A different generalization was introduced in [4]. In this sort of problem, one has an affine mapping  $f(x) = q + Nx$  where  $N$  is of order  $\sum_{j=1}^k p_j \times n$  partitioned into  $k$  blocks; the vectors  $q$  and  $y = f(x)$  are partitioned conformably. Thus,

$$y^j = q^j + N^j x \quad \text{for } j = 1, \dots, k.$$

The problem is to find a solution of the system

$$y = q + Nx,$$

$$x, y \geq 0,$$

$$x_j \prod_{i=1}^{p_j} y_i^j = 0, \quad j = 1, \dots, k.$$

In recently years, many publications, e. g. [9] and [24], have further investigated this *vertical linear complementarity problem* (VLCP). Interest in the model which is at the heart of [30] and is now called the *horizontal linear complementarity problem* (HLCP) was revived in [38] where it is used as the conceptual framework for the convergence analysis of infeasible interior point methods. (The problem also comes up in [20].) In some cases, HLCPs can be reduced to ordinary LCPs. This subject is explored in [33] which gives an algorithm for doing this when it is possible. A further generalization called *extended linear complementarity problem* (ELCP) was introduced in [23] and subsequently developed in [11,12] and [32]. To this collection of LCP variants can be added the ELCP presented in [31]. The form of this model captures the previously mentioned HLCP, VLCP and ELCP.

Inequality systems; Duality; Certificate; Transposition theorem

If one has two systems of *linear relations*, where each relation is either a *linear equation* (or *linear equality relation*) or a *linear inequality relation* (of type  $>$ ,  $\geq$ ,  $<$ ,  $\leq$  or  $\neq$ ), and exactly one of the two systems has a solution, then one says that the two given systems are each others *alternative*. A mathematical theorem stating that two systems are alternative systems is called a *theorem of the alternative*, or also a *transposition theorem*. Many such theorems are known. The table lists ten results of this type, with their inventors and dates. The table is a modified version of tables of H. Greenberg [16] and in [8]. In each case the alternative systems are labelled by  $a$  and  $b$ , respectively.

Consider by way of example the two systems  $4a$  and  $4b$  in the table. The corresponding theorem of the alternative is known as *Farkas' lemma*. Assume that  $4a$  has a solution  $x$ , so  $Ax \leq b$ . Then we have for each non-negative vector  $y$  that  $y^T Ax \leq y^T b$ . Hence, if  $y^T A = 0$  then we will have  $y^T b \geq 0$ . Thus it follows that if  $4a$  has a solution then  $4b$  does not have a solution. This is the easy part of the proof of Farkas' lemma. The proof of the other implication is much harder. For a discussion of several proof techniques, see ► **Farkas lemma**.

In the above example we used that for  $y \geq 0$  the inequality  $y^T Ax \leq y^T b$  is implied by the system  $Ax \leq b$ . Note that the *implied inequality*  $y^T Ax \leq y^T b$  is obtained from the separate inequalities in  $Ax \leq b$  by combining them in a linear fashion. Fixing  $y$ , one easily understands that the implied inequality has no solution  $x$  if and only if  $y^T A = 0$  and  $y^T b < 0$ . Together with  $y \geq 0$  these are precisely the relations in the alternative system  $4b$ . Thus, it may be concluded that Farkas' lemma can be restated by saying that the system  $Ax \leq b$  is feasible if and only if it does not imply (in a linear fashion) the 'contradiction'  $0^T x < 0$ . The 'if'-part is obvious: if the system has an implied inequality  $0^T x < 0$  then it must be inconsistent. But the 'only if'-part is a very deep result: it states that if the system has no contradictory implied inequality then it has a solution. The other theorems of the alternative in the table admit a similar interpretation.

The relevance of a theorem of the alternative is the following. Given some system  $S$  of relations the cru-

1	J.B.J. Fourier (1826) [4]
$a$	$Ax \leq 0, Bx < 0, Cx = 0$
$b$	$y^T A + v^T B + w^T C = 0,$ $y \geq 0, 0 \neq v \geq 0$
2	P. Gordan (1873) [7]
$a$	$Ax > 0$
$b$	$y^T A = 0, 0 \neq y \geq 0$
3	J.Farkas (1902) [3]

$a$	$Ax > 0, x > 0$
$b$	$y^T A \leq 0, y \geq 0, y \neq 0, \text{ or } A^T y \neq 0$
9	A.W. Tacket (1956) [14]
$a$	$Ax \geq 0, Ax \neq 0, Bx \geq 0, Cx = 0$
$b$	$y^T A + v^T B + w^T C = 0, y > 0, v \geq 0$
10	D. Gale (1960) [5]
$a$	$Ax \leq b$
$b$	$y^T A = 0, y^T b = -1, y \geq 0$

**Ten pairs of alternative systems**

cial question is whether the system has a solution or not. Knowing the answer to this question one is able to answer many other questions. For example, if one has a *linear optimization problem LO* in the *standard form*

$$\min_x \{c^T x : Ax = b, x \geq 0\},$$

a given real number  $\underline{z}$  is a strict lower bound for the optimal value of the problem if and only if the system

$$Ax = b, \quad c^T x \leq \underline{z}, \quad x \geq 0,$$

has no solution, i. e. is *infeasible*. On the other hand, a given real number  $\bar{z}$  is an upper bound for the optimal

value of the problem if and only if the system

$$Ax = b, \quad c^\top x \geq \underline{z}, \quad x \geq 0,$$

has a solution, i. e. is *feasible*.

If a system  $S$  has a solution then this is easy to certify, namely by giving a solution of the system. The solution then serves as a *certificate* for the feasibility of  $S$ . If  $S$  is infeasible, however, it is more difficult to give an easy certificate. One is then faced with the problem of how to certify a negative statement. This is in general a very nontrivial problem that also occurs in many real life situations. For example, when accused for murder, how should one prove his innocence? In circumstances like these it may be impossible to find an easy to verify certificate for the negative statement ‘not guilty’. A practical solution is the rule ‘a person is innocent until his/her guilt is certified’. Clearly, from the mathematical point of view this approach is unsatisfactory.

Now suppose that there is an alternative system  $T$  and there exists a theorem of the alternative for  $S$  and  $T$ . Then we know that exactly one of the two systems has a solution. Therefore,  $S$  has a solution if and only if  $T$  has no solution. In that case, any solution of  $T$  provides a certificate for the unsolvability of  $S$ . Thus it is clear that a theorem of the alternative provides an easy to verify certificate for the unsolvability of a system of linear relations.

The proof of any theorem of the alternative consists of two parts. Assuming the existence of a solution of one system one needs to show that the other system is infeasible, and vice versa. It has been demonstrated above for Farkas’ lemma that one of the two implications is easy to prove. This seems to be true for each theorem of the alternative: in all cases one of the implications is almost trivial, but the other implication is highly nontrivial and very hard to prove. On the other hand, having proved one theorem of the alternative the other theorems of the alternative easily follow. In this sense one might say that all the listed theorems of the alternative are equivalent: accepting one of them to be true, the validity of each of the other theorems can be verified easily. The situation resembles a number of cities on a high plateau. Travel between them is not too difficult; the hard part is the initial ascent from the plains below [1].

It should be pointed out that Farkas’ lemma, or each of the other theorems of the alternative, is equivalent

to the most deep result in linear optimization, namely the duality theorem for linear optimization: this theorem can be easily derived from Farkas’ lemma, and vice versa (cf. also ► [Linear programming](#)). In fact, in many textbooks on linear optimization the duality theorem is derived in this way [5,17], whereas in other textbooks the opposite occurs: the duality theorem is proved first and then Farkas’ lemma follows as a corollary [11]. This phenomenon is a consequence of a simple, and basic, logical principle that any duality theorem is actually equivalent to a theorem of the alternative, as has been shown in [9].

Both the Farkas’ lemma and the duality theorem for linear optimization can be derived from a more general result which states that for any *skew-symmetric matrix*  $K$  (i. e.,  $K = -K^\top$ ) there exists a vector  $x$  such that

$$Kx \geq 0, \quad x \geq 0, \quad x + Kx > 0.$$

This result is due to Tucker [14] who also derives Farkas’ lemma from it, whereas A.J. Goldman and Tucker [6] show how this result implies the duality theorem for linear optimization. For recent proofs, see [12].

The linear ordering problem (LOP) has a wide range of applications in several fields, such as scheduling, sports, social sciences, and economics. Due to its combinatorial nature, it has been shown to be *NP*-hard [5]. Like many other computationally hard problems, the linear ordering problem has captured the researcher attention for developing efficient solution procedures. A comprehensive treatment of the state-of-art approximation algorithms for solving the linear order problem is contained in [15]. The scope of this article is to introduce the reader to this problem, providing its definition and some of the algorithms proposed in literature for solving it efficiently.

### Problem Description

The linear ordering problem (LOP) can be formulated as follows: Given a *complete digraph*  $D_n = (V_n, E_n)$  on  $n$  nodes and given arc weights  $c(i, j)$  for each arc  $(i, j) \in E_n$ , find a *spanning acyclic tournament* in  $D_n$  such that the sum of the weights of its arcs is as large as possible.

An equivalent mathematical formulation of LOP ([11]) is the following: Given a matrix of weights  $E = \{e_{ij}\}_{m \times m}$ , find a permutation  $p$  of the columns (and rows) in order to maximize the sum of the weights in the upper triangle. Formally, the problem is to maximize

$$C_E(p) = \sum_{i=1}^{m-1} \sum_{j=i+1}^m e_{p_i p_j},$$

where  $p_i$  is the index of the column (and row) occupying the position  $i$  in the permutation.

The best known among the applications of LOP occurs in economics. In fact, it is equivalent to the so-called *triangulation problem for input-output tables*. In this economical application, the economy (regional or national) is subdivided into sectors. An  $m \times m$  input-output matrix is then created, whose entry  $(i, j)$  represents the flow of money from the sector  $i$  to the sector  $j$ . The sectors have to be ordered so that suppliers tend to come first followed by costumers. This scope can be achieved by permuting the rows and the columns of the built matrix so that the sum of entries above the diagonal is maximized, which is exactly the objective of the linear ordering problem.

## Review of Exact and Approximation Algorithms

The pioneer heuristic method for solving LOP has been proposed by H.B. Chenerly and T. Watanabe [3]. Their method tries to obtain plausible rankings of the sectors of an input-output table in the triangulation problem by ranking first those sectors that have a small share of inputs from other sectors and of outputs to final demand. An extensive discussion about the heuristics proposed until 1981 can be found in [16], while more recent work has been done in [2,11]. In [11] a heuristic algorithm is proposed based on the *tabu search methodology* and incorporating strategies for search intensification and diversification are given. For search intensification M. Laguna and others experimented with *path relinking*, a strategy proposed in connection with tabu search by F. Glover and Laguna [6] and still rarely used in actual implementations. In [2] an algorithm is presented implementing a *scatter search* strategy, which is a population-based method that has been shown to lead to promising outcomes for solving combinatorial and nonlinear difficult problems.

The development of exact algorithms for LOP can be seen connected to the development of methods for solving general integer programming problems, since any such method can be slightly modified to solve the triangulation problem. Most of those exact algorithms belong either to the branch and bound family or to the linear programming methods.

## Branch and Bound Algorithms

One of the earliest published computational results using a branch and bound strategy is due to J.S. DeCani in 1972 [4]. He originally studied how to rank  $n$  objects on the basis of a number of paired comparisons. Since  $k$  persons have to pairwise compare  $n$  objects according to some criterion, a matrix  $E = \{e_{ij}\}$  is built, where  $e_{ij}$  is the number of persons that prefer object  $i$  to object  $j$ . The problem is to find a linear ranking of the objects reflecting the outcome of the experiment as closely as possible. In the branch and bound strategy proposed by DeCani partial rankings are built up and each branching operation in the tree corresponds to inserting a further object at some position in the partial ranking. At level  $n$  of the tree a complete ranking of the objects is found. The upper bounds are exploited in the usual way

for backtracking and excluding parts of the tree from further consideration.

A further method for solving LOP is the *lexicographic search algorithm* proposed in [9,10]. It lexicographically enumerates all permutations of the  $n$  sectors by fixing at level  $k$  of the enumeration tree the  $k$ th position of the permutations. In more detail, if at level  $k$  a node is generated, then the first  $k$  positions  $\sigma(1), \dots, \sigma(k)$  are fixed. Based on this fixing several Helmsstädter's conditions can be tested. If one of them is violated, then there is no relatively optimum having  $\sigma(1), \dots, \sigma(k)$  in the first  $k$  positions. Therefore, the node currently under consideration can be ignored and a backtracking is performed. By using this method all relatively optimum solutions are enumerated, since there is no bounding according to objective function values. At the end the best one among them is kept. Starting from lexicographic search, [8] proposed a lexicographic branch and bound scheme.

Other authors have proposed branch and bound methods, such as [7,12], and [14].

## Linear Programming Algorithms

All linear programming approaches are based on the consideration that the triangulation problem can be formulated as a 0–1 integer programming problem using the 3-dicycle inequalities. In [13] the LP relaxation using the tournament polytope  $P_C^n$  is proposed and the corresponding full linear program is solved in its dual version. In [1] LP relaxation is used for solving scheduling problems with precedence constraints. It is easy to see that the scheduling problem of minimizing the total weighted completion time of a set of processes on a single processor can be formulated as a linear ordering problem.

Other possibilities for theoretically solving linear ordering problems are methods as *dynamic programming* or by formulating the problem as *quadratic assignment problem* ([10]).

Linear programming; Basic solution; Simplex method; Pivoting; Nondegenerate

Linear programming (LP) is a fundamental optimization problem in which a linear objective function is to be optimized subject to a set of linear constraints. Due to the wide applicability of linear programming models, an immense amount of work has appeared regarding theory and algorithms for LP, since G.B. Dantzig proposed the simplex algorithm in 1947. It is not surprising that in a recent survey of Fortune 500 companies, 85% of those responding said that they had used linear programming. The history, theory, and applications of linear programming may be found in [3]. Several books

have been published on the subject (see the references section).

**Problem Description**

Consider the linear programming problem (in standard form):

$$\begin{cases} \min & c^T x \\ \text{s.t.} & Ax = b, \\ & x \geq 0 \end{cases} \quad (1)$$

where  $c \in \mathbb{R}^n$ ,  $b \in \mathbb{R}^m$  and  $A$  is an  $m \times n$  matrix of rank  $m$  (i. e. we do not have any redundant constraints). The feasible domain

$$P = \{x \in \mathbb{R}^n : Ax = b, x \geq 0\}$$

is a polytope. We assume that (1) has a finite optimal solution. Let  $B$  be a submatrix of  $A$  formed by  $m$  linearly independent columns. We may assume that  $A = [B, N]$ , i. e. the first columns of  $A$  are linearly independent. Then the linear system  $Bx_B = b$  has a unique solution. If  $x = (x_B, 0)$  then  $Ax = b$  and  $x = (x_B, 0)$  is called a *basic solution*. The components of  $x$  associated with the columns of  $B$  are called *basic variables*. If one of the basic variables in a basic solution is zero, that solution is called a *degenerate basic solution*. A basic solution that is feasible (i. e.  $x \geq 0$ ) is called a *basic feasible solution*.

The following theorem identifies the special importance of the basic feasible solutions.

**Theorem 1** Assume that  $P$  in (1) is nonempty. Then a feasible point  $x \in P$  is a vertex of  $P$  if and only if  $x$  is a basic feasible solution.

Existence of basic feasible solutions is established by the following fundamental theorem of linear programming.

**Theorem 2** Given the linear programming problem (1), the following statements are true:

- 1) If  $P$  is nonempty, there exists a basic feasible solution.
- 2) If (1) has an optimal solution, then there is an optimal basic feasible solution.

Therefore, the linear programming problem can be solved by searching among its basic feasible solutions (i. e. vertices of  $P$ ). Since there are at most

$$\binom{m}{n}$$

basic solutions, the above theorem gives a finite, but a very inefficient algorithm. A more systematic search among the basic feasible solutions, is given by the simplex method, which was developed by Dantzing in 1947.

**The Simplex Method**

The simplex method has a simple geometric motivation which is described by the following two phases.

I	An initial vertex $x_0$ of $P$ (basic feasible solution) is computed.
II	Starting from the vertex $x_0$ , a sequence of vertices $x_0, \dots, x_N$ is computed such a way that $x_{i+1}$ is adjacent to $x_i$ , $i = 0, \dots, N-1$ , and such that $c^T x_{i+1} < c^T x_i$ . The method terminates if either none of the edges adjacent to $x_N$ is decreasing the objective function (i.e., $x_N$ is the solution) or if an unbounded edge adjacent to $x_N$ is found, improving the objective function (i.e. the problem is unbounded).

Each step of the simplex method, moving from one vertex to an adjacent one, is called *pivoting*. The integer  $N$  gives the number of pivot steps in the simplex method. Phase I can be solved in a similar way to Phase II. In problems of the canonical form:

$$\begin{cases} \min & c^T x \\ \text{s.t.} & Ax = b, \\ & x \geq 0, \quad b \geq 0, \end{cases} \quad (2)$$

there is no need for Phase I, because an initial vertex ( $x_0 = 0$ ) is at hand. We start by considering Phase II of the simplex method, by assuming that an initial vertex (basic feasible solution) is available. Let  $x_0$  be a basic feasible solution with  $x_{10}, \dots, x_{m0}$  its basic variables, and let  $B = \{A_{B(i)} : i = 1, \dots, m\}$  the corresponding basis. If  $A_j$  denotes the  $j$ th column of  $A$ , ( $A_j \notin B$ ), then

$$\sum_{i=1}^m x_{ij} A_{B(i)} = A_j. \quad (3)$$

In addition,

$$\sum_{i=1}^m x_{i0} A_{B(i)} = b. \quad (4)$$

Multiply (3) by  $\theta > 0$  and subtract the result from (4) to obtain:

$$\sum_{i=1}^m (x_{i0} - \theta x_{ij}) A_{B(i)} + \theta A_j = b. \tag{5}$$

Assume that  $x_0$  is nondegenerate. How much can we increase  $\theta$  and still have a solution? We can increase  $\theta$  until the first component of  $(x_{i0} - \theta x_{ij})$  becomes zero or equivalently

$$\theta_0 = \min_i \left\{ \frac{x_{i0}}{x_{ij}} : x_{ij} > 0 \right\}. \tag{6}$$

If  $\theta_0 = x_{i0}/x_{ij}$ , then column  $A_l$  leaves the basis and  $A_j$  enters the basis.

If a tie occurs in (6), then the new solution is degenerate. In addition, if all  $x_{ij} \leq 0$ , then we move arbitrarily far without becoming infeasible. In that case the problem is unbounded.

Define the new point  $x_0'$  by

$$x_{i0}' = \begin{cases} x_{i0} - \theta x_{ij}, & i \neq l, \\ \theta_0, & i = l, \end{cases} \tag{7}$$

and

$$B'(i) = \begin{cases} B(i), & i \neq l, \\ j, & i = l. \end{cases}$$

It is easy to see that the  $m$  columns  $A_{B'(i)}$  are linearly independent. Let

$$\sum_{i=1}^m x_i A_{B'(i)} = x_l A_j + \sum_{\substack{i=1 \\ i \neq l}}^m x_i A_{B(i)} = 0.$$

Using (3) we have:

$$\sum_{\substack{i=1 \\ i \neq l}}^m (a_i x_{ij} + a_i) A_{B(i)} + a_l x_{lj} A_{B(l)} = 0$$

and by linear independence of the columns  $A_{B(i)}$  we have

$$a_l = 0, \quad a_i(l + x_{ij}) = 0 \rightarrow a_1, \dots, a_m = 0.$$

Hence, the new point  $x_0'$  whose basic variables are given by (7) is a new basic feasible solution. When the basic feasible solution  $x_0$  is degenerate then some of the ba-

sic variables are zero. Therefore more than  $n-m$  of the constraints  $x_j \geq 0$  are satisfied as equations (are active) and so  $x_0$  satisfies more than  $n$  equations. From (6) it follows that if  $x_{i0} = 0$  and the corresponding  $x_{ij} > 0$ , then  $\theta_0 = 0$  and therefore we remain at the same vertex.

Note that when a basic feasible solution  $x_0$  is degenerate, there can be an enormous number of basis associated with it. In fact, if  $x_0$  has  $k > m$  positive components, then there may be as many as  $\binom{n-k}{n-m}$  different bases. In that case we may compute  $x_0$  as many times as there are basis, but the set of variables that we label basic and nonbasic are different.

The cost (value of objective function) as a basic feasible solution  $x$ , with corresponding basis  $B$  is:

$$z_0 = \sum_{l=1}^n x_{i_0} c_{B(i)}$$

Suppose we bring column  $A_j$  into the new basis. The following economic interpretation can be used to select the pivot column  $A_j$ : For every unit of the variable  $x_j$  that enters the basis, an amount  $x_{ij}$  of each of the variables  $x_{B(i)}$  must leave. Hence, a unit increase in the variable  $x_j$  results in a net change in the cost, equal to:

$$\bar{c}_j = c_j - z_j$$

(relative cost of column  $j$ ), where  $z_j = \sum_{i=1}^m x_{ij} c_{B(i)}$ . It is profitable to bring column  $j$  into the basis exactly when  $\bar{c}_j < 0$ . Choosing the most negative  $\bar{c}_j$  corresponds to a kind of steepest descent. However, many other selection criteria can be used (e. g., Blad's rule, etc).

If all reduced costs satisfy  $\bar{c}_j \geq 0$ , then we are at an optimal solution and the simplex method terminates. Note that relations (1) can be expressed in matrix notation by:

$$BX = A \quad \text{or} \quad X = B^{-1}A,$$

that is, the matrix  $X = (x_{ij})$  is obtained by diagonalizing the basic columns of  $A$ . Then

$$z_j = \sum_{l=1}^m x_{lj} c_{B(l)} \quad \text{or} \quad z^T = c_B^T X = c_B^T B^{-1}A.$$

Suppose  $\bar{c} = c - z \geq 0$ . Let  $y$  be a feasible point. Then,

$$c^T y \geq z^T y \geq c_B^T B^{-1}Ay = c_B^T B^{-1}b = c^T x_0$$

and therefore  $x_0$  is an optimal solution.

Under the assumption of nondegeneracy with our pivot selection,  $x_{l_0} > 0$  (see (6)) and

$$\bar{z}_0 = z_0 - \frac{x_{l_0}}{x_{l_j}}(z_j - c_j) > z_0 \quad (z_j - c_j < 0).$$

Note that corresponding to any basis there is a unique  $z_0$ , and hence, we can never return to a previous basis. Therefore, each iteration gives a different basis and the simplex method terminator after  $N \leq \binom{n}{m}$  pivots.

Linear programming; Interior point methods; Polynomial time algorithm

An enormous amount of research on interior point algorithms for linear programming (LP) has been conducted since N.K. Karmarkar [8] announced his celebrated *projective algorithm* in 1984. Interior point algorithms for LP are interesting for two different reasons. First, many interior point methods are *polynomial time algorithms* for LP. Consider a standard form problem:

$$\text{LP} \quad \begin{cases} \min & c^\top x \\ \text{s.t.} & Ax = b \\ & x \geq 0, \end{cases}$$

where  $A$  is an  $m \times n$  matrix. For the purpose of characterizing the complexity of algorithms it is common to assume that the data of LP is integral. If  $L$  is the number of bits required to encode the data, then an algorithm for LP is polynomial time if the number of

operations required to solve LP is a polynomial function of  $n$ ,  $m$ , and  $L$ . Throughout we use ‘operations’ to refer to arithmetic operations in infinite precision, although for an algorithm to be rigorously polynomial time in the rational model of computation the number of bits required to perform all computations should also be polynomially bounded. Karmarkar’s projective algorithm solves LP in  $O(nL)$  iterations and  $O(n^4L)$  total operations. This overall complexity is required to obtain a solution of LP whose objective is within a tolerance  $2^{-O(L)}$  of optimality; an exact optimal solution can then be obtained using a ‘rounding’ procedure in  $O(n^3)$  operations. Karmarkar also described a *partial updating* procedure that reduced the overall complexity of his algorithm to  $O(n^{3.5}L)$  operations. The idea of partial updating is to allow for some error in the specification of the projection equations that are solved on each iteration of the algorithm.

Interior point algorithms are also interesting because they perform well in practice. When the projective algorithm was first announced Karmarkar made well-publicized claims that his algorithm was several times faster than the simplex method in solving large LP problems. It was eventually discovered that most of Karmarkar’s claims were actually for an implementation of the *affine scaling algorithm*, a simplified version of Karmarkar’s algorithm that avoids the use of projective transformations. Initial attempts to replicate Karmarkar’s results were mainly failures, but eventually it was convincingly established that interior point algorithms are highly competitive with the simplex method on large scale problems.

The announcement of Karmarkar’s algorithm led to the development of a variety of different types of interior point methods for LP. The simplest of these are affine scaling methods, which were independently devised by E. Barnes [2] and R.J. Vanderbei, M.J. Meke-ton, and B.A. Freedman [21]. It was eventually realized that in fact the affine scaling method was discovered by I.I. Dikin [3] in 1967. The affine scaling method is not a polynomial time algorithm for LP, and it is now known that the algorithm may not even converge if the stepsize is too long [12]. Nevertheless its practical performance is often quite good, as indicated by Karmarkar’s early claims.

Another type of interior point method, the *path following algorithm*, was discovered by J. Renegar [17].

Renegar’s algorithm requires only  $O(\sqrt{n}L)$  iterations to solve LP, as opposed to  $O(nL)$  iterations for Karmarkar’s algorithm. By adapting Karmarkar’s partial updating technique to the path following framework, C.C. Gonzaga [5] and P.M. Vaidya [19] devised the first algorithms for LP with overall complexities of  $O(n^3L)$  operations. The iterates of path following algorithms lie in a small neighborhood of the *central path* or *central trajectory*, which is defined to be the set of minimizers of the *logarithmic barrier function*

$$f_\mu(x) = \frac{c^\top x}{\mu} - \sum_{i=1}^n \ln(x_i),$$

over  $\{x: Ax = b, x > 0\}$ , for  $\mu \in (0, \infty)$ . Later C. Roos and J.-Ph. Vial [18], and Gonzaga [6] developed ‘long step’ path following algorithms. These algorithms are based on properties of the central path, but the iterates are not constrained to remain in a small neighborhood of the path. Long step path following algorithms are very closely related to the classical sequential unconstrained minimization technique (SUMT) of A.V. Fiacco and G.P. McCormick [4].

