-template ensembles, they performed de novo design, which was based on genetic algorithms, on their Genome@home distributed grid system for 253 naturally occurring proteins. They obtained sequences that exhibited higher diversity than the corresponding natural sequence alignments, as well as good agreement on the sequence entropies of the designed sequences from the same template family [32,33].

In order to incorporate protein flexibility, Kraemer-Pecore et al. [30] executed a Monte Carlo simulation to generate 30 fixed backbones that were within 0.3 Å rmsd of the initial template. A genetic-algorithm-based sequence prediction algorithm [43] which combines filtering and sampling rotamers and energy minimization was then employed for sequence search on each template under the fixed backbone assumption. The work led to the identification of a sequence that folded into the WW domain.

In designing protein conformational switches, Ambroggio and Kuhlman [1,2] also used the Monte Carlo based RosettaDesign to search for sequences for multiple fixed-template structures.

### Approaches Which Iterate Between Sequence Space and Structure Space

There are two good examples which belong to this class. The first example is a genetic algorithm/Monte Carlo based framework used by Desjarlais and Handel [5], in which a starting population of backbones is generated by small angle perturbations to the template, rotamers are randomly selected on each backbone, and a genetic algorithm is subsequently used which exchanges not only rotamers but also backbone torsional information in recombination. The framework is ended with a Monte Carlo stage which refines the backbone structures. Using this novel approach, Desjarlais and Handel [5] designed three new core variants of the protein 434 cro. They also compared results on 434 cro and T4 lysozyme with those obtained earlier using fixed-template models and found that they were similar, given that the fixed-

template models scan over a much larger rotamer space.

The second one was proposed by Kuhlman et al. [31] and Saunders and Baker [31,47]. Their method starts with a set of initial backbones, searches by a Monte Carlo method for the sequence with the lowest energy for each of them, performs atomic-resolution structure prediction for the sequences to allow shifts in the structure space, and continues until the number of iterations hits a predetermined number. They successfully designed a new sequence for Top 7, a 93-residue  $\alpha/\beta$  protein with a novel fold [31]. They also claimed that the new method better captures sequence variation than approaches that separate sequence selection and backbone movement explicitly.

### Flexible Template via Continuum Template and Discrete Rotamers

This method of constituting a continuum template via backbone parameterization and performing sequence search from rotamer libraries was proposed by Harbury et al. [18,19,40]. On the basis of the algebraic parameterization equations developed for coiled-coils by Crick [4], they allowed backbone movement by treating the parameters as variables during sequence search for energy minimization, which was in turn done by the local optimization methods of steepest descent minimization and adopted-basis Newton–Raphson minimization.

#### Successes

Harbury et al. [18,19,40] adopted this approach to design a family of  $\alpha$ -helical bundle proteins with right-handed superhelical twist. The crystal structure of the designed sequences with the optimal specificity was experimentally validated to match the design template.

### Flexible Template via Continuum Template and NMR Structure Refinement

Considering discrete rotamers is certainly not the best approach to adopt in de novo design, as about 15% of side-chain conformations are not represented by common rotamer libraries [8]. A recent two-stage de novo design approach proposed by the Floudas group [10,11,26,27] considers a continuum design template without

using discrete rotamers for the possible side-chain conformations. The first stage selects a rank-ordered list of low-energy sequences using novel quadratic assignment-like models [13,14] driven by pairwise residue contact potentials, which were developed by the group by solving a linear programming parameter estimation problem, requiring that the native conformations for a large training set of 1250 proteins be ranked energetically more favorably than their high-resolution decoys [35,44,45]. The forcefields developed were found to produce very good Z scores in recognizing the native folds for a large test set of proteins [35,44,45]. Rather than being continuous, the dependence of contact potential on distance is discretized into bins. This designed feature serves to make the energy objective function insensitive to a limited degree of backbone movement. For example, in the high resolution  $C^\alpha$ - $C^\alpha$  forcefield [44], if the pair of amino acids selected at two positions  $i$  and  $k$ , which are 3.5 Å apart in the template, are Arg and Glu, respectively, their energy contribution to the objective function is Minus 7.77 kcal/mol. Despite small distance variations, this energy value is constant for all Arg–Glu interactions as long as the  $C^\alpha$  positions of the two residues are 3–4 Å (bin 1) apart. To perform sequence selection based on a flexible template of multiple structures, Fung et al. [14] also developed two novel formulations: a weighted model which considers the distance between any two positions as the weighted average of their distances in all structures, and a binary distance bin model that decides which bin the distance falls into during energy optimization. The latter approach is in a sense similar to the backbone parameterization approach of Harbury et al. [18,19,40] in which there are distance variables associated with the backbone.

The second stage of the approach confirms fold specificity of the sequences generated in the first stage based on a full-atomistic forcefield. The group used to perform the task via ASTRO-FOLD [20,21,22,23,24,25,28,36], a protein structure prediction method via global optimization. Conformational ensembles are generated for each sequence under two sets of conditions. In the first circumstance, the structure is constrained to vary, with some imposed fluctuations, around the template structure. In the second condition, a free folding calculation is performed for which only a limited number of restraints (e.g., disulfide bridges), but not the un-

derlying template structure, are enforced. The relative fold specificity of the sequence,  $f_{\text{spec}}$ , can be found by summing the statistical weights for those conformers from the free folding simulation that resemble the template structure (denoted as set *temp*), and dividing this sum by the summation of statistical weights for all conformers from the free folding simulation (denoted as set *total*):

$$f_{\text{spec}} = \frac{\sum_{i \in \text{temp}} \exp[-\beta E_i]}{\sum_{i \in \text{total}} \exp[-\beta E_i]}$$

where  $\exp[-\beta E_i]$  is the statistical weight for conformer *i*.

Note that in this nonrotamer approach, in both the template-constrained and the free folding calculations, all continuous  $C^\alpha$ - $C^\alpha$  and angle values between upper and lower bounds input by the user are considered in sampling the conformers. True backbone flexibility [9] is thus conserved.

Lately the Floudas group developed an approximate fold validation method which is computationally less expensive than ASTRO-FOLD. Through the CYANA 2.1 software for NMR structure refinement [16,17], an ensemble of several hundred conformers is generated for both a new sequence from the first stage and the native sequence. The energies of the conformers are then minimized using TINKER [42], and the fold specificity of the new sequence is calculated using the formula

$$f_{\text{spec}} = \frac{\sum_{i \in \text{conformers for new sequence}} \exp[-\beta E_i]}{\sum_{i \in \text{conformers for native sequence}} \exp[-\beta E_i]}$$

based on the assumption that the fold specificity to the flexible template is unity for the native sequence.

Like the fold-validation method via ASTRO-FOLD, all continuous distance and dihedral angle values between their upper and lower bounds, which are input into CYANA on the basis of observations about the template structures, are considered in generating the conformers. This distinguishes the method from the common rotamer approach in which only discrete side-chain conformations are allowed.

## Successes

The novel two-stage de novo strategy was applied to (1) the design of new sequences for compstatin, a synthetic 13-residue cyclic peptide that binds to complement protein 3 (C3) and inhibits the activation of the

complement system (part of innate immunity) [10,26,27,38,39], (2) the design of a potential peptide-drug candidate derived from the C-terminal sequence of the C3a fragment of C3 [15], and (3) the full sequence of human  $\beta$ -defensin-2, a 41-residue cationic peptide in the immune system [12]. In the case of the compstatin redesign, sequences with 16-fold and 45-fold improvement in specificity over the native sequence were confirmed in experiments [26,27]. For the design of the peptide drug from C3a, the best sequence identified corresponds to 15-fold improvement [15].

### Introduction

Computational protein design efforts were first initiated with the premise that the three-dimensional coordinates of the design template or backbone were fixed. This simplification was first proposed in [39], and was appealing because it greatly reduced the combinatorial complexity of the search. Together with consideration of only a limited set of most frequently observed side-chain conformations called rotamers [29,40], the assumption enhanced the efficiency of the initial de novo design efforts, most of which focused on protein cores [5,16,32,41,42], in exploring search spaces. The reason why protein cores were selected instead of the boundary or surface regions was based on the thesis that protein folding is primarily driven by hydrophobic collapse, and thus a good core tends to provide a well-folded and stable structure for the de novo

designed protein [10]. The scope of the de novo design encompassed intermediate and surface residues in subsequent years, and obviously the problem became more challenging. In this chapter, we outline the different deterministic and stochastic methods that search for sequences specific to the fixed rigid design template. It should be noted that they all discretize the side-chain conformational space into rotamers for tractability of the search problem. After the introduction of each method we also review examples of successes.

### Sequence Search Methods

De novo design algorithms can be classified into two main categories, namely, deterministic and stochastic [8]. The two main methods that fall into the deterministic category are dead-end elimination (DEE) and self-consistent mean field (SCMF), whereas the two major stochastic type frameworks are Monte Carlo and genetic algorithms. Some methods search for low-energy sequences, whereas others assign probability to each of the 20 amino acids for each design position in a sequence in order to maximize the conformational entropy.

### Deterministic Methods

**The Dead-End Elimination Criteria** DEE, which is arguably the most popular rotamer search algorithm, operates on the basis of the systematic elimination of rotamers that cannot be parts of the sequence with the lowest energy. The energy function in DEE is written in the form of the sum of an individual term (rotamer–template) and a pairwise term (rotamer–rotamer):

$$E = \sum_{i=1}^N E(i_a) + \sum_{i=1}^{N-1} \sum_{j>i}^N E(i_a, j_b), \quad (1)$$

where  $E(i_a)$  is the rotamer–template energy for rotamer  $i_a$  of amino acid  $i$ ,  $E(i_a, j_b)$  is the rotamer–rotamer energy of rotamer  $i_a$  and rotamer  $j_b$  of amino acids  $i$  and  $j$ , respectively, and  $N$  is the total number of positions. The original DEE pruning criterion is based on the concept that if the pairwise energy between rotamer  $i_a$  and rotamer  $j_b$  is higher than that between rotamer  $i_c$  and rotamer  $j_b$  for all rotamer  $j_b$  in a certain rotamer set  $\{B\}$ , then rotamer  $i_a$  cannot be in the global energy minimum conformation and thus can be eliminated. It was

proposed in [9] and can be expressed in the following mathematical form:

$$E(i_a) + \sum_{j \neq i}^N E(i_a, j_b) > E(i_c) + \sum_{j \neq i}^N E(i_c, j_b) \quad \forall \{B\}. \quad (2)$$

Rotamer  $i_a$  can be pruned if the above holds true. Bounds implied by (1) can be utilized to generate the following computationally more tractable inequality [9]:

$$E(i_a) + \sum_{j \neq i}^N \min_b E(i_a, j_b) > E(i_c) + \sum_{j \neq i}^N \max_b E(i_c, j_b). \quad (3)$$

The above equations for eliminating rotamers at a single position (or singles) can be extended to eliminating rotamer pairs at two distinct positions (doubles), rotamer triplets at three distinct positions (triples), or above [9,37]. In the case of doubles, the equation becomes

$$\varepsilon(i_a, j_b) + \sum_{k \neq i, j}^N \min_c \varepsilon(i_a, j_b, k_c) > \varepsilon(i_{a'}, j_{b'}) + \sum_{k \neq i, j}^N \max_c \varepsilon(i_{a'}, j_{b'}, k_c), \quad (4)$$

where  $\varepsilon$  is the total energy of rotamer pairs:

$$\varepsilon(i_a, j_b) = E(i_a) + E(j_b) + E(i_a, j_b), \quad (5)$$

$$\varepsilon(i_a, j_b, k_c) = E(i_a, k_c) + E(j_b, k_c). \quad (6)$$

It determines a rotamer pair  $i_a$  and  $j_b$  which always contributes higher energies than rotamer pair  $i_{a'}$  and  $j_{b'}$  for all possible rotamer combinations. Goldstein [14] improved the original DEE criterion by stating that rotamer  $i_a$  can be pruned if the energy contribution is always reduced by an alternative rotamer  $i_c$ :

$$E(i_a) - E(i_c) + \sum_{j \neq i}^N \min_b [E(i_a, j_b) - E(i_c, j_b)] > 0. \quad (7)$$

This can be generalized to the use of a weighted average of  $C$  rotamers  $i_c$  to eliminate  $i_a$  [14]:

$$E(i_a) - \sum_{c=1, \dots, C} w_c E(i_c) + \sum_{j \neq i}^N \min_b [E(i_a, j_b) - \sum_{c=1, \dots, C} w_c E(i_c, j_b)] > 0. \quad (8)$$

Lasters et al. [25] proposed that the most suitable weights  $w_c$  can be determined by solving a linear programming problem.

In addition to these criteria proposed by Goldstein [14], Pierce et al. [38] introduced the split DEE, which splits the conformational space into partitions and thus eliminated the dead-ending rotamers more efficiently:

$$E(i_a) - E(i_c) + \sum_{j, j \neq k \neq i}^N \{\min_{a'} [E(i_a, j_{a'}) - E(i_c, j_{a'})]\} + [E(i_a, k_{b'}) - E(i_c, k_{b'})] > 0. \quad (9)$$

In general,  $n$  splitting positions can be assigned for more efficient but computationally expensive rotamer elimination:

$$E(i_a) - E(i_c) + \sum_{j, j \neq k_1, \dots, k_n \neq i}^N \{\min_{a'} [E(i_a, j_{a'}) - E(i_c, j_{a'})]\} + \sum_{k=k_1, \dots, k_n} [E(i_a, k_{b'}) - E(i_c, k_{b'})] > 0. \quad (10)$$

Looger and Hellinga [27] also introduced the generalized DEE by ranking the energy of rotamer clusters instead of that of individual rotamers and increased the ability of the algorithm to deal with higher levels of combinatorial complexity. Further revisions and improvements on DEE were performed by Wernisch et al. [47] and Gordon et al. [15].

Being deterministic in nature, the different forms of DEE reviewed above all yield the same globally optimal solution upon convergence.

**Successes Using Dead-End Elimination:** Based on operating the DEE algorithm on a fixed template, the Mayo group devised their optimization of rotamers

by an iterative technique (ORBIT) program and applied it to numerous de novo protein designs. Examples are the full-sequence design of the  $\beta\beta\alpha$  fold of a zinc finger domain [6], improvement of calmodulin binding affinity [45], full core design of the variable domains of the light and heavy chains of catalytic antibody 48G7 FAB, full core/boundary design, full surface design, and full-sequence design of the  $\beta 1$  domain of protein G [15], as well as the redesign of the core of T4 lysozyme [32]. They also adjusted secondary structure parameters to build the “idealized backbone” and used it as a fixed template to design an  $\alpha/\beta$ -barrel protein [33]. The Hellinga group applied DEE with a fixed backbone structure to introduce iron and oxygen binding sites into thioredoxin [2,3], design receptor and sensor proteins with novel ligand-binding functions [28], and confer novel enzymatic properties onto ribose-binding protein [11].

**The Self-Consistent Mean-Field Method** The SCMF optimization method is an iterative procedure that predicts the values of the elements of a conformational matrix  $P(i, a)$  for the probability of a design position  $i$  adopting the conformation of rotamer  $a$ . Note that  $P(i, a)$  sums to unity over all rotamers  $a$  for each position  $i$ . Koehl and Delarue [19] were among those who introduced such a method for protein design. They started the iteration with an initial guess for the conformational matrix, which assigns equal probability to all rotamers:

$$P(i, a) = \frac{1}{A} \quad a = 1, 2, \dots, A. \quad (11)$$

Most importantly, they applied the mean-field potential,  $E(i, a)$ , which depends on the conformational matrix  $P(i, a)$ :

$$E(i, a) = U(x_{ia}) + U(x_{ia}, x_0) + \sum_{j=1, j \neq i}^N \sum_{b=1}^B P(j, b) U(x_{ia}, x_{jb}), \quad (12)$$

where  $x_0$  corresponds to the coordinates of atoms in the fixed template, and  $x_{ia}$  and  $x_{jb}$  correspond to the coordinates of the atoms of position  $i$  assuming the conformation of rotamer  $a$  and those of position  $j$  assuming the conformation of rotamer  $b$ , respectively. The classical Lennard-Jones (12-6) potential can be used to de-

scribe potential energy  $U$  [19]. The conformational matrix can be subsequently updated using the mean-field potential and the Boltzmann law:

$$P_1(i, a) = \frac{e^{-\frac{E(i, a)}{RT}}}{\sum_{a=1}^A e^{-\frac{E(i, a)}{RT}}}. \quad (13)$$

The update on  $P(i, a)$ , namely,  $P_1(i, a)$ , can then be used to repeat the calculation of the mean-field potential and another update until convergence is attained. Koehl and Delarue [19] set the convergence criterion to be  $10^{-4}$  to define self-consistency. They also proposed the introduction of memory of the previous step to minimize oscillations during convergence:

$$P(i, a) = \lambda P_1(i, a) + (1 - \lambda) P(i, a), \quad (14)$$

with the optimal step size  $\lambda$  to be 0.9 [19].

The Saven group [12,24,44,48] extended the SCMF theory and formulated de novo design as an optimization problem maximizing the sequence entropy subject to composition constraints and mean-field energy constraints. In addition to the site probabilities, their method also predicts the number of sequences for a combinatorial library of arbitrary size for the fixed template as a function of energy.

It should be highlighted that though deterministic in nature, the SCMF method does not guarantee convergence to the global optimal solution [26].

### Successes Using the Self-Consistent Mean-Field Method

Koehl and Delarue [20] applied the SCMF approach to design protein loops. In their optimization procedure, they first selected the loop fragment from a database with the highest site probabilities. Then they placed side chains on the fixed loop backbone from a rotamer library. Kono and Doi [23] also used an energy minimization with an automata network, which bears some resemblance to the SCMF method, to design the cores of the globular proteins of cytochrome  $b_{562}$ , triosephosphate isomerase, and barnase. The SCMF method is related to the design of combinatorial libraries of new sequences with good folding properties, which was reviewed in several papers [17,34,35,43].

### Stochastic Methods

The fact that de novo design is nondeterministic polynomial-time hard [13,36] means that in the worst

case the time required to solve the problem scales non-polynomially with the number of design positions. As the problem complexity exceeds a certain level, deterministic methods may reach their limits and in such instances we may have to resort to stochastic methods, which perform searches for only locally optimal solutions. Monte Carlo methods and genetic algorithms are the two most commonly used types of stochastic methods for de novo protein design.

**Monte Carlo Methods** Different variants of the Monte Carlo methods have been applied for sequence design. In the classic Monte Carlo method, mutation is performed at a certain position in the sequence and energies of the sequence in the fixed template are calculated before and after the mutation. This usually involves the use of discrete rotamer libraries to simplify the consideration of possible side-chain conformations. The new sequence after mutation is accepted if the energy becomes lower. If the energy is higher, the Metropolis acceptance criterion [30] is used

$$p_{\text{accept}} = \min(1, \exp(-\beta\Delta E)) \quad \beta = \frac{1}{kT}, \quad (15)$$

and the sequence is updated if  $p_{\text{accept}}$  is larger than a random number uniformly distributed between 0 and 1.

In the configurational bias Monte Carlo method, at each step a local energy is used which does not include those positions where a mutation has not been attempted [49]. Cootes et al. [4] reported that the method was more efficient at finding good solutions than the conventional Monte Carlo method, especially for complex systems. Zoz and Savan [49] also devised the mean-field biased Monte Carlo method which biases the sequence search with predetermined site probabilities, which are in turn calculated using SCMF theory. They claimed their new method converges to low-energy sequences faster than classic Monte Carlo and configurational bias Monte Carlo methods.

**Successes of Monte Carlo Methods** Imposing sequence specificity by keeping the amino acid composition fixed, which reduced significantly the complexity, Koehl and Levitt [21,22] designed new sequences for the fixed backbones of the  $\beta 1$  domain of protein G,  $\lambda$

repressor, and sperm whale myoglobin using the conventional Monte Carlo method. The Baker group also utilized the classic Monte Carlo algorithm in their computational protein design program RosettaDesign. Examples of applications of the program include the redesign of nine globular proteins: the src SH3 domain,  $\lambda$  repressor, U1A, protein L, tenascin, procarboxypeptidase, acylphosphatase, S6, and FKBP12 using fixed templates [7].

**Genetic Algorithms** Originating in genetics and evolution, genetic algorithms generate a multitude of random amino acid sequences and exchange them for a fixed template. Sequences with low energies form hybrids with other sequences, while those with high energies are eliminated in an iterative process which only terminates when a converged solution is attained [46].

**Successes of Genetic Algorithms** With fixed backbones, Belda et al. [1] applied genetic algorithms to the design of ligands for prolyl oligopeptidase, p53, and DNA gyrase. In addition, with a cubic lattice and empirical contact potentials Hohm et al. [18] and Miyazawa and Jernigan [31] also employed evolutionary methods to design short peptides that resemble the antibody epitopes of thrombin and blood coagulation factor VIII with high stability.

## Introduction

Consider the following unconstrained minimization problem:

$$\text{minimize } f(x) \text{ subject to } x \in \mathbb{R}^n, \quad (1)$$

where the objective function  $f$  is assumed to be Lipschitz continuous.

Nonsmooth unconstrained optimization problems appear in many applications and in particular in data mining. Over more than four decades different methods have been developed to solve problem (1). We mention among them the bundle method and its different variations (see, for example, [11,12,13,14,17,20]), algorithms based on smoothing techniques [18], and the gradient sampling algorithm [8].

In most of these algorithms at each iteration the computation of at least one subgradient or approximating gradient is required. However, there are many practical problems where the computation of even one subgradient is a difficult task. In such situations derivative-free methods seem to be a better choice since they do not use the explicit computation of subgradients.

Among derivative-free methods, the generalized pattern search methods are well suited for nonsmooth optimization [1,19]. However their convergence are proved under quite restrictive differentiability assumptions. It was shown in [19] that when the objective function  $f$  is continuously differentiable in  $\mathbb{R}^n$ , then the lower limit of the norm of the gradient of the sequence of points generated by the generalized pattern search algorithm goes to zero. The paper [1] provides convergence analysis under less restrictive differentiability assumptions. It was shown that if  $f$  is strictly differentiable near the limit of any refining subsequence, then the gradient at that point is zero. However, in many practically important problems this condition is not satisfied, because in such problems the objective functions are not differentiable at local minimizers.

In the paper [15] a derivative-free algorithm for a linearly constrained finite minimax problem was proposed. The original problem was converted into a smooth one using a smoothing technique. This algorithm is globally convergent toward stationary points of the finite minimax problem.

In this paper we describe a derivative-free method based on the notion of a discrete gradient for solving

unconstrained nonsmooth optimization problems. Its convergence is proved for a broad class of nonsmooth functions.

### Definitions

We use the following notation:  $\mathbb{R}^n$  is an  $n$ -dimensional space, where the scalar product will be denoted by  $\langle x, y \rangle$ :

$$\langle x, y \rangle = \sum_{i=1}^n x_i y_i$$

and  $\|\cdot\|$  will denote the associated norm. The gradient of a function  $f: \mathbb{R}^n \rightarrow \mathbb{R}^1$  will be denoted by  $\nabla f$  and the closed  $\delta$ -ball at  $x \in \mathbb{R}^n$  by  $S_\delta(x)$  (by  $S_\delta$  if  $x = 0$ ):  $S_\delta(x) = \{y \in \mathbb{R}^n : \|x - y\| \leq \delta\}$ ,  $\delta > 0$ .

### The Clarke Subdifferential

Let  $f$  be a function defined on  $\mathbb{R}^n$ . Function  $f$  is called locally Lipschitz continuous if for any bounded subset  $X \subset \mathbb{R}^n$  there exists an  $L > 0$  such that

$$|f(x) - f(y)| \leq L\|x - y\| \forall x, y \in X.$$

We recall that a locally Lipschitz function  $f$  is differentiable almost everywhere and that we can define for it a Clarke subdifferential [9] by

$$\partial f(x) = \text{co} \left\{ v \in \mathbb{R}^n : \exists (x^k \in D(f), x^k \rightarrow x, k \rightarrow +\infty) : v = \lim_{k \rightarrow +\infty} \nabla f(x^k) \right\},$$

where  $D(f)$  denotes the set where  $f$  is differentiable and  $\text{co}$  denotes the convex hull of a set. It is shown in [9] that the mapping  $\partial f(x)$  is upper semicontinuous and bounded on bounded sets.

The generalized directional derivative of  $f$  at  $x$  in the direction  $g$  is defined as

$$f^0(x, g) = \limsup_{y \rightarrow x, \alpha \downarrow 0} \alpha^{-1} [f(y + \alpha g) - f(y)].$$

If function  $f$  is locally Lipschitz continuous, then the generalized directional derivative exists and

$$f^0(x, g) = \max \{ \langle v, g \rangle : v \in \partial f(x) \}.$$

$f$  is called a Clarke regular function on  $\mathbb{R}^n$  if it is differentiable with respect to any direction  $g \in \mathbb{R}^n$  and

$f'(x, g) = f^0(x, g)$  for all  $x, g \in \mathbb{R}^n$ , where  $f'(x, g)$  is a derivative of function  $f$  at point  $x$  with respect to direction  $g$ :

$$f'(x, g) = \lim_{\alpha \downarrow 0} \alpha^{-1} [f(x + \alpha g) - f(x)].$$

It is clear that the directional derivative  $f'(x, g)$  of the Clarke regular function  $f$  is upper semicontinuous with respect to  $x$  for all  $g \in \mathbb{R}^n$ .

Let  $f$  be a locally Lipschitz continuous function defined on  $\mathbb{R}^n$ . For point  $x$  to be a minimum point of function  $f$  on  $\mathbb{R}^n$ , it is necessary that  $0 \in \partial f(x)$ .

### Semismooth Functions

The function  $f: \mathbb{R}^n \rightarrow \mathbb{R}^1$  is called semismooth at  $x \in \mathbb{R}^n$ , if it is locally Lipschitz continuous at  $x$  and for every  $g \in \mathbb{R}^n$ , the limit

$$\lim_{g' \rightarrow g, \alpha \downarrow 0, v \in \partial f(x + \alpha g')} \langle v, g \rangle$$

exists. It should be noted that the class of semismooth functions is fairly wide and it contains convex, concave, max- and min-type functions [16]. The semismooth function  $f$  is directionally differentiable and

$$f'(x, g) = \lim_{g' \rightarrow g, \alpha \downarrow 0, v \in \partial f(x + \alpha g')} \langle v, g \rangle.$$

### Quasidifferentiable Functions

A function  $f$  is called quasidifferentiable at a point  $x$  if it is locally Lipschitz continuous and directionally differentiable at this point and there exist convex, compact sets  $\underline{\partial}f(x)$  and  $\overline{\partial}f(x)$  such that

$$f'(x, g) = \max_{u \in \underline{\partial}f(x)} \langle u, g \rangle + \min_{v \in \overline{\partial}f(x)} \langle v, g \rangle.$$

The set  $\underline{\partial}f(x)$  is called a subdifferential, the set  $\overline{\partial}f(x)$  is called a superdifferential, and the pair of sets  $[\underline{\partial}f(x), \overline{\partial}f(x)]$  is called a quasidifferential of function  $f$  at a point  $x$  [10].

## Methods

### Approximation of Subgradients

We consider a locally Lipschitz continuous function  $f$  defined on  $\mathbb{R}^n$  and assume that this function is quasidifferentiable. We also assume that both sets  $\underline{\partial}f(x)$  and

$\bar{\partial}f(x)$  at any  $x \in \mathbb{R}^n$  are polytopes, that is, at a point  $x \in \mathbb{R}^n$  there exist sets

$$A = \{a^1, \dots, a^m\}, a^i \in \mathbb{R}^n, i = 1, \dots, m, m \geq 1$$

and

$$B = \{b^1, \dots, b^p\}, b^j \in \mathbb{R}^n, j = 1, \dots, p, p \geq 1$$

such that

$$\partial f(x) = \text{co } A, \bar{\partial}f(x) = \text{co } B.$$

This assumption is true, for example, for functions represented as a maximum, minimum, or max-min of a finite number of smooth functions.

We take a direction  $g \in \mathbb{R}^n$  such that

$$g = (g_1, \dots, g_n), |g_i| = 1, i = 1, \dots, n$$

and consider the sequence of  $n$  vectors  $e^j = e^j(\alpha), j = 1, \dots, n$  with  $\alpha \in (0, 1]$ :

$$\begin{aligned} e^1 &= (\alpha g_1, 0, \dots, 0), \\ e^2 &= (\alpha g_1, \alpha^2 g_2, 0, \dots, 0), \\ \dots &= \dots \dots \dots \\ e^n &= (\alpha g_1, \alpha^2 g_2, \dots, \alpha^n g_n). \end{aligned}$$

We introduce the following sets:

$$\begin{aligned} \underline{R}_0 &= A, \bar{R}_0 = B, \\ \underline{R}_j &= \left\{ v \in \underline{R}_{j-1} : v_j g_j = \max\{w_j g_j : w \in \underline{R}_{j-1}\} \right\}, \\ \bar{R}_j &= \left\{ v \in \bar{R}_{j-1} : v_j g_j = \min\{w_j g_j : w \in \bar{R}_{j-1}\} \right\}. \\ & j = 1, \dots, n. \end{aligned}$$

It is clear that

$$\underline{R}_j \neq \emptyset, \forall j \in \{0, \dots, n\}, \underline{R}_j \subseteq \underline{R}_{j-1}, \forall j \in \{1, \dots, n\}$$

and

$$\bar{R}_j \neq \emptyset, \forall j \in \{0, \dots, n\}, \bar{R}_j \subseteq \bar{R}_{j-1}, \forall j \in \{1, \dots, n\}.$$

Moreover,

$$v_r = w_r \quad \forall v, w \in \underline{R}_j, r = 1, \dots, j \quad (2)$$

and

$$v_r = w_r \quad \forall v, w \in \bar{R}_j, r = 1, \dots, j. \quad (3)$$

Consider the following two sets:

$$\begin{aligned} \underline{R}(x, e^j(\alpha)) &= \left\{ v \in A : \langle v, e^j \rangle = \max_{u \in A} \langle u, e^j \rangle \right\}, \\ \bar{R}(x, e^j(\alpha)) &= \left\{ w \in B : \langle w, e^j \rangle = \min_{u \in B} \langle u, e^j \rangle \right\}. \end{aligned}$$

**Proposition 1** Assume that function  $f$  is quasidifferentiable and its subdifferential and superdifferential are polytopes at a point  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$\underline{R}(x, e^j(\alpha)) \subset \underline{R}_j, \bar{R}(x, e^j(\alpha)) \subset \bar{R}_j, j = 1, \dots, n$$

for all  $\alpha \in (0, \alpha_0)$ .

**Corollary 1** Assume that function  $f$  is quasidifferentiable and its subdifferential and superdifferential are polytopes at a point  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$\begin{aligned} f'(x, e^j(\alpha)) &= f'(x, e^{j-1}(\alpha)) + v_j \alpha^j g_j + w_j \alpha^j g_j, \\ & \forall v \in \underline{R}_j, w \in \bar{R}_j, j = 1, \dots, n \end{aligned}$$

for all  $\alpha \in (0, \alpha_0]$

**Proposition 2** Assume that function  $f$  is quasidifferentiable and its subdifferential and superdifferential are polytopes at a point  $x$ . Then the sets  $\underline{R}_n$  and  $\bar{R}_n$  are singletons.

*Remark 1* In the next subsection we propose an algorithm to approximate subgradients. This algorithm finds a subgradient that can be represented as a sum of elements of the sets  $\underline{R}_n$  and  $\bar{R}_n$ .

### Computation of Subgradients

Let  $g \in \mathbb{R}^n, |g_i| = 1, i = 1, \dots, n$  be a given vector and  $\lambda > 0, \alpha > 0$  be given numbers. We define the following points:

$$x^0 = x, x^j = x^0 + \lambda e^j(\alpha), j = 1, \dots, n.$$

It is clear that

$$x^j = x^{j-1} + (0, \dots, 0, \lambda \alpha^j g_j, 0, \dots, 0), j = 1, \dots, n.$$

Let  $v = v(\alpha, \lambda) \in \mathbb{R}^n$  be a vector with the following coordinates:

$$v_j = (\lambda \alpha^j g_j)^{-1} [f(x^j) - f(x^{j-1})], j = 1, \dots, n. \quad (4)$$

For any fixed  $g \in \mathbb{R}^n$ ,  $|g_i| = 1$ ,  $i = 1, \dots, n$  and  $\alpha > 0$  we introduce the following set:

$$V(g, \alpha) = \left\{ w \in \mathbb{R}^n : \exists (\lambda_k \rightarrow +0, k \rightarrow +\infty), \right. \\ \left. w = \lim_{k \rightarrow +\infty} v(\alpha, \lambda_k) \right\}.$$

**Proposition 3** Assume that  $f$  is a quasidifferentiable function and its subdifferential and superdifferential are polytopes at  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$V(g, \alpha) \subset \partial f(x)$$

for all  $\alpha \in (0, \alpha_0]$ .

*Remark 2* It follows from Proposition 3 that in order to approximate subgradients of quasidifferentiable functions one can choose a vector  $g \in \mathbb{R}^n$  such that  $|g_i| = 1$ ,  $i = 1, \dots, n$ , sufficiently small  $\alpha > 0$ ,  $\lambda > 0$ , and apply (4) to compute a vector  $v(\alpha, \lambda)$ . This vector is an approximation to a certain subgradient.

### Computation of Subdifferentials and Discrete Gradients

In the previous subsection we demonstrated an algorithm for the computation of subgradients. In this subsection we consider an algorithm for the computation of subdifferentials. This algorithm is based on the notion of a discrete gradient. We start with the definition of the discrete gradient, which was introduced in [2] (for more details, see also [3,4]).

Let  $f$  be a locally Lipschitz continuous function defined on  $\mathbb{R}^n$ . Let

$$S_1 = \{g \in \mathbb{R}^n : \|g\| = 1\}, G = \{e \in \mathbb{R}^n : \\ e = (e_1, \dots, e_n), |e_j| = 1, j = 1, \dots, n\},$$

$$P = \{z(\lambda) : z(\lambda) \in \mathbb{R}^1, z(\lambda) > 0, \\ \lambda > 0, \lambda^{-1}z(\lambda) \rightarrow 0, \lambda \rightarrow 0\}.$$

Here  $S_1$  is the unit sphere,  $G$  is the set of vertices of the unit hypercube in  $\mathbb{R}^n$ , and  $P$  is the set of univariate positive infinitesimal functions.

We take any  $g \in S_1$  and define  $|g_i| = \max\{|g_k|, k = 1, \dots, n\}$ . We also take any  $e = (e_1, \dots, e_n) \in G$ , a positive number  $\alpha \in (0, 1]$ , and define the sequence of  $n$  vectors  $e^j(\alpha)$ ,  $j = 1, \dots, n$  as in

Sect. “**Approximation of Subgradients.**” Then for given  $x \in \mathbb{R}^n$  and  $z \in P$  we define a sequence of  $n + 1$  points as follows:

$$\begin{aligned} x^0 &= x + \lambda g, \\ x^1 &= x^0 + z(\lambda)e^1(\alpha), \\ x^2 &= x^0 + z(\lambda)e^2(\alpha), \\ \dots &= \dots \dots \\ x^n &= x^0 + z(\lambda)e^n(\alpha). \end{aligned}$$

**Definition 1** The discrete gradient of function  $f$  at point  $x \in \mathbb{R}^n$  is the vector  $\Gamma^i(x, g, e, z, \lambda, \alpha) = (\Gamma_1^i, \dots, \Gamma_n^i) \in \mathbb{R}^n$ ,  $g \in S_1$  with the following coordinates:

$$\begin{aligned} \Gamma_j^i &= [z(\lambda)\alpha^j e_j]^{-1} [f(x^j) - f(x^{j-1})], \\ & \quad j = 1, \dots, n, j \neq i, \\ \Gamma_i^i &= (\lambda g_i)^{-1} \left[ f(x + \lambda g) - f(x) - \lambda \sum_{j=1, j \neq i}^n \Gamma_j^i g_j \right]. \end{aligned}$$

It follows from the definition that

$$f(x + \lambda g) - f(x) = \lambda \langle \Gamma^i(x, g, e, z, \lambda, \alpha), g \rangle \quad (5)$$

for all  $g \in S_1$ ,  $e \in G$ ,  $z \in P$ ,  $\lambda > 0$ ,  $\alpha > 0$ .

*Remark 3* One can see that the discrete gradient is defined with respect to a given direction  $g \in S_1$ , and in order to compute the discrete gradient  $\Gamma^i(x, g, e, z, \lambda, \alpha)$ , first we define a sequence of points  $x^0, \dots, x^n$  and compute the values of function  $f$  at these points; that is, we compute  $n + 2$  values of this function including point  $x$ .  $n - 1$  coordinates of the discrete gradient are defined similarly to those of the vector  $v(\alpha, \lambda)$  from the Sect. “**Approximation of Subgradients,**” and the  $i$ th coordinate is defined so as to satisfy equality (5), which can be considered as a version of the mean value theorem.

**Proposition 4** Let  $f$  be a locally Lipschitz continuous function defined on  $\mathbb{R}^n$  and  $L > 0$  its Lipschitz constant. Then for any  $x \in \mathbb{R}^n$ ,  $g \in S_1$ ,  $e \in G$ ,  $\lambda > 0$ ,  $z \in P$ ,  $\alpha > 0$

$$\|\Gamma^i\| \leq C(n)L, C(n) = (n^2 + 2n^{3/2} - 2n^{1/2})^{1/2}.$$

For a given  $\alpha > 0$  we define the following set:

$$\begin{aligned} B(x, \alpha) = & \{v \in \mathbb{R}^n : \exists (g \in S_1, e \in G, z_k \in P, \\ & z_k \rightarrow +0, \lambda_k \rightarrow +0, k \rightarrow +\infty), \\ & v = \lim_{k \rightarrow +\infty} \Gamma^i(x, g, e, z_k, \lambda_k, \alpha)\}. \end{aligned} \quad (6)$$

**Proposition 5** Assume that  $f$  is a semismooth, quasidifferentiable function and its subdifferential and superdifferential are polytopes at a point  $x$ . Then there exists  $\alpha_0 > 0$  such that

$$\text{co } B(x, \alpha) \subset \partial f(x)$$

for all  $\alpha \in (0, \alpha_0]$ .

*Remark 4* Proposition 5 implies that discrete gradients can be applied to approximate subdifferentials of a broad class of semismooth, quasidifferentiable functions.

*Remark 5* One can see that the discrete gradient contains three parameters:  $\lambda > 0$ ,  $z \in P$ , and  $\alpha > 0$ .  $z \in P$  is used to exploit the semismoothness of function  $f$ , and it can be chosen sufficiently small. If  $f$  is a semismooth quasidifferentiable function and its subdifferential and superdifferential are polytopes at any  $x \in \mathbb{R}^n$ , then for any  $\delta > 0$  there exists  $\alpha_0 > 0$  such that  $\alpha \in (0, \alpha_0]$  for all  $y \in S_\delta(x)$ . The most important parameter is  $\lambda > 0$ . In the sequel we assume that  $z \in P$  and  $\alpha > 0$  are sufficiently small.

Consider the following set:

$$\begin{aligned} D_0(x, \lambda) = & \text{cl co } \{v \in \mathbb{R}^n : \exists (g \in S_1, e \in G, z \in P) : \\ & v = \Gamma^i(x, g, e, \lambda, z, \alpha)\}. \end{aligned}$$

Proposition 4 implies that the set  $D_0(x, \lambda)$  is compact and it is also convex for any  $x \in \mathbb{R}^n$ .

**Corollary 2** Let  $f$  be a quasidifferentiable semismooth function. Assume that in the equality

$$f(x + \lambda g) - f(x) = \lambda f'(x, g) + o(\lambda, g), \quad g \in S_1$$

$\lambda^{-1}o(\lambda, g) \rightarrow 0$  as  $\lambda \rightarrow +0$  uniformly with respect to  $g \in S_1$ . Then for any  $\varepsilon > 0$  there exists  $\lambda_0 > 0$  such that

$$D_0(x, \lambda) \subset \partial f(x) + S_\varepsilon$$

for all  $\lambda \in (0, \lambda_0)$ .

Corollary 2 shows that the set  $D_0(x, \lambda)$  is an approximation to the subdifferential  $\partial f(x)$  for sufficiently small

$\lambda > 0$ . However, it is true at a given point. To get convergence results for a minimization algorithm based on discrete gradients, we need some relationship between the set  $D_0(x, \lambda)$  and  $\partial f(x)$  in some neighborhood of a given point  $x$ . We will consider functions satisfying the following assumption.

**Assumption 1** Let  $x \in \mathbb{R}^n$  be a given point. For any  $\varepsilon > 0$  there exist  $\delta > 0$  and  $\lambda_0 > 0$  such that

$$D_0(y, \lambda) \subset \partial f(x + \bar{S}_\varepsilon) + S_\varepsilon \quad (7)$$

for all  $y \in S_\delta(x)$  and  $\lambda \in (0, \lambda_0)$ . Here

$$\begin{aligned} \partial f(x + \bar{S}_\varepsilon) &= \bigcup_{y \in \bar{S}_\varepsilon(x)} \partial f(y), \quad \bar{S}_\varepsilon(x) \\ &= \{y \in \mathbb{R}^n : \|x - y\| \leq \varepsilon\}. \end{aligned}$$

### A Necessary Condition for a Minimum

Consider problem (1), where  $f : \mathbb{R}^n \rightarrow \mathbb{R}^1$  is an arbitrary function.

**Proposition 6** Let  $x^* \in \mathbb{R}^n$  be a local minimizer of function  $f$ . Then there exists  $\lambda_0 > 0$  such that

$$0 \in D_0(x, \lambda)$$

for all  $\lambda \in (0, \lambda_0)$ .

**Proposition 7** Let  $0 \notin D_0(x, \lambda)$  for a given  $\lambda > 0$  and  $v^0 \in \mathbb{R}^n$  be a solution to the following problem:

$$\text{minimize } \|v\|^2 \text{ subject to } v \in D_0(x, \lambda).$$

Then the direction  $g^0 = -\|v^0\|^{-1}v^0$  is a descent direction.

Proposition 7 shows how the set  $D_0(x, \lambda)$  can be used to compute descent directions. However, in many cases the computation of the set  $D_0(x, \lambda)$  is not possible. In the next section we propose an algorithm for the computation of descent directions using a few discrete gradients from  $D_0(x, \lambda)$ .

### Computation of Descent Directions

In this subsection we describe an algorithm for the computation of descent directions of the objective function  $f$  of Problem (1).

Let  $z \in P, \lambda > 0, \alpha \in (0, 1]$ , the number  $c \in (0, 1)$ , and a tolerance  $\delta > 0$  be given.

*Algorithm 1* An algorithm for the computation of the descent direction.

*Step 1.* Choose any  $g^1 \in S_1, e \in G$ ; compute  $i = \operatorname{argmax} \{|g_j|, j = 1, \dots, n\}$  and a discrete gradient  $v^1 = \Gamma^i(x, g^1, e, z, \lambda, \alpha)$ . Set  $\bar{D}_1(x) = \{v^1\}$  and  $k = 1$ .

*Step 2.* Compute the vector  $\|w^k\|^2 = \min\{\|w\|^2 : w \in \bar{D}_k(x)\}$ . If

$$\|w^k\| \leq \delta, \tag{8}$$

then stop. Otherwise go to Step 3.

*Step 3.* Compute the search direction by  $g^{k+1} = -\|w^k\|^{-1}w^k$ .

*Step 4.* If

$$f(x + \lambda g^{k+1}) - f(x) \leq -c\lambda \|w^k\|, \tag{9}$$

then stop. Otherwise go to Step 5.

*Step 5.* Compute  $i = \operatorname{argmax} \{|g_j^{k+1}| : j = 1, \dots, n\}$  and a discrete gradient

$$v^{k+1} = \Gamma^i(x, g^{k+1}, e, z, \lambda, \alpha),$$

construct the set  $\bar{D}_{k+1}(x) = \operatorname{co}\{\bar{D}_k(x) \cup \{v^{k+1}\}\}$ , set  $k = k + 1$ , and go to Step 2.

In what follows we provide some explanations of Algorithm 1. In Step 1 we compute the discrete gradient with respect to an initial direction  $g^1 \in \mathbb{R}^n$ . The distance between the convex hull  $\bar{D}_k(x)$  of all computed discrete gradients and the origin is computed in Step 2. This problem is solved using the algorithm from [21]. If this distance is less than the tolerance  $\delta > 0$ , then we accept point  $x$  as an approximate stationary point (Step 2); otherwise we compute another search direction in Step 3. In Step 4 we check whether this direction is a descent direction. If it is, we stop and the descent direction has been computed; otherwise we compute another discrete gradient with respect to this direction in Step 5 and update the set  $\bar{D}_k(x)$ . At each iteration  $k$  we improve the approximation of the subdifferential of function  $f$ .

The next proposition shows that Algorithm 1 is terminating.

**Proposition 8** *Let  $f$  be a locally Lipschitz function defined on  $\mathbb{R}^n$ . Then, for  $\delta \in (0, \bar{C})$ , either condition (8) or*

*condition (9) satisfies after  $m$  computations of the discrete gradients, where*

$$m \leq 2(\log_2(\delta/\bar{C})/\log_2 r + 1), r = 1 - [(1-c)(2\bar{C})^{-1}\delta]^2,$$

$\bar{C} = C(n)L$ , and  $C(n)$  is a constant from Proposition 4.

*Remark 6* Proposition 4 and equality (5) are true for any  $\lambda > 0$  and for any locally Lipschitz continuous functions. This means that Algorithm 1 can compute descent directions for any  $\lambda > 0$  and for any locally Lipschitz continuous functions in a finite number of iterations. Sufficiently small values of  $\lambda$  give an approximation to the subdifferential, and in this case Algorithm 1 computes local descent directions. However, larger values of  $\lambda$  do not give an approximation to the subdifferential and in this case descent directions computed by Algorithm 1 can be considered global descent directions.

### The Discrete Gradient Method

In this section we describe the discrete gradient method. Let sequences  $\delta_k > 0, z_k \in P, \lambda_k > 0, \delta_k \rightarrow +0, z_k \rightarrow +0, \lambda_k \rightarrow +0, k \rightarrow +\infty$ , sufficiently small number  $\alpha > 0$ , and numbers  $c_1 \in (0, 1), c_2 \in (0, c_1]$  be given.

*Algorithm 2* Discrete gradient method

*Step 1.* Choose any starting point  $x^0 \in \mathbb{R}^n$  and set  $k = 0$ .

*Step 2.* Set  $s = 0$  and  $x_s^k = x^k$ .

*Step 3.* Apply Algorithm 1 for the computation of the descent direction at  $x = x_s^k, \delta = \delta_k, z = z_k, \lambda = \lambda_k, c = c_1$ . This algorithm terminates after a finite number of iterations  $l > 0$ . As a result we get the set  $\bar{D}_l(x_s^k)$  and an element  $v_s^k$  such that

$$\|v_s^k\|^2 = \min\{\|v\|^2 : v \in \bar{D}_l(x_s^k)\}.$$

Furthermore, either  $\|v_s^k\| \leq \delta_k$  or for the search direction  $g_s^k = -\|v_s^k\|^{-1}v_s^k$

$$f(x_s^k + \lambda_k g_s^k) - f(x_s^k) \leq -c_1 \lambda_k \|v_s^k\|. \tag{10}$$

*Step 4.* If

$$\|v_s^k\| \leq \delta_k, \tag{11}$$

then set  $x^{k+1} = x_s^k, k = k + 1$  and go to Step 2. Otherwise go to Step 5.

*Step 5.* Construct the following iteration  $x_{s+1}^k = x_s^k + \sigma_s g_s^k$ , where  $\sigma_s$  is defined as follows:

$$\sigma_s = \operatorname{argmax} \left\{ \sigma \geq 0 : f(x_s^k + \sigma g_s^k) - f(x_s^k) \leq -c_2 \sigma \|v_s^k\| \right\}.$$

*Step 6.* Set  $s = s + 1$  and go to Step 3.

For the point  $x^0 \in \mathbb{R}^n$  we consider the set  $M(x^0) = \{x \in \mathbb{R}^n : f(x) \leq f(x^0)\}$ .

**Proposition 9** *Assume that function  $f$  is semismooth quasidifferentiable, its subdifferential and superdifferential are polytopes at any  $x \in \mathbb{R}^n$ , Assumption 1 is satisfied, and the set  $M(x^0)$  is bounded for starting points  $x^0 \in \mathbb{R}^n$ . Then every accumulation point of  $\{x^k\}$  belongs to the set  $X^0 = \{x \in \mathbb{R}^n : 0 \in \partial f(x)\}$ .*

*Remark 7* Since Algorithm 1 can compute descent directions for any values of  $\lambda > 0$ , we take  $\lambda_0 \in (0, 1)$ , some  $\beta \in (0, 1)$ , and update  $\lambda_k, k \geq 1$  as follows:

$$\lambda_k = \beta^k \lambda_0, k \geq 1.$$

Thus in the discrete gradient method we use approximations to subgradients only at the final stage of the method, which guarantees convergence. In most iterations we do not use explicit approximations of subgradients. Therefore it is a derivative-free method.

*Remark 8* It follows from (10) and  $c_2 \leq c_1$  that always  $\sigma_s \geq \lambda_k$  and therefore  $\lambda_k > 0$  is a lower bound for  $\sigma_s$ . This leads to the following rule for the computation of  $\sigma_s$ . We define a sequence:

$$\theta_m = m \lambda_k, m \geq 1,$$

and  $\sigma_s$  is defined as the largest  $\theta_m$  satisfying the inequality in Step 5.

## Applications

There are many problems from applications where the objective and/or constraint functions are not regular. We will consider one of them, the cluster analysis problem, which is an important application area in data mining.

Clustering is also known as the unsupervised classification of patterns; it deals with problems of organizing a collection of patterns into clusters based on similarity. Clustering has many applications in information retrieval, medicine, etc.

In cluster analysis we assume that we have been given a finite set  $C$  of points in the  $n$ -dimensional space  $\mathbb{R}^n$ , that is,

$$C = \{c^1, \dots, c^m\}, \text{ where } c^i \in \mathbb{R}^n, i = 1, \dots, m.$$

We consider here partition clustering, that is, the distribution of the points of set  $C$  into a given number  $q$  of disjoint subsets  $C^i, i = 1, \dots, q$  with respect to predefined criteria such that:

- (1)  $C^i \neq \emptyset, i = 1, \dots, q$ ;
- (2)  $C^i \cap C^j = \emptyset, i, j = 1, \dots, q, i \neq j$ ;
- (3)  $C = \bigcup_{i=1}^q C^i$ .

The sets  $C^i, i = 1, \dots, q$  are called clusters. The strict application of these rules is called *hard clustering*, unlike *fuzzy clustering*, where the clusters are allowed to overlap. We assume that no constraints are imposed on the clusters  $C^i, i = 1, \dots, q$ , that is, we consider the hard unconstrained clustering problem.

We also assume that each cluster  $C^i, i = 1, \dots, q$  can be identified by its center (or centroid). There are different formulations of clustering as an optimization problem. In [5,6,7] the cluster analysis problem is reduced to the following nonsmooth optimization problem:

$$\begin{aligned} & \text{minimize } f(x^1, \dots, x^q) \\ & \text{subject to } (x^1, \dots, x^q) \in \mathbb{R}^{n \times q}, \end{aligned} \quad (12)$$

where

$$f(x^1, \dots, x^q) = \frac{1}{m} \sum_{i=1}^m \min_{s=1, \dots, q} \|x^s - c^i\|^2. \quad (13)$$

Here  $\|\cdot\|$  is the Euclidean norm and  $x^s \in \mathbb{R}^n$  stands for the  $s$ th cluster center. If  $q > 1$ , then the objective function (13) in problem (12) is nonconvex and nonsmooth. Moreover, function  $f$  is a nonregular function, and the computation of even one subgradient of this function is quite a difficult task. This function can be represented as the difference of two convex functions as follows:

$$f(x) = f_1(x) - f_2(x),$$

where

$$f_1(x) = \frac{1}{m} \sum_{i=1}^m \sum_{s=1}^q \|x^s - c^i\|^2,$$

$$f_2(x) = \frac{1}{m} \sum_{i=1}^m \max_{s=1, \dots, q} \sum_{k=1, k \neq s}^q \|x^k - c^i\|^2.$$

It is clear that function  $f$  is quasidifferentiable and its subdifferential and are polytopes at any point.

Thus, the discrete gradient method can be applied to solve clustering problem.

## Conclusions

We have discussed a derivative-free discrete gradient method for solving unconstrained nonsmooth optimization problems. This algorithm can be applied to a broad class of optimization problems including problems with nonregular objective functions. It is globally convergent toward stationary points of semismooth, quasidifferentiable functions whose subdifferential and superdifferential are polytopes.

## Introduction

The optimal design of stochastic systems like queueing or inventory systems is a specific stochastic optimization problem.

Let  $Y_x(t)$  be an ergodic Markov process with discrete time  $t = 1, 2, \dots$  and values in  $\mathbf{R}^m$ , depending on a control parameter  $x \in \mathbf{R}^d$ . Let  $H(x, \cdot)$  be some cost function. The problem is to find the control  $x$  which minimizes the expected costs of the system either under the transient or under the stationary regime:

- 1) Under the *transient regime*, the process is started at time 0 in a specific starting state  $y_0$  and observed until time  $T$ . The optimality problem reads

$$\begin{cases} \min & F(x) = \sum_{t=1}^T \mathbb{E}[H(x, Y_x(t))] \\ \text{s.t.} & x \in S \subseteq \mathbb{R}^d. \end{cases} \quad (1)$$

- 2) Under the *stationary regime* it is assumed that  $Y_x(\infty)$  is distributed according to the stationary distribution of the process, which is — by ergodicity — the asymptotic distribution of  $Y_x(t)$  as  $t$  tends to infinity. The optimality problem reads

$$\begin{cases} \min & F(x) = \mathbb{E}[H(x, Y_x(\infty))] \\ \text{s.t.} & x \in S \subseteq \mathbb{R}^d. \end{cases} \quad (2)$$

As an example, consider the problem of optimally determining the decision limits  $(x_1, x_2)$  in an inventory policy (if the inventory at hand has fallen below  $x_1$  order the amount needed to bring the inventory up to  $x_2$ ). Assuming that the sales are of random size, the inventory system can be modeled as a Markov process depending on control parameters  $(x_1$  and  $x_2)$ .

The solution method for such an optimization problem is a version of the stochastic quasigradient method (cf. also ► [Stochastic quasigradient methods](#)). The solution is stepwise improved by moving it into the direction of an estimate of the negative gradient of the objective function.

The basic problem is therefore to find good estimates for the gradient  $\nabla_x F(x)$ . This problem is a generalization of the problem of finding derivatives of probability measures (cf. ► [Derivatives of probability measures](#)). The general notions of *distributional derivatives* (direct differentiability) and *process derivatives* (inverse differentiability) are applicable here.

## Process Derivatives

Suppose that the process  $Y_x(\cdot)$  has a representation of the form

$$Y_x(t+1) = K_t(x, Y_x(t), \xi_t),$$

where  $\xi_t$  is a sequence of random variables, the distribution of which does not depend on  $x$ . If the derivatives  $\nabla_x K_t(x, y, \xi)$ ,  $\nabla_y K_t(x, y, \xi)$  and  $\nabla_y H(y)$  exist, we get by elementary calculus

$$\begin{aligned} \nabla_x H(Y_x(t)) &= \nabla_y H(Y_x(t)) \\ &\times \left[ \sum_{i=0}^{t-1} \left( \prod_{j=i+1}^{t-1} \nabla_y K_j(x, Y_x(j), \xi_j) \right) \right. \\ &\quad \left. \nabla_x K_i(x, z_x(i), \xi_i) \right], \end{aligned} \quad (3)$$

where the order of multiplication in the product is here and in the following from left to right by *descending index*. Formula (3) may be computed recursively, as follows.

Define the  $[m \times d]$  (random) matrices  $N_t$  by

$$\begin{aligned} N_t &= \sum_{i=1}^{t-1} \left( \prod_{j=i+1}^{t-1} \nabla_y K_j(x, Y_x(j), \xi_j) \right) \\ &\quad \times \nabla_x K_i(x, Y_x(i), \xi_i). \end{aligned}$$

This sequence follows the forward recursion

$$\begin{aligned} N_0 &= 0, \\ N_{t+1} &= \nabla_x K_t(x, Y_x(t), \xi_t) + \nabla_y K_t(x, Y_x(t), \xi_t) \cdot N_t. \end{aligned}$$

After having found  $N_t$  by this recursion, one may calculate

$$\nabla_x H(Y_x(t)) = \nabla_y H(Y_x(t)) \cdot N_t.$$

This pointwise calculation carries over to the expectation under the standard assumptions of dominated convergence, yielding

$$\nabla_x \mathbb{E}[H(Y_x(t))] = \mathbb{E}[\nabla_y H(Y_x(t)) \cdot N_t].$$

Now, the estimate for the problem in transient regime is

$$\widehat{\nabla_x F}(x) = \sum_{t=1}^T H(Y_x(t)) \cdot N_t.$$

whereas for the stationary regime one uses

$$\widehat{\nabla_x F}(x) = \frac{1}{T - \tau} \sum_{t=\tau+1}^T H(Y_x(t)) \cdot N_t,$$

where  $T$  is large and  $\tau$  stands for the warmup-phase of the process, which is skipped for the estimation. Of course, the latter estimate is biased, its bias decreases with increasing  $T$  and  $\tau$ .

### Distributional Derivatives

Suppose that the Markov transition has transition density  $p_x(y_1 | y_0)$ , i. e.

$$P(Y_x(t+1) \in A | Y_x(t) = y_0) = \int_A p_x(y_1 | y_0) dy_1$$

and starts in state  $y_0$ . The expectation of  $H(Y_x(t))$  is

$$\begin{aligned} E[H(Y_x(t))] &= \int \cdots \int H(y_t) \prod_{i=1}^t p_x(y_i | y_{i-1}) dy_t \cdots dy_1. \end{aligned}$$

Introduce the *score function*

$$s_x(y_0, \dots, y_t) = \sum_{i=1}^t \frac{\nabla_x p_x(y_i | y_{i-1})}{p_x(y_i | y_{i-1})}.$$

By the product rule we get the formula

$$\begin{aligned} \nabla_x E[H(Y_x(t))] &= \int \cdots \int H(y_t) s_x(y_0, \dots, y_t) \\ &\quad \times \prod_{i=1}^t p_x(y_i | y_{i-1}) \cdots dy_t \cdots dy_1. \end{aligned}$$

An estimate for  $\nabla_x E[H(Y_x(t))]$  is

$$H(Y_x(t)) \cdot W_x(t),$$

where  $W_x(t) = s_x(Y_x(0), \dots, Y_x(t))$  is called the *score function martingale*. As before, the estimate for the problem in transient regime is

$$\widehat{\nabla_x F}(x) = \sum_{t=1}^T H(Y_x(t)) \cdot W_x(t),$$

whereas the estimate for the stationary regime is

$$\widehat{\nabla_x F}(x) = \frac{1}{T - \tau} \sum_{t=\tau}^T H(Y_x(t)) \cdot W_x(t).$$

It is asymptotically unbiased for  $T, \tau \rightarrow \infty$  (see [2]).

There is also the a way of attacking directly the derivative of the stationary distribution: Let  $P_x$  represent the transition matrix (transition operator) of the Markov process. The stationary distribution  $\pi_x$  satisfies

$$\pi_x = \pi_x \cdot P_x$$

and therefore

$$\nabla_x \pi_x = [\nabla_x \pi_x] \cdot P_x + \pi_x \cdot [\nabla_x P_x],$$

i. e.

$$\nabla_x \pi_x = \pi_x [\nabla_x P_x] S_x, \quad (4)$$

with

$$S_x = \sum_{k=0}^{\infty} (P_x^k - 1 \cdot \pi_x).$$

Here  $1 \cdot \pi_x$  is the transition with rows being identical to  $\pi_x$ . The operator  $S_x$  solves the *Poisson equation*

$$S_x(I - P_x) = I,$$

where  $I$  is the identity operator. There is a method, to use equation(4) as the basis for estimating  $\nabla_x E[Y_x(\cdot)]$ , see [1, Chapt. 3].

### Regenerative Processes

Recall that a set  $A$  is a *regenerative set* of the ergodic Markov transition  $P$  if

- i)  $u \rightarrow P(u, B)$  is independent of  $u \in A$ , for all  $B$ ; and
- ii)  $\pi(A) > 0$ , where  $\pi$  is the unique stationary probability measure pertaining to  $P$ .

Suppose that  $A$  is a regenerative set for all transitions  $P_x$ . The sequence of *regenerative stopping times* of  $Y_x(t)$  is

$$T_1^{(A)} = \min \{t: Y_x(t) \in A\},$$

$$T_{i+1}^{(A)} = \min \{t > T_i^{(A)}: Y_x(t) \in A\}.$$

These stopping times cut the process into independent pieces. For a process  $Y_x$  started in  $A$ , the following fundamental equation relates the finite time behavior to the stationary, i. e. long run behavior:

$$\mathbb{E}[H(Y_x(\infty))] = \frac{\mathbb{E}\left[\sum_{t=1}^{T^{(A)}} H(Y_x(t))\right]}{\mathbb{E}(T^{(A)})}. \quad (5)$$

The score method for derivative estimation gives

$$\nabla_x \mathbb{E}\left[\sum_{t=1}^{T^{(A)}} H(Y_x(t))\right] = \mathbb{E}\left[\sum_{t=1}^{T^{(A)}} H(Y_x(t)) W_x(t)\right]$$

and

$$\nabla_x \mathbb{E}[T^{(A)}] = \mathbb{E}\left[\sum_{t=1}^{T^{(A)}} W_x(t)\right]$$

and — by the quotient rule —

$$\begin{aligned} \nabla_x \mathbb{E}[H(Y_x(\infty))] &= \frac{\mathbb{E}(T^{(A)}) \cdot \nabla_x \mathbb{E}\left[\sum_{t=1}^{T^{(A)}} H(Y_x(t))\right]}{[\mathbb{E}(T^{(A)})]^2} \\ &= \frac{\mathbb{E}\left[\sum_{t=1}^{T^{(A)}} H(Y_x(t))\right] \cdot \nabla_x \mathbb{E}(T^{(A)})}{[\mathbb{E}(T^{(A)})]^2} \end{aligned}$$

(see [2]). For the estimation of  $\nabla_x \mathbb{E}[H(Y_x(\infty))]$ , all expectations of the right-hand side have to be replaced by estimates.

Probability function; Derivative of an integral; Gradient of an integral; Derivative of a probability function; Gradient of a probability function

*Probability functions* are commonly used for the analysis of models with uncertainties or variabilities in parameters. For instance, in risk and reliability analysis, performance functions, characterizing the operation of systems, are formulated as probabilities of successful or unsuccessful accomplishment of their missions (core damage probability of a nuclear power plant, probability of successful landing of an aircraft, probability of profitable transactions in a stock market, or percentiles of the risks in public risk assessments). Sensitivity analysis of such performance functions involves evaluating of their derivatives with respect to the parameters. Also, the derivatives of the probability function can be used to solve *stochastic optimization* problems [1].

A probability function can be formally presented as an expectation of a discontinuous indicator function of a set, or as an integral over a domain — depending upon parameters. Nevertheless, differentiability conditions of the probability function do not follow from similar conditions of the expectations of continuous (smooth or convex) functions.

The derivative of the probability function has many equivalent representations. It can be represented as an integral over the surface, an integral over the volume, or a sum of integrals over the volume and over the surface. Also, it can be calculated using weak derivatives of the probability measures or conditional expectations.

The first general result on the differentiability of the probability function was obtained by E. Raik [8]. He represented the gradient of the probability function with one constraint in the form of the surface integral. S. Uryasev [10] extended Raik’s formula for probability functions with many constraints. A.I. Kibzun and G.L. Tretyakov [3] extended it to the piecewise smooth constraint and probability density function. Special cases of probability function with normal and gamma distributions were investigated by A. Prékopa [6]. G.Ch. Pflug [5] represented the gradient of probability function in the form of an expectation using weak probability measures.

Uryasev [9] expressed the gradient of the probability function as a volume integral. Also, using a change of variables, K. Marti [4] derived the probability function gradient in the form of the volume integral.

A general analytical formula for the *derivative of probability functions* with many constraints was obtained by Uryasev [10]; it calculates the gradient as an integral over the surface, an integral over the volume, or the sum of integrals over the surface and the volume. Special cases of this formula correspond to the Raik formula [8], the Uryasev formula [9], and the change-of-variables approach [4].

The gradient of the quantile function was obtained in [2].

**Notations and Definitions**

Let an *integral over the volume*

$$F(x) = \int_{f(x,y) \leq 0} p(x, y) dy \tag{1}$$

be defined on the Euclidean space  $\mathbf{R}^n$ , where  $f: \mathbf{R}^n \times \mathbf{R}^m \rightarrow \mathbf{R}^k$  and  $p: \mathbf{R}^n \times \mathbf{R}^m \rightarrow \mathbf{R}$  are some functions. The inequality  $f(x, y) \leq 0$  in the integral is a system of inequalities

$$f_i(x, y) \leq 0, \quad i = 1, \dots, k.$$

Both the kernel function  $p(x, y)$  and the function  $f(x, y)$  defining the integration set depend upon the parame-

ter  $x$ . For example, let

$$F(x) = P\{f(x, \zeta(\omega)) \leq 0\} \tag{2}$$

be a *probability function*, where  $\zeta(\omega)$  is a random vector in  $\mathbf{R}^m$ . The random vector  $\zeta(\omega)$  is assumed to have a probability density  $p(x, y)$  that depends on a parameter  $x \in \mathbf{R}^n$ . The probability function can be represented as an *expectation of an indicator function*, which equals one on the integration set, and equals zero outside of it. For example, let

$$\begin{aligned} F(x) &= E [I_{\{f(x,\zeta) \leq 0\}} g(x, \zeta)] \\ &= \int_{f(x,y) \leq 0} g(x, y) \rho(x, y) dy \\ &= \int_{f(x,y) \leq 0} p(x, y) dy, \end{aligned} \tag{3}$$

where  $I_{\{\cdot\}}$  is an indicator function, and the random vector  $\zeta$  in  $\mathbf{R}^m$  has a probability density  $\rho(x, y)$  that depends on a parameter  $x \in \mathbf{R}$ .

**Integral Over the Surface Formula**

The following formula calculates the gradient of an integral (1) over the set given by nonlinear inequalities as sum of integral over the volume plus integral over the surface of the integration set. We call this the *integral over the surface formula* because if the density  $p(x, y)$  does not depend upon  $x$  the gradient of the integral (1) equals an integral over the surface. This formula for the case of one inequality was obtained by Raik [8] and generalized for the case with many inequalities by Uryasev [10].

Let us denote by  $\mu(x)$  the integration set

$$\begin{aligned} \mu(x) &= \{y \in \mathbb{R}^m : f(x, y) \leq 0\} \\ &:= \{y \in \mathbb{R}^m : f_l(x, y) \leq 0, 1 \leq l \leq k\} \end{aligned}$$

and by  $\partial\mu(x)$  the surface of this set  $\mu(x)$ . Also, let us denote by  $\partial_i\mu(x)$  a part of the surface which corresponds to the function  $f_i(x, y)$ , i. e.,

$$\partial_i\mu(x) = \mu(x) \cap \{y \in \mathbb{R}^m : f_i(x, y) = 0\}.$$

If the constraint functions are differentiable and the following integral exists, then gradient of integral (1)

equals

$$\begin{aligned} \nabla_x F(x) &= \int_{\mu(x)} \nabla_x p(x, y) dy \\ &\quad - \sum_{i=1}^k \int_{\partial_i \mu(x)} \frac{p(x, y)}{\|\nabla_y f_i(x, y)\|} \nabla_x f_i(x, y) dS. \end{aligned} \quad (4)$$

A potential disadvantage of this formula is that in multidimensional case it is difficult to calculate the integral over the nonlinear surface. Most well known numerical techniques, such as Monte-Carlo algorithms, are applicable to volume integrals. Nevertheless, this formula can be quite useful in various special cases, such as the linear case.

*Example 1* (Linear case: Integral over the surface formula [10].)

Let  $A(\omega)$ , be a random  $l \times n$  matrix with the joint density  $p(A)$ . Suppose that  $x \in \mathbb{R}^n$  and  $x_j \neq 0, j = 1, \dots, n$ . Let us define

$$\begin{aligned} F(x) &= P\{A(\omega)x \leq b, A(\omega) \geq 0\}, \\ b &= (b_1, \dots, b_l) \in \mathbb{R}^l, \quad x \in \mathbb{R}^n, \end{aligned} \quad (5)$$

i. e.  $F(x)$  is the probability that the linear constraints  $A(\omega)x \leq b, A(\omega) \geq 0$  are satisfied. The constraint,  $A(\omega) \geq 0$ , means that all elements  $a_{ij}(\omega)$  of the matrix  $A(\omega)$  are nonnegative. Let us denote by  $A_i$  and  $A^i$  the  $i$ th row and column of the matrix  $A$

$$A = \begin{pmatrix} A_1 \\ \vdots \\ A_l \end{pmatrix} = (A^1, \dots, A^n);$$

then

$$f(x, A) = \begin{pmatrix} f_1(x, A) \\ \vdots \\ f_k(x, A) \end{pmatrix} = \begin{pmatrix} A_1 x - b_1 \\ \vdots \\ A_l x - b_l \\ -A^1 \\ \vdots \\ -A^n \end{pmatrix},$$

$$k = l + l \times n.$$

The function  $F(x)$  equals

$$F(x) = \int_{f(x, A) \leq 0} p(A) dA. \quad (6)$$

We use formula (4) to calculate the gradient  $\nabla_x F(x)$  as an integral over the surface. The function  $p(A)$  does not depend upon  $x$  and  $\nabla_x p(A) = 0$ . Formula (4) implies that  $\nabla_x F(x)$  equals

$$- \sum_{i=1}^k \int_{\partial_i \mu(x)} \frac{p(A)}{\|\nabla_A f_i(x, A)\|} \nabla_x f_i(x, A) dS.$$

Since  $\nabla_x f_i(x, A) = 0$  for  $i = l + 1, \dots, k$ , then  $\nabla_x F(x)$  equals

$$\begin{aligned} & - \sum_{i=1}^l \int_{\partial_i \mu(x)} \frac{p(A)}{\|\nabla_A f_i(x, A)\|} \nabla_x f_i(x, A) dS \\ &= - \sum_{i=1}^l \int_{\partial_i \mu(x)} \frac{p(A)}{\|x\|} A_i^\top dS \\ &= - \|x\|^{-1} \sum_{i=1}^l \int_{\substack{Ax \leq b, \\ A \geq 0 \\ A_i x = b_i}} p(A) A_i^\top dS. \end{aligned}$$

### Integral Over the Volume Formula

This section presents gradient of the function (1) in the form of volume integral. Let us introduce the following shorthand notations

$$\begin{aligned} f_{1l}(x, y) &= \begin{pmatrix} f_1(x, y) \\ \vdots \\ f_l(x, y) \end{pmatrix}, \quad f(x, y) = f_{1k}(x, y), \\ \nabla_y f(x, y) &= \begin{pmatrix} \frac{\partial f_1(x, y)}{\partial y_1} & \dots & \frac{\partial f_k(x, y)}{\partial y_1} \\ \vdots \\ \frac{\partial f_1(x, y)}{\partial y_m} & \dots & \frac{\partial f_k(x, y)}{\partial y_m} \end{pmatrix}. \end{aligned}$$

Divergence for the  $n \times m$  matrix  $H$  consisting of the elements  $h_{ji}$  is denoted by

$$\operatorname{div}_y H = \begin{pmatrix} \sum_{i=1}^m \frac{\partial h_{1i}}{\partial y_i} \\ \vdots \\ \sum_{i=1}^m \frac{\partial h_{ni}}{\partial y_i} \end{pmatrix}.$$

Following [10], the derivative of the function (1) is represented as an integral over the volume

$$\begin{aligned} \nabla_x F(x) &= \int_{\mu(x)} \nabla_x p(x, y) dy \\ &\quad + \int_{\mu(x)} \operatorname{div}_y (p(x, y) H(x, y)) dy, \end{aligned} \quad (7)$$

where a matrix function  $H: \mathbf{R}^n \times \mathbf{R}^m \rightarrow \mathbf{R}^{n \times m}$  satisfies the equation

$$H(x, y)\nabla_y f(x, y) + \nabla_x f(x, y) = 0. \tag{8}$$

The last system of equations may have many solutions, therefore formula (7) provides a number of equivalent expressions for the gradient. The following section gives analytical solutions of this system of equations. In some cases, this system does not have any solution, and formula (7) is not valid. The following section deals with such cases and provides a general formula where system of equations can be solved only for some of the functions defining the integration set.

*Example 2* (Linear case: Integral over the volume formula [10].)

With formula (7), the gradient of the probability function (5) with linear constraints considered in Example 1 can be represented as the integral over the volume. It can be shown that equation (8) does not have a solution in this case. Nevertheless, we can slightly modify the constraints, such that integration set is not changed and equation (8) has a solution. In the vector function  $f(x, A)$  we multiply column  $A^i$  on  $x^i$  if  $x^i$  is positive or multiply it on  $-x^i$  if  $x^i$  is negative. Therefore, we have the following constraint function

$$f(x, A) = \begin{pmatrix} A_1x - b_1 \\ \vdots \\ A_lx - b_l \\ -(+)x_1A^1 \\ \vdots \\ -(+)x_nA^n \end{pmatrix}, \tag{9}$$

where  $-(+)$  means that we take an appropriate sign. It can be directly checked that, the matrix  $H_l^*(x, A)$

$$H^*(x, A) = \left( h^1(x, A_1), \dots, h^l(x, A_l) \right),$$

$$h^i(x, A_i) = - \begin{pmatrix} a_{i1}x_1^{-1} & & 0 \\ & \ddots & \\ 0 & & a_{in}x_n^{-1} \end{pmatrix}$$

is a solution of system (8). As it will be shown in the next section, this analytical solution follows from the fact that change of the variables  $Y^i = x_iA^i, i = 1, \dots,$

$n$ , eliminates variables  $x^i, i = 1, \dots, n$ , from the constraints (9).

Since  $\nabla_x p(A) = 0$  and  $\text{div}_A(p(A)H^*(x, A))$  equals

$$- \begin{pmatrix} x_1^{-1} \left( lp(A) + \sum_{i=1}^l a_{i1} \frac{\partial}{\partial a_{i1}} p(A) \right) \\ \vdots \\ x_n^{-1} \left( lp(A) + \sum_{i=1}^l a_{in} \frac{\partial}{\partial a_{in}} p(A) \right) \end{pmatrix},$$

formula (7) implies that  $\partial F(x)/\partial x_j$  equals

$$-x_j^{-1} \int_{\substack{A_{xx} \leq b \\ A \geq 0}} \left( lp(A) + \sum_{i=1}^l a_{ij} \frac{\partial}{\partial a_{ij}} p(A) \right) dA.$$

### General Formula

Further, we give a general formula [9,10] for the differentiation of integral (1). A gradient of the integral is represented as a sum of integrals taken over a volume and over a surface. This formula is useful when system of equations (8) does not have a solution. We split the set of constraints  $K := \{1, \dots, k\}$  into two subsets  $K_1$  and  $K_2$ . Without loss of generality we suppose that

$$K_1 = \{1, \dots, l\}, \quad K_2 = \{l + 1, \dots, k\}.$$

The derivative of integral (1) can be represented as the sum of the volume and surface integrals

$$\begin{aligned} \nabla_x F(x) &= \int_{\mu(x)} \nabla_x p(x, y) dy \\ &+ \int_{\mu(x)} \text{div}_y (p(x, y)H_l(x, y)) dy \\ &- \sum_{i=l+1}^k \int_{\partial_i \mu(x)} \frac{p(x, y)}{\|\nabla_y f_i(x, y)\|} \\ &\times [\nabla_x f_i(+x, y) + H_l(x, y)\nabla_y f_i(x, y)] dS, \end{aligned} \tag{10}$$

where the matrix  $H_l: \mathbf{R}^n \times \mathbf{R}^m \rightarrow \mathbf{R}^{n \times m}$  satisfies the equation

$$H_l(x, y)\nabla_y f_{il}(x, y) + \nabla_x f_{il}(x, y) = 0. \tag{11}$$

The last equation can have a lot of solutions and we can choose an arbitrary one, differentiable with respect to the variable  $y$ .

The general formula contains as a special cases the integral over the surface formula (4) and integral over the volume formula (7). When the set  $K_1$  is empty, the

matrix  $H_l$  is absent and the general formula is reduced to the integral over the surface. Also, when the set  $K_2$  is empty we have integral over the volume formula (7). Except these extreme cases, the general formula provides number of intermediate expressions for the gradient in the form of the sum of an integral over the surface and an integral over the volume. Thus, we have a number of equivalent representations of the gradient corresponding to the various sets  $K_1$  and  $K_2$  and solutions of equation (11).

Equation (11) (and equation (8) which is a partial case of equation (11)) can be solved explicitly. Usually, this equation has many solutions. The matrix

$$-\nabla_x f_{1l}(x, y) \times \left( \nabla_y^T f_{1l}(x, y) \nabla_y f_{1l}(x, y) \right)^{-1} \nabla_y^T f_{1l}(x, y) \quad (12)$$

is a solution of equation (11). Also, in many cases there is another way to solve equation (11) using change of variables. Suppose that there is a change of variables

$$y = \gamma(x, z)$$

which eliminates vector  $x$  from the function  $f(x, y)$  defining integration set, i. e., function  $f(x, \gamma(x, z))$  does not depend upon the variable  $x$ . Denote by  $\gamma^{-1}(x, y)$  the inverse function, defined by the equation

$$\gamma^{-1}(x, \gamma(x, z)) = z.$$

Let us show that the following matrix

$$H(x, y) = \nabla_x \gamma(x, z)|_{z=\gamma^{-1}(x, y)} \quad (13)$$

is a solution of (11). Indeed, the gradient of the function  $\gamma(x, \gamma(x, z))$  with respect to  $x$  equals zero, therefore

$$\begin{aligned} 0 &= \nabla_x f_{1l}(x, \gamma(x, z)) \\ &= \nabla_x \gamma(x, z) \nabla_y f_{1l}(x, y)|_{y=\gamma(x, z)} \\ &\quad + \nabla_x f_{1l}(x, y)|_{y=\gamma(x, z)}, \end{aligned}$$

and function  $\nabla_x \gamma(x, z)|_{z=\gamma^{-1}(x, y)}$  is a solution of (11).

Formula (7) with matrix (13) gives the derivative formulas which can be obtained with change of variables in the integration set [4].

*Example 3* While investigating the operational strategies for inspected components (see [7]) the following

integral was considered

$$F(x) = \int_{\substack{b(y) \leq x, \\ y_i \geq \theta, \\ i=1, \dots, m}} p(y) dy, \quad (14)$$

where  $x \in \mathbf{R}^1, y \in \mathbf{R}^m, p: \mathbf{R}^m \rightarrow \mathbf{R}^1, \theta > 0, b(y) = \sum_{i=1}^m y_i^\alpha$ . In this case

$$f(x, y) = \begin{pmatrix} b(y) - x \\ \theta - y_1 \\ \vdots \\ \theta - y_m \end{pmatrix},$$

and

$$F(x) = \int_{f(x, y) \leq 0} p(y) dy = \int_{\mu(x)} p(y) dy.$$

Let us consider that  $l = 1$ , i. e.  $K_1 = \{1\}$  and  $K_2 = \{2, \dots, m + 1\}$ . The gradient  $\nabla_x F(x)$  equals

$$\begin{aligned} &\int_{\mu(x)} [\nabla_x p(y) + \text{div}_y (p(y)H_1(x, y))] dy \\ &- \sum_{i=2}^{m+1} \int_{\partial_i \mu(x)} \frac{p(y)}{\|\nabla_y f_i(x, y)\|} \\ &\times [\nabla_x f_i(x, y) + H_1(x, y) \nabla_y f_i(x, y)] dS, \quad (15) \end{aligned}$$

Where the matrix  $H_1(x, y)$  satisfies (11). In view of

$$\nabla_y f_1(x, y) = \alpha \begin{pmatrix} y_1^{\alpha-1} \\ \vdots \\ y_m^{\alpha-1} \end{pmatrix}, \quad \nabla_x f_1(x, y) = -1.$$

a solution  $H_1^*(x, y)$  of (11) equals

$$\begin{aligned} H_1^*(x, y) &= h(y) := (h_1(y_1), \dots, h_m(y_m)) \\ &= \frac{1}{\alpha m} (y_1^{1-\alpha}, \dots, y_m^{1-\alpha}). \quad (16) \end{aligned}$$

Let us denote

$$\begin{aligned} (\theta_i | y) &= (y_1, \dots, y_{i-1}, \theta, y_{i+1}, \dots, y_m), \\ y^{-i} &= (y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_m), \\ b(\theta_i | y) &= \theta^\alpha + \sum_{\substack{j=1 \\ j \neq i}}^m y_j^\alpha. \end{aligned}$$

We denote by  $y^{-i} \geq \theta$  the set of inequalities

$$y_j \geq \theta, \quad j = 1, \dots, i - 1, \quad i + 1, \dots, m.$$

The sets  $\partial_i \mu(x)$ ,  $i = 2, \dots, m + 1$ , have a simple structure

$$\begin{aligned} \partial_i \mu(x) &= \mu(x) \cap \{y \in \mathbb{R}^m : y_i = \theta\} \\ &= \{y^{-i} \in \mathbb{R}^{m-1} : b(\theta_i|y) \leq x, y^{-i} \geq \theta\}. \end{aligned}$$

For  $i = 2, \dots, m + 1$ , we have

$$(\nabla_y f_i(y))_j = 0, \quad j = 1, \dots, m, \quad j \neq i - 1, \quad (17)$$

$$(\nabla_y f_i(y))_{i-1} = -1, \quad \|\nabla_y f_i(y)\| = 1. \quad (18)$$

The function  $p(y)$  and the functions  $f_i(y)$ ,  $i = 2, \dots, m + 1$ , do not depend on  $x$ , consequently

$$\nabla_x p(y) = 0, \quad (19)$$

$$\nabla_x f_i(y) = 0, \quad i = 2, \dots, m + 1. \quad (20)$$

Equations (15)–(20) imply

$$\begin{aligned} \nabla_x F(x) &= \int_{\mu(x)} \operatorname{div}_y (p(y)h(y)) \, dy \\ &\quad - \sum_{i=2}^{m+1} \int_{\partial_i \mu(x)} \frac{p(y)}{\|\nabla_y f_i(y)\|} h(y) \nabla_y f_i(y) \, dS \\ &= \int_{\mu(x)} \operatorname{div}_y (p(y)h(y)) \, dy \\ &\quad + \sum_{i=2}^{m+1} h_{i-1}(\theta) \int_{\partial_i \mu(x)} p(y) \, dS \\ &= \int_{\substack{b(y) \leq x, \\ y_i \geq \theta, \\ i=1, \dots, m}} \operatorname{div}_y (p(y)h(y)) \, dy \\ &\quad + \sum_{i=1}^m \frac{\theta^{1-\alpha}}{\alpha m} \int_{\substack{b(\theta_i|y) \leq x, \\ y^{-i} \geq \theta}} p(\theta_i|y) \, dy^{-i}. \end{aligned}$$

Since

$$\begin{aligned} \operatorname{div}_y (p(y)h(y)) &= h(y) \nabla_y p(y) + p(y) \operatorname{div}_y h(y) \\ &= \frac{1}{\alpha m} \sum_{i=1}^m \frac{\partial p(y)}{\partial y_i} y_i^{1-\alpha} + p(y) \frac{1-\alpha}{\alpha m} \sum_{i=1}^m y_i^{-\alpha}, \end{aligned}$$

we, finally, obtain that the gradient  $\nabla_x F(x)$  equals

$$\int_{\substack{b(y) \leq x, \\ y_i \geq \theta, \\ i=1, \dots, m}} \sum_{i=1}^m \frac{y_i^{-\alpha}}{\alpha m} \left[ y_i \frac{\partial p(y)}{\partial y_i} + (1-\alpha)p(y) \right] \, dy$$

$$+ \frac{\theta^{1-\alpha}}{\alpha m} \sum_{i=1}^m \int_{\substack{b(\theta_i|y) \leq x, \\ y^{-i} \geq \theta}} p(\theta_i|y) \, dy^{-i}.$$

The formula for  $\nabla_x F(x)$  is valid for an arbitrary sufficiently smooth function  $p(y)$ .

### Keywords

Derivatives; Stochastic optimization

For stochastic optimization problems of the form

$$\begin{cases} \min & F(x) = \int H(x, \nu) d\mu_x(\nu) \\ \text{s.t.} & x \in S \subseteq \mathbb{R}^d \end{cases} \quad (1)$$

where  $H(x, \nu)$  is a cost function,  $\mu_x$  a family of probability measures indexed by  $x$  and  $F(x)$  the objective value function (OVF), the necessary condition  $\nabla_x F(x) = 0$  must be expressed in terms of the derivatives of  $H(x, \cdot)$  and  $\mu_x$  w.r.t.  $x$ . In particular, concepts of differentiability of probability measures are needed.

### Direct Differentiability

Suppose that the family  $(\mu_x)$  is *dominated*, i. e. there is a Borel measure  $\nu$  such that the densities

$$g_x(\nu) = \frac{d\mu_x}{d\nu}(\nu)$$

exist for all  $x$ . Then the differentiability of the measures may be defined by the differentiability of the densities.

**Definition 1** The family of densities  $(g_x(\nu))$  is called *strongly  $L_1(\nu)$ -differentiable* if there is a vector of integrable functions  $\nabla_x g_x = (g'_{x,1}, \dots, g'_{x,d})^\top$  such that

$$\int |g_{x+h}(\nu) - g_x(\nu) - h^\top \cdot \nabla_x g_x(\nu)| d\nu(\nu) = o(\|h\|) \quad \text{as } \|h\| \downarrow 0. \quad (2)$$

The family of densities  $(g_x(\nu))$  is called *weakly  $L_1(\nu)$ -differentiable* if there is a vector of  $L_1(\nu)$  functions  $\nabla_x g_x = (g'_{x,1}, \dots, g'_{x,d})^\top$  such that for every bounded measurable function  $H$

$$\begin{aligned} \int [g_{x+h}(\nu) - g_x(\nu) - h^\top \cdot \nabla_x g_x(\nu)] H(\nu) d\nu(\nu) \\ = o(\|h\|) \quad \text{as } \|h\| \downarrow 0. \quad (3) \end{aligned}$$

Weak differentiability implies strong differentiability but not vice versa.

There is also a notion of differentiability for families  $(\mu_x)$ , which do not possess densities (see [3]).

If the densities  $(g_x)$  are differentiable and  $H(x, \nu)$  is boundedly differentiable in  $x$  and bounded and continuous in  $\nu$ , then the gradient of  $F(x) = \int H(x, \nu) g_x(\nu) d\nu(\nu)$  is

$$\begin{aligned} \int \nabla_x H(x, \nu) g_x(\nu) d\nu(\nu) \\ + \int H(x, \nu) \nabla_x g_x(\nu) d\nu(\nu). \end{aligned}$$

### Inverse Differentiability

The family  $(\mu_x)$  is called *process differentiable* if there exists a family of random variables  $V_x(\omega)$  — the *process representation* — defined on some probability space  $(\Omega, \mathcal{A}, \mathbb{P})$ , such that:

- $V_x(\cdot)$  has distribution  $\mu_x$  for all  $x$ ; and
- $x \mapsto V_x(\omega)$  is differentiable a.s.

As an example, let  $\mu_x$  be exponential distributions with densities  $g_x(\nu) = x \exp(-x \cdot \nu)$ . Then  $V_x(\omega) = (1/x)U$  for  $U \sim \text{Uniform}[0, 1]$  is a process representation in the sense of a) and differentiable in the sense of b) with derivative  $\nabla_x V_x(\omega) = -(1/x^2)U$ .

Process differentiability does not imply and is not implied by weak differentiability. If  $G_x(u) = \int_{-\infty}^u g_x(\nu) d\nu$  is the distribution function, then process differentiability is equivalent to the differentiability of  $x \mapsto G_x^{-1}(u)$ , whereas the weak differentiability is connected to the differentiability of  $x \mapsto G_x(u)$ .

If  $V_x(\cdot)$  is a process representation of  $(\mu_x)$ , then the objective function

$$F(x) = \int H(x, \nu) d\mu_x(\nu) = \mathbb{E}[H(x, V_x)]$$

has derivative

$$\nabla_x F(x) = \mathbb{E}[H_x(x, V_x) + H_\nu(x, V_x) \cdot \nabla_x V_x].$$

where  $H_x(x, \nu) = \nabla_x H(x, \nu)$  and  $H_\nu(x, \nu) = \nabla_\nu H(x, \nu)$ .

**Simulation of Derivatives**

If the objective function  $F$  in (1) is easily calculated, then the stochastic optimization problem reduces to a standard nonlinear deterministic optimization problem. This is however the exception. In the majority of applications, the objective function value has to be approximated either by a numeric integration technique or a Monte-Carlo (MC) estimate. In the same manner, the gradient  $\nabla_x F(x)$  may be approximated either by numerical integration or by Monte-Carlo simulation. We discuss here the construction of MC estimates for the gradient  $\nabla_x F(x)$ . For simplicity, we treat only the univariate case  $x \in \mathbf{R}^1$ .

We begin with recalling the Monte-Carlo (MC) method for estimating  $F(x)$ . If  $(V_x^{(i)})$  is a sequence of independent identically distributed random variables with distribution function  $G_x$ , then the MC estimate

$$\widehat{F}_n(x) = \frac{1}{n} \sum_{i=1}^n H(x, V_x^{(i)})$$

is an unbiased estimate of  $F(x)$ .

**Process Derivatives**

If the family  $(\mu_x)$  has differentiable process representation  $(V_x)$ , then

$$\widehat{\nabla_x F}_n(x) = \frac{1}{n} \sum_{i=1}^n \left[ H_x(x, V_x^{(i)}) + H_v(x, V_x^{(i)}) \cdot \nabla_x V_x^{(i)} \right] \quad (4)$$

is a MC estimate of  $\nabla_x F(x)$ . The method of using the process derivative (4) is also called *perturbation analysis* ([1,2]).

**Distributional Derivatives**

If the densities  $g_x$  are differentiable, there are two possibilities to construct estimates. First, one may define the *score function*  $s_x(v) = [\nabla_x g_x(v)]/g_x(v)$  and construct the score function estimate [4]

$$\widehat{\nabla_x F}_n(x) = \frac{1}{n} \sum_{i=1}^n \left[ H_x(x, V_x^{(i)}) + H(x, V_x^{(i)}) s_x(V_x^{(i)}) \right],$$

which is unbiased.

Alternatively, one may write the function  $\nabla_x g_x(v)$  in the form

$$\nabla_x g_x(v) = c_x [\dot{g}_x(v) - \ddot{g}_x(v)], \quad (5)$$

where  $\dot{g}_x$  and  $\ddot{g}_x$  are probability densities w.r.t.  $v$ , and  $c_x$  is a nonnegative constant. One possibility is to set  $\dot{g}_x$  resp.  $\ddot{g}_x$  as the appropriately scaled positive, resp. negative, part of  $\nabla_x g_x$ , but other representations are possible as well. Let now  $\dot{V}_x^{(i)}$ , resp.  $\ddot{V}_x^{(i)}$ , be random variables with distributions  $\dot{g}_x d\nu$ , resp.  $\ddot{g}_x d\nu$ . The *difference estimate* is

$$\widehat{\nabla_x F}_n(x) = \frac{1}{n} \times \sum_{i=1}^n \left\{ H_x(x, V_x^{(i)}) + c_x [H(x, \dot{V}_x^{(i)}) - H(x, \ddot{V}_x^{(i)})] \right\},$$

which is unbiased (see [3]).

*Example 2* Assume again that  $(\mu_x)$  are exponential distributions with expectation  $x$ . The probability  $\mu_x$  has density

$$g_x(y) = x \cdot \exp(-xy).$$

Let  $V_x$  be distributed according to  $\mu_x$ . For simplicity, assume that the cost function  $H$  does not depend explicitly on  $x$ . We need estimates for  $\nabla_x E(H(V_x))$ . The three methods are:

1) Score derivative: The score function is

$$\frac{\nabla_x g_x(v)}{g_x(v)} = \frac{1}{x} - v$$

and the score function estimate is

$$\widehat{\nabla_x F}^{(1)} = H \left( V_x \right) \left( \frac{1}{x} - V_x \right).$$

2) Difference derivative: There are several representations in the sense of (5). One could use the decomposition of  $\nabla_x g_x(\cdot)$  into its positive and negative part (*Jordan-Hahn decomposition*) and get the estimate

$$\widehat{\nabla_x F}^{(2a)} = \frac{1}{x} (H(\dot{V}_x) - H(\ddot{V}_x)),$$

where  $\dot{V}_x$  has density

$$x e(1 - xv) e^{-xv} \cdot \mathbf{1}_{v \leq \frac{1}{x}}$$

and  $\ddot{V}_x$  has density

$$xe^{(xv-1)}e^{-xv} \cdot 1_{v>\frac{1}{x}}$$

and both are independent.

Another possibility is to set

$$\dot{V}_x = -\frac{1}{x} \log U_1,$$

$$\ddot{V}_x = -\frac{1}{x} (\log U_1 + \log U_2),$$

where  $U_1, U_2$  are independent Uniform  $[0, 1]$  variates. The final difference estimate is

$$\widehat{\nabla_x F^{(2b)}} = \frac{1}{x} (H(\dot{V}_x) - H(\ddot{V}_x)).$$

- 3) Process derivative: A process representation of  $(\mu_x)$  is

$$V_x = -\frac{1}{x} \log(1 - U), \quad U \sim \text{Uniform}[0, 1].$$

A process derivative of  $H(V_x)$  is

$$\widehat{\nabla_x F_x^{(3)}} := H_x(V_x) \left(-\frac{1}{x} V_x\right).$$

Notice that in methods 1) and 2) the function  $H$  need not to be differentiable and may be an indicator function – as is required in some applications. In method 3), the function  $H$  must be differentiable.

Whenever a MC estimate  $\widehat{\nabla_x F(x)}$  has been defined, it can be used in a stochastic quasigradient method (SQG; cf. also ► [Stochastic quasigradient methods](#)) for optimization

$$X_{s+1} = \text{pr}_S[X_s - \rho_s \widehat{\nabla_x F_n}(X_s)]$$

where  $\text{pr}_S$  is the projection on the set  $S$  and  $(\rho_s)$  are the stepsizes. The important feature of such algorithms is the fact that they work with stochastic estimates. In particular, the sample size  $n$  per step can be set to 1 and still convergence holds under regularity assumptions. To put it differently, the SQG allows to approach quickly a neighborhood of the solution even with much noise corrupted estimates.

## Keywords

Optimization; Computational fluid dynamics

## Synonyms

Design Optimization in CFD

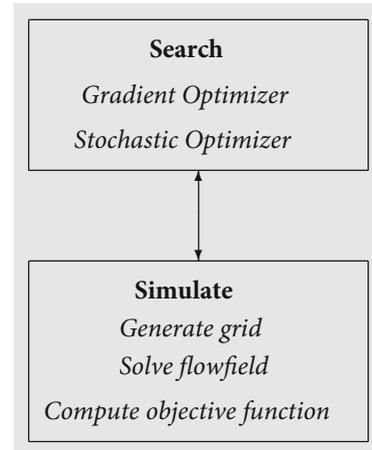

## Focus

The article focuses on design optimization using computational fluid dynamics (CFD). *Design* implies the creation of an engineering prototype (e.g., a pump) or engineering process (e.g., particle separator). *Optimization* indicates the selection of a ‘best’ design. *Computational fluid dynamics* (CFD) represents a family of models of fluid motion implemented on a digital computer. In recent years, efforts have focused on merging elements of these three disciplines to improve design effectiveness and efficiency.

## Framework

Consider the design of a prototype or process with  $n$  design variables  $\{x_i; i = 1, \dots, n\}$  denoted by  $\mathbf{x}$ . It is assumed that  $n$  is finite, although infinite-dimensional design spaces also exist (e.g., the shape of a civilian transport aircraft). The domain of  $\mathbf{x}$  constitutes the *design space*. A scalar *objective function*  $f(\mathbf{x})$  is assumed to be defined for some (or possibly all) points in the design space. This is the simplest design optimization problem. Oftentimes, however, the optimization cannot be easily cast into this form, and other methods (e.g., Pareto optimality) are employed. The purpose of the design optimization is to find the design point  $\mathbf{x}^*$  which minimizes  $f$ . Note that there is no loss of generality in assuming the objective is to minimize  $f$ , since the maximization of an objective function  $\tilde{f}(\mathbf{x})$  is equivalent to the minimization of  $f = -\tilde{f}$ .

The design optimization is typically an iterative process involving two principal elements. The first element is the *simulation* which evaluates the objective function by (in the case of computational fluid dynamics) a fluid flow code (*flow solver*). The second element is the *search* which determines the direction for traversing the design space. The search engine is the *optimizer* of which they are several different types as described later. The design optimization process is an iterative procedure involving repetitive simulation and search steps until

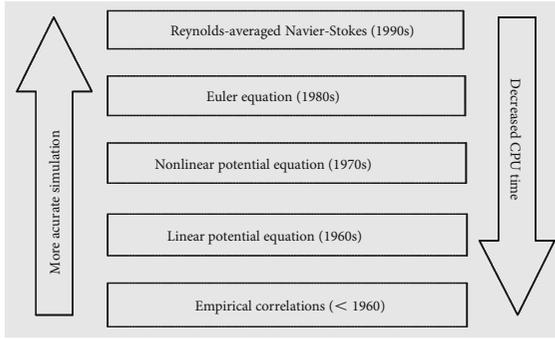

Design Optimization in Computational Fluid Dynamics, Figure 1

### Elements of design optimization

a predefined convergence criteria is met. This is illustrated in Fig. 1.

### Levels of Simulation

There are five levels of complexity for CFD simulation Fig. 2. *Empirical methods* represent correlations of experimental data and possibly simple one-dimensional analytical models. An example is the NIDA code [15] employed for analysis of two-dimensional and axisymmetric inlets. The code is restricted to a limited family of geometries and flow conditions (e.g., no sideslip). Codes based on the *linear potential* equations (e.g., PANAIR [6]; see also [17]) and *nonlinear potential* equations (e.g., [8]; see also [7]) incorporate increased geometric flexibility while implementing a simplified model of the flow physics (i.e., it is assumed that the shock waves are weak and there is no significant flow separation). Codes employing the *Euler equations* (e.g., [22]) allow for strong shocks and vorticity although neglect viscous effects. *Reynolds-averaged Navier–Stokes codes* (RANS codes) (e.g., GASP [31]) employ a model for the effects of turbulence. The range of execution time between the lowest and highest levels is roughly three orders of magnitude, e.g., on a conventional workstation the NIDA code requires only a few seconds execution time while a 2-dimensional RANS simulation would typically require a few hours.

Design Optimization in Computational Fluid Dynamics, Figure 2

### Levels of CFD simulation

### The Stages of Design

There are typically three stages of design: *conceptual*, *preliminary* and *detailed*. As the names suggest, the design specification becomes more precise at successive design stages. Thus, for example, a conceptual design of a civilian transport aircraft may consider a (discrete) design space with the possibility of two, three or four engines, while the preliminary design space assumes a fixed number of engines and considers the details of the engine (e.g., nacelle shapes). It is important to note that the CFD algorithms employed in each of these three stages are likely to be different. Typically, the conceptual design stage employs empirical formulae, while the preliminary design stage may also include simplified CFD codes (e.g., linearized and nonlinear potential methods, and Euler codes), and the detailed design stage may utilize full Reynolds-averaged Navier–Stokes methods. Additionally, experiment is oftentimes essential to verify key features of the design.

### Emergence of Automated Design Optimization Using CFD

Although the first numerical simulation of viscous fluid flow was published in 1933 by A. Thom [51], CFD as a discipline emerged with the development of digital mainframe computers in the 1960s. With the principal exception of the work on inverse design methods for airfoils (see, for example, the review [30] and [48]), CFD has mainly been employed in *design analysis* as a cost-effective replacement for some types of experiments. However, CFD can now be employed as part of

an *automated design optimization process*. This opportunity has arisen for five reasons. First, the continued rapid improvements in computer performance (e.g., doubling of microprocessor performance every 18 to 24 months [3]) enable routine numerical simulations of increasing sophistication and complexity. Second, improvements in the accuracy, efficiency and robustness of CFD algorithms (see, for example, [18]) likewise contribute to the capability for simulation of more complex flows. Third, the development of more accurate turbulence models provides increased confidence in the quality of the flow simulations [16]. Fourth, the development of efficient and robust optimizers enable automated search of design spaces [33]. Finally, the development of sophisticated shell languages (e.g., Perl [43]) provide effective control of pathological events which may occur in an automated design cycle using CFD (e.g., square root of a negative number, failure to converge within a predetermined number of iterations, etc.).

### Problem Definition

The general scalar *nonlinear optimization problem* (also known as the *nonlinear programming problem*) is [11,33,52]

$$\text{minimize } f(\mathbf{x}), \quad (1)$$

where  $f(\mathbf{x})$  is the scalar *objective function* and  $\mathbf{x}$  is the vector of design variables. Typically there are limits on the allowable values of  $\mathbf{x}$ :

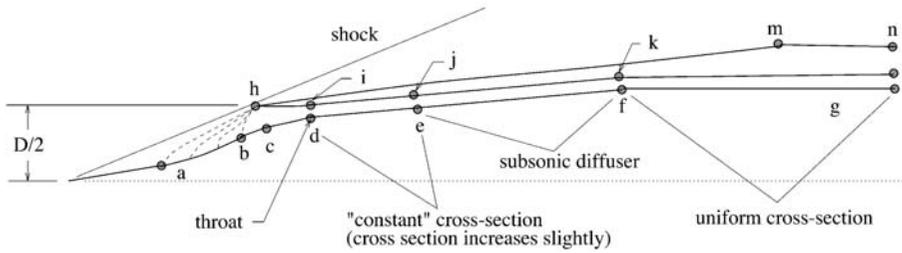

$$\mathbf{a} \leq \mathbf{x} \leq \mathbf{b}, \quad (2)$$

and  $m$  additional *linear* and/or *nonlinear constraints*

$$\begin{cases} c_i(\mathbf{x}) = 0, & i = 1, \dots, m', \\ c_i(\mathbf{x}) \leq 0, & i = m' + 1, \dots, m. \end{cases} \quad (3)$$

If  $f$  and  $c_i$  are linear functions, then the optimization problem is denoted the *linear programming problem*, while if  $f$  is quadratic and the  $c_i$  are linear, then the optimization problem is denoted the *quadratic programming problem*.

An example of a nonlinear optimization problem using CFD is the design of the shape of an inlet for a supersonic missile. The geometry model of an axisymmetric inlet [53] is shown in Fig. 3.

**Design Optimization in Computational Fluid Dynamics, Figure 3**  
**Geometry of high speed inlet**

The eight design variables are listed below.

Item	Definition
$\theta_1$	initial cone angle
$\theta_2$	final cone angle
$x_d$	x-coordinate of throat
$r_d$	r-coordinate of throat
$x_e$	x-coordinate of end of 'constant' cross section
$\theta_3$	internal cowl lip angle
$H_{ej}$	height at end of 'constant' cross section
$H_{fk}$	height at beginning of 'constant' cross section

There are no general methods for guaranteeing that the *global* minimum of an *arbitrary* objective function  $f(\mathbf{x})$  can be found in a finite number of steps [4,11]. Typically, methods focus on determining a *local* minimum with additional (often heuristic) techniques to avoid convergence to a local minimum which is not the global minimum.

A point  $\mathbf{x}^*$  is a (strong) *local minimum* [11] if there is a region surrounding  $\mathbf{x}^*$  wherein the objective function is defined and  $f(\mathbf{x}) > f(\mathbf{x}^*)$  for  $\mathbf{x} \neq \mathbf{x}^*$ . Provided  $f(\mathbf{x})$  is twice continuously differentiable (this is not always true; see, for example, [53]), necessary and sufficient conditions for the existence of a solution to (1) subject to (3) may be obtained [11]. In the one-dimensional case with no constraints the sufficient conditions for a minimum at  $x^*$  are

$$g = 0 \text{ and } H > 0 \text{ at } x = x^*,$$

where  $g = df/dx$  and  $H = d^2f / dx^2$ . For the multidimensional case with no constraints

$$|g_i| = 0 \text{ and } H \text{ is positive definite at } x = x^*, \quad (4)$$

where  $g_i = \partial f / \partial x_i$ ,  $|g_i|$  is the norm of the vector  $g_i$ , and  $H = H_{ij}$  is the *Hessian matrix*

$$H = \begin{pmatrix} \frac{\partial^2 f}{\partial x_1^2} & \cdots & \frac{\partial^2 f}{\partial x_1 \partial x_n} \\ \vdots & & \vdots \\ \frac{\partial^2 f}{\partial x_1 \partial x_n} & \cdots & \frac{\partial^2 f}{\partial x_n \partial x_n} \end{pmatrix}.$$

The matrix  $H$  is positive definite if all of the eigenvalues of  $H$  are positive.

### Algorithms for Optimization

The efficacy of an optimization algorithm depends strongly on the nature of the design space. In engineering problems, the design space can manifest pathological characteristics. The objective function  $f$  may possess multiple local optima [36] arising from physical and/or numerical reasons. Examples of the latter include noise introduced in the objective function by grid refinement between successive flow simulations, and incomplete convergence of the flow simulator. Also, the objective function  $f$  and/or its gradient  $g_i$  may exhibit near discontinuities for physical reasons. For example, a small change in the the design state  $\mathbf{x}$  of a mixed compression supersonic inlet operating at critical conditions can cause the terminal shock to be expelled, leading to a rapid decrease in total pressure recovery [44]. Moreover, the objective function  $f$  may not be evaluable at certain points. This may be due to constraints in the flow simulator such as a limited range of applicability for empirical data tables.

A brief description of some different classes of general optimizers is presented. These methods are described for the unconstrained optimization problem for reasons of brevity. See [33] for an overview of opti-

mization algorithms and software packages, and [11] for a comprehensive discussion of the constrained optimization problem. Detailed mathematical exposition of optimization problems is presented in [19].

### Gradient Optimizers

If the objective function  $f$  can be approximated in the vicinity of a point  $\tilde{\mathbf{x}}$  by a quadratic form, then

$$f \approx \tilde{f} + \tilde{g}_i(x_i - \tilde{x}_i) + \frac{1}{2}(x_i - \tilde{x}_i)\tilde{H}_{ij}(x_j - \tilde{x}_j), \quad (5)$$

where  $\tilde{f}$ ,  $\tilde{g}$  and  $\tilde{H}_{ij}$  imply evaluation at  $\tilde{\mathbf{x}}$  and the Einstein summation convention is implied. In the relatively simple *method of steepest descent* [40], the quadratic term in (5) is ignored, and a line minimization is performed along the direction of  $-g_i$ , i. e., a sequence of values of the design variable  $\mathbf{x}^{(v)}$ ,  $v = 1, \dots$ , are formed according to

$$\mathbf{x}^{(v)} = \tilde{\mathbf{x}} + \delta\mathbf{x}^{(v)}$$

where

$$\delta x_i^{(v)} = -\lambda^{(v)} \tilde{g}_i |\tilde{g}_i|^{-1}$$

and  $\lambda^{(v)}$ ,  $v = 1, \dots$ , are an increasing sequence of displacements. The estimated decrease in the objective function  $f$  is  $-\lambda^{(v)} |\tilde{g}_i|$ . The objective function  $f$  is evaluated at each iteration  $v$  and the search is terminated when  $f$  begins to increase. At this location, the gradient  $g_i$  is computed and the procedure is repeated. This method, albeit straightforward to implement, is inefficient for design spaces which are characterized by long, narrow ‘valleys’ [40].

The *conjugate gradient methods* [40] are more efficient than the method of steepest descent, since they perform a sequence of line minimizations along specific directions in the design space which are mutually orthogonal in the context of the objective function. Consider a line minimization of  $f$  along a direction  $\mathbf{u} = \{u_i; i = 1, \dots, n\}$ . At any point on the line, the gradient of  $f$  in the direction of  $\mathbf{u}$  is  $u_i \tilde{g}_i$  by definition. At the minimum point  $\tilde{\mathbf{x}}$  in the line search,

$$u_i \tilde{g}_i = 0$$

by definition. Consider a second line minimization of  $f$  along a direction  $\mathbf{v}$ . From (5) and noting that  $H_{ij}$  is symmetric, the change in  $g_i$  along the direction  $\mathbf{v}$  is  $\tilde{H}_{ij} v_j$ .

Thus, the condition that the second line minimization also remain a minimization along the first direction  $\mathbf{u}$  is

$$u_i \tilde{H}_{ij} v_j = 0$$

When this condition is satisfied,  $\mathbf{u}$  and  $\mathbf{v}$  are denoted *conjugate pairs*. Conjugate gradient methods (CGM) generate a sequence of directions  $\mathbf{u}, \mathbf{v}, \dots$  which are mutually conjugate. If  $f$  is exactly quadratic, then CGM yield an  $n$ -step sequence to the minimum.

*Sequential quadratic programming methods* employ the Hessian  $H$  which may be computed directly when economical or may be approximated from the sequence of gradients  $g_i$  generated during the line search (the *quasi-Hessian* [33]). Given the gradient and Hessian, the location  $x_i^*$  of the minimum value of  $f$  may be found from (5) as

$$\tilde{H}_{ij}(x_j^* - \tilde{x}_j) = -\tilde{g}_i.$$

For the general case where  $f$  is not precisely quadratic, a line minimization is typically performed in the direction  $(x_i^* - \tilde{x}_i)$ , and the process is repeated.

*Variational sensitivity* employs the concept of direct differentiation of the optimization function  $f$  and governing fluid dynamic equations (in continuous or discrete form) to obtain the gradient  $g_i$ , and optimization using a gradient-based method. It is related to the theory of the control of systems governed by partial differential equations [29,39]. For example, the boundary shape (e.g., airfoil surface) is viewed as the (theoretically infinite-dimensional) design space which controls the objective function  $f$ . Several different formulations have been developed depending on the stage at which the numerical discretization is performed, and the use of direct or adjoint (costate) equations. Detailed descriptions are provided in [23] and [24]. Additional references include [2,5,20,21,37,38,50].

The following summary follows the presentation in [24] which employs the adjoint formulation. The objective function  $f$  is considered to be a function of the flowfield variables  $w$  and the physical shape  $S$ . The differential change in the objective function is therefore

$$\delta f = \frac{\partial f}{\partial w} \delta w + \frac{\partial f}{\partial S} \delta S. \quad (6)$$

The discretized governing equations of the fluid motion are represented by the vector of equations

$$R(w; S) = 0$$

and therefore

$$\delta R = \frac{\partial R}{\partial w} \delta w + \frac{\partial R}{\partial S} \delta S = 0, \quad (7)$$

where  $\delta R$  is a vector. Assume a vector Lagrange multiplier  $\psi$  and combining (6) and (7)

$$\delta f = \left\{ \frac{\partial f}{\partial w} - \psi^\top \frac{\partial R}{\partial w} \right\} \delta w + \left\{ \frac{\partial f}{\partial S} - \psi^\top \frac{\partial R}{\partial S} \right\} \delta S,$$

where  $\top$  indicates vector transpose. If  $\psi$  is chosen to satisfy the adjoint (costate) equation

$$\psi^\top \frac{\partial R}{\partial w} = \frac{\partial f}{\partial w}, \quad (8)$$

then

$$\delta f = G \delta S,$$

where

$$G = \frac{\partial f}{\partial S} - \psi^\top \frac{\partial R}{\partial S}.$$

This yields a straightforward method for optimization using, for example, the method of steepest descent. The increment in the shape is

$$\delta S = -\lambda G,$$

where  $\lambda$  is a positive scalar. The variational sensitivity approach is particularly advantageous when the dimension  $n$  of the design space (which defines  $S$ ) is large, since the gradient of  $S$  is obtained from a single flowfield solution (7) plus a single adjoint solution (8) which is comparable to the flowfield solution in cost. Constraints can be implemented by projecting the gradient onto an allowable subspace in which the constraints are satisfied.

*Response surface methods* employ an approximate representation of the objective function using smooth functions which are typically quadratic polynomials [25]. For example, the objective function may be approximated by

$$f \approx \hat{f} = \alpha + \sum_{1 \leq i \leq n} \beta_i x_i + \sum_{1 \leq i \leq j \leq n} \gamma_{ij} x_i x_j$$

where  $\alpha$ ,  $\beta_i$  and  $\gamma_{ij}$  are coefficients which are determined by fitting  $\hat{f}$  to a discrete set of data using the method of least squares. The minimum of  $\hat{f}$  can then be found by any of the gradient optimizers, with optional recalibration of the coefficients of  $\hat{f}$  as needed. There are many different implementations of the response surface method (see, for example, [12,34] and [46]).

## Stochastic Optimizers

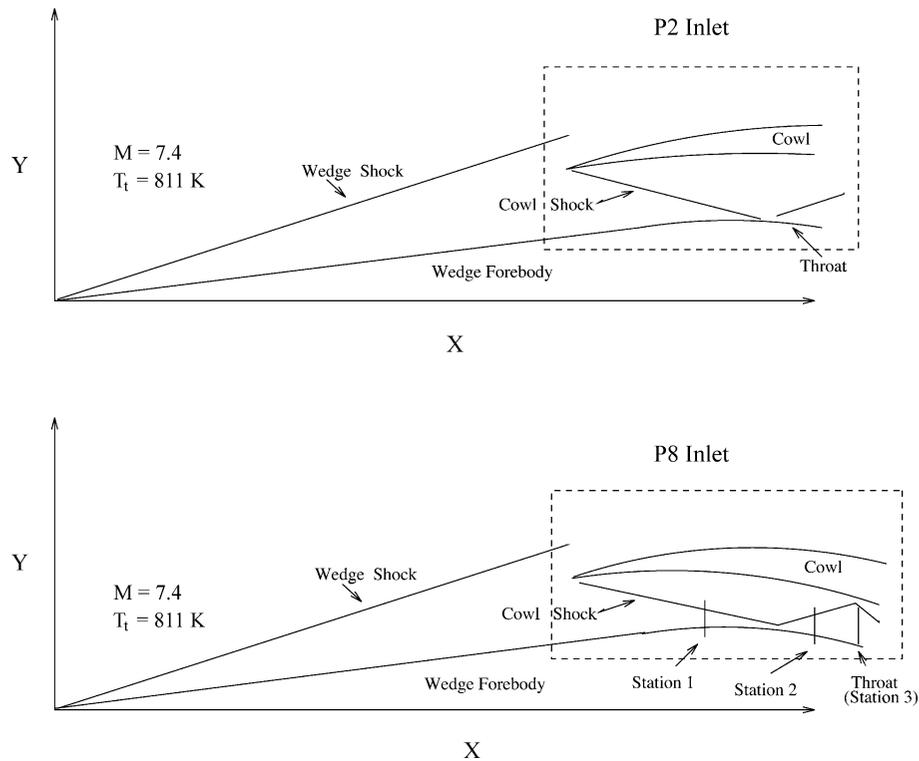

Often the objective function is not well behaved in a portion or all of the design space as discussed above. In such situations, gradient methods can stop without achieving the global optimum (e. g., at an infeasible point, or a local minimum). Stochastic optimizers seek to avoid these problems by incorporating a measure of randomness in the optimization process, albeit often-times at a cost of a significant increase in the number of evaluations of the objective function  $f$ .

*Simulated annealing* [26,27,32] mimics the process of crystallization of liquids or annealing of metals by minimizing a function  $E$  which is analogous to the energy of a thermodynamic system. Consider a current point (state) in the design space  $\tilde{\mathbf{x}}$  and its associated ‘energy’  $\tilde{E}$ . A candidate for the next state  $\mathbf{x}^*$  is selected by randomly perturbing typically one of the components  $\tilde{x}_j$ ,  $1 \leq j \leq n$ , of  $\tilde{\mathbf{x}}$  and its energy  $E^*$  is evaluated (typically, each component of  $\mathbf{x}$  is perturbed in sequence). If  $E^* < \tilde{E}$  then  $\tilde{\mathbf{x}} = \mathbf{x}^*$ , i. e., the next state is  $\mathbf{x}^*$ . If  $E^* > \tilde{E}$  then the probability of selecting  $\mathbf{x}^*$  as the next design state is

$$p = \exp\left(-\frac{E^* - \tilde{E}}{kT}\right),$$

where  $k$  is the ‘Boltzman constant’ (by analogy to statistical mechanics) and  $T$  is the ‘temperature’ which is successively reduced during the optimization according to an assumed schedule [27]. (Of course, only the value of the product  $kT$  is important.) The stochastic nature can be implemented by simply calling a random number generator to obtain a value  $r$  between zero and one. Then the state  $\mathbf{x}^*$  is selected if  $r < p$ . Therefore, during the sequence of design states, the algorithm permits the selection of a design state with  $E > \tilde{E}$ , but the probability of selecting such a state decreases with increasing  $E - \tilde{E}$ . This feature tends to enable (but does not guarantee) the optimizer to ‘jump out’ of a local minimum.

*Genetic algorithms* (GAs) mimic the process of biological evolution by means of random changes (mutations) in a set of designs denoted the *population* [14]. At each step, the ‘least fit’ member(s) of the population (i. e., those designs with the highest value of  $f$ ) are typically removed, and new members are generated by a recombination of some (or all) of the remaining members. There are numerous GA variants. In the approach of [41], an initial population  $P$  of designs is generated

**Design Optimization in Computational Fluid Dynamics, Figure 4**  
P2 and P8 inlets

by randomly selecting points  $\mathbf{x}_i$ ,  $i = 1, \dots, p$ , satisfying (2). The two best designs (i. e., with the lowest values of  $f$ ) are joined by a straight line in the design space. A random point  $\mathbf{x}'$  is chosen on the line connecting the two best designs. A mutation is performed by randomly selecting a point  $\mathbf{x}_{p+1}$  within a specified distance of  $\mathbf{x}'$ . This new point is added to the population. A member of the population is then removed according to a heuristic criterion, e. g., among the  $k$  members with the highest  $f$ , remove the member closest to  $\mathbf{x}_{p+1}$ , thus maintaining a constant number of designs in the population. The removal of the closest member tends to prevent clustering of the population (i. e., maintains diversity). The process is repeated until convergence.

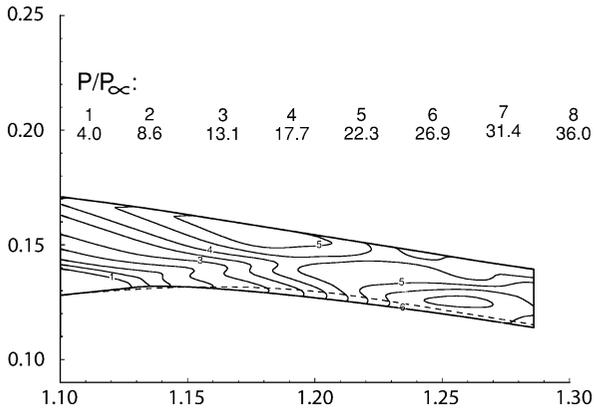

### Examples

Examples of the above algorithms for optimization using CFD are presented. All of the examples are single discipline involving CFD only. It is emphasized that

multidisciplinary optimization (MDO) involving computational fluid dynamics, structural dynamics, electromagnetics, materials and other disciplines is a very active and growing field, and many of the optimization algorithms described herein are appropriate to MDO also. A recent review is presented in [49].

### Sequential Quadratic Programming

V. Shukla et al. applied a sequential quadratic programming algorithm CFSQP [28] to the optimal design of two hypersonic inlets (denoted P2 and P8) at Mach 7.4. The geometric model is shown in Fig. 4. The optimization criteria was the minimization of the strength of the shock wave which reflected from the centerbody (lower) surface. This is the same criteria as originally posed in the design of the P2 and P8 inlets [13]. The NPARC flow solver [47] was employed for the P2 optimization, and the GASP flow solver [31] for the P8 optimization.

Design Optimization in Computational Fluid Dynamics, Figure 5

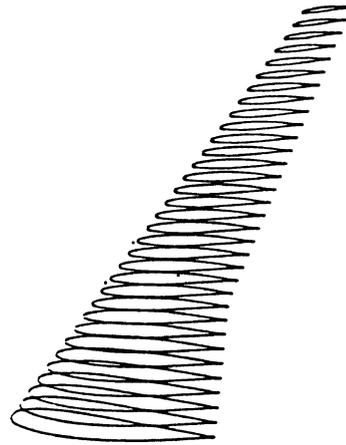

Static pressure contours for optimal P8 inlet (the original centerbody contour is shown by the dotted line)

The optimization criteria was met for both inlets. In Fig. 5, the static pressure contours for the optimized P8 inlet are shown. The strength of the reflected shock is negligible.

### Variational Sensitivity

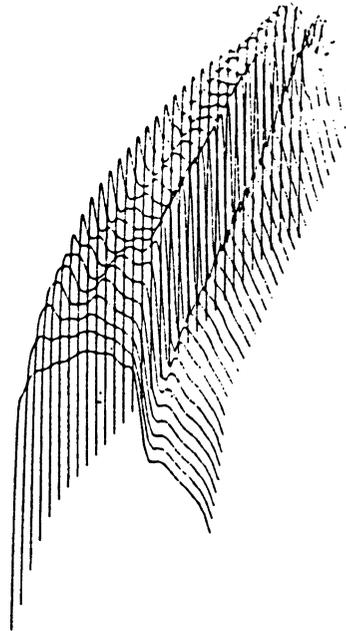

A. Jameson et al. [24] applied the methodology of variational sensitivity (control theory) to the optimization of a three-dimensional wing section for a subsonic wide-body commercial transport. The design objective was to minimize the drag at a given lift coefficient  $C_L = 0.55$  at Mach 0.83 while maintaining a fixed planform. A two stage procedure was implemented. The first stage employed the Euler equations, while the second stage used the full Reynolds-averaged Navier–Stokes equations. In the second stage, the pressure distribution obtained from the Euler optimization is used as the target pressure distribution.

The initial starboard wing shape is shown in Fig. 6 as a sequence of sections in the spanwise direction. The initial pressure distribution on the upper surface, shown as the pressure coefficient  $c_p$  plotted with negative values upward, is presented in Fig. 7. A moderately strong shock wave is evident, as indicated by the sharp drop in  $-c_p$  at roughly the mid-chord line. After sixty design cycles of the first stage, the drag coefficient was reduced by 15 counts from 0.0196 to 0.0181, and the shock wave eliminated as indicated in the  $c_p$  distribution in Fig. 8. A subsequent second stage optimization

Design Optimization in Computational Fluid Dynamics, Figure 6

Initial shape of wing

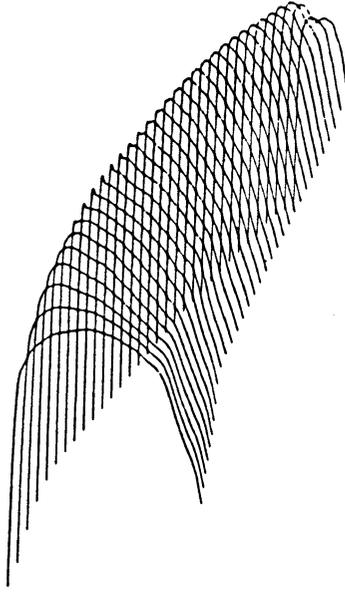

Design Optimization in Computational Fluid Dynamics, Figure 7

Initial surface pressure distribution

using the Reynolds-averaged Navier–Stokes equations yielded only slight modifications.

### Response Surface

R. Narducci et al. [35] applied a response surface method to the optimal design of a two-dimensional

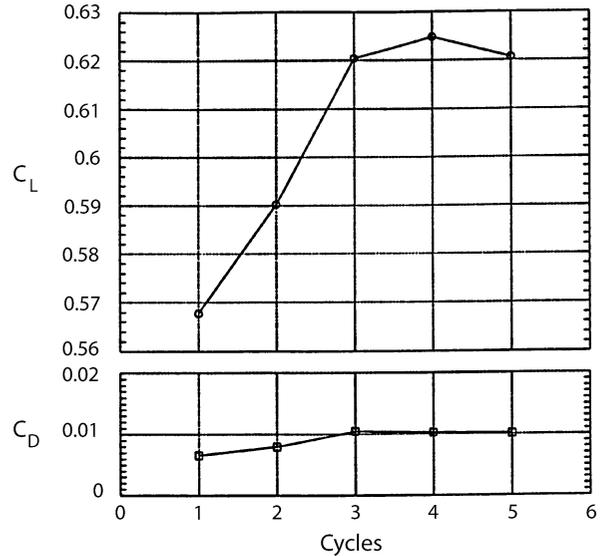

Design Optimization in Computational Fluid Dynamics, Figure 8  
Optimized surface pressure distribution

transonic airfoil. The design objective was to maximize the lift coefficient  $C_L$  at Mach 0.75 and zero degrees angle of attack, while satisfying the constraints that the drag coefficient  $C_D \leq 0.01$  and the thickness ratio  $0.075 \leq t \leq 0.15$  where  $t$  is the ratio of the maximum airfoil thickness to the airfoil chord. The airfoil surface was represented by a weighted sum of six different shapes which included four known airfoils (a different set of basis functions were employed in [9] for airfoil optimization using a conjugate gradient method). The objective function  $f$  was represented by a quadratic polynomial. An inviscid flow solver was employed.

A successful optimization was achieved in five response surface cycles. The history of the convergence of  $C_L$  and  $C_D$  is shown in Fig. 9. A total of twenty three flow solutions were required for each response surface.

### Simulated Annealing

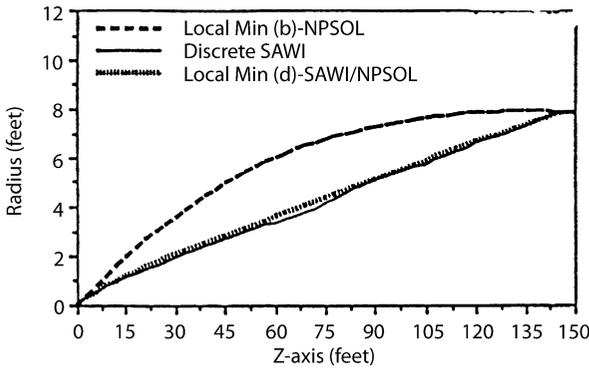

S. Aly et al. [1] applied a modified simulated annealing algorithm to the optimal design of an axisymmetric forebody in supersonic flow. The design objective was to minimize the pressure drag on the forebody of a vehicle at Mach 2.4 and zero angle of attack, subject to constraints on the allowable range of the body radius as

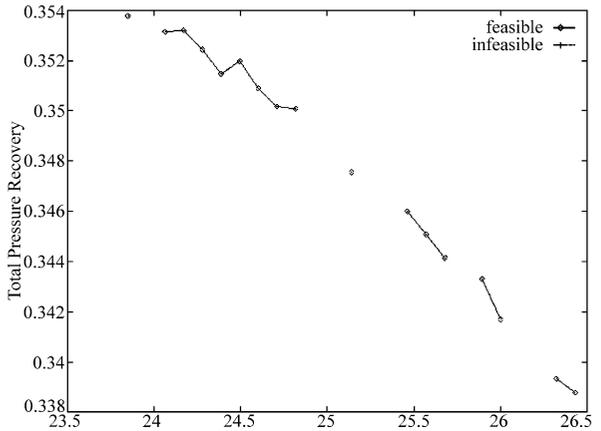

Design Optimization in Computational Fluid Dynamics, Figure 9  
Convergence history for transonic airfoil

a function of axial position. Two different variants of SA were employed, and compared to a gradient optimizer NPSOL [10] which is based on a sequential quadratic programming algorithm. All optimizers employed the same initial design which satisfied the constraints but was otherwise a clearly nonoptimal shape. Optimizations were performed for two different initial shapes. The flow solver was a hybrid finite volume implicit Euler marching method [45].

The first method, denoted simulated annealing with iterative improvement (SAWI), employed SA for the initial phase of the optimization, and then switched to a random search iterative improvement method when close to the optimum. This method achieved from 8% to 31% reduction in the pressure drag, compared to optimal solution obtained NPSOL alone, while requiring fewer number of flowfield simulations (which constitute the principal computational cost). The second method employed SA for the initial phase of the optimization, followed by NPSOL. This approach achieved from 31% to 39% reduction in the pressure drag, compared to the optimal solution obtained by NPSOL alone, while requiring comparable (or less) cputime. The forebody shapes obtained using SA, SA with NPSOL and NPSOL alone are shown in Fig. 10.

Total pressure recovery coefficient versus axial location of throat

**Genetic Algorithms**

G. Zha et al. applied a modified genetic algorithm (GADO [42]) to the optimal design of an axisymmetric supersonic mixed compression inlet at Mach 4 and 60 kft altitude cruise conditions (see above). The geometric model included eight degrees of freedom (see above), and the optimization criteria was maximization of the inlet total pressure recovery coefficient. The constraints included the requirement for the inlet to start at Mach 2.6, plus additional constraints on the inlet geometry including a minimum cowl thickness and leading edge angle. The constraints were incorporated into the GA using a penalty function. The flow solver was the empirical inlet analysis code NIDA [15]. This code is very efficient, requiring only a few seconds cputime on a workstation, but is limited to 2-dimensional or axisymmetric geometries. Moreover, the design space generated by NIDA (i. e., the total pressure recovery coefficient as a function of the eight degrees of freedom) is nonsmooth with numerous local minima and gaps attributable to the use of empirical data Fig. 11.

The GA achieved a 32% improvement in total pressure recovery coefficient compared to a trial-and-error method [53]. A total of 50 hours on a DEC-2100 workstation was employed. A series of designs generated during the optimization were selected for evaluation by a full Reynolds-averaged Navier–Stokes code (GASP [31]). A close correlation was observed between the predictions of NIDA and GASP Fig. 12.

**Design Optimization in Computational Fluid Dynamics, Figure 12**  
Total pressure recovery coefficient from NIDA and GASP for several different inlet designs

**Conclusion**

Computational fluid dynamics has emerged as a vital tool in design optimization. The five levels of CFD analysis are utilized in various optimization methodologies. Complex design optimizations have become commonplace. A significant effort is focused on multidisciplinary optimization involving fluid dynamics, solid mechanics, materials and other disciplines.

### Introduction/Background

Model predictive control (MPC) is very popular for its capacity to deal with multivariable, constraints-model-based control problems for a variety of complex linear or non-linear processes [13]. MPC is based on the receding-time-horizon philosophy where an open-loop, constrained optimal control problem is solved online at each sampling time to obtain the optimal control actions. The optimal control problem is solved repet-

itively at each time when a new measurement or estimate of the state is available, thus establishing an implicit feedback control method [14,15]. The main reasons for the popularity of MPC are its optimal performance, its capability to handle constraints and its inherent robustness due to feedback control properties.

Despite the widely acknowledged capabilities of MPC, there are two main shortcomings that have been a major concern for the industrial and academic communities. The first shortcoming is that MPC implementation is limited to slowly varying processes due to the demanding online computational effort for solving the online optimal control problem. The second is that, despite its inherent robustness due to the implicit feedback, MPC cannot guarantee the satisfaction of constraints and optimal performance in the presence of uncertainties and input disturbances, since usually it relies on nominal models (uncertainty-free models) for the prediction of future states and control actions [14,20,22].

The first shortcoming of MPC can be overcome by employing the so-called parametric MPC (pMPC) or multiparametric MPC (mp-MPC) [4,16,20]. Parametric MPC controllers are based on the well-known *parametric optimization* techniques [9,18] for solving the open-loop optimal control problem offline and obtain the complete map of the optimal control actions as functions of the states. Thus, a feedback control law is obtained offline and the online computational effort is reduced to simple function evaluations of the feedback control. The inevitable presence of uncertainties and disturbances have been ignored by the pMPC community, and only recently has the research started focusing on control problems with uncertainty [2,20]. In traditional MPC the issue of robustness under uncertainty has been dealt with using various methods such as robust model predictive control [3,8], model predictive tubes [6,12] and min-max MPC [21,22]. However, this is still an unexplored area for pMPC, apart from the recent work presented in [2,20].

In this manuscript we discuss the challenges of robust parametric model predictive control (RpMPC) and we present a method for RpMPC for linear, discrete-time dynamic systems with exogenous disturbances (input uncertainty) and a method for RpMPC for systems with model uncertainty. In both cases the uncertainty is described by the realistic scenario where

no uncertainty model (stochastic or deterministic) is known but it is assumed that the uncertainty variables satisfy a set of inequalities.

### Definitions

Consider the following linear, discrete-time system:

$$\begin{aligned} x_{t+1} &= Ax_t + Bu_t + W\theta_t \\ y_t &= Bx_t + Du_t + F\theta_t, \end{aligned} \quad (1)$$

where  $x \in \mathcal{X} \subset \mathbb{R}^n$ ,  $u \in \mathcal{U} \subset \mathbb{R}^m$ ,  $y \in \mathcal{Y} \subset \mathbb{R}^q$  and  $\theta \in \Theta \subset \mathbb{R}^w$  are the state, input, output and disturbance (or uncertain) input vectors respectively and  $A, B, C, D, W$  and  $F$  are matrices of appropriate dimensions. The disturbance input  $\theta$  is assumed to be bounded in the set  $\Theta = \{\theta \in \mathbb{R}^w | \theta_i^L \leq \theta_i \leq \theta_i^U, i = 1, \dots, w\}$ . This type of uncertainty is used to characterize a broad variety of input disturbances and modeling uncertainties including non-linearities or hidden dynamics [7,11]. This type of uncertainty in general may result in infeasibilities and performance degradation.