A different class of interior point algorithms is based on Karmarkar’s use of a *potential function*, a surrogate for the original objective, to monitor the progress of his projective algorithm. Gonzaga [7] and Y. Ye [23] devised the first *potential reduction algorithms*. These algorithms are based on reducing a potential function but do not employ projective transformations. Ye’s potential reduction algorithm requires  $O(\sqrt{n}L)$  iterations, like path following algorithms, and provides an  $O(n^3L)$  algorithm for LP when implemented with partial updating.

All of the algorithms mentioned to this point are based on solving LP, or alternatively the dual problem:

$$\text{LD} \quad \begin{cases} \max & b^\top y \\ \text{s.t.} & A^\top y + s = c \\ & s \geq 0. \end{cases}$$

Algorithms for solving LP typically generate feasible solutions to LD, and vice versa, but the algorithms are not symmetric in their treatment of the two problems. A different class of interior point methods, known as *primal-dual algorithms*, is completely symmetric in the

variables  $x$  and  $s$ . Primal-dual algorithms are based on applying Newton's method directly to the system of equations:

$$\text{PD}(\mu) \quad \begin{cases} Ax = b \\ A^\top y + s = c \\ x \circ s = \mu e, \end{cases}$$

where  $e \in \mathbf{R}^n$  is the vector of ones,  $\mu$  is a positive scalar, and  $x \circ s$  is the vector whose  $i$ th component is  $x_i s_i$ . Solutions  $x > 0$  and  $s > 0$  to  $\text{PD}(\mu)$  are exactly on the central paths for LP and LD, respectively. Most primal-dual algorithms fit into the path following framework. The idea of a primal-dual path following algorithm was first suggested by N. Megiddo [13], and complete algorithms were first devised by R.C. Monteiro and I. Adler [15] and M. Kojima, S. Mizuno, and Y. Yoshise [10]. It is widely believed that primal-dual methods are in practice the best performing interior point algorithms for LP.

One advantage of the system  $\text{PD}(\mu)$  is that Newton's method can be applied even when the current  $x > 0$  and  $s > 0$  are not feasible in LP and LD. This *infeasible interior point* (IIP) strategy was first employed in the OB1 code of I.J. Lustig, M.E. Marsten, and D.F. Shanno [11]. The solution to the Newton equations with  $\mu = 0$  is referred to as the predictor, or primal-dual affine scaling direction, while the solution with  $\mu = x^\top s/n$ , for the current solutions  $x$  and  $s$ , is called the *corrector*, or *centering direction*. The primal-dual *predictor-corrector algorithm* alternates between the use of these two directions. One implementation of the IIP predictor-corrector strategy, due to S. Mehrotra [14], has worked particularly well in practice. Despite the fact that primal-dual IIP algorithms were very successfully implemented it proved to be quite difficult to characterize the convergence of these methods. The first such analyses, by Kojima, Megiddo, and Mizuno [9], and Y. Zhang [25], were followed by a large number of papers giving convergence/complexity results for various IIP algorithms. Ye, M.J. Todd, and Mizuno [24] devised a 'selfdual homogeneous' interior point method that has many of the practical features of IIP methods but at the same time has stronger convergence properties. An implementation of the homogeneous algorithm [22] exhibits excellent behavior, particularly when applied to infeasible or near-infeasible problems.

Many interior point algorithms for LP can be extended to more general optimization problems. Primal-dual algorithms generalize very naturally to the monotone linear complementarity problem (LCP; cf. ► [linear complementarity problem](#)); in fact many papers on primal-dual algorithms (for example [25]) are written in terms of the LCP. As a result these algorithms immediately provide interior point solution methods for convex quadratic programming (QP) problems. Interior point algorithms can also be generalized to apply to quadratically constrained quadratic programming (QCQP), optimization over *second order cone* (SOC) constraints, and semidefinite programming (SDP); for details on these and other extensions see [16]. The application of interior point methods to SDP has particularly rich applications, as described in [1], and [20], and remains the topic of extensive research.

Linear programming; Interior point methods; Projective transformation; Potential function; Polynomial time algorithm

In his groundbreaking paper [6], N.K. Karmarkar described a new *interior point method* for linear programming (LP). As originally described by Karmarkar, his algorithm applies to a LP problem of the form:

$$\text{KLP} \quad \begin{cases} \min & c^T x \\ \text{s.t.} & Ax = 0 \\ & x \in S, \end{cases}$$

where  $x \in \mathbf{R}^n$ ,  $A$  is an  $m \times n$  matrix, and  $S$  is the simplex  $S = \{x \in \mathbf{R}^n : x \geq 0, e^T x = n\}$ . Throughout  $e$  denotes the vector with each component equal to one. It is assumed that  $e$  is feasible in KLP, and that the optimal objective value in KLP is exactly zero. These assumptions may seem restrictive, but it is easy to show that a standard form LP problem:

$$\begin{cases} \min & c^T x \\ \text{s.t.} & Ax = b \\ & x \geq 0, \end{cases} \quad (1)$$

can be converted into a problem of the form KLP by combining the problem with its dual, and minimizing the gap between the two problems.

In addition to the special form of the LP problem, Karmarkar employed two novel ingredients in the specification of his algorithm. The first was the use of a *projective transformation* in the construction of the algorithm's iterative process. The algorithm is initialized at  $x^0 = e$ . For an iterate  $x^k > 0, k \geq 0$ , let  $X^k$  be the diagonal matrix with  $X^k_{ii} = x^k_i, i = 1, \dots, n$ . On the  $k$ th iteration, the algorithm uses a projective change of coordinates  $T^k: S \rightarrow S$ ,

$$T_k(x) = \frac{n(X^k)^{-1}x}{e^T(X^k)^{-1}x},$$

to map the point  $x^k$  to  $e$ . Under the assumption that the optimal value in KLP is zero, KLP is equivalent to the transformed problem:

$$\begin{cases} \min & \bar{c}^T \bar{x} \\ \text{s.t.} & \bar{A} \bar{x} = 0 \\ & \bar{x} \in S, \end{cases}$$

where  $\bar{x} = T^k(x), \bar{c} = X^k c$  and  $\bar{A} = AX^k$ . The algorithm then takes a projected gradient step in the transformed problem, and uses the inverse projective transformation to define the next iterate in the original coordinates:

$$x^{k+1} = T_k^{-1} \left( e - \alpha \frac{\bar{c}_p}{\|\bar{c}_p\|} \right), \tag{2}$$

where  $\alpha$  is a positive steplength and  $\bar{c}_p$  is the projection of  $\bar{c}$  onto the nullspace of  $\bar{A}$  and  $e^T$ .

Karmarkar's second innovation was the use of a *potential function* to monitor the algorithm's progress. Karmarkar's potential function is:

$$f(x) = n \ln(c^T x) - \sum_{i=1}^n \ln(x_i).$$

Karmarkar proved that on each iteration, the steplength  $\alpha$  in (2) can be chosen so that  $f(\cdot)$  is reduced by an absolute constant  $\delta$ . It is then easy to show that the iterates satisfy  $c^T x^k \leq e^{-k\delta/n} c^T x^0$  for all  $k$ . For any positive  $L$ , it follows that if  $c^T x^0 \leq 2^{O(L)}$ , then the algorithm obtains an iterate  $x^k$  having  $c^T x^k \leq 2^{-O(L)}$  in  $k =$

$O(nL)$  iterations, each requiring  $O(n^3)$  operations. For a problem of the form KLP with integer data, it can be shown that if  $c^T x^k \leq 2^{-O(L)}$ , where  $L$  is the number of bits required to represent the problem, then an exact optimal solution can be obtained from  $x^k$  via a 'rounding' procedure. These facts together imply that Karmarkar's algorithm is a *polynomial time algorithm* for linear programming, requiring  $O(n^4L)$  operations for a problem with  $n$  variables, and integer data of bit size  $L$ . Karmarkar also described a *partial updating* technique that reduces the total complexity of his algorithm to  $O(n^{3.5}L)$  operations. Partial updating is based on using a scaling matrix  $\tilde{X}^k$  which is an approximation of  $X^k$ , and only 'updating' components  $\tilde{X}^k_{ii}$  which differ from  $X^k_{ii}$  by more than a fixed factor.

Karmarkar's algorithm created a great deal of interest for two reasons. First, the algorithm was a polynomial time method for LP. Second, Karmarkar claimed that unlike the *ellipsoid algorithm*, the other well-known polynomial time method for LP, his method performed extremely well in practice. There was some controversy at the time regarding these claims, and eventually it was discovered that most of Karmarkar's computational results were based on the *affine scaling algorithm*, a simplified version of his algorithm that avoids the use of projective transformations. In any case it soon became clear that the performance of interior point algorithms for LP could be highly competitive with the *simplex method*, the usual solution technique, on large problems.

There is a great deal of research connected with Karmarkar's algorithm. Several authors ([1,3,4,5,9]) showed that the special form of KLP was unnecessary, and instead the projective algorithm could be directly applied to a standard form problem (1). This 'standard form variant' adds logic which maintains a lower bound on the unknown optimal value in (1). Later it was shown that the projective transformations could also be eliminated, giving rise to so-called *potential reduction algorithms* for LP. The best known potential reduction algorithm, due to Y. Ye [8], requires only  $O(\sqrt{n}L)$  iterations, and with an adaptation of Karmarkar's partial updating technique has a total complexity of  $O(n^3L)$  operations. The survey articles [2] and [7] give extensive references to research connected with Karmarkar's algorithm, and related potential reduction methods.

The problem of determining the worst-case behavior of the simplex algorithm remained an outstanding open problem for more than two decades. In the beginning of the 1970s, V. Klee and G.J. Minty [9] solved this problem by constructing linear examples on which an exponential number of iterations is required before optimality occurs. In this article we present the Klee–Minty examples and show how they can be used to show exponential worst-case behavior for some well known *pivoting rules*.

**Introduction**

The problem of determining the worst-case behavior of the simplex algorithm remained an outstanding open problem for more than two decades. In the beginning of the 1970s, Klee and Minty in their classical paper [9] showed that the most commonly used pivoting rule, i. e., *Dantzig’s largest coefficient pivoting rule* [5], performs exponentially bad on some specially constructed linear problems, known today as Klee–Minty examples. Later on, R.G. Jeroslow [8] showed similar behavior for the maximum improvement pivoting rule. He showed this result by slightly modifying Klee–Minty examples.

The Klee–Minty examples have been used by several researchers to show exponential worst-case behavior for the great majority of the practical pivoting rules. D. Avis and V. Shvatal [1] and independently, K.G. Murty [10, p. 439] showed exponential behavior for *Bland’s least index pivoting rule* [2] and D. Goldfarb and W. Sit [7] for the *steepest edge simplex method* [5]. Recently,

C. Roos [13] established exponential behavior for Terlaký’s criss-cross method [14] and K. Paparrizos [11] for a number of pivoting rules some of which use past history. Similar results have been derived by Paparrizos [12] for his dual exterior point algorithm and K. Dostos and Paparrizos [6] for a new primal dual pivoting rule [3].

In this paper we present the Klee–Minty examples and show some of their properties that are used in deriving complexity results of the simplex algorithm. These properties are then used to show exponential behavior for two pivoting rules; the least index and the maximum coefficient pivoting rule.

The paper is self contained. Next section describes a particular form of the simplex algorithm. The Klee–Minty examples and their properties are presented in Section 3. Section 4 is devoted to complexity results.

**Simplex Algorithm**

In describing our results we find it convenient to use the dictionary form [4] of the simplex algorithm. We will see in the next section that this form exhibits some advantages in describing the properties of the Klee–Minty examples.

Consider the linear problem in standard form

$$\begin{cases} \max & z = c^T x \\ \text{s.t.} & Ax = b, \\ & x \geq 0, \end{cases} \tag{1}$$

where  $c, x \in \mathbf{R}^n, b \in \mathbf{R}^m, A \in \mathbf{R}^{m \times n}$  and superscript  $T$  denotes transposition. Without loss of generality we may assume that  $A$  is of full row rank, i. e.,  $\text{rank}(A) = m (m < n)$ .

A basis for problem (1) is a set of indices  $B \subset \{1, \dots, n\}$  containing exactly  $m$  indices. The element of  $B$ , the components of  $c$  and  $x$  and the columns of  $A$  indexed by  $B$  are called *basic* while the remaining ones are called *nonbasic*. The set of nonbasic indices is denoted by  $N, N = \{1, \dots, n\} \sim B$ . We also denote by  $B(N)$  the submatrix of  $A$  containing the columns indexed by  $B(N)$ . The components of a vector  $x$  indexed by  $B(N)$  are denoted by  $x_B(x_N)$ .

With this notation at hand the equality constraints of (1) are written in the form

$$Bx_B + Nx_N = b. \tag{2}$$

If  $B$  is a nonsingular matrix we can set  $x_N = 0$  and compute  $x_B$  from (2). Then, we find  $x_B = B^{-1}b$ . The nonsingular matrix  $B$  is called *basic matrix* or *basis*. The solution  $x_N = 0$  and  $x_B = B^{-1}b$  is called *basic solution*. If, in addition, it is  $x_B = B^{-1}b \geq 0$ , then  $x_B, x_N$  is a *basic feasible solution*. Geometrically, a basic feasible solution of (1) corresponds to a vertex of the polyhedral set of the feasible region.

If  $B$  is nonsingular, we can express the basic variables  $x_B$  as a function of the non basic variable  $x_N$ . We have from (2) that

$$x_B = -B^{-1}Nx_N + B^{-1}b. \tag{3}$$

Using (3), the objective function of problem (1) is written in the form

$$\begin{aligned} z &= c_B^T x_B + c_N^T x_N \\ &= c_B^T (-B^{-1}Nx_N + B^{-1}b) + c_N^T x_N \\ &= (-c_B^T B^{-1}N + c_N^T)x_N + c_B^T B^{-1}b. \end{aligned} \tag{4}$$

At every iteration the simplex algorithm constructs the system of equations (3) and (4).

Let the current feasible basis be  $B$ . The corresponding system of equations is written in the form

$$\begin{aligned} z &= (-c_B^T B^{-1}N + c_N^T)x_N + c_B^T B^{-1}b, \\ x_B &= -B^{-1}Nx_N + B^{-1}b. \end{aligned} \tag{5}$$

We denote the coefficients of  $x_N$  and the constant terms of (5) by  $H$ , i. e.,

$$\begin{pmatrix} c_N^T - c_B^T B^{-1}N & c_B^T B^{-1}b \\ -B^{-1}N & B^{-1}b \end{pmatrix} = H.$$

The top row of  $H$ , row zero, is devoted to the objective function. Some times we call it *cost row*. The remaining rows are numbered  $1, \dots, m$ . The  $i$ th row,  $1 \leq i \leq m$ , corresponds to the basic variable  $x_{B[i]}$ , where  $B[i]$  denotes the  $i$ th element of  $B$ . Similarly, the  $j$ th column of  $H$ ,  $1 \leq j \leq n-m$ , corresponds to the nonbasic variable  $x_{N[j]}$ . The last column of  $H$  corresponds to the constant terms. We denote the entries of  $H$  by  $h_{ij}$ .

It is well known that if  $h_{0j} \leq 0$ , for  $j = 1, \dots, n-m$ , then  $x_B, x_N$  is an optimal solution to (1). In this case the algorithm terminates. Otherwise, a nonbasic variable  $x_{N[q]} = x_l$  such that  $h_{0, N[q]} > 0$  is chosen. Variable  $x_l$  is called *entering variable*. If the condition

$$h_{i, N[q]} \geq 0, \quad \text{for } i = 1, \dots, m,$$

holds, problem (1) is unbounded and the algorithm stops. Otherwise, the basic variable  $x_{B[p]} = x_k$ , is determined by the following *minimum ratio test*

$$\frac{x_{B[p]}}{-h_{r,N[q]}} = \min \left\{ \frac{h_{i,n-m+1}}{-h_{i,N[q]}} : 1 \leq i \leq m, h_{i,N[q]} < 0 \right\}.$$

The basic variable  $x_k$  is called *leaving variable*. Then, the entering variable  $x_l$  takes the place of the leaving variable and vice versa, i. e., it is set

$$B[p] \leftarrow N[q] \quad \text{and} \quad N[q] \leftarrow B[p].$$

Thus, a new basis  $\bar{B}$  is constructed and the procedure is repeated. Let  $\bar{H}$  be the tableau corresponding to the new basis  $\bar{B}$ . It is easily seen that

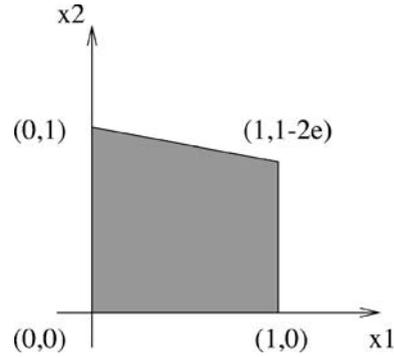

$$\bar{h}_{ij} = \begin{cases} -\frac{h_{pj}}{h_{pq}} & \text{if } i = p, \\ \frac{h_{iq}}{h_{pq}} & \text{if } i \neq p, j = q, \\ h_{ij} \frac{h_{pj}}{h_{pq}} & \text{otherwise.} \end{cases} \quad (6)$$

### Klee–Minty Examples

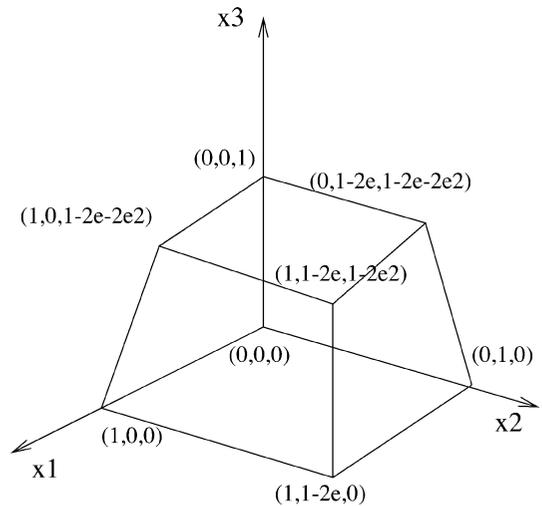

The Klee–Minty examples of order  $n$  are the linear problems of the form

$$\begin{cases} \max & \sum_{j=1}^n \varepsilon^{n-j} x_j \\ \text{s.t.} & x_1 \leq 1 \\ & 2 \sum_{j=1}^{i-1} \varepsilon^{i-j} x_j + x_i \leq 1, \\ & i = 2, \dots, n, \\ & x_j \geq 0, \quad j = 1, \dots, n, \end{cases} \quad (7)$$

where  $0 < \varepsilon \leq 1/3$ . In this section we will show that the feasible region of (7) is a slightly perturbed cube of dimension  $n$ , see Fig. 1 and Fig. 2. The optimal solution is  $(0, 0, \dots, 1) \in \mathbf{R}^n$  and the optimal value is 1. A cube of dimension  $n$  has  $2^n$  vertices. In the next section we will describe pivoting rules that force the simplex method to pass through all the vertices of the Klee–Minty examples. These pivoting rules require  $2^n - 1$  iterations before optimality is reached and, hence, they are exponential.

Linear Programming: Klee–Minty Examples, Figure 1  
Feasible region of Klee–Minty example of order  $n = 2$

Linear Programming: Klee–Minty Examples, Figure 2  
Feasible region of Klee–Minty example of order  $n = 3$

The standard form of linear problem (1) is

$$\begin{cases} \max & \sum_{j=1}^n \varepsilon^{n-j} x_j \\ \text{s.t.} & x_1 + x_{n+1} = 1, \\ & 2 \sum_{j=1}^{i-1} \varepsilon^{i-j} x_j + x_{n+i} = 1, \\ & i = 2, \dots, n, \\ & x_j \geq 0, \quad j = 1, \dots, 2n, \end{cases} \quad (8)$$

where  $x_{n+i}$ ,  $1 \leq i \leq n$ , is the slack variable corresponding to the  $i$ th inequality constraint of problem (7).

We will be interested in basic solutions of (8) such that, for each  $j = 1, \dots, n$  either  $x_j$  or  $x_{n+j}$  is basic but

not both. Such a basic solution is called *distinguished*. A tableau corresponding to a distinguished basis is called *distinguished tableau*. In order to facilitate the presentation it is convenient to introduce the set  $Q$  of all zero-one  $n$ -sequences  $(a_1, \dots, a_n)$  such that

$$a_j = \begin{cases} 0 & \text{if } x_j \text{ is nonbasic and } x_{n+j} \text{ is basic,} \\ 1 & \text{if } x_{n+j} \text{ is nonbasic and } x_j \text{ is basic.} \end{cases}$$

We denote the distinguished basis corresponding to the sequence  $(0, \dots, 0)$  by  $\widehat{B}$  and the tableau corresponding to  $\widehat{B}$  by  $\widehat{H}$ . We have  $\widehat{B} = \{n + 1, \dots, 2n\}$ . It is easily verified that

$$\widehat{h}_{ij} = \begin{cases} \varepsilon^{n-j} & \text{if } i = 0, j \leq n, \\ -1 & \text{if } 1 \leq i = j \leq n, \\ 0 & \text{if } 1 \leq i < j, j \neq n + 1, \\ -2\varepsilon^{i-j} & \text{if } i > j, \\ 1 & \text{if } i \geq n \text{ and } j = n + 1. \end{cases} \quad (9)$$

Tableau  $\widehat{H}$  is sometimes called *initial*.

A distinguished tableau  $H$  corresponding to  $(a_1, \dots, a_n) \in Q$  is constructed by starting from  $\widehat{H}$  and pivoting only on elements  $h_{pp}$  such that  $a_p = 1$ . Using this procedure and relations (6) and (9) we easily conclude that

$$\begin{aligned} h_{pp} &= -1 \text{ for } p = 1, \dots, n, \\ h_{ij} &= 0 \text{ for } 1 \leq i \leq n - 1, i \leq j \leq n, \end{aligned} \quad (10)$$

for each distinguished tableau  $H$ .

**Lemma 1** *Let  $B$  be an arbitrary distinguished basis and  $H$  the corresponding tableau. Then*

$$h_{ij} + h_{pj}h_{ip} = -h_{ij}, \quad j < p < n, i \geq 2, \quad (11)$$

$$h_{0j} + h_{pj}h_{0j} = 0, \quad j < p \leq n, i = 0. \quad (12)$$

*Proof* It suffices to show the following induction hypothesis. If the distinguished tableau  $\overline{H}$  satisfies (11) and (12) and a pivot operation is performed on  $h_{rr}$ ,  $1 \leq r \leq n$ , resulting in tableau  $H$ , then  $H$  satisfies (11) and (12) as well. Observe that relations (11) and (12) are satisfied by the initial tableau  $\widehat{H}$ .

So, assume that  $H$  satisfies (11) and (12) and a pivot operation is performed on element  $h_{rr} = -1$ . Then, we

have from (6) and (10)

$$h_{ij} = \begin{cases} \overline{h}_{ij} + \overline{h}_{rj}\overline{h}_{ir}, & i \neq r, j \neq r, \\ -\overline{h}_{ij}, & i \neq r, j = r, \\ \overline{h}_{ij}, & \text{otherwise.} \end{cases} \quad (13)$$

Combining (13) and the induction hypothesis we have

$$h_{ij} = \begin{cases} -\overline{h}_{ij} & \text{if } i = 0, j \leq r, \\ -\overline{h}_{ij} & \text{if } i > r, j \leq r, \\ -\overline{h}_{ij} + \overline{h}_{rj}\overline{h}_{ir} & \text{if } i > r, j = n + 1, \\ -\overline{h}_{ii} + \overline{h}_{rj}\overline{h}_{ir} & \text{if } i = 0, j = n + 1, \\ -\overline{h}_{ij}, & \text{otherwise.} \end{cases} \quad (14)$$

There are two cases to be considered,  $p \leq r$  and  $p > r$ . From relations (14) we have, for  $p \leq r$ ,

$$h_{ij} = -\overline{h}_{ij}, \quad h_{ip} = -\overline{h}_{ip}, \quad h_{pj} = \overline{h}_{pj}$$

and for  $p > r$

$$h_{ij} = -\overline{h}_{ij}, \quad h_{ip} = \overline{h}_{ij}, \quad h_{pj} = -\overline{h}_{pj}.$$

In both cases,

$$\begin{aligned} h_{ij} + h_{pj}h_{ip} &= -\overline{h}_{ij} - \overline{h}_{ij}h_{ip}h_{pj} \\ &= \overline{h}_{ij} = -h_{ij}. \end{aligned}$$

This proves (11). The proof of (12) is similar.

Lemma 1 shows that pivoting on element  $h_{pp}$  of a distinguished tableau  $H$  is very easily performed. Just change the signs of the entries  $h_{ij}$  such that  $i = p$  and  $j \leq p$  or  $i > p$  and  $j \leq p$  and set

$$h_{i,n+1} \leftarrow h_{i,n+1} + h_{ip}h_{p,n+1}$$

for  $i = 0$  or  $i > p$ .

Figure 3 illustrates the entries of  $H$  that change value when pivoting on  $h_{pp}$ . In particular, the entries in areas  $A$  and  $B$  just change sign.