**Definition 1** The robust controller is defined as the controller that provides a single control sequence that steers the plant into the feasible operating region for a specific range of variations in the uncertain variables.

The general robust parametric MPC (RpMPC) problem is defined as [20]

$$\phi(x_{t|t}) = \min_{u^N \in V^N} \left\{ x_{t+N|t}^T P x_{t+N|t} + \sum_{k=0}^{N-1} \left[ y_{t+k|t}^T Q y_{t+k|t} + u_{t+k}^T R u_{t+k} \right] \right\} \quad (2)$$

$$\text{s.t. } x_{t+k+1|t} = Ax_{t+k|t} + Bu_{t+k} + W\theta_{t+k}, \quad k \geq 0 \quad (3)$$

$$y_{t+k|t} = Cx_{t+k|t} + Du_{t+k} + F\theta_{t+k}, \quad k \geq 0 \quad (4)$$

$$g(x_{t+k|t}, u_{t+k}) = C_1 x_{t+k|t} + C_2 u_{t+k} + C_3 \leq 0, \quad k = 0, 1, \dots, N-1 \quad (5)$$

$$h(x_{t+N|t}) = D_1 x_{t+N|t} + D_2 \leq 0 \quad (6)$$

$$u_{t+k} = Kx_{t+k|t}, \quad k \geq N \quad (7)$$

$$x_{t|t} = x^* \quad (8)$$

where  $g: \mathcal{X} \times \mathcal{U} \rightarrow \mathbb{R}^{n_g}$  and  $h: \mathcal{X} \rightarrow \mathbb{R}^{n_h}$  are the path and terminal constraints respectively,  $x^*$  is the initial state,  $u^N = \{u_t, \dots, u_{t+N-1}\} \in \mathcal{U} \times \dots \times \mathcal{U} = \mathcal{U}^N$  are the predicted future inputs and  $\theta^N = \{\theta_t, \dots, \theta_{N-1}\} \in \Theta^N$  are the current and future values of the disturbance.

### Formulation

The design of a robust control scheme is obtained by solving a receding horizon constrained optimal control problem where the objective is the deviations expected over the entire uncertainty set, or the nominal value of the output and input deviations. In order to ensure feasibility of (2)–(8) for every possible uncertainty scenario  $\theta_{t+k} \in \Theta$ ,  $k = 0, \dots, N-1$ , the set of constraints of (2)–(8) is usually augmented with an extra set of feasibility constraints. The type of these constraints, as will be described later, will determine if the RpMPC is an open-loop or closed-loop controller.

### Open-Loop Robust Parametric Model Predictive Controller

To define the set of extra feasibility constraints the future state prediction

$$x_{t+k|t} = A^k x^* + \sum_{j=0}^{k-1} (A^j B u_{t+k-1-j} + A^j W \theta_{t+k-1-j}) \quad (9)$$

is substituted into the inequality constraints (5)–(6), which then become

$$\begin{aligned} \bar{g}_j(x^*, u^N, \theta^N) \leq 0, \quad j = 1, \dots, J \Leftrightarrow \\ \sum_{i=1}^n \gamma 1_{i,j} x_i^* + \sum_{k=0}^{N-1} \sum_{i=1}^q \gamma 2_{i,k,j} u_{t+k,i} \\ + \sum_{k=0}^{N-1} \sum_{i=1}^w \gamma 3_{i,k,j} \theta_{t+k,i} + t + k, i + \gamma 4_j \leq 0 \quad (10) \end{aligned}$$

where  $\gamma 1, \gamma 2, \gamma 3$  are coefficients that are explicit functions of the elements of matrices  $A, B, C, D, W, F, C_1, C_2, C_3, D_1, D_2, Q, R, P$ . The set of feasibility constraints is defined as

$$\psi(x^*, u^N) \leq 0 \Leftrightarrow \forall \theta^N \in \Theta^N (\forall j = 1, \dots, J [\bar{g}_j(x^*, u^N, \theta^N) \leq 0, u^N \in \mathcal{U}^N, x^* \in \mathcal{X}]) \quad (11)$$

The constraints  $\psi \leq 0$  ensure that, given a particular state realization  $x^*$ , the single control action  $u^N$  satisfies all the constraints for all possible bounded disturbance scenarios over the time horizon. However, this feasibility constraint represents an infinite set of constraints since the inequalities are defined for every possible value of  $\theta^N \in \Theta^N$ . In order to overcome this problem one has to notice that (11) is equivalent to

$$\begin{aligned} \max_{\theta^N} \max_j \{ \bar{g}_j(x^*, u^N, \theta^N) | \\ j = 1, \dots, J, u^N \in \mathcal{U}^N, x^* \in \mathcal{X}, \theta^N \in \Theta^N \} \leq 0 \quad (12) \end{aligned}$$

Adding (12) into (2)–(8) and minimizing the expectation of the objective function (2) over all uncertain realizations  $\theta_{t+k}$  one obtains the following robust model predictive control problem:

$$\begin{aligned} \phi(x_{t|t}) = \min_{u^N \in \mathcal{U}^N} E_{\theta^N \in \Theta^N} \left\{ x_{t+N|t}^T P x_{t+N|t} + \right. \\ \left. \sum_{k=0}^{N-1} \left[ y_{t+k|t}^T Q y_{t+k|t} + u_{t+k}^T R u_{t+k} \right] \right\} \quad (13) \end{aligned}$$

$$\text{s.t. (3)–(8) and (11)} \quad (14)$$

Problem (13)–(14) is a bilevel program that has as constraint a maximization problem, which, as will be shown later, can be solved parametrically and then replaced by a set of linear inequalities of  $u^N, x^*$ . The solution to this problem corresponds to a robust control law as it is defined in Definition 1. Problem (13)–(14) is an open-loop robust control formulation in that it obtains the optimal control actions  $u^N$  for the worst-case realization of the uncertainty only, as expressed by inequality (12), and does not take into account the information of the past uncertainty values in the future measurements, thus losing the benefit of the prediction property. This implies that the future control actions can be readjusted to compensate for any variation in the past uncertainty realizations, thereby obtaining more “realistic” and less conservative values for the optimal control actions. This problem can be overcome if we consider the following closed-loop formulation of the problem (2)–(8).

### Closed-Loop Robust Parametric Model-Based Control

To acquire a closed-loop formulation of the general RpMPC problem, a dynamic programming approach is used to formulate the worst-case closed-loop MPC problem, which requires the solution of a number of embedded optimization problems that in the case of a quadratic objective are non-linear and non-differentiable. Feasibility analysis is used to directly address the problem and a set of constraints is again incorporated in the optimization problem to preserve feasibility and performance for all uncertainty realizations. Future measurements of the state contain information about the past uncertainty values. This implies that the future control actions can be readjusted to compensate for the past disturbance realizations by deriving a closed-loop MPC problem as shown next. The main idea is to introduce constraints into the control optimization problem (2)–(8) that preserve feasibility and performance for all disturbance realizations. These constraints are given as

$$\begin{aligned}
& \psi^{\theta_{t+\ell}}(x^*, [u_{t+k}]_{k=0,\dots,\ell}) \Leftrightarrow \\
& \forall \theta_{t+\ell} \in \Theta \{ \exists u_{t+\ell+1} \in \mathcal{U} \{ \forall \theta_{t+\ell+1} \\
& \in \Theta \{ \exists u_{t+\ell+2} \in \mathcal{U} \dots \{ \forall \theta_{t+N-2} \\
& \in \Theta \{ \exists u_{t+N-1} \in \mathcal{U} \{ \forall \theta_{t+N-1} \in \Theta \\
& \{ \forall j = 1, \dots, J [ \bar{g}_j(x^*, [u_{t+k}]_{k=0,\dots,N-1}, \\
& [\theta_{t+k}]_{k=0,\dots,N-1}) \leq 0 ] \} \} \dots \} \} \}, \\
& u_{t+k} \in \mathcal{U}, \quad k = 0, \dots, \ell, \quad x^* \in \mathcal{X}, \quad \theta_{t+k} \in \Theta, \\
& \quad k = 0, \dots, \ell - 1, \quad \ell = 0, \dots, N - 1. \quad (15)
\end{aligned}$$

The constraints of (15) are incorporated into (2)–(8) and give rise to a semi-infinite dimensional program that can be posed as a min–max bilevel optimization problem:

$$\begin{aligned}
\phi(x^*) = \min_{u^N \in \mathcal{V}^N} & \left\{ x_{t+N|t}^T P x_{t+N|t} + \right. \\
& \left. \sum_{k=0}^{N-1} \left[ y_{t+k|t}^T Q y_{t+k|t} + u_{t+k}^T R u_{t+k} \right] \right\} \quad (16)
\end{aligned}$$

$$\begin{aligned}
\text{s.t.} \quad & \max_{\theta_{t+N-1,j}} \bar{g}_j(x^*, u^N, \theta^N) \leq 0 \\
& \vdots \\
& \vdots \quad (17)
\end{aligned}$$

$$\begin{aligned}
\max_{\theta_{t+1}} \min_{u_{t+2}} \dots \max_{\theta_{t+N-2}} \min_{u_{t+N-1}} \max_{\theta_{t+N-1}} \max_j \quad (18) \\
\bar{g}_j(x^*, u^N, \theta^N) \leq 0
\end{aligned}$$

$$\begin{aligned}
\max_{\theta_t} \min_{u_{t+1}} \max_{\theta_{t+1}} \min_{u_{t+2}} \dots \max_{\theta_{t+N-2}} \min_{u_{t+N-1}} \max_{\theta_{t+N-1}} \max_j \quad (19) \\
\bar{g}_j(x^*, u^N, \theta^N) \leq 0
\end{aligned}$$

$$u^N \in \mathcal{U}^N, \quad x^* \in \mathcal{X}, \quad \theta^N \in \Theta^N. \quad (20)$$

The difference between the above formulation and formulation (13)–(14) is that at every time instant  $t+k$  the future control actions  $\{u_{t+k+1}, \dots, u_{t+N-1}\}$  are readily adjusted to offset the effect of the past uncertainty  $\{\theta_t, \dots, \theta_{t+k}\}$  to satisfy the constraints. In contrast, in formulation (13)–(14) the control sequence has to ensure constraint satisfaction for all possible disturbance scenarios. The main issue for solving the above optimization problem is how to solve parametrically each of (17)–(19) and replace them with a set of inequalities of  $u^N, x^*$  suitable to formulate a multiparametric programming problem. This is shown in the following section.

### Methods/Applications

#### Parametric Solution of the Inner Maximization Problem of the Open-Loop Robust pMPC Problem

An algorithm for solving parametrically the maximization problem of (12), which forms the inner maximization problem of the open-loop RpMPC (13)–(14), comprises the following steps:

**Step 1.** Solve  $G_j(x^*, u^N) = \max_{\theta^N} \{ \bar{g}_j(x^*, u^N, \theta^N) | \theta^N, L \leq \theta^N \leq \theta^{N,U} \}$ ,  $j = 1, \dots, J$  as a parametric program with respect to  $\theta^N$  and by recasting the control elements and future states as parameters. The parametric solution can be obtained by following the method in [19], where the critical disturbance points for each maximization are identified as follows:

1. If  $\frac{\partial \bar{g}_j}{\partial \theta_{t+k,i}} = \gamma 3_{i,k} > 0 \Rightarrow \theta_{t+k,i}^{cr} = \theta_{t+k,i}^U$ ,  $j = 1, \dots, J$ , then  $k = 0, \dots, N-1$ ,  $i = 1, \dots, w$ ;
2. If  $\frac{\partial \bar{g}_j}{\partial \theta_{t+k,i}} = \gamma 3_{i,k} < 0 \Rightarrow \theta_{t+k,i}^{cr} = \theta_{t+k,i}^L$ ,  $j = 1, \dots, J$ , then  $k = 0, \dots, N-1$ ,  $i = 1, \dots, w$ .

Substituting  $\theta_{t+k,i}^{cr}$  in the constraints  $\bar{g} \leq 0$  we obtain  $G_j(x^*, u^N) = \bar{g}_j(x^*, u^N, \theta^{N,cr})$ , where  $\theta^{N,cr}$  is the sequence of the critical values of the uncertainty vector  $\theta_t^{cr}$  over the horizon  $N$ .

**Step 2.** Compare the parametric profiles  $G_j(x^*, u^N)$  over the joint space of  $u^N$  and  $x^*$  and retain the upper bounds. A multiparametric linear program is formulated:

$$\begin{aligned} \psi(x^*, u^N) &= \max_j G_j \\ \Leftrightarrow \psi(x^*, u^N) &= \min_{\varepsilon} \{ \varepsilon \mid \varepsilon \geq G_j, j = 1, \dots, J \}, \\ u^N &\in \mathcal{U}^N, \quad x^* \in \mathcal{X}, \end{aligned} \quad (21)$$

which is equivalent to the comparison procedure of [1].

**Step 3.** Problem (21) is a multiparametric linear programming problem; hence the solution consists of a set of piece-wise linear expressions for  $\psi_i$  in terms of the parameters  $u^N$  and  $x^*$  and a set of regions  $\Psi_i$ ,  $i = 1, \dots, \hat{N}_{\text{reg}}$  where these expressions are valid. This statement was proven in [20], sect. 2.2, theorem 2.1, and in [10]. Note that no region  $\Psi_s$  exists such that  $\psi_s \leq \psi_i$ ,  $\forall \{x^*, u^N\} \in \Psi_s$  and  $\forall i \neq s$  since  $\psi$  is convex. Thus, inequality (11) can be replaced by the inequalities  $\psi_i(x^*, u^N) \leq 0$ . In this way problem (13)–(14) can be recast as a single-level stochastic program:

$$\begin{aligned} \phi(x^*) &= \min_{u^N \in \mathcal{U}^N} \{ \Phi(x^*, u^N, \theta^{N,n}) \} \\ \bar{g}_j(x^*, u^N, \theta^{N,n}) &\leq 0, \quad j = 1, \dots, J, \\ \psi(x^*, u^N) &\leq 0, \quad i = 1, \dots, \hat{N}_{\text{reg}}, \end{aligned} \quad (22)$$

where  $\Phi$  is the quadratic objective (13) after substituting (9). The superscript  $n$  in  $\theta^{N,n}$  denotes the nominal value of  $\theta^N$ , which is usually zero. An approximate solution to the above stochastic problem can be obtained by discretizing the uncertainty space into a finite set of scenarios  $\theta^{N,i}$ ,  $i = 1, \dots, ns$  with associated objective weights ([20]), thus leading to a multiperiod optimization problem where each period corresponds to a particular uncertainty scenario. By treating the control variables  $u^N$  as the optimization variables and the current state  $x^*$  as parameters, (22) is recast as multiparametric quadratic program.

**Theorem 1** *The solution of (22) is a piece-wise linear control law  $u_i(x^*) = \mathcal{A}_c x^* + b_c$  and  $CR_c x^* + cr_c$ ,  $c = 1, \dots, N_c$  is the polyhedral critical region where this control law is valid and guarantees that (5) and (6) are feasible for all  $\theta_{t+k} \in \Theta$ ,  $k = 0, \dots, N-1$ .*

The proof of the theorem is straightforward from (21) and [20] and is omitted for brevity's sake. It shows that the solution to (22), and hence (13)–(14), can be obtained as an explicit multiparametric solution [9].

### Solution of the Closed-Loop RpMPC Problem

In order to solve the problem (16)–(20), the inner max–min–max problem in (17)–(19) have to be solved parametrically and replaced by simpler linear inequalities, so the resulting problem is a simple multiparametric quadratic program. For simplicity, we only present an algorithm for solving the most difficult problem (19). The same thought process can be performed for the remaining constraints. The algorithm consists of the following steps:

**Step 1.** Solve

$$\begin{aligned} G_j^{\theta_{t+N-1}}(x^*, u^N, [\theta_{t+k}]_{k=0, \dots, N-2}) \\ = \max_{\theta_{t+N-1}} \{ \bar{g}_j(x^*, u^N, \theta^N), \theta^{N,L} \leq \theta^N \leq \theta^{N,U} \}, \\ j = 1, \dots, J, \end{aligned} \quad (23)$$

as a multiparametric optimization problem by recasting  $x^*$  and  $u^N$  as parameters and by following again the method of [19] or [20], sect. 2.2.

**Step 2.** Compare the parametric profiles  $G_j^{\theta_{t+N-1}}(x^*, u^N, [\theta_{t+k}]_{k=0, \dots, N-2})$  over the joint space of  $u^N$ ,  $[\theta_{t+k}]_{k=0, \dots, N-2}$  and  $x^*$  to retain the upper bounds. For this comparison a multiparametric program is formulated and then solved by following the comparison procedure in [1]:

$$\begin{aligned} \psi^{\theta_{t+N-1}}(x^*, u^N, [\theta_{t+k}]_{k=0, \dots, N-2}) &= \max_j G_j^{\theta_{t+N-1}} \\ \Leftrightarrow \psi^{\theta_{t+N-1}}(x^*, u^N, [\theta_{t+k}]_{k=0, \dots, N-2}) \\ &= \min_{\varepsilon} \{ \varepsilon \mid \text{s.t. } G_j^{\theta_{t+N-1}} \leq \varepsilon, j = 1, \dots, J \}. \end{aligned} \quad (24)$$

The solution of the above optimization consists of a set of linear expressions for  $\psi_i^{\theta_{t+N-1}}$  in terms of the parameters  $x^*$ ,  $u^N$ ,  $[\theta_{t+k}]_{k=0, \dots, N-2}$  and a set of polyhedral regions  $\Psi_i^{\theta_{t+N-1}}$ ,  $i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_{t+N-1}}$ , where these expressions are valid.

**Step 3.** Set  $\ell = N-1$ .

**Step 4.** Solve the following multiparametric optimization problem over  $u^\ell$

$$\begin{aligned} & \psi^{u_{t+\ell}}(x^*, u^\ell, \theta^\ell) \\ = & \min_{u_{t+\ell} \in U} \{ \psi_i^{\theta_{t+\ell}}(x^*, [u_{t+k}]_{k=0, \dots, \ell}, [\theta_{t+k}]_{k=0, \dots, \ell-1}), \\ & \text{if } \Psi_i^{\theta_{t+\ell}} \leq 0, i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_{t+\ell}} \}. \end{aligned} \quad (25)$$

The above problem can be solved parametrically by following the procedure in [20], appendix A, or [17], chap. 3, sect. 3.2. The solution to (25) is a convex piecewise affine function of  $\psi^{u_{t+\ell}}$  in terms of the parameters  $x^*, u^N, [\theta_{t+k}]_{k=0, \dots, N-2}$  that is defined over a set of polyhedral regions  $\Psi_i^{u_{t+\ell}}, i = 1, \dots, \hat{N}_{\text{reg}}^{u_{t+\ell}}$ .

**Step 5.** Set  $\ell = \ell - 1$  and solve the following maximization problem over  $\theta^{\ell-1}$ :

$$\begin{aligned} & \psi^{\theta_{t+\ell}}(x^*, [u_{t+k}]_{k=0, \dots, \ell}, [\theta_{t+k}]_{k=0, \dots, \ell-1}) \\ = & \max_{\theta_{t+\ell}} \{ \psi_i^{\theta_{t+\ell}}(x^*, [u_{t+k}]_{k=0, \dots, \ell}, [\theta_{t+k}]_{k=0, \dots, \ell-1}), \\ & \text{if } \Psi_i^{u_{t+\ell+1}} \leq 0, i = 1, \dots, \hat{N}_{\text{reg}}^{u_{t+\ell+1}} \}. \end{aligned} \quad (26)$$

Since the function on the left-hand side of the above equality is a convex piecewise affine function, its maximization with respect to  $[\theta_{t+k}]_{k=0, \dots, \ell-1}$  reduces to the method of [19] followed by a comparison procedure as described in step 2.

**Step 6.** If  $\ell > 0$ , then go to step 4, else terminate the procedure and store the affine functions  $\psi_i^{\theta_t}, i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_t}$ .

**Step 7.** The expressions  $\psi_i^{\theta_t}(u_t, x^*)$  are the max-min constraint (19). Similarly, the remaining max-min-max constraints are replaced by the set of inequalities

$$\begin{aligned} & \psi_i^{\theta_{t+1}}(x^*, [u_t^T, u_{t+1}^T]^T, \theta_t) \leq 0, \\ & \dots, \\ & \psi_i^{\theta_{t+N-2}}(x^*, [u_t^T, u_{t+1}^T, \dots, u_{t+N-2}^T]^T, \\ & \quad [\theta_t^T, \theta_{t+1}^T, \dots, \theta_{t+N-3}^T]^T) \leq 0, \\ & \psi_i^{\theta_{t+N-1}}(x^*, [u_t^T, u_{t+1}^T, \dots, u_{t+N-1}^T]^T, \\ & \quad [\theta_t^T, \theta_{t+1}^T, \dots, \theta_{t+N-2}^T]^T) \leq 0. \end{aligned}$$

Substituting the inequalities in step 7 into the max-min-max constraints of (16)–(20) we obtain the follow-

ing stochastic multiparametric program:

$$\begin{aligned} \phi(x^*) = & \min_{u^N \in U^N} E_{\theta^N \in \Theta^N} \{ \Phi(x^*, u^N, \theta^{N,n}) \} \\ \text{s.t. } & \bar{g}_j(x^*, u^N, \theta^{N,n}) \leq 0 \\ & \psi_i^{\theta_t}(x^*, u_t) \leq 0, i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_0} \\ & \psi_i^{\theta_{t+1}}(x^*, [u_t^T, u_{t+1}^T]^T, \theta_t^n), i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_1} \\ & \vdots \\ & \psi_i^{\theta_{t+N-2}}(x^*, [u_{t+k}]_{k=0, \dots, N-2}, [\theta_{t+k}^n]_{k=0, \dots, N-3}), \\ & \quad i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_{t+N-2}} \\ & \psi_i^{\theta_{t+N-1}}(x^*, [u_{t+k}]_{k=0, \dots, N-1}, [\theta_{t+k}^n]_{k=0, \dots, N-2}), \\ & \quad i = 1, \dots, \hat{N}_{\text{reg}}^{\theta_{t+N-1}} \\ & x_{t|t} = x^*, j = 1, \dots, J, \end{aligned} \quad (27)$$

where  $\Phi$  is again the quadratic objective function in (16). By discretizing the expectation of the value function to a set of discrete uncertainty scenarios and by treating the current state  $x^*$  as parameter and the control actions as optimization variables and the problem is recast as a parametric quadratic program. The solution is a complete map of the control variables in terms of the current state. The results for the closed-loop RpMPC controller are summarized in the following theorem.

**Theorem 2** *The solution of (27) is obtained as a linear piecewise control law  $u_t(x^*) = \mathcal{A}_c x^* + b_c$  and a set of polyhedral regions  $\mathcal{C}R_c = \{x^* \in \mathcal{X} | \mathcal{C}R_c x^* + cr_c \leq 0\}$  in the state space for which system (1) satisfies constraints (5)–(6) for all  $\theta^N \in \Theta^N$ .*

## Cases

A special case of the RpMPC problem (2)–(8) arises when the system matrices in the first equation in (1) are uncertain in that their entries are unknown but bounded within specific bounds. For simplicity we will consider the simpler case where  $W, F = 0$  and the entries  $a_{ij}$  and  $b_{ij}$  of matrices  $A$  and  $B$  are not known but satisfy

$$\begin{aligned} a_{ij} &= \bar{a}_{ij} + \delta a_{ij}, \quad b_{i\ell} = \bar{b}_{i\ell} + \delta b_{i\ell} \\ \delta a_{ij} &\in \mathcal{A}_{ij} = \{ \delta a_{ij} \in \mathbb{R} | -\varepsilon |\bar{a}_{ij}| \leq \delta a_{ij} \leq \varepsilon |\bar{a}_{ij}| \}, \end{aligned} \quad (28)$$

$$\delta b_{i\ell} \in \mathcal{B}_{i\ell} = \{\delta b_{i\ell} \in \mathbb{R} \mid -\varepsilon|\bar{b}_{i\ell}| \leq \delta b_{i\ell} \leq \varepsilon|\bar{b}_{i\ell}|\}, \quad (29)$$

where  $\bar{a}_{ij}$ ,  $\bar{b}_{i\ell}$  are the nominal values of the entries of  $A$ ,  $B$  respectively and  $\delta a_{ij}$ ,  $\delta b_{i\ell}$  denote the uncertainty in the matrix entries, which is assumed to be bounded as in (28)–(29). The general RpMPC formulation (2)–(8) must be redefined to include the introduced model uncertainty by adding the extra constraints

$$\begin{aligned} a_{ij} &= \bar{a}_{ij} + \delta a_{ij}, b_{i\ell} = \bar{b}_{i\ell} + \delta b_{i\ell} \\ \forall \delta a_{ij} &\in \mathcal{A}_{ij}, \forall \delta b_{i\ell} \in \mathcal{B}_{i\ell}, \end{aligned} \quad (30)$$

The new formulation of the RpMPC (2)–(8) and (30) gives rise to a semi-infinite dimensional problem with a rather high computational complexity.

**Definition 2** A feasible solution  $u^N$  for problem (2)–(8) and (30), for a given initial state  $x^*$ , is called a *robust* or *reliable* solution.

Obviously, a robust solution for a given  $x^*$  is a control sequence  $u^N$  (future prediction vector) for which constraints (5)–(6) are satisfied for all admissible values of the uncertainty. Since it is difficult to solve this MPC formulation by the known parametric optimization methods, the problem must be reformulated in a multi-parametric quadratic programming (mpQP) form. Our objective in this section is to obtain such a form by considering the worst-case values of the uncertainty, i. e. those values of the uncertain parameters for which the linear inequalities of (5)–(6) are critically satisfied. Usually, the objective function (2) is formulated to penalize the nominal system behavior; thus one must substitute  $x_{t+k|t} = \bar{A}^k x^* + \sum_{j=0}^{k-1} \bar{A}^j \bar{B} u_{t+k-1-j}$  in (2). In this way the objective function is a quadratic function of  $u^N$  and  $x^*$ . Finally, the uncertain evolution of the system  $x_{t+k|t} = A^k x^* + \sum_{j=0}^{k-1} A^j B u_{t+k-1-j}$  is replaced in the constraints (5)–(6) to formulate a set of linear inequalities. Thus the following formulation of the RpMPC is obtained:

$$\phi(x^*) = \min_{u^N \in U^N} \left\{ \frac{1}{2} (u^N)^T H u^N + x^{*T} F u^N + \frac{1}{2} (x^*)^T Y x^* \right\}, \quad (31)$$

$$\begin{aligned} \text{s.t. } C_{1i}^T A^k x^* + \sum_{j=0}^{k-1} C_{1i}^T A^j B u_{t+k-1-j} \\ + C_{2i}^T u_{t+k} + C_{3i} \leq 0, \\ k = 1, \dots, N-1, \quad i = 1, \dots, n_g, \end{aligned} \quad (32)$$

$$\begin{aligned} D_{1\ell}^T A^N x^* + \sum_{j=0}^{N-1} D_{1\ell}^T A^j B u_{t+k-1-j} + D_{2\ell} \leq 0, \\ \ell = 1, \dots, n_h, \end{aligned} \quad (33)$$

$$\begin{aligned} \forall \delta a_{ij} \in \mathcal{A}_{ij}, \quad \forall \delta b_{i\ell} \in \mathcal{B}_{i\ell}, \\ i, j = 1, \dots, n, \quad \ell = 1, \dots, m. \end{aligned} \quad (34)$$

It is evident that the new formulation of the RpMPC problem (31)–(34) is also a semi-infinite dimensional problem. This formulation can be further simplified if one considers that for any uncertain matrices  $A$  and  $B$ , the entries of the matrices  $A^k$  and  $A^k B$  for all  $k \geq 0$  are given respectively by [17]

$$a_{i\ell}^k = \bar{a}_{i\ell}^k + \delta a_{i\ell}^k, \quad -\varepsilon|\delta a_{i\ell}^k|_{\min} \leq \delta a_{i\ell}^k \leq \varepsilon|\delta a_{i\ell}^k|_{\max}, \quad (35)$$

$$\begin{aligned} ab_{i\ell}^k = \bar{a}_{i\ell}^k + \delta ab_{i\ell}^k, \\ -\varepsilon|\delta ab_{i\ell}^k|_{\min} \leq \delta ab_{i\ell}^k \leq \varepsilon|\delta ab_{i\ell}^k|_{\max}. \end{aligned} \quad (36)$$

The analysis on (35)–(36) follows from [17], chap. 3, and is omitted for brevity's sake.

### Robust Counterpart (RC) Problem

Using the basic properties of matrix multiplication and (35)–(36), problem (31)–(34) reformulates into

$$\phi(x^*) = \min_{u^N \in U^N} \left\{ \frac{1}{2} (u^N)^T H u^N + x^{*T} F u^N + \frac{1}{2} (x^*)^T Y x^* \right\}, \quad (37)$$

$$\begin{aligned} \sum_{j=1}^{k-1} \sum_{q=1}^n \sum_{\ell=1}^m C_{1iq} ab_{q\ell}^j u_{t+k-1-j,\ell} \\ + \sum_{\ell} C_{2i\ell} u_{t+k,\ell} + \sum_{q=1}^n \sum_{\ell=1}^m C_{1iq} a_{q\ell}^k x_{\ell}^* + C_{3i} \leq 0, \end{aligned} \quad (38)$$

$$\begin{aligned}
& k = 1, \dots, N-1, i = 1, \dots, n_g \\
& \sum_{j=1}^{N-1} \sum_{q=1}^n \sum_{\ell=1}^m D_{1iq} a b_{q\ell}^j u_{t+k-1-j,\ell} \\
& \quad + \sum_{q=1}^n \sum_{\ell=1}^n D_{1iq} a_{q\ell}^k x_{\ell}^* + D_{2i} \leq 0 \quad (39)
\end{aligned}$$

$$\begin{aligned}
& i = 1, \dots, n_h \forall \delta a_{ij} \in \mathcal{A}_{ij}, \\
& \forall \delta b_{i\ell} \in \mathcal{B}_{i\ell}, i, j = 1, \dots, n, \ell = 1, \dots, m. \quad (40)
\end{aligned}$$

This is a robust multiparametric QP problem (robust mp-QP) where the coefficients of the linear inequalities in the constraints are uncertain, the vector  $u^N$  is the optimization variable and the initial states  $x^*$  are the parameters. A similar robust LP problem was studied in [5] where the coefficients of the linear constraints are uncertain, similar to (35)–(36); however, no multiparametric programming problems were considered.

In a similar fashion to the analysis in [5] we construct the *robust counterpart* of the robust mp-QP problem (37)–(40):

$$\begin{aligned}
\phi(x^*) = \min_{u^N \in \mathcal{U}^N} \left\{ \frac{1}{2} (u^N)^T H u^N \right. \\
\left. + x^{*T} F u^N + \frac{1}{2} (x^*)^T Y x^* \right\}, \quad (41)
\end{aligned}$$

s.t.

$$\begin{aligned}
& \sum_{j=1}^{k-1} \sum_{q=1}^n \sum_{\ell=1}^m C_{1iq} \bar{a} \bar{b}_{q\ell}^j u_{t+k-1-j,\ell} \\
& + \sum_{j=1}^{k-1} \sum_{q=1}^n \sum_{\ell=1}^m \epsilon \max\{|C_{1iq}| |\delta a b_{q\ell}^k|, \\
& \quad |C_{1iq}| |\delta a_{q\ell}^k| |\delta a_{q\ell, \max}^k| \} |u_{t+k-1-j,\ell}| + \sum_{\ell} C_{2i\ell} u_{t+k,\ell} \\
& + \sum_{q=1}^n \sum_{\ell=1}^n C_{1iq} \bar{a}_{q\ell}^k x_{\ell}^* + \sum_{q=1}^n \sum_{\ell=1}^n \epsilon \max\{|C_{1iq}| |\delta a_{q\ell}^k|, \\
& \quad |C_{1iq}| |\delta a_{q\ell, \max}^k| \} |x_{\ell}^*| + C_{3i} \leq 0
\end{aligned}$$

$$k = 1, \dots, N-1, \quad i = 1, \dots, n_g,$$

(42)

$$\begin{aligned}
& \sum_{j=1}^{N-1} \sum_{q=1}^n \sum_{\ell=1}^m D_{1iq} \bar{a} \bar{b}_{q\ell}^j u_{t+k-1-j,\ell} \\
& + \sum_{j=1}^{N-1} \sum_{q=1}^n \sum_{\ell=1}^m \max\{|D_{1iq}| |\delta a b_{q\ell}^k|, \\
& \quad |D_{1iq}| |\delta a_{q\ell}^k| |\delta a_{q\ell, \max}^k| \} |u_{t+k-1-j,\ell}| \\
& + \sum_{q=1}^n \sum_{\ell=1}^n D_{1iq} \bar{a}_{q\ell}^k x_{\ell}^* + \sum_{q=1}^n \sum_{\ell=1}^n \max\{|D_{1iq}| |\delta a_{q\ell}^k|, \\
& \quad |D_{1iq}| |\delta a_{q\ell, \max}^k| \} |x_{\ell}^*| + D_{2i} \leq 0 \\
& i = 1, \dots, n_h, \quad (43)
\end{aligned}$$

$$u^N \in \mathcal{U}^N, \quad x^* \in \mathcal{X}. \quad (44)$$

In this way the initial semi-infinite dimensional problem (37)–(40) becomes the above multiparametric non-linear program (mp-NLP). However, the parametric solution of this mp-NLP problem is still very difficult.

### Interval Robust Counterpart Problem

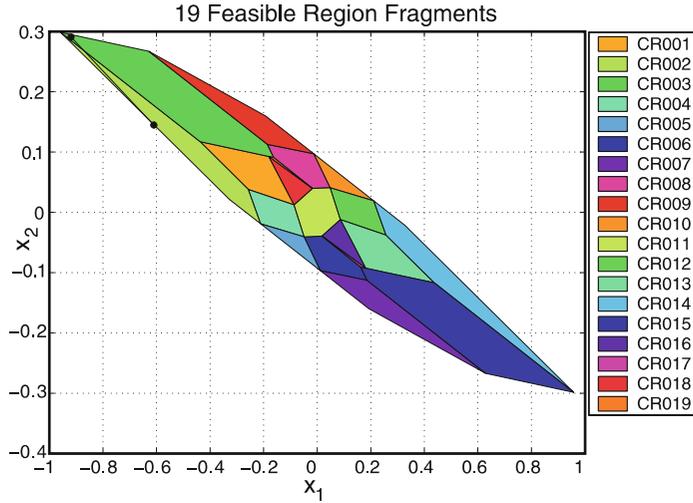

The interval robust counterpart (IRC) problem can then be formulated as follows:

$$\begin{aligned}
\phi(x^*) = \min_{u^N \in \mathcal{U}^N} \left\{ \frac{1}{2} (u^N)^T H u^N \right. \\
\left. + x^{*T} F u^N + \frac{1}{2} (x^*)^T Y x^* \right\}, \quad (45)
\end{aligned}$$

$$\begin{aligned}
& \text{s.t.} \quad \sum_{j=1}^{k-1} \sum_{q=1}^n \sum_{\ell=1}^m C_{1iq} \bar{a} \bar{b}_{q\ell}^j u_{t+k-1-j,\ell} \\
& + \sum_{j=1}^{k-1} \sum_{q=1}^n \sum_{\ell=1}^m \epsilon \max\{|C_{1iq}| |\delta a b_{q\ell}^k|, \\
& \quad |C_{1iq}| |\delta a_{q\ell}^k| |\delta a_{q\ell, \max}^k| \} |z_{t+k-1-j,\ell}| + \sum_{\ell} C_{2i\ell} u_{t+k,\ell} \\
& + \sum_{q=1}^n \sum_{\ell=1}^n C_{1iq} \bar{a}_{q\ell}^k x_{\ell}^* \\
& + \sum_{q=1}^n \sum_{\ell=1}^n \epsilon \max\{|C_{1iq}| |\delta a_{q\ell}^k|, \\
& \quad |C_{1iq}| |\delta a_{q\ell, \max}^k| \} |w_{\ell}| + C_{3i} \leq 0
\end{aligned}$$

$$k = 1, \dots, N-1, \quad i = 1, \dots, n_g,$$

(46)

Design of Robust Model-Based Controllers via Parametric Programming, Figure 1  
Critical regions for the nominal parametric MPC and state trajectory

$$\begin{aligned}
 & \sum_{j=1}^{N-1} \sum_{q=1}^n \sum_{\ell=1}^m D_{1iq} \bar{a} b_{q\ell}^j u_{t+k-1-j, \ell} \\
 & + \sum_{j=1}^{N-1} \sum_{q=1}^n \sum_{\ell=1}^m \max\{|D_{1iq}| |\delta a b_{q\ell, \min}^k|, \\
 & \quad |D_{1iq}| |\delta a b_{q\ell, \max}^k| \} z_{t+k-1-j, \ell} \\
 & + \sum_{q=1}^n \sum_{\ell=1}^n D_{1iq} \bar{a}_{q\ell}^k x_{\ell}^* + \sum_{q=1}^n \sum_{\ell=1}^n \max\{|D_{1iq}| |\delta a_{q\ell, \min}^k|, \\
 & \quad |D_{1iq}| |\delta a_{q\ell, \max}^k| \} w_{\ell} + D_{2i} \leq 0 \\
 & i = 1, \dots, n_h,
 \end{aligned} \tag{47}$$

$$-z_{t+k-1-j, \ell} \leq u_{t+k-1-j, \ell} \leq z_{t+k-1-j, \ell}, \tag{48}$$

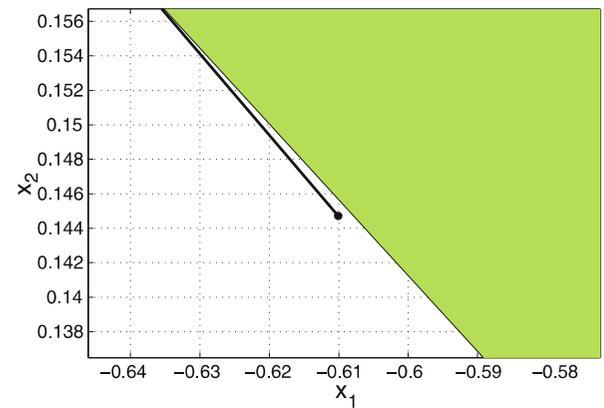

$$-w_{\ell} \leq x_{\ell}^* \leq w_{\ell}, \tag{49}$$

$$u^N \in \mathcal{U}^N, \quad x^* \in \mathcal{X}, \tag{50}$$

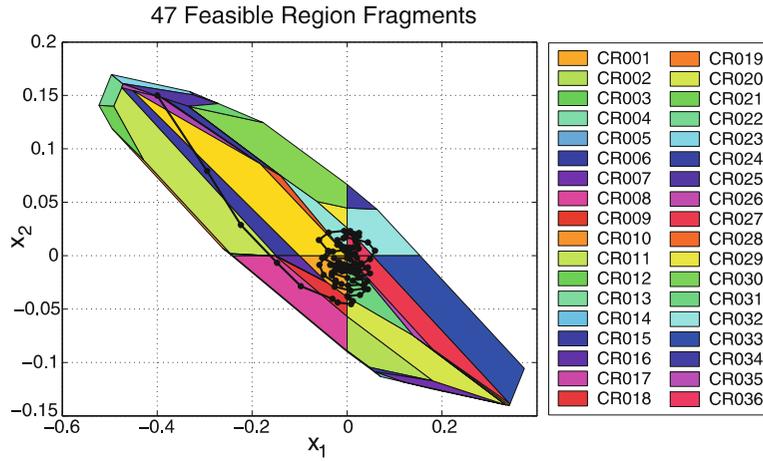

where the non-linear inequalities (42)–(43) have been replaced by four new linear inequalities. Two new variables have been introduced to replace the absolute values of the  $u_{t+k-1-j, \ell}$  and  $x_{\ell}^*$ , thus leading to the relaxed IRC problem.

The IRC is a mpQP problem with a quadratic index and linear inequalities, where the optimization vari-

ables now are the vectors  $u_{t+k-1-j}$ ,  $z_{t+k-1-j}$  and  $w$  and the parameters are the states  $x^*$ . The IRC problem can be solved with the known parametric optimization methods [4,9,16] since the objective function is strictly convex by assumption. The optimal control inputs  $u^N$ , optimization variables  $z$  and  $w$  and hence the optimal control  $u_t$  can then be obtained as explicit functions  $u^N(x^*)$ ,  $z(x^*)$  and  $w(x^*)$  of the initial state  $x^*$ . Furthermore, the control input  $u_t$  is obtained as the explicit, optimal control

Design of Robust Model-Based Controllers via Parametric Programming, Figure 2  
Magnification of Fig. 1 around the state trajectory at the second time instant

Design of Robust Model-Based Controllers via Parametric Programming, Figure 3  
Critical regions for the nominal parametric MPC and state trajectory

law [9]  $u_i(x^*) = \mathcal{A}_c x^* + b_c$  which is valid in the polyhedral region  $CR_c = \{x^* \in \mathcal{X} | CR_c x^* + cr \leq 0\}$ ,  $c = 1, \dots, N_c$ , where  $N_c$  is the number of critical regions obtained from the parametric programming algorithm.

The general RpMPC problem obtained from the case where the dynamic system (1) pertains to model uncertainties have now been transformed into the IRC problem and can be solved as a mp-QP problem. It is obvious that a feasible solution for the IRC problem is also a feasible solution for the RC and hence the initial RpMPC problem (2)–(8) and (30). Hence:

**Lemma 1** *If  $u^N$  is a feasible solution for the IRC problem, then it is also a feasible solution for the RC problem, and hence it is a robust solution for the initial RpMPC problem (2)–(8), (30).*

*Example 2* Consider a two-dimensional, discrete-time linear system (1) where  $W = F = 0$  and

$$A = \begin{bmatrix} 0.7326 + \delta a & -0.0861 \\ 0.1722 & 0.0064 \end{bmatrix}, \quad (51)$$

$$B = \begin{bmatrix} 0.0609 + \delta b \\ 0.0064 \end{bmatrix},$$

where the entries  $a_{11}$  and  $b_1$  of the  $A$  and  $B$  matrices are uncertain, where  $\delta a$  and  $\delta b$  are bounded as in (28)–(29) with  $\epsilon = 10\%$  and the nominal values are  $\bar{a}_{11} = 0.7326$

and  $\bar{b}_1 = 0.0609$ . The state and control constraints are  $-3 \leq [0 \ 1.4142]^T x \leq 3$ ,  $-2 \leq u \leq 2$ , and the terminal constraint is

$$\begin{bmatrix} 0.070251 & 1 \\ -0.070251 & -1 \\ 0.21863 & 1 \\ -0.21863 & -1 \end{bmatrix} x \leq \begin{bmatrix} 0.02743 \\ 0.02743 \\ 0.022154 \\ 0.022154 \end{bmatrix}. \quad (52)$$

Moreover,

$$Q = \begin{bmatrix} 0 & 0 \\ 0 & 2 \end{bmatrix} R = 0.01, \quad P = \begin{bmatrix} 1.8588 & 1.2899 \\ 1.2899 & 6.7864 \end{bmatrix}. \quad (53)$$

Initially, the MPC problem (2)–(8) is formulated and solved only for the nominal values of  $A$  and  $B$ , thus solving a multiparametric quadratic programming problem as described in [4,16]. Then the IRC problem is formulated as in (45)–(50) by using POP software [9]. The resulting regions for both cases are shown in Figs. 1 and 3 respectively. A simulation of the state trajectories of the nominal and the uncertain system are shown in Figs. 1 and 3 respectively. In these simulations the uncertain parameters  $\delta a$  and  $\delta b$  were simulated as a sequence of random numbers that take their values on the upper or lower bounds of  $\delta a$ ,  $\delta b$  i.e. a time-varying uncertainty. It is clear from Fig. 1 (and Fig. 2, which displays the magnified area around the state trajectory at the second

time instant) that the nominal solution to problem (2)–(8) cannot guarantee robustness in the presence of the uncertainty and the nominal system trajectory results in constraint violation. On the other hand, the controller obtained with the method discussed here manages to retain the trajectory in the set of feasible initial states (obtained by the critical regions of the parametric solution) and drives the trajectory close to the origin. One should notice that the space of feasible initial states (Fig. 3) given by the critical regions of the parametric solution is smaller than the one given in the nominal system's case (Fig. 1).

## Conclusions

In this chapter two robust parametric MPC problems were analyzed. In the first problem two methods for robust parametric MPC are discussed, an open-loop and a closed-loop method, for treating robustness issues arising from the presence of input disturbances/uncertainties. In the second problem, a robust parametric MPC procedure was discussed for the control of dynamic systems with uncertainty in the system matrices by employing robust parametric optimization methods.

## Introduction

Clustering is probably the most important unsupervised learning problem and involves finding coherent structures within a collection of unlabeled data. As such it gives rise to data groupings so that the patterns are similar within each group and remote between different groups. Besides having been extensively applied in areas such as image processing and pattern recognition, clustering also sees rich applications in biology, market research, social network analysis, and geology. For instance, in marketing and finance, cluster analysis is used to segment and determine target markets, position new products, and identify clients in a banking database having a heavy real estate asset base. In libraries, clustering is used to aid in book ordering and in insurance, clustering helps to identify groups of motor insurance policy holders with high average claim costs. Given its broad utility, it is unsurprising that a substantial number of clustering methods and approaches have been proposed.

On the other hand, fewer solutions to systematically evaluate the quality or validity of clusters have been presented [1]. Indeed, the prediction of the optimal number of groupings for any clustering algorithm remains a fundamental problem in unsupervised classification. To address this issue, numerous cluster indices have been proposed to assess the quality and the results of cluster analysis. These criteria may then be used to compare the adequacy of clustering algorithms and different dissimilarity measures, or to choose the optimal

number of clusters. Some of these measures are introduced in the following section.

## Methods

### Dunn's Validity Index

This technique [2,5] is based on the idea of identifying the cluster sets that are compact and well separated. For any partition of clusters, where  $c_i$  represent the  $i$ th cluster of such a partition, Dunn's validation index,  $D$ , can be calculated as

$$D = \min_{1 \leq i \leq n} \left\{ \min_{\substack{1 \leq j \leq n \\ i \neq j}} \left\{ \frac{d(c_i, c_j)}{\max_{1 \leq k \leq n} d'(c_k)} \right\} \right\}.$$

Here,  $d(c_i, c_j)$  is the distance between clusters  $c_i$  and  $c_j$  (intercluster distance),  $d'(c_k)$  is the intracluster distance of cluster  $c_k$ , and  $n$  is the number of clusters. The goal of this measure is to maximize the intercluster distances and minimize the intracluster distances. Therefore, the number of cluster that maximizes  $D$  is taken as the optimal number of clusters to be used.

### Davies–Bouldin Validity Index

This index [4] is a function of the ratio of the sum of within-cluster scatter to between-cluster separation:

$$DB = \frac{1}{n} \sum_{i=1}^n \max_{i \neq j} \left\{ \frac{S_n(Q_i) + S_n(Q_j)}{S(Q_i, Q_j)} \right\}.$$

In this expression,  $DB$  is the Davies–Bouldin index,  $n$  is the number of clusters,  $S_n$  is the average distance of all objects from the cluster to their cluster center, and  $S(Q_i, Q_j)$  is the distance between cluster centers. Hence, the ratio is small if the clusters are compact and far from each other. Consequently, the Davies–Bouldin index will have a small value for a good clustering.

The silhouette validation technique [22] calculates the silhouette width for each sample, the average silhouette width for each cluster, and the overall average silhouette width for a total data set. With use of this approach each cluster can be represented by a so-called silhouette, which is based on the comparison of its tightness and separation. The average silhouette width can be applied for the evaluation of clustering validity and can also be used to decide how good are the number of selected clusters. To construct the silhouettes  $S(i)$  the

following formula is used:

$$S(i) = \frac{(b(i) - a(i))}{\max \{a(i), b(i)\}}.$$

Here,  $a(i)$  is the average dissimilarity of the  $i$ th object to all other objects in the same cluster and  $b(i)$  is the minimum average dissimilarity of the  $i$ th object to all objects in the other clusters.

It follows from the formula that  $s(i)$  lies between  $-1$  and  $1$ . If the silhouette value is close to  $1$ , it means that sample is “well clustered” and has been assigned to a very appropriate cluster. If the silhouette value is close to  $0$ , it means that that sample could be assigned to another “closest” cluster as well, and the sample lies equally far away from both clusters. If the silhouette value is close to  $-1$ , it means that sample is “misclassified” and is merely somewhere in-between the clusters. The overall average silhouette width for the entire plot is simply the average of the  $S(i)$  for all objects in the whole dataset and the largest overall average silhouette indicates the best clustering (number of clusters). Therefore, the number of clusters with the maximum overall average silhouette width is taken as the optimal number of the clusters.

### Measure of Krzanowski and Lai

This index is based on the decrease of the within-cluster sum of squares (WSS) [15] and is given by

$$KL(k) = \left| \frac{DIFF(k)}{DIFF(k+1)} \right|, \quad \text{where}$$

$$DIFF(k) = (k-1)^{\frac{2}{p}} WSS(k-1) - k^{\frac{2}{p}} WSS(k).$$

Assuming that  $g$  is the ideal cluster number for a given dataset, and  $k$  is a particular number of clusters, then  $WSS(k)$  is assumed to decrease rapidly for  $k \leq g$  and decreases only slightly for  $k > g$ . Thus, it is expected that  $KL(k)$  will be maximized for the optimal number of clusters.

### Measure of Calinski and Harabasz

This method [3] assesses the quality of  $k$  clusters via the index

$$CH(k) = \frac{BSS(k-1)/(k-1)}{WSS(k)/(n-k)}.$$

Here,  $WSS(k)$  and  $BSS(k)$  are the WSS and the between-cluster sums of squares, for a dataset of  $n$  members. The measure seeks to choose clusters that are well isolated from one another and coherent, but at the same time keep the number of clusters as small as possible, thus maximizing the criterion at the optimal cluster number. Incidentally, a separate study comparing 28 validation criteria [18] found this measure to perform the best.

In addition, some other measures to determine the optimal number of clusters are (i) the C index [10], (ii) the Goodman–Kruskal index [8]), (iii) the isolation index [19], (iv) the Jaccard index [11], and (v) the Rand index [20].

### Applications

As can be seen, while it is relatively easy to propose indices of cluster validity, it is difficult to incorporate these measures into clustering algorithms and to appoint suitable thresholds on which to define key decision values [9,12]. Most clustering algorithms do not contain built-in screening functions to determine the optimal number of clusters. This implies that for a given clustering algorithm, the most typical means of determining the optimal cluster number is to repeat the clustering numerous times, each with a different number of groupings, and hope to catch a maximum or minimum turning point for the cluster validity index in play.

Nonetheless, there have been attempts to incorporate measures of cluster validity into clustering algorithms. One such method [21] introduces a validity index:

$$Validity = \frac{Intra - Cluster}{Inter - Cluster}.$$

Since it is desirable for the intracluster distance and the intercluster distance to be minimized and maximized, respectively, the above validity measure should be as small as possible. Using the K-means algorithm, Ray and Turi [21] proposed running the process for two up to a predetermined maximum number of clusters. At each stage, the cluster with the maximum variance is split into two and clustering is repeated with these updated centers, until the desired turning point for the validity measure is observed. Another approach [16] is based on simulated annealing, which was originally formulated to simulate a collection of atoms in equilibrium at a given temperature [14,17]. It assumes two

given parameters  $D$ , which is the cutoff cluster diameter, and  $P$ , a  $P$ -value statistic, as well as  $p(d)$ , the distribution function of the Euclidean distances between the members in a dataset. Then, the upper boundary for the fraction of incorrect vector pairs is given by

$$f(D, K = 1) = \int_D^\infty p(x) dx.$$

On the other hand, it is possible to define a lower boundary for  $f(D, K)$  with a preassigned  $P$ -value cutoff. The clustering algorithm then sequentially increases the cluster number until the two indicators converge.

### A Novel Clustering Approach with Optimal Cluster Determination

See also the article on “Gene Clustering: A Novel Optimization-Based Approach”.

Recently, we proposed a novel clustering approach [23,24] that expeditiously contains a method to predict the optimal cluster number. The clustering seeks to minimize the Euclidean distances between the data and the assigned cluster centers as

$$\text{MIN}_{w_{ij}, z_{jk}} \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} (a_{ik} - z_{jk})^2.$$

To make the nonlinear problem tractable, we apply a variant of the generalized benders decomposition algorithm [6,7], the global optimum search. The global optimum search decomposes the problem into a primal problem and the master problem. The former solves the continuous variables while fixing the integer variables and provides an upper-bound solution, while the latter finds the integer variables and the associated Lagrange multipliers while fixing the continuous variables and provides a lower-bound solution. The two sequences are iteratively updated until they converge at an optimal solution in a finite number of steps.

In determining the optimal cluster number, we note that the optimal number of clusters occurs when the intercluster distance is maximized and the intracluster distance is minimized. We adapt the novel work of Jung et al. [13] in defining a clustering balance, which has been shown to have a minimum value when intracluster similarity is maximized and intercluster similarity is minimized. This provides a measure of how optimal is

a certain number of clusters used for a particular clustering algorithm. Given  $n$  data points, each having  $k$  feature points,  $j$  clusters, and a binary decision variable for cluster membership  $w_{ij}$ , we introduce the following:

$$\text{Global center, } z_k^o = \frac{1}{n} \sum_{i=1}^n a_{ik}, \quad \forall k,$$

Intracluster error sum,

$$\Lambda = \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} \|a_{ik} - z_{jk}\|_2^2,$$

$$\text{Intercluster error sum, } \Gamma = \sum_{j=1}^c \sum_{k=1}^s \|z_{jk} - z_k^o\|_2^2.$$

Jung et al. [13] next proposed a clustering balance parameter, which is the  $\alpha$ -weighted sum of the two error sums:

$$\text{Clustering balance, } \varepsilon = \alpha \Lambda + (1 - \alpha) \Gamma.$$

We note here that the right  $\alpha$  ratio is 0.5. There are two ways to come to this conclusion. We note that the factor  $\alpha$  should balance the contributive weights of the two error sums to the clustering balance. At extreme cluster numbers, that is, the largest and smallest numbers possible, the sum of the intracluster and intercluster error sums at both cluster numbers should be balanced. In the minimal case, all the data points can be placed into a single cluster, in which case the intercluster error sum is zero and the intracluster error sum can be calculated with ease. In the maximal case, each data point forms its own cluster, in which case the intracluster error sum is zero and the intercluster error sum can be easily found. Obviously the intracluster error sum in the minimal case and the intercluster error sum in the maximal case are equal, suggesting that the most appropriate weighting factor to use is in fact 0.5. The second approach uses a clustering gain parameter proposed by Jung et al. [13]. This gain parameter is the difference between the decreased intercluster error sum  $\gamma_j$  compared with the value at the initial stage and the increased intracluster error sum  $\lambda_j$  compared with the value at the initial stage, and is given by

$$\gamma_{jk} = \sum_{i=1}^n w_{ij} \|a_{ik} - z_k^o\|_2^2 - \|z_{jk} - z_k^o\|_2^2,$$

$$\forall j, \forall k,$$

$$\lambda_{jk} = \sum_{i=1}^n w_{ij} \|a_{ik} - z_{jk}\|_2^2, \quad \forall j, \forall k,$$

$$\text{Gain, } \Delta_{jk} = \sum_{i=1}^n w_{ij} \|a_{ik} - z_k^o\|_2^2 - \|z_{jk} - z_k^o\|_2^2 \\ - \sum_{i=1}^n w_{ij} \|a_{ij} - z_{jk}\|_2^2, \forall j, \forall k.$$

With the identities

$$\sum_{i=1}^n w_{ij} a_{ik} = n_j z_{jk}, \forall j, \forall k, \\ \sum_{i=1}^n w_{ij} = n_j, \forall j,$$

where  $n_j$  denotes the number of data points in cluster  $j$ , the gain can be simplified to

$$\Delta_{jk} = (n_j - 1) \|z_k^o - z_{jk}\|_2^2, \forall j, \forall k, \\ \Delta = \sum_{j=1}^c \sum_{k=1}^s (n_j - 1) \|z_k^o - z_{jk}\|_2^2.$$

Jung et al. [13] showed the clustering gain to have a maximum value at the optimal number of clusters, and demonstrated that the sum total of the clustering gain and balance parameters is a constant. As can be seen from the following derivation, this is only possible if the  $\alpha$  ratio is 0.5:

$$\begin{aligned} & \text{Sum of clustering balance and clustering gain, } \Omega \\ &= \varepsilon + \Delta \\ &= \Lambda + \Gamma + \Delta \\ &= \left[ \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} \|a_{ik} - z_{jk}\|_2^2 \right] \\ & \quad + \left[ \sum_{j=1}^c \|z_{jk} - z_k^o\|_2^2 \right] + \dots \\ & \quad \left[ \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} \|a_{ik} - z_k^o\|_2^2 - \sum_{j=1}^c \|z_{jk} - z_k^o\|_2^2 \right. \\ & \quad \left. - \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} \|a_{ik} - z_{jk}\|_2^2 \right] \\ &= \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} \|a_{ik} - z_k^o\|_2^2 \\ &= \sum_{i=1}^n \sum_{k=1}^s \|a_{ik} - z_k^o\|_2^2, \end{aligned}$$

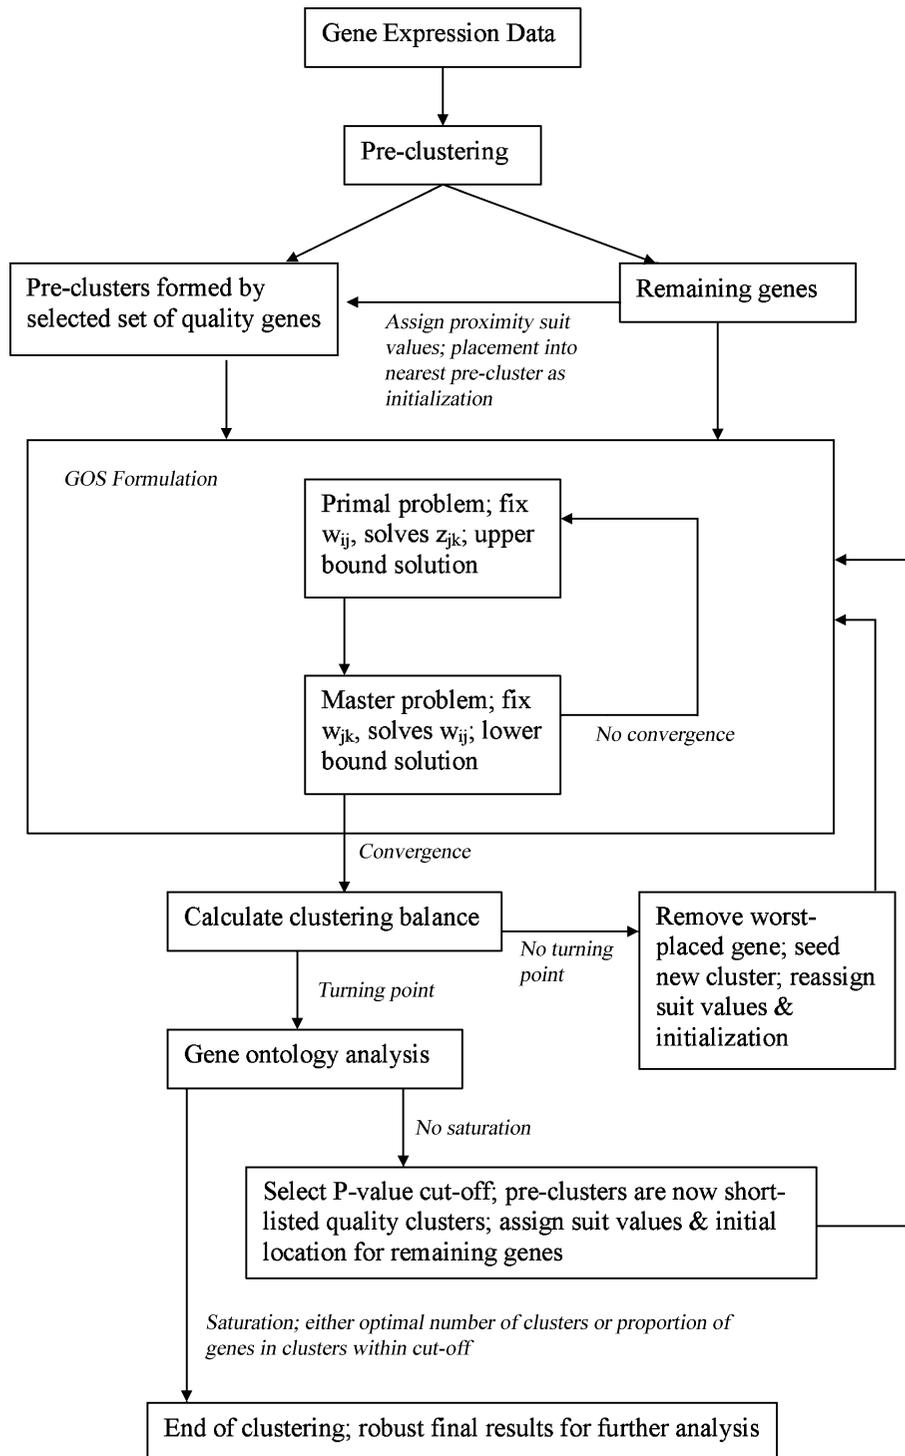

which is a constant for any given dataset.

### Extension for Biological Coherence Refinement

Today, the advent of DNA microarray technology has made possible the large-scale monitoring of genomic behavior. In working with gene expression data, it is often useful to utilize external validation in evaluating clusters of gene expression data. Besides assessing the biological meaning of a cluster through the functional annotations of its constituent genes using gene ontology resources, other indications of strong biological coherence [25] are (i) the proportion of genes that reside in clusters with good P-value scores, (ii) cluster correlation, since closely related genes are expected to exhibit very similar patterns of expression, and (iii) cluster specificity, which is the proportion of genes within a cluster that annotates for the same function. A novel extension of the previously described work [25] allows not just for the determination of the optimal cluster number within the framework of a robust yet intuitive clustering method, but also for an iterative refinement of biological validation for the clusters. The algorithm is as follows.

**Gene Preclustering** We precluster the original data by proximity studies to reduce the computational demands by (i) identifying genes with very similar responses and (ii) removing outliers deemed to be insignificant to the clustering process. To provide just adequate discriminatory characteristics, preclustering can be done by reducing the expression vectors into a set of representative variables  $\{+, o, -\}$ , or by pregrouping genes that are close to one another by correlation or some other distance function.

**Iterative Clustering** We let the initial clusters be defined by the genes preclustered previously, and find the distance between each of the remaining genes and these initial clusters and as a good initialization point place these genes into the nearest cluster. For each gene, we allow its suitability in a limited number of clusters on the basis of the proximity study. In the primal problem of the global optimum search algorithm, we solve for  $z_{jk}$ . These, together with the Lagrange multipliers, are used in the master problem to solve for  $w_{ij}$ . The primal problem gives an upper-bound solution and the master problem gives a lower bound. The optimal solution is obtained when both bounds converge. Then, the worst-

Determining the Optimal Number of Clusters, Figure 1  
Iterative clustering procedure. GOS global optimum search

placed gene is removed and used as a seed for a new cluster. This gene has already been subjected to a membership search, so there is no reason for it to belong to any of the older clusters. The primal and master problems are iterated and the number of clusters builds up gradually until the optimal number is attained.

**Iterative Extension** Indication of strong biological coherence is characterized by good P values based on gene ontology resources and the proportion of genes that reside in such clusters. As an extension, we would like to mine for the maximal amount of relevant information from the gene expression data and sieve out the least relevant data. This is important because information such as biological function annotation drawn from the cluster content is often used in the further study of coregulated gene members, common reading frames, and gene regulatory networks. From the clustered genes, we impose a coherence floor, based on some or all of the possible performance factors such as functional annotation, cluster specificity, and correlation, to demarcate genes that have already been well clustered. We then iterate to offer the poorly placed genes an opportunity to either find relevant membership in one of the strongly coherent clusters, or regroup amongst themselves to form quality clusters. Through this process, a saturation point will be reached eventually whereby the optimal number of clusters becomes constant as the proportion of genes distributed within clusters of high biological coherence levels off. Figure 1 shows a schematic of the entire clustering algorithm.

A classification problem is concerned with categorizing a data point (entity) into one of  $G$  ( $G \geq 2$ ) mutually exclusive groups based upon  $m$  (positive integer) specific measurable features of the entity. A classification rule is typically constructed from a sample of entities, where the group classifications are known or labeled (training or supervised learning). Then it can be used to classify new unlabeled entities. Many classification methods are based on distance measures. A common approach is to find a hyperplane to classify two groups ( $G = G_1 \cup G_2$ ). The hyperplane can be represented in a form of  $A\omega = \gamma$ , where  $A$  denotes an  $n \times m$  input data matrix,  $n$  is the total number of input data points, and  $m$  is the total number of data features/attributes. The classification rule is then made by the weight vector  $\omega$  to map data points onto a hyperplane, and the scalar  $\gamma$ , which are best selected by solving a mathematical programming model. The goal is to have entities of Group 1 ( $G_1$ ) lie on one side of the hyperplane and entities of Group 2 ( $G_2$ ) lie on the other side. Support Vector Machines (SVM) is the most studied hy-

perplane construction method. The SVM concept is to construct a hyperplane that minimizes the upper bound on the out-of-sample error. The critical step of SVM is to transform (or map) data points on to a high dimensional space, known as *kernel transformation*, and classify data points by a separating plane [9]. Subsequently, the hybrid linear programming discriminant model is proposed by [12,13,20]. The hybrid model does not depend on data transformation, where the objective is to find a plane that minimizes violations and maximizes satisfactions of the classified groups. Glover [19] proposed a mixed integer programming (MIP) formulation for the hybrid model by adding binary variables for misclassified entities. Other MIP formulations that are subsequently developed include [1,15,16]. Recently, a new technique that use multiple hyperplanes for classification has been proposed by [17]. This technique constructs a piecewise-linear model that gives convex separating planes. Subsequently, Better, Glover and Samorani [6] proposed multi-hyperplane formulations that generate multiple linear hyperplanes simultaneously with the consequence of forming a binary decision tree.

In classification, the selection of data's features/attributes is also very critical. Many mathematical programming methods have been proposed for selecting well represented features/attributes. Bennett and Mangasarian [5,23] gives a feature selection formulation such that the model not only separates entities into two groups, but also tries to suppress nonsignificant features. In a more recent study, Chaovalitwongse et al. (2006) proposed Support Feature Machine (SFM) formulations can be used to find a set of features that gives the highest classification performance [10].

Bayesian decision method has also been widely studied in classification. However, there are only few studies incorporating the Bayesian model with mathematical programming approaches. Among those studies, Asparouhov and Danchev [4] formulates a MIP model with binary variables, which are conformed with the Bayesian decision theory. In the case of multi-group classification, Anderson [2] developed a mathematical formulation that incorporates the population densities and prior probabilities of training data. This model yields classification rules for multi-groups with a reject option, (a set having entities that does not belong to any group) [22].

## Deterministic Optimization Models

### Support Vector Machines

Support Vector Machines (SVM) is aimed at finding a hyperplane that separates the labeled input data into two groups,  $G_1$  and  $G_2$ . Then the optimal plane can be used for classifying new data point. The hyperplane can be mathematically expressed by  $A\omega = \gamma$ , where  $\omega \in \mathfrak{R}^m$  is an  $m$ -dimensional vector of real numbers,  $m$  is total number of attributes/features used to represent a data entity, and  $\gamma \in \mathfrak{R}^n$  is a scalar vector. All elements from  $G_1$  and  $G_2$  will be separated by this hyperplane under the assumption that the sets  $G_1$  and  $G_2$  are separable. Define margin as the minimum distance from the plane to elements in a group,  $G_1$  or  $G_2$ . The objective function of SVM is to find a separating hyperplane with the largest margin. The data set  $G_1$  can be represented by the matrix  $A_i \in \mathfrak{R}^{k \times m}$ ,  $i \in G_1$  and the set  $G_2$  can be represented by the matrix  $A_j \in \mathfrak{R}^{(n-k) \times m}$ ,  $j \in G_2$ , where  $k$  are number of data points (entities) of group  $G_1$ . Two open half spaces defined by the hyperplane are  $\{A_i\omega < \gamma\}$  and  $\{A_j\omega > \gamma\}$ . One contains elements of  $G_1$  and the other contains elements of  $G_2$ . Therefore, a linear programming (LP) problem can be formulated to determine the optimal values of vectors  $\omega$  and  $\gamma$ . To construct valid inequalities for linear programming, we rescale the variables  $(\omega, \gamma)$ , by dividing them by the positive value  $\min_{i \in G_1, j \in G_2} \{A_i\omega - \gamma, -A_j\omega + \gamma\}$ . Let  $e$  denote a vector of ones, and the resulting inequalities become

$$A_i\omega \geq e\gamma + e, \quad A_j\omega \leq e\gamma - e. \quad (1)$$

The performance of the SVM relies heavily on the kernel transformation, the data mapping to a high dimension. SVM can also incorporate nonlinear mapping  $\phi(\cdot)$ . If the new dimension is sufficiently high enough, the data from two classes can always be separated by a hyperplane [9,11]. Examples of SVM kernel functions include linear, polynomial, radial basis function (RBF) and sigmoid. Recently, Shimodaira et al. [24] has proposed the Dynamic Time-Alignment Kernel for time series data.

### Robust LP for SVM

It is important to note that the above LP model assumes that  $A_i$  and  $A_j$  are perfectly separable, which is usually

not a case in practice. In other words, it is possible that the inequalities in Eq. (1) provide no solution as the data are not perfectly separable. Bennett and Mangasarian [5] proposed an improved formulation that minimizes an average misclassifications given by

$$\begin{aligned} \min_{\omega, \gamma, y, z} \quad & \frac{e^T y}{m} + \frac{e^T z}{k} \\ \text{s.t.} \quad & A_i\omega - e\gamma - e \geq y, \\ & -A_j\omega + e\gamma - e \geq z, \\ & y \geq 0, z \geq 0. \end{aligned}$$

It is easy to see that the variables  $y$  and  $z$  are, in fact, the vectors representing the violations of inequalities in Eq. (2) and minimizing the objective function would lead to the minimum average violation.

### Feature Selection with SVM

We note that an extension of the robust LP formulation can be used for feature selection [5,23]. A new term is added in the objective function in the robust LP model to suppress the components of  $\omega$ . This would try to eliminate all unnecessary features. Let  $v$  denote the absolute value of the weight vector  $\omega$ ,  $\log$  is the base of the natural logarithm, and  $\lambda \in (0, 1)$ . The mathematical program with a concave objective function and linear constraints for feature selection is given by

$$\begin{aligned} \min_{\omega, \gamma, y, z, v} \quad & (1 - \lambda)\left(\frac{e^T y}{m} + \frac{e^T z}{k}\right) + \lambda e^T (e - \log^{-\alpha v}) \\ \text{s.t.} \quad & A_i\omega - e\gamma - e \geq y, \\ & -A_j\omega + e\gamma - e \geq z, \\ & y \geq 0, z \geq 0, \\ & -v \leq \omega \leq v. \end{aligned}$$

Note that when  $\lambda = 0$ , the model gives a plane that separates  $A_i$  and  $A_j$  without considering feature suppression. On the other hand, when  $\lambda > 0$ , the objective not only tries to separate  $A_i$  and  $A_j$ , but also tries to eliminate as many of  $\omega$  components as possible. Specifically, for each  $v_i$  ( $i = 1, \dots, n$ ), we minimize an exponential smoothing of the step function  $(1 - \log^{-\alpha v_i})$ . This step function enables the deletion of irrelevant components of  $\omega$ . There also exists a finitely-terminating algorithm that solves this problem using successive linear programming [8].

### Hybrid LP Discriminant Model

A hybrid LP discriminant model is proposed in [12,13,20]. This model is guaranteed to give the optimal solution regardless of the nature of the data. Therefore, the solution is invariant to transformations. This model is improved to overcome many shortcomings of contemporary linear discriminant formulations, which are reviewed and discussed in [21]. Recall that  $m$  is the number of attributes, all data points in  $G_1$  are represented by an  $k \times m$  matrix  $A_i$ ,  $i \in G_1$ , and all data points in  $G_2$  are represented by an  $(n - k) \times m$  matrix  $A_j$ ,  $j \in G_2$ . For the simplicity of mathematical representation, the membership in  $G_1$  or  $G_2$  can be represented by  $i \in G_1$  or  $i \in G_2$ , respectively. This model will give a hyperplane of the form  $A^T \omega = \gamma$ , where the model seeks for the optimal weight vector  $\omega$ , and a scalar  $\gamma$ , where data points of Group 1 lie on one side of the hyperplane and data points of Group 2 lie on the other side (i. e.,  $A_i \omega < \gamma$ ,  $i \in G_1$  and  $A_i \omega > \gamma$ ,  $i \in G_2$ ). Let  $y_i$  and  $z_i$  represent external and internal deviation variables referring to the point violations and satisfactions of the classification rule. More specifically, they are the magnitudes of the data points lying outside or inside their targeted half spaces. The objective is to minimize violations and maximize the satisfactions of the classified groups. Thus, in the objective function, variable  $h_i$ 's discourage external deviations and variable  $k_i$ 's encourage internal deviations. Then  $h_i \leq k_i$  for  $i = 0$  and  $i \in G$ , must be satisfied. The hybrid model is given by

$$\begin{aligned}
 \min \quad & h_0 y_0 + \sum_{i \in G} h_i y_i - k_0 z_0 - \sum_{i \in G} k_i z_i \\
 \text{s.t.} \quad & \mathbf{A}_i \omega - y_0 - y_i + z_0 + z_i = \gamma, \quad i \in G_1 \\
 & \mathbf{A}_i \omega + y_0 + y_i - z_0 - z_i = \gamma, \quad i \in G_2 \\
 & z_0 + \sum_i z_i = 1, \quad i \in G \\
 & y_0, z_0 \geq 0 \\
 & y_i, z_i \geq 0, \quad i \in G \\
 & \omega, \gamma \quad \text{unrestricted.}
 \end{aligned} \tag{2}$$

We note that Eq. (2) is a normalization constraint that is necessary for avoiding a trivial solution where all  $\omega_j = 0$  and  $\gamma = 0$ . Glover [18] identifies more normalization methods to conquer the problem with null weighting.

### MIP Discriminant Model

There are several related mixed integer formulations in the literature [1,15,16]. In general, due to the computational requirements, these standard MIP formulations can only be applied to classification problems with a relatively small number of observations. Glover [19] proposed a compact mathematical program for discriminant model, which is a variant of the above-mentioned hybrid LP model. This objective of this model is to minimize the number of misclassified entities. The MIP discriminant model is given by

$$\begin{aligned}
 \min \quad & \sum_{i \in G} z_i \\
 \text{s.t.} \quad & A_i x - M z_i + \beta_i = b, \quad i \in G_1 \\
 & A_i x + M z_i - \beta_i = b, \quad i \in G_2 \\
 & \beta_i \geq 0, \quad i \in G \\
 & z_i \in \{0, 1\}, \quad i \in G \\
 & x, b \quad \text{unrestricted,}
 \end{aligned}$$

where  $\beta_i$  are slack variables, and  $M$  is a large constant chosen so that when  $z_i = 1$ ,  $A_i x \leq b + M z_i$  will be redundant for  $i \in G_1$  and  $A_i x \geq b - M z_i$  will be redundant for  $i \in G_2$ . This model can incorporate a normalization constraint,  $(-n_2 \sum_{i \in G_1} A_i + n_1 \sum_{i \in G_2} A_i)x = 1$ , where  $n_1$  and  $n_2$  are the number of entities in  $G_1$  and  $G_2$ , respectively.

### Multi-hyperplane Classification

Multi-hyperplane formulations, given by Better et al. [6], generate multiple linear hyperplanes simultaneously with the consequence of forming a decision tree. The hyperplanes are generated from an extension of the Discriminant Model proposed by Glover [18]. Instead of using kernel transformation that projects data into a high dimensional space to improve the performance of SVM, the multi-hyperplane approach approximates a nonlinear separation by constructing multiple hyperplanes. Let  $d = 0$  when we are at a root node of a binary tree, where none of the classifications have been done. Let  $d = D$  when the tree has two leaf nodes corresponding to the final separation step. In order to explain the model, we define the following terms.

- Successive Perfect Separation (SPS) is a procedure that forces all elements of Group 1 ( $G_1$ ) and Group 2 ( $G_2$ ) to lie on one side of the hyperplane at each node

for any depth  $d \in \{0, \dots, D-1\}$ . SPS is a special use of a variant based on a proposal of Glover [18].

- SPS decision tree is a tree that results from the two-group classification iteratively applying the SPS procedure. The root node ( $d = 0$ ) contains all the entities in the data set, and at  $d = D$  the two leaf nodes correspond to the final separation step.

For a given maximum depth  $D$ , an initial multi-hyperplane model considers each possible SPS tree type of depth  $d$ , for  $d = 0, \dots, D-1$ . A root node is viewed as a “problem” node where all data points from both groups need to be separated. A leaf node, on the other hand, is considered to be a “decision” node where data points are classified into two groups. Define slicing variables  $sl_i$  for  $i \in \{1, \dots, D-1\}$ . There are total of  $D-1$  slicing variables needed for a tree having maximum depth  $D$ . Specifically, at depth  $d = 1$ ,  $sl_1 = 0$  if the “left” node constitutes a leaf node while the “right” node constitutes a root (or problem) node. Without loss of generality, we herein consider  $D = 3$  for the initial multi-hyperplane model. The mathematical model for multi-hyperplane SVM can be formally defined as follows.

Let  $M$  and  $\varepsilon$  denote large and small positive constants, respectively, and  $G$  denote a set of the union of entities in  $G_1$  and  $G_2$ . Suppose there are  $n$  entities in the training data set. Define a binary variable  $z_i^* = 0$  if object  $i$  is correctly classified by the “tree”, otherwise  $z_i^* = 1$ . Define a binary variable and  $z_{hi}^* = 0$  if object  $i$  is correctly classified by “hyperplane  $h$ ”, otherwise  $z_{hi}^* = 1$ . The multi-hyperplane SVM model also includes traditional hyperplane constraints for each depth  $d$  of the tree and the normalization constraint, which is similar to the mixed integer programming model in [18]. Then,  $\varepsilon$  is added to prevent data points from lying on the hyperplane. Tree-type constraints are included to identify the optimal tree structure for the data set, which will be in part of the optimal classification rule. Binary variables  $y_i$  are used for tree types (0,1) and (1,0) to activate or deactivate either-or constraints. The SPS decision tree formulation for the depth  $D = 3$  is given by

$$\begin{aligned} & \min \sum_{i=1}^n z_i^* \\ & \text{s.t. } A_i x_d - M z_{di} + \beta_i = b_d - \varepsilon \\ & \quad i \in G_1, d = 1, 2, 3 \end{aligned} \quad (3)$$

$$\begin{aligned} A_i x_d + M z_{di} - \beta_i &= b_d + \varepsilon \\ & i \in G_2, d = 1, 2, 3 \end{aligned} \quad (4)$$

$$\begin{aligned} M(sl_1 + sl_2) + z_i^* \\ \geq z_{1i} + z_{2i} + z_{3i} - 2 \end{aligned} \quad i \in G_1 \quad (5)$$

$$\begin{aligned} M(sl_1 + sl_2) + M z_i^* \\ \geq z_{1i} + z_{2i} + z_{3i} \end{aligned} \quad i \in G_2 \quad (6)$$

$$\begin{aligned} M(2 - sl_1 - sl_2) + M z_i^* \\ \geq z_{1i} + z_{2i} + z_{3i} \end{aligned} \quad i \in G_1 \quad (7)$$

$$\begin{aligned} M(2 - sl_1 - sl_2) + z_i^* \\ \geq z_{1i} + z_{2i} + z_{3i} - 2 \end{aligned} \quad i \in G_2 \quad (8)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + z_i^* \geq z_{1i} - M y_i \\ i \in G_1 \end{aligned} \quad (9)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + M z_i^* \\ \geq z_{2i} + z_{3i} - M[1 - y_i] \end{aligned} \quad i \in G_1 \quad (10)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + z_i^* \geq z_{1i} \\ i \in G_2 \end{aligned} \quad (11)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + z_i^* \\ \geq z_{2i} + z_{3i} - 1 \end{aligned} \quad i \in G_2 \quad (12)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + z_i^* \geq z_{1i} \\ i \in G_1 \end{aligned} \quad (13)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + z_i^* \geq z_{2i} + z_{3i} - 1 \\ i \in G_1 \end{aligned} \quad (14)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + z_i^* \geq z_{1i} - M y_i \\ i \in G_2 \end{aligned} \quad (15)$$

$$\begin{aligned} M(1 + sl_1 - sl_2) + M z_i^* \\ \geq z_{2i} + z_{3i} - M[1 - y_i] \end{aligned} \quad i \in G_2 \quad (16)$$

$$\sum_{j=1}^n \sum_{d=1}^3 x_{jd} = 1 \quad (17)$$

$$z_i^* \in \{0, 1\}, z_{di} \in \{0, 1\}, y_i \in \{0, 1\},$$

$$i \in G, d = 1, 2, 3$$

$$sl_k \in \{0, 1\} \quad k = 1, 2, \quad x, b \text{ unrestricted,}$$

where the constraints in Eqs. (3)-(4) are the hyper-plane constraints, Eqs. (5)-(6) are the constraints for tree type (0,0), Eqs. (7)-(8) are the constraints for tree type (1,1), Eqs. (9)-(12) are the constraints for tree type (0,1), Eqs. (13)-(16) are the constraints for tree type (1,0), and Eq. (17) is the normalization constraint. This small model with  $D = 3$  performs well for small depths and has computational limitations. The reader should refer to [6] for a greater detail of an improved and generalized structure model for all types of SPS trees.

### Support Feature Machines

Support Feature Machines (SFM) proposed in [10] is a mathematical programming technique used to identify a set of features that gives the highest performance in classification using the nearest neighbor rule. SFM can be formally defined as follows. Assume there are  $n$  data points, each with  $m$  features, we define the decision variables  $x_j \in \{0, 1\}$  ( $j = 1, \dots, m$ ) indicating if feature  $j$  is selected by SFM and  $y_i \in \{0, 1\}$  ( $i = 1, \dots, n$ ) indicating if sample  $i$  can be correctly classified by SFM. There are two versions of SFM, *voting* and *averaging*. Each version uses different weight matrices, which are provided by user's classification rule.

The objective function of voting SFM is to maximize the total correct classification as in Eq. (18). There are two sets of constraints used to ensure that the training samples are classified based on the voting nearest neighbor rule as in Eqs. (19)-(20). There is a set of logical constraints in Eq. (21) used to ensure that at least one feature is used in the voting nearest neighbor rule. The mixed-integer program for voting SFM is given by:

$$\max \sum_{i=1}^n y_i \quad (18)$$

$$\text{s.t.} \sum_{j=1}^m a_{ij}x_j - \sum_{j=1}^m \frac{x_j}{2} \leq My_i$$

$$\text{for } i = 1, \dots, n$$

$$\sum_{j=1}^m \frac{x_j}{2} - \sum_{j=1}^m a_{ij}x_j + \epsilon \leq M(1 - y_i) \quad (20)$$

for  $i = 1, \dots, n$

$$\sum_{j=1}^m x_j \geq 1 \quad (21)$$

$$x \in \{0, 1\}^m, \quad y \in \{0, 1\}^n,$$

where  $a_{ij} = 1$  if the nearest neighbor rule correctly classified sample  $i$  at electrode  $j$ , 0 otherwise,  $n$  is total number of training samples,  $m$  is total number of features,  $M = m/2$ , and  $\epsilon$  is a small positive number used to break a tie during the voting ( $0 < \epsilon < 1/2$ ).

The objective function of averaging SFM is to maximize the total correct classification as in Eq. (22). There are two sets of constraints used to ensure that the training samples are classified based on the distance averaging nearest neighbor rule as in Eqs. (23)-(24). There is a set of logical constraints in Eq. (25) used to ensure that at least one feature is used in the distance averaging nearest neighbor rule. The mixed-integer program for averaging SFM is given by:

$$\max \sum_{i=1}^n y_i \quad (22)$$

$$\text{s.t.} \sum_{j=1}^m \bar{d}_{ij}x_j - \sum_{j=1}^m d_{ij}x_j \leq M_{1i}y_i \quad (23)$$

for  $i = 1, \dots, n$

$$\sum_{j=1}^m d_{ij}x_j - \sum_{j=1}^m \bar{d}_{ij}x_j \leq M_{2i}(1 - y_i) \quad (24)$$

for  $i = 1, \dots, n$

$$\sum_{j=1}^m x_j \geq 1 \quad (25)$$

$$x \in \{0, 1\}^m, \quad y \in \{0, 1\}^n,$$

where  $d_{ij}$  is the average statistical distance between sample  $i$  and all other samples from the same class at feature  $j$  (*intra-class distance*),  $\bar{d}_{ij}$  is the average statistical distance between sample  $i$  and all other samples from different class at feature  $j$  (*inter-class distance*),  $M_{1i} = \sum_{j=1}^m \bar{d}_{ij}$ , and  $M_{2i} = \sum_{j=1}^m d_{ij}$ .

**Probabilistic Optimization Models**

The deterministic classification models in the previous section make a strong assumption that the data are separable. In the case that the data may not be well separated, using the deterministic models may lead to a high misclassification rate. The classification models that incorporate probabilities may be a better option for such noisy data. When the population densities and prior probabilities are known, there are probabilistic models that consider constrained rules with a reject option [2] as well as a Bayesian-based model [4].

**Bayesian-Based Mathematical Program**

The Bayesian-based mathematical program that are conformed with the Bayesian decision theoretic approach is proposed by Asparouhov and Danchev [4]. The model can be formally defined as follows. Denote  $c \in \mathfrak{R}$  as a cut-off value,  $x \in B^m$  as a vector of  $m$  binary values, and  $\omega \in \mathfrak{R}^m$  is a decision variable having  $m$ -dimensional vector of real numbers. A preprocessing needs to be performed so that if  $x^T \omega \leq c$ , the entity  $x$  belong to class 1; otherwise it belongs to class 2. Suppose we have a set of  $n$  data points,  $n_1$  data points are in  $G_1$  and  $n_2$  data points are in  $G_2$ , ( $n = n_1 + n_2$ ). Let  $s$  be a non empty multinomial cell. Denote  $n_{is}$  as the number of design set observation from the class  $i$ , where  $i = 1, 2$ , falling in this cell  $s$ . There are  $2^m$  number of multinomial cells. Each cell is unique and all observations that belongs to it have exactly the same values of the  $m$  binary variables. Denote  $M$  as a sufficiently large positive real number, and  $\epsilon$  as a small positive number. In addition to having a geometric interpretation, this formulation is inspired from Bayesian decision theoretic approach and having prior probabilities,  $n_i/n > \forall i$ , incorporated. Experimental studies in [4] suggest this Bayesian-based model can give better performance than other contemporary linear discriminant models. The Bayesian-based classification formulation is given by

$$\begin{aligned} \min_{\omega, z_s, c} \quad & \sum_s (|n_{1s} - n_{2s}| z_s + \min(n_{1s}, n_{2s})) \\ \text{s.t.} \quad & \mathbf{x}_s^T \omega - Mz_s \leq c \text{ if } n_{1s} \geq n_{2s} \\ & \mathbf{x}_s^T \omega + Mz_s \geq c + \epsilon \text{ if } n_{1s} < n_{2s} \\ & n_{1s} + n_{2s} \neq 0 \\ & z_s \in \{0, 1\}, \omega \in \mathfrak{R}^m, c \in \mathfrak{R}. \end{aligned}$$

**Probabilistic Models for Classification**

An optimization model proposed by Anderson [2] incorporates population densities, prior probabilities from all groups, and misclassification probabilities. This method is aimed to find a partition  $\{R_0, R_1, \dots, R_G\}$  of  $\text{Re}^m$  where  $m$  is the number of features. This method naturally forms a multi-group classification. The objective is to maximize the probability of correct allocation subject to constraints on the misclassification probabilities. The mathematical model can be formally defined as follows. Let  $f_h, h = 1, \dots, G$ , denote the group conditional density functions. Let  $\pi_g$  denote the prior probability that a randomly selected entity is from group  $g, g = 1, \dots, G$ , and  $\alpha_{hg}, h \neq g$ , are constants between 0 and 1. The probabilistic classification model is then given by

$$\begin{aligned} \min \quad & \sum_{g=1}^G \pi_g \int_{R_g} f_g(w) dw \\ \text{s.t.} \quad & \int_{R_g} f_h(w) dw \leq \alpha_{hg} \\ & \text{for } h, g = 1, \dots, G, h \neq g. \end{aligned}$$

The optimal rule that can be used as a classification method is given by

$$R_g = \left\{ x \in \mathfrak{R}^k : L_g(x) = \max_{h \in \{0, 1, \dots, G\}} L_h(x) \right\}, \quad (26)$$

where  $g = 0, \dots, G, L_0(x) = 0$ , and  $L_h(x) = \pi_h f_h(x) - \sum_{i=1, i \neq h}^G \lambda_{ih} f_i(x)$ , for  $h = 1, \dots, G$ . In general, there exist nonnegative constants  $\lambda_{ih}, i, h \in 1, \dots, G, i \neq h$ , such that this optimal rule holds. The procedure for deriving a discriminant rule is composed of two stages. The first stage is to compute  $\hat{f}_h$ , which are estimated density functions  $f_h$ , and  $\hat{\pi}_h$ , which are estimated prior probabilities  $\pi_h$ , for  $h = 1, \dots, G$ . There are many methods proposed for density estimation. The second stage is to estimate the optimal  $\lambda'_{jh}$ s, given the estimates  $\hat{f}'_h$ s and  $\hat{\pi}'_h$ s. For estimating the  $\lambda'_{jh}$ s, there is a MIP approach proposed in [14], and a LP approach proposed in [22].

The MIP approach uses binary variables to record whether each entity was allocated to each region. This approach measures the probabilities of correct classification and misclassification for any candidate set of

$\lambda'_{ih}s$ , which are calculated as the proportion of training samples that fall into each of the regions. The objective is to maximize a linear combination of variables representing correct allocation. The proportions of training samples misclassified were incorporated in constraints on misclassification probabilities. On the other hand, the LP approach does not have binary variables to incorporate proportions of misclassified training data points, and to provide a mechanism for modeling a priori bounds on misclassification probabilities. Instead, the LP approach provides a mechanism for estimating  $\lambda'_{ih}s$  that balances the minimization of misclassifications and the maximization of correct classifications. This can be demonstrated as follows. Redefine the function  $L_h$ ,  $h = 1, \dots, G$ , as

$$L_h(x) = \pi_h p_h(x) - \sum_{i=1, i \neq h}^G \lambda_{ih} p_i(x), \quad (27)$$

where  $p_i(x) = f_i(x) / \sum_{t=1}^G f_t(x)$ . This is analogous to the definition of original  $p_i$  in Eq. (26) since  $R_g$  can be expressed as  $R_g = \{x \in \mathfrak{R}^k : L_g(x) \leq L_h(x), h = 0, \dots, G\}$ , if and only if,  $\left( (1 / \sum_{t=1}^G f_t(x)) f_i(x) \right) L_g(x) \leq \left( (1 / \sum_{t=1}^G f_t(x)) f_i(x) \right) L_h(x)$ . Note that this new definition of  $L_h$  is just an assumption. In addition, we also assume that we have a training sample of  $n$  data points whose group classifications are known. There are  $n_g$  data points in group  $g$  and  $\sum_{g=1}^G n_g = n$ . For notational convenience, let  $\gamma = 1, \dots, G$  and  $N_g = 1, \dots, n_g$ . Each data point  $x$  has  $k$  attributes, denoted as  $x^{gj} \in \mathfrak{R}^k$  for  $g = 1, \dots, G$  and  $j = 1, \dots, n_g$ .

### MIP Formulation for Anderson's Model

In order to find the optimal estimation of the second stage for solving Anderson's formula in Eq. (27), after the estimates  $\hat{f}'_h$ s and  $\hat{\pi}'_h$ s are given, the optimal  $\lambda'_{jh}$ s is the final goal. For estimating the  $\lambda'_{jh}$ s, Gallagher et al. [14] proposed a MIP formulation. Same notation used in Anderson's formula in last section is applied here. The model ensures that the proportion of training data points and total data points  $n_g$  of group  $g$  in region  $R_h$  is less than or equal to a pre-specified percentage,  $\alpha_{hg} > (0 < \alpha_{hg} < 1)$ , for  $h, g \in \gamma$  and  $h \neq g$ . The original formulation of the approach is a nonlinear

MIP model given by

$$\min_{L_{hgj}, \gamma_{gj}, \lambda_{ih}, u_{gj}} \sum_{g \in \gamma} \sum_{j \in N_g} u_{ggj}$$

s.t.

$$L_{hgj} = \pi_h \hat{p}_h(x^{gj}) - \sum_{i \in \gamma \setminus \{h\}} \lambda_{ih} \hat{p}_i(x^{gj}) \quad (28)$$

$$\text{for } h, g \in \gamma, j \in N_g$$

$$\gamma_{gj} = \max \{0, L_{hgj} : h = 1, \dots, G\} \quad (29)$$

$$\text{for } g \in \gamma, j \in N_g$$

$$\gamma_{gj} - L_{ggj} \leq M(1 - u_{ggj}) \quad (30)$$

$$\text{for } g \in \gamma, j \in N_g$$

$$\gamma_{gj} - L_{hgj} \geq \varepsilon(1 - u_{hgj}) \quad (31)$$

$$\text{for } h, g \in \gamma, h \neq g, j \in N_g$$

$$\sum_{j \in N_g} u_{hgj} \leq \lfloor \alpha_{hg} n_g \rfloor \quad (32)$$

$$\text{for } h, g \in \gamma, h \neq g$$

$$-\infty < L_{hgj} < \infty \quad \text{for } h, g \in \gamma, j \in N_g$$

$$\gamma_{gj} \geq 0 \quad \text{for } g \in \gamma, j \in N_g$$

$$\lambda_{ih} \geq 0 \quad \text{for } i \in N_g, h \in \gamma$$

$$u_{gj} \in \{0, 1\} \quad \text{for } g \in \gamma, j \in N_g$$

The above nonlinear mixed integer programming model can be transformed to an equivalent linear mixed integer model. The transformation is made by replacing the constraint in Eq. (29) with the following constraints:

$$\gamma_{gj} \geq L_{hgj} \quad h, g \in \gamma, j \in N_g$$

$$\tilde{y}_{hgj} - L_{hgj} \leq M(1 - v_{ghj}) \quad h, g \in \gamma, j \in N_g$$

$$\tilde{y}_{hgj} \leq \pi_h \hat{p}_h(x^{gj}) v_{ghj} \quad h, g \in \gamma, j \in N_g$$

$$\sum_{h \in G} v_{hgj} \leq 1 \quad g \in \gamma, j \in N_g$$

$$\sum_{h \in G} \tilde{y}_{hgj} = \gamma_{gj} \quad g \in \gamma, j \in N_g,$$

where  $\tilde{y}_{hgj} \geq 0$  and  $v_{ghj} \in \{0, 1\}$ , for  $h, g \in \gamma, j \in N_g$ . The constraints in Eq. (28) define the decision variable  $L_{hgj}$  as a function value of  $L_h$  at  $x^{gj}$ . The variable  $y_{gj}$  in Eq. (29) gives a result that  $x^{gj}$  lies in region  $R_h$ , if and only if,  $y_{gj} = L_{hgj}$ . The binary variable  $u_{hgj}$  is used to indicate whether or not  $x^{gj}$  lies in region  $R_h$ . The constraints in Eq. (30) together with the objective function ensure that  $u_{ggj} = 1$ , if and only if, the  $j$ th entity from group  $g$  is correctly allocated to group  $g$ . The constraints in Eqs. (31)-(32) ensure that at most  $\lfloor \alpha_{hg} n_g \rfloor$  data points of group  $g$  are allocated to group  $h, h \neq g$ . Note that the condition of indicator variables,  $u_{hgj} = 0, h \neq g$ , implies that  $x^{gj} \notin R_h$  by Eq. (31), but the converse need not hold. As a result, the number of misclassifications may be overcounted. To force the converse hold, (that is  $u_{hgj} = 1$ , if and only if,  $x^{gj} \in R_h, \forall h, g \in \gamma$ ), one can include the following constraints:  $y_{gj} - L_{hgj} \leq M(1 - u_{hgj})$  for  $h, g \in \gamma, j \in N_g$ . However, the addition of such constraints substantially increases the solution times and the actual amount of overcounting is minimal.  $M$  and  $\varepsilon$  are large and small positive constants, respectively. Since this MIP formulation is very difficult to solve, especially it involves 2GN binary variables. There is a preprocessing strategy suggested in [14] by aggregating variables and constraints. Special branching strategies for solving the MIP model is also suggested in [14]. Those strategies include branching on the smallest indexed fractional-valued binary variable, branching on the most infeasible fractional-valued binary variable, pseudo reduced-cost branching schemes, and strong branching [3,7].

### LP Formulation for Anderson's Model

In order to estimate the  $\lambda'_{jh}$ s for solving Anderson's formula in the second stage in Eq. (27), Lee et al. [22] proposed the Linear Programming (LP) model that minimizes a penalty function in order to allocate each training entity to its correct group or to the reserved-judgment region. Note that same notation used in the MIP approach and Anderson's formula is consistent here. The method is given by

$$\min_{L_{hgj}, \omega_{gj}, y_{gj}, \lambda_{ih}} \sum_{g \in \gamma} \sum_{j \in N_g} (c_1 \omega_{gj} + c_2 y_{gj})$$

s.t.

$$L_{hgj} = \pi_h \hat{p}_h(x^{gj}) - \sum_{i \in \gamma \setminus \{h\}} \lambda_{ih} \hat{p}_i(x^{gj}) \quad (33)$$

$$\text{for } h, g \in \gamma, j \in N_g$$

$$L_{ggj} - L_{hgj} + \omega_{gj} \geq 0 \quad (34)$$

$$\text{for } h, g \in \gamma, h \neq g, j \in N_g$$

$$L_{ggj} + \omega_{gj} \geq 0 \quad (35)$$

$$\text{for } g \in \gamma, j \in N_g$$

$$-L_{hgj} + y_{gj} \geq 0 \quad (36)$$

$$\text{for } h, g \in \gamma, j \in N_g$$

$$-\infty < L_{hgj} < \infty \quad \text{for } h, g \in \gamma, j \in N_g$$

$$\omega_{gj} \geq 0 \quad \text{for } g \in \gamma, j \in N_g$$

$$y_{gj} \geq 0 \quad \text{for } g \in \gamma, j \in N_g$$

$$\lambda_{ih} \geq 0 \quad \text{for } i \in N_g, h \in \gamma.$$

The constraints in Eq. (33) define the decision variable  $L_{hgj}$  as a function value of  $L_h$  for  $x^{gj}$ . If the optimal solution yields  $\omega_{gj} = 0$ , for some  $(g, j)$  pair, the constraints in Eqs. (34)-(35) imply that  $L_{ggj} = \max\{0, L_{hgj} : h \in \gamma\}$ . Thus, when  $\omega_{gj} = 0$ , it means that the  $j$ th entity from group  $g$  is correctly classified. If  $y_{gj} = 0$  is the case for some  $(g, j)$  pair, then the constraints in Eq. (36) implies that  $L_{ggj} = \max\{0, L_{hgj} : h \in \gamma\} = 0$ . Hence, the  $j$ th entity from group  $g$  is placed in the reserved-judgment region. If both  $\omega_{gj}$  and  $y_{gj}$  are positive, the  $j$ th entity from group  $g$  is misclassified. The optimization solver is attempting either to correctly classify training data points ( $\omega_{gj} = 0$ ), or to place them in the reserved-judgment region ( $y_{gj} = 0$ ). The optimizer's emphasis can be realized by varying the weights  $c_1$  and  $c_2$ . It is possible for both  $\omega_{gj}$  and  $y_{gj}$  to be zero. One should decide how to interpret in such situation. Recall the optimal rule in Eq. (26), which constrains that if  $x$  belongs to the reserved judgment region ( $h = 0$ ) then it gives the function value  $L_0(x) = 0$ .

Global optimization; Stochastic differential equation

Let  $\mathbf{N}$  be the set of natural numbers. Let  $N \in \mathbf{N}$  and  $\mathbf{R}^N$  be the  $N$ -dimensional real Euclidean space, let  $\mathbf{C}^N$  be the  $N$ -dimensional complex Euclidean space,  $\mathbf{R}, \mathbf{C}$  are used in place of  $\mathbf{R}^1, \mathbf{C}^1$  respectively. Let  $\mathbf{R}^+ = \{x \in \mathbf{R}: x \geq 0\}$ . Let  $x \in \mathbf{R}$ ; then  $|x|$  denotes the absolute value of  $x$ . Let  $\mathbf{x}, \mathbf{y} \in \mathbf{R}^N$ ; then  $(\mathbf{x}, \mathbf{y})$  denotes the scalar product in  $\mathbf{R}^N$  and  $\|\mathbf{x}\|$  denotes the euclidean norm in  $\mathbf{R}^N$ . Let  $\mathbf{S}^N = \{\mathbf{x} \in \mathbf{R}^{N+1}: \|\mathbf{x}\| = 1\}$ .

Let  $D \subseteq \mathbf{R}^N$  be a connected domain, let  $F: D \rightarrow \mathbf{R}$  be a given function. The following problem is considered:

$$\min_{\mathbf{x} \in D} F(\mathbf{x}). \tag{1}$$

When  $D = \mathbf{R}^N$  problem (1) is called the *global unconstrained optimization problem*. When  $D \subset \mathbf{R}^N$  it is called the *global constrained optimization problem*.

Without loss of generality one considers only the minimization problem, that is, problem (1), since the maximization problem can be easily reduced to a minimization problem.

To solve problem (1) means to find a point  $\mathbf{x}^* \in D$  such that  $F(\mathbf{x}^*) \leq F(\mathbf{x}), \forall \mathbf{x} \in D$ .

A large number of problems with great theoretical and practical interest can be formulated as global optimization problems, that is, as problem (1).

In this article the global optimization problems are studied only from the point of view of numerical optimization and in particular of numerical methods based on differential equations. Many other fruitful points of view are possible to study that include the set of global minimizers of  $F$  on  $D$  or in general the set of critical points of  $F$  on  $D$  depending on the hypotheses made on  $F$  and  $D$ .

A method to solve problem (1) in the sense of numerical optimization is usually an iterative scheme that from a given initial guess  $\mathbf{x}^0 \in D$  is able to compute a sequence  $\{\mathbf{x}^n \in D: n \in \mathbf{N}\}$  such that  $\mathbf{x}^n \rightarrow \mathbf{x}^*$  when  $n \rightarrow \infty$ .

Problem (1) can be easily solved in some special cases, that is, when the function  $F$  and the domain  $D$  have special forms, for example one can recall the following two important cases:

- *linear programming problem:*  $F$  linear function,  $D$  convex polyhedron, i. e.,  $D \subset \mathbf{R}^N$  is defined implicitly by means of equalities and inequalities between linear functions;

- *convex programming problem:*  $F$  convex function,  $D \subset \mathbf{R}^N$  convex region.

One notes that the linear programming problem can be considered as a special case of the convex programming problem. For both cases effective methods to solve problem (1) are known, e. g., for the linear programming problem the simplex method, see [7], and for the convex programming problem the Newton method coupled with some strategy to treat the constraints that define  $D$ , for example active set strategy, see [9].

In general, problem (1) is a difficult one since the property of being a global minimizer is not a local property. That is, a global minimizer  $\mathbf{x}^*$  cannot be recognized from local properties of the function  $F$  at  $\mathbf{x}^*$ , such as the value of  $F$  and its derivatives at  $\mathbf{x}^*$ . Numerical algorithms to recognize global properties are unusual and in general computationally expensive.

For example, let  $D = \mathbf{R}, m, \alpha \in \mathbf{R}, \delta > 0$ , one considers the following two functions:

$$F_1(x) = -\frac{1}{1+x^2},$$

$$F_2(x) = -\frac{1}{1+x^2} + m \begin{cases} e^{\frac{1}{(x-\alpha)^2-\delta^2}} e^{\frac{1}{\delta^2}}, & x \in (\alpha-\delta, \alpha+\delta), \\ 0, & x \notin (\alpha-\delta, \alpha+\delta). \end{cases}$$

Function  $F_1$  has in  $x = 0$  the unique local minimizer which is also the global minimizer, i. e.  $x^* = 0$ . Let  $m < -1, 0 < \delta < |\alpha|$ ; then function  $F_2$  has several critical points including two local minimizers, one is  $x = 0$  and the other is  $x = x_2 \in (\alpha - \delta, \alpha + \delta)$ . Moreover the global minimizer of  $F_2$  is  $x = x^* = x_2$ . One notes that  $F_1, F_2$  are smooth functions and that they coincide, for every  $x \in \mathbf{R} \setminus (\alpha - \delta, \alpha + \delta)$  where  $\delta > 0$  is arbitrary.

Let  $D = \mathbf{R}^N$ , let  $F: D \rightarrow \mathbf{R}$  be a continuously differentiable function, let  $\nabla F$  be the gradient of  $F$ , let  $\mathbf{x} \in D$  be such that  $(\nabla F)(\mathbf{x}) \neq 0$  then the vector  $-(\nabla F)(\mathbf{x})$  gives the direction of steepest descent for the function  $F$  at the point  $\mathbf{x}$ . One can consider the following system of differential equations:

$$\frac{d\mathbf{x}}{dt}(t) = -(\nabla F)(\mathbf{x}(t)), \quad t > 0, \tag{2}$$

$$\mathbf{x}(0) = \mathbf{x}^0. \tag{3}$$

Under some hypotheses on  $F$ , the solution of problem (2), (3) is a trajectory in  $\mathbf{R}^N$  starting from  $\mathbf{x}^0$  and

ending in the critical point  $\mathbf{x}_{\text{loc}}^*(\mathbf{x}^0)$  of  $F$  whose attraction region contains  $\mathbf{x}^0$ . Using a numerical integration scheme for (2), (3) one can obtain a numerical optimization method, for example choosing the Euler integration scheme with variable stepsize from (2), (3) one obtains the so-called *steepest descent algorithm*. Let  $\xi^k \in \mathbf{R}^N$  be the approximation of  $\mathbf{x}(t_k)$ ,  $k \in \mathbf{N}$ , where  $t_0 = 0$ ,  $0 < t_k < t_{k+1} < +\infty$ ,  $k = 1, 2, \dots$ , and  $t_k \rightarrow +\infty$  when  $k \rightarrow \infty$ , obtained with a numerical optimization method coming from (2), (3). Suppose  $\{\xi^k, k \in \mathbf{N}\}$  is a sufficiently good approximation of the solution  $\mathbf{x}(t)$ ,  $t > 0$  of (2), (3) one has  $\lim_{k \rightarrow \infty} \xi^k = \lim_{t \rightarrow +\infty} \mathbf{x}(t) = \mathbf{x}_{\text{loc}}^*(\mathbf{x}^0)$ , thus the numerical optimization methods obtained from (2), (3) compute critical points that depend on the initial guess  $\mathbf{x}^0$ . So that these critical points usually are not global minimizers of  $F$ .

One can consider numerical optimization methods due to other differential equations instead of (2), that is differential equations taking in account higher order derivatives of  $F$  or of  $\mathbf{x}(t)$ . However the minimizers computed with these numerical optimization methods depend only on local properties of the function  $F$ , thus in general they will not be global minimizers of  $F$ . So that methods based on ordinary differential equations are inadequate to deal with problem (1).

In this article it is described how to use stochastic differential equations to avoid this difficulty. In fact one wants to destabilize the trajectories generated by problem (2), (3) using a stochastic perturbation in order to be able to reach global minimizers. This must be an appropriate perturbation, that is the corresponding perturbed trajectories must be able to leave the attraction region of a local minimizer of  $F$  to go in an attraction region of another minimizer of  $F$  obtaining as  $t \rightarrow +\infty$  the solution of problem (1). This is done by adding a stochastic term, i. e., a Brownian motion on the right-hand side of equation (2). Moreover this stochastic term takes into account the domain  $D$ , when  $D \subset \mathbf{R}^N$ . This is done introducing the solution of the Skorokhod reflection problem.

In the second section one gives some mathematical background about stochastic differential equations that is necessary to state the results of the third and fourth sections. In the third section, the unconstrained version of problem (1) is treated, i. e.,  $D = \mathbf{R}^N$ . In the fourth section, the constrained version of problem (1) is treated, i. e.,  $D \subset \mathbf{R}^N$ . In both these sections one gives methods,

convergence analysis and discussion when possible of a relevant software library. In the last section one gives some information about new application areas of global optimization such as graph theory and game theory.

## Mathematical Background

Let  $\Omega \subseteq \mathbf{R}$ ,  $\Sigma$  be a  $\sigma$ -field of subsets of  $\Omega$  and  $P$  be a probability measure on  $\Sigma$ . The triple  $(\Omega, \Sigma, P)$  is called a *probability measure space*, see [5] for a detailed introduction to probability theory. Let  $\Omega' \subseteq \mathbf{R}$ ,  $\mathcal{Y}$  be a topology of subsets of  $\Omega'$ . Then  $X : \Omega \rightarrow \Omega'$  is a random variable if  $\{X \in A\} \in \Sigma$  for every  $A \in \mathcal{Y}$ .

The *distribution function*  $G_X : \mathbf{R} \rightarrow [0, 1]$  of  $X$  is defined by  $G_X(x) = P\{X \leq x\}$ ,  $x \in \mathbf{R}$  and one denotes with  $g_X$  its density. The expected value or the mean value of  $X$  is defined as follows:

$$m(X) = \int_{\mathbb{R}} x G_X(dx) = \int_{\mathbb{R}} x g_X(x) dx \quad (4)$$

and the variance of  $X$  is given by:

$$v(X) = m((X - m(X))^2). \quad (5)$$

For example, a random variable  $X$  has discrete distribution, or is concentrated on  $x_1, \dots, x_n$ , when  $g_X(x) = \sum_{i=1}^n p_i \delta(x - x_i)$ , where  $p_i > 0$ ,  $x_i \in \Omega'$ ,  $i = 1, \dots, n$ ,  $\sum_{i=1}^n p_i = 1$  and  $\delta$  is the Dirac delta. Given  $m \in \mathbf{R}$ ,  $v > 0$  a random variable has normal distribution when

$$g_X(x) = \frac{1}{\sqrt{2\pi v}} e^{-\frac{(x-m)^2}{2v}},$$

one notes that  $m(X) = m$  and  $v(X) = v$ .

A *stochastic process* is a family of random variables depending on a parameter  $t$ , that is,  $\{X(t) : \Omega \rightarrow \Omega', t \geq 0\}$ . A *Brownian motion* is a stochastic process  $\{w(t) : t \geq 0\}$  having the following properties:

- $P\{w(0) = 0\} = 1$ ;
- for every choice of  $t_i$ ,  $i = 1, \dots, k$ ,  $0 \leq t_i < t_{i+1} < +\infty$ ,  $i = 1, \dots, k-1$ , the increments  $w(t_{i+1}) - w(t_i)$ ,  $i = 1, \dots, k-1$ , are independent and normally distributed random variables with mean value equal to zero and variance equal to  $t_{i+1} - t_i$ .

An *N-dimensional Brownian motion* is a  $N$ -dimensional process

$$\{\mathbf{w}(t) = (w_1(t), \dots, w_N(t)) : t \geq 0\}$$

where its components  $\{w_i(t) : \Omega \rightarrow \Omega', t \geq 0\}$ ,  $i = 1, \dots, N$ , are independent Brownian motions. The Brownian

motion is a good mathematical model to describe phenomena that are the superposition of a large number of chaotic elementary independent events. The most famous example of Brownian motion is the motion of pollen grains immersed in a fluid, the grains have a chaotic perpetual motion due to the collisions with the molecules of the fluid, see [15, p. 39].

Let  $\Pi = \Omega' \times \dots \times \Omega' \subset \mathbb{R}^N$ , where  $\times$  denotes the Cartesian product of sets. Let  $\mathcal{Y}'$  be a topology of subsets of  $\Pi$ . Let  $s, t$ , be such that  $0 \leq s \leq t$ , let  $\mathbf{x} \in \Pi$ ,  $A \in \mathcal{Y}'$ , then the transition distribution function of a  $N$ -dimensional stochastic process  $\{\mathbf{X}(t) : t \geq 0\}$  is defined as follows:

$$T(s, \mathbf{x}, t, A) = P\{\mathbf{X}(t) \in A \text{ and } \mathbf{X}(s) = \mathbf{x}\}. \tag{6}$$

When  $T$  can be written as:

$$T(s, \mathbf{x}, t, A) = \int_A p(s, \mathbf{x}, t, \mathbf{y}) \, d\mathbf{y} \tag{7}$$

for every  $0 \leq s \leq t$ ,  $\mathbf{x} \in \Pi$ ,  $A \in \mathcal{Y}'$  then the function  $p$  is called the *transition probability density* of the process  $\{\mathbf{X}(t) : t \geq 0\}$ .

Finally, if there exists a density distribution function  $\pi$  that depends only on  $\mathbf{x} \in \Pi$  such that:

$$\pi(\mathbf{x}) = \lim_{t \rightarrow +\infty} p(s, \mathbf{u}, t, \mathbf{x}), \tag{8}$$

then  $\pi$  is called the *steady-state distribution density* of the process  $\{\mathbf{X}(t) : t \geq 0\}$ .

One considers the following stochastic differential equation:

$$d\mathbf{Z}(t) = \boldsymbol{\alpha}(\mathbf{Z}(t), t) \, dt + \beta(\mathbf{Z}(t), t) \, d\mathbf{w}(t), \tag{9}$$

$$t > 0,$$

$$\mathbf{Z}(0) = \mathbf{x}^0, \tag{10}$$

where  $\mathbf{w}$  is the  $N$ -dimensional Brownian motion,  $\boldsymbol{\alpha}$  is the drift coefficient and  $\beta$  is the diffusion coefficient, see [8, p. 98] or [8, p. 196] for a detailed discussion. One notes that  $d\mathbf{w}$  cannot be considered as a differential in the elementary sense and must be understood as a stochastic differential, see [8, p. 59]. Under regularity assumptions on  $\boldsymbol{\alpha}$  and  $\beta$  there exists a unique solution  $\{\mathbf{Z}(t) : t > 0\}$  of (9), (10), see [8, p. 98].

When  $\boldsymbol{\alpha}$  is minus the gradient of a potential function equation (9) is called the *Smoluchowski-Kramers equation*. The Smoluchowski-Kramers equation is a singular limit of the Langevin equation.

The Langevin equation expresses Newton principle for a particle subject to a random force field, see [15, p. 40].

Let  $\text{div}_{\mathbf{y}}$  be the divergence operator with respect to the variables  $\mathbf{y}$ ,  $\Delta_{\mathbf{y}}$  be the Laplace operator with respect to the variables  $\mathbf{y}$  and  $L_{\beta, \boldsymbol{\alpha}}(\cdot) = \text{div}_{\mathbf{y}}(\cdot \boldsymbol{\alpha}) - (1/2)\Delta_{\mathbf{y}}(\cdot \beta^2)$ . Under regularity assumptions on  $\boldsymbol{\alpha}$  and  $\beta$ , the transition probability density  $p(s, \mathbf{x}, t, \mathbf{y})$ ,  $0 \leq s < t$ ,  $\mathbf{x}, \mathbf{y} \in \mathbb{R}^N$ , associated to the solution  $\{\mathbf{Z}(t) : t \geq 0\}$  of problem (9), (10) exists and satisfies the Fokker-Planck equation, (see [8, p. 149]) that is, given  $\mathbf{x} \in \mathbb{R}^N$ ,  $s \geq 0$  one has:

$$\frac{\partial p}{\partial t} + L_{\beta, \boldsymbol{\alpha}}(p) = 0, \quad \mathbf{y} \in \mathbb{R}^N, \quad t > s, \tag{11}$$

$$\lim_{t \rightarrow s, t > s} p(s, \mathbf{x}, t, \mathbf{y}) = \delta(\mathbf{x} - \mathbf{y}), \quad \mathbf{y} \in \mathbb{R}^N. \tag{12}$$

For the treatment of the constrained global optimization, that is, problem (1) with  $D \subset \mathbb{R}^N$ , a stochastic process depending on the domain  $D$  must be considered. Let  $\nu(\mathbf{x}) \subset \mathbb{S}^{N-1}$  be the set-valued function that gives the outward unit normals of the boundary  $\partial D$  of  $D$  at the point  $\mathbf{x} \in \partial D$ . One notes that when  $\mathbf{x}$  is a regular point of  $\partial D$ ,  $\nu(\mathbf{x})$  is a singleton. Let  $\eta: [0, T] \rightarrow \mathbb{R}^N$ , with possibly  $[0, T] = \mathbb{R}^+$ , let  $|\eta|(t)$  be the total variation of  $\eta$  in the interval  $[0, t]$ , where  $t < T$ . The *Skorokhod problem* is defined as follows: let  $\phi, \psi, \eta: [0, T] \rightarrow \mathbb{R}^N$ , then the triple  $(\phi, \psi, \eta)$  satisfies the Skorokhod problem, on  $[0, T]$  with respect to  $D$ , if  $|\eta|(T) < +\infty$ ,  $\phi(0) = \psi(0)$  and for  $t \in [0, T]$  the following relations hold:

$$\boldsymbol{\phi}(t) = \boldsymbol{\psi}(t) + \boldsymbol{\eta}(t), \tag{13}$$

$$\boldsymbol{\phi}(t) \in D, \tag{14}$$

$$|\boldsymbol{\eta}|(t) = \int_0^t \chi_{\{r \in \mathbb{R} : \boldsymbol{\phi}(r) \in \partial D\}}(s) \, d|\boldsymbol{\eta}|(s), \tag{15}$$

$$\boldsymbol{\eta}(t) = - \int_0^t \boldsymbol{\gamma}(s) \, d|\boldsymbol{\eta}|(s), \tag{16}$$

where  $\chi_S$  is the characteristic function of the set  $S$  and  $\boldsymbol{\gamma}(s) \in \nu(\boldsymbol{\phi}(s))$ , when  $s \in [0, T]$  and  $\boldsymbol{\phi}(s) \in \partial D$  and  $\boldsymbol{\gamma}(s) = \mathbf{0}$  elsewhere. Viewing  $\boldsymbol{\psi}(t)$ ,  $t \in [0, T]$ , as the trajectory of a point  $\mathbf{A} \in \mathbb{R}^N$ , one has that at time zero  $\mathbf{A}$  is inside  $D$ , since  $\boldsymbol{\psi}(0) \in D$ . Moreover the trajectory of  $\mathbf{A}$  is reflected from the boundary of  $D$  and the reflected trajectory can be viewed as  $\boldsymbol{\phi}(t)$ ,  $t \in [0, T]$ . That is,  $\boldsymbol{\phi}$  is equal to  $\boldsymbol{\psi}$  until  $\mathbf{A} \in D$ , when  $\mathbf{A}$  goes out of  $D$  it is brought back on  $\partial D$  in the normal direction to  $\partial D$ . One

notes that the function  $\eta$  gives the reflection rule with respect to the boundary of  $D$  of the function  $\psi$ . In [16] it is proved that under suitable assumptions on  $D$  and  $F$  there exists a unique solution of the Skorokhod problem.

One considers the following stochastic differential equation with reflection term, that is:

$$d\mathbf{Z}(t) = \alpha(\mathbf{Z}(t), t) dt + \beta(\mathbf{Z}(t), t) d\mathbf{w}(t) + d\eta(t), \quad t > 0, \quad (17)$$

$$\mathbf{Z}(0) = \mathbf{x}^0, \quad (18)$$

where

$$(\mathbf{Z}, \mathbf{Z} - \eta, \eta) \quad (19)$$

is the solution of the Skorokhod problem. One notes that relations (14), (19) imply that the solution of (17), (18) verifies  $\mathbf{Z}(t) \in D, t > 0$ . In [16] it is proved that under some hypotheses there exists a unique solution  $\{\mathbf{Z}(t): t \geq 0\}$  of (17), (18), (19) for every  $\mathbf{x}^0 \in D$ .

### Global Unconstrained Optimization

Given problem (1) with  $D = \mathbf{R}^N$  one considers the following stochastic differential equation:

$$d\mathbf{Z}(t) = -(\nabla F)(\mathbf{Z}(t)) dt + \sigma(t)d\mathbf{w}(t), \quad t > 0, \quad (20)$$

$$\mathbf{Z}(0) = \mathbf{x}^0, \quad (21)$$

where  $\{\mathbf{w}(t): t \geq 0\}$  is the  $N$ -dimensional Brownian motion and  $\sigma(t)$  is a suitable decreasing function that guarantees the convergence of the stochastic process  $\{\mathbf{Z}(t): t \geq 0\}$  to a random variable with density concentrated on the global minimizers of  $F$ . Under some assumptions on  $F$ , the transition probability density  $p(0, \mathbf{x}^0, t, \mathbf{x}), \mathbf{x} \in \mathbf{R}^N, t > 0$ , of the process  $\{\mathbf{Z}(t): t \geq 0\}$  exists and verifies equations (11), (12); moreover, when  $\sigma \equiv \epsilon, \epsilon > 0$ , for the steady-state distribution density  $\pi_\epsilon(\mathbf{x}), \mathbf{x} \in \mathbf{R}^N$ , the following equation holds:

$$L_{\epsilon, -\nabla F}(\pi_\epsilon) = 0, \quad \mathbf{x} \in \mathbf{R}^N, \quad (22)$$

one has:

$$\pi_\epsilon(\mathbf{x}) = C_\epsilon e^{-\frac{2F(\mathbf{x})}{\epsilon^2}}, \quad \mathbf{x} \in \mathbf{R}^N, \quad \epsilon > 0, \quad (23)$$

where:

$$C_\epsilon = \left( \int_{\mathbf{R}^N} e^{-\frac{2F(\mathbf{y})}{\epsilon^2}} d\mathbf{y} \right)^{-1}, \quad \epsilon > 0. \quad (24)$$

One assumes  $C_\epsilon < +\infty$  for  $\epsilon > 0$ . Moreover, one has:

$$p(0, \mathbf{x}^0, t, \mathbf{x}) = \pi_\epsilon(\mathbf{x}) + e^{-\frac{2F(\mathbf{x}^0)}{\epsilon^2}} \sum_{n=1}^{\infty} \pi_\epsilon^n(\mathbf{x}) \pi_\epsilon^n(\mathbf{x}^0) e^{\lambda_\epsilon^n t}, \quad (25)$$

where  $\pi_\epsilon^n$  is the eigenfunction of  $L_{\epsilon, -\nabla F}$  corresponding to the eigenvalue  $\lambda_\epsilon^n, n = 1, 2, \dots$ , and  $0 = \lambda_\epsilon^0 > \lambda_\epsilon^1 > \dots$ . One notes that the eigenfunctions  $\pi_\epsilon^n, n = 1, 2, \dots$ , are appropriately normalized and  $\pi_\epsilon$  is the eigenfunction of  $L_{\epsilon, -\nabla F}$  corresponding to the eigenvalue  $\lambda_\epsilon^0 = 0$ . Consider  $N = 1$ , the function  $F$  smooth and with three extrema in  $x^-, x^0, x^+ \in \mathbf{R}$  such that  $x^- < x^0 < x^+$ . Moreover,  $F$  increases in  $(x^-, x^0)$  and in  $(x^+, +\infty)$  and decreases in  $(-\infty, x^-)$  and in  $(x^0, x^+)$ . Let:

$$\begin{cases} c^- = \frac{d^2 F}{dx^2}(x^-), \\ c^0 = \frac{d^2 F}{dx^2}(x^0), \\ c^+ = \frac{d^2 F}{dx^2}(x^+). \end{cases} \quad (26)$$

One assumes  $c^\pm, c^0$  to be nonzero. In [1] it is shown that when  $F(x^-) < F(x^+)$ , one has  $\pi_\epsilon(x) \rightarrow \delta(x - x^-)$  as  $\epsilon \rightarrow 0$  while when  $F(x^-) = F(x^+)$  one has  $\pi_\epsilon(x) \rightarrow \gamma \delta(x - x^-) + (1 - \gamma) \delta(x - x^+)$ , where  $\gamma = [1 + \sqrt{\frac{c^-}{c^+}}]^{-1}$  as  $\epsilon \rightarrow 0$ , and the limits are taken in distribution sense. That is in [1] it is shown that the steady-state distribution density tends to Dirac deltas concentrated on the global minimizers of  $F$  when  $\epsilon \rightarrow 0$ .

In [12] it is shown that:

$$\lambda_\epsilon^1 \approx -\frac{\sqrt{c^+ c^0}}{2\pi} e^{-\frac{2}{\epsilon^2} \delta F} \quad \text{as } \epsilon \rightarrow 0, \quad (27)$$

where  $\delta F = \max\{F(x^0) - F(x^-), F(x^0) - F(x^+)\}$ . Formula (25) shows that  $p$  converges to  $\pi_\epsilon$  when  $t \rightarrow +\infty$ , but the rate of convergence becomes slow when  $\epsilon$  is small. Replacing  $\epsilon$  with  $\sigma(t)$  a slowly decreasing function such that  $\sigma(t) \rightarrow 0$  when  $t \rightarrow +\infty$ , using elementary adiabatic perturbation theory one can expect that

the condition:

$$\int_0^{+\infty} e^{-\frac{2}{\sigma^2(t)}\delta F} dt = +\infty \tag{28}$$

guarantees that  $\{Z(t) : t > 0\}$  is a solution of (20), (21) when  $t \rightarrow +\infty$  converges to a random variable concentrated on the global minimizers of  $F$ .

In [6] the following result is proved:

**Theorem 1 (convergence theorem)** *Let  $F : \mathbf{R}^N \rightarrow \mathbf{R}$  be a twice continuously differentiable function satisfying the following properties:*

$$\min_{\mathbf{x} \in \mathbf{R}^N} F(\mathbf{x}) = 0, \tag{29}$$

$$\lim_{\|\mathbf{x}\| \rightarrow +\infty} F(\mathbf{x}) = \lim_{\|\mathbf{x}\| \rightarrow +\infty} \|(\nabla F)(\mathbf{x})\| = +\infty, \tag{30}$$

$$\lim_{\|\mathbf{x}\| \rightarrow +\infty} \|(\nabla F)(\mathbf{x})\|^2 - (\Delta F)(\mathbf{x}) > -\infty, \tag{31}$$

let  $\sigma(t) = \sqrt{(c)/(\log t)}$  for  $t \rightarrow +\infty$ , where  $c > c_F > 0$  and  $c_F$  is a constant depending on the function  $F$ . Then the transition probability density  $p$  of the process  $\{Z(t) : t \geq 0\}$ , solution of (20), (21), converges weakly to a stationary distribution  $\pi$ , that is:

$$p(0, \mathbf{x}, t, \cdot) \rightarrow \pi \text{ when } t \rightarrow +\infty. \tag{32}$$

Moreover the distribution  $\pi$  is the weak limit of  $\pi_\epsilon$ , given by (23), as  $\epsilon \rightarrow 0$ .

One notes that (20), (21) is obtained perturbing the trajectories given by the steepest descent equation for  $F$  with the Brownian motion and  $\sigma$  is a factor that controls the amplitude of this perturbation. The fact that  $\sigma(t) \rightarrow 0$  when  $t \rightarrow +\infty$  makes possible the stabilization of the perturbed trajectories at the minimizers of  $F$ . With the assumptions of the convergence theorem it is possible to conclude that  $\pi$  is concentrated on the global minimizers of  $F$ , so that the random variable  $Z(t) = (Z_1(t), \dots, Z_N(t))$  ‘converges’ to  $\mathbf{x}^*$ , solution of problem (1), as  $t \rightarrow +\infty$ . That is, when  $\mathbf{x}^*$  is the unique global minimizer of  $F$ , then  $P\{Z_i(t) = x_i^*\} \rightarrow 1$  when  $t \rightarrow +\infty$  for  $i = 1, \dots, N$ .

The stochastic differential equation (20) can be integrated numerically to obtain an algorithm for the solution of problem (1). Let  $t_0 = 0, t_k = \sum_{l=0}^{k-1} h_l$ , where  $h_l > 0, l = 0, 1, \dots$ , are such that  $t_k \rightarrow +\infty$  when  $k \rightarrow \infty$  then using the Euler method one has:

$$\zeta^0 = \mathbf{x}^0, \tag{33}$$

$$\begin{aligned} \zeta^{k+1} = \zeta^k &- h_k(\nabla F)(\zeta^k) \\ &+ \sigma(t_k)(\mathbf{w}(t_k + h_k) - \mathbf{w}(t_k)), \end{aligned} \tag{34}$$

where  $k = 0, 1, \dots$  and  $\zeta^k \in \mathbf{R}^N$  is the approximation of  $Z(t_k), k = 1, 2, \dots$ , see [2,3].

In (34) due to the presence of the stochastic term, one can substitute the gradient of  $F$  with a kind of ‘stochastic gradient’ of  $F$  in order to save computational work, see [2,3] for details.

One notes that the sequence  $\{\zeta^k : k \in \mathbf{N}\}$  depends on the particular realization of the Brownian motion  $\{\mathbf{w}(t_k) : k = 0, 1, \dots\}$ . That is, solving several times problem (20), (21), by means of (33), (34), the solutions obtained are not necessarily the same. However, the convergence theorem states that ‘all’ the solutions  $\{\zeta^k : k \in \mathbf{N}\}$  obtained by (33), (34) tend to  $\mathbf{x}^*$  as  $k \rightarrow +\infty$ .

So that in the numerical algorithm derived from (20), (21) using (33), (34) one can approximate by means of  $n_T$  independent realizations (i. e., trajectories) of the stochastic process  $\{Z(t) : t \geq 0\}$ , solution of (20), (21). A possible strategy for a numerical algorithm is the following: after an ‘observation period’ the various trajectories are compared, one of them is discarded and is not considered any more, another one is branched. The new set of trajectories are computed throughout the next observation period. The following stopping conditions are used:

- uniform stop: the final values of the function  $F$  at the end of the various trajectories are numerically equal;
- maximum trial duration: a maximum number of observation periods has been reached.

One notes that the algorithms based on the discretization of the stochastic differential equations have sound mathematical basis, that is for a wide class of functions  $F$  some convergence results such as the convergence theorem given above are available. These algorithms usually have a slow convergence rate, this can be seen from the kind of function  $\sigma$  which is required in the convergence theorem. This implies that the algorithms based on stochastic differential equations have an high computational cost, so that their use is usually restricted to low-dimensional problems. However these algorithms can be parallelized with a significant computational advantage, for example in the algorithm described above each trajectory can be computed independently from the others until the end of an observation period. One notes that the algorithms derived

from (20), (21) are in some sense similar to the simulated annealing algorithm (cf. also ► **Simulated annealing methods in protein folding**) introduced in combinatorial optimization in [11].

### Global Constrained Optimization

Given problem (1) with  $D \subset \mathbf{R}^N$  the following stochastic differential equation with reflection term is considered:

$$\begin{aligned} d\mathbf{Z}(t) &= -(\nabla F)(\mathbf{Z}(t)) dt \\ &+ \sigma(t) d\mathbf{w}(t) + d\eta(t), \\ t &> 0, \end{aligned} \quad (35)$$

$$\mathbf{Z}(0) = \mathbf{x}^0, \quad (36)$$

where  $\mathbf{x}^0 \in D$ ,  $\{\mathbf{w}(t) : t \geq 0\}$  is the  $N$ -dimensional Brownian motion,  $\sigma(t)$  is a suitable decreasing function that guarantees the convergence of the stochastic process  $\{\mathbf{Z}(t) : t > 0\}$  to a random variable with density concentrated on the global minimizers of  $F$  on  $D$  when  $t \rightarrow +\infty$  and  $\eta(t)$  is a suitable function to assure  $\mathbf{Z}(t) \in D$ ,  $t > 0$ , that is,  $(\mathbf{Z}, \mathbf{Z} - \eta, \eta)$  is the solution of the Skorokhod problem in  $\mathbf{R}^+$  respect to  $D$ .

Let  $\text{int}(D)$  be the set of the interior points of  $D$ . One assumes that  $D$  is the closure of  $\text{int}(D)$ . Let  $p(0, \mathbf{x}^0, t, \mathbf{x})$ ,  $\mathbf{x}^0, \mathbf{x} \in \text{int}(D)$ ,  $t > 0$ , be the transition probability density of the process  $\{\mathbf{Z}(t) : t > 0\}$ , solution of (35), (36), when  $\sigma \equiv \epsilon$ ,  $\epsilon > 0$ . Then  $p$  satisfies the Fokker–Planck equation:

$$\frac{\partial p}{\partial t} + L_{\epsilon, -\nabla F}(p) = 0, \quad \mathbf{x} \in \text{int}(D), \quad (37)$$

$$\lim_{t \rightarrow 0^+} p(0, \mathbf{x}^0, t, \mathbf{x}) = \delta(\mathbf{x} - \mathbf{x}^0), \quad \mathbf{x} \in \text{int}(D), \quad (38)$$

$$\begin{aligned} \left( \frac{\epsilon^2}{2} \nabla_{\mathbf{x}} p + p \nabla F, \mathbf{n}(\mathbf{x}) \right) &= 0, \\ \mathbf{x} \in \partial D, \quad t > 0, \end{aligned} \quad (39)$$

where  $L_{\epsilon, -\nabla F}$  is defined in (11) (12) and  $\mathbf{n}(\mathbf{x}) \in \nu(\mathbf{x})$  is the outward unit normal to  $\partial D$  in  $\mathbf{x} \in \partial D$ . One notes that boundary condition (39) assures that  $P\{\mathbf{Z}(t) \in D\} = 1$  for every  $t > 0$ . This boundary condition follows from the requirement that  $(\mathbf{Z}, \mathbf{Z} - \eta, \eta)$  is the solution of the Skorokhod problem.

One assumes the following properties of  $F$  and  $D$ :

- $F : D \rightarrow \mathbf{R}$  is twice continuously differentiable;

- $D \subset \mathbf{R}^N$  is a bounded convex domain such that exists  $p$  satisfying (37), (38), (39) and exists the steady-state distribution density  $\pi$  of the process solution of (35), (36);
- let  $\pi_\epsilon$  be the steady-state distribution density of the process solution of (35), (36) when  $\sigma \equiv \epsilon$ ,  $\epsilon > 0$ , that is:

$$\pi_\epsilon(\mathbf{x}) = C_\epsilon e^{-\frac{2F(\mathbf{x})}{\epsilon^2}}, \quad \mathbf{x} \in D, \quad (40)$$

$$C_\epsilon = \left( \int_D e^{-\frac{2F(\mathbf{y})}{\epsilon^2}} d\mathbf{y} \right)^{-1} \quad (41)$$

and  $\pi$  is the weak limit of  $\pi_\epsilon$  as  $\epsilon \rightarrow 0$ .

In analogy with the unconstrained case one can conjecture that when  $D \subset \mathbf{R}^N$  and  $F : D \rightarrow \mathbf{R}$  satisfy the properties listed above and when  $\sigma(t) = \sqrt{(c)/(\log t)}$  for  $t \rightarrow +\infty$ , where  $c > c_F > 0$  and  $c_F$  is a constant depending on  $F$ , then the transition probability density  $p(0, \mathbf{x}^0, t, \mathbf{y})$ ,  $\mathbf{x}^0, \mathbf{x} \in D$ ,  $t > 0$  of the process  $\{\mathbf{Z}(t) : t \geq 0\}$ , solution of (35), (36) converges to a steady-state distribution density  $\pi$  when  $t \rightarrow +\infty$  and  $\pi$  is the distribution density obtained as weak limit of  $\pi_\epsilon$  when  $\epsilon \rightarrow 0$ . That is, the process  $\{\mathbf{Z}(t) : t \geq 0\}$  converges in law to a random variable concentrated at the points  $\mathbf{x}^* \in D$  that solve problem (1).

A numerical algorithm to solve problem (1), with  $D \subset \mathbf{R}^N$ , can be obtained using a numerical method to integrate problem (35), (36). This is done integrating numerically problem (20), (21) and ‘adding’ the constraints given by  $D$ . In the numerical algorithm the trajectories can be computed using formulas (33), (34) when the trajectories are in  $D$ , when a trajectory violates the constraints, it is brought back on  $\partial D$  putting to zero its normal component with respect to the violated constraints. Finally the stopping conditions are the same ones considered in the previous section.

Analogously to the unconstrained problem, the algorithms based on the stochastic differential equations for the constrained case have slow convergence rate. However these algorithms have a high rate of parallelism.

### Miscellaneous Results

In this section are shown two mathematical problems that are somewhat unusual as optimization problems.

**Clique Problem**

Let  $I = \{1, \dots, N\} \subset \mathbb{N}$  be a finite set, let  $I * I$  be the set of unordered pairs of elements of  $I$ . Let  $E \subseteq I * I$ . Then a graph  $G$  is a pair  $G = (I, E)$ , where  $I$  is the set of the nodes of  $G$  and  $E$  is the set of the edges of  $G$ , i. e.  $\{i, j\} \in E$  implies that  $G$  has an edge joining nodes  $i, j \in I$ . A graph  $G = (I, E)$  is said to be *complete* or to be a *clique* when  $E = I * I$ . A graph  $G' = (I', E')$  is a subgraph of  $G = (I, E)$  when  $I' \subseteq I$  and  $E' \subseteq E \cap (I' * I')$ .

The *maximum clique problem* can be defined as follows: Given  $G = (I, E)$ , find the largest subgraph  $G'$  of  $G$  which is complete. Let  $k(G)$  be the number of nodes of the graph  $G'$ .

Several algorithms exist to obtain a numerical solution of the maximum clique problem see, for example, [14] where the branch and bound algorithm is described.

One considers here the maximum clique problem as a continuous optimization problem. The adjacency matrix  $A$  of the graph  $G = (I, E)$  is a square matrix of order equal to the number of nodes of  $G$  and its generic entry  $A_{i,j}$ , at row  $i$  and at column  $j$ , is defined equal to 1 if  $\{i, j\} \in E$  and is equal to 0 otherwise. Then in [13] it is shown that:

$$1 - \frac{1}{k(G)} = \max_{\mathbf{x} \in S} \mathbf{x}^t \mathbf{A} \mathbf{x}, \tag{42}$$

where

$$S = \left\{ \mathbf{x} = (x_1, \dots, x_N)^t \in \mathbb{R}^N : \sum_{i=1}^N x_i = 1, x_i \geq 0, i = 1, \dots, N \right\}.$$

One notes that many maximizers of (42) can exist, however there exists always a maximizer  $\mathbf{x}^* = (x_1^*, \dots, x_N^*)^t$  of problem (42) such that for  $i = 1, \dots, N$  one has  $x_i^* = 1/k(G)$  if  $i \in G'$  and  $x_i^* = 0$  if  $i \notin G'$ . That is the maximum clique problem is reduced to a continuous global optimization problem that can be treated with the algorithms described above. Several other problems in graph theory can be reformulated as continuous optimization problems.

**Quasivariational Inequalities**

Let  $X \subset \mathbb{R}^N$  be a nonempty set, let  $\Omega(\mathbf{x}) \subset X$ ,  $\mathbf{x} \in X$ , be a set-valued function and let  $\mathbf{F} : \mathbb{R}^N \rightarrow \mathbb{R}^N$ . The *quasivariational inequality* problem, is defined as follows:

Find a vector  $\mathbf{x}^* \in \Omega(\mathbf{x}^*)$  such that:

$$(\mathbf{F}(\mathbf{x}^*), \mathbf{y} - \mathbf{x}^*) \geq 0, \quad \forall \mathbf{y} \in \Omega(\mathbf{x}^*), \tag{43}$$

see [4] for a detailed introduction to quasivariational inequalities. This problem can be reduced to the search of a fixed-point of a function defined implicitly by a variational inequality.

The quasivariational inequalities have many applications such as for example the study of the generalized Nash equilibrium points of an  $N$ -player noncooperative game. See [10] for a detailed discussion on  $N$ -player noncooperative games.

### Directional Derivatives

Let  $f$  be a function defined on some open set  $X \subset \mathbb{R}^n$  and taking its values in  $\overline{\mathbb{R}} = \mathbb{R} \cup \{-\infty, +\infty\}$ . The set  $\text{dom } f = \{x \in X : |f(x)| < +\infty\}$  is called the *effective set* (or *domain*) of the function  $f$ . Take  $x \in \text{dom } f$ ,  $g \in \mathbb{R}^n$ . Put

$$f_D^\uparrow(x, g) := \limsup_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha g) - f(x)], \quad (1)$$

$$f_D^\downarrow(x, g) := \liminf_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha g) - f(x)]. \quad (2)$$

Here  $\alpha \downarrow 0$  means that  $\alpha \rightarrow +0$ .

The quantity  $f_D^\uparrow(x, g)$  (respectively,  $f_D^\downarrow(x, g)$ ) is called the *Dini upper* (respectively, *lower*) derivative of the function  $f$  at the point  $x$  in the direction  $g$ .

The limit

$$f'(x, g) = f_D'(x, g) := \lim_{\alpha \downarrow 0} \frac{1}{\alpha} [f(x + \alpha g) - f(x)], \quad (3)$$

is called the *Dini derivative* of  $f$  at the point  $x$  in the direction  $g$ . If the limit in (3) exists, then  $f_D^\uparrow(x, g) = f_D^\downarrow(x, g) = f'(x, g)$ .

The quantity

$$f_H^\uparrow(x, g) := \limsup_{[\alpha, g'] \rightarrow [+0, g]} \frac{1}{\alpha} [f(x + \alpha g') - f(x)] \quad (4)$$

(respectively,

$$f_H^\downarrow(x, g) := \liminf_{[\alpha, g'] \rightarrow [+0, g]} \frac{1}{\alpha} [f(x + \alpha g') - f(x)], \quad (5)$$

is called the *Hadamard upper* (respectively, *lower*) derivative of the function  $f$  at the point  $x$  in the direction  $g$ .

The limit

$$f_H'(x, g) := \lim_{[\alpha, g'] \rightarrow [+0, g]} \frac{1}{\alpha} [f(x + \alpha g') - f(x)] \quad (6)$$

is called the *Hadamard derivative* of  $f$  at  $x$  in the direction  $g$ .

If the limit in (6) exists, then  $f_H^\uparrow(x, g) = f_H^\downarrow(x, g)$ .

Note that the limits in (1), (2), (4) and (5) always exist but are not necessarily finite.

*Remark 1* In the one-dimensional case ( $\mathbf{R}^n = \mathbf{R}$ ) the Hadamard directional derivatives coincide with the corresponding Dini directional derivatives:

$$\begin{aligned} f_H^\uparrow(x, g) &= f_D^\uparrow(x, g), \\ f_H^\downarrow(x, g) &= f_D^\downarrow(x, g), \\ f_H'(x, g) &= f_D'(x, g). \end{aligned}$$

If the limit in (3) exists and is finite, then the function  $f$  is called *differentiable* (or *Dini differentiable*) at  $x$  in the direction  $g$ . The function  $f$  is called *Dini directionally differentiable* (Dini d.d.) at the point  $x$  if it is Dini differentiable at  $x$  for every  $g \in \mathbf{R}^n$ . Analogously, if the limit in (6) exists and is finite, the function  $f$  is called *Hadamard differentiable* at  $x$  in the direction  $g$ . The function  $f$  is called *Hadamard directionally differentiable* (Hadamard d.d.) at the point  $x$  if it is Hadamard differentiable at  $x$  for every  $g \in \mathbf{R}^n$ .

If the limit in (6) exists and is finite, then the limit in (3) also exists and  $f_H'(x, g) = f'(x, g)$ . The converse is not necessarily true.

All these derivatives are *positively homogeneous* (of degree one) functions of direction:

$$f_Q^*(x, \lambda g) = \lambda f_Q^*(x, g), \quad \forall \lambda \geq 0. \tag{7}$$

(Here  $*$  is either  $\uparrow$ , or  $\downarrow$ , and  $Q$  is either  $D$ , or  $H$ .)

A function  $f$  defined on an open set  $X$  is called *Dini uniformly directionally differentiable* at a point  $x \in X$  if it is directionally differentiable at  $x$  and for every  $\varepsilon > 0$  there exists a real number  $\alpha_0 > 0$  such that

$$\begin{aligned} \frac{1}{\alpha} [f(x + \alpha g) - f(x) - \alpha f'(x, g)] &< \varepsilon, \\ \forall \alpha \in (0, \alpha_0), \quad \forall g \in S, \end{aligned}$$

where  $S = \{g \in \mathbf{R}^n : \|g\| = 1\}$  is the unit sphere.

**Proposition 2** (see [2, Thm. I.3.2]) *A function  $f$  is Hadamard d.d. at a point  $x \in X$  if and only if it is Dini uniformly differentiable at  $x$  and its directional derivative  $f'(x, g)$  is continuous as a function of direction.*

*Remark 3* If  $f$  is locally Lipschitz and Dini directionally differentiable at  $x \in X$ , then it is Hadamard d.d. at  $x$ , too.

For Dini and Hadamard derivatives (see (3) and (6)) there exists a calculus:

**Proposition 4** *Let functions  $f_1$  and  $f_2$  be Dini (Hadamard) directionally differentiable at a point  $x \in X$ . Then their sum, difference, product and quotient (if  $f_2(x) \neq 0$ ) are also Dini (Hadamard) d.d. at this point and the following formulas hold:*

$$(f_1 \pm f_2)'_Q(x, g) = f'_{1Q}(x, g) \pm f'_{2Q}(x, g), \tag{8}$$

$$(f_1 f_2)'_Q(x, g) = f_1(x)f'_{2Q}(x, g) + f_2(x)f'_{1Q}(x, g), \tag{9}$$

$$\left(\frac{f_1}{f_2}\right)'_Q(x, g) = -\frac{1}{(f_2(x))^2} (f_1(x)f'_{2Q}(x, g) - f_2(x)f'_{1Q}(x, g)). \tag{10}$$

Here  $Q$  is either  $D$ , or  $H$ .

These formulas follow from the classical theorems of differential calculus.

**Proposition 5** *Let*

$$\varphi(x) = \max_{i \in 1:N} f_i(x), \tag{11}$$

where the functions  $f_i$  are defined and continuous on an open set  $X \subset \mathbf{R}^n$  and Dini (Hadamard) d.d. at a point  $x \in X$  in a direction  $g$ . Then the function  $\varphi$  is also Dini (Hadamard) d.d. at  $x$  and

$$\varphi'_Q(x, g) = \max_{i \in R(x)} f'_i(x, g), \tag{12}$$

where  $R(x) = \{i \in 1 : N : f_i(x) = \varphi(x)\}$  (see [2, Cor. I.3.2]).

If  $\varphi$  is defined by

$$\varphi(x) = \max_{y \in Y} f_i(x, y),$$

where  $Y$  is some set, then under some additional conditions a formula, analogous to (12), also holds (see [2, Chap. I, Sec. 3]).

A theorem on the differentiability of a composition can also be stated.

Unfortunately, formulas similar to (8)–(10) and (12) are not valid for Dini (Hadamard) upper and lower derivatives.

The Dini and Hadamard upper and lower directional derivatives are widely used in nonsmooth analysis and nondifferentiable optimization. For example, the following *mean value theorem* holds.

**Proposition 6** (see [2, Thm. I.3.1]) *Let  $f$  be defined and continuous on the interval  $\{y: y = x + \alpha g, \alpha \in [0, \alpha_0], \alpha_0 > 0\}$ . Put*

$$m = \inf_{\alpha \in [0, \alpha_0]} f_D^\downarrow(x + \alpha g, g),$$

$$M = \sup_{\alpha \in [0, \alpha_0]} f_D^\uparrow(x + \alpha g, g).$$

Then [1]

$$m\alpha_0 \leq f(x + \alpha_0 g) - f(x) \leq M\alpha_0.$$

The following first order approximations may be constructed via the Dini and Hadamard derivatives.

**Proposition 7** *Let  $f$  be defined on an open set  $X \subset \mathbf{R}^n$ , and Dini d.d. at a point  $x \in X$ . Then*

$$f(x + \Delta) = f(x) + f'_D(x, \Delta) + o_D(x, \Delta). \quad (13)$$

If  $f$  is Hadamard d.d. at  $x$ , then

$$f(x + \Delta) = f(x) + f'_H(x, \Delta) + o_H(x, \Delta). \quad (14)$$

Let  $f$  be defined on an open set  $X \subset \mathbf{R}^n$  and finite at  $x \in X$ . Then

$$f(x + \Delta) = f(x) + f_D^\uparrow(x, \Delta) + \bar{o}_D(x, \Delta), \quad (15)$$

$$f(x + \Delta) = f(x) + f_D^\downarrow(x, \Delta) + \underline{o}_D(x, \Delta), \quad (16)$$

$$f(x + \Delta) = f(x) + f_H^\uparrow(x, \Delta) + \bar{o}_H(x, \Delta), \quad (17)$$

$$f(x + \Delta) = f(x) + f_H^\downarrow(x, \Delta) + \underline{o}_H(x, \Delta), \quad (18)$$

where

$$\frac{o_D(x, \alpha\Delta)}{\alpha} \xrightarrow{\alpha \downarrow 0} 0, \quad \forall \Delta \in \mathbf{R}^n, \quad (19)$$

$$\frac{o_H(x, \alpha\Delta)}{\|\Delta\|} \xrightarrow{\|\Delta\| \rightarrow 0} 0, \quad (20)$$

$$\limsup_{\alpha \downarrow 0} \frac{\bar{o}_D(x, \alpha\Delta)}{\alpha} = 0, \quad \forall \Delta \in \mathbf{R}^n, \quad (21)$$

$$\liminf_{\alpha \downarrow 0} \frac{\underline{o}_D(x, \alpha\Delta)}{\alpha} = 0, \quad \forall \Delta \in \mathbf{R}^n, \quad (22)$$

$$\limsup_{[\alpha, \Delta'] \rightarrow [+0, \Delta]} \frac{\bar{o}_H(x, \alpha\Delta')}{\alpha} \geq 0, \quad \forall \Delta \in \mathbf{R}^n, \quad (23)$$

$$\liminf_{[\alpha, \Delta'] \rightarrow [+0, \Delta]} \frac{\underline{o}_H(x, \alpha\Delta')}{\alpha} \leq 0, \quad \forall \Delta \in \mathbf{R}^n. \quad (24)$$

## First Order Necessary and Sufficient Conditions for an Unconstrained Optimum

Let a function  $f$  be defined on an open set  $X \subset \mathbf{R}^n$ ,  $\Omega$  be a subset of  $X$ . A point  $x^* \in \Omega$  is called a *local minimum point* (*local minimizer*) of the function  $f$  on the set  $\Omega$  if there exists  $\delta > 0$  such that

$$f(x) \geq f(x^*), \quad \forall x \in \Omega \cap B_\delta(x^*),$$

where  $B_\delta(x^*) = \{x \in \mathbf{R}^n: \|x - x^*\| \leq \delta\}$ . If  $\delta = +\infty$ , then the point  $x^*$  is called a *global minimum point* (*global minimizer*) of  $f$  on  $\Omega$ . A point  $x^* \in \Omega$  is called a *strict local minimum point* (*strict local minimizer*) of  $f$  on  $\Omega$  if there exists  $\delta > 0$  such that

$$f(x) > f(x^*), \quad \forall x \in \Omega \cap B_\delta(x^*), \quad x \neq x^*.$$

Analogously one can define local, global and strict *local maximum points* (*maximizers*) of  $f$  on  $\Omega$ .

It may happen that the set of local (global, strict local) minimizers (maximizers) is empty.

If  $\Omega = X$  then the problem of finding a minimum or a maximum of  $f$  on  $X$  is called an *unconstrained optimization problem*.

**Proposition 8** *Let a function  $f$  be Dini (Hadamard) directionally differentiable on  $X$ . For a point  $x^* \in \text{dom } f$  to be a local or global minimizer of  $f$  on  $X$  it is necessary that*

$$f'_D(x^*, g) \geq 0, \quad \forall g \in \mathbf{R}^n, \quad (25)$$

$$(f'_H(x^*, g) \geq 0 \quad \forall g \in \mathbf{R}^n). \quad (26)$$

If  $f$  is Hadamard d.d. at  $x^*$  and

$$f'_H(x^*, g) > 0, \quad \forall g \in \mathbf{R}^n, \quad g \neq 0_n, \quad (27)$$

then  $x^*$  is a *strict local minimizer* of  $f$ .

Here  $0_n = (0, \dots, 0)$  is the zero element of  $\mathbf{R}^n$ .

**Proposition 9** *Let  $f$  be Dini (Hadamard) d.d. on  $X$ . For a point  $x^{**} \in \text{dom } f$  to be a local or global maximizer of  $f$  on  $X$  it is necessary that*

$$f'_D(x^{**}, g) \leq 0, \quad \forall g \in \mathbf{R}^n, \quad (28)$$

$$(f'_H(x^{**}, g) \leq 0, \quad \forall g \in \mathbf{R}^n). \quad (29)$$

If  $f$  is Hadamard d.d. at  $x^{**}$  and

$$f_H'(x^{**}, g) < 0, \quad \forall g \in \mathbb{R}^n, \quad g \neq 0_n, \quad (30)$$

then  $x^{**}$  is a strict local maximizer of  $f$ .

Note that (26) implies (25), and (29) implies (28). In the smooth case  $f_H'(x, g) = (f'(x), g)$  ( $f'(x)$  being the gradient of  $f$  at  $x$ ) and the conditions (27) and (30) are impossible. It means that the sufficient conditions (27) and (30) are essentially nonsmooth.

**Proposition 10** Let  $f$  be defined on an open set on  $X \subset \mathbb{R}^n$ . For a point  $x^* \in \text{dom } f$  (i. e.,  $|f(x)| < +\infty$ ) to be a local or global minimizer of  $f$  on  $X$  it is necessary that

$$f_D^\downarrow(x^*, g) \geq 0, \quad \forall g \in \mathbb{R}^n, \quad (31)$$

$$f_H^\downarrow(x^*, g) \geq 0, \quad \forall g \in \mathbb{R}^n. \quad (32)$$

If

$$f_H^\downarrow(x^*, g) > 0, \quad \forall g \in \mathbb{R}^n, \quad g \neq 0_n, \quad (33)$$

then  $x^*$  is a strict local minimizer of  $f$ .

Note that (32) implies (31) but (31) does not necessarily imply (32).

**Proposition** Let  $f$  be defined on an open set on  $X \subset \mathbb{R}^n$ . For a point  $x^{**} \in \text{dom } f$  to be a local or global maximizer of  $f$  on  $X$  it is necessary that

$$f_D^\uparrow(x^{**}, g) \leq 0, \quad \forall g \in \mathbb{R}^n \quad (34)$$

and

$$f_H^\uparrow(x^{**}, g) \leq 0, \quad \forall g \in \mathbb{R}^n. \quad (35)$$

If

$$f_H^\uparrow(x^{**}, g) < 0, \quad \forall g \in \mathbb{R}^n, \quad g \neq 0_n, \quad (36)$$

then  $x^{**}$  is a strict local maximizer of  $f$ .

The condition (35) implies (34) but (34) does not necessarily imply (35).

**Remark 12** Observe that the conditions for a minimum are different from the conditions for a maximum.

A point  $x^*$  satisfying the conditions (25) or (31) is called a *Dini inf-stationary point* of  $f$ , while a point  $x^*$  satisfying (26) or (32) is called an *Hadamard inf-stationary*

*point*. A point  $x^{**}$  satisfying the conditions (28) or (34) is called a *Dini sup-stationary point* of  $f$ , while a point  $x^{**}$  satisfying (28) or (35) is called an *Hadamard sup-stationary point*.

**Remark 13** Note that the function  $f$  is not assumed to be continuous or even finite-valued.

Let  $x_0 \in \text{dom } f$  and assume that the condition (31) does not hold, i. e.  $x_0$  is not a Dini inf-stationary point. If  $g_0 \in \mathbb{R}^n$ ,  $\|g_0\| = 1$ ,

$$f_D^\downarrow(x_0, g_0) = \inf_{\|g\|=1} f_D^\downarrow(x_0, g),$$

then  $g_0$  is called a *Dini steepest descent direction* of  $f$  at  $x_0$  ( $\|g\|$  is the Euclidean norm).

If (32) does not hold and if  $g_0 \in \mathbb{R}^n$ ,  $\|g_0\| = 1$ ,

$$f_H^\downarrow(x_0, g_0) = \inf_{\|g\|=1} f_H^\downarrow(x_0, g),$$

then  $g_0$  is called an *Hadamard steepest descent direction* of  $f$  at  $x_0$ .

Analogously if  $x_0$  is not a Dini sup-stationary point and if  $g^0 \in \mathbb{R}^n$ ,  $\|g^0\| = 1$ ,

$$f_D^\uparrow(x_0, g^0) = \sup_{\|g\|=1} f_D^\uparrow(x_0, g),$$

then  $g^0$  is called a *Dini steepest ascent direction* of  $f$  at  $x_0$ .

If  $x_0$  is not an Hadamard sup-stationary point of  $f$  (i. e. (35) does not hold) and if  $g^0 \in \mathbb{R}^n$ ,  $\|g^0\| = 1$ ,

$$f_H^\uparrow(x_0, g^0) = \sup_{\|g\|=1} f_H^\uparrow(x_0, g),$$

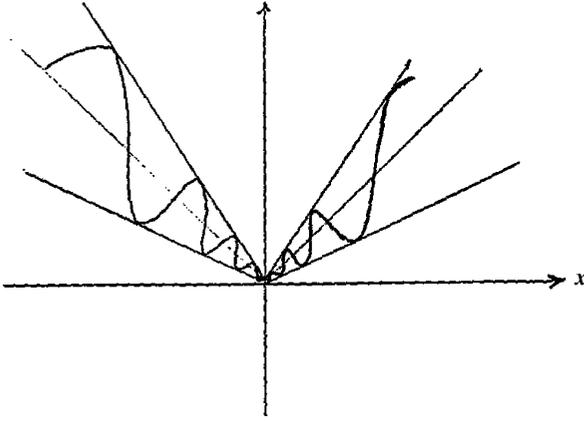

then  $g^0$  is called an *Hadamard steepest ascent direction* of  $f$  at  $x_0$ .

Of course it is possible that there exist many steepest descent or/and steepest ascent directions of  $f$  at  $x_0$ .

It may also happen that some direction is a direction of steepest ascent and, at the same time, a direction of steepest ascent as well (which is impossible in the smooth case).

**Example 14** Let  $X = \mathbb{R}$ ,

$$f(x) = \begin{cases} |x| + \frac{1}{2}x \sin \frac{1}{x}, & x \neq 0, \\ 0, & x = 0. \end{cases}$$

Dini and Hadamard Derivatives in Optimization, Figure 1

Take  $x_0 = 0$ . It is clear that (see Fig. 1):

$$f_D^\uparrow(x_0, g) = |g| + \frac{1}{2} |g| = \frac{3}{2} |g|,$$

$$f_D^\downarrow(x_0, g) = |g| - \frac{1}{2} |g| = \frac{1}{2} |g|.$$

As  $X = \mathbf{R}$ , the Hadamard derivatives coincide with the Dini ones (see Remark 1).

$$f_D^\downarrow(x_0, g) > 0, \quad \forall g \neq 0,$$

we may conclude (see (32)) that  $x_0$  is a strict local minimizer (in fact it is a global minimizer but our theory does not allow us to claim this).

Note that  $f_D^\uparrow$  and  $f_D^\downarrow$  are positively homogeneous (see (7)), therefore it is sufficient to consider (in  $\mathbf{R}$ ) only two directions:  $g_1 = 1$  and  $g_2 = -1$ .

*Example 15* Let  $X = \mathbf{R}$ ,  $x_0 = 0$ ,

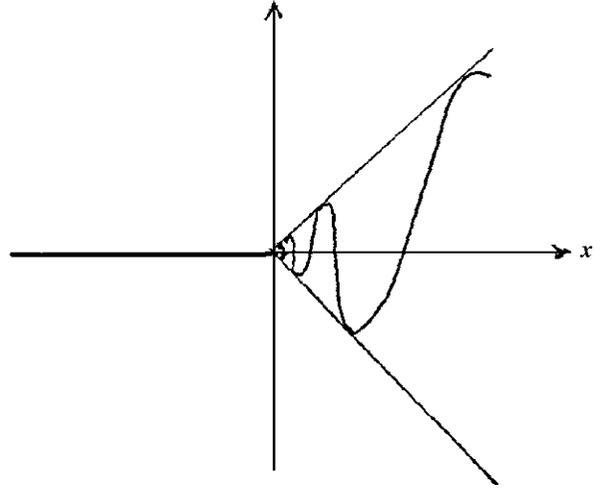

$$f(x) = \begin{cases} x \sin \frac{1}{x}, & x > 0, \\ 0, & x \leq 0. \end{cases}$$

It is clear that (see Fig. 2) that

$$f_D^\uparrow(x_0, g) = \begin{cases} |g|, & g > 0, \\ 0, & g \leq 0, \end{cases}$$

$$f_D^\downarrow(x_0, g) = \begin{cases} -|g|, & g > 0, \\ 0, & g \leq 0. \end{cases}$$

Neither the condition (25) nor the condition (31) holds, therefore we conclude that  $x_0$  is neither a local

Dini and Hadamard Derivatives in Optimization, Figure 2

minimizer nor a local maximizer. Since

$$\begin{aligned} & \max_{\|g\|=1} f_D^\uparrow(x_0, g) \\ &= \max\{f_D^\uparrow(x_0, +1), f_D^\uparrow(x_0, -1)\} \\ &= \max\{1, 0\} = f_D^\uparrow(x_0, +1) = +1, \end{aligned}$$

then  $g_1 = +1$  is a steepest ascent direction.

Since

$$\begin{aligned} & \min_{\|g\|=1} f_D^\downarrow(x_0, g) \\ &= \min\{f_D^\downarrow(x_0, +1), f_D^\downarrow(x_0, -1)\} \\ &= \min\{-1, 0\} = f_D^\downarrow(x_0, +1) = -1, \end{aligned}$$

then  $g_1 = +1$  is a steepest descent direction as well.

### Conditions for a Constrained Optimum

Let a function  $f$  be defined on an open set  $X \subset \mathbf{R}^n$ ,  $\Omega$  be a subset of  $X$ . Let  $x \in \Omega$ ,  $|f(x)| < +\infty$ ,  $g \in \mathbf{R}^n$ . The limit

$$f_D^\uparrow(x, g; \Omega) = \limsup_{\substack{\alpha \downarrow 0 \\ x + \alpha g \in \Omega}} \frac{f(x + \alpha g) - f(x)}{\alpha} \quad (37)$$

is called the *Dini conditional upper derivative* of the function  $f$  at the point  $x$  in the direction  $g$  with respect to  $\Omega$ . If no sequence  $\{\alpha_k\}$  exists such that  $\alpha_k \downarrow 0$ ,  $x + \alpha_k g \in \Omega$  for all  $k$ , then, by definition, we set  $f_D^\uparrow(x, g; \Omega) = -\infty$ .

The limit

$$f_D^\downarrow(x, g; \Omega) = \liminf_{\substack{\alpha \downarrow 0 \\ x + \alpha g \in \Omega}} \frac{f(x + \alpha g) - f(x)}{\alpha} \quad (38)$$

is called the *Dini conditional lower derivative* of the function  $f$  at the point  $x$  in the direction  $g$  with respect to  $\Omega$ . If no sequence  $\{\alpha_k\}$  exists such that  $\alpha_k \downarrow 0$ ,  $x + \alpha_k g \in \Omega$  for all  $k$ , then, by definition, we set  $f_D^\downarrow(x, g; \Omega) = +\infty$ .

The limit

$$f_H^\uparrow(x, g; \Omega) = \limsup_{\substack{[\alpha, g'] \rightarrow [+0, g] \\ x + \alpha g' \in \Omega}} \frac{f(x + \alpha g') - f(x)}{\alpha} \quad (39)$$

is called the *Hadamard conditional upper derivative* of the function  $f$  at the point  $x$  in the direction  $g$  with respect to  $\Omega$ . If no sequences  $\{\alpha_k\}, \{g_k\}$  exist such that  $[\alpha_k, g_k] \rightarrow [+0, g], x + \alpha_k g_k \in \Omega$  for all  $k$ , then, by definition, we set  $f_H^\uparrow(x, g; \Omega) = -\infty$ .

The limit

$$f_H^\downarrow(x, g; \Omega) = \liminf_{\substack{[\alpha, g'] \rightarrow [+0, g] \\ x + \alpha g' \in \Omega}} \frac{f(x + \alpha g') - f(x)}{\alpha} \quad (40)$$

is called the *Hadamard conditional lower derivative* of  $f$  at  $x$  in the direction  $g$  with respect to  $\Omega$ . If no sequences  $\{\alpha_k\}, \{g_k\}$  exist such that  $[\alpha_k, g_k] \rightarrow [+0, g], x + \alpha_k g_k \in \Omega$  for all  $k$ , then, by definition, we set  $f_H^\downarrow(x, g; \Omega) = +\infty$ .

**Proposition 16 (see [1])** For a point  $x^* \in \Omega$  and such that  $|f(x^*)| < \infty$  to be a local or global minimizer of  $f$  on  $\Omega$  it is necessary that

$$f_D^\downarrow(x^*, g; \Omega) \geq 0, \quad \forall g \in \mathbb{R}^n, \quad (41)$$

$$f_H^\downarrow(x^*, g; \Omega) \geq 0, \quad \forall g \in \mathbb{R}^n. \quad (42)$$

Furthermore, if

$$f_H^\downarrow(x^*, g; \Omega) > 0, \quad \forall g \in \mathbb{R}^n, \quad g \neq 0_n, \quad (43)$$

then  $x^*$  is a strict local minimizer of  $f$  on  $\Omega$ .

A point  $x^* \in \Omega$  satisfying (41) ((42)) is called a *Dini (Hadamard) inf-stationary point* of  $f$  on  $\Omega$ .

**Proposition 17** For a point  $x^{**} \in \Omega$  and such that  $|f(x^{**})| < \infty$  to be a local or global minimizer of  $f$  on  $\Omega$  it is necessary that

$$f_D^\uparrow(x^{**}, g; \Omega) \leq 0, \quad \forall g \in \mathbb{R}^n, \quad (44)$$

$$f_H^\uparrow(x^{**}, g; \Omega) \leq 0, \quad \forall g \in \mathbb{R}^n. \quad (45)$$

If

$$f_H^\uparrow(x^{**}, g; \Omega) < 0, \quad \forall g \in \mathbb{R}^n, \quad g \neq 0, \quad (46)$$

then  $x^{**}$  is a strict local maximizer of  $f$  on  $\Omega$ .

A point  $x^{**} \in \Omega$  satisfying (44) ((45)) is called a *Dini (Hadamard) sup-stationary point* of  $f$  on  $\Omega$ .

The condition (41) is equivalent to

$$f_D^\downarrow(x^*, g; \Omega) \geq 0, \quad \forall g \in K(x^*, \Omega), \quad (47)$$

where

$$K(x^*, \Omega) = \left\{ g \in \mathbb{R}^n : \exists \alpha_k : \begin{array}{l} x^* + \alpha_k g \in \Omega, \\ \forall k \end{array} \right\}. \quad (48)$$

Analogously, the condition (44) is equivalent to

$$f_D^\uparrow(x^{**}, g; \Omega) \leq 0, \quad \forall g \in K(x^{**}, \Omega). \quad (49)$$

The condition (42) is equivalent to

$$f_H^\downarrow(x^*, g; \Omega) \geq 0, \quad \forall g \in \Gamma(x^*, \Omega), \quad (50)$$

where

$$\begin{aligned} & \Gamma(x^*, \Omega) \\ &= \left\{ g \in \mathbb{R}^n : \exists \{[\alpha_k, g_k]\} : \begin{array}{l} [\alpha_k, g_k] \rightarrow [+0, g], \\ x^* + \alpha_k g_k \in \Omega, \\ \forall k \end{array} \right\}. \end{aligned} \quad (51)$$

Analogously, the condition (45) is equivalent to

$$f_H^\uparrow(x^{**}, g; \Omega) \leq 0, \quad \forall g \in \Gamma(x^{**}, \Omega). \quad (52)$$

Note that the cones  $K(x^*, \Omega)$  and  $K(x^{**}, \Omega)$  are not necessarily closed, while the cones  $\Gamma(x^*, \Omega)$  and  $\Gamma(x^{**}, \Omega)$  are the Bouligand cones to  $\Omega$  at  $x^*$  and  $x^{**}$ , respectively, and therefore always closed.

Now it is possible to define conditional steepest ascent and descent directions.

*Remark 18* It is also possible (see [3, p. 156]) to define the Dini and Hadamard conditional directional derivatives as follows:

$$f_D^\uparrow(x, g; \Omega) = \lim_{\substack{\alpha \downarrow 0 \\ x + \alpha g \in \Omega}} \frac{f(x + \alpha g) - f(x)}{\alpha}, \quad (53)$$

$$f'_H(x, g; \Omega) = \lim_{\substack{[\alpha, g'] \rightarrow [+0, g] \\ x + \alpha g' \in \Omega}} \frac{f(x + \alpha g') - f(x)}{\alpha}. \quad (54)$$

A function  $f$  is called *Dini (Hadamard) conditionally differentiable* at  $x$  in a direction  $g$  if the limit in (53) ((54)) exists and is finite.

*Remark 19* The conditional directional derivatives defined by (37)–(40) essentially depend on the set  $\Omega$ .

In some cases it is possible to ‘separate’ the function  $f$  and the set  $\Omega$  in the necessary conditions (47), (49), (50) and (52). For example, if  $f$  is Lipschitz and directionally differentiable at  $x$ , then

$$\begin{aligned} f_D^\uparrow(x, g; \Omega) &= f_D^\downarrow(x, g; \Omega) \\ &= f_H^\uparrow(x, g; \Omega) = f_H^\downarrow(x, g; \Omega) \\ &= f'(x, g) \quad \forall g \in K(x, \Omega). \end{aligned}$$

In this case the derivatives at the left-hand sides of (47), (49) and (50), (52) should be replaced by  $f'(x^*, g)$  or  $f'(x^{**}, g)$  respectively.

Note that if  $g \in \Gamma(x, g)$  but  $g \notin K(x, g)$  then  $f_D^\uparrow(x, g; \Omega)$  and  $f_D^\downarrow(x, g; \Omega)$  are not finite, by definition, while

$$f_D^\uparrow(x, g; \Omega) = f_D^\downarrow(x, g; \Omega) = f'(x, g).$$

*Remark 20* The necessary optimality conditions for unconstrained and constrained optimization problems described above can be used to construct numerical methods for finding corresponding (inf- or sup-stationary) points.

For special classes of functions (e. g., convex, concave, max-type, minmax-type, quasidifferentiable functions), the derivative (3) has a more ‘constructive’ form and therefore the conditions (25)–(36) and (41)–(46) take also more ‘constructive’ forms (see, e. g., [2]).

*Remark 22* The limits in (4), (5), (6), (39) and (40) are taken if

$$[\alpha, g'] \rightarrow [+0, g]. \quad (55)$$

Sometimes, in the literature instead of this relation one can see two relations

$$\alpha \rightarrow +0, \quad g' \rightarrow g. \quad (56)$$

It was demonstrated in [4] that the limits resulting from (55) and (56) do not necessarily coincide. This warning should be taken into account.

## Keywords and Phrases

Optical networks; Path coloring; Bipartite edge coloring; Approximation algorithms

Technological developments in the field of optical communication networks using *wavelength-division multiplexing* have triggered intensive research in an optimization problem concerning the assignment of colors to paths in a directed tree. Here, the term *directed tree* refers to the graph obtained from an undirected tree by replacing each undirected edge by two directed edges with opposite directions. This *path coloring problem* was first studied by M. Mihail, C. Kaklamani and S. Rao [19]. An instance of it is given by a directed tree  $T = (V, E)$  and a set  $P = \{p_1, \dots, p_t\}$  of directed simple (i. e., not visiting any vertex twice) paths in  $T$ , where each path is specified by an ordered pair of vertices (start vertex and end vertex). The task is to assign colors to the given paths such that paths receive different colors if they share a directed edge. The goal is to minimize the number of different colors used. For given  $T = (V, E)$  and  $P$ , let  $L(e)$  denote the load on directed edge  $e \in E$ , i. e., the number of paths containing  $e$ . Obviously, the maximum load  $L = \max_{e \in E} L(e)$  is a lower bound on the number of colors in an optimal coloring. Consider Fig. 1 for an example of a tree with six vertices and paths from  $a$  to  $e$ , from  $f$  to  $e$ , from  $f$  to  $c$ , from  $d$  to  $b$ , and from  $a$  to  $b$ . A possible valid coloring is to assign these paths the colors 1, 2, 1, 2, and 3, respectively. The maximum load of the paths is 2, because 2 paths use the edge  $(d, c)$ . It is not possible to color these paths with 2 colors, because the *conflict graph* of the paths (a graph with a vertex for each path and an edge between vertices if the corresponding paths share an edge) is a cycle of length 5. Hence, the coloring with three colors is an optimal coloring.

Directed Tree Networks, Figure 1  
Example path coloring instance

The path coloring problem models the *assignment of wavelengths* to directed connection requests in *all-optical networks with tree topology*. In such networks data is transmitted in optical form via laser beams [13]. Two adjacent nodes of the network are connected by a pair of optical fiber links, one for each direction. When wavelength-division multiplexing is used, multiple signals can be transmitted over the same link if they use different wavelengths, and the nodes are capable of switching an incoming signal onto any outgoing link depending on the wavelength of the signal. However, the wavelength of a signal cannot be changed, and every connection uses the same wavelength on the whole transmitter-receiver path. If two signals using the same wavelength are transmitted over the same directed link, the data is lost due to interference. The number of available wavelengths is called *optical bandwidth*, and it is a scarce resource. Therefore, one is interested in minimizing the number of wavelengths necessary to route a given set of requests. This optimization problem corresponds to the path coloring problem defined above: paths correspond to connection requests, and colors correspond to wavelengths.

## Complexity Results

Whereas the path coloring problem can be solved in linear time in *chain networks* as it is equivalent to *interval graph coloring*, it is *NP-hard* in directed tree networks. More precisely, it is *NP-complete* to decide whether a set of paths in a directed tree of arbitrary degree can be colored using at most 3 colors [8,9], and it is *NP-*

complete to decide whether a set of paths in a directed binary tree can be colored using at most  $k$  colors if  $k$  is part of the input [7,9,17]. The respective *reductions* will be outlined in the following. It should be remarked that the special case in which both the maximum degree of the tree as well as the maximum load of the paths are bounded by a constant can be solved optimally in polynomial time [7,9].

### Reduction from Edge Coloring

It is an *NP*-complete problem to decide whether the edges of a given 3-regular undirected graph  $G$  can be colored with three colors such that edges receive different colors if they are incident to the same vertex [14]. Let  $G$  be a 3-regular undirected graph with  $n$  vertices and  $m$  edges. A directed tree  $T$  with  $n' = 10n + 1$  vertices and a set  $P$  of  $t = 4m$  paths in  $T$  can be constructed in polynomial time such that the paths in  $T$  can be colored using three colors if and only if the edges of  $G$  can be colored with three colors.  $T$  consists of a root  $r$ , one child  $c_v$  of the root for every vertex  $v$  of  $G$ , three children  $c_v^1, c_v^2$  and  $c_v^3$  of every  $c_v$ , and two children  $c_v^{i,1}$  and  $c_v^{i,2}$  of every  $c_v^i$ . For each edge  $e = \{v, w\}$  of  $G$ , four paths in  $T$  are created: one from  $c_v^{i,1}$  to  $c_w^{j,2}$  and one from  $c_w^{j,1}$  to  $c_v^{i,2}$ , called real paths, and two copies of the path from  $c_v^{i,1}$  to  $c_v^{i,2}$ , called blockers. Here  $i$  and  $j$  are chosen such that the subtree rooted at  $c_v^i$  resp.  $c_w^j$  is not used by any paths other than the paths created for this particular edge  $e$ . Figure 2 shows an example of a 3-regular graph  $G$ , the constructed tree  $T$  (two of the four subtrees are represented by dotted triangles), and the paths created for the edge between the black vertices of  $G$ .

If the paths in  $T$  are to be colored with three colors, the blockers ensure that the two real paths correspond-

ing to  $e$  receive the same color and, therefore, this color cannot be used by any other real path corresponding to an edge incident to  $v$  or  $w$ . If there exists a 3-coloring of the paths in  $T$ , a 3-coloring of the edges of  $G$  can be obtained by assigning each edge the color of its corresponding real paths. On the other hand, if there exists a 3-coloring of the edges of  $G$ , a 3-coloring of the paths in  $T$  can be obtained by assigning the real paths corresponding to edge  $e$  the same color as  $e$  and coloring the blockers with the remaining two colors. Hence, a solution to the path coloring problem in  $T$  would also solve the *edge coloring* problem in  $G$ .

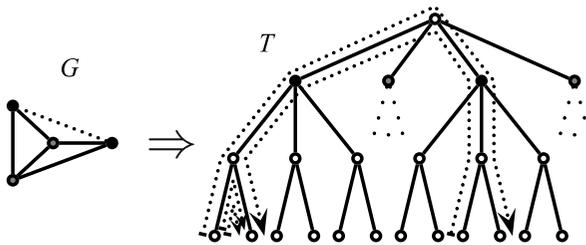

Since it has just been proved *NP*-complete to decide whether paths in a directed tree can be colored with three colors, it follows that there cannot be an approximation algorithm for path coloring with absolute *approximation ratio*  $< 4/3$  unless  $P = NP$ .

### Reduction from Arc Coloring

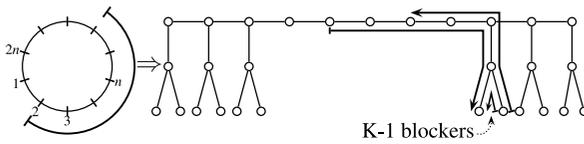

The *NP*-complete *arc coloring* problem [12] is to decide for a given set of  $n$  arcs  $A_1, \dots, A_n$  on a circle and a given integer  $k$  whether the arcs can be colored with  $k$  colors such that arcs receive different colors if they intersect. Without loss of generality, assume that each arc is specified by a pair  $(a_i, b_i)$  with  $a_i \neq b_i$  and  $1 \leq a_i, b_i \leq 2n$ . The span of arc  $A_i$  is  $sp(A_i) = \{a_i + 1, a_i + 2, \dots, b_i\}$  if  $a_i < b_i$  and  $sp(A_i) = \{a_i + 1, \dots, 2n, 1, 2, \dots, b_i\}$  if  $a_i > b_i$ . Two arcs  $A_i$  and  $A_j$  intersect iff  $sp(A_i) \cap sp(A_j) \neq \emptyset$ . Note that one can view the arc coloring problem as a path coloring problem on a cycle.

If a number is contained in the span of more than  $k$  arcs, then the arcs can surely not be colored with  $k$  colors and the answer to this instance of arc coloring is *no*. Otherwise, one can assume that every number  $i$ ,  $1 \leq i \leq 2n$  is contained in the span of exactly  $k$  arcs; if this were not the case, one could simply add arcs of the form  $(i, i + 1)$  until the condition holds, without changing the answer of the coloring problem.

Now consider a chain of  $n$  vertices  $v_1, v_2, \dots, v_n$ . Imagine the chain drawn from left to right, with  $v_1$  the start vertex at its left end. The directed edges from left to right followed by the directed edges from right to left make up a cycle of length  $2n$ . The given circular arcs can be translated into directed paths on this cycle such that two paths share a directed edge iff the corre-

Directed Tree Networks, Figure 2  
Reduction from edge coloring

**Directed Tree Networks, Figure 3**  
Reduction from arc coloring

sponding arcs intersect, but these paths do not yet constitute a valid path coloring problem because some of the paths are not simple: an arc  $(1, 2n)$  would correspond to a path running from  $v_1$  to  $v_n$  and back to  $v_1$ , for example. Nevertheless, it is possible to obtain a valid instance of the path coloring problem by splitting paths that are not simple into two or three simple paths and by using blockers to make sure that the paths derived from one non-simple path must receive the same color in any valid  $k$ -coloring.

For this purpose, extend the chain by adding  $k$  vertices on both ends, resulting in a chain of length  $n + 2k$ . Connect each of the newly added vertices to a distinct subtree consisting of a new vertex with two leaf children. The resulting network is a binary tree  $T$ . If a path arrives at vertex  $v_n$  coming from the left (i. e., from  $v_{n-1}$ ) and “turns around” to revisit  $v_{n-1}$ , divide the path into two: one coming from the left, passing through  $v_n$  and ending at the left leaf of one of the subtrees added on the right side of the chain; the other one starting at the right leaf of that subtree, passing through  $v_n$  and continuing left. In addition, add  $k - 1$  blockers in that subtree, i. e., paths from the right leaf to the left leaf. Observe that there are no more than  $k$  paths containing  $v_n$  as an inner vertex, and a different subtree can be chosen for each of these paths. A symmetric splitting procedure is applied to the paths that contain  $v_1$  as an inner vertex, i. e., the paths that arrive at  $v_1$  coming from the right (i. e., from  $v_2$ ) and “turn around” to revisit  $v_2$ . This way, all non-simple paths are split into two or three simple paths, and a number of blockers are added.

The resulting set of paths in  $T$  can be colored with  $k$  colors if and only if the original arc coloring instance is a *yes*-instance. The blockers ensure that all paths corresponding to the same arc receive the same color in any  $k$ -coloring. Hence, a  $k$ -coloring of the paths can be used to obtain a  $k$ -coloring of the arcs by assigning each arc the color of its corresponding paths. Also, a  $k$ -coloring

of the arcs can be turned into a  $k$ -coloring of the paths by assigning all paths corresponding to an arc the same color as the arc and by coloring the blockers with the remaining  $k - 1$  colors. This shows that the decision version of the path coloring problem is *NP*-complete already for binary trees.

### Approximation Algorithms

Since the path coloring problem in directed tree networks is *NP*-hard, one is interested in polynomial-time *approximation algorithms* with provable *performance guarantee*. All such approximation algorithms that have been developed so far belong to the class of *greedy algorithms*. A greedy algorithm picks a start vertex  $s$  in the tree  $T$  and assigns colors to the paths touching (starting at, ending at, or passing through)  $s$  first. Then it visits the remaining vertices of the tree in some order that ensures that the current vertex is adjacent to a previously visited vertex; for example, a *depth-first search* can be used to obtain such an order. When the algorithm processes vertex  $v$ , it assigns colors to all paths touching  $v$  without changing the color of paths that have been colored at a previous vertex. Each such step is referred to as *coloring extension*. Furthermore, the only information about the paths touching the current vertex that the algorithm considers is which edges incident to the current vertex they use. To emphasize this latter property, greedy algorithms are sometimes referred to as *local greedy algorithms*.

Whereas all greedy algorithms follow this general strategy, individual variants differ with respect to the solution to the coloring extension substep. The best known algorithm was presented by T. Erlebach, K. Jansen, C. Kaklamanis, and P. Persiano in [11,16] (see also [10]). It colors a set of paths with maximum load  $L$  in a directed tree network of arbitrary degree with at most  $\lceil 5L/3 \rceil$  colors. In the next section this will be shown to be best possible in the class of greedy algorithms.

For the sake of clarity, assume that the load on all edges is exactly  $L$  and that  $L$  is divisible by 3. The algorithm maintains two *invariants*: (a) the number of colors used is at most  $5L/3$ , and (b) for each pair of directed edges with opposite directions the number of colors used to color paths going through either of these edges is at most  $4L/3$ . First, the algorithm picks a leaf  $s$

of  $T$  as the start vertex and colors all paths starting or ending at  $s$  using at most  $L$  colors. Therefore, the invariants are satisfied initially. It remains to show that they still hold after a coloring extension step if they were satisfied at the beginning of this step.

### Reduction to Constrained Bipartite Edge Coloring

The coloring extension problem at a current vertex  $v$  is reduced to a *constrained edge coloring* problem in a *bipartite graph*  $G_v$  with left vertex set  $V_1$  and right vertex set  $V_2$ . This reduction was introduced by M. Mihail, C. Kaklamani and S. Rao in [19]. Let  $n_0, n_1, \dots, n_k$  be the neighbors of  $v$  in  $T$ , and let  $n_0$  be the unique neighbor that was processed before  $v$ . For every neighbor  $n_i$  of  $v$  the graph  $G_v$  contains four vertices: vertices  $w_i$  and  $z_i$  in  $V_1$ , and vertices  $x_i$  and  $y_i$  in  $V_2$ . Vertex  $w_i$  is said to be opposite  $x_i$ , and  $z_i$  is opposite  $y_i$ . A pair of opposite vertices is called a *line* of  $G_v$ . A line *sees* a color if it appears on an edge incident to a vertex of that line. For every path touching  $v$  there is one edge in  $G_v$ : an edge  $(w_i, x_j)$  for each path coming from  $n_i$ , passing through  $v$  and going to  $n_j$ ; an edge  $(w_i, y_i)$  for each path coming from  $n_i$  and ending at  $v$ ; and an edge  $(z_i, x_i)$  for each path starting at  $v$  and going to  $n_i$ .

It is easy to see that coloring the paths touching  $v$  is equivalent to coloring the edges of  $G_v$ . Note that the vertices  $w_i$  and  $x_i$  have degree  $L$  in  $G_v$ , while the other vertices may have smaller degree. If this is the case, the algorithm adds dummy edges (shown dashed in Fig. 4) in order to make the graph  $L$ -regular.

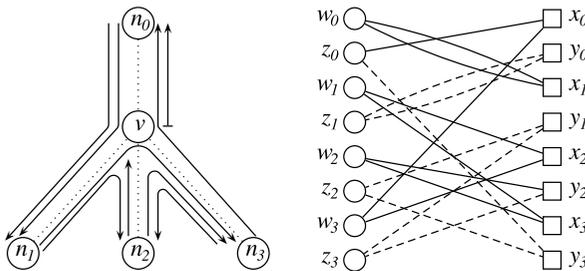

As the paths that contain the edges  $(n_0, v)$  or  $(v, n_0)$  have been colored at a previous vertex, the edges incident to  $w_0$  and  $x_0$  are already colored with at most  $4L/3$  colors by invariant (b). These edges are called *color-*

*forced* edges. A color that appears on exactly one color-forced edge is a *single color*. A color that appears on two color-forced edges is a *double color*. Since there are at most  $4L/3$  colors on  $2L$  color-forced edges, there must be at least  $2L/3$  double colors. Furthermore, one can assume that there are exactly  $2L/3$  double colors and  $2L/3$  single colors, because if there are too many double colors then it is possible to split an appropriate number of double colors into two single colors for the duration of the current coloring extension step. In order to maintain invariant (a), the algorithm must color the uncolored edges of  $G_v$  using at most  $L/3$  new colors (colors not used on the color-forced edges). Invariant (b) is satisfied by ensuring that no line of  $G_v$  sees more than  $4L/3$  colors.

### Partition Into Matchings

$G_v$  is an  $L$ -regular bipartite graph and its edges can thus be partitioned into  $L$  *perfect matchings* efficiently. Each *matching* is classified according to the colors on its two color-forced edges: SS-matchings contain two single colors, ST-matchings contain one single color and one double color, PP-matchings contain the same (preserved) double color on both color-forced edges, and TT-matchings contain two different double colors. Next, the  $L$  matchings are grouped into chains and cycles: a chain of length  $\ell \geq 2$  is a sequence of  $\ell$  matchings  $M_1, \dots, M_\ell$  such that  $M_1$  and  $M_\ell$  are ST-matchings,  $M_2, \dots, M_{\ell-1}$  are TT-matchings, and two consecutive matchings share a double color; a cycle of length  $\ell \geq 2$  is a sequence of  $\ell$  TT-matchings such that consecutive matchings as well as the first and the last matching share a double color. Obviously, the set of  $L$  matchings is in this way entirely partitioned into SS-matchings, chains, cycles, and PP-matchings. In addition, if a chain or cycle contains parallel color-forced edges, then the algorithm exchanges these edges in the respective matchings, thus dividing the original chain or cycle into a shorter sequence of the same type and an extra cycle.

Now the algorithm chooses *triplets*, i. e., groups of three matchings, and colors the uncolored edges of each triplet using at most one new color and at most four *active* colors. The active colors are selected among the colors on color-forced edges of that triplet, and a color is active in at most one triplet. The algorithm ensures

Directed Tree Networks, Figure 4  
Construction of the bipartite graph

that a line that sees the new color does not see one of the active colors of that triplet. This implies that no line of  $G_v$  sees more than  $4L/3$  colors altogether, as required to maintain invariant (b).

### Coloring of Triplets

The rules for choosing triplets ensure that each triplet contains two color-forced edges with single colors and four color-forced edges with double colors. Furthermore, most triplets are chosen such that one double color appears twice, and this double color as well as the two single colors can be reused without considering conflicts outside the triplet. V. Kumar and E.J. Schwabe proved in [18] that such triplets can be colored as required using three active colors and one new color. This coloring procedure can be sketched as follows. Partition the edges of the triplet into a matching on all vertices except  $w_0$  and  $x_0$  and a *gadget*, i. e., a subgraph in which  $w_0$  and  $x_0$  have degree 3 while all other vertices have degree 2. A gadget consists of a number of cycles of even length not containing  $w_0$  or  $x_0$  and either three disjoint paths from  $w_0$  to  $x_0$  or one path from  $w_0$  to  $x_0$ , one path from  $w_0$  to  $w_0$ , and one path from  $x_0$  to  $x_0$ . A careful case analysis shows that the triplet can be colored by reusing the single colors and the double color to color the gadget and using a new color for the matching. If a partitioning into gadget and matching does not exist, the triplet contains a PP-matching and can be colored using the double color of the PP-matching for the uncolored edges of the PP-matching and a single color and a new color for the uncolored edges of the cycle cover consisting of the other two matchings.

In the following, the terms *even sequence* and *odd sequence* refer to sequences of TT-matchings of even resp. odd length such that consecutive matchings share a double color. Note that an even sequence can be grouped into triplets by combining two consecutive matchings of the sequence with an SS-matching as long as SS-matchings are available and combining each remaining TT-matching with a chain of length 2. There are always enough SS-matchings or chains of length 2 because the ratio between color-forced edges with double colors and color-forced edges with single colors is  $2 : 1$  in  $G_v$  initially and remains the same after extracting triplets. Similarly, an odd sequence can be grouped into triplets if there is at least one chain of length 2,

which can be used to form a triplet with the first matching of the sequence, leaving an even sequence behind.

### Selection of Triplets

Now the rules for selecting triplets are as follows. From chains of odd length, combine the first two matchings and the last matching to form a triplet. The remainder of the chain (if non-empty) is an even sequence and can be handled as described above. Cycles of even length are even sequences and can be handled the same way. As long as there is a chain of length 2 left, chains of even length  $\geq 4$  and odd cycles can be handled, too. Pairs of PP-matchings can be combined with an SS-matching, single PP-matchings can be combined with chains of length 2. If there are two chains of even length  $\geq 4$ , combine the first two matchings of one chain with the last matching of the other and the last two matchings of the first chain with the first matching of the other, leaving two even sequences behind. So far, all triplets contained a double color twice and could be colored as outlined above. What remains is a number of cycles of odd length, at most one chain of even length, at most one PP-matching, and some SS-matchings. To deal with these, it is necessary to form some triplets that contain four distinct double colors. However, it is possible to ensure that the set of color-forced edges of  $G_v$  (inside and outside the triplet) colored with one of these double colors does not contain parallel edges; T. Erlebach, K. Jansen, C. Kaklamanis and P. Persiano showed in [11] that such a triplet can be colored as required using its single colors, two of its double colors, and one new color.

In the end, the entire graph  $G_v$  has been partitioned into triplets, and each triplet has been colored using at most one new color and such that a line that sees a new color in a triplet does not see one of the active colors of that triplet. Hence, invariants (a) and (b) hold at the end of the coloring extension step, and once the coloring extension step has been performed for all vertices of  $T$  all paths have received one of  $\lceil 5L/3 \rceil$  colors. Since the number  $OPT$  of colors necessary in an optimal coloring is at least  $L$ , this implies that the algorithm uses at most  $\lceil 5OPT/3 \rceil$  colors to color the paths. From the lower bound in the next section it will be clear that the algorithm (and any other greedy algorithm) is not better than  $5OPT/3$  in the worst case.

Note that greedy algorithms are well-suited for practical distributed implementation in optical networks: one node of the network initiates the wavelength assignment by assigning wavelengths to all connections going through that node; then it transfers control to its neighbors who can extend the assignment independently and in parallel, transferring control to their neighbors in turn once they are done.

It should be mentioned that simpler variants of greedy algorithms are known that are restricted to *binary trees* and color a given set of paths with load  $L$  using  $\lceil 5L/3 \rceil$  colors. These algorithms do not make use of the reduction to constrained bipartite edge coloring [6,15].

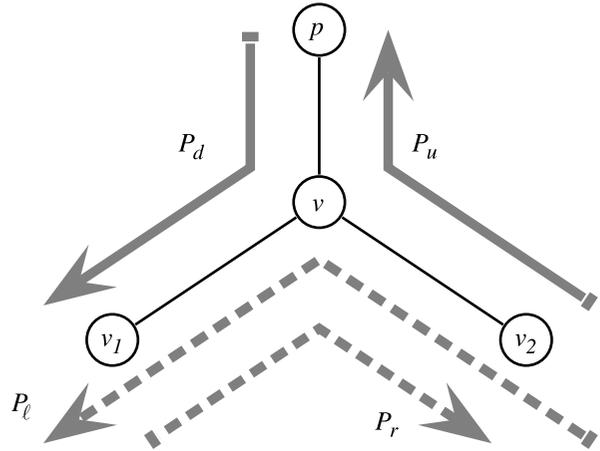

### Lower Bounds

Two kinds of *lower bounds* have been investigated for path coloring in directed tree networks. First, one wants to determine the best *worst-case performance guarantee* achievable by any greedy algorithm. Second, it is interesting to know how many colors are required even in an optimal coloring for a given set of paths with load  $L$  in the worst case.

### Lower Bound for Greedy Algorithms

For a given local greedy algorithm  $A$  and positive integer  $L$ , an *adversary* can construct an instance of path coloring in a directed binary tree network such that  $A$  uses at least  $\lceil 5L/3 \rceil$  colors while an optimal solution uses only  $L$  colors [15]. The construction proceeds inductively. As  $A$  considers only the edges incident to a vertex  $v$  when it colors the paths touching  $v$ , the adversary can determine how these paths should continue and introduce new paths not touching  $v$  depending on the coloring  $A$  produces at vertex  $v$ .

Assume that there are  $\alpha_i L/2$  paths going through each of the directed edges between vertex  $v$  and its parent, and that these paths have been colored with  $\alpha_i L$  different colors. Initially, this assumption can be satisfied for  $\alpha_0 = 1$  by introducing  $L$  paths in either direction on the link between the start vertex picked by algorithm  $A$  and one of its neighbors and letting appropriately chosen  $L/2$  of these paths start resp. end at that neighbor. Denote the set of paths coming down from the parent by  $P_d$  and let them continue to (pass through) the left child  $v_1$  of  $v$ . Denote the set of paths

Directed Tree Networks, Figure 5  
Lower bound for greedy algorithms

going up to the parent by  $P_u$  and let them pass through the right child  $v_2$  of  $v$ . Introduce a set  $P_\ell$  of  $(1 - \alpha_i/2)L$  paths coming from  $v_2$  and going left to  $v_1$ , and a set  $P_r$  of  $L$  paths coming from  $v_1$  and going right to  $v_2$ .

Algorithm  $A$  must use  $(1 - \alpha_i/2)L$  new colors to color the paths in  $P_\ell$ . No matter which colors it chooses for the paths in  $P_r$ , it will use at least  $(1 + \alpha_i/4)L$  different colors on the connection between  $v$  and  $v_1$  or on the connection between  $v$  and  $v_2$ . The best it can do with respect to minimizing the number of colors appearing between  $v$  and  $v_1$  and between  $v$  and  $v_2$  is to color  $(1 - \alpha_i/2)L$  paths of  $P_r$  with colors used for  $P_\ell$ ,  $\alpha_i L/4$  paths of  $P_r$  with colors used for  $P_d$ , and  $\alpha_i L/4$  paths of  $P_r$  with colors used for  $P_u$ . In that case, it uses  $(1 + \alpha_i/4)L$  colors on each of the downward connections of  $v$ . Any other assignment uses more colors on one of the downward connections.

If the algorithm uses at least  $(1 + \alpha_i/4)L$  different colors for paths on, say, the connection between  $v$  and  $v_1$ , let  $(1 + \alpha_i/4)L/2$  of the downward paths and equally many of the upward paths extend to the left child of  $v_1$ , such that all of these paths use different colors, and let the remaining paths terminate or begin at  $v_1$ . Now the inductive assumption holds for the left child of  $v_1$  with  $\alpha_{i+1} = 1 + \alpha_i/4$ . Hence, the number of colors on a pair of directed edges can be increased as long as  $\alpha_i < 4/3$ . When  $\alpha_i = 4/3$ ,  $4L/3$  colors are used for the paths touching  $v$  and its parent, and algorithm  $A$  must use  $L/3$  new colors to color the paths in  $P_\ell$ , using  $5L/3$  colors altogether.

The previous calculations have assumed that all occurring terms like  $(1 + \alpha_i/4)L/2$  are integers. If one takes the possibility of non-integral values into account and carries out the respective calculations for all cases, one can show that, for every  $L$ , every greedy algorithm can be forced to use  $\lceil 5L/3 \rceil$  colors on a set of paths with maximum load  $L$  [15].

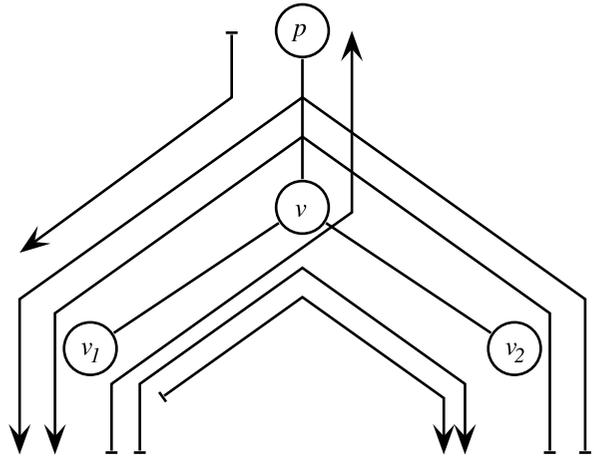

Furthermore, it is not difficult to show that the paths resulting from this worst-case construction for greedy algorithms can be colored optimally using only  $L$  colors. Hence, this yields also a lower bound of  $\lceil 5OPT/3 \rceil$  colors for any greedy algorithm.

**Lower Bounds for Optimal Colorings**

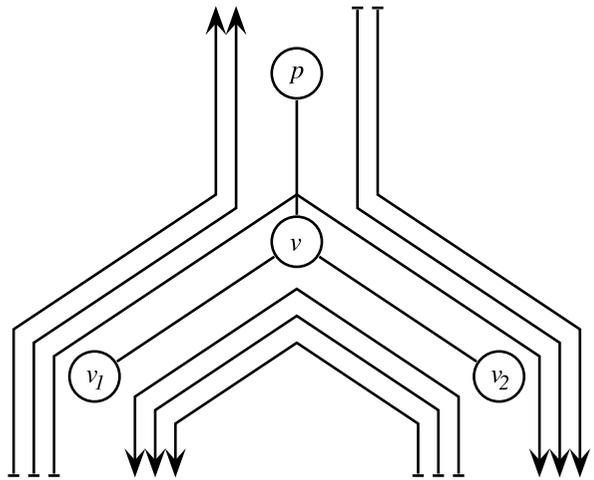

The instance of path coloring depicted in Fig. 1 consists of 5 paths in a binary tree with maximum load  $L = 2$  such that even an optimal coloring requires 3 colors. Consider the instances of path coloring obtained from this instance by replacing each path by  $\ell$  identical copies. Such an instance consists of  $5\ell$  paths with maximum load  $L = 2\ell$ , and an optimal coloring requires at least  $\lceil 5\ell/2 \rceil = \lceil 5L/4 \rceil$  colors because no more than two of the given paths can be assigned the same color. Furthermore,  $\lceil 5\ell/2 \rceil$  colors are also sufficient to color these instances: for example, if  $\ell$  is even, use colors  $1, \dots, \ell$  for paths from  $a$  to  $e$ , colors  $\ell + 1, \dots, 2\ell$  for paths from  $f$  to  $e$ , colors  $1, \dots, \ell/2$  and  $2\ell + 1, \dots, 5\ell/2$  for paths from  $f$  to  $c$ , colors  $\ell/2 + 1, \dots, 3\ell/2$  for paths from  $d$  to  $b$ , and colors  $3\ell/2 + 1, \dots, 5\ell/2$  for paths from  $a$  to  $b$ . Hence, for every even  $L$  there is a set of paths in a binary tree with load  $L$  such that an optimal coloring requires  $\lceil 5L/4 \rceil$  colors [4,18].

While the path coloring instance with  $L = 2$  and  $OPT = 3$  could be specified easily, K. Jansen used a more involved construction to obtain an instance with  $L = 3$  and  $OPT = 5$  [15]. It makes use of three components as building blocks. Each component consists of a vertex  $v$  with its parent and two children and a specification of the usage of edges incident to  $v$  by paths touching  $v$ .

The root component ensures that at least 3 colors are used either on the left downward connection (extending below  $v_1$ ) or on the right downward connection (extending below  $v_2$ ). Each child of the root component is connected to a type A component, i. e., the child is identified with the parent vertex of a type A com-

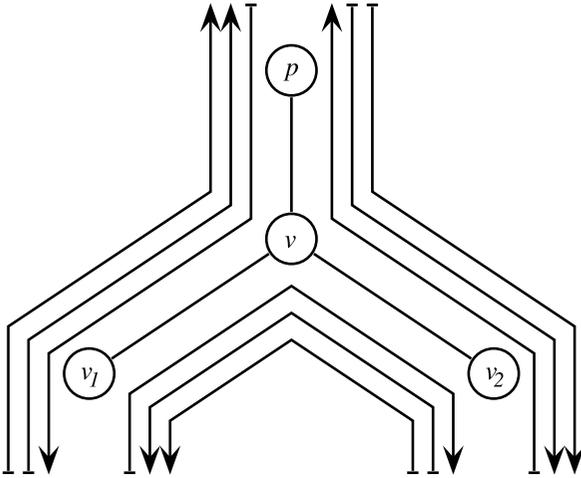

Directed Tree Networks, Figure 6  
Root component

Directed Tree Networks, Figure 7  
Type A component

ponent and the corresponding paths are identified as well.

Type A components have the property that, if the paths touching  $v$  and its parent are colored with 3 colors, at least 4 colors must be used either for the paths touching  $v$  and  $v_1$  or for those touching  $v$  and  $v_2$ . (If the paths touching  $v$  and its parent are colored with 4 colors, the remaining paths of the type A component require even 5 colors.) Hence, there is at least one child in one of the two type A components below the root component such that the paths touching this child and its parent are colored with four colors.

Directed Tree Networks, Figure 8  
Type B component

The final component used is of type B. It has the property that, if the paths touching  $v$  and its parent are colored with 4 colors, at least 4 colors must be used either for the paths touching  $v$  and  $v_1$  or for those touching  $v$  and  $v_2$ . For certain arrangements of colors on the paths touching  $v$  and its parent, 5 colors are necessary. It is possible to arrange a number of type B components in a binary tree such that for any combination of four colors on paths entering the tree of type B components at its root, 5 colors are necessary to complete the coloring. Hence, if one attaches a copy of this tree of type B components to each of the children of a type A component, it is ensured that at least one of the trees will be entered by paths with four colors and consequently 5 colors are necessary to color all paths. Since the load on every directed edge is at most 3, this gives a worst-case example for path coloring in binary trees with  $L = 3$  and  $OPT = 5$ .

### Randomized Algorithms

In [1,2], V. Auletta, I. Caragiannis, C. Kaklamani and G. Persiano presented a class of *randomized algorithms* for path coloring in directed tree networks. They gave a randomized algorithm that, with high probability, uses at most  $7/5L + o(L)$  colors for coloring any set of paths of maximum load  $L$  on binary trees of height  $o(L^{1/3})$ . The analysis of the algorithm uses tail inequalities for hypergeometrical probability distributions such as *Azuma's inequality*. Moreover, they proved that no

randomized greedy algorithm can achieve, with high probability, a performance ratio better than  $3/2$  for trees of height  $\Omega(L)$  and better than  $1.293 - o(1)$  for trees of constant height.

These results have been improved in [5] by I. Caragiannis, A. Ferreira, C. Kaklamani, S. Pérennes, and H. Rivano, who gave a randomized approximation algorithm for bounded-degree trees that has approximation ratio  $1.61 + o(1)$ . The algorithm first computes in polynomial time an optimal solution for the fractional path coloring problem and then applies *randomized rounding* to obtain an integral solution.

### Related Topics

A number of further results related to the path coloring problem in directed tree networks or in networks with different topology are known. The number of colors required for sets of paths that have a special form have been investigated, e. g., *one-to-all instances*, *all-to-all instances*, *permutations*, and *k-relations*. A survey of many of these results can be found in [4]. The undirected version of the path coloring problem has been studied by P. Raghavan and E. Upfal in [20]; here, the network is represented by an undirected graph and paths must receive different colors if they share an undirected edge. Approximation results for directed and undirected path coloring problems in *ring networks*, *mesh networks*, and arbitrary networks (all of these are *NP-hard* no matter whether the paths are fixed or can be chosen by the algorithm [7]) have been derived.

An on-line variant of path coloring was studied by Y. Bartal and S. Leonardo in [3]. Here, the algorithm is given connection requests one by one and must determine a path connecting the corresponding vertices and a color for this path without any knowledge of future requests. The worst-case ratio between the number of colors used by the *on-line algorithm* and that used by an optimal off-line algorithm with complete advance knowledge is the *competitive ratio*. In [3] on-line algorithms with competitive ratio  $O(\log n)$  are presented for trees, trees of rings, and meshes with  $n$  vertices.

### Keywords

Global optimization; Black-box optimization; Nonsmooth optimization; Constraints; Deterministic optimization

For a *black-box global optimization* algorithm to be truly global, some effort must be allocated to global search, that is, search done primarily to ensure that potentially good parts of the space are not overlooked. On the other hand, to be efficient, some effort must also be placed on local search near the current best solution. Most algorithms either move progressively from global to local search (e.g., simulated annealing) or combine a fundamentally global method with a fundamentally local method (e.g., multistart, tunneling).

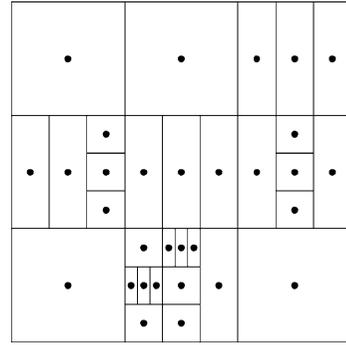

DIRECT introduces a new approach: in each iteration several search points are computed using all possible weights on local versus global search (how this is done will be made clear shortly). This approach eliminates the need for ‘*tuning parameters*’ that set the balance between local and global search, resulting in an algorithm that is robust and easy-to-use.

DIRECT is especially valuable for *engineering optimization* problems. In these problems, the objective and constraint functions are often computed using time-consuming computer simulations, so there is a need to be efficient in the use of function evaluations. The problems may contain both continuous and integer variables, and the functions may be nonlinear, non-smooth, and multimodal. While many algorithms address these problem features individually, DIRECT is one of the few that addresses them collectively. However, the versatility of DIRECT comes at a cost: the algorithm suffers from a curse of dimensionality that limits it to low-dimensional problems (say, no more than 20 variables).

The general problem solved by DIRECT can be written as follows:

$$\left\{ \begin{array}{l} \min \quad f(x_1, \dots, x_n) \\ \text{s.t.} \quad g_1(x_1, \dots, x_n) \leq 0, \\ \quad \quad \quad \vdots \\ \quad \quad \quad g_m(x_1, \dots, x_n) \leq 0, \\ \quad \quad \quad \ell_i \leq x_i \leq u_i, \\ \quad \quad \quad x_i \in I \text{ integer.} \end{array} \right.$$

To prove convergence, we must assume that the objective and constraint functions are continuous in the neighborhood of the optimum, but the functions can otherwise be nonlinear, nondifferentiable, nonconvex, and multimodal. While DIRECT does not explicitly handle equality constraints, problems with equalities can often be rewritten as problems with *inequality constraints* (either by replacing the equality with an inequality that becomes binding in the solution, or by using the equalities to eliminate variables). The set  $I$  in the above problem is the set of variables that are restricted to *integer* values. DIRECT works best when the integer variables describe an ordered quantity, such as the number of teeth on a gear. It is less effective when the integer variables are categorical.

Direct Global Optimization Algorithm, Figure 1

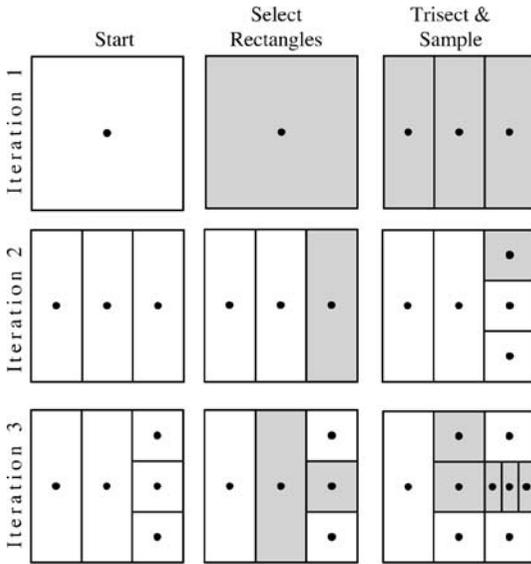

In what follows, we begin by describing how DIRECT works when there are no inequality and integer constraints. This basic version corresponds, with minor differences, to the originally published algorithm [2]. After describing the basic version, we then introduce extensions to handle inequality and integer constraints (this article is the first publication to document these extensions). We conclude with a step-by-step description of the algorithm.

The bounds on the variables limit the search to an  $n$ -dimensional hyper-rectangle. DIRECT proceeds by *partitioning* this rectangle into smaller rectangles, each of which has a ‘sampled point’ at its center, that is, a point where the functions have been evaluated. An example of such a partition for  $n = 2$  is shown in Fig. 1.

We have drawn the rectangle as a square because later, whenever we measure distances or lengths, we will weight each dimension so that the original range ( $u_i - \ell_i$ ) has a weighted distance of one. Drawing the hyper-rectangle as a hyper-cube allows us to visualize relative lengths as they will be used in the algorithm.

Figure 2 shows the first three iterations of DIRECT on a hypothetical two-variable problem. At the start of each iteration, the space is partitioned into rectangles. DIRECT then selects one or more of these rectangles for further search using a technique described later. Finally, each selected rectangle is *trisected* along one of its long sides, after which the center points of the outer thirds are sampled. In this way, we sample two new points in the rectangle and maintain the property that every sampled point is at the center of a rectangle (this property would not be preserved if the rectangle were bisected).

At the beginning of iteration 1, there is only one rectangle (the entire space). The process of selecting

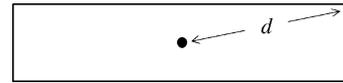

Direct Global Optimization Algorithm, Figure 2

rectangles is therefore trivial, and this rectangle is trisected as shown. At the start of iteration 2, the selection process is no longer trivial because there are three rectangles. In the example, we select just one rectangle, which is then trisected and sampled. At the start of iteration 3, there are 5 rectangles; in this example, two of them are selected and trisected.

The key step in the algorithm is the selection of rectangles, since this determines how search effort is allocated across the space. The trisection process and other details are less important, and we will defer discussion of them until later.

To motivate how DIRECT selects rectangles, let us begin by considering the extremes of pure global search and pure local search. A pure global search strategy would select one of the biggest rectangles in each iteration. If this were done, all the rectangles would become small at about the same rate. In fact, if we always trisected one of the biggest rectangles, then after  $3^{kn}$  function evaluations every rectangle would be a cube with side length  $3^{-k}$ , and the sampled points would form a uniform grid. By looking everywhere, this pure global strategy avoids overlooking good parts of the space.

A pure local strategy, on the other hand, would sample the rectangle whose center point has the best objective function value. This strategy is likely to find good

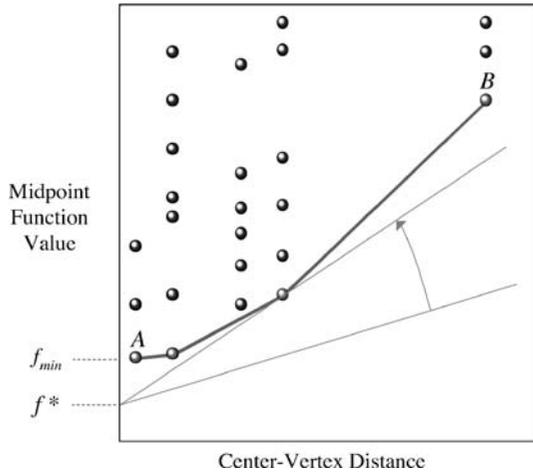

Direct Global Optimization Algorithm, Figure 3

solutions quickly, but it could overlook the rectangle that contains the global optimum (this would happen if the rectangle containing the global optimum had a poor objective function value at the center).

To select just one 'best' rectangle, we would have to introduce a tuning parameter that controlled the local/global balance. Unfortunately, the algorithm would then be extremely sensitive to this parameter, since the proper setting would depend on the (unknown) difficulty of the problem at hand.

DIRECT avoids tuning parameters by rejecting the idea of selecting just one rectangle. Instead, several rectangles are selected using all possible relative weightings of local versus global search. The idea of using all possible weightings may seem impractical, but with the help of a simple diagram this idea can actually be made quite intuitive. For this diagram, we will need a way to measure of the size of a rectangle. We will measure size using the distance between the center point and the vertices, as shown in Fig. 3.

With this measure of rectangle size, we can now turn our attention to Fig. 4 which shows how rectangles are selected. In the figure, each rectangle in the partition is represented by a dot. The horizontal coordinate of a dot is the size of the rectangle, measured by the center-vertex distance. The vertical coordinate is the function value at the midpoint of the rectangle. The dot labeled *A* represents the rectangle with the lowest function value, and so this would be the rectangle selected by a pure local strategy. Similarly, the dot labeled *B* represents one of the biggest rectangles, and so it would be selected by a pure global strategy. DIRECT selects not only these two extremes but also all the rectangles on the lower-right convex hull of the cloud of dots (the dots connected by the line). These rectangles represent 'efficient trade-offs' between local versus global search, in the sense that each of them is best for some relative weighting of midpoint function value and center-vertex distance. (We will explain the other lines in Fig. 4. shortly.)

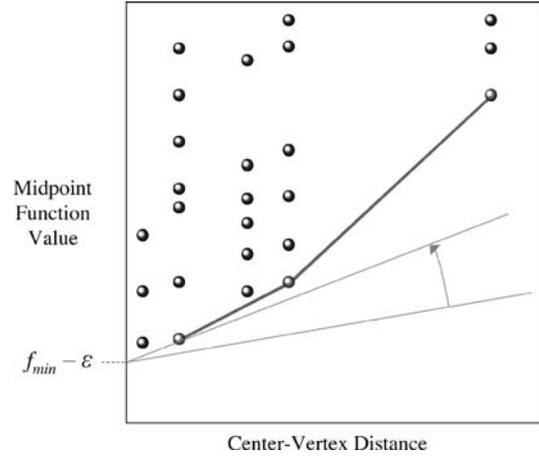

Direct Global Optimization Algorithm, Figure 4

One might think that the idea illustrated in Fig. 4 would extend naturally to the constrained case; that is, we would simply select any rectangle that was best for some weighting of objective value, center-vertex distance, and constraint values. Unfortunately, this does not work because it leads to excessive sampling in the infeasible region. However, as we explain next, there is an alternative way of thinking about the lower-right convex hull that does extend to the constrained case.

For the sake of the exposition, let us suppose for the moment that we know the optimal function value  $f^*$ . For the function to reach  $f^*$  within rectangle  $r$ , it would have to undergo a rate of change of at least  $(f_r - f^*)/d_r$ , where  $f_r$  is the function value at the midpoint of rectangle  $r$  and  $d_r$  is the center-vertex distance. This follows because the function value at the center is  $f_r$  and the maximum distance over which the function can fall to  $f^*$  is the center-vertex distance  $d_r$ . Intuitively, it seems ‘more reasonable’ to assume that the function will undergo a gradual change than to assume it will make a steep descent to  $f^*$ . Therefore, if only we knew the value  $f^*$ , a reasonable criterion for selecting a rectangle would be to choose the one that minimizes  $(f_r - f^*)/d_r$ .

Figure 4 shows a graphical way to find the rectangle that minimizes  $(f_r - f^*)/d_r$ . Along the vertical axis we show the current best function value,  $f_{\min}$ , as well as the supposed global minimum  $f^*$ . Now suppose we anchor a line at the point  $(0, f^*)$  and slowly swing it upwards. When we first encounter a dot, the slope of the line will be precisely the ratio  $(f_r - f^*)/d_r$ , where  $r$  is the index

Direct Global Optimization Algorithm, Figure 5

of the rectangle corresponding to the encountered dot. Moreover, since this is the first dot touched by the line, rectangle  $r$  must be the rectangle that minimizes  $(f_r - f^*)/d_r$ .

Of course, in general we will not know the value of  $f^*$ . But we do know that, whatever  $f^*$  is, it satisfies  $f^* \leq f_{\min}$ . So imagine that we repeat the line-sweep exercise in Fig. 4 for all values of  $f^*$  ranging from  $f_{\min}$  to  $-\infty$ . How many rectangles could be selected? Well, with a little thought, it should be clear that the set of dots that can be selected via these line sweeps is precisely the lower-right convex hull of the dots.

This alternative approach to deriving the lower-right convex hull suggests a small but important modification to the selection rule. In particular, to prevent DIRECT from wasting function evaluations in pursuit of very small improvements, we will insist that the value of  $f^*$  satisfy  $f^* \leq f_{\min} - \epsilon$ . That is, we are only interested in selecting rectangles where it is reasonable that we can find a ‘significantly better’ solution. A natural value of  $\epsilon$  would be the desired accuracy of the solution. In our implementation, we have set  $\epsilon = \max(10^{-4}[f_{\min}], 10^{-8})$ .

As shown in Fig. 5, the implication of this modification is that some of the smaller rectangles on the lower-right convex hull may be skipped. In fact, the smallest rectangle that will be selected is the one chosen when  $f^* = f_{\min} - \epsilon$ .

The version of DIRECT described so far corresponds closely to the originally published version [2].

The only difference is that, in the original version, a selected rectangle was trisected not just on a single long side, but rather on all long sides. This approach eliminated the need to arbitrarily select a single long side when there were more than one and, as a result, it added an element of robustness to the algorithm. Experience has since shown, however, that the robustness benefit is small and that trisecting on a single long side (as here) accelerates convergence in higher dimensions.

Let us now consider how the rectangle selection procedure can be extended to handle inequality constraints. The key to handling constraints in DIRECT is to work with an *auxiliary function* that combines information on the objective and constraint functions in a special manner. To express this auxiliary function, we will need some additional notation. Let  $g_{rj}$  denote the value of constraint  $j$  at the midpoint of rectangle  $r$ . In addition, let  $c_1, \dots, c_m$  be positive weighting coefficients for the inequality constraints (we will discuss how these coefficients are computed later). Finally, for the sake of the exposition, let us again suppose that we know the optimal function value  $f^*$ . The auxiliary function, evaluated at the center of rectangle  $r$ , is then as follows:

$$\max(f_r - f^*, 0) + \sum_{j=1}^m c_j \max(g_{rj}, 0)$$

The first term of the auxiliary function exacts a penalty for any deviation of the function value  $f_r$  above the global minimum value  $f^*$ . Note that, in a constrained problem, it is possible for  $f_r$  to be less than  $f^*$  by violating the constraints; due to the maximum operator, the auxiliary function gives no credit for values of  $f_r$  below  $f^*$ . The second term in the auxiliary function is a sum of weighted constraint violations. Clearly, the lowest possible value of the auxiliary function is zero and occurs only at the global minimum. At any other point, the auxiliary function is positive either due to suboptimality or infeasibility.

This auxiliary function is not a *penalty function* in the standard sense. A standard penalty function would be a weighted sum of the objective function and constraint violations; it would not include the value  $f^*$  since this value is generally unknown. Moreover, in the standard approach, it is critical that the penalty coefficients be sufficiently large to prevent the penalty function from being minimized in the infeasible region.

This is not true for our auxiliary function: as long as  $f^*$  is the optimal function value, the auxiliary function is minimized at the global optimum for *any* positive constraint coefficients.

For the global minimum to occur in rectangle  $r$ , the auxiliary function must fall to zero starting from its (positive) value at the center point. Moreover, the maximum distance over which this change can occur is the center-vertex distance  $d_r$ . Thus, to reach the global minimum in rectangle  $r$ , the auxiliary function must undergo a minimum rate of change, denoted  $h_r(f^*)$ , given by

$$h_r(f^*) = \frac{\max(f_r - f^*, 0) + \sum_{j=1}^m c_j \max(g_{rj}, 0)}{d_r}.$$

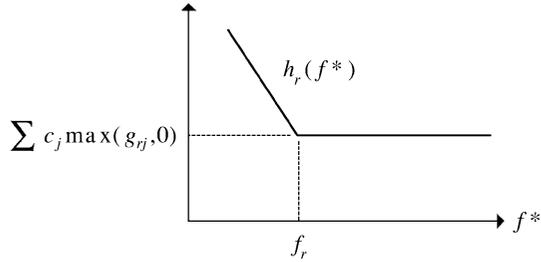

Since it is more reasonable to expect gradual changes than abrupt ones, a reasonable way to select a rectangle would be to select rectangle that minimizes the rate of change  $h_r(f^*)$ . Of course, this is impractical because we generally will not know the value  $f^*$ . Nevertheless, it is possible to select the set of rectangles that minimize  $h_r(f^*)$  for *some*  $f^* \leq f_{\min} - \epsilon$ . This is how we select rectangles with constraints—assuming a feasible point has been found so that  $f_{\min}$  is well-defined (we will show how this is implemented shortly). If no feasible point has been found, we simply select the rectangle that minimizes

$$\frac{\sum_{j=1}^m c_j \max(g_{rj}, 0)}{d_r}.$$

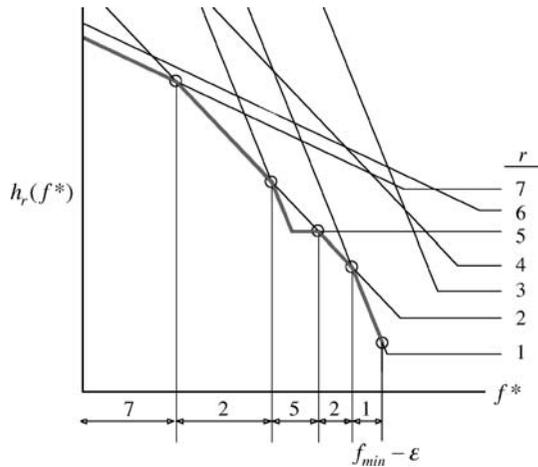

That is, we select the rectangle where the weighted constraint violations can be brought to zero with the least rate of change.

To implement this selection rule, it is again helpful to draw a diagram. This new selection diagram is based on plotting the rate-of-change function  $h_r(f^*)$  as a function of  $f^*$ . Figure 6 illustrates this function. For values of  $f^* \geq f_r$ , the first term in the numerator of  $h_r(f^*)$  is zero, and so  $h_r(f^*)$  is constant. As  $f^*$  falls below  $f_r$ , however, the  $h_r(f^*)$  increases, because we now exact a penalty for  $f_r$  being above the supposed global minimum  $f^*$ . The slope of  $h_r(f^*)$  function to the left of  $f_r$  is  $-1/d_r$ .

Figure 7 superimposes, in one diagram, the rate-of-change functions for a hypothetical set of seven rectangles. For a particular value of  $f^*$ , we can visually find the rectangle that minimizes  $h_r(f^*)$  by starting at the point

Direct Global Optimization Algorithm, Figure 6

Direct Global Optimization Algorithm, Figure 7

$(f^*, 0)$  along the horizontal axis and moving vertically until we first encounter a curve. What we want, however, is the set of *all* rectangles that can be selected in this way using *any*  $f^* \leq f_{\min} - \epsilon$ . This set can be found as follows (see Fig. 7). We start with  $f^* = f_{\min} - \epsilon$  and move upwards until we first encounter a curve for some rectangle. We note this rectangle and follow its curve to the left until it intersects the curve for another rectangle (these intersections are circled in Figure 7). When this happens, we note this other rectangle and follow its curve to the left. We continue in this way until we find a curve that is never intersected by another one. This procedure will identify all the  $h_r(f^*)$  functions that participate in the lower envelope of the curves to the left of  $f_{\min} - \epsilon$ . The set of rectangles found in this way is the set selected by DIRECT.

Along the horizontal axis in Fig. 7, we identify ranges of  $f^*$  values for which different rectangles have the lowest value of  $h_r(f^*)$ . As we scan from  $f_{\min} - \epsilon$  to

the left, the rectangles that participate in the lower envelope are 1, 2, 5, 2, and 7. This example illustrates that it is possible to encounter a curve more than once (here rectangle 2), and care must be taken not to double count such rectangles. It is also possible for some curves to coincide along the lower envelope, and so be ‘tied’ for the least rate of change (this does not happen in Fig. 7). In such cases, we select all the tied rectangles.

Tracing the lower envelope in Fig. 7 is not computationally intense. To see this, note that each selected rectangle corresponds to a curve on the lower envelope, and for each such curve the work we must do is to find the intersection with the next curve along the lower envelope. Finding this next intersection requires computing the intersection of the current curve with all the other curves. It follows that the work required for each selected rectangle (and hence for every two sampled points) is only on the order of the total number of rectangles in the partition.

The tracing of the lower envelope can also be accelerated by some pre-processing. In particular, it is possible to quickly identify rectangles whose curves lie completely above other curves. For example, in Fig. 7, curve 3 lies above curve 1, and curve 4 lies above curve 2. These curves cannot possibly participate in the lower envelope, and so they can be deleted from consideration before the lower envelope is traced.

It remains to explain how the constraint coefficients  $c_1, \dots, c_m$  are computed, as well as a few other details about trisection and the handling of integer variables. We will cover these details in turn, and then bring everything together into a step-by-step description of the algorithm.

To understand how we compute the constraint coefficient  $c_j$ , suppose for the moment that we knew the average rate of change of the objective function, denoted  $a_0$ , and the average rate of change of constraint  $j$ , denoted  $a_j$ . Furthermore, suppose that at the center of a rectangle we have  $g_j > 0$ . At the average rate of change of constraint  $j$ , we would have to move a distance equal to  $g_j/a_j$  to get rid of the constraint violation. If during this motion the objective function got worse at its average rate of change, it would get worse by  $a_0$  times the distance, or  $a_0(g_j/a_j) = (a_0/a_j) g_j$ . Thus we see that the ratio  $a_0/a_j$  provides a way of converting units of constraint violation into potential increases in the objective function. For this reason, we will set  $c_j = a_0/a_j$ .

The average rates of change are estimated in a very straightforward manner. We maintain a variable  $s_0$  for the sum of observed rates of change of the objective function. Similarly we maintain variables  $s_1, \dots, s_m$  for the sum of observed rates of change for each of the  $m$  constraints. All of these variables are initialized to zero at the start of the algorithm and updated each time a rectangle is trisected. Let  $x^{\text{mid}}$  denote the midpoint of the parent rectangle and let  $x^{\text{left}}$  and  $x^{\text{right}}$  denote the midpoints of the left and right child rectangles after trisection. The variables are updated as follows:

$$s_0 = s_0 + \sum_{\text{child}=\text{left}}^{\text{right}} \frac{|f(x^{\text{child}}) - f(x^{\text{mid}})|}{\|x^{\text{child}} - x^{\text{mid}}\|}$$

$$s_j = s_j + \sum_{\text{child}=\text{left}}^{\text{right}} \frac{|g_j(x^{\text{child}}) - g_j(x^{\text{mid}})|}{\|x^{\text{child}} - x^{\text{mid}}\|}.$$

Now the average rates of change are  $a_0 = s_0/N$  and  $a_j = s_j/N$ , where  $N$  is the number of rates of change accumulated into the sums. It follows that

$$\frac{a_0}{a_j} = \frac{\frac{s_0}{N}}{\frac{s_j}{N}} = \frac{s_0}{s_j}.$$

We may therefore compute  $c_j$  using

$$c_j = \frac{s_0}{\max(s_j, 10^{-30})},$$

where we use the maximum operator in the denominator to prevent division by zero.

So far we have said that we will always trisect a rectangle along one of its long sides. However, as shown in Fig. 2, several sides may be tied for longest, and so we need some way to break these ties. Our tie breaking mechanism is as follows. We maintain counters  $t_i$  ( $i = 1, \dots, n$ ) for how many times we have split along dimension  $i$  over the course of the entire search. These counters are initialized to zero at the beginning of the algorithm, and counter  $t_i$  is incremented each time a rectangle is trisected along dimension  $i$ . If we select a rectangle that has several sides tied for being longest, we break the tie in favor of the side with the lowest  $t_i$  value. If several long sides are also tied for the lowest  $t_i$  value, we break the tie arbitrarily in favor of the lowest-indexed dimension. This tie breaking strategy has the effect of equalizing the number of times we split on the different dimensions.

Let us now turn to the calculation of the center-vertex distance. Recall that we measure distance using a weighted metric that assigns a length of one to the initial range of each variable ( $u_i - \ell_i$ ). Each time a rectangle is split, the length of that side is then reduced by a factor of  $1/3$ . Now consider a rectangle that has been trisected  $T$  times. Let  $j = \text{mod}(T, n)$ , so that we may write  $T = kn + j$  where  $k = (T - j)/n$ . After the first  $kn$  trisections, all of the  $n$  sides will have been trisected  $k$  times and will therefore have length  $3^{-k}$ . The remaining  $j$  trisections will make  $j$  of the sides have length  $3^{-(k+1)}$ , leaving  $n - j$  sides with length  $3^{-k}$ . Simple algebra then shows that the distance  $d$  from the center to the vertices is given by

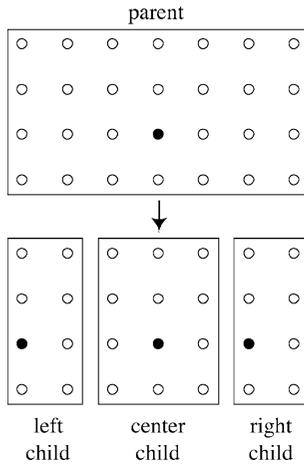

$$d = \frac{3^{-k}}{2} \left( \frac{j}{9} + n - j \right)^{0.5}.$$

(This is not obvious, but can be easily verified.)

The handling of integer variables is amazingly simple, involving only minor changes to the trisection routine and to the way the midpoint of a rectangle is defined. For example, consider an integer variable with range  $[1, 8]$ . We could not define the midpoint to be 4.5 because this is not an integer. Instead, we will use the following procedure. Suppose the range of a rectangle along an integer dimension is  $[a, b]$ , with both  $a$  and  $b$  being integers. We will define the ‘midpoint’ as  $\lfloor (a + b)/2 \rfloor$ , that is, it is the floor of algebraic average (the floor of  $z$ , denoted  $\lfloor z \rfloor$ , is the greatest integer less than or equal to  $z$ ).

To trisect along the integer dimension, we first compute  $\Delta = \lfloor (b - a + 1)/3 \rfloor$ . If  $\Delta \geq 1$ , then after trisection the left child will have the range  $[a, a + \Delta - 1]$ , the center child will have the range  $[a + \Delta, b - \Delta]$ , and the right child will have range  $[b - \Delta + 1, b]$ . If  $\Delta = 0$ , then the integer side must have a range of two (i. e.,  $b = a + 1$ ). In this case, the center child will have the range  $[a, a]$  the right child will have the range  $[b, b]$ , and there will be no left child. This procedure maintains the property that the midpoint of the parent rectangle always becomes the midpoint of the center child. As an example, Fig. 8 shows how a rectangle would be trisected when there are two integer dimensions. In the figure, the circles represent possible integer combinations, and the filled circles represent the midpoints.

Integer variables introduce three other complications. The first, which may be seen in Fig. 8, is that the

Direct Global Optimization Algorithm, Figure 8

sampled point may not be in the true geometric center of the rectangle. As a result, the center-vertex distance will not be unique but will vary from vertex to vertex. We ignore this detail and simply use the formula given above for the continuous case, which only depends upon the number of times a rectangle has been trisected.

The second complication concerns how we define a ‘long’ side. In the continuous case, the length of a side is directly related to the number of times it has been trisected along that dimension. Specifically, if a rectangle has been split  $k$  times along some side, then the side length will be  $3^{-k}$  (recall that we measure distance relative to the original range of each variable). In the continuous case, therefore, the set of long sides is the same as the set of sides that have been split upon the least. When there are integers, however, the side lengths will no longer be multiples of  $1/3$ . To keep things simple, however, we ignore this and continue to define a ‘long’ side as one that has been split upon the least. However, if an integer side has been split so many times that its side length is zero (i. e., the range contains a single integer), then this side will not be considered long.

The third and final complication is that, if *all* the variables are integer, then it is possible for a rectangle to be reduced to a single point. If this happens, the rectangle would be fathomed; hence, it should be ignored in the rectangle selection process in all subsequent iterations.

DIRECT stops when it reaches a user-defined limit on function evaluations. It would be preferable, of course, to stop when we have achieved some desired accuracy in the solution. However, for black-box problems where we only assume continuity, better stopping rules are hard to develop.

As for convergence, it is easy to show that, as  $f^*$  moves to  $-\infty$ , DIRECT will select one of the largest rectangles. Because we always select one of the largest rectangles, and because we always subdivide on a long side, every rectangle will eventually become very small and the sampled points will be dense in the space. Since we also assume the functions are continuous in the neighborhood of the optimum, this insures that we will get within any positive tolerance of the optimum after a sufficiently large number of iterations.

Although we have now described all the elements of DIRECT, our discussion has covered several pages, and so it will be helpful to bring everything together in a step-by-step description of the algorithm.

1) Initialization.

Sample the center point of the entire space. If the center is feasible, set  $x_{\min}$  equal to the center point and  $f_{\min}$  equal to the objective function value at this point. Set  $s_j = 0$  for  $j = 0, \dots, m$ ;  $t_i = 0$  for  $i = 1, \dots, n$ ; and  $\text{neval} = 1$  (function evaluation counter). Set  $\text{maxeval}$  equal to the limit on the number of function evaluations (stopping criterion).

2) Select rectangles.

Compute the  $c_j$  values using the current values of  $s_0$  and  $s_j$ ,  $j = 1, \dots, m$ . If a feasible point has *not* been found, select the rectangle that minimizes the rate of change required to bring the weighted constraint violations to zero. On the other hand, if a feasible point has been found, identify the set of rectangles that participate in the lower envelope of the  $h_r(f^*)$  functions for some  $f^* \leq f_{\min} - \epsilon$ . A good value for  $\epsilon$  is  $\epsilon = \max(10^{-4} |f_{\min}|, 10^{-8})$ . Let  $S$  be the set of selected rectangles.

3) Choose any rectangle  $r \in S$ .

4) Trisect and sample rectangle  $r$ .

Choose a splitting dimension by identifying the set of long sides of rectangle  $r$  and then choosing the long side with the smallest  $t_i$  value. If more than one side is tied for the lowest  $t_i$  value, choose the one with the lowest-dimensional index. Let  $i$  be the resulting splitting dimension. Note that a ‘long side’

is defined as a side that has been split upon the least and, if integer, has a positive range. Trisect rectangle  $r$  along dimension  $i$  and increment  $t_i$  by one. Sample the midpoint of the left third, increment  $neval$  by one, and update  $x_{\min}$  and  $f_{\min}$ . If  $neval = \maxeval$ , go to Step 7. Otherwise, sample the midpoint of the right third, increment  $neval$  by one, and update  $x_{\min}$  and  $f_{\min}$  (note that there might not be a right child when trisecting on an integer variable). Update the  $s_j$   $j = 0, \dots, m$ . If all  $n$  variables are integer, check whether a child rectangle has been reduced to a single point and, if so, delete it from further consideration. Go to Step 5.

5) Update  $S$ .

Set  $S = S - \{r\}$ . If  $S$  is not empty, go to Step 3. Otherwise go to Step 6.

6) Iterate.

Report the results of this iteration, and then go to Step 2.

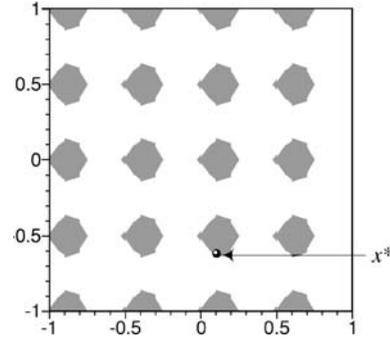

7) Terminate.

The search is complete. Report  $x_{\min}$  and  $f_{\min}$  and stop.

The results of DIRECT are slightly sensitive to the order in which the selected rectangles are trisected and sampled because this order affects the  $t_i$  values and, hence, the choice of splitting dimensions for other selected rectangles. In our current implementation, we select the rectangles in Step 3 in the same order that they are found as we scan the lower envelope in Fig. 7 from  $f^* = f_{\min} - \epsilon$  towards  $f^* = -\infty$ .

On the first iteration, all the  $s_j$  will be zero in Step 2 and, hence, all the  $c_j$  will be zero when computed using  $c_j = s_0 / \max(s_j, 10^{-30})$ . Thus, in the beginning the constants  $c_j$  will not be very meaningful. This is not important, however, because on the first iteration there is only one rectangle eligible for selection (the entire space), and so the selection process is trivial. As the iterations proceed, the  $s_j$  will be based on more observations, leading to more meaningful  $c_j$  constants and better rectangle selections.

When there are no inequality constraints, the above step-by-step procedure reduces to the basic version of DIRECT described earlier. To see this, note that, when there are no constraints, every point is feasible and so  $f_r \geq f_{\min} \geq f^*$  for all rectangles  $r$ . This fact, combined with the lack of any constraint violations, means that the  $h_r(f^*)$  function given earlier reduces to  $(f_r - f^*)/d_r$ ,

Direct Global Optimization Algorithm, Figure 9

which is precisely the rate-of-change function we minimized in the unconstrained version. Thus, in the unconstrained case, tracing the lower envelope in Fig. 7 identifies the same rectangles as tracing the lower-right convex hull in Fig. 5.

We will illustrate DIRECT on the following two-dimensional test function:

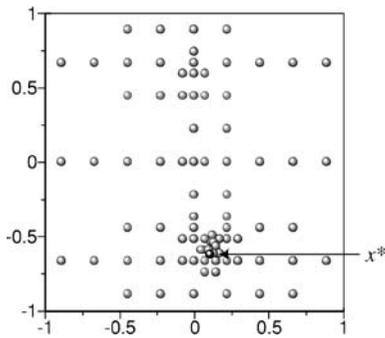

$$\begin{cases} \min & f(x_1, x_2) \\ \text{s.t.} & g(x_1, x_2) \leq 0 \\ & -1 \leq x_1, x_2 \leq +1, \end{cases}$$

where

$$\begin{aligned} f(x_1, x_2) &= \left(4 - 2.1x_1^2 + \frac{x_1^4}{3}\right)x_1^2 + x_1x_2 + (-4 + 4x_2^2)x_2^2, \\ g(x_1, x_2) &= -\sin(4\pi x_1) + 2\sin^2(2\pi x_2). \end{aligned}$$

We call this problem the *Gomez #3 problem* since it was listed as the third test problem in an article by S. Gomez and A. Levy [1]. The global minimum of the Gomez #3 problem occurs at the point (0.109, -0.623) where the function value is -0.9711. The problem is difficult because the feasible region consists of many disconnected, approximately circular parts, giving rise to many local optima (see Fig. 9).

For this test function, DIRECT gets within 1% of the optimum after 89 function evaluations and within 0.01% after 513 function evaluations. The first 89 sampled points are shown in Fig. 10. For comparison, the tunneling algorithm of Gomez and Levy [1] converged using an average of 1053 objective function evaluations and 1873 constraint evaluations (averaged over 20 random starting points). One reason DIRECT converges

Direct Global Optimization Algorithm, Figure 10

quickly is that it searches both globally and locally during each iteration; as a result, as soon as the global part of the algorithm finds the basin of convergence of the optimum, the local part of the algorithm automatically exploits it.

In this example, DIRECT quickly gets close to the optimum but takes longer to achieve a high degree of accuracy. This suggests that the best performance would be obtained by combining DIRECT with a good local optimizer. The simplest way to do this is to run DIRECT for a predetermined number of function evaluations and then use the resulting solution as a starting point for a local optimization. While straightforward, this approach is highly sensitive to the number of function evaluations used in the global phase with DIRECT. If one uses too few function evaluations, DIRECT might not discover the basin of convergence of the global minimum.

To ensure that the global optimum is eventually found, we must somehow return to the global phase after we have performed a local search. One way of doing this is as follows. We start the local optimizer the very first time a feasible point is found (or perhaps after a minimum initial phase of 50–100 evaluations). After the local finishes, we return to DIRECT. However, DIRECT does not proceed the same as it would have without the local optimizer. Instead, the search will be more global, because the local optimizer will have reduced the value of  $f_{\min}$  (which affects rectangle selection). DIRECT will now be looking for a point that improves upon the local solution—in effect, it will be looking for the basin of convergence of a better minimum. If DIRECT finds such an improving point, then

we run a local search from this point and again return to DIRECT. This process continues until we reach a predetermined limit on the total number of function evaluations (for both DIRECT and the local optimizer). Used in this way, DIRECT becomes an intelligent routine for selecting starting points for the local optimizer.

While DIRECT works well on the Gomez #3 problem and on test functions reported in [2], the algorithm is not without its disadvantages. For example, DIRECT's use of a space-partitioning approach requires the user to have relatively tight lower and upper bounds on all the variables. DIRECT will perform miserably if one specifies wide bounds such as  $[-10^{30}, +10^{30}]$ . The space-partitioning approach also limits the algorithm to low-dimensional problems (say, less than 20). While integer variables are handled, they must be ordered, such as the number of gear teeth, since only then can we expect the function value at a rectangle's midpoint to be indicative of what the function is like in the rest of the rectangle. Another limitation is that equality constraints are not handled. Finally, the stopping criterion—a limit on function evaluations—is weak.

The advantages of DIRECT, however, are considerable. The algorithm can handle nonsmooth, nonlinear, multimodal, and even discontinuous functions (as long as the discontinuity is not close to the global optimum). The algorithm works well in the presence of noise, since a small amount of noise usually has little impact on the set of selected rectangles until late in the search. Computational overhead is low, and the algorithm can exploit parallel processing because it generates several new points per iteration. Based on the comparisons in [2], the algorithm also appears to be efficient in terms of the number of function evaluations required to get close to the global minimum. But the most important advantage of DIRECT stems from its unique approach to balancing local and global search—the simple idea of not sampling just one point per iteration, but rather sampling several points using all possible weightings of local versus global search. This approach leads to an algorithm with no tuning parameters, making the algorithm easy-to-use and robust.

Optimization; Direct search; Nonseparable problem optimization; Sensitivity; Global optimization

Direct search optimization procedures are attractive because of the ease with which they can be used. Optimization procedures where auxiliary functions such

as gradients are not calculated are desirable for problems where discontinuous functions are encountered, or where numerous constraints make the calculation and use of gradients very difficult in searching for the global optimum. The reliability of getting to the vicinity of the global optimum is an additional feature that makes the use of direct search optimization an attractive means of optimization.

The need for an efficient and easy to use optimization procedure was illustrated in [1], in attempting to obtain the best weighting factors in a Liapunov function used for time suboptimal control of a linear gas absorber. Although at that time the best optimization procedure for that problem was the hill-climbing procedure due to H.H. Rosenbrock [35], the method encountered difficulties in establishing the global optimum. In the 1970s a large number of direct search optimization procedures were introduced. One such method is due to R. Luus and T.H.I. Jaakola [29], which has been called in the literature by numerous authors as the *LJ optimization procedure*. The method is based on using a number of randomly chosen test points over some region and contracting the region after every iteration, always starting the iteration with the best point found from the previous iteration as the center of the region. The ease of programming and the ease with which inequality constraints can be handled make this direct search procedure attractive.

## Optimization Problem

We consider the problem of minimizing the *performance index* or *cost function*

$$I = f(x_1, \dots, x_n) \quad (1)$$

subject to  $p$  inequality constraints

$$g_j(x_1, \dots, x_n) \geq 0, \quad j = 1, \dots, p, \quad (2)$$

through the appropriate choice of  $x_1, \dots, x_n$ . The direct search optimization procedure suggested in [29] involves only three steps:

- Choose a number of points in the  $n$ -dimensional space through the equation

$$\mathbf{x} = \mathbf{x}^* + \mathbf{D}\mathbf{r}, \quad (3)$$

where  $\mathbf{D}$  is a diagonal matrix with diagonal elements chosen at random between  $-1$  and  $+1$ , and  $\mathbf{r}$  is the region size vector.

- Check the feasibility of each point with respect to (2), and for each feasible point evaluate the performance index  $I$  in (1).
- At the end of each iteration,  $\mathbf{x}^*$  is replaced by the best feasible value of  $\mathbf{x}$  obtained in Step 2, and the region size vector  $\mathbf{r}$  is reduced in size by

$$\mathbf{r}^{(j+1)} = \gamma \mathbf{r}^{(j)}, \quad (4)$$

where  $\gamma$  is a contraction factor such as 0.95. This procedure is continued for a number of iterations and the results are examined.

If adequate convergence is not obtained, then the procedure can be repeated by carrying out another pass, using the information obtained from the previous pass. This optimization procedure enabled several difficult optimization problems to be solved in the original paper [29], and provided a means to solve a wide variety of problems in optimal control, such as time sub-optimal control [9,8,7] and gave good approximation to optimal control by providing a means of obtaining the elements for the feedback gain matrix. The LJ optimization procedure was found very useful for stabilizing systems through shifting of poles [30] and testing stabilizability of linear systems [13]. Research was done to improve the likelihood of getting the global optimum for nonunimodal systems [37], but even without any modification, the reliability of the LJ procedure was found to be very good [38], even for the difficult bifunctional catalyst blend problem [26]. Therefore, the LJ optimization procedure could be used effectively for optimization of complex systems such as heat exchanger networks [17], a transformer design problem [36], design of structural columns in such a way that the amount of material would be minimized [3], and problems dealing with metallurgical processes [34]. The simplicity of the method was illustrated by the computer program given in its entirety in reference [17].

When the variables are restricted to be integers, special procedures may be necessary [12], since we cannot simply search on integer values to get the global optimum. Thus the scope of problems where LJ optimization procedure has been successfully applied is quite wide. In parameter estimation, N. Kalogerakis and Luus [6] found that by LJ optimization reliable estimates could be obtained for parameters in very

few iterations, so that these estimates could then be used as starting values for quadratically convergent Gauss–Newton method, without having to worry about nonconvergence. In model reduction the LJ method has been found useful to match the reduced system’s Nyquist plot to that of the original system [15], or used directly in time domain [40]. LJ optimization procedure has also been used successfully in model reduction in sampled-data systems [39] and is illustrated with several examples in [23].

### Handling Equality Constraints

Suppose that in addition to the inequality constraints in (2), we also have  $m$  equality constraints

$$h_i(x_1, \dots, x_n) = 0, \quad i = 1, \dots, m, \quad (5)$$

where these equality constraints are ‘difficult’ in the sense that they can not be used to solve for some particular variable.

Although a two-pass method to deal with equality constraints [10] was effective to solve optimization problems involving recycle streams [11], the general approach for handling *equality constraints* with LJ optimization procedure was not solved satisfactorily, until it was shown [4] that *penalty functions* can be used very effectively in direct search optimization. The work was extended in [33], and now it appears that the use of a quadratic penalty function incorporating a shifting term is the best way of dealing with difficult equality constraints [19]. We consider the *augmented performance index*

$$J = I + \theta \sum_{i=1}^m (h_i - s_i)^2, \quad (6)$$

where a shifting term  $s_i$  is introduced for each equality constraint. To solve the optimization problem, LJ optimization procedure is used in a multipass fashion, where at the beginning of each pass consisting of a number of iterations, the region sizes are restored to a fraction of the sizes used at the beginning of the previous pass. The shifting terms  $s_i$  are updated after every pass simply by adjusting the values at the beginning of pass  $(q+1)$  based on the deviation of the left-hand side

in (5) from zero; i. e.,

$$s_i^{(q+1)} = s_i^{(q)} - h_i, \quad i = 1, \dots, m, \quad (7)$$

where  $q$  is the pass number. Upon optimization the product  $-2\theta s_i$  gives the Lagrange multiplier associated with the  $i$ th equality constraint, yielding useful sensitivity information. Full details are given in [19]. This approach to dealing with equality constraints was used in [31] in using *iterative dynamic programming* (IDP) to solve an optimal control problem where the final state was specified, and in [28] where the volume of the fed-batch reactor was specified at the final time.

Another approach to deal with equality constraints is to solve the algebraic equations at each iteration by grouping the equations [21]. For several optimization problems this approach yielded very rapid convergence to the global optimum [22].

### Use of LJ Optimization Procedure for High-Dimensional Problems

In [2] it was found that LJ optimization can be used quite effectively to solve optimal control problems, where the system is divided into a number of time stages. This approach was used in [27] to solve a very difficult optimal control problem involving the determination of the optimum drug delivery schedule to minimize the tumor size at the end of 12 weeks. The problem was broken into 84 time stages, each consisting of a single day. In spite of the *state constraints* and *discontinuous functions*, this 84-dimensional optimization problem was solved successfully on a personal computer in reasonable computation time. Especially now that the personal computers are much faster, such a problem is considerably easier to solve. To solve high-dimensional problems a multipass method was used for LJ optimization where after a pass, the region would be restored to a value smaller than used at the beginning of the previous pass and the procedure was repeated. In the case of the *cancer chemotherapy* problem, the problem required a number of runs for successful solution [27].

### Determination of Region Size

One of the problems that was outstanding for the LJ optimization procedure was how to choose the region size

vector  $\mathbf{r}$  effectively at the beginning of the iterations, especially when a multipass procedure was used. This problem was recently solved in [20], by suggesting that the initial region size be determined by the extent of the variation of the variable during the previous pass. With the use of reliable values for the region size at the beginning of each pass in a multipass run, the computational effort is decreased quite substantially. For example, when we consider the *nonseparable optimization problem* introduced in [32], where we have a system described by three difference equations:

$$\begin{aligned} x_1(k+1) &= \frac{x_1(k)}{1 + 0.01u_1(k)(3 + u_2(k))}, \\ x_2(k+1) &= \frac{x_2(k) + u_1(k)x_1(k+1)}{1 + u_1(k)(1 + u_2(k))}, \\ x_3(k+1) &= \frac{x_3(k)}{1 + 0.01u_2(k)(1 + u_3(k))}, \end{aligned}$$

with the initial condition

$$\mathbf{x}(0) = [2 \quad 5 \quad 7]^\top.$$

The control variables are constrained by

$$\begin{aligned} 0 &\leq u_1(k) \leq 4, \\ 0 &\leq u_2(k) \leq 4, \\ 0 &\leq u_3(k) \leq 0.5. \end{aligned}$$

The performance index to be minimized is

$$\begin{aligned} I &= x_1^2(P) + x_2^2(P) + x_3^2(P) \\ &+ \left[ \left( \sum_{k=1}^P x_1^2(k-1) + x_2^2(k-1) + 2u_3^2(k-1) \right) \right. \\ &\cdot \left. \left( \sum_{k=1}^P x_3^2(k-1) + 2u_1^2(k-1) + 2u_2^2(k-1) \right) \right]^{\frac{1}{2}} \end{aligned}$$

where  $P$  is the number of stages. When  $P$  is taken as 100, then we have a 300 variable optimization problem, because at each stage there are three control variables

to be determined. Without the use of a reliable way of determining the region sizes over which to take the control variables, the problem is very difficult, but with the method suggested in [20] the problem was solved quite readily by the LJ optimization procedure by using 100 random points per iteration and 60 passes, each consisting of 201 iterations, to yield  $I = 258.3393$ . Although the computational requirements appear enormous, the actual computation time was less than 20 minutes on a Pentium-120 personal computer [20], which corresponds to less than one minute on the Pentium4/2.4 GHz personal computer. This value of the performance index is very close to the value  $I = 258.3392$  obtained by use of iterative dynamic programming [18]. To solve this problem, IDP is much more efficient in spite of the nonseparability of the problem, because in IDP the problem is solved as a 3 variable problem over 100 stages, rather than a 300 variable optimization problem. Therefore, the LJ procedure is useful in checking the optimal control policy obtained by some other method. Here, the control policies obtained by IDP and LJ optimization procedure are almost identical, where a sudden change at around stage 70 occurs in the control variables  $u_1$  and  $u_2$ . Therefore, LJ optimization procedure is ideally suited for checking results obtained by other methods, especially when the optimal control policy differs from what is expected, as is the case with this particular example.

Recently it was shown that the convergence of the LJ optimization procedure in the vicinity of the optimum can be improved substantially by incorporating a simple line search to choose the best center point for a subsequent pass [24]. For a typical model reduction problem, to reach the global optimum the computation time was reduced by a factor of four when the line search was incorporated. Due to its simplicity, the LJ optimization procedure can be programmed very easily. Computational experience with numerous optimization problems has shown that the method has high reliability of obtaining the *global optimum*, so the LJ optimization procedure provides a very good means of obtaining the optimum for very complex problems.

### Keywords

Discontinuous optimization; Nondifferentiable optimization; Piecewise linear programming; Active set methods; Exact penalty method

Continuous optimization refers to optimization involving objective functions whose domain of definition is a continuum, as opposed to a set of discrete points in combinatorial (or discrete) optimization. Discontinuous optimization is the special case of continuous optimization in which the objective function, although defined over a continuum (let us suppose over  $\mathbf{R}^n$ ), is not necessarily a continuous function.

We define the discontinuous optimization problem as:

$$\begin{cases} \inf & \tilde{f}(x) \\ \text{s.t.} & f_i(x) = 0, \quad i \in E, \\ & f_i(x) \geq 0, \quad i \in I, \end{cases} \quad (1)$$

where the index sets  $E$  and  $I$  are finite and disjoint and  $\tilde{f}$  and  $f_i$ ,  $i \in E \cup I$  are a collection of (possibly discontinuous) piecewise differentiable functions that map  $\mathbf{R}^n$  to  $\mathbf{R}$ . A *piecewise differentiable function*  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  is a function whose derivative is defined everywhere except over a subset of a finite number of sets, called *ridges*, of the form  $\{x \in \mathbf{R}^n: r(x) = 0\}$ , where  $r$  is a differentiable function, and these ridges partition the domain into subdomains over each of which  $f$  is differentiable. By abuse of language, we shall call  $r(x)$  a ridge of  $f$ .

Without loss of generality, we can restrict our attention to the *unconstrained optimization problem*:  $\inf_x f(x)$ , where  $f$  is a (possibly discontinuous) piecewise differentiable function. Indeed, in order to solve problem (1), one can consider the unconstrained  $l_1$  exact penalty function

$$f_\gamma(x) := \gamma \tilde{f}(x) + \sum_{i \in E} |f_i(x)| - \sum_{i \in I} \min[0, f_i(x)]$$

for a succession of decreasing positive values of the penalty parameter  $\gamma$  ( $f_\gamma$  is clearly a piecewise differentiable function). Notice however that using the  $l_1$  penalty function (and dealing with the decrease of a penalty parameter) is only one approach to handling the constrained problem and may not be the best way.

Given a (possibly discontinuous) piecewise differentiable function  $f$  defined over  $\mathbf{R}^n$  and the finite set  $\{r_i(x)\}_{i \in \mathcal{R}}$  of its ridges, we define a *cell* of  $f$  to be a nonempty set  $C \subseteq \mathbf{R}^n$  such that for all  $x, y \in C$  we have  $\text{sign}(r_i(x)) = \text{sign}(r_i(y)) \neq 0$ , for all  $i \in \mathcal{R}$ , where the function  $\text{sign}$  is either 1,  $-1$  or 0, according to whether its argument is positive, negative or zero. Thus,  $f$  is differentiable over a cell.

Considering the optimization of functions which are nonsmooth and even discontinuous is motivated by applications in VLSI and floor-planning problems, plant layout, batch production, switching regression, discharge allocation for hydro-electric generating stations, fixed-charge problems, for example (see [4, Introd.] for references). Note that most of these problems can alternatively be modeled within the context of mixed integer programming, a field straddling combinatorial optimization and continuous optimization.

The inescapable nonconvexity nature of discontinuous functions gives rise to the existence of several local optima in discontinuous optimization problems. We do not address here the difficult issue of global optimization. We are concerned with finding a *local* infimum of the above optimization problem. An algorithm looking for local optima can however be used as an adjunct to some heuristic or global optimization method for discontinuous optimization problems but

the inherent combinatorial nature of such an approach is often ultimately dominant. More importantly, it provides a framework allowing the optimizer to deal directly with the nonsmoothness and discontinuities involved, and thereby, improve solutions found by heuristic methods, when this is possible.

Leaving aside the heuristic methods (which many people facing practical discontinuous optimization problems rely upon in order to solve mixed integer programming formulation of discontinuous optimization problems), previous work on discontinuous optimization includes smoothing algorithms. The *smoothing algorithms* express discontinuities by means of a step function, and then they approximate the step function by a function which is not only continuous but moreover smooth, so that the resulting problem can be solved by a gradient technique (cf. also ► **Conjugate-gradient methods**). Both I.I. Imo and D.J. Leech [7] and I. Zang [9] developed methods in which the objective function is replaced only in the neighborhood of the discontinuities. Two drawbacks of these methods are the potential numerical instability when we want this neighborhood to be small, and the cost of evaluating the smoothed functions. In many instances the discontinuities of the first derivative are exactly the regions of interest and smoothing has the effect of making such regions less discernible.

Another approach, which deals explicitly with the discontinuities within the framework of continuous optimization, is the following *active set method* (introduced in [4]). Recall the following definitions relevant to active set methods: the *null space* of  $M$ , denoted by  $\mathcal{N}(M)$ , is defined by

$$\mathcal{N}(M) \equiv \left\{ x \in \mathbf{R}^n : Mx = \vec{0} \right\}.$$

We say that a ridge  $r$  is *active* at  $\hat{x}$  if  $r(\hat{x}) = 0$ . Let  $\mathcal{A}(\hat{x}) \subseteq \mathcal{R}$  be the (finite) index set of the ridges that are active at the current point  $\hat{x}$ , and let  $A(\hat{x})$  be the *matrix of activities*, having as columns the gradients of the ridges that are active at  $\hat{x}$ . In the case of linear ridges,  $r_i(x) := a_i^\top x - b_i$ , a direction  $d \in \mathcal{N}(A^\top(\hat{x}))$  is said to *preserve* each activity  $i \in \mathcal{A}(\hat{x})$  since for each  $i \in \mathcal{A}(\hat{x})$  we have  $r_i(\hat{x} + \alpha d) = r_i(\hat{x}) = 0$ .

If  $\mathcal{A}(\hat{x}) \neq \emptyset$ , then  $\nabla f(\hat{x})$  is not necessarily defined. This is because we cannot talk about the gradient of the

function at  $\hat{x}$  since there is no vector  $g \in \mathbf{R}^n$  such that  $g^\top d$  is the first order change of  $f$  in direction  $d$ , for any  $d \in \mathbf{R}^n$ . Thus, we cannot use, as in the smooth situation, the negative gradient direction as a descent direction. We term any  $(n \times 1)$ -vector  $g_{\hat{x}}$  such that

$$f'(\hat{x}; d) = g_{\hat{x}}^\top d, \quad \text{for all } d \in \mathcal{N}(A^\top),$$

a *restricted gradient* of  $f$  at  $\hat{x}$ , because it is the gradient of the restriction of  $f$  to the space  $\mathcal{N}(A^\top(\hat{x}))$ .

Let us first consider the continuous piecewise linear case. We assume that the ridges of  $f$  are given, and also we assume that the restriction of  $f$  to any cell is known. Hence, we are assuming that more information on the structure of the objective function is available than, for example, in a bundle method [8], which assumes that only one element of the subdifferential is known at any point.

It is shown in [4] that, under some nondegeneracy assumptions (e. g. the gradients of the ridges which are active at  $\bar{x}$  are linearly independent), any continuous piecewise linear function  $f$  can be *decomposed* in a neighborhood of  $\hat{x}$  into a smooth function and a sum of continuous functions having a single ridge as follows:

$$f(x) = f(\hat{x}) + g_{\hat{x}}^\top (x - \hat{x}) + \sum_{i \in \mathcal{A}(\hat{x})} v_{\hat{x}}^i \min(0, a_i^\top (x - \hat{x})),$$

for some scalars  $\{v_{\hat{x}}^i\}_{i \in \mathcal{A}(\hat{x})}$ , and some vector  $g_{\hat{x}} \in \mathbf{R}^n$ . We term  $g_{\hat{x}}$  the *restricted gradient* of  $f$  at  $\hat{x}$ . Note that if  $m$  ridges of  $f$  are active at  $\hat{x}$ , it means that there are  $2^m$  cells in any small neighborhood of  $\hat{x}$ . The vector  $g_{\hat{x}}$  and the  $m$  scalars  $\{v_{\hat{x}}^i\}_{i \in \mathcal{A}(\hat{x})}$ , together with the  $m$  gradients of the activities,  $\{a_i\}_{i \in \mathcal{A}(\hat{x})}$ , thus completely characterize the behavior of  $f$  over the  $2^m$  cells in the neighborhood of  $\hat{x}$ !

With such a decomposition at any point of  $\mathbf{R}^n$ , an algorithm for finding a local minimum of a continuous piecewise linear function  $f$  is readily obtained, as long as we assume no degeneracy at any iterate and at any breakpoint encountered in the line search (we shall discuss later the degenerate situation):

```

1   Choose any  $x^1 \in \mathbf{R}^n$  and set  $k \leftarrow 1$ .
BEGIN REPEAT
2   Identify the activities,  $\mathcal{A}(x^k)$ , and compute  $d^k \equiv -P(g_{x^k})$ , the projection of the restricted gradient onto the space orthogonal to the gradients of the activities.
   IF  $d^k = \vec{0}$  ( $x^k$  is a dead point); compute a single-dropping descent direction or establish optimality), THEN
3   Compute  $\{u_i\}_{i \in \mathcal{A}(x^k)}$ , the coefficients of  $\{a_i\}_{i \in \mathcal{A}(x^k)}$  in the linear combination of  $g_{x^k}$  in terms of the columns of  $\mathcal{A}(x^k)$ .
4   IF  $u_i < 0$  or  $u_i > -v_{x^k}^i$ , for some  $i \in \mathcal{A}(x^k)$  (violated optimality condition), THEN
5   (Drop activity  $i$ )
   Redefine  $d^k = P_{-i}(a_i)$ , if the violated inequality found corresponds to  $u_i \geq 0$ ; otherwise  $d^k = -P_{-i}(a_i)$  if it is  $u_i \leq -v_{x^k}^i$ , where  $P_{-i}$  is the orthogonal projector onto the space orthogonal to the gradients of all the activities but activity  $i$ .
   ELSE stop:  $x^k$  is a local minimum of  $f$ .
   ENDIF ENDIF
6   (Line search)
   Determine the step size  $\alpha^k$  by solving  $\min_{\alpha > 0} f(x^k + \alpha d^k)$ . This line search can be done from  $x^k$ , moving from one break-point of  $f$  to the next, in the direction  $d^k$ , until either we establish unboundedness of the objective function or the value of  $f$  starts increasing.
7   Update  $x^{k+1} = x^k + \alpha^k d^k$ ,  $k \leftarrow k + 1$ .
END REPEAT

```

**Continuous piecewise linear minimization algorithm**

Remark that in step 6, the directional derivative of the objective function in the direction  $d^k$  can easily be updated from one breakpoint to the other in terms of the scalar  $v_{\bar{x}}^i$ , where  $i$  is the index of the ridge crossed at breakpoint  $\bar{x}$ .

Let us now consider the case where  $f$  is still piecewise linear but with possibly discontinuities across some ridges. We term such ridges: *faults*, and  $\mathcal{F}(\hat{x})$  denotes the faults that are active at  $\hat{x}$ .

Note first that a (local) minimum does not always exist in the discontinuous case. Consider for example the following univariate function, having  $x = 0$  as a fault:

$$f(x) = \begin{cases} x + 1 & \text{if } x \geq 0, \\ -x & \text{otherwise.} \end{cases}$$

Hence, we rather look for a *local infimum*. In order to find such a local infimum of a function  $f$  having some faults, we shall simply generalize the algorithm for the continuous problem by implicitly considering any discontinuity or *jump* across a fault  $i$  in  $f$  as the limiting case of a continuous situation. Since we are looking for a local infimum, without loss of generality we shall henceforth only consider functions  $f$  such that

$$f(x) = \liminf_{\bar{x} \rightarrow x} f(\bar{x}),$$

in other words, we consider the lower semicontinuous envelope of  $f$ .