**Theorem 2** *Let  $H$  be a distinguished tableau of problem (8) and  $a = (a_1, \dots, a_n)$  be the corresponding  $n$ -sequence. Then the following relations hold.*

For  $i = 1, \dots, n$  and  $j = 1, \dots, n$  we have

$$h_{ij} = \begin{cases} -1, & i = j, \\ 0, & i < j, \end{cases} \quad (15)$$

		P		
		A		
	-1	0	0	
		-1	-1	
P				
	B			
		-1	0	
				-1

**Linear Programming: Klee–Minty Examples, Figure 3**  
 Entries of a distinguished tableau  $H$  that change value after pivoting on element  $h_{pp}$

while for  $i > j$ ,

$$h_{ij} = \begin{cases} -2\varepsilon^{i-j}, & \sum_{k=j}^{i-1} a_k \text{ even,} \\ 2\varepsilon^{i-j}, & \sum_{k=j}^{i-1} a_k \text{ odd.} \end{cases} \quad (16)$$

For  $i = 0$  and  $j = 1, \dots, n$  we have

$$h_{0j} = \begin{cases} \varepsilon^{n-j}, & \sum_{k=j}^n a_k \text{ even,} \\ -\varepsilon^{n-j}, & \sum_{k=j}^n a_k \text{ odd.} \end{cases} \quad (17)$$

For  $i = 1, \dots, n$  and  $j = n + 1$  we have

$$h_{i,n+1} = \begin{cases} 1, & i = 1, \\ 1 - \sum_{k=1}^{i-1} a_k h_{ik}, & 2 \leq i \leq n. \end{cases} \quad (18)$$

*Proof* The proof is by induction. We assume that distinguished tableau  $\bar{H}$  satisfies (15)–(18), and show that tableau  $H$  computed by pivoting on  $\bar{h}_{pp}$  satisfies (15)–(18) as well. Observe that initial tableau  $\bar{H}$  satisfies (15)–(18).

Let  $\bar{a} = (\bar{a}_1, \dots, \bar{a}_n)$  be the sequence corresponding to tableau  $\bar{H}$ . Then

$$\bar{a}_j = \begin{cases} a_j, & j \neq p, \\ 1 - a_j, & j = p. \end{cases}$$

*Proof of (15)–(16)*. Relations (15) have already been shown. From Lemma 1 we have

$$\bar{h}_{ij} = h_{ij} \quad \text{and} \quad \sum_{k=j}^{i-1} a_k = \sum_{k=j}^{i-1} \bar{a}_k$$

for  $i \leq p$  or  $i > p$  and  $j > p$ . For  $i > p$  and  $j \leq p$  we have

$$\sum_{k=j}^{i-1} \bar{a}_k = \sum_{k=j}^{i-1} a_k - 2a_p.$$

Hence, if  $\sum_{k=j}^{i-1} \bar{a}$  is odd (even),  $\sum_{k=j}^{i-1} \bar{a}_k$  is even (odd). Also, from Lemma 1 we have  $\bar{h}_{ij} = -h_{ij}$ . Hence, (16) holds in all cases.

*Proof of (17)*. It is easily seen that

$$\text{sign}(h_{0j}) = \text{sign}(h_{mj}), \quad \text{for } i \leq n.$$

Now the proof comes from the proof of (16).

*Proof of (18)*. If  $i \leq p$  we have  $\bar{h}_{i,n+1} = h_{i,n+1}$ . Hence, (18) holds trivially from the induction hypothesis. If  $i > p$ , then

$$\begin{aligned} \bar{h}_{i,n+1} &= h_{i,n+1} + h_{p,n+1}h_{ip} \\ &= 1 - \sum_{k=1}^{i-1} a_k h_{ik} + \left(1 - \sum_{k=1}^{p-1} a_k h_{pk}\right) h_{ip} \\ &= 1 - \sum_{k=1}^{p-1} a_k (h_{ik} + h_{pk}h_{ip}) \\ &\quad + h_{ip} - a_k h_{pp}h_{ip} - \sum_{k=1}^{i-1} a_k h_{ik} \\ &= 1 - \sum_{k=1}^{p-1} \bar{a}_k \bar{h}_{ik} - (1 - a_p)\bar{h}_{ip} - \sum_{k=p+1}^{i-1} \bar{a}_k \bar{h}_{ik} \\ &= 1 - \sum_{k=1}^{i-1} \bar{a}_k \bar{h}_{ik}. \end{aligned}$$

**Theorem 3** *The feasible region of problem (8) is a slightly perturbed cube.*

*Proof* It suffices to show that the feasible region has precisely  $2^n$  vertices. We show that each distinguished tableau,  $H$ , is feasible and all the adjacent tableaus are distinguished.

From Theorem 2 we have

$$\begin{aligned} h_{i,n+1} &= 1 - \sum_{k=1}^{i-1} a_k h_{ik} \\ &> 1 - 2\varepsilon(1 + \varepsilon + \varepsilon^2 + \dots) \\ &= 1 - \frac{2\varepsilon}{1 - \varepsilon} \geq 0. \end{aligned}$$

We show that if  $x_{N[p]}$  is entering, then  $x_{B[p]}$  is leaving variable. Let  $h_{ip} < 0$  ( $i < p$ ). We show that

$$\frac{h_{p,n+1}}{h_{pp}} \leq \frac{h_{i,n+1}}{-h_{ip}}.$$

The last relation is equivalently written

$$-h_{ip} \left( 1 - \sum_{k=1}^{p-1} a_k h_{pk} \right) < 1 - \sum_{k=1}^{i-1} a_k h_{ik}.$$

Using Lemma 1 we get

$$-h_{ip} - 2 \sum_{k=1}^{p-1} a_k h_{ik} < 1 - \sum_{k=1}^{i-1} a_k h_{ik}$$

or

$$\begin{aligned} 0 &< 1 + h_{ip} + \sum_{k=1}^{p-1} a_k h_{ik} - \sum_{k=p}^{i-1} a_k h_{ik} \\ &= 1 + \sum_{k=1}^{p-1} a_k h_{ik} + (1 - a_k)h_{ip} + \sum_{k=p+1}^{i-1} a_k h_{ik}. \end{aligned}$$

We have already shown that the last relation holds.

### Applications

Now, we are ready to show exponential behavior for some pivoting rules. Let  $a \neq b$  be sequences of  $Q$ . We write  $a < b$  if for the largest index  $j$  such that  $a_j \neq b_j$  it is  $\sum_{j=1}^n a_k$  even and  $\sum_{k=1}^n b_k$  odd.

Let now  $f(a)$  be the objective value at the vertex corresponding to  $a \in Q$ . It is easily seen that  $f(a) < f(b)$ , if  $a < b$ . The immediate successor of a sequence  $a \in Q$  is the sequence  $(a_1, \dots, a_r, 1 - a_p, a_{p+1}, \dots, a_n)$ , where  $p$  is the smallest index such that  $\sum_{j=p}^n a_j$  is even.

Given a distinguished tableau  $H$ , a nonbasic variable  $x_{N[q]}$  is called *eligible* if  $h_{0,N[p]} > 0$ .

A pivoting rule that forces the simplex algorithm to pass through all vertices of Klee–Minty examples is the

following. For the ease of reference we call it *generic pivoting rule*. Let  $a \in Q$  be the sequence corresponding to  $H$ . The entering variable is  $x_{N[p]}$ , where  $p$  is the smallest index such that  $\sum_{k=p}^n a_k$  is even. From Theorem 2 we see that  $h_{0,N[p]} = \varepsilon^{n-p} > 0$ . Hence,  $x_{N[p]}$  is eligible, and the generic pivoting rule requires  $2^n - 1$  iterations on Klee–Minty examples of order  $n$ .

### Smallest Index Rule

In the *smallest index rule*, the entering variable is the eligible variable with the smallest index. We show that the smallest index rule, called also *Bland’s rule*, performs exponentially on the slightly modified Klee–Minty examples

$$\left\{ \begin{array}{l} \max \quad \sum_{j=1}^n \varepsilon^{n-j} x_{2j-1} \\ \text{s.t.} \quad x_1 \leq 1 \\ \quad \quad 2 \sum_{j=1}^{i-1} \varepsilon^{i-j} x_{2j-1} + x_{2i-1} \leq 1, \\ \quad \quad i = 2, \dots, n, \\ \quad \quad x_j \geq 0, \quad j = 1, \dots, n. \end{array} \right. \quad (19)$$

We introduce the slack variable  $x_{2i}$  to the  $i$ th constraint of problem (19).

**Theorem 4** *The least index pivoting rule performs exponentially on example (19).*

*Proof* We show that the simplex algorithm employing the least index pivoting rule requires  $2^n - 1$  iterations when applied to problem (19) and initialized with the basis corresponding to the sequence  $(0, \dots, 0) \in Q$ . Clearly, all the bases generated by the algorithm are distinguished i. e. for each  $i$  either  $x_{2i-1}$  or  $x_{2i}$  is basic but not both. Let  $H$  be the current distinguished tableau corresponding to the sequence  $a \in Q$ . Let also  $p$  be the smallest index such that  $\sum_{k=p}^n a_k$  is even.

Then  $h_{0,N[p]} > 0$  and, hence,  $x_{N[p]}$  is eligible. Because of the indexing of the variable in problem (19),  $N[p] = 2p$  or  $2p - 1$ . If  $q$  is another index such that  $h_{0,N[q]} > 0$  ( $\sum_{k=q}^n a_k$  is even), then  $q > p$  and, hence,  $N[q] > N[p]$ . Hence, the next basis corresponds to the immediate successor of  $a \in Q$ . This completes the proof.

### Largest Coefficient Rule

In the *largest coefficient rule* the entering variable  $x_{N[p]}$  is chosen so that

$$h_{0,N[p]} = \max \{h_{0,N[j]} : h_{0,N[j]} > 0\}.$$

This rule solves problem (7) in one iteration when the initial basis is  $(0, \dots, 0) \in Q$ .

We modify problem (7) as follows. We set

$$\begin{aligned} \epsilon &= \frac{1}{\mu}, \\ x_j &= y_j e^{2(j-1)}, \end{aligned} \tag{20}$$

and divide the  $i$ th constraint by  $\epsilon^{2(i-1)}$  and the objective function by  $\epsilon^{2(n-1)}$ . Then, problem (7) is written in the equivalent form

$$\begin{cases} \max & \sum_{j=1}^n \mu^{n-j} y_j \\ \text{s.t.} & 2 \sum_{j=1}^{i-1} \mu^{i-j} y_j + y_i \leq \mu^{2(i-1)}, \\ & i = 1, \dots, n, \\ & y_j \geq 0, \quad j = 1, \dots, n, \end{cases} \tag{21}$$

where  $\mu = 1/\epsilon \geq 3$ .

**Theorem 5** *The largest coefficient rule performs exponentially on problem (21).*

*Proof* Problem (21) is a scaled version of problem (7). Let  $x_{n+i}$  be the slack of constraint  $i$ . Then, all the results of the previous section, except those involving the RHS, hold true for problem (21). Because of relation (20),  $c_j \geq 0$  if and only if  $y_j \geq 0$ . Hence, every distinguished basis of (21) is feasible. Now, it suffices to show that the generic and the largest coefficient rule coincide when applied to problem (21). However, this statement holds because  $\mu > 1$ .

### Introduction

The *G*-group classification problem (*discriminant problem*) seeks to classify members of some population into one of *G* predefined groups based on the value of a *scoring function*  $f$  applied to a vector  $\mathbf{x} \in \mathfrak{R}^p$  of observed attributes. The scoring function is constructed using *training samples* drawn from each group. Of several criteria available for selecting a scoring function, expected accuracy (measured either in terms of frequency of misclassification or average cost of misclassification) predominates. The scoring function  $f$  can be vector-valued, but when two groups are involved it is almost always scalar-valued, and scalar functions may be used even when there are more than two groups.

As discussed in [8], statistical methods for constructing scoring functions revolve around estimating, directly or indirectly, the density functions of the distributions of the various groups. In contrast, a number of approaches have been proposed that in essence ignore the underlying distributions and simply try to classify the training samples with maximal accuracy, hoping that this accuracy carries over to the larger population. The use of mathematical programming was suggested at least as early as 1965 by Mangasarian [11]; interest in it grew considerably with the publication of a pair of papers by Freed and Glover in 1981 [3,4], which led to parallel streams of research in algorithm development and algorithm analysis.

Though nonlinear scoring functions can be constructed, virtually all research into mathematical programming methods other than support vector machines [1] restricts attention to linear functions. This is motivated largely by tractability of the mathematical programming problems, but is bolstered by the fact that the Fisher linear discriminant function, the seminal statistically derived scoring function, is regarded as a good choice under a wide range of conditions. For the remainder of this article, we assume  $f$  to be linear. Directly maximizing accuracy on the training samples dic-

tates the use of a mixed integer program to choose the scoring function (► [Mixed Integer Classification Problems](#)). The number of binary variables in such a formulation is proportional to the size of the training samples, and so computation time grows in a nonpolynomial manner as the sample sizes increase. It is therefore natural that attention turned to more computationally efficient linear programming classification models (LPCMs). Erenguc and Koehler [2] give a thorough survey of the spectrum of mathematical programming classification models as of 1989, and Stam [14] provides a somewhat more recent view of the field. Comparisons, using both “real-world” data and Monte Carlo experiments, of the accuracy of scoring functions produced by mathematical programming models with that of statistically-derived functions has produced mixed results [14], but there is evidence that LPCMs are more robust than statistical methods to large departures from normality in the population (such as populations with mixture distributions, discrete attributes, and outlier contamination).

### Models

When  $G = 2$  and  $f$  is linear and scalar-valued, classification of  $\mathbf{x}$  is based without loss of generality on whether  $f(\mathbf{x}) < 0$  or  $f(\mathbf{x}) > 0$ . (If  $f(\mathbf{x}) = 0$ ,  $\mathbf{x}$  can be assigned to either group with equal plausibility. This should be treated as a classification failure.) Barring the degenerate case  $f \equiv 0$ , the solution set to  $f(\mathbf{x}) = 0$  forms a *separating hyperplane*. Ideally, though not often in practice, each group resides within one of the half-spaces defined by that hyperplane. An early precursor to linear programming models, the *perceptron algorithm* [12], constructs an appropriate linear classifier in finite time when the samples are separable, but can fail if the samples are not separable.

There being no way to count misclassifications in an optimization model without introducing integer variables, LPCMs must employ a surrogate criterion. A variety of criteria have been tried, all revolving around measurements of the displacement of the sample points from the separating hyperplane. Let  $f(\mathbf{x}) = \mathbf{w}'\mathbf{x} + w_0$  for some non-null coefficient vector  $\mathbf{w} \in \mathfrak{R}^p$  and some scalar  $w_0$ . The euclidean distance from  $\mathbf{x}$  to the separating hyperplane is easily shown to be  $|f(\mathbf{x})| / \|\mathbf{w}\|$ . So the value of the scoring function at each training observa-

tion measures (to within a scalar multiple) how far the observation falls from the separating hyperplane. That distance is in turn identified as either an *internal deviation* or an *external deviation* depending on whether the observation falls in the correct or incorrect half-space. Figure 1 illustrates both types of deviation.

The “hybrid” model of Glover et al. [6] is sufficiently flexible to capture the key features of most two-group models. Let  $\mathbf{X}_g$  be an  $N_g \times p$  matrix of training observations from group  $g$ , and let  $\mathbf{0}$  and  $\mathbf{1}$  denote vectors of appropriate dimension, all of whose components are 0 and 1 respectively. The core of the hybrid model, to be expanded later, is:

$$\begin{aligned} \min \sum_{g=1}^2 (\alpha_g \cdot \mathbf{1}' \mathbf{e}_g - \beta_g \cdot \mathbf{1}' \mathbf{d}_g + \gamma_g e_{g0} - \delta_g d_{g0}) \\ \text{s.t. } \mathbf{X}_1 \mathbf{w} + w_0 \cdot \mathbf{1} + \mathbf{d}_1 - \mathbf{e}_1 + d_{10} \cdot \mathbf{1} - e_{10} \cdot \mathbf{1} \leq \mathbf{0} \\ \mathbf{X}_2 \mathbf{w} + w_0 \cdot \mathbf{1} - \mathbf{d}_2 + \mathbf{e}_2 - d_{20} \cdot \mathbf{1} + e_{20} \cdot \mathbf{1} \geq \mathbf{0} \\ \mathbf{w}, w_0 \text{ free; } \mathbf{d}_g, \mathbf{e}_g, d_{g0}, e_{g0} \geq 0. \end{aligned}$$

Variables  $\mathbf{d}_g$  and  $\mathbf{e}_g$  are intended to capture the internal and external deviations respectively of individual observations from group  $g$ , while  $e_{g0}$  and  $d_{g0}$  are intended to capture the maximum (or minimum) external and internal deviations respectively across the sample from group  $g$ . (The original hybrid model had  $d_{10} = d_{20}$  and  $e_{10} = e_{20}$ , which is unnecessarily restrictive.) The intent of Glover *et al.* in presenting the hybrid model was to subsume a number of previously proposed models, and so the hybrid model should be viewed as a framework. When applied, not all of the deviation variables need be present. For example, omission of  $\mathbf{e}_g$  and  $\mathbf{d}_g$  would yield a version of the “MMD” model [2], with  $e_{g0}$

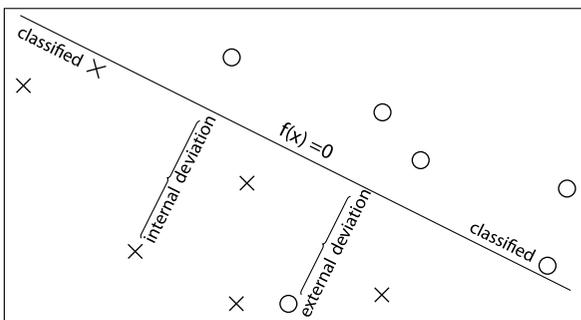

the worst external deviation of any group  $g$  observation if any is misclassified (in which case  $d_{g0} = 0$ ) and  $d_{g0}$  the minimum internal deviation of any group  $g$  observation if none is misclassified (in which case  $e_{g0} = 0$ ). On the other hand, omission of  $e_{g0}$  and  $d_{g0}$  results in a variation of the “MSID” model [2], with the objective function penalizing individual external deviations ( $\mathbf{e}_g$ ) and rewarding individual internal deviations ( $\mathbf{d}_g$ ). The nonnegative objective coefficients  $\alpha_g, \beta_g, \gamma_g, \delta_g$  must be chosen so that the penalties for external deviations exceed the rewards for internal deviations; otherwise, the linear program becomes unbounded, as adding an equal amount to both  $e_{gn}$  and  $d_{gn}$  improves the objective value.

**Pathologies**

Due to their focus on minimizing error count, mixed integer classification models tend to be feasible (the trivial function  $f \equiv 0$  is often a feasible solution) and bounded (one cannot do better than zero misclassifications). LPCMs, in contrast, tend to be “naturally” feasible but may require explicit bounding constraints. If the training samples are perfectly separable, a solution exists to the partial hybrid model with  $e_{gn} = 0$  for all  $g$  and  $n$  and  $d_{gn} > 0$  for some  $g$  and  $n$ ; any positive scalar multiple of that solution is also feasible, and so the objective value is unbounded below. One way to correct this is to introduce bounds on the coefficients of the objective function, say

$$-1 \leq \mathbf{w} \leq +1.$$

Another potential problem has to do with what is variously referred to as the “trivial” or “unacceptable” solution, namely  $f \equiv 0$ . Consider the partial hybrid model above. The trivial solution (all variables equal to zero) is certainly feasible, with objective value zero. Given the requirement that the objective coefficients of external deviation variables dominate those of internal deviation variables, any solution with a negative objective value must perfectly separate the training samples. Contrastively, then, if the training samples cannot be separated, the objective value cannot be less than zero, in which case the trivial solution is in fact optimal. This is undesirable: the trivial function does not classify anything. The trick is to make the trivial solution suboptimal. Some authors try to accomplish this by fixing the

**Linear Programming Models for Classification, Figure 1**  
Two-Group Problem with Linear Classifier

constant term  $w_0$  of the classification function at some nonzero value (typically  $w_0 = 1$ ). The trivial discriminant function  $\mathbf{w} = \mathbf{0}$  with nonzero constant term now misclassifies one group completely, and is unlikely to be the model's optimal solution even when the training samples cannot be separated. There is the possibility, however, that the best linear classifier has  $w_0 = 0$ , in which case this approach dooms the model to finding an inferior solution.

Other approaches include various attempts to make  $\mathbf{w} = \mathbf{0}$  infeasible, such as adding the constraint  $\|\mathbf{w}\| = 1$ . Unfortunately, trying to legislate the trivial solution out of existence results in a nonconvex feasible region, destroying the computational advantage of linear programming. Yet another strategy for weeding out trivial solutions is the introduction of a so-called *normalization* constraint. The normalization constraint proposed by Glover et al. for the hybrid model is

$$\sum_{g=1}^2 \sum_{n=0}^{N_g} d_{gn} = 1.$$

Various pathologies have been connected to injudicious use of normalization constraints [9,10,13], including: unboundedness; trivial solutions; failure of the resulting discriminant function to adapt properly to rescaling or translation of the data (the optimal discriminant function after scaling or translating the data should be a scaled or translated version of the previously optimal discriminator, and the accuracy should be unchanged); and failure to find a discriminant function with perfect accuracy on the training samples when, in fact, they can be separated (which suggests that the discriminant function found will have suboptimal accuracy on the overall population). Indeed, Glover later changed the normalization of the hybrid model to [5]

$$-N_2 \cdot \mathbf{1}'\mathbf{X}_1\mathbf{w} + N_1 \cdot \mathbf{1}'\mathbf{X}_2\mathbf{w} = 1$$

to avoid some of these pathologies.

### Multiple Group Problems

The use of a scalar-valued scoring function in an LPCM with  $G > 2$  groups requires the a priori imposition of both a specific ordering and prescribed interval widths on the scores of the groups. This being impractical, attention turns to vector-valued functions. Whether us-

ing methods based on statistics or mixed integer programming, a common approach to the multiple group problem is to develop a separate scoring function for each group, and assign observations to the group whose scoring function yields the largest value at that observation. The linear programming analog would be to reward amounts by which the score  $f_i(\mathbf{x})$  of an observation  $\mathbf{x}$  from group  $i$  exceeds each  $f_j(\mathbf{x}), j \neq i$  (or  $\max_{j \neq i} f_j(\mathbf{x})$ ) and penalize differences in the opposite direction. This induces a proliferation of deviation variables (on the order of  $(G-1) \sum_{g=1}^G N_g$ ). Other approaches may construct discriminant functions for all pairs of groups, or for each group versus all others, and then using a "voting" procedure to classify observations [15].

A good example of the use of a vector-valued scoring function is the work of Gochet et al. [7]. They begin with one scoring function per group, and in cases where two of those functions wind up identical, add additional functions to serve as tie-breakers. Their model is:

$$\begin{aligned} \min & \sum_{g=1}^G \sum_{g \neq h=1}^G \mathbf{1}'\mathbf{e}_{gh} \\ \text{s.t. } & \mathbf{X}_g(\mathbf{w}_g - \mathbf{w}_h) + (w_{g0} - w_{h0}) \cdot \mathbf{1} + \mathbf{e}_{gh} - \mathbf{d}_{gh} = \mathbf{0} \\ & \sum_{g=1}^G \sum_{g \neq h=1}^G \mathbf{1}'(\mathbf{d}_{gh} - \mathbf{e}_{gh}) = q \\ & \mathbf{w}_g, w_{g0} \text{ free; } \mathbf{d}_{gh}, \mathbf{e}_{gh} \geq \mathbf{0}. \end{aligned}$$

The scoring function corresponding to group  $g$  is  $f_g(\mathbf{x}) = \mathbf{w}'_g\mathbf{x} + w_{g0}$ . "Internal" and "external" deviations now represent amounts by which the scores of observations generated by the correct functions exceed or fall short of their scores from functions belonging to other groups. The first constraint is repeated for every pair of groups  $g, h = 1, \dots, G, g \neq h$ . The second constraint, in which  $q$  is an arbitrary positive constant, is a normalization constraint intended to render infeasible both the trivial solution (all  $\mathbf{w}_g$  identical) and solutions for which the total of the external deviations exceeds that of the internal deviations. If  $\mathbf{w}_g = \mathbf{w}_h$  and  $w_{g0} = w_{h0}$  for some  $g \neq h$ , the model is applied recursively to the subsamples from only those groups (possibly more than just  $g$  and  $h$ ) that yielded identical scoring functions. The additional functions generated are used as tie-breakers.

## Methods

The number of constraints in an LPCM approximately equals the number of training observations, while the number of variables can range from slightly more than the number of attributes to slightly more than the sum of the number of observations and the number of attributes, depending on which deviation variables are included in the model. In practice, the number of observations will exceed the number of attributes; indeed, if the difference is not substantial, the model runs the risk of overfitting the scoring function (in the statistical sense). When the number of deviation variables is small, then, the LPCM tends to have considerably more constraints than variables, and a number of authors have suggested solving its dual linear program instead, to reduce the amount of computation. Improvements in both hardware and software have lessened the need for this, but it may still be useful when sample sizes reach the tens or hundreds of thousands (which can happen, for example, when rating consumer credit, and in some medical applications).

Linear algebra

Let  $F$  be a field, whose elements are referred to as *scalars*. A *linear space*  $V$  over  $F$  is a nonempty set on which the operations of addition and scalar multiplication are defined. That is, for any  $x, y \in V$ , we have  $x + y \in V$ , and for any  $x \in V$  and  $\alpha \in F$  we have  $\alpha x \in V$ . Furthermore, the following properties must be satisfied:

- 1)  $x + y = y + x, \forall x, y \in V$ .
- 2)  $(x + y) + z = x + (y + z), \forall x, y, z \in V$ .
- 3) There exists an element  $0 \in V$ , such that  $x + 0 = x, \forall x \in V$ .
- 4)  $\forall x \in V$ , there exists  $-x \in V$  such that  $x + (-x) = 0$ .
- 5)  $\alpha(x + y) = \alpha x + \alpha y, \forall \alpha \in F, \forall x, y \in V$ .
- 6)  $(\alpha + \beta)x = \alpha x + \beta x, \forall \alpha, \beta \in F, \forall x \in V$ .