The algorithm for the discontinuous case is essentially the same as in the continuous case except that we consider dropping an active fault from a dead point,  $x$ , only if we do so along a direction  $d$  such that

$$\lim_{\delta \rightarrow 0^+} f(x + \delta d) = f(x)$$

(i.e. as  $\delta > 0$  is small, the value of  $f$  does not jump up from  $x$  to  $x + \delta d$ ). Thus, virtually only step 4 must be adapted from the continuous problem algorithm in order to solve the discontinuous case. To make more carefully the intuitive concept of directions jumping up or down, we define the set of *soaring directions* from a point  $\hat{x}$  to be:

$$S(\hat{x}) := \left\{ d \in \mathbb{R}^n : \begin{array}{l} \exists \epsilon > 0, \bar{\delta} > 0 : \\ \forall 0 < \delta < \bar{\delta} : \\ f(\hat{x} + \delta d) - f(\hat{x}) > \epsilon \end{array} \right\}.$$

If we define, for a nondegenerate point  $\hat{x}$ ,

$$S^+(\hat{x}) := \left\{ i \in \mathcal{A}(\hat{x}) : \begin{array}{l} \text{if } d^{i^+} \in \mathcal{N}(A_{-i}^\top) \\ \text{and } a_i^\top d^{i^+} > 0 \\ \text{then } d^{i^+} \in S(\hat{x}) \end{array} \right\},$$

$$S^-(\hat{x}) := \left\{ i \in \mathcal{A}(\hat{x}) : \begin{array}{l} \text{if } d^{i^-} \in \mathcal{N}(A_{-i}^\top) \\ \text{and } a_i^\top d^{i^-} < 0 \\ \text{then } d^{i^-} \in S(\hat{x}) \end{array} \right\},$$

then the set of soaring single-dropping directions from  $\hat{x}$  are simply the directions dropping an activity  $i \in S^+(\hat{x})$  positively and the directions dropping an  $i \in S^-(\hat{x})$  negatively (we say that activity  $i$  is *dropped positively (negatively)* if all current activities, except for the  $i$ th, are preserved and if, moreover,  $a_i^\top d$  is positive (negative)). A fault can now be defined more rigorously: a *positive (negative) fault* of  $f$  at a point  $\hat{x}$  is a ridge  $i \in \mathcal{R}$  such that for any neighborhood,  $B(\hat{x})$ , of  $\hat{x}$ , there exists a nondegenerate point  $x' \in B(\hat{x})$  with  $i \in S^+(x')$  (with  $i \in S^-(x')$ ). The set of all positive (negative) faults at  $\hat{x}$  is denoted by  $\mathcal{F}^+(\hat{x})$   $\mathcal{F}^-(\hat{x})$ ). The *set of faults* of  $f$  at a point  $\hat{x}$  is denoted by

$$\mathcal{F}(\hat{x}) := \mathcal{F}^+(\hat{x}) \cup \mathcal{F}^-(\hat{x}).$$

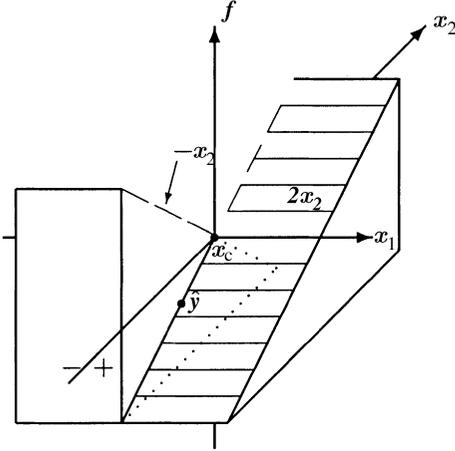

We modify the continuous problem algorithm in such a way that, at a nondegenerate dead point,  $x^k$ , we do not need to verify the optimality conditions corresponding to soaring single-dropping directions ( $u_i \geq 0$ ,  $i \in S^+(x^k)$  and  $u_i \leq -v^i$ ,  $i \in S^-(x^k)$ ), so that we never consider such single-dropping directions in order to establish whether  $x^k$  is optimal. This is reasonable since we are looking for a local minimum. The line-search step (step 6) is modified similarly: when we encounter a breakpoint  $\bar{x}$  on a fault along a direction  $d \in S(\bar{x})$  (jump up), we stop; while if  $d$  is such that  $-d \in S(\bar{x})$ , (jump down), we carry on to the next breakpoint, and update properly the directional derivative along  $d$ .

Note that one has to be careful at a ‘contact’ point  $x_c \in \mathbf{R}$  (defined below). At  $x_c$ , contrary to at other points of a fault, we can drop activity  $i$  *both* positively and negatively.

The function  $f: \mathbf{R}^2 \rightarrow \mathbf{R}$ , given by

$$f(x) = \begin{cases} 2x_2 & \text{if } x_1 > 0 \text{ or} \\ & (x_1 = 0 \text{ and } x_2 \leq 0), \\ -x_2 & \text{otherwise,} \end{cases} \quad (2)$$

illustrates well the situation. Figure 1 shows the graph of  $f$  in a neighborhood of  $x_c := (0, 0)^\top$  (the dotted lines are simply lines that could be seen if the hatched surface were transparent). The point  $x_c$  is a contact point with respect to the fault  $x_1 = 0$ .

Formally, we define  $x_c \in \mathbf{R}^n$  to be a *contact point* of  $f$  with respect to  $i \in \mathcal{A}(x_c)$ , when  $i \in \mathcal{F}(x_c)$  such that either

- 1)  $i \in \mathcal{F}^+(x_c) \cap \mathcal{F}^-(x_c)$ , or
- 2) there exist  $\sigma^+, \sigma^- \in \mathbb{3}^{|\mathcal{R}|}$  such that  $\sigma_i^+ = 1, \sigma_i^- = -1$  and

$$\lim_{\substack{x \rightarrow x_c, \\ \sigma(x) = \sigma^+}} f(x) = \lim_{\substack{x \rightarrow x_c, \\ \sigma(x) = \sigma^-}} f(x)$$

(continuity when crossing ridge  $i$ , which is a fault, at  $x_c$ ), where  $\sigma(x)$  is the vector whose  $k$ th component is  $\text{sign}(r_k(x))$ .

Note that the fault  $x_1 = 0$  and the point  $x_c = (0, 0)^T$  satisfy both conditions 1) and 2) in the above definition of a contact point for the function  $f$  defined by (2). They however satisfy only condition 1) for the function  $f: \mathbf{R}^2 \rightarrow \mathbf{R}$ , defined by

$$f(x) = \begin{cases} 1 & \text{if } x_1 \geq 0 \text{ and } x_2 \geq 0, \\ 2 & \text{if } x_1 \leq 0 \text{ and } x_2 \leq 0 \\ & \text{and } x \neq (0, 0)^T, \\ 3 & \text{if } x_1 > 0 \text{ and } x_2 < 0, \\ 4 & \text{otherwise,} \end{cases}$$

with faults  $x_1 = 0$  and  $x_2 = 0$ . For the function  $f: \mathbf{R}^2 \rightarrow \mathbf{R}$  given by

$$f(x) = \begin{cases} -x_2 & \text{if } x_1 > 0 \text{ and } x_2 < 0, \\ 0 & \text{otherwise,} \end{cases}$$

with fault  $x_1 = 0$ , we satisfy only condition 2) ( $\mathcal{F}^-(x_c)$  is empty).

An algorithm similar to the one introduced in the continuous case, but which does not consider soaring single-dropping directions, will encounter no difficulty with the discontinuity in  $f$  at any noncontact point (e. g. for (2), at any point other than  $x_c$ ). Let us assume, without loss of generality, that at the  $k$ th iterate,  $x^k, \mathcal{F}(x^k) = \mathcal{F}^-(x^k)$ . The only step of the continuous algorithm which need to be modified is (assuming moreover that all points encountered in the algorithm are noncontact points):

4 | IF  $u_i < 0$  for some  $i \in \mathcal{A}(x^k)$ , or  $u_i > -v_{x^k}^i$  for some  $i \in \mathcal{A}(x^k) \setminus \mathcal{F}(x^k)$  (violated optimality condition), THEN

The paper [4] describes techniques (including perturbation) to cope with problems that occur in certain cases where the hypothesis of nondegeneracy is not satisfied at points encountered in the course of the algorithm. One cannot however extend this algorithm to deal with *dead-point iterates* (i. e. not encountered as breakpoint along the line search) without considering carefully the combinatorial nature of the problem of degeneracy. Nevertheless, no difficulties were encountered in the computational experiments reported in [4], although serious problems can still arise at certain singular points (contact points and dead-point iterates, at which the objective function is not decomposable). Indeed, in the discontinuous case, there is no straightforward extension of this approach to the cases where the algorithm encounters a contact point. In the continuous case, the behavior of  $f$  over two juxtaposed cells are linked. At contact points however, there is coincidence of the values of restrictions of  $f$  to subdomains not otherwise linked to each other.

Let us now discuss the extension to the nonlinear case. An advantage of the active set approach for the continuous piecewise linear optimization problem, over, for example, the simplex-format algorithm of R. Fourer [6], is that it generalizes it not only to the discontinuous situation but also to the nonseparable and certain (decomposable) nonconvex cases. Above all, the active set approach is readily extendable to the nonlinear case, by adapting conventional techniques for nonlinear programming, as was done above with the projected gradient method for the (possibly discontinuous)

piecewise linear case. The definition of decomposition must first be generalized so that it expresses the first order behavior of a piecewise differentiable function in the neighborhood of a point. The piecewise linear algorithm described above used descent directions attempting to decrease the smooth part of the function while maintaining the value of its nonsmooth part (when preserving the current activities). A first order algorithm for the nonlinear case could obtain these two objectives *up to first order changes*, as in the approach of A.R. Conn and T. Pietrzykowski to nonlinear optimization, via an  $l_1$  exact penalty function [5]. In order to develop a second order algorithm, assuming now that  $f$  is (possibly discontinuous) *piecewise twice-differentiable* (i. e. twice differentiable everywhere except over a finite number of ridges), one must first extend the definition of first order decomposition to that of *second order decomposition*. One could then consider extending the strategies used by T.F. Coleman and Conn [2] on the exact penalty function approach to nonlinear programming (although the  $l_1$  exact penalty function involves only first order types of nondifferentiabilities – ridges). The main idea is to attempt to find a direction which minimizes the change in  $f$  (up to second order terms) subject to preserving the activities (up to second order terms). Specifically, second order conditions must be derived (which are the first order conditions plus a condition on the ‘definiteness’ of the *reduced Hessian* of the *twice-differentiable part* of  $f$  (in the second order decomposition of  $f$ )). An analog of the Newton step (or of a modification of the Newton method; cf. also ► [Gauss-Newton method: Least squares, relation to Newton’s method](#)) using a nonorthogonal projection [3] is then taken (or a single-dropping direction is used). An algorithm following these lines would be expected to possess global convergence properties (regardless of starting point) and a fast (2-step superlinear) asymptotic convergence rate as in [1].

## Introduction

Many problems in stochastic optimization, as for instance optimal stochastic structural design problems, stochastic control problems, problems of scenario analysis, etc., can be described [3,5] by mean value minimization problems of the type

$$\begin{cases} \min & F(x) \\ \text{s.t.} & x \in D, \end{cases} \quad (1)$$

where the objective function  $F = F_u$  is the *mean value function*, defined by

$$F(x) = \mathbb{E}u(A(\omega)x - b(\omega)), \quad x \in \mathbb{R}. \quad (2)$$

Here,  $(A(\omega), b(\omega))$  is a random  $m \times (n + 1)$  matrix,  $\mathbb{E}$  denotes the expectation operator,  $D$  is a convex subset of  $\mathbb{R}^n$  and  $u : \mathbb{R}^m \rightarrow \mathbb{R}$  designates a convex loss function measuring the loss arising from the deviation  $z = A(\omega)x - b(\omega)$  between the output  $A(\omega)x$  of the stochastic linear system  $x \rightarrow A(\omega)x$  and the random target  $b(\omega)$ .

Solving (1), (2), the loss function  $u$  should be exactly known. However, in practice mostly there is some uncertainty about the appropriate selection of  $u$ , for instance due to difficulties in assigning appropriate penalty costs to the deviation  $z = A(\omega)x - b(\omega)$  between the output  $A(\omega)x$  and the target  $b(\omega)$ . We suppose that  $u \in U$ , where  $U$  is a given set of convex loss functions containing the true, but unknown loss function  $u_0$ . A possible way out in this situation of uncertainty about  $u$  is either to construct (feasible) descent directions  $h$  of  $F$  at a (iteration) point  $x$  being valid for a large class  $U$  of loss functions, or to provide the decision maker with a certain set  $E = E_{D,U} (\subset D)$  of *efficient points* or solutions, being substitutes for an optimal solution  $x^*$  of (1), (2); hence, this set  $E_{D,U}$  or at least its closed hull  $\overline{E_{D,U}}$  should contain an optimal solution  $x^*$

$= x_u^*$  of (1), (2) for each  $u \in U$ . An important class  $U = C_m^J$  of loss functions  $u$  is the set of partially monotonous increasing convex loss functions on  $\mathbb{R}^m$  defined as follows:

**Definition 1** Let  $J$  be a given subset of  $\{1, \dots, m\}$ . For  $J = \emptyset$  we put  $C_m^\emptyset = C_m$ , where  $C_m$  is the set of all convex functions  $u$  on  $\mathbb{R}^m$ . If  $J \neq \emptyset$ , then  $C_m^J$  denotes the set of all convex functions  $u : \mathbb{R}^m \rightarrow \mathbb{R}$  having the following property:

$$z_I \leq w_I, z_{II} \leq w_{II} \implies u(z) \leq u(w). \quad (3)$$

Here,  $z_I \in \mathbb{R}^{|J|}$ ,  $z_{II} \in \mathbb{R}^{m-|J|}$  is the partition of any  $z \in \mathbb{R}^m$  into the subvectors  $z_I = (z_i)_{i \in J}$ ,  $z_{II} = (z_i)_{i \notin J}$ . Moreover,  $z_I \leq w_I$  means that  $z_j \leq w_j$  for all  $j \in J$ .

*Remark 2* In many cases one has loss functions  $u \in C_m^J$  with one of the following additional strict partial monotonicity property:

$$\begin{cases} z_I \leq w_I, \\ z_{II} = w_{II}, \\ z_i < w_i \text{ for some } i \in J \end{cases} \implies u(z) < u(w), \quad (4)$$

$$z_I < w_I, z_{II} = w_{II} \implies u(z) < u(w), \quad (5)$$

where  $z_I < w_I$  means that  $z_j < w_j$  for all  $j \in J$ .

For a given set  $U$  of convex loss functions  $u$  containing the true, but unknown loss function  $u_0$ , a first definition of efficient solutions can be given as follows:

**Definition 3** A point  $x \in D$  is called a *nondominated, admissible or Pareto optimal solution* of (1), (2) if there is no vector  $\tilde{x} \in D$ ,  $\tilde{x} \neq x$ , such that

$$F_u(\tilde{x}) \leq F_u(x) \quad \text{for all } u \in U, \quad (6)$$

$$F_{\tilde{u}}(\tilde{x}) < F_{\tilde{u}}(x) \quad \text{for some } \tilde{u} \in U, \quad (7)$$

where  $F_u(x) := \mathbb{E}u(A(\omega)x - b(\omega))$ . Let  $E_{D,U}^0$  denote the set of all nondominated solutions of (1), (2).

## Discretely Distributed Stochastic Programs

In the following we consider the construction of descent directions and efficient solutions for (1), (2) in the case that  $(A(\omega), b(\omega))$  has a discrete distribution

$$P_{(A(\cdot), b(\cdot))} = \sum_{i=1}^r \alpha_i \epsilon_{(A^i, b^i)}, \quad (8)$$

where  $r > 1$  is an integer,  $\alpha_i > 0$ ,  $i = 1, \dots, r$ ,  $\sum_{i=1}^r \alpha_i = 1$ , and  $\epsilon_{(A^i, b^i)}$  denotes the one-point measure in the given  $m \times (n + 1)$  matrix  $(A^i, b^i)$ ,  $i = 1, \dots, r$ .

### Example: Scenario Analysis

Given a certain planning problem, in *scenario analysis* [1,2,6,7,8] the future evolution or development of the system to be considered is anticipated or explored by means of a (usually small) number  $r$  (e. g.,  $r = 3, 4, 5, 6$ ) of so-called scenarios  $s^1, \dots, s^r$ . Scenarios  $s^i$ ,  $i = 1, \dots, r$ , are plausible alternative models of the future development given by ‘extreme points’ of a certain set of basic or key variables. An individual scenario or a certain mixture of the scenarios  $s^1, \dots, s^r$  is assumed then to be revealed in the considered future time period. We assume now that the planning problem can be described mathematically by the optimization problem

$$\begin{cases} \min & c'x \\ \text{s.t.} & Tx = (\leq) h, \quad x \in D. \end{cases} \quad (9)$$

Here,  $D$  is a given convex subset of  $\mathbf{R}^n$ , and the data  $(c, T, h)$  are given by  $(c, T, h) = (c^i, T^i, h^i)$  for scenario  $s^i$ ,  $i = 1, \dots, r$ , where  $c^i$  is an  $n$ -vector,  $T^i$  an  $m \times n$  matrix and  $h^i$  an  $m$ -vector. Having written here the scenarios  $s^1, \dots, s^r$  by means of (9) and the data  $(c^i, T^i, h^i)$ ,  $i = 1, \dots, r$ , and facing therefore the subproblems

$$\begin{cases} \min & c^i x \\ \text{s.t.} & T^i x = (\leq) h^i, \quad x \in D, \end{cases} \quad (10)$$

for  $i = 1, \dots, r$ , the decision maker has then to select an appropriate decision  $x \in D$ . Since one is unable in general to predict with certainty which scenario  $s^i$  will occur, scenario analysts are looking for decisions  $x^0$  which are ‘robust’ with respect to the different scenarios or ‘scenario-independent’, cf. [6,7,8]. Obviously, this robustness concept is closely related to the idea of detecting ‘similarities’ within the family of optimal solutions  $x^*(s^i)$ ,  $i = 1, \dots, r$ , of the individual subproblems (10)<sub>(i)</sub>,  $i = 1, \dots, r$ . Let  $\alpha_1, \dots, \alpha_r$  with  $\alpha_i > 0$ ,  $i = 1, \dots, r$ ,  $\sum_{i=1}^r \alpha_i = 1$ , be (subjective) probabilities for the occurrence of  $s^1, \dots, s^r$ , or weights reflecting the relative importance of  $s^1, \dots, s^r$ . Considering loss functions  $u \in C_m^J$  for evaluating the violations  $z^i = T^i x - h^i$  of the constraint  $T^i x = h^i$ ,  $T^i x \leq h^i$ , resp., in (10)<sub>(i)</sub>, a class of robust or

scenario-independent decisions are obviously the efficient solutions of

$$\min_{x \in D} \sum_{i=1}^r \alpha_i (c^i x + u(T^i x - h^i)), \quad (11)$$

which is a discretely distributed stochastic optimization problem of the type (1), (2).

### A System of Linear Relations for the Construction of Descent Directions

Fundamental for the computation of the set  $E_{D, U}$  of efficient solutions of (1), (2) is the following construction method for descent directions of the objective function  $F$  of (1), (2), cf. [3,4]. We suppose that the true, but unknown loss function  $u$  in (1) is, see Definition 1, an element of  $C_m^J$  for some known index set  $J \subset \{1, \dots, m\}$ . We recall that for any vector  $z \in \mathbf{R}^m$  the subvectors  $z_I, z_{II}$  are defined by  $z_I = (z_i)_{i \in J}$ ,  $z_{II} = (z_i)_{i \notin J}$ ; see (3). Of course, if  $J = \emptyset$ , then  $z = z_{II}$  and  $z_I$  does not exist. For any  $m \times (n + 1)$  matrix  $(A, b)$ , let  $(A_I, b_I)$ ,  $(A_{II}, b_{II})$ , resp., denote the submatrices of  $(A, b)$  having the rows  $(A_i, b_i)$  with  $i \in J$ ,  $i \in \{1, \dots, m\} \setminus J$ , respectively.

Given an  $n$ -vector  $x$  (e. g., the  $t$ th iteration point of an algorithm for solving (1), (2)), we consider, in extension of [3, system (3.1)–(3.4b)], the following system of linear relations for the unknowns  $(y, \Pi)$ , where  $y \in \mathbf{R}^n$  and  $\Pi = (\pi_{ij})$  is an auxiliary  $r \times r$  matrix:

$$\sum_{j=1}^r \pi_{ij} = 1, \quad \pi_{ij} \geq 0, \quad i, j = 1, \dots, r, \quad (12)$$

$$\alpha_j = \sum_{i=1}^r \alpha_i \pi_{ij}, \quad j = 1, \dots, r, \quad (13)$$

$$A_I^j y - b_I^j \leq \sum_{i=1}^r \frac{\alpha_i \pi_{ij}}{\alpha_j} (A_I^i x - b_I^i), \quad j = 1, \dots, r, \quad (14)$$

$$A_{II}^j y - b_{II}^j = \sum_{i=1}^r \frac{\alpha_i \pi_{ij}}{\alpha_j} (A_{II}^i x - b_{II}^i), \quad j = 1, \dots, r. \quad (15)$$

The transition probability measure

$$K^j = \sum_{i=1}^r \beta_{ij} \epsilon_{z^i}, \quad \beta_{ij} = \frac{\alpha_i \pi_{ij}}{\alpha_j}, \quad z^i = A^i x - b^i, \quad (16)$$

is not a one-point measure for at least one  $j$ ,  $1 \leq j \leq r$ .

There exists at least one  $j$ ,  $1 \leq j \leq r$ , such that for all  $i = 1, \dots, r$

$$K^j \text{ is not a one-point measure and } \pi_{ij} > 0. \quad (17)$$

At least one inequality in (14) holds with  $<$ . (18)

The constraint  $x \in D$  in (1) can be handled by adding the condition

$$y \in D. \quad (19)$$

*Remark 4*

- By  $\epsilon_z$  we denote the one-point measure in a point  $z \in \mathbf{R}^m$ .
- According to (12),  $\Pi$  is a stochastic matrix. System (12)–(15) has always the trivial solution  $(y, \Pi) = (x, \text{Id})$ , where  $\text{Id}$  is the  $r \times r$  identity matrix.
- If  $(y, \Pi)$  solves (12)–(15), then

$$\bar{A}_I y \leq \bar{B}_I x, \quad \bar{A}_{II} y = \bar{B}_{II} x, \quad (20)$$

where  $\bar{A}_I = \mathbb{E}A_I(\omega)$ ,  $\bar{A}_{II} = \mathbb{E}A_{II}(\omega)$ .

- If  $\mathbb{P}_{A_{II}(\cdot)y - b_{II}(\cdot)}$  denotes the probability distribution of the random  $(m - |J|)$ -vector  $A_{II}(\omega)x - b_{II}(\omega)$ , then (12), (13) and (15) mean that the distributions  $\mathbb{P}_{A_{II}(\cdot)y - b_{II}(\cdot)}$  and  $\mathbb{P}_{A_{II}(\cdot)x - b_{II}(\cdot)}$  corresponding to  $y, x$ , resp., are related by

$$\begin{aligned} \mathbb{P}_{A_{II}(\cdot)x - b_{II}(\cdot)} &= K \mathbb{P}_{A_{II}(\cdot)y - b_{II}(\cdot)} \\ &= \int K(w, \cdot) \mathbb{P}_{A_{II}(\cdot)y - b_{II}(\cdot)}(dw), \end{aligned} \quad (21)$$

where  $K(w, \cdot)$  is the Markov kernel defined by

$$K(w^j, \cdot) := K^j = \sum_{i=1}^r \frac{\alpha_i \pi_{ij}}{\alpha_j} \epsilon_{z^i}, \quad (22)$$

with  $w^j = A^j y - b^j$ ,  $z^i = A^i x - b^i$ ,  $i, j = 1, \dots, r$ . Since  $\int zK(w, dz) = w$ , the Markov kernel  $K$  is also called a *dilatation*.

- If  $n$ -vectors  $x, y$  are related by (21), (22), then for every convex subset  $B \subset \mathbf{R}^m - |J|$  we have that

$$\mathbb{P}_{A_{II}(\cdot)x - b_{II}(\cdot)}(B) = 1 \implies \mathbb{P}_{A_{II}(\cdot)y - b_{II}(\cdot)}(B) = 1;$$

hence, the distribution of  $A_{II}(\cdot)y - b_{II}(\cdot)$  is concentrated to the convex hull of the support of  $\mathbb{P}_{A_{II}(\cdot)x - b_{II}(\cdot)}$ .

- If  $J = \emptyset$ , then (14) vanishes and (15) reads

$$A^j y - b^j = \sum_{i=1}^r \frac{\alpha_i \pi_{ij}}{\alpha_j} (A^i x - b^i), \quad j = 1, \dots, r. \quad (23)$$

In the special case

$$(A_I^j, b_I^j) = (\bar{A}_I, \bar{b}_I) \quad \text{for all } j = 1, \dots, r, \quad (24)$$

i. e., if  $(A_I(\omega), b_I(\omega))$  is constant with probability one, then (14) is reduced, cf. (20), to

$$\bar{A}_I y \leq \bar{A}_I x. \quad (25)$$

The meaning of (12)–(15) and the additional conditions (16)–(18) for the basic mean value minimization problem (1), (2) with objective function  $F$  is summarized in the next result.

**Theorem 5** *Let  $J$  be any fixed subset of  $\{1, \dots, m\}$ .*

- If  $(y, \Pi)$  is a solution of (12)–(15), then  $F(y) \leq F(x)$  for every  $u \in \mathcal{C}_m^J$ . For  $J = \emptyset$  also the converse holds: If there is a vector  $y$  such that  $F(y) \leq F(x)$  for all  $u \in \mathcal{C}_m^J$  ( $\mathcal{C}_m^{\emptyset}$ ), then there exists an  $r \times r$  matrix  $\Pi$  such that  $(y, \Pi)$  satisfies (12), (13) and (23).
- If  $(y, \Pi)$  is a solution of (12)–(15) and (16), then  $F(y) < F(x)$  for every  $u \in \mathcal{C}_m^J$  which is strictly convex on  $\text{conv}\{z^i : 1 \leq i \leq r\}$ .
- If  $(y, \Pi)$  is a solution of (12)–(15) and (17), then  $F(y) < F(x)$  for every  $u \in \mathcal{C}_m^J$  which is not affine-linear on  $\text{conv}\{z^i : 1 \leq i \leq r\}$ .
- If  $(y, \Pi)$  fulfills (12)–(15) and (18), then  $F(y) < F(x)$  for every  $u \in \mathcal{C}_m^J$  satisfying (4).

*Proof* If  $x$  and  $(y, \Pi)$  are related by (12)–(15), then  $F(y) \leq \sum_{j=1}^r \alpha_j u(\sum_{i=1}^r \beta_{ij} z^i)$  for every  $u \in \mathcal{C}_m^J$ .

If  $x, (y, \Pi)$  are related by (12)–(15) and (18), then  $F(y) < \sum_{j=1}^r \alpha_j u(\sum_{i=1}^r \beta_{ij} z^i)$  for every  $u \in \mathcal{C}_m^J$  fulfilling (4). The rest can then be shown as in [3, Thm. 2.2].

A simple, but important consequence of the above theorem is stated next:

**Corollary 6** *For given  $x \in \mathbf{R}^n$  or  $x \in D$  let  $(y, \Pi)$  be any solution of (12)–(15) such that  $y \neq x$ ,  $y \in D \setminus \{x\}$ , respectively.*

- Then  $h = y - x$  is a descent direction, a feasible descent direction, resp., of  $F$  at  $x$  for every  $u \in \mathcal{C}_m^J$  such that  $F$  is not constant on the line segment  $xy$  joining  $x$  and  $y$ .

b) If  $(y, II)$  fulfills also (16), (17), (18), resp., then  $h = y - x$  is a (feasible) descent direction of  $F$  at  $x$  for every  $u \in \mathcal{C}_m^J$  which is strictly convex on  $\text{conv}\{z^i : 1 \leq i \leq r\}$ , is not affine-linear on  $\text{conv}\{z^i : 1 \leq i \leq r\}$ , fulfills (4), respectively.

### Efficient Solutions of (1), (2)

In the following we suppose that the unknown loss function  $u$  is an element of  $\mathcal{C}_m^J$ , where  $J$  is a given subset of  $\{1, \dots, m\}$ . For a given point  $x \in D$ , the descent direction-finding procedure described in the previous section only can fail completely if for each solution  $(y, II)$  of (12)–(15) with  $x \in D$  we have that

$$A^j y = A^j x \quad \text{for each } j = 1, \dots, r. \quad (26)$$

Indeed, in this case we either have  $y = x$ , or, for arbitrary loss functions  $u$ , the objective function  $F$  of (1), (2) is constant on the whole line through the points  $x, y$ . This observation suggests the following basic efficiency concept.

**Definition 7** A point  $x \in D$  is called a  $(\mathcal{C}_m^J)$ -efficient point or a  $(\mathcal{C}_m^J)$ -efficient solution of (1), (2) if and only if for each solution  $(y, II)$  of (12)–(15) with  $y \in D$  we have that  $A^j y = A^j x$  for each  $j = 1, \dots, r$ , i. e.,  $A(\omega)x = A(\omega)y$  with probability 1. Let  $E_{D,J}$  denote the set of all efficient points of (1), (2).

For deriving parametric representations of  $E_{D,J}$  we need the following definitions and lemmas.

For a given  $n$ -vector  $x$  and  $z^i = A^i x - b^i$ ,  $i = 1, \dots, r$ , let  $S = S_x \subset \{1, \dots, r\}$  with  $|S| = s$  be an index set such that  $\{z^i : 1 \leq i \leq r\} = \{z^i : i \in S\}$ , where  $z_i \neq z_j$  for  $i, j \in S$ ,  $i \neq j$ . Defining for  $i \in S, j = 1, \dots, r$ , the quantities

$$\begin{aligned} \tilde{\alpha}_i &:= \sum_{z^t = z^i} \alpha_t, \\ \tau_{ij} &:= \frac{1}{\tilde{\alpha}_i} \sum_{z^t = z^i} \alpha_t \pi_{tj}, \quad \tilde{\beta}_{ij} := \frac{\tilde{\alpha}_i \tau_{ij}}{\alpha_j}, \end{aligned} \quad (27)$$

we find that relations (12)–(15) can also be represented by

$$\sum_{j=1}^r \tau_{ij} = 1, \quad \tau_{ij} \geq 0, \quad j = 1, \dots, r, \quad i \in S, \quad (28)$$

$$\alpha_j = \sum_{i \in S} \tilde{\alpha}_i \tau_{ij}, \quad j = 1, \dots, r, \quad (29)$$

$$A_1^j y - b_1^j \leq \sum_{i \in S} \tilde{\beta}_{ij} z_1^i, \quad j = 1, \dots, r, \quad (30)$$

$$A_{II}^j y - b_{II}^j = \sum_{i \in S} \tilde{\beta}_{ij} z_{II}^i, \quad j = 1, \dots, r. \quad (31)$$

For the next lemma we still need the  $s \times r$  matrix  $T^0 = (\tau_{ij}^0)$  defined by

$$\tau_{ij}^0 = \begin{cases} 0 & \text{if } z^i \neq z^j, \\ \frac{\alpha_j}{\alpha_i} & \text{if } z^j = z^i, \end{cases} \quad \text{for } i \in S, j = 1, \dots, r. \quad (32)$$

**Lemma 8** Let  $(y, II)$  be a solution of (12)–(15), and let  $T = T(II) = (\tau_{ij})$  be the  $s \times r$  matrix having the elements  $\tau_{ij}$  given by (27). If (26) holds, then  $T(II) = T^0$  and (14) holds with ‘=’.

Lemma 8 implies the following important property of efficient solutions:

**Corollary 9** Let  $x \in D$  be an efficient solution of (1), (2). If  $(y, II)$  is any solution of (21)–(22) with  $y \in D$ , then  $T(II) = T^0$  and (14) holds with ‘=’.

For  $J = \emptyset$  we obtain the set  $E_D := E_{D, \emptyset}$  of all  $C_m$ -efficient solutions of (1), (2). This set is studied in [3]. An important relationship between  $E_D$  and  $E_{D,J}$  for any  $J \subset \{1, \dots, m\}$  is given next:

**Lemma 10**  $E_{D,J} \subset E_D$  for every  $J \subset \{1, \dots, m\}$ .

### Comparison of Definitions 7 and 3

Comparing the efficient solutions according to Definition 7 and the nondominated solutions according to Definition 3, first for  $J = \emptyset$ , i. e.,  $U = C_m$ , we find the following correspondence:

**Theorem 11**  $E_{D, \emptyset} = E_{D, C_m}^{(0)}$ .

The next corollary follows immediately from the above theorem and Lemma 10.

**Corollary 12**  $E_{D,J} \subset E_{D, \emptyset} = E_{D, C_m}^{(0)}$  for  $J \subset \{1, \dots, m\}$ .

Considering now  $U = C_m^J$  we have this inclusion:

**Theorem 13**  $E_{D,J} \supset E_{D, C_m^J}^{(0)}$  for  $J \subset \{1, \dots, m\}$ .

The following inclusion follows from Corollary 12 and Theorem 13.

**Corollary 14**  $E_{D, C_m^J}^{(0)} \subset E_{D,J} \subset E_{D, C_m}^{(0)}$  for  $J \subset \{1, \dots, m\}$ .

A converse statement to Theorem 13 can be obtained for (24):

**Theorem 15** If  $(A_I(\omega), b_I(\omega)) = (\bar{A}_I, \bar{b}_I)$  with probability 1, then  $E_{D,J} = E_{D,C_m^J}^{(0)}$  for each  $J \subset \{1, \dots, m\}$ .

**Further Characterization of  $E_{D,J}$**

The  $C_m^J$ -efficiency of a point  $x \in D$  can also be described in the following way.

**Theorem 16** A point  $x \in D$  is  $(C_m^J)$ -efficient if and only if for every solution  $(y, II)$  of (12)-(15) we have that  $A^j y = A^j x$  for all  $j = 1, \dots, r$ , or  $h = y - x$  is not a feasible direction for  $D$  at  $x$ .

**Necessary Optimality Conditions**

**Without Using (Sub)Gradients**

If  $x \in D$  is efficient, then, cf. Theorem 16, the descent direction-finding method described in the previous Section fails at  $x$ . Since especially in any optimal solution  $x^*$  of (1), (2) no feasible descent direction may exist, efficient points are candidates for optimal solutions:

**Theorem 17** Suppose that for every  $x \in D$  and every solution  $(y, II)$  of (12)-(15) with  $y \in D$  the objective function  $F$  of (1), (2) with a loss function  $u \in C_m^J$  is constant on the line segment  $xy$  if and only if  $A^j y = A^j x$  for every  $j = 1, \dots, r$ . If  $x^*$  is an optimal solution of (1), (2), then  $x^* \in E_{D,J}$ .

*Remark 18* The assumption in Theorem 17 concerning  $F$  is fulfilled, e. g., if  $u \in C_m^J$  is strictly convex on the convex hull  $\text{conv} \{(A^j y - b^j)(A^j x - b^j) : x, y \in D, 1 \leq j \leq r\}$  generated by the line segments  $(A^j y - b^j)(A^j x - b^j)$  joining  $(A^j y - b^j)$  and  $(A^j x - b^j)$ .

If the assumption in Theorem 17 concerning  $F$  does not hold, then it may happen that  $F$  is constant on a certain line segment  $xy$  though  $A^j y \neq A^j x$  for at least one index  $j, 1 \leq j \leq r$ . Hence, Theorem 17 can not be applied then directly. However, in this case the following modification of Theorem 17 holds true.

**Theorem 19** Let  $u$  be an arbitrary loss function from  $C_m^J$  for some  $J \subset \{1, \dots, m\}$ . If  $D$  is a compact convex subset of  $\mathbb{R}^n$ , then there exists at least one optimal solution  $x^*$  of (1), (2) lying in the closure  $\bar{E}_{D,J}$  of the set  $E_{D,J}$  of efficient solutions of (1), (2).

**Parametric Representation of  $E_{D,J}$**

Suppose that  $u \in C_m^J$  for some index set  $J \subset \{1, \dots, m\}$ . For solving the descent direction-generating relations

(12)-(15) and (16)-(18), resp., we may use, see Theorem 5 and Corollary 6, the quadratic program, cf. [3,4],

$$\left\{ \begin{array}{l} \min \quad \eta'(\bar{A}_I y - \bar{A}_I x) + \sum_{j=1}^r \alpha_j \sum_{i \in S} \tilde{\beta}_{ij}^2 \\ \text{s.t.} \quad \sum_{j=1}^r \tau_{ij} = 1, \quad \tau_{ij} \geq 0, \\ \quad \quad j = 1, \dots, r, \quad i \in S, \\ \quad \quad \alpha_j = \sum_{i \in S} \tilde{\alpha}_i \tau_{ij}, \quad j = 1, \dots, r, \\ \quad \quad A_I^j y - b_I^j \leq \sum_{i \in S} \tilde{\beta}_{ij} z_I^i, \quad j = 1, \dots, r, \\ \quad \quad A_{II}^j y - b_{II}^j = \sum_{i \in S} \tilde{\beta}_{ij} z_{II}^i, \quad j = 1, \dots, r, \\ \quad \quad y \in D, \end{array} \right. \quad (33)$$

where  $\eta = (\eta_l)$  is a  $|J|$ -vector having fixed positive components  $\eta_l, l \in J$ . Efficient solutions of (1), (2) can be characterized as follows:

**Lemma 20** A vector  $x \in D$  is an efficient solution of (1), (2) if and only if (33) has an optimal solution  $(y^*, T^*)$  such that  $A^j y^* = A^j x$  for all  $j = 1, \dots, r$ .

*Remark 21* According to Lemma 8 we have then also that  $T^* = T^0$  and (14) holds with ‘ = ’.

We suppose now that the feasible domain  $D$  of (1), (2) is given by

$$D = \{x \in \mathbb{R}^n : g_k(x) \leq 0, k = 1, \dots, \kappa\}. \quad (34)$$

Here,  $g_1, \dots, g_\kappa$  are differentiable, convex functions. Moreover, we suppose that (33) has a feasible solution  $(y, T)$  such that for each nonaffine linear function  $g_k$

$$g_k(y) < 0. \quad (35)$$

No constraint qualifications are needed in the important special case  $D = \{x \in \mathbb{R}^n : G_x \leq g\}$ , where  $(G, g)$  is a given  $\kappa \times (n + 1)$  matrix.

By means of the Kuhn-Tucker conditions of (33), the following parametric representation of  $E_{D,J}$  can be derived [3,4]:

**Theorem 22** Let  $D$  be given by (34), and assume that the constraint qualification (35) holds for every  $x \in D$ . An  $n$ -vector  $x$  is an efficient solution of (1), (2) if and

only if  $x$  satisfies the linear relations

$$\lambda_j - \lambda_i - \left( \frac{\widehat{\gamma}_j}{\alpha_j} - \frac{\widehat{\gamma}_i}{\alpha_i} \right)' z^i = 2 \left( \frac{1}{\alpha_i} - \frac{1}{\alpha_j} \right),$$

if  $z^i = z^j$ , (36)

$$\lambda_j - \lambda_i - \left( \frac{\widehat{\gamma}_j}{\alpha_j} - \frac{\widehat{\gamma}_i}{\alpha_i} \right)' z^i \geq \frac{2}{\alpha_i},$$

if  $z^i \neq z^j$ , (37)

where  $\lambda_1, \dots, \lambda_r$  are arbitrary real parameters, and the parameter  $m$ -vectors  $\gamma_1, \dots, \gamma_r$  and further parameter vectors  $\rho \in \mathbf{R}^{\kappa}$ ,  $y \in \mathbf{R}^n$  are selected such that

$$\sum_{j=1}^r A^j \widehat{\gamma}_j + \sum_{k=1}^{\kappa} \rho_k \nabla g_k(y) = 0, \quad (38)$$

$$\gamma_{ji} \geq 0, \quad j = 1, \dots, r, \quad (39)$$

$$g_k(x) \leq 0, \quad k = 1, \dots, \kappa, \quad (40)$$

$$g_k(y) \leq 0, \quad \rho_k g_k(y) = 0, \quad \rho_k \geq 0, \quad (41)$$

$k = 1, \dots, \kappa,$

$$A^j y = A^j x, \quad j = 1, \dots, r, \quad (42)$$

and the vectors  $\widehat{\gamma}_j$  are defined by  $\widehat{\gamma}_j = \begin{pmatrix} \alpha_j \eta + \gamma_{ji} \\ \gamma_{ji} \end{pmatrix}$ ,  $j = 1, \dots, r$ .

A *stochastic combinatorial optimization* problem is of the form

$$\begin{cases} \min & F(x) = \int H(x, v) d\mu_x(v) \\ \text{s.t.} & x \in S \end{cases} \quad (1)$$

where  $S = \{x_1, \dots, x_N\}$  is a finite discrete feasible set. If the value of the objective function  $F$  is easily obtainable, the problem is just a deterministic combinatorial optimization problem. In most applications however, the value of the objective function  $F$  has to be approximated by numerical integration or Monte-Carlo simulation.

Some problems of type (1) exhibit a special structure, which can be exploited for solution methods, like the *stochastic linear optimization problems*, where  $S$  are the integer points of a convex polyhedron and  $H$  is piecewise linear (see ► [Stochastic integer programming: Continuity, stability, rates of convergence](#)). In this contribution, we discuss problems with an arbitrary and unstructured feasible set  $S$ .

An example is the stochastic single machine tardiness problem (SSMTP): The optimal sequence of  $m$  jobs, which are processed on a single machine has to be found. Each job has a random processing time, which is distributed according to the distribution function  $G_i$ ,  $i = 1, \dots, m$  (independent of all others), and a fixed due date  $d_i$ . The feasible set  $S$  is the set of all  $m!$  permutations  $\pi$  of  $\{1, \dots, m\}$ . If  $\pi$  is the solution found, we process job  $\pi(1)$  as the first,  $\pi(2)$  as the second and so on.

Let  $c_i(u)$  be the costs for job  $i$  being late  $u$  time units ( $c_i(u) = 0$  for  $u \leq 0$ ). The SSMTP is

$$\begin{cases} \min & \sum_{i=1}^m E[c_i(V_{\pi(1)} + \dots + V_{\pi(i)} - d_{\pi(i)})] \\ \text{s.t.} & \pi \in S \end{cases} \quad (2)$$

where  $V_i$  are random variables distributed independently according to  $G_i$ . The analytic calculation of the objective function (OF) in (2) involves multiple integrals (the convolution of up to  $m$  distribution functions). A simple way of approximating the OF is by Monte-Carlo simulation. Let  $V_i^{(1)}, \dots, V_i^{(n)}$  be independent random (pseudorandom) variables, each with distribution  $G_i$ . The true expectation  $F(\pi) = E[c_i(V_{\pi(1)} + \dots + V_{\pi(i)} - d_{\pi(i)})]$  is approximated by the estimate

$$\begin{aligned} \widehat{F}_n(\pi) \\ = \frac{1}{n} \sum_{j=1}^n \sum_{i=1}^m [c_i(V_{\pi(1)}^{(j)} + \dots + V_{\pi(i)}^{(j)} - d_{\pi(i)})]. \end{aligned}$$

In principle, all exact (branch and bound) and heuristic (evolutionary algorithms, tabu search, ant systems, random search, simulated annealing, genetic algorithms) methods for combinatorial optimization may be applied to stochastic combinatorial optimization — just that the exact values  $F(x)$  have to be replaced by stochastic estimates  $\widehat{F}_n(x)$ , which are based on sample size  $n$ .

The main difficulty in stochastic combinatorial optimization is the fact that even if  $F(x_1) \leq F(x_2) - \delta$ , it may happen with positive probability that  $\widehat{F}_n(x_1) > \widehat{F}_n(x_2)$ , that is we may wrongly conclude that  $x_2$  is better than  $x_1$ . The probability of this error decreases to zero with sample size  $n$  increasing to infinity. A compromise between the quality of the solution and the costs of very large samples has to be found in stochastic optimization.

If the random distribution  $\mu_x$  in (1) does not depend on  $x$ , *common random numbers* may be taken. To be more precise, let  $V^{(1)}, \dots, V^{(n)}$  be a sample from  $\mu$  and let

$$\widehat{F}_n(x_i) = \frac{1}{n} \sum_{j=1}^n H(x_i, V^{(j)}).$$

The estimates  $\widehat{F}$  are now correlated, and the probability that  $\widehat{F}_n(x_1) > \widehat{F}_n(x_2)$  although  $\widehat{F}_n(x_1) \leq \widehat{F}_n(x_2) - \delta$

is typically much smaller for such a choice than with samples taken independently for each  $x_j$  (see [6]).

If the estimates  $\widehat{F}$  are difficult to get (e.g. they need real observation or expensive simulation) allocation rules decide, which estimate or which set of estimates has to be taken next. These rules try to exclude quickly subsets of the feasible set, which – with high statistical evidence – do not contain optimal solutions. The effort is then concentrated on the (shrinking) set of not yet excluded points. Allocation rules may be based on *subset selection* (see [3]) or *ordinal optimization* (see [5]). There is also a connection to experimental design, in particular to *sequential experimental design*: In experimental design one has to choose the next point(s) for sampling, which – based on the information gathered so far – will give the best additional information which we need to solve the underlying estimation or optimization problem (for experimental design literature see [1] and the references therein).

For large sets  $S$ , which have graph-neighborhood or partition structures, ‘stochastic’ variants of neighbor search or branch and bound methods may be used. In particular, stochastic simulated annealing and stochastic branch and bound have been studied in literature.

### Stochastic Simulated Annealing

This is a variant of ordinary simulated annealing (cf. ► **Simulated annealing**): The Metropolis rule for the acceptance probability is calculated on the basis of the current stochastic estimates of the objective function, i. e. the new state  $x_j$  is preferred to the current state  $x_i$  with probability

$$\min \left( \exp \left( -\frac{\widehat{F}_n(x_j) - \widehat{F}_n(x_i)}{k_B T} \right), 1 \right)$$

where  $k_B$  is the Boltzmann constant and  $T$  is the temperature. The estimates  $\widehat{F}$  are improved in each step by taking additional observations, i. e. increasing the sample size  $n$ . For an analysis of this algorithm see [4].

### Stochastic Branch and Bound

For the implementation of a stochastic branch and bound method (cf. also ► **Integer programming: Branch and bound methods**), an estimate of a lower bound function is needed. Recall that a function  $\mathbf{F}$ , defined on the subsets of  $S$ , is called a *lower bound function*

if

$$\inf \{F(x) : x \in T\} \geq \mathbf{F}(T)$$

for all  $T \subseteq S$ .

In stochastic branch and bound an estimate  $\widehat{\mathbf{F}}$  of  $\mathbf{F}$  can be found for instance by sampling  $\widehat{F}_n(x_i)$  for each  $x_i$  in  $T$  with  $E(\widehat{F}_n(x_i)) = F(x_i)$  and setting

$$\widehat{\mathbf{F}}(T) = \inf \{ \widehat{F}_n(x_i) : x_i \in T \}.$$

The bound-step of the branch and bound method is replaced by a statistical test, whether the lower bound estimate of a branch is significantly larger than the estimate of an intermediate solution. After each step, all estimates are improved by taking additional observations. For details see [2] and [7].

In all these algorithms, common random numbers may decrease the variance.

### Abstract

In this chapter, we present classification models based on mathematical programming approaches. We first provide an overview of various mathematical programming approaches, including linear programming, mixed integer programming, nonlinear programming, and support vector machines. Next, we present our effort of novel optimization-based classification models that are general purpose and suitable for develop-

ing predictive rules for large heterogeneous biological and medical data sets. Our predictive model simultaneously incorporates (1) the ability to classify any number of distinct groups; (2) the ability to incorporate heterogeneous types of attributes as input; (3) a high-dimensional data transformation that eliminates noise and errors in biological data; (4) the ability to incorporate constraints to limit the rate of misclassification, and a reserved-judgment region that provides a safeguard against overtraining (which tends to lead to high misclassification rates from the resulting predictive rule); and (5) successive multistage classification capability to handle data points placed in the reserved-judgment region. To illustrate the power and flexibility of the classification model and solution engine, and its multigroup prediction capability, application of the predictive model to a broad class of biological and medical problems is described. Applications include the differential diagnosis of the type of erythematous-squamous diseases; predicting presence/absence of heart disease; genomic analysis and prediction of aberrant CpG island methylation in human cancer; discriminant analysis of motility and morphology data in human lung carcinoma; prediction of ultrasonic cell disruption for drug delivery; identification of tumor shape and volume in treatment of sarcoma; multistage discriminant analysis of biomarkers for prediction of early atherosclerosis; fingerprinting of native and angiogenic microvascular networks for early diagnosis of diabetes, aging, macular degeneracy, and tumor metastasis; prediction of protein localization sites; and pattern recognition of satellite images in classification of soil types. In all these applications, the predictive model yields correct classification rates ranging from 80 to 100%. This provides motivation for pursuing its use as a medical diagnostic, monitoring and decision-making tool.

### Introduction

Classification is a fundamental machine learning task whereby rules are developed for the allocation of independent observations to groups. Classic examples of applications include medical diagnosis – the allocation of patients to disease classes on the basis of symptoms and laboratory tests – and credit screening – the acceptance or rejection of credit applications on the basis of applicant data. Data are collected concerning observa-

tions with known group membership. These *training data* are used to develop rules for the classification of future observations with unknown group membership.

In this introduction, we briefly describe some terminologies related to classification, and provide a brief description of the organization of this chapter.

### Pattern Recognition, Discriminant Analysis, and Statistical Pattern Classification

*Cognitive science* is the science of learning, knowing, and reasoning. *Pattern recognition* is a broad field within *cognitive science*, which is concerned with the process of recognizing, identifying, and categorizing input information. These areas intersect with computer science, particularly in the closely related areas of *artificial intelligence*, *machine learning*, and *statistical pattern recognition*. Artificial intelligence is associated with constructing machines and systems that reflect human abilities in cognition. Machine learning refers to how these machines and systems replicate the learning process, which is often achieved by seeking and discovering patterns in data, or statistical pattern recognition.

*Discriminant analysis* is the process of discriminating between categories or populations. Associated with discriminant analysis as a statistical tool are the tasks of determining the features that best discriminate between populations, and the process of classifying new objects on the basis of these features. The former is often called *feature selection* and the latter is referred to as *statistical pattern classification*. This work will be largely concerned with the development of a viable statistical pattern classifier.

As with many computationally intensive tasks, recent advances in computing power have led to a sharp increase in the interest and application of discriminant analysis techniques. The reader is referred to Duda et al. [25] for an introduction to various techniques for pattern classification, and to Zopounidis and Doumpos [121] for examples of applications of pattern classification.

### Supervised Learning, Training, and Cross-Validation

An *entity* or *observation* is essentially a data point as commonly understood in statistics. In the framework of statistical pattern classification, an entity is a set

of quantitative measurements (or qualitative measurements expressed quantitatively) of *attributes* for a particular object. As an example, in medical diagnosis an entity could be the various blood chemistry levels of a patient. With each entity is associated one or more *groups* (or *populations*, *classes*, *categories*) to which it belongs. Continuing with the medical diagnosis example, the groups could be the various classes of heart disease. Statistical classification seeks to determine rules for associating entities with the groups to which they belong. Ideally, these associations align with the associations that human reasoning would produce on the basis of information gathered on objects and their apparent categories.

*Supervised learning* is the process of developing classification rules based on entities for which the classification is already known. Note that the process implies that the populations are already well defined. *Unsupervised learning* is the process of discovering patterns from unlabeled entities and thereby discovering and describing the underlying populations. Models derived using supervised learning can be used for both functions of discriminant analysis – feature selection and classification. The model that we consider is a method for supervised learning, so we assume that populations are previously defined.

The set of entities with known classification that is used to develop classification rules is the *training set*. The training set may be partitioned so that some entities are withheld during the model-development process, also known as the *training* of the model. The withheld entities form a *test set* that is used to determine the validity of the model, a process known as *cross-validation*. Entities from the test set are subjected to the rules of classification to measure the performance of the rules on entities with unknown group membership.

Validation of classification models is often performed using *m*-fold cross-validation where the data with known classification are partitioned into *m* *folds* (subsets) of approximately equal size. The classification model is trained *m* times, with the *m*th fold withheld during each run for testing. The performance of the model is evaluated by the classification accuracy on the *m* test folds, and can be represented using a *classification matrix* or *confusion matrix*.

The classification matrix is a square matrix with the number of rows and columns equal to the number of

groups. The  $ij$ th entry of the classification matrix contains the number or proportion of test entities from group  $i$  that were classified by the model as belonging to group  $j$ . Therefore, the number or proportion of correctly classified entities is contained in the diagonal elements of the classification matrix, and the number or proportion of misclassified entities is in the off-diagonal entries.

### Bayesian Inference and Classification

The popularity of *Bayesian inference* has risen drastically over the past several decades, perhaps in part due to its suitability for statistical learning. The reader is referred to O'Hagan [92] for a thorough treatment of Bayesian inference. Bayesian inference is usually contrasted against *classical inference*, though in practice they often imply the same methodology.

The Bayesian method relies on a *subjective* view of probability, as opposed to the *frequentist* view upon which classical inference is based [92]. A subjective probability describes a degree of belief in a *proposition* held by the investigator based on some information. A frequency probability describes the likelihood of an *event* given an infinite number of trials.

In Bayesian statistics, inferences are based on the *posterior distribution*. The posterior distribution is the product of the *prior probability* and the *likelihood function*. The prior probability distribution represents the initial degree of belief in a proposition, often before empirical data are considered. The likelihood function describes the likelihood that the behavior is exhibited, given that the proposition is true. The posterior distribution describes the likelihood that the proposition is true, given the observed behavior.

Suppose we have a proposition or random variable  $\theta$  about which we would like to make inferences, and data  $x$ . Application of Bayes's theorem gives

$$dF(\theta|x) = \frac{dF(\theta)dF(x|\theta)}{dF(x)}.$$

Here,  $F$  denotes the (cumulative) distribution function. For ease of conceptualization, assume that  $F$  is differentiable, then  $dF = f$ , and the above equality can be rewritten as

$$f(\theta|x) = \frac{f(\theta)f(x|\theta)}{f(x)}.$$

For classification, a prior probability function  $\pi(g)$  describes the likelihood that an entity is allocated to group  $g$  regardless of its exhibited feature values  $x$ . A group density function  $f(x|g)$  describes the likelihood that an entity exhibits certain measurable attribute values, given that it belongs to population  $g$ . The posterior distribution for a group  $P(g|x)$  is given by the product of the prior probability and group density function, normalized over the groups to obtain a unit probability over all groups. The observation  $x$  is allocated to group  $h$  if  $h = \arg \max_{g \in \mathcal{G}} P(g|x) = \arg \max_{g \in \mathcal{G}} \frac{\pi(g)f(x|g)}{\sum_{j \in \mathcal{G}} \pi(j)f(x|j)}$ , where  $\mathcal{G}$  denotes the set of groups.

### Discriminant Functions

Most classification methods can be described in terms of *discriminant functions*. A discriminant function takes as input an observation and returns information about the classification of the observation. For data from a set of groups  $\mathcal{G}$ , an observation  $x$  is assigned to group  $h$  if  $h = \arg \max_{g \in \mathcal{G}} l_g(x)$ , where the functions  $l_g$  are the discriminant functions. Classification methods restrict the form of the discriminant functions, and training data are used to determine the values of the parameters that define the functions.

The optimal classifier in the Bayesian framework can be described in terms of discriminant functions. Let  $\pi_g = \pi(g)$  be the prior probability that an observation is allocated to group  $g$  and let  $f_g(x) = f(x|g)$  be the likelihood that data  $x$  are drawn from population  $g$ . If we wish to minimize the probability of misclassification given  $x$ , then the optimal allocation for an entity is to the group  $h = \arg \max_{g \in \mathcal{G}} P(g|x) = \arg \max_{g \in \mathcal{G}} \frac{\pi_g f_g(x)}{\sum_{j \in \mathcal{G}} \pi_j f_j(x)}$ . Under the Bayesian framework,

$$P(g|x) = \frac{\pi_g f(x|g)}{f(x)} = \frac{\pi_g f(x|g)}{\sum_{j \in \mathcal{G}} \pi_j f(x|j)}.$$

The discriminant functions can be  $l_g(x) = P(g|x)$  for  $g \in \mathcal{G}$ . The same classification rule is given by  $l_g(x) = \pi_g f(x|g)$  and  $l_g(x) = \log f(x|g) + \log \pi_g$ . The problem then becomes finding the form of the prior functions and likelihood functions that match the data.

If the data are multivariate normal with equal covariance matrices ( $f(x|g) \sim N(\mu_g, \Sigma)$ ), then a linear discriminant function (LDF) is optimal:

$$\begin{aligned} l_g(x) &= \log f(x|g) + \log \pi_g \\ &= -1/2(x - \mu_g)^T \Sigma^{-1}(x - \mu_g) - 1/2 \log |\Sigma_g| \\ &\quad - d/2 \log 2\pi + \log \pi_g \\ &= w_g^T x + w_{g0}, \end{aligned}$$

where  $d$  is the number of attributes,  $w_g = \Sigma^{-1}\mu_g$ , and  $w_{g0} = -1/2\mu_g^T \Sigma^{-1}\mu_g + \log \pi_g + x^T \Sigma^{-1}x - d/2 \log 2\pi$ . Note that the last two terms of  $w_{g0}$  are constant for all  $g$  and need not be calculated. When there are two groups ( $G = \{1, 2\}$ ) and the priors are equal ( $\pi_1 = \pi_2$ ), the discriminant rule is equivalent to Fisher's linear discriminant rule [30]. Fisher's rule can also be derived, as it was by Fisher, by choosing  $w$  so that  $(w^T \mu_1 - w^T \mu_2)^2 / (w^T \Sigma w)$  is maximized.

These LDFs and quadratic discriminant functions (QDFs) are often applied to data sets that are not multivariate normal or continuous (see pp. 234–235 in [98]) by using approximations for the means and covariances. Regardless, these models are *parametric* in that they incorporate assumptions about the distribution of the data. Fisher's LDF is *nonparametric* because no assumptions are made about the underlying distribution of the data. Thus, for a special case, a parametric and a nonparametric model coincide to produce the same discriminant rule. The LDF derived above is also called the *homoscedastic model*, and the QDF is called the *heteroscedastic model*. The exact form of discriminant functions in the Bayesian framework can be derived for other distributions [25].

Some classification methods are essentially methods for finding coefficients for LDFs. In other words, they seek coefficients  $w_g$  and constants  $w_{g0}$  such that  $l_g(x) = w_g x + w_{g0}$ ,  $g \in G$  is an optimal set of discriminant functions. The criteria for optimality are different for different methods. LDFs project the data onto a linear subspace and then discriminate between entities in that subspace. For example, Fisher's LDF projects two-group data on an optimal line, and discriminates on that line. A good linear subspace may not exist for data with overlapping distributions between groups and therefore the data will not be classified accurately using these methods. The hyperplanes defined by the

discriminant functions form boundaries between the group regions. A large portion of the literature concerning the use of mathematical programming models for classification describes methods for finding coefficients of LDFs [121].

Other classification methods seek to determine parameters to establish QDFs. The general form of a QDF is  $l_g(x) = x^T W_g x + w_g^T x + w_{g0}$ . The boundaries defining the group regions can assume any hyperquadratic form, as can the Bayes decision rules for arbitrary multivariate normal distributions [25].

In this paper, we survey the development and advances of classification models via the mathematical programming techniques, and summarize our experience in classification models applied to prediction in biological and medical applications. The rest of this chapter is organized as follows. Section “**Mathematical Programming Approaches**” first provides a detailed overview of the development and advances of mathematical programming based classification models, including linear programming (LP), mixed integer programming (MIP), nonlinear programming, and support vector machine (SVM) approaches. In Sect. “**Mixed Integer Programming Based Multigroup Classification Models and Applications to Medicine and Biology**”, we describe our effort in developing optimization-based multigroup multistage discriminant analysis predictive models for classification. The use of the predictive models for various biological and medical problems is presented. Section “**Progress and Challenges**” provides several tables to summarize the progress of mathematical programming based classification models and their characteristics. This is followed by a brief description of other classification methods in Sect. “**Other Methods**”, and by a summary and concluding remarks in Sect. “**Summary and Conclusion**”.

## Mathematical Programming Approaches

Mathematical programming methods for statistical pattern classification emerged in the 1960s, gained popularity in the 1980s, and have grown drastically since. Most of the mathematical programming approaches are nonparametric, which has been cited as an advantage when analyzing contaminated data sets over methods that require assumptions about the distribution of the

data [107]. Most of the literature about mathematical programming methods is concerned with either using mathematical programming to determine the coefficients of LDFs or *support vector machines* (SVMs).

The following notation will be used. The subscripts  $i$ ,  $j$ , and  $k$  are used for the observation, attribute, and group, respectively. Let  $x_{ij}$  be the value of attribute  $j$  of observation  $i$ . Let  $m$  be the number of attributes,  $K$  be the number of groups,  $G_k$  represent the set of data from group  $k$ ,  $M$  be a big positive number, and  $\epsilon$  be a small positive number. The abbreviation “urs” is used in reference to a variable to denote “unrestricted in sign.”

### Linear Programming Classification Models

The use of linear programs to determine the coefficients of LDFs has been widely studied [31,46,50,74]. The methods determine the coefficients for different objectives, including minimizing the sum of the distances to the separating hyperplane, minimizing the maximum distance of an observation to the hyperplane, and minimizing other measures of badness of fit or maximizing measures of goodness of fit.

**Two-Group Classification** One of the earliest LP classification models was proposed by Mangasarian [74] to construct a hyperplane to separate two groups of data. Separation by a nonlinear surface using LP was also proposed when the surface parameters appear linearly. Two sets of points may be inseparable by one hyperplane or surface through a single-step LP approach, but they can be strictly separated by more planes or surfaces via a multistep LP approach [75]. In [75] real problems with up to 117 data points, ten attributes, and three groups were solved. The three-group separation was achieved by separating group 1 from groups 2 and 3, and then group 2 from group 3.

Studies of LP models for the discriminant problem in the early 1980s were carried out by Hand [47], Freed and Glover [31,32], and Bajgier and Hill [5]. Three LP models for the two-group classification problem, including minimizing the sum of deviations (MSD), minimizing the maximum deviation (MMD), and minimizing the sum of interior distances (MSID) were proposed. Freed and Glover [33] provided computational studies of these models where the test conditions involved normal and nonnormal populations.

MSD:

$$\begin{aligned} & \text{Minimize} && \sum_i d_i \\ & \text{subject to} && w_0 + \sum_j x_{ij} w_j - d_i \leq 0 \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij} w_j + d_i \geq 0 \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d_i \geq 0 \quad \forall i. \end{aligned}$$

MMD:

$$\begin{aligned} & \text{Minimize} && d \\ & \text{subject to} && w_0 + \sum_j x_{ij} w_j - d \leq 0 \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij} w_j + d \geq 0 \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d \geq 0. \end{aligned}$$

MSID:

$$\begin{aligned} & \text{Minimize} && pd - \sum_i e_i \\ & \text{subject to} && w_0 + \sum_j x_{ij} w_j - d + e_i \leq 0 \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij} w_j + d - e_i \geq 0 \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d \geq 0, \\ & && e_i \geq 0 \quad \forall i, \end{aligned}$$

where  $p$  is a weight constant.

The objective function of the MSD model is the  $L_1$ -norm distance, while the objective function of MMD is the  $L_\infty$ -norm distance. They are special cases of  $L_p$ -norm classification [50,108].

In some models the constant term of the hyperplane is a fixed number instead of a decision variable. The model minimize the sum of deviations with constant cutoff score  $\text{MSD}^0$  shown below is an example where the cutoff score  $b$  replaces  $w_0$  in the formulation. The same replacement could be used in other formulations.

MSD<sup>0</sup>:

$$\begin{aligned} & \text{Minimize} && \sum_i d_i \\ & \text{subject to} && \sum_j x_{ij}w_j - d_i \leq b \quad \forall i \in G_1, \\ & && \sum_j x_{ij}w_j + d_i \geq b \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d_i \geq 0 \quad \forall i. \end{aligned}$$

A gap can be introduced between the two regions determined by the separating hyperplane to prevent degenerate solutions. Take MSD as an example; the separation constraints become

$$\begin{aligned} w_0 + \sum_j x_{ij}w_j - d_i &\leq -\epsilon \quad \forall i \in G_1, \\ w_0 + \sum_j x_{ij}w_j + d_i &\geq \epsilon \quad \forall i \in G_2. \end{aligned}$$

The small number  $\epsilon$  can be normalized to 1.

Besides introducing a gap, another normalization approach is to include constraints such as  $\sum_{j=0}^m w_j = 1$  or  $\sum_{j=1}^m w_j = 1$  in the LP models to avoid unbounded or trivial solutions.

Specifically, Glover et al. [45] gave the hybrid model, as follows.

Hybrid model:

$$\begin{aligned} & \text{Minimize} && pd + \sum_i p_i d_i - qe - \sum_i q_i e_i \\ & \text{subject to} && w_0 + \sum_j x_{ij}w_j - d - d_i + e + e_i = 0 \\ & && \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij}w_j + d + d_i - e - e_i = 0 \\ & && \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d, e \geq 0, \\ & && d_i, e_i \geq 0 \quad \forall i, \end{aligned}$$

where  $p, p_i, q, q_i$  are the costs for different deviations. Including different combinations of deviation terms in the objective function then leads to variant models.

Joachimsthaler and Stam [50] reviewed and summarized LP formulations applied to two-group classi-

fication problems in discriminant analysis, including MSD, MMD, MSID, and MIP models, and the hybrid model. They summarized the performance of the LP methods together with the traditional classification methods such as Fisher's LDF [30], Smith's QDF [106], and a logistic discriminant method. In their review, MSD sometimes but not uniformly improves classification accuracy, compared with traditional methods. On the other hand, MMD is found to be inferior to MSD. Erenguc and Koehler [27] presented a unified survey of LP models and their experimental results, in which the LP models include several versions of MSD, MMD, MSID, and hybrid models. Rubin [99] provided experimental results comparing these LP models with Fisher's LDF and Smith's QDF. He concluded that QDF performs best when the data follow normal distributions and that QDF could be the benchmark when seeking situations for advantageous LP methods. In summary, the above mentioned review papers [27,50,99] describe previous work on LP classification models and their comparison with traditional methods. However, it is difficult to make definitive statements about the conditions under which one LP model is superior to others, as stated in [107].

Stam and Ungar [110] introduced the software package RAGNU, a utility program in conjunction with the LINDO optimization software, for solving two-group classification problems using LP-based methods. LP formulations such as MSD, MMD, MSID, hybrid models, and their variants are contained in the package.

There are some difficulties in LP-based formulations, in that some models could result in unbounded, trivial, or unacceptable solutions [34,87], but possible remedies are proposed. Koehler [51,52,53] and Xiao [114,115] characterized the conditions of unacceptable solutions in two-group LP discriminant models, including MSD, MMD, MISD, the hybrid model, and their variants. Glover [44] proposed the normalization constraint  $\sum_{j=1}^m (-|G_2| \sum_{i \in G_1} x_{ij} + |G_1| \sum_{i \in G_2} x_{ij})w_j = 1$ , which is more effective and reliable. Rubin [100] examined the separation failure for two-group models and suggested applying the models twice, reversing the group designations the second time. Xiao and Feng [116] proposed a regularization method to avoid multiple solutions in LP discriminant analysis by adding the term  $\epsilon \sum_{j=1}^m w_j^2$  in the objective functions.

Bennett and Mangasarian [9] proposed the following model which minimizes the average of the deviations, which is called robust LP (RLP):

$$\begin{aligned} & \text{Minimize} && \frac{1}{|G_1|} \sum_{i \in G_1} d_i + \frac{1}{|G_2|} \sum_{i \in G_2} d_i \\ & \text{subject to} && w_0 + \sum_j x_{ij} w_j - d_i \leq -1 \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij} w_j + d_i \geq 1 \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d_i \geq 0 \quad \forall i. \end{aligned}$$

It is shown that this model gives the null solution  $w_1 = \dots = w_m = 0$  if and only if  $\frac{1}{|G_1|} \sum_{i \in G_1} x_{ij} = \frac{1}{|G_2|} \sum_{i \in G_2} x_{ij}$  for all  $j$ , in which case the solution  $w_1 = \dots = w_m = 0$  is guaranteed to be not unique. Data of different diseases have been tested by the proposed classification methods, as in most of Mangasarian's papers.

Mangasarian et al. [86] described two applications of LP models in the field of breast cancer research, one in diagnosis and the other in prognosis. The first application is to discriminate benign from malignant breast lumps, while the second one is to predict when breast cancer is likely to recur. Both of them work successfully in clinical practice. The RLP model [9] together with the multisurface method tree algorithm [8] is used in the diagnostic system.

Duarte Silva and Stam [104] included the second-order (i. e., quadratic and cross-product) terms of the attribute values in the LP-based models such as MSD and hybrid models and compared them with linear models, Fisher's LDF, and Smith's QDF. The results of the simulation experiments show that the methods which include second-order terms perform much better than first-order methods, given that the data substantially violate the multivariate normality assumption. Wanarat and Pavur [113] investigated the effect of the inclusion of the second-order terms in the MSD, MIP, and hybrid models when the sample size is small to moderate. However, the simulation study shows that second-order terms may not always improve the performance of a first-order LP model even with data configurations that are more appropriately classified by Smith's QDF. Another result of the simulation study is

that inclusion of the cross-product terms may hurt the model's accuracy, while omission of these terms causes the model to be not invariant with respect to a nonsingular transformation of the data.

Pavur [94] studied the effect of the position of the contaminated normal data in the two-group classification problem. The methods for comparison in that study included MSD, minimizing the number of misclassifications (MM; (described in the "Mixed Integer Programming Classification Models" section), Fisher's LDF, Smith's QDF, and nearest -neighbor models. The nontraditional methods such as LP models have potential for outperforming the standard parametric procedures when nonnormality is present, but this study shows that no one model is consistently superior in all cases.

Asparoukhov and Stam [3] proposed LP and MIP models to solve the two-group classification problem where the attributes are binary. In this case the training data can be partitioned into multinomial cells, allowing for a substantial reduction in the number of variables and constraints. The proposed models not only have the usual geometric interpretation, but also possess a strong probabilistic foundation. Let  $s$  be the index of the cells,  $n_{1s}, n_{2s}$  be the number of data points in cell  $s$  from groups 1 and 2, respectively, and  $(b_{s1}, \dots, b_{sm})$  be the binary digits representing cell  $s$ . The model shown below is the LP model of minimizing the sum of deviations for two-group classification with binary attributes.

Cell conventional MSD:

$$\begin{aligned} & \text{Minimize} && \sum_{s: n_{1s} + n_{2s} > 0} (n_{1s} d_{1s} + n_{2s} d_{2s}) \\ & \text{subject to} && w_0 + \sum_j b_{sj} w_j - d_{1s} \leq 0 \quad \forall s: n_{1s} > 0, \\ & && w_0 + \sum_j b_{sj} w_j + d_{2s} > 0 \quad \forall s: n_{2s} > 0, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d_{1s}, d_{2s} \geq 0 \quad \forall s. \end{aligned}$$

Binary attributes are usually found in medical diagnoses data. In this study three real data sets of disease discrimination were tested: developing postoperative pulmonary embolism or not, having dissecting aneurysm or other diseases, and suffering from post-

traumatic epilepsy or not. In these data sets the MIP model for binary attributes (BMIP), which will be described later, performs better than other LP models or traditional methods.

**Multigroup Classification** Freed and Glover [32] extended the LP classification models from two-group to multigroup problems. One formulation which uses a single discriminant function is given below:

$$\begin{aligned}
& \text{Minimize} && \sum_{k=1}^{K-1} c_k \alpha_k \\
& \text{subject to} && \sum_j x_{ij} w_j \leq U_k \quad \forall i \in G_k \quad \forall k, \\
& && \sum_j x_{ij} w_j \geq L_k \quad \forall i \in G_k \quad \forall k, \\
& && U_k + \epsilon \leq L_{k+1} + \alpha_k \\
& && \forall k = 1, \dots, K-1, w_j \text{ urs} \quad \forall j, \\
& && U_k, L_k \text{ urs} \quad \forall k, \\
& && \alpha_k \text{ urs} \quad \forall k = 1, \dots, K-1,
\end{aligned}$$

where the number  $\epsilon$  could be normalized to be 1, and  $c_k$  is the misclassification cost. However, single-function classification is not as flexible and general as multiple-function classification. Another extension from the two-group case to the multigroup case in [32] is to solve two-group LP models for all pairs of groups and determine classification rules based on these solutions. However, in some cases the group assignment is not clear and the resulting classification scheme may be suboptimal [107].

For the multigroup discrimination problem, Bennett and Mangasarian [10] defined the piecewise-linear separability of data from  $K$  groups as the following: The data from  $K$  groups are piecewise-linear-separable if and only if there exist  $(w_0^k, w_1^k, \dots, w_m^k) \in R^{m+1}$ ,  $k = 1, \dots, K$ , such that  $w_0^h + \sum_j x_{ij} w_j^h \geq w_0^k + \sum_j x_{ij} w_j^k + 1$ ,  $\forall i \in G_h \quad \forall h, k \neq h$ . The following LP will generate a piecewise-linear separation for the  $K$  groups if one exists, otherwise it will generate an error-minimizing separation:

$$\text{Minimize} \quad \sum_h \sum_{k \neq h} \frac{1}{|G_h|} \sum_{i \in G_h} d_i^{hk}$$

$$\begin{aligned}
& \text{subject to} && d_i^{hk} \geq -(w_0^h + \sum_j x_{ij} w_j^h) \\
& && \quad + (w_0^k + \sum_j x_{ij} w_j^k) + 1 \\
& && \forall i \in G_h \quad \forall h, k \neq h, \\
& && w_j^k \text{ urs} \quad \forall j, k, \\
& && d_i^{hk} \geq 0 \quad \forall i \in G_h \quad \forall h, k \neq h.
\end{aligned}$$

The method was tested in three data sets. It performs pretty well in two of the data sets which are totally (or almost totally) piecewise-linear separable. The classification result is not good in the third data set, which is inherently more difficult. However, combining the multisurface method tree algorithm [8] results in an improvement in performance.

Gochet et al. [46] introduced an LP model for the general multigroup classification problem. The method separates the data with several hyperplanes by sequentially solving LPs. The vectors  $w^k$ ,  $k = 1, \dots, K$ , are estimated for the classification decision rule. The rule is to classify an observation  $i$  into group  $s$ , where  $s = \arg \max_k \{w_0^k + \sum_j x_{ij} w_j^k\}$ .

Suppose observation  $i$  is from group  $h$ . Denote the goodness of fit for observation  $i$  with respect to group  $k$  as

$$\begin{aligned}
& G_{hk}^i(w^h, w^k) \\
& = \left[ (w_0^h + \sum_j x_{ij} w_j^h) - (w_0^k + \sum_j x_{ij} w_j^k) \right]^+, \\
& \text{where } [a]^+ = \max\{0, a\}.
\end{aligned}$$

Likewise, denote the badness of fit for observation  $i$  with respect to group  $k$  as

$$\begin{aligned}
& B_{hk}^i(w^h, w^k) \\
& = \left[ (w_0^h + \sum_j x_{ij} w_j^h) - (w_0^k + \sum_j x_{ij} w_j^k) \right]^-, \\
& \text{where } [a]^- = -\min\{0, a\}.
\end{aligned}$$

The total goodness of fit and total badness of fit are then defined as

$$\begin{aligned}
G(w) &= G(w^1, \dots, w^K) = \sum_h \sum_{k \neq h} \sum_{i \in G_h} G_{hk}^i(w^h, w^k), \\
B(w) &= B(w^1, \dots, w^K) = \sum_h \sum_{k \neq h} \sum_{i \in G_h} B_{hk}^i(w^h, w^k).
\end{aligned}$$

The LP is to minimize the total badness of fit, subject to a normalization equation, in which  $q > 0$ :

$$\begin{aligned} & \text{Minimize} && B(w), \\ & \text{subject to} && G(w) - B(w) = q, \\ & && w \text{ urs.} \end{aligned}$$

Expanding  $G(w)$  and  $B(w)$  and substituting  $G_{hk}^i(w^h, w^k)$  and  $B_{hk}^i(w^h, w^k)$  by  $\gamma_{hk}^i$  and  $\beta_{hk}^i$  respectively, the LP becomes

$$\begin{aligned} & \text{Minimize} && \sum_h \sum_{k \neq h} \sum_{i \in G_h} \beta_{hk}^i \\ & \text{subject to} && \left( w_0^h + \sum_j x_{ij} w_j^h \right) - \left( w_0^k + \sum_j x_{ij} w_j^k \right) \\ & && = \gamma_{hk}^i - \beta_{hk}^i \quad \forall i \in G_h \quad \forall h, k \neq h, \\ & && \sum_h \sum_{k \neq h} \sum_{i \in G_h} (\gamma_{hk}^i - \beta_{hk}^i) = q, \\ & && w_j^k \text{ urs} \quad \forall j, k, \\ & && \gamma_{hk}^i, \beta_{hk}^i \geq 0 \quad \forall i \in G_h \quad \forall h, k \neq h. \end{aligned}$$

The classification results for two real data sets show that this model can compete with Fisher's LDF and the nonparametric  $k$ -nearest-neighbor method.

The LP-based models for classification problems highlighted above are all nonparametric models. In Sect. "Mixed Integer Programming Based Multigroup Classification Models and Applications to Medicine and Biology", we describe LP-based and MIP-based classification models that utilize a parametric multigroup discriminant analysis approach [39,40,60,63]. These latter models have been employed successfully in various multigroup disease diagnosis and biological/medical prediction problems [16,28,29,56,57,59,60,64,65].

### Mixed Integer Programming Classification Models

While LP offers a polynomial-time computational guarantee, MIP allows more flexibility in (among other things) modeling misclassified observations and/or misclassification costs.

**Two-Group Classification** In the two-group classification problem, binary variables can be used in the formulation to track and minimize the exact number of misclassifications. Such an objective function is also considered as the  $L_0$ -norm criterion [107].

MM:

$$\begin{aligned} & \text{Minimize} && \sum_i z_i \\ & \text{subject to} && w_0 + \sum_j x_{ij} w_j \leq M z_i \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij} w_j \geq -M z_i \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && z_i \in \{0, 1\} \quad \forall i. \end{aligned}$$

The vector  $w$  is required to be a nonzero vector to prevent the trivial solution.

In the MIP formulation the objective function could include the deviation terms, such as those in the hybrid models, as well as the number of misclassifications [5]; or it could represent expected cost of misclassification [1,6,101,105]. In particular, there are some variant versions of the basic model.

Stam and Joachimsthaler [109] studied the classification performance of MM and compared it with that of MSD, Fisher's LDF, and Smith's QDF. In some cases the MM model performs better, but in some cases it does not. MIP formulations are in the review studies of Joachimsthaler and Stam [50] and Erenguc and Koehler [27], and are contained in the software developed by Stam and Ungar [110]. Computational experiments show that the MIP model performs better when the group overlap is higher [50,109], although it is still not easy to reach general conclusions [107].

Since the MIP model is  $\mathcal{NP}$ -hard, exact algorithms and heuristics are proposed to solve it efficiently. Koehler and Erenguc [54] developed a procedure to solve MM in which the condition of nonzero  $w$  is replaced by the requirement of at least one violation of the constraints  $w_0 + \sum_j x_{ij} w_j \leq 0$  for  $i \in G_1$  or  $w_0 + \sum_j x_{ij} w_j \geq 0$  for  $i \in G_2$ . Banks and Abad [6] solved the MIP of minimizing the expected cost of misclassification by an LP-based algorithm. Abad and Banks [1] developed three heuristic procedures for the problem of minimizing the expected cost of misclassification.

sification. They also included the interaction terms of the attributes in the data and applied the heuristics [7]. Duarte Silva and Stam [105] introduced the divide and conquer algorithm for the classification problem of minimizing the misclassification cost by solving MIP and LP subproblems. Rubin [101] solved the same problem by using a decomposition approach, and tested this procedure on some data sets, including two breast cancer data sets. Yanev and Balev [119] proposed exact and heuristic algorithms for solving MM, which are based on some specific properties of the vertices of a polyhedral set neatly connected with the model.

For the two-group classification problem where the attributes are binary, Asparoukhov and Stam [3] proposed LP and MIP models which partition the data into multinomial cells and result in fewer variables and constraints. Let  $s$  be the index of the cells,  $n_{1s}, n_{2s}$  be the number of data points in cell  $s$  from groups 1 and 2, respectively, and  $(b_{s1}, \dots, b_{sm})$  be the binary digits representing cell  $s$ . Below is the BMIP, which performs best in the three real data sets in [3]:

BMIP

$$\begin{aligned} & \text{Minimize} && \sum_{s: n_{1s} + n_{2s} > 0} \{ |n_{1s} - n_{2s}| z_s + \min(n_{1s}, n_{2s}) \} \\ & \text{subject to} && w_0 + \sum_j b_{sj} w_j \leq M z_s \quad \forall s: n_{1s} \geq n_{2s}; \\ & && n_{1s} > 0, \\ & && w_0 + \sum_j b_{sj} w_j > -M z_s \quad \forall s: n_{1s} < n_{2s}, \\ & && w_j \text{ urs} \quad \forall j, \\ & && z_s \in \{0, 1\} \quad \forall s: n_{1s} + n_{2s} > 0. \end{aligned}$$

Pavur et al. [96] included different secondary goals in model MM and compared their misclassification rates. A new secondary goal was proposed, which maximizes the difference between the means of the discriminant scores of the two groups. In this model the term  $-\delta$  is added to the minimization objective function as a secondary goal with a constant multiplier, while the constraint  $\sum_j \tilde{x}_j^{(2)} w_j - \sum_j \tilde{x}_j^{(1)} w_j \geq \delta$  is included, where  $\tilde{x}_j^{(k)} = 1/|G_k| \sum_{i \in G_k} x_{ij} \quad \forall j$ , for  $k = 1, 2$ . The results of simulation study show that an MIP model with the proposed secondary goal has better performance than the other models studied.

Glen [42] proposed integer programming (IP) techniques for normalization in the two-group discriminant analysis models. One technique is to add the constraint  $\sum_{j=1}^m |w_j| = 1$ . In the proposed model,  $w_j$  for  $j = 1, \dots, m$  is represented by  $w_j = w_j^+ - w_j^-$ , where  $w_j^+, w_j^- \geq 0$ , and binary variables  $\delta_j$  and  $\gamma_j$  are defined such that  $\delta_j = 1 \Leftrightarrow w_j^+ \geq \epsilon$  and  $\gamma_j = 1 \Leftrightarrow w_j^- \geq \epsilon$ . The IP normalization technique is applied to MSD and MMD, and the MSD version is presented below.

MSD – with IP normalization:

$$\begin{aligned} & \text{Minimize} && \sum_i d_i \\ & \text{subject to} && w_0 + \sum_{j=1}^m x_{ij} (w_j^+ - w_j^-) - d_i \leq 0 \\ & && \forall i \in G_1, \\ & && w_0 + \sum_{j=1}^m x_{ij} (w_j^+ - w_j^-) + d_i \geq 0 \\ & && \forall i \in G_2, \\ & && \sum_{j=1}^m (w_j^+ + w_j^-) = 1, \\ & && w_j^+ - \epsilon \delta_j \geq 0 \quad \forall j = 1, \dots, m, \\ & && w_j^+ - \delta_j \leq 0 \quad \forall j = 1, \dots, m, \\ & && w_j^- - \epsilon \gamma_j \geq 0 \quad \forall j = 1, \dots, m, \\ & && w_j^- - \gamma_j \leq 0 \quad \forall j = 1, \dots, m, \\ & && \delta_j + \gamma_j \leq 1 \quad \forall j = 1, \dots, m, \\ & && w_0 \text{ urs}, \\ & && w_j^+, w_j^- \geq 0 \quad \forall j = 1, \dots, m, \\ & && d_i \geq 0 \quad \forall i, \\ & && \delta_j, \gamma_j \in \{0, 1\} \quad \forall j = 1, \dots, m. \end{aligned}$$

The variable coefficients of the discriminant function generated by the models are invariant under origin shifts. The proposed models were validated using two data sets from [45,87]. The models were also extended for attribute selection by adding the constraint  $\sum_{j=1}^m (\delta_j + \gamma_j) = p$ , which allows only a constant number,  $p$ , of attributes to be used for classification.

Glen [43] developed MIP models which determine the thresholds for forming dichotomous variables as well as the discriminant function coefficients,  $w_j$ . For each continuous attribute to be formed as a dichotomous attribute, the model finds the threshold among possible thresholds while determining the separating hyperplane and optimizing the objective function such as minimizing the sum of deviations or minimizing the number of misclassifications. Computational results of a real data set and some simulated data sets show that the MSD model with dichotomous categorical variable formation can improve classification performance. The reason for the potential of this technique is that the LDF generated is a nonlinear function of the original variables.

**Multigroup Classification** Gehrlein [41] proposed MIP formulations of minimizing the total number of misclassifications in the multigroup classification problem. He gave both a single-function classification scheme and a multiple-function classification scheme, as follows.

General single-function classification (GSFC) – minimizing the number of misclassifications:

$$\begin{aligned}
 & \text{Minimize} && \sum_i z_i \\
 & \text{subject to} && w_0 + \sum_j x_{ij} w_j - M z_i \leq U_k \quad \forall i \in G_k, \\
 & && w_0 + \sum_j x_{ij} w_j + M z_i \geq L_k \quad \forall i \in G_k, \\
 & && U_k - L_k \geq \delta' \quad \forall k, \\
 & && \left. \begin{aligned} L_g - U_k + M y_{gk} &\geq \delta \\ L_k - U_g + M y_{kg} &\geq \delta \\ y_{gk} + y_{kg} &= 1 \end{aligned} \right\} \forall g, k, g \neq k, \\
 & && w_j \text{ urs} \quad \forall j, \\
 & && U_k, L_k \text{ urs} \quad \forall k, \\
 & && z_i \in \{0, 1\} \quad \forall i, \\
 & && y_{gk} \in \{0, 1\} \quad \forall g, k, g \neq k,
 \end{aligned}$$

where  $U_k, L_k$  denote the upper and lower endpoints of the interval assigned to group  $k$ , and  $y_{gk} = 1$  if the interval associated with group  $g$  precedes that with group

$k$  and  $y_{gk} = 0$  otherwise. The constant  $\delta'$  is the minimum width of an interval of a group and the constant  $\delta$  is the minimum gap between adjacent intervals.

General multiple-function classification (GMFC) – minimizing the number of misclassifications:

$$\begin{aligned}
 & \text{Minimize} && \sum_i z_i \\
 & \text{subject to} && w_0^h + \sum_j x_{ij} w_j^h - w_0^k \\
 & && \quad - \sum_j x_{ij} w_j^k + M z_i \geq \epsilon \\
 & && \forall i \in G_h, \forall h, k \neq h, \\
 & && w_j^k \text{ urs} \quad \forall j, k, \\
 & && z_i \in \{0, 1\} \quad \forall i.
 \end{aligned}$$

Both models work successfully on the iris data set provided by Fisher [30].

Pavur [93] solved the multigroup classification problem by sequentially solving the GSFC in one dimension each time. LDFs were generated by successively solving the GSFC with the added constraints that all linear discriminants are uncorrelated to each other for the total data set. This procedure could be repeated for the number of dimensions that is believed to be enough. According to the simulation results, this procedure substantially improves the GSFC model and sometimes outperforms GMFC, Fisher's LDF, or Smith's QDF.

To solve the three-group classification problem more efficiently, Loucopoulos and Pavur [71] made a slight modification to the GSFC and proposed the model MIP3G, which also minimizes the number of misclassifications. Compared with GSFC, MIP3G is also a single-function classification model, but it reduces the possible group orderings from six to three in the formulation and thus becomes more efficient. Loucopoulos and Pavur [72] reported the results of a simulation experiment on the performance of GMFC, MIG3G, Fisher's LDF, and Smith's QDF for a three-group classification problem with small training samples. Second-order terms were also considered in the experiment. Simulation results show that GMFC and MIP3G can outperform the parametric procedures in some nonnormal data sets and that the inclusion of second-order terms can improve the performance

of MIP3G in some data sets. Pavur and Loucopoulos [95] investigated the effect of the gap size in the MIP3G model for the three-group classification problem. A simulation study illustrates that for fairly separable data, or data with small sample sizes, a non-zero-gap model can improve the performance. A possible reason for this result is that the zero-gap model may be overfitting the data.

Gallagher et al. [39,40,63] and Lee [59,60] proposed MIP models, both heuristic and exact, as a computational approach to solving the constrained discriminant method described by Anderson [2]. These models are described in detail in Sect. “**Mixed Integer Programming Based Multigroup Classification Models and Applications to Medicine and Biology**”.

### Nonlinear Programming Classification Models

Nonlinear programming approaches are natural extensions for some of the LP-based models. Thus far, nonlinear programming approaches have been developed for two-group classification.

Stam and Joachimsthaler [108] proposed a class of nonlinear programming methods to solve the two-group classification problem under the  $L_p$ -norm objective criterion. This is an extension of MSD and MMD, for which the objectives are the  $L_1$ -norm and  $L_\infty$ -norm, respectively.

Minimize the general  $L_p$ -norm distance:

$$\begin{aligned} & \text{Minimize} && (\sum_i d_i^p)^{1/p} \\ & \text{subject to} && \sum_j x_{ij}w_j - d_i \leq b \quad \forall i \in G_1, \\ & && \sum_j x_{ij}w_j + d_i \geq b \quad \forall i \in G_2, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d_i \geq 0 \quad \forall i. \end{aligned}$$

The simulation results show that, in addition to the  $L_1$ -norm and the  $L_\infty$ -norm, it is worth the effort to compute other  $L_p$ -norm objectives. Restricting the analysis to  $1 \leq p \leq 3$ , plus  $p = \infty$ , is recommended. This method was reviewed by Joachimsthaler and Stam [50] and Erenguc and Koehler [27].

Mangasarian et al. [85] proposed a nonconvex model for the two-group classification problem:

$$\begin{aligned} & \text{Minimize} && d^1 + d^2 \\ & \text{subject to} && \sum_j x_{ij}w_j - d^1 \leq 0 \quad \forall i \in G_1, \\ & && \sum_j x_{ij}w_j + d^2 \geq 0 \quad \forall i \in G_2, \\ & && \max_{j=1,\dots,m} |w_j| = 1, \\ & && w_j \text{ urs} \quad \forall j, \\ & && d^1, d^2 \text{ urs}, \end{aligned}$$

This model can be solved in polynomial-time by solving  $2m$  linear programs, which generate a sequence of parallel planes, resulting in a piecewise-linear nonconvex discriminant function. The model works successfully in clinical practice for the diagnosis of breast cancer.

Further, Mangasarian [76] also formulated the problem of minimizing the number of misclassifications as a linear program with equilibrium constraints (LPEC) instead of the MIP model MM described previously:

$$\begin{aligned} & \text{Minimize} && \sum_{i \in G_1 \cup G_2} z_i \\ & \text{subject to} && w_0 + \sum_j x_{ij}w_j - d_i \leq -1 \quad \forall i \in G_1, \\ & && z_i(w_0 + \sum_j x_{ij}w_j - d_i + 1) = 0 \\ & && \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij}w_j + d_i \geq 1 \quad \forall i \in G_2, \\ & && z_i(w_0 + \sum_j x_{ij}w_j + d_i - 1) = 0 \\ & && \quad \forall i \in G_2, \\ & && d_i(1 - z_i) = 0 \quad \forall i \in G_1 \cup G_2, \\ & && 0 \leq z_i \leq 1 \quad \forall i \in G_1 \cup G_2, \\ & && d_i \geq 0 \quad \forall i \in G_1 \cup G_2, \\ & && w_j \text{ urs} \quad \forall j. \end{aligned}$$

The general LPEC can be converted to an exact penalty problem with a quadratic objective and linear

constraints. A stepless Frank–Wolfe-type algorithm is proposed for the penalty problem, terminating at a stationary point or a global solution. This method is called the parametric misclassification minimization (PMM) procedure, and numerical testing is included in [77].

To illustrate the next model, we first define the step function  $s: R \rightarrow \{0, 1\}$  as

$$s(u) = \begin{cases} 1 & \text{if } u > 0, \\ 0 & \text{if } u \leq 0. \end{cases}$$

The problem of minimizing the number of misclassifications is equivalent to

$$\begin{aligned} & \text{Minimize} && \sum_{i \in G_1 \cup G_2} s(d_i) \\ & \text{subject to} && w_0 + \sum_j x_{ij} w_j - d_i \leq -1 \quad \forall i \in G_1, \\ & && w_0 + \sum_j x_{ij} w_j + d_i \geq 1 \quad \forall i \in G_2, \\ & && d_i \geq 0 \quad \forall i \in G_1 \cup G_2, \\ & && w_j \text{ urs} \quad \forall j. \end{aligned}$$

Mangasarian [77] proposed a simple concave approximation of the step function for nonnegative variables:  $t(u, \alpha) = 1 - e^{-\alpha u}$ , where  $\alpha > 0, u \geq 0$ . Let  $\alpha > 0$  and approximate  $s(d_i)$  by  $t(d_i, \alpha)$ . The problem then reduces to minimizing a smooth concave function bounded below on a nonempty polyhedron, which has a minimum at a vertex of the feasible region. A finite successive linearization algorithm (SLA) was proposed, terminating at a stationary point or a global solution. Numerical tests of SLA were done and compared with the PMM procedure described above. The results show that the much simpler SLA obtains a separation that is almost as good as PMM in considerably less computing time.

Chen and Mangasarian [21] proposed an algorithm on a defined hybrid misclassification minimization problem, which is more computationally tractable than the  $\mathcal{NP}$ -hard misclassification minimization problem. The basic idea of the hybrid approach is to obtain iteratively  $w_0$  and  $(w_1, \dots, w_m)$  of the separating hyperplane:

1. For a fixed  $w_0$ , solve RLP [9] to determine  $(w_1, \dots, w_m)$ .
2. For this  $(w_1, \dots, w_m)$ , solve the one-dimensional misclassification minimization problem to determine  $w_0$ .

Comparison of the hybrid method is made with the RLP method and the PMM procedure. The hybrid method performs better in the testing sets of the ten-fold cross-validation and is much faster than PMM.

Mangasarian [78] proposed the model of minimizing the sum of arbitrary-norm distances of misclassified points to the separating hyperplane. For a general norm  $\|\cdot\|$  on  $R^m$ , the dual norm  $\|\cdot\|'$  on  $R^m$  is defined as  $\|x\|' = \max_{\|y\|=1} x^T y$ . Define  $[a]^+ = \max\{0, a\}$  and let  $w = (w_1, \dots, w_m)$ . The formulation can then be written as

$$\begin{aligned} & \text{Minimize} && \sum_{i \in G_1} \left[ w_0 + \sum_j x_{ij} w_j \right]^+ \\ & && + \sum_{i \in G_2} \left[ -w_0 - \sum_j x_{ij} w_j \right]^+ \\ & \text{subject to} && \|w\|' = 1, \\ & && w_0, w \text{ urs}. \end{aligned}$$

The problem is to minimize a convex function on a unit sphere. A decision problem related to this minimization problem is shown to be  $\mathcal{NP}$ -complete, except for  $p = 1$ . For a general  $p$ -norm, the minimization problem can be transformed via an exact penalty formulation to minimizing the sum of a convex function and a bilinear function on a convex set.

### Support Vector Machine

A support vector machine (SVM) is a type of mathematical programming approach [112]. It has been widely studied, and has become popular in many application fields in recent years. The introductory description of SVMs given here is summarized from the tutorial by Burges [20]. In order to maintain consistency with SVM studies in published literature, the notation used below is slightly different from the notation used to describe the mathematical programming methods in earlier sections.

In the two-group separable case, the objective function is to maximize the margin of a separating hyper-

plane,  $2/\|w\|$ , which is equivalent to minimizing  $\|w\|^2$ :

$$\begin{aligned} & \text{Minimize} && w^T w, \\ & \text{subject to} && x_i^T w + b \geq +1 \quad \text{for } y_i = +1, \\ & && x_i^T w + b \leq -1 \quad \text{for } y_i = -1, \\ & && w, b \text{ urs}, \end{aligned}$$

where  $x_i \in R^m$  represents the values of attributes of observation  $i$  and  $y_i \in \{-1, 1\}$  represents the group of observation  $i$ .

This problem can be solved by solving its Wolfe dual problem:

$$\begin{aligned} & \text{Maximize} && \sum_i \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j x_i^T x_j, \\ & \text{subject to} && \sum_i \alpha_i y_i = 0, \\ & && \alpha_i \geq 0 \quad \forall i. \end{aligned}$$

Here,  $\alpha_i$  is the Lagrange multiplier for the training point  $i$ , and the points with  $\alpha_i > 0$  are called the support vectors (analogous to the support of a hyperplane, and thus the introduction of the name “support vector”). The primal solution  $w$  is given by  $w = \sum_i \alpha_i y_i x_i$ .  $b$  can be computed by solving  $y_i(w^T x_i + b) - 1 = 0$  for any  $i$  with  $\alpha_i > 0$ .

For the nonseparable case, slack variables  $\xi_i$  are introduced to handle the errors. Let  $C$  be the penalty for the errors. The problem becomes

$$\begin{aligned} & \text{Minimize} && \frac{1}{2} w^T w + C \left( \sum_i \xi_i \right)^k, \\ & \text{subject to} && x_i^T w + b \geq +1 - \xi_i \quad \text{for } y_i = +1, \\ & && x_i^T w + b \leq -1 + \xi_i \quad \text{for } y_i = -1, \\ & && w, b \text{ urs}, \\ & && \xi_i \geq 0 \quad \forall i. \end{aligned}$$

When  $k$  is chosen to be 1, neither the  $\xi_i$  nor their Lagrange multipliers appear in the Wolfe dual problem:

$$\begin{aligned} & \text{Maximize} && \sum_i \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j x_i^T x_j, \\ & \text{subject to} && \sum_i \alpha_i y_i = 0, \\ & && 0 \leq \alpha_i \leq C \quad \forall i. \end{aligned}$$

The data points can be separated nonlinearly by mapping the data into some higher-dimensional space

and applying linear SVM to the mapped data. Instead of knowing explicitly the mapping  $\Phi$ , SVM needs only the dot products of two transformed data points  $\Phi(x_i) \cdot \Phi(x_j)$ . The kernel function  $K$  is introduced such that  $K(x_i, x_j) = \Phi(x_i) \cdot \Phi(x_j)$ . Replacing  $x_i^T x_j$  by  $K(x_i, x_j)$  in the above problem, the separation becomes nonlinear, while the problem to be solved remains a quadratic program. In testing a new data point  $x$  after training, the sign of the function  $f(x)$  is computed to determine the group of  $x$ :

$$f(x) = \sum_{i=1}^{N_s} \alpha_i y_i \Phi(s_i) \cdot \Phi(x) + b = \sum_{i=1}^{N_s} \alpha_i y_i K(s_i, x) + b,$$

where the  $s_i$  are the support vectors and  $N_s$  is the number of support vectors. Again the explicit form of  $\Phi(x)$  is avoided.

Mangasarian provided a general mathematical programming framework for SVM, called generalized SVM or GSVM [79,83]. Special cases can be derived from GSVM, including the standard SVM.

Many SVM-type methods have been developed by Mangasarian and others to solve huge classification problems more efficiently. These methods include successive overrelaxation for SVM [82], proximal SVM [36,38], smooth SVM [68], reduced SVM [67], Lagrangian SVM [84], incremental SVMs [37], and other methods [13,81]. Mangasarian [80] summarized some of the developments. Examples of applications of SVM include breast cancer studies [69,70] and genome research [73].

Hsu and Lin [49] compared different methods for multigroup classification using SVMs. Three methods studied were based on several binary classifiers: one against one, one against all, and directed acyclic graph (DAG) SVM. The other two methods studied are methods with decomposition implementation. The experimental results show that the one-against-one and DAG methods are more suitable for practical use than the other methods. Lee et al. [66] proposed a generic approach to multigroup problems with some theoretical properties, and the proposed method was well applied to microarray data for cancer classification and satellite radiance profiles for cloud classification.

Gallagher et al. [39,40,63] offered the first discrete SVM for multigroup classification with reserved judgement. The approach has been successfully applied to

a diverse variety of biological and medical applications (see Sect. “**Mixed Integer Programming Based Multigroup Classification Models and Applications to Medicine and Biology**”).

### **Mixed Integer Programming Based Multigroup Classification Models and Applications to Medicine and Biology**

Commonly used methods for classification, such as LDFs, decision trees, mathematical programming approaches, SVMs, and artificial neural networks, can be viewed as attempts at approximating a *Bayes optimal rule* for classification; that is, a rule that maximizes (minimizes) the total probability of correct classification (misclassification). Even if a Bayes optimal rule is known, intergroup misclassification rates may be higher than desired. For example, in a population that is mostly healthy, a Bayes optimal rule for medical diagnosis might misdiagnose sick patients as healthy in order to maximize total probability of correct diagnosis. As a remedy, a constrained discriminant rule that limits the misclassification rate is appealing.

Assuming that the group density functions and prior probabilities are known, Anderson [2] showed that an optimal rule for the problem of maximizing the probability of correct classification subject to constraints on the misclassification probabilities must be of a specific form when discriminating among multiple groups with a simplified model. The formulae in Anderson’s result depend on a set of parameters satisfying a complex relationship between the density functions, the prior probabilities, and the bounds on the misclassification probabilities. Establishing a viable mathematical model to describe Anderson’s result, and finding values for these parameters that yield an optimal rule are challenging tasks. The first computational models utilizing Anderson’s formulae were proposed in [39,40].

#### **Discrete Support Vector Machine Predictive Models**

As part of the work carried out at Georgia Institute of Technology’s Center for Operations Research in Medicine, we have developed a general-purpose discriminant analysis modeling framework and computational engine that are applicable to a wide variety of applications, including biological, biomedical, and lo-

gistics problems. Utilizing the technology of large-scale discrete optimization and SVMs, we have developed novel classification models that simultaneously include the following features: (1) the ability to classify any number of distinct groups; (2) the ability to incorporate heterogeneous types of attributes as input; (3) a high-dimensional data transformation that eliminates noise and errors in biological data; (4) constraints to limit the rate of misclassification, and a reserved-judgment region that provides a safeguard against overtraining (which tends to lead to high misclassification rates from the resulting predictive rule); and (5) successive multistage classification capability to handle data points placed in the reserved-judgment region. Studies involving tumor volume identification, ultrasonic cell disruption in drug delivery, lung tumor cell motility analysis, CpG island aberrant methylation in human cancer, predicting early atherosclerosis using biomarkers, and fingerprinting native and angiogenic microvascular networks using functional perfusion data indicate that our approach is adaptable and can produce effective and reliable predictive rules for various biomedical and biobehavior phenomena [16,28,29,56,57,59,60,64,65].

Based on the description in [39,40,59,60,63], we summarize below some of the classification models we have developed.

**Modeling of Reserved-Judgment Region for General Groups** When the population densities and prior probabilities are known, the constrained rules with a reject option (reserved judgment), based on Anderson’s results, call for finding a partition  $\{R_0, \dots, R_G\}$  of  $\mathbb{R}^k$  that maximizes the probability of correct allocation subject to constraints on the misclassification probabilities; i. e.,

$$\begin{aligned} & \text{Maximize} && \sum_{g=1}^G \pi_g \int_{R_g} f_g(w) dw && (1) \\ & \text{subject to} && \int_{R_g} f_h(w) dw \leq \alpha_{hg}, h, g = 1, \dots, G, \\ & && h \neq g, && (2) \end{aligned}$$

where  $f_h, h \in \{1, \dots, G\}$ , are the group conditional density functions,  $\pi_g$  denotes the prior probability that a randomly selected entity is from group  $g, g \in \{1, \dots, G\}$ , and  $\alpha_{hg}, h \neq g$ , are constants between 0 and 1. Under quite general assumptions, it was shown

that there exist unique (up to a set of measure zero) nonnegative constants  $\lambda_{ih}$ ,  $i, h \in \{1, \dots, G\}$ ,  $i \neq h$ , such that the optimal rule is given by

$$R_g = \{x \in \mathbb{R}^k : L_g(x) = \max_{h \in \{0, 1, \dots, G\}} L_h(x)\}, \quad (3)$$

$$g = 0, \dots, G,$$

where

$$L_0(x) = 0, \quad (4)$$

$$L_h(x) = \pi_h f_h(x) - \sum_{i=1, i \neq h}^G \lambda_{ih} f_i(x), \quad h = 1, \dots, G. \quad (5)$$

For  $G = 2$  the optimal solution can be modeled rather straightforwardly. However, finding optimal  $\lambda_{ih}$ 's for the general case,  $G \geq 3$ , is a difficult problem, with the difficulty increasing as  $G$  increases. Our model offers an avenue for modeling and finding the optimal solution in the general case. It is the first such model to be computationally viable [39,40].

Before proceeding, we note that  $R_g$  can be written as  $R_g = \{x \in \mathbb{R}^k : L_g(x) \geq L_h(x) \text{ for all } h = 0, \dots, G\}$ . So, since  $L_g(x) \geq L_h(x)$  if, and only if,  $(1/\sum_{t=1}^G f_t(x)) L_g(x) \geq (1/\sum_{t=1}^G f_t(x)) L_h(x)$ , the functions  $L_h$ ,  $h = 1, \dots, G$ , can be redefined as

$$L_h(x) = \pi_h p_h(x) - \sum_{i=1, i \neq h}^G \lambda_{ih} p_i(x), \quad h = 1, \dots, G, \quad (6)$$

where  $p_i(x) = f_i(x)/\sum_{t=1}^G f_t(x)$ . We assume that  $L_h$  is defined as in (6) in our model.

**Mixed Integer Programming Formulations** Assume that we are given a training sample of  $N$  entities whose group classifications are known; say,  $n_g$  entities are in group  $g$ , where  $\sum_{g=1}^G n_g = N$ . Let the  $k$ -dimensional vectors  $x^{gj}$ ,  $g = 1, \dots, G$ ,  $j = 1, \dots, n_g$ , contain the measurements on  $k$  available characteristics of the entities. Our procedure for deriving a discriminant rule proceeds in two stages. The first stage is to use the training sample to compute estimates,  $\hat{f}_h$ , either parametrically or nonparametrically, of the density functions  $f_h$  [89] and estimates,  $\hat{\pi}_h$ , of the prior probabilities  $\pi_h$ ,  $h = 1, \dots, G$ . The second stage is to determine

the optimal  $\lambda_{ih}$ 's given these estimates. This stage requires being able to estimate the probabilities of correct classification and misclassification for any candidate set of  $\lambda_{ih}$ 's. One could, in theory, substitute the estimated densities and prior probabilities into (5), and directly use the resulting regions  $R_g$  in the integral expressions given in (1) and (2). This would involve, even in simple cases such as normally distributed groups, the numerical evaluation of  $k$ -dimensional integrals at each step of a search for the optimal  $\lambda_{ih}$ 's. Therefore, we have designed an alternative approach. After substituting the  $\hat{f}_h$ 's and  $\hat{\pi}_h$ 's into (5), we simply calculate the proportion of training sample points which fall in each of the regions  $R_1, \dots, R_G$ . The MIP models discussed below attempt to maximize the proportion of training sample points correctly classified while satisfying constraints on the proportions of training sample points misclassified. This approach has two advantages. First, it avoids having to evaluate the potentially difficult integrals in (1) and (2). Second, it is nonparametric in controlling the training sample misclassification probabilities. That is, even if the densities are poorly estimated (by assuming, for example, normal densities for non-normal data), the constraints are still satisfied for the training sample. Better estimates of the densities may allow a higher correct classification rate to be achieved, but the constraints will be satisfied even if poor estimates are used. Unlike most SVM models that minimize the sum of errors, our objective is driven by the number of correct classifications, and will not be biased by the distance of the entities from the supporting hyperplane.

A word of caution is in order. In traditional unconstrained discriminant analysis, the true probability of correct classification of a given discriminant rule tends to be smaller than the rate of correct classification for the training sample from which it was derived. One would expect to observe such an effect for the method described herein as well. In addition, one would expect to observe an analogous effect with regard to constraints on misclassification probabilities – the true probabilities are likely to be greater than any limits imposed on the proportions of training sample misclassifications. Hence, the  $\alpha_{hg}$  parameters should be carefully chosen for the application in hand.

Our first model is a nonlinear 0/1 MIP model with the nonlinearity appearing in the constraints. Model 1

maximizes the number of correct classifications of the given  $N$  training entities. Similarly, the constraints on the misclassification probabilities are modeled by ensuring that the number of group  $g$  training entities in region  $R_h$  is less than or equal to a prespecified percentage,  $\alpha_{hg}$  ( $0 < \alpha_{hg} < 1$ ), of the total number,  $n_g$ , of group  $g$  entities,  $h, g \in \{1, \dots, G\}$ ,  $h \neq g$ .

For notational convenience, let  $\mathbf{G} = \{1, \dots, G\}$  and  $\mathbf{N}_g = \{1, \dots, n_g\}$ , for  $g \in \mathbf{G}$ . Also, analogous to the definition of  $p_i$ , define  $\hat{p}_i$  by  $\hat{p}_i = \hat{f}_i(x) / \sum_{i=1}^G \hat{f}_i(x)$ . In our model, we use binary indicator variables to denote the group classification of entities. Mathematically, let  $u_{hgi}$  be a binary variable indicating whether or not  $x^{gj}$  lies in region  $R_h$ ; i. e., whether or not the  $j$ th entity from group  $g$  is allocated to group  $h$ . Then model 1 can be written as follows.

Discriminant analysis MIP (DAMIP):

$$\begin{aligned} & \text{Maximize} && \sum_{g \in \mathbf{G}} \sum_{j \in \mathbf{N}_g} u_{ggj} \\ & \text{subject to} && L_{hgj} = \hat{\pi}_h \hat{p}_h(x^{gj}) - \sum_{i \in \mathbf{G} \setminus h} \lambda_{ih} \hat{p}_i(x^{gj}), \\ & && h, g \in \mathbf{G}, j \in \mathbf{N}_g, \end{aligned} \quad (7)$$

$$y_{gj} = \max\{0, L_{hgj} : h = 1, \dots, G\}, \quad g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (8)$$

$$y_{gj} - L_{ggj} \leq M(1 - u_{ggj}), \quad g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (9)$$

$$y_{gj} - L_{hgj} \geq \epsilon(1 - u_{hgj}), \quad h, g \in \mathbf{G}, j \in \mathbf{N}_g, h \neq g, \quad (10)$$

$$\sum_{j \in \mathbf{N}_g} u_{hgj} \leq \lfloor \alpha_{hg} n_g \rfloor, \quad h, g \in \mathbf{G}, h \neq g, \quad (11)$$

$$-\infty < L_{hgj} < \infty, y_{gj} \geq 0, \lambda_{ih} \geq 0, u_{hgi} \in \{0, 1\}.$$

Constraint (7) defines the variable  $L_{hgi}$  as the value of the function  $L_h$  evaluated at  $x^{gj}$ . Therefore, the continuous variable  $y_{gj}$ , defined in constraint (8), represents  $\max\{L_h(x^{gj}) : h = 0, \dots, G\}$ ; and consequently,  $x^{gj}$  lies in region  $R_h$  if, and only if,  $y_{gj} = L_{hgj}$ . The binary variable  $u_{hgi}$  is used to indicate whether or not  $x^{gj}$  lies in region  $R_h$ ; i. e., whether or not the  $j$ th entity from group  $g$  is allocated to group  $h$ . In particular, constraint

(9), together with the objective, forces  $u_{ggj}$  to be 1 if, and only if, the  $j$ th entity from group  $g$  is correctly allocated to group  $g$ ; and constraints (10) and (11) ensure that at most  $\lfloor \alpha_{hg} n_g \rfloor$  (i. e., the greatest integer less than or equal to  $\alpha_{hg} n_g$ ) group  $g$  entities are allocated to group  $h$ ,  $h \neq g$ . One caveat regarding the indicator variables  $u_{hgi}$  is that although the condition  $u_{hgi} = 0$ ,  $h \neq g$ , implies (by constraint (10)) that  $x^{gj} \notin R_h$ , the converse need not hold. As a consequence, the number of misclassifications may be overcounted. However, in our preliminary numerical study we found that the actual amount of overcounting is minimal. One could force the converse (thus,  $u_{hgi} = 1$  if and only if  $x^{gj} \in R_h$ ) by adding constraints  $y_{gj} - L_{hgj} \leq M(1 - u_{hgj})$ , for example. Finally, we note that the parameters  $M$  and  $\epsilon$  are extraneous to the discriminant analysis problem itself, but are needed in the model to control the indicator variables  $u_{hgi}$ . The intention is for  $M$  and  $\epsilon$  to be, respectively, large and small positive constants.

**Model Variations** We explore different variations in the model to grasp the quality of the solution and the associated computational effort.

A first variation involves transforming model 1 to an equivalent linear mixed integer model. In particular, model 2 replaces the  $N$  constraints defined in (8) with the following system of  $3GN + 2N$  constraints:

$$y_{gj} \geq L_{hgj}, \quad h, g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (12)$$

$$\tilde{y}_{hgj} - L_{hgj} \leq M(1 - v_{hgj}), \quad h, g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (13)$$

$$\tilde{y}_{hgj} \leq \hat{\pi}_h \hat{p}_h(x^{gj}) v_{hgj}, \quad h, g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (14)$$

$$\sum_{h \in \mathbf{G}} v_{hgj} \leq 1, \quad g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (15)$$

$$\sum_{h \in \mathbf{G}} \tilde{y}_{hgj} = y_{gj}, \quad g \in \mathbf{G}, j \in \mathbf{N}_g, \quad (16)$$

where  $\tilde{y}_{hgj} \geq 0$  and  $v_{hgj} \in \{0, 1\}$ ,  $h, g \in \mathbf{G}, j \in \mathbf{N}_g$ . These constraints, together with the nonnegativity of  $y_{gj}$  force  $y_{gj} = \max\{0, L_{hgj} : h = 1, \dots, G\}$ .

The second variation involves transforming model 1 to a heuristic linear MIP model. This is done by replacing the nonlinear constraint (8) with  $y_{gj} \geq L_{hgj}$ ,  $h, g \in \mathbf{G}, j \in \mathbf{N}_g$ , and including penalty terms in the objective function. In particular, model 3

has the objective

$$\text{Maximize } \sum_{g \in G} \sum_{j \in N_g} \beta u_{ggj} - \sum_{g \in G} \sum_{j \in N_g} \gamma y_{gj},$$

where  $\beta$  and  $\gamma$  are positive constants. This model is heuristic in that there is nothing to force  $y_{gj} = \max\{0, L_{hgj}; h = 1, \dots, G\}$ . However, since in addition to trying to force as many  $u_{ggj}$ 's to 1 as possible, the objective in model 3 also tries to make the  $y_{gj}$ 's as small as possible, and the optimizer tends to drive  $y_{gj}$  towards  $\max\{0, L_{hgj}; h = 1, \dots, G\}$ . We remark that  $\beta$  and  $\gamma$  could be stratified by group (i.e., introduce possibly distinct  $\beta_g, \gamma_g, g \in G$ ) to model the relative importance of certain groups to be correctly classified.

A reasonable modification to models 1, 2, and 3 involves relaxing the constraints specified by (11). Rather than placing restrictions on the number of type  $g$  training entities classified into group  $h$ , for all  $h, g \in G, h \neq g$ , one could simply place an upper bound on the *total* number of misclassified training entities. In this case, the  $G(G-1)$  constraints specified by (11) would be replaced by the single constraint

$$\sum_{g \in G} \sum_{h \in G \setminus \{g\}} \sum_{j \in N_g} u_{hgj} \leq \lfloor \alpha N \rfloor, \quad (17)$$

where  $\alpha$  is a constant between 0 and 1. We will refer to models 1, 2, and 3 modified in this way as models 1T, 2T, and 3T, respectively. Of course, other modifications are also possible. For instance, one could place restrictions on the total number of type  $g$  points misclassified for each  $g \in G$ . Thus, in place of the constraints specified in (17), one would include the constraints  $\sum_{h \in G \setminus \{g\}} \sum_{j \in N_g} u_{hgj} \leq \lfloor \alpha_g N \rfloor, g \in G$ , where  $0 < \alpha_g < 1$ .

We also explore a heuristic linear model of model 1. In particular, consider the linear program (DALP):

$$\text{Maximize } \sum_{g \in G} \sum_{j \in N_g} (c_1 w_{gj} + c_2 y_{gj}) \quad (18)$$

$$\text{subject to } L_{hgj} = \pi_h \hat{p}_h(x^{gj}) - \sum_{i \in G \setminus h} \lambda_{ih} \hat{p}_i(x^{gj}),$$

$$h, g \in G, j \in N_g, \quad (19)$$

$$L_{ggj} - L_{hgj} + w_{gj} \geq 0, \quad h, g \in G, h \neq g, j \in N_g, \quad (20)$$

$$L_{ggj} + w_{gj} \geq 0, \quad g \in G, j \in N_g, \quad (21)$$

$$-L_{hgj} + y_{gj} \geq 0, \quad h, g \in G, j \in N_g, \quad (22)$$

$$-\infty < L_{hgj} < \infty, w_{gj}, y_{gj}, \lambda_{ih} \geq 0.$$

Constraint (19) defines the variable  $L_{hgj}$  as the value of the function  $L_h$  evaluated at  $x^{gj}$ . As the optimization solver searches through the set of feasible solutions, the  $\lambda_{ih}$  variables will vary, causing the  $L_{hgj}$  variables to assume different values. Constraints (20), (21), and (22) link the objective-function variables with the  $L_{hgj}$  variables in such a way that correct classification of training entities and allocation of training entities into the reserved-judgment region are captured by the objective-function variables. In particular, if the optimization solver drives  $w_{gj}$  to zero for some  $g, j$  pair, then constraints (20) and (21) imply that  $L_{ggj} = \max\{0, L_{hgj}; h \in G\}$ . Hence, the  $j$ th entity from group  $g$  is correctly classified. If, on the other hand, the optimal solution yields  $y_{gj} = 0$  for some  $g, j$  pair, then constraint (22) implies that  $\max\{0, L_{hgj}; h \in G\} = 0$ . Thus, the  $j$ th entity from group  $g$  is placed in the reserved-judgment region. (Of course, it is possible for both  $w_{gj}$  and  $y_{gj}$  to be zero. One should decide prior to solving the linear program how to interpret the classification in such cases.) If both  $w_{gj}$  and  $y_{gj}$  are positive, the  $j$ th entity from group  $g$  is misclassified.

The optimal solution yields a set of  $\lambda_{ih}$ 's that best allocates the training entities (i.e., "best" in terms of minimizing the penalty objective function). The optimal  $\lambda_{ih}$ 's can then be used to define the functions  $L_h, h \in G$ , which in turn can be used to classify a new entity with feature vector  $x \in \mathbb{R}^k$  by simply computing the index at which  $\max\{L_h(x); h \in \{0, 1, \dots, G\}\}$  is achieved.

Note that model DALP places no a priori bound on the number of misclassified training entities. However, since the objective is to minimize a weighted combination of the variables  $w_{gj}$  and  $y_{gj}$ , the optimizer will attempt to drive these variables to zero. Thus, the optimizer is, in essence, attempting either to correctly classify training entities ( $w_{gj} = 0$ ), or to place them in the reserved-judgment region ( $y_{gj} = 0$ ). By varying the weights  $c_1$  and  $c_2$ , one has a means of controlling the optimizer's emphasis for correctly classifying training entities versus placing them in the reserved-

Disease Diagnosis: Optimization-Based Methods, Table 1

Model size

Model	Type	Constraints	Total variables	0/1 Variables
1	Nonlinear MIP	$2GN + N + G(G - 1)$	$2GN + N + G(G - 1)$	$GN$
2	Linear MIP	$5GN + 2N + G(G - 1)$	$4GN + N + G(G - 1)$	$2GN$
3	Linear MIP	$3GN + G(G - 1)$	$2GN + N + G(G - 1)$	$GN$
1T	Nonlinear MIP	$2GN + N + 1$	$2GN + N + G(G - 1)$	$GN$
2T	Linear MIP	$5GN + 2N + 1$	$4GN + N + G(G - 1)$	$2GN$
3T	Linear MIP	$3GN + 1$	$2GN + N + G(G - 1)$	$GN$
DALP	Linear program	$3GN$	$NG + N + G(G - 1)$	0

judgment region. If  $c_2/c_1 < 1$ , the optimizer will tend to place a greater emphasis on driving the  $w_{gj}$  variables to zero than driving the  $y_{gj}$  variables to zero (conversely, if  $c_2/c_1 > 1$ ). Hence, when  $c_2/c_1 < 1$ , one should expect to get relatively more entities correctly classified, fewer placed in the reserved-judgment region, and more misclassified, than when  $c_2/c_1 > 1$ . An extreme case is when  $c_2 = 0$ . In this case, there is no emphasis on driving  $y_{gj}$  to zero (the reserved-judgment region is thus ignored), and the full emphasis of the optimizer is to drive  $w_{gj}$  to zero.

Table 1 summarizes the number of constraints, the total number of variables, and the number of 0/1 variables in each of the discrete SVM models, and in the heuristic LP model (DALP). Clearly, even for moderately sized discriminant analysis problems, the MIP instances are relatively large. Also, note that model 2 is larger than model 3, in terms of both the number of constraints and the number of variables. However, it is important to keep in mind that the difficulty of solving an MIP problem cannot, in general, be predicted solely by its size; problem structure has a direct and substantial bearing on the effort required to find optimal solutions. The LP relaxation of these MIP models poses computational challenges as commercial LP solvers return (optimal) LP solutions that are infeasible, owing to the equality constraints, and the use of big  $M$  and small  $\epsilon$  in the formulation.

It is interesting to note that the set of feasible solutions for model 2 is “tighter” than that for model 3. In particular, if  $F_i$  denotes the set of feasible solutions of model  $i$ , then

$$F_1 = \{(L, \lambda, u, y): \text{there exists } \tilde{y}, v \text{ such that } (L, \lambda, u, y, \tilde{y}, v) \in F_2\} \subsetneq F_3. \quad (23)$$

The novelties of the classification models developed herein include the following: (1) they are suitable for discriminant analysis given any number of groups, (2) they accept heterogeneous types of attributes as input, (3) they use a parametric approach to reduce high-dimensional attribute spaces, and (4) they allow constraints on the number of misclassifications, and utilize a reserved judgment to facilitate the reduction of misclassifications. The lattermost point opens the possibility of performing multistage analysis.

Clearly, the advantage of an LP model over an MIP model is that the associated problem instances are computationally much easier to solve. However, the most important criterion in judging a method for obtaining discriminant rules is how the rules perform in correctly classifying new unseen entities. Once the rule has been developed, applying it to a new entity to determine its group is trivial. Extensive computational experiments have been performed to gauge the qualities of solutions of different models [17,19,40,59,60,63].

**Validation of Model and Computational Effort** We performed tenfold cross-validation, and designed simulation and comparison studies on our models. The results reported in [40,63] demonstrate that our approach works well when applied to both simulated data and data sets from the machine learning database repository [91]. In particular, our methods compare favorably and at times superior to other mathematical programming methods, including the GSFC model by Gehrlein [41], and the LP model by Gochet et al. [46], as well as Fisher’s LDF, artificial neural networks, quadratic discriminant analysis, tree classification, and other SVMs, on real biological and medical data.

### Classification Results for Real-World Biological and Medical Applications

The main objective in discriminant analysis is to derive rules that can be used to classify entities into groups. Computationally, the challenge lies in the effort expended to develop such a rule. Once the rule has been developed, applying it to a new entity to determine its group is trivial. Feasible solutions obtained from our classification models correspond to predictive rules. Empirical results [40,63] indicate that the resulting classification model instances are computationally very challenging, and even intractable by competitive commercial MIP solvers. However, the resulting predictive rules prove to be very promising, offering correct classification rates on new unknown data ranging from 80 to 100% for various types of biological/medical problems. Our results indicate that the general-purpose classification framework that we have designed has the potential to be a very powerful predictive method for clinical settings.

The choice of MIP as the underlying modeling and optimization technology for our SVM classification model is guided by the desire to simultaneously incorporate a variety of important and desirable properties of predictive models within a general framework. MIP itself allows for incorporation of continuous and discrete variables, and linear and nonlinear constraints, providing a flexible and powerful modeling environment.

Our mathematical modeling and computational algorithm design shows great promise as the resulting predictive rules are able to produce higher rates of correct classification for new biological data (with unknown group status) compared with existing classification methods. This is partly due to the transformation of raw data via the set of constraints in (7). While most mathematical programming approaches directly determine the hyperplanes of separation using raw data, our approach transforms the raw data via a probabilistic model, before the determination of the supporting hyperplanes. Further, the separation is driven by maximizing the sum of binary variables (representing correct classification or not of entities), instead of maximizing the margins between groups, or minimizing a sum of errors (representing distances of entities from hyperplanes), as in other SVMs. The combination of these two strategies offers better classification capabil-

ity. Noise in the transformed data is not as profound as in raw data. And the magnitudes of the errors do not skew the determination of the separating hyperplanes, as all entities have *equal* importance when correct classification is being counted.

To highlight the broad applicability of our approach, below we briefly summarize the application of our predictive models and solution algorithms to ten different biological problems. Each of the projects was carried out in close partnership with experimental biologists and/or clinicians. Applications to finance and other industry applications are described elsewhere [17,40,63].

### Determining the Type of Erythematous-Squamous Disease

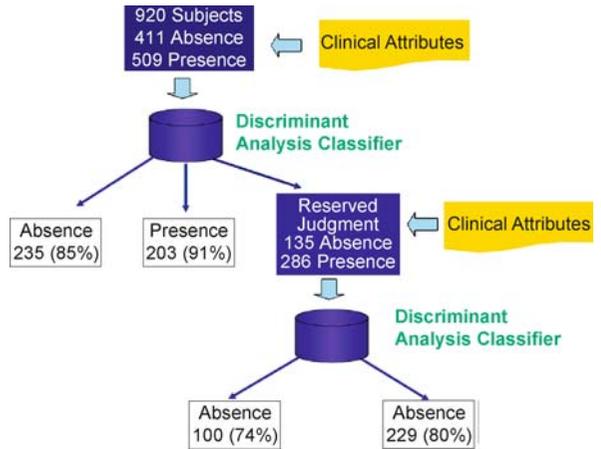

The differential diagnosis of erythematous-squamous diseases is an important problem in dermatology [60]. They all share the clinical features of erythema and scaling, with very little differences. The six groups are psoriasis, seboric dermatitis, lichen planus, pityriasis rosea, chronic dermatitis, and pityriasis rubra pilaris. Usually a biopsy is necessary for the diagnosis but unfortunately these diseases share many histopathological features as well. Another difficulty for the differential diagnosis is that a disease may show the features of another disease at the beginning stage and may have the characteristic features at the following stages [91].

The six groups consisted of 366 subjects (112, 61, 72, 49, 52, and 20 respectively) with 34 clinical attributes. Patients were first evaluated clinically with 12 features. Afterwards, skin samples were taken for the evaluation of 22 histopathological features. The values of the histopathological features were determined by an analysis of the samples under a microscope. The 34 attributes include (1) clinical attributes (erythema, scaling, definite borders, itching, koebner phenomenon, polygonal papules, follicular papules, oral mucosal involvement, knee and elbow involvement, scalp involvement, family history, age) and (2) histopathological attributes (melanin incontinence, eosinophils in the infiltrate, polymorphonuclear leukocyte infiltrate, fibrosis of the papillary dermis, exocytosis, acanthosis, hyperkeratosis, parakeratosis, clubbing of the rete ridges, elongation of the rete ridges, thinning of the suprapapillary epidermis, spongiform pustule, Munro microabscess, focal hypergranulosis, disappearance of the granular

layer, vacuolization and damage of basal layer, spongiosis, sawtooth appearance of retes, follicular horn plug, perifollicular parakeratosis, inflammatory mononuclear infiltrate, band-like infiltrate).

Our multigroup classification model selected 27 discriminatory attributes, and successfully classified the patients into six groups, each with an unbiased correct classification of greater than 93% (with 100% correct rate for groups 1, 3, 5, and 6) with an average overall accuracy of 98%. Using 250 subjects to develop the rule, and testing the remaining 116 patients, we obtained a prediction accuracy of 91%.

**Predicting Presence/Absence of Heart Disease** The four databases concerning heart disease diagnosis were collected by Dr. Andras Janosi of the Hungarian Institute of Cardiology, Budapest; Dr. William Steinbrunn of University Hospital, Zurich; Dr. Matthias Pfisterer of University Hospital, Basel; and Dr. Robert Detrano of V.A. Medical Center, Long Beach, and Cleveland Clinic Foundation [60]. Each database contains the same 76 attributes. The “goal” field refers to the presence of heart disease in the patient. The classification attempts to distinguish presence (values 1, 2, 3, 4, involving a total of 509 subjects) from absence (value 0, involving 411 subjects) [91]. The attributes include demographics, physiocardiovascular conditions, traditional risk factors, family history, personal lifestyle, and cardiovascular exercise measurements. This data set has posed some challenges to past analysis via various classification approaches, resulting in less than 80% correct classification. Applying our classification model without reserved judgment, we obtained 79 and 85% correct classification for each group respectively. To determine the usefulness of multistage analysis, we applied two-stage classification. In the first stage, 14 attributes were selected as discriminatory. One hundred and thirty-five group absence subjects were placed into the reserved-judgment region, with 85% of the remaining being classified as group absence correctly; while 286 group presence subjects were placed into the reserved-judgment region, and 91% of the remaining were classified correctly into the group presence. In the second stage, 11 attributes were selected with 100 and 229 classified into group absence and presence respectively. Combining the two stages, we obtained a correct classification of 82 and 85%, respectively, for diagnosis of absence or pres-

ence of heart disease. Figure 1 illustrates the two-stage classification.

**Predicting Aberrant CpG Island Methylation in Human Cancer** More details of this work can be found in [28,29]. Epigenetic silencing associated with aberrant methylation of promoter-region CpG islands is one mechanism leading to loss of tumor suppressor function in human cancer. Profiling of CpG island methylation indicates that some genes are more frequently methylated than others, and that each tumor type is associated with a unique set of methylated genes. However, little is known about why certain genes succumb to this aberrant event. To address this question, we used restriction landmark genome scanning (RLGS) to analyze the susceptibility of 1749 unselected CpG islands to de novo methylation driven by overexpression of DNMT1. We found that whereas the overall incidence of CpG island methylation was increased in cells overexpressing DNMT1, not all loci were equally affected. The majority of CpG islands (69.9%) were resistant to de novo methylation, regardless of DNMT1 overexpression. In contrast, we identified a subset of methylation-prone CpG islands (3.8%) that were consistently hypermethylated in multiple DNMT1 overexpressing clones. Methylation-prone and methylation-resistant CpG islands were not significantly different with respect to size, C+G content, CpG frequency, chromosomal location, or gene association or pro-

moter association. To discriminate methylation-prone from methylation-resistant CpG islands, we developed a novel DNA pattern recognition model and algorithm [61], and coupled our predictive model described herein with the patterns found. We were able to derive a classification function based on the frequency of seven novel sequence patterns that was capable of discriminating methylation-prone from methylation-resistant CpG islands with 90% correctness upon cross-validation, and 85% accuracy when tested against blind CpG islands unknown to us regarding the methylation status. The data indicate that CpG islands differ in their intrinsic susceptibility to de novo methylation, and suggest that the propensity for a CpG island to become aberrantly methylated can be predicted on the basis of its sequence context.

The significance of this research is twofold. First, the identification of sequence patterns/attributes that distinguish methylation-prone CpG islands will lead to a better understanding of the basic mechanisms underlying aberrant CpG island methylation. Because genes that are silenced by methylation are otherwise structurally sound, the potential for reactivating these genes by blocking or reversing the methylation process represents an exciting new molecular target for chemotherapeutic intervention. A better understanding of the factors that contribute to aberrant methylation, including the identification of sequence elements that may act to target aberrant methylation, will be an important step in achieving this long-term goal. Secondly, the classification of the more than 29,000 known (but as yet unclassified) CpG islands in human chromosomes will provide an important resource for the identification of novel gene targets for further study as potential molecular markers that could impact on both cancer prevention and treatment. Extensive RLGS fingerprint information (and thus potential training sets of methylated CpG islands) already exists for a number of human tumor types, including breast, brain, lung, leukemias, hepatocellular carcinomas, and primitive neuroectodermal tumor [23,24,35,102]. Thus, the methods and tools developed are directly applicable to CpG island methylation data derived from human tumors. Moreover, new microarray-based techniques capable of “profiling” more than 7000 CpG islands have been developed and applied to human breast cancers [15,117,118]. We are uniquely poised to take ad-

vantage of the tumor CpG island methylation profile information that will likely be generated using these techniques over the next several years. Thus, our general-predictive modeling framework has the potential to lead to improved diagnosis and prognosis and treatment planning for cancer patients.

#### **Discriminant Analysis of Cell Motility and Morphology Data in Human Lung Carcinoma**

Refer to [16] for more details of this work. This study focuses on the differential effects of extracellular matrix proteins on the motility and morphology of human lung epidermoid carcinoma cells. The behavior of carcinoma cells is contrasted with that of normal L-132 cells, resulting in a method for the prediction of metastatic potential. Data collected from time-lapsed videomicroscopy were used to simultaneously produce quantitative measures of motility and morphology. The data were subsequently analyzed using our discriminant analysis model and algorithm to discover relationships between motility, morphology, and substratum. Our discriminant analysis tools enabled the consideration of many more cell attributes than is customary in cell motility studies. The observations correlate with behaviors seen in vivo and suggest specific roles for the extracellular matrix proteins and their integrin receptors in metastasis. Cell translocation in vitro has been associated with malignancy, as has an elongated phenotype [120] and a rounded phenotype [97]. Our study suggests that extracellular matrix proteins contribute in different ways to the malignancy of cancer cells, and that multiple malignant phenotypes exist.

#### **Ultrasound-Assisted Cell Disruption for Drug Delivery**

Reference [57] discusses this in detail. Although biological effects of ultrasound must be avoided for safe diagnostic applications, ultrasound’s ability to disrupt cell membranes has attracted interest as a method to facilitate drug and gene delivery. This preliminary study seeks to develop rules for predicting the degree of cell membrane disruption based on specified ultrasound parameters and measured acoustic signals. Too much ultrasound destroys cells, while cell membranes will not open up for absorption of macromolecules when too little ultrasound is applied. The key is to increase cell permeability to allow absorption of macromolecules, and to apply ultrasound transiently to disrupt viable cells so

as to enable exogenous material to enter without cell damage. Thus our task is to uncover a “predictive rule” of ultrasound-mediated disruption of red blood cells using acoustic spectrums and measurements of cell permeability recorded in experiments.