- 7)  $(\alpha\beta)x = \alpha(\beta x), \forall \alpha, \beta \in F, \forall x \in V.$   
 8)  $1x = x, \forall x \in V.$

The elements of  $V$  are called *vectors*, and  $V$  is also called a *vector space*.

Approximation problem; Minimum distance problem; Best approximation; Best estimate; Selection; Continuous selection operator; Lipschitzian selection operator; Bounded function; Continuous function; Uniform norm; Quasiconvex function; Convex function; Isotone functions; Majorants and minorants

Stated in simplest terms, this article considers, in an abstract mathematical framework, a curve fitting or estimation problem where a given set of data points  $f$  is approximated or estimated by an element from a set  $K$  so that the estimate of  $f$  is least affected by perturbations in  $f$ .

Let  $X$  be a normed linear space with norm  $\|\cdot\|$  and  $K$  be any (not necessarily convex) nonempty subset of  $X$ . For any  $f$  in  $X$ , let

$$d(f, K) = \inf \{\|f - h\| : h \in K\} \quad (1)$$

denote the shortest distance from  $f$  to  $K$ . Let also, for  $f$  in  $X$ ,

$$P(f) = P_K(f) = \{h \in K : \|f - h\| = d(f, K)\}.$$

The set-valued mapping  $P$  on  $X$  is called the *metric projection* onto  $K$ . It is also called the *nearest point mapping*, *best approximation operator*, *proximity map*, etc. If  $P(f) \neq \emptyset$ , then each element in it is called a *best approximation* to (or a *best estimate* of)  $f$  from  $K$ . In practical curve fitting or estimation problems,  $f$  represents the given data and the set  $K$  is dictated by the underlying process that generates  $f$ . Because of random disturbance or noise,  $f$  is in general not in  $K$ , and it is required to estimate  $f$  by an element of  $K$ . See [7,12] and other references given there for a discussion of such problems and the use of various norms or distance functions in approximation. An approximation problem or a minimum distance problem such as (1) involves finding a best approximation, investigating its uniqueness and other properties, and developing algorithms for its computation. If  $P(f) \neq \emptyset$  (respectively,  $P(f)$  is a singleton) for each  $f \in X$ , then  $K$  is called *proximal* (respectively, *Chebyshev*).

If  $K$  is proximal, then we define a *selection operator*, or simply a *selection*, to be any (single valued) function  $T$  on  $X$  into  $K$  so that  $T(f) \in P(f)$  for every  $f \in X$ . If  $K$  is Chebyshev, then clearly  $T = P$  and  $T$  is unique. A *continuous selection operator* is a selection  $T$  which is continuous. There is a vast literature available on the existence and properties of continuous selections including some survey papers. See, e. g., [1,2,3,6,8] and other references given there. A more difficult problem is finding a *Lipschitzian selection operator* (LSO) i. e., a selection  $T$  which satisfies

$$\|T(f) - T(h)\| \leq c(T) \|f - h\|, \quad \text{all } f, h \in X, \quad (2)$$

where  $c(T)$  (a positive constant depending upon  $T$ ) is the smallest value satisfying (2). An LSO  $T$  is called an *optimal Lipschitzian selection operator* (OLSO) if  $c(T) \leq c(T')$  for all LSO  $T'$ . If the operator  $T$  in (2) is OLSO, then (2) shows that the estimate  $T(f)$  of  $f$  is least sensitive to changes in the given data  $f$ . Consequently,  $T(f)$  is the most desirable estimate of  $f$ . The concept of an OLSO was introduced in [12] and the existence of an LSO and OLSO was investigated in [13,14,15,16,17]. If  $X$  is a Hilbert space and  $K \subset X$  is nonempty, closed and

convex, then  $K$  is Chebyshev. Then  $T$ , which maps  $f$  to its unique best approximation, is an LSO, i. e.,  $T$  satisfies (2) with  $c(T) = 1$ . For a proof see [5, p. 100]. Since  $T$  is unique, it is also trivially OLSO. For other spaces, the results are not so straightforward.

In this paper we present several results which identify LSOs and OLSOs in approximation problems on the space of bounded or continuous functions. We illustrate these results by examples.

### Lipschitzian Selection Operators

Let  $S$  be any set and  $B$  denote the Banach space of real bounded functions  $f$  on  $S$  with the uniform norm  $\|f\| = \sup\{|f(s)|: s \in S\}$ . Similarly, when  $S$  is topological, denote by  $C = C(S)$ , the space of real bounded and continuous functions on  $S$ , again, with the uniform norm  $\|\cdot\|$ . Let  $X = B$  or  $C$  in what follows. We let  $f \in X$ ,  $K \subset X$  and  $d(f, K)$  as above. We let  $d(f) = d(f, K)$  for convenience. For  $f$  in  $X$ , define  $K_f = \{k \in K: k \leq f\}$  and  $K'_f = \{k \in K: k \geq f\}$ . Let

$$\begin{aligned}\bar{f}(s) &= \sup \{k(s): k \in K_f\}, \quad s \in S, \\ \underline{f}(s) &= \inf \{k(s): k \in K'_f\}, \quad s \in S.\end{aligned}$$

We state three conditions below, they are identical for  $X = B$  or  $C$ .

- 1) If  $k \in K$ , then  $k + c \in K$  for all real  $c$ .
- 2) If  $f \in X$ , then  $\bar{f} \in K$ .
- 3) If  $f \in X$ , then  $\underline{f} \in K$ .

If  $\bar{f}$  and  $\underline{f}$  are in  $K$ , then they are called the *greatest  $K$ -minorant* and the *smallest  $K$ -majorant* of  $f$ , respectively. Note that condition 2) (respectively, 3)) implies that the pointwise maximum (respectively, minimum) of any two functions in  $K$  is also in  $K$ . This can be easily established by letting  $f = \max\{f_1, f_2\}$  (respectively,  $f = \min\{f_1, f_2\}$ ) where  $f_1, f_2 \in K$ . We call a  $g \in K$  the *maximal* (respectively, *minimal*) *best approximation* to  $f \in X$  if  $g \geq g'$  (respectively, if  $g \leq g'$ ) for all best approximations  $g'$  to  $f$ .

**Theorem 1** Consider (1) with  $X = B$  or  $C$ , and any  $K \subset X$ .

- a) Assume  $K$  is not necessarily convex. Suppose that conditions 1) and 2) hold for  $K$ . Then  $d(f) = \|f - \bar{f}\|/2$  and  $f' = \bar{f} + d(f)$  is the maximal best approximation to  $f$ . Also  $\|f' - h'\| \leq 2\|f - h\|$  for

all  $f, h \in X$ . The operator  $T$  defined  $T(f) = f'$  is an LSO with  $c(T) = 2$ .

- b) Assume  $K$  is not necessarily convex. Suppose that conditions 1) and 3) hold for  $K$ . Then a) holds with  $\bar{f}$  replaced by  $\underline{f}$  and with  $f' = \underline{f} - d(f)$ , which is the minimal best approximation to  $f$ .
- c) Assume  $K$  is convex. Suppose that conditions 1), 2) and 3) hold for  $K$ . Then a) and b) given above apply. In addition,  $d(f) = (\|f - \bar{f}\|)/2$ . A  $g$  in  $K$  is a best approximation to  $f$  if and only if  $\underline{f} - d(f) \leq g \leq \bar{f} + d(f)$ . Moreover, if  $f' = (\underline{f} + \bar{f})/2$ , then  $f'$  is a best approximation to  $f$  and  $\|f' - h'\| \leq \|f - h\|$  for all  $f, h \in X$ . The operator  $T$  defined by  $T(f) = f'$  is an OLSO with  $c(T) = 1$ .

The following theorem shows that the existence of a maximal (respectively, minimal) best approximation to (1) implies condition 2) (respectively, 3)).

**Theorem 2** Consider (1) with  $X = B$  or  $C$ , and any  $K \subset X$ . Assume condition 1) holds for  $K$ . Assume that the pointwise maximum (respectively, minimum) of two function in  $K$  is also in  $K$ . Then condition 2) (respectively, 3)) holds if the maximal (respectively, minimal) best approximation to  $f$  exists. This best approximation then equals  $\bar{f} + d(f)$  (respectively,  $\underline{f} - d(f)$ ).

The above theorems and the next one appear in [14,15]. Their proofs are available there. We now define another approximation problem, closely related to (1). Let

$$\bar{d}(f) = d(f, K_f) = \inf \{\|f - h\| : h \in K_f\}. \quad (3)$$

The problem is to find a  $g \in \{h \in K_f : \|f - h\| = d(f, K_f)\}$ , called a *best approximation* to  $f$  from  $K_f$ .

**Theorem 3** Consider (3) with  $X = B$  or  $C$ , and any  $K \subset X$  which is not necessarily convex.

- a) Suppose that conditions 1) and 2) hold for  $K$ . Then  $\bar{f}$  is the maximal best approximation to  $f$  and  $\bar{d}(f) = \|f - \bar{f}\| = 2d(f)$ . The operator  $T$  defined by  $T(f) = \bar{f}$  is the unique OLSO with  $c(T) = 1$ .
- b) Assume condition 1) holds for  $K$ . Assume that the pointwise maximum of two functions in  $K$  is also in  $K$ . Then condition 2) holds if the maximum best approximation to  $f$  exists. This best approximation then equals  $\bar{f}$ .

### Examples and Applications

*Example 4 (Approximation by quasiconvex functions.)* Let  $S \subset \mathbf{R}^n$  be nonempty convex and consider  $B = B(S)$ . For  $C = C(S)$  assume  $S$  is nonempty, compact and convex. A function  $h \in B$  is called *quasiconvex* if

$$h(\lambda s + (1 - \lambda)t) \leq \max\{h(s), h(t)\}, \tag{4}$$

for all  $s, t \in S, \quad 0 \leq \lambda \leq 1$ .

Equivalently,  $h$  in  $B$  is quasiconvex if one of the following conditions holds [9,10]:

- $\{h \leq c\}$  is convex for all real  $c$ ;
- $\{h < c\}$  is convex for all real  $c$ .

Let  $K$  be the set of all quasiconvex functions in  $B$ . It is easy to show that  $K$  and  $K \cap C$  are closed cones which are not convex and both satisfy condition 1) above ( $K$  is a cone if  $\lambda h \in K$  whenever  $h \in K$  and  $\lambda \geq 0$ ). The greatest  $K$ -minorant of  $f$  is called the *greatest quasiconvex minorant* of  $f$ . Using (4) it is easy to show that if  $f \in B$  then such a minorant  $\bar{f}$  exists in  $B$ . The next proposition shows that if  $f \in C$  then  $\bar{f} \in C$ .

Let  $\Pi$  be the set of all convex subsets of  $S$ . Clearly,  $\varphi, S \in \Pi$ . For any  $A \subset \mathbf{R}^n$ , we denote by  $\text{co}(A)$  the *convex hull* of  $A$ , i. e., the smallest convex set containing  $A$ .

**Proposition 5** *Let  $f \in X$  and let*

$$f^0(P) = \inf \{f(t) : t \in S \setminus P\}, \quad P \in \Pi,$$

$$\bar{f}(s) = \sup \{f^0(P) : P \in \Pi, s \in S \setminus P\}, \quad s \in S.$$

*Then the following holds:*

- If  $f \in B$  (respectively,  $C$ ) then  $\bar{f} \in B$  (respectively,  $C$ ) and is quasiconvex. It is the greatest quasiconvex minorant of  $f$ .
- An  $h \in B$  is the greatest quasiconvex minorant of  $f \in B$  if and only if

$$\{h < c\} = \text{co}\{f < c\} \quad \text{for all real } c. \tag{5}$$

- An  $h \in B$  is the greatest quasiconvex minorant of  $f \in C$  if and only if (5) holds or, equivalently,  $\{h \leq c\} = \text{co}\{h \leq c\}$  for all real  $c$ .

This proposition and its proof appear in [15]. The proposition shows that condition 2) holds for  $K$  and  $K \cap C$ . Hence, Theorems 1a) and 3a) apply to  $X = B$  and  $K$ , and also to  $X = C$  and  $K \cap C$ . In particular, Theorem 1a) shows that in each of these two cases the operator  $T$

mapping  $f$  to  $\bar{f}$  is LSO with  $c(T) = 2$ . Now the example given in [13, p. 332] shows that  $T$  is OLSO.

*Example 6 (Approximation by convex functions.)* Let  $S \subset \mathbf{R}^n$  be nonempty convex and consider  $B = B(S)$ . A function  $h \in B$  is called *convex* if  $h(\lambda s + (1 - \lambda)t) \leq \lambda h(s) + (1 - \lambda)h(t)$ , for all  $s, t \in S$  and all  $0 \leq \lambda \leq 1$ . Clearly, a convex function is quasiconvex. Let  $K$  be the set of all convex functions in  $B$ . It is easy to show that  $K$  is a closed convex cone and satisfies condition 1). The greatest  $K$ -minorant of  $f$  is called the *greatest convex minorant* of  $f$ . It follows at once from the definition of a convex function that if  $f \in B$  then such a minorant  $\bar{f}$  exists in  $B$ . Condition 2) therefore holds for  $K$ . Hence, Theorems 1a) and 3a) apply to  $X = B$  and  $K$ . In particular, the LSO  $T$  of Theorem 1a) mapping  $f$  to  $\bar{f}$  with  $c(T) = 2$  can be shown to be an OLSO by using an example as in [13, p. 334].

Now consider approximation of a continuous function by continuous convex functions. For this case we let  $S \subset \mathbf{R}^n$  be a polytope which is defined to be the convex hull of a finitely many points in  $\mathbf{R}^n$ . It is compact, convex and locally simplicial [11]. Let  $K \subset C = C(S)$  be the set of continuous convex functions. It is easy to show that  $K$  is a closed convex cone. Again condition 1) holds for  $K$ . We assert that if  $f \in C$ , then  $\bar{f}$  is convex and continuous. This will establish that  $\bar{f}$  is the greatest convex minorant of  $f$ . To establish the assertion note that  $\bar{f}$  is convex since it is the pointwise supremum of convex functions. Since  $S$  is locally simplicial, [11, Corol. 17.2.1; Thm. 10.2] show that  $\bar{f}$  is continuous on  $S$ . Thus, condition 2) holds for  $K$ . Hence Theorems 1a) and 3a) apply to  $X = C$  and  $K$ . In particular, the LSO  $T$  of Theorem 1a) mapping  $f$  to  $\bar{f}$  with  $c(T) = 2$  can be shown to be an OLSO by using the same example as in the bounded case above since the sequence used in that example consists of continuous functions [13].

*Example 7 (Approximation by isotone functions.)* Let  $S$  be any set with partial order  $\leq$ . A *partial order* is a relation  $\leq$  on  $S$  satisfying [4, p. 4]:

- *reflexivity*, i. e.,  $s \leq s$  for all  $s \in S$ ; and
- *transitivity*, i. e., if  $s, t, v \in S$ , and  $s \leq t$  and  $t \leq v$ , then  $s \leq v$ .

A partial order is *antisymmetric* if  $s \leq t$  and  $t \leq s$  imply  $s = t$ . We do not include this antisymmetry condition in the partial order for sake of generality. We consider  $B = B(S)$  as before, and define a function  $k$  in  $B$  to be *isotone*

if  $k(s) \leq k(t)$  whenever  $s, t \in S$  and  $s \leq t$ . Let  $K \subset B$  be the set of all isotone functions. It is easy to see that  $K$  is a closed convex cone. It is nonempty since the zero function is in  $K$ . It is easy to verify that conditions 1), 2) and 3) apply to  $K$ . Thus the greatest isotone minorant  $\underline{f}$  and the smallest isotone majorant  $\overline{f}$  of an  $f$  in  $B$  exist. Theorem 1c) and 3a) apply and we conclude that the operator  $T$  of Theorem 1c), mapping  $f$  to  $(\underline{f} + \overline{f})/2$ , is OLSO with  $c(T) = 1$  [15].

The next proposition gives explicit expressions for  $\underline{f}$  and  $\overline{f}$ . We call a subset  $E$  of  $S$  a *lower* (respectively, *upper*) set if whenever  $t \in E$  and  $v \leq t$  (respectively,  $t \leq v$ ), then  $v \in E$ . For  $s$  in  $S$ , let  $L_s = \{t \in S, t \leq s\}$  and  $U_s = \{t \in S, s \leq t\}$ . Then,  $L_s$  (respectively,  $U_s$ ) is the smallest lower (respectively, upper) set containing  $s$ , as may be easily seen.

**Proposition 8**

$$\underline{f}(s) = \sup \{f(t) : t \in L_s\},$$

$$\overline{f}(s) = \inf \{f(t) : t \in U_s\}.$$

For a proof, see [15].

Now we consider an application to  $C$ . Define  $S = \times \{[a_i, b_i] : 1 \leq i \leq n\} \subset \mathbf{R}^n$ , where  $a_i < b_i$ , and let  $\leq$  be the usual partial order on vectors. Let  $C = C(S)$  and let  $K$  be the set of isotone functions in  $C$ . It is easy to verify that  $K$  is a closed convex cone. Furthermore, if  $f \in C$ , then  $\underline{f}, \overline{f} \in C$ . We conclude, as before, that Theorems 1c) and 3a) apply. Various generalizations of this problem exist. See, for example, [12, Sect. 5], [15, Ex. 4.3], and [17].

As was observed in [16], the dual cone of  $K$  plays an important role in duality and approximation from  $K$ . Some properties of the cone  $K$  of isotone functions on a finite partially ordered set  $S$  and its dual cone are obtained in [18].

Parallel algorithm; Load balancing; Tree search; Graph search

Discrete optimization problems are solved using a variety of state space search techniques. The choice of technique is influenced by a variety of factors such as availability of heuristics and bounds, structure of state space, underlying machine architecture, availability of memory, and optimality of desired solution. The computational requirements of these techniques necessitates the use of large scale parallelism to solve realistic problem instances. In this chapter, we discuss parallel processing issues relating to state space search.

Parallel platforms have evolved significantly over the past two decades. Symmetric multiprocessors (SMPs), tightly coupled message passing machines, and clusters of workstations and SMPs have emerged as the dominant platforms. From an algorithmic standpoint, the key issues of locality of data reference and load balancing are key to effective utilization of all these platforms. However, message latencies, hardware support for shared address space and mutual exclusion, communication bandwidth, and granularity of parallelism all play important roles in determining suitable parallel formulations. A variety of metrics have also been developed to evaluate the performance of these formulations. Due to the nondeterministic nature of the computation, traditional metrics such as parallel runtime and speedup are difficult to quantify analytically. The scalability metric, Isoefficiency, has been used with excellent results for analytical modeling of parallel state space search.

The state spaces associated with typical optimization problems can be fashioned in the form of either a graph or a tree. Exploiting concurrency in graphs is more difficult compared to trees because of the need

for replication checking. The availability of heuristics for best-first search imposes constraints on parallel exploration of states in the state space. For the purpose of parallel processing, we can categorize search techniques loosely into three classes: *depth-first tree search techniques* (a tree search procedure in which the deepest of the current nodes is expanded at each step), *best-first tree search techniques* (a tree search procedure in which nodes are expanded based on a global (heuristic) measure of how likely they are to lead to a solution), and *graph search techniques* (a search requiring additional computation for checking if a node has been encountered before, since a node can be reached from multiple paths). Many variants of these basic schemes fall into each of these categories as well.

## Parallel Depth-First Tree Search

Search techniques in this class include ordered depth-first search, iterative deepening A\* (IDA\*), and depth—first branch and bound (DFBB). In all of these techniques, the key ingredient is the depth-first search of a state space (cost-bounded in the case of IDA\* and DFBB). DFS was among the first applications explored on early parallel computers. This is due to the fact that DFS is very amenable to parallel processing. Each subtree in the state space can be explored independently of other subtrees in the space. In simple DFS, there is no exchange of information required for exploring different subtrees. This implies that it is possible to devise simple parallel formulations by assigning a distinct subtree to each processor. However, the space associated with a problem instance can be highly unstructured. Consequently, the work associated with subtrees rooted at different nodes can be very different. Therefore, a naive assignment of a subtree rooted at a distinct node to each processor can result in considerable idling overhead and poor parallel performance. The problem of designing efficient parallel DFS algorithms can be viewed in two steps: the partitioning problem and the assignment problem. The partitioning problem addresses the issue of breaking up a given search space into two subspaces. The assignment problem then maps subspaces to individual processors.

There are essentially two techniques for partitioning a given search space: node splitting and stack splitting. In node splitting, the root node of a subtree is expanded

to generate a set of successor nodes. Each of these nodes represents a distinct subspace. While node splitting is easy to understand and implement, it can result in search spaces of widely varying sizes. Since the objective of the assignment problem is to balance load while minimizing work transfers, widely varying subtask sizes are not desirable. An alternate technique called stack splitting attempts to partition a search space into two by assigning some nodes at all levels leading up to the specified node. Thus if the current node is at level 4, stack splitting will split the stack by assigning some nodes at levels 1, 2, and 3 to each partition. In general, stack splitting results in a more even partitioning of search spaces than node splitting.

We can now formally state the assignment problem for parallel DFS as a mapping of subtasks to processors such that:

- the work available at any processor can be partitioned into independent work pieces as long as it is more than some nondecomposable unit;
- the cost of splitting and transferring work to another processor is not excessive (i. e. the cost associated with transferring a piece of work is much less than the computation cost associated with it);
- a reasonable work splitting mechanism is available; i. e., if work  $w$  at one processor is partitioned in 2 parts  $\psi w$  and  $(1 - \psi)w$ , then  $1 - \alpha > \psi > \alpha$ , where  $\alpha$  is an arbitrarily small constant;
- it is not possible (or is very difficult) to estimate the size of total work at a given processor.

A number of mapping techniques have been proposed and analyzed in literature [5,7,8,9,11,16]. These mapping techniques are either initiated by a processor with work (*sender initiated*, the processor with work initiates the work transfer) or a processor looking for work (*receiver initiated*, an idle processor initiates the work transfer). In the *global round robin request* (GRR, idle processors in the global round robin scheme request processors for work in a round-robin fashion using a single (global) counter) receiver initiated scheme, a single counter specifies the processor that must receive the next request for work. This ensures that work requests are uniformly distributed across all processors. However, this scheme suffers from contention at the processor holding the counter. Consequently, the performance of this scheme is poor beyond a certain number of processors. A message combining variant of this

scheme (*GRR-M*, a variant of the global round robin scheme in which requests for value of global counter are combined to alleviate contention overheads) relies on combining intermediate requests for the counter into single request. This alleviates the contention and performance bottleneck of the GRR scheme. The *asynchronous round robin balancing* (ARR, i. e. each processor selects a target for work request in a round robin manner using a local counter) uses one counter at each processor. Each processor uses its counter to determine the next processor to query for work. While this scheme balances work requests in a local sense, these requests may become clustered in a global sense. In the *random polling scheme* (RP, i. e. idle processors send work requests to a randomly selected target processor), each processor selects a random processor and requests work. In *near-neighbor load balancing scheme* (NN, i. e. an idle processor requests one of its immediate neighbors for work), processors request work from their immediate neighbors. This scheme has the drawback that localized hot-spots may take a long time to even out.

In sender initiated schemes a processor with work can give some of its work to a selected processor [6,16]. This class of schemes includes the master-slave (MS) and randomized allocation (RA) schemes. In the *MS scheme*, a processor, designated master, generates a fixed number of work pieces. These work-pieces are assigned to processors as they exhaust previously assigned work. The master may itself become the bottleneck when the number of processors is large. Multilevel master-slave algorithms have been used to alleviate this bottleneck. *Randomized allocation schemes* are sender initiated counterparts of RP schemes. In randomized allocation, a processor sends a part of its work to a randomly selected processor.

The performance and scalability of these techniques is often dependent on the underlying architecture. Many of these techniques are, in principle scalable, i. e., they result in linear speedup on increasing the number of processors  $p$  as long as the size of the search space grows fast enough with  $p$ . It is desirable that this required rate of growth of problem size (also referred to as the iso-efficiency metric [10]) be as small as possible since it allows the use of a larger number of processors effectively for solving a given problem instance. In Table 1, we summarize the iso-efficiency functions of various load balancing techniques.

**Scalability results of receiver initiated load balancing schemes for various architectures**

Arch Scheme	Shared	H-cube	Mesh (2D)	W/S Cluster
ARR	$p^2 \log p$	$p^2 \log^2 p$	$p^{2.5} \log p$	$p^3 \log p$
NN	$p^2 \log p$	$p^{\log \frac{1+\alpha}{2}}$	$k\sqrt{p}$	$p^3 \log p$
GRR	$p^2 \log p$	$p^2 \log p$	$p^2 \log p$	$p^2 \log p$
GRR-M	$p \log p$	$p \log^2 p$	$p^{1.5} \log p$	
RP	$p \log^2 p$	$p \log^2 p$	$p^{1.5} \log^2 p$	$p^2 \log^2 p$
Lower Bound	$p$	$p \log p$	$p^{1.5}$	$p^2$

IDA\* and DFBB search techniques use this basic parallel DFS algorithm for searching state space. In IDA\*, each processor has a copy of the global cost bound. Processors perform parallel DFS with this cost bound. At the end of each phase, the cost is updated using a single global operation. Some schemes for allowing different processors to work with different cost bound have also been explored. In this case, a solution cannot be deemed optimal until search associated with all previous cost bounds has been completed. DFBB technique uses a global current best solution to bound parallel DFS. Whenever a processor finds a better solution, it updates this global current best solution (using a broadcast in message passing machines and a lock-set in shared memory machines). DFBB and IDA\* using these parallel DFS algorithms has been shown to yield excellent performance for various optimization problems [3,13,19].

In many optimization problems, the successors of nodes tend to be strongly ordered. In such cases, naive parallel formulations that ignore this ordering information will perform poorly since they are likely to expand a much larger subspace than those that explore nodes in the right order. Parallel DFS formulations for such spaces associate priorities with nodes. Nodes with largest depth and highest likelihood of yielding a solution are assigned the highest priority. Parallel ordered DFS then expands these nodes in a prioritized fashion.