Our predictive model and solver for generating prediction rules were applied to data obtained from a sequence of experiments on bovine red blood cells. For each experiment, the attributes consisted of four ultrasound parameters, acoustic measurements at 400 frequencies, and a measure of cell membrane disruption. To avoid overtraining, various feature combinations of the 404 predictor variables were selected when developing the classification rule. The results indicate that the variable combination consisting of ultrasound exposure time and acoustic signals measured at the driving frequency and its higher harmonics yields the best rule, and our method compares favorably with classification tree and other ad hoc approaches, with a correct classification rate of 80% upon cross-validation and 85% when classifying new unknown entities. Our methods used for deriving the prediction rules are broadly applicable, and could be used to develop prediction rules in other scenarios involving different cell types or tissues. These rules and the methods used to derive them could be used for real-time feedback about ultrasound’s biological effects. For example, it could assist clinicians during a drug delivery process, or could be imported into an implantable device inside the body for automatic drug delivery and monitoring.

**Identification of Tumor Shape and Volume in Treatment of Sarcoma** Reference [56] includes the detailed analysis. This project involves the determination of tumor shape for adjuvant brachytherapy treatment of sarcoma, based on catheter images taken after surgery. In this application, the entities are overlapping consecutive triplets of catheter markings, each of which is used for determining the shape of the tumor contour. The triplets are to be classified into one of two groups: group 1 (triplets for which the middle catheter marking should be bypassed) and group 2 (triplets for which the middle marking should not be bypassed). To develop and validate a classification rule, we used clinical data collected from 15 soft-tissue sarcoma patients. Cumulatively, this comprised 620 triplets of catheter markings. By careful (and tedious) clinical analysis of

the geometry of these triplets, 65 were determined to belong to group 1, the “bypass” group, and 555 were determined to belong to group 2, the “do-not-bypass” group.

A set of measurements associated with each triplet was then determined. The choice of what attributes to measure to best distinguish triplets as belonging to group 1 or group 2 is nontrivial. The attributes involved the distance between each pair of markings, angles, and the curvature formed by the three triplet markings. On the basis of the attributes selected, our predictive model was used to develop a classification rule. The resulting rule provides 98% correct classification on cross-validation, and was capable of correctly determining/predicting 95% of the shape of the tumor with new patients’ data. We remark that the current clinical procedure requires manual outline based on markers in films of the tumor volume. This study was the first to use automatic construction of tumor shape for sarcoma adjuvant brachytherapy [56,62].

**Discriminant Analysis of Biomarkers for Prediction of Early Atherosclerosis** More detail on this work can be found in [65]. Oxidative stress is an important etiologic factor in the pathogenesis of vascular disease. Oxidative stress results from an imbalance between injurious oxidant and protective antioxidant events, of which the former predominate [88,103]. This results in the modification of proteins and DNA, alteration in gene expression, promotion of inflammation, and deterioration in endothelial function in the vessel wall, all processes that ultimately trigger or exacerbate the atherosclerotic process [22,111]. It was hypothesized that novel biomarkers of oxidative stress would predict early atherosclerosis in a relatively healthy non-smoking population free from cardiovascular disease. One hundred and twenty-seven healthy nonsmokers, without known clinical atherosclerosis had carotid intima media thickness (IMT) measured using ultrasound. Plasma oxidative stress was estimated by measuring plasma lipid hydroperoxides using the determination of reactive oxygen metabolites (d-ROMs) test. Clinical measurements include traditional risk factors, including age, sex, low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglycerides, cholesterol, body-mass index (BMI), hypertension, diabetes mellitus, smoking history, family history of coronary artery

disease, Framingham risk score, and high-sensitivity C-reactive protein.

For this prediction, the patients were first clustered into two groups: (group 1,  $IMT \geq 0.68$ ; group 2,  $IMT < 0.68$ ). On the basis of this separator, 30 patients belonged to group 1, and 97 belonged to group 2. Through each iteration, the classification method trains and learns from the input training set and returns the most discriminatory patterns among the 14 clinical measurements; ultimately resulting in the development of a prediction rule based on observed values of these discriminatory patterns among the patient data. Using all 127 patients as a training set, the predictive model identified age, sex, BMI, HDL cholesterol, family history of coronary artery disease under 60, high-sensitivity C-reactive protein, and d-ROM as discriminatory attributes that together provide unbiased correct classification of 90 and 93%, respectively, for group 1 ( $IMT \geq 0.68$ ) and group 2 ( $IMT < 0.68$ ) patients. To further test the power of the classification method for correctly predicting the IMT status of new/unseen patients, we randomly selected a smaller patient training set of size 90. The predictive rule from this training set yielded 80 and 89% correct rates for predicting the remaining 37 patients as group 1 and group 2 patients, respectively. The importance of d-ROM as a discriminatory predictor for IMT status was confirmed during the machine learning process. This biomarker was selected in every iteration as the “machine” learned and was trained to develop a predictive rule to correctly classify patients in the training set. We also performed predictive analysis using Framingham risk score and d-ROM; in this case the unbiased correct classification rates (for the 127 individuals) for groups 1 and 2 were 77 and 84%, respectively. This is the first study to illustrate that this measure of oxidative stress can be effectively used along with traditional risk factors to generate a predictive rule that can potentially serve as an inexpensive clinical diagnostic tool for prediction of early atherosclerosis.

#### **Fingerprinting Native and Angiogenic Microvascular Networks Through Pattern Recognition and Discriminant Analysis of Functional Perfusion Data**

The analysis and findings are described in [64]. The cardiovascular system provides oxygen and nutrients to the entire body. Pathological conditions that impair

normal microvascular perfusion can result in tissue ischemia, with potentially serious clinical effects. Conversely, development of new vascular structures fuels the progression of cancer, macular degeneration, and atherosclerosis. Fluorescence microangiography offers superb imaging of the functional perfusion of new and existent microvasculature, but quantitative analysis of the complex capillary patterns is challenging. We developed an automated pattern-recognition algorithm to systematically analyze the microvascular networks, and then applied our classification model described herein to generate a predictive rule. The pattern-recognition algorithm identifies the complex vascular branching patterns, and the predictive rule demonstrates, respectively, 100 and 91% correct classification for perturbed (diseased) and normal tissue perfusion. We confirmed that transplantation of normal bone marrow to mice in which genetic deficiency resulted in impaired angiogenesis eliminated predicted differences and restored normal-tissue perfusion patterns (with 100% correctness). The pattern-recognition and classification method offers an elegant solution for the automated fingerprinting of microvascular networks that could contribute to better understanding of angiogenic mechanisms and be utilized to diagnose and monitor microvascular deficiencies. Such information would be valuable for early detection and monitoring of functional abnormalities before they produce obvious and lasting effects, which may include improper perfusion of tissue, or support of tumor development.

The algorithm can be used to discriminate between the angiogenic response in a native healthy specimen compared with groups with impairment due to age or chemical or other genetic deficiency. Similarly, it can be applied to analyze angiogenic responses as a result of various treatments. This will serve two important goals. First, the identification of discriminatory patterns/attributes that distinguish angiogenesis status will lead to a better understanding of the basic mechanisms underlying this process. Because therapeutic control of angiogenesis could influence physiological and pathological processes such as wound and tissue repairing, cancer progression and metastasis, or macular degeneration, the ability to understand it under different conditions will offer new insight into developing novel therapeutic interventions, monitoring and treatment, especially in aging, and heart disease. Thus, our study

and the results form the foundation of a valuable diagnostic tool for changes in the functionality of the microvasculature and for discovery of drugs that alter the angiogenic response. The methods can be applied to tumor diagnosis, monitoring, and prognosis. In particular, it will be possible to derive microangiographic fingerprints to acquire specific microvascular patterns associated with early stages of tumor development. Such “angioprinting” could become an extremely helpful early diagnostic modality, especially for easily accessible tumors such as skin cancer.

**Prediction of Protein Localization Sites** The protein localization database consists of eight groups with a total of 336 instances (143, 77, 52, 35, 20, 5, 2, and 2, respectively) with seven attributes [91]. The eight groups are eight localization sites of protein, including cytoplasm (cp), inner membrane without signal sequence (im), periplasm (pp), inner membrane, uncleavable signal sequence (imU), outer membrane (om), outer membrane lipoprotein (omL), inner membrane lipoprotein (imL), inner membrane, and cleavable signal sequence (imS). However, the last four groups were taken out of our classification experiment since the population sizes are too small to ensure significance.

The seven attributes include McGeoch’s method for signal sequence recognition (mcg), von Heijne’s method for signal sequence recognition (gvh), von Heijne’s signal peptidase II consensus sequence score (lip), presence of charge on N-terminus of predicted lipoproteins (chg), score of discriminant analysis of the amino acid content of outer membrane and periplasmic proteins (aac), score of the ALOM membrane spanning region prediction program (alm1), and score of the ALOM program after excluding putative cleavable signal regions from the sequence (alm2).

In the classification we use four groups, 307 instances, with seven attributes. Our classification model selected the discriminatory patterns mcg, gvh, alm1, and alm2 to form the predictive rule with unbiased correct classification rates of 89%, compared with 81% by other classification models [48].

**Pattern Recognition in Satellite Images for Determining Types of Soil** The satellite database consists of the multispectral values of pixels in  $3 \times 3$  neighbor-

hoods in a satellite image, and the classification associated with the central pixel in each neighborhood. The aim is to predict this classification, given the multispectral values. In the sample database, the class of a pixel is coded as a number. There are six groups with 4435 samples in the training data set and 2000 samples in the testing data set; and each sample entity has 36 attributes describing the spectral bands of the image [91].

The original Landsat Multi-Spectral Scanner (MSS) image data for this database were generated from data purchased from NASA by the Australian Centre for Remote Sensing. The Landsat satellite data are one of the many sources of information available for a scene. The interpretation of a scene by integrating spatial data of diverse types and resolutions including multispectral and radar data, maps indicating topography, land use, etc. is expected to assume significant importance with the onset of an era characterized by integrative approaches to remote sensing (for example, NASA’s Earth Observing System commencing this decade).

One frame of Landsat MSS imagery consists of four digital images of the same scene in different spectral bands. Two of these are in the visible region (corresponding approximately to green and red regions of the visible spectrum) and two are in the (near) infrared. Each pixel is an 8-bit binary word, with 0 corresponding to black and 255 to white. The spatial resolution of a pixel is about  $80 \text{ m} \times 80 \text{ m}$ . Each image contains  $2340 \times 3380$  such pixels.

The database is a (tiny) subarea of a scene, consisting of  $82 \times 100$  pixels. Each line of data corresponds to a  $3 \times 3$  square neighborhood of pixels completely contained within the  $82 \times 100$  subarea. Each line contains the pixel values in the four spectral bands (converted to ASCII) of each of the nine pixels in the  $3 \times 3$  neighborhood and a number indicating the classification label of the central pixel. The number is a code for the following six groups: red soil, cotton crop, gray soil, damp gray soil, soil with vegetation stubble, and very damp gray soil. Running our classification model, we selected 17 discriminatory attributes to form the classification rule, producing an unbiased prediction with 85% accuracy.

### Further Advances

Brooks and Lee [17,18] devised other variations of the basic DAMIP model. They also showed that

DAMIP is strongly universally consistent (in some sense) with very good rates of convergence from Vapnik and Chervonenkis theory. A polynomial-time algorithm for discriminating between two populations with the DAMIP model was developed, and DAMIP was shown to be  $\mathcal{NP}$ -complete for a general number of groups. The proof demonstrating  $\mathcal{NP}$ -completeness employs results used in generating edges of the conflict graph [4,11,12,55]. Exploiting the necessary and sufficient conditions that identify edges in the conflict graph is the central contribution to the improvement in solution performance over industry-standard software. The conflict graph is the basis for various valid inequalities, a branching scheme, and for conditions under which integer variables are fixed for all solutions. Additional solution methods are identified which include a heuristic for finding solutions at nodes in the branch-and-bound tree, upper bounds for model parameters, and necessary conditions for edges in the conflict hypergraph [26,58]. Further, we have concluded that DAMIP is a computationally feasible, consistent, stable, robust, and accurate classifier.

### Progress and Challenges

We summarize in Table 2 the mathematical programming techniques used in classification problems as reviewed in this chapter.

As noted by current research efforts, multigroup classification remains  $\mathcal{NP}$ -complete and much work is needed to design effective models as well as to derive novel and efficient computational algorithms to solve these multigroup instances.

### Other Methods

While most classification methods can be described in terms of discriminant functions, some methods are not trained in the paradigm of determining coefficients or parameters for functions of a predefined form. These methods include *classification and regression trees*, *nearest-neighbor* methods, and *neural networks*.

Classification and regression trees [14] are nonparametric approaches to prediction. Classification trees seek to develop classification rules based on successive binary partitions of observations based on attribute values. Regression trees also employ rules consisting of bi-

nary partitions, but are used to predict continuous responses.

The rules generated by classification trees are easily viewable by plotting them in a treelike structure, from which the name arises. A test entity may be classified using rules in a tree plot by first comparing the entity's data with the root node of the tree. If the root node condition is satisfied by the data for a particular entity, the left branch is followed to another node; otherwise, the right branch is followed to another node. The data from the observation are compared with conditions at subsequent nodes until a leaf node is reached.

Nearest-neighbor methods begin by establishing a set of labeled prototype observations. The nearest-neighbor classification rule assigns test entities to groups according to the group membership of the nearest prototype. Different measures of distance may be used. The  $k$ -nearest-neighbor rule assigns entities to groups according to the group membership of the  $k$  nearest prototypes.

Neural networks are classification models that can also be interpreted in terms of discriminant functions, though they are used in a way that does not require finding an analytic form for the functions [25]. Neural networks are trained by considering one observation at a time, modifying the classification procedure slightly with each iteration.

### Summary and Conclusion

In this chapter, we presented an overview of mathematical programming based classification models, and analyzed their development and advances in recent years. Many mathematical programming methods are geared toward two-group analysis only, and their performance is often compared with Fisher's LDF or Smith's QDF. It has been noted that these methods can be used for multiple group analysis by finding  $G(G - 1)/2$  discriminants for each pair of groups ("one against one") or by finding  $G$  discriminants for each group versus the remaining data ("one against all"), but these approaches can lead to ambiguous classification rules [25].

Mathematical programming methods developed for multiple group analysis have been described [10,32,39,40,41,46,59,60,63,93]. Multiple group formulations for SVMs have been proposed and tested [17,36,40,49,59,60,66], but are still considered computationally in-

tensive [49]. The “one-against-one” and “one-against-all” methods with SVMs have been successfully applied [49,90].

We also discussed a class of multigroup general-purpose predictive models that we have developed based on the technology of large-scale optimization and SVMs [17,19,39,40,59,60,63]. Our models seek to maximize the correct classification rate while constraining the number of misclassifications in each group. The models incorporate the following features: (1) the ability to classify any number of distinct groups; (2) allow incorporation of heterogeneous types of attributes as input; (3) a high-dimensional data transformation that eliminates noise and errors in biological data;

(4) constrain the misclassification in each group and a reserved-judgment region that provides a safeguard against overtraining (which tends to lead to high misclassification rates from the resulting predictive rule); and (5) successive multistage classification capability to handle data points placed in the reserved-judgment region. The performance and predictive power of the classification models is validated through a broad class of biological and medical applications.

Classification models are critical to medical advances as they can be used in genomic, cell, molecular, and system-level analyses to assist in early prediction, diagnosis and detection of disease, as well as for intervention and monitoring. As shown in the CpG

island study for human cancer, such prediction and diagnosis opens up novel therapeutic sites for early intervention. The ultrasound application illustrates its application to a novel drug delivery mechanism, assisting clinicians during a drug delivery process, or in devising devices that can be implanted into the body for automated drug delivery and monitoring. The lung cancer cell motility study offers an understanding of how cancer cells behave in different protein media, thus assisting in the identification of potential gene therapy and target treatment. Prediction of the shape of a cancer tumor bed provides a personalized treatment design, replacing manual estimates by sophisticated computer predictive models. Prediction of early atherosclerosis through inexpensive biomarker measurements and traditional risk factors can serve as a potential clinical diagnostic tool for routine physical and health maintenance, alerting physicians and patients to the need for early intervention to prevent serious vascular disease. Fingerprinting of microvascular networks opens up the possibility for early diagnosis of perturbed systems in the body that may trigger disease (e.g., genetic deficiency, diabetes, aging, obesity, macular degeneracy, tumor formation), identification of target sites for treatment, and monitoring prognosis and success of treatment. Determining the type of erythemato-squamous disease and the presence/absence of heart disease helps clinicians to correctly diagnose and effectively treat patients. Thus, classification models serve as a basis for predictive medicine where the desire is to diagnose early and provide personalized target intervention. This has the potential to reduce healthcare costs, improve success of treatment, and improve quality of life of patients.

reformulation; Convex hull; Mixed integer 0–1  
programs; Polynomial programs; Nonconvex  
programs

Disjunctive programming (DP) problems can be stated  
in the form

$$(DP) \quad \text{Minimize } \{f(x) : x \in X, x \in \cup_{h \in H} S_h\},$$

where  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  is a lower semicontinuous function,  $X$   
is a closed convex subset of the nonnegative orthant of  
 $\mathbf{R}^n$ , and  $H$  is an index set for the collection of nonempty  
polyhedra

$$S_h = \left\{x : A^h x \geq b^h, x \geq 0\right\}, \quad h \in H. \quad (1)$$

The name for this class of problems arises from the  
feature that the constraints in (1) include the *disjunc-  
tion* that at least one of the (linear) sets of constraints  
defining  $S_h$ , for  $h \in H$ , must be satisfied. Problems  
including other logical conditions such as conjunc-  
tions, negations, and implications can be cast in the  
framework of this problem. Problem (DP) subsumes  
the classes of 0–1 *mixed integer problems*, the general-  
ized lattice point problem, the cardinality constrained

linear program, the extreme point optimization prob-  
lem, the linear complementarity problem, among nu-  
merous others, and finds application in several re-  
lated problems such as orthogonal production schedul-  
ing, scheduling on identical machines, multistage as-  
signment, location-allocation problems, load balancing  
problems, the segregated storage problem, the fixed-  
charge problem, project/portfolio selection problems,  
goal programming problems, and many other game  
theory and decision theory problems (see [35] for a de-  
tailed discussion of such problems and applications).

The theory and algorithms for disjunctive program-  
ming problems are mainly supported by the fundamen-  
tal *disjunctive cut principle*. The forward part of this re-  
sult due to E. Balas [4,5] states that for any nonnegative  
surrogate multiplier vectors  $\lambda^h$ ,  $h \in H$ , the inequality

$$\sup_{h \in H} \{\lambda^h A^h\} x \geq \inf_{h \in H} \{\lambda^h b^h\} \quad (2)$$

is valid for (or is implied by) the disjunction  $x \in$   
 $\cup_{h \in H} S_h$ , where the  $\sup\{\cdot\}$  and  $\inf\{\cdot\}$  are taken compo-  
nentwise in (2). More importantly, the converse part of  
this result due to R.G. Jeroslow [16] states that for any  
given valid inequality  $\pi x \geq \pi_0$  for the disjunction  $x \in$   
 $\cup_{h \in H} S_h$ , there exist nonnegative surrogate multipliers  
 $\lambda^h$ ,  $h \in H$ , such that the disjunctive cut (2) implies this  
given valid inequality, or uniformly dominates it, over  
the nonnegative orthant. This disjunctive cut principle  
also arises from the setting of convexity cuts and poly-  
hedral annexation methods as propounded by F. Glover  
[11,12], and it subsumes as well as can improve upon  
many types of classical cutting planes such as Gomory's  
mixed integer cuts, intersection cuts, and reverse outer  
polar cuts for 0–1 programs (see [4,5,11,12,35]). H.P.  
Williams [39] provides some additional insights into  
disjunctive formulations.

The generation of particular types of 'deep cuts' to  
delete a given solution (say, the origin, without loss of  
generality) based on the criteria of maximizing the Eu-  
clidean distance or the rectilinear distance between the  
origin and the nonnegative region feasible to the cut-  
ting plane, or maximizing the surplus in the cut with  
respect to the origin subject to suitable normalization  
constraints has also been explored in [34,37]. The in-  
tent behind such cutting plane methods is to generate  
*nondominated valid inequalities* that are supports (and  
hopefully, facets) of the closure convex hull of solutions

feasible to the disjunction. H.D. Sherali and C.M. Shetty [35,37] discuss how different alternate formulations of the disjunctive statement can influence the strength of the cut derived therefrom, and demonstrate how a sequence of augmented formulations can be used to sequentially tighten a given valid inequality. This process turns out to be precisely the Glover polyhedral annexation scheme in [12]. In contrast with this sequence dependent ‘lifting’ procedure, Sherali and Shetty [37] propose a ‘simultaneous lifting’ variant of this approach. Other types of disjunctive cutting planes for special problems include the cuts of [4,5,10,11,12,20], and [32] for linear knapsack, multiple choice and combinatorial disjunctions, [29] for linear complementarity problems, and the facet cuts of [25] based on the convex hull of certain types of disjunctions.

Balas [3] also provides an algebraic characterization for the closure *convex hull* of a union of polyhedra. This characterization is particularly useful in the study of the important class of facial disjunctive programs, that subsumes mixed integer 0–1 problems and linear complementarity problems, for example. A *facial disjunctive program* (FDP) can be stated as follows.

$$(FDP) \quad \text{Minimize } \{cx : x \in X \cap Y\},$$

where  $X$  is a nonempty polytope in  $\mathbf{R}^n$ , and where  $Y$  is a conjunction of some  $\widehat{h}$  disjunctions given in the so-called *conjunctive normal form* (conjunction of disjunctions)

$$Y = \bigcap_{h \in H} \left[ \bigcup_{i \in Q_h} \{x : a_i^h x \geq b_i^h\} \right]. \quad (3)$$

Here,  $H = \{1, \dots, \widehat{h}\}$  and for each  $h \in H$  we have specified a disjunction that requires at least one of the inequalities  $a_i^h x \geq b_i^h$ , for  $i \in Q_h$ , to be satisfied. The terminology ‘facial’ conveys the feature that  $X \cap \{x : a_i^h x \geq b_i^h\}$  defines a face of  $X$  for each  $i \in Q_h$ ,  $h \in H$ . For example, in the context of 0–1 mixed integer problems, the set  $X$  represents the linear programming relaxation of the problem, and for each binary variable  $x_h$ ,  $h \in H$ , the corresponding disjunction in (3) states that  $x_h \leq 0$  or  $x_h \geq 1$  should hold true (where  $0 \leq x_h \leq 1$  is included within  $X$ ). Balas [3] shows that for facial disjunctive programs, the convex hull of feasible solutions can be constructed inductively by starting with  $K_0 = X$  and

then determining

$$K_h = \text{conv} \left[ \bigcup_{i \in Q_h} \left( K_{h-1} \cap \{x : a_i^h x \geq b_i^h\} \right) \right] \\ \text{for } h = 1, \dots, \widehat{h}, \quad (4)$$

where  $K_{\widehat{h}}$  produces  $\text{conv}(X \cap Y)$ . Based on this, a hierarchy of relaxations  $K_0, \dots, K_{\widehat{h}}$  is generated for (FDP) that spans the spectrum from the linear programming to the convex hull representation [6]. Each member in this hierarchy can also be viewed as being obtained by representing the feasible region of the original problem as the intersection of the union of certain polyhedra, and then taking a hull-relaxation of this representation. Here, for a set  $D = \bigcap_j D_j$ , where each  $D_j$  is the union of certain polyhedra, the hull-relaxation of  $D$  [3] is defined as  $h - \text{rel}(D) = \bigcap_j \text{conv}(D_j) \supseteq \text{conv}(D)$ .

In the context of 0–1 mixed integer problems (MIP), Sherali and W.P. Adams [27,28] develop a *reformulation-linearization technique* (RLT) for generating a hierarchy of such relaxations, introducing the notion of multiplying constraints using factors composed of  $x_h$  and  $(1 - x_h)$ ,  $h \in H$ , to reformulate the problem, followed by a variable substitution to linearize the resulting problem. Approaches based on such constraint product and linearization strategies were used by these authors earlier in the context of several special applications [1,2,26]. Later, L. Lovász and A. Schrijver [17] independently used more general constraint factors to generate a similar hierarchy for 0–1 problems. The foregoing RLT construct can be specialized to derive  $K_h$  defined by (4) for 0–1 MIPs, where in this case,

$$K_h \equiv \text{conv} \left[ (K_{h-1} \cap \{x : x_h \leq 0\}) \cup (K_{h-1} \cap \{x : x_h \geq 1\}) \right]$$

can be obtained by multiplying the (implicitly defined) constraints of  $K_{h-1}$  by  $x_h$  and  $(1 - x_h)$  and then linearizing the resulting problem. This RLT approach is used in [8] in the ‘lift-and-project’ hierarchy of relaxations. However, the RLT process of [27,28] generates tighter relaxations at each level which can be viewed as hull relaxations produced by the intersection of the convex hull of the union of certain specially constructed polyhedra. No direct realization of (4) can produce these relaxations. For a survey on RLT approaches and for further enhancements, see [29,30].

In the context of general facial disjunctive programs, Jeroslow [15] presented a cutting plane algorithm that generates suitable facetial inequalities at each stage of the procedure such that an overall finite convergence is guaranteed via (4). This is accomplished by showing that in the worst case, the hierarchy  $K_0, \dots, K_h$  would be generated. The lift-and-project algorithm of [8] employs this cutting plane procedure based on the foregoing hierarchy of relaxations. Balas [7] also addresses an enhanced procedure that considers two variables at a time to define the disjunctions. The RLT process is used to construct partial convex hulls, and the resulting relaxations are embedded in a branch and cut algorithm.

Furthermore, for general facial disjunctive programs, Sherali and Shetty [36] present another finitely convergent cutting plane algorithm. At each step, this procedure searches for *extreme faces* of  $X$  relative to the cuts generated thus far (these are faces that do not contain any feasible points lying in a lower-dimensional face of  $X$ , see [18]), and based on the dimension of this extreme face and its feasibility to  $Y$ , either a disjunctive face cut or a disjunctive intersection cut is generated. This procedure was specialized for *bilinear programming* problems in [33] to derive a first nonenumerative finitely convergent algorithm for this class of problems.

Other disjunctive cutting plane algorithms include the Sherali–Sen procedures [31] for solving the general class of *extreme point mathematical programs*, the Baptiste–LePape procedures [9], and the Pinto–Grossmann procedures [21] for solving certain scheduling problems having disjunctive logic constraints. S. Sen and Sherali [24] also discuss issues related to designing convergent cutting plane algorithms, and present examples to show nonconvergence of certain iterative disjunctive cutting plane methods. Sensitivity and stability issues related to feasible and optimal sets of disjunctive programs have been addressed in [14]; [13] deals with the problem of solving algebraic systems of disjunctive equations. For other applications of disjunctive methods to process systems engineering, and to logic programming, see [19,23,38].

### Abstract

Protein force fields play an important role in protein structure prediction. Knowledge based force fields use the database information to derive the interaction energy between different residues or atoms of a protein. These simplified force fields require less computational effort and are relatively easy to use. A  $C^\alpha$ - $C^\alpha$  distance dependent high resolution force field has been developed using a set of high quality (low rmsd) decoys. A linear programming based formulation was used in which non-native “decoy” conformers are forced to take a higher energy compared to the corresponding native structure. This force field was tested on an independent test set and was found to excel on all the metrics that are widely used to measure the effectiveness of a force field.

## Keywords

Force field; Potential model; High resolution decoys; Protein structure prediction; Linear optimization; Protein design potential

## Introduction

Predicting the structure of a protein from its amino acid sequence is one of the biggest and yet most fundamental problems in computational structural biology. Anfinsen's hypothesis [1] is one of the main approaches used to solve this problem, which says that for a given physiological set of conditions the native structure of a protein corresponds to the global Gibbs free energy minimum. Thus, one needs a force field to calculate the energy of different conformers and pick the one with the lowest energy.

Physics-based force fields consider various types of interactions (for example, van der Waals interactions, hydrogen bonding, electrostatic interactions etc.) occurring at the atomic level of a protein to calculate the energy of a conformer. CHARMM [19], AMBER [5], ECEPP [20], ECEPP/3 [21] and GROMOS [24] are a few examples of the physics-based force fields. On the other hand, knowledge-based force fields use information from databases. Researchers have used the Boltzmann distribution [4,7,26], optimization based techniques [17,27] and many other approaches [6,12,13,14,15,16,18,23,25] to calculate these parameters. A recent review on such potentials can be found in Floudas et al. [8].

This work presents a novel  $C^\alpha$ - $C^\alpha$  distance dependent high resolution force field that has been generated using linear optimization based framework [22]. The emphasis is on the high resolution, which would enable us to differentiate between native and non-native structures that are very similar to each other (rmsd < 2 Å). The force field is called high resolution because it has been trained on a large set of high resolution decoys (small rmsd with respect to the native) and it intends to effectively distinguish high resolution decoys structures from the native structure.

The basic framework used in this work is similar to the one developed by Loose et al. [17]. However, it has been improved and applied to a diverse and enhanced (both in terms of quantity and quality) set of high resolution decoys. The new proposed model has

resulted in remarkable improvements over the LKF potential. These high resolution decoys were generated using torsion angle dynamics in combination with restricted variations of the hydrophobic core within the native structure. This decoy set highly improves the quality of training and testing. The force field developed in this paper was tested by comparing the energy of the native fold to the energies of decoy structures for proteins separate from those used to train the model. Other leading force fields were also tested on this high quality decoy set and the results were compared with the results of our high resolution potential. The comparison is presented in the Results section.

## Theory and Modeling

In this model, amino acids are represented by the location of its  $C^\alpha$  atom on the amino acid backbone. The conformation of a protein is represented by a coordinate vector,  $X$ , which includes the location of the  $C^\alpha$  of each amino acid. The native conformation is denoted as  $X_n$ , while the set  $i = 1, \dots, N$  is used to denote the decoy conformations  $X_i$ . Non-native decoys are generated for each of  $p = 1, \dots, P$  proteins and the energy of the native fold for each protein is forced to be lower than those of the decoy conformations (Anfinsen's hypothesis). This constraint is shown in the following equation:

$$E(X_{p,i}) - E(X_{p,n}) > \varepsilon \quad (1)$$

$$p = 1, \dots, P \quad i = 1, \dots, N$$

Equation (1) requires the native conformer to be always lower in energy than its decoy. A small positive parameter  $\varepsilon$  is used to avoid the trivial solution in which all energies are set to zero. An additional constraint (Eq. 2) is used to produce a nontrivial solution by constraining the sum of the differences in energies between decoy and native folds to be greater than a positive constant [28]. For the model presented in this paper, the values of  $\varepsilon$  and  $\Gamma$  were set to 0.01 and 1000, respectively.

$$\sum_p \sum_i [E(X_{p,i}) - E(X_{p,n})] > \Gamma \quad (2)$$

The energy of each conformation is taken as the arithmetic sum of pairwise interactions corresponding to each amino acid combination at a particular "contact" distance. A contact exists when the  $C^\alpha$  carbons of two

## Distance Dependent Protein Force Field via Linear Optimization, Table 1

### Distance dependent bin definition [17]

Bin ID	$C^\alpha$ Distance [Å]
1	3–4
2	4–5
3	5–5.5
4	5.5–6
5	6–6.5
6	6.5–7
7	7–8
8	8–9

amino acids are within 9 Å of each other. The energy of each interaction is a function of the  $C^\alpha$ – $C^\alpha$  distances and the identity of the interacting amino acids. To formulate the model, the energy of an interaction between a pair of amino acids, IC, within a distance bin, ID, was defined as  $\theta^{\text{IC, ID}}$ . The eight distance bins defined for the formulation are shown in Table 1. The energy for any fold  $X$ , of decoy  $i$ , for a protein  $p$ , is given by Eq. (3).

$$E(X_{p,i}) = \sum_{\text{IC}} \sum_{\text{ID}} N_{p,i,\text{IC, ID}} \theta_{\text{IC, ID}} \quad (3)$$

In this equation,  $N_{p,i,\text{IC, ID}}$  is the number of interactions between an amino acid pair IC, at a  $C^\alpha$ – $C^\alpha$  distance ID. The set IC ranges from 1 to 210 to account for the 210 unique combinations of the 20 naturally occurring amino acids. These bin definitions yield a total of 1680 interaction parameters to be determined by this model. To determine these parameters, a linear programming formulation is used in which the energy of a native protein is compared with a large number of its decoys. The violations, in which a non-native fold has a lower energy than the natural conformation, are minimized by optimizing with respect to these interaction parameters.

Equation (1) can be rewritten in terms of  $N_{p,i,\text{IC, ID}}$  as Eq. (4), where the slack parameters,  $S_p$ , are positive variables (Eq. 5) that represent the difference between the energies of the decoys and the native conformation of a given protein.

$$\sum_{\text{IC}} \sum_{\text{ID}} [N_{p,i,\text{IC, ID}} - N_{p,n,\text{IC, ID}}] \theta_{\text{IC, ID}} + S_p \geq \varepsilon$$

$$p = 1, \dots, P \quad i = 1, \dots, N \quad (4)$$

$$S_p \geq 0 \quad p = 1, \dots, P \quad (5)$$

$$\min_{\theta(\text{IC, ID})} \sum_p S_p \quad (6)$$

The objective function for this formulation is to minimize the sum of the slack variables,  $S_p$ , written in the form of Eq. (6). The relative magnitude of  $\theta_{\text{IC, ID}}$  is meaningless because if all  $\theta_{\text{IC, ID}}$  parameters are multiplied by a common factor then Eqs. (4) and (5) are still valid. In this formulation,  $\theta_{\text{IC, ID}}$  values were bound between  $-25$  and  $25$ .

### Physical Constraints

The above mentioned equations constitute the basic constraints needed to solve this model. However, this set does not guarantee a physically realistic solution. It is possible to come up with a set of parameters that can satisfy Eqs. (2,3,4,5,6) but would not reflect the actual interaction occurring between amino acids in a real system. To prohibit these unrealistic cases, another set of constraints based on the physical properties of the amino acids was imposed. Statistical results presented in Bahar and Jernigan [2] were also incorporated through the introduction of hydrophilic and hydrophobic constraints. The details of these physical constraints are given elsewhere [22].

### Database Selection and Decoy Generation

The protein database selection is critical to force field training. This set should adequately represent the PDB set [3]. At the same time, it should not be too large, as the training becomes difficult with an increase in the size of the training set. Zhang and Skolnick [29] developed a set of 1,489 nonhomologous single domain proteins. High resolution decoys were generated for these proteins and used for training and testing purposes. High quality decoy generation was based on the hypothesis that high-quality decoy structures should preserve information about the distances within the hydrophobic core of the native structure of each protein. For each of the proteins in the database, a number of distance constraints are introduced based on the hydrophobic-hydrophobic distances within the native structure. Using a set of proximity parameters, a large number of decoy structures are generated using DYANA [9]. The rmsd distribution of decoy structures can be found elsewhere [22].

## Training and Test Set

Of the 1400 proteins used for decoy generation, 1250 were randomly selected for training and the rest were used for testing purposes. For every protein in the set, 500–1600 decoys were generated depending on the fraction of secondary structure present in the native structure of the protein. These decoys were sorted based on their  $C^\alpha$  rmsd to the native structure and then 500 decoys were randomly selected to represent the whole rmsd range. This creates a training set of  $500 \times 1250 = 625,000$  decoys. However, because of computer memory limitations, it is not possible to include all of these decoys at the same time for training. An iterative scheme, “Rank and Drop”, was employed to overcome the memory problem while effectively using all the high quality structures. In this scheme, a subset of decoys is used to generate a force field. This force field is then used to rank all the decoys and a set of most challenging decoys (based on their energy value) is selected for the next round of force field generation. This process of force field generation and decoy ranking is repeated until there is no improvement in the ranking of the decoys [22]. This force field model was solved using the GAMS modeling language coupled with the CPLEX linear programming package [11].

It is equally important to test a force field on a difficult and rigorous testing set to confirm its effectiveness. The test set was comprised of 150 randomly selected proteins (41–200 amino acids in length). For each of the 150 test proteins, 500 high resolution decoys were generated using the same technique that was used to generate training decoys. The minimum  $C^\alpha$  based rmsds for these non-native structures were in the range of 0–2 Å. This HR force field was also tested on another set of medium resolution decoys [17]. This set has 200 decoys for 151 proteins. The minimum RMSD of the decoys of this set ranged from 3–16 Å. This set, along with the high resolution decoy set, spans the practical range of possible protein structures that one might encounter during protein structure prediction.

## Results and Discussion

A linear optimization problem was solved using information from 625,000 decoy structures and the values of all the energy parameters were obtained. The ability to distinguish between the native structure and native-

## Distance Dependent Protein Force Field via Linear Optimization, Table 2

Testing force fields on 150 proteins of the high resolution decoy set. TE13 force field was only tested on 148 cases

FF-Name	Average Rank	No of Firsts	Average rmsd
HR	1.87	113 (75.33%)	0.451
LKF	39.45	17 (11.33%)	1.721
TE13	19.94	92 (62.16%)	0.813
HL	44.93	70 (46.67%)	1.092

like conformers is the most significant test for any force field. The HR force field was tested on 500 decoys of the 150 test proteins. In this testing, the relative position, or rank, of the native conformation among its decoys was calculated. An ideal force field should be able to assign rank 1 to the native structures of all the test proteins. Other force fields like LKF [17], TE13 [27], and HL [10] were also tested on this set of high resolution decoys. All these force fields are fundamentally different from each other in their methods of energy estimation. Comparing the results obtained with these force fields aims to assess the fundamental utility of the HR force field. The comparison of the energy rankings obtained using different force fields is presented in Table 2. From this table it is evident that the HR force field is the most effective in identifying the native structures by rank. The HR force field correctly identified the native folds of 113 proteins out of a set of 150 proteins, which compares favorably to a maximum of 92 (out of 148) by the TE13 force field.

Another analysis was carried out to evaluate the discrimination ability of these potentials. In this evaluation, all the decoys of the test set were ranked using these potentials. For each test protein, the  $C^\alpha$  rmsd of the rank 1 conformer was calculated with respect to the native structure of that protein. The  $C^\alpha$  rmsd would be zero for the cases in which a force field selects the native structure as rank 1. However, it will not be zero for all other cases in which a non-native conformer is assigned the top rank. The average of these rmsds represents the spatial separation of the decoys with respect to the native structure. The average rmsd value obtained for each of the force fields is shown in Table 2. It can be seen that the average  $C^\alpha$  rmsd value is least for the HR force field. The average  $C^\alpha$  rmsd value for the HR force field is 0.451 Å, which is much less compared to 1.721 Å by the LKF, and 0.813 Å by TE13 force field. This means

that the structures predicted by the HR force fields have the least spatial deviation from their corresponding native structures.

The HR force field was also tested on the test set published by Loose et al. [17] and was found to do better than other force fields. The comparison results for this test can be found elsewhere [22]. The effectiveness of the HR force field is further reinforced by its success on the medium resolution decoy test set. On the test set of 110 medium resolution decoys, it was capable of correctly identifying 78.2 % of the native structures, significantly more than other force fields.

## Conclusions

The HR force field was developed using an optimization based linear programming formulation, in which the model is trained using a diverse set of high quality decoys. Physically observed interactions between certain amino acids were written in the form of mathematical constraints and included in the formulation.

The decoys were generated based on the premise that high quality decoy structures should preserve information about the distance within the hydrophobic core of the native structure of each protein. The set of interaction energy parameters obtained after solving the model were found to be of very good discriminatory capacity. This force field performed well on a set of independent, non-homologous high resolution decoys. This force field can become a powerful tool for fold recognition and de novo protein design.

## Introduction

*Exact algorithms* allow one to find optimal solutions to NP-hard combinatorial optimization (CO) problems. Many research papers report on solving large instances of some NP-hard problems (see, e. g., [25,27]). The running time of exact algorithms is often very high for large instances (many hours or even days), and very large instances remain beyond the capabilities of exact algorithms. Even for instances of moderate size, if we wish to remain within seconds or minutes rather than hours or days of running time, only heuristics can be used. Certainly, with heuristics, we are not guaranteed to find optimum, but good heuristics normally produce near-optimal solutions. This is enough in most applications since very often the data and/or mathematical model are not exact anyway.

Research on CO heuristics has produced a large variety of heuristics especially for well-known CO problems. Thus, we need to choose the best ones among them. In most of the literature, heuristics are compared in computational experiments. While experi-

## Domination Analysis in Combinatorial Optimization

GREGORY GUTIN

Department of Computer Science, Royal Holloway, University of London, Egham, UK

mental analysis is of definite importance, it cannot cover all possible families of instances of the CO problem at hand and, in particular, it practically never covers the hardest instances.

*Approximation Analysis* [3] is a frequently used tool for theoretical evaluation of CO heuristics. Let  $\mathcal{H}$  be a heuristic for a combinatorial minimization problem  $P$  and let  $\mathcal{I}_n$  be the set of instances of  $P$  of size  $n$ . In approximation analysis, we use the performance ratio  $r_{\mathcal{H}}(n) = \max\{f(I)/f^*(I) : I \in \mathcal{I}_n\}$ , where  $f(I)$  ( $f^*(I)$ ) is the value of the heuristic (optimal) solution of  $I$ . Unfortunately, for many CO problems, estimates for  $r_{\mathcal{H}}(n)$  are not constants and provide only a vague picture of the quality of heuristics. Moreover, even constant performance ratio does not guarantee that the heuristic often outputs good-quality solutions, see, e. g., the discussion of the DMST heuristic below.

*Domination Analysis* (DA) (for surveys, see [22,24]) provides an alternative and a complement to approximation analysis. In DA, we are interested in the domination number or domination ratio of heuristics. *Domination number (ratio)* of a heuristic  $H$  for a combinatorial optimization problem  $P$  is the maximum number (fraction) of all solutions that are not better than the solution found by  $H$  for any instance of  $P$  of size  $n$ . In many cases, DA is very useful. For example, we will see later that the greedy algorithm has domination number 1 for many CO problems. In other words, the greedy algorithm, in the worst case, produces the unique worst possible solution. This is in line with latest computational experiments with the greedy algorithm, see, e. g., [25], where the authors came to the conclusion that the greedy algorithm ‘might be said to self-destruct’ and that it should not be used even as ‘a general-purpose starting tour generator’.

The *Asymmetric Traveling Salesman Problem* (ATSP) is the problem of computing a minimum weight tour (Hamilton cycle) passing through every vertex in a weighted complete digraph  $K_n^*$  on  $n$  vertices. The *Symmetric TSP* (STSP) is the same problem, but on a complete undirected graph. When a certain fact holds for both ATSP and STSP, we will simply speak of *TSP*. Sometimes, the maximizing version of TSP is of interest, we denote it by *Max TSP*.

APX is the class of CO problems that admit polynomial time approximation algorithms with a constant performance ratio [3]. It is well known that while Max

TSP belongs to APX, TSP does not. This is at odds with the simple fact that a ‘good’ approximation algorithm for Max TSP can be easily transformed into an algorithm for TSP. Thus, it seems that both Max TSP and TSP should be in the same class of CO problems. The above asymmetry was already viewed as a drawback of performance ratio already in the 1970’s, see, e. g. [11,28,33]. Notice that from the DA point view Max TSP and TSP are equivalent problems.

Zemel [33] was the first to characterize measures of quality of approximate solutions (of binary integer programming problems) that satisfy a few basic and natural properties: the measure becomes smaller for better solutions, it equals 0 for optimal solutions and it is the same for corresponding solutions of equivalent instances. While the performance ratio and even the relative error (see [3]) do not satisfy the last property, the parameter  $1-r$ , where  $r$  is the domination ratio, does satisfy all of the properties.

Local Search (LS) is one of the most successful approaches in constructing heuristics for CO problems. Recently, several researchers investigated LS with Very Large Scale Neighborhoods (see, e. g., [1,12,24]). The hypothesis behind this approach is that the larger the neighborhood the better quality solution are expected to be found [1]. However, some computational experiments do not support this hypothesis; sometimes an LS with small neighborhoods proves to be superior to that with large neighborhoods. This means that some other parameters are responsible for the relative power of neighborhoods. Theoretical and experimental results on TSP indicate that one such parameter may well be the domination number of the corresponding LS.

In our view, it is advantageous to have bounds for both performance ratio and domination number (or, domination ratio) of a heuristic whenever it is possible. Roughly speaking this will enable us to see a 2D rather than 1D picture. For example, consider the double minimum spanning tree heuristic (DMST) for the Metric STSP (i. e., STSP with triangle inequality). DMST starts from constructing a minimum weight spanning tree  $T$  in the complete graph of the STSP, doubles every edge in  $T$ , finds a closed Euler trail  $E$  in the ‘double’  $T$ , and cancels any repetition of vertices in  $E$  to obtain a TSP tour  $H$ . It is well-known and easy to prove that the weight of  $H$  is at most twice the weight

of the optimal tour. Thus, the performance ratio for DMST is bounded by 2. However, Punnen, Margot and Kabadi [29] proved that the domination number of DMST is 1. Interestingly, in practice DMST often performs much worse than the well-known 2-Opt LS heuristic. For 2-Opt LS we cannot give any constant approximation guarantee, but the heuristic is of very large domination number [29].

The above example indicates that it makes sense to use DA to rank heuristics for the CO problem under consideration. If the domination number of a heuristic  $\mathcal{H}$  is larger than the domination of a heuristic  $\mathcal{H}'$  (for all or ‘almost all’ sizes  $n$ ), we may say that  $\mathcal{H}$  is better than  $\mathcal{H}'$  in the worst case (from the DA point of view). Berend, Skiena and Twitto [10] used DA to rank some well-known heuristics for the Vertex Cover problem (and, thus, the Independent Set and Clique problems). The three problems and the heuristics will be defined in the corresponding subsection of the Cases section. Ben-Arieh et al. [7] studied three heuristics for the *Generalized TSP*: the vertices of the complete digraph are partitioned into subsets and the goal is to find a minimum weight cycle containing exactly one vertex from each subset. In the computational experiment in [7] one of the heuristics was clearly inferior to the other two. The best two behaved very similarly. Nevertheless, the authors of [7] managed to ‘separate’ the two heuristics by showing that one of the heuristics was of much larger domination number.

One might wonder whether a heuristic  $\mathcal{A}$ , which is significantly better than another heuristic  $\mathcal{B}$  from the DA point of view, is better than  $\mathcal{B}$  in computational experiments. In particular, whether the ATSP greedy algorithm, which is of domination number 1, is worse, in computational experiments, than any ATSP heuristic of domination number at least  $(n-2)!$ ? Generally speaking the answer to this natural question is negative. This is because computational experiments and DA indicate different aspects of quality of heuristics. Nevertheless, it seems that many heuristics of very small domination number such as the ATSP greedy algorithm perform poorly also in computational experiments and, thus, cannot be recommended to be widely used in computational practice.

The rest of the entry is organized as follows. We give additional terminology and notation in the section Definitions. In the section Methods, we describe two pow-

erful methods in DA. In the section Cases, we consider DA results for some well-known CO problems.

## Definitions

Let  $\mathcal{P}$  be a CO problem and let  $\mathcal{H}$  be a heuristic for  $\mathcal{P}$ . The *domination number*  $\text{domn}(\mathcal{H}, \mathcal{I})$  of  $\mathcal{H}$  for an instance  $\mathcal{I}$  of  $\mathcal{P}$  is the number of solutions of  $\mathcal{I}$  that are not better than the solution  $s$  produced by  $\mathcal{H}$  including  $s$  itself. For example, consider an instance  $\mathcal{T}$  of the STSP on 5 vertices. Suppose that the weights of tours in  $\mathcal{T}$  are 2,5,5,6,6,9,9,11,11,12,12,15 (every instance of STSP on 5 vertices has 12 tours) and suppose that the greedy algorithm computes the tour  $T$  of weight 6. Then  $\text{domn}(\text{greedy}, \mathcal{T}) = 9$ . In general, if  $\text{domn}(\mathcal{H}, \mathcal{I})$  equals the number of solutions in  $\mathcal{I}$ , then  $\mathcal{H}$  finds an optimal solution for  $\mathcal{I}$ . If  $\text{domn}(\mathcal{H}, \mathcal{I}) = 1$ , then the solution found by  $\mathcal{H}$  for  $\mathcal{I}$  is the unique worst possible one.

The *domination number*  $\text{domn}(\mathcal{H}, n)$  of  $\mathcal{H}$  is the minimum of  $\text{domn}(\mathcal{H}, \mathcal{I})$  over all instances  $\mathcal{I}$  of size  $n$ . Since the ATSP on  $n$  vertices has  $(n-1)!$  tours, an algorithm for the ATSP with domination number  $(n-1)!$  is exact. The domination number of an exact algorithm for the STSP is  $(n-1)!/2$ . If an ATSP heuristic  $\mathcal{A}$  has domination number equal 1, then there is an assignment of weights to the arcs of each complete digraph  $K_n^*$ ,  $n \geq 2$ , such that  $\mathcal{A}$  finds the unique worst possible tour in  $K_n^*$ .

While studying TSP we normally consider only feasible solutions (tours), for several other problems some authors take into consideration also infeasible solutions [10]. One example is the *Maximum Independent Set* problem, where given a graph  $G$ , the aim is to find an independent set in  $G$  of maximum cardinality. Every non-empty set of vertices is considered to be a solution by Berend, Skiena and Twitto [10]. To avoid dealing with infeasible solutions (and, thus, reserving the term ‘solution’ only for feasible solutions) we also use the notion of the *blackball number* introduced in [10]. The *blackball number*  $\text{bbn}(\mathcal{H}, \mathcal{I})$  of  $\mathcal{H}$  for an instance  $\mathcal{I}$  of  $\mathcal{P}$  is the number of solutions of  $\mathcal{I}$  that are better than the solution produced by  $\mathcal{H}$ . The *blackball number*  $\text{bbn}(\mathcal{H}, n)$  of  $\mathcal{H}$  is the maximum of  $\text{domn}(\mathcal{H}, \mathcal{I})$  over all instances  $\mathcal{I}$  of size  $n$ .

When the number of solutions depends not only on the size of the instance of the CO problem at hand (for

example, the number of independent sets of vertices in a graph  $G$  on  $n$  vertices depends on the structure of  $G$ , the domination ratio of an algorithm  $\mathcal{A}$  is of interest: the *domination ratio* of  $\mathcal{A}$ ,  $\text{domr}(\mathcal{A}, n)$ , is the minimum of  $\text{domn}(\mathcal{A}, \mathcal{I})/\text{sol}(\mathcal{I})$ , where  $\text{sol}(\mathcal{I})$  is the number of solutions of  $\mathcal{I}$ , taken over all instances  $\mathcal{I}$  of size  $n$ . Clearly, domination ratio belongs to the interval  $(0, 1]$  and exact algorithms are of domination ratio 1.

**Methods**

Currently, there are two powerful methods in DA. One is used to prove that the heuristic under consideration is of domination number 1. For this method to be useful, the heuristic has to be a greedy-type algorithm for a CO problem on independence systems. We describe the method and its applications in the subsection Greedy-Type Algorithms. The other method is used prove that the heuristic under consideration is of very large domination number. For many problems this follows from the fact that the heuristic always finds a solution that is not worse than the average solution. This method is described in the subsection Better-Than-Average Heuristics.

**Greedy-Type Algorithms**

The main practical message of this subsection is that one should be careful while using the classical greedy algorithm and its variations in combinatorial optimization (CO): there are many instances of CO problems for which such algorithms will produce the unique worst possible solution. Moreover, this is true for several well-known optimization problems and the corresponding instances are not exotic, in a sense. This means that not always the paradigm of greedy optimization provides any meaningful optimization at all.

An *independence system* is a pair consisting of a finite set  $E$  and a family  $\mathcal{F}$  of subsets (called *independent sets*) of  $E$  such that (I1) and (I2) are satisfied.

- (I1) the empty set is in  $\mathcal{F}$ ;
- (I2) If  $X \in \mathcal{F}$  and  $Y$  is a subset of  $X$ , then  $Y \in \mathcal{F}$ .

All maximal sets of  $\mathcal{F}$  are called *bases*. An independence system is *uniform* if all its bases are of the same cardinality.

Many combinatorial optimization problems can be formulated as follows. We are given an independence

system  $(E, \mathcal{F})$ , a set  $W \subseteq \mathbb{Z}_+$  and a weight function  $w$  that assigns a weight  $w(e) \in W$  to every element of  $E$  ( $\mathbb{Z}_+$  is the set of non-negative integers). The weight  $w(S)$  of  $S \in \mathcal{F}$  is defined as the sum of the weights of the elements of  $S$ . It is required to find a base  $B \in \mathcal{F}$  of minimum weight. We will consider only such problems and call them the  $(E, \mathcal{F}, W)$ -*optimization problems*.

If  $S \in \mathcal{F}$ , then let  $I(S) = \{x : S \cup \{x\} \in \mathcal{F}\} - S$ . This means that  $I(S)$  consists of those elements from  $E - S$ , which can be added to  $S$ , in order to have an independent set of size  $|S| + 1$ . Note that by (I2)  $I(S) \neq \emptyset$  for every independent set  $S$  which is not a base.

The *greedy algorithm* tries to construct a minimum weight base as follows: it starts from an empty set  $X$ , and at every step it takes the current set  $X$  and adds to it a minimum weight element  $e \in I(X)$ , the algorithm stops when a base is built. We assume that the greedy algorithm may choose any element among equally weighted elements in  $I(X)$ . Thus, when we say that the greedy algorithm *may construct* a base  $B$ , we mean that  $B$  is built provided the appropriate choices between elements of the same weight are made.

An *ordered partitioning* of an ordered set  $Z = \{z_1, z_2, \dots, z_k\}$  is a collection of subsets  $A_1, A_2, \dots, A_q$  of  $Z$  such that if  $z_r \in A_i$  and  $z_s \in A_j$  where  $1 \leq i < j \leq q$  then  $r < s$ . Some of the sets  $A_i$  may be empty and  $\cup_{i=1}^q A_i = Z$ .

The following theorem by Bang-Jensen, Gutin and Yeo [6] characterizes all uniform independence systems  $(E, \mathcal{F})$  for which there is an assignment of weights to the elements of  $E$  such that the greedy algorithm solving the  $(E, \mathcal{F}, \{1, 2, \dots, r\})$ -optimization problem may construct the unique worst possible solution.

**Theorem 1** *Let  $(E, \mathcal{F})$  be a uniform independence system and let  $r \geq 2$  be a natural number. There exists a weight assignment  $w : E \rightarrow \{1, 2, \dots, r\}$  such that the greedy algorithm may produce the unique worst possible base if and only if  $\mathcal{F}$  contains some base  $B$  with the property that for some ordering  $x_1, \dots, x_k$  of the elements of  $B$  and some ordered partitioning  $A_1, A_2, \dots, A_r$  of  $x_1, \dots, x_k$  the following holds for every base  $B' \neq B$  of  $\mathcal{F}$ :*

$$\sum_{j=0}^{r-1} |I(A_{0,j}) \cap B'| < \sum_{j=1}^r j \cdot |A_j|, \tag{1}$$

where  $A_{0,j} = A_0 \cup \dots \cup A_j$  and  $A_0 = \emptyset$ .

The special case  $r = 2$  has an ‘easier’ characterization also proved in [6].

**Theorem 2** *Let  $(E, \mathcal{F})$  be a uniform independence system. For every choice of distinct natural numbers  $a, b$  there exists a weight function  $w: E \rightarrow \{a, b\}$  such that the greedy algorithm may produce the unique worst base if and only if  $\mathcal{F}$  contains a base  $B = \{x_1, x_2, \dots, x_k\}$  such that for some  $1 \leq i < k$  the following holds:*

- (a) *If  $B'$  is a base such that  $\{x_1, \dots, x_i\} \subseteq B'$  then  $B' = B$ .*
- (b) *If  $B'$  is a base such that  $\{x_{i+1}, \dots, x_k\} \subseteq B'$  then  $B' = B$ .*

Using Theorem 1, the authors of [6] proved the following two corollaries.

**Corollary 3** *Consider STSP as an  $(E, \mathcal{H}, W)$ -optimization problem. Let  $n \geq 3$ .*

- (a) *If  $n \geq 4$  and  $|W| \leq \lfloor \frac{n-1}{2} \rfloor$ , then the greedy algorithm never produces the unique worst possible base (i. e., tour).*
- (b) *If  $n \geq 3$ ,  $r \geq n - 1$  and  $W = \{1, 2, \dots, r\}$ , then there exists a weight function  $w: E \rightarrow \{1, 2, \dots, r\}$  such that the greedy algorithm may produce the unique worst possible base (i. e., tour).*

**Corollary 4** *Consider ATSP as an  $(E, \mathcal{H}, W)$ -optimization problems. Let  $n \geq 3$ .*

- (a) *If  $|W| \leq \lfloor \frac{n-1}{2} \rfloor$ , then the greedy algorithm never produces the unique worst possible base (i. e., tour).*
- (b) *For every  $r \geq \lceil \frac{n+1}{2} \rceil$  there exists a weight function  $w: E(K_n^*) \rightarrow \{1, 2, \dots, r\}$  such that the greedy algorithm may produce the unique worst possible base (i. e., tour).*

Let  $\mathcal{F}$  be the sets of those subsets  $X$  of  $E(K_{2n})$  which induce a bipartite graph with at most  $n$  vertices in each partite set. Then  $(E(K_{2n}), \mathcal{F})$  is a uniform independence system and the bases of  $(E(K_{2n}), \mathcal{F})$  correspond to copies of the complete balanced bipartite graph  $K_{n,n}$  in  $K_{2n}$ . The  $(E(K_{2n}), \mathcal{F}, \mathbb{Z}_+)$ -optimization problem is called the *Minimum Bisection Problem*. Theorem 2 implies the following:

**Corollary 5** [6] *Let  $n \geq 4$ . The greedy algorithm for the  $(E(K_{2n}), \mathcal{F}, W)$ -optimization problem may produce the unique worst solution even if  $|W| = 2$ .*

For  $W = \mathbb{Z}_+$ , the following sufficient condition can often be used:

**Theorem 6** [21] *Let  $(E, \mathcal{F})$  be an independence system which has a base  $B' = \{x_1, x_2, \dots, x_k\}$  such that the following holds for every base  $B \in \mathcal{F}$ ,  $B \neq B'$ ,*

$$\sum_{j=0}^{k-1} |I(x_1, x_2, \dots, x_j) \cap B| < k(k+1)/2.$$

*Then the greedy algorithm for the  $(E, \mathcal{F}, \mathbb{Z}_+)$ -optimization problem may produce the unique worst solution.*

Gutin, Yeo and Zverovich [23] considered the well-known *nearest neighbor (NN)* TSP heuristic: the tour starts at any vertex  $x$  of the complete directed or undirected graph; we repeat the following loop until all vertices have been included in the tour: add to the tour a vertex (among vertices not yet in the tour) closest to the vertex last added to the tour. It was proved in [23] that the domination number of NN is 1 for any  $n \geq 3$ .

Bendall and Margot [8] studied greedy-type algorithms for many CO problems. Greedy-type algorithms were introduced in [18]. They include NN and were defined as follows. A *greedy-type* algorithm  $\mathcal{H}$  is similar to the greedy algorithm: start with the partial solution  $X = \emptyset$ ; and then repeatedly add to  $X$  an element of minimum weight in  $I_{\mathcal{H}}(X)$  (ties are broken arbitrarily) until  $X$  is a base of  $\mathcal{F}$ , where  $I_{\mathcal{H}}(X)$  is a subset of  $I(X)$  that does not depend on the cost function  $c$ , but only on the independence system  $(E, \mathcal{F})$  and the set  $X$ . Moreover,  $I_{\mathcal{H}}(X)$  is non-empty if  $I(X) \neq \emptyset$ , a condition that guarantees that  $\mathcal{H}$  always outputs a base. Bendall and Margot [8] obtained complicated sufficient conditions for an independent system  $(E, \mathcal{F})$  that ensure that every greedy-type algorithm is of domination number 1 for the  $(E, \mathcal{F}, \mathbb{Z}_+)$ -optimization problem.

The conditions imply that every greedy-type algorithm is of domination number 1 for the following classical CO problems [8]: (1) The *Minimum Bisection Problem*; (2) The *k-Clique Problem*: find a set of  $k$  vertices in a complete graph so that the sum of the weights of the edges between them is minimum; (3) ATSP; (4) STSP; (5) The *MinMax Matching Subgraph Problem*:

find a maximal (with respect to inclusion) matching so that the sum of the weights of the edges in the matching is minimum; (6) The *Assignment Problem*: find a perfect matching in a weighted complete bipartite graph so that the sum of the weights of the edges in the matching is minimum.

**Better-Than-Average Heuristics**

The idea of this method is to show that a heuristic is of very large domination number if it always produces a solution that is not worse than the average solution. The first such result was proved by Rublineckii [31] for the STSP.

**Theorem 7** *Every STSP heuristic that always produces a tour not worse than the average tour (of the instance) is of domination number at least  $(n - 2)!$  when  $n$  is odd and  $(n - 2)!/2$  when  $n$  is even.*

The following similar theorem was proved by Sarvanov [32] for  $n$  odd and Gutin and Yeo [20] for  $n$  even.

**Theorem 8** *Every ATSP heuristic that always produces a tour not worse than the average tour (of the instance) is of domination number at least  $(n - 2)!$  for each  $n \neq 6$ .*

The two theorems has been used to prove that a wide variety of TSP heuristics have domination number at least  $\Omega((n - 2)!)$ . We discuss two families of such heuristics.

Consider an instance of the ATSP (STSP). Order the vertices  $x_1, x_2, \dots, x_n$  of  $K_n^*$  ( $K_n$ ) using some rule. The *generic vertex insertion algorithm* proceeds as follows. Start with the cycle  $C_2 = x_1x_2x_1$ . Construct the cycle  $C_j$  from  $C_{j-1}$  ( $j = 3, 4, 5, \dots, n$ ), by inserting the vertex  $x_j$  into  $C_{j-1}$  at the optimum place. This means that for each arc  $e = xy$  which lies on the cycle  $C_{j-1}$  we compute  $w(xx_j) + w(x_jy) - w(xy)$ , and insert  $x_j$  into the arc  $e = xy$ , which obtains the minimum such value. Here  $w(uv)$  denotes the weight of an arc  $uv$ . E.M. Lifshitz (see [31]) was the first to prove that the generic vertex insertion algorithm always produces a tour not worse than the average tour. Thus, we have the following:

**Corollary 9** *The generic vertex insertion algorithm has domination number at least  $(n - 2)!$  ( $n \neq 6$ ).*

In TSP local search (LS) heuristics, a neighborhood  $N(T)$  is assigned to every tour  $T$ ;  $N(T)$  is a set of tours

in some sense close to  $T$ . The *best improvement* LS proceeds as follows. We start from a tour  $T_0$ . In the  $i$ 'th iteration ( $i \geq 1$ ), we search in the neighborhood  $N(T_{i-1})$  for the best tour  $T_i$ . If the weights of  $T_{i-1}$  and  $T_i$  do not coincide, we carry out the next iteration. Otherwise, we output  $T_i$ .

The  $k$ -Opt,  $k \geq 2$ , neighborhood of a tour  $T$  consists of all tours that can be obtained by replacing a collection of  $k$  edges (arcs) by a collection of  $k$  edges (arcs). It is easy to see that one iteration of the best improvement  $k$ -Opt LS can be completed in time  $O(n^k)$ . Rublineckii [31] showed that every local optimum for the best improvement 2-Opt or 3-Opt LS for STSP is of weight at least the average weight of a tour and, thus, by Theorem 7 is of domination number at least  $(n - 2)!/2$  when  $n$  is even and  $(n - 2)!$  when  $n$  is odd. Observe that this result is of restricted interest since to reach a  $k$ -Opt local optimum one may need exponential time (cf. Section 3 in [26]). However, Punnen, Margot and Kabadi [29] managed to prove that, in polynomial time, the best improvement 2-Opt and 3-Opt LS's for STSP produce a tour of weight at least the average weight of a tour. Thus, we have the following:

**Corollary 10** *For the STSP the best improvement 2-Opt LS produces a tour, which is not worse than at least  $\Omega((n-2)!)$  other tours, in at most  $O(n^3 \log n)$  iterations.*

Corollary 10 is also valid for the best improvement 3-Opt LS and some other LS heuristics for TSP, see [24,29]. In the next section, we will give further examples of better-than-average heuristics for problems other than TSP.

**Cases**

**Traveling Salesman Problem**

In the previous sections, we discussed several TSP heuristics. However, there are many more TSP heuristics and, in this subsection, we consider some of them. In the next subsection, some general upper bounds are given on the domination number of TSP heuristics.

Gutin, Yeo and Zverovich [23] considered the *repeated nearest neighbor* (RNN) heuristic, which is the following variation of the NN heuristic: construct  $n$  tours by starting NN from each vertex of the complete (di)graph and choose the best tour among the  $n$  tours. The authors of [23] proved that for the ATSP, RNN al-

ways produces a tour, which is not worse than at least  $n/2 - 1$  other tours, but for some instance it finds a tour, which is not worse than at most  $n - 2$  other tours,  $n \geq 4$ . We also show that, for some instance of the STSP on  $n \geq 4$  vertices, RNN produces a tour not worse than at most  $2^{n-3}$  tours.

Another ATSP heuristic, max-regret-fc (fc abbreviates First Coordinate), was first introduced by Ghosh et al. [13]. Extensive computational experiments in [13] demonstrated a clear superiority of max-regret-fc over the greedy algorithm and several other construction heuristics from [14]. Therefore, the result of Theorem 11 obtained by Gutin, Goldengorin and Huang [15] was somewhat unexpected.

Let  $K_n^*$  be a complete digraph with vertices  $V = \{1, 2, \dots, n\}$ . The weight of an arc  $(i, j)$  is denoted by  $w_{ij}$ . Let  $Q$  be a collection of disjoint paths in  $K_n^*$ . An arc  $a = (i, j)$  is a *feasible addition* to  $Q$  if  $Q + a$  is either a collection of disjoint paths or a tour in  $K_n^*$ . Consider the following two ATSP heuristics: max-regret-fc and max-regret.

The heuristic *max-regret-fc* proceeds as follows. Set  $W = T = \emptyset$ . While  $V \neq W$  do the following: For each  $i \in V \setminus W$ , compute two lightest arcs  $(i, j)$  and  $(i, k)$  that are feasible additions to  $T$ , and compute the difference  $\Delta_i = |w_{ij} - w_{ik}|$ . For  $i \in V \setminus W$  with maximum  $\Delta_i$  choose the lightest arc  $(i, j)$ , which is a feasible addition to  $T$  and add  $(i, j)$  to  $M$  and  $i$  to  $W$ .

The heuristic *max-regret* proceeds as follows. Set  $W^+ = W^- = T = \emptyset$ . While  $V \neq W^+$  do the following: For each  $i \in V \setminus W^+$ , compute two lightest arcs  $(i, j)$  and  $(i, k)$  that are feasible additions to  $T$ , and compute the difference  $\Delta_i^+ = |w_{ij} - w_{ik}|$ ; for each  $i \in V \setminus W^-$ , compute two lightest arcs  $(j, i)$  and  $(k, i)$  that are feasible additions to  $T$ , and compute the difference  $\Delta_i^- = |w_{ji} - w_{ki}|$ . Compute  $i' \in V \setminus W^+$  with maximum  $\Delta_{i'}^+$  and  $i'' \in V \setminus W^-$  with maximum  $\Delta_{i''}^-$ . If  $\Delta_{i'}^+ \geq \Delta_{i''}^-$ , choose the lightest arc  $(i', j')$ , which is a feasible addition to  $T$  and add  $(i', j')$  to  $M$ ,  $i'$  to  $W^+$  and  $j'$  to  $W^-$ . Otherwise, choose the lightest arc  $(j'', i'')$ , which is a feasible addition to  $T$  and add  $(j'', i'')$  to  $M$ ,  $i''$  to  $W^-$  and  $j''$  to  $W^+$ .

Notice that in max-regret-fc, if  $|V \setminus W| = 1$  we set  $\Delta_i = 0$ . A similar remark applies to max-regret.

**Theorem 11** *The domination number of both max-regret-fc and max-regret equals 1 for each  $n \geq 2$ .*

## Upper Bounds for Domination Numbers of ATSP Heuristics

It is realistic to assume that any ATSP algorithm spends at least one unit of time on every arc of  $K_n^*$  that it considers. We use this assumption in this subsection.

**Theorem 12** [17] *Let  $\mathcal{A}$  be an ATSP heuristic of running time  $t(n)$ . Then the domination number of  $\mathcal{A}$  does not exceed  $\max_{1 \leq n' \leq n} (t(n)/n')^{n'}$ .*

**Corollary 13** [17] *Let  $\mathcal{A}$  be an ATSP heuristic of complexity  $t(n)$ . Then the domination number of  $\mathcal{A}$  does not exceed  $\max\{e^{t(n)/e}, (t(n)/n)^n\}$ , where  $e$  is the basis of natural logarithms.*

The next assertion follows directly from the proof of Corollary 13.

**Corollary 14** [17] *Let  $\mathcal{A}$  be an ATSP heuristic of complexity  $t(n)$ . For  $t(n) \geq en$ , the domination number of  $\mathcal{A}$  does not exceed  $(t(n)/n)^n$ .*

We finish this subsection with a result from [17] that improves (and somewhat clarifies) Theorem 20 in [29].

**Theorem 15** *Unless  $P = NP$ , there is no polynomial time ATSP algorithm of domination number at least  $(n - 1)! - \lfloor n - n^\alpha \rfloor!$  for any constant  $\alpha < 1$ .*

## Multidimensional Assignment Problem (MAP)

In case of  $s$  dimensions, MAP is abbreviated by  $s$ -AP and defined as follows. Let  $X_1 = X_2 = \dots = X_s = \{1, 2, \dots, n\}$ . We will consider only vectors that belong to the Cartesian product  $X = X_1 \times X_2 \times \dots \times X_s$ . Each vector  $e$  is assigned a weight  $w(e)$ . For a vector  $e$ ,  $e_j$  denotes its  $j$ th coordinate, i. e.,  $e_j \in X_j$ . A *partial assignment* is a collection  $e^1, e^2, \dots, e^t$  of  $t \leq n$  vectors such that  $e_j^i \neq e_j^k$  for each  $i \neq k$  and  $j \in \{1, 2, \dots, s\}$ . An *assignment* is a partial assignment with  $n$  vectors. The *weight* of a partial assignment  $A = \{e^1, e^2, \dots, e^t\}$  is  $w(A) = \sum_{i=1}^t w(e^i)$ . The objective is to find an assignment of minimum weight. Notice that  $s$ -AP has  $(n!)^{s-1}$  solutions (assignments).

$s$ -AP can be considered as the  $(X, \mathcal{F}, \mathbb{Z}_+)$ -optimization problem. ( $\mathcal{F}$  consists of partial assignments including the empty one.) This allows us to define the greedy algorithm for  $s$ -AP and to conclude from Theorem 6 that the greedy algorithm is of domination number 1 (for every fixed  $s \geq 3$ ).

In the subsection Traveling Salesman Problem, we considered the *max-regret-fc* and *max-regret heuristics*. In fact, max-regret was first introduced for 3-AP by Balas and Saltzman [4]. (See [15] for detailed description of the *s*-AP max-regret-fc and max-regret heuristics for each  $s \geq 2$ .) In computational experiments, Balas and Saltzman [4] compared the greedy algorithm with max-regret and concluded that max-regret is superior to the greedy algorithm with respect to the quality of solutions. However, after conducting wider computational experiments, Robertson [30] came to a different conclusion: the greedy algorithm and max-regret are of similar quality for 3-AP. Gutin, Goldengorin and Huang [15] share the conclusion of Robertson: both max-regret and max-regret-fc are of domination number 1 (similarly to the greedy algorithm) for *s*-AP for each  $s \geq 3$ . Moreover, there exists a family of *s*-AP instances for which all three heuristics will find the unique worst assignment [15] (for each  $s \geq 3$ ).

Similarly to TSP, we may obtain MAP heuristics of factorial domination number if we consider better-than-average heuristics. This follows from the next theorem:

**Theorem 16** [15] *Let  $\mathcal{H}$  be a heuristic that for each instance of *s*-AP constructs an assignment of weight at most the average weight of an assignment. Then the domination number of  $\mathcal{H}$  is at least  $((n - 1)!)^{s-1}$ .*

Balas and Saltzman [4] introduced a *3-Opt heuristic* for 3-AP which is similar to the 3-Opt TSP heuristic. The *3-Opt neighborhood* of an assignment  $A = \{e^1, e^2, \dots, e^n\}$  is the set of all assignments that can be obtained from  $A$  by replacing a triple of vectors with another triple of vectors. The 3-Opt is a local search heuristic that uses the 3-Opt neighborhood. It is proved in [15] that an assignment, that is the best in its 3-Opt neighborhood, is at least as good as the average assignment. This implies that 3-Opt is of domination number at least  $((n-1)!)^2$ . We cannot guarantee that 3-Opt local search will stop after polynomial number of iterations. Moreover, 3-Opt is only for 3-AP. Thus, the following heuristic introduced and studied in [15] is of interest.

*Recursive Opt Matching (ROM)* proceeds as follows. Compute a new weight  $\hat{w}(i, j) = w(X_{ij})/n^{s-2}$ , where  $X_{ij}$  is the set of all vectors with last two coordinates equal  $i$  and  $j$ , respectively. Solving the 2-AP with the new weights to optimality, find an optimal assign-

ment  $\{(i, \pi_s(i)) : i = 1, 2, \dots, n\}$ , where  $\pi_s$  is a permutation on  $X_s$ . While  $s \neq 1$ , introduce  $(s-1)$ -AP with weights given as follows:  $w'(f^i) = w(f^i, \pi_s(i))$  for each vector  $f^i \in X'$ , where  $X'_n = X_1 \times X_2 \times \dots \times X_{s-1}$ , with last coordinate equal  $i$  and apply ROM recursively. As a result we have obtained permutations  $\pi_s, \pi_{s-1}, \dots, \pi_2$ . The output is the assignment  $\{(i, \pi_2(i), \dots, \pi_s(\pi_{s-1}(\dots(\pi_2(i)))) \dots) : i = 1, 2, \dots, n\}$ .

Clearly, ROM is of running time  $O(n^3)$  for every fixed  $s \geq 3$ . Using Theorem 16, it is proved in [15] that ROM is of domination number at least  $((n - 1)!)^{s-1}$ .

**Minimum Partition and Multiprocessor Scheduling Problems**

In this subsection,  $N$  always denotes the set  $\{1, 2, \dots, n\}$  and each  $i \in N$  is assigned a positive integral weight  $\sigma(i)$ .  $\mathcal{A} = (A_1, A_2, \dots, A_p)$  is a *p-partition* of  $N$  if each  $A_i \subseteq N$ ,  $A_i \cap A_j = \emptyset$  for each  $i \neq j$  and the union of all sets in  $\mathcal{A}$  equals  $N$ . For a subset  $A$  of  $N$ ,  $\sigma(A) = \sum_{i \in A} \sigma(i)$ . The *Minimum Multiprocessor Scheduling Problem (MMS)* [3] can be stated as follows. We are given a triple  $(N, \sigma, p)$ , where  $p$  is an integer,  $p \geq 2$ . We are required to find a *p-partition*  $C$  of  $N$  that minimizes  $\sigma(\mathcal{A}) = \max_{1 \leq i \leq p} \sigma(A_i)$  over all *p-partitions*  $\mathcal{A} = (A_1, A_2, \dots, A_p)$  of  $N$ .

Clearly, if  $p \geq n$ , then MMS becomes trivial. Thus, in what follows,  $p < n$ . The size  $s$  of MMS is  $\Theta(n + \sum_{i=1}^n \log \sigma(i))$ . Consider the following heuristic  $\mathcal{H}$  for MMS. If  $s \geq p^n$ , then we simply solve the problem optimally. This takes  $O(s^2)$  time, as there are at most  $O(s)$  solutions, and each one can be evaluated and compared to the current best in  $O(s)$  time. If  $s < p^n$ , then we sort the elements of the sequence  $\sigma(1), \sigma(2), \dots, \sigma(n)$ . For simplicity of notation, assume that  $\sigma(1) \geq \sigma(2) \geq \dots \geq \sigma(n)$ . Compute  $r = \lceil \log n / \log p \rceil$  and solve MMS for  $(\{1, 2, \dots, r\}, \sigma, p)$  to optimality. Suppose we have obtained a *p-partition*  $\mathcal{A}$  of  $\{1, 2, \dots, r\}$ . Now for  $i$  from  $r+1$  to  $n$  add  $i$  to the set  $A_j$  of the current *p-partition*  $\mathcal{A}$  with smallest  $\sigma(A_j)$ . The following result was proved by Gutin, Jensen and Yeo [16].

**Theorem 17** *The heuristic  $\mathcal{H}$  runs in time  $O(s^2 \log s)$  and  $\lim_{s \rightarrow \infty} \text{domr}(\mathcal{H}, s) = 1$ .*

The *Minimum Partition Problem (MP)* is MMS with  $p=2$ . Alon, Gutin and Krivelevich [2] proved Theorem 17 for MP with  $s$  replaced by  $n$ .

### Max Cut Problem

The *Max Cut (MC)* is the following problem: given a weighted graph  $G=(V,E)$ , find a bipartition (a *cut*)  $(X,Y)$  of  $V$  such that the sum of weights of the edges with one end vertex in  $X$  and the other in  $Y$ , called the *weight of the cut*  $(X,Y)$ , is maximum. For this problem, there are some better-than-average heuristics. The simplest is probably the following greedy-like heuristic  $C$ ; order the vertices arbitrarily and put each vertex in its turn either in  $X$  or in  $Y$  in order to maximize in each step the total weight of crossing edges.

Using an advanced probabilistic approach Alon, Gutin and Krivelevich [2] proved that the heuristic  $C$  is of domination ratio larger than 0.025. For the unweighted MC (all weights are equal), a better quality algorithm can be designed as described in [2]. Its domination ratio is at least  $1/3 - o(1)$ .

### Constraint Satisfaction Problems

Let  $r$  be a fixed positive integer, and let  $\mathcal{F} = \{f_1, f_2, \dots, f_m\}$  be a collection of Boolean functions, each involving at most  $r$  of the  $n$  variables, and each having a positive weight  $w(f_i)$ . The *Max- $r$ -Constraint Satisfaction Problem* (or *Max- $r$ -CSP*, for short), is the problem of finding a truth assignment to the variables so as to maximize the total weight of the functions satisfied. Note that this includes, as a special case, the Max Cut problem. Another interesting special case is the Max- $r$ -SAT problem, in which each of the Boolean functions  $f_i$  is a clause of at most  $r$  literals.

Alon, Gutin and Krivelevich [2] proved the following:

**Theorem 18** *For each fixed integer  $r \geq 1$  there exists a linear time algorithm for the Max- $r$ -CSP problem, whose domination ratio exceeds  $\frac{1}{2^{4/3 \cdot 26^r}}$ .*

### Vertex Cover, Independent Set and Clique Problems

A *clique* in a graph  $G$  is a set of vertices in  $G$  such that every pair of vertices in the set are connected by an edge. The *Maximum Clique Problem (MCL)* is the problem of finding a clique of maximum cardinality in a graph. A *vertex cover* in a graph  $G$  is a set  $S$  of vertices in  $G$  such that every edge is incident to a vertex in  $S$ . The *Minimum Vertex Cover Problem (MVC)* is the

problem of finding a minimum cardinality vertex cover. An *independent set* in a graph is a set  $S$  of vertices such that no edge joins two vertices in  $S$ . The *Maximum Independent Set Problem (MIS)* is the problem of finding a minimum cardinality independent set in a graph. It is easy to see that the number of cliques and independent sets in a graph depends on its structure, and not only on the number of vertices. The same holds for vertex covers.

Note that if  $C$  is a vertex cover of a graph  $G$ , then  $V(G) \setminus C$  is an independent set in  $G$ ; if  $Q$  is a clique in  $G$ , then  $Q$  is an independent set in the complement of  $G$ . These well-known facts imply that if there is a heuristic for one of the problem of domination ratio at least  $r(n)$ , all other problems admit a heuristic of domination ratio at least  $r(n)$ .

MCL, MIS and MVC are somewhat different from the previous problems we have considered. Firstly, the number of feasible solutions, for an input of size  $n$ , depends on the actual input, and not just its size. The second difference is that the three problems do not admit polynomial-time heuristics of domination ratio at least  $1/p(n)$  for any polynomial  $p(n)$  in  $n$  unless  $P=NP$ . This was proved by Gutin, Vainshtein and Yeo [19].

Because of the first difference, it is better to compare heuristics for the problems using the blackball number rather than domination number. Since a heuristic for MVC can be easily transformed into a heuristic for the other two problems, we restrict ourselves only to MVC heuristics.

The *incremental deletion heuristic* starts with an arbitrary permutation  $\pi$  of vertices of  $G$  and an initial solution  $S=V(G)$ . We consider each vertex of  $G$  in turn (according to  $\pi$ ), deleting it from  $S$  if the resulting subset remains a (feasible) solution. A seemingly better heuristic for MVC is obtained by ordering the vertices by degree (lower degrees first), and then applying the incremental deletion heuristic. We call it the *increasing-degree deletion heuristic*. The well-known *maximal matching heuristic* constructs a maximal matching  $M$  and outputs both end-vertices of all edges in  $M$  as a solution. Berend, Skiena and Twitto [10] proved that the incremental deletion heuristic (increasing-degree deletion heuristic, maximal matching heuristic) is of blackball number  $2^{n-1} - n$  (of blackball number larger than  $(2 - \epsilon)^n$  for each  $\epsilon > 0$ , of blackball number approximately  $1.839^n$ ). Clearly, the maximal matching heuris-

tic is the best among the three heuristics from the DA point of view.

### Quadratic Assignment Problem

The *Quadratic Assignment Problem* (QAP) can be formulated as follows. We are given two  $n \times n$  matrices  $A = [a_{ij}]$  and  $B = [b_{ij}]$  of integers. Our aim is to find a permutation  $\pi$  of  $\{1, 2, \dots, n\}$  that minimizes the sum

$$\sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{\pi(i)\pi(j)}.$$

Gutin and Yeo [23] described a better-than-average heuristic for QAP and proved that the heuristic is of domination number at least  $n!/\beta^n$  for each  $\beta > 1$ . Moreover, the domination number of the heuristic is at least  $(n-2)!$  for every prime power  $n$ . These results were obtained using a group-theoretical approach.

### Abstract

Duality gaps in optimization problems arise because of the nonconvexities involved in the objective function or constraints. The Lagrangian dual of a nonconvex optimization problem can also be viewed as a two-person zero-sum game. From this viewpoint, the occurrence of duality gaps originates from the order in which the two players select their strategies. Therefore, duality theory can be analyzed as a zero-sum game where the order of play generates an asymmetry. One can conjecture that

this asymmetry can be eliminated by allowing one of the players to select strategies from a larger space than that of the finite-dimensional Euclidean space. Once the asymmetry is removed, then there is zero duality gap. The aim of this article is to review two methods by which this process can be carried out. The first is based on randomization of the primal problem. The second extends the space from which the dual variables can be selected. Duality gaps are important in mathematical programming and some of the results reviewed here are more than 50 years old, but only recently methods have been discovered to take advantage of them. The theory is elegant and helps appreciate the game-theoretic origins of the dual problem and the role of Lagrange multipliers.

### Background

We discuss how duality gaps arise, and how they can be eliminated in nonconvex optimization problems. A standard optimization problem is stated as follows:

$$\begin{aligned} \min \quad & f(x), \\ & g(x) \leq 0, \\ & x \in X, \end{aligned} \quad (1)$$

where  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  and  $g: \mathbb{R}^n \rightarrow \mathbb{R}^m$  are assumed to be smooth and nonconvex. The feasible region of (1) is denoted by  $\mathcal{F}$ , and it is assumed to be nonempty and compact.  $X$  is some compact convex set.

In order to understand the origins of duality in mathematical programming, consider devising a strategy to determine whether a point, say  $y$ , is the globally optimal solution of (1). Such a strategy can be concocted as follows: if  $f(y)$  is the global solution of (1) then the following system of inequalities

$$\begin{aligned} f(x) &< f(y), \\ g(x) &\leq 0, \\ x &\in X \end{aligned} \quad (2)$$

will not have a solution. We can reformulate (2) in a slightly more convenient framework. Indeed, suppose that there exist  $m$  positive scalars  $\lambda_i$ ,  $i = 1, \dots, m$ , such that

$$L(x, \lambda) = f(x) + \sum_{i=1}^m \lambda_i g_i(x) < f(y) \quad (3)$$

has no solution. Then (2) does not have a solution either. The left-hand side of (3) is called the Lagrangian function associated with (1). It is clear from the discussion above that the Lagrangian can be used to answer questions about the optimal solutions of (1). The usefulness of the dual function emanates from the following duality observation: Let  $f^*$  be the optimal objective function value of (1), and let  $L: \mathbb{R}^m \rightarrow \mathbb{R}$  be defined as follows:

$$L(\lambda) = \inf_{x \in X} L(x, \lambda).$$

Then it is easy to prove that:

$$\sup_{\lambda \geq 0} L(\lambda) \leq f^*. \tag{4}$$

This result is known as the weak duality theorem, and it is valid with a quite general set of assumptions. The strong duality theorem asserts that if  $f$  and  $g$  are convex,  $f^* > -\infty$ , and the interior of  $\mathcal{F}$  is not empty, then

$$\sup_{\lambda \geq 0} L(\lambda) = f^*.$$

Proofs of the weak and strong duality theorems can be found in [1,10].

**Game Theory Interpretation**

There is an interesting relationship between (1) and the following optimization problem:

$$\sup_{\lambda \geq 0} \inf_{x \in X} f(x) + \sum_{i=1}^m \lambda_i g_i(x). \tag{5}$$

We refer to (1) as the primal problem, while (5) is referred to as the Lagrangian dual. The  $\lambda$ 's that appear in (5) are called the Lagrange multipliers (or dual variables).

It is interesting to note that (1) can equivalently be restated as follows:

$$\inf_{x \in X} \sup_{\lambda \geq 0} f(x) + \sum_{i=1}^m \lambda_i g_i(x). \tag{6}$$

The relationship between (6) (or (1)) and (5) can be analyzed as a two-person zero-sum game. In this game player A chooses the  $x$  variables, and player B chooses

the  $\lambda$  variables. If player A chooses  $x'$ , and player B chooses  $\lambda'$ , then player A pays  $L(x', \lambda')$  to player B. Naturally, player A wishes to minimize this quantity, while player B attempts to maximize it.

In game theory equilibria play an important role. An equilibrium, in the present context means a point from which no player will gain by a unilateral change of strategy. For the game outlined above an equilibrium point  $(x^*, \lambda^*)$  must satisfy

$$L(x, \lambda^*) \geq L(x^*, \lambda^*) \geq L(x^*, \lambda) \quad \forall x \in X, \quad \forall \lambda \in \mathbb{R}_+^m. \tag{7}$$

A point satisfying the preceding equation is also known as a saddle point of  $L$ . To see that (7) is an equilibrium point we argue as follows: Given that player A wishes to minimize the amount paid to player B, then it is obvious that if player B chooses  $\lambda^*$  and player A selects anything other than  $x^*$ , player A will be worse off. Similarly, if player A chooses  $x^*$ , then if player B chooses anything other than  $\lambda^*$ , then player B will be worse off.

By the strong duality theorem, we know that the game has an equilibrium point under convexity assumptions. For the general case, insight can be obtained by interpreting (5) and (6) as two different games. A saddle point will exist if the optimal values of the two games are equal.

Our next task is to interpret (5) and (6) as games. Indeed consider the following situation: Player A chooses a strategy first, and then player B chooses a strategy. Thus, player B already knows the strategy that player A has chosen. As a result player B will have an advantage. Player A will argue as follows: "If I choose  $x$ , then player B will choose  $\sup_{\lambda \geq 0} L(x, \lambda)$ , therefore I had better choose the strategy that will minimize my losses." In other words player A will choose the optimal strategy given by solving (6).

Now consider the same game, but with the order of play reversed, i. e., player B chooses first, and player A second. Then applying the rules of rational behavior (as above), we see that player B will select the  $\lambda$  that solves (5).

Consequently, duality gaps originate from the order in which the two players select their strategies. In the next section we see how this asymmetry can be eliminated by allowing one of the players to select strategies from a larger space than that of the finite-dimensional

Euclidean space. Once the asymmetry is eliminated, then there is zero duality gap.

## Methods

As argued above, the player that chooses first is disadvantaged, since the other player can adjust. In this section we discuss two methods in which this asymmetry in the order of play can be eliminated. Both methods were proposed early in the history of mathematical programming. The first method proceeds by randomization (increasing the powers of player A). It is difficult to say who suggested this strategy first. Since the origins of the idea emanate from mixed strategies in game theory, one could argue that the idea was first suggested by Borel in the 1920s [14]. A modern proof can be found in [2]. The second method allows player B to select the dual variables from a larger space. This idea seems to have been suggested by Everett [3], and then by Gould [6]. A review can be found in [11]. Algorithms that attempt to reduce the duality gap appeared in [4,5,7,8,9,12].

## Randomization

Assume that player A chooses first, then the game can be described by

$$P^* = \inf_{x \in X} \sup_{\lambda \geq 0} L(x, \lambda),$$

and in general by

$$P^* \geq D^* = \sup_{\lambda \geq 0} \inf_{x \in X} L(x, \lambda).$$

Player A has a handicap since player B will choose a strategy knowing what player A will do. In order to avoid having a duality gap, we consider giving more flexibility to player A. We thus allow player A to choose strategies from  $\mathcal{M}(X)$ , where  $\mathcal{M}(X)$  denotes the space of probability measures on  $\mathcal{B}$  (the  $\sigma$ -field generated by  $X$ ). Player A will therefore choose a strategy by solving

$$\begin{aligned} P^* &= \inf_{\mu \in \mathcal{M}(X)} \int_X f(x) d\mu(x) \\ &\quad \int_X g(x) d\mu(x) \leq 0 \\ &\quad \int_X d\mu(x) = 1. \end{aligned} \quad (8)$$

Equivalently:

$$\begin{aligned} P^* &= \inf_{\mu \in \mathcal{M}(X)} \sup_{\lambda \geq 0} \int_X f(x) d\mu(x) \\ &\quad + \sum_{i=1}^m \lambda_i \int_X g(x) d\mu(x) + \lambda_0 \left( \int_X d\mu(x) - 1 \right). \end{aligned}$$

The dual of (8) is given by

$$\begin{aligned} D^* &= \sup_{\lambda \geq 0} \inf_{\mu \in \mathcal{M}(X)} \int_X f(x) d\mu(x) \\ &\quad + \sum_{i=1}^m \lambda_i \int_X g(x) d\mu(x) + \lambda_0 \left( \int_X d\mu(x) - 1 \right). \end{aligned}$$

Then it can be shown that  $P^* = D^*$ . The proof is beyond the scope of this article; it can be found in [2].

## Functional Lagrange Multipliers

We now consider the case where player B chooses first. From the previous section, it follows that player B will choose a strategy according to:

$$D^* = \sup_{\lambda \geq 0} \inf_{x \in X} L(x, \lambda). \quad (9)$$

We have already pointed out that the following holds:

$$D^* \leq \inf_{x \in X} \sup_{\lambda \geq 0} L(x, \lambda).$$

In order for the preceding equation to hold as an equality, without any convexity assumptions, we consider increasing the space of available strategies of B. This was suggested in [3,6]. The exposition here is based on [11]. Let  $\mathcal{H}$  denote all the feasible right-hand sides for (1):

$$\mathcal{H} = \{b \in \mathbb{R}^m \mid \exists x \in X: g(x) \leq b\}.$$

Let  $\mathcal{D}$  denote the following set of functions:

$$\begin{aligned} \mathcal{D} &= \{z: \mathbb{R}^m \rightarrow \mathbb{R} \mid z(d_1) \leq z(d_2), \text{ if } d_1 \leq d_2, \\ &\quad \forall d_1, d_2 \in \mathcal{H}\}. \end{aligned}$$

The following dual can be defined using the concepts above:

$$\begin{aligned} D^* &= \sup_z z(0) \\ &\quad z(g(x)) \leq f(x) \quad \forall x \in X \quad z \in \mathcal{D}. \end{aligned} \quad (10)$$

The dual in (10) is different from the type of duals that we have been discussing in this article. If, however, we

assume that  $c + \mathcal{D} \subset \mathcal{D}$ , then it was shown in [11] that (10) is equivalent to the following:

$$D^* = \sup_{z \in \mathcal{D}} \inf_{x \in X} f(x) + z(g(x))$$

dual problem. A proof that the duality gap between (10) and (1) is zero can be found in [11].

## Conclusions

We have discussed Lagrangian duality, and the existence of duality gaps from a game-theoretic viewpoint. We have discussed two ways in which duality gaps can be eliminated. The first is randomization and the second is the use of functional Lagrange multipliers. Unfortunately none of the two methods are immediately applicable to real-world problems. However, for certain classes of problems the functional Lagrange multiplier approach can be useful. It was shown in [13] that if the original problem involves the optimization of polynomial functions, and if the Lagrange multipliers are allowed to be themselves polynomials then there will be no duality gap. Unlike the general case discussed in this article, polynomial Lagrange multipliers can be manipulated numerically. This approach can potentially help develop efficient algorithms for a large class of problems.

### Keywords

Control problems; First order partial differential equations; Duality theory; Necessary and sufficient optimality conditions

Consider the following optimal control problem with first order ordinary or partial differential equations:

$$(P) \quad \min J(x, u) = \int_{\Omega} r(t, x(t), u(t)) dt$$

subject to functions  $(x, u) \in W_p^{1,n}(\Omega) \times L_p^v(\Omega)$ , fulfilling

- the *state equations*

$$x_{t\alpha}^i(t) = g_{\alpha}^i(t, x(t), u(t)) \quad \text{a.e. on } \Omega,$$

$$(\alpha = 1, \dots, m; \quad i = 1, \dots, n);$$

- the *control restrictions*

$$u(t) \in U \subseteq \mathbb{R}^v \quad \text{a.e. on } \Omega;$$

- the *state constraints*

$$x(t) \in \overline{G(t)} \subseteq \mathbb{R}^n \quad \text{on } \overline{\Omega};$$

- and the *boundary conditions*

$$x(s) = \varphi(s) \quad \text{on } \partial\Omega.$$

The data of problem (P) satisfies the following hypothesis:

- H1) For  $m = 1$  we have  $1 \leq p \leq \infty$ , for  $m \geq 2$  we have  $m < p < \infty$ .
- H2) The sets  $\Omega$  and

$$X := \{(t, \xi) \in \mathbb{R}^m \times \mathbb{R}^n : t \in \Omega, \xi \in G(t)\}$$

are strongly Lipschitz domains in the sense of C.B. Morrey and S. Hildebrandt [6]; the set  $U$  is closed.

- H3) The functions  $r, r_{\xi}, g_{\alpha}^i, (g_{\alpha}^i)_{\xi}, \varphi$  are continuous with respect to all arguments.
- H4) The set of all admissible pairs  $(x, u)$ , denoted by  $\mathcal{Z}$ , is nonempty.

The characterization of optimal solutions of special variational problems by dual or complementary problems has been well known in physics for a long time, e. g.,

- in elasticity theory, the principle of the minimum of potential energy (Dirichlet's principle) and the principle of tension (Castigliano's principle) are dual or complementary to each other.
- in the theory of electrostatic fields, the principle of the minimum of potential energy and the Thomson (Lord Kelvin) principle are dual problems.

A first systematic approach to duality for special problems in calculus of variations was given by K. Friedrichs ([4], 1928). In the 1950s and 1960s, this concept was extended by W. Fenchel [3], J.-J. Moreau, R.T. Rockafellar [19,20] and I. Ekeland and R. Temam [2] to larger classes of variational and control problems. Basing on Legendre transformation (or Fenchel conjugation), it was proved to be a suitable tool to handle convex problems.

Nonconvex problems (P) require an extended concept of duality. The construction of R. Klötzler, given in 1977 [7], can be regarded as a further development of Hamilton–Jacobi field theory.

### Construction of a Dual Problem

In a very general setting, a problem (D) of maximization of an (extended real-valued) functional  $L$  over an arbitrary set  $S \neq \emptyset$  is said to be a *dual problem* to (P) if the *weak duality relation*

$$\sup (D) \leq \inf (P)$$

is satisfied.

The different notions of duality given in the introduction can be embedded into the following construction scheme:

1	The set of admissible pairs $(x, u) = z \in \mathcal{Z}$ is represented by the intersection of two suitable nonempty sets $\mathcal{Z}_0$ and $\mathcal{Z}_1$ .
2	For an (extended real-valued) functional $\Phi : \mathcal{Z}_0 \times S_0 \rightarrow \overline{\mathbb{R}}$ the <i>equivalence relation</i>
	$\inf_{z \in \mathcal{Z}} J(z) = \inf_{z \in \mathcal{Z}_0} \sup_{S \in S_0} \Phi(z, S),$
	holds.
3	Assuming $L_0(S) := \inf_{z \in \mathcal{Z}_0} \Phi(z, S)$ , each problem
	$(D) \quad \begin{cases} \max L(S) \\ \text{s.t. } S \in S_1 \subseteq S_0 \end{cases}$
	is a (weak) dual problem to (P) if $L(S) \leq L_0(S)$ for all $S \in S_1$ .

The proof of the *weak duality relation* results from the well-known inequality

$$\inf_{z \in Z_0} \sup_{S \in S_0} \Phi(z, S) \geq \sup_{S \in S_0} \inf_{z \in Z_0} \Phi(z, S).$$

**Fenchel–Rockafellar Duality**

In accordance with [2], we transform (P) into a general variational problem:

$$(V) \quad \begin{cases} \min & \int_{\Omega} l(t, x(t), x_{t\alpha}(t)) dt \\ \text{s.t.} & x \in \mathcal{X} \end{cases}$$

where  $l: \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^{nm} \rightarrow \overline{\mathbb{R}}$  is given by

$$l(t, \xi, w) := \begin{cases} \inf\{r(t, \xi, v) : \\ v \in U \text{ with} \\ w = g(t, \xi, v)\}, & (t, \xi) \in \overline{X}, \\ \infty & \text{else.} \end{cases}$$

and  $\mathcal{X} = \{x \in W_p^{1,n}(\Omega) : x(s) = \varphi(s) \text{ on } \partial\Omega\}$ .

Then (P) is called *convex* if (V) is convex in the sense of [2, p. 113]. In this case both problems are equivalent [15]. The Fenchel-dual problem is obtained by the following settings in the above construction scheme:

- 1)  $Z_0 = \{z = (x, u) \in W_p^{1,n}(\Omega) \times L_p^{1,\nu}(\Omega) : \begin{aligned} &u(t) \in U \text{ a.e. on } \Omega, \\ &x(t) \in \overline{G(t)} \text{ on } \Omega, \\ &x(s) = \varphi(s) \text{ on } \partial\Omega \}, \\ &Z_1 = \{z = (x, u) \in W_p^{1,n}(\Omega) \times L_p^{1,\nu}(\Omega) : \\ &x_{t\alpha}^i(t) = g_{\alpha}^i(t, x(t), u(t)) \text{ a.e. on } \Omega, \\ &\alpha = 1, \dots, m; i = 1, \dots, n\}. \end{aligned}$
- 2)  $S_0 = L_q^{n(1+m)}(\Omega)$  ( $p^{-1} + q^{-1} = 1$ ),  $\Phi$  is the classical *Lagrange functional*,

$$\Phi(z, S) = J(z) + \sum_{i,\alpha} \langle x_{t\alpha}^i - g_{\alpha}^i(\cdot, x, u), y_i^{\alpha} \rangle,$$

where  $\langle \cdot, \cdot \rangle$  is the bilinear canonical pairing over  $L_p(\Omega) \times L_p^*(\Omega)$ , [15]. By use of the *Hamiltonian* of (P),

$$\begin{aligned} \mathcal{H} &: \mathbb{R}^1 \times \mathbb{R}^n \times \mathbb{R}^{nm} \rightarrow \overline{\mathbb{R}}, \\ \mathcal{H}(t, \xi, \eta) &= \sup \{H(t, \xi, v, \eta) : v \in U\} \end{aligned}$$

with

$$H(t, \xi, v, \eta) = -r(t, \xi, v) + \sum_{i,\alpha} \eta_i^{\alpha} g_{\alpha}^i(t, \xi, v)$$

it can be formulated as follows [15]:

$$(D_R)_q \quad \begin{cases} \max & \left[ - \int_{\Omega} \left( \sup_{\xi \in G(t)} [\mathcal{H}(t, \xi, -y(t)) - y_0(t)^{\top} \xi] \right) dt \right. \\ & \left. - \sup_{\xi \in X} \left[ \int_{\Omega} (y_0(t)^{\top} \xi(t) + \sum_{i,\alpha} y_i^{\alpha}(t) \xi_{t\alpha}^i(t)) dt \right] \right] \\ \text{s.t.} & (y_0, y) \in L_q^{n(1+m)}(\Omega). \end{cases}$$

**Duality in the Sense of Klötzler**

The duality in the sense of Klötzler is realized by the following settings in the general construction scheme [14]:

- 1)  $Z_0$  and  $Z_1$  are chosen as before.
- 2)  $S_0 = W_q^{1,n}(\overline{X})$ , and  $\Phi$  is an extended Lagrange functional,

$$\begin{aligned} \Phi(z, S) &= J(z) \\ &+ \sum_{i,\alpha} x_{t\alpha}^i - g_{\alpha}^i(\cdot, x, u), S_{\xi_{\alpha}^i}(\cdot, x), \end{aligned}$$

where  $\langle \cdot, \cdot \rangle$  is again the bilinear canonical pairing over  $L_p(\Omega) \times L_p^*(\Omega)$ .

By use of Gauss' theorem, the dual problem reads as follows [8]:

$$(D_K)_q \quad \begin{cases} \max & \int_{\partial\Omega} S(s, \zeta(s)) \mathfrak{n}(s) do(s) \\ \text{s.t.} & S \in S_1, \end{cases}$$

where

$$S_1 := \left\{ S \in S_0 : \begin{aligned} &\sum_{\alpha=1}^m S_{t\alpha}^{\alpha}(t, \xi) \\ &+ \mathcal{H}(t, \xi, S(t, \xi)) \leq 0 \\ &\text{a.e. on } \overline{X} \end{aligned} \right\},$$

$\mathfrak{n}(\cdot)$  is the exterior unit normal vector to  $\partial\Omega$ .

In this way we can characterize minimizers of (P) in terms of solutions of the *Hamilton–Jacobi inequality* or of the *Hamilton–Jacobi equation*. Since classical solutions of the latter equation may fail to exist, on the one hand techniques were developed to construct generalized solutions of this equation (viscosity solutions [11], generalized solutions involving the Clarke generalized gradient [1] or lower Dini derivatives [24]). On

the other hand, optimization techniques for parametric problems in finite-dimensional spaces are used to minimize the defect in the Hamilton–Jacobi inequality and to get sufficient conditions for (local) optimality [16,17,27,28,29].

### Bidual Problems, Generalized Flows, Relaxed Controls

Duality allows to associate the bidual problem with a *flow problem* or a *relaxed control problem*.  $(D_K)_q$ , interpreted as an infinite linear programming problem, [13], has a dual problem again, which can be identified as a generalized flow problem in the sense of L.C. Young [26]: Assuming compactness of the control set  $U$ , one obtains the bidual problem  $(D_K)_q^* = (F)$ :

$$(F) \quad \begin{cases} \min & \int_D r(t, \xi, \nu) d\nu(t, \xi, \nu) \\ \text{s.t.} & \nu \in \mathfrak{N}_D, \end{cases}$$

with

$$\begin{aligned} \mathfrak{N}_D &:= \left\{ \nu \in \mathcal{R}_D : \right. \\ &\int_{\partial\Omega} \sum_{\alpha} \psi^{\alpha}(s, \zeta(s)) \mathfrak{n}_{\alpha}(s) d\sigma(s) \\ &= \int_D \left( \psi_{t_{\alpha}}^{\alpha}(t, \xi) + \sum_{i, \alpha} \psi_{\xi_i}^{\alpha}(t, \xi) g_{\alpha}^i(t, \xi, \nu) \right) \\ &\left. d\nu(t, \xi, \nu), \forall \psi \in C^{1,m}(\overline{X}) \right\}, \end{aligned}$$

where  $\mathcal{R}_D$  is the set of all nonnegative Radon measures on  $D := \overline{X} \times U$ .  $\mathfrak{N}_D$  contains special measures

$$d\nu(t, \xi, \nu) = d\delta_{x(t)} d\mu_t(\nu) dt,$$

with  $\mu = \{\mu_t : t \in \Omega\} \in \mathfrak{M}_U$ ,  $\mathfrak{M}_U$  is a *regular family of probability measures*, concentrated on  $U$ , [5], and  $\delta_{\xi}$  are Dirac measures concentrated on the point  $\xi \in \overline{G}(t)$ .

Thus the relaxed control problem

$$\overline{(P)} \quad \begin{cases} \min & \int_{\Omega} \int_U r(t, x(t), \nu) d\mu_t(\nu) dt \\ \text{s.t.} & (x, \mu) \in W_p^{1,n}(\Omega) \times \mathfrak{M}_U, \end{cases}$$

satisfying  $x(t) \in \overline{G}(t)$  and fulfilling the following variational equation for all  $\psi \in C^{1,m}(\overline{X})$ ,

$$\begin{aligned} &\int_{\partial\Omega} \sum_{\alpha} \psi^{\alpha}(s, \zeta(s)) \mathfrak{n}_{\alpha}(s) d\sigma(s) \\ &= \int_{\Omega} \left[ \sum_{\alpha} \psi_{t_{\alpha}}^{\alpha}(t, x(t)) \right. \\ &\left. + \sum_{i, \alpha} \psi_{\xi_i}^{\alpha}(t, x(t)) \int_U g_{\alpha}^i(t, x(t), \nu) d\mu_t(\nu) \right] dt \end{aligned}$$

has the embedding (F), and

$$\sup (D_K)_{\infty} = \inf (F) \leq \inf \overline{(P)}$$

holds, [13].

### Strong Duality Results

The property of strong duality between (P) and (D) is defined by the equation

$$\sup (D) = \inf (P),$$

and this common value is called *settle-value* of  $\Phi$ .

### Case A

Control problems with single integrals and ordinary differential equations,  $\Omega = [0, T]$ .

For convex problems (P),

$$\sup (D_R)_q = \min (P)$$

holds, [2]. Moreover, in  $(D_R)_q$  the optimal solution  $(y_0^*, y^*)$  exists and fulfills

$$y^* \in W_p^{1,n}(\Omega)$$

and

$$\frac{d}{dt} y^*(t) = y_0^*(t) \text{ a.e. on } (0, T),$$

[15]. Both dual problems,  $(D_R)_q$  and  $(D_K)_q$ , coincide, if in  $(D_K)_q$  a linear setting

$$S(t, \xi) = a(t) + \xi^T y(t)$$

is chosen, [14].

For nonconvex control problems with compact  $U$  it was shown by different techniques, that (P) as well as

$\overline{(P)}$  possess a same dual problem, [12,22,23], and strong duality

$$\sup (D_K)_\infty = \min \overline{(P)}$$

holds. The variational equation appearing in  $\overline{(P)}$  is in this case equivalent to the *generalized state equations*

$$\frac{d}{dt}x^i(t) = \int_U g^i(t, x(t), v) d\mu_t(v) \text{ a.e. on } (0, T)$$

with the *boundary conditions*

$$x(s) = \varphi(s) \quad \text{for } s = 0, s = T.$$

The question of existence of a solution of the dual problem  $(D_K)_\infty$  was discussed in [21].

**Case B**

Control problems with multiple integrals and first order partial differential equations.

As before, for convex problems

$$\sup (D_R)_q = \min (P)$$

holds. The equivalence of  $(D_R)_q$  and  $(D_K)_q$  is lost in general. Results concerning strong duality between (D) and  $\overline{(P)}$  in the nonconvex case are largely missing.

**Sufficient Optimality Conditions**

First- and second order sufficient optimality conditions for global minimizers can be derived by means of duality. In the general concept,  $(x^*, u^*) \in \mathcal{Z}$  is a global minimizer of (P) if

$$\begin{aligned} J(x^*, u^*) &= \inf_{z \in \mathcal{Z}_0} \sup_{S \in \mathcal{S}_0} \Phi(z, S) \\ &= \max_{S \in \mathcal{S}_0} \inf_{z \in \mathcal{Z}_0} \Phi(z, S) \end{aligned}$$

and it exists an  $S^* \in \mathcal{S}_1$  with

$$L_0(S^*) = \max_{S \in \mathcal{S}_1} L(S) = \max_{S \in \mathcal{S}_0} L_0(S).$$

Following the concept of Klötzler, these equations are satisfied if and only if for  $S^* \in W_\infty^{1,n}(\overline{X})$  the following conditions are fulfilled:

a) the *Hamilton–Jacobi inequality*

$$\begin{aligned} \Lambda(t, \xi) &:= \sum_{\alpha} S_{t\alpha}^{*\alpha}(t, \xi) \\ &+ \mathcal{H}(t, \xi, S_{\xi}^*(t, \xi)) \leq 0 \text{ on } \overline{X}; \end{aligned}$$

b) the *Hamilton–Jacobi equation*

$$\begin{aligned} \sum_{\alpha} S_{t\alpha}^{*\alpha}(t, x^*(t)) \\ + \mathcal{H}(t, x^*(t), S_{\xi}^*(t, x^*(t))) = 0 \text{ on } \overline{\Omega}; \end{aligned}$$

c) the *maximum condition*

$$\begin{aligned} \mathcal{H}(t, x^*(t), S_{\xi}^*(t, x^*(t))) \\ = \mathcal{H}(t, x^*(t), u^*(t), S_{\xi}^*(t, x^*(t))) \text{ a.e. on } \Omega. \end{aligned}$$

From conditions a) and b) follows that  $x^*(t)$  must be a global minimizer of the parametric optimization problem

$$(P)_t \quad \begin{cases} \max & \Lambda(t, \xi) \\ \text{s.t.} & \xi \in \overline{G(t)} \end{cases}$$

with parameter  $t \in \overline{\Omega}$ . For this last problem  $(P)_t$  first- and second order sufficient optimality conditions can be derived with the quadratic setting

$$\begin{aligned} S^{*\alpha}(t, \xi) &= a^\alpha(t) + y^{\alpha\top}(t)(\xi - x(t)) \\ &+ \frac{1}{2}(\xi - x^*(t))Q^\alpha(t)(\xi - x^*(t)) \end{aligned}$$

in the dual problem  $(D_K)_\infty$ , where  $y^\alpha \in W_\infty^{1,n}(\Omega)$  and  $Q^\alpha \in W_\infty^{1,nn}(\Omega)$  symmetric.

The ideas, mentioned above, can be used for identifying *strong local minimizers* of (P) too. In this case  $\overline{X}$  is to be replaced by

$$\begin{aligned} \overline{X}_\varepsilon &= \overline{X} \\ &\cap \{(t, \xi) \in \mathbb{R}^{n+1} : \|\xi - x(t)\| < \varepsilon, t \in \overline{\Omega}\}, \end{aligned}$$

[16,17,27,28,29]. The second order condition for  $(P)_t$  yields a definiteness condition for a Riccati-type expression which generalizes the known theory of conjugated points in the calculus of variations in one independent variable.

**Duality and Maximum Principle**

**Case A**

Control problems with single integrals,  $\Omega = [0, T]$ . For convex problems (P) it can be shown that the *Pontryagin maximum principle* is not only a necessary but also

a sufficient optimality condition. In this case the canonical variables in the Maximum principle solve at the same time the dual problem  $(D_K)_\infty$ , [15].

### Case B

Control problems with multiple integrals,  $\Omega \subseteq \mathbf{R}^m$ ,  $m \geq 2$ . For convex problems (P) or relaxed problems  $(\bar{P})$  a maximum principle was proved in the beginning of the 1990s, [10,18,25]. It turns out, that the canonical variables in this principle are not necessarily functions but contents or measures from  $L_\infty^*(\Omega)$  or  $C^*(\Omega)$ . A corresponding duality theory with dual variables in these measure spaces was developed by Klötzler [9] and strong duality was shown. As before, in the convex case the canonical variables of the maximum principle solve the dual problem.

### Keywords

Semidefinite programming; Convex programming; Lagrangian duality; Strong and weak duality; Constraint qualification; Complementarity

### Synonyms

SDP duality

### Basic Properties

Consider the primal *semidefinite program*

$$\text{SDP } \mu^* := \begin{cases} \min & C \bullet X \\ \text{s.t.} & AX = b \\ & X \succeq 0, \end{cases}$$

where  $C \bullet X = \text{trace } CX$  denotes the inner product of the symmetric matrices  $C, X$ ;  $X \succeq Y$  denotes that the symmetric matrix  $X - Y$  is positive semidefinite; and  $\mathcal{A}: \mathcal{S}^n \rightarrow \mathbf{R}^m$  is a linear operator on the space of symmetric matrices, with adjoint  $\mathcal{A}^*$ . Equivalently, the linear constraint can be written using symmetric matrices  $A_i, i = 1, \dots, m$ , as

$$\mathcal{A}_i \bullet X = b_i \quad \text{for all } i = 1, \dots, m;$$

while the adjoint operation on  $y \in \mathbf{R}^m$  is

$$\mathcal{A}^* y := \sum_{i=1}^m y_i A_i.$$

The *Lagrangian* function is

$$\mathcal{L}(X, y) := C \bullet X + y^\top (b - \mathcal{A}X).$$

The primal problem is equivalent to

$$\mu^* = \min_{X \succeq 0} \max_y \mathcal{L}(X, y) = C \bullet X + y^\top (b - \mathcal{A}X).$$

The equivalence can be seen by using the *hidden constraint* in the outer minimization problem  $b - \mathcal{A}X = 0$ , i. e. if this constraint does not hold then the inner maximum value is  $+\infty$ .

By interchanging the maximum and minimum and rewriting the order of terms in the Lagrangian, we get the dual problem and *weak duality*:

$$\mu^* \geq v^* := \max_y \min_{X \succeq 0} b^\top y + (C - \mathcal{A}^* y) \bullet X.$$

Using the hidden constraint in the outer maximization problem  $C - \mathcal{A}^* y \succeq 0$ , this becomes equivalent to

$$(D) \quad v^* = \begin{cases} \max & b^\top y \\ \text{s.t.} & \mathcal{A}^* y \preceq C. \end{cases}$$

The dual pair SDP and (D) look very much like a dual pair of linear programs (denoted LP) where the

adjoint operator replaces the transpose and positive semidefiniteness of matrix variables replaces nonnegativity of vector variables. In fact, duality theory for SDP has a lot of similarities with that of LP: *weak duality*  $\mu^* \geq \nu^*$  follows from the interchange of maximum and minimum; from this we get that unboundedness of SDP (respectively, (D)) implies infeasibility of (D) (respectively, (D)).

Weak duality illustrates one of the powerful uses of the dual program, i. e. it provides lower bounds on the optimal value of the primal program.

Other formulations of SDP provide similar duals. In fact, SDP is a special case of cone programming. Let  $K, L$  be two *convex cones*, i. e.  $K$  (and  $L$ ) satisfy: the Minkowski sum  $K + K \subset K$  and  $\alpha K \subset K$  for all  $\alpha \in \mathbf{R}$ . Define the primal cone program as

$$(PC) \quad \nu^* = \begin{cases} \min & \langle C, X \rangle \\ \text{s.t.} & \mathcal{A}X \succeq_K b \\ & X \succeq_L 0, \end{cases}$$

where  $X \succeq_L Y$  denotes  $X - Y \in L$  (and similarly for  $K$ ), and  $\langle \cdot, \cdot \rangle$  denotes the appropriate inner product. Then the above min-max argument yields the dual cone program

$$(DC) \quad \nu^* = \begin{cases} \max & \langle b, y \rangle \\ \text{s.t.} & \mathcal{A}^*y \preceq_{L^+} C \\ & y \succeq_{K^+} 0, \end{cases}$$

where  $\cdot^+$  denotes taking the *polar cone*.

It is an interesting exercise to see that this elegant dual formulation works for linear programs that have mixtures of inequality and equality constraints with mixtures of free and nonnegative variables.

### Strong Duality

However, unlike linear programming, *strong duality* for SDP needs a constraint qualification, e. g. strict primal feasibility (called *Slater's condition*),

$$\text{there exists a } \widehat{X} \succ 0 \text{ with } \mathcal{A}\widehat{X} = b.$$

This constraint qualification implies strong duality holds, i. e. that  $\mu^* = \nu^*$  and  $\nu^*$  is attained. Conversely,

$$\mathcal{A}^*y \prec_{L^+} C$$

also implies that  $\mu^* = \nu^*$  but with  $\mu^*$  attained. If Slater's condition does not hold, then a duality gap  $\mu^* > \nu^*$  can exist, and/or the dual (or primal) optimal value may not be attained, see e. g. [10].

*Example 1* If the dual is

$$(D) \quad \nu^* = \begin{cases} \sup & x_2 \\ \text{s.t.} & \begin{pmatrix} x_2 & 0 & 0 \\ 0 & x_1 & x_2 \\ 0 & x_2 & 0 \end{pmatrix} \preceq \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \end{cases}$$

then the primal is

$$(P) \quad \mu^* = \begin{cases} \inf & U_{11} \\ \text{s.t.} & U_{22} = 0 \\ & U_{11} + 2U_{23} = 1 \\ & U \succeq 0 \end{cases}$$

and we have the duality gap

$$\nu^* = 0 < \mu^* = 1.$$

If strong duality holds, we get the following primal-dual characterization of optimality for the dual pair  $X, y$ , with  $X \succeq 0$ :

- $\mathcal{A}X = b$  (primal feasibility);
- $\mathcal{A}^*y \preceq C$  (dual feasibility);
- $X(\mathcal{A}^*y - C) = 0$  (complementary slackness).

These optimality conditions provide the basis for:

- i) the primal simplex method (maintain primal feasibility and complementary slackness while striving for dual feasibility);
- ii) the dual simplex method (maintain dual feasibility and complementary slackness while striving for primal feasibility); and
- iii) the interior point methods (maintain primal and dual feasibility while striving for complementary slackness).

Unlike the LP case, there are currently no efficient algorithms for primal or dual simplex methods for SDP; however, interior point methods have proven to be very successful. Thus we see the importance of duality for both theoretical and algorithmic purposes.

## Strict Complementarity

Another example of the difference between LP and SDP arises in the complementary slackness conditions. If an optimal pair  $X, y$  exist, then in the LP case there also exists an optimal pair that satisfies strict complementarity, i. e.

$$X + (C - \mathcal{A}^* y) \succ 0,$$

where in the LP case this is a sum of nonnegative diagonal matrices, see [4,5]. However, in the SDP case, there may not exist such a strict complementary optimal pair, though the existence is generic, see [8].

## Closing the Duality Gap

Both the strict complementarity and strict feasibility, or Slater's constraint qualification, are generic, see [8]. But there are classes of problems where strong duality fails, e. g. relaxations that arise from hard combinatorial problems, e. g. [13].

One can regularize semidefinite programs and guarantee that Slater's constraint qualification holds, e. g. [2,3,12]. This involves finding the minimal face of the semidefinite cone that contains the feasible set, i. e. the so-called *minimal cone*. A numerical procedure for regularization is presented in [3]. However, this process is not computationally tractable. An equivalent approach is the extended Lagrange–Slater dual program of M. Ramana [9,10]. This provides a means of writing down a regularized program that is of polynomial size. Thus strong duality can be attained theoretically using the above techniques and exploiting the structure of specific problems. However, lack of regularity (Slater's condition) is an indication of an ill-posed problem. Thus, the question of whether regularization can be done computationally for general problems is still an open question, see e. g. [7].

## Extensions

The SDPs considered above have all contained linear objectives and constraints. There is no reason to restrict SDPs to this special case. Duality for general cone programs with possible nonlinear objectives and constraints is considered in [2,3,11]. Applications for quadratic objectives SDP appear in, e. g., [1,6].

SuperLagrangian; Biduality; Clarke duality;  
Hamiltonian system

It is known that in convex optimization, the Lagrangian associated with a constrained problem is usually a saddle function, which leads to the classical *saddle Lagrange duality* (i. e. the *monoduality*) theory. In nonconvex optimization, a so-called superLagrangian was introduced in [1], which leads to a nice biduality theory in convex *Hamiltonian systems* and in the so-called *d.c. programming*.

### SuperLagrangian Duality

**Definition 1** Let  $L(x, y^*)$  be an arbitrary given real-valued function on  $\mathcal{X} \times \mathcal{Y}^*$ .

A function  $L: \mathcal{X} \times \mathcal{Y}^* \rightarrow \mathbf{R}$  is said to be a *supercritical function* (or a  $\partial^+$ -function) on  $\mathcal{X} \times \mathcal{Y}^*$  if it is concave in each of its arguments.

A function  $L: \mathcal{X} \times \mathcal{Y}^* \rightarrow \mathbf{R}$  is said to be a *subcritical function* (or a  $\partial^-$ -function) on  $\mathcal{X} \times \mathcal{Y}^*$  if  $-L$  is a supercritical function on  $\mathcal{X} \times \mathcal{Y}^*$ .

A point  $(\bar{x}, \bar{y}^*)$  is said to be a *supercritical point* (or a  $\partial^+$ -critical point) of  $L$  on  $\mathcal{X} \times \mathcal{Y}^*$  if

$$L(\bar{x}, y^*) \leq L(\bar{x}, \bar{y}^*) \geq L(x, \bar{y}^*) \quad (1)$$

holds for all  $(x, y^*) \in \mathcal{X} \times \mathcal{Y}^*$ .

A point  $(\bar{x}, \bar{y}^*)$  is said to be a *subcritical point* (or a  $\partial^-$ -critical point) of  $L$  on  $\mathcal{X} \times \mathcal{Y}^*$  if

$$L(\bar{x}, y^*) \geq L(\bar{x}, \bar{y}^*) \leq L(x, \bar{y}^*) \quad (2)$$

holds for all  $(x, y^*) \in \mathcal{X} \times \mathcal{Y}^*$ .

Clearly, a point  $(\bar{x}, \bar{y}^*)$  is a subcritical point of  $L$  on  $\mathcal{X} \times \mathcal{Y}^*$  if and only if it is a supercritical point of  $-L$  on  $\mathcal{X} \times \mathcal{Y}^*$ . A supercritical function  $L(x, y^*)$  is called the *superLagrangian* if it is a *Lagrange form* associated with a constrained optimization problem.  $L(x, y^*)$  is called the *subLagrangian* if  $-L(x, y^*)$  is a superLagrangian.

For example, the quadratic function

$$L(x, y) = axy - \frac{1}{2}bx^2 - \frac{1}{2}cy^2, \quad b, c > 0,$$

is concave for each  $x$  and  $y$ , and hence is a supercritical point function on  $\mathbf{R} \times \mathbf{R}$ . But  $L(x, y)$  is not concave on the vector  $(x, y)$  since the Hessian matrix of  $L$

$$D^2L(x, y) = \begin{pmatrix} -b & a \\ a & -c \end{pmatrix}$$

is not necessarily to be negative-definite for any  $a \in \mathbf{R}$  and  $b, c > 0$ .  $L$  is a subcritical function if  $b, c < 0$ . But  $L$  may not be convex on  $(x, y)$  for the same reason.

Since  $L$  is a subLagrangian if and only if  $-L$  is a superLagrangian, here we only consider the duality theory for the superLagrangian.

**Theorem 2 (Supercritical point)** Let  $L(x, y^*)$  be an arbitrary given function, partially Gâteaux differentiable on an open subset  $\mathcal{X}_a \times \mathcal{Y}_a^* \subset \mathcal{X} \times \mathcal{Y}^*$ . If  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_a^*$  is either a supercritical or subcritical point of  $L$ , then  $(\bar{x}, \bar{y}^*)$  is a critical point of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ .

Any critical point of a Gâteaux differentiable superLagrangian is a supercritical point. However, if  $(\bar{x}, \bar{y}^*)$  is a supercritical point of  $L$ , it does not follow that  $L$  is a superLagrangian. In the d.c. programming or variational analysis of convex Hamiltonian systems, the following statements are of important theoretical value.

S1) Under certain necessary and sufficient conditions we have

$$\inf_{x \in \mathcal{X}_a} \sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*) = \inf_{y^* \in \mathcal{Y}_a^*} \sup_{x \in \mathcal{X}_a} L(x, y^*). \quad (3)$$

A statement of this type is called a *superminimax theorem* and the pair  $(\bar{x}, \bar{y}^*)$  is called a *superminimax point* of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ .

S2) Under certain conditions, a pair  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_a^*$  exists such that

$$L(x, \bar{y}^*) \leq L(\bar{x}, \bar{y}^*) \geq L(\bar{x}, y^*) \quad (4)$$

holds for all  $(x, y^*) \in \mathcal{X}_a \times \mathcal{Y}_a^*$ . A statement of this type is called a *supercritical point theorem*.

By the fact that the maxima of  $L(x, y^*)$  can be taken in either order on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ , the equality

$$\sup_{x \in \mathcal{X}_a} \sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*) = \sup_{y^* \in \mathcal{Y}_a^*} \sup_{x \in \mathcal{X}_a} L(x, y^*) \quad (5)$$

always holds. A pair  $(\bar{x}, \bar{y}^*)$  which maximizes  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_a^*$  is called a *supermaximum point* of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ .

For a given superLagrangian  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$ , we let  $\mathcal{X}_k \subseteq \mathcal{X}_a$  and  $\mathcal{Y}_s^* \subseteq \mathcal{Y}_a^*$  be such that

$$\sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*) < +\infty, \quad \forall x \in \mathcal{X}_k,$$

$$\sup_{x \in \mathcal{X}_a} L(x, y^*) < +\infty, \quad \forall y^* \in \mathcal{Y}_s^*.$$

**Theorem 3 (superLagrangian duality)** *Let the Lagrangian  $L: \mathcal{X} \times \mathcal{Y}^* \rightarrow \mathbf{R}$  be an arbitrary given function. If there exists either a supermaximum point  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_a^*$  such that*

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \max_{x \in \mathcal{X}_a} \max_{y^* \in \mathcal{Y}_a^*} L(x, y^*) \\ &= \max_{y^* \in \mathcal{Y}_a^*} \max_{x \in \mathcal{X}_a} L(x, y^*), \end{aligned} \quad (6)$$

or a superminimax point  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_a^*$  such that

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \min_{x \in \mathcal{X}_a} \max_{y^* \in \mathcal{Y}_a^*} L(x, y^*) \\ &= \min_{y^* \in \mathcal{Y}_a^*} \max_{x \in \mathcal{X}_a} L(x, y^*), \end{aligned} \quad (7)$$

then  $(\bar{x}, \bar{y}^*)$  is a supercritical point of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ .

Conversely, if  $L$  is partially Gâteaux differentiable on an open subset  $\mathcal{X}_a \times \mathcal{Y}_a^* \subset \mathcal{X} \times \mathcal{Y}^*$ , and  $(\bar{x}, \bar{y}^*)$  is a supercritical point of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ , then either the supermaximum theorem in the form

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \max_{x \in \mathcal{X}_k} \max_{p \in \mathcal{Y}_a^*} L(x, p) \\ &= \max_{y^* \in \mathcal{Y}_s^*} \max_{x \in \mathcal{X}_a} L(x, y^*), \end{aligned} \quad (8)$$

holds, or the superminimax theorem in the form

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \min_{x \in \mathcal{X}_k} \max_{y^* \in \mathcal{Y}_a^*} L(x, y^*) \\ &= \min_{y^* \in \mathcal{Y}_s^*} \max_{x \in \mathcal{X}_a} L(x, y^*) \end{aligned} \quad (9)$$

holds.

This superLagrangian duality theorem shows a very important fact in Hamiltonian systems, i. e. the critical points of the Lagrangian  $L$  either maximize or minimize  $L$  on  $\mathcal{X}_k \times \mathcal{Y}_s^*$  in either order.

### Nonconvex Primal and Dual Problems

Let  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  be an arbitrary given supercritical function. For any fixed  $x \in \mathcal{X}_a$ , let

$$P(x) = \sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*). \quad (10)$$

Clearly, the function  $P(x)$  need not be either convex or concave. Let  $\mathcal{X}_k \subset \mathcal{X}_a$  be the *primal feasible set* such that  $P: \mathcal{X}_k \rightarrow \mathbf{R}$  is finite and Gâteaux differentiable. Then for a nonconvex function  $P$ , two primal problems can be proposed as:

$$(\mathcal{P}_{\text{inf}}): \quad P(x) \rightarrow \min, \quad \forall u \in \mathcal{X}_k, \quad (11)$$

$$(\mathcal{P}_{\text{sup}}): \quad P(x) \rightarrow \max, \quad \forall u \in \mathcal{X}_k. \quad (12)$$

The problems  $(\mathcal{P}_{\text{inf}})$  and  $(\mathcal{P}_{\text{sup}})$  are realisable if the primal feasible set  $\mathcal{X}_k$  is not empty.

Dually, for any fixed  $y^* \in \mathcal{Y}_a^*$ , let

$$P^d(y^*) = \sup_{x \in \mathcal{X}_a} L(x, y^*) \quad (13)$$

with the *dual feasible set*  $\mathcal{Y}_s^* \subset \mathcal{Y}_a^*$  such that  $P^d: \mathcal{Y}_s^* \rightarrow \mathbf{R}$  is finite and Gâteaux differentiable. The two nonconvex dual problems are:

$$(\mathcal{P}_{\text{inf}}^d): \quad P^d(y^*) \rightarrow \min, \quad \forall y^* \in \mathcal{Y}_s^*, \quad (14)$$

$$(\mathcal{P}_{\text{sup}}^d): \quad P^d(y^*) \rightarrow \max, \quad \forall y^* \in \mathcal{Y}_s^*. \quad (15)$$

These two dual problems are realisable if the dual feasible set  $\mathcal{Y}_s^*$  is not empty.

**Theorem 4 (Biduality theorem)** *Let  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  be a given arbitrary function such that  $P$  and  $P^d$  are well-defined by (10) and (13) on the open subsets  $\mathcal{X}_k$  and  $\mathcal{Y}_s^*$ , respectively.*

- 1) If  $(\bar{x}, \bar{y}^*)$  is a supercritical point of  $L$  on  $\mathcal{X}_k \times \mathcal{Y}_s^*$ , then  $DP(\bar{x}) = 0$ ,  $DP^d(\bar{y}^*) = 0$ , and

$$P(\bar{x}) = L(\bar{x}, \bar{y}^*) = P^d(\bar{y}^*). \quad (16)$$

- 2) If  $(\bar{x}, \bar{y}^*)$  is a supercritical point of  $L$  on  $\mathcal{X}_k \times \mathcal{Y}_s^*$ , then  $\bar{x}$  is a minimizer of  $P$  on  $\mathcal{X}_k$  if and only if  $\bar{y}^*$  is a minimizer of  $P^d$  on  $\mathcal{Y}_s^*$ , i. e. the double-min duality

$$P(\bar{x}) = \inf_{x \in \mathcal{X}_k} P(x) \Leftrightarrow \inf_{y^* \in \mathcal{Y}_s^*} P^d(y^*) = P^d(\bar{y}^*) \quad (17)$$

holds.

- 3) If  $(\bar{x}, \bar{y}^*)$  is a supercritical point of  $L$  on  $\mathcal{X}_k \times \mathcal{Y}_s^*$ , then  $\bar{x}$  is a maximizer of  $P$  on  $\mathcal{X}_k$  if and only if  $\bar{y}^*$  is a maximizer of  $P^d$  on  $\mathcal{Y}_s^*$ , i. e. the double-max duality

$$P(\bar{x}) = \sup_{x \in \mathcal{X}_k} P(x) \Leftrightarrow \sup_{y^* \in \mathcal{Y}_s^*} P^d(y^*) = P^d(\bar{y}^*) \quad (18)$$

holds.

### D.C. Programming and Hamiltonian

In d.c. programming, the primal function  $P: \mathcal{X}_k \rightarrow \mathbf{R}$  can be written as

$$P(x) = W(\Lambda x) - F(x),$$

where  $\Lambda: \mathcal{X} \rightarrow \mathcal{Y}$  is a linear operator,  $W: \mathcal{Y}_a \rightarrow \mathbf{R}$  and  $F: \mathcal{X}_a \rightarrow \mathbf{R}$  are two convex, Gâteaux differentiable real-valued functions, satisfying the *Legendre duality relations*

$$\begin{aligned} x^* &= DF(x) \Leftrightarrow x = DF^*(x^*) \\ &\Leftrightarrow \langle x, x^* \rangle = F(x) + F^*(x^*) \end{aligned}$$

on  $\mathcal{X}_a \times \mathcal{X}_a^*$ , and

$$\begin{aligned} y^* &= DW(y) \Leftrightarrow y = DW^*(y^*) \\ &\Leftrightarrow \langle y, y^* \rangle = W(y) + W^*(y^*) \end{aligned}$$

on  $\mathcal{Y}_a \times \mathcal{Y}_a^*$ , where  $F^*: \mathcal{X}_a^* \rightarrow \mathbf{R}$  and  $W^*: \mathcal{Y}_a^* \rightarrow \mathbf{R}$  are the *Legendre conjugates* of  $F$  and  $W$ , respectively.

In dynamical systems, if  $\Lambda = d/dt$  is a differential operator, its adjoint associated with the standard bilinear forms in  $\mathcal{L}^2$  is  $\Lambda^* = -d/dt$ . If  $W$  denotes the kinetic energy,  $F$  stands for potential energy, then the primal function  $P(x) = W(\Lambda x) - F(x)$  is the *total action* of the system. The primal feasible set  $\mathcal{X}_k \subset \mathcal{X}$ , defined by

$$\mathcal{X}_k = \{x \in \mathcal{X}_a: \Lambda x \in \mathcal{Y}_a\},$$

is called the *kinetically admissible space*. Clearly,  $P: \mathcal{X}_k \rightarrow \mathbf{R}$  is nonconvex.

The *Lagrangian form* associated with the nonconvex primal problems is defined by

$$L(x, y^*) = \langle \Lambda x; y^* \rangle - W^*(y^*) - F(x), \quad (19)$$

which is Gâteaux differentiable on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ . The critical condition  $DL(\bar{x}, \bar{y}^*) = 0$  leads to the Lagrange equations:

$$\Lambda \bar{x} = DW^*(\bar{y}^*), \quad \Lambda^* \bar{y}^* = DF(\bar{x}).$$

Clearly,  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  is a supercritical function, and

$$P(x) = \sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*), \quad \forall x \in \mathcal{X}_k.$$

Dually, for any given dual feasible  $y^* \in \mathcal{Y}_s^*$ ,

$$P^d(y^*) = \sup_{x \in \mathcal{X}_a} L(x, y^*) = F^*(\Lambda^* y^*) - W^*(y^*),$$

where the dual feasible set  $\mathcal{Y}_s^* \subset \mathcal{Y}_a^*$  is defined by

$$\mathcal{Y}_s^* = \{y^* \in \mathcal{Y}_a^*: \Lambda^* y^* \in \mathcal{X}_a^*\}.$$

The criticality conditions  $DL(\bar{x}, \bar{y}^*) = 0$ ,  $DP(\bar{x}) = 0$  and  $DP^d(\bar{y}^*) = 0$  are equivalent to each other.

The *Hamiltonian*  $H: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  associated with the Lagrangian  $L$  is defined by

$$\begin{aligned} H(x, y^*) &= \langle \Lambda x; y^* \rangle - L(x, y^*) \\ &= W^*(y^*) + F(x). \end{aligned} \quad (20)$$

For d.c. programming,  $H(x, y^*)$  is a convex function on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ . The critical point  $(\bar{x}, \bar{y}^*)$  of  $L$  satisfies the *Hamiltonian canonical form*

$$\Lambda \bar{x} = D_{y^*} H(\bar{x}, \bar{y}^*), \quad \Lambda^* \bar{y}^* = D_x H(\bar{x}, \bar{y}^*).$$

Particularly, if  $W(\Lambda x) = 1/2 \langle \Lambda x, C \Lambda x \rangle$  is a quadratic function,  $C: \mathcal{Y}_a \rightarrow \mathcal{Y}_a^*$  is a symmetric operator such that the composite operator  $A = \Lambda^* C \Lambda = A^*$  is selfadjoint, then the total action can be written as

$$P(x) = \frac{1}{2} \langle x, Ax \rangle - F(x).$$

Let  $P^c(x) = -P^d(C \Lambda x)$ ; then the function  $P^c: \mathcal{X}_a \rightarrow \mathbf{R}$

$$P^c(x) = \frac{1}{2} \langle x, Ax \rangle - F^*(Ax)$$

is the so-called *Clarke dual action* (see [1]).

**Theorem 5 (Clarke duality theorem)** Let  $A: \mathcal{X}_k \subset \mathcal{X}_a \rightarrow \mathcal{X}_a^*$  be a closed selfadjoint operator, and  $\text{Ker } A = \{x \in \mathcal{X}: Ax = 0 \in \mathcal{X}^*\}$  the null space of  $A$ . If  $\bar{x} \in \mathcal{X}_k$  is a critical point of  $P$ , then any vector  $x \in \text{Ker } A + \bar{x}$  is a critical point of  $P^c$ .

Conversely, if there exists a  $x_o \in \mathcal{X}_k$  such that  $Ax_o \in \mathcal{X}_a^*$ , then for a given critical point  $\bar{x}$  of  $P^c$ , any vector  $x \in \text{Ker } A + \bar{x}$  is a critical point of  $P$ .

**Example 6** Let us consider a very simple one-dimensional optimization problem with constraint

$$\begin{cases} F(x) = \frac{1}{2}kx^2 - fx \rightarrow \max \\ \text{s.t.} \quad a \leq x \leq b, \end{cases} \quad (21)$$

where  $k > 0$  and  $f \in \mathbf{R}$  are given constants. We assume that  $-\infty < a < 0 < b < \infty$ . Since  $F(x)$  is strictly convex on the closed set  $[a, b]$ , the maximum is attained only on the boundary, i. e.

$$\sup_{x \in [a, b]} F(x) = \max\{F(a), F(b)\} < \infty.$$

The classical Lagrange multiplier method cannot be used for this nonconvex problem. To set this problem within our framework, we need only set  $\mathcal{X} = \mathbf{R}$ ,  $\mathcal{X}_a = [a, b]$  and let  $\Lambda = 1$ , so that

$$y = \Lambda x = x \in \mathcal{Y} = \mathbf{R}.$$

Thus, the range of the mapping  $\Lambda: \mathcal{X}_a \rightarrow \mathcal{Y} = \mathbf{R}$  is  $\mathcal{Y}_a = [a, b]$ . Let

$$W(y) = \begin{cases} 0 & \text{if } y \in \mathcal{Y}_a, \\ +\infty & \text{if } y \notin \mathcal{Y}_a. \end{cases}$$

It is not difficult to check that  $W: \mathcal{Y} \rightarrow \mathbf{R} \cup \{+\infty\}$  is convex. On  $\mathcal{Y}_a$ ,  $W$  is finite and differentiable. Thus, the primal feasible space can be defined by

$$\mathcal{X}_k = \{x \in \mathcal{X}_a: Ax = x \in \mathcal{Y}_a\} = [a, b].$$

Clearly, on  $\mathcal{X}_k$   $P(x) = W(\Lambda x) - F(x) = F(x)$ . The constrained maximization problem (21) is then equivalent to the standard nonconvex minimization problem  $(\mathcal{P}_{\text{inf}}): P(x) \rightarrow \min, \forall x \in \mathcal{X}_k$ .

Since  $F(x)$  is strictly convex and differentiable on  $\mathcal{X}_a = [a, b]$ , and

$$x^* = DF(x) = kx - f \in \mathcal{X}_a^*$$

is invertible, where

$$\mathcal{X}_a^* = [ak - f, bk - f] \subset \mathcal{X}^* = \mathbf{R},$$

the Legendre conjugate  $P^c: \mathcal{X}_a^* \rightarrow \mathbf{R}$  can easily be obtained as

$$F^*(x^*) = \max_{x \in \mathcal{X}_a} \{xx^* - F(x)\} = \frac{1}{2k}(x^* + f)^2.$$

By the Fenchel transformation, the conjugate of the nonsmooth function  $W$  can be obtained as

$$\begin{aligned} W^*(y^*) &= \sup_{y \in \mathcal{Y}} \{yy^* - W(y)\} = \max_{y \in \mathcal{Y}_a} yy^* \\ &= \begin{cases} by^* & \text{if } y^* > 0, \\ 0 & \text{if } y^* = 0, \\ ay^* & \text{if } y^* < 0. \end{cases} \end{aligned}$$

It is convex and differentiable on  $\mathcal{Y}_a^* = \mathcal{Y}^* = \mathbf{R}$ .

On  $\mathcal{X}_a \times \mathcal{Y}_a^* = [a, b] \times \mathbf{R}$ , the Lagrange form for this nonconvex programming is well-defined by

$$\begin{aligned} L(x, y^*) &= y^* \Lambda x - W^*(y^*) - F(x) \\ &= \begin{cases} xy^* - by^* - \frac{1}{2}kx^2 + fx & \text{if } y^* \geq 0, \\ xy^* - ay^* - \frac{1}{2}kx^2 + fx & \text{if } y^* < 0. \end{cases} \end{aligned}$$

Since both  $W^*$  and  $F$  are convex,  $L(x, y^*)$  is a supercritical point function. If  $x \in \mathcal{X}_k = [a, b]$ , then

$$P(x) = \sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*).$$

On the other hand, for any  $y^*$  in the dual feasible space

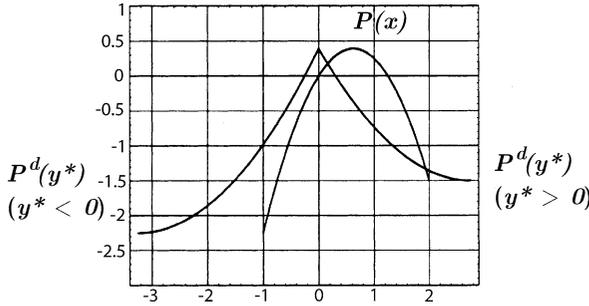

$$\begin{aligned} \mathcal{Y}_s^* &= \{y^* \in \mathcal{Y}_a^* = \mathbf{R}: \Lambda^* y^* = y^* \in \mathcal{X}_a^*\} \\ &= [ak - f, bk - f], \end{aligned}$$

the dual function is obtained by

$$\begin{aligned} P^d(y^*) &= \sup_{x \in \mathcal{X}_a} L(x, y^*) \\ &= \sup_{x \in \mathbf{R}} \{(\Lambda x)y^* - F(x)\} - W^*(y^*) \\ &= F^*(\Lambda^* y^*) - W^*(y^*), \end{aligned}$$

where

$$\begin{aligned} F^*(\Lambda^* y^*) &= \sup_{x \in \mathcal{X}_a} \{(\Lambda x)y^* - F(x)\} \\ &= \sup_{x \in \mathbf{R}} \{x(y + f) - \frac{1}{2}kx^2\} \\ &= \frac{1}{2k}(y^* + f)^2. \end{aligned}$$

**Duality Theory: Biduality in Nonconvex Optimization, Figure 1**

**Biduality in constrained nonconvex optimization**

Thus, the dual action  $P^d$  is well defined on  $\mathcal{Y}_s^*$  by

$$P^d(y^*) = \begin{cases} \frac{1}{2k}(y^* + f)^2 - by^* & \text{if } y^* > 0, \\ \frac{1}{2k}f^2 & \text{if } y^* = 0, \\ \frac{1}{2k}(y^* + f)^2 - ay^* & \text{if } y^* < 0. \end{cases} \quad (22)$$

This is a double-well function on  $\mathbf{R}$  (see Fig. 1.). The dual problem

$$(P_{\text{inf}}^d): \quad P^d(y^*) \rightarrow \min, \quad \forall y^* \in \mathcal{Y}_s^*,$$

is a convex optimization problem on either

$$\mathcal{Y}_s^{*+} = \{y^* \in \mathcal{Y}_s^*: y^* > 0\}$$

or

$$\mathcal{Y}_s^{*-} = \{y^* \in \mathcal{Y}_s^*: y^* < 0\}.$$

In  $n$ -dimensional problems, this dual problem is much easier than the primal problem. The criticality condition leads to

$$\bar{y}^* = \begin{cases} bk - f & \text{if } \bar{y}^* > 0, \\ 0 & \text{if } \bar{y}^* = 0 \\ ak - f & \text{if } \bar{y}^* < 0. \end{cases}$$

It is easy to check that the following duality theorems hold:

$$\begin{aligned} \min_{x \in \mathcal{X}_k} P(x) &= \min_{y^* \in \mathcal{Y}_s^*} P^d(y^*), \\ \max_{x \in \mathcal{X}_k} P(x) &= \max_{y^* \in \mathcal{Y}_s^*} P^d(y^*). \end{aligned}$$

The graphs of  $P(x)$  and  $P^d(y^*)$  are shown in Fig. 1.

Duality; Convex optimization; Saddle Lagrangian;

Legendre duality; Fenchel–Rockafellar duality;

Complementarity; Linear programming; Center path

The concept of *duality* is one of the most successful ideas in modern mathematics and science. Inner beauty in natural phenomena is bound up with duality, which has always been a rich source of inspiration in human knowledge through the centuries. Duality in mathematics, roughly speaking, is a fundamental concept that underlies many aspects of *extremum principles* in natural systems. Eigenvectors, geodesics, minimal surfaces, KKT conditions, harmonic maps, Hamiltonian canonical equations and equilibrium states of many field equations are all critical points of certain functions on some appropriate constraint sets or manifolds. Considerable

attention has been attracted on this fascinating research subject during the last years. A comprehensive study on duality theory in general nonconvex and nonsmooth systems is given in [1]. In global optimization problems, duality falls principally into three categories:

- 1) the classical *saddle Lagrange duality* (i. e. monoduality) in convex optimization;
- 2) the nice *biduality* in convex Hamilton systems or the *d.c. programming* (difference of convex functions); and
- 3) the interesting *triduality* in general nonconvex systems.

### Saddle Lagrange Duality

Let  $(\mathcal{X}, \mathcal{X}^*)$  and  $(\mathcal{Y}, \mathcal{Y}^*)$  be two pairs real vector spaces, finite- or infinite-dimensional, and let  $\langle *, * \rangle: \mathcal{X} \times \mathcal{X}^* \rightarrow \mathbf{R}$  and  $\langle *, * \rangle: \mathcal{Y} \times \mathcal{Y}^* \rightarrow \mathbf{R}$  be certain *bilinear forms* which put the paired spaces  $(\mathcal{X}, \mathcal{X}^*)$  and  $(\mathcal{Y}, \mathcal{Y}^*)$  in *duality*, respectively. In classical convex optimization, a real-valued function  $L: \mathcal{X} \times \mathcal{Y}^* \rightarrow \mathbf{R}$  is said to be a *saddle function* if it is convex in one variable and concave in the other one.

A pair  $(\bar{x}, \bar{y}^*)$  is called a *right saddle point* of  $L$  on a subspace  $\mathcal{X}_a \times \mathcal{Y}_{a^*} \subset \mathcal{X} \times \mathcal{Y}^*$  if

$$L(\bar{x}, y^*) \leq L(\bar{x}, \bar{y}^*) \leq L(x, \bar{y}^*)$$

holds for any  $(x, y^*) \in \mathcal{X}_a \times \mathcal{Y}_{a^*}$ .

A pair  $(\bar{x}, \bar{y}^*)$  is called a *left saddle point* of  $L$  on a subspace  $\mathcal{X}_a \times \mathcal{Y}_{a^*} \subset \mathcal{X} \times \mathcal{Y}^*$  if it is a right saddle point of  $-L$  on the subspace  $\mathcal{X}_a \times \mathcal{Y}_{a^*}$ .

A pair  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_{a^*}$  is called a *critical point* of  $L$  if  $L$  is partially Gâteaux differentiable at  $(\bar{x}, \bar{y}^*)$  and

$$D_x L(\bar{x}, \bar{y}^*) = 0, \quad D_{y^*} L(\bar{x}, \bar{y}^*) = 0,$$

where  $D_x L: \mathcal{X}_a \rightarrow \mathcal{X}^*$  and  $D_{y^*} L: \mathcal{Y}_{a^*} \rightarrow \mathcal{Y}$  denote, respectively, the partial Gâteaux derivatives of  $L$  with respect to  $x$  and  $y^*$ .

Any critical point of a Gâteaux differentiable saddle function is a saddle point. However, if  $(\bar{x}, \bar{y}^*)$  is a saddle point of  $L$  it does not follow that  $L$  is a saddle function. In convex optimization problems, the following statements are of important theoretical value.

S1) Under certain necessary and sufficient conditions, suppose that

$$\inf_{x \in \mathcal{X}_a} \sup_{y^* \in \mathcal{Y}_{a^*}} L(x, y^*) = \sup_{y^* \in \mathcal{Y}_{a^*}} \inf_{x \in \mathcal{X}_a} L(x, y^*). \quad (1)$$

A statement of this type is called a *saddle-minimax theorem* and the pair  $(\bar{x}, \bar{y}^*)$  is called a *saddle-minimax point* of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_{a^*}$ .

S2) Under certain conditions, suppose that a pair  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_{a^*}$  exists such that

$$L(x, \bar{y}^*) \geq L(\bar{x}, \bar{y}^*) \geq L(\bar{x}, y^*) \quad (2)$$

holds for any  $(x, y^*) \in \mathcal{X}_a \times \mathcal{Y}_{a^*}$ . A statement of this type is called a *right saddle-point theorem*.

Let  $\mathcal{X}_k$  be a subset of  $\mathcal{X}_a$  such that  $\mathcal{X}_k$  contains all point  $u \in \mathcal{X}_a$  for which the supremum  $\sup_{y^*} L(x, y^*)$  is finite, i. e.

$$\sup_{y^* \in \mathcal{Y}_{a^*}} L(x, y^*) < +\infty, \quad \forall x \in \mathcal{X}_k.$$

Dually, let  $\mathcal{Y}_s$  be a subset of  $\mathcal{Y}_{a^*}$  such that  $\mathcal{Y}_s$  contains all points  $y^* \in \mathcal{Y}_{a^*}$  for which the infimum  $\inf_x L(x, y^*)$  is finite, i. e.

$$\inf_{x \in \mathcal{X}_a} L(x, y^*) > -\infty, \quad \forall y^* \in \mathcal{Y}_s.$$

The sets  $\mathcal{X}_k$  and  $\mathcal{Y}_s$  may be either empty or  $\mathcal{X}_k = \mathcal{X}_a$  and  $\mathcal{Y}_s = \mathcal{Y}_{a^*}$ . The connection between the minimax theorem and the saddle-point theorem is given by the following results.

**Theorem 1 (Saddle-minimax theorem)** *Let  $L: \mathcal{X}_a \times \mathcal{Y}_{a^*} \rightarrow \mathbf{R}$  be a given arbitrary function. If there exists a saddle-minimax point  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_a \times \mathcal{Y}_{a^*}$  such that*

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \min_{x \in \mathcal{X}_a} \max_{y^* \in \mathcal{Y}_{a^*}} L(x, y^*) \\ &= \max_{y^* \in \mathcal{Y}_{a^*}} \min_{x \in \mathcal{X}_a} L(x, y^*), \end{aligned} \quad (3)$$

*then  $(\bar{x}, \bar{y}^*)$  is a saddle point of  $L$  on  $\mathcal{X}_a \times \mathcal{Y}_{a^*}$ .*

*Conversely, if  $L(x, y^*)$  possesses a saddle point  $(\bar{x}, \bar{y}^*)$  on  $\mathcal{X}_a \times \mathcal{Y}_{a^*}$ , then the saddle-minimax theorem in the form*

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \min_{x \in \mathcal{X}_k} \max_{y^* \in \mathcal{Y}_{a^*}} L(x, y^*) \\ &= \max_{y^* \in \mathcal{Y}_s} \min_{x \in \mathcal{X}_a} L(x, y^*) \end{aligned} \quad (4)$$

*holds.*

Let  $L: \mathcal{X}_a \times \mathcal{Y}_{a^*} \rightarrow \mathbf{R}$  be a given arbitrary right saddle function. For any fixed  $x \in \mathcal{X}_a$ , let

$$P(x) = \sup_{y^* \in \mathcal{Y}_{a^*}} L(x, y^*). \quad (5)$$

Let  $\mathcal{X}_k \subset \mathcal{X}_a$  be the domain of  $P$  such that  $P: \mathcal{X}_k \rightarrow \mathbf{R}$  is finite and Gâteaux differentiable. Then the inf-problem

$$(\mathcal{P}_{\text{inf}}): \quad P(x) \rightarrow \min, \quad \forall x \in \mathcal{X}_k, \quad (6)$$

is called the *primal problem*.

Dually, for any fixed  $y^* \in \mathcal{Y}_a^*$ , let

$$P^d(y^*) = \sup_{x \in \mathcal{X}_a} L(x, y^*) \quad (7)$$

with domain  $\mathcal{Y}_s^* \subset \mathcal{Y}_a^*$ , on which,  $P^d: \mathcal{Y}_s^* \rightarrow \mathbf{R}$  is finite and Gâteaux differentiable. Thus, the sup-problem

$$(\mathcal{P}_{\text{sup}}^d): \quad P^d(y^*) \rightarrow \max, \quad \forall y^* \in \mathcal{Y}_s^*, \quad (8)$$

is referred as the *dual problem*. The problems  $(\mathcal{P}_{\text{inf}})$  and  $(\mathcal{P}_{\text{sup}}^d)$  are *realisable* if  $\mathcal{X}_k$  and  $\mathcal{Y}_s^*$  are not empty, i. e., there exists a pair  $(\bar{x}, \bar{y}^*) \in \mathcal{X}_k \times \mathcal{Y}_s^*$  such that

$$\begin{aligned} P(\bar{x}) &= \min_{x \in \mathcal{X}_k} P(x) = \inf_{x \in \mathcal{X}_k} P(x), \\ P^d(\bar{y}^*) &= \max_{y^* \in \mathcal{Y}_s^*} P^d(y^*) = \sup_{y^* \in \mathcal{Y}_s^*} P^d(y^*). \end{aligned}$$

**Theorem 2 (Saddle duality theorem)** *Let  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  be a given arbitrary function such that  $P$  and  $P^d$  are well-defined by (5) and (7) on the open subsets  $\mathcal{X}_k$  and  $\mathcal{Y}_s^*$ , respectively. If  $(\bar{x}, \bar{y}^*)$  is a saddle point of  $L$  on  $\mathcal{X}_k \times \mathcal{Y}_s^*$ ,  $P$  is Gâteaux differentiable at  $\bar{x}$ , and  $P^d$  is Gâteaux differentiable at  $\bar{y}^*$ , then  $DP(\bar{x}) = 0$ ,  $DP^d(\bar{y}^*) = 0$ , and*

$$P(\bar{x}) = L(\bar{x}, \bar{y}^*) = P^d(\bar{y}^*). \quad (9)$$

**Theorem 3 (Weak duality theorem)** *The inequality*

$$P(x) \geq P^d(y^*) \quad (10)$$

*holds for all  $(x, y^*) \in \mathcal{X}_k \times \mathcal{Y}_s^*$ .*

**Theorem 4 (Strong duality theorem)**  *$(\bar{x}, \bar{y}^*)$  is a saddle-point of  $L$  on  $\mathcal{X}_k \times \mathcal{Y}_s^* \subseteq \mathcal{X}_a \times \mathcal{Y}_a^*$  if and only if the equality*

$$P(\bar{x}) = \inf_{x \in \mathcal{X}_k} P(x) = \sup_{y^* \in \mathcal{Y}_s^*} P^d(y^*) = P^d(\bar{y}^*) \quad (11)$$

*holds.*

## Fenchel–Rockafellar Duality

Very often, the primal function  $P: \mathcal{X}_k \rightarrow \mathbf{R}$  can be written as

$$P(x) = W(\Lambda x) - F(x),$$

where  $\Lambda: \mathcal{X} \rightarrow \mathcal{Y}$  is a linear operator,  $W: \mathcal{Y}_a \rightarrow \mathbf{R}$  and  $F: \mathcal{X}_a \rightarrow \mathbf{R}$  are Gâteaux differentiable real-valued functions. The feasible set  $\mathcal{X}_k \subset \mathcal{X}$  is then defined by

$$\mathcal{X}_k = \{x \in \mathcal{X}_a: \Lambda x \in \mathcal{Y}_a\}.$$

Clearly,  $P: \mathcal{X}_k \rightarrow \mathbf{R}$  is convex if  $W$  is convex on  $\mathcal{Y}_a$  and  $F$  is concave on  $\mathcal{X}_a$ .

The *conjugate function*  $W^*: \mathcal{Y}_a^* \rightarrow \mathbf{R}$  of  $W(y)$  is defined by the *Fenchel transformation*, i. e.

$$W^*(y^*) = \sup_{y \in \mathcal{Y}_a} \{\langle y; y^* \rangle - W(y)\}, \quad (12)$$

which is always l.s.c. and convex on  $\mathcal{Y}^*$ . The following *Fenchel–Young inequality*

$$W(y) \geq \langle y; y^* \rangle - W^*(y^*) \quad (13)$$

holds on  $\mathcal{Y}_a \times \mathcal{Y}_a^*$ . If  $W$  is strictly convex, and Gâteaux differentiable on  $\mathcal{Y}_a \subset \mathcal{Y}$ , then the following *Legendre duality relations*

$$\begin{aligned} y^* &= DW(y) \Leftrightarrow y = DW^*(y^*) \\ &\Leftrightarrow \langle y; y^* \rangle = W(y) + W^*(y^*) \end{aligned}$$

hold on  $\mathcal{Y}_a \times \mathcal{Y}_a^*$ . In this case, we have  $W(y) = W^{**}(y)$ , the biconjugate of  $W$ , and the Fenchel transformation (12) is equivalent to the classical *Legendre transformation*

$$W^*(y^*) = \langle y(y^*); y^* \rangle - W(y(y^*)).$$

The *Lagrangian form* associated with  $(\mathcal{P}_{\text{inf}})$  is defined by

$$L(x, y^*) = \langle \Lambda x; y^* \rangle - W^*(y^*) - F(x), \quad (14)$$

which is Gâteaux differentiable on  $\mathcal{X}_a \times \mathcal{Y}_a^*$ . The critical condition  $DL(\bar{x}, \bar{y}^*) = 0$  leads to the *Lagrange equations*:

$$\Lambda \bar{x} = DW^*(\bar{y}^*), \quad \Lambda^* \bar{y}^* = DF(\bar{x}), \quad (15)$$

where  $\Lambda^*: \mathcal{Y}_a^* \rightarrow \mathcal{X}_a^*$  is the adjoint operator of  $\Lambda$ . Clearly,  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  is a right saddle function if

$F(x)$  is concave on  $\mathcal{X}_a$ . For convex function  $W(y)$ , we have

$$P(x) = \sup_{y^* \in \mathcal{Y}_a^*} L(x, y^*), \quad \forall x \in \mathcal{X}_k.$$

The Fenchel conjugate function of a concave function  $F: \mathcal{X}_a \rightarrow \mathbf{R}$  is defined by

$$F^*(x^*) = \inf_{x \in \mathcal{X}_a} \{ \langle x, x^* \rangle - F(x) \}. \quad (16)$$

Thus, for any given dual admissible  $y^* \in \mathcal{Y}_s^*$  with

$$\mathcal{Y}_s^* = \{ y^* \in \mathcal{Y}_a^* : \Lambda^* y^* \in \mathcal{X}_a^* \},$$

the Fenchel–Rockafellar dual function  $P^d: \mathcal{Y}_k^* \rightarrow \mathbf{R}$  can be obtained as

$$P^d(y^*) = \inf_{x \in \mathcal{X}_a} L(x, y^*) = F^*(\Lambda^* y^*) - W^*(y^*).$$

If  $P$  is Gâteaux differentiable on  $\mathcal{X}_k$ , the critical condition  $DP(\bar{x}) = 0$  leads to the *Euler–Lagrange equation* of the primal problem ( $\mathcal{P}_{\text{inf}}$ ):

$$\Lambda^* DW(\Lambda \bar{x}) - DF(\bar{x}) = 0. \quad (17)$$

Similarly, the critical condition  $DP^d(\bar{y}^*) = 0$  gives the *dual Euler–Lagrange equation* of ( $\mathcal{P}_{\text{sup}}^d$ ):

$$\Lambda DF^*(\Lambda^* \bar{y}^*) - DW^*(\bar{y}^*) = 0. \quad (18)$$

Clearly, the critical point theorem (9) holds if the Lagrange equation (15), Euler–Lagrange equation (17) and its dual equation (18) are equivalent to each others.

For any given  $F$  and  $W$ , the weak duality theorem (10) always holds on  $\mathcal{X}_k \times \mathcal{F}_s^*$ . The difference  $\inf P - \sup P^d$  is the so-called *duality gap*. For convex primal problem, the duality gap is zero and the strong Lagrange duality theorem (11) holds, which is also referred as the *Fenchel–Rockafellar duality theory*.

### Linear Programming and Central Path

Let us now demonstrate how the above scheme fits in with finite-dimensional linear programming. Let  $\mathcal{X} = \mathcal{X}^* = \mathbf{R}^n$ ,  $\mathcal{Y} = \mathcal{F}^* = \mathbf{R}^m$ , with the standard inner products  $\langle x, x^* \rangle = x^\top x^*$  in  $\mathbf{R}^n$ , and  $\langle y, y^* \rangle = y^\top y^*$  in  $\mathbf{R}^m$ . For fixed  $\bar{x}^* = c \in \mathbf{R}^n$  and  $\bar{y} = b \in \mathbf{R}^m$ , the primal problem is a constrained linear optimization problem:

$$\begin{cases} \min_{x \in \mathbf{R}^n} & \langle c, x \rangle \\ \text{s.t.} & \Lambda x = b, \quad x \geq 0, \end{cases} \quad (19)$$

where  $\Lambda \in \mathbf{R}^{m \times n}$  is a matrix, and its adjoint is simply  $\Lambda^* = \Lambda^\top \in \mathbf{R}^{n \times m}$ . To reformulate this linear constrained optimization problem in the model form ( $\mathcal{P}_{\text{inf}}$ ), we need to set  $\mathcal{X}_a = \{x \in \mathbf{R}^n : x \geq 0\}$ , which is a convex cone in  $\mathbf{R}^n$ ,  $\mathcal{Y}_a = \{y \in \mathbf{R}^m : y = b\}$ , a hyperplane in  $\mathbf{R}^m$ , and let

$$F(x) = -\langle c, x \rangle, \quad \forall x \in \mathcal{X}_a,$$

$$W(y) = 0, \quad \forall y \in \mathcal{Y}_a.$$

Thus on the primal feasible set

$$\mathcal{X}_k = \{x \in \mathbf{R}^n : \Lambda x = b, x \geq 0\}$$

we have  $P(x) = W(\Lambda x) - F(x) = \langle c, x \rangle$ . The conjugate functions in this elementary case may be calculated at once as

$$W^*(y^*) = \sup_{y \in \mathcal{Y}_a} \langle y, y^* \rangle = \langle b, y^* \rangle,$$

$$\forall y^* \in \mathcal{Y}_a^* = \mathbf{R}^m,$$

$$F^*(x^*) = \inf_{x \in \mathcal{X}_a} \langle x, x^* + c \rangle = 0, \quad \forall x^* \in \mathcal{X}_a^*,$$

where  $\mathcal{X}_a^* = \{x^* \in \mathbf{R}^n : x^* + c \geq 0\}$  is a polar cone of  $\mathcal{X}_a$ . Thus, on the dual feasible space

$$\mathcal{Y}_s^* = \{y^* \in \mathbf{R}^m : \Lambda^* y^* + c \geq 0\},$$

the problem dual to the linear programming (19) reads

$$\max_{p \in \mathbf{R}^m} P^d(y^*) = -\langle b, y^* \rangle, \quad \forall y^* \in \mathcal{Y}_s^*. \quad (20)$$

The Lagrangian  $L: \mathcal{X}_a \times \mathcal{Y}_a^* \rightarrow \mathbf{R}$  associated with this constrained linear programming is

$$\begin{aligned} L(x, y^*) &= \langle \Lambda x, y^* \rangle - \langle b, y^* \rangle + \langle c, x \rangle \\ &= \langle x, \Lambda^* y^* + c \rangle - \langle b, y^* \rangle. \end{aligned}$$

But for inequality constraints in  $\mathcal{X}_a$ , the Lagrange multiplier  $x^* = \Lambda^* y^* \in \mathbf{R}^n$  has to satisfy the following *KKT optimality conditions*

$$\begin{aligned} \Lambda x &= b, \quad s = c + \Lambda^* y^*, \\ x &\geq 0, \quad s \geq 0, \quad s^\top x = 0, \end{aligned} \quad (21)$$

where the vector  $s \in \mathbf{R}^n$  is called the *dual slacks*. The problem of finding  $(\bar{x}, \bar{y}^*, \bar{s})$  satisfying (21) is also known as the *mixed linear complementarity problem*.

By using the vector of dual slacks  $s \in \mathbf{R}^n$ , the dual problem can be rewritten as

$$\begin{cases} \max_{p \in \mathbf{R}^m} & \langle b, p \rangle \\ \text{s.t.} & \Lambda^* y^* + c - s = 0, \quad s \geq 0. \end{cases} \quad (22)$$

We can see that the primal variable  $x$  is the Lagrange multiplier for the constraint  $\Lambda^* y^* + c \geq 0$  in the dual problem. However, the dual variables  $y^*$  and  $s$  are respectively Lagrange multipliers for the constraints  $\Lambda x = b$  and  $x \geq 0$  in the primal problem. These choices are not accidents.

**Theorem 5** *The vector  $\bar{x} \in \mathbb{R}^n$  is a solution of (19) if and only if there exists a Lagrange multipliers  $(\bar{y}^*, \bar{s}) \in \mathbb{R}^m \times \mathbb{R}^n$  for which the KKT optimality conditions (21) hold for  $(\bar{x}, \bar{y}^*, \bar{s})$ . Dually, the vector  $(\bar{y}^*, \bar{s}) \in \mathbb{R}^m \times \mathbb{R}^n$  is a solution of (22) if and only if there exists a Lagrange multiplier  $\bar{x} \in \mathbb{R}^n$  such that the KKT conditions (21) hold for  $(\bar{x}, \bar{y}^*, \bar{s})$ .*

The vector  $(\bar{x}, \bar{y}^*, \bar{s})$  is called a *primal-dual solution* of (19). The so-called *primal-dual methods* in mathematical programming are those methods to find primal-dual solutions  $(\bar{x}, \bar{y}^*, \bar{s})$  by applying variants of Newton's method to the three equations in (21) and modifying the search directions and steplengths so that the inequalities in (21) are satisfied at every iteration. If the inequalities are strictly satisfied, the methods are called *primal-dual interior-point methods*. In these methods, the so called *central path*  $\mathcal{C}_{\text{path}}$  plays a vital role in the theory of primal-dual algorithms. It is a parametrical curve of strictly feasible points defined by

$$\mathcal{C}_{\text{path}} = \{(x_\tau, y_\tau^*, s_\tau)^\top \in \mathbb{R}^{2n+m} : \tau > 0\}, \quad (23)$$

where each point  $(x_\tau, y_\tau^*, s_\tau)$  solves the following system:

$$\begin{aligned} \Lambda x &= b, & \Lambda^* y^* + c &= s, \\ x &> 0, & s > 0, & \quad u_i s_i = \tau, \quad i = 1, \dots, n. \end{aligned} \quad (24)$$

This problem has a unique solution  $(x_\tau, y_\tau^*, s_\tau)$  for each  $\tau > 0$  if and only if the *strictly feasible set*

$$\mathcal{F}_o = \left\{ (x, p, s) : \begin{array}{l} \Lambda x = b, \Lambda^* y^* + c = s, \\ x > 0, s > 0 \end{array} \right\}$$

is nonempty. A comprehensive study of the primal-dual interior-point methods in mathematical programming has been given in [3] and [2].

Duality; Nonconvexity; Global minimization;  
SuperLagrangian; Triduality; Triality

Consider the following general nonconvex extremum problem ( $\mathcal{P}$ ):

$$P(x) = \Phi(x, \Lambda(x)) \rightarrow \text{extremum}, \quad \forall x \in \mathcal{X}, \quad (1)$$

where  $\mathcal{X}$  is a locally convex topological vector space (l.c.s.),  $P: \mathcal{X} \rightarrow \overline{\mathbb{R}} := \mathbb{R} \cup \{-\infty\} \cup \{+\infty\}$  is a nonconvex and nonsmooth extended function, whose effective domain

$$\mathcal{X}_k = \text{dom } P = \{x \in \mathcal{X} : |P(x)| < +\infty\}$$

is a nonempty convex subset of  $\mathcal{X}$ ; the operator  $\Lambda: \mathcal{X} \rightarrow \mathcal{Y}$  is a continuous, generally nonlinear, mapping from  $\mathcal{X}$  to another l.c.s.  $\mathcal{Y}$ , and  $\Phi: \mathcal{X} \times \mathcal{Y} \rightarrow \overline{\mathbb{R}}$  is an associated extended function. Since the cost function  $P(x)$  is usually nonconvex, the problem ( $\mathcal{P}$ ) may possess many locally extremum (either minimum or maximum) solutions. The goal of *global optimization* is to find all the

local extrema of  $P(x)$  over the feasible set  $\mathcal{X}_k$ . Generally speaking, traditional direct approaches and algorithms for solving nonconvex, nonsmooth global optimization problems are usually very difficult. The classical saddle Lagrange duality methods as well as the well-known Fenchel–Rockafellar duality theory can be used mainly for solving convex problems. For nonconvex problems, there exists a so-called *duality gap* between the primal and the classical dual problems.

The *canonical dual transformation method* and associated *triduality theory* were proposed originally in finite deformation theory [1]. The key idea of this method is to choose a suitable nonlinear operator  $\Lambda: \mathcal{X} \rightarrow \mathcal{Y}$  such that  $\Phi(x, y)$  is either convex or concave in each of its variables. This method can be used to solve many nonconvex, nonsmooth global optimization problems.

### Canonical Dual Transformation

Let  $(\mathcal{X}, \mathcal{X}^*)$  be a pair of real linear spaces, placed in duality by a bilinear form  $\langle \cdot, \cdot \rangle: \mathcal{X} \times \mathcal{X}^* \rightarrow \mathbf{R}$ . For a given extended real-valued function  $P: \mathcal{X} \rightarrow \overline{\mathbf{R}}$ , the *subdifferential* of  $P$  at  $\bar{x} \in \mathcal{X}$  is a convex subset  $\partial^- P(\bar{x}) \subset \mathcal{X}^*$  such that for each  $\bar{x}^* \in \partial^- P(\bar{x})$ , we have

$$\langle \bar{x}^*, x - \bar{x} \rangle \leq P(x) - P(\bar{x}), \quad \forall x \in \mathcal{X}.$$

Dually, the *superdifferential* of  $P$  at  $\bar{x} \in \mathcal{X}$  is a convex subset  $\partial^+ P(\bar{x}) \subset \mathcal{X}^*$  such that for each  $\bar{x}^* \in \partial^+ P(\bar{x})$ , we have

$$\langle \bar{x}^*, x - \bar{x} \rangle \geq P(x) - P(\bar{x}), \quad \forall x \in \mathcal{X}.$$

Clearly, we always have  $\partial^+ P = -\partial^-(-P)$ . In convex analysis, it is convention that  $\partial^-$  is simply written as  $\partial$ . In nonconvex analysis,  $\partial$  stands for either  $\partial^-$  or  $\partial^+$ , i. e.

$$\partial = \{\partial^-, \partial^+\}.$$

If  $P$  is smooth, Gâteaux-differentiable at  $\bar{x} \in \mathcal{X}_a \subset \mathcal{X}$ , then

$$\partial P(\bar{x}) = \partial^- P(\bar{x}) = \partial^+ P(\bar{x}) = \{DP(\bar{x})\},$$

where  $DP: \mathcal{X}_a \rightarrow \mathcal{X}^*$  denotes the Gâteaux derivative of  $P$  at  $\bar{x}$ .

**Definition 1** The set of functions  $P: \mathcal{X} \rightarrow \overline{\mathbf{R}}$  which are either convex or concave is denoted by  $\Gamma(\mathcal{X})$ . In

particular, let  $\check{\Gamma}(\mathcal{X})$  denote the subset of functions  $P \in \Gamma(\mathcal{X})$  which are convex and  $\bar{\Gamma}(\mathcal{X})$  the subset of  $P \in \Gamma(\mathcal{X})$  which are concave.

The *canonical function space*  $\Gamma_G(\mathcal{X}_a)$  is a subset of functions  $P \in \Gamma(\mathcal{X}_a)$  which are Gâteaux differentiable on  $\mathcal{X}_a \subset \mathcal{X}$  and the duality mapping  $DP: \mathcal{X}_a \rightarrow \mathcal{X}_a^* \subset \mathcal{X}^*$  is invertible.

The *extended canonical function space*  $\Gamma_0(\mathcal{X})$  is a subset of functions  $P \in \Gamma(\mathcal{X})$  which are either convex, lower semicontinuous or concave, upper semicontinuous, and if  $P$  takes the values  $\pm\infty$ , then  $P$  is identically equal to  $\pm\infty$ .

By the Legendre–Fenchel transformation, the *supconjugate function* of an extended function  $P: \mathcal{X} \rightarrow \overline{\mathbf{R}}$  is defined by

$$P^\#(x^*) = \sup_{x \in \mathcal{X}} \{ \langle x, x^* \rangle - P(x) \}.$$

By the theory of convex analysis,  $P^\#: \mathcal{X}^* \rightarrow \overline{\mathbf{R}} := \mathbf{R} \cup \{+\infty\}$  is always convex and lower semicontinuous, i. e.  $P^\# \in \check{\Gamma}_0(\mathcal{X}^*)$ . Dually, the *subconjugate function* of  $P$ , defined by

$$P^b(x^*) = \inf_{x \in \mathcal{X}} \{ \langle x, x^* \rangle - P(x) \},$$

is always concave and upper semicontinuous, i. e.  $P^b \in \widehat{\Gamma}_0(\mathcal{X}^*)$ , and  $P^b = -P^\#$ . Both the super- and subconjugates are called *Fenchel conjugate functions* and we write  $P^* = \{P^b, P^\#\}$ . Thus the extended Fenchel transformation can be written as

$$P^*(x^*) = \text{ext} \{ \langle x, x^* \rangle - P(x) : \forall x \in \mathcal{X} \}, \quad (2)$$

where *ext* stands for extremum. Clearly, if  $P \in \Gamma_0(\mathcal{X})$ , we have the Fenchel equivalent relations, namely,

$$\begin{aligned} x^* \in \partial P(x) &\Leftrightarrow x \in \partial P^*(x^*) \\ &\Leftrightarrow P(x) + P^*(x^*) = \langle x, x^* \rangle. \end{aligned} \quad (3)$$

The pair  $(x, x^*)$  is called the *Fenchel duality pair* on  $\mathcal{X} \times \mathcal{X}^*$  if and only if equation (3) holds on  $\mathcal{X} \times \mathcal{X}^*$ .

The conjugate pair  $(x, x^*)$  is said to be a *Legendre duality pair* on  $\mathcal{X}_a \times \mathcal{X}_a^* \subset \mathcal{X} \times \mathcal{X}^*$  if and only if the equivalent relations

$$\begin{aligned} x^* = DP(x) &\Leftrightarrow x = DP^*(x^*) \\ &\Leftrightarrow P(x) + P^*(x^*) = \langle x, x^* \rangle \end{aligned} \quad (4)$$

hold on  $\mathcal{X}_a \times \mathcal{X}_a^*$ .

Let  $(\mathcal{Y}, \mathcal{Y}^*)$  be an another pair of locally convex topological real linear spaces paired in separating duality by the second bilinear form  $\langle \cdot; \cdot \rangle : \mathcal{Y} \times \mathcal{Y}^* \rightarrow \mathbf{R}$ . The so-called *geometrical operator*  $\Lambda : \mathcal{X} \rightarrow \mathcal{Y}$  is a continuous, Gâteaux differentiable operator such that for any given  $x \in \mathcal{X}_a \subset \mathcal{X}$ , there exists a  $y \in \mathcal{Y}_a \subset \mathcal{Y}$  satisfying the *geometrical equation*

$$y = \Lambda(x).$$

The directional derivative of  $y$  at  $\bar{x}$  in the direction  $x \in \mathcal{X}$  is then defined by

$$\delta y(\bar{x}; x) := \lim_{\theta \rightarrow 0^+} \frac{y(\bar{x} + \theta x) - y(\bar{x})}{\theta} = \Lambda_t(\bar{x})x,$$

where  $\Lambda_t(\bar{x}) = D\Lambda(\bar{x})$  denotes the Gâteaux derivative of the operator  $\Lambda$  at  $\bar{x}$ . For a given  $y^* \in \mathcal{Y}^*$ ,  $G_y^*(x) = \langle \Lambda(x); y^* \rangle$  is a real-valued function of  $x$  on  $\mathcal{X}$ . Its Gâteaux derivative at  $\bar{x} \in \mathcal{X}_a$  in the direction  $x \in \mathcal{X}$  is

$$\delta G_{y^*}(\bar{x}; x) = \langle \Lambda_t(\bar{x})x; y^* \rangle = \langle x, \Lambda_t^*(\bar{x})y^* \rangle,$$

where  $\Lambda_t^*(\bar{x}) : \mathcal{Y}^* \rightarrow \mathcal{X}^*$  is the adjoint operator of  $\Lambda_t$  associated with the two bilinear forms.

Let  $\Phi : \mathcal{X} \times \mathcal{Y} \rightarrow \overline{\mathbf{R}}$  be an extended function such that  $P(x) = \Phi(x, \Lambda(x))$ . If  $\Phi : \mathcal{X} \times \mathcal{Y} \rightarrow \overline{\mathbf{R}}$  is an extended canonical function, i. e.  $\Phi \in \Gamma_0(\mathcal{X}) \times \Gamma_0(\mathcal{Y})$ , the duality relations between the paired spaces  $(\mathcal{X}, \mathcal{X}^*)$  and  $(\mathcal{Y}, \mathcal{Y}^*)$  can be written as

$$x^* \in \partial_x \Phi(x, y), \quad y^* \in \partial_y \Phi(x, y). \quad (5)$$

On the product space  $\mathcal{X}_a \times \mathcal{Y}_a \subset \mathcal{X} \times \mathcal{Y}$ , if the canonical function  $\Phi(x, y)$  is finite and Gâteaux differentiable such that the feasible space  $\mathcal{X}_k$  can be written as

$$\mathcal{X}_k = \{x \in \mathcal{X}_a : \Lambda(x) \in \mathcal{Y}_a\}, \quad (6)$$

then on  $\mathcal{X}_k$ , the critical condition  $\delta P(\bar{x}; x) = \langle x, DP(\bar{x}) \rangle = 0, \forall x \in \mathcal{X}_k$ , leads to the Euler equation

$$D_x \Phi(\bar{x}, \Lambda(\bar{x})) + \Lambda_t^*(\bar{x})D_y \Phi(\bar{x}, \Lambda(\bar{x})) = 0, \quad (7)$$

where  $D_x \Phi$  and  $D_y \Phi$  denote the partial Gâteaux derivatives of  $\Phi$  with respect to  $x$  and  $y$ , respectively. Since  $\Phi \in \Gamma_G(\mathcal{X}_a) \times \Gamma_G(\mathcal{Y}_a)$  is a canonical function, the Gâteaux derivative  $D\Phi : \mathcal{X}_a \times \mathcal{Y}_a \rightarrow \mathcal{X}_a^* \times \mathcal{Y}_a^* \subset \mathcal{X}^* \times \mathcal{Y}^*$  is a monotone mapping, i. e. there exists a pair  $(\bar{x}^*, \bar{y}^*) \in \mathcal{X}^* \times \mathcal{Y}^*$  such that

$$-\bar{x}^* = D_x \Phi(\bar{x}, \Lambda(\bar{x})), \quad \bar{y}^* = D_y \Phi(\bar{x}, \Lambda(\bar{x})).$$

Thus, in terms of canonical dual variables  $\bar{x}^*$  and  $\bar{y}^*$ , the Euler equation (7) can be written in the so-called *balance* (or *equilibrium*) equilibrium

$$\bar{x}^* = \Lambda_t^*(\bar{x})\bar{y}^*, \quad (8)$$

which linearly depends on the dual variable  $\bar{y}^*$ .

**Definition 2** Suppose that for a given problem  $(\mathcal{P})$ , the geometrical operator  $\Lambda : \mathcal{X} \rightarrow \mathcal{Y}$  can be chosen in such a way that  $P(x) = \Phi(x, \Lambda(x))$ ,  $\Phi \in \Gamma_G(\mathcal{X}_a) \times \Gamma_G(\mathcal{Y}_a)$  and  $\mathcal{X}_k = \{x \in \mathcal{X}_a : \Lambda(x) \in \mathcal{Y}_a\}$ . Then

- 1) the transformation  $\{P; \mathcal{X}_k\} \rightarrow \{\Phi; \mathcal{X}_a \times \mathcal{Y}_a\}$  is called the *canonical transformation*, and  $\Phi : \mathcal{X}_a \times \mathcal{Y}_a \rightarrow \mathbf{R}$  is called the *canonical function associated with  $\Lambda$* ;
- 2) the problem  $(\mathcal{P})$  is called *geometrically nonlinear* (respectively, *geometrically linear*) if  $\Lambda : \mathcal{X} \rightarrow \mathcal{Y}$  is nonlinear (respectively, linear); it is called *physically nonlinear* (respectively, *physically linear*) if the duality mapping  $D\Phi : \mathcal{X}_a \times \mathcal{Y}_a \rightarrow \mathcal{X}_a^* \times \mathcal{Y}_a^*$  is nonlinear (respectively, linear); it is called *fully nonlinear* if it is both geometrically and physically nonlinear.

The canonical transformation plays a fundamental role in duality theory of global optimization. By this definition, the governing equation (7) for fully nonlinear problems can be written in the *tricanonical forms*, namely,

- 1) geometrical equation:  $y = \Lambda(x)$ ;
- 2) physical relations:  $(-x^*, y^*) \in \partial \Phi(x, y)$ ;
- 3) balance equation:  $x^* = \Lambda_t^*(x)y^*$ .

Since  $\Lambda : \mathcal{X} \rightarrow \mathcal{Y}$  is Gâteaux differentiable, for any given  $x \in \mathcal{X}$  we have the *operator decomposition*

$$\Lambda(x) = \Lambda_t(x)x + \Lambda_c(x), \quad (9)$$

where  $\Lambda_c = \Lambda - \Lambda_t$  is the *complementary operator* of  $\Lambda_t$ . By this operator decomposition, the relation between the two bilinear forms reads

$$\langle \Lambda(x); y^* \rangle = \langle x, \Lambda_t^*(x)y^* \rangle - G(x, y^*),$$

where  $G(x, y^*) = \langle -\Lambda_c(x); y^* \rangle$  is the so-called *complementary gap function*, introduced in [2]. This gap plays an important role in the canonical dual transformation methods. A framework for the fully nonlinear system is

$$\begin{array}{ccc} x \in \mathcal{X} & \leftarrow \langle x, x^* \rangle \rightarrow & \mathcal{X}^* \ni x^* \\ \Lambda_t + \Lambda_c = \Lambda \downarrow & & \uparrow \Lambda_t^* = (\Lambda - \Lambda_c)^* \\ y \in \mathcal{Y} & \leftarrow \langle y, y^* \rangle \rightarrow & \mathcal{Y}^* \ni y^* \end{array}$$

Extensive illustrations of the canonical transformation and the tricanonical forms in mathematical physics and variational analysis can be found in [1].

Very often, the extended canonical function  $\Phi$  can be written in the form

$$\Phi(x, y) = W(y) - F(x),$$

where  $F \in \Gamma(\mathcal{X})$  and  $W \in \Gamma(\mathcal{Y})$  are extended canonical functions. The duality relations (5) in this special case take the forms

$$x^* \in \partial F(x), \quad y^* \in \partial W(y).$$

If  $F \in \Gamma_G(\mathcal{X}_a)$  and  $W \in \Gamma_G(\mathcal{Y}_a)$  are Gâteaux differentiable, the Euler equation (7) reads

$$\Lambda_t^*(\bar{x})DW(\Lambda(\bar{x})) - DF(\bar{x}) = 0.$$

If  $\Lambda : \mathcal{X} \rightarrow \mathcal{Y}$  is linear, and  $W \in \Gamma(\mathcal{Y})$  is quadratic such that  $DW = Cy$ , where  $C : \mathcal{Y} \rightarrow \mathcal{Y}^*$  is a linear operator, then the governing equations for linear system can be written as

$$\Lambda^*CAx = Ax = x^*.$$

For conservative systems, the operator  $A = \Lambda^*CA$  is usually symmetric. In static systems,  $C$  is usually positive definite and the associated total potential  $P$  is convex. However, in dynamical systems,  $C$  is indefinite and  $P$  is called the total action, which is usually a d.c. function in convex Hamilton systems.

### Triality Theory

We assume that for any given nonconvex extended function  $P : \mathcal{X} \rightarrow \overline{\mathbb{R}}$ , there exists a general nonlinear operator  $\Lambda : \mathcal{X} \rightarrow \mathcal{Y}$  and a canonical function  $W \in \Gamma(\mathcal{Y})$  such that the canonical transformation can be written as

$$P(x) = W(\Lambda(x)) - \langle x, c \rangle, \tag{10}$$

where  $c \in \mathcal{X}^*$  is a given source variable. Since  $F(x) = x, c$  is a linear function, the Hamiltonian  $H(x, y^*) = W^*(y^*) + x, c$  is a canonical function on  $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}^*$  and the extended Lagrangian reads

$$L(x, y^*) = \langle \Lambda(x); y^* \rangle - W^*(y^*) - \langle x, c \rangle. \tag{11}$$

For a fixed  $y^* \in \mathcal{Y}^*$ , the convexity of  $L(\cdot, y^*) : \mathcal{X} \rightarrow \overline{\mathbb{R}}$  depends on  $\Lambda(x)$  and  $y^* \in \mathcal{Y}^*$ .

Let  $\mathcal{Z}_a = \mathcal{X}_a \times \mathcal{Y}_a^* \subset \mathcal{Z}$  be the effectivedomain of  $L$ , and let  $\mathcal{L}_c \subset \mathcal{Z}_a$  be a critical point set of  $L$ , i. e.

$$\mathcal{L}_c = \{(\bar{x}, \bar{y}) \in \mathcal{X}_a \times \mathcal{Y}_a^* : DL(\bar{x}, \bar{y}^*) = 0\}.$$

For any given critical point  $(\bar{x}, \bar{y}^*) \in \mathcal{L}_c$ , we let  $\mathcal{X}_r \times \mathcal{Y}_r^*$  be its neighborhood such that on  $\mathcal{X}_r \times \mathcal{Y}_r^*$ , the pair  $(\bar{x}, \bar{y}^*)$  is the only critical point of  $L$ . The following results of fundamental importance in global optimization.

**Theorem 3 (Triality theorem)** *Suppose that  $W \in \Gamma(\mathcal{Y}_a)$  is convex,  $(\bar{x}, \bar{y}^*) \in \mathcal{L}_c$  is a critical point of  $L$  and  $\mathcal{X}_r \times \mathcal{Y}_r^*$  is a neighborhood of  $(\bar{x}, \bar{y}^*)$ .*

*If  $\langle \Lambda(x); \bar{y}^* \rangle$  is convex on  $\mathcal{X}_r$ , then*

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \min_{x \in \mathcal{X}_r} \max_{y^* \in \mathcal{Y}_r^*} L(x, y^*) \\ &= \max_{y^* \in \mathcal{Y}_r^*} \min_{x \in \mathcal{X}_r} L(x, y^*). \end{aligned} \tag{12}$$

*However, if  $\langle \Lambda(x); \bar{y}^* \rangle$  is concave on  $\mathcal{X}_r$ , then either*

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \min_{x \in \mathcal{X}_r} \max_{y^* \in \mathcal{Y}_r^*} L(x, y^*) \\ &= \min_{y^* \in \mathcal{Y}_r^*} \max_{x \in \mathcal{X}_r} L(x, y^*), \end{aligned} \tag{13}$$

or

$$\begin{aligned} L(\bar{x}, \bar{y}^*) &= \max_{x \in \mathcal{X}_r} \max_{y^* \in \mathcal{Y}_r^*} L(x, y^*) \\ &= \max_{y^* \in \mathcal{Y}_r^*} \max_{x \in \mathcal{X}_r} L(x, y^*). \end{aligned} \tag{14}$$

Since  $W \in \Gamma(\mathcal{Y}_a)$  is a canonical function, we always have

$$P(x) = \text{ext} \{L(x, y^*) : y^* \in \mathcal{Y}^*\}, \quad \forall x \in \mathcal{X}_k. \tag{15}$$

On the other hand, for a given Gâteaux differentiable geometrical mapping  $\Lambda : \mathcal{X}_a \rightarrow \mathcal{Y}_a$ , the criticality condition  $D_x L(\bar{x}, y^*) = 0$  leads to the equilibrium equation

$$\Lambda_t^*(\bar{x})y^* = c. \tag{16}$$

If there exists a subspace  $\mathcal{Y}_s^* \subset \mathcal{Y}_a^*$  such that for any  $y^* \in \mathcal{Y}_s^*$  and a given source variable  $c \in \mathcal{X}^*$ , the equation (16) can be solved for  $\bar{x} = \bar{x}(y^*)$ , then by the operator decomposition (9), the dual function  $P^d : \mathcal{Y}_s^* \rightarrow \mathbf{R}$  can be written explicitly in the form

$$\begin{aligned} P^d(y^*) &= \text{sta} \{L(x, y^*) : x \in \mathcal{X}\} \\ &= -G^d(y^*) - W^*(y^*), \quad \forall y^* \in \mathcal{Y}_s^*, \end{aligned}$$

where  $G^d: \mathcal{Y}^* \rightarrow \mathbf{R}$  is the so-called *pure complementary gap function*, defined by

$$G^d(y^*) = G(\bar{x}(y^*), y^*) = -\langle \Lambda_c(\bar{x}(y^*)); y^* \rangle.$$

For any given critical point  $(\bar{x}, \bar{y}^*) \in \mathcal{L}_c$ , we have  $G^d(\bar{y}^*) = \langle \bar{x}, c \rangle - \langle \Lambda(\bar{x}(\bar{y}^*)); \bar{y}^* \rangle$ . Thus, the Legendre duality relations among the canonical functions  $W$  and  $W^*$  lead to

$$P(\bar{x}) - P^d(\bar{y}^*) = 0, \quad \forall (\bar{x}, \bar{y}^*) \in \mathcal{L}_c. \quad (17)$$

This identity shows that there is no duality gap between the nonconvex function  $P$  and its canonical dual function  $P^d$ . Actually the duality gap, which exists in classical duality theories, is now recovered by the complementary gap function  $G(\bar{x}, \bar{y}^*)$ .

**Theorem 4 (Triduality theorem)** *Suppose that  $W \in \check{I}(\mathcal{Y}_a)$  is a critical point of  $L$  and  $\mathcal{X}_r \times \mathcal{Y}_r^*$  is a neighborhood of  $(\bar{x}, \bar{y}^*)$ . If  $\langle \Lambda(x); \bar{y}^* \rangle$  is convex on  $\mathcal{X}_r$ , then*

$$P(\bar{x}) = \min_{x \in \mathcal{X}_r} P(x) \Leftrightarrow P^d(\bar{y}^*) = \max_{y^* \in \mathcal{Y}_r^*} P^d(y^*).$$

However, if  $\langle \Lambda(x); \bar{y}^* \rangle$  is concave on  $\mathcal{X}_r$ , then

$$\begin{aligned} P(\bar{x}) &= \min_{x \in \mathcal{X}_r} P(x) \Leftrightarrow P^d(\bar{y}^*) = \min_{y^* \in \mathcal{Y}_r^*} P^d(y^*); \\ P(\bar{x}) &= \max_{x \in \mathcal{X}_r} P(x) \Leftrightarrow P^d(\bar{y}^*) = \max_{y^* \in \mathcal{Y}_r^*} P^d(y^*). \end{aligned}$$

**Example 5** We now illustrate the application of the interesting triduality theory for solving the following nonconvex optimization problem in  $\mathcal{X} = \mathbf{R}^n$ ,

$$P(x) = \frac{a}{2} \left( \frac{1}{2} \|Ax\|^2 - \mu \right)^2 - x^\top c \rightarrow \text{sta}, \quad \forall x,$$

where  $a, \mu > 0$  are given parameters,  $c \in \mathbf{R}^n$  is a given vector, and  $A: \mathbf{R}^n \rightarrow \mathbf{R}^m$  is a matrix. The Euler equation associated with this nonconvex stationary problem is a nonlinear algebraic equation in  $\mathbf{R}^n$

$$a \left( \frac{1}{2} \|A\bar{x}\|^2 - \mu \right) C\bar{x} = c,$$

where  $C = A^\top A = C^\top \in \mathbf{R}^{nn}$ . We are interested in finding all the critical points of  $P$ . To set this nonconvex problem in our framework, we let  $\mathcal{X} = \mathbf{R}^n = \mathcal{X}^*$ , and  $\Lambda: \mathbf{R}^n \rightarrow \mathcal{Y} = \mathbf{R}$  a quadratic operator

$$y = \Lambda(x) = \frac{1}{2} \|Ax\|^2 - \mu = \frac{1}{2} x^\top Cx - \mu.$$

Since  $F(x) = \langle x, c \rangle = x^\top c$  is a linear function on  $\mathbf{R}^n$ , the admissible space  $\mathcal{X}_a = \mathcal{X} = \mathbf{R}^n$ . By the fact that  $x^* = DF(x) = c$ , the range for the canonical mapping  $DF: \mathcal{X} \rightarrow \mathcal{X}^* = \mathbf{R}$  is a hyperplane in  $\mathbf{R}^n$ , i. e.

$$\mathcal{X}_a^* = \{x^* \in \mathbf{R}^n: x^* = c\}.$$

The feasible set for the primal problem is  $\mathcal{X}_k = \{x \in \mathcal{X}_a: \Lambda(x) \in \mathcal{Y}_a\} = \mathbf{R}^n$ .

By the fact that  $x^\top Cx \geq 0, \forall x \in \mathcal{X}_a = \mathcal{X} = \mathbf{R}^n$ , the range for the geometrical mapping  $\Lambda: \mathcal{X}_a \rightarrow \mathbf{R}$  is a closed convex set in  $\mathbf{R}$

$$\mathcal{Y}_a = \{y \in \mathbf{R}: y \geq -\mu\} \subset \mathcal{Y} = \mathbf{R}.$$

On the admissible subset  $\mathcal{Y}_a \subset \mathcal{Y} = \mathbf{R}$ , the canonical function  $W(y) = (1/2)ay^2$  is quadratic. The range for the constitutive mapping  $DW: \mathcal{Y}_a \rightarrow \mathcal{Y}^* = \mathbf{R}$  is also a closed convex set in  $\mathbf{R}$ ,

$$\mathcal{Y}_a^* = \{y^* \in \mathbf{R}: y^* \geq -a\mu\}.$$

On  $\mathcal{Y}_a^*$ , the Legendre conjugate of  $W$  is also strictly convex

$$W^*(y^*) = \frac{1}{2} a^{-1} y^{*2}, \quad (18)$$

and the Legendre duality relations hold on  $\mathcal{Y}_a \times \mathcal{Y}_a^*$ .

On  $\mathcal{X}_a \times \mathcal{Y}_a^* = \mathbf{R}^n \times \mathbf{R}$ , the extended Lagrangian in this case reads

$$L(x, y^*) = \frac{1}{2} y^* x^\top Cx - \mu y^* - \frac{1}{2} a^{-1} y^{*2} - x^\top c.$$

It is easy to check that the dual function associated with  $L$  is

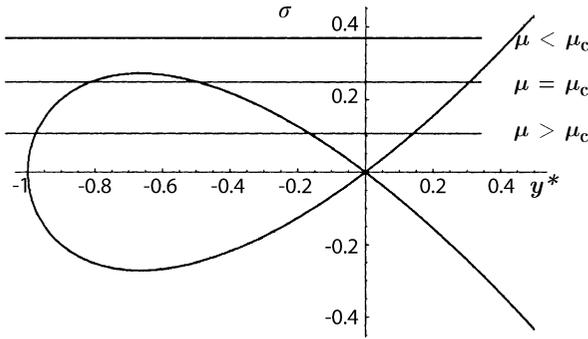

$$P^d(y^*) = \frac{1}{2} (y^*)^{-1} c^\top Cc - \mu y^* - \frac{1}{2a} y^{*2}.$$

The dual Euler-Lagrange equation is an algebraic equation in  $\mathbf{R}$ :

$$(\mu + a^{-1} y^*) y^{*2} = \frac{1}{2} \sigma^2, \quad (19)$$

where  $\sigma^2 = c^\top Cc$  is a constant. Since  $C \in \mathbf{R}^{nn}$  is positive definite, this equation holds only on  $\mathcal{Y}_a^*$ .

In algebraic geometry, the dual Euler-Lagrange equation (19) is the so-called singular algebraic curve in  $(y^*, \sigma)$ -space (see Fig. 1). For a given parameter  $\mu$  and  $c$

Duality Theory: Triduality in Global Optimization, Figure 1  
Singular algebraic curve

$\in \mathbf{R}^n$ , this dual equation has at most three real roots  $y_k^*$   $\in \mathcal{Y}_a^*$ ,  $k = 1, 2, 3$ , which leads to the primal solution

$$x_k = y_k^* C^+ c, \quad k = 1, 2, 3,$$

where  $C^+$  stands for the generalized inverse of  $C$ . We know that each  $(x_k, y_k^*)$  is a critical point of  $L$  and

$$P(x_k) = L(x_k, y_k^*) = P^d(y_k^*), \quad k = 1, 2, 3.$$

In the case of  $n = 1$ , the cost function

$$P(x) = \frac{1}{2} a \left( \frac{1}{2} x^2 - \mu \right)^2 - cx$$

is a *double-well function* (see Fig. 2, solid line), which appears in many physical systems. The graph of the canonical dual function

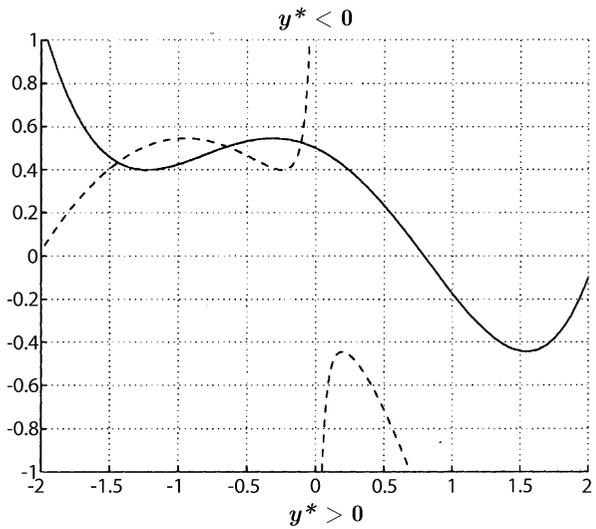

$$P^d(y^*) = \frac{1}{2} \frac{c^2}{y^*} - \mu y^* - \frac{y^{*2}}{2a}$$

has two branches (Fig. 2, dashed line). It is easy to prove (see [1]) that if  $\mu > \mu_c = 1.5 (\sigma/a)^{2/3}$ , the dual Euler-Lagrange equation (19) has three roots  $y_1^* > 0 > y_2^* > y_3^*$ , corresponding to three critical points of  $P^d$  (see Fig. 2). Then,  $y_1^*$  is a global maximizer of  $P^d$ ,  $x_1 = \sigma/y_1^*$  is a global minimizer of  $P$ ,  $P^d$  takes local minimum and local maximum values at  $y_2^*$  and  $y_3^*$ , respectively,  $x_2 = \sigma/y_2^*$  is a local maximizer of  $P$ , while  $x_3 = \sigma/y_3^*$  is a local minimizer.

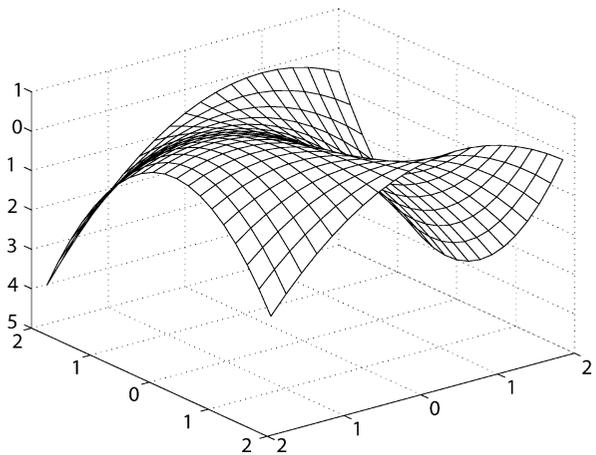

The Lagrangian associated with this double-well energy is

$$L(x, y^*) = \frac{1}{2} x^2 y^* - \left( \frac{1}{2a} y^{*2} + \mu y^* \right) - y^* x.$$

It is a saddle function for  $y^* > 0$ . If  $y^* < 0$ , it is a supercritical point function (see Fig. 3).

### Introduction

We consider the application of Dijkstra's algorithm for solving the following optimization problem

$$\min_{x \in \Omega} \|x^0 - x\|, \quad (1)$$

where  $x^0$  is a given point,  $\Omega$  is a closed and convex set, and  $\|z\|^2 = \langle z, z \rangle$  defines a real inner product in the space. The solution  $x^*$  is called the projection of  $x^0$  onto  $\Omega$  and is denoted by  $P_\Omega(x^0)$ . Dijkstra's algorithm for solving (1) has been extensively studied since it fits in many different applications (see [5,21,22,23,27,28,29,32,24,42,42,45]).

For simplicity, we consider the case

$$\Omega = \cap_{i=1}^p \Omega_i, \quad (2)$$

where  $\Omega_i$  are closed and convex sets in  $\mathbb{R}^n$ , for  $i = 1, 2, \dots, p$ , and  $\Omega \neq \emptyset$ . Moreover, we assume that for any  $z \in \mathbb{R}^n$  the calculation of  $P_\Omega(z)$  is not trivial; whereas, for each  $\Omega_i$ ,  $P_{\Omega_i}(z)$  is easy to obtain as in the case of a box, an affine subspace, or a sphere. For the not feasible case (i.e., when  $\Omega = \emptyset$ ) the behavior of Dijkstra's algorithm is treated in [2,6,37].

Dijkstra's alternating projection algorithm is a cyclic scheme for finding asymptotically the projection of a given point onto the intersection of a finite number of closed convex sets. Roughly speaking, it iterates by projecting in a clever way onto each of the convex sets individually. The algorithm was originally proposed by Dijkstra [20] for closed and convex cones in the Euclidean space  $\mathbb{R}^n$ , and later extended by Boyle and Dijkstra [7] for closed and convex sets in a Hilbert space. It was rediscovered by Han [30] using duality theory, and the linear rate of convergence was established by Deutsch and Hundal [18] for the polyhedral case (see also [19,43,44]).

Dijkstra's algorithm belongs to the general family of alternating projection methods, that dates back to von Neumann [46] who treated the problem of finding the projection of a given point in a Hilbert space onto the intersection of two closed subspaces. Later, Cheney and Goldstein [15] extended the analysis of von Neumann's alternating projection scheme to the case of two closed and convex sets. In particular, they established convergence under mild assumptions. However, the limit point need not be the closest in the intersection. Therefore, the alternating projection method, proposed by von Neumann, is not useful for problem (1). Fortunately, Dijkstra [20] found the clever modification of von Neumann's scheme for which convergence to the solution point is guaranteed. For a complete discussion on alternating projection methods see Deutsch [17].

Dijkstra's algorithm has been extended in several different ways. Gaffke and Mathar [24] proposed, via duality, a family of simultaneous Dijkstra's algorithm in Hilbert space. Later Iusem and De Pierro [37] established the convergence of the simultaneous version considering also the inconsistent case in the Euclidean space  $\mathbb{R}^n$ . Bauschke and Borwein [2] further analyzed Dijkstra's algorithm for two sets, that appears frequently in applications and in particular generalized the results in [37]. In [36] it was established that for linear inequality constraints the method of Dijkstra re-

duces to the method proposed by Hildreth [33] in his pioneer work on dual alternating projections. See also [40] for further analysis and extensions.

Dykstra’s algorithm has also been generalized by Deutsch and Hundal [35] to an infinite family of sets, and also to allow a random ordering, instead of cyclic, of the projections onto the closed convex sets. More recently, it has also been generalized by Bregman et al. [9] to avoid the projection onto each one of the convex sets in every cycle. Instead, projections onto either a suitable half space of the intersection of two half spaces are used. Further results concerning the connection between Bregman distances and Dykstra’s algorithm can be found in [3,4,8,14]. For the advantages of projecting cyclically onto suitable half spaces, see the previous work by Iusem and Svaiter [38,39].

A computational experiment comparing Dykstra’s algorithm and the Halpern-Lions-Wittmann-Bauschke algorithm [1] on linear best approximation test problems can be found in [12].

**Formulations**

**Dykstra’s Algorithm**

Dykstra’s algorithm solves (1), (2) by generating two sequences: the iterates  $\{x_i^k\}$  and the increments  $\{y_i^k\}$ . These sequences are defined by the following recursive formulae:

$$\begin{aligned} x_0^k &= x_p^{k-1}, \\ x_i^k &= P_{\Omega_i}(x_{i-1}^k - y_i^{k-1}), \quad i = 1, 2, \dots, p, \\ y_i^k &= x_i^k - (x_{i-1}^k - y_i^{k-1}), \quad i = 1, 2, \dots, p, \end{aligned} \tag{3}$$

for  $k = 1, 2, \dots$  with initial values  $x_p^0 = x^0$  and  $y_i^0 = 0$  for  $i = 1, 2, \dots, p$ .

**Remarks**

1. For the sake of simplicity, the projecting control index  $i(k)$  used in (3) is the most common one:  $i(k) = k \bmod p + 1$ , for all  $k \geq 0$ . However, more advanced control indices can also be used, as long as they satisfy some minimal theoretical requirements (see e. g., [35]).
2. The increment  $y_i^{k-1}$  associated with  $\Omega_i$  in the previous cycle is always subtracted before projecting onto  $\Omega_i$ . Only one increment (the last one) for each  $\Omega_i$  needs to be stored.

3. If  $\Omega_i$  is a closed affine subspace, then the operator  $P_{\Omega_i}$  is linear and it is not required, in the  $k$ th cycle, to subtract the increment  $y_i^{k-1}$  before projecting onto  $\Omega_i$ . Thus, for affine subspaces, Dykstra’s procedure reduces to the alternating projection method of von Neumann [46].
4. For  $k = 1, 2, \dots$  and  $i = 1, 2, \dots, p$ , it is clear from (3) that the following relations hold

$$x_p^{k-1} - x_1^k = y_1^{k-1} - y_1^k, \tag{4}$$

$$x_{i-1}^k - x_i^k = y_i^{k-1} - y_i^k, \tag{5}$$

where  $x_p^0 = x^0$  and  $y_i^0 = 0$ , for all  $i = 1, 2, \dots, p$ . For the sake of completeness we now present the key theorem associated with Dykstra’s algorithm.

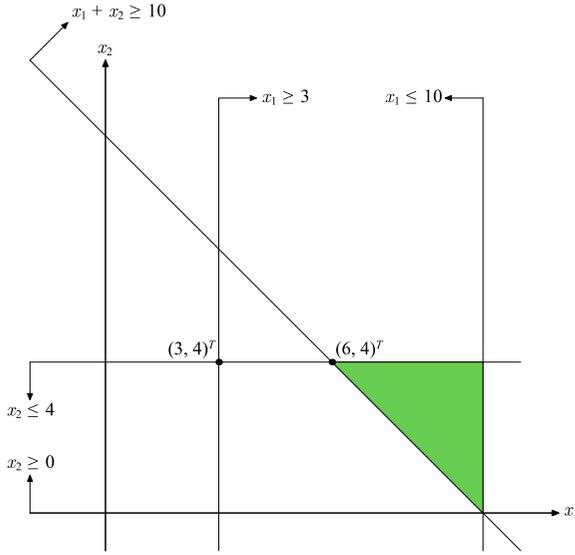

**Theorem 1 Boyle and Dykstra, 1986 [7]** *Let  $\Omega_1, \dots, \Omega_p$  be closed and convex sets of  $\mathbb{R}^n$  such that  $\Omega = \bigcap_{i=1}^p \Omega_i \neq \emptyset$ . For any  $i = 1, 2, \dots, p$  and any  $x^0 \in \mathbb{R}^n$ , the sequence  $\{x_i^k\}$  generated by (3) converges to  $x^* = P_{\Omega}(x^0)$  (i. e.,  $\|x_i^k - x^*\| \rightarrow 0$  as  $k \rightarrow \infty$ ).*

We now discuss the delicate issue of stopping Dykstra’s algorithm within a certain previously established tolerance that indicates the distance of the current iterate to the unique solution.

**Difficulties with some Commonly Used Stopping Criteria**

In some applications it is possible to obtain a *somehow* natural stopping rule, associated with the problem at hand. For example, when solving a linear system,  $Ax = b$ , by alternating projection methods [10,25], the residual vector ( $r(x) = b - Ax$ ) is usually available and yields some interesting and robust stopping rules. Another example appears in image reconstruction for which a *good and feasible* image tells the user that it is time to stop the process [13,16]. Similar circumstances are present in some other specific applications (e. g. saddle point problems [31], and molecular biology [28,29]).

However, in general, this is not the case, and we are left with the information produced only by the internal computations, i. e., the sequence of iterates and perhaps the sequence of increments, and some inner products. For this general case, a popular stopping rule

**Dijkstra's Algorithm and Robust Stopping Criteria, Figure 1**  
 Feasible set  $\Omega = \Omega_1 \cap \Omega_2$  in  $\mathbb{R}^2$

is to monitor the subsequence of projections onto one particular convex set,  $\Omega_i$ , and stop the process when the distance, in norm, of two consecutive projections is less than or equal to a previously established tolerance [26,27,32,41].

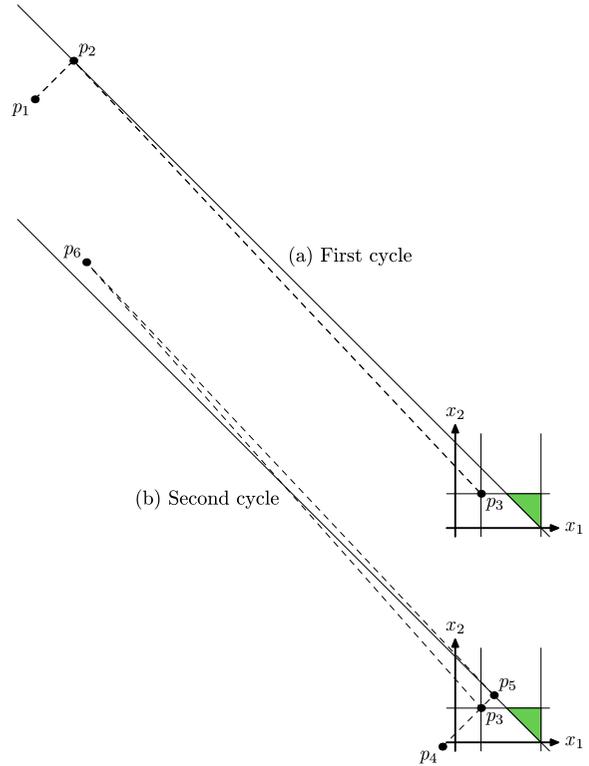

Another commonly used criterion, that is claimed to improve the previous one (e.g. [7,22,28,45]) is to somehow compute an average of all the projections at each cycle of projections, and then stop the process when the distance, in norm, of two consecutive of those average projections is less than or equal to a previously established tolerance.

Finally, we would like to mention that another criterion, that is also designed to improve any of the two criteria above, is to check any of the previously described rules during  $N$  consecutive cycles, where  $N$  is a fixed positive integer.

None of these stopping rules is a trustable choice. In [6], Birgin and Raydan presented the example below to establish that they can fail even for a two dimensional problem. (see Figs. 1 and 2).

Consider the closed and convex set  $\Omega = \Omega_1 \cap \Omega_2$ , where  $\Omega_1 = \{x \in \mathbb{R}^2 \mid x_1 + x_2 \geq 10\}$  is a half space and  $\Omega_2 = \{x \in \mathbb{R}^2 \mid 3 \leq x_1 \leq 10, 0 \leq x_2 \leq 4\}$  is a box. This closed and convex set in  $\mathbb{R}^2$  is shown in Fig. 1.

Let  $x^0 = (-49, 50)^T$  and let us use Dijkstra's algorithm to find the closest point to  $x^0$  in  $\Omega$ . In Fig. 2

**Dijkstra's Algorithm and Robust Stopping Criteria, Figure 2**  
 First two cycles of Dijkstra's algorithm to find the projection of  $x^0 = (-49, 50)^T$  onto  $\Omega = \Omega_1 \cap \Omega_2$

we can see the first two cycles of this convergent process. Since  $y_1^0 = y_2^0 = 0$  (null initial increments) then for the first cycle we project  $x^0$  onto  $\Omega_1$  to obtain  $p_2 = x_1^1 = (-44.5, 54.5)^T$  and then we project  $p_2$  onto  $\Omega_2$  to obtain  $p_3 = x_2^1 = (3, 4)^T$ . For the second cycle, the increments are not null ( $y_1^1 = (4.5, 4.5)^T$  and  $y_2^1 = (47.5, -50.5)^T$ ), and we start from  $p_3$ . First we project  $p_4 = p_3 - y_1^1$  onto  $\Omega_1$  to obtain  $p_5 = x_1^2$ . Then we project  $p_6 = p_5 - y_2^1$  onto  $\Omega_2$  to obtain  $p_3$  again. Hence  $x_2^2 = x_2^1$ . The increment associated with  $\Omega_2$  is large enough to take the iterate back to the quadrant where the projection onto the box is again  $p_3$ . As discussed in [6], this phenomenon will occur until cycle 32, i.e.,  $p_3 = x_2^1 = x_2^2 = \dots = x_2^{32}$ .

Moreover, by choosing  $x^0$  far enough, this misleading event can be repeated for as many cycles as any previously established positive integer  $N$ . Eventually the size of the increments will be reduced and convergence to  $x^*$  will be observed.

## Robust Stopping Criteria

After a close inspection of the proof of the Boyle and Dykstra's theorem, Birgin and Raydan [6] proposed some robust stopping criteria for Dykstra's algorithm. For that they first established the following result.

**Theorem 2** *Let  $x^0$  be any element of  $\mathbb{R}^n$ . Consider the sequences  $\{x_i^k\}$  and  $\{y_i^k\}$  generated by (3) and define  $c^k$  as*

$$c^k = \sum_{m=1}^k \sum_{i=1}^p \|y_i^{m-1} - y_i^m\|^2 + 2 \sum_{m=1}^{k-1} \sum_{i=1}^p \langle y_i^m, x_i^{m+1} - x_i^m \rangle. \quad (6)$$

Then, in the  $k$ th cycle of Dykstra's algorithm,

$$\|x^0 - x^*\|^2 \geq c^k. \quad (7)$$

Moreover, at the limit when  $k$  goes to infinity, equality is attained in (7).

Based on the previous theorem, let us now write  $c^k$  as follows:

$$c^k = c_L^k + c_S^k,$$

where

$$c_L^k = \sum_{m=1}^k c_I^m, \quad (8)$$

$$c_I^m = \sum_{i=1}^p \|y_i^{m-1} - y_i^m\|^2 \quad (9)$$

and

$$c_S^k = 2 \sum_{m=1}^{k-1} \sum_{i=1}^p \langle y_i^m, x_i^{m+1} - x_i^m \rangle.$$

Both  $c_L^k$  and  $c_S^k$  are monotonically nondecreasing by definition. Moreover in [6], the following theorem is also established.

**Theorem 3** *Consider the sequences  $\{x_i^k\}$  and  $\{y_i^k\}$  generated by (3), and  $c^k$ ,  $c_L^k$  and  $c_I^k$  as defined in (6), (8) and (9), respectively. For any  $k \in \mathbb{N}$ , if  $x^k \neq x^*$  then  $c_I^{k+1} > 0$  and, hence,  $c_L^k < c_L^{k+1}$  and  $c^k < c^{k+1}$ .*

The results established in Theorems 2 and 3 are combined in [6] to propose robust stopping criteria. Notice that  $\{c_L^k\}$  and  $\{c^k\}$  are monotonically increasing and

convergent, and also that  $\{c_I^k\}$  converges to zero. Therefore we can stop the process when

$$c_I^k = \sum_{i=1}^p \|y_i^{k-1} - y_i^k\|^2 \leq \varepsilon$$

or, similarly, when

$$c^k - c^{k-1} = c_I^k + 2 \sum_{i=1}^p \langle y_i^{k-1}, x_i^k - x_i^{k-1} \rangle \leq \varepsilon, \quad (10)$$

where  $\varepsilon > 0$  is a sufficiently small tolerance. As  $c^k$  may grow fast, computing  $c^k - c^{k-1}$  may give inaccurate results due to loss of accuracy in floating point representation and, hence, cancellation. So, for the criterion in (10), it is recommendable to test convergence with the second expression.

The computation of  $c_I^k$  involves the squared-norm  $\|y_i^{k-1} - y_i^k\|^2$ , for  $i = 1, 2, \dots, p$ . By (5),  $y_i^k = y_i^{k-1} + v$ , where  $v = x_i^k - x_i^{k-1}$  is a temporary  $n$ -dimensional array needed in the computation of Dykstra's algorithm. So, the computational cost involved in the calculation of  $c_I^k$  is just the cost of the extra inner product  $\langle v, v \rangle$  at each iteration.

The computation of  $c^k$  involves the calculation of  $c_I^k$  plus an extra term. The computational of this extra term is also small and involves an inner product and the difference of two vectors per iteration. But, in contrast with the computation of  $c_I^k$  which does not require additional savings, the computation of the extra term requires to save  $p$  extra  $n$ -dimensional arrays (the same amount of memory required in Dykstra's algorithm to save the increments). So, the computation of  $c^k$  requires some additional calculations and memory savings, and hence it is more expensive. However, it also has the advantage of revealing the optimal distance:  $\|x^0 - x^*\|^2$ , that could be of interest in some applications.

We close this section with some comments concerning the behavior of the stopping criteria when the problem is not feasible. In this case ( $\Omega = \emptyset$ ), there is no solution and we know from Theorem 3 that the sequences  $\{c_L^k\}$  and  $\{c^k\}$  are monotonically increasing. Moreover, under some mild assumptions on the sets  $\Omega_i$ , the sequences  $\{x_i^k\}$  converge for  $1 \leq i \leq p$ , and there exists a real constant  $\delta > 0$  such that  $\sum_{i=1}^p \|x_{i-1}^k - x_i^k\|^2 \geq \delta$  for all  $k$ . A discussion on this topic is presented in [2, Section 6], including a notion

of *distance* between all the sets  $\Omega_i$  (see also [37]). Now using (5), we obtain

$$\sum_{i=1}^p \|x_{i-1}^k - x_i^k\|^2 = \sum_{i=1}^p \|y_i^{k-1} - y_i^k\|^2 = c_I^k.$$

Therefore, the sequence  $\{c_I^k\}$  remains bounded away from zero, whereas  $\{c_L^k\}$  and  $\{c^k\}$  tend to infinity. Consequently, none of the proposed stopping criteria will be satisfied for any  $k$ , as expected.

*Dynamic programming* deals with optimal decision making problems in the presence of uncertainty that addresses systems in which events occur sequential. In general the state transitions are described by stationary dynamic systems of the form:

$$x_{k+1} = f(x_k, u_k, \omega_k), \quad k = 0, \dots,$$

where for each time instance (stage)  $k$ , the state of the system is an element of the space  $S$ , the control action  $u$  that is to be implemented so as to achieve optimality belong to a space  $C$ , and finally the uncertainty is modeled through a set of random disturbances  $\omega$  that belong to a *countable set*  $D$ . Furthermore, it is assumed that the control  $u_k$  is constrained to take values in a given nonempty set  $U(x_k) \in C$ , which depends of the current state  $x_k$ . The random disturbances  $\omega_k$ ,  $k = 0, \dots$ , have identical statistics and the probability distributions  $P(\cdot | x_k, u_k)$  are defined on  $D$ . These may depend explicitly on  $x_k$  and  $u_k$  but not on prior disturbances. Given an initial state  $x_0$ , we seek a policy  $\pi$  such that  $\pi = \{\mu_0, \mu_1, \dots\}$  for which:

$$\mu_k: S \rightarrow C \rightarrow, \quad \mu_k(x_k) \in U(x_k), \quad \forall x_k \in S,$$

that minimizes a cost function defined as:

$$J_\pi(x_0) = \lim_{N \rightarrow \infty} \mathbb{E} \left\{ \sum_{k=1}^{N-1} \alpha^k g(x_k, \mu_k(x_k), \omega_k) \right\}.$$

The function  $g()$  is the cost per stage such that:  $g: S \times C \times D \rightarrow \mathbf{R}$  and is assumed to be given. Finally, the parameter  $\alpha$  is termed *discount factor* and it holds that:  $0 < \alpha \leq 1$ . We denote by  $\Pi$  the set of all admissible policies  $\pi = \{\mu_0, \mu_1, \dots\}$ , that is the set of all sequences of such functions for which:

$$\mu_k: S \rightarrow C, \quad \mu_k(x_k) \in U(x_k), \quad \forall x_k \in S.$$

The optimal cost function  $J^*$  is then defined as:

$$J^* = \min_{\pi \in \Pi} J_\pi(x), \quad x \in S.$$

An admissible policy of the form  $\pi = \{\mu, \mu, \dots\}$  is termed *stationary* and its corresponding cost is  $J_\mu$ .

When studying problems of this kind the assumption is made that either the discount factor is  $\alpha < 1$  (*discounted problems*, [3]) or that naturally there exists a special cost-free absorbing state (*stochastic shortest path problems*, [3]). In either of these two cases the

## Dynamic Programming: Average Cost Per Stage Problems

Average cost per stage

total expected cost is finite, and the minimization, the way it was previously stated, is well defined. In situations where either the discount factor is 1, or a terminal state does not exist it is more meaningful to optimize an average expected cost as:

$$J_{\pi}(x_0) = \lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E} \left\{ \sum_{k=0}^{N-1} g(x_k, u_k, \omega_k) \right\}.$$

The problems are known as *average cost per stage problems* and although they bare various similarities with both discounted and stochastic shortest path problems, they have some distinct characteristics. One of the earliest studies was that of D. Blackwell, [7], which made the connection between the optimal average return and the optimal return for values of  $\alpha \rightarrow 1$ . Precisely these characteristics make the analysis of average cost per stage problems the target of intense research, [1]. Connections are made, for developing the associated theory, with both the associated discounted problem, but also recently with an associated stochastic shortest path problem, [4].

Since the theory for analyzing average cost dynamic programming problems has been largely based on the associated theory for discounted and stochastic shortest path problems, most of the results and computational methods bare major similarities. As a prelude to what follows, it should be pointed out that for the average cost per stage problems:

- 1) the optimal average cost per stage is independent of the initial state for most problems;
- 2) *Bellman's equation* will take a slightly modified form that would include *differential cost* for each state;
- 3) there exist computational analogues of all methods developed for either discounted or stochastic shortest path problems.

The cost function of average cost per stage problems are closely related the associated  $\alpha$ -discounted problem for a given stationary policy as follows:

- For any stationary policy  $\mu$  and for any  $\alpha \in (0, 1)$  we have:

$$J_{\alpha, \mu} = (1 - \alpha)^{-1} J_{\mu} + h_{\mu} + O(|1 - \alpha|),$$

where

$$J_{\mu} = \left( \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=1}^{n-1} P_{\mu}^k \right) g_{\mu}$$

is the average cost corresponding to policy  $\mu$ , for

a process with a transition probability matrix  $P_{\mu}$  and costs  $g_{\mu}$ . The matrix  $O$  is such that:  $\lim_{\alpha \rightarrow 1} O(|1 - \alpha|) = 0$ , and the vector  $h_{\mu}$  satisfies:  $J_{\mu} + h_{\mu} = g_{\mu} + P_{\mu} h_{\mu}$ .

In the above, the matrix  $P_{\mu}$  is the *transition probability matrix* for a given stationary policy  $\mu$ , given by:

$$P_{\mu} = \begin{pmatrix} p_{11}(\mu(1)) & \cdots & p_{1n}(\mu(1)) \\ \cdots & \cdots & \cdots \\ p_{n1}(\mu(1)) & \cdots & p_{nn}(\mu(n)) \end{pmatrix}$$

and  $g_{\mu}$  the associated cost vector:

$$g_{\mu} = \begin{pmatrix} g(1, \mu(1)) \\ \cdots \\ g(n, \mu(n)) \end{pmatrix}.$$

The vector  $h_{\mu}$  is termed *differential cost vector*, and it represents the difference in  $N$ -stage expected optimal cost due to starting at stage  $i$  rather than starting at stage  $j$ . The key optimality results irrespective of initial states is based on ideas first formulated in [6]. An important element of this analysis is that of a *unichain policy*. Given a *stationary-state Markov chain*, [10], the subset of states that communicate, i. e., there exist transitions  $k_1$  and  $k_2$  for which state transitions probabilities  $p_{ij}^{k_1}$  and  $p_{ji}^{k_2}$  are positive, is termed a *recurrent class of states*. States that do not belong to a recurrent class are termed *transient*. A stationary policy whose associated Markov chain has a single recurrent class and a possibly empty set of transient states is called *unichain*. In view of the above, the form of the Bellman's equation for characterizing an optimal policy, [9], for the average cost per stage problem takes the following from:

- Assume that any of the following conditions hold:
  - 1) Every policy that is optimal within the class of stationary policies is unichain.
  - 2) For every two states  $i$  and  $j$ , there exists a stationary policy  $\pi(i, j)$ , such that for some  $k$ :
 
$$P(x_k = j | x_0 = i, \pi) > 0.$$
  - 3) There exist a state  $t$ , a constant  $L > 0$ , and  $\bar{\alpha} \in (0, 1)$  such that:
 
$$|J_{\alpha}(i) - J_{\alpha}(t)| \leq L,$$

$$i = 1, \dots, n,$$

$$\alpha \in (\bar{\alpha}, 1),$$

where  $J_{\alpha}$  is the  $\alpha$ -discounted optimal cost vector.

Then:

- 1) The optimal average cost per stage cost has the same value,  $\lambda$ , for all intimal states, and it satisfies:

$$\lambda = \lim_{\alpha \rightarrow 1} (1 - \alpha) J_\alpha(i),$$

$$i = 1, \dots, n.$$

- 2) For any state  $t$ , the vector of differential cost,  $h$  is given by:

$$h(i) = \lim_{\alpha \rightarrow 1} (J_\alpha(i) - J_\alpha(t)),$$

$$i = 1, \dots, n,$$

together with  $\lambda$ , satisfies Bellman's equation:

$$\lambda + h(i)$$

$$= \lim_{u \in U(i)} \left[ g(i, u) + \sum_{j=1}^n p_{ij}(u) h(j) \right],$$

$$i = 1, \dots, n,$$

and  $\lambda$  is the optimal average cost per stage for all states  $i$ , i. e.,

$$\lambda = J^*(x) = \min_{\pi} J_{\pi}(i),$$

$$i = 1, \dots, n.$$

The above result is also discussed in [2] where the minimization of an expected cost without discounting is considered. All classical methods for computing optimal policies and costs in dynamic programming have their counterparts for addressing average cost per stage problems. Certain alterations are nevertheless necessary. Let us consider first the *value iteration* method exhaustively analyzed in [11,12]. This is a method based on the premise that the limit of steps of the basic dynamic programming algorithm:

$$\lim_{k \rightarrow \infty} \frac{1}{k} T^k J = J^*.$$

Two issues arise with average cost per stage problems. First, some elements of the sequence  $T^k J$  may diverge to  $+\infty$  or  $-\infty$  making the numerical calculation troublesome. Furthermore, since we found that the quantity described as the differential cost is important it would

be appropriate to develop methods that allow the parallel computation of  $h$  as well. [14] developed the fundamentals based on which a *relative value iteration* of the form:

$$h^{k+1}(i) = (Th^k)(i) - (Th^k)(t),$$

$$i = 1, \dots, n,$$

for some fixed state  $t$ , converges to vector  $h$  such that  $(Th)(t)$  is equal to the optimal average cost per stage for all initial states, and  $h$  is the associated differential cost vector. [3] discusses various technical details required for proving convergence. Tight bounds that could improve the computational behavior of the value iteration method were proposed by [8] which modified the approach set forth in [14] to prove that upper and lower bounds on the maximal gain could be readily obtained. These are given according to:

$$\underline{c}_k \leq \underline{c}_{k+1} \leq \lambda \leq \bar{c}_{k+1} \leq \bar{c}_k,$$

where  $\lambda$  is the optimal average cost per stage for all initial states and

$$\underline{c}_k = \min_i [(Th^k)(i) - h^k(i)],$$

$$\bar{c}_k = \max_i [(Th^k)(i) - h^k(i)].$$

Recently, [4], by exploiting the connection between the average cost and the stochastic shortest path problem developed a new value iteration method by making use of *weighter sup-norm contraction* arising in the stochastic shortest path problem. One of the key advantages of this approach is that it admits a *Gauss-Seidel* implementation, thus it is amenable to a distributed implementation. *Policy iteration* methods can also be developed. The policy iteration algorithms generate sequences of stationary policies, each with improved cost over the preceding one. These methods are comprised of two basic steps, a policy evaluation and a policy improvement step. During the first step, for a given stationary policy,  $\mu^k$ , we obtain the corresponding average and differential costs via the solution of the following system of equations which solution provides the  $k$ th iterate of  $\lambda$ , and  $h$ :

$$\lambda^k + h^k(i) = g(i, \mu^k(i)) + \sum_{j=1}^n p_{ij}(\mu^k(i)) h^k(j),$$

$$j = 1, \dots, n.$$

The policy improvement step, consists of finding a policy  $\mu^{k+1}$ , where for all state  $i$ , is such that:

$$g(i, \mu^{k+1}(i)) + \sum_{j=1}^n p_{ij}(\mu^{k+1}(i))h^k(j) \\ = \min_{u \in U(i)} \left[ g(i, u) + \sum_{j=1}^n p_{ij}(u)h^k(j) \right].$$

In [7], the scope of policy iteration is expanded so as to address problems in which the optimal average cost per stage is not the same for every initial state. It can also be shown, [3], that the optimal vector  $(\lambda^*, h^*)$  is equivalent to the optimal solution of the following linear program:

$$\begin{cases} \max & \lambda \\ \text{s.t.} & \lambda + h(i) \leq g(i, u) + \sum_{j=1}^n p_{ij}(u)h(j) \\ & u \in U(i) \\ & i = 1, \dots, n. \end{cases}$$

In [9] the *dual problem* of the above-mentioned formulation is considered, whose optimal value is the optimal value of the *primal problem*. The form of the dual is:

$$\begin{cases} \min & \sum_{i=1}^n \sum_{u \in U(i)} q(i, u)g(i, u) \\ \text{s.t.} & \sum_{u \in U(i)} q(j, u) = \sum_{i=1}^n \sum_{u \in U(i)} q(i, u)p_{ij}(u) \\ & j = 1, \dots, n \\ & \sum_{i=1}^n \sum_{u \in U(i)} q(i, u) = 1 \\ & q(i, u) \geq 0, \quad i = 1, \dots, n \\ & u \in U(i). \end{cases}$$

Simulation-based methods are presented in [3,5] that use the basic concepts of *Monte-Carlo simulation* as well as ideas of *reinforcement learning*, [13].

Combinatorial optimization; Dynamic programming; Clustering; Classification; Ultrametric; Unidimensional scaling; Seriation

Many of the data analysis tasks that arise in the field of *classification* and *clustering* can be given some type of combinatorial characterization that involves the identification of object groupings, *partitions*, or *sequences*. These combinatorial structures are generally defined by certain properties of optimality for some loss (or merit) criterion based on data given in the form of an  $n \times n$  *symmetric proximity* matrix  $\mathbf{P}$  between distinct pairs of objects from a set  $S = \{O_1, \dots, O_n\}$ . The focus of this entry will be solely in this context and the use of a general optimization strategy referred to as the *General Dynamic Programming Paradigm* (GDPP), which allows the construction of *recursive procedures* to solve a range of *combinatorial optimization* tasks encountered in the field of classification and clustering. The GDPP will be presented in a general form below with later sections indicating how it can be operationalized for a number

of specific problem types. For a more extensive presentation of the topics introduced in this entry and for generalizations to proximity matrices that may not be symmetric or that are defined between objects from (two) distinct sets, the monograph [12] should be consulted. This latter source also provides numerical illustrations for the topics introduced here plus instructions on how to obtain a collection of programs (available on the World Wide Web) to carry out the various optimization tasks presented in this entry and [12]. For a recent and comprehensive review of cluster analysis and the use of mathematical programming techniques in general, see [7].

### The GDPP

To present the GDPP, a collection of  $K$  sets of entities is first defined,  $\Omega_1, \dots, \Omega_K$ , where it is possible by some operation to transform entities in  $\Omega_{k-1}$  to certain entities in  $\Omega_k$  for  $2 \leq k \leq K$ . Each such transformation can be assigned a *merit* (or *cost*) value based *only* on the entity in  $\Omega_{k-1}$  and the transformed entity in  $\Omega_k$ . An entity in  $\Omega_k$  is denoted by  $A_k$ , and  $\mathcal{F}(A_k)$  is the optimal value that can be assigned to  $A_k$  based on the sum of the merit (or cost) increments necessary to transform an entity in  $\Omega_1$ , step-by-step, to  $A_k \in \Omega_k$ . If  $A_{k-1} \in \Omega_{k-1}$  can be transformed into  $A_k \in \Omega_k$ , the merit (or cost) of that single transition will be denoted by  $M(A_{k-1}, A_k)$  (or  $C(A_{k-1}, A_k)$ ), and where the latter *does not depend* on how  $A_{k-1}$  may have been arrived at starting from an entity in  $\Omega_1$ . Given these conditions, and assuming the values  $\mathcal{F}(A_1)$  for  $A_1 \in \Omega_1$  are available to initialize the recursive system,  $\mathcal{F}(A_k)$  may be constructed for  $k = 2, \dots, K$  (when merit is to be maximized) as

$$\mathcal{F}(A_k) = \max[\mathcal{F}(A_{k-1}) + M(A_{k-1}, A_k)],$$

where  $A_k \in \Omega_k$ ,  $A_{k-1} \in \Omega_{k-1}$ , and the maximum is taken over all  $A_{k-1}$  that can be transformed into  $A_k$ . Or, if cost is to be minimized,

$$\mathcal{F}(A_k) = \min[\mathcal{F}(A_{k-1}) + C(A_{k-1}, A_k)].$$

In addition, both max/min and min/max forms could be considered as:

$$\mathcal{F}(A_k) = \max[\min(\mathcal{F}(A_{k-1}), M(A_{k-1}, A_k))],$$

$$\mathcal{F}(A_k) = \min[\max(\mathcal{F}(A_{k-1}), C(A_{k-1}, A_k))].$$

The leading maximization or minimization is over all  $A_{k-1} \in \Omega_{k-1}$  that can be transformed into  $A_k$ . In all instances, an optimal solution is identified by some value for  $\mathcal{F}(A_K)$  for a specific  $A_K \in \Omega_K$ , and the actual optimal solution obtained by working backwards through the recursion to see how  $\mathcal{F}(A_K)$  was constructed.

### Partitioning

The most direct characterization of the partitioning task can be stated as follows: given  $S = \{O_1, \dots, O_n\}$  and  $\mathbf{P} = \{p_{ij}\}$ , find a collection of  $M$  mutually exclusive and exhaustive subsets (or clusters) of  $S$ , say,  $S_1, \dots, S_M$ , such that for some measure of *heterogeneity*  $H(\cdot)$  that attaches a value to each possible subset of  $S$ , either the sum  $\sum_{m=1}^M H(S_m)$ , or alternatively,  $\max\{H(S_1), \dots, H(S_M)\}$ , is minimized. This stipulation assumes that heterogeneity has a cost interpretation and that smaller values of the heterogeneity indices represent the 'better' subsets (or clusters). If  $H(S_m)$  for some  $S_m \subseteq S$  depends only on those proximities from  $\mathbf{P}$  that are within  $S_m$  and/or between  $S_m$  and  $S - S_m$ , an application of the GDPP is possible. Define  $K$  to be  $M$ , and let each of the sets  $\Omega_1, \dots, \Omega_M$  contain *all* of the  $2^n - 1$  nonempty subsets of the  $n$  object subscripts;  $\mathcal{F}(A_k)$  is the optimal value for a partitioning into  $k$  classes of the object subscripts present in  $A_k$ . A transformation of an entity  $A_{k-1} \in \Omega_{k-1}$  to  $A_k \in \Omega_k$  is possible if  $A_{k-1} \subset A_k$ , with cost  $C(A_{k-1}, A_k) \equiv H(A_k - A_{k-1})$ . Thus, beginning with the heterogeneity indices  $H(A_1)$  for *every* subset  $A_1 \subseteq S$ , the recursion can be carried out, with the optimal solution represented by  $\mathcal{F}(A_M)$  when  $A_M = S$ .

The first discussion of this general type of recursive solution for the partitioning task was in [14] but limited to one specific measure of subset heterogeneity defined by the sum of proximities within a subset divided by twice the number of objects in the subset. If the original proximities in  $\mathbf{P}$  happened to be squared *Euclidean distances* between numerically given vectors (or profiles) for the  $n$  objects over some set of variables, then this subset heterogeneity measure is equivalent to the sum of squared Euclidean distances between each profile and the mean profile for the subset (this quantity is usually called the *sum of squared error* or the *k-means criterion*, e. g., see [16], p. 52) A major advantage of the GDPP formulation is that a variety of heterogeneity measures can be considered under

a common rubric, with the sole requirement that the measure chosen be dependent only on the proximities within a subset and/or between the subset and its complement. For example, in [12] some twelve different alternatives are illustrated using a program implementation that can effectively deal with object set sizes in their lower 20's with the type of computational equipment and storage capacity now commonly available. As noted in a later section, it is also possible to extend the GDPP heuristically to allow for much larger object set sizes, although an absolute guarantee of globally optimality for the identified structures is sacrificed.

### Admissibility Restrictions on Partitions

A specific restriction discussed at some length in the literature (see [8, Chapt. 5], [16, pp. 61–64], [6]) that would permit the construction of optimal partitions (subject to the restriction) for very large object sets is when there is an a priori assumed object *ordering* along a continuum that can be taken without loss of generality as  $O_1 < \dots < O_n$ , and the only *admissible clusters* are those for which the objects in the cluster form a consecutive sequence or segment. Thus, an optimal partition will consist of  $M$  clusters, each of which defines a consecutive segment along the given object ordering. To tailor the GDPP to a consecutive-ordering admissibility criterion, each of the sets  $\Omega_1, \dots, \Omega_M$  is now defined by the  $n$  subsets of  $S$  that contain the objects  $\{O_1, \dots, O_i\}$  for  $1 \leq i \leq n$ ;  $\mathcal{F}(A_k)$  is the optimal value for a partitioning of  $A_k$  into  $k$  classes; a transformation of an entity  $A_{k-1} \in \Omega_{k-1}$  to  $A_k \in \Omega_k$  is possible if  $A_{k-1} \subset A_k$ ; and the cost of the transition is  $H(A_k - A_{k-1})$ , where  $A_k - A_{k-1}$  must contain a consecutive sequence of objects. Again,  $\mathcal{F}(A_M)$  for  $A_M = S$  identifies an optimal solution.

The selection of some prespecified ordering that constrains admissible clusters in a partition obviously does not lead necessarily to the same unconstrained optimal partitions, even though the identical subset heterogeneity measure and optimization criterion are being used. There are, however, several special instances where the original proximity matrix  $\mathbf{P}$  is appropriately defined and/or patterned so that the imposition of a particular order constraint does invariably lead to partitions that would also be optimal even when no such order constraint was imposed. One such result dates back to W.D. Fisher [6] who showed that when proxim-

ities are squared differences between the values on some (unidimensional) variable, and the order constraint is derived from the ordering of the objects on this variable, then the selection of the sum of squared error as the subset heterogeneity measure, and minimizing this sum as an optimization criterion, leads to partitions that are not only optimal under the order constraint but also optimal when unconstrained, i. e., an unconstrained optimal partition will include only those subsets defined by objects consecutive in the given order. (The subset heterogeneity measure in this unidimensional case reduces to the sum of squared deviations of the univariate values for the objects from their mean value within the subset.) A more general result appears in [3] where the special case is discussed when a proximity matrix  $\mathbf{P}$  can be row- and column-reordered to display an anti-Robinson form (a matrix pattern first introduced in [15]). As stated more formally below, a matrix has an *anti-Robinson* form if the entries within each row and column of  $\mathbf{P}$  never decrease when moving away from a main diagonal entry in any direction. For certain subset heterogeneity measures and optimization criteria, imposing the order constraint that displays the anti-Robinson pattern in the row- and column-reordered proximity matrix leads to partitions that are also optimal when unconstrained.

The choice of an ordering that can be imposed to constrain the search domain for optimal partitions could be directly tied to a task, discussed later, of finding an (optimal) sequencing of the objects along a continuum. Somewhat more generally, one possible data analysis strategy for seeking partitions as close to optimal as possible, would be to construct an object ordering through an initial optimization process, and possibly one based on another analysis method that could then constrain the domain of search for an optimal partition. Obviously, if one were successful in generating an appropriate object ordering, partitions that would be optimal when constrained would also be optimal without the constraint. The obvious key here is to have some mechanism for identifying an appropriate order to give this possible equivalence (between an optimal constrained partition and one that is optimal without constraint) a chance to succeed. As one example of how such a process might be developed for constructing partitions based on an empirically generated ordering for the objects, a three-stage process is proposed in [1]

and [2]. First, the objects to be partitioned are embedded in a *Euclidean representation* with a specific *multi-dimensional scaling* strategy. Second, by heuristic methods, a path among the  $n$  objects in the Euclidean representation is identified (hopefully, with close to minimal length) and used to define a prior ordering for the objects and to constrain the subsets present in a partition. Finally, a recursive strategy of the same general form just described is carried out to obtain a partitioning of  $S$ .

## Hierarchical Clustering

The problem of hierarchical clustering will be characterized by the search for an optimal collection of partitions of  $S$ , which are denoted generically as  $\mathcal{P}_1, \dots, \mathcal{P}_n$ . Here,  $\mathcal{P}_1$  is the (trivial) partition where all  $n$  objects from  $S$  are placed into  $n$  separate classes,  $\mathcal{P}_n$  is the (also trivial) partition where a single subset contains all  $n$  objects, and  $\mathcal{P}_k$  is obtained from  $\mathcal{P}_{k-1}$  by uniting some pair of classes present in  $\mathcal{P}_{k-1}$ . As an optimization criterion the sum of transition costs is minimized, irrespective of how the costs might be defined, between successive partitions in a hierarchy. Specifically, suppose  $T(\mathcal{P}_{k-1}, \mathcal{P}_k)$  denotes some measure of transition cost between two partitions  $\mathcal{P}_{k-1}$  and  $\mathcal{P}_k$ , where  $\mathcal{P}_k$  is constructed from  $\mathcal{P}_{k-1}$  by uniting two classes in the latter partition. An optimal *partition hierarchy*  $\mathcal{P}_1, \dots, \mathcal{P}_n$  will be one for which the sum of the transition costs,  $\sum_{k>2} T(\mathcal{P}_{k-1}, \mathcal{P}_k)$ , is minimized. To apply the GDPP, first define  $n$  sets  $\Omega_1, \dots, \Omega_n$ , where  $\Omega_k$  contains all partitions of the  $n$  objects in  $S$  into  $n - k + 1$  classes. The value  $\mathcal{F}(A_k)$  for  $A_k \in \Omega_k$  is the optimal sum of transition costs up to the partition  $A_k$ ; a transformation of an entity  $A_{k-1} \in \Omega_{k-1}$  to  $A_k \in \Omega_k$  is possible if  $A_k$  is obtainable from  $A_{k-1}$  by uniting two classes in  $A_{k-1}$ , and has cost  $C(A_{k-1}, A_k) \equiv T(A_{k-1}, A_k)$ . Beginning with an assumed value for  $\mathcal{F}(A_1)$  of 0 for the single entity  $A_1 \in \Omega_1$  (which is the partition of  $S$  into  $n$  subsets each containing a single object), and constructing  $\mathcal{F}(A_k)$  recursively for  $2, \dots, n$ , an optimal solution is identified by  $\mathcal{F}(A_n)$  for the single entity  $A_n \in \Omega_n$  defined by the partition containing all  $n$  objects in a single class.

A concept routinely encountered in discussions of hierarchical clustering is that of an *ultrametric*, which can be characterized by any nonnegative  $n \times n$  symmetric dissimilarity matrix for distinct pairs of the objects in  $S$ , denoted generically as  $\mathbf{U} = \{u_{ij}\}$ , where  $u_{ij} = 0$  if and

only if  $i = j$  and the entries in  $\mathbf{U}$  satisfy the ultrametric inequality:  $u_{ij} \leq \max\{u_{ik}, u_{jk}\}$  for  $1 \leq i, j, k \leq n$ . Any ultrametric identifies a specific partition hierarchy,  $\mathcal{P}_1, \dots, \mathcal{P}_n$ , where those object pairs defined between subsets united in  $\mathcal{P}_{t-1}$  to form  $\mathcal{P}_t$  all have a common ultrametric value; moreover, this latter value is not smaller than those for object pairs defined within these same subsets. One approach to the development of hierarchical clustering methods is by directly fitting an ultrametric to  $\mathbf{P}$  minimizing a loss criterion defined by an  $L_p$ -norm between  $\{p_{ij}\}$  and a (to be identified) ultrametric matrix  $\{u_{ij}\}$ . To be specific, for a given partition hierarchy,  $\mathcal{P}_1, \dots, \mathcal{P}_n$ , let  $C_{t-1}^{(u)}$  and  $C_{t-1}^{(v)}$  denote the two classes united in  $\mathcal{P}_{t-1}$  to form  $\mathcal{P}_t$ , and specify  $b_{t-1}$  to be some appropriate aggregate (or ‘average’) value of the proximities for object pairs between  $C_{t-1}^{(u)}$  and  $C_{t-1}^{(v)}$ . The loss functions used to index the adequacy of a given partition hierarchy in producing an ultrametric fitted to  $\mathbf{P}$  are for the  $L_1$ -norm:

$$\sum_{t=2}^n \sum_{\substack{O_{i'} \in C_{t-1}^{(u)}, \\ O_{j'} \in C_{t-1}^{(v)}}} |p_{i'j'} - b_{t-1}|,$$

where  $b_{t-1}$  is the median proximity between  $C_{t-1}^{(u)}$  and  $C_{t-1}^{(v)}$ ; for the  $L_2$ -norm:

$$\sum_{t=2}^n \sum_{\substack{O_{i'} \in C_{t-1}^{(u)}, \\ O_{j'} \in C_{t-1}^{(v)}}} (p_{i'j'} - b_{t-1})^2,$$

where  $b_{t-1}$  is the mean proximity between  $C_{t-1}^{(u)}$  and  $C_{t-1}^{(v)}$ ; and for the  $L_\infty$ -norm:

$$\sum_{t=2}^n \max_{\substack{O_{i'} \in C_{t-1}^{(u)}, \\ O_{j'} \in C_{t-1}^{(v)}}} |p_{i'j'} - b_{t-1}|,$$

where  $b_{t-1}$  is the average of the minimum and maximum proximities between  $C_{t-1}^{(u)}$  and  $C_{t-1}^{(v)}$ . For all three  $L_p$ -norms, an optimal ultrametric will be one for which the order constraint on the between-subset aggregate values holds:  $b_1 \leq \dots \leq b_{n-1}$ , and the norm is minimized. For such an optimal solution,  $b_1, \dots, b_{n-1}$  define the distinct entries in an (optimal) fitted ultrametric. To implement a *dynamic programming* approach for locating an optimal ultrametric,  $C(A_{k-1}, A_k)$  is the incremental cost of transforming  $A_{k-1}$  to  $A_k$  character-

ized by the appropriate  $L_p$ -norm when that pair of subsets in  $A_{k-1}$  is united to form  $A_k$ . As developed in detail in [11], an explicit admissibility criterion must also be imposed for defining a permissible transition from  $A_{k-1}$  to  $A_k$  that could ensure a nondecreasing sequence of between-subset aggregate values.

### Constrained Hierarchical Clustering

Analogously to the admissibility conditions for partitions, one constraint that might be imposed on each partition in  $\Omega_k$  is for the constituent subsets to contain objects consecutive in some given *ordering* (which could be taken as  $O_1 < \dots < O_n$  without loss of any generality). Thus,  $\Omega_k$  will be redefined to contain those partitions that include  $n - k + 1$  classes, and where each class is a segment in the given object ordering.

### Optimal Sequencing of an Object Set

A combinatorial optimization task closely related to both partitioning and hierarchical clustering is the search for an optimal *sequencing* of the object set  $S$  based on the proximity matrix  $\mathbf{P}$ . A best reordering is sought for the rows and columns of  $\mathbf{P}$  that will optimize, over all possible row/column reorderings, some specified measure of patterning for the entries of the re-ordered matrix. Irrespective of the particular measure chosen, the GDPP is specialized as follows: A collection of sets  $\Omega_1, \dots, \Omega_n$  is defined, where  $\Omega_k$  includes all the subsets that have  $k$  members from the integer set  $\{1, \dots, n\}$ . The value  $\mathcal{F}(A_k)$  is the optimal contribution to the total measure of matrix patterning for the objects in  $A_k$  when they occupy the first  $k$  positions in the (re)ordering. A transformation is now possible between  $A_{k-1} \in \Omega_{k-1}$  and  $A_k \in \Omega_k$  if  $A_{k-1} \subset A_k$  (i. e.,  $A_{k-1}$  and  $A_k$  differ by one integer). The contribution to the total measure of patterning generated by placing the single integer in  $A_{k-1} - A_k$  at the  $k$ th order position is  $M(A_{k-1}, A_k)$ . As always, the validity of the recursive process will require the incremental merit index,  $M(A_{k-1}, A_k)$ , to depend only on the unordered sets  $A_{k-1}$  and  $A_k$ , and the complement  $S - A_k$ , and specifically *not* on how  $A_{k-1}$  may have been obtained beginning with  $\Omega_1$ . Assuming  $\mathcal{F}(A_1)$  for all  $A_1 \in \Omega_1$  are available, the recursive process can be carried out from  $\Omega_1$  to  $\Omega_n$ , with  $\mathcal{F}(A_n)$  for the single set  $A_n = \{1, \dots, n\} \in \Omega_n$  defining the optimal value for the specified measure of matrix patterning.

Two general classes of measures of matrix patterning are mentioned here. The first is a row and column *gradient index* motivated by the ideal of reordering a symmetric proximity matrix to have an anti-Robinson form (and which is the same structure noted briefly in the clustering context when an optimal order-constrained partition might also be optimal when unconstrained). Specifically, suppose  $\rho(\cdot)$  is some permutation of the first  $n$  integers that reorders both the rows and columns of  $\mathbf{P}$  (i. e.,  $\mathbf{P}_\rho \equiv \{p_{\rho(i)\rho(j)}\}$ ). As noted earlier, the reordered matrix  $\mathbf{P}_\rho$  is said to have an anti-Robinson form if the entries within the rows and within the columns of  $\mathbf{P}_\rho$  moving away from the main diagonal in any direction never decrease; or formally, two gradient conditions must be satisfied:

- within rows:  $p_{\rho(i)\rho(k)} \leq p_{\rho(i)\rho(j)}$  for  $1 \leq i < k < j \leq n$ ;
- within columns:  $p_{\rho(k)\rho(j)} \leq p_{\rho(i)\rho(j)}$  for  $1 \leq i < k < j \leq n$ .

It might be noted that whenever  $\mathbf{P}$  is an ultrametric, or if  $\mathbf{P}$  has an exact Euclidean representation in a single dimension (i. e.,  $\mathbf{P} = \{|x_j - x_i|\}$ , for some collection of coordinate values,  $x_1, \dots, x_n$ ), then  $\mathbf{P}$  can be row/column reordered to display a perfect anti-Robinson pattern. Thus, the notion of an anti-Robinson form can be interpreted as generalizing either a perfect discrete classificatory structure induced by a partition hierarchy (through an ultrametric) or as the pattern expected in  $\mathbf{P}$  if there exists an exact *unidimensional Euclidean representation* for the objects in  $S$ . In any case, if a matrix can be row/column reordered to display an anti-Robinson form, then the objects are orderable along a continuum so that the degree of separation between objects in the ordering is reflected perfectly by the dissimilarity information in  $\mathbf{P}$ , i. e., for the object ordering,  $O_{\rho(i)} < O_{\rho(k)} < O_{\rho(j)}$  (for  $i < k < j$ ),  $p_{\rho(i)\rho(k)} \leq p_{\rho(i)\rho(j)}$  and  $p_{\rho(k)\rho(j)} \leq p_{\rho(i)\rho(j)}$ .

A natural (merit) measure of how well a reordered proximity matrix  $\mathbf{P}_\rho$  satisfies these two gradient conditions would rely on an aggregate index of the violations/nonviolations over all distinct object triples, as given by the expression:

$$\sum_{i < k < j} f(p_{\rho(i)\rho(k)}, p_{\rho(i)\rho(j)}) + \sum_{i < k < j} f(p_{\rho(k)\rho(j)}, p_{\rho(i)\rho(j)}), \quad (1)$$

where  $f(\cdot, \cdot)$  is some function indicating how a violation/nonviolation of a particular gradient condition for an object triple within a row or within a column (and defined above the main diagonal of  $\mathbf{P}_\rho$ ) is to be counted in the total measure of merit. The one option concentrated on here will be  $f(z, y) = \text{sign}(z - y) = +1$  if  $z > y$ ;  $0$  if  $z = y$ ; and  $-1$  if  $z < y$ ; thus, the (row) number of satisfactions minus the number of dissatisfactions of the gradient conditions *within rows* above the main diagonal of  $\mathbf{P}_\rho$  is given by the first term in (1), and the (row) number of satisfactions minus dissatisfactions of the gradient conditions *within columns* above the main diagonal of  $\mathbf{P}_\rho$  is given by the second term. To carry out the GDPP based on the measure in (1), an explicit form must be given for the incremental contribution,  $M(A_{k-1}, A_k)$ , to the total merit measure of patterning generated by placing the single integer  $A_k - A_{k-1}$  at the  $k$ th order position. For any ordering  $\rho(\cdot)$  of the rows and columns of  $\mathbf{P}$ , the merit increment for placing an integer, say,  $k'$  ( $\equiv \rho(k)$ ) (i. e.,  $\{k'\} = A_k - A_{k-1}$ ) at the  $k$ th order position can be defined as  $\sum_{k=1}^n I_{\text{row}}(\rho(k)) + \sum_{k=1}^n I_{\text{col}}(\rho(k))$ , where

$$I_{\text{row}}(\rho(k)) = \sum_{i' \in A_{k-1}} \sum_{j' \in S - A_k} f(p_{i'k'}, p_{i'j'}),$$

$$I_{\text{col}}(\rho(k)) = \sum_{i' \in A_{k-1}} \sum_{j' \in S - A_k} f(p_{k'j'}, p_{i'j'}),$$

and  $A_{k-1} = \{\rho(1), \dots, \rho(k-1)\}$ ,  $S - A_k = \{\rho(k+1), \dots, \rho(n)\}$ . Thus, letting  $\mathcal{F}(A_1) = 0$  for all  $A_1 \in \Omega_1$ , and using the specification for  $f(\cdot, \cdot)$  suggested above, the recursion can be carried out to identify an optimal row/column reordering of the given proximity matrix  $\mathbf{P}$  to maximize this gradient measure over all row/column reorderings of  $\mathbf{P}$ .

A second class of measures of matrix patterning can be derived indirectly from the auxiliary problem of attempting to fit a given proximity matrix  $\mathbf{P}$  by some type of unidimensional scaling representation (i. e., a *seriation*). Suppose the search is for a set of  $n$  ordered coordinate values,  $x_1 \leq \dots \leq x_n$  (such that  $\sum_k x_k = 0$ ), and a permutation  $\rho(\cdot)$  to minimize the *least squares criterion*

$$\sum_{i < j} (p_{\rho(i)\rho(j)} - |x_j - x_i|)^2.$$

After some algebraic reduction (see [5]), this latter least squares criterion can be rewritten as

$$\sum_{i < j} p_{ij}^2 + n \sum_k [x_k - \left(\frac{1}{n}\right) G(\rho(k))]^2 - \frac{1}{n} \sum_k [G(\rho(k))]^2,$$

where

$$G(\rho(k)) = \sum_{i=1}^{k-1} p_{\rho(k)\rho(i)} - \sum_{i=k+1}^n p_{\rho(k)\rho(i)}.$$

If the measure

$$\sum_{k=1}^n [G(\rho(k))]^2 \quad (2)$$

is maximized over all row/column reorderings of  $\mathbf{P}$ , and denoting the optimal permutation by  $\rho^*(\cdot)$ , then  $G(\rho^*(1)) \leq \dots \leq G(\rho^*(n))$ , and the optimal coordinates can be retrieved as  $x_k = (1/n)G(\rho^*(k))$ , for  $1 \leq k \leq n$ . To execute the GDPP recursion using (2), the merit increment for placing the integer, say  $k'$  ( $\equiv \rho(k)$ ) (i. e.,  $\{k'\} = A_k - A_{k-1}$ ) in the  $k$ th order position can be written as  $[G(\rho(k))]^2$ , where

$$G(\rho(k)) = \sum_{i' \in A_{k-1}} p_{k'i'} - \sum_{j' \in S - A_k} p_{k'j'},$$

with  $A_{k-1} = \{\rho(1), \dots, \rho(k-1)\}$ ,  $S - A_k = \{\rho(k+1), \dots, \rho(n)\}$ , and  $\mathcal{F}(A_1)$  for  $A_1 = \{k'\} \in \Omega_1$  defined by

$$\left( \sum_{j' \in S - \{k'\}} p_{k'j'} \right)^2.$$

### Optimal Sequencing Based on the Construction of Optimal Paths

To tailor the GDPP (and for the moment emphasizing the minimization of the sum of adjacent object proximities in constructing a path among the objects in  $S$ ), a collection of sets  $\Omega_1, \dots, \Omega_n$  is defined so that each entity in  $\Omega_k$ ,  $1 \leq k \leq n$ , is now an ordered pair  $(A_k, j_k)$ . Here,  $A_k$  is a  $k$  element subset of the  $n$  subscripts on the objects in  $S$ , and  $j_k$  is one subscript in  $A_k$  (to be interpreted as the subscript for the last-placed object in a sequencing of the objects contained within  $A_k$ ). The

function value  $\mathcal{F}((A_k, j_k))$  is the optimal contribution to the total measure of matrix patterning for the objects in  $A_k$  when they are placed in the first  $k$  positions in the (re)ordering, and the object with subscript  $j_k$  occupies the  $k$ th. A transformation is possible between  $(A_{k-1}, j_{k-1}) \in \Omega_{k-1}$  and  $(A_k, j_k) \in \Omega_k$  if  $A_{k-1} \subset A_k$  and  $A_k - A_{k-1} = \{j_k\}$  (i. e.,  $A_{k-1}$  and  $A_k$  differ by the one integer  $j_k$ ). The cost increment  $C((A_{k-1}, j_{k-1}), (A_k, j_k))$  is simply  $p_{(j_{k-1})j_k}$  for the contribution to the total measure of patterning generated by placing the object with the single integer subscript in  $A_k - A_{k-1}$  at the  $k$ th order position (i. e., the proximity between the adjacently-placed objects with subscripts  $j_{k-1}$  and  $j_k$ ). The type of GDPP recursion used for the construction of optimal *linear paths* can be modified easily for the construction of optimal *circular paths*: choose object  $O_1$  as an (arbitrary) origin and force the construction of the optimal linear paths to include  $O_1$  as the initial object by defining  $\mathcal{F}((A_1, j_1)) = 0$  for  $j_1 = 1$  and  $A_1 = \{1\}$ , and otherwise by a very large positive or negative value (depending on whether the task is a minimization or a maximization, respectively). The function values  $\mathcal{F}((A_n, j_n))$  for all  $j_n$ ,  $1 \leq j_n \leq n$  for  $(A_n, j_n) \in \Omega_n$  and  $A_n = \{1, \dots, n\}$  can then be used to obtain the optimal circular paths depending on the chosen optimization criteria as follows:

- *minimum path length:*

$$\min[\mathcal{F}((A_n, j_n)) + p_{j_n 1}];$$

- *maximum path length:*

$$\max[\mathcal{F}((A_n, j_n)) + p_{j_n 1}];$$

- *minimax path length:*

$$\min[\max(\mathcal{F}((A_n, j_n)), p_{j_n 1})];$$

- *maximin path length:*

$$\max[\min(\mathcal{F}((A_n, j_n)), p_{j_n 1})].$$

For the first discussions in the literature on constructing optimal paths through DP, see [4,9]; for applications to a variety of data analysis tasks, see [13].

### Optimal Ordered Partitions

The task of constructing an *ordered partition* of an object set  $S = \{O_1, \dots, O_n\}$  into  $M$  ordered classes,  $S_1 < \dots < S_M$ , using some (merit) measure of matrix patterning

and a proximity matrix  $\mathbf{P}$ , can be approached through the GDPP recursive process applied to the partitioning task but with appropriate variation in defining the merit increments. Explicitly, the sets  $\Omega_1, \dots, \Omega_M$  will each contain all  $2^n - 1$  nonempty subsets of the  $n$  object subscripts;  $\mathcal{F}(A_k)$  for  $A_k \in \Omega_k$  is the optimal value for placing  $k$  classes in the first  $k$  positions, and the subset  $A_k$  is the union of these  $k$  classes. A transformation from  $A_{k-1} \in \Omega_{k-1}$  to  $A_k \in \Omega_k$  is possible if  $A_{k-1} \subset A_k$ ; the merit increment  $M(A_{k-1}, A_k)$  is based on placing the class  $A_{k-1} - A_k$  at the  $k$ th position (which will depend on  $A_{k-1}$ ,  $A_k$ , and  $S - A_k$ ). Beginning with  $\mathcal{F}(A_1)$  for all  $A_1 \in \Omega_1$  (i. e., the merit of placing the class  $A_1$  at the first position), the recursion proceeds from  $\Omega_1$  to  $\Omega_M$ , with  $\mathcal{F}(A_M)$  for  $A_M = S \in \Omega_M$  defining the optimal merit value for an ordered partition into  $M$  classes.

To generalize the gradient measure given in (1), the merit increment for placing the class  $A_k - A_{k-1}$  at the  $k$ th order position is  $I_{\text{row}}(A_k - A_{k-1}) + I_{\text{col}}(A_k - A_{k-1})$ , where

$$\begin{aligned} I_{\text{row}}(A_k - A_{k-1}) &= \sum_{i' \in A_{k-1}} \sum_{k' \in A_k - A_{k-1}} \sum_{j' \in S - A_k} f(p_{i'k'}, p_{i'j'}), \end{aligned}$$

and

$$\begin{aligned} I_{\text{col}}(A_k - A_{k-1}) &= \sum_{i' \in A_{k-1}} \sum_{k' \in A_k - A_{k-1}} \sum_{j' \in S - A_k} f(p_{k'j'}, p_{i'j'}). \end{aligned}$$

To initialize the recursion, let  $\mathcal{F}(A_1) = 0$  for all  $A_1 \in \Omega_1$ .

A merit measure based on a coordinate representation for each of the  $M$  ordered classes,  $S_1 < \dots < S_M$ , that generalizes (2) can also be developed directly. Here,  $M$  coordinates,  $x_1 \leq \dots \leq x_M$ , are to be identified so that the residual sum-of-squares

$$\sum_{k \leq k'} \sum_{\substack{i_k \in S_k, \\ j_{k'} \in S_{k'}}} (p_{i_k j_{k'}} - |x_{k'} - x_k|)^2,$$

is minimized (the notation  $p_{i_k j_{k'}}$  indicates those proximities in  $\mathbf{P}$  defined between objects with subscripts  $i_k \in S_k$  and  $j_{k'} \in S_{k'}$ ). A direct extension of the argument that led to optimal coordinate representation for single objects would require the maximization of

$$\sum_{k=1}^M \left( \frac{1}{n_k} \right) (G(A_k - A_{k-1}))^2, \quad (3)$$

where

$$\begin{aligned} G(A_k - A_{k-1}) &= \sum_{k' \in A_k - A_{k-1}} \left( \sum_{i' \in A_{k-1}} p_{k'i'} - \sum_{i' \in S - A_k} p_{k'i'} \right), \end{aligned}$$

and  $n_k$  denotes the number of objects in  $A_k - A_{k-1}$ . The merit increment for placing the subset  $A_k - A_{k-1}$  at the  $k$ th order position would be  $(1/n_k)(G(A_k - A_{k-1}))^2$ , with the recursion initialized by

$$\mathcal{F}(A_1) = \left( \frac{1}{n_1} \right) \left( \sum_{k' \in A_1} \sum_{i' \in S - A_1} p_{k'i'} \right)^2,$$

for all  $A_1 \in \Omega_1$ . If an optimal ordered partition that maximizes (3) is denoted by  $S_1^* < \dots < S_M^*$ , the optimal coordinates for each of the  $M$  classes can be given as

$$x_k^* = \left( \frac{1}{n} \right) \left( \frac{G(S_k^*)}{n_k} \right),$$

where  $x_1^* \leq \dots \leq x_M^*$ , and  $\sum_k n_k x_k^* = 0$ . A more complete discussion of constructing optimal ordered partitions appears in [10].

### Heuristic Applications of the GDPP

When faced with the task of finding a single optimal partition for a (large) object set  $S$ , if one had knowledge that for an optimal  $M$ -class partition the classes could be allocated to two (or more) groups, then the aggregate collections of the objects within these latter groups could be separately and optimally partitioned and an optimal  $M$ -class partition for the complete object set identified directly. Or, if it were known that certain elemental subsets of the objects in  $S$  had to appear within the classes of an optimal  $M$ -class partition, one could begin with these elemental subsets as the objects to be analyzed, and an optimal  $M$ -class partition could again be retrieved. The obvious difficulty is to identify either the larger aggregate groups that might be dealt with separately, or an appropriate collection of elemental subsets, and in a size and number that might be handled by the recursive optimization strategy. For the latter task of identifying elemental subsets, one possible approach would be to begin with a partition of  $S$  into several classes (possibly obtained through another heuristic process), and where each class con-

tained a number of objects that could be optimally analyzed. Based on these separate subset analyses, a (tentative) collection of elemental subsets would be identified. These could then be used to obtain a subdivision of  $S$ , and again within each group of this subdivision, the objects could be optimally partitioned to generate a possibly better collection of elemental subsets. This process could be continued until no change occurred in the particular elemental subsets identified. As an alternative, one could start with some collection of tentative *elemental subsets* obtained through another (*heuristic*) optimization strategy and try, if possible, to improve upon these through the same type of procedure. This latter approach is illustrated in [12]. Similarly, the tasks of constructing a (hopefully optimal) partition hierarchy or object order for a (large) set could be approached through the identification of a collection of elemental subsets, which would then be operated on as the basic entities for the generation of a partition hierarchy or an object sequence.