### Parallel Best-First Tree Search

Best-first tree search algorithms rely on an *open list* (i. e. a list of unexplored configurations sorted on their qual-

ity) to sort available states on the basis of their heuristic solution estimate. If this heuristic solution estimate is guaranteed to be an underestimate (as is the case in the A\* algorithm), it can be shown that the solution found by BFS is the optimal solution. The presence of a globally ordered open list makes it more difficult to parallelize BFS. In fact, at the first look, BFS may appear inherently serial since a node with higher estimated solution cost must be explored only after all nodes with lower costs have been explored. However, it is possible that there may be multiple nodes with the best heuristic cost. If the number of such nodes is less than the number of available processors, then some of the nodes with poorer costs may also be explored. Since it is possible that these nodes are never explored by the serial algorithm, this may result in excess work by the parallel formulation resulting in deceleration anomalies. These issues of speedup anomalies resulting from excess (or lesser) work done by the parallel formulations of state space search are discussed later.

A simple parallel formulation of BFS uses a global open list. Each processor locks the list, extracts the best available node and unlocks the list. The node is expanded and heuristic estimates are determined for each successor. The open list is locked again and all successors are inserted into the open list. Note that since the state space is a tree, no replication checking is required. The open list is typically maintained in the form of a global heap. The use of a global heap is a source of contention. If the time taken to lock, remove, and unlock the top element of the heap is  $t_{\text{access}}$  and time for expansion is  $t_{\text{exp}}$ , then the speedup of the formulation is bounded by  $(t_{\text{access}} + t_{\text{exp}})/t_{\text{access}}$ . A number of techniques have been developed to effectively reduce the access time [17]. These techniques support concurrent access to heaps stored in shared memory while maintaining strict insertion and deletion ordering. While these increase the upper bound on possible speedup, the performance of these schemes is still bounded.

The contention associated with the global data structure can be alleviated by distributing the open list across processors. Now, instead of  $p$  processors sharing a single list, they operate on  $k$  distinct open lists. In the limiting case, each processor has its own open list. A simple parallel formulation based on this framework starts off with the initial state in one heap. As additional states are generated, they are shipped off to

the other heaps. As nodes become available in other heaps, processors start exploring associated state space using local BFS. While it is easy to keep all processors busy using this framework, it is possible that some of the processors may expand nodes with poor heuristic estimates that are never expanded by the serial formulation. To avoid this, we must ensure that all open lists have a share of the best globally available nodes. This is also referred to as *quality equalization* (the process of ensuring that all processors are working on regions of state-space of high quality). Since the quality of nodes evolves with time, quality equalization must be performed periodically. Several triggering mechanisms have been developed to integrate quality equalization with load balancing [1,19]. A simple triggering mechanism tracks the best node in the system. The best node in the local heap is compared to the best node in the system and if it is considerably worse, an equalization process is initiated. Alternately, an equalization process may be initiated periodically. The movement of nodes between various heaps may itself be fashioned in a well defined topology. Lists may be organized into rings, shared blackboards, or hierarchical structures. These have been explored for several applications and architectures. Speedups in excess of 950 have been demonstrated on 1024 processor hypercubes in the context of TSPs formulated as best-first tree search problems [2].

### Searching State Space Graphs

Searching state space graphs presents additional challenges since we must check for replicated states during search. The simplest strategy for dealing with graphs is to unroll them into trees. The overhead of unrolling a graph into a tree may range from a constant to an exponential factor. If the overhead is a small constant factor, the resulting tree may be searched using parallel DFS or BFS based techniques. However, for most graph search problems, this is not a feasible solution.

Graph search problems rely on a *closed list* (i. e. a list of all configurations that have been previously encountered) that keeps track of all nodes that have already been explored. Closed lists are typically maintained as hash tables for searching. In a shared memory context, insertion of nodes into the closed list requires locking of the list. If there is a single lock associated with the entire list, the list must be locked approximately as many

times as the total number of nodes expanded. This represents a serial bottleneck. The bottleneck can be alleviated by associating multiple locks with the closed list. Processors lock only relevant parts of the closed list into which the node is being inserted.

Distributed memory versions of this parallel algorithm physically distribute the closed list across the processors. As nodes are generated, they are hashed to the appropriate processor that holds the respective part of the hash table. Search is performed locally at this processor and the node is explored further at this processor if required. This has two effects: if the hash function associated with the closed list is truly randomized, this has the effect of load balancing using randomized allocation. Furthermore, since nodes are randomly allocated to processors, there is a probabilistic quality equalization for heuristic search techniques. These schemes have been studied by many researchers [14,15]. Assuming a perfectly random hash function, it has been shown that if the number of nodes originating at each processor grows as  $O(\log p)$ , then each processor will have asymptotically equal number of nodes after the hash operation [15]. Since each node is associated with a communication, this puts constraints on the architecture bandwidth. Specifically, the bisection width of the underlying architecture must increase linearly with the number of processors for this formulation to be scalable.

A major drawback of graph search techniques such as BFS is that its memory requirement grows linearly with the search space. For large problems, this memory requirement becomes prohibitive. Many limited-memory variants of heuristic search have been developed. These techniques rely on retraction or delayed expansion of less promising nodes to reduce memory requirement. In the parallel processing context, retractions lead to additional communication and indexing for parent-child relationships [4].

### Anomalies in Parallel Search

As we have seen above, it is possible for parallel formulations to do more or less work than the serial search algorithm. The ratio of nodes searched by the parallel and serial algorithms is called the *search overhead factor* (i. e. the ratio of excess work done by a parallel search formulation with respect to its serial formula-

tion). A search overhead factor of greater than one indicates a deceleration anomaly and less than one indicates an acceleration anomaly. An acceleration anomaly manifests itself in a speedup greater than  $p$  on  $p$  processors. It can be argued however that in these cases, the base sequential algorithm is suboptimal and a time-multiplexed serialization of the parallel algorithm is in fact a superior serial algorithm.

In DFS and related techniques, parallel formulations might detect solutions available close to the root on alternate branches, whereas serial formulations might search large parts of the tree to the left before reaching this node. Conversely, parallel formulations might also expand a larger number of nodes than the serial version. There are situations, in which parallel DFS can have a search overhead factor of less than 1 on the average, implying that the serial search algorithm in the situation is suboptimal. V. Kumar and V.N. Rao [18] show that if no heuristic information is available to order the successors of a node, then on the average, the speedup obtained by parallel DFS is superlinear if the distribution of solutions is nonuniform.

In BFS, the strength of the heuristic determines the search overhead factor. When strong heuristics are available, it is likely that expanding nodes with lower heuristic values will result in wasted effort. In general, it can be shown that for any given instance of BFS, there exists a number  $k$  such that expanding more than  $k$  nodes in parallel from a global open list leads to wasted computation [12]. This situation gets worse with distributed open lists since expanded nodes have locally minimum heuristics that are not the best nodes across all open lists. In contrast, the search overhead factor can be less than one if there are multiple nodes with identical heuristic estimates and one of the processors picks the right one.

### Applications of Parallel Search Techniques

Parallel search techniques have been applied to a variety of problems such as integer and mixed integer programming, and quadratic assignment for applications ranging from path planning and resource location to VLSI packaging. Quadratic assignment problems from the Nugent–Eschermann test suites with up to  $4.8 \times 10^{10}$  nodes have been solved on parallel machines in days. Traveling salesman problems with thousands of cities and mixed integer programming problems with

thousands of integer variable are within the reach of large scale parallel machines. While the use of parallelism increases the range of solvable problems, designing effective heuristic functions is critical. This has the effect of reducing effective branching factor and thus inter-node concurrency. However, the computation of the heuristic can itself be performed in parallel. The use of intra-node parallelism in addition to inter-node parallelism has also been explored. While significant amounts of progress has been made in effective use of parallelism in discrete optimization, with the development of new heuristic functions, opportunities for significant contributions abound.

### Keywords

Unconstrained minimization; Gradient-related descent; Newtonian descent; Singular local attractors; Asymptotic convergence rates

In the classic unconstrained minimization problem, a continuously differentiable real-valued function  $f$  is given on a normed vector space  $\mathbf{X}$  and the goal is to find points in  $\mathbf{X}$  where the *infimum* of  $f$  is achieved or closely approximated. Descent methods for this problem start with some nonoptimal point  $x^0$ , search for a neighboring point  $x^1$  where  $f(x^1) < f(x^0)$ , and so on ad infinitum. At each stage, the search is typically guided by a *local* model based on derivatives of  $f$ .

If  $f$  is convex and every local minimizer is therefore automatically a global minimizer, then well-designed descent methods can indeed generate *minimizing sequences*, i. e., sequences  $\{x^k\}$  for which

$$\lim_{k \rightarrow \infty} f(x^k) = \inf_{x \in \mathbf{X}} f(x). \quad (1)$$

On the other hand, nonconvex cost functions can have multiple *local minimizers* and any of these may attract the iterates of the standard descent schemes. This behavior is examined here for a large class of gradient-related descent methods, and for local minimizers that need not satisfy the usual nonsingularity hypotheses. In addition, the analytical formulation adopted yields nontrivial local convergence theorems in infinite-dimensional normed vector spaces  $\mathbf{X}$ . Such theorems are not without computational significance since

they often help to explain emerging trends in algorithm behavior for increasingly refined finite-dimensional approximations to underlying infinite-dimensional optimization problems.

**Differentials and Gradients**

In a general normed vector space  $\mathbf{X}$ , the first (Fréchet) differential of  $f$  at a point  $x$  is a linear function  $f'(x): \mathbf{X} \rightarrow \mathbf{R}^1$  that satisfies the following conditions:

$$\|f'(x)\| \stackrel{\text{def}}{=} \sup_{\|u\|=1} |f'(x)u| < \infty, \tag{2}$$

$$\lim_{\|d\| \rightarrow 0} \frac{|f(x+d) - f(x) - f'(x)d|}{\|d\|} = 0. \tag{3}$$

Since  $f'(x)d$  is linear in  $d$ , condition (2) holds if and only if  $f'(x)d$  is continuous in  $d$ . Condition (2) is automatically satisfied in any finite-dimensional space  $\mathbf{X}$ . The remaining condition (3) asserts that  $f(x)+f'(x)d$  asymptotically approximates  $f(x+d)$  with an  $o(\|d\|)$  error as  $d$  approaches zero. At most one linear function can satisfy these conditions in some norm on  $\mathbf{X}$ . If conditions (2) and (3) do hold in the norm  $\|\cdot\|$ , then  $f$  is said to be (Fréchet) *differentiable* at  $x$  (relative to the norm  $\|\cdot\|$ ). If  $f$  is differentiable near  $x \in \mathbf{X}$  and if

$$\lim_{\|y-x\| \rightarrow 0} \|\|f'(y) - f'(x)\|\| = 0, \tag{4}$$

then  $f$  is continuously differentiable at  $x$ . Note that in finite-dimensional spaces, all norms are equivalent and conditions (2)–(4) hold in any norm if they hold in some norm. However, two norms on the same infinite-dimensional space need not be equivalent, and continuity and differentiability are therefore *norm-dependent properties* at this level of generality.

In the Euclidean space  $\mathbf{X} = \mathbf{R}^n$ ,  $f$  is continuously differentiable if and only if the partial derivatives of  $f$  are continuous; moreover, when  $f$  has continuous partial derivatives,  $f'(x)$  is specified by the familiar formula,

$$f'(x)d = \langle \nabla f(x), d \rangle, \tag{5}$$

where  $\langle \cdot, \cdot \rangle$  is the standard Euclidean inner product and  $\nabla f(x)$  is the corresponding *gradient* of  $f$  at  $x$ , i. e.,

$$\langle x, y \rangle = \sum_{i=1}^n x_i y_i$$

and

$$\nabla f(x) = \left( \frac{\partial f}{\partial x_1}(x), \dots, \frac{\partial f}{\partial x_n}(x) \right).$$

When  $\nabla f(\cdot)$  is continuous, conditions (2)–(4) can be proved for the linear function in (5) with a straightforward application of the chain rule, Cauchy’s inequality and the one-dimensional mean value theorem. In addition, it can be shown that  $d = \nabla f(x)$  is the unique solution of the equations,

$$\|d\| = \|\|f'(x)\|\| \tag{6}$$

and

$$f'(x)d = \|\|f'(x)\|\| \|d\|, \tag{7}$$

where  $\|\cdot\|$  and  $\|\|\cdot\|\|$  are induced by the Euclidean inner product on  $\mathbf{R}^n$ .

The circumstances in the Euclidean space  $\mathbf{R}^n$  suggest a natural extension of the gradient concept in general normed vector spaces  $\mathbf{X}$ . Let  $f$  be differentiable at  $x \in \mathbf{X}$ . Then any vector  $d \in \mathbf{X}$  that satisfies conditions (6)–(7) will be called a *gradient vector* for  $f$  at  $x$ . Note that the symbols  $\|\cdot\|$  and  $\|\|\cdot\|\|$  in (6)–(7) now signify the norm provided on  $\mathbf{X}$  and the corresponding operator norm in (2). Depending on the space  $\mathbf{X}$ , its norm  $\|\cdot\|$  and the point  $x$ , conditions (6)–(7) may have no solutions for  $d$ , or a unique solution, or infinitely many solutions.

In any finite-dimensional space  $\mathbf{X}$ , linear functions are continuous, the unit sphere  $\{u \in \mathbf{X}: \|u\| = 1\}$  is compact, the supremum in (2) is therefore attained at some unit vector  $u$ , and the existence of solutions  $d$  for (6)–(7) is consequently guaranteed. On the other hand,  $f$  may have infinitely many distinct gradients at a point  $x$  if the norm on  $\mathbf{X}$  is not strictly convex. For example, if  $\mathbf{X} = \mathbf{R}^n$  and  $\|x\| = \max_{1 \leq i \leq n} |x_i|$ , then  $f'(x)$  is prescribed by (5), and

$$\|\|f'(x)\|\| = \sum_{i=1}^n \left| \frac{\partial f}{\partial x_i}(x) \right|.$$

Moreover,  $d$  is a gradient vector for  $f$  at  $x$  if and only if

$$d = \|\|f'(x)\|\| u$$

and

$$u_i \in \text{sgn} \left( \frac{\partial f}{\partial x_i}(x) \right),$$

where  $\text{sgn}(t) = \{-1\}$  or  $[-1, 1]$  or  $\{1\}$  for  $t < 0$ ,  $t = 0$  and  $t > 0$ , respectively.

The existence of gradients can also be proved in reflexive infinite-dimensional spaces  $\mathbf{X}$  where bounded linear functions are weakly continuous and closed unit balls are weakly compact. In nonreflexive spaces, conditions (6)–(7) may not have solutions  $d$ ; however, in any normed vector space and for any fixed arbitrarily small  $\nu \in (0, 1)$ , the relaxed conditions,

$$\|d\| = \| \|f'(x)\| \| \quad (8)$$

and

$$f'(x)d \geq (1 - \nu) \| \|f'(x)\| \| \|d\|, \quad (9)$$

always have solutions  $d$ . This follows easily from (2) and the meaning of sup. The solutions of (8)–(9) will be called  $\nu$ -approximate gradients of  $f$  at  $x$ . They occupy a central position in the present formulation of the subject algorithms.

### Gradient-Related Descent Methods

If  $f'(x) = 0$ , then  $x$  is called a *stationary point* of  $f$ . If  $f'(x) \neq 0$ , then  $x$  is not stationary and the set  $\{d \in \mathbf{X}: f'(x)d < 0\}$  is a nonempty open half-space. An element  $d$  in this half-space is called a *descent vector* since condition (3) immediately implies that  $f(x + td) < f(x)$  when  $t$  is positive and sufficiently small. If  $d$  is a  $\nu$ -approximate gradient at a nonstationary point  $x$ , then according to (8)–(9),

$$f'(x)(-d) \leq -(1 - \nu) \| \|f'\|^2 < 0.$$

Hence  $-d$  is a descent vector. In particular, if  $d$  is a gradient at a nonstationary point  $x$ , then  $-d$  is a *steepest descent vector* in the sense that

$$f'(x)(-d) \leq f'(x)v, \quad (10)$$

for all  $v \in \mathbf{X}$  such that  $\|v\| = \|d\|$ .

Suppose that  $\nu$ ,  $\mu_1$ , and  $\mu_2$  are fixed positive numbers, with  $\nu \in (0, 1)$  and  $\mu_2 \geq \mu_1 > 0$ . At each  $x \in \mathbf{X}$ , let  $G^\nu(x)$  denote the nonempty set of  $\nu$ -approximate gradients for  $f$  at  $x$  and let  $G(x)$  be a nonempty subset of the set of all multiples  $\mu d$  with  $\mu \in [\mu_1, \mu_2]$  and  $d \in G^\nu(x)$ , i. e.,

$$\emptyset \neq G(x) \subset \bigcup_{\mu \in [\mu_1, \mu_2]} \mu G^\nu(x). \quad (11)$$

The corresponding set-valued mapping  $G(\cdot)$  is referred to here as a *gradient-related set function* with parameters  $\nu$ ,  $\mu_1$  and  $\mu_2$ . In the present development, a gradient-related iterative descent method consists of a gradient-related set function  $G(\cdot)$ , and a rule that selects a vector  $d^k \in G(x^k)$  at each iterate  $x^k$ , and another rule that determines the *steplength* parameter  $s^k \in (0, 1]$  in the recursion,

$$x^{k+1} = x^k - s^k d^k, \quad (12)$$

once  $d^k$  has been chosen. The sequences  $\{x^k\}$  generated by this recursion are called gradient-related successive approximations. (For related formulations, see [3,4,10].) The convergence theorems described later in this article depend only on basic properties of gradient-related set functions and the steplengths  $s^k$ , hence the precise nature of the rule for selecting  $d^k$  in  $G(x^k)$  is not important here. This rule may refer to prior iterates  $\{x^i\}_{i \leq k}$ , or may even be random in nature. There are also many alternative steplength rules that achieve sufficient reductions in  $f$  at each iteration in (12) and move the successive approximations  $x^k$  toward regions in the domain of  $f$  that are interesting in at least a local sense [3,4,10].

### Descent Method Prototypes

When gradients of  $f$  exist and  $f$  attains its infima on lines in  $\mathbf{X}$ , the steepest descent and exact line minimization rules for  $d$  and  $s$  yield the prototype *steepest descent method*,

$$x^{k+1} = x^k - s^k d^k, \quad (13)$$

where

$$s^k \in \arg \min_{t > 0} f(x^k - td^k) \quad (14)$$

and  $d^k$  is any solution of (6)–(7) for  $x = x^k$ . Note that the actual reduction in  $f$  achievable on a steepest descent half-line  $\{y \in \mathbf{X}: \exists t > 0, y = x - td\}$  may be *smaller* than that attainable on other half-lines, since (10) merely refers to norm-dependent local directional rates of change for  $f$  at  $x$ . Thus the name of this method is somewhat misleading.

Newtonian descent algorithms also amount to special gradient-related descent methods near a certain type of *nonsingular local minimizer*  $x^*$ . These schemes

employ variants of the restricted line minimization steplength rule,

$$s^k \in \arg \min_{t \in (0,1]} f(x^k - td^k), \quad (15)$$

and replace the gradients  $d^k$  in a steepest descent iteration by descent vectors that approximate the Newton increment,

$$d^N(x^k) = f''(x^k)^{-1} f'(x^k). \quad (16)$$

Gradient-related descent vector approximations to  $d^N(x^k)$  are generated in some neighborhood of  $x^*$  by various quasi-Newton auxiliary recursions, provided that the following (interdependent) nonsingularity conditions hold:

- i)  $f$  is twice continuously (Fréchet) differentiable at  $x^*$ ;
- ii)  $f''(x^*)$  satisfies the coercivity condition

$$(f''(x^*)v)v \geq c \|v\|^2$$

for some  $c > 0$  and all  $v \in \mathbf{X}$ ;

- iii) A bounded inverse map  $f''(x)^{-1}$  exists for all  $x$  sufficiently near  $x^*$ ;
- iv)  $f''(\cdot)^{-1}$  is continuous at  $x^*$ .

Near a nonsingular local minimizer, the local convergence rates for Newtonian descent methods are generally much faster than the steepest descent convergence rate [8,10]. On the other hand, near singular local minimizers the Newton increments  $d^N(x^k)$  and their quasi-Newton approximations are typically not confined to the image sets  $G(x^k)$  of some gradient-related set function  $G(\cdot)$ , and may actually be *undefined* on continuous manifolds in  $\mathbf{X}$  containing  $x^*$ . Under these circumstances, the unmodified Newtonian scaling principles can degrade or even destroy local convergence. In any case, the convergence properties of Newtonian descent methods near singular local minimizers  $x^*$  are not well-understood, and are likely to depend on the higher order structure of the singularity at  $x^*$ .

### The Armijo Steplength Rule

The line minimization steplength rules in (14) and (15) can be very effective in special circumstances; however, they are more often difficult or impossible to implement, and are not intrinsically ‘optimal’ in any general sense when coupled with standard descent direction rules based on local models of  $f$ . By their very

nature, such schemes do not anticipate the effect of current search direction and steplength decisions on the reductions achievable in  $f$  in later stages of the calculation. Therefore, over many iterations, the exact line minimization rule may well produce *smaller* total reductions in  $f$  than other much simpler steplength rules that merely aim for local reductions in  $f$  that are ‘large enough’ compared with  $\|f'(x)\|$  at each iteration. A. Goldstein and L. Armijo proposed the first practical steplength rules of this kind in [1,8,9] for steepest descent and Newtonian descent methods in  $\mathbf{R}^n$ . These rules and other related schemes described in [10] and [4] are easily adapted to general gradient-related iterations. The present development focusses on the local convergence properties of the simple Armijo rule described below; however, with minor modifications, the theorems set forth here extend readily to the Goldstein rule and other similar line search formulations.

Let  $G(\cdot)$  be a gradient-related set function with parameters  $\nu$ ,  $\mu_1$  and  $\mu_2$ . Fix  $\beta$  in  $(0, 1)$  and  $\delta$  in  $(0, 1)$ , and for each  $x$  in  $\mathbf{X}$  and  $d$  in  $G(x)$  construct  $s(x, d) \in (0, 1]$  with the *Armijo steplength rule*,

$$s(x, d) = \max t \quad (17)$$

subject to

$$t \in \{1, \beta, \beta^2, \dots\}$$

and

$$f(x) - f(x - td) \geq \delta t f'(x)d.$$

When  $x$  is not stationary and  $-d$  is any descent vector, the rule (17) admits *precisely one* associated steplength  $s(x, d) \in (0, 1]$ . This is true because  $\beta^k$  converges to zero as  $k \rightarrow \infty$  and

$$\begin{aligned} f(x) - f(x - td) &= \delta f'(x)td + (1 - \delta)f'(x)td + o(t) \\ &\geq \delta f'(x)td \end{aligned}$$

for  $t$  positive and sufficiently small, in view of (3). When  $x$  is stationary, (17) yields  $s(x, d) = 1$  trivially for every vector  $d$ .

### Fixed Points

Descent methods based on gradient-related set functions and Armijo’s rule generate sequences  $\{x^k\}$  that sat-

isfy

$$x^{k+1} \in T(x^k), \quad k = 0, 1, \dots, \tag{18}$$

where

$$T(x) \stackrel{\text{def}}{=} \{y: \exists d \in G(x), y = x - s(x, d)d\}. \tag{19}$$

The convergence theory outlined in the following sections addresses the behavior of all such Armijo gradient-related sequences near fixed points of the set-valued map  $T(\cdot): \mathbf{X} \rightarrow 2^{\mathbf{X}}$ . The roots of this theory lie in Bertsekas' convergence proof for steepest descent iterates near nonsingular local minimizers in  $\mathbf{R}^n$  [2], and subsequent modifications of this proof strategy for gradient projection methods and singular local minimizers in finite-dimensional or infinite-dimensional vector spaces with inner products [6,7]. For related nonlocal theories, see [10] and [4].

By definition,  $x^*$  is a *fixed point* of  $T(\cdot)$  if and only if

$$x^* \in T(x^*).$$

Since Armijo's rule produces nonzero steplengths  $s(x, d)$ , it follows that  $x^*$  is a fixed point of  $T(\cdot)$  if and only if  $x^*$  is a stationary point of  $f$ . More precisely,

**Proposition 1** *Let  $T(\cdot)$  be an Armijo gradient-related iteration map in (19). Then for all  $x \in \mathbf{X}$ ,*

$$\begin{aligned} x \in T(x) &\Leftrightarrow T(x) = \{x\} \\ &\Leftrightarrow G(x) = \{0\} \Leftrightarrow f'(x) = 0. \end{aligned} \tag{20}$$

According to Proposition 1, any Armijo gradient-related sequence  $\{x^k\}$  that intercepts a fixed point  $x^*$  of  $T(\cdot)$  must terminate in  $x^*$ . Conversely, if  $\{x^k\}$  terminates in a vector  $x^*$ , then  $x^*$  is a fixed point of  $T(\cdot)$ , and hence a stationary point of  $f$ . On the other hand, Armijo gradient-related sequences that merely pass *near* some stationary point  $x^*$  may or may not converge to  $x^*$ .

**Local Attractors: Necessary Conditions**

A vector  $x^*$  is said to be a *local attractor* for an Armijo gradient-related iteration (18) if and only if there is a nonempty open ball,

$$B(x^*, \rho) = \{x \in \mathbf{X}: \|x - x^*\| < \rho\}$$

with center  $x^*$  and radius  $\rho > 0$  such that every sequence  $\{x^k\}$  which satisfies (18) and enters the ball  $B(x^*, \rho)$  must converge to  $x^*$ , i. e.,

$$\exists l, x^l \in B(x^*, \rho) \Rightarrow \lim_{k \rightarrow \infty} \|x^k - x^*\| = 0. \tag{21}$$

With Proposition 1 and another rudimentary result for gradient-related set functions and Armijo steplengths, it is readily shown that a local attractor must be a *strict local minimizer* of  $f$  and an *isolated stationary point* of  $f$ .