## Keywords

Dynamic programming; Continuous-time optimal control

Even though *dynamic programming* [1] was originally developed for systems with discrete types of decisions, it can be applied to continuous problems as well. In this article the application of dynamic programming to the solution of continuous time optimal control problems is discussed.

## Problem Formulation

Consider the following continuous time dynamical system:

$$\begin{cases} \dot{z}(t) = f(z(t), u(t)), \\ z(0) = z_0, \end{cases} \quad 0 \leq t \leq T, \quad (1)$$

where  $z(t) \in \mathbf{R}^n$  is the state vector at time  $t$  with time derivative given by  $\dot{z}(t)$ ,  $u(t) \in U \subset \mathbf{R}^m$  is the control vector at time  $t$ ,  $U$  is the set of control constraints, and  $T$  is the terminal time. The function  $f(z(t), u(t))$  is continuously differentiable with respect to  $z$  and continuous with respect to  $u$ . The set of admissible control trajectories are given by the piecewise constant functions,  $\{u(t): u(t) \in U, \forall t \in [0, T]\}$ . It is assumed that for any admissible control trajectory, that a state trajectory  $z^u(t)$  exists and is unique. For a full treatment of existence and uniqueness, see [4].

The objective is to determine a control trajectory and the corresponding state trajectory which minimizes a cost function of the form:

$$h(z^u(T)) + \int_0^T g(z^u(t), u(t)) dt, \quad (2)$$

where the functions  $g$ , and  $h$  are continuously differentiable with respect to both  $z$  and  $u$ .

## Example

As a simple example, consider the problem of moving a unit mass from an initial point to a given final point.

The position of the mass along a line is given by the state  $z_1(t)$  and its velocity by  $z_2(t)$ . The control  $u(t)$  is the force applied to the mass, and is bounded  $u(t) \in [-1, 1]$ . This system is described by:

$$\begin{aligned} \dot{z}_1(t) &= z_2(t), & \dot{z}_2(t) &= u(t), \\ z(0) &= [z_1(0), z_2(0)], & t &\in [0, T], \\ u(t) &\in [-1, 1]. \end{aligned}$$

The objective is to move this mass as near to the final state point,  $[\bar{z}_1, \bar{z}_2]$ , as possible. This can be formulated as the minimization of the square error at the final time point.

$$\min_{u(t)} \sum_{i=1}^2 (z_i(T) - \bar{z}_i(T))^2.$$

Converting this cost function into the form given by (2) results in:

$$\begin{aligned} h(z(T)) &= \sum_{i=1}^2 (z_i(T) - \bar{z}_i(T))^2, \\ g(z^u(t), u(t)) &= 0, \quad \forall t \in [0, T]. \end{aligned}$$

## Hamilton–Jacobi–Bellman Equation

The time horizon is divided into  $N$  equally spaced intervals with  $\delta = T/N$ . This converts the problem into the discrete-time domain and the dynamic programming approach can be applied. Once the approach is applied, the result is converted back into the continuous-time domain by taking the limit as  $\delta \rightarrow 0$ . The result is the following partial differential equation,

$$\begin{aligned} 0 &= \min_{u \in U} \\ &[g(z, u) + \nabla_x J^*(t, z) + \nabla_x J^*(t, z)^T f(z, u)], \quad (3) \\ J^*(T, z) &= h(z), \quad \forall z, \end{aligned}$$

where  $J^*(t, z)$  is the optimal cost-to-go function. This equation is called the *Hamilton–Jacobi–Bellman equation*. It is also referred to as the *continuous-time analog of the dynamic programming equation*.

## Pontryagin Minimum Principle

It is possible to derive the *Pontryagin minimum principle* using the Hamilton–Jacobi–Bellman equation given

above. Using the system given by (1), the classic principle results:

$$\begin{aligned}\dot{p}(t) &= -\nabla_z H(z^*(t), u^*(t), p(t)), \\ p(T) &= \nabla h(z^*(T)), \\ H(z^*(t), u^*(t), p(t)) \\ &= g(z^*(t), u^*(t)) + p^\top(t) f(z^*(t), u^*(t)), \\ u^*(t) &= \arg \min_{u \in U} H(z^*(t), u(t), p(t)),\end{aligned}$$

where  $z^*(t)$  and  $u^*(t)$  are the optimal state and control trajectories, respectively.

A more detailed description of these two results are given in the following sections. For dynamic programming and optimal control problems, see [2] as well as the classic optimal control text [3].

Dynamic programming; Infinite horizon problems; Discounted problem

*Dynamic programming* addresses models of decision making systems of an inherent sequential character. The problem of interest is defined as follows. We consider a discrete-time dynamic system:

$$x_{k+1} = f(x_k, u_k, \omega_k), \quad k = 0, 1, \dots$$

The state transitions,  $f$ , that define the evolution of the system from time  $k$  to time  $k + 1$  depend on the current state of the system,  $x_k$ , external disturbances,  $\omega_k$ , which are considered to be random variables, and finally on a set of control, or policy, actions,  $u_k$ . The state of the system,  $x_k, k = 0, 1, \dots$ , is an element of a space  $S$ , the control variables,  $u_k, k = 0, 1, \dots$ , belong to space  $C$ , and the random external disturbance belongs to a countable space  $D$ . The control variables are such that:  $u_k \in U(x_k) \subset C, k = 0, 1, \dots$ , and depend on the current state  $x_k, k = 0, 1, \dots$ . The random disturbances,  $\omega_k, k = 0, 1, \dots$ , have identical, known, distributions which depend on the current state and control,  $P(\omega_k | x_k, u_k)$ . Note that  $\omega_k$  does not depend on previous values of the disturbances, but may depend explicitly on the values of  $x_k$ , and  $u_k$ . Given an initial state  $x_0$ , the problem is to find a control law  $\pi = \{\mu_0, \mu_1, \dots\}$ , belonging to the set of *admissible policies*,  $\Pi$ , which is the set of all sequences of functions  $\pi = \{\mu_0, \mu_1, \dots\}$  with:

$$\begin{aligned} \mu_k: S &\rightarrow C, & \mu_x(x_k) &\in U(x_k), \\ \forall x_k \in S, & & k &= 0, 1, \dots, \end{aligned}$$

that minimizes the cost functional:

$$J_\pi(x_0) = \lim_{N \rightarrow \infty} E \left\{ \sum_{k=0}^{k=N-1} \alpha^k g_k(x_k, u_k, \omega_k) \right\}.$$

The optimal cost function  $J^*$  is thus defined as:

$$J^*(x) = \min_{\pi \in \Pi} J_\pi(x), \quad x \in S.$$

The cost,  $J_\pi(x_0)$ , for any  $x_0 \in S$  and a given policy  $\pi$ , represents the limit of the expected finite horizon costs and these are well defined. The *discounted problems with bounded cost per stage* are such that the following assumption holds:

*Assumption 1*

- 1)  $\forall(x, u, \omega) \in S \times C \times D$  the functions defining the cost per stage  $g$  are *uniformly* bounded:

$$0 \leq |g_k(x_k, u_k, \omega_k)| \leq M;$$

- 2)  $M \in \mathbf{R}$ , and  $0 < \alpha < 1$ .

This type of problem was first address through the pioneering work of D. Blackwell, [6]. The scalar,  $\alpha$ , is

the *discount factor*, and the range of its admissible values implies that future costs matter less that costs incurring at the present time, particularly when the cost per stage has a monetary interpretation. Mathematically, the presence of the discount factor guarantees the finiteness of the cost functional provided that the per stage costs are bounded uniformly. Furthermore, although the assumption of an infinite number of stages may never be satisfied in practice, it constitutes a reasonable approximation for problems involving a large number of stages. A rather typical example of a discounted infinite horizon dynamic problem is the so-called *asset selling problem* where the reward for selling a particular asset at a given time  $k$  diminishes as time progresses.

For any function  $J: S \rightarrow \mathbf{R}$  we define the operator  $(T(\cdot))$  as:

$$(TJ)(x) = \min_{u \in U(x)} E\{g(x, u, \omega) + \alpha J(f(x, u, \omega))\}.$$

This is in essence the function obtained when applying the standard dynamic programming mapping to  $J$ . Note that  $(TJ)$  represents essentially the optimal cost for a one-stage problem that has stage cost  $g$  and terminal cost  $\alpha J$ . For this operator, it can be shown, [4], that:

- For any bounded function  $J$ , the optimal cost function satisfies:

$$J^*(x) = \lim_{N \rightarrow \infty} (T^N J)(x), \quad \forall x \in S.$$

In other words, the *dynamic programming algorithm* converges to the optimal cost function. The above result relies on Assumption 1. It should be noted that the operator  $(TJ)$  can be shown to be:

- 1) *monotonic*:

$$J(x) \leq J'(x) \Rightarrow (T^k J)(x) \leq (T^k J')(x)$$

for any functions  $J: S \rightarrow \mathbf{R}$  and  $J': S \rightarrow \mathbf{R}$  and,

- 2) *contractive*:

$$\begin{aligned} \max_{x \in S} \left| (T^k J)(x) - (T^k J')(x) \right| \\ \leq \alpha^k \max_{x \in S} |J(x) - J'(x)| \end{aligned}$$

for any bounded functions  $J: S \rightarrow \mathbf{R}$  and  $J': S \rightarrow \mathbf{R}$ .

Both of these properties are important so as to show not only theoretical convergence of the dynamic programming algorithm but also to construct numerical solution schemes. Furthermore, the optimal cost function  $J^*$  can be shown to satisfy *Bellman's equation*, i. e.,  $\forall x \in S$ :

$$J^*(x) = \min_{u \in U(x)} E\{g(x, u, \omega) + \alpha J^*(f(x, u, \omega))\};$$

in other words:  $J^* = TJ^*$ . This proposition essentially defines the necessary and sufficient condition for the optimality of a policy  $\mu$ , i. e.  $\mu(x)$  is optimal if and only if it attains the minimum in Bellman's equation for every  $x \in S$ .

For the case where the state, control and disturbance space are finite, i. e., each set has a definite number of elements which can be found in principle, [9], several approaches exist for numerically solving the discounted problem with bounded cost per stage. It should be pointed out that under these conditions the problem is equivalent to a *finite-state Markov chain*. The first, *value iteration*, is based on a successive computation of  $TJ, T^2J, \dots$ , since we know that  $\lim_k \rightarrow \infty (T^k J) = J^*$ . Recall that the operator  $(TJ)$  is defined as the minimum over all possible disturbances with respect to the controls. Therefore, asymptotically we approach the optimal cost as well as the optima policy. Tight upper and lower bounds on the iterations can be derived, [3,4], which substantially improve the convergence rate of the successive approximations. More specifically, it can be shown that for every vector  $J$ , state  $i$ , and time  $k$ :

$$(T^k J)(i) + \underline{c}_k \leq J^*(i) \leq (T^k J)(i) + \bar{c}_k,$$

where:

$$\underline{c}_k = \frac{\alpha}{1 - \alpha} \min_{i=1, \dots, n} [(T^k J)(i) - (T^{k-1} J)(i)],$$

$$\bar{c}_k = \frac{\alpha}{1 - \alpha} \max_{i=1, \dots, n} [(T^k J)(i) - (T^{k-1} J)(i)].$$

In fact, these error bounds can be used so as to further prove the finite convergence of the value iteration after  $k < k'$  steps,  $k' \in \mathbf{N}$ . It can also be observed that instead of performing the value iteration simultaneously for all policies, one can perform the iteration in a *Gauss-Seidel* fashion, [10]. The contractive characteristics of the operator  $(FJ)$  make it possible to develop similar schemes. Instead of iterating on the operator  $(TJ)$ , we

define a new sequence based on the operator  $(FJ)$ :

$$(FJ)(1) = \min_{u \in U(1)} \left[ g(1, u) + \alpha \sum_{j=1}^N p_{1j}(u) J(j) \right],$$

$$(FJ)(i) = \lim_{u \in U(i)} \left[ g(i, u) + \alpha \sum_{j=1}^{i-1} p_{ij}(FJ)(j) + \alpha \sum_{j=i}^n p_{ij}(u) J(j) \right],$$

$$i = 1, \dots, n.$$

In fact, when the error bounds are not used, a very interesting property can be shown, [4]:

- If  $J$  satisfies:

$$J(i) \leq (TJ)(i) \leq J^*(i), \quad i = 1, \dots, n,$$

then:

$$(T^k J)(i) \leq (F^k J)(i) \leq J^*(i),$$

$$i = 1, \dots, n; \quad k = 1, 2, \dots$$

In other words, the Gauss-Seidel iteration converges faster than the ordinary, i. e., *Jacobi*, value iteration. An excellent treatment of the comparisons between Gauss-Seidel and Jacobi iterations and their parallel implementation can be found in [14]. Although the value iteration can be shown to be convergent even when the state and control spaces are infinite, the actual implementation can only proceed via approximations. In other words, instead of actually computing  $TJ$  we can only compute  $J'$ , such that:  $\max_{x \in S} |J'(x) - (TJ)(x)| \leq \epsilon$ . For such approximate methods to be in order, we do not necessarily need infinite spaces but even spaces with a very large number of states in which the actual computation is deemed inappropriate. Any function  $J'$  that satisfies the above criterion can in principle be used. Details regarding discretization approaches and computational techniques for addressing infinite state spaces can be found in [2,11].

The value iteration, thus far presented, is based on successive evaluations of the cost functions. Early on, [1], it was suggested that an alternate approach is to iterate on policies so as to generate sequences of stationary policies with improved, over the preceding one, costs. This method is known as the *policy iteration*. The method proceeds in three steps:

- 1) initialize control policy,  $u^0$ .
- 2) given a stationary policy,  $\mu^k$ , evaluate the cost function  $J_{\mu^k}$  by solving:

$$(I - \alpha P_{\mu^k})J_{\mu^k} = g_{\mu^k}.$$

- 3) Obtain a new policy such that it satisfies:  $T_{\mu^{k+1}} J_{\mu^k} = TJ_{\mu^k}$ .

In the above, the matrix  $P_{\mu}$  is the *transition probability matrix* for a given stationary policy  $\mu$ , given by:

$$P_{\mu} = \begin{pmatrix} p_{11}(\mu(1)) & \cdots & p_{1n}(\mu(1)) \\ \cdots & \cdots & \cdots \\ p_{n1}(\mu(1)) & \cdots & p_{nn}(\mu(n)) \end{pmatrix}$$

and  $g_{\mu}$  the associated cost vector:

$$g_{\mu} = \begin{pmatrix} g(1, \mu(1)) \\ \cdots \\ g(n, \mu(n)) \end{pmatrix}.$$

Termination is detected once  $J_{\mu^k} = TJ_{\mu^k}$ , i.e., a *fixed point* of the operator  $TJ$  has been identified. Notice that because of the assumption that the policy space is finite, the algorithm will terminate in a finite number of steps. Similarly to the value iteration, infinite state and control spaces pose problems when implementing policy iterations. Specifically, the policy evaluation and policy improvement steps can only be performed via approximations.

In [5] an *adaptive aggregation method* is proposed so as to address the issue of occasional slow convergence. The fundamental premise is to lump states of the original problem so as to generate a smaller dimension problem. In other words, the state space  $S$  is partitioned into smaller-dimensional spaces as:  $S = S_1 \cup \cdots \cup S_m$ . Given such a partitioning one can further define the transition probabilities for the aggregate states as:

$$r_{ij} = \sum_{s \in S_i} q_{is} \sum_{t \in S_j} p_{st}(\mu(s)),$$

which is the probability that the next state will belong to  $S_j$  given that the current state is  $S_i$ .  $q_{ij}$  are the elements of an  $m \times n$  matrix  $Q$ , such that  $q_{is} \neq 0$ , if  $s \in S$ .

Finally, [7], noticed that since in the limit  $J \leq J^* = TJ^*$ , the optimal policy can be derived as the solution of

the following *linear programming problem*:

$$\begin{cases} \max & \sum_{i \in S} \lambda_i \\ \text{s.t.} & \lambda_i \leq g(i, u) + \alpha \sum_{j=1}^n p_{ij}(u)\lambda_j, \\ & u \in U(i), \\ & i = 1, \dots, n. \end{cases}$$

In the above formulation  $p_{ij}(u)$  denote the transition probabilities:  $p_{ij}(u) = \{ P(x_{k+1} = j | x_k = i, u_k = u) \}$ ,  $i, j \in S, u \in U(i)$ . These can either be given or derived based on the discrete dynamic system,  $x_{k+1} = f(x_k, u_k, \omega_k)$ , and the known probability distribution  $P(\cdot | x, u)$  of the input disturbance  $\omega_k$ . Linear programming formulations can also be used to derive cost and policy evaluation approximations. One possibility is to approximate  $J^*$  by a set of known basis functions as:  $J'(x, r) = \sum_{k=1}^m r_k \omega_k(x)$ . The vector  $r$  is an  $m$ -dimensional vector of known parameters, and for each state  $x$  we have chosen a set of known scalars  $\omega_k(x)$ . The vector  $r$  can be determined as the solution of:

$$\begin{cases} \max & \sum_{x \in S'} J'(x, r) \\ \text{s.t.} & J'(x, r) \leq g(x, u) + \alpha \sum_{y \in S} p_{xy} J'(y, r), \\ & x \in S' \subset S, \\ & u \in U'(x) \subset U(x). \end{cases}$$

Furthermore, the cost function  $J_{\mu}$  for a given policy  $\mu$  can be approximated via linear programming formulations by identifying a vector  $r$  so as to minimize:  $\max_{x \in S} |J'(x, r) - J_{\mu}(x)|$ . This can be shown, [4], to be equivalent to solving:

$$\begin{cases} \min & z \\ \text{s.t.} & \left| J'(x, r) - g(x, \mu(x)) \right. \\ & \left. - \alpha \sum_{y \in S} p_{xy}(\mu(x)) J'(y, r) \right| \leq z, \\ & x \in S' \subset S. \end{cases}$$

Extensions of the general ideas are discussed in [12] where work on including constraints in the general formulation of the discounted dynamic programming problem is presented. Furthermore, [8] expanded the

scope of these models so as to address dynamic programming optimization problems involving multiple criteria by identifying the set of non-inferior, *Pareto optimal*, solutions.

Dynamic programming; Infinite horizon problems

*Dynamic programming* deals with situations where optimal decisions are being sought in systems operating in stages. Events occur in a specific order, such that the decision at time  $k+1$  depends on the state of the system at time  $k$ . In general the key variables of the basic formulation are as follows:

- $k$  represents discrete time;
- $x_k$  represents the state of the system at time  $k$ ;
- $\mu(x_k)$  represents the control, or decision, variable to be selected at time  $k$ ;
- $\omega_k$  represents a random disturbance occurring at time  $k$ ;
- $N$  represents the time horizon.

Given the aforementioned variables, the basic dynamic programming formulation requires the following ingredients:

- a discrete-time dynamic system:

$$x_{k+1} = f_k(x_k, \mu_k, \omega_k);$$

- an additive cost function of the form:

$$g_N(x_N) + \sum_{k=1}^{k=N-1} g_k(x_k, \mu_k, \omega_k),$$

where  $g_k$  corresponds to the cost incurred at time  $k$ . One is therefore wishing to identify that control policy,  $\pi = \{\mu_0, \dots, \mu_{N-1}\}$ , which minimizes the expected cost:

$$J^*(x_0) = \min_{\pi \in \Pi} J_\pi(x_0) = E \left\{ g_N(x_N) + \sum_{k=1}^{k=N-1} g_k(x_k, \mu_k, \omega_k) \right\}.$$

The expectancy operator is needed since the presence of the random parameters  $\omega_k$  the cost function becomes itself a random variable. As further complication, one might also minimize the expected cost not only for a given initial state of the system,  $x_0$ , but also with respect to all possible initial states.

*Infinite horizon problems* are further characterized by the fact that the number of stages  $N$  is infinite. In such a case, the cost functional over an infinite number of stages for a given control policy  $\pi = \{\mu_0, \mu_1, \dots\}$ , and initial state  $x_0$ , is given by:

$$J_\pi(x_0) = \lim_{n \rightarrow \infty} E \left\{ \sum_{k=1}^{k=N-1} \alpha^k g_k(x_k, \mu_k, \omega_k) \right\}.$$

The factor  $\alpha$  is termed *discount factor* and is a positive scalar  $0 < \alpha \leq 1$  which simply implies that future costs matter less than similar costs incurred at the present time. Infinite horizon problems are by definition the limit of the corresponding  $N$ -stage problem, as  $N \rightarrow \infty$ . Three points are pivotal in the analysis of infinite-dimensional dynamic programming problems:

- The optimal cost for the infinite horizon is the limit of the corresponding  $N$ -stage optimal cost, i. e.,  $J^* = \lim_{N \rightarrow \infty} J_N$ .
- The optimal costs satisfy *Bellman's equation*, i. e.,

$$J^*(x) = \min_{u \in U(x)} E \{ g(x, \mu, w) + J^*(f(x, \mu, w)) \}.$$

- If the optimal policy that correspond to the minimum of Bellman's equation is  $\mu(x)$ , then the policy  $\pi = \{\mu, \mu, \dots\}$  should be optimal.

The assumption of an infinite number of stages may not be satisfied in practice but is a very important one in terms of analyzing the asymptotic behavior of systems involving a finite but large number of stages. Depending on the nature of the cost per stage and the discount factor, the following categories of infinite horizon dynamic programming problems can be identified, [1]:

- *stochastic shortest path problems*: this problem is actually a generalization of the *deterministic shortest path problem* in the sense that we select not a successor but rather a probability distribution  $p_{ij}(\mu)$ . Obviously, if the probability  $p_{ij}(\mu) = 1$  for a unique state  $j$ , then we recover the deterministic shortest path problem. One key feature of the stochastic shortest path problem is that the termination state  $t$  is cost-free termination state such that once the system reaches that state it never leaves from it. In other words,  $p_{tt}(\mu) = 1$  and  $g(t, \mu) = 0$ , for all policies  $\mu$ . In effect, the horizon is finite but the actual length is random. Furthermore, there exists at least one policy for which the destination state will be reached inevitably. A key assumption required for guaranteeing eventual termination states that there exists an integer  $m$  such that for every initial state and policy, there is a positive probability that the termination state will be reached after no more than  $m$  stages.

- *discounted problems with bounded cost per stage*: this type of infinite horizon dynamic programming encompasses problems for which:

$$|g(x, \mu, \omega)| \leq M, \forall (x, \mu, \omega) \in S \times C \times D,$$

i. e., there exists a finite scalar,  $M$ , that bounds the per stage cost. Furthermore, the discount factor is such that  $0 < \alpha < 1$ .

Both of these conditions are important so as to show that:

$$\lim_{K \rightarrow \infty} E \left\{ \sum_{k=N}^K \alpha^k g(x_k, \mu(x_k), \omega_k) \right\} \rightarrow 0.$$

Boundedness and discounting results in successive approximation mappings which are *contraction mappings*, [2], thus proving the convergence of such schemes to the optimal solution of the discounted with bounded costs infinite horizon dynamic programming problems.

- *undiscounted problems*: this type of infinite horizon problems covers situations in which the discount

factor  $\alpha = 1$ , which greatly complicates the analysis. The key distinction is that the lack of a discount factor may result in infinite costs even when the per cost stage is bounded.

- *average cost per stage problems*: In cases where neither discounting nor a cost-free termination state exists, it is often meaningful to optimize the average per stage cost starting from state  $i$ .

$$J(i) = \lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E} \left\{ \sum_{k=1}^{N-1} g(x_k, \mu_k(x_k), \omega_k) : x_0 = i \right\}.$$

In essence what is assumed is that for most problems of interest the average and the optimal per stage cost are independent of the initial state. As a result, costs that incurred in the early stages do not matter since their contributions vanishes, i. e.,

$$\lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E} \left\{ \sum_{k=0}^K g(x_k, \mu_k(x_k), \omega_k) \right\} = 0.$$

For discrete state and transition spaces, it is helpful to consider the associated finite-state Markov chain. Let the state space  $S$  consist of  $n$  states, denoted by  $1, \dots, n$ :

$$S = \{1, \dots, n\}.$$

The transitions probabilities from state  $i$  to state  $j$  are:

$$p_{ij}(u) = \mathbb{P}(x_{k+1} = j | x_k = i, u_k = u), \\ i, j \in S, \quad u \in U(i).$$

The dynamics of the state transitions  $x_{k+1} = f(x_k, u_k, \omega_k)$  can actually be used to compute the state transitions. Given the above, the per stage expected cost can be expressed as:  $g(i, u) = \sum_{j=1}^n p_{ij}(u) g'(i, u, j)$  Given the above definitions, a very important mapping can now be defined:

$$(TJ)(i) = \min_{u \in U(i)} \left[ g(i, u) + \alpha \sum_{j=1}^n p_{ij}(u) J(j) \right], \\ i = 1, 2, \dots,$$

and also

$$(T_\mu J)(i) = g(i, \mu(i)) + \alpha \sum_{j=1}^n p_{ij}(\mu(i)) J(j), \\ i = 1, 2, \dots,$$

This operator can actually be written as:

$$T_\mu J = g_\mu + \alpha P_\mu J.$$

Therefore, a stationary policy has a corresponding cost,  $J_\mu$ , which is the solution to the equation:

$$(I - \alpha P_\mu) J_\mu = g_\mu.$$

Computationally, two major families of approaches exists for determining the optimal additive costs and the optimal policies. The first one, *value iteration*, is based on the idea of successive approximations. It can be shown, under conditions depending of the specific type of infinite horizon problem, that:

$$\lim_{k \rightarrow \infty} (T^k J)(i) = J^*(i).$$

This property essentially implies that the successive application of the mapping  $(TJ)$  will in the limit provide the optimal cost.

On the other hand *policy iteration* operates on the policy space and tries to identify a converging sequence of stationary policies converging to the optimal one. In all cases, the following basic three steps define the iteration:

- *Initialization*: guess an initial stationary policy,  $\mu^0$ .
- *Policy evaluation*: given a stationary policy,  $\mu^k$ , compute the corresponding cost function,  $J_{\mu^k}$  from the system:

$$(I - \alpha P_{\mu^k}) J_{\mu^k} = g_{\mu^k}.$$

- *Policy improvement*: obtain a new stationary policy satisfying:

$$T_{\mu^{k+1}} J_{\mu^k} = T J_{\mu^k}.$$

Dynamic programming; Inventory control

Consider the problem of ordering a quantity of a certain item at each of the  $N$  periods so as to meet some stochastic demand. In mathematical terms the problem is defined as follows:

- $x_k$ , the stock of a particular commodity available at the beginning of the  $k$ th period.
- $u_k$  the stock to be ordered and immediately delivered at the beginning of the  $k$ th period.
- $\omega_k$  the demand during the  $k$ th period, whose probability distribution is assumed to be known.

The demand distributions are assumed to be independent random variables for each time period  $k$ . A simple stock balance at the beginning of each time period

provides the description of the discrete-time evolution equation as:

$$x_{k+1} = x_k + u_k - \omega_k.$$

In other words, the state of the system (stock) at the beginning of period  $k + 1$  was the state of the system (stock) at period  $k$  plus the ordered stock minus the demand at period  $k$ . The form of the replenishment of policy is very important and sits at the heart of the analysis of similar problems. The one just presented is, as will be seen, one of the two major assumptions regarding the stock balance equations. Given the above definitions, the cost incurred at period  $k$  has two components:

- a cost  $r(x_k)$  representing either a penalty for positive stock, storage, or negative stocks, shortage for unfilled demand.
- a surcharging cost,  $cu_k$ , where  $c$  is the per unit surcharged cost.

The problem just described is known as the *inventory control problem*, one of the most important ones in the area of operations research. The preceding formulation illustrates the main characteristics of the inventory control problem:

- a discrete-time system that defines the system evolution in time of the form:

$$x_k = f_k(x_k, u_k, \omega_k);$$

- a set of independent random disturbances, representing commodity demands;
- a set of control constraints that depend on the state of the system at time  $k$ ,  $x_k$ , that is  $u_k \in U(x_k)$ ;
- a period of  $N$  time intervals over which the operating cost has an additive form as:

$$\mathbb{E} \left( g_N(x_N) + \sum_{k=0}^{N-1} g_k(x_k, u_k, \omega_k) \right);$$

and, finally,

- we wish to optimally select the control actions at every time interval  $k$ , so as to optimize over all possible control policies the cost of operating the inventory system.

Clearly, the above definition of the inventory control problem, formulates the problem as *dynamic programming* problem in which we try to minimize an expected additive cost function.

Stochastic inventory problems were first considered by [6,10], were an abstract stochastic inventory model that allowed for possible constraints on the inventory after ordering were considered. In the literature of stochastic inventory models, there are two different assumptions about the excess demand unfilled from existing inventories: the *backlog assumption* and the *lost sales assumption*. These affect the form of the stock balance equation. The backlog assumption is historically more popular in the literature because of the inventory studies with spare parts inventory management problems. This assumption essentially states that an unfilled demand is being accumulated and satisfied at later times. The lost sales assumption states that unfilled demand is lost, which is the situation arising in retail establishments. Under either assumption, an important issue has been to establish the optimality of the  $(s, S)$ -type policy, [7]. It defines a very simple replenishment rule:

$$\mu^*(x_k) = \begin{cases} S_k - x_k, & x_k < s_k, \\ 0, & x_k \geq s_k. \end{cases}$$

The above rule is referred to as the  $(s, S)$  policy, implying that when the current level is less than the reorder point,  $s$ , an order up to the reorder level,  $S$ , has to be placed. Under an  $(s, S)$  policy if the inventory level at the beginning of a period is less than the reorder point  $s$ , then a sufficient quantity must be re-ordered to achieve an inventory level  $S$  upon replenishment. The key concept of  $K$ -convexity, [1], was instrumental in proving the optimality of the  $(s, S)$  policies. A real-valued function  $g$  is  $K$ -convex, where  $K \geq 0$ , if:

$$K + g(z + y) \geq g(y) + z \left( \frac{g(y) - g(y - b)}{b} \right), \\ \forall z \geq 0, b > 0, y.$$

The parameter  $K$  is the fixed cost associated with a positive inventory order:

$$C(u) = \begin{cases} K + cu, & u > 0, \\ 0, & u = 0. \end{cases}$$

The concept of  $K$ -convexity is one of the most important tools for the analysis of inventory control problem. It essentially expands the concept of convexity and is instrumental in proving the optimality of policies in inventory control problems. Regarding  $K$ -convexity, [2], the following hold true:

- 1) A real-valued convex function  $g$  is also 0-convex and hence also  $K$ -convex for all  $K \geq 0$ .
- 2) If  $g_1(y)$  and  $g_2(y)$  are  $K$ -convex and  $L$ -convex ( $K \geq 0, L \geq 0$ ), respectively, then  $\alpha g_1(y) + \beta g_2(y)$  is  $(\alpha K + \beta L)$ -convex for all  $\alpha > 0$  and  $\beta > 0$ .
- 3) If  $g(y)$  is  $K$ -convex and  $\omega$  is a random variable, then  $E_\omega\{g(y-\omega)\}$  is also  $K$ -convex, provided  $E_\omega\{|g(y-\omega)|\} < \infty$ , for all  $y$ .
- 4) If  $g$  is a continuous  $K$ -convex function and  $g(y) \rightarrow \infty$  as  $|y| \rightarrow \infty$ , then there exist scalars  $s$  and  $S$  with  $s \leq S$  such that:
  - a)  $g(S) \leq g(y)$ , for all scalars  $y$ ;
  - b)  $g(S) + K = g(s) < g(y)$ , for all  $y < s$ ;
  - c)  $g(y)$  is a decreasing function on  $(-\infty, s)$ ;
  - d)  $g(y) \leq g(z) + K$ , for all  $y, z$  with  $z \leq y \leq z$ .

If we further define a holding/storage cost as:

$$r(x) = p \max(0, -x) + h \max(0, x),$$

the function  $H$  as:

$$H(y) = pE(\max(0, \omega_k - y)) + E(\max(0, y - \omega_k)).$$

Application of the *dynamic programming algorithm* for zero final cost gives:

$$J_k(x_k) = \min \left\{ G_k(x_k), \min_{u_k > 0} \{K + cu_k + G_k(x_k + u_k)\} \right\},$$

with  $G_k(x_k)$  defined as:

$$G_k(y) = cyH(y) + E(J_{k+1}(y - \omega))$$

and  $y_k = x_k + u_k$ . Because of the  $K$ -convexity of  $G$ , it can actually be shown, [7], that the  $(s, S)$  policy is optimal. See [11] for the optimality of the  $(s, S)$  policy in the case of lost sales. For the case where the unfilled demand is not backlogged but rather lost, the system dynamic equation is defined as:

$$x_{k+1} = \max(0, x_k + u_k - \omega_k).$$

Additional  $K$ -convexity results and the optimality of the  $(s, S)$  for the case of lost-sales is presented and analyzed in [4]. Finite storage capacity in most real-life situations imposes an upper bound on theory that can be kept. The recent analysis of [3] considers the multi-product inventory model with stochastic demands and

warehousing constraints. This is a fairly general model in that it does not allow for surplus disposal,  $u_k \geq 0$ , and imposes constraints on the stored stock,  $x_k + u_k \in \Gamma$ .

Similar ideas pertain the analysis of inventory control problems over an infinite horizon. *Infinite horizon problems* need not necessarily correspond to physically realistic situations, but nevertheless, they define the vehicle for a thorough analysis of the asymptotic response of the inventory system. A discounted version of the backlogged problem can be stated as:

$$J_\pi(x_0) = \lim_{N \rightarrow \infty} \mathbb{E} \left( \sum_{k=1}^{N-1} \alpha^k (c\mu_k(x_k) + H(x_k + \mu(x_k) - \omega_k)) \right),$$

where:

$$H(y) = p \max(0, -y) + h \max(0, y).$$

The case of  $\alpha < 1$ , i. e., a *discounted infinite horizon problem*, has also been analyzed, [8], and the existence of an optimal state-dependent  $(s, S)$ -type policy for problems with discounted costs was rigorously established.

The classical papers [5,10] were also devoted to stochastic inventory problems with the criterion of long-run average cost. In other words, one is interested in minimizing an average expected cost within an infinite horizon

$$J_\pi(x_0) = \lim_{N \rightarrow \infty} \frac{1}{N} \times \mathbb{E} \left( \sum_{k=1}^{N-1} \alpha^k (c\mu_k(x_k) + H(x_k + \mu(x_k) - \omega_k)) \right).$$

This analysis also concludes that  $(s, S)$ -type policies are as well optimal for the long time average-return problem. The  $(s, S)$ -type of optimal policies are very important and they have been shown to be optimal for a wide variety of inventory problems including systems with continuous demands and discrete order sizes, [9], in other words for the cases where the orders  $u_k$  are assumed to be nonnegative integers, as well as the case where special structure in the form of periodicity of various components of the formulation such as demands, prices, and cost, [2].

Undoubtedly, one of the most appealing features of inventory theory has been the fact that  $(s, S)$  policies are optimal for the class of dynamic inventory prob-

lems with random demands. However, real-life inventory problems impose constraints that make the assumption imposed on the analysis apparently too restrictive. The nature of demand, for instance, is an important factor in determining optimal policies. Classical models have assumed demand in each period to be a random variable independent of demands in other periods and of environmental factors at other times. Nevertheless, fluctuating economic conditions and uncertain market conditions can have a major effect. Furthermore, various constraints are observed in real life that limit the nature of ordering decisions and inventory levels. The recent work of [8] addresses similar issues so as to incorporate cyclic or seasonal demand, as well as constraints imposed on the ordering periods, storage and service level constraints. Nevertheless, it is still shown that  $(s, S)$  policies are also optimal for these types of generalized models.

## Discrete-Time Optimal Control

The cost function in the standard  $k$ -stage discrete-time optimal control problem is defined by

$$J = l_{k+1}(x_{k+1}) + \sum_{i=1}^k l_i(u_i, x_i) \quad (1)$$

and the recursion

$$\begin{cases} x_1 = a, \\ x_{i+1} = f_i(u_i, x_i), \quad i = 1, \dots, k. \end{cases} \quad (2)$$

In these equations,  $u_i$  is a *control vector* in  $\mathbf{R}^m$  and  $x_i$  is a *state vector* in  $\mathbf{R}^n$ . For each vector-valued  $k$ -tuple  $u = (u_1, \dots, u_k)$  in the direct sum  $\mathbf{R}^{km} = \oplus_{i=1}^k \mathbf{R}^m$ , there is a unique state vector-valued  $(k+1)$ -tuple  $x(u) = (x_1(u), \dots, x_{k+1}(u)) \in \mathbf{R}^{(k+1)n}$  satisfying (2), and a corresponding unique value  $J(u)$  in (1). For present purposes, the state transition functions  $f_i$ , the terminal loss function  $l_{k+1}$  and the stage-wise loss functions  $l_i$ ,  $i = 1, \dots, k$ , are assumed to be twice continuously differentiable. The functions  $x(\cdot)$  and  $J(\cdot)$  are then also twice continuously differentiable, and Newton's method is formally applicable to the problem of minimizing  $J(\cdot)$  over  $\mathbf{R}^{km}$ . Moreover, for fixed  $m$  and  $n$  the  $km \times km$  linear system associated with the Newton iteration map for (1), (2) can be solved efficiently with *dynamic programming recursions* in  $O(k)$  floating point operations as  $k$  increases without bound. In contrast, it requires  $O(k^3)$  floating point operations to assemble and solve the Newtonian linear system for a general cost function  $J$  on  $\mathbf{R}^{km}$  by standard Gaussian elimination methods.

The following discussion conforms to [4]. See [7] and [8] for an alternative development with connections to *differential dynamic programming*, and for a related but nonequivalent treatment of discrete-time optimal control problems based on the Riccati transformation. For analogous constructions in the setting of continuous-time optimal control problems, see [4] and the original papers [5] and [6]. For extensions to Newtonian projection methods and input-constrained optimal control problems, see [2] and [3].

## Newton's Method

If  $J$  is any continuously differentiable real-valued function on  $\mathbf{R}^N$  with global or local minimizing vectors  $\bar{u}$ ,

then all such vectors must satisfy the *first order necessary condition*,

$$\nabla J(u) = 0, \quad (3)$$

where

$$\nabla J(u) = \left( \frac{\partial J}{\partial u_1}(u), \dots, \frac{\partial J}{\partial u_N}(u) \right).$$

A solution of (3) is called a *stationary point*.

Condition (3) comprises  $N$  scalar equations in  $N$  scalar unknowns  $u_i$ . If  $J$  is a quadratic function, then (3) is a linear system which can be treated with standard elimination algorithms or other techniques capable of exploiting whatever structure may exist in the coefficient matrix for (3). On the other hand, if  $J$  is a non-quadratic nonlinear function, then (3) is a nonlinear system and iterative methods are generally needed to generate successive approximations to a solution of (3). One such method is Newton's recursive linearization scheme,

$$\begin{aligned} u &\rightarrow u + \bar{v}, \\ \nabla J(u) + \nabla^2 J(u)\bar{v} &= 0. \end{aligned} \quad (4)$$

When  $J$  is twice continuously differentiable, the vector-valued map  $\nabla J(\cdot): \mathbf{R}^N \rightarrow \mathbf{R}^N$  is continuously differentiable and its first differential at  $u$  is the Hessian operator  $\nabla^2 J(u): \mathbf{R}^N \rightarrow \mathbf{R}^N$  defined by

$$(\nabla^2 J(u)v)_i = \sum_{j=1}^N \frac{\partial^2 J}{\partial u_i \partial u_j}(u)v_j$$

for  $i = 1, \dots, N$ . In such cases, (4) is formally applicable to the nonlinear system (3). Furthermore, if  $\nabla^2 J(\bar{u})$  is invertible at a solution  $\bar{u}$  for (3), then in some neighborhood  $N$  of  $\bar{u}$ ,  $\nabla^2 J(u)$  is also invertible and for each starting point  $u^0 \in N$ , the iteration (4) generates a sequence of vectors,  $u^0, u^1, \dots$ , which remain in  $N$  and converge rapidly to  $\bar{u}$ . More precisely, either  $u^i = \bar{u}$  eventually, or the errors  $\|u^i - \bar{u}\| = \langle (u^i - \bar{u}, u^i - \bar{u}) \rangle^{\frac{1}{2}}$  satisfy the *superlinear convergence condition*,

$$\lim_{i \rightarrow \infty} \frac{\|u^{i+1} - \bar{u}\|}{\|u^i - \bar{u}\|} = 0. \quad (5)$$

A solution of (3) at which  $\nabla^2 J(u)$  is invertible is said to be a *regular stationary point*. Note that solutions of (3) can be local maximizers or saddle points of  $J$ , and

that regular points of this kind can also attract the Newton iterates. Hence for minimization problems, a simple steepest descent iteration is often employed at the outset to seek out likely starting points  $u^0$  for (4) near some *regular local minimizer* for  $J$ .

If  $J$  is twice continuously differentiable, then every global or local minimizer  $\bar{u}$  must also satisfy the *second order necessary condition*,

$$\forall v \in \mathbf{R}^N, \quad \langle v, \nabla^2 J(\bar{u})v \rangle \geq 0, \quad (6)$$

where  $\langle \cdot, \cdot \rangle$  is the standard Euclidean inner product,

$$\langle v, w \rangle = \sum_{i=1}^N v_i w_i.$$

In  $\mathbf{R}^N$ ,  $\bar{u}$  is therefore a regular local minimizer if and only if  $\nabla^2 J(\bar{u})$  is *positive definite*, i. e.,

$$\forall v \in \mathbf{R}^N, \quad v \neq 0 \Rightarrow \langle v, \nabla^2 J(\bar{u})v \rangle > 0. \quad (7)$$

The gap between (6) and (7) is not large, hence regular local minimizers are commonly encountered in  $\mathbf{R}^N$ .

By continuity, property (7) extends to  $\nabla^2 J(u)$  in some neighborhood of  $\bar{u}$ . At each fixed  $u$  in this neighborhood, the linear system in Newton's iteration (4) is equivalent to a corresponding unconstrained *accessory minimum problem*

$$\bar{v} \in \arg \min_{v \in \mathbf{R}^N} \phi(v) \quad (8)$$

with a strictly convex quadratic cost function

$$\phi(v) = \langle \nabla J(u), v \rangle + \frac{1}{2} \langle v, \nabla^2 J(u)v \rangle, \quad (9)$$

and a unique global minimizer  $\bar{v}$ . This equivalence is computationally significant for unconstrained minimization problems in general and discrete-time optimal control problems in particular.

### The Accessory Minimum Problem

If  $J$  is the cost function of a discrete-time optimal control problem, then it can be shown that the accessory minimum problem (8)–(9) is also a discrete-time control problem with quadratic loss functions and linear state transition functions. Near a regular minimizer for  $J$ , this linear-quadratic (LQ) problem has a strictly

convex cost function that can be minimized with dynamic programming recursions. The required control-theoretic construction for  $\phi$  and the related dynamic programming algorithms are outlined below.

In the following development, the symbol  $u$  may denote a vector in  $\mathbf{R}^m$  or a vector-valued  $k$ -tuple in  $\mathbf{R}^{km}$ . Similarly,  $x$  may indicate a vector in  $\mathbf{R}^n$  or a vector-valued  $(k+1)$ -tuple in  $\mathbf{R}^{(k+1)n}$ , and the bracket  $\langle \cdot, \cdot \rangle$  may denote the Euclidean inner product in any of the spaces  $\mathbf{R}^m$ ,  $\mathbf{R}^n$ ,  $\mathbf{R}^{km}$ , or  $\mathbf{R}^{(k+1)n}$ . In each case, the correct interpretation is always clear from the context. Now suppose that  $J(\cdot)$  is defined by (1)–(2) on  $\mathbf{R}^{km}$ , and fix  $u \in \mathbf{R}^{km}$ . Then for all  $v \in \mathbf{R}^{km}$  the chain rule gives,

$$\begin{aligned} \langle \nabla J(u), v \rangle &= \frac{d}{ds} J(u + sv)|_{s=0} \\ &= \sum_{i=1}^{k+1} \langle \nabla_x l_i, y_i \rangle + \sum_{i=1}^k \langle \nabla_u l_i, v_i \rangle \end{aligned} \quad (10)$$

and

$$\begin{aligned} \langle v, \nabla^2 J(u)v \rangle &= \frac{d^2}{ds^2} J(u + sv)|_{s=0} \\ &= \sum_{i=1}^{k+1} \langle \nabla_x l_i, z_i \rangle + \sum_{i=1}^{k+1} \langle y_i, \nabla_{xx}^2 l_i y_i \rangle \\ &\quad + 2 \sum_{i=1}^k \langle y_i, \nabla_{xu}^2 l_i v_i \rangle + \sum_{i=1}^k \langle v_i, \nabla_{uu}^2 l_i v_i \rangle, \end{aligned} \quad (11)$$

where

$$\begin{aligned} y_i &= \frac{d}{ds} x_i(u + sv)|_{s=0}, \\ z_i &= \frac{d^2}{ds^2} x_i(u + sv)|_{s=0}, \end{aligned} \quad (12)$$

and where all partial gradients and Hessians of  $l_{k+1}$  and  $l_i$ ,  $i = 1, \dots, k$ , are evaluated at  $x_{k+1}(u) \in \mathbf{R}^n$  and  $(u_i, x_i(u)) \in \mathbf{R}^m \oplus \mathbf{R}^n$ , respectively.

Equations (2) and (12) and the chain rule also establish that  $y_i$  and  $z_i$  are recursively generated by the equations of variation,

$$\begin{cases} y_1 = 0, \\ y_{i+1} = A_i y_i + B_i v_i, \quad i = 1, \dots, k, \end{cases} \quad (13)$$

and

$$\begin{cases} z_1 = 0, \\ z_{i+1} = A_i z_i \\ \quad + (C_i y_i) y_i + 2(D_i y_i) v_i + (E_i v_i) v_i \end{cases} \quad (14)$$

for  $i = 1, \dots, k$ , with linear differential maps,

$$A_i = \frac{\partial f_i}{\partial x}, \quad B_i = \frac{\partial f_i}{\partial u}$$

and

$$C_i = \frac{\partial^2 f_i}{\partial x \partial x}, \quad D_i = \frac{\partial^2 f_i}{\partial x \partial u}, \quad E_i = \frac{\partial^2 f_i}{\partial u \partial u}$$

evaluated at  $(u_i, x_i(u))$ . Useful control-theoretic representations for  $\nabla J(u)$  and  $\phi$  can now be constructed by removing  $y_i$  from formula (10) and  $z_i$  from formula (11) with the aid of an *adjoint recursion* for (13) and (14).

Equations (13) and (14) are special instances of

$$\begin{cases} w_1 = 0, \\ w_{i+1} = A_i w_i + \xi_i, \quad i = 1, \dots, k, \end{cases} \quad (15)$$

with  $w = (w_1, \dots, w_{k+1}) \in \mathbf{R}^{(k+1)n}$  and  $\xi = (\xi_1, \dots, \xi_k) \in \mathbf{R}^{kn}$ . For each  $\xi$ , there is a unique  $w = \Phi \xi$  satisfying (15), and the resulting correspondence defines a linear map  $\Phi: \mathbf{R}^{kn} \rightarrow \mathbf{R}^{(k+1)n}$ . The map  $\Phi$  has an associated *adjoint linear map*  $\Phi^*: \mathbf{R}^{(k+1)n} \rightarrow \mathbf{R}^{kn}$  which, in principle, is uniquely determined by the requirement,

$$\langle \Phi^* \eta, \xi \rangle = \langle \eta, \Phi \xi \rangle, \quad (16)$$

imposed for all  $\xi \in \mathbf{R}^{kn}$  and  $\eta \in \mathbf{R}^{(k+1)n}$ . The matrix representor for  $\Phi^*$  in the standard basis for  $\mathbf{R}^{(k+1)n}$  is obtained by transposing the analogous matrix representor for  $\Phi$ ; however, the adjoint map can also be computed directly with recursions derived from (15), *without prior construction of  $\Phi$* . More precisely, for each  $\eta \in \mathbf{R}^{(k+1)n}$ ,

$$(\Phi^* \eta)_i = \psi_{i+1} \quad (17)$$

for  $i = 1, \dots, k$ , where  $\psi$  is the unique solution of the adjoint recursion,

$$\begin{cases} \psi_{k+1} = \eta_{k+1}, \\ \psi_i = A_i^* \psi_{i+1} + \eta_i, \quad i = 1, \dots, k. \end{cases} \quad (18)$$

To see this, note that if  $w$  and  $\psi$  are solutions of (15) and (18) respectively, then

$$\begin{aligned} \langle \eta_{k+1}, w_{k+1} \rangle &= \langle \psi_{k+1}, w_{k+1} \rangle - \langle \psi_1, w_1 \rangle \\ &= \sum_{i=1}^k (\langle \psi_{i+1}, w_{i+1} \rangle - \langle \psi_i, w_i \rangle) \\ &= \sum_{i=1}^k \langle \psi_{i+1}, A_i w_i + \xi_i \rangle \\ &\quad - \sum_{i=1}^k \langle A_i^* \psi_{i+1} + \eta_i, w_i \rangle \\ &= \sum_{i=1}^k \langle \psi_{i+1}, \xi_i \rangle - \sum_{i=1}^k \langle \eta_i, w_i \rangle. \end{aligned}$$

Hence for all  $\xi \in \mathbf{R}^{kn}$  and  $\eta \in \mathbf{R}^{(k+1)n}$  condition (16) gives,

$$\langle \Phi^* \eta, \xi \rangle = \langle \eta, \Phi \xi \rangle = \langle \eta, w \rangle = \sum_{i=1}^k \langle \psi_{i+1}, \xi_i \rangle,$$

and this establishes (17).

With the preceding formulas, it is now possible to write  $\phi$  as a sum of linear and quadratic terms in the variables  $v_1, \dots, v_k$  and  $y_1, \dots, y_{k+1}$ , with coefficients derived from the partial gradients and Hessians of *Hamiltonian functions*,

$$\begin{aligned} H_i(u_i, x_i, \psi_{i+1}) \\ = l_i(u_i, x_i) + \langle \psi_{i+1}, f_i(u_i, x_i) \rangle. \end{aligned} \quad (19)$$

Fix  $u$  and  $v$  in  $\mathbf{R}^{km}$ , let  $\eta_i(u) = \nabla_x l_i$  for  $i = 1, \dots, k+1$ , and let  $\psi(u) \in \mathbf{R}^{(k+1)n}$  be the corresponding solution of the adjoint recursion,

$$\begin{cases} \psi_{k+1} = \nabla_x l_{k+1}, \\ \psi_i = A_i^* \psi_{i+1} + \nabla_x l_i, \quad i = 1, \dots, k. \end{cases} \quad (20)$$

In addition, let  $y$  and  $z$  be the unique solutions of (13) and (14) respectively. Then with reference to (15)–(17) and (20),

$$\begin{aligned} \sum_{i=1}^{k+1} \langle \nabla_x l_i, y_i \rangle &= \sum_{i=1}^k \langle \psi_{i+1}, B_i v_i \rangle \\ &= \sum_{i=1}^k \langle B_i^* \psi_{i+1}, v_i \rangle \end{aligned}$$

and

$$\begin{aligned} \sum_{i=1}^{k+1} \langle \nabla_x l_i, z_i \rangle &= \sum_{i=1}^k \langle \psi_{i+1}, (C_i y_i) y_i \rangle \\ &\quad + 2 \sum_{i=1}^k \langle \psi_{i+1}, (D_i y_i) v_i \rangle + \sum_{i=1}^k \langle \psi_{i+1}, (E_i v_i) v_i \rangle. \end{aligned}$$

When these expressions are substituted into (9)–(11), it follows from (19) that  $\phi$  is prescribed by

$$\phi(v) = q_{k+1}(y_{k+1}) + \sum_{i=1}^k q_i(v_i, y_i) \quad (21)$$

and the recursions,

$$\begin{cases} y_1 = 0, \\ y_{i+1} = A_i y_i + B_i v_i, \quad i = 1, \dots, k, \end{cases} \quad (22)$$

where  $A_i$  and  $B_i$  are the differential maps

$$A_i = \frac{\partial f_i}{\partial x}, \quad B_i = \frac{\partial f_i}{\partial u}$$

as before, and the loss functions  $q$  are given by

$$q_{k+1}(y) = \frac{1}{2} \langle y, Q_{k+1} y \rangle$$

and

$$\begin{aligned} q_i(v, y) &= \langle r_i, v \rangle + \frac{1}{2} \langle y, Q_i y \rangle \\ &\quad + \langle y, R_i v \rangle + \frac{1}{2} \langle v, S_i v \rangle, \end{aligned}$$

for  $i = 1, \dots, k$ , with

$$\begin{aligned} Q_{k+1} &= \nabla_{xx}^2 l_{k+1}, \\ r_i &= \nabla_u H_i, \end{aligned}$$

and

$$Q_i = \nabla_{xx}^2 H_i, \quad R_i = \nabla_{xu}^2 H_i, \quad S_i = \nabla_{uu}^2 H_i$$

for  $i = 1, \dots, k$ . Moreover, the cost gradient  $\nabla J(u)$  is separately recoverable from

$$\begin{aligned} \nabla J(u) &= (r_1, \dots, r_k) \\ &= (\nabla_u H_1, \dots, \nabla_u H_k). \end{aligned} \quad (23)$$

In these equations, the Hessian of  $l_{k+1}$  is evaluated at  $x_{k+1}(u)$  and the Hamiltonian gradients and Hessians are evaluated at  $(u_i, x_i(u), \psi_{i+1}(u))$ .

### Dynamic Programming Recursions

Recall that  $\nabla^2 J(u)$  is positive definite in some neighborhood of a regular local minimizer for  $J$ . When  $\nabla^2 J(u)$  is positive definite, the quadratic accessory minimum problem with cost function (21)–(22) can be solved by dynamic programming techniques, which rest on a simple embedding scheme and a few elementary theorems stated below without proof. For a fuller discussion of dynamic programming, see [1].

For  $j = 1, \dots, k$  and  $y \in \mathbf{R}^n$ , define the family of cost functions  $\phi_j(\cdot; y): \mathbf{R}^{(k+1-j)m} \rightarrow \mathbf{R}^1$  by

$$\phi_j(v_j, \dots, v_k; y) = q_{k+1}(y_{k+1}) + \sum_{i=j}^k q_i(v_i, y_i) \quad (24)$$

and the recursions,

$$\begin{cases} y_j = y \\ y_{i+1} = A_i y_i + B_i v_i, \quad i = j, \dots, k, \end{cases} \quad (25)$$

where  $q_i$ ,  $A_i$  and  $B_i$  are  $u$ -dependent entities defined as before. Evidently, the cost function  $\phi$  in (21)–(22) is recovered from the equation,

$$\phi(v) = \phi_1(v_1, \dots, v_k; 0). \quad (26)$$

Moreover, the cost functions  $\phi_j$  are recursively generated by

$$\phi_k(v_k; y) = q_k(v_k; y) + q_{k+1}(A_k y + B_k v_k)$$

and

$$\begin{aligned} \phi_j(v_j, \dots, v_k; y) &= q_j(v_j; y) \\ &\quad + \phi_{j+1}(v_{j+1}, \dots, v_k; A_j y + B_j v_j), \end{aligned}$$

for  $j = k-1, \dots, 1$ . It is likewise readily seen that

$$\begin{aligned} \phi_j(v_j, \dots, v_k; 0) &= \phi(0, \dots, 0, v_j, \dots, v_k), \\ \nabla_{vv}^2 \phi_j(v_j, \dots, v_k; y) &= \nabla_{vv}^2 \phi_j(v_j, \dots, v_k; 0), \end{aligned}$$

and

$$\nabla_{vv}^2 \phi(v) = \nabla^2 J(u)$$

for  $j = 1, \dots, k$ ,  $v \in \mathbf{R}^{km}$  and  $y \in \mathbf{R}^n$ . Note also that since  $\phi(\cdot)$  and  $\phi_j(\cdot; y)$  are quadratic functions, their corresponding  $v$ -Hessians are independent of  $v$  as well as  $y$ . These facts and the basic principles of dynamic programming yield the following theorems.

**Theorem 1** *The following statements are equivalent:*

- 1) *The quadratic function  $\phi(\cdot)$  has a unique global minimizer  $\bar{v} \in \mathbf{R}^{km}$ .*
- 2)  *$\nabla^2 J(u)$  is positive definite.*
- 3) *For all  $j = 1, \dots, k$ ,  $\nabla_{vv}^2 \phi_j$  is positive definite.*
- 4) *For all  $j = 1, \dots, k$  and all  $y \in \mathbf{R}^n$ , the quadratic function  $\phi_j(\cdot; y)$  has a unique global minimizer  $(\bar{v}_j, \dots, \bar{v}_k) \in \mathbf{R}^{(k+1-j)m}$ .*

**Theorem 2** *The following statements are equivalent:*

- 1) *For all  $j = 1, \dots, k$  and  $y \in \mathbf{R}^n$ ,*

$$\phi_j^0(y) := \inf_{v_j, \dots, v_k} \phi_j(v_j, \dots, v_k; y) > -\infty, \quad (27)$$

- 2) *The real-valued functions  $\phi_1^0(\cdot), \dots, \phi_k^0(\cdot)$  satisfy the backward functional recursion,*

$$\phi_j^0(y) = \inf_{v \in \mathbf{R}^m} [q_j(v, y) + \phi_{j+1}^0(A_j y + B_j v)] \quad (28)$$

for  $j = k, \dots, 1$ , with

$$\phi_{k+1}^0(y) := q_{k+1}(y).$$

**Theorem 3** *Let  $r_i$ ,  $A_i$ ,  $B_i$ ,  $Q_i$ ,  $R_i$ , and  $S_i$  be the vectors and linear maps appearing in the representations (21)–(22) and (24)–(25) for the functions  $\phi(\cdot)$  and  $\phi_j(\cdot; y)$ . Then the following statements are equivalent for all  $\bar{v} = (\bar{v}_1, \dots, \bar{v}_k) \in \mathbf{R}^{km}$ :*

- 1)  *$\bar{v}$  is the unique global minimizer for  $\phi$  in  $\mathbf{R}^{km}$ , i. e.,*

$$\arg \min_{v \in \mathbf{R}^{km}} \phi(v) = \{\bar{v}\}.$$

- 2) *The vector  $\bar{v} \in \mathbf{R}^{km}$  is generated by the forward recursions*

$$\begin{cases} y_1 = 0, \\ y_{j+1} = A_j y_j + B_j \bar{v}_j, \end{cases} \quad (29)$$

$$\begin{aligned} \{\bar{v}_j\} &= \arg \min_{v \in \mathbf{R}^m} [q_j(v, y_j) + \phi_{j+1}^0(A_j y_j + B_j v)] \\ &= \{y_j + \Gamma_j y_j\}, \end{aligned} \quad (30)$$

for  $j = 1, \dots, k$ , where

$$\begin{aligned} q_j(v, y) &= \langle r_j, v \rangle + \frac{1}{2} \langle y, Q_j y \rangle \\ &\quad + \langle y, R_j v \rangle + \frac{1}{2} \langle v, S_j v \rangle, \\ \phi_j^0(y) &= \alpha_j + \langle \beta_j, y \rangle + \frac{1}{2} \langle y, \Theta_j y \rangle, \end{aligned}$$

$S_j + B_j^* \Theta_{j+1} B_j$  is positive definite,

$$\gamma_j = -(S_j + B_j^* \Theta_{j+1} B_j)^{-1} (r_j + B_j^* \beta_{j+1}), \quad (31)$$

$$\Gamma_j = -(S_j + B_j^* \Theta_{j+1} B_j)^{-1} (R_j^* + B_j^* \Theta_{j+1} A_j), \quad (32)$$

and the linear maps  $\Theta_j$ , vectors  $\beta_j$ , and numbers  $\alpha_j$  satisfy the backward recursions,

$$\begin{cases} \Theta_{k+1} = 0, \\ \Theta_j = Q_j + A_j^* \Theta_{j+1} A_j \\ \quad + (R_j^* + B_j^* \Theta_{j+1} A_j)^* \Gamma_j, \end{cases} \quad (33)$$

$$\begin{cases} \beta_{k+1} = 0, \\ \beta_j = (A_j + B_j \Gamma_j)^* \beta_{j+1} + \Gamma_j^* r_j, \end{cases} \quad (34)$$

and

$$\begin{cases} \alpha_{k+1} = 0, \\ \alpha_j = \alpha_{j+1} - \frac{1}{2} \langle \gamma_j, (S_j + B_j^* \Theta_{j+1} B_j) \gamma_j \rangle \end{cases} \quad (35)$$

for  $j = k, \dots, 1$ .

These theorems support the following efficient scheme for computing the Newton increment  $\bar{v}$  in (4).

- 1 Given  $u \in \mathbf{R}^{km}$ , solve the forward recursion (2) for  $x(u)$ , and construct the corresponding linear maps  $A_j$  and  $B_j$ , and vectors  $\eta_j = \nabla_x l_j$ .
- 2 Solve the backward adjoint recursion (20) for  $\psi(u)$  and construct the corresponding vectors  $r_j$ .
- 3 Construct the linear maps  $Q_i$ ,  $R_i$  and  $S_i$ , solve the backward dynamic programming recursions (33) and (34) for  $\Theta_j$  and  $\beta_j$ , and compute  $\gamma_j$  and  $\Gamma_j$  in (31) and (32).
- 4 Solve the forward recursions (29)–(30) for  $y$  and  $\bar{v}$ .

#### Algorithm

Stages 1 and 2 in the foregoing algorithm are always well-posed, and yield the cost gradient  $\nabla J(u)$  (see (23)). The calculation for the Newton increment  $\bar{v}$  is well-posed if and only if stage 3 produces invertible linear maps  $S_j + B_j^* \Theta_{j+1} B_j$  for  $j = k, \dots, 1$ . The calculation for

$\bar{v}$  is well-posed and stage 3 concludes with  $k$  positive definite linear maps  $S_j + B_j^* \Theta_{j+1} B_j$  if and only if  $\nabla^2 J(u)$  is positive definite. If a positive semidefinite, indefinite or singular linear map  $S_j + B_j^* \Theta_{j+1} B_j$  is encountered at some point in stage 3, it follows that  $\nabla^2 J(u)$  is not positive definite and the accessory minimum problem may have no global minimizers or stationary points, or infinitely many such points. In such cases, it may be advantageous or even necessary to abort stage 3 and abandon Newton's method temporarily in favor of a descent iteration that employs the negative gradient  $-\nabla J(u)$  computed in stages 1 and 2, or some other descent direction. Alternative *quasi-Newtonian* descent directions can be obtained by replacing  $S_j$  in stage 3 with  $S_j + \lambda_j I$  where  $\lambda_j I$  is a positive shift added where necessary to maintain positive definiteness of  $S_j + \lambda_j I + B_j^* \Theta_{j+1} B_j$ . This variant of stage 3 is automatically well-posed and produces the unique global minimizer  $\bar{v}$  of the perturbed cost function,

$$\phi(v) + \frac{1}{2} \langle v, \Lambda(u)v \rangle,$$

where

$$\Lambda(u)v = (\lambda_1 v_1, \dots, \lambda_k v_k).$$

By construction,  $\nabla^2 J(u) + \Lambda(u)$  is positive definite and

$$\bar{v} = -(\nabla^2 J(u) + \Lambda(u))^{-1} \nabla J(u).$$

Hence  $\bar{v}$  is a descent vector for  $J$ . On the other hand, the simple steepest descent direction  $-\nabla J(u)$  may be more cost-efficient, particularly when  $u$  is far from a local minimizer for  $J$ .

If the work required to compute the differentials for  $f_j$  and  $l_j$  in each time step  $j$  is uniformly bounded in  $j$ , with  $m$  and  $n$  fixed, then the number of arithmetic operations required to execute the foregoing algorithm (or its shifted variants) is directly proportional to  $k$ . This compares very favorably with the standard  $O(k^3)$  estimate for general Newtonian calculations in  $\mathbf{R}^{km}$ .

Finally, references [9] and [10] revise the basic serial dynamic programming algorithm for parallel computation, and thereby achieve significant reductions in the time needed to calculate each Newton iteration.

Optimal control; Optimization; Approximation algorithms; Singular control; Time-delay; Nonseparable problem; Sensitivity

A very powerful method for optimization of a system that can be separated into stages is *dynamic programming* developed by R. Bellman [1]. The main concept of this technique lies in the *principle of optimality* which can be stated as follows:

An optimal policy has the property that whatever the initial state and the initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

Many engineering systems are in the form of individual stages, or can be broken into stages, so the idea of breaking up a complex problem into simpler subproblems so that optimization could be carried out systematically by optimizing the subproblems was received enthusiastically. Numerous applications of the principle of optimality in dynamic programming were given in [2], and there was a great deal of interest in applying dynamic programming to optimal control problems. In the 1960s many books and numerous papers were written to explore the use of dynamic programming as a means of optimization for optimal control problems. Since an optimal control problem, involving *optimization over a trajectory*, can be broken into a sequence of time stages, it appeared that dynamic programming would be ideally suited for such problems.

Although dynamic programming could be successfully applied to some simple optimal control problems, one of the greatest problems in using dynamic programming, however, was the *interpolation problem* encountered when the trajectory from a grid point did not reach exactly the *grid point* at the next stage [12]. This interpolation difficulty coupled with the dimensionality restriction and the requirement of a very large number of grid points limited the use of dynamic programming to only very simple optimal control problems. The limitations imposed by the ‘*curse of dimensionality*’ and the ‘*menace of the expanding grid*’ for solving optimal control problems kept dynamic programming from being used for practical types of optimal control problems,

until R. Luus [14] suggested effective means of overcoming both the interpolation and the dimensionality problems.

## Optimal Control Problem

We consider the continuous dynamic system described by the vector differential equation

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \quad (1)$$

with the initial state  $\mathbf{x}(0)$  given, where  $\mathbf{x}$  is an  $(n \times 1)$  state vector and  $\mathbf{u}$  is an  $(m \times 1)$  control vector bounded by

$$\alpha_j \leq u_j(t) \leq \beta_j, \quad j = 1, \dots, m. \quad (2)$$

The *performance index* associated with this system is a scalar function of the state at the given final time  $t_f$ ; i. e.,

$$I = \Phi(\mathbf{x}(t_f)). \quad (3)$$

We may have also state constraints, but for simplicity we shall leave these for later. The optimal control problem is to find the control  $\mathbf{u}$  in the time interval  $0 \leq t < t_f$ , so that the performance index in (3) is either minimized or maximized. To set up the problem into a staged form, we may approximate the optimal control problem by requiring a *piecewise constant control* policy instead of a continuous control policy, over  $P$  stages, each of length  $L$ , so that

$$L = \frac{t_f}{P}, \quad (4)$$

and we can consider the system at the grid points set up at these  $P$  stages. We may also use a piecewise linear approximation and the stages do not necessarily have to be of equal length.

## Iterative Dynamic Programming

M. DeTremblay and Luus [10] suggested that instead of interpolation, an approximation can be used when the trajectory from a grid point does not reach a grid point at the next stage. They suggested that the control policy that was found to be optimal for the closest grid point be used to continue the integration to the next stage. If a large number of grid points are taken at each stage then a reasonable approximation may be ob-

tained, but the resulting control policy can still be quite far from the optimum. Therefore, this simplification by itself gives only a crude approximation.

However, by making a small change to the procedure, the *accuracy* with which the optimum is obtained can be improved substantially. This change requires the use of the procedure repeatedly in an iterative fashion [16], so that after every iteration, where the best value is used as the center point, the regions for the allowable values for control and for the grid points are reduced in size. The idea of *region reduction* in optimization was successfully used by Luus and T.H.I. Jaakola [37] in *direct search optimization*. As was shown by Luus [16], dynamic programming can be used in this fashion to give a sufficiently accurate optimal control policy. Although easy to program, the method was not computationally attractive until the idea of using *accessible states* as grid points [14]. With this latter change, the method was recognized as a *feasible approach* to solving optimal control problems.

The advantage of generating the state grid points is also that the dimensionality of the state vector then does not matter. The application of the method to a nonlinear system described by 7 differential equations and having 4 control variables was solved quite easily [15]. Also the method was used for system of *difference equations*, which is actually easier, since no discretization is necessary [40]. In essence, the ‘curse of dimensionality’ was eliminated and the new computational procedure became known as *iterative dynamic programming* (IDP).

### Early Applications of IDP

Iterative dynamic programming provided a very convenient way of investigating the effect of the choice of the final time in optimal control problems [18]. However, by generating the grid points, it was no longer possible to guarantee a *global optimum*. This was illustrated by Luus and M. Galli [36]. Even the use of a very large number of grid points does not guarantee getting the global optimum. In fact, the number of grid points can be quite small in many cases and the global optimum is still obtained with good accuracy [4].

A very challenging problem is the bifunctional catalyst problem, where it is necessary to determine the blend of the catalyst along a tubular reactor to

maximize the yield of a desired component [35]. By using *successive quadratic programming* (SQP) and starting from 100 randomly chosen starting points, 26 local optima were located, but the global optimum was not obtained. With IDP, however, the global optimum was readily obtained with the use of a single grid point [34]. To avoid the numerous local optima, all that was required for this system was to take a sufficiently large initial region size for the control.

Although the optimal control of *fed-batch reactors* was very difficult to obtain by methods based on *Pontryagin’s maximum principle*, iterative dynamic programming provided a reliable means of obtaining the global optimum, and the results were even marginally better than had been previously reported [20,22]. The additional advantage of IDP is that the computations are straightforward and the algorithm can be easily programmed to run on a personal computer.

### Choice of Candidates for Control

In the early work with IDP, the test values for the control variables were chosen over a uniform distribution. This was easy to program and was easy to visualize. For each control variable we could have a minimum of 3 values, namely  $-r$ , 0, and  $r$ , where  $r$  is the region size. For  $m$  control variables we must examine then  $3^m$  candidates at each grid point. This is fine if  $m$  is less than 4, but if  $m$  is large, this number becomes excessively large.

An alternative method for choosing candidates for control was suggested by V. Tassone and Luus [47], but a better approach as shown by B. Bojkov and Luus [3] was to choose such candidates at random inside the allowable range. This meant that in theory there was no upper limit on  $m$ . Conceptually  $m$  could be greater than 100. In fact, IDP was used successfully on a system with 130 differential equations and 130 control variables [21] and later with 250 differential equations with 250 control variables [26].

### Piecewise Linear Continuous Control

In the early work with IDP, the given time interval was divided into  $P$  time stages of equal length and at each time-stage we would have constant control. In many cases the optimal control policy is quite smooth, and therefore it may be beneficial to approximate the control policy by linear sections. This, indeed, gives a bet-

ter result with a smaller number of time stages as was shown by Luus [23], and allowed an optimal control policy for very high-dimensional systems to be determined accurately [15,26]. For a *piecewise linear control* we calculate the control policy in the time interval  $(t_k, t_{k+1})$  by the expression

$$\mathbf{u}(t) = \mathbf{u}(k) + \frac{\mathbf{u}(k+1) - \mathbf{u}(k)}{L}(t - t_k), \quad (5)$$

where  $\mathbf{u}(k)$  is the value of  $\mathbf{u}$  at the time  $t_k$  and  $\mathbf{u}(k+1)$  is the value of  $\mathbf{u}$  at time  $t_{k+1}$ .

### Algorithm for IDP

To illustrate the underlying logic in IDP, an algorithm is given to solve the optimal control problem as outlined in (1)-(4), where it is required to minimize the performance index in (3) with the use of piecewise constant control over  $P$  stages, each of same length:

- 1) Divide the time interval  $[0, t_f]$  into  $P$  time stages, each of length  $L$ .
- 2) Choose the number of test values for  $\mathbf{u}$ , denoted by  $R$ , an initial control policy and the initial region size  $\mathbf{r}_{in}$ ; also choose the region contraction factor  $\gamma$  used after every iteration and the number of grid points  $N$ .
- 3) Choose the total number of iterations to be used in every pass and set the iteration number index to  $j = 1$ .
- 4) Set the region size vector  $\mathbf{r}^{(j)} = \mathbf{r}_{in}$ .
- 5) By using the best control policy (the initial control policy for the first iteration) as reference, integrate (1) from  $t = 0$  to  $t_f$   $N$  times with different values for control inside the allowable region to generate  $N\mathbf{x}$ -trajectories and store the values of  $\mathbf{x}$  at the beginning of each time stage as grid points, so that  $\mathbf{x}(k-1)$  corresponds to the value of  $\mathbf{x}$  at beginning of stage  $k$ .
- 6) Starting at stage  $P$ , corresponding to time  $t_f - L$ , for each of the  $N$  stored values for  $\mathbf{x}(P-1)$  from step 5 (grid points) integrate (1) from  $t_f - L$  to  $t_f$ , with each of the  $R$  allowable values for the control vector calculated from

$$\mathbf{u}(P-1) = \mathbf{u}(P-1)^{* (j)} + \mathbf{D}\mathbf{r}^{(j)}, \quad (6)$$

where  $\mathbf{u}(P-1)^{* (j)}$  is the best value obtained in the previous iteration and  $\mathbf{D}$  is a diagonal matrix of different random numbers between  $-1$  and  $1$ . Out of

the  $R$  values for the performance index, choose the control values that give the minimum value, and store these values as  $\mathbf{u}(P-1)$ . We now have the best control for each of these  $N$  grid points.

- 7) Step back to stage  $P-1$ , corresponding to time  $t_f - 2L$ , and for each of the  $N$  grid points do the following calculations. Choose  $R$  values for  $\mathbf{u}(P-2)$  as in the previous step, and by taking as the initial state  $\mathbf{x}(P-2)$  integrate (1) over one stage length. Continue integration over the last time stage by using the stored value of  $\mathbf{u}(P-1)$  from step 6 by choosing the control policy corresponding to the grid point that is closest to the values of the state vector that has been reached. Compare the  $R$  values of the performance index and store the  $\mathbf{u}(P-2)$  that gives the minimum value for the performance index.
- 8) Continue the procedure until stage 1, corresponding to the initial time  $t = 0$  and the given initial state, is reached. This stage has only a single grid point, since the initial state is specified. As before, integrate (1) and compare the  $R$  values of the performance index and store the control  $\mathbf{u}(0)$  that gives the minimum performance index. Store also the corresponding  $\mathbf{x}$ -trajectory.
- 9) Reduce the region for allowable control

$$\mathbf{r}^{(j+1)} = \gamma\mathbf{r}^{(j)}, \quad (7)$$

where  $j$  is the iteration number index. Use the best control policy from step 8 as the midpoint for the allowable values for the control denoted by the superscript  $*$ .

- 10) Increment the iteration index  $j$  by 1 and go to step 5 and continue the procedure for the specified number of iterations and interpret the results.

The application of this algorithm is illustrated with several examples in [33], where also the computer program in FORTRAN is given for IDP.

### Time-Delay Systems

The great advantage of IDP over Pontryagin's maximum principle is that no auxiliary variables have to be calculated and no derivatives are required. The state equation is integrated forward and there is no need to integrate any equations backward. Therefore, the method is applicable to more complex systems, such as

*time-delay systems*. The initial attempt to apply IDP to time-delay systems was made by S.A. Dadebo and Luus [8]. By using piecewise linear continuous control very good results for a difficult nonlinear time-delay CSTR system were obtained by Luus et al. [43]. The method is further illustrated in [32].

### State Constraints

Control constraints actually simplify the problem by decreasing the range over which the admissible values of control are to be taken. Research in how to handle *state constraints* is still continuing, but already very useful results have been obtained. As was shown in [39] and [17], the use of penalty functions appears to be the best way to deal with state constraints. The best type of penalty function has not yet been firmly established. Although Dadebo and K.B. McAuley [9] suggested the use of absolute value type of penalty function for state equality constraints, the recent work of Luus [27], and Luus and C. Storey [41] show that a quadratic penalty function with shifting terms also works very well. The advantage of using the quadratic penalty function with shifting terms is that, at the optimum, the shifting terms yield useful sensitivity information with respect to the constraints. Handling of state inequality constraints can be achieved by introducing through differential equations auxiliary variables that are increased in value whenever the constraint is violated and then including these auxiliary variables at the final time as penalty functions in the augmented performance index [46]. The use of differential equations is better than the use of difference equations as was used by Luus [17], because this will prevent violation of the constraint inside a time stage. The auxiliary variables when incorporated into the augmented performance index through a penalty function with a sufficiently large penalty function factor thus prevent a violation of the state constraint anywhere in the time interval.

### Singular Control Problems

When Pontryagin's maximum principle is used, computational difficulties arise if the Hamiltonian is not an explicit function of the control for a portion of the trajectory. Such problems do not arise when IDP is used, and therefore this area was investigated by using IDP. The early work [19] showed that IDP can be used with-

out much difficulty for such problems, and Luus [29] was able to obtain solutions to *singular control problems* that had eluded many investigators. For these problems the main difficulty is the very low *sensitivity* of the performance index on control.

### Sensitivity of Control Policy

Especially for batch reactors, it is found that the cause of computational difficulties lies in the sensitivity of control policy with respect to the yield that is to be maximized [24]. Whereas we are not concerned with more than four figure accuracy in the yield, we would nevertheless like to know what the optimal control policy is. The very low sensitivity was brought out by Luus [25] where in the optimal control of a fed-batch reactor, it was shown that the optimal control policy is relatively smooth.

### Use of Variable Stage-Lengths

Bojkov and Luus [5,6] suggested the use of flexible stage-lengths in IDP for *time optimal control problems* where the time of *switching* is very important. For general type of optimal control problems the use of *variable stage-lengths* enabled the optimum to be more accurately obtained, and in some instances the local optima encountered with the use of stages of fixed length could be avoided [7]. The problem of applying this idea to problems where the final time was specified was overcome by the use of shifting terms in a quadratic penalty function [27]. The use of flexible stage-lengths provides a means of obtaining accurate *switching times* and allowed some optimal control problems, that had gone by unsolved for several decades, to be readily solved [29]. The use of variable stage lengths and a quadratic penalty function with shifting terms enables time optimal control problems to be solved directly [31], so that a difficult boundary value problem is avoided. Further illustration of the usefulness of variable stage lengths is given in [30] and [33].

### Nonseparable Problems

Problems where the performance index is a function of all the control variables and states, and where separation into stages as required for dynamic programming is not possible, constitutes an interesting class

of problems. D. Li and Y.Y. Haimes [13] suggested a method of tackling such problems, and Luus and Tassone [42] considered the application of IDP to *nonseparable problems*. Luus [28] showed that even for complex nonseparable problems a large number of grid points is not necessary, and the optimum can be obtained quite readily. If the number of stages is large, then IDP has a great advantage over direct search optimization where optimization is carried out simultaneously over all the stages. The best means for the application of IDP to nonseparable problems are still to be determined. The strategy of using the values for some of the variables from previous iteration appears to work very well, however.

### Future Directions

Iterative dynamic programming has been developed into a useful optimization procedure. As has been shown in [11], IDP has certain advantages over other optimization procedures for the optimization of a fed-batch reactor. The *reliability* of getting the *global optimum* is very high. Now that the personal computers have become very powerful, the method can be easily used on very complex optimal control problems. When G. Marroquin and W.L. Luyben [44] suggested operating a batch reactor at its best isothermal temperature as the set point, the computational power of the existing computers was relatively low and the cost of computation was very high. It appeared then that optimal control could not be used for realistic systems. Now, however, we can, in effect, have a *feedback control* if the measurements of the pertinent state variables can be done sufficiently fast, by solving the optimal control problem many times during the time of operation of the batch reactor. If the trend in the enhancement of computer speed continues, we can use realistic models and carry out optimization ‘on-line’, so that optimal control calculations can be carried out during the operation and the required changes in the control can be immediately implemented. Then the optimal control’s application will not be only for investigation of design possibilities, but will constitute an important part of the actual operation of the process.

The viability of using IDP for on-line optimal control has been illustrated for reactor control by Luus and O.N. Okongwu [38].

Since derivatives are not required in the use of IDP, the method is applicable to more general types of optimal control problems. Also, since no *auxiliary variables* are necessary, except to handle state inequality constraints, the method is easier to use than variational methods based on Pontryagin’s maximum principle. As convergence properties of IDP are studied in greater detail, further improvements will inevitably be introduced, to make IDP even more useful. Luus [30] showed that variable stage lengths can be incorporated into optimal control problems where *state inequality constraints* are also present, by combining the approach of Bojkov and Luus [7] along with that of W. Mekarapiruk and Luus [46]. Although the best choice for the *penalty function* to be used in IDP has not yet been established, good progress has been made in this field [45] and further research in this area is continuing. Furthermore, since no *derivatives* are required for IDP, the method should have important applications where *non-differentiable functions* are encountered.

Dynamic programming; Infinite horizon problems; Stochastic shortest path

The *shortest path problem* is considered to be one of the classical and most important combinatorial optimization problems. Given a directed graph and a length  $\alpha_{ij}$  for each arc  $(i, j)$ , the problem is to find a path of minimum length that leads from any node  $i$  to a node  $t$ , called the destination node. So, for each node  $i$ , we need to optimally identify a successor node  $u(i)$  so as to reach the destination at the minimum sum of arc lengths over all paths that start at  $i$  and terminate at  $t$ . Of particular relevance is, in the area of distributed computation, the problem of data routing within a computer communication network. In such a case, the cost associated with a particular link  $(i, j)$  is related to an average delay. The *stochastic shortest path problem* is a generalization whereby for each node  $i$  we must select a probability distribution over all possible successor nodes  $j$  out of a given set of probability distributions  $p_{ij}(u)$ , parameterized by a control  $u \in U(i)$ . Clearly, the path traversed and its length are random variables, but the optimal path should lead to the destination with probability 1 and have the minimum expected length. Furthermore, if the probability distributions are such that they assign a probability of 1 to a single successor we then recover the deterministic shortest path problem. Clearly, sequential decisions have to be made optimally so as to determine the sequence of controls that would produce for any current state, i. e. node, a successor state, i. e. node, so as to minimize the expected length for reaching the terminal state. If we were to assume that a particular policy  $\pi$ , i. e., set of control actions, has been selected the total expected cost starting from an initial state  $i$ , using this policy would be:

$$J^\pi(i) = \lim_{N \rightarrow \infty} \mathbb{E} \left\{ \sum_{k=0}^{N-1} \alpha^k g(i_k, \mu_k(i), i_{k+1}) : i_0 = i \right\}.$$

The optimal cost-to-go starting from state  $i$  is denoted by

$$J^* = \min_{\pi} J^{\pi}(i).$$

This problem is defined as a special case of the *total cost infinite horizon problem*. The need to assume an infinite horizon is not required by the actual description of the problem, but rather it is a necessity since the actual length is random as well as unknown. The following are the key characteristics of the stochastic shortest path problem description within the infinite horizon dynamic programming framework:

- 1) There is no discounting,  $\alpha = 1$ .
- 2) The state space is  $S = \{1, \dots, n, t\}$ .
- 3) The transitions probabilities are:

$$p_{ij}(u) = \mathbb{P}(x_{k+1} = j | x_k = i, u_k = u), \\ i, j \in S, \quad u \in U(i).$$

- 4) The state  $t$  is absorbing, that is,

$$p_{tt}(u) = 1, \quad \forall u \in U(t);$$

the state  $t$ , the termination state, is special in the sense that reaching it is inevitable.

- 5) The control set  $U(i)$  is finite.
- 6) The destination is cost-free, i. e.,

$$g(t, u, t) = 0, \quad \forall u \in U(t).$$

If we denote by  $g'(i, u, j)$  the cost of moving from  $i$  to  $j$  using control  $u$ , then the expected cost per stage will be defined as:

$$g'(i, u) = \sum_{j=1}^n p_{ij}(u)g(i, u, j).$$

The concept of the absorbing state implies that this state will either be reached inevitably, or there is an incentive to reach it with the minimum expected cost. The stochastic shortest path problem was first formulated in [3] while addressing a fundamental problem in control theory, namely finding the input that would take a given system to a specified terminal state at minimum cost. A fundamental assumption regarding the types of stochastic shortest path problems that can be analyzed states that:

*Assumption 1* There exists at least one proper policy.

A *proper policy*  $\mu$  is a *stationary policy* which, when used, results in a positive probability that the destination state will be reached after at most  $n$  stages, regardless of the initial state. That is:

$$\rho_{\mu} = \max_{i=1, \dots, n} \mathbb{P}\{x_n \neq t : x_0 = i, \mu\} < 1.$$

A stationary policy is a policy of the form  $\pi = \{\mu, \mu, \dots\}$ .

For analysis purposes, the following operator for any vector  $J$  is defined:

$$(TJ)(i) = \min_{u \in U(i)} \left[ g(i, u) + \sum_{j=1}^n p_{ij}(u)J(j) \right], \\ i = 1, \dots, n,$$

which is obtained by applying one iteration of the basic *dynamic programming algorithm* to the cost function  $J$ , by realizing that the expectancy operator can be reformulated based on the functional form of the state transition probabilities  $p_{ij}$ . It can actually be shown, [1], that  $T$  is a *contraction mapping* with respect to a *weighter sup norm*. In other words there exist positive constants  $v_1, \dots, v_n$ , and some  $\gamma$  with  $0 < \gamma < 1$ , such that for all  $J_1, J_2$ :

$$\max_{i=1, \dots, n} \frac{1}{v_i} |(TJ_1)(i) - (TJ_2)(i)| \\ \leq \gamma \max_{i=1, \dots, n} \frac{1}{v_i} |J_1(i) - J_2(i)|.$$

Furthermore, the operator  $T$  is *monotone*, that is: for any vector  $J$  and  $\bar{J}$  such that  $J(i) \leq \bar{J}(i), i = 1, \dots, n$ , and for any stationary policy  $\mu$  we have:

$$(T^k J)(i) \leq (T^k \bar{J})(i), \\ (T_{\mu}^k J)(i) \leq (T_{\mu}^k \bar{J})(i), \\ i = 1, \dots, n, \quad k = 1, 2, \dots$$

The main results of the theoretical analysis of stochastic shortest path problems are analogous to those for *discounted problems*:

- i) The optimal cost vector is a solution to *Bellman's equation*:  $J^* = TJ^*$ .
- ii) For every proper policy the cost vector  $J$  satisfies:

$$\lim_{k \rightarrow \infty} (T^k J)(i) = J^*(i), \quad i = 1, \dots, n.$$

- iii) A stationary policy  $\mu$  is optimal if and only if  $T_\mu J^* = T_\mu J^*$ .
- iv) For every proper policy  $\mu$ :

$$\lim_{k \rightarrow \infty} T_\mu^k J = J^\mu,$$

$$J^\mu = T_\mu J^\mu.$$

A thorough analysis of the computational complexity of stochastic shortest path problems has been presented in [5].

In order to address computationally stochastic shortest path problems the general methods, i. e., *value iteration*, and *policy iteration*, as well as approximation schemes along the lines presented in [1] as developed for discounted problems. A detailed account can also be found in [6]. Value iteration is a principal method for calculating optimal cost  $J^*$  by generating sequences  $T^k J$  starting from some  $J$ . Issues related to the *Gauss-Seidel* implementation of the value iteration are discussed in [2]. Although in principle an infinite number of iterations will be required, under certain conditions finite convergence can be achieved. An alternative way is to perform policy iterations, in the sense that starting with a proper policy  $\mu_0$ , a sequence of policies converging to the optimal one is constructed. According to property iv), for any given policy  $\mu$ , the cost vector can be evaluate as the solution of a system of linear equations:

$$J(i) = \sum_{j=1}^n p_{ij}(\mu_k(i))(g(i, \mu_k(i), j) + J(j)),$$

$$i = 1, \dots, n.$$

A policy improvement can be know determined as in:

$$\mu_{k+1}(i)$$

$$= \arg \min_{u \in U(i)} \sum_{j=0}^n p_{ij}(u)(g(i, u, j) + J^{\mu_k}(j)).$$

These approaches assume that mathematical models for the cost structure and the transition probabilities of the system exist. In may cases however, such information is not available and methods based on simulation have been developed. This information can be derived by simulating, for given control and state spaces, the system's response so as to derive the associated transition costs  $g(i, u, j)$ . The ideas of *Monte-Carlo simulation* can

be utilized so as to use simulation for policy evaluations. A straightforward way of computing the corresponding cost vector  $J_\mu$  for a given policy  $\mu$ , is to generate many sample trajectories starting at  $i$ , average the corresponding costs, therefore obtaining an estimate for  $J_\mu(i)$ . An alternative way, is to perform an infinite (large) number of simulation runs from various initial states up to the destination state, and any time that state  $i$  is encountered we record the corresponding cost of reaching state  $t$ :

$$c(i, m) = g(i, i_1) + g(i_1, i_2) + \dots + g(i_N, t).$$

By averaging the simulations we obtain:

$$J_\mu(i) = \lim_{M \rightarrow \infty} \frac{1}{M} \sum_{m=1}^M c(i, m).$$

The iterative implementation of the update process results in:

$$J_\mu(i_k) = J_\mu(i_k)$$

$$+ \gamma_k (g(i_k, i_{k+1}) + g(i_{k+1}, i_{k+2})$$

$$+ \dots + g(i_N, t) - J_\mu(i_k)),$$

$$k = 1, \dots, N,$$

$$\gamma_k = \frac{1}{m}, \quad m = 1, 2, \dots$$

Using simulation to perform the policy evaluation as just described, can be utilized so as to improve on the actual policies in order to achieve optimality. The concept of temporal differences, [7], was proposed recently as an alternative way so as to develop policy iterations, [1,2]. This concept originated in the field of reinforcement learning, and the key premise is to adjust the estimations appropriately so as to modify prior predictions when a temporal difference if observed, by essentially looking back in time and correcting previous predictions. The *temporal difference* is defined as the quantity:

$$d_k = g(i_k, i_{k+1}) + J_{\mu_{k+1}} - J_{\mu_k},$$

$$k = 1, \dots, N.$$

The temporal difference represents the difference between the current estimate  $J_\mu(i_k)$  of expected *cost-to-go* to the termination state and the predicted *cost-to-go* to the termination state  $g(i_k, i_{k+1}) + J_{\mu_{k+1}}$ . The key idea of the Monte-Carlo simulation using temporal differences is to update the individual *cost-to-go* as soon as

the cost to go of the successor has been estimated. In other words  $J_\mu(i_1)$  is update as soon as  $g(i_1, i_2)$  and  $i_2$  are generated during the simulation runs. Then update both  $J_\mu(i_1)$  and  $J_\mu(i_2)$  immediately after  $g(i_2, i_3)$  and  $i_3$  are generated, etc.

For the cases where the number of stages becomes prohibitively large, approximations schemes can be used so as to derive accurate estimates of either the optimal cost,  $J^*$ , or the optimal policy,  $\mu$ . By approximating the optimal cost,  $J^*$ , we need to generate for a given state  $i$  and approximation  $J'(i, r)$  of  $J^*(i)$ , where  $r$  a parameter vector that is to be determined by using some type of least squares minimization. Once the cost is know, it can then be used so as to generate suboptimal policies as:

$$\begin{aligned} \mu'(i) &= \arg \min_{u \in U(i)} \sum_{j=1}^n p_{ij}(u)(g(i, u, j) + J'(j, r)). \end{aligned}$$

The type of the approximation is nonunique but usually the approximations are of the form:

$$J'(i, r) = \sum_{k=1}^m r_k \omega_k(i).$$

In essence the approximation is a linear combination of a set of basis functions.

Recently (1994), [8], presented an approximation scheme referred to as *feature-based aggregation*. The idea is to develop an approximation by making use of the fact that several states may share some common characteristics (features). For a stochastic shortest path problem with  $n$  states, one can identify  $m$  disjoint subsets  $S_k$ ,  $k = 1, \dots, m$ , such that:

$$S = S_1 \cup \dots \cup S_m.$$

The basis functions  $\omega_k(i)$  can therefore be defined as:

$$\omega_k(i) = \begin{cases} 1 & \text{if } i \in S_k, \\ 0 & \text{if } i \notin S_k. \end{cases}$$

The approximate cost can thus be defined as:

$$J'(i, r) = \sum_{k=1}^m r_k \omega_k(i).$$

The optimal vector  $r$  can be determined as the solution of the aggregate stochastic shortest path problem, for which the aggregate transition probabilities  $q_{ki}$  express the probability of moving from any state in  $S_k$  to state  $i$ . The vector  $r$  solves the corresponding Bellman's equation of the aggregate problem:

$$\begin{aligned} r_k &= \sum_{i=1}^n q_{ki} \\ &\times \min_{u \in U(i)} \sum_{j=1}^n p_{ij}(u) \left( g(i, u, j) + \sum_{s=1}^m r_s \omega_s(j) \right), \\ k &= 1, \dots, m. \end{aligned}$$

For the aggregate problem, the simulation ideas previously developed can be utilized so as to obtain the optimal vector  $r$  and therefore obtain the required approximation.

Approximation and simulation schemes can also be combined so as to provide alternatives to performing policy iterations, [1]. For a given stationary policy  $\mu$ , a number of simulations,  $M$ , can be performed so as to obtain the estimates  $c(i, m)$ . subsequently, a least squares optimization can be solved to provide an approximation to the costs  $J_\mu'(i, r)$ , and the coefficients  $r$  are derived by solving the following optimization problem:

$$\min_r \sum_{i \in S} \sum_{m=1}^M |J'(i, r) - c(i, m)|^2.$$

Once the costs function have been determined, and improved policy,  $\bar{\mu}(i)$  is identified as:

$$\bar{\mu}(i) = \arg \min_{u \in U(i)} \sum_j p_{ij}(u)(g(i, u, j) + J'(i, r)).$$

In essence, the method iterates between a policy evaluation and a policy improvement step, using both simulation techniques for obtaining, for a given state  $i$  and policy  $\mu$ , sample costs and approximation techniques for obtaining representation of these costs. There are subsequently used so as to estimate improved policies and the iterations continue. The concept of *Q-learning*, [9], was recently proposed as an alternative way of implementing the concept of re-enforcement learning in the solution of dynamic programming, [4].

Dynamic programming; Infinite horizon problems; Discounted problem

Total cost *infinite horizon problems* deal with optimal decision making problems in the presence of uncertainty of systems in which events occur sequential. In general, the state transitions are described by a stationary dynamic system of the form:

$$x_{k+1} = f(x_k, u_k, \omega_k), \quad k = 0, 1, \dots,$$

where for each time instance (stage)  $k$ , the state of the system is an element of the space  $S$ , the control action  $u$  that is to be implemented so as to achieve optimality belong to a space  $C$ , and finally the uncertainty is modeled through a set of random disturbances  $\omega$  that belong to a *countable set*  $D$ . Furthermore, it is assumed that the control  $u_k$  is constrained to take values in a given nonempty set  $U(x_k) \in C$ , which depends of the current state  $x_k$ . The random disturbances  $\omega_k$ ,  $k = 0, 1, \dots$ , have identical statistics and the probability distributions  $\mathcal{P}(\cdot|x_k, u_k)$  are defined on  $D$ . These may depend explicitly on  $x_k$  and  $u_k$  but not on prior disturbances. Given an initial state  $x_0$ , we seek a policy  $\pi$  such that  $\pi = \{\mu_0, \mu_1, \dots\}$  for which:

$$\begin{aligned} \mu_k: S &\rightarrow C, \\ \mu_k(x_k) &\in U(x_k), \quad \forall x_k \in S, \end{aligned}$$

that minimizes a cost function defined as:

$$J_\pi(x_0) = \lim_{N \rightarrow \infty} \mathbf{E} \left\{ \sum_{k=1}^{N-1} \alpha^k g(x_k, \mu_k(x_k), \omega_k) \right\}.$$

The function  $g()$  is the cost per stage such that:  $g: S \times C \times D \rightarrow \mathbf{R}$  and is assumed to be given. Finally, the parameter  $\alpha$  is termed *discount factor* and it holds that:  $0 < \alpha \leq 1$ . We denote by  $\Pi$  the set of all admissible policies  $\pi = \{\mu_0, \mu_1, \dots\}$ , that is, the set of all sequences of

such functions for which:

$$\begin{aligned} \mu_k: S &\rightarrow C, \\ \mu_k(x_k) &\in U(x_k), \quad \forall x_k \in S. \end{aligned}$$

The optimal cost function  $J^*$  is then defined as:

$$J^* = \min_{\pi \in \Pi} J_\pi(x), \quad x \in S.$$

An admissible policy of the form  $\pi = \{\mu, \mu, \dots\}$  is termed *stationary* and its corresponding cost is  $J_\mu$ .

Nevertheless, it is often the case that either the discount factor,  $\alpha$ , does not have to be less than one, or even the cost per stage does not have to be bounded from either above or below. If that is the case, then it is quite possible that for some initial states  $x_0$ , the cost functional  $J_\pi(x_0)$  may become infinite.

D. Blackwell [4] was among the first to analyze the case in which the discount factor  $\alpha$  becomes 1. His approach was based on the idea of studying the behavior as the discount factor approaches 1. Based on the ideas introduced in [7], undiscounted problems are analyzed under either of the following assumptions:

- Positivity assumption:

$$0 \leq g(x, u, \omega), \quad \forall (x, u, \omega) \in S \times C \times D;$$

- Negativity assumption:

$$g(x, u, \omega) \leq 0, \quad \forall (x, u, \omega) \in S \times C \times D.$$

Having costs per stages being bounded from either above or below may result in the complication of having unbounded costs for some initial states. Therefore, the assumption will be made that  $\infty, (-\infty)$ , are admissible costs  $J_\pi$ , under the positivity (negativity) assumption. Defining the following two mappings, greatly simplifies the analysis. For any function  $J$  defined in  $S$  that takes the values  $[0, +\infty]$  under the positivity assumption, or the values  $[-\infty, 0]$  under the negativity assumption, the mappings  $T$  and  $T_\mu$  are defined as:

$$(TJ)(x) = \min_{u \in U(x)} E\{g(x, u, \omega) + J(f(x, u, \omega))\}.$$

Furthermore, for any admissible *stationary policy*, the mapping  $T_\mu$  is defined as:

$$(T_\mu J)(x) = E\{g(x, \mu(x), \omega) + J(f(x, \mu(x), \omega))\}.$$

Under both the positivity or negativity assumptions, it can be shown, [1], that *Bellman's equation* is satisfied:

- Under either the positivity or the negativity assumption, the optimal cost function,  $J^*$  satisfies:

$$J^*(x) = \min_{u \in U(x)} E\{g(x, u, \omega) + J^*(f(x, u, \omega))\}$$

Clearly, the optimality conditions requires that:

$$J^* = TJ^*.$$

Equivalently, for any stationary policy, it holds true that:

$$J_\mu = T_\mu(J_\mu).$$

It is to be noted though that for undiscounted problems,  $\alpha = 1$ , the function  $J^*$  need not be the unique function minimizes Bellman's equation. In other words, the mapping  $T$  does not have a unique fixed point. Nevertheless, the optimal cost vector,  $J^*$ , is the smallest fixed point, under the positivity assumption, or the largest fixed point, under the negativity assumption.

- Under the positivity assumption, if  $J': S \rightarrow [0, +\infty]$  satisfies  $J' = TJ'$ , then:

$$J^* \leq J'.$$

- Under the negativity assumption, if  $J': S \rightarrow [-\infty, 0]$  satisfies  $J' = TJ'$ , then:

$$J' \leq J^*.$$

It should be pointed out, that in the analysis of undiscounted problems the concept of monotonicity plays a key role. The following *monotone convergence theorem* summarizes the key properties, [3]:

**Theorem** Let  $P = (p_1, p_2, \dots)$  be a probability distribution over  $S = \{1, 2, \dots\}$ . Let  $\{h_N\}$  be a sequence of extended real-valued functions on  $S$  such that for all  $i \in S$  and  $N = 1, 2, \dots$ :

$$0 \leq h_N(i) \leq h_{N+1}(i).$$

Let  $h: S \rightarrow [0, \infty]$  be the limit function:

$$h(i) = \lim_{N \rightarrow \infty} h_N(i).$$

Then:

$$\begin{aligned} \lim_{N \rightarrow \infty} \sum_{i=1}^{\infty} p_i h_N(i) &= \sum_{i=1}^{\infty} p_i \lim_{N \rightarrow \infty} h_N(i) \\ &= \sum_{i=1}^{\infty} p_i h(i). \end{aligned}$$

As examples of undiscounted problems, let us consider two types of problems that define interesting classes that can be cast as undiscounted dynamic programming problems, namely the *optimal stopping* and the *optimal gambling* strategy problem. The former defines a situation in which at each state  $x$  of the state space there are two possible actions that are available. One may either decide to stop, by selecting control  $u_1$ , and pay a terminal cost  $t(x)$ , or, select control  $u_2$ , pay a cost  $c(x)$  and continue the process, with a new state be given by:

$$x_{k+1} = f(x_k, \omega_k).$$

For completeness purposes one also defines a termination state  $s$  that is entered once the stopping decision is made. In other words,

$$x_{k+1} = s \quad \text{if } u_k = u_1 \text{ or } x_k = s.$$

If it is further assumed that both the termination and the continuation costs are positive (or negative), then the problem satisfies the positivity (negativity) assumption. The mapping  $T$  defined earlier takes now the form:

$$(TJ)(x) = \min \{t(x), c(x) + E\{J(f(x, \omega))\}\}, \\ \forall x \in S.$$

The objective is to find the optimal stopping policy that minimizes the total expected costs over an infinite number of stages. Insofar regarding external disturbances,  $\omega$ , it is assumed that they have the same probability distribution for all time instances and depend only on the current state  $x_k$ .

The early work [5] details the gambling problem, but was also one of the early works on undiscounted problems. The problem is defined as one in which a player may stake at any time  $k$  any amount  $u_k \geq 0$  that does not exceed his/her current fortune,  $x_k$ . The stake is won back with probability  $p$ , and lost with probability  $1 - p$ . The discrete-time state evolution is described by:

$$x_{k+1} = x_k + \omega_k u_k, \quad k = 1, 2, \dots$$

The disturbance  $\omega_k$  is considered to be 1 with probability  $p$ , and  $-1$  with probability  $1 - p$ . The gambling is continued until reaching given fortune or losing the entire initial capital. The problem is to determine that optimal gambling strategy that maximizes the probability of reaching the target fortune. As gambling strategy

is defined the specific rule that specifies what the stakes should be at time  $k$ . It can be shown that the *bold strategy* is an optimal policy. The bold strategy is defined as:

$$\mu^*(x) = \begin{cases} x, & 0 < x \leq \frac{1}{2}, \\ 1 - x, & \frac{1}{2} \leq x < 1. \end{cases}$$

As suggested by the theory of undiscounted problems, the bold strategy is simply an optimal strategy and others can also be derived, [5].

From a computational standpoint it is important to know whether the method of *successive approximations*, i. e., *value iteration*, converges to the optimal cost function. In other words, it is important to know whether the basic dynamic programming algorithm converges. Under either of the two basic assumptions we have:

- Positivity assumption:

$$J_0 \leq T(J_0) \leq \dots \leq T^k(J_0) \leq \dots$$

- Negativity assumption:

$$J_0 \geq T(J_0) \geq \dots \geq T^k(J_0) \geq \dots$$

In either case

$$J_\infty(x) = \lim_{k \rightarrow \infty} T^k(J_0)(x), \quad x \in S.$$

In other words, the sequence generated by successive approximation, i. e., by successively applying the mapping  $T$ , converges and the limit is well defined, including the values of  $+\infty$  and  $-\infty$ . For the value iteration method though to be valid we also need to have that  $J_\infty = J^*$ . In order for the above to be true under the positivity assumptions, an additional condition needs to be satisfied, [2]:

- Let the positivity assumption be satisfied and assume that the sets:

$$U_k(x, \lambda) = \left\{ u \in U(x) : \right. \\ \left. E\{g(x, u, \omega) + T^k(J_0)(f(x, u, \omega))\} \leq \lambda \right\}$$

are compact subsets of a Euclidean space for every  $x \in S$ ,  $\lambda \in \mathbf{R}$ , and for all  $k$  greater than some integer  $\bar{k}$ . Then:

$$J_\infty = T(J_\infty) = J^*.$$

It should be noted that since  $U(x)$  is assumed to be finite, the above condition is satisfied. A detailed account of the value iteration method of undiscounted Markov decision problems can also be found in [6].

It can also be shown, [3], that it is possible to devise computational methods based on mathematical programming when the state, control, and disturbance spaces are finite. Under the negativity assumption, the vector  $J$  solves the following linear programming problem:

$$\begin{cases} \max & \sum_{i=1}^n \lambda_i \\ \text{s.t.} & \lambda_i \leq g(i, u) + \sum_{j=1}^n p_{ij}(u) \lambda_j \\ & i = 1, 2, \dots \end{cases}$$

Under the positivity assumption, the corresponding program takes the form:

$$\begin{cases} \min & \sum_{i=1}^n \lambda_i \\ \text{s.t.} & \lambda_i \geq \min_{u \in U(x)} \left\{ g(i, u) + \sum_{j=1}^n p_{ij}(u) \lambda_j \right\}, \\ & i = 1, 2, \dots \end{cases}$$

Unfortunately, this two-level optimization problem is neither linear nor convex, and therefore its solution highly nontrivial.

Congested urban transportation networks represent complex systems in which travelers interact so as to determine unilaterally their cost-minimizing routes of

travel between their points of origin and their destinations. The governing concept here is that of ‘user-optimization’, which dates to J.G. Wardrop [19] (and was so termed by S.C. Dafermos and F.T. Sparrow [4]), and states that, in equilibrium, all used paths connecting an origin/destination pair of nodes will have travel costs that are equal and minimal.

The complexity of user-optimized transportation networks, sometimes also referred to as the ‘traffic assignment’ problem, has stimulated much research in the past several decades, both from methodological perspectives, as well as in terms of practical application. Notable developments include: the proof by M.J. Beckmann, C.B. McGuire, and C.B. Winsten [1] that, under certain symmetry assumptions on the link travel cost functions (and travel disutility functions), the traffic network equilibrium solution also satisfies the Kuhn–Tucker conditions of an appropriately constructed optimization problem, and the identification by Dafermos [2] that the traffic network equilibrium conditions, as formulated by M.J. Smith [17] (without any imposition of a symmetry assumption), satisfy a variational inequality problem. Books that discuss methodological approaches to static traffic equilibrium problems include [9,14,16] (see also [6]).

The study of dynamic travel route choice models on general transportation networks, where time is explicitly incorporated into the framework, was initiated by D.K. Merchant and G.L. Nemhauser [8], who focused on dynamic system-optimal networks with the characteristic of many origins and a single destination. In system-optimal networks, in contrast to user-optimal networks, one seeks to determine the path flow and link load patterns that minimize the total cost in the network, rather than the individual path travel costs.

M.J. Smith [18], in turn, proposed a dynamic traffic user-optimized model with fixed demands. H. Mahmassani [7] also proposed dynamic traffic models and investigated them experimentally. The recent book [15] provides an overview of the history of dynamic traffic network models and discusses distinct approaches for their analysis and computation.

Here we present a dynamic traffic model with elastic demands proposed by P. Dupuis and A. Nagurney [5], who, along with D. Zhang and Nagurney [22], established the foundations for a new methodology, that of ‘projected dynamical systems’ theory. The notable fea-

ture of a projected dynamical system is that its set of stationary points coincides with the set of solutions of the corresponding variational inequality problem. There, thus, exists a fundamental linkage between the static world of finite-dimensional variational inequality problems and the dynamic world exhibited by a new class of dynamical system.

The dynamic adjustment process that is presented here models the travelers’ *day-to-day* dynamic behavior of making trip decisions and route choices associated with a travel disutility perspective. Subsequently, some of the stability results of this travel-route choice adjustment process obtained by Zhang and Nagurney [21] are reviewed, which address whether and how the travelers’ dynamic behavior in attempting to avoid congestion leads to a traffic equilibrium pattern. Finally, we recall the discrete-time algorithms devised for the computation of traffic network equilibria with elastic demands and with known travel disutility functions. The convergence of these discrete-time algorithms was established by Zhang and Nagurney [10,13]. Additional dynamic traffic network models, as well as qualitative and numerical results, using this methodology can be found in [11,12], and [22]. For alternative dynamic traffic network models and approaches, see [15], and the references therein.

## A Dynamic Traffic Network Model

The model that we present is due to Dupuis and Nagurney [5]. It is a dynamic counterpart to the static traffic network equilibrium model with elastic travel demands developed by Dafermos [3].

We consider a network  $[N, L]$  consisting of nodes  $[N]$  and directed links  $[L]$ . Let  $a$  denote a link of the network connecting a pair of nodes, and let  $p$  denote a path (assumed to be acyclic) consisting of a sequence of links connecting an origin/destination (O/D) pair  $w$ .  $P_w$  denotes the set of paths connecting the O/D pair  $w$  with  $n_{P_w}$  paths. We let  $W$  denote the set of O/D pairs and  $P$  the set of paths in the network.

Let  $x_p$  represent the flow on path  $p$  and let  $f_a$  denote the load on link  $a$ . The following conservation of flow equation must hold for each link  $a$ :

$$f_a = \sum_p x_p \delta_{ap},$$

where  $\delta_{ap} = 1$ , if link  $a$  is contained in path  $p$ , and 0 otherwise. The expression states that the load on a link  $a$  is equal to the sum of all the path flows on paths that contain the link  $a$ .

Moreover, if we let  $d_w$  denote the demand associated with an O/D pair  $w$ , then we must have that for each O/D pair  $w$

$$d_w = \sum_{p \in P_w} x_p,$$

where  $x_p \geq 0$ , for all  $p$ , that is, the sum of all the path flows on paths connecting the O/D pair  $w$  must be equal to the demand  $d_w$ . Let  $x$  denote the column vector of path flows with dimension  $n_p$ .

Let  $c_a$  denote the user cost associated with traversing link  $a$ , and let  $C_p$  denote the user cost associated with traversing path  $p$ . Then

$$C_p = \sum_a c_a \delta_{ap}.$$

In other words, the cost of a path is equal to the sum of the costs on the links comprising that path. We group the link costs into the column vector  $c$  with  $n_A$  components, and the path costs into the column vector  $C$  with  $n_p$  components. We also assume that we are given a travel disutility function  $\lambda_w$  for each O/D pair  $w$ . We group the travel disutilities into the column vector  $\lambda$  with  $J$  components.

We assume that, in general, the cost associated with a link may depend upon the entire link load pattern, that is,

$$c_a = c_a(f)$$

and that the travel disutility associated with an O/D pair may depend upon the entire demand pattern, that is,

$$\lambda_w = \lambda_w(d),$$

where  $f$  is the  $n_A$ -dimensional column vector of link loads and  $d$  is the  $J$ -dimensional column vector of travel demands.

We now, for completeness, recall the traffic network equilibrium conditions.

**Definition 1 (traffic network equilibrium, [1,3])** A vector  $x^* \in \mathbf{R}_+^{n_p}$ , which induces a vector  $d^*$  through the

demand equations, is a traffic network equilibrium if for each path  $p \in P_w$  and every O/D pair  $w$ :

$$C_p(x^*) \begin{cases} = \lambda_w(d^*), & \text{if } x_p^* > 0 \\ \geq \lambda_w(d^*), & \text{if } x_p^* = 0. \end{cases}$$

In equilibrium, only those paths connecting an O/D pair that have minimal user costs are used, and their costs are equal to the travel disutility associated with traveling between the O/D pair.

The equilibrium conditions have been formulated as a variational inequality problem by Dafermos (cf. [2,3]). In particular, we have:

**Theorem 2 [3]**  $(x^*, d^*) \in K^1$  is a traffic network equilibrium pattern, that is, satisfies the equilibrium conditions if and only if it satisfies the variational inequality problem (path flow formulation):

$$\langle C(x^*)^\top, x - x^* \rangle - \langle \lambda(d^*)^\top, d - d^* \rangle \geq 0, \quad \forall (x, d) \in K^1,$$

where  $K^1 \equiv \{(x, d) : x \geq 0, \text{ and the demand constraints hold}\}$ .

Note that, in view of the demand constraints, one may define  $\widehat{\lambda}(x) \equiv \lambda(d)$ , in which case one may rewrite the variational inequality in the path flow variables  $x$  only, that is, we seek to determine  $x^* \in \mathbf{R}_+^{n_p}$ , such that

$$\langle (C(x^*) - \widehat{\lambda}(x^*))^\top, x - x^* \rangle \geq 0, \quad \forall x \in \mathbf{R}_+^{n_p},$$

where  $\widehat{\lambda}(x)$  is the  $n_{p_{w_1}} \times \dots \times n_{p_{w_J}}$ -dimensional column vector with components:

$$(\widehat{\lambda}_{w_1}(x), \dots, \widehat{\lambda}_{w_1}(x), \dots, \widehat{\lambda}_{w_J}(x), \dots, \widehat{\lambda}_{w_J}(x)),$$

where  $J$  is the number of O/D pairs. If we now let  $F(x) \equiv (C(x) - \widehat{\lambda}(x))$  and  $K \equiv \{x : x \in \mathbf{R}_+^{n_p}\}$ , then, clearly, this inequality can be placed into standard variational inequality form.

### The Trip-Route Choice Adjustment Process

The dynamical system, first presented in [5], whose stationary points correspond to solutions of the latter variational inequality problem above, is given by:

$$\dot{x} = \Pi_K(x, \widehat{\lambda}(x) - C(x)), \quad x(0) = x_0 \in K,$$

where, assuming that the feasible set  $K$  is a convex polyhedron (as is the case here), and given  $x \in K$  and  $v \in \mathbf{R}^n$ , we define the projection of the vector  $v$  at  $x$  (with respect to  $K$ ) by

$$\Pi_K(x, v) = \lim_{\delta \rightarrow 0} \frac{P_K(x + \delta v) - x}{\delta},$$

where  $P_K$  is defined as:

$$P_K(x) = \arg \min_{z \in K} \|x - z\|,$$

and  $\|\cdot\|$  denotes the Euclidean norm.

This dynamical system is a *projected dynamical system* (cf. [10,22]), since the right-hand side, which is a projection operator, is discontinuous.

The adjustment process interpretation of the dynamical system, as discussed in [5], is as follows: Users of a transportation network choose, at the greatest rate, those paths whose differences between the travel disutilities (demand prices) and path costs are maximal; in other words, those paths whose costs are minimal relative to the travel disutilities. If the travel cost on a path exceeds the travel disutility associated with the O/D pair, then the flow on that path will decrease; if the travel disutility exceeds the cost on a path, then the flow on that path will increase. If the difference between the travel disutility and the path cost drives the path flow to be negative, then the projection operator guarantees that the path flow will be zero. The process continues until there is no change in path flows, that is, until all used paths have path costs equal to the travel disutilities, whereas unused paths will have costs which exceed the disutilities. Specifically, the travelers adjust their route choices until an equilibrium is reached.

The following example, given in a certain discrete-time realization, shows how the dynamic mechanism of the above trip-route choice adjustment would reallocate the traffic flow among the paths and would react to changes in the travel disutilities.

*Example 3* Consider a simple transportation network consisting of two nodes, with a single O/D pair  $w$ , and two links  $a$  and  $b$  representing the two disjoint paths connecting the O/D pair. Suppose that the link costs are:

$$c_a(f_a) = f_a + 2, \quad c_b(f_b) = 2f_b,$$

and the travel disutility function is given by:

$$\lambda_w(d_w) = -d_w + 5.$$

Note that here a path consists of a single link and, hence, we can use  $x$  and  $f$  interchangeably. Suppose that, at time  $t = 0$ , the flow on link  $a$  is 0.7, the flow on link  $b$  is 1.5; hence, the demand is 2.2, and the travel disutility is 2.8, that is,

$$\begin{aligned} x_a(0) &= 0.7, & x_b(0) &= 1.5, \\ d_w(0) &= 2.2, & \lambda_w(0) &= 2.8, \end{aligned}$$

which yields travel costs:  $c_a(0) = 2.7$  and  $c_b(0) = 3.0$ .

According to the above trip-route choice adjustment process, the flow changing rates at time  $t = 0$  are:

$$\begin{aligned} \dot{x}_a(0) &= \lambda_w(0) - c_a(0) = 0.1, \\ \dot{x}_b(0) &= \lambda_w(0) - c_b(0) = -0.2. \end{aligned}$$

If a time increment of 0.5 is used, then at the next moment  $t = 0.5$ , the flows on link  $a$  and link  $b$  are:

$$\begin{aligned} x_a(0.5) &= x_a(0) + 0.5\dot{x}_a(0) \\ &= 0.7 + 0.5 \times 0.1 = 0.75, \\ x_b(0.5) &= x_b(0) + 0.5\dot{x}_b(0) \\ &= 1.5 - 0.5 \times 0.2 = 1.4, \end{aligned}$$

which yields travel costs:  $c_a(0.5) = 2.75$  and  $c_b(0.5) = 2.8$ , a travel demand  $d_w(0.5) = 2.15$ , and a travel disutility  $\lambda_w(0.5) = 2.85$ . Now, the flow changing rates are given by:

$$\begin{aligned} \dot{x}_a(0.5) &= \lambda_w(0.5) - c_a(0.5) \\ &= 2.85 - 2.75 = 0.1, \\ \dot{x}_b(0.5) &= \lambda_w(0.5) - c_b(0.5) \\ &= 2.85 - 2.8 = 0.05. \end{aligned}$$

The flows on link  $a$  and link  $b$  at time  $t = 1.0$  would, hence, then be:

$$\begin{aligned} x_a(1.0) &= x_a(0.5) + 0.5\dot{x}_a(0.5) \\ &= 0.75 + 0.5 \times 0.1 = 0.80, \\ x_b(1.0) &= x_b(0.5) + 0.5\dot{x}_b(0.5) \\ &= 1.4 + 0.5 \times 0.05 = 1.425, \end{aligned}$$

which yields travel costs:  $c_a(1.0) = 2.80$  and  $c_b(1.0) = 2.85$ , a travel demand  $d_w(1.0) = 2.225$ , and a travel disutility  $\lambda_w(1.0) = 2.775$ . Now, the flow changing rates are

given by:

$$\begin{aligned}\dot{x}_a(1.0) &= \lambda_w(1.0) - c_a(1.0) \\ &= 2.775 - 2.800 = 0.025, \\ \dot{x}_b(1.0) &= \lambda_w(1.0) - c_b(1.0) \\ &= 2.775 - 2.850 = -0.075.\end{aligned}$$

The flows on link  $a$  and link  $b$  at time  $t = 1.5$  would be:

$$\begin{aligned}x_a(1.5) &= x_a(1.0) + 0.5\dot{x}_a(1.0) \\ &= 0.8 - 0.5 \times 0.025 = 0.7875, \\ x_b(1.5) &= x_b(1.0) + 0.5\dot{x}_b(1.0) \\ &= 1.425 - 0.5 \times 0.075 = 1.3875,\end{aligned}$$

which yields travel costs:  $c_a(1.5) = 2.7875$  and  $c_b(1.5) = 2.775$ , a travel demand  $d_w(1.5) = 2.175$ , and a travel disutility  $\lambda_w(1.0) = 2.82$ .

In this example, hence, as time elapses, the trip-route choice adjustment process adjusts the flow volume on the two links so that the difference between the travel costs of link  $a$  and link  $b$  is being reduced, from 0.3, to 0.05, and, finally, to 0.0125; and, the difference between the disutility and the travel costs on the used links is also being reduced from 0.2, to 0.1, and to 0.045. In fact, the traffic equilibrium with:  $x_a^* = 0.8$  and  $x_b^* = 1.4$ , which induces the demand  $d_w^* = 2.2$ , is almost attained in only 1.5 time units.

### Stability Analysis

We now present the stability results of the trip route choice adjustment process. The results described herein are due to Zhang and Nagurney [21]. For example, the questions that motivate transportation planners and analysts to study the stability of a transportation system include: Will any initial flow pattern be driven to an equilibrium by the adjustment process? In addition, will a flow pattern near an equilibrium always stay close to it? These concerns of *system stability* are important in traffic assignment and form, indeed, a critical base for the very concept of an equilibrium flow pattern.

For the specific application of transportation network problems, the following definitions of stability of the transportation system and the local stability of an equilibrium are adapted from the general stability concepts of projected dynamical systems (cf. [22]).

**Definition 4 (stability at an equilibrium)** An equilibrium flow pattern  $x^*$  is stable if it is a global monotone attractor for the corresponding route choice adjustment process.

**Definition 5 (asymptotical stability at an equilibrium)** An equilibrium flow pattern  $x^*$  is asymptotically stable if it is a strictly global monotone attractor for the corresponding route choice adjustment process.

**Definition 6 (stability of the system)** A route choice adjustment process is stable if all its equilibrium flow patterns are stable.

**Definition 7 (asymptotical stability of the system)** A route choice adjustment process is asymptotically stable if all its equilibrium flow patterns are asymptotically stable.

We now present the stability results in [21] for the trip-route choice adjustment process.

**Theorem 8 ([21])** *Suppose that the link cost functions  $c$  are monotone increasing in the link load pattern  $f$  and that the travel disutility functions  $\lambda$  are monotone decreasing in the travel demand  $d$ . Then the trip-route choice adjustment process is stable.*

**Theorem 9 ([21])** *Assume that there exists some equilibrium path flow pattern. Suppose that the link cost functions  $c$  and negative disutility functions  $-\lambda$  are strictly monotone in the link load  $f$  and the travel demand  $d$ , respectively. Then the trip-route choice adjustment process is asymptotically stable.*

The first theorem states that, provided that monotonicity of the link cost functions and the travel disutility functions holds true, then any flow pattern near an equilibrium will stay close to it forever. Under the strict monotonicity assumption, on the other hand, the second theorem can be interpreted as saying that any initial flow pattern will eventually be driven to an equilibrium by the route choice adjustment process.

### Discrete Time Algorithms

The Euler method and the Heun method were employed in [13] and [10] for the computation of solutions to dynamic elastic demand traffic network problems with known travel disutility functions, and their convergence was also established therein. We refer the

reader to these references for numerical results, including traffic network examples that are solved on a massively parallel computer architecture.

In particular, at iteration  $\tau$ , the *Euler method* computes

$$x^{\tau+1} = P_K(x^\tau - a_\tau F(x^\tau)),$$

whereas, according to the *Heun method*, at iteration  $\tau$  one computes

$$\begin{aligned} x^{\tau+1} &= P_K \left( x^\tau - a_\tau \frac{1}{2} [F(x^\tau) + F(P(x^\tau - a_\tau F(x^\tau)))] \right). \end{aligned}$$

In the case that the sequence  $\{a_\tau\}$  in the Euler method is fixed, say,  $\{a_\tau\} = \rho$ , for all iterations  $\tau$ , then the Euler method collapses to a projection method (cf. [2,6,9], and [14]).

In the context of the dynamic traffic network problem with known travel disutility functions, the projection operation in the above discrete-time algorithms can be evaluated explicitly and in closed form. Indeed, each iteration  $\tau$  of Euler method takes the form: For each path  $p \in P$  in the transportation network, compute the path flow  $x_p^{\tau+1}$  according to:

$$x_p^{\tau+1} = \max\{0, x_p^\tau + a_\tau(\lambda_w(d^\tau) - C_p(x^\tau))\}.$$

Each iteration of the Heun method, in turn, consists of two steps. First, at iteration  $\tau$  one computes the approximate path flows:

$$\begin{aligned} \bar{x}_p^\tau &= \max\{0, x_p^\tau + a_\tau(\lambda_w(d^\tau) - C_p(x^\tau))\}, \\ &\quad \forall p \in P, \end{aligned}$$

and updates the approximate travel demands:

$$\bar{d}_w^\tau = \sum_{p \in P_w} \bar{x}_p^\tau, \quad \forall w \in W.$$

Let

$$\bar{x}^\tau = \{\bar{x}_p^\tau, p \in P\}$$

and

$$\bar{d}^\tau = \{\bar{d}_w^\tau, w \in W\}.$$

Then, for each path  $p \in P$  in the transportation network one computes the updated path flows  $x_p^{\tau+1}$  according to:

$$\begin{aligned} x_p^{\tau+1} &= \max\{0, \\ &x_p^\tau + \frac{a_\tau}{2} [\lambda_w(d^\tau) - C_p(x^\tau) + \lambda_w(\bar{d}^\tau) - C_p(\bar{x}^\tau)]\}, \\ &\quad \forall p \in P, \end{aligned}$$

and updates the travel demands  $d_w^{\tau+1}$  according to:

$$d_w^{\tau+1} = \sum_{p \in P_w} x_p^{\tau+1}, \quad \forall w \in W.$$

It is worth noting that both the Euler method and the Heun method at each iteration yield subproblems in the path flow variables, each of which can be solved not only in closed form, but also, simultaneously. Hence, these algorithms in the context of this model can be interpreted as massively parallel algorithms and can be implemented on massively parallel architectures. Indeed, this has been done so by Nagurney and Zhang [13] (see also [11] for the case where the demand functions are given, rather than the travel disutility functions).

In order to establish the convergence of the Euler method and the Heun method, one regularizes the link cost structures.

**Definition 10 (regular cost function)** The link cost function  $c$  is called regular if, for every link  $a \in L$ ,

$$c_a(f) \rightarrow \infty, \quad \text{as } f_a \rightarrow \infty,$$

holds uniformly true for all link flow patterns.

We note that the above regularity condition on the link cost functions is natural from a practical point of view and it does not impose any substantial restrictions. In reality, any link has an upper bound in the form of a capacity. Therefore, letting  $f_a \rightarrow \infty$  is an artificial device under which one can reasonably deduce that  $c_a(f) \rightarrow \infty$ , due to the congestion effect. Consequently, any practical link cost structure can be theoretically extended to a regular link cost structure to allow for an infinite load.

The theorem below shows that both the Euler method and the Heun method converge to the traffic network equilibrium under reasonable assumptions.

**Theorem 11** ([10,13]) *Suppose that the link cost function  $c$  is regular and strictly monotone increasing, and that the travel disutility function  $\lambda$  is strictly monotone decreasing. Let  $\{a_\tau\}$  be a sequence of positive real numbers that satisfies*

$$\lim_{\tau \rightarrow \infty} a_\tau = 0$$

and

$$\sum_{\tau=0}^{\infty} a_\tau = \infty.$$

*Then both the Euler method and the Heun method produce sequences  $\{x^\tau\}$  that converge to some traffic network equilibrium path flow pattern.*

### Introduction

A considerable amount of effort has been spent on studying and developing efficient solution procedures for the economic lot-sizing problem. This problem had been solved in 1958, but there is still continuing interest in the problem. The main reason for the continuing interest in this problem is its practical applications. For example, economic lot-sizing is the core problem in

aggregate production planning in MRP systems (Nahmias [25]). For an extensive review, see Aggarwal and Park [1], Bahl et al. [2], Belvaux and Wolsey [6,7,8], Nemhauser and Wolsey [26], and Wolsey [36].

The economic lot-sizing problem can be defined as follows. Given the demand, the unit production cost, the unit inventory holding cost for a commodity, the production capacities, and the setup costs for each time period over a finite, discrete-time horizon, find a production schedule that would satisfy demand at minimum cost.

This model assumes a fixed and a variable component of production costs. The fixed cost consists of manpower and materials to start up the machines. To reduce the fixed cost per unit, large lot sizes are desired. On the other hand, for every unit produced there are associated production and inventory holding costs, and the total variable cost (production plus inventory) increases with the number of units produced. Solving the lot-sizing problem means finding a production schedule that would satisfy demand at every period and minimize the total of fixed and variable costs.

The work by Harris [18] in 1913 has been cited as the first study of the economic lot-sizing problem that assumes deterministic demands. This model, known as the Economic Order Quantity (EOQ) model, proposes a production schedule to satisfy the demand for a single commodity with a constant demand rate. Production takes place continuously over time, and the model does not incorporate capacity limits.

A major limitation of the above model is that the demand is continuous over time and has a constant rate. Manne [23] and Wagner and Whitin [35] studied the lot-sizing problem with a finite time horizon consisting of a number of discrete periods, each with its own deterministic and independent demand.

**Formulation**

Let  $T$  be the length of the planning horizon, and  $c_t, h_t, s_t, b_t$  denote the unit production cost, the unit inventory holding cost, the setup cost, and the demand in period  $t$  ( $1 \leq t \leq T$ ), respectively. The following are the decision variables for this problem:

- $q_t$ : amount of production in period  $t$
- $I_t$ : inventory level at the end of period  $t$
- $y_t = \begin{cases} 1 & \text{if production occurs in period } t \\ 0 & \text{otherwise} \end{cases}$

A mixed-integer programming formulation of the classical economic lot-sizing problem is

$$\text{minimize } \sum_{t=1}^T (c_t q_t + s_t y_t + h_t I_t)$$

subject to (C-ELS)

$$q_t + I_{t-1} = b_t + I_t, \quad 1 \leq t \leq T, \tag{1}$$

$$q_t \leq b_{tT} y_t, \quad 1 \leq t \leq T, \tag{2}$$

$$I_T = 0, \tag{3}$$

$$y_t \in \{0, 1\}, \quad 1 \leq t \leq T, \tag{4}$$

$$q_t, I_t \geq 0, \quad 1 \leq t \leq T, \tag{5}$$

where  $b_{tT}$  is the total demand in periods  $t, \dots, T$ .

Below, some of the approaches that have been used to solve the economic lot-sizing problem are summarized.

**Dynamic Programming Algorithm**

In 1958, Wagner and Whitin [35] developed a dynamic programming algorithm to solve the economic lot-sizing problem. This algorithm runs in  $O(T^2)$ .

The special structure of the optimal solutions to the economic lot-sizing problem contributed to developing an efficient dynamic programming algorithm. For this purpose, it is useful to view the problem as a fixed charge network flow problem. The optimal solution for this network flow problem will be a tree since the objective function is concave and the arcs do not have capacity restrictions. This property of an optimal solution implies that:

**Theorem 1** *An optimal solution to the economic lot-sizing problem satisfies the following:*

- (i.)  $q_t I_{t-1} = 0$  for  $1 \leq t \leq T$ ,
- (ii.) If  $q_t > 0$ , then  $q_t = \sum_{\tau=t}^{\tau'} b_\tau$  for  $t \leq \tau' \leq T$ .

Property (i.) shows that production takes place when the inventory carried forward is zero. This property is known as the *Zero-Inventory Ordering* (ZIO) property. Property (ii.) shows that if production takes place in period  $t$ , the amount produced will be exactly equal to the total demand for a number of periods ( $t$  to  $\tau'$ ). Property (ii.) is used to develop the dynamic programming algorithm for the economic lot-sizing problem.

Let  $v(t)$  be the minimum cost of a solution for periods  $1, \dots, t$ . If  $\tau \leq t$  is the last period in which production occurs, then  $q_\tau = b_{\tau t}$  and  $I_{\tau-1} = 0$ . This implies that the problem can be divided into two smaller subproblems, and the least-cost solution  $v(\tau - 1)$  is optimal for the first subproblem (periods  $1, \dots, \tau - 1$ ). This leads to the following recursive function:

$$v(t) = \min_{1 \leq \tau \leq t} \{v(\tau - 1) + s_\tau + c_\tau b_{\tau t} + \sum_{s=\tau}^{t-1} h_s b_{s+1,t}\}$$

with  $v(0)=0$ .

Calculating  $v(t)$  for  $t = 1, \dots, T$  leads to the optimal solution  $v(T)$  of the economic lot-sizing problem.

**Shortest Path Algorithm**

The economic lot-sizing problem has also been solved as a shortest-path algorithm in an acyclic network (Eppen and Martin [13], Martin [24], Zangwill [38]). The acyclic network,  $G$ , is built in the following way: let the total number of nodes in  $G$  be equal to  $T + 1$ , one for each time period along with a dummy node. The traversing arc  $(t, t') \in G$  ( $1 \leq t \leq t' \leq T + 1$ ) represents the choice of producing in period  $t$  to satisfy the demand in periods  $t, \dots, t' - 1$ . Thus, the cost of arc  $(t, t')$  is calculated using the following cost function:

$$g_{t,t'} = s_t + c_t b_{t,t'-1} + \sum_{\tau=t}^{t'-2} h_\tau b_{\tau+1,t'-1}$$

The shortest path from node “1” to node “ $T + 1$ ” provides the set of production intervals of minimum cost and therefore solves the economic lot-sizing problem. The shortest-path algorithm is solved in order  $O(m)$ ,

where  $m$  is the number of arcs in the directed, acyclic network. The total number of arcs in  $G$  is in the order of  $T^2$ ; therefore, this shortest-path algorithm solves the economic lot-sizing problem in  $O(T^2)$ .

### Primal-Dual Algorithm

Almost 30 years later (after Wagner and Whitin developed their dynamic programming algorithm), Wagelmans et al. [34], Aggarwal and Park [1], and Federgruen and Tzur [15] showed that the running time of the dynamic programming algorithm could be reduced to  $O(T \log T)$  in the general case and to  $O(T)$  when the costs have a special structure. This special structure ( $h_t + p_t \geq p_{t+1}$ ) is also referred to as the absence of speculative motives. They developed a primal-dual algorithm to get these results.

Below, we present a reformulation of the economic lot-sizing problem. In this formulation,  $q_{t\tau}$  ( $\tau = t, \dots, T$ ) is defined as the amount produced in period  $t$  to satisfy demand in period  $\tau$  (Krarup and Bilde [20], van Hoesel [31]). The reformulation is

$$\text{minimize } \sum_{t=1}^T \left[ \bar{c}_t \sum_{\tau=t}^T q_{t\tau} + s_t y_t \right]$$

subject to (Ex-ELS)

$$\sum_{t=1}^{\tau} q_{t\tau} = b_{\tau}, \quad 1 \leq \tau \leq T, \tag{7}$$

$$q_{t\tau} - b_{\tau} y_t \leq 0, \quad 1 \leq t \leq \tau \leq T, \tag{8}$$

$$q_{t\tau} \geq 0, \quad 1 \leq t \leq \tau \leq T, \tag{9}$$

$$y_t \in \{0, 1\}, \quad 1 \leq t \leq T, \tag{10}$$

where  $\bar{c}_t = p_t + \sum_{s=t+1}^T h_s$ .