**Proposition 2** *Let  $\nu \in (0, 1)$ ,  $\mu_1 > 0$ , and  $\delta \in (0, 1)$  be fixed parameter values in the gradient-related set function  $G(\cdot)$  and Armijo rule (17), and put  $c_1 = \delta(1 - \nu)\mu_1 > 0$ . Then for all  $x \in \mathbf{X}$  and  $d \in G(x)$ ,*

$$f(x) - f(x - s(x, d)d) \geq c_1 s(x, d) \|f'(x)\|^2. \tag{22}$$

**Corollary 3** *Let  $T(\cdot)$  be the Armijo gradient-related iteration map in (19). If  $\{x^k\}$  is generated by the corresponding gradient-related iteration (18), then for all  $k = 0, 1, \dots$ ,*

$$f(x^{k+1}) \leq f(x^k) \tag{23}$$

and

$$f'(x^k) \neq 0 \Rightarrow f(x^{k+1}) < f(x^k). \tag{24}$$

Since  $f$  is continuous, the claimed necessary conditions for local attractors are now immediate consequences of Proposition 1 and Corollary 3.

**Theorem 4** *A vector  $x^*$  is a local attractor for an Armijo gradient-related iteration (18) only if  $x^*$  is an isolated stationary point and a strict local minimizer of  $f$ , i. e., only if there is a nonempty open ball  $B(x^*, \rho^*)$  that excludes every other stationary point  $x \neq x^*$ , and also excludes points  $x \neq x^*$  at which  $f(x) \leq f(x^*)$ .*

The conclusion in Theorem 4 actually applies more generally to set-valued iteration maps  $T(\cdot)$  prescribed by any steplength rule that guarantees the fixed-point characterization (20) and the descent property (23)–(24). On the other hand, related converse assertions are tied more closely to special properties of the Armijo rule and its variants, and to certain local uniform growth conditions on  $f$  and  $\|f'(\cdot)\|$ . If  $\mathbf{X}$  is a finite-dimensional space, and  $x^*$  is a strict local minimizer

and an isolated stationary point, then the requisite uniform growth conditions automatically hold near  $x^*$  and the full converse of Theorem 4 can be proved. If  $\mathbf{X}$  is an infinite-dimensional space, the growth conditions become hypotheses in a weaker but still nontrivial partial converse of Theorem 4. This is explained in greater detail below.

**Local Attractors: Sufficient Conditions**

If  $x^*$  is a strict local minimizer of  $f$ , then for some  $\rho^* > 0$  and all  $x$  in the closed ball,

$$\bar{B}(x^*, \rho^*) = \{x \in \mathbf{X}: \|x - x^*\| \leq \rho^*\},$$

the quantity  $f(x) - f(x^*)$  is strictly positive when  $x \neq x^*$ . In finite-dimensional spaces, it is possible to say more. If  $\dim \mathbf{X} < \infty$ , then for each  $t \in (0, \rho^*]$  the corresponding closed annulus,

$$A(t, \rho^*) = \{x: t \leq \|x - x^*\| \leq \rho^*\}, \tag{25}$$

is compact. Since the function  $f(\cdot) - f(x^*)$  is continuous and positive in  $A(t, \rho^*)$ , it must attain a positive minimum value in this set, i. e.,

$$\alpha(t) \stackrel{\text{def}}{=} \min_{x \in A(t, \rho^*)} f(x) - f(x^*) > 0, \tag{26}$$

for each  $t \in (0, \rho^*]$ . Put  $\alpha(0) = 0$  and note that for all  $t_1, t_2, 0 < t_1 < t_2 \leq \rho^* \Rightarrow A(t_1, \rho^*) \supset A(t_2, \rho^*) \Rightarrow \alpha(t_1) \leq \alpha(t_2)$ . This establishes the following uniform growth property for strict local minimizers in finite-dimensional spaces.

**Lemma 5** *Let  $\mathbf{X}$  be a finite-dimensional normed vector space. If  $x^*$  is a strict local minimizer for  $f$ , then there is a positive number  $\rho^*$  and a positive definite nondecreasing real-valued function  $\alpha(\cdot)$  on  $[0, \rho^*]$  such that,*

$$f(x) - f(x^*) \geq \alpha(\|x - x^*\|), \tag{27}$$

for all  $x \in \bar{B}(x^*, \rho^*)$ .

In infinite-dimensional spaces, the uniform growth condition (27) need not hold at every strict local minimizer; however, when this condition is satisfied, the minimizer  $x^*$  has a crucial stability property for gradient-related descent methods. More specifically, suppose that (27) holds and  $T(\cdot)$  is an Armijo iteration map (19) with associated parameter  $\mu_2 > 0$ . Since descent directions can not exist at a local minimizer, the

vector  $x^*$  must be a stationary point. Fix  $\epsilon \in (0, \rho^*]$  and note that since  $f'(\cdot)$  is continuous and  $f'(x^*) = 0$ , there is a  $\tau_\epsilon \in (0, \epsilon]$  for which

$$\|x - x^*\| + \mu_2 \|f'(x)\| < \epsilon \tag{28}$$

for all  $x \in B(x^*, \tau_\epsilon)$ . Now construct the corresponding set,

$$I(\epsilon) = \{x \in B(x^*, \epsilon): f(x) - f(x^*) < \alpha(\tau_\epsilon)\}. \tag{29}$$

By Proposition 2, the simple descent property,

$$f(x - s(x, d)d) \leq f(x) \tag{30}$$

holds for all  $x$  and all  $d \in G(x)$ , hence the restriction (28) and the properties of  $\alpha(\cdot)$  insure that  $I(\epsilon)$  is an invariant set for  $T(\cdot)$ , i. e.,  $T(x) \subset I(\epsilon)$  for all  $x \in I(\epsilon)$ . Moreover, since  $f$  is continuous, the minimizer  $x^*$  is clearly an interior point of the set  $I(\epsilon)$ , and this proves the following stability lemma for Armijo gradient-related iterations (or indeed, any gradient-related method with the descent property (30)).

**Lemma 6** *Suppose that the uniform growth condition (27) holds near a local minimizer  $x^*$  for  $f$ . Let  $T(\cdot)$  be an Armijo gradient-related iteration map in (19). Then for every  $\epsilon > 0$  there is a corresponding  $\rho \in (0, \epsilon]$  such that for all sequences  $\{x^k\}$  satisfying (18), and all indices  $l$ ,*

$$x^l \in B(x^*, \rho) \Rightarrow \forall k \geq l \ x^k \in B(x^*, \epsilon). \tag{31}$$

According to Lemma 6, the uniform growth condition (27) guarantees that an Armijo gradient-related sequence  $\{x^k\}$  will remain in any specified arbitrarily small open ball  $B(x^*, \epsilon)$  provided  $\{x^k\}$  enters a sufficiently small sub-ball of  $B(x^*, \epsilon)$ . This property alone does not imply that  $\{x^k\}$  converges to  $x^*$ ; however, it is an essential ingredient in the local convergence proof outlined below. This proof requires two additional technical estimates for the Armijo rule and gradient-related set functions, a local uniform growth condition for  $\|f'(\cdot)\|$  analogous to (27), and a local uniform continuity hypothesis on  $f'(\cdot)$ . The first pair of estimates are straightforward consequences of the Armijo rule and the one-dimensional mean value theorem. The last two requirements are automatically satisfied in finite-dimensional spaces, once again because closed bounded sets are compact in these spaces.

**Proposition 7** Let  $v \in (0, 1)$ ,  $\mu_2 > 0$ ,  $\beta \in (0, 1)$ , and  $\delta \in (0, 1)$  be fixed parameter values in the gradient-related set function  $G(\cdot)$  and Armijo rule (17), and put  $c_2 = \delta(1-v)\mu_2^{-1} > 0$ . Then for all  $x \in X$  and  $d \in G(x)$ ,

$$f(x) - f(x - s(x, d)d) \geq c_2 s(x, d)^2 \|d\|^2. \tag{32}$$

Moreover, if  $s(x, d) < 1$  and  $c_3 = (1 - \delta)(1 - v)$ , then there is a vector  $\xi$  in the line segment joining  $x$  to  $x - \beta^{-1}s(x, d)d$  such that

$$\|f'(\xi) - f'(x)\| \geq c_3 \|f'(x)\| \tag{33}$$

and

$$\|\xi - x\| \leq \beta^{-1}s(x, d) \|d\|. \tag{34}$$

**Lemma 8** Let  $X$  be a finite-dimensional normed vector space. If  $x^*$  is an isolated stationary point for  $f$ , then there is a positive number  $\rho^*$  and a positive definite non-decreasing real-valued function  $\beta(\cdot)$  on  $[0, \rho^*]$  such that,

$$\|f'(x)\| \geq \beta(\|x - x^*\|), \tag{35}$$

for all  $x \in \bar{B}(x^*, \rho^*)$ .

The proof of Lemma 8 is similar to the proof of Lemma 5.

Now suppose that the growth conditions (27) and (35) both hold in the ball  $\bar{B}(x^*, \rho^*)$ , and that  $f'(\cdot)$  is uniformly continuous in this ball. By Lemma 6, there is a positive number  $\rho \in (0, \rho^*/2]$  such that every sequence  $\{x^k\}$  which satisfies (18) and enters the ball  $B(x^*, \rho)$ , thereafter remains in the larger ball  $B(x^*, \rho^*/2)$ . But if  $\{x^k\}$  is eventually confined to the ball  $B(x^*, \rho^*/2)$ , then the mean value theorem insures that the nonincreasing real sequence  $\{f(x^k)\}$  is bounded below and therefore converges to some finite limit. In this case, the differences  $f(x^k) - f(x^{k+1})$  converge to zero and Propositions 2 and 7 therefore yield,

$$\lim_{k \rightarrow \infty} s(x^k, d^k) \|f'(x^k)\|^2 = 0, \tag{36}$$

and

$$\lim_{k \rightarrow \infty} s(x^k, d^k) \|d^k\| = 0, \tag{37}$$

where  $d^k \in G(x^k)$  and  $s(x^k, d^k) d^k = x^{k+1} - x^k$  for all  $k$ . It follows easily from the remainder of Proposition 7 and the growth condition (35) that

$$\lim_{k \rightarrow \infty} \|f'(x^k)\| = 0 \tag{38}$$

and therefore

$$\lim_{k \rightarrow \infty} \|x^k - x^*\| = 0. \tag{39}$$

To see that (38) must hold, construct the index sets,  $\psi = \{k: s(x^k, d^k) = 1\}$  and  $\phi = \{k: s(x^k, d^k) < 1\}$ . If  $\psi$  is an infinite set, then,

$$\lim_{\substack{k \in \psi \\ k \rightarrow \infty}} \|f'(x^k)\| = 0,$$

by (36). On the other hand, if  $\phi$  is an infinite set, then

$$\lim_{\substack{k \in \phi \\ k \rightarrow \infty}} \|f'(x^k)\| = 0,$$

by (37), (33), (34), and the local uniform continuity of  $f'(\cdot)$ . This establishes (38) and proves the following local convergence results.

**Theorem 9** If the uniform growth conditions (27) and (35) hold simultaneously in the closed ball  $\bar{B}(x^*, \rho^*)$  for some  $\rho^* > 0$ , and if  $f'(\cdot)$  is uniformly continuous in  $\bar{B}(x^*, \rho^*)$  then  $x^*$  is a local attractor for Armijo gradient-related iterations (18).

**Corollary 10** If  $X$  is a finite-dimensional normed vector space and  $x^*$  is a strict local minimizer and an isolated stationary point for  $f$ , then  $x^*$  is a local attractor for Armijo gradient-related iterations (18).

**Nonsingular Attractors**

The nonsingularity conditions i) and ii) and Taylor’s formula imply that in some neighborhood of  $x^*$ , the objective function  $f$  is convex and satisfies the local growth condition (27) with

$$\alpha(t) = a t^2 \tag{40}$$

for some  $a > 0$ . But if  $f$  is locally convex near  $x^*$ , then

$$f(x) - f(x^*) \leq f'(x)(x - x^*) \leq \|f'(x)\| \|x - x^*\| \tag{41}$$

near  $x^*$ , and therefore (27) and (40) imply (35) with

$$\beta(t) = a t. \tag{42}$$

These observations and Theorem 9 immediately yield the following extension of the convergence result in [2] for steepest descent processes in  $\mathbf{R}^n$ .

**Corollary 11** Every nonsingular local minimizer  $x^*$  is a local attractor for Armijo gradient-related iterations (18).

### Singular Attractors and Local Convexity

The growth condition (27) alone does not imply local convexity of  $f$ , or condition (35), or the local attractor property. In fact, (27) can hold even if  $x^*$  is the limit of some infinite sequence of local minimizers for  $f$ . This is readily demonstrated by the following simple function  $F: \mathbf{R}^1 \rightarrow \mathbf{R}^1$ :

$$F(x) = x^2 \left[ \sqrt{2} - \sin \left( \frac{5\pi}{6} - \sqrt{3} \ln x^2 \right) \right]. \quad (43)$$

This function has a strict absolute minimizer at  $x^* = 0$ , with

$$(\sqrt{2} - 1)x^2 \leq F(x) \leq (\sqrt{2} + 1)x^2$$

for all  $x \in \mathbf{R}^1$ . However,  $F$  also has infinitely many (non-singular) local minimizers,

$$x_m^\pm = \pm \exp \left[ \frac{(1 - 8m)\pi}{8\sqrt{3}} \right]$$

for  $m = 1, 2, \dots$ , and these local minimizers *accumulate* at 0. Since each  $x_m^\pm$  is a stationary point and not an absolute minimizer, it follows that  $F$  is not convex in any neighborhood of the absolute minimizer at  $x^* = 0$ , that (35) cannot hold at  $x^*$ , and that  $x^*$  is not a local attractor for gradient-related descent processes. Evidently,  $x^* = 0$  is a singular minimizer for  $F$ ; in fact,  $F''(x)$  does not exist at  $x = 0$ . (Apart from a minor alteration in one of its constants, (43) is taken directly from [6, Example 1.1]. The erroneous constant in [6] was kindly called to the author’s attention by D. Bertsekas.)

The growth conditions (27) and (35) *together* still do not imply convexity of  $f$  near  $x^*$ , and indeed  $f$  may not be convex in any neighborhood of a singular local attractor. This is shown by another function  $F: \mathbf{R}^2 \rightarrow \mathbf{R}^1$  from [6, Example 1.2], viz.

$$F(x) = x_1^2 - 1.98x_1 \|x\|^2 + \|x\|^4, \quad (44)$$

where  $x = (x_1, x_2)$  and  $\|\cdot\|$  is the Euclidean norm in  $\mathbf{R}^2$ . This function has a singular absolute minimizer at  $x^* = 0$ , and  $F(x)$  and  $\|F'(x)\|$  grow like  $\|x\|^4$  and  $\|x\|^3$ , respectively, near 0. On the other hand, since every neighborhood of 0 contains points  $x$  where  $F'(x)(x - 0)$  is *negative*, it follows that  $F$  is not convex (or even pseudoconvex) near 0. Nevertheless,  $x^* = 0$  is a local attractor for Armijo gradient-related iterations, according to Corollary 10.

Although  $f$  need not be convex near a singular local attractor  $x^*$ , there are many instances where some sort of local convexity property is observed. (The function  $f(x) = x^4$  provides a simple illustration.) If the local pseudoconvexity condition,

$$\kappa(f(x) - f(x^*)) \leq f'(x)(x - x^*), \quad (45)$$

is satisfied for some  $\kappa > 0$  and all  $x$  in the ball  $\bar{B}(x^*, \rho^*)$ , then

$$\kappa(f(x) - f(x^*)) \leq \|f'(x)\| \|x - x^*\|$$

near  $x^*$ , and condition (35) follows at once from (27), with

$$\beta(t) = \kappa(\rho^*)^{-1} \alpha(t)$$

for all  $t \in [0, \rho^*]$ . These considerations immediately yield two additional corollaries of Theorem 9.

**Corollary 12** *Suppose that the uniform growth condition (27) holds in the closed ball  $\bar{B}(x^*, \rho^*)$  for some  $\rho^* > 0$ . In addition, suppose that in  $\bar{B}(x^*, \rho^*)$ ,  $f'(\cdot)$  is uniformly continuous and  $f$  satisfies the pseudoconvexity condition (45). Then  $x^*$  is a local attractor for Armijo gradient-related iterations (18).*

**Corollary 13** *If  $X$  is a finite-dimensional normed vector space, if  $x^*$  is a strict local minimizer for  $f$ , and if  $f$  satisfies the pseudoconvexity condition (45), then  $x^*$  is a local attractor for Armijo gradient-related iterations (18).*

### Local Convexity and Convergence Rates

A local version of the convergence rate proof strategy in [5] also works in the present setting when  $f'(\cdot)$  is locally Lipschitz continuous and  $f$  satisfies the pseudoconvexity condition (45) and the growth condition (27) near  $x^*$ . Under these circumstances, the worst-case convergence rate estimate,

$$f(x^k) - f(x^*) = O(k^{-1}), \quad (46)$$

can be proved for Armijo gradient-related sequences  $\{x^k\}$  that pass sufficiently near  $x^*$ . More refined order estimates are possible if the first two hypotheses hold and

$$f(x) - f(x^*) \geq a \|x - x^*\|^r \quad (47)$$

for some  $a > 0$  and  $r \in (1, \infty)$ , and all  $x \in \bar{B}(x^*, \rho^*)$ . In such cases, it can be shown that

$$f(x^k) - f(x^*) = O(k^{-\frac{r}{r-2}}) \quad (48)$$

for  $r \in (2, \infty)$ , and

$$\exists \lambda \in [0, 1) \quad f(x^k) - f(x^*) = O(\lambda^k) \quad (49)$$

for  $r \in (1, 2]$ . (The latter estimate is comparable to the basic geometric convergence rate theorem for steepest descent iterates near nonsingular local minimizers [2].) The proof strategy in [5] can also produce still more precise local convergence rate estimates that relate the constants implicit in the order estimates (48) and (49) to local Lipschitz constants for  $f'(\cdot)$  and parameters in the gradient-related set functions  $G(\cdot)$ , the growth condition (47), the pseudoconvexity condition (45), and the Armijo steplength rule (17).

In the absence of local convexity assumptions, it is harder to establish analogous asymptotic convergence rate theorems; however, the analysis in [6] and [7] has established  $O(k^{-2})$  rate estimates for Hilbert space steepest descent iterations and a class of nonlinear functions  $f$  that contains the example (44).

### Concluding Remarks

In a finite-dimensional space any two norms are equivalent and it can be seen that the gradient-related property and the local attractor property are therefore norm-invariant qualitative features of set-valued maps  $G(\cdot): \mathbf{X} \rightarrow 2^{\mathbf{X}}$  and local minimizers  $x^*$ . On the other hand, even in finite-dimensional spaces, the Lipschitz constants, growth rate constants, and gradient-related set function parameters in the present formulation are *not* norm-invariant, and this is reflected in norm-dependent convergence rates and norm-dependent size and shape parameters for the domains that are sent to a local attractor  $x^*$  by gradient-related iterations. These facts have potentially important computational manifestations when gradient-related methods are applied to large scale finite-dimensional problems that approximate some limiting problem in an infinite-dimensional space. Note that infinite-dimensional spaces can support multiple nonequivalent norms, and a set-valued function  $G(\cdot)$  that is gradient-related in one norm need not be gradient-related relative to some other

nonequivalent norm. Similarly, the local attractor property for a minimizer  $x^*$ , and indeed local optimality itself, are also typically norm-dependent at this level of generality.

## Introduction

In the last few years, the need for an integrated logistic system has become a primary objective of every company manager. Managers recognize that there is a strong relation between the location of facilities, the allocation of suppliers, vehicles, and customers to the facilities, and the design of routes around the facilities. In a **location routing problem (LRP)**, the optimal number, the capacity, and the location of facilities are determined, and the optimal set of vehicle routes from each facility is also sought.

In most location models, it is assumed that the customers are served directly from the facilities being located. Each customer is served on his or her own route. In many cases, however, customers are not served individually from the facilities. Rather, customers are consolidated into routes that may contain many customers. One of the reasons for the added difficulty in solving these problems is that there are far more decisions that need to be made by the model. These decisions include:

- How many facilities to locate,
- Where the facilities should be,
- Which customers to assign to which depots,
- Which customers to assign to which routes,
- In what order customers should be served on each route.

In the LRP, a number of facilities are located among candidate sites and delivery routes are established for a set of users in such a way that the total system cost is minimized. As Perl and Daskin [51] pointed out, LRPs involve three interrelated, fundamental decisions: where to locate facilities, how to allocate customers to facilities, and how to route vehicles to serve customers.

The difference between the LRP and the classic vehicle routing problem is that not only routing must be designed but the optimal depot location must be simultaneously determined as well. The main difference between the LRP and the classical location-allocation

problem is that, once the facility is located, the former requires a visitation of customers through tours while the latter assumes that the customer will be visited from the vehicle directly, and then the vehicle will return to the facility without serving any other customer ([47]). In general terms, the combined location routing model solves the joint problem of determining the optimal number, capacity, and location of facilities serving more than one customer and finding the optimal set of vehicle routes. In the LRP, the distribution cost is decreased due to the assignment of the customers to vehicles while the main objective is the design of the appropriate routes of the vehicles.

## Variants of the Location Routing Problem

Laporte et al. [39] considered three variants of LRPs, including (1) capacity-constrained vehicle routing problems, (2) cost-constrained vehicle routing problems, and (3) cost-constrained location routing problems. The authors examined multidepot, asymmetrical problems and developed an optimal solution procedure that enables them to solve problems with up to 80 nodes. Chan et al. [11] solved a multidepot, multivehicle location routing problem with stochastically processed demands, which are defined as demands that are generated upon completing site-specific service on their predecessors. Min et al. [47] synthesized the past research and suggested some future research directions for the LRP. An extended recent literature review is included in the survey paper published by Nagy and Salhi [48]. They proposed a classification scheme and looked at a number of problem variants. The most important exact and heuristic algorithms were presented and analyzed in this survey paper.

## Exact Algorithms for the Solution of the Location Routing Problem

A number of exact algorithms for the problem was presented by Laporte et al. [38]. Applications and formulations and exact and approximation algorithms for LRPs under capacity and maximum cost restrictions are studied in the survey of Laporte [34]. Nonlinear programming exact algorithms for the solution of the LRP have been proposed in [20,61]. Dynamic programming exact algorithms for the solution of the LRP have been proposed in [5]. Integer programming exact al-

gorithms for the solution of the LRP have been proposed in [35,37,46]. Mixed integer goal programming exact algorithms for the solution of the LRP have been proposed in [65]. Two branching strategies have been proposed in [36]. An iterative exact procedure has been proposed in [9]. A branch-and-bound technique on the LP relaxation has been proposed in [17].

### Heuristic Algorithms for the Solution of the Location Routing Problem

The LRP is very difficult to solve using exact algorithms, especially if the number of customers or the candidate for location facilities is very large due to the fact that this problem belongs to the category of *NP-hard problems*, i. e. there are no known polynomial-time algorithms that can be used to solve them. Madsen [43] presented a survey of heuristic methods. Christofides and Eilon [16] were the first to consider the problem of locating a depot from which customers are served by tours rather than individual trips. They proposed an approximation algorithm for the solution of the problem. Watson-Gandy and Dohrn [63] proposed an algorithm where the problem is solved by transforming its location part into an ordinary location problem using the Christofides–Eilon approximation algorithm. The routing part of the algorithm is solved using the Clarke and Wright algorithm. Jacobsen and Madsen [31] proposed three algorithms. The first is called a tree-tour heuristic. The second is called ALA–SAV and is a three-phase heuristic, where in the first phase a location–allocation problem is solved and in the second and third phases a Clarke and Wright heuristic is applied for solving the problem. Finally, the third proposed algorithm is called SAV–DROP and is a heuristic algorithm that combines the Clarke–Wright method and the DROP algorithm. A two-phase heuristic is presented in [4], where in the first phase the set of open plants is determined and a priori routes are considered, while in the second phase the routes are optimized. Other two-phase heuristics have been proposed in [7,12,13,30,33,42,49,50,58]. Cluster analysis algorithms are presented in [6,18,60]. Iterative approaches have been proposed by [27,59]. Min ([46]) considered a two-level location–allocation problem of terminals to customer clusters and supply sources using a hierarchical approach consisting of both exact and

heuristic procedures. Insertion methods have been proposed in [15]. A partitioning heuristic algorithm is proposed in [35], and a sweep heuristic is proposed in [21].

### Metaheuristic Algorithms for the Solution of the Location Routing Problem

Several metaheuristic algorithms have been proposed for the solution of the LRP. In what follows, an analytical presentation of these algorithms is given.