Krarup and Bilde show that the linear programming relaxation of (Ex-ELS) (obtained by relaxing constraints  $y \in \{0, 1\}$ ) always has an integer solution. The corresponding dual problem has a special structure that enables developing a primal-dual-based algorithm. The following is the formulation of the dual problem:

$$\text{maximize } \sum_{t=1}^T b_t v_t$$

subject to (D-ELS)

$$\sum_{\tau=t}^T b_{\tau} \max(0, v_{\tau} - \bar{c}_t) \leq s_t \quad 1 \leq t \leq T. \tag{11}$$

The dual variables have the following property:  $v_t \geq v_{t+1}$  for  $1 \leq t \leq T - 1$ . This property of the dual variables is used to show that the dual-ascent algorithm gives the optimal solution to the economic lot-sizing problem. Note that formulation (Ex-ELS) of the economic lot-sizing problem is a special case of the facility location problem. The primal-dual algorithm, in principle, is similar to the primal-dual scheme proposed by Erlenkotter [14] for the facility location problem. The primal-dual algorithm for the economic lot-sizing problem developed by Wagelmans et al. [34] runs in  $O(T \log T)$ .

### Cutting Plane Algorithm

Many researchers studying lot-sizing problems also focused on determining a partial polyhedral description of the set of the feasible solutions and applying branch-and-cut methods (Pochet et al. [28], Leung et al. [21], Barany et al. [5]). The main motivation for studying the polyhedral structure of the single item lot-sizing problem is to use the results from these studies to develop efficient algorithms for problems such as the multi-commodity economic lot-sizing problem. However, the branch-and-cut approach has not yet resulted in competitive algorithms for the single-item lot-sizing problem itself. The reason is that generating a single cut could be as time-consuming as solving the whole problem.

Barany et al. [4,5] provide a set of valid inequalities for the single-commodity lot-sizing problem and show that these inequalities are facets of the convex hull of the feasible region. Furthermore, they show that the inequalities fully describe the convex hull of the feasible region. Their separation algorithm runs in order  $O(T^2)$ .

Pereira and Wolsey [27] study a family of unbounded polyhedra arising in an uncapacitated lot-sizing problem with Wagner-Whitin type costs ( $h_t + p_t - p_{t+1} \geq 0$ ). They characterize the bounded faces of maximal dimension completely and show that they are integral. For a problem with  $T$  periods they derive an  $O(T^2)$  algorithm to express any point within the polyhedron as a convex combination of the extreme points and the extreme rays of the polyhedron. They observe that for a given objective function, the face of optimal solutions can be found in  $O(T^2)$ .

## Cases

### Capacitated Economic Lot-Sizing Problem

The capacitated lot-sizing problem is *NP*-hard even for many special cases (Florian et al. [16] and Bitran and Yanasse [9]). In 1971, Florian and Klein presented a remarkable result. They developed an  $O(T^4)$  algorithm for solving the capacitated lot-sizing problem with equal capacities in all periods. This result uses a dynamic programming approach combined with some important properties of optimal solutions to these problems. Recently, van Hoesel and Wagelmans [32] showed that this algorithm can be improved to  $O(T^3)$  if backlogging is not allowed and the holding cost functions are linear.

Several solution approaches have been proposed for *NP*-hard special cases of the capacitated lot-sizing problem. These methods are typically based on branch-and-bound (see, for instance, Baker et al. [3] and Erengüç and Aksoy [12]), dynamic programming (Kirca [19] and Chen and Lee [10]) or a combination of the two (Chung and Lin [11] and Lofti and Yoon [22]).

Shaw and Wagelmans [29] considered the capacitated lot-sizing problem with piecewise linear production costs and general holding costs. They showed that this is an *NP*-hard problem and presented an algorithm that runs in pseudopolynomial time.

### Multi-commodity Economic Lot-Sizing Problem

The multicommodity version of the problem has attracted much attention. Manne [23] uses the ZIO property to develop a column generation approach to solve this problem. Barany et al. [5] solve the multicommodity capacitated lot-sizing problem without setup times optimally using a cutting-plane procedure followed by branch-and-bound. Moreover, Manne introduces upper bounds on the production capacities.

Other extensions to the classic economic lot-sizing problem consider setup times, backorders, and other factors. Zangwill [37] extends Wagner and Whitin's model by allowing backlogging and introducing general concave cost functions. Veinott [33] studies an uncapacitated model with convex cost structures. Trigeiro et al. [30] show that a capacitated lot-sizing problem with setup times is much harder to solve than a capacitated lot-sizing problem without setup times. It is easy to check if the capacitated lot-sizing problem without

setup times has a feasible solution or not. This can be done by computing cumulative demand and cumulative capacity. When setup times are considered, the feasibility problem is *NP*-complete. Also, the bin-packing problem is a special case of capacitated lot-sizing problem with setup times (Garey and Johnson [17, p. 226]).

Upper and lower bounds to eigenvalues; Rayleigh–Ritz method; Lehmann–Maehly method

Selfadjoint eigenvalue problems for ordinary differential equations are very important in the sciences and in engineering. The characterization of eigenvalues by a minimum-maximum principle for the *Rayleigh quotient* forms the basis for the famous *Rayleigh–Ritz method*. This method allows for an efficient computation of nonincreasing upper eigenvalue bounds. N.J. Lehmann and H.J. Maehly [6,7,8] independently developed complementary characterizations that can be used to compute lower bounds. These methods are based on extremal principles for the *Temple quotient*. In general, however, an application of the *Lehmann–Maehly method* requires that certain quantities can be determined explicitly. This may be difficult or even impossible when dealing with partial differential equations. Of great importance is therefore a generalization, the

Goerisch method [3,4,5], that may be used to overcome these problems. Nevertheless, the original Lehmann–Maehly method can easily be applied to a large class of ordinary differential equations; in [10] it is shown, that the method can be interpreted as a special application of the Rayleigh–Ritz method.

**Inclusion Method**

Let  $(H, (\cdot|\cdot))$  be an infinite-dimensional Hilbert space with the inner product  $(\cdot|\cdot)$  and the norm  $\|\cdot\|$ . Suppose that  $V$  is a dense subspace of  $H$  and that one has the inner product  $[\cdot|\cdot]$  in  $V$  such that  $(V, [\cdot|\cdot])$  is a Hilbert space (the norm in  $V$  is denoted by  $\|\cdot\|_V$ ). The embedding  $V \hookrightarrow H$  is assumed to be compact.

One can consider the right-definite eigenvalue problem

$$\begin{cases} \text{Find } \lambda \in \mathbb{R} \text{ and } \varphi \in V, \varphi \neq 0, \\ \text{s.t. } [\varphi|v] = \lambda(\varphi|v) \text{ for all } v \in V. \end{cases} \quad (1)$$

Problem (1) has a countable spectrum of eigenvalues, and the eigenvalues can be ordered by magnitude:

$$0 < \lambda_1 \leq \lambda_2 \leq \dots, \quad \lim_{j \rightarrow \infty} \lambda_j = \infty.$$

The Rayleigh–Ritz procedure for calculating upper bounds is a discretization of the Poincaré principle (cf. [9, Chapt. 22])

$$\lambda_j = \min_{\substack{E \subset V \\ \dim E = j}} \max_{\substack{u \in E \\ u \neq 0}} \frac{[u|u]}{(u|u)}, \quad j \in \mathbb{N}. \quad (2)$$

If the linearly independent trial functions

$$u_1, \dots, u_n \in V, \quad n \in \mathbb{N},$$

are chosen, one can reduce (2) to the  $n$ -dimensional subspace  $V_n$  (the span of the chosen functions  $\{u_1, \dots, u_n\}$ ) and obtains the values

$$\Lambda_1^{[n]} \leq \dots \leq \Lambda_n^{[n]},$$

which are upper bounds to the following  $\lambda_j$ :

$$\lambda_j \leq \Lambda_j^{[n]}, \quad j = 1, \dots, n.$$

$\Lambda_j^{[n]}$  is called a *Rayleigh–Ritz bound* for  $\lambda_j$ . Now one forms the real  $n \times n$ -matrices

$$\begin{cases} A_0 := ((u_i|u_k))_{i,k=1,\dots,n}, \\ A_1 := ([u_i|u_k])_{i,k=1,\dots,n}, \end{cases} \quad (3)$$

the Rayleigh–Ritz bounds are the eigenvalues of the matrix eigenvalue problem

$$A_1 x = \Lambda^{[n]} A_0 x, \quad (\Lambda^{[n]}, x) \in \mathbb{R} \times \mathbb{R}^n. \quad (4)$$

The Rayleigh–Ritz bounds are monotonically decreasing in  $n \in \mathbb{N}$ .

The Lehmann–Goerisch procedure (see [3,4,5,6,7]) for calculating lower bounds can be understood as the discretization of a variational principle for characterizing the eigenvalues as well. This principle and a proof of the method is due to S. Zimmermann and U. Mertins [10].

Let  $\rho \in \mathbb{R}$  be a spectral parameter such that for an  $N \in \mathbb{N}$  the inequality

$$\lambda_N < \rho < \lambda_{N+1} \quad (5)$$

holds true. One expresses the first  $N$  eigenvalues in the form

$$\lambda_{N+1-i} = \rho + \frac{1}{\sigma_i}, \quad i = 1, \dots, N$$

(assuming  $\sigma_i < 0$ ). For  $u \in V$ ,  $w_u \in H$  denotes the uniquely determined solution of the equation

$$[u|v] = (w_u|v) \quad \text{for all } v \in V,$$

the following  $\sigma_i$  therefore are characterized by

$$\sigma_i = \inf_{\substack{E \subset V \\ \dim E = i}} \max_{\substack{u \in E \\ u \neq 0}} \frac{[u|u] - \rho(u|u)}{(w_u|w_u) - 2\rho[u|u] + \rho^2(u, u)}, \quad (6)$$

$i = 1, \dots, N$ . A negative upper bound for  $\sigma_i$  results in a lower bound for  $\lambda_{N+1-i}$ . In order to discretize (6), one determines  $w_1, \dots, w_n \in H$  such that

$$[u_i|v] = (w_i|v) \quad \text{for all } v \in V, \quad (7)$$

then one defines the matrix

$$A_2 := ((w_i|w_k))_{i,k=1,\dots,n}, \quad (8)$$

and solves the matrix eigenvalue problem

$$(A_1 - \rho A_0) x = \tau (A_2 - 2\rho A_1 + \rho^2 A_0) x, \quad (\tau, x) \in \mathbb{R} \times \mathbb{R}^n. \quad (9)$$

If for  $n \in \mathbf{N}$  the condition  $\Lambda_N^{[n]} < \rho$  is fulfilled, then (9) has exactly  $N$  negative eigenvalues  $\tau_1 \leq \dots \leq \tau_N < 0 \leq \dots \leq \tau_n$ . These  $\tau_i$  are upper bounds for our  $\sigma_i$  ( $\sigma_i \leq \tau_i$ ,  $i = 1, \dots, N$ ). One obtains the lower bounds

$$\Lambda_j^{\rho[n]} := \rho + \frac{1}{\tau_{N+1-j}} \leq \lambda_j, j = 1, \dots, N. \quad (10)$$

This discretization (9), (10) is the Lehmann–Goerisch procedure.  $\Lambda_j^{\rho[n]}$  is called a *Lehmann–Goerisch bound* for  $\lambda_j$ .

**Numerical Example**

The numerical example is the well known Mathieu equation. This equation has been considered by several authors, bounds for eigenvalues of the Mathieu equation can be found in [1,9] and [3]. The eigenvalue problem reads as follows

$$\begin{aligned} -\Phi''(x) + s \cos^2(x)\Phi(x) &= \lambda\Phi(x), \quad x \in \left[0, \frac{\pi}{2}\right], \\ \Phi'(0) = \Phi'\left(\frac{\pi}{2}\right) &= 0, \end{aligned}$$

where  $s \in \mathbf{R}$ ,  $s > 0$ , is a parameter.

In order to treat this problem, the required quantities can be defined as follows:  $I := (0, \pi/2)$ ,

$$H := L_2(I), \quad V := H^1(I).$$

The inner products  $(\cdot, \cdot)$  and  $[\cdot, \cdot]$  are given by

$$\begin{aligned} (f, g) &:= \int_0^{\frac{\pi}{2}} f(x)g(x) \, dx \quad \text{for all } f, g \in H, \\ [f, g] &:= \int_0^{\frac{\pi}{2}} (f'(x)g'(x) + s \cos^2(x)f(x)g(x)) \, dx \end{aligned}$$

for all  $f, g \in V$ .

With this definition the inner product  $[\cdot, \cdot]$  and the usual  $H^1$  inner product are equivalent; the embedding  $(V, [\cdot, \cdot]) \hookrightarrow (H, (\cdot, \cdot))$  is compact.

Now the eigenvalue problem

$$\begin{cases} \text{Find } \lambda \in \mathbf{R} \text{ and } \varphi \in V, \varphi \neq 0 \\ \text{s.t. } [\varphi|\nu] = \lambda(\varphi|\nu) \text{ for all } \nu \in V. \end{cases}$$

is equivalent to the Mathieu equation. The trial functions  $v_k \in V$  are defined by

$$\begin{aligned} v_1(x) &:= 1, \\ v_k(x) &:= \cos(2(k-1)x) \end{aligned} \quad (11)$$

for  $x \in I$ ,  $k = 2, \dots, n$ .

With these trial functions the Rayleigh–Ritz upper bounds  $\Lambda_i^{[n]}$  (cf. (3), (4)) can be computed. For  $n = 5$  one obtains

$i$	$\Lambda_i^{[5]}$
1	2.28404873592
2	8.4560567005
3	19.606719005
4	39.5439779
5	67.609198

The quality of these upper bounds can be increased by increasing  $n$ .

An application of the Lehmann–Goerisch procedure requires a spectral parameter  $\rho$  which is a rough eigenvalue bound (cf. (5)). For this aim the Mathieu equation is considered for  $s = 0$ . This is a second order problem with constant coefficients and can be solved in closed form. Its eigenvalues are  $\tilde{\lambda}_i = 4(i-1)^2$ ,  $i \in \mathbf{N}$ . From the comparison theorem (see [3]) one can see that the  $\tilde{\lambda}_i$  are lower bounds for the eigenvalues of the Mathieu equation with  $s > 0$ ; this can be used to verify the left hand side inequality of (5), the right-hand side inequality can be examined by means of the Rayleigh–Ritz bounds. For  $N = 4$  one obtains

$$\lambda_3 \leq \Lambda_3^{[n]} \leq 19.607 < \rho := \tilde{\lambda}_4 = 36 < \lambda_4.$$

If  $s$  is increased dramatically, it may be impossible to satisfy (5). If this happens, one can link the eigenvalue problem under consideration and the comparison problem by a homotopy method (cf. [3]).

The next task is the determination of  $w_i \in H$  such that (7) holds true. In general this is a problem, but for differential equations, where the right-hand side is the identity, one can proceed as follows: The operator on the left-hand side of the differential equation is denoted by  $M$ ; then the trial functions  $v_i$  are chosen from  $D(M)$  (that means sufficiently smooth) such that all essential and natural boundary conditions are satisfied. Now  $w_i := M v_i$  fulfills (7). For the Mathieu equation one can define

$$(Mf)(x) := -f''(x) + s \cos^2(x)f(x)$$

and

$$\tilde{V} := \left\{ f \in H^2(I) : f'(0) = f'\left(\frac{\pi}{2}\right) = 0 \right\};$$

now it is easy to see that the  $v_i$  from (11) fulfill  $v_i \in \tilde{V}$  and  $w_i := M v_i$  can be used in (7), (8).

From the eigenvalues of the matrix eigenvalue problem (9) one obtains the following bounds:

$i$	$\Lambda_i^{\rho[5]}$	$\Lambda_i^{[5]}$
1	2.28404873561	2.28404873592
2	8.4560566942	8.4560567005
3	19.6067171	19.6067191

For an example with a system of ordinary differential equations see [2].

### Abstract

In this article, we give an overview of the Ellipsoid Method. We start with a historic introduction and provide a basic algorithm in Sect. “[Method](#)”. Techniques to avoid two important assumptions required by this algorithm are considered in Sect. “[Polynomially Running Time: Avoiding The Assumptions](#)”. After the discussion of some implementation aspects, we are able to show the polynomial running time of the Ellipsoid Method. The second section is closed with some modifications in order to speed up the running time of the ellipsoid algorithm. In Sect. “[Applications](#)”, we discuss some theoretical implications of the Ellipsoid Method to linear programming and combinatorial optimization.

## Introduction

In 1979, the Russian mathematician Leonid G. Khachiyan published his famous paper with the title “A Polynomial Algorithm in Linear Programming”, [11]. He was able to show that linear programs (LPs) can be solved efficiently; more precisely that LP belongs to the class of polynomially solvable problems. Khachiyan’s approach was based on ideas similar to the Ellipsoid Method arising from convex optimization. These methods were developed by David Yudin and Arkadi Nemirovski, [24,25,26], and independently by Naum Shor, [20], preceded by other methods as for instance the Relaxation Method, Subgradient Method or the Method of Central Sections, [2]. Khachiyan’s effort was to modify existing methods enabling him to prove the polynomial running time of his proposed algorithm. For his work, he was awarded with the Fulkerson Prize of the American Mathematical Society and the Mathematical Programming Society, [16,21].

Khachiyan’s four-page note did not contain proofs and was published in the journal *Soviet Mathematics Doklady* in February 1979 in Russian language. At this time he was 27 years young and quite unknown. So it is not surprising that it took until the Montreal Mathematical Programming Symposium in August 1979 until Khachiyan’s breakthrough was discovered by the mathematical world and a real flood of publications followed in the next months, [23]. In the same year, *The New York Times* made it front-page news with the title “A Soviet Discovery Rocks World of Mathematics”. In October 1979, the *Guardian* titled “Soviet Answer to Traveling Salesmen” claiming that the Traveling Salesman problem has been solved – based on a fatal misinterpretation of a previous article. For an amusing outline of the interpretation of Khachiyan’s work in the world press, refer to [15].

## Method

The Ellipsoid Method is designed to solve decision problems rather than optimization problems. Therefore, we first consider the decision problem of finding a feasible point to a system of linear inequalities

$$A^T x \leq b \quad (1)$$

where  $A$  is a  $n \times m$  matrix and  $b$  is an  $n$ -dimensional vector. From now on, we assume all data to be inte-

gral and  $n$  to be greater or equal than 2. The goal is to find a vector  $x \in \mathbb{R}^n$  satisfying (1) or to prove that no such  $x$  exists. We see in Sect. “Linear Programming” that this problem is equivalent to a linear programming optimization problem of the form

$$\min_x c^T x \quad \text{s.t.} \quad A^T x \leq b, \quad x \geq 0,$$

in the sense that any algorithm solving one of the two problems in polynomial time can be modified to solve the other problem in polynomial time.

## The Basic Ellipsoid Algorithm

Roughly speaking, the basic idea of the Ellipsoid Method is to start with an initial ellipsoid containing the solution set of (1). The center of the ellipsoid is in each step a candidate for a feasible point of the problem. After checking whether this point satisfies all linear inequalities, one either produced a feasible point and the algorithm terminates, or one found a violated inequality. This is used to construct a new ellipsoid of smaller volume and with a different center. Now the procedure is repeated until either a feasible point is found or a maximum number of iterations is reached. In the latter case, this implies that the inequality set has no feasible point.

Let us now consider the presentation of ellipsoids. It is well known, that the  $n$ -dimensional ellipsoid with center  $x^0$  and semi-axis  $g_i$  along the coordinate axis is defined as the set of vectors satisfying the equality

$$\sum_{i=1}^n \frac{(x_i - x_i^0)^2}{g_i^2} = 1. \quad (2)$$

More general, we can formulate an ellipsoid algebraically as the set

$$E := \{x \in \mathbb{R}^n \mid (x - x^0)^T B^{-1} (x - x^0) = 1\}, \quad (3)$$

with symmetric, positive definite, real-valued  $n \times n$  matrix  $B$ . This can be seen with the following argument. As matrix  $B$  is symmetric and real-valued, it can be diagonalized with a quadratic matrix  $Q$ , giving  $D = Q^{-1} B Q$ , or equivalently,  $B = Q D Q^{-1}$ . The entries of  $D$  are the eigenvalues of matrix  $B$ , which are positive and real-valued. They will be the quadratic, reciprocal values of the semi-axis  $g_i$ . Inserting the relationship for  $B$  into (3)

yields to  $(x-x^0)^T Q D^{-1} Q^{-1} (x-x^0) = 1$  which is equivalent to

$$((x-x^0)^T Q) D^{-1} ((x-x^0)^T Q)^T = 1.$$

Hence, we can interpret matrix  $Q$  as a coordinate transform to the canonical case where the semi-axis of the ellipse are along the coordinate axis. Recognize that in the case when matrix  $B$  is a multiple of the unit matrix,  $B = r^2 \cdot I$ , then the ellipsoid gets a sphere with radius  $r > 0$  and center  $x^0$ . We abbreviate this in the following by  $S(x^0, r)$ .

We start with a somewhat basic version of the ellipsoid algorithm. This method requires two important assumptions on the polyhedron

$$P := \{x \in \mathbb{R}^n \mid Ax \leq b\}.$$

We assume that

1. the polyhedron  $P$  is bounded and that
2.  $P$  is either empty or full-dimensional.

In Sect. “Polynomially Running Time: Avoiding The Assumptions”, we will see how this algorithm can be modified not needing these assumptions. This will allow us to conclude that a system of linear inequalities can be solved in polynomial running time with the Ellipsoid Method.

Let us now discuss some consequences of these two assumptions. The first assumption allows us to construct a sphere  $S(c_0, R)$  with center  $c_0$  and radius  $R$  containing  $P$  completely:  $P \subseteq S(c_0, R)$ . The sphere  $S(c_0, R)$  can be constructed, for instance, in the following two ways. If we know the bounds on all variables  $x$ , e.g.  $L_i \leq x_i \leq U_i$ , one can use a geometric argument to see that with

$$R := \sqrt{\sum_{i=1}^n \max\{|L_i|, |U_i|\}^2},$$

the sphere  $S(0, R)$  will contain the polytope  $P$  completely. In general, when such bounds are not given explicitly, one can use the integrality of the data and proof, see for instance [6], that the sphere with center 0 and radius

$$R := \sqrt{n} 2^{(A)+(b)-n^2} \tag{4}$$

contains  $P$  completely, where  $\langle \cdot \rangle$  denotes the encoding length of some integral data. For an integer number  $b_i$ ,

we define

$$\langle b_i \rangle := 1 + \lceil \log_2(|b_i| + 1) \rceil,$$

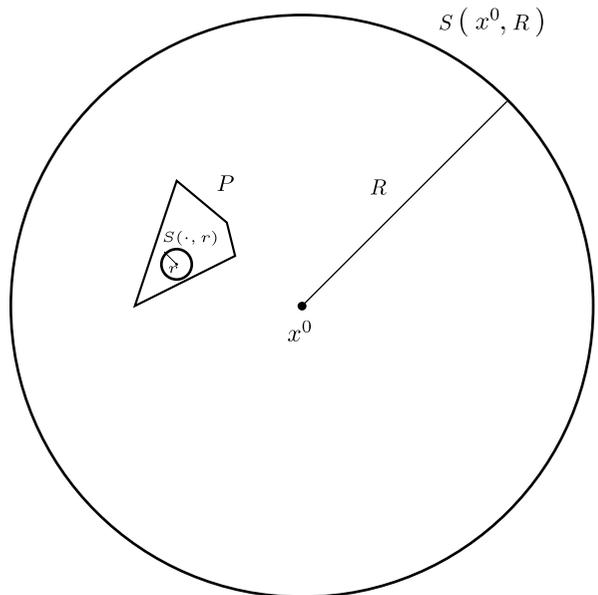

which is the number of bits needed to encode integer  $b_i$  in binary form; one bit for the sign and  $\lceil \log_2(|b_i| + 1) \rceil$  bits to encode  $|b_i|$ . With this, the encoding length of a vector  $b$  is the sum of the encoding lengths of its components. Similarly, for a matrix  $A$ , the encoding length is given by  $\langle A \rangle := \sum_{i=1}^m \langle a_i \rangle$ .

The second assumption implies that if  $P$  is non-empty, its volume is strictly positive, meaning that there is an  $n$ -dimensional sphere of radius  $r > 0$  which is contained in  $P$ . More precisely, it is possible to show that

$$vol(P) \geq 2^{-(n+1)\langle A \rangle + n^3}, \tag{5}$$

in the case that  $P$  is not empty, see [5]. This will help us to bound the number of iterations of the basic ellipsoid algorithm. The graphical interpretation of the positive volume of polytope  $P$  is that the solution set of system (1) is not allowed to have mass zero, for instance, not to be a hyperplane.

Figure 1 illustrates the effect of the two assumptions in the case that  $P$  is non-empty. As this is a two-dimensional example, the second assumption implies that

Ellipsoid Method, Figure 1  
P is bounded and full-dimensional

polytope  $P$  is not just a line segment but instead contains a sphere of positive radius  $r$ .

Now, we are ready to discuss the main steps of the basic ellipsoid algorithm. Consider therefore Algorithm 1. In the first six steps the algorithm is initialized. The first ellipsoid is defined in step three. The meaning of the parameters for the ellipsoid and especially number  $k^*$  will be discussed later in this section. For now, let us also ignore step seven. Then, for each iteration  $k$ , it is checked in step eight if center  $x^k$  satisfies the linear inequality system (1). This can be done for instance by checking each of the  $m$  inequalities explicitly. In the case that all inequalities are satisfied,  $x^k$  is a feasible point and the algorithm terminates. In the other case there is an inequality  $a_j^T x \leq b_j$  which is violated by  $x^k$ , step nine. In the next two steps, a new ellipsoid  $E_{k+1}$  is constructed. This ellipsoid has the following properties. It contains the half ellipsoid

$$H := E_k \cap \{x \in \mathbb{R}^n \mid a_j^T x \leq a_j^T x^k\} \quad (6)$$

which insures that the new ellipsoid  $E_{k+1}$  also contains polytope  $P$  completely, assuming that the initial ellipsoid  $S(0, R)$  contained  $P$ . Furthermore, the new ellipsoid has the smallest volume of all ellipsoids satisfying (6), see [2]. The central key for the proof of polynomial running time of the basic ellipsoid Algorithm 1 is another property, the so called *Ellipsoid Property*. It provides the following formula about the ratio of the volumes of the ellipsoids

$$\frac{\text{vol}E_{k+1}}{\text{vol}E_k} = \sqrt{\left(\frac{n}{n+1}\right)^{n+1} \left(\frac{n}{n-1}\right)^{n-1}} < \exp\left(-\frac{1}{2n}\right), \quad (7)$$

for a proof see, for instance, [5,17]. As  $\exp(-1/(2n)) < 1$  for all natural numbers  $n$ , the new ellipsoid has a strict smaller volume than the previous one. We also notice that  $\exp(-1/(2n))$  is a strictly increasing function in  $n$  which has the consequence that the ratio of the volumes of the ellipsoids is closer to one when the dimension of the problem increases.

Now, let us discuss the situation when  $P$  is empty. In this case, we want Algorithm 1 to terminate in step seven. To do so, we will derive an upper bound  $k^*$  on the number of iterations needed to find a center  $x^k$  satisfying the given system of linear inequalities for the

**Input:** Matrix  $A$ , vector  $b$ ; sphere  $S(c_0, R)$  containing  $P$

**Output:** feasible  $\bar{x}$  or proof that  $P = \emptyset$

```

// Initialize
1:  $k := 0$ 
2:  $k^* := 2n(2n + 1) < C > + 2n^2(\log(R) - n^2 + 1)$ 
   // Max number of iterations
3:  $x^0 = c_0, B_0 = R^2 \cdot I$  // Initial ellipsoid
4:  $\tau := \frac{1}{n+1}$  // Parameter for ellipsoid: step
5:  $\sigma := \frac{2}{n+1}$  // Parameter for ellipsoid: dilation
6:  $\delta := \frac{n^2}{n^2-1}$  // Parameter for ellipsoid: expansion
   // Check if polytope  $P$  is empty
7: if  $k = k^*$  return  $P = \emptyset$ 
   // Check feasibility
8: if  $Ax^k \leq b$  return  $\bar{x} := x^k$  //  $\bar{x}$  is a feasible point
9: else let  $a_j^T x^k > b_j$ 
   // Construct new ellipsoid
10:  $B_{k+1} := \delta(B_k - \sigma \frac{B_k a_j (B_k a_j)^T}{a_j^T B_k a_j})$ 
11:  $x^{k+1} := x^k - \tau \frac{B_k a_j}{\sqrt{a_j^T B_k a_j}}$ 
   // Loop
12:  $k \leftarrow k + 1$  and goto step 7
    
```

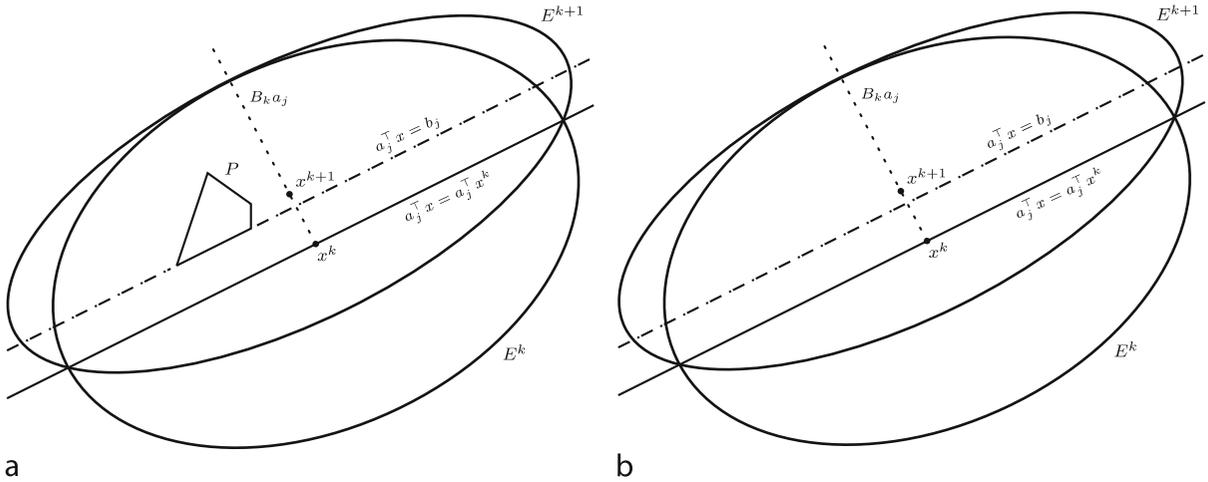

**Ellipsoid Method, Algorithm 1**  
**Basic Ellipsoid Algorithm**

case that  $P$  is not empty. Clearly, if the algorithm would need more than  $k^*$  iterations, the polytope  $P$  must be empty. Therefore, let us assume again that  $P \neq \emptyset$ . In this case (5) provides a lower bound for the volume of  $P$  and an upper bound of its volume is given, for instance, by (4). In addition, according to the construction of the ellipsoids, we know that each of the  $E_{k+1}$  contains  $P$  completely. Together with the Ellipsoid Property (7) we get the relation

$$\text{vol}(E_{k^*}) < \exp\left(\frac{-k^*}{2n}\right) \text{vol}(E_0) < 2^{\frac{k^*}{2n} + n + n \log(R)} \stackrel{!}{=} 2^{-(n+1)C + n^3} \leq \text{vol}(P).$$

This chain provides an equation defining the maximum number of iterations

$$k^* := 2n(2n + 1) \langle C \rangle + 2n^2(\log(R) - n^2 + 1). \quad (8)$$

**Ellipsoid Method, Figure 2**  
**Basic ellipsoid algorithm. a  $P \neq \emptyset$ . b  $P = \emptyset$**

A geometric interpretation is that the volume of the ellipsoid in the  $k^*$ th iteration would be too small to contain the polytope  $P$ . Obviously, this implies that  $P$  has to be empty. With this, we have shown that the presented basic ellipsoid algorithm works correctly.

One iteration of the basic ellipsoid algorithm, for the case of a non-empty polytope  $P$ , is illustrated in Fig. 2a. We recognize that  $P$  is contained completely in  $E_k$ . The dashed line shows equality  $a_j^T x \leq b_j$  corresponding to one of the inequalities which are violated by  $x^k$ . Geometrically, this equality is moved in parallel until it contains center  $x^k$ . Recognize that the new ellipsoid  $E_{k+1}$  contains the half ellipsoid (6). In this case, the new center  $x_{k+1}$  is again not contained in polytope  $P$  and at least one more step is required. The case that polytope  $P$  is empty is illustrated in Fig. 2b which is mainly the same as Fig. 2a.

In the case that  $B_k$  is a multiple of the identity, the ellipsoid is an  $n$ -dimensional sphere. According to the initialization of the basic ellipsoid algorithm in step three, this is the case for the first iteration when  $k = 0$ . This gives us an interpretation of the values of  $\delta$  and  $\tau$ . The new ellipsoid  $E_{k+1}$  is shrunk by the factor  $\sqrt{\delta(1-\sigma)} = n/(n+1)$  in the direction of vector  $a_j$  and expanded in all orthogonal directions by factor  $\sqrt{\delta} = n/\sqrt{n^2-1}$ . Hence, we see that in the next step we do no longer get a sphere if we start with one. The third parameter, the step, gives intuitively the measure how far we go from point  $x^k$  in the direction of

vector  $B_k a_j$ , multiplied by factor  $1/\sqrt{a_j^T B_k a_j}$ . For more details we refer to the survey of Bland, Goldfarb and Todd, [2].

After all the discussions above, we are now able to conclude the polynomial running time of the basic ellipsoid Algorithm 1 for the case that the polyhedron  $P$  is bounded and either empty or full-dimensional. For an algorithm to have polynomial running time in the deterministic Turing-machine concept, there has to be a polynomial in the encoding length of the input data describing the number of elementary steps needed to solve an arbitrary instance of the problem. Therefore, let  $L := \langle A, b \rangle$  be the encoding length of the input data. Obviously, each of the steps of Algorithm 1 can be done in polynomial many steps in  $L$ . The maximum number of iterations is given through  $k^*$  which is also a polynomial in  $L$ ; consider therefore equations (8) and (4). Hence, we conclude that the ellipsoid Algorithm 1 has a polynomial running time. During the reasoning above, we required implicitly one more important assumption, namely to have exact arithmetic. Normally, this is of more interest in numerics rather than in theoretical running time analysis. However, it turns out that for the Ellipsoid Method this is crucial as the Turing-machine concept also requires finite precision. Let us postpone this topic to the end of the next subsection and rather discuss methods to avoid the two major assumptions on polyhedron  $P$ .

### Polynomially Running Time: Avoiding the Assumptions

In order to prove that the Ellipsoid Method can solve the system of linear inequalities (1) in polynomial time, one has to generalize the basic ellipsoid Algorithm 1 to need not the assumptions that 1. polyhedron  $P$  is bounded, 2.  $P$  is either empty or full-dimensional and 3. that exact arithmetic is necessary.

In 1980, Khachiyan published a paper, [12], discussing all the details and proofs about the Ellipsoid Method which were neglected in his paper from 1979. In Lemma 1, he showed that

$$P \cap S(0, 2^L) \neq \emptyset, \quad (9)$$

in the case that  $P \neq \emptyset$ . With this, one can use for  $R$  of (4) value  $2^L$ . However, we cannot just adopt the algorithm above to the new situation. Instead of a lower bound for  $\text{vol}(P)$ , as given in (5), we would need a lower bound for  $\text{vol}(P \cap S(0, 2^L))$ . To achieve this, we follow a trick introduced by Khachiyan and consider the perturbed system of linear inequalities

$$2^L a_i^T x \leq 2^L \beta_i + 1 \quad i = 1, \dots, m. \quad (10)$$

Let us abbreviate the corresponding solution set with  $P'$ , which is in general a polyhedron. Khachiyan was able to prove a one-to-one correspondence of the original system (1) and the perturbed one (10). This means that  $P$  is empty if and only if  $P'$  is empty, it is possible to construct a feasible point for (1) out of (10) in polynomial time and the formulation of the perturbed system is polynomial in  $L$ . Furthermore, the new inequality system has the additional property that if  $P' \neq \emptyset$  it is full-dimensional. Hence, it is possible to find a (non-empty) sphere included in  $P'$ . It can be shown, that

$$S(\bar{x}, 2^{-2L}) \subseteq P' \cap S(0, 2^L),$$

where  $\bar{x}$  is any feasible point of the original system (1) and hence  $\bar{x} \in P$ . With this argument at hand, it is possible to derive an upper bound for the number of iterations for the Ellipsoid Method by solving the perturbed system (10). It can be shown that a feasible point can be found in at most  $6n(n+1)L$  iterations, [2].

With the perturbation of the original system and property (9), we do no longer require that  $P$  is bounded. As a byproduct, polyhedron  $P$  has not to be of full-dimension in the case that it is non empty; as system (10) is of full-dimension independent of whether  $P$  is or not, assuming that  $P \neq \emptyset$ . As a consequence, the basic ellipsoid algorithm can be generalized to apply for any polyhedron  $P$  and the two major assumptions are no longer necessary.

During all of the reasoning, we assumed to have exact arithmetic, meaning that no rounding errors during the computation are allowed. This implies that all data have to be stored in a mathematically correct way. As we use the Turing-machine concept for the running time analysis, we require that all computations have to be done in finite precision. Let us now have a closer look for the reason why this is crucial for ellipsoid Algorithm 1.

The presentation of the ellipsoid with the matrix  $B_k$  in (3) yields to the convenient update formulas for the new ellipsoid, parameterized by  $B_{k+1}$  and  $x^{k+1}$ . However, to obtain the new center  $x^{k+1}$  one has to divide by factor  $\sqrt{a_j^T B_k a_j}$ . If we work with finite precision, rounding errors are the consequence, and it is likely that matrix  $B_k$  is no longer positive definite. This may cause that  $a_j^T B_k a_j$  becomes zero or negative, implying that the ellipsoid algorithm fails.

Hence, to implement the ellipsoid method, one has to use some modifications to make it numerically stable. One basic idea is to use factorization

$$B_k = L_k D_k L_k^T$$

for the positive definite matrix  $B_k$ , with  $L$  being a lower triangular matrix with unit diagonal and diagonal matrix  $D_k$  with positive diagonal entries. Obtaining such a factorization is quite expensive as it is of order  $n^3$ . But there are update formulae applying for the case of the ellipsoid algorithm which have only quadratic complexity. Already in 1975, for such a type of factorization, numerically stable algorithms have been developed, insuring that  $D_k$  remains positive definite, see [7]. We skip the technical details here and refer instead to Golfarb and Todd, [9].

With a method at hand which can handle the ellipsoid algorithm in finite precision numerically stable, the proof of its polynomial running time is complete.

## Modifications

In this subsection, we briefly discuss some straightforward modifications of the presented ellipsoid method in order to improve its convergence rate. Therefore, let us consider Fig. 2 once more. From this figure it is intuitively clear that an ellipsoid containing set  $\{x \in E_k \mid a_j^T x \leq b\}$  has a smaller volume than the one containing the complete half-ellipsoid (6). In the survey paper of Bland et al. it is shown that the smallest ellipsoid, arising from the so called deep cut  $a_j^T x \leq b$ , can be obtained by choosing the following parameters for Algorithm 1

$$\begin{aligned}\tau &:= \frac{1 + n\alpha}{n + 1}, \\ \sigma &:= \frac{2 + 2n\alpha}{(n + 1)(1 + \alpha)}, \\ \delta &:= \frac{n^2}{(n^2 - 1)(1 - \alpha^2)},\end{aligned}$$

with

$$\alpha := \frac{a_j^T - b_j}{\sqrt{a_j^T B_k a_j}}.$$

The parameter  $\alpha$  gives an additional advantage of this deep cut, as it is possible to check infeasibility or for redundant constraints, [19].

Another idea could be to use a whole system of violated inequalities as a cut instead of only one. Such type of cuts are called surrogate cuts and were discussed by Goldfarb and Todd. An iterative procedure to generate these cuts was described by Krol and Mirman, [14].

Consider now the case that the inequality system (1) contains two parallel constraints which means that they differ only in the right hand side. With this it is possible to generate a new ellipsoid containing the information of both inequalities. These cuts are called *parallel cuts*. Update formulas for  $B_k$  and  $x^k$  were discovered independently by several authors. For more details, we refer to [2,19].

However, all modifications which have been found so far do not allow to reduce the worst case running time significantly – they especially do not allow to avoid the presence of  $L$ . This implies that the running time does not only depend on the size of the problem but also on the magnitude of the data.

At the end of the second chapter, we point out that the Ellipsoid Method can also be generalized to use other convex structures as ellipsoids. Methods working for instance only with spheres, or triangles, are possible. The only crucial point is that one has to make sure that its polynomial running time can be proven. Furthermore, the underlying polytope can be generalized to any convex set; for which the separation problem can be solved in polynomial time, see Sect. “[Separation and Optimization](#)”.

## Applications

In 1981, Grötschel, Lovász and Schrijver used the Ellipsoid Method to solve many open problems in combinatorial optimization. They developed polynomial algorithms, for instance, for the vertex packing in perfect graphs, and could show that the weighted fractional chromatic number is  $\mathcal{NP}$ -hard, [5]. Their proofs were mainly based on the relation of separation and optimization, which could be established with the help of the Ellipsoid Method. We discuss this topic in Sect. “[Separation and Optimization](#)” and give one application for the maximum stable set problem. For all other interesting results, we refer to [5]. But first, we consider another important application of the Ellipsoid Method. We examine two concepts showing the equivalence of solving a system of linear inequalities and to find an optimal solution to a LP. This will prove that LP is polynomial solvable.

## Linear Programming

As we have seen in the last section, the Ellipsoid Method solves the problem of finding a feasible point of a system of linear inequalities. This problem is closely related to the problem of solving the linear program

$$\max_x c^T x \quad \text{s.t.} \quad A^T x \leq b, \quad x \geq 0. \quad (11)$$

Again, we assume that all data are integral. In the following we briefly discuss two methods of how the optimization problem (11) can be solved in polynomial time via the Ellipsoid Method. This will show that LP is in the class of polynomially solvable problems.

From duality theory, it is well known that solving the linear optimization problem (11) is equivalent to

finding a feasible point of the following system of linear inequalities

$$\begin{aligned} A^T x &\leq b, \\ -x &\leq 0, \\ -A y &\leq -c, \\ -y &\leq 0, \\ -c^T x + b^T y &\leq 0. \end{aligned} \quad (12)$$

The third and fourth inequality come from the dual problem of (11), insuring primal and dual feasibility of  $x$  and  $y$ , respectively. The last inequality results from the Strong Duality Theorem, implying that this inequality always has zero slack. The equivalence of the two problems means in this case that vector  $\bar{x}$  of each solution pair  $(\bar{x}, \bar{y})$  of (12) is an optimal solution of problem (11) and  $\bar{y}$  is an optimum for the dual problem of (11). In addition, to each solution of the optimization problem exists a vector such that this pair is feasible for problem (12).

From the equivalence of the two problems (11) and (12) we immediately conclude that the linear programming problem can be solved in polynomial time; as the input data of (12) are polynomially bounded in the length of the input data of (11). This argument was used by Gács and Lovász in their accomplishment to Khachiyan's work, see [4]. The advantage of this method is that the primal and dual optimization problem are solved simultaneously. However, note that with this method, one has no idea whether the optimization problem is infeasible or unbounded in the case when the Ellipsoid Method proves that problem (12) is infeasible. Another disadvantage is that the dimension of the problem increases from  $n$  to  $n + m$ .

Next we discuss the so called bisection method which is also known as binary search or sliding objective hyperplane method. Starting with an upper and lower bound of an optimal solution, the basic idea is to make the difference between the bounds smaller until they are zero or small enough. Solving system  $A^T x \leq b$ ,  $x \geq 0$  with the Ellipsoid Method gives us either a vector  $\bar{x}$  providing the lower bound  $l := c^T \bar{x}$  for problem (11) or in the case that the polyhedron is empty, we know that the optimization problem is infeasible. An upper bound can be obtained, for instance, by finding a feasible vector to the dual problem  $Ay \geq c$ ,  $y \geq 0$ .

If the Ellipsoid Method proves that the polytope of the dual problem is empty, we can use the duality theory (as we already know that problem (11) is not infeasible) to conclude that the optimization problem (11) is unbounded. In the other case we obtain vector  $\bar{y}$  yielding to the upper bound  $u := b^T \bar{y}$  of problem (11), according to the Weak Duality Theorem. Once bounds are obtained, one can iteratively use the Ellipsoid Method to solve the modified problem  $A^T x \leq b$ ,  $x \geq 0$  with the additional constraint

$$-c^T x \leq -\frac{u + l}{2},$$

which is a constraint on the objective function value of the optimization problem. If the new problem is infeasible, one can update the upper bound to  $\frac{u+l}{2}$ , and in the case that the ellipsoid algorithm computes a vector  $\bar{x}$ , the lower bound can be increased to  $c^T \bar{x}$  which is greater or equal to  $\frac{u+l}{2}$ . In doing so, one at least bisects the gap in each step. However, this method does not immediately provide a dual solution. Note that only one inequality is added during the process, keeping the problem size small. More details and especially the polynomial running time of this method are discussed by Padberg and Rao [1].

### Separation and Optimization

An interesting property of the ellipsoid algorithm is that it does not require an explicit list of all inequalities. In fact, it is enough to have a routine which solves the so called Separation Problem for a convex body  $K$ :

*Given  $z \in \mathbb{R}^n$ , either conclude that  $z \in K$  or give a vector  $\pi \in \mathbb{R}^n$  such that inequality  $\pi^T x < \pi^T z$  holds for all  $x \in K$ .*

In the latter case we say that vector  $\pi$  separates  $z$  from  $K$ . In the following, we restrict the discussion to the case when  $K$  is a polytope meeting the two assumptions of Sect. "The Basic Ellipsoid Algorithm". To be consistent with the notation, we write  $P$  for  $K$ . From the basic ellipsoid Algorithm 1 follows immediately that if one can solve the separation problem for polytope  $P$  polynomially in  $L$  and  $n$ , then the corresponding optimization problem

$$\max_x c^T x \quad \text{s.t.} \quad x \in P$$

can also be solved in polynomial time in  $L$  and  $n$ ;  $L$  is again the encoding length of the input data, see Sect. “[The Basic Ellipsoid Algorithm](#)”. The converse statement was proven by Groetschel et al., yielding to the following equivalence of separation and optimization:

*The separation problem and the optimization problem over the same family of polytopes are polynomially equivalent.*

Consider now an example to see how powerful the concept of separation is. Given a graph  $G = (V, E)$  with node set  $V$  and edges  $e \in E$ . A stable set  $S$  of graph  $G$  is defined as a subset of  $V$  with the property that any two nodes of  $S$  are not adjacent; which means that no edge between them exists in  $E$ . To look for a maximum one is the maximum stable set problem. This is a well known optimization problem and proven to be  $\mathcal{NP}$ -hard, see [3]. It can be modeled, for instance, as the integer program

$$\begin{aligned} \max_x \quad & c^T x \\ \text{s.t.} \quad & x_i + x_j \leq 1 \quad \forall (i, j) \in E \quad x \in \{0, 1\} \end{aligned} \quad (13)$$

with incidence vector  $x$ , meaning that  $x_i = 1$  if node  $i$  is in a maximum stable set, otherwise it is zero. Constraints (13) are called edge inequalities. Relaxing the binary constraints for  $x$  gives the so-called trivial inequalities

$$0 \leq x \leq 1 \quad (14)$$

yielding to a linear program. However, this relaxation is very weak; consider therefore a complete graph. To improve it, one can consider the odd-cycle inequalities

$$\sum_{i \in C} x_i \leq \frac{|C| - 1}{2} \quad (15)$$

for each odd cycle  $C$  in  $G$ . Recognize that there are in general exponentially many such inequalities in the size of graph  $G$ . Obviously, every stable set satisfies them and hence they are valid inequalities for the stable set polytope. The polytope satisfying the trivial-, edge- and odd-cycle inequalities

$$P := \{x \in \mathbb{R}^{|V|} \mid x \text{ satisfies (14), (15) and (16)}\} \quad (16)$$

is called the cycle-constraint stable set polytope. Notice that this polytope is contained strictly in the stable set polytope. It can be shown that the separation problem for polytope (16) can be solved in polynomial time. One idea is based on a construction of an auxiliary graph  $H$  with a double number of nodes. Solving a sequence of  $n$  shortest path problems on  $H$  solves then the separation problem with a total running time of order  $|V| \cdot |E| \cdot \log(|V|)$ . With the equivalence of optimization and separation, the stable set problem over the cycle-constraint stable set polytope can be solved in polynomial time. This is quite a remarkable conclusion as the number of odd-cycle inequalities may be exponential. However, note that it does not imply that the solution will be integral and hence, we cannot conclude that the stable set problem can be solved in polynomial time. But we can conclude that the stable set problem for  $t$ -perfect graphs can be solved in polynomial time; where a graph is called  $t$ -perfect, if the stable set polytope is equal to the cycle-constraint stable set polytope (16). For more details about this topic see, for instance [8,18].

## Conclusion

In 1980, the Ellipsoid Method seemed to be a promising algorithm to solve problems practically [23]. However, even though many modifications to the basic ellipsoid algorithm have been made, the worst case running time still remains a function in  $n$ ,  $m$  and especially  $L$ . This raises two main questions. First, is it possible to modify the ellipsoid algorithm to have a running time which is independent of the magnitude of the data, but instead depends only on  $n$  and  $m$  – or at least any other algorithm with this property solving LPs? (This concept is known as strongly polynomial running time.) The answer to this question is still not known and it remains an open problem. In 1984, Karmarkar introduced another polynomial running time algorithm for LP which was the start of the Interior Point Methods, [10]. But also his ideas could not be used to solve this question. For more details about this topic see [17,22]. The second question, coming into mind, is how the algorithm performs in practical problems. Unfortunately, it turns out that the ellipsoid algorithm tends to have a running time close to its worst-case bound and is inefficient compared to other methods. The Simplex Method

developed by George B. Dantzig in 1947, was proven by Klee and Minty to have exponential running time in the worst case, [13]. In contrast, its practical performance is much better and it normally requires only a linear number of iterations in the number of constraints.

Until now, the Ellipsoid Method has not played a role for solving linear programming problems in practice. However, the property that the inequalities themselves have not to be explicitly known, distinguishes the Ellipsoid Method from others, for instance from the Simplex Method and the Interior Point Methods. This makes it a theoretically powerful tool, for instance attacking various combinatorial optimization problems which was impressively shown by Grötschel, Lovász and Schrijver.

### Introduction

Natural disasters (such as fires, hurricanes, tornadoes, flash floods, tsunamis, earthquakes, etc.) or man-made disasters (such as nuclear power plant explosions, chemical plant explosions, hazmat releases, dirty bomb threats, etc.) affect millions of people every year. Evacuation is an emergency management strategy used to ensure a population's safety in these type of situations. *Emergency evacuation is defined as the relocation of a threatened population to a safer area due to an immediate or predictable life-threatening danger* [25].

Prior to 1979, the models developed for evacuating people and vehicles from dangerous locations were mainly qualitative. However, the accident at the Three Mile Island nuclear power plant near Middletown, Pennsylvania, in 1979 provided a major motive for

quantifying emergency response plans [36]. Since then, a number of optimization- and simulation-based models have been developed to identify evacuation strategies for communities (urban and rural areas), buildings and industrial plants, and residential areas. The most recent and challenging developments in this area are real-time traffic management and agent-based models.

### Applications

#### Community Evacuation

Southworth [35] models a community evacuation plan using a five-step procedure that involves trip generation, trip departure time, trip destination, trip route selection, and evacuation plan set-up and analysis. The factors that affect any of these steps are the distribution of the population that is at risk, human behavior, transportation infrastructure, road capacity, vehicle utilization, accessibility of warning technologies, time available before the occurrence of the hazard, evacuees' route and destination selection, promptness in cleaning and preparing to operate the affected highways and roads, traffic management actions and the availability of non-evacuation based protective actions, such as in site sheltering [6,7,10,35,36]. The next sections of this article provide a summary of the research related to the above mentioned steps.

#### Community Evacuation: Trip Generation

The trip generation step determines the number of vehicles loaded to the traffic network during the evacuation. The number of vehicles loaded in the network depends on the population of the evacuation zone (which is space and time dependent), number of vehicles per household and vehicle utilization rate. The population of an evacuation area consists of the *permanent residents*, the *transients* (tourists and daily workers), and the *residents of special facilities* such as students, prisoners, patients, customers in shopping malls, and members at recreational facilities [35,36]. For a given residential area with a population size equal to  $N$ , Southworth [35] estimates the daytime population using the following equation:

$$D = H + W + P + S,$$

where  $W$ ,  $P$ , and  $S$  denote the number of workers, students, and residents of special facilities, respectively.  $H$  denotes the number of people who stay at home during the day and is estimated by

$$H = [N - (W + P)] * (1 - s),$$

where  $s$  is the probability that a non-working adult (or a child) is not being engaged in shopping, recreational or social activities.

Based on Southworth [35], the vehicle utilization rate depends on the time of the evacuation, the household size, the average number of commuters per vehicle and the average number of workers and licensed drivers per household. Estimating vehicle utilization rate is challenging. This is why some post evacuation surveys report significantly different utilization rates. For example, Baker [1] estimates the vehicle utilization rate to be 52% and Lindell and Perry [23] 75%.

### Community Evacuation: Trip Departure Time

This is the time it takes one to evacuate once the evacuation warning is released. The trip departure time consists of the time required to receive the official evacuation warning, the time required to leave the current location to get home, the time required to arrive home, and the time to prepare to leave home. Next, we give a summary of the approaches used to calculate trip departure time.

In 1984, Jamei [18] introduced the *mobilization curve* to estimate the percent of evacuees that enter the traffic network in specific time intervals. The mobilization curve is represented using the following equation:

$$P_t = \frac{1}{(1 + \exp[-z(t - h)])},$$

where  $P_t$  is the cumulative percentage of traffic volume loaded in the network by time  $t$ ,  $z$  is the response rate of the public to the disaster and is known as the slope of the mobilization curve, and  $h$  is the “half loading time”. The loading time depends on the incident and its relative severity. Radwan et al. [29] and Hobeika and Kim [17] have incorporated the mobilization curve in mass evacuation computer programs (MASSVAC 3.0 and MASSVAC 4.0) to determine the loading rate of evacuees. This approach relies on the planner’s judgment in calibrating the model parameters  $z$  and  $h$ .

In 2000, Urbanik [36] developed a *probability distribution* of the trip departure time. He defined the probability distribution of an activity time based on the percentage of the population that completed the activity within a given time span. To simplify, he assumed that the probability distribution of trip departure sub-activity times were independent. Then, he derived the probability distributions of trip departure time as the join probability distribution of sub-activities involved.

None of the above mentioned approaches consider the impact of human behavior on trip departure time. The work by Murray et al. [27,28] addresses the tendency of households to gather and then evacuate as a single unit. They believe that this type of behavior increases the departure time and, as a consequence, the evacuation time. Their evacuation model is based on a network flow formulation of the problem. In this network, the nodes represent residential and other possible meeting locations. The arcs represent the shortest path between nodes. Two linear integer programming formulations of the problem are given that consider a realistic presentation of human behavior in emergency situations. The first formulation determines the household meeting location while minimizing the maximum travel time of family members. The second formulation determines the route assignment along with the non-drivers’ pickup schedule by minimizing the linear trade-off between waiting time and travel time. For a more extensive review of the impact of human behavior in trip departure time, see [20,22,33,40].

### Community Evacuation: Trip Destination Selection

In emergency situations, the most straightforward approach that evacuees follow in choosing a destination is the shortest evacuation plan (SEP) [38]. Based on SEP, the evacuees seek the closest exit that flows them away from the danger area. In 1996, Yamada [38] presented an emergency evacuation plan for a city using two network flow optimization models. In these models, the residential areas (RA) and places of refuge (PR) are the nodes of the network, and the roads between them are the arcs. Yamada assumes that the roads are bi-directional with the same travel time in both directions and that the evacuees traverse roads on foot at

a uniform speed. He introduces a dummy node,  $v^+$ .  $v^+$  is then connected to each RA node. The new network is denoted by  $G^+(V^+, E^+)$ , and  $V^+ = V \cup \{v^+\}$ ,  $E^+ = E \cup \{(v^+, d) | d \in D\}$ .  $V$  is the original set of nodes (RA and PR nodes),  $E$  is the original set of arcs and  $D$  is the set of RA nodes only.

The first model does not consider node and arc capacities. The model minimizes the individual and total travel distance. Yamada applied the Dijkstra algorithm with  $v^+$  as the source node and PR as the demand nodes. This algorithm runs in  $O(|V^+|^2)$ . The optimal solution for this network flow problem is a forest of trees with exactly one PR in each tree. The solution determines the best possible destination for each RA.

The second model considers capacity constraints on PR nodes. Yamada uses a minimum cost network flow formulation to model this problem. He modified the original graph by adding a dummy source node ( $v_*$ ), a dummy sink node ( $v^*$ ), and a set of arcs connecting ( $v_*$ ) to RA and  $v^*$  to PR nodes. The new network is denoted by  $G^*(V^*, E^*)$ , where  $V^* = V \cup \{v_*, v^*\}$  and  $E^* = E \cup \{(v_*, r) | r \in R\} \cup \{(d, v^*) | d \in D\}$ .

The following is the problem formulation:

$$\text{minimize } \sum_{(u,v) \in E} k(u, v)x(u, v)$$

subject to

$$\begin{aligned} \sum_{u \in V^*} x(u, v) &= \sum_{w \in V^*} x(v, w) \quad \forall v \in V \\ \sum_{d \in D} x(d, v^*) &= P \\ 0 \leq x(u, v) &\leq c(u, v) \quad \forall (u, v) \in E^*, \end{aligned}$$

where  $k(u, v)$ ,  $c(u, v)$ , and  $x(u, v)$  are the cost coefficient, the capacity, and the number of evacuees traversing arc  $(u, v)$ , respectively.  $P$  is the size of the population, and  $R$  is the set of RA nodes. Due to the capacity constraints, the solution may not be a forest of trees and, as a result, evacuees of an RA node may be assigned to multiple PR nodes that may not necessary be the closest.

The SEP minimizes the total travel distance by routing evacuees to the closest exit. This approach causes congestion in certain exits, which in turn increases the total evacuation time. Cova and Johnson [10] overcame this difficulty by developing an optimal lane-based evacuation routing plan. They formulated the

problem as an integer extension of the minimum cost network flow problem. The objective, again, is to minimize the total travel distance. However, the model generates routing plans that trade total vehicle travel distance against merging conflicts while preventing traffic-crossing conflicts at intersections. They use a microscopic traffic simulation to compare the relative efficiency of the plans. The model is then used to identify evacuation routing plans for Salt Lake City, Utah.

The selection of a specific destination limits the route choices of evacuees and increases congestion of the roads that lead to safety. To avoid congestion, Hobeika et al. [17] have developed a model that routes the evacuees to the outside boundary of the risk area and lets them seek a safe place afterwards. They have extended the traffic network by adding dummy links that connect the final destinations to the network at the boundary areas. The dummy links have infinite capacity and short travel time. The objective is to minimize the total evacuation time.

Similarly to the trip departure step, human behavior significantly affects the destination choice of evacuees in emergency situations. Evacuees may change their intended destination if they notice considerable traffic backed up ahead of them [35]. In situations when the household members are scattered throughout the evacuation area, the individuals' tendency to meet before evacuating affects the destination selection choice. Murray and Mahmassani [27] point out that depending on the current location of family members, evacuees may decide to meet in a place that is close to the danger rather than far from it.

### Community Evacuation: Trip Route Selection

The trip route selection, also known as trip route assignment, identifies the movement of evacuees during the evacuation process. Numerous *optimization*, *simulation* and combinatorial *optimization-simulation* approaches have been used to model route selection procedures in the last four decades. The most common objectives of these models are to minimize the total travel time, to minimize the total evacuation time, or to maximize the flow of evacuees from the risk area to safety [3,10,27,28,38]. The travel time depends on the speed of a vehicle on a highway segment. The average speed is a non-increasing function of the traffic vol-

ume [15]. The following equation demonstrates the relationship between speed and volume and is referred to as the BPR (Bureau of Public Roads) equation.

$$SP_{it} = \frac{SP_i}{[1 + \alpha(\frac{V_{it}}{C_i})^\beta]}$$

where,  $SP_i$  is the speed limit on segment  $i$ ,  $SP_{it}$  is the average speed of a vehicle on segment  $i$  at time  $t$ ,  $C_i$  is the capacity of segment  $i$ ,  $V_{it}$  vehicle flow entering segment  $i$  at time  $t$ ,  $\alpha$  and  $\beta$  are constants.

Evacuation time depends not only on the traffic density, but also on traffic delays at intersections. The limited capacity, merging conflicts and crossing conflicts at intersections create unavoidable bottlenecks. The lane-based routing approach, presented by Cova and Johnson [10] in 2003, speeds up the evacuating process by increasing the intersection capacity and alleviating conflicts. They formulate the problem as a minimum cost network flow problem that minimizes the total travel distance, considering intersection conflicts, lane changing, and left-hand turns, simultaneously. Murray et al. [27,28] have formulated the evacuation routing as a vehicle routing problem (VRP). Unlike the classic VRP, they assume that vehicles have different capacities and are not located in a single depot but scattered throughout the network. In addition, the objective function minimizes not only the total travel time, but also the waiting time of evacuees at the meeting locations.

Besides *optimization* approaches, *simulation* based approaches have also been used to model evacuation routing. The employed route selection logic in simulation models might be simple, static or dynamic [35]. In a simple routing approach, the drivers either select the least congested route based on their myopic perception or follow some pre-determined set of routes. This approach has been used in microscopic simulation models such as CLEAR and NETSIM to simulate evacuation routing in small urban and rural areas [26,30].

The static route assignment models assume that traffic conditions remain unchanged during the simulation period. A mesoscopic simulation package, DYNEV, developed by KLD Associates Inc., uses such models to create evacuation routing plans for large urban areas [21].

Considering the dynamic nature of emergency evacuation, the dynamic traffic route assignment mod-

els are superior to simple and static approaches [16,17,31,32,36]. To route the evacuees to safety, the dynamic routing approach does not follow a pre-determined set of turning movements at intersections; instead, turning movements are function of dynamic traffic flow and evacuee behavioral considerations. These behavioral considerations address a driver's prior knowledge of the best direction leading to safety and her/his myopic perception of traffic conditions.

In combinatorial *optimization-simulation* approaches, an optimal route assignment model is integrated with a traffic simulation model. MASSVAC [17,29] and Dynasmart-P [4] are examples of macroscopic simulation packages that rely on combinatorial approaches. The objective of the optimization model in MASSVAC is to minimize the number of casualties. This model generates an optimal set of routes along with an optimal evacuation schedule. Dynasmart-P is a dynamic traffic network analysis and evaluation tool that determines a time-dependent assignment of vehicles to different network paths. Thus, the assignment of a driver to a path is made not only based on the length of the path, but also evacuation time. The objective is to minimize the travel time for each individual traveler. A set of outflow constraints limits the total number of vehicles leaving the link at an intersection approach. Additionally, a set of inflow constraints limits the maximum number of vehicles allowed to enter a link from all approaches [19].

## Building Evacuation

The issues discussed above are applicable in many emergency scenarios. However, the inevitable differences of some cases demand special considerations. Evacuating a building due to a disaster, such as the threat of smoke, fire, earthquake, bomb or toxic gas leak, requires a different approach. Lindell and Prater [24] have identified major differences between building and community evacuation. First, the social units within a building are not as clear as residential units within a community. Second, the employers can exercise more control strategies than public agencies. Finally, the departure time for building evacuation is shorter because of limited required preparation activities.

A number of studies have been devoted to describing the behavior of building inhabitants in emergency situations. For an extensive review, see Bryan [1]. However, fewer studies have been conducted to model evacuation procedures. One of the earliest attempts by Chalmet et al. [3] uses a capacitated network flow problem as the basis for modeling a building. Workplaces, halls, stairwells, and elevators represent the nodes of the network, and movement paths between them represent the arcs. The static capacity of nodes is the maximum number of individuals who are allowed to be in building components simultaneously. And the dynamic capacity of arcs is an upper bound on the number of individuals who can traverse the pathways in each time interval.

Chalmet et al. have used three different optimization models to solve the problem: a dynamic model, a graphical model and an intermediate model. The dynamic model is a multi objective optimization model that represents the evacuation as it evolves over time. In contrast, the graphical and intermediate models are not time dependent; they treat time as a parameter. They are simpler than the dynamic model; however, they provide almost the same insight about the building evacuation process.

The objectives of the dynamic model are to minimize the average number of time periods spent by each individual to evacuate the building, to maximize the total number of people saved, and to minimize the total evacuation time. The dynamic model is formulated as a minimum cost flow problem and efficiently solved using the GNET Algorithm [2].

The graphical approach to model building evacuation was originally presented by Francis [13,14]. The model assigns people to evacuation routes with the objective of minimizing the evacuation time. Two implicit assumptions of this model are that all evacuees have a uniform accessibility to the exit routes and that route clearance time depends on the number of people using the route. Given  $k$  to be the number of individuals in a building that has  $n$  exit routes, the formulation is

$$\text{minimize } \max\{t_j(x_j) | 1 \leq j \leq n\}$$

subject to

$$\begin{aligned} x_1 + \dots + x_n &= k \\ x_1, \dots, x_n &\geq 0 \end{aligned}$$

where  $t_j(x_j)$  is the time required to clear route  $j$  if the total number of evacuees on this route is  $x_j$ .  $t_j$  is a continuous function and is strictly increasing with respect to  $x_j$ . Note that  $t_j(0) = 0$ . Considering the assumptions made by this model, the minimum evacuation time happens when all routes are cleared in the same time.

The intermediate model uses the same network structure as the dynamic model. However, it is superior to the dynamic model in view of the required input data and computational time. Similar to the dynamic model, the arcs are capacitated, but there is no traverse time on arcs. For a given subset  $A$  of arcs, called *critical arcs*, there is no capacity constraint; instead, the function  $t_{ij}(x_{ij})$  estimates the time it takes to traverse arc  $(i, j) \in A$  when the flow of evacuees on this arc is  $x_{ij}$ . Clearly,  $t_{ij}(0) = 0$ . The objective is to minimize the building evacuation time which is explained as minimizing the traverse time on critical arcs. A heuristic bisection search algorithm and an exact minimax algorithm were used to solve the problem.

### Small-Area Evacuation

The standard approach for developing an evacuation plan for regions, buildings, ships, etc starts with determining the evacuation zone around a known hazard and then exploring some important factors that affect the evacuation plan (e. g., population distribution, road capacities and human behavior). To delimit the evacuation zone, a boundary is established around the affected area. In nuclear power plant evacuations, the boundary of the evacuation area is defined to  $X$  miles of radius from the plant, and  $X$  depends on the type of plant and the type of accident. In building evacuations such a boundary is defined by the shell of the building. However, for some emergency situations, such as urban firestorms or toxic spills on highways, the spatial impact of the hazard is unknown. In these kind of situations, defining the evacuation zone and its boundary can not be done in advance. This is usually the case for small urban and rural areas that could be subject to different hazardous events with uncertain spatial effects. Thus, the focus has been on general planning and mock drills rather than attempting to develop neighborhood specific evacuation plans. Cova and Church [8] were the

first to analyze the potential for evacuation difficulty at the neighborhood scale.

Little is known about small area evacuation as it is nearly impossible to measure accurately during an emergency. But, there has been an interest in looking for those areas that might be difficult to evacuate safely in an emergency. Church and Cova [6] introduce a network-based model to search for small contiguous areas or neighborhoods, within a urban/rural area, that may face difficulties in a sudden evacuation scenario. Their model classifies a neighborhood based on the degree of evacuation difficulty. The evacuation difficulty is measured by the evacuation risk factor which is defined as the number of vehicles per exit road. Church and Cova formulate the problem as a nonlinear network partitioning problem. The objective is to identify a critical neighborhood (critical cluster) that has the highest evacuation risk factor. In their network the nodes represent the households and the arcs represent the road segments connecting them. The demand of each node is estimated by multiplying the number of people per household with the average number of vehicles per person. The problem is transformed to an integer linear program whose objective is to identify an evacuation area that has a risk factor greater than a specific minimum threshold. This problem is solved for each node of the network. As a result, each node is labelled by the risk factor of its corresponding critical neighborhood. Finally, for each node the critical risk value is the highest value related to the critical clusters that this node has been part of. An exact and a heuristic approach are proposed to solve the integer-linear programming problem. Since the exact approach is time consuming, the heuristic approach is used to find a contiguous critical area around a given node. The heuristic approach follows a region growing basis. The base node is selected arbitrarily from the network. The area around the node is expanded iteratively by selecting a node randomly from a list of candidate nodes within a specific distance from the base node that most improves the objective function.

Cove and Church [8] have applied a similar methodology to generate an evacuation vulnerability map which classifies a local area based on the evacuation difficulty.

### Real-Time Traffic Management

Real-time traffic management for emergency evacuation dynamically controls the traffic flow to achieve certain system objectives such as maximum utilization of transportation system and minimum fatalities and property losses. This approach considers the evolution of the traffic flow in a traffic network to generate a real-time feedback traffic management system by using in-vehicle and on-route surveillance systems [5,25]. Briefly stated, the current condition of dynamic traffic flow is *monitored* by surveillance systems and a reference model that generates the desired traffic status and the “safest evacuation strategy” is developed to satisfy the designated objectives. The objectives are defined based on the nature of the hazard and the involvement of the emergency authorities. Possible objectives are minimizing the total travel time, minimizing the network clearance time or minimizing the number of casualties. The generated real-time *control* strategies include routing assignments, split rates at intersections, or traffic control advisories that are passed on to evacuees cyclically. In fact, the control strategies are not necessarily practiced by all evacuees in emergency situations. Therefore, these strategies are *modified* based on the differences between the current traffic status and the desired traffic status defined by the reference model. The “monitor, control, and modify” framework is repeated frequently in a closed feedback loop to decrease discrepancies between the the original plan and the current traffic status [25]. Some evacuation models include aspects of human behavior to provide more realistic control strategies that alleviate the deviations. The evacuation route choice model developed by Chiu et al. [5] is an example. This model replicates the route-selection procedure of evacuees when they are provided with safe evacuation routes. The probability that an evacuee will select a particular route depends on his familiarity with the route, the degree of overlap between the routes and his preference of using freeways.

### Agent-Based Modeling

Agent-based modeling is also known as individual-oriented modeling. This is an increasingly powerful modeling technique to simulate individual interactions in dynamic routing situations such as emergency evacuations. Agent-based modeling treats the individual

vehicles as intelligent decision-making entities [11]. A model of agents and a model of their environment are two basic components of agent-based modeling [39]. The behavior of an agent and its interaction with other agents is modeled by a set of rules such as accelerating, decelerating, and lane-changing rules. The traffic environment is modeled using a traffic network topology, road category, traffic lights, and traffic signs [12,37].

In emergency evacuations, the agent-based simulation captures the collective behavior of agents, which greatly affects the evacuation plan. As a result, more realistic strategies are developed by including the individual behavior of evacuees and their interactions in panic situations. In 1993 Sinuany-Stern and Stern [34] used agent-based simulation for spontaneous urban evacuation. They examined the sensitivity of network clearance time to several traffic factors (such as interaction with pedestrians, intersection traversing time, and car ownership), and route choice mechanisms (such as shortest path selection or myopic-based selection). Cova and Johnson [9] assessed the spatial affect of a proposed second access road on household evacuation time using an agent-based microsimulation model. Church and Sexton [7] used Paramics, an agent-based microsimulation software, to simulate evacuation scenarios in a small neighborhood. They estimated the impact of different evacuation scenarios, such as opening an alternative exit, invoking traffic control plans, and changing the number of vehicles leaving a household, on evacuation time.

## Conclusions

Emergency evacuation is a management strategy to ensure population safety in emergency situations. Communities, buildings, and residential areas are prone to disasters, thus detailed evacuation planning is necessary. Evacuation planning models consist of a five-step procedure that involves trip generation, trip departure time, trip destination, trip route selection, and evacuation plan set-up and analysis. We have presented here a summary of some noteworthy research on each of the above mentioned steps of the planning process. This review also focuses on the special features of community, building and small area evacuation planning. In addition,

real-time traffic management and agent-based models are discussed. The real-time traffic management models consider the dynamic nature of traffic flow and generate a real-time feedback traffic management system in emergency situation. The agent-based models provide realistic emergency evacuation strategies by considering the individual behavior of evacuees (agents) and their interactions.

## Keywords

Entropy optimization; Interior point methods;  
Primal-dual algorithm; Polynomial time convergence

This section introduces the interior point approach to solving entropy optimization problems with linear constraints. In particular, we consider the following problem:

Program EL:

$$\begin{cases} \min & f(\mathbf{x}) \equiv \mathbf{c}^\top \mathbf{x} + \sum_{j=1}^n d_j x_j \ln x_j \\ \text{s.t.} & \mathbf{A}\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathbf{0}, \end{cases} \quad (1)$$

where  $\mathbf{c} \in \mathbf{R}^n$ ,  $\mathbf{d} \in \mathbf{R}^n$ ,  $\mathbf{d} > \mathbf{0}$ ,  $\mathbf{b} \in \mathbf{R}^m$ ,  $\mathbf{A}$  is an  $(m \times n)$ -matrix,  $\mathbf{0}$  is an  $n$ -dimensional zero vector, and  $0 \ln 0 \equiv 0$ . When  $\mathbf{c} = \mathbf{0}$  and  $d_j = 1$ ,  $j = 1, \dots, n$ , Program EL becomes a pure entropy optimization problem.

Denote the feasible region of Program EL by  $F_p \equiv \{\mathbf{x} \in \mathbf{R}^n: \mathbf{A}\mathbf{x} = \mathbf{b}; \mathbf{x} \geq \mathbf{0}\}$  and the (relative) interior of  $F_p$  by  $F_p^0 \equiv \{\mathbf{x} \in \mathbf{R}^n: \mathbf{A}\mathbf{x} = \mathbf{b}; \mathbf{x} > \mathbf{0}\}$ . An  $n$ -vector  $\mathbf{x}$  is called an *interior solution* of Program EL if  $\mathbf{x} \in F_p^0$ . With these definitions, we have the following verifiable result:

**Lemma 1** *If  $F_p$  is nonempty, then Program EL has a unique optimal solution. Moreover, if  $F_p$  has a nonempty interior, then the unique optimal solution is strictly positive.*

All *interior point methods*, including those to be discussed in this section, require the fundamental assumption that  $F_p$  has a nonempty interior, i. e.,  $F_p^0 \neq \emptyset$ . A Lagrangian dual can be derived in the following manner. For all  $\mathbf{x} \in \mathbf{R}^n$ ,  $\mathbf{y} \in \mathbf{R}^m$ , and  $\mathbf{z} \in \mathbf{R}_+^n \equiv \{\mathbf{x} \in \mathbf{R}^n, \mathbf{x} \geq \mathbf{0}\}$ , define the following Lagrangian function:

$$\begin{aligned} L(\mathbf{x}, \mathbf{y}, \mathbf{z}) \equiv & \sum_{j=1}^n c_j x_j + \sum_{j=1}^n d_j e(x_j) \\ & - \sum_{i=1}^m \left( \sum_{j=1}^n a_{ij} x_j - b_i \right) y_i - \sum_{j=1}^n z_j x_j, \end{aligned} \quad (2)$$

where

$$e(x) \equiv \begin{cases} x \ln x & \text{if } x \geq 0, \\ \infty & \text{if } x < 0, \end{cases}$$

is a proper convex function with the set  $\{x: x \in \mathbf{R}, x \geq 0\}$  being its effective domain [6]. The concept of proper

convex function has often been used to simplify convex analysis. For details about the theory of using Lagrange multipliers for solving constrained optimization problems defined in terms of proper convex functions, the reader is referred to [6, Chap. 28].

Rearranging terms in (2) results in

$$\begin{aligned} L(\mathbf{x}, \mathbf{y}, \mathbf{z}) = & \sum_{j=1}^n c_j x_j + \sum_{j=1}^n d_j e(x_j) \\ & + \sum_{i=1}^m b_i y_i - \sum_{j=1}^n \left( \sum_{i=1}^m a_{ij} y_i + z_j \right) x_j. \end{aligned}$$

Considering the fact that  $d_j > 0$  and the shape of the entropic function  $x \ln x$ , we know that, for any given  $\mathbf{y} \in \mathbf{R}^m$  and  $\mathbf{z} \in \mathbf{R}_+^n$ ,  $L(\mathbf{x}, \mathbf{y}, \mathbf{z})$  achieves its unique minimum at  $\mathbf{x}^* > \mathbf{0}$ . Also, its first derivative at  $\mathbf{x}^*$  vanishes. This implies

$$d_j \ln x_j^* - \sum_{i=1}^m a_{ij} y_i + c_j + d_j = z_j \geq 0. \quad (3)$$

Multiplying both sides of (3) by  $x_j^*$  and summing over  $j$  produces

$$\begin{aligned} & \sum_{j=1}^n c_j x_j^* + \sum_{j=1}^n d_j x_j^* \ln x_j^* \\ & - \sum_{j=1}^n \left( \sum_{i=1}^m a_{ij} y_i + z_j \right) x_j^* \\ & = - \sum_{j=1}^n d_j x_j^*. \end{aligned}$$

Consequently, for any  $\mathbf{y} \in \mathbf{R}^m$  and  $\mathbf{z} \in \mathbf{R}_+^n$ ,

$$L(\mathbf{x}^*, \mathbf{y}, \mathbf{z}) = \sum_{i=1}^m b_i y_i - \sum_{j=1}^n d_j x_j^*,$$

where  $\mathbf{x}^*$  satisfies (3). Therefore, a Lagrangian *dual* of Program EL becomes

$$\begin{cases} \max_{\substack{\mathbf{y} \in \mathbf{R}^m \\ \mathbf{z} \in \mathbf{R}_+^n}} & L(\mathbf{y}, \mathbf{z}) \equiv \sum_{i=1}^m b_i y_i - \sum_{j=1}^n d_j x_j^* \\ \text{s.t.} & d_j \ln x_j^* - \sum_{i=1}^m a_{ij} y_i + c_j + d_j = z_j, \\ & j = 1, \dots, n. \end{cases}$$

This dual is equivalent to  
Program DEL:

$$\begin{cases} \max_{\substack{\mathbf{y} \in \mathbb{R}^m \\ \mathbf{0} < \mathbf{x} \in \mathbb{R}^n}} L(\mathbf{x}, \mathbf{y}) \equiv \sum_{i=1}^m b_i y_i - \sum_{j=1}^n d_j x_j \\ \text{s.t.} & d_j \ln x_j + c_j + d_j - \sum_{i=1}^m a_{ij} y_i \geq 0, \\ & j = 1, \dots, n. \end{cases} \quad (4)$$

Note that  $\mathbf{x}$  is strictly positive because  $\ln 0$  is not well-defined. However, if we define  $\ln 0 = -\infty$ , the domain of  $\mathbf{x}$  in Program DEL can be replaced by  $\{\mathbf{x}: \mathbf{x} \in \mathbb{R}^n, \mathbf{x} \geq \mathbf{0}\}$ . Denote the excess vector  $\nabla f(\mathbf{x}) - \mathbf{A}^\top \mathbf{y}$  by  $\mathbf{s}$ . The  $j$ th component of  $\mathbf{s}$  is simply  $d_j \ln x_j + c_j + d_j - \sum_{i=1}^m a_{ij} y_i$ , which is the left-hand side of (4). Denote the feasible region of Program DEL by  $F_d \equiv \{(\mathbf{x}, \mathbf{y}): \nabla f(\mathbf{x}^*) - \mathbf{A}^\top \mathbf{y}^* \geq \mathbf{0}\}$ , and assume that  $F_d$  has a nonempty interior.

We now derive the Karush–Kuhn–Tucker conditions for Program DEL. First, define, for all  $\mathbf{u} \geq \mathbf{0}$ , the following Lagrangian:

$$\begin{aligned} L'(\mathbf{x}, \mathbf{y}, \mathbf{u}) &\equiv \sum_{i=1}^m b_i y_i - \sum_{j=1}^n d_j x_j \\ &+ \sum_{j=1}^n u_j \left( d_j \ln x_j + c_j + d_j - \sum_{i=1}^m a_{ij} y_i \right). \end{aligned}$$

Setting the partial derivatives with respect to  $y_i$  and  $x_j$  to zero gives

$$\begin{aligned} b_i - \sum_{j=1}^n a_{ij} u_j &= 0, \quad i = 1, \dots, m, \\ -d_j + \frac{u_j d_j}{x_j} &= 0, \quad j = 1, \dots, n. \end{aligned} \quad (5)$$

Note that (5) is equivalent to  $u_j = x_j$ . Therefore, the KKT conditions for Program DEL become

- There exists  $\mathbf{x} \in \mathbb{R}^n$  such that  $\mathbf{A}\mathbf{x} = \mathbf{b}$  and  $\mathbf{x} \geq \mathbf{0}$ . This can be viewed as the ‘primal feasibility condition’.
- There exists  $\mathbf{y} \in \mathbb{R}^m$  such that, together with  $\mathbf{x}$ ,  $d_j \ln x_j + c_j + d_j - \sum_{i=1}^m a_{ij} y_i \geq 0$  or  $\nabla f(\mathbf{x}) - \mathbf{A}^\top \mathbf{y} \geq \mathbf{0}$ . Similarly, this can be viewed as the ‘dual feasibility condition’.
- For all  $j = 1, \dots, n$ ,  $(d_j \ln x_j + c_j + d_j - \sum_{i=1}^m a_{ij} y_i) x_j = 0$ . This can be viewed as the ‘complementary slackness condition’.

Note that, by (5), the Lagrange multipliers associated with the constraints of Program DEL at its optimal solution happen to coincide with the  $\mathbf{x}$ -component of the optimal solution of Program DEL. This, together with the fact that the dual of Program DEL is Program EL, imply that the optimal solution of Program DEL contains the optimal solution of Program EL.

Also note that an alternative *dual* program can be defined by considering the following Lagrangian:

$$\begin{aligned} L''(\mathbf{x}, \mathbf{y}) &\equiv \sum_{j=1}^n c_j x_j + \sum_{j=1}^n d_j x_j \ln x_j \\ &- \sum_{i=1}^m \left( \sum_{j=1}^n a_{ij} x_j - b_i \right) y_i, \end{aligned}$$

for  $\mathbf{x} \geq \mathbf{0}$  and  $\mathbf{y} \in \mathbb{R}^m$ . In this expression, no Lagrange multipliers are defined for the constraints  $\mathbf{x} \geq \mathbf{0}$ , and it leads to the following dual program:

$$\begin{aligned} \max_{\mathbf{y} \in \mathbb{R}^m} & \sum_{i=1}^m b_i y_i \\ & - \sum_{j=1}^n d_j \exp \left\{ \frac{\sum_{i=1}^m a_{ij} y_i - c_j}{d_j} - 1 \right\}. \end{aligned}$$

Since this dual program is *unconstrained*, any solution algorithm can be viewed as an interior point algorithm. For details about this approach and companion efficient solution *algorithms*, see [2].

In the rest of this section, we focus on the development of a *primal-dual* interior point algorithm [5]. Note that, to obtain the algorithm, Program DEL, rather than the unconstrained dual program, was used in [5]. The primal-dual interior point algorithm starts with an initial primal feasible solution  $\mathbf{x}^0$  and an initial dual feasible solution  $\mathbf{y}^0$ . While the algorithm iterates, it maintains the primal and dual feasibility conditions and reduces the complementary slackness. In other words, the algorithm iterates from a pair of interior solutions  $(\mathbf{x}^k, \mathbf{y}^k)$ , with  $\mathbf{A}\mathbf{x}^k = \mathbf{b}$ ,  $\mathbf{x}^k > \mathbf{0}$  and  $\mathbf{s}^k = \nabla f(\mathbf{x}^k) - \mathbf{A}^\top \mathbf{y}^k > \mathbf{0}$ , to a new interior solution pair  $(\mathbf{x}^{k+1}, \mathbf{y}^{k+1})$  such that the complementary slackness is reduced from  $\delta_k \equiv (\mathbf{x}^k)^\top \mathbf{s}^k$  to  $\delta_{k+1} \equiv (\mathbf{x}^{k+1})^\top \mathbf{s}^{k+1}$ . The algorithm terminates when  $\delta_k \leq \epsilon$ , for some given  $\epsilon > 0$  (or when the difference between  $f(\mathbf{x}^k)$  and the optimum is sufficiently small).

To describe the algorithm, we use the boldface upper-case letters  $\mathbf{X}$ ,  $\mathbf{S}$ , and  $\mathbf{W}$  to denote the diagonal matrices formed by the components of vectors  $\mathbf{x}$ ,  $\mathbf{s}$ , and  $\mathbf{w}$ , respectively. We also denote the vectors of all ones of appropriate dimensions by  $\mathbf{e}$ , the  $l_2$  norm by  $\|\cdot\|$ , and the vector whose components are  $\ln(x_j)$ 's,  $j = 1, \dots, n$ , by  $\ln \mathbf{x}$ .

Rather than dealing with the complementary slackness  $\delta_k$  directly, the following *primal-dual potential function* [8]

$$\psi(\mathbf{x}, \mathbf{s}) = \rho \ln(\mathbf{x}^\top \mathbf{s}) - \sum_{j=1}^n \ln(x_j s_j),$$

where  $\rho \geq n + \sqrt{n}$ , can be used as a surrogate measure [5].

Given the initial solution pair, the potential of the associated complementary slackness can be calculated. Given the inaccuracy tolerance  $\epsilon$ , a target potential can be calculated. Therefore, the amount of required potential reduction can be calculated. The primal-dual interior point algorithm, under proper conditions, will reduce the potential by a constant amount in each iteration.

Note that two different pairs of  $(\mathbf{x}, \mathbf{s})$  that have the same complementary slackness measure may have different potentials. Therefore, to ensure that the target potential is sufficiently small, we need to find the minimum potential among all those  $(\mathbf{x}, \mathbf{s})$  pairs such that  $\mathbf{x}^\top \mathbf{s} = \epsilon$ , or a lower bound of this minimum potential.

Rewrite the potential function as

$$\psi(\mathbf{x}, \mathbf{s}) = (\rho - n) \ln(\mathbf{x}^\top \mathbf{s}) - \sum_{j=1}^n \ln\left(\frac{x_j s_j}{\mathbf{x}^\top \mathbf{s}}\right).$$

Applying the geometric-arithmetic inequality results in

$$\prod_{j=1}^n \left(\frac{x_j s_j}{\mathbf{x}^\top \mathbf{s}}\right)^{\frac{1}{n}} \leq \frac{1}{n} \sum_{j=1}^n \left(\frac{x_j s_j}{\mathbf{x}^\top \mathbf{s}}\right) = \frac{1}{n}.$$

Taking the natural logarithm leads to

$$\frac{1}{n} \sum_{j=1}^n \ln\left(\frac{x_j s_j}{\mathbf{x}^\top \mathbf{s}}\right) \leq \ln\left(\frac{1}{n}\right) = -\ln n.$$

Consequently,

$$\sum_{j=1}^n \ln\left(\frac{x_j s_j}{\mathbf{x}^\top \mathbf{s}}\right) \leq -n \ln n.$$

Therefore, the target potential should be  $(\rho - n) \ln \epsilon + n \ln n$ . Given the potential associated with the initial solution, the exact amount of potential reduction is  $\psi(\mathbf{x}^0, \mathbf{s}^0) - (\rho - n) \ln \epsilon - n \ln n$ . Note that for a given inaccuracy tolerance  $\epsilon$ , the target potential is indeed the minimum of all the potentials associated with all  $(\mathbf{x}, \mathbf{s})$  pairs such that  $\mathbf{x}^\top \mathbf{s} = \epsilon$ . This is indicated by the tight geometric-arithmetic inequality.

Given the knowledge of how much potential reduction needs to be, if an algorithm reduces the potential by a constant amount in each iteration, then the complexity of the algorithm is  $O(\psi(\mathbf{x}^0, \mathbf{s}^0) - (\rho - n) \ln \epsilon - n \ln n)$ .

Assume that, in iteration  $k$ , we have a primal-dual feasible solution pair  $(\mathbf{x}^k, \mathbf{y}^k)$  and the slack vector  $\mathbf{s}^k \equiv \nabla f(\mathbf{x}^k) - \mathbf{A}^\top \mathbf{y}^k > \mathbf{O}$ . Ideally, one would like to find  $(\mathbf{x}^{k+1}, \mathbf{y}^{k+1})$  such that the KKT conditions are met, i. e.,

$$\begin{aligned} \mathbf{A}\mathbf{x}^{k+1} &= \mathbf{b}, \quad \mathbf{x}^{k+1} \geq \mathbf{O}, \\ \nabla f(\mathbf{x}^{k+1}) - \mathbf{A}^\top \mathbf{y}^{k+1} &\geq \mathbf{O}, \\ \mathbf{X}^{k+1}(\nabla f(\mathbf{x}^{k+1}) - \mathbf{A}^\top \mathbf{y}^{k+1}) &= \mathbf{O}. \end{aligned}$$

Define

$$\begin{aligned} \Delta \mathbf{x} &\equiv \mathbf{x}^{k+1} - \mathbf{x}^k, \\ \Delta \mathbf{y} &\equiv \mathbf{y}^{k+1} - \mathbf{y}^k, \\ \Delta \mathbf{s} &\equiv \mathbf{s}^{k+1} - \mathbf{s}^k, \\ \Delta \mathbf{X} &\equiv \mathbf{X}^{k+1} - \mathbf{X}^k. \end{aligned}$$

With these definitions, the conditions stated above become

$$\begin{aligned} \mathbf{A}(\mathbf{x}^k + \Delta \mathbf{x}) &= \mathbf{b}, \quad \mathbf{x}^k + \Delta \mathbf{x} \geq \mathbf{O}, \\ \nabla f(\mathbf{x}^k + \Delta \mathbf{x}) - \mathbf{A}^\top (\mathbf{y}^k + \Delta \mathbf{y}) &\geq \mathbf{O}, \\ (\mathbf{X}^k + \Delta \mathbf{X}) & \\ \times [\nabla f(\mathbf{x}^k + \Delta \mathbf{x}) - \mathbf{A}^\top (\mathbf{y}^k + \Delta \mathbf{y})] &= \mathbf{O}. \end{aligned} \tag{6}$$

Note that quantity in the bracket of (6) is simply  $\mathbf{s}^{k+1} = \mathbf{s}^k + \Delta \mathbf{s}$ , where

$$\Delta \mathbf{s} \equiv \nabla f(\mathbf{x}^k + \Delta \mathbf{x}) - \nabla f(\mathbf{x}^k) - \mathbf{A}^\top \Delta \mathbf{y}.$$

Therefore, we have

$$(\mathbf{X}^k + \Delta \mathbf{X})(\mathbf{s}^k + \Delta \mathbf{s}) = \mathbf{O},$$

or

$$\mathbf{X}^k \mathbf{s}^k + \mathbf{X}^k \Delta \mathbf{s} + \Delta \mathbf{X} \mathbf{s}^k + \Delta \mathbf{X} \Delta \mathbf{s} = \mathbf{O},$$

or

$$\mathbf{X}^k \Delta \mathbf{s} + \mathbf{S}^k \Delta \mathbf{x} = -\Delta \mathbf{X} \Delta \mathbf{s} - \mathbf{X}^k \mathbf{s}^k.$$

Solving the equations

$$\mathbf{A}(\mathbf{x}^k + \Delta \mathbf{x}) = \mathbf{b},$$

$$\mathbf{X}^k \Delta \mathbf{s} + \mathbf{S}^k \Delta \mathbf{x} = -\Delta \mathbf{X} \Delta \mathbf{s} - \mathbf{X}^k \mathbf{s}^k,$$

subject to the condition

$$\nabla f(\mathbf{x}^k + \Delta \mathbf{x}) - \mathbf{A}^\top (\mathbf{y}^k + \Delta \mathbf{y}) \geq \mathbf{O}$$

is in general difficult.

Given  $\mathbf{O} < \mathbf{x}^k \in F_p$ ,  $\mathbf{s}^k = \nabla f(\mathbf{x}^k) - \mathbf{A}^\top \mathbf{y}^k > \mathbf{O}$ , and  $\delta^k = (\mathbf{x}^k)^\top \mathbf{s}^k$ , the algorithm proposed in [4] solves the following system of nonlinear equations for  $\Delta \mathbf{x}$  and  $\Delta \mathbf{y}$ :

$$\mathbf{X}^k \Delta \mathbf{s} + \mathbf{S}^k \Delta \mathbf{x} = \theta \mathbf{p}^k, \quad (7)$$

$$\mathbf{A} \Delta \mathbf{x} = \mathbf{O}, \quad (8)$$

where  $\theta > 0$  is a constant to be specified later and

$$\mathbf{p}^k \equiv \frac{\delta^k}{\rho} \mathbf{e} - \mathbf{X}^k \mathbf{S}^k \mathbf{e},$$

and  $n + \sqrt{n} \leq \rho < 2n$ .

By choosing

$$\theta = \frac{\beta \min_j (\sqrt{x_j^k s_j^k})}{\|(\mathbf{X}^k \mathbf{S}^k)^{-0.5} \mathbf{p}^k\|}$$

for some  $0 < \beta < 1$  yet to be determined, we obtain

$$\psi(\mathbf{x}^{k+1}, \mathbf{s}^{k+1}) \leq \psi(\mathbf{x}^k, \mathbf{s}^k) - \gamma$$

for a constant  $\gamma > 0$ . Let  $C > 0$  be a real number. Choose  $\beta$  such that

$$0 < \beta < 1, \quad (9)$$

$$\beta(1 + C\beta) \leq \frac{1}{2}, \quad 1 - C\beta \geq 0. \quad (10)$$

It can be shown [5] that, to reduce the potential by a constant amount in each iteration, solving a linear approximation of equations (7) and (8) can achieve the required accuracy.

Suppose that  $n + \sqrt{n} \leq \rho < 2n$  and that  $\Delta \mathbf{x}$  and  $\Delta \mathbf{y}$  satisfy

$$\begin{aligned} \mathbf{A} \Delta \mathbf{x} &= \mathbf{O}, & \mathbf{X}^k \Delta \mathbf{s} + \mathbf{S}^k \Delta \mathbf{x} &= \theta \mathbf{p}^k + \mathbf{z}^k, \\ \|\mathbf{z}^k\| &\leq C\beta^2 \min(x_j^k s_j^k), \end{aligned} \quad (11)$$

then

$$\psi(\mathbf{x}^k, \mathbf{s}^k) - \psi(\mathbf{x}^{k+1}, \mathbf{s}^{k+1}) > \gamma,$$

where  $\gamma = (\frac{\sqrt{3}}{2})\beta(1 - C\beta) - \beta^2(1 + C\beta)^2$ .

Condition (11) can be achieved by solving the following set of linear equations:

$$\mathbf{X}^k (\nabla^2 f(\mathbf{x}^k) \Delta \mathbf{x} - \mathbf{A}^\top \Delta \mathbf{y}) + \mathbf{S}^k \Delta \mathbf{x} = \theta \mathbf{p}^k, \quad (12)$$

$$\mathbf{A} \Delta \mathbf{x} = \mathbf{O}. \quad (13)$$

Note that the vector  $\nabla^2 f(\mathbf{x}^k) \Delta \mathbf{x}$  replaces  $\nabla f(\mathbf{x}^k + \Delta \mathbf{x}) - \nabla f(\mathbf{x}^k)$  of (7) and serves as a simple linear approximation. Equations (12) and (13) are key to the 'potential-reduction' primal-dual interior point algorithm.

Given an initial interior point solution, an interior point algorithm can be stated as follows.

*Initialization:*

Given an initial primal interior point solution  $\mathbf{x}^0$  and an initial dual solution  $\mathbf{y}^0$  such that  $\mathbf{A}\mathbf{x}^0 = \mathbf{b}$ ,  $\mathbf{x}^0 > \mathbf{O}$ , and  $\mathbf{s}^0 = \nabla f(\mathbf{x}^0) - \mathbf{A}^\top \mathbf{y}^0 > \mathbf{O}$ , calculate  $\delta^0 = (\mathbf{x}^0)^\top \mathbf{s}^0$ ;  
set  $k \leftarrow 0$ .

*Iteration:*

IF  $\delta^k < \epsilon$ , THEN STOP

ELSE

solve (12), (13) for  $\Delta \mathbf{x}$  and  $\Delta \mathbf{y}$ ;

set

$$\mathbf{x}^{k+1} \equiv \mathbf{x}^k + \Delta \mathbf{x};$$

$$\mathbf{y}^{k+1} \equiv \mathbf{y}^k + \Delta \mathbf{y};$$

$$\mathbf{s}^{k+1} \equiv \nabla f(\mathbf{x}^{k+1}) - \mathbf{A}^\top \mathbf{y}^{k+1};$$

$$\delta^{k+1} \equiv (\mathbf{x}^{k+1})^\top \mathbf{s}^{k+1};$$

reset  $k \leftarrow k + 1$  for the next iteration.

END IF

With a standard procedure for obtaining an initial solution [1], the following theorem of *polynomial time convergence* was shown in [5].

**Theorem 2** Suppose that  $\epsilon > 0$  and  $2n \geq \rho \geq n + \sqrt{n}$ . Then, in the  $k$ th iteration,  $\mathbf{x}^k > \mathbf{O}$ ,  $\mathbf{s}^k > \mathbf{O}$ , and  $\mathbf{x}^k$  and  $\mathbf{y}^k$  are feasible for Programs EL and DEL. Moreover, the interior point algorithm terminates in at most  $O(\psi(\mathbf{x}^0, \mathbf{s}^0) - (\rho - n) \ln \epsilon - n \ln n)$  iterations.

It was also suggested that, in practical implementation, the stepsize can be set to  $\bar{\eta}$  based on a line search such

that  $\bar{\eta} \equiv \arg \min_{\eta \geq 0} \psi(\mathbf{x}^k + \eta \Delta \mathbf{x}, \mathbf{s}^k + \eta \Delta \mathbf{s})$ . With this stepsize, one can set  $\mathbf{x}^{k+1} \equiv \mathbf{x}^k + \bar{\eta} \Delta \mathbf{x}$ ,  $\mathbf{y}^{k+1} \equiv \mathbf{y}^k + \bar{\eta} \Delta \mathbf{y}$ .

The search direction is a combination of a decent direction and a centering direction. To enable local quadratic convergence, a computable criterion was developed under which a pure Newton method for solving  $\nabla f(\mathbf{x}) - \mathbf{A}^\top \mathbf{y} = \mathbf{O}$ ,  $\mathbf{A}\mathbf{x} = \mathbf{b}$  (by solving the linear system of  $\nabla^2 f(\mathbf{x}^k) \Delta \mathbf{x} - \mathbf{A}^\top \Delta \mathbf{y} = -\mathbf{s}^k$  and  $\mathbf{A} \Delta \mathbf{x} = \mathbf{O}$ ) can be applied for the rest of the search process. Note that when  $\mathbf{x}^k$  is close to the optimal solution, we have  $\mathbf{x}^k$  being strictly positive, and therefore  $\nabla f(\mathbf{x}) - \mathbf{A}^\top \mathbf{y}$  should be close to  $\mathbf{O}$ . Implementation of primaldual interior point algorithms proposed in [5] is discussed in [3].

In addition to the ‘potential-reduction’ interior point method described above, the ‘*path following interior point method*’, which follows an ideal interior trajectory to reach an optimal solution, was proposed in [7,9]. The convergence of the path following interior point method has been established. However, to the best of our knowledge, possible polynomial time convergence behavior remains an open issue.

Maximum entropy; Parameter estimation; Model identification

## Introduction

Entropy optimization has been applied to problems in various fields of interest from thermodynamics to financial planning. In this context ‘entropy’ refers to the amount of uncertainty in a system, rather than the amount of disorder. A detailed definition of entropy can be found in [4].

One area of application, which has not received much attention in recent years, is that of parameter estimation. The estimation of parameters in semi-empirical mathematical models is a process which is important in many disciplines in the sciences and engineering. This article will focus on a few different areas of the parameter estimation problem which have been approached from an entropy perspective. *Jaynes’ maximum entropy* principle allows for the estimation of parameters in a statistical distribution function by specification of the characteristic moments. This method can also be used to derive the principle of *maximum likelihood*, one of the most widely used parameter estimation approaches. Entropy principles have also been used to derive theoretical ‘best estimators’ for recursive parameter estimation schemes. These results can then be used to gauge the performance of various nonoptimal approaches. A final application involves the development of a measure which not only allows for the estimation of model parameters, but also simultaneously choosing the best mathematical form of the model.

## Entropy Measures

In order to optimize entropy, one must possess some quantitative measure of the entropy of a given distribution. One such measure was developed by C.E. Shannon [8]. Shannon arrived at the function by postulating a set of properties which the measure should have, and then deriving a form which possesses those properties. For a probability distribution  $\mathbf{p} = (p_1, \dots, p_n)$ , the function takes the form of:

$$S = - \sum_{i=1}^n p_i \ln p_i. \quad (1)$$

Shannon also proved that this function was unique for the postulated set of properties. Other researchers have postulated different sets of properties, but arrived at the same result [4].

Another measure of entropy, in this case the cross entropy or distance between two distributions, was presented by S. Kullback and R.A. Leibler [5]. For two given distributions,  $\mathbf{p} = (p_1, \dots, p_n)$ , and  $\mathbf{q} = (q_1, \dots, q_n)$ , the function takes the form:

$$I = \sum_{i=1}^n p_i \ln \frac{p_i}{q_i}. \quad (2)$$

It is assumed that when  $q_i = 0$ , the associated  $p_i$  also is zero and  $0 \ln \frac{0}{0} \equiv 0$ . This function is referred to as the *Kullback–Leibler measure of cross-entropy*.

## Jaynes’ Maximum Entropy for Continuous Distributions

Since most distributions encountered in practice are continuous in nature, Jaynes’ principle of maximum entropy (*MaxEnt*), must first be extended to continuous distributions. This extension is straight forward and results in:

$$\begin{cases} \max & - \int_a^b f(x) \ln f(x) dx \\ \text{s.t.} & \int_a^b f(x) dx = 1 \\ & \int_a^b f(x) g_r(x) dx = a_r, \\ & r = 1, \dots, m, \end{cases} \quad (3)$$

where  $f(x)$  is a continuous probability density function from  $a$  to  $b$ . The Lagrange function takes the form of:

$$\begin{aligned} L \equiv & - \int_a^b f(x) \ln f(x) dx \\ & - (\lambda_0 - 1) \left[ \int_a^b f(x) dx - 1 \right] \\ & - \sum_{r=1}^m \lambda_r \left[ \int_a^b f(x) g_r(x) dx - a_r \right]. \end{aligned} \quad (4)$$

Using the Euler–Lagrange equation the following expression results:

$$f(x) = \exp \left[ -\lambda_0 - \lambda_1 g_1(x) \cdots - \lambda_m g_m(x) \right]. \quad (5)$$

A detailed discussion can be found in [4].

### MaxEnt Estimation Method

The estimation of parameters in a statistical distribution using MaxEnt follows these steps:

- 1) Specify  $m$  characterizing functions,  $g_1(x), \dots, g_m(x)$ .
- 2) Use MaxEnt to find  $f(x)$ , which is given by (5).
- 3) Find estimates of the values of the moment equations from the observed data set  $\mathbf{x} = \{x_1, \dots, x_n\}$  through the relationship:

$$\hat{a}_r = \frac{1}{n} [g_r(x_1) + \dots + g_r(x_n)]. \quad (6)$$

- 4) Determine estimates of the Lagrange multipliers,  $\hat{\lambda}_0, \dots, \hat{\lambda}_m$ , from:

$$a_r = \frac{\int_a^b g_r(x) e^{-\hat{\lambda}_1 g_1(x) - \dots - \hat{\lambda}_m g_m(x)} dx}{\int_a^b e^{-\hat{\lambda}_1 g_1(x) - \dots - \hat{\lambda}_m g_m(x)} dx} \quad (7)$$

and

$$e^{\hat{\lambda}_0} = \int_a^b e^{-\hat{\lambda}_1 g_1(x) - \dots - \hat{\lambda}_m g_m(x)} dx. \quad (8)$$

- 5) The estimated function then takes the form:

$$f(x) = \exp \left[ -\hat{\lambda}_0 - \dots - \hat{\lambda}_m g_m(x) \right]. \quad (9)$$

### Maximum Likelihood From MaxEnt

The principle of maximum likelihood has been widely used to estimate the parameters of both statistical distributions and semi-empirical models. Maximum likelihood assumes that information exists about a random variable in the form of an observation,  $x_1, \dots, x_n$ , and a density function,  $f(x; \theta_1, \dots, \theta_m)$ , unlike in MaxEnt where the forms of the characterizing moments are known. The approach seeks to maximize the likelihood that the given observations will occur given a set of parameters. If each observation is independent, then this 'likelihood' is defined as:

$$L(\mathbf{X}; \Theta) = \prod_{i=1}^n f(x_i | \Theta). \quad (10)$$

The log likelihood function is most often used:

$$\ln L(\mathbf{X}; \Theta) = \sum_{i=1}^n \ln f(x_i | \Theta). \quad (11)$$

The  $\ln L$  is maximized to determine the optimal parameter estimates  $\hat{\Theta}$ .

The same objective can also be derived using the concept of MaxEnt, even though the former predates the latter. The parameters need to be chosen such that the entropy which remains after the observed values are known is large as possible. This implies that the entropy of the observation itself has to be a minimum. The entropy is given by:

$$-\int_a^b f(x, \Theta) \ln f(x, \Theta) dx = \int_a^b \ln f(x, \Theta) dF. \quad (12)$$

The knowledge which is given by the observation is:

$$\begin{cases} F(x, \Theta) = 0 & \text{when } x < x_1 \\ F(x, \Theta) = \frac{1}{n} & \text{when } x_1 \leq x < x_2 \\ \vdots & \vdots \\ F(x, \Theta) = \frac{r}{n} & \text{when } x_r \leq x < x_{r+1} \\ \vdots & \vdots \\ F(x, \Theta) = 1 & \text{when } x_n \leq x \end{cases}$$

where  $F(x, \Theta)$  is the cumulative density. Thus the entropy of the sample is then written as:

$$-\frac{1}{n} [\ln f(x_1, \Theta) + \dots + \ln f(x_n, \Theta)], \quad (13)$$

which is equal to:

$$-\frac{1}{n} [L(x_1, \dots, x_n; \theta_1, \dots, \theta_m)], \quad (14)$$

where  $L$  is the same as described by (11). Therefore to minimize the entropy of the sample the likelihood function must be maximized.

### Recursive Parameter Estimation

The determination of the parameters of a dynamical system on-line is a key step in the implementation of a wide range of control schemes. The estimation procedure is conducted in a recursive fashion in which the estimates from the previous time step are combined with the current state observations to calculate a new set of parameter estimates. The analysis of the estimation process used is typically approached from a mean square error criterion. This method requires some assumptions about the error to be made and the

form of the data processor to be restricted. H.L. Weidemann and E.B. Stear [9] presented an approach based on entropy concepts which has various benefits over the mean squared error method:

- The form of the optimal data processor is not constrained nor does it have to be known.
- Errors are not restricted to have a normal probability distribution.
- None of the operators in the system are required to be linear.

Before continuing with the analysis, various measures need to be defined. The entropy of a  $K$ -dimensional random vector  $\mathbf{X}$  with the joint probability density function,  $p_x(x_1, \dots, x_k)$  is defined as:

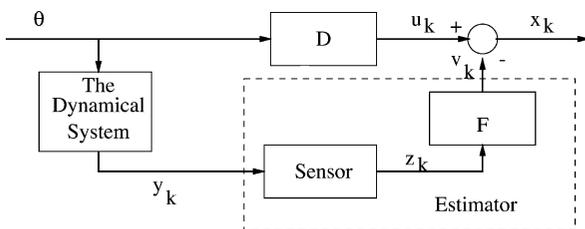

$$H(\mathbf{X}) = - \int_{-\infty}^{\infty} p_x(\mathbf{X}) \ln p_x(\mathbf{X}) d\mathbf{X}. \quad (15)$$

If  $R_x$  is the covariance matrix of the vector  $\mathbf{X}$  then the following holds:

$$H(\mathbf{X}) \leq \frac{1}{2} \ln \{(2\pi e)^K \det[R_x]\}. \quad (16)$$

When  $\mathbf{X}$  is a Gaussian random vector then (16) holds as an equality. Another quantity which will be used in the analysis is referred to as the *mutual information* between  $\mathbf{X}$  and  $\mathbf{Y}$ .

$$I(\mathbf{X}; \mathbf{Y}) = \int \int_{-\infty}^{\infty} p_{xy}(\mathbf{X}, \mathbf{Y}) \ln \frac{p_{xy}(\mathbf{X}, \mathbf{Y})}{p_y(\mathbf{Y})p_x(\mathbf{X})} d\mathbf{X} d\mathbf{Y}. \quad (17)$$

Entropy Optimization: Parameter Estimation, Figure 1  
Typical parameter estimator

The object is to estimate a vector  $\Theta$  of unknown parameters with the joint probability density function,  $p_\theta(\theta_1, \dots, \theta_m)$ . The output of the dynamical model as a function of these parameters is expressed as  $y_k(\theta_1, \dots,$

$\theta_m, k)$ . These outputs are then measured by a sensor to produce  $\{z_k\}$ . These measurements are then used by the data processor  $F$  to produce an  $r$ -dimensional vector  $\mathbf{V}$  which is an estimate of  $D(\Theta)$ . The estimation error is given by:

$$\mathbf{X} = D(\Theta) - \mathbf{V} = D(\Theta) - F(\mathbf{Z}) = \mathbf{U} - \mathbf{V}. \quad (18)$$

Also, under certain conditions, the transform  $D(\Theta)$  will possess a property that for any given random vector  $\xi$ , the following holds:

$$I(\xi; \Theta) = I(\xi; D(\Theta)), \quad (19)$$

or, in words, that  $D(\Theta)$  preserves energy. When this does not hold,  $I(\xi; \Theta) > I(\xi; D(\Theta))$ .

The problem now is to determine the function  $\hat{F}$  which will produce an optimal estimator. The theoretically best function results in a minimum of the error entropy, defined to be  $\hat{H}_0$ . The only constraint on the approach is that the mutual information,  $I(\Theta; \mathbf{Z})$ , must be known. With that the following can be stated:

- The minimum entropy of the error vector is given by:

$$H_0 = H(\mathbf{U}) - I(\mathbf{U}; \mathbf{Z}). \quad (20)$$

- Minimizing the mutual information,  $I(\mathbf{X}; \mathbf{Z})$ , is equivalent to the minimization of the error vector. This is achieved by choosing  $F(\mathbf{Z})$  such that  $\mathbf{Z}$  and  $\mathbf{X}$  are independent.
- Whether or not  $D(\Theta)$  preserves energy, the reduction in the processed parameter entropy,  $H(\mathbf{U})$ , is bounded above by  $I(\Theta; \mathbf{Z})$ , that is,

$$H(D(\Theta)) - H(\mathbf{X}) \leq I(\Theta; \mathbf{Z}), \quad (21)$$

and the equality holds when  $D(\Theta)$  preserves energy and the optimal processor,  $\hat{F}$ , is used.

These three statements now make it possible to determine the best possible performance an estimator can achieve for a given system. The proofs of these statements and a simple example can be found in [9]. The extension of the theorems to the continuous time case is given in [6], and to the similar problem of state estimation in [7].

## Parameter Estimation and Model Selection

For most problems of any physical significance the form of the model equations are not known with absolute certainty. In this lies the problem of not only estimated unknown parameters, but also determining the

best fitting model. Given a set of  $N$  independent observations,  $x_1, \dots, x_N$ , of a random variable from an unknown true distribution  $g(x)$ , the objective is to estimate this true distribution by choosing a member of a family of distributions given by  $f(x|\Theta)$  where  $\Theta$  is a vector of parameters. In order to accomplish this, the distance between the two distributions needs to be minimized. The entropy of the true distribution is given by:

$$S(g; g) = \int g(x) \ln g(x) dx \quad (22)$$

while a measure of the *cross-entropy* is given by:

$$S(g; f(x|\Theta)) = \int g(x) \ln f(x|\Theta) dx. \quad (23)$$

The Kullback–Leibler (K-L) measure is defined as:

$$I = S(g; g) - S(g; f(x|\Theta)) = \int g(x) \ln \frac{g(x)}{f(x|\Theta)} dx. \quad (24)$$

Therefore the solution involves the minimization of the K-L measure [3].

Take the example of a family of possible distributions each one having a different number,  $k$ , of unknown parameters,  $\Theta_k$ . These are denoted by  $f(x|\Theta_k)$ . The resulting form of the measure to choose the correct distribution is referred to as *Akaike's information criterion* (AIC) [1]:

$$\text{AIC}(k) = -2 \ln L(\hat{\Theta}_k) + 2k, \quad (25)$$

where  $\ln L(\hat{\Theta}_k)$  is the value of the log likelihood function with optimally determined parameters  $\hat{\Theta}_k$ . It is proven in [3] that this result is obtained by the minimization of the K-L measure given by (24).

A secondary problem in the area of model selection, is sequential design of experiments. The concept of entropy has been applied to this problem in [2]. A total entropy criterion is developed which includes the uncertainty in the model selected as well as the uncertainty in the parameter values in each model. The use of this measure leads to a choice of an experiment for which the outcome is the most uncertain.

### Keywords

Entropy; Cross-entropy; Maximum entropy principle; Minimum cross-entropy principle

The word *entropy* originated in the literature on thermodynamics around 1865 in Germany and was coined by R. Clausius [4] to represent a measure of the amount of energy in a thermodynamic system as a function of

the temperature of the system and the heat that enters the system. Clausius wanted a word similar to the German word *energie* (i. e., energy) and found it in the Greek word  $\eta\tau\rho\pi\eta$ , which means transformation [1]. The word entropy had belonged to the domain of physics until 1948 when C.E. Shannon, while developing his theory of communication at Bell Laboratories, used the term to represent a measure of information after a suggestion made by J. von Neumann. Shannon wanted a word to describe his newly found *measure of uncertainty* and sought Von Neumann's advice. Von Neumann's reasoning to Shannon [25] was that: 'No one really understands entropy. Therefore, if you know what you mean by it and you use it when you are in an argument, you will win every time.'

Whatever the reason for the name is, the concept of Shannon's entropy has penetrated a wide range of disciplines, including statistical mechanics [12], thermodynamics [12], statistical inference [24], business and finance [5], nonlinear spectral analysis [21], image reconstruction [3], transportation and regional planning [26], queueing theory [10], information theory [9,20], statistics [17], econometrics [8], and linear and nonlinear programming [6,7].

The concept of entropy is closely tied to the concept of *uncertainty embedded in a probability distribution*. In fact, entropy can be defined as a measure of probabilistic uncertainty. For example, suppose the probability distribution for the outcome of a coin-toss experiment is (0.0001, 0.9999), with 0.0001 being the probability of having a tail. One is likely to notice that there is much more 'certainty' than 'uncertainty' about the outcome of this experiment and hence about the probability distribution. In fact, one is almost certain that the outcome will be a head. If, on the other hand, the probability distribution governing that same experiment were (0.5, 0.5), one would realize that there is much less 'certainty' and much more 'uncertainty,' when compared to the previous distribution. Generalizing this observation to the case of  $n$  possible outcomes, we conclude that the uniform distribution has the highest uncertainty out of all possible probability distributions. This implies that, if one had to choose a probability distribution for a chance experiment without any prior knowledge about that distribution, it would seem reasonable to pick the uniform distribution. This is because one would have no reason to choose any other and because

that distribution maximizes the 'uncertainty' of the outcome. This is called *Laplace's principle of insufficient reasoning* [15]. Note that we are able to justify this principle without resorting to a rigorous definition of 'uncertainty.' However, this principle is inadequate when one has some prior knowledge about the distribution. Suppose, for example, that one knows some particular moments of the distribution, e. g., the expected value. In this case, a mathematical definition of 'uncertainty' is crucial. This is the case where Shannon's measure of uncertainty, or Shannon's entropy, plays an indispensable role [20].

To define *entropy*, Shannon proposed some axioms that he thought any measure of uncertainty should satisfy and deduced a unique function, up to a multiplicative constant, that satisfies them. It turned out that this function actually possesses many more desirable properties. In later years, many researchers modified and replaced some of his axioms in an attempt to simplify the reasoning. However, they all deduced that same function.

We first focus on finite-dimensional entropy, i. e., Shannon's entropy defined on discrete probability distributions that have a finite number of outcomes (or states). Let  $\mathbf{p} \equiv (p_1, \dots, p_n)^T$  be a probability distribution associated with  $n$  possible outcomes, denoted by  $\mathbf{x} \equiv (x_1, \dots, x_n)^T$ , of an experiment. Denote its entropy by  $S_n(\mathbf{p})$ . Among those defining axioms, J.N. Kapur and H.K. Kesavan stated the following [15]:

- 1)  $S_n(\mathbf{p})$  should depend on all the  $p_j$ 's,  $j = 1, \dots, n$ .
- 2)  $S_n(\mathbf{p})$  should be a continuous function of  $p_j$ ,  $j = 1, \dots, n$ .
- 3)  $S_n(\mathbf{p})$  should be permutationally symmetric. In other words, if the  $p_j$ 's are merely permuted, then  $S_n(\mathbf{p})$  should remain the same.
- 4)  $S_n(1/n, \dots, 1/n)$  should be a monotonically increasing function of  $n$ .
- 5)  $S_n(p_1, \dots, p_n) = S_{n-1}(p_1 + p_2, p_3, \dots, p_n) + (p_1 + p_2) S_2(p_1/(p_1 + p_2), p_2/(p_1 + p_2))$ .

Properties 1, 2 and 3 are obvious. Property 4 states that the maximum uncertainty of a probability distribution should increase as the number of possible outcomes increases. Property 5 is the least obvious but states that the uncertainty of a probability distribution is the sum of the uncertainty of the probability distribution that combines two of the outcomes and the uncertainty of the probability distribution consisting of only

those two outcomes adjusted by the combined probabilities of the two outcomes.

It turns out that the unique family of functions that satisfy the defining axioms has the form  $S_n(\mathbf{p}) = -k \sum_{j=1}^n p_j \ln p_j$ , where  $k$  is a positive constant,  $\ln$  represents the natural logarithmic function, and  $0 \ln 0 \equiv 0$  [15]. Shannon chose  $-\sum_{j=1}^n p_j \ln p_j$  to represent his concept of entropy [20]. Among its many other desirable properties, we state the following:

- 6) Shannon's measure is nonnegative and concave in  $p_1, \dots, p_n$ .
- 7) The measure does not change with the inclusion of a zero-probability outcome.
- 8) The entropy of a probability distribution representing a completely certain outcome is 0, and the entropy of any probability distribution representing uncertain outcomes is positive.
- 9) Given any fixed number of outcomes, the maximum possible entropy is that of the uniform distribution.
- 10) The entropy of the joint distribution of two independent distributions is the sum of the individual entropies.
- 11) The entropy of the joint distribution of two dependent distributions is no greater than the sum of the two individual entropies.

Property 6 is desirable because it is much easier to maximize a concave function than a nonconcave one. Properties 7 and 8 are appealing because a zero-probability outcome contributes nothing to uncertainty, and neither does a completely certain outcome. Property 9 was discussed earlier. Properties 10 and 11 state that joining two distributions does not affect the entropy, if they are independent, and may actually reduce the entropy, if they are dependent.

Shannon's entropy was originally defined for a probability distribution over a finite sample space, i.e., a finite number of possible outcomes, and can be interpreted as a measure of uncertainty of the probability distribution. It has subsequently been defined for general discrete and continuous random vectors. It has been rigorously proved that Shannon's entropy is the unique measure of uncertainty (up to a multiplicative constant) of a finite probability distribution that satisfies a set of axioms considered necessary for any reasonable measure of uncertainty [16,19,20]. The concept of entropy, when extended for probability distributions

defined on a countably infinite sample space, takes the form of  $-\sum_{j=1}^{\infty} p_j \ln p_j$ . It can still be viewed as a measure of uncertainty but such an interpretation does not enjoy the same degree of mathematical rigor as its finite-sample-space counterpart. When the concept is extended for continuous probability distributions, it is defined to be  $-\int p(x) \ln p(x) dx$ . However, it can no longer be interpreted as a measure of uncertainty at all [9,11]. Rather, it can only be viewed as a measure of relative uncertainty [15].

Note that, with Shannon's entropy as the measure of uncertainty, in the absence of any prior information about the underlying probability distribution, the best course of action suggested by the principle of insufficient reasoning is to choose the uniform distribution because it possesses maximum uncertainty. Given the knowledge of some moments of the underlying distribution, the same reasoning leads to the following principle:

- Out of all possible distributions that are consistent with the moment constraints, choose the one that has maximum entropy.

This principle was proposed by E.T. Jaynes ([5, Chapter 2]), and has been known as the *principle of maximum entropy* or Jaynes' *maximum entropy principle*. It has often been abbreviated as *MaxEnt* in literature.

Let  $X$  be a random variable with  $n$  possible outcomes  $\{x_1, \dots, x_n\}$  and  $\mathbf{p} \equiv (p_1, \dots, p_n)^T$  be a vector consisting of corresponding probabilities. Suppose that  $g_1(X), \dots, g_m(X)$  are  $m$  functions of  $X$  with known expected values  $a_1, \dots, a_m$ , respectively. The principle of maximum entropy leads to the following mathematical optimization problem:

$$\left\{ \begin{array}{l} \max \quad H_1(\mathbf{p}) = -\sum_{j=1}^n p_j \ln p_j \\ \text{s.t.} \quad \sum_{j=1}^n p_j g_i(x_j) = a_i, \quad i = 1, \dots, m, \\ \quad \quad \sum_{j=1}^n p_j = 1, \\ \quad \quad p_j \geq 0, \quad j = 1, \dots, n. \end{array} \right.$$

This is a convex programming problem with linear constraints. The nonnegativity constraints are not binding for the optimal solution  $\mathbf{p}^*$  because each  $p_j^*$  can be expressed as an exponential function in terms

of the Lagrange multipliers associated with the equality constraints. Note that, in the absence of the moment constraints, the solution to the problem is the uniform probability distribution, whose entropy is  $\ln n$ . As such, the maximum entropy principle can be viewed as an extension of the Laplace's principle of insufficient reasoning. The distribution selected under the maximum entropy principle has also been interpreted as one that is the 'most probable' in the sense that the maximum entropy distribution coincides with the frequency distribution that can be realized in the greatest number of ways [3]. An explanation of this linkage in the context of the well-known application of entropy maximization in transportation planning can be found in [7].

Recall that the above discussion was originally motivated by the task of choosing a probability distribution among those that are consistent with some given moments. Now, in addition to the moment constraints, suppose that we have an *a priori* probability distribution  $\mathbf{p}^0$  that we think our probability distribution  $\mathbf{p}$  should be close to. In fact, in the absence of the moment constraints, we would like to choose  $\mathbf{p}^0$  for  $\mathbf{p}$  because it is clearly the closest to  $\mathbf{p}^0$ . However, in the presence of some moment constraints which  $\mathbf{p}^0$  does not satisfy, we need a precise definition of 'closeness' or 'deviation'. In other words, we need to define some sort of deviation or, more precisely, '*directed divergence*' [15] on the space of discrete probability distributions where the distribution is chosen from. Note that we deliberately avoid calling this measure a 'distance'. This is because a distance measure should be symmetric and should satisfy the triangular inequality, but these two properties are not important in this context. In fact, we can be content with a 'one-way (asymmetric) deviation measure',  $D(\mathbf{p}, \mathbf{p}^0)$ , from  $\mathbf{p}$  to  $\mathbf{p}^0$ . If a 'one-way deviation measure' from  $\mathbf{p}$  to  $\mathbf{p}^0$  is not satisfactory, one can consider using a symmetric measure defined as the sum of  $D(\mathbf{p}, \mathbf{p}^0)$  and  $D(\mathbf{p}^0, \mathbf{p})$ . What is desirable for this 'directed divergence' measure includes the following properties:

- 1)  $D(\mathbf{p}, \mathbf{p}^0)$  should be nonnegative for all  $\mathbf{p}$  and  $\mathbf{p}^0$ .
- 2)  $D(\mathbf{p}, \mathbf{p}^0) = 0$  if and only if  $\mathbf{p} = \mathbf{p}^0$ .
- 3)  $D(\mathbf{p}, \mathbf{p}^0)$  should be a convex function of  $p_1, \dots, p_n$ .
- 4) When  $D(\mathbf{p}, \mathbf{p}^0)$  is minimized subject to moment constraints but without the explicit presence of the nonnegativity constraints, the resulting  $p_j$ 's should be nonnegative.

Property 1 is desirable for any such measure of deviation. If property 2 were not satisfied, then it would be possible to choose a vector  $\mathbf{p}$  that has a zero directed divergence from  $\mathbf{p}^0$ , i. e., one that is as 'close' to  $\mathbf{p}^0$  as  $\mathbf{p}^0$  itself, but differs from  $\mathbf{p}^0$ . Property 3 makes minimizing the measure much simpler, and property 4 spares us from explicitly considering  $n$  nonnegativity constraints. Fortunately, there are many measures that satisfy these properties. We may even be able to find one that satisfies the triangular inequality. But, simplicity of the measure is also desirable. The simplest and most important of those measures is the Kullback–Leibler measure ([5, Chapt. 4]), defined as  $D(\mathbf{p}, \mathbf{p}^0) = \sum_{j=1}^n p_j \ln(p_j/p_j^0)$ , with the convention that, whenever  $p_j^0$  is 0,  $p_j$  is set to 0 and  $0 \ln(0/0)$  is defined to be 0. This measure is also known as the *cross-entropy*, *relative entropy*, *directed divergence* or *expected weight of evidence* of  $\mathbf{p}$  with respect to  $\mathbf{p}^0$ . A. Hobson [1] provided an axiomatic characterization of *cross-entropy*. He interpreted  $D(\mathbf{p}, \mathbf{p}^0)$  as the 'information in  $\mathbf{p}$  relative to  $\mathbf{p}^0$ ', and showed that the only function  $I(\mathbf{p}, \mathbf{p}^0)$  satisfying the following five properties has the form of  $k \sum_{j=1}^n p_j \ln(p_j/p_j^0)$ , where  $k$  is a positive constant:

- 5)  $I(\mathbf{p}, \mathbf{p}^0)$  is a continuous function of  $\mathbf{p}$  and  $\mathbf{p}^0$ .
- 6)  $I(\mathbf{p}, \mathbf{p}^0)$  is permutationally symmetric, i. e., the measure does not change if the pairs of  $(p_j, p_j^0)$  are permuted among themselves.
- 7)  $I(\mathbf{p}, \mathbf{p}) = 0$ .
- 8) For any pair of integers  $n$  and  $n_0$  such that  $n_0 \geq n > 0$ ,  $I(1/n, \dots, 1/n, 0, \dots, 0; 1/n_0, \dots, 1/n_0)$  is an increasing function of  $n_0$  and a decreasing function of  $n$ , where  $I(1/n, \dots, 1/n, 0, \dots, 0; 1/n_0, \dots, 1/n_0)$  denotes the information obtained when the number of equally likely possibilities is reduced from  $n_0$  to  $n$ .

$$9) \quad I(p_1, \dots, p_n; p_1^0, \dots, p_n^0) = I(q_1, q_2; q_1^0, q_2^0) \\ + q_1 I\left(\frac{p_1}{q_1}, \dots, \frac{p_r}{q_1}; \frac{p_1^0}{q_1^0}, \dots, \frac{p_r^0}{q_1^0}\right) \\ + q_2 I\left(\frac{p_{r+1}}{q_2}, \dots, \frac{p_n}{q_2}; \frac{p_{r+1}^0}{q_2^0}, \dots, \frac{p_n^0}{q_2^0}\right),$$

where  $1 \leq r \leq n$ ,  $q_1 \equiv p_1 + \dots + p_r$ ,  $q_2 \equiv p_{r+1} + \dots + p_n$ ,  $q_1^0 \equiv p_1^0 + \dots + p_r^0$ ,  $q_2^0 \equiv p_{r+1}^0 + \dots + p_n^0$ .

Property 8 says, for example, that the information obtained upon reducing the number of equally likely sides on a die from 6 to 3 is greater than the information obtained upon reducing the number from 6 to 4. Prop-

erty 9 says that one may give information about the outcome associated with the random event either by specifying the probabilities  $p_1, \dots, p_n$  directly, or by specifying the probabilities  $q_1$  and  $q_2$  first and then specifying the conditional probabilities  $p_i/q_1$  and  $p_i/q_2$ .

In addition to the nine properties discussed above, we state the following desirable properties for cross-entropy:

- 10)  $D(\mathbf{p}, \mathbf{p}^0)$  is convex in both  $\mathbf{p}$  and  $\mathbf{p}^0$ .
- 11)  $D(\mathbf{p}, \mathbf{p}^0)$  is not symmetric.
- 12) If  $\mathbf{p}$  and  $\mathbf{q}$  are independent and  $\mathbf{r}$  and  $\mathbf{s}$  are also independent, then  $D(\mathbf{p} * \mathbf{q}, \mathbf{r} * \mathbf{s}) = D(\mathbf{p}, \mathbf{r}) + D(\mathbf{q}, \mathbf{s})$ , where  $*$  denotes the convolution operation between two independent distributions.
- 13) In general, the triangular inequality does not hold. But, if distribution  $\mathbf{p}$  minimizes  $D(\mathbf{p}, \mathbf{p}^0)$  subject to some moment constraints and  $\mathbf{q}$  is any other distribution that satisfies those same constraints, then  $D(\mathbf{q}, \mathbf{p}^0) = D(\mathbf{q}, \mathbf{p}) + D(\mathbf{p}, \mathbf{p}^0)$ . Thus, in this special case, the triangular inequality holds, but as an equality.

*Kullback and Leibler's cross-entropy* was also originally defined for probability distributions with a finite sample space and can be interpreted as a measure of deviation of one probability distribution from another. It has been extended subsequently for distributions defined on countably infinite and continuous sample spaces. The corresponding forms become  $\sum_{j=1}^{\infty} p_j \ln(p_j/p_j^0)$  and  $\int p(x) \ln(p(x)/p^0(x)) dx$ , respectively. It has also been derived rigorously as the unique measure of deviation of one probability distribution from another that satisfies a set of axioms considered as necessary for any reasonable measure of deviation, for both finite probability distributions [11] and continuous distributions [14]. Cross-entropy for probability distributions with countably infinite sample space can be viewed and has been used as a measure of deviation, although the justification is not as strong as their finite-sample-space and continuous counterparts.

With cross-entropy interpreted as a measure of 'deviation', the Kullback–Leibler's *principle of minimum cross-entropy*, or *MinxEnt*, can be stated as follows [15]:

Out of all possible distributions that are consistent with the moment constraints, choose the one that minimizes the cross-entropy with respect to the given *a priori* distribution.

Mathematically, we consider the following *optimization* problem:

$$\left\{ \begin{array}{l} \min \quad H_2(\mathbf{p}) = \sum_{j=1}^n p_j \ln \frac{p_j}{p_j^0} \\ \text{s.t.} \quad \sum_{j=1}^n p_j g_i(x_j) = a_i, \quad i = 1, \dots, m, \\ \quad \quad \sum_{j=1}^n p_j = 1, \\ \quad \quad p_j \geq 0, \quad j = 1, \dots, n. \end{array} \right.$$

Note that the nonnegativity constraints are not binding, for the same reason as in the MaxEnt problem. For a detailed discussion of the properties of MinxEnt, the reader is referred to [23].

Note that, if there is no *a priori* information, then one may use the uniform distribution, denoted by  $\mathbf{u}$ , as the *a priori* distribution. In this case,  $D(\mathbf{p}, \mathbf{p}^0) = D(\mathbf{p}, \mathbf{u}) = \sum_{j=1}^n p_j \ln(p_j/(1/n)) = \ln n + \sum_{j=1}^n p_j \ln p_j$ . Since minimizing  $\sum_{j=1}^n p_j \ln p_j$  is equivalent to maximizing  $-\sum_{j=1}^n p_j \ln p_j$ , minimizing the cross-entropy with respect to the uniform distribution is equivalent to maximizing entropy and, therefore, MaxEnt is a special case of MinxEnt. These two principles can now be combined into a general principle:

Out of all probability distributions satisfying the given moment constraints, choose the distribution that minimizes the cross-entropy with respect to the given *a priori* distribution and, in the absence of it, choose the distribution that minimizes the cross-entropy with respect to the uniform distribution.

Both the MaxEnt and MinxEnt principles for selecting finite-sample-space probability distributions and the MinxEnt principle for selecting continuous probability distributions can be *axiomatically derived* [22]. Under four consistency axioms, it was shown that the two principles are uniquely correct methods for inductive inference when new information is given in the form of expected values. Many well-known and widely used distributions, including the normal, gamma and geometric distributions, can actually be derived as solutions to some MaxEnt or MinxEnt problems [15].

The maximum entropy principle has also been shown to be a dual principle of the *maximum likelihood*

*principle* for the exponential family of probability distributions in the sense that a dual problem to the linearly constrained entropy maximization problem is equivalent to the problem of maximizing a likelihood function with respect to the parameters of an exponential family [2]. This principle has also been shown to be related to the *Bayesian parameter estimation* problem [7]. *Duality theory* and major mathematical *algorithms* for solving finite-dimensional MaxEnt or MinxEnt problems can be found in [7] and the references therein.