- **Tabu search (TS)** was introduced by Glover [22,23] as a general iterative metaheuristic for solving combinatorial optimization problems. Computational experience has shown that TS is a well-established approximation technique that can compete with almost all known techniques and that, by its flexibility, can beat many classic procedures. It is a form of local neighbor search. Each solution  $S$  has an associated set of neighbors  $N(S)$ . A solution  $S' \in N(S)$  can be reached from  $S$  by an operation called a *move*. TS can be viewed as an iterative technique that explores a set of problem solutions by repeatedly making moves from one solution  $S$  to another solution  $S'$  located in the neighborhood  $N(S)$  of  $S$  [24]. TS moves from a solution to its best admissible neighbor, even if this causes the objective function to deteriorate. To avoid cycling, solutions that have been recently explored are declared *forbidden or tabu* for a number of iterations. The tabu status of a solution is overridden when certain criteria (*aspiration criteria*) are satisfied. Sometimes, *intensification* and *diversification* strategies are used to improve the search. In the first case, the search is accentuated in the promising regions of the feasible domain. In the second case, an attempt is made to consider solutions in a broad area of the search space. Tuzun and Burke [62] proposed a two-phase tabu search architecture for the solution of the LRP. TS algorithms for the LRP are also presented in [10,14,41,45,57].
- **Simulated annealing (SA)** [1,3,32] plays a special role within local search for two reasons. First, SA appears to be quite successful when applied to a broad range of practical problems. Second, some threshold accepting algorithms such as SA have a stochastic component, which facilitates a theoretical analysis of their asymptotic convergence. SA [2] algorithms are stochastic algorithms that allow random

uphill jumps in a controlled fashion in order to provide possible escapes from poor local optima. Gradually the probability allowing the objective function value to increase is lowered until no more transformations are possible. SA owes its name to an analogy with the annealing process in condensed-matter physics, where a solid is heated to a maximum temperature at which all particles of the solid randomly arrange themselves in the liquid phase, followed by cooling through careful and slow reduction of the temperature until the liquid is frozen with the particles arranged in a highly structured lattice and minimal system energy. This ground state is reachable only if the maximum temperature is sufficiently high and the cooling sufficiently slow. Otherwise a metastable state is reached. The metastable state is also reached with a process known as quenching, in which the temperature is instantaneously lowered. Its predecessor is the so-called Metropolis filter. Wu et al. [64] proposed an algorithm that divides the original problem into two subproblems, i. e., the location-allocation problem and the general vehicle routing problem, respectively. Each subproblem is, then, solved in a sequential and iterative manner by the SA algorithm embedded in the general framework for the problem-solving procedure. SA algorithms for the LRP are presented in [8,40,41].

- **Greedy randomized adaptive search procedure (GRASP)** [56] is an iterative two-phase search method that has gained considerable popularity in combinatorial optimization. Each iteration consists of two phases, a construction phase and a local search procedure. In the construction phase, a randomized greedy function is used to build up an initial solution. This randomized technique provides a feasible solution within each iteration. This solution is then exposed for improvement attempts in the local search phase. The final result is simply the best solution found over all iterations. Prins et al. [52] proposed a GRASP with a path-linking phase for the solution of the capacitated location routing problem.
- **Genetic algorithms (GAs)** are search procedures based on the mechanics of natural selection and natural genetics. The first GA was developed by John H. Holland in the 1960s to allow computers to evolve solutions to difficult search and combinatorial problems such as function optimization and machine learning [28]. Genetic algorithms offer a particularly attractive approach to problems like location routing problems since they are generally quite effective for the rapid global search of large, nonlinear, and poorly understood spaces. Moreover, GAs are very effective in solving large-scale problems. GAs [25] mimic the evolution process in nature. They are based on an imitation of the biological process in which new and better populations among different species are developed during evolution. Thus, unlike most standard heuristics, GAs use information about a population of solutions, called individuals, when they search for better solutions. A GA is a stochastic iterative procedure that maintains the population size constant in each iteration, called a generation. Their basic operation is the mating of two solutions to form a new solution. To form a new population, a binary operator called a crossover and a unary operator called a mutation are applied [54,55]. Crossover takes two individuals, called parents, and produces two new individuals, called offspring, by swapping parts of the parents. Marinakis and Marinaki [44] proposed a bilevel GA for a real-life LRP. A new formulation based on bilevel programming was proposed. Based on the fact that in the LRP decisions are made at a strategic level and at an operational level, we formulate the problem in such a way that in the first level, the decisions of the strategic level are made, namely, the top manager finds the optimal location of the facilities, while in the second level, the operational-level decisions are made, namely, the operational manager finds the optimal routing of vehicles. Other evolutionary approaches for the solution of the LRP have been proposed in [29,53].
- **Variable neighborhood search (VNS)** is a metaheuristic for solving combinatorial optimization problems whose basic idea is systematic change of a neighborhood within a local search [26]. VNS algorithms for the LRP are presented in [45].
- The **ant colony optimization (ACO)** metaheuristic is a relatively new technique for solving combinatorial optimization problems (COPs). Based strongly on the ant system (AS) metaheuristic developed by Dorigo, Maniezzo, and Colorni [19], ACO is derived

from the foraging behavior of real ants in nature. The main idea of ACO is to model the problem as the search for a minimum cost path in a graph. Artificial ants walk through this graph looking for good paths. Each ant has a rather simple behavior so that it will typically only find rather poor-quality paths on its own. Better paths are found as the emergent result of the global cooperation among ants in the colony. An ACO algorithm consists of a number of cycles (iterations) of solution construction. During each iteration a number of ants (which is a parameter) construct complete solutions using heuristic information and the collected experiences of previous groups of ants. These collected experiences are represented by a digital analog of trail pheromone that is deposited on the constituent elements of a solution. Small quantities are deposited during the construction phase while larger amounts are deposited at the end of each iteration in proportion to solution quality. Pheromone can be deposited on the components and/or the connections used in a solution depending on the problem. ACO algorithms for the LRP are presented in [8].

## Logconcave Measures, Logconvexity

### Keywords

Logconcave function; Logconcave measure; Logconvex function; Logconvex measure;  $\alpha$ -concave function;  $\alpha$ -concave measure; Quasiconcave function; Quasiconcave measure

A nonnegative function  $f: \mathbf{R}^n \rightarrow \mathbf{R}^1$  is called a *logconcave* (point) function if for every  $\mathbf{x}, \mathbf{y} \in \mathbf{R}^n$  and  $0 < \lambda < 1$  we have the inequality

$$f(\lambda \mathbf{x} + (1 - \lambda)\mathbf{y}) \geq [f(\mathbf{x})]^\lambda [f(\mathbf{y})]^{1-\lambda}.$$

A probability measure  $P$  defined on the Borel sets of  $\mathbf{R}^n$  is called *logconcave* if for any Borel sets  $A, B \subset \mathbf{R}^n$  and  $0 < \lambda < 1$  we have the inequality

$$P(\lambda A + (1 - \lambda)B) \geq [P(A)]^\lambda [P(B)]^{1-\lambda},$$

provided that  $\lambda A + (1 - \lambda)B$  is also a Borel set. If  $P$  is a logconcave measure in  $\mathbf{R}^n$  and  $A \subset \mathbf{R}^n$  is a convex set, then  $P(A + \mathbf{z})$  is a logconcave point function in  $\mathbf{R}^n$ . In particular, the probability distribution function  $F(\mathbf{z}) = P(\{\mathbf{x}: \mathbf{x} \leq \mathbf{z}\}) = P(\{\mathbf{x}: \mathbf{x} \leq \mathbf{0}\} + \mathbf{z})$ , of the probability measure  $P$ , is a logconcave point function. If  $n = 1$ , then also  $1 - F(\mathbf{z})$  is logconcave.

The basic theorem concerning logconcave measures [5,6] states that if the probability measure  $P$  is generated by a logconcave probability density function  $f$ , i. e.,

$$P(C) = \int_C f(\mathbf{x}) \, d\mathbf{x}$$

for every Borel set  $C \subset \mathbf{R}^n$ , then  $P$  is a logconcave measure.

Examples for logconcave probability distributions are the multivariate normal, the uniform (on a convex set) and for special parameter values the Wishart, the beta, the univariate and some multivariate gamma distributions.

A closely related theorem [5] states that if  $f: \mathbf{R}^{n+m} \rightarrow \mathbf{R}^1$  is a logconcave function, then

$$\int_{\mathbf{R}^m} f(\mathbf{x}, \mathbf{y}) \, d\mathbf{y}$$

is a logconcave function in  $\mathbf{R}^n$ . This implies that the convolution of two logconcave functions is also logconcave [3,5].

Logconcave probability distributions play important role in probabilistic constrained stochastic programming problems. If the problem is:

$$\begin{cases} \min & \mathbf{c}^\top \mathbf{x} \\ \text{s.t.} & P(T\mathbf{x} \geq \boldsymbol{\xi}) \geq p, \\ & A\mathbf{x} = \mathbf{b}, \quad \mathbf{x} \geq \mathbf{0}, \end{cases}$$

and the random vector  $\boldsymbol{\xi}$  has continuous distribution with logconcave probability density function, then the set of feasible solutions is convex (for more general results see [6]). On the other hand, if the problem is solved by a barrier function method with logarithmic penalty function, then the function, to be minimized in each step, is convex.

The basic theorem of logconcave measures has the following generalization [1,2]: If  $-\infty \leq \alpha \leq \infty$ ,  $0 < \lambda < 1$ , and the probability density function  $f: \mathbf{R}^n \rightarrow \mathbf{R}^1$  satisfies  $(\mathbf{x}, \mathbf{y} \in \mathbf{R}^n)$ :

$$\begin{aligned} & f(\lambda \mathbf{x} + (1 - \lambda)\mathbf{y}) \\ & \geq [\lambda f^\alpha(\mathbf{x}) + (1 - \lambda)f^\alpha(\mathbf{y})]^\frac{1}{\alpha}, \end{aligned}$$

then for any Borel sets  $A, B \subset \mathbf{R}^n$  such that  $\lambda A + (1 - \lambda)B$  is also a Borel set, we have

$$P(\lambda A + (1 - \lambda)B) \tag{1}$$

$$\geq \left\{ \lambda [P(A)]^\gamma + (1 - \lambda) [P(B)]^\gamma \right\}^{\frac{1}{\gamma}}, \quad (2)$$

where  $\gamma = \alpha/(1 + n\alpha)$ . The cases  $\alpha, \gamma = -\infty, 0, \infty$  are interpreted by continuity. Logconcavity corresponds to the case  $\alpha = \gamma = 0$ . If  $f, P$  satisfy the above inequalities, then  $f$  is called an  $\alpha$ -concave function and  $P$  a  $\gamma$ -concave probability measure. If  $\alpha, \gamma = -\infty$ , then  $f$  and  $P$  are called *quasiconcave*.

A nonnegative function  $f: \mathbf{R}^n \rightarrow \mathbf{R}^1$  is called *logconvex* in the convex set  $D \in \mathbf{R}^n$  if for every  $\mathbf{x}, \mathbf{y} \in D$  and  $0 < \lambda < 1$  we have the inequality

$$f(\lambda \mathbf{x} + (1 - \lambda)\mathbf{y}) \leq [f(\mathbf{x})]^\lambda [f(\mathbf{y})]^{1-\lambda}.$$

Similarly, the probability measure  $P$  defined on the Borel subsets of the convex set  $D \subset \mathbf{R}^n$  is called *logconvex* if for any Borel sets  $A, B \subset D$  we have the inequality

$$P(\lambda A + (1 - \lambda)B) \leq [P(A)]^\lambda [P(B)]^{1-\lambda}.$$

It follows, by Hölder's inequality, that the sum of logconvex functions is also logconvex. This fact, in turn, implies that if  $f$  is logconvex in  $D$ , then the function of the variable  $\mathbf{t} \in \mathbf{R}^n$

$$g(\mathbf{t}) = \int_{C+\mathbf{t}} f(\mathbf{x}) \, d\mathbf{x}$$

is logconvex for any fixed Borel set  $C \subset \mathbf{R}^n$  in the sense that  $g(\lambda \mathbf{t}_1 + (1 - \lambda) \mathbf{t}_2) \leq [g(\mathbf{t}_1)]^\lambda [g(\mathbf{t}_2)]^{1-\lambda}$  provided that  $C + \mathbf{t}_1 \subset D, C + \mathbf{t}_2 \subset D$  and  $0 < \lambda < 1$ .

Discrete logconcave distributions; Poisson distribution; Binomial distribution; Hypergeometric distribution; Geometric distribution; Trinomial distribution

The univariate discrete probability distribution  $\{p_k: k \in \mathbf{Z}\}$  is called *logconcave* if for every  $k$  we have the inequality  $p_k^2 \geq p_{k-1} p_{k+1}$ . This inequality implies that if  $k = \lambda i + (1 - \lambda)j$ , where  $i, j, k$  are integers and  $0 < \lambda < 1$ , then we have the inequality  $p_k \geq p_i^\lambda p_j^{(1-\lambda)}$ . Examples are the binomial, Poisson, hypergeometric, geometric distributions.

A classical theorem by M. Fekete [3] states that the convolution of two logconcave univariate discrete distributions is also logconcave.

The multivariate discrete logconcavity [2] is not a direct generalization of its univariate counterpart. The discrete probability distribution  $\{P(\mathbf{x}): \mathbf{x} \in \mathbf{Z}^m\}$  is said to be *logconcave* if there exists a convex function  $g: \mathbf{R}^m \rightarrow \mathbf{R}$  such that

$$-\log P(\mathbf{x}) = g(\mathbf{x}) \quad \text{for } \mathbf{x} \in \mathbf{Z}^m.$$

If  $P(\mathbf{x}) = 0$ , then by definition  $-\log P(\mathbf{x}) = +\infty$ .

The convolution theorem, mentioned above in connection with logconcave univariate distributions, does not carry over to the multivariate case. We know, however, that the trinomial distribution:

$$P(k_1, k_2) = \frac{n!}{k_1! k_2! (n - k_1 - k_2)!} \times p_1^{k_1} p_2^{k_2} (1 - p_1 - p_2)^{n - k_1 - k_2}$$

is logconcave and the convolution of trinomial distributions is also logconcave [5]. For the use of discrete logconcavity in stochastic programming consult [6].

Other definitions and results, concerning multivariate discrete logconcavity, can be found in [1,4].

### Introduction

Turkay and Grossmann [7] proposed a logic version of the outer-approximation algorithm for MINLP by Du-

ran and Grossmann [2] for solving a special class of generalized disjunctive programming (GDP) problems. The problem arises in the optimization of process networks and involves two-term disjunctions in which the first term is activated when a unit or node is selected, while the second term enforces zero values to a subset of the continuous variables. The specific form of the GDP problem is as follows:

$$\begin{aligned}
 \min Z &= \sum_{k \in K} c_k + f(x) \\
 \text{s.t. } r(x) &\leq 0 \\
 \left[ \begin{array}{c} Y_k \\ g_k(x) \leq 0 \\ c_k = \gamma_k \end{array} \right] &\vee \left[ \begin{array}{c} \neg Y_k \\ B^k x = 0 \\ c_k = 0 \end{array} \right] \quad k \in K \quad (\text{GDP}) \\
 \Omega(Y) &= \text{True} \\
 x \in R^n, \quad c &\in R^m, \quad Y \in \{\text{true}, \text{false}\}^m,
 \end{aligned}$$

where  $Y_k$  are the Boolean variables that decide whether the first term or second term in a disjunction  $k \in K$  is true or false, and  $x$  are the continuous variables. The objective function involves the term  $f(x)$  for the continuous variables and the charges  $c_k$  that depend on the discrete choices in each disjunction  $k \in K$ . The constraints  $r(x) \leq 0$  must hold regardless of the discrete choices. In contrast,  $g_k(x) \leq 0$  are conditional constraints that must hold when  $Y_k$  is true in the  $k$ th disjunction; otherwise ( $\neg Y_k$ ) a subset of the  $x$  variables is set to zero with the proper definition of the matrix  $B^i$ . In particular, we define  $B^i = [b^T]$  such that  $b_j^T = e^T$  if  $x_j = 0$ , and  $b_j^T = 0^T$  if  $x_j \neq 0$ . In this way only a subset of the variables  $x$  is forced to zero (typically flows). The cost variables  $c_k$  correspond to the fixed charges, and their value equals  $\gamma_k$  if the Boolean variable  $Y_k$  is true; otherwise they are zero.  $\Omega(Y) = \text{True}$  are logical relations for the Boolean variables expressed as propositional logic. It is assumed for the derivation of basic methods that the functions are convex, although in practical applications these often correspond to nonconvex functions.

### NLP and Master Subproblems

Following the original algorithm [2], the logic-based outer-approximation algorithm consists of solving NLP subproblems and disjunctive or MILP master problems.

As described in Turkay and Grossmann [7], for fixed values of the Boolean variables,  $Y_k = \text{true}$  and  $Y_k = \text{false}$ , the corresponding NLP subproblem is as follows:

$$\begin{aligned} \min Z &= \sum_{k \in K} c_k + f(x) \\ \text{s.t. } r(x) &\leq 0 \\ &\left. \begin{aligned} g_k(x) &\leq 0 \\ c_k &= \gamma_k \end{aligned} \right\} \text{ for } Y_k = \text{true} \quad k \in K \\ &\left. \begin{aligned} B^k x &= 0 \\ c_k &= 0 \end{aligned} \right\} \text{ for } Y_k = \text{false} \quad k \in K \\ x &\in R^n, \quad c_i \in R^m, \end{aligned} \tag{NLPD}$$

Note that for every disjunction  $k \in K$  only constraints corresponding to the Boolean variable  $Y_k$  that is true are imposed, thus leading to a reduction in the size of the problem. Also, fixed charges  $\gamma_k$  are only applied to these terms. Assuming that  $NF$  subproblems (NLPD) are solved in which sets of linearizations  $l = 1, \dots, NF$  are generated for subsets of disjunction terms  $L_k = \{l | Y_k^l = \text{true}\}$ , one can define the following disjunctive OA master problem:

$$\begin{aligned} \text{Min} Z &= \sum_k c_k + \alpha \\ \text{s.t. } &\left. \begin{aligned} \alpha &\geq f(x^l) + \nabla f(x^l)^T(x - x^l) \\ r(x^l) + \nabla r(x^l)^T(x - x^l) &\leq 0 \end{aligned} \right\} l = 1, \dots, L \\ &\left[ \begin{array}{l} Y_k \\ g_k(x^l) + \nabla g_k(x^l)^T(x - x^l) \leq 0 \\ l \in L_k \\ c_k = \gamma_k \end{array} \right] \vee \left[ \begin{array}{l} \neg Y_k \\ B^k x = 0 \\ c_k = 0 \end{array} \right] \\ &k \in K \\ &\Omega(Y) = \text{True} \\ \alpha \in R, \quad x \in R^n, \quad c \in R^m, \quad Y \in \{\text{true}, \text{false}\}^m \end{aligned} \tag{MGDP}$$

It should be noted that before applying the above master problem it is necessary to solve various subproblems (NLPD) so as to produce at least one linear approximation of each of the terms in the disjunctions. As shown by Turkay and Grossmann [7], selecting the smallest number of subproblems amounts to solving a set covering problem, which is of small size and easy

to solve. In the context of a process flowsheet synthesis problem, another way of generating the linearizations in (MGDP) is by starting with an initial flowsheet and suboptimizing the remaining subsystems.

The above problem (MGDP) can be solved by the methods described by Beaumont [1], Raman and Grossmann [6], and Hooker [4]. Turkay and Grossmann [4] have shown that if the convex hull representation of the disjunctions is used in (MGDP), then converting the logic relations  $\Omega(Y)$  into the inequalities  $Ay \leq a$  leads to the following MILP problem:

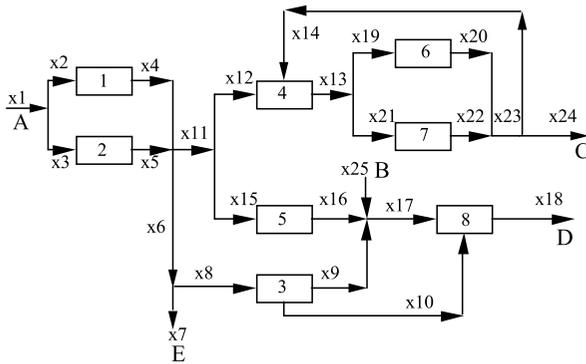

$$\begin{aligned} \text{Min} Z &= \sum_k y_k \gamma_k + \alpha \\ \text{s.t. } &\left. \begin{aligned} \alpha &\geq f(x^l) + \nabla f(x^l)^T(x - x^l) \\ r(x^l) + \nabla r(x^l)^T(x - x^l) &\leq 0 \end{aligned} \right\} l = 1, \dots, L \\ &\nabla_{x_{z_k}} g_k(x^l)^T x_{z_k} + \nabla_{x_{N_k}} g_k(x^l)^T x_{N_k}^1 \\ &\leq \left[ -g_k(x^l) + \nabla_x g_k(x^l)^T x^l \right] y_k \\ &l \in L_k, \quad k \in K \\ &x_{N_k} = x_{N_k}^1 + x_{N_k}^2 \\ &0 \leq x_{N_k}^1 \leq x_{N_k}^U y_k \\ &0 \leq x_{N_k}^2 \leq x_{N_k}^U (1 - y_k) \\ &Ay \leq a \\ &x \in R^n, \quad x_{N_k}^1 \geq 0, \quad x_{N_k}^2 \geq 0, \quad y \in \{0, 1\}^m \end{aligned} \tag{MIPDF}$$

where the vector  $x$  is partitioned into the variables  $(x_{z_k}, x_{N_k})$  for each disjunction  $k$  according to the definition of the matrix  $B^i$  (i.e.,  $x_z$  refers to nonzero rows of this matrix). It is interesting to note that the logic-based outer-approximation algorithm represents a generalization of the modeling/decomposition strategy of Kocis and Grossmann [5] for the synthesis of process flowsheets.

**Steps of Algorithm**

Assuming feasible NLP subproblems, the steps of the proposed logic-based outer-approximation method are as follows:

- Step 1:** Model the problem in generalized disjunctive form as in (GDP).
- Step 2:** Identify the NF subproblems to be solved either from inspection or from set covering problems.

Logic-Based Outer Approximation, Figure 1  
Process network example

**Step 3:** Solve NLP subproblems (NLPD) for the NF subproblems determined in step 2. The lowest-cost solution of these NLPs yields an upper bound,  $Z_U$ , for the problem.

**Step 4:** Linearize the objective function and constraints of the current NLP subproblem(s) and set up the MILP master problem (MIPDF). The solution of this problem gives the lower bound,  $Z_L$ , for the problem.

**Step 5:** If  $|Z_U - Z_L| \leq \varepsilon$ , where  $\varepsilon$  is a tolerance, then stop. The solution with the current  $Z_U$  is the optimal solution. Otherwise go to step 6.

**Step 6:** Solve NLP subproblem (NLPD) by fixing the Boolean variables predicted by the master problem. The objective function value of the solution is  $Z_{NLP}$ . If  $Z_{NLP} < Z_U$ , then set  $Z_U = Z_{NLP}$ .

**Step 7:** Compare the upper bound  $Z_U$  with the lower bound  $Z_L$ . If  $|Z_U - Z_L| \leq \varepsilon$ , then stop; the solution with the current  $Z_U$  is the optimal solution. Otherwise go to step 4.

It should be noted that one can also derive a logic-based version of Generalized Benders Decomposition as described in [7]. The logic outer-approximation algorithm described above has been implemented in the computer code LOGMIP by Vecchietti and Grossmann [8], which can be accessed from <http://www.logmip.ceride.gov.ar>

### Example

Consider the following (GDP) problem from [7] that deals with a simplified version of the synthesis of a process network shown in Fig. 1.

The GDP model is as follows:

#### 1. Objective function:

$$\begin{aligned} \min Z = & c_1 + c_2 + c_3 + c_4 + c_5 + c_6 + c_7 + c_8 + x_2 \\ & - 10x_3 + x_4 - 15x_5 - 40x_9 + 15x_{10} + 15x_{14} \\ & + 80x_{17} - 65x_{18} + 25x_{19} - 60x_{20} \\ & + 35x_{21} - 80x_{22} - 35x_{25} + 122 \end{aligned}$$

#### 2. Material balances at mixing/splitting points:

$$\begin{aligned} x_1 - x_2 - x_3 &= 0 \\ x_4 + x_5 - x_6 - x_{11} &= 0 \\ x_{13} - x_{19} - x_{21} &= 0 \\ x_{17} - x_9 - x_{16} - x_{25} &= 0 \\ x_{11} - x_{12} - x_{15} &= 0 \\ x_6 - x_7 - x_8 &= 0 \\ x_{23} - x_{20} - x_{22} &= 0 \\ x_{23} - x_{14} - x_{24} &= 0 \end{aligned}$$

#### 3. Specifications on the flows:

$$\begin{aligned} x_{10} - 0.8x_{17} &\leq 0 \\ x_{10} - 0.4x_{17} &\geq 0 \\ x_{12} - 5x_{14} &\leq 0 \\ x_{12} - 2x_{14} &\geq 0 \end{aligned}$$

#### 4. Disjunctions:

$$\begin{aligned} \text{Unit 1: } & \begin{bmatrix} Y_1 \\ \exp(x_4) - 1 - x_2 \leq 0 \\ c_1 = 5 \end{bmatrix} \\ & \vee \begin{bmatrix} -Y_1 \\ x_2 = x_4 = 0 \\ c_1 = 0 \end{bmatrix} \\ \text{Unit 2: } & \begin{bmatrix} Y_2 \\ \exp(x_5/1.2) - 1 - x_3 \leq 0 \\ c_2 = 8 \end{bmatrix} \\ & \vee \begin{bmatrix} -Y_2 \\ x_4 = x_3 = 0 \\ c_2 = 0 \end{bmatrix} \\ \text{Unit 3: } & \begin{bmatrix} Y_3 \\ 1.5x_9 - x_8 + x_{10} = 0 \\ c_3 = 6 \end{bmatrix} \\ & \vee \begin{bmatrix} -Y_3 \\ x_8 = x_9 = x_{10} = 0 \\ c_3 = 0 \end{bmatrix} \end{aligned}$$

$$\begin{aligned}
 \text{Unit 4: } & \left[ \begin{array}{l} Y_4 \\ 1.5(x_{12} + x_{14}) - x_{13} = 0 \\ c_4 = 10 \end{array} \right] \\
 \vee & \left[ \begin{array}{l} \neg Y_4 \\ x_{12} = x_{13} = x_{14} = 0 \\ c_4 = 0 \end{array} \right] \\
 \text{Unit 5: } & \left[ \begin{array}{l} Y_5 \\ x_{15} - 2x_{16} = 0 \\ c_5 = 6 \end{array} \right] \\
 \vee & \left[ \begin{array}{l} \neg Y_5 \\ x_{15} = x_{16} = 0 \\ c_5 = 0 \end{array} \right] \\
 \text{Unit 6: } & \left[ \begin{array}{l} Y_6 \\ \exp(x_{20}/1.5) - 1 - x_{19} \leq 0 \\ c_6 = 7 \end{array} \right] \\
 \vee & \left[ \begin{array}{l} \neg Y_6 \\ x_{19} = x_{20} = 0 \\ c_6 = 0 \end{array} \right] \\
 \text{Unit 7: } & \left[ \begin{array}{l} Y_7 \\ \exp(x_{22}) - 1 - x_{21} \leq 0 \\ c_7 = 4 \end{array} \right] \\
 \vee & \left[ \begin{array}{l} \neg Y_7 \\ x_{21} = x_{22} = 0 \\ c_7 = 0 \end{array} \right] \\
 \text{Unit 8: } & \left[ \begin{array}{l} Y_8 \\ \exp(x_{18}) - 1 - x_{10} - x_{17} \leq 0 \\ c_8 = 5 \end{array} \right] \\
 \vee & \left[ \begin{array}{l} \neg Y_8 \\ x_{10} = x_{17} = x_{18} = 0 \\ c_8 = 0 \end{array} \right]
 \end{aligned}$$

5. Propositional Logic [ $\Omega = (Y_i)$ ]:

$$\begin{aligned}
 Y_1 &\Rightarrow Y_3 \vee Y_4 \vee Y_5 \\
 Y_2 &\Rightarrow Y_{13} \vee Y_4 \vee Y_5 \\
 Y_3 &\Rightarrow Y_1 \vee Y_2, \quad Y_3 \Rightarrow Y_8 \\
 Y_4 &\Rightarrow Y_1 \vee Y_2, \quad Y_4 \Rightarrow Y_6 \vee Y_7 \\
 Y_5 &\Rightarrow Y_1 \vee Y_2, \quad Y_5 \Rightarrow Y_8 \\
 Y_6 &\Rightarrow Y_4 \\
 Y_7 &\Rightarrow Y_4 \\
 Y_8 &\Rightarrow Y_3 \vee Y_5 \vee (\neg Y_3 \wedge \neg Y_5)
 \end{aligned}$$

Logic-Based Outer Approximation, Table 1  
Progress of iterations

Subproblem	Objective value
NLPD1	73.277
NLPD2	103.584
NLPD3	113.789
MGDP	67.948
NLPD4	68.009

6. Specifications:

$$\begin{aligned}
 Y_1 \vee Y_2 \\
 Y_4 \vee Y_5 \\
 Y_6 \vee Y_7
 \end{aligned}$$

7. Variables:

$$\begin{aligned}
 x_j, \quad c_i \geq 0, \quad Y_i = \{\text{True, False}\} \\
 i = 1, 2, \dots, 8, \quad j = 1, 2, \dots, 25
 \end{aligned}$$

Applying LOGMIP to solve this problem, and starting with three NLP subproblems at

$$\begin{aligned}
 \text{NLPD1 : } Y_2 = Y_3 = Y_4 = Y_5 = Y_8 = \text{True} \\
 \text{NLPD2 : } Y_1 = Y_3 = Y_4 = Y_7 = Y_8 = \text{True} \\
 \text{NLPD2 : } Y_2 = Y_4 = Y_6 = Y_7 = \text{True}
 \end{aligned}$$

the predicted optimum solution is given by  $Z = 68.009$ . Table 1 shows the progress of the iterations.

### Introduction

Let  $G(V, E)$  be a simple undirected graph,  $V = \{1, 2, \dots, n\}$ . The *adjacency matrix* of  $G$  is a matrix  $A_G = (a_{ij})_{n \times n}$ , where  $a_{ij} = 1$  if  $(i, j) \in E$  and  $a_{ij} = 0$  otherwise. The set of vertices *adjacent* to a vertex  $i \in V$  will be denoted by  $N(i) = \{j \in V : (i, j) \in E\}$  and called the *neighborhood* of the vertex  $i$ . We will also consider the *complementary graph*  $\tilde{G}(V, \tilde{E})$  having the same set of vertices  $V$ , but an edge  $(i, j) \in \tilde{E}$  if and only if  $i$  and  $j$  are not adjacent in  $G$ .

An *independent set*  $S$  is a subset of  $V$  such that no two vertices of  $S$  are adjacent, i. e.,  $\forall i \in S N(i) \cap S = \emptyset$ . The set  $S$  is called a *maximal* independent set if any vertex  $i \in V \setminus S$  has at least one adjacent vertex in  $S$ , i. e.,  $\forall i \in V \setminus S N(i) \cap S \neq \emptyset$ . Finally, the set  $S$  is called a *maximum* independent set if it has the largest cardinality among all independent sets of the graph. This cardinality will be denoted by  $\alpha(G)$  and called the *independence* (or *stability*) *number* of the graph  $G$ .

In addition to the maximum cardinality stable sets, we will consider the *maximum weight independent sets*.

Let there be a given vector  $w = (w_1, w_2, \dots, w_n)^T$  of nonnegative *vertex weights*. A maximum weight independent set is such an independent set  $S \subseteq V$  that has the largest weight  $\alpha(G, w) = \max_S \sum_{i \in S} w_i$ .

Similarly, a *clique*  $Q$  of the graph  $G$  is a subset of  $V$  such that any two vertices in it are adjacent, i. e.,  $\forall i \in Q N(i) \cap Q = Q \setminus \{i\}$ . The clique  $Q$  is called *maximal* if for any vertex  $i \in V \setminus Q$  there is at least one vertex in  $Q$  non-adjacent to  $i$ , i. e.,  $\forall i \in V \setminus Q N(i) \cap Q \neq \emptyset$ . If  $Q$  has the largest cardinality among all cliques of the graph, it is called a *maximum* clique. The cardinality of a maximum clique will be denoted by  $\omega(G)$  and called the *clique number* of the graph  $G$ . A *maximum weight clique* is a clique having the largest weight  $\omega(G, w) = \max_Q \sum_{i \in Q} w_i$ .

It is easy to see that independent sets of the graph  $G$  correspond to cliques of  $\tilde{G}$ , and vice versa.

We will denote by  $\chi(G)$  the *chromatic number* of the graph  $G$  (i. e. the minimum number of colors to which the graph vertices can be colored without using one color for any two adjacent vertices.) The number  $\chi(\tilde{G})$ , giving the minimum number of cliques of  $G$  to which the vertex set  $V$  can be partitioned, will be also denoted by  $\tilde{\chi}(G)$  and called the *clique partition number* of the graph  $G$ .

Next, for two graphs  $G_1(V_1, E_1)$  and  $G_2(V_2, E_2)$  we define their *strong product*  $G_1 \cdot G_2$  as the graph, whose vertex set is the Cartesian product  $V_1 \times V_2$  and in which a vertex  $(i, j)$  is adjacent to a vertex  $(i', j')$  if and only if  $(i, i') \in E_1$  and  $(j, j') \in E_2$ . The strong product of  $k$  copies of  $G$  will be denoted by  $G^k$ .

### Formulation

#### Lovász Number as an Upper Bound of Shannon Capacity

Let us consider the set  $V = \{1, 2, \dots, n\}$  to be an alphabet in which the adjacency means that the two letters can be confused. Then any set of one-letter messages that cannot be confused with each other corresponds to an independent set of the graph and vice versa. Furthermore, the maximum number of one-letter messages that cannot be confused with each other is equal to  $\alpha(G)$ , and the maximum number of  $k$ -letter messages that cannot be confused with each other is equal to  $\alpha(G^k)$ . It is easy to see that there are at least  $\alpha(G)^k$   $k$ -letter messages that cannot be confused with each other,

so  $\alpha(G^k) \geq \alpha(G)^k$ . So,

$$\Theta(G) = \sup_k \sqrt[k]{\alpha(G^k)} = \lim_{k \rightarrow \infty} \sqrt[k]{\alpha(G^k)} \geq \alpha(G). \quad (1)$$

The value  $\Theta(G)$  is called the *Shannon zero-error capacity* of the graph  $G$  [14]. Generally, it is extremely hard to compute, and nowadays  $\Theta(G)$  is not even known for the graph  $C_7$  (cycle of 7 vertices).

Thus, the independence number  $\alpha(G)$  gives a *lower* bound on  $\Theta(G)$ . In 1979, L. Lovász defined a new non-trivial *upper* bound on the Shannon zero-error capacity of a graph in his seminal paper [11]. This function was named later *Lovász number* (or  $\vartheta$ -function) of a graph.

First, define an *orthonormal representation* of the graph  $G$  as a system  $(u_1, u_2, \dots, u_n)$  of unit vectors in a Euclidean space such that whenever two vertices  $i$  and  $j$  are not adjacent, the vector  $u_i$  is orthogonal to the vector  $u_j$ . It is easy to see that such systems of vectors do exist, e. g., any  $n$  orthonormal vectors from the space  $\mathbb{R}^n$ . The  $\vartheta$ -function is defined as the following minimax value:

$$\vartheta(G) = \min_{\{c, (u_i)\}} \max_{i \in V} \frac{1}{(c^T u_i)^2}, \quad (2)$$

where  $c$  ranges over unit vectors of the same dimensionality that the vectors  $u_i$  are. The vector  $c$  was called by Lovász the *handle* of the representation.

It can be shown that for a strong product of graphs,  $\vartheta(G \cdot H) \leq \vartheta(G)\vartheta(H)$ . To show that  $\alpha(G) \leq \vartheta(G)$  one needs to observe that if  $S$  is a maximum independent set of  $G$ , then  $1 = c^2 \geq \sum_{i \in S} (c^T u_i)^2 \geq \alpha(G)/\vartheta(G)$ . From here it is obvious that  $\Theta(G) \leq \vartheta(G)$  as  $\alpha(G^k) \leq \vartheta(G^k) \leq \vartheta(G)^k$ .

Similarly, we introduce the weighted  $\vartheta$ -function:

$$\vartheta(G, w) = \min_{\{c, (u_i)\}} \max_{i \in V} \frac{w_i}{(c^T u_i)^2}, \quad (3)$$

which gives an upper bound for  $\alpha(G, w) \leq \vartheta(G, w)$ .

In contrast to  $\Theta(G)$  and  $\alpha(G, w)$ , which are hard to compute,  $\vartheta(G, w)$  can be computed with an arbitrary precision in a polynomial time by either the ellipsoid method or an interior point method due to its semidefinite programming formulation considered below (see also [7,9,13]). This makes  $\vartheta$ -function attractive for estimating these intractable numbers.

### The Sandwich Theorem

Other equivalent formulations implying a number of interesting properties of  $\vartheta(G)$  were established in [7] (see also the extensive survey [9]). To introduce them, let us define three specific convex sets in  $\mathbb{R}^n$  associated with the graph:

$$STAB(G) = \text{hull}(\{x \in \{0, 1\}^n \mid x_j + x_k \leq 1, \forall (j, k) \in E\}),$$

$$TH(G) = \{x \geq 0 \mid \sum_{j \in V} (c^T u_j)^2 x_j \leq 1,$$

$$\forall \text{ ort. lab. } (u_j) \text{ of } G, \|c\| = 1\},$$

$$QSTAB(G) = \{x \geq 0 \mid \sum_{j \in Q} x_j \leq 1,$$

$$\forall \text{ cliques } Q \text{ of } G\}.$$

Let  $x^S \in \{0, 1\}^n$  be the *incidence vector* of an independent set  $S$ , that is,  $x_i^S = 1$  if  $i \in S$ , and  $x_i = 0$  otherwise. Then, obviously, for any orthonormal representation  $(u_i)$  and a unit vector  $c$ ,

$$\sum_{j \in V} (c^T u_j)^2 x_j^S = \sum_{j \in S} (c^T u_j)^2 \leq 1.$$

So, any  $x \in STAB(G)$  satisfy the constraints of  $TH(G)$ . Let  $Q$  be any clique of  $G$ . Then we can construct an orthonormal representation as follows. Let all vectors  $(u_i)_{i \in V \setminus Q}$  be mutually orthogonal, and also each of them be orthogonal to another unit vector  $c$ . We set all  $(u_i)_{i \in Q}$  to be equal to  $c$ . If we consider the constraint  $\sum_{j \in V} (c^T u_j)^2 x_j \leq 1$  over only such orthonormal representations, we obtain the clique constraints defining the set  $QSTAB(G)$ . Hence, we have

$$STAB(G) \subseteq TH(G) \subseteq QSTAB(G). \quad (4)$$

Obviously,

$$\alpha(G, w) = \max_x \{w^T x \mid x \in STAB(G)\}. \quad (5)$$

Let us also denote

$$\kappa(G, w) = \max_x \{w^T x \mid x \in QSTAB(G)\}. \quad (6)$$

We will prove that

$$\vartheta(G, w) = \max_x \{w^T x \mid x \in TH(G)\} \quad (7)$$

and henceforth conclude that

$$\alpha(G, w) \leq \vartheta(G, w) \leq \kappa(G, w). \tag{8}$$

The double inequality (8) constitutes the famous *sandwich theorem*.

Let us denote by  $S_n$  the set of all  $n \times n$  symmetric matrices, and by  $S_n^+$  the set of all *positive semidefinite*  $n \times n$  matrices:

$$S_n^+ = \{A \in S_n \mid x^T A x \geq 0 \ \forall x \in \mathbb{R}^n\}.$$

We also denote by  $z = (\sqrt{w_1}, \sqrt{w_2}, \dots, \sqrt{w_n})^T$  the vector of square roots of the vertex weights. Consider the following functions of the graph and vertex weights:

$$\begin{aligned} \vartheta_2(G, w) &= \min_{A \in S_n} \lambda_{\max}(A), \\ \text{s.t. } a_{ij} &= \sqrt{w_i w_j}, \quad \forall (i, j) \notin E, \end{aligned}$$

where  $\lambda_{\max}(A)$  denotes the largest eigenvalue of  $A$ ;

$$\begin{aligned} \vartheta_3(G, w) &= \max_{X \in S_n^+} z^T X z, \\ \text{s.t. } x_{ij} &= 0, \quad \forall (i, j) \in E, \quad \text{tr}(X) = 1, \end{aligned}$$

where  $\text{tr}(X) = \sum_{i=1}^n x_{ii}$  denotes the *trace* of the matrix  $X$ ;

$$\vartheta_4(G, w) = \max_{\{d, (v_i)\}} \sum_{i \in V} (d^T v_i)^2 w_i,$$

where  $(v_i)_{i \in V}$  range over all orthonormal representations of the complementary graph  $\bar{G}$  and  $\|d\| = 1$ .

**Theorem 1**

$$\begin{aligned} \vartheta(G, w) &= \vartheta_2(G, w) = \vartheta_3(G, w) = \vartheta_4(G, w) \\ &= \max_x \{w^T x \mid x \in \mathcal{TH}(G)\}. \end{aligned}$$

*Proof* First we show that  $\vartheta(G, w) \leq \vartheta_2(G, w)$ . Consider a matrix  $A \in S_n$  such that  $a_{ij} = \sqrt{w_i w_j}$ ,  $\forall (i, j) \notin E$ , and let  $t = \lambda_{\max}(A)$ . Then  $tI - A \in S_n^+$ , and hence there exists  $X \in \mathbb{R}^{n \times n}$  such that  $tI - A = X^T X$ . Let  $x_i \in \mathbb{R}^n$  be the  $i$ -th column of  $X$ . Then

$$x_i^T x_i = t - w_i, \quad \forall i \in V$$

and

$$x_i^T x_j^T = -\sqrt{w_i w_j}, \quad \forall i, j \text{ nonadjacent in } G.$$

Note that  $\text{rank}(X) < n$  since the matrix  $tI - A$  has a zero eigenvalue. This implies that there exists a unit vector  $c \in \mathbb{R}^n$  orthogonal to all  $x_i$ ,  $i \in V$ . Consider the vectors

$$u_i = (\sqrt{w_i}c + x_i)/\sqrt{t}, \quad i \in V.$$

It is easy to see that

$$u_i^T u_i = \frac{(w_i c^T c + x_i^T x_i)}{t} = 1$$

and for any two nonadjacent vertices  $i, j \in V$ ,

$$u_i^T u_j = \frac{(\sqrt{w_i w_j} c^T c + x_i^T x_j)}{t} = 0.$$

Hence, the vectors  $(u_i)$  form an orthonormal representation of  $G$  and

$$\vartheta(G, w) \leq \max_{i \in V} \frac{w_i}{(c^T u_i)^2} = \max_{i \in V} \frac{w_i}{w_i/t} = t = \lambda_{\max}(A).$$

Now, we show that  $\vartheta_2(G, w) \leq \vartheta_3(G, w)$ . We have  $z^T X z \leq \vartheta_3 \cdot \text{tr}(X)$  for any  $X \in S_n^+$  such that  $x_{ij} = 0 \ \forall (i, j) \in E$ . This inequality is equivalent to  $(W - \vartheta_3 I) \bullet X \leq 0$ , where  $W = (\sqrt{w_i w_j})_{n \times n}$  and “ $\bullet$ ” denotes the Euclidian inner product in  $\mathbb{R}^{n \times n}$ , i.e.,  $A \bullet B = \sum_{i,j} a_{ij} b_{ij}$ . From here it can be inferred that the matrix  $\vartheta_3 I - W$  is a sum of some positive semidefinite matrix  $D \in S_n^+$  and another symmetric matrix  $A = (a_{ij}) \in S_n$  such that if  $(i, j) \notin E$ , then  $a_{ij} = 0$ . This implies that  $\vartheta_3 I - W - A \in S_n^+$  and hence  $\vartheta_3 \geq \lambda_{\max}(W + A) \geq \vartheta_2$ .

Next, we show that  $\vartheta_3(G, w) \leq \vartheta_4(G, w)$ . Let  $X = (x_{ij}) \in \mathbb{R}^{n \times n}$  be an optimum matrix for the program defining  $\vartheta_3$ . Since  $X \in S_n^+$ , there exists a matrix  $Y \in \mathbb{R}^{n \times n}$  such that  $X = Y^T Y$ . Let  $x_i$  denote the  $i$ -th column of  $X$  and  $y_i$  denote the  $i$ -th column of  $Y$ . Construct an orthonormal system of vectors  $(u_i)_{i \in V}$  in  $\mathbb{R}^n$  such that there is the vector  $u_i = y_i / \|y_i\|$  whenever  $y_i \neq 0$ . Since  $y_i^T y_j = x_{ij} = 0 \ \forall (i, j) \in E$ , the system  $(u_i)$  is an orthonormal representation of  $\bar{G}$ . Furthermore,  $z^T Y^T Y z = z^T X z = \vartheta_3$  and hence  $d = Yz / \sqrt{\vartheta_3}$  is a unit vector. Whenever  $y_i \neq 0$ ,

$$d^T v_i = \frac{z^T Y^T y_i}{(\sqrt{\vartheta_3} \|y_i\|)} = \frac{z^T x_i}{(\sqrt{\vartheta_3} \|y_i\|)}.$$

Thus,  $\|y_i\| d^T v_i = z^T x_i / \sqrt{\vartheta_3}$ ,  $\forall i \in V$ , and

$$\begin{aligned} \sum_{i \in V} \|y_i\| \sqrt{w_i} d^T v_i &= \frac{1}{\sqrt{\vartheta_3}} \sum_{i \in V} z^T x_i \sqrt{w_i} \\ &= \frac{1}{\sqrt{\vartheta_3}} z^T X z = \sqrt{\vartheta_3}. \end{aligned}$$

Using the Cauchy–Schwarz inequality,

$$\begin{aligned} \vartheta_3 &= \left( \sum_{i \in V} \|y_i\| \sqrt{w_i} d^T v_i \right)^2 \\ &\leq \left( \sum_{i \in V} \|y_i\|^2 \right) \left( \sum_{i \in V} w_i (d^T v_i)^2 \right) \\ &= \left( \sum_{i \in V} x_{ii} \right) \left( \sum_{i \in V} w_i (d^T v_i)^2 \right) \\ &= \sum_{i \in V} w_i (d^T v_i)^2 \leq \vartheta_4(G, w). \end{aligned}$$

Next, we prove that  $\vartheta_4(G, w) \leq \max_x \{w^T x \mid x \in \mathcal{TH}(G)\}$ . Let  $(v_i)_{i \in V}$  and  $d$  be correspondingly an optimum orthogonal representation of  $\tilde{G}$  and its handle for the program defining  $\vartheta_4$ . We show that the vector  $((d^T v_i)^2)_{i \in V}$  belongs to  $\mathcal{TH}(G)$ . Consider some orthonormal representation of  $G$ ,  $(u_i)_{i \in V}$ ,  $u_i \in \mathbb{R}^n$ , and let  $c \in \mathbb{R}^n$  be some unit vector. The matrices  $u_i v_i^T \in \mathbb{R}^{n \times n}$  are mutually orthogonal and have the unit norm with respect to the inner product “ $\bullet$ ”, i. e.,

$$(u_i v_i^T) \bullet (u_j v_j^T) = (u_i^T u_j)(v_i^T v_j) = \begin{cases} 1, & \text{if } i = j, \\ 0, & \text{if } i \neq j. \end{cases}$$

Now we may conclude that

$$\begin{aligned} \sum_{i \in V} (c^T u_i)^2 (d^T v_i)^2 &= \sum_{i \in V} ((cd^T) \bullet (u_i v_i^T))^2 \\ &\leq (cd^T) \bullet (cd^T) = 1. \end{aligned}$$

Hence  $((d^T v_i)^2)_{i \in V} \in \mathcal{TH}(G)$  and

$$\begin{aligned} \vartheta_4(G, w) &= \sum_{i \in V} w_i (d^T v_i)^2 \\ &\leq \max_x \{w^T x \mid x \in \mathcal{TH}(G)\}. \end{aligned}$$

The final step is to show that  $\max_x \{w^T x \mid x \in \mathcal{TH}(G)\} \leq \vartheta(G, w)$ . Let  $x^*$  be a vector maximizing  $w^T x$  over  $\mathcal{TH}(G)$ . Choosing any orthonormal representation  $(u_i)_{i \in V}$  and a unit vector  $c$ , we have

$$\begin{aligned} w^T x^* &\leq \left( \max_i \frac{w_i}{(c^T u_i)^2} \right) \sum_{i \in V} (c^T u_i)^2 x_i^* \\ &\leq \max_i \frac{w_i}{(c^T u_i)^2} \leq \vartheta(G, w). \end{aligned}$$

The four inequalities established above can hold if and only if all the  $\vartheta$ 's are equal. QED.  $\square$

Let us denote by  $\kappa(G)$  the value of  $\kappa(G, w)$  when all vertex weights are 1's. It is easy to see that  $\kappa(G) \leq \tilde{\chi}(G)$ . Indeed, if we take a minimum clique partition  $\{Q_1, Q_2, \dots, Q_{\tilde{\chi}}\}$  of  $G$ , then  $\tilde{\chi}(G)$  is equal to the optimum value of the program:

$$\begin{aligned} \max_{x \in \mathbb{R}^n} \sum_{i \in V} x_i, \\ \text{s.t. } \sum_{i \in Q_k} x_i \leq 1, \quad k = 1, 2, \dots, \tilde{\chi}, \quad x \geq 0. \end{aligned}$$

This program has the same objective as the program for  $\kappa(G)$ , but its set of constraints is a subset of constraints of  $QSTAB(G)$ . So, we may extend the sandwich inequality to

$$\alpha(G) \leq \vartheta(G) \leq \kappa(G) \leq \tilde{\chi}(G).$$

Omitting  $\kappa(G)$  and applying the inequalities to the complementary graph, we obtain

$$\omega(G) \leq \vartheta(\tilde{G}) \leq \chi(G), \tag{9}$$

which expresses another famous form of the sandwich theorem stating that a polynomial-time computable number  $\vartheta(\tilde{G})$  lies in between the two NP-hard numbers: the clique number and the chromatic number.

### Lovász Number as a Dual Bound of Quadratic Maximization

Consider the following quadratic formulation of the maximum weight independent set problem:

$$\begin{aligned} \alpha(G, w) &= \max w^T x \\ \text{s.t. } x_i x_j &= 0, \quad \forall (i, j) \in E, \\ x_i^2 - x_i &= 0, \quad i = 1, \dots, n. \end{aligned} \tag{10}$$

It has been shown by N.Z. Shor that the optimal Lagrangian dual bound of program (10) is equal to  $\vartheta(G, w)$  [15]. One can compute this bound for a maximization problem with a quadratic objective subject to a set of linear and quadratic constraints minimizing a convex non-differentiable function defined over a parametric (linearly dependent on Lagrangian multipliers) set of negative semidefinite symmetric matrices.

Indeed, the Lagrangian of program (10) is

$$L(x, \Lambda) = w^T x + \sum_{i=1}^n \lambda_{ii}(x_i^2 - x_i) + \sum_{(i,j) \in E} \lambda_{ij} x_i x_j.$$

The considered optimization problem is equivalent to

$$\max_x \min_{\Lambda} L(x, \Lambda),$$

while the optimal Lagrangian dual bound is derived as

$$\min_{\Lambda} \max_x L(x, \Lambda).$$

From here it follows that in the dual problem  $\Lambda$  should always be chosen in such a way that the quadratic form of  $L(x, \Lambda)$  is negative semidefinite with respect to  $x$  (otherwise the inner maximization with respect to  $x$  will deliver infinity), while minimization with respect to  $\Lambda$  turns out to be convex non-differentiable [15].

## Applications

### Perfect Graphs

A graph is called *perfect* if, for all its vertex-induced subgraphs, the clique number is equal to the chromatic number. In this case the inequalities (9) become the equalities:

$$\omega(G) = \vartheta(\bar{G}) = \chi(G).$$

So, both the clique number and the chromatic number can be computed in a polynomial time by means of the  $\vartheta$ -function. It is also easy to see how the  $\vartheta$ -function can be used to actually find a maximum clique of a perfect graph. Indeed, a vertex  $i$  of a perfect graph  $G$  belongs to some maximum clique if and only if  $\vartheta$ -function of the subgraph induced by the neighborhood  $N(i)$  is equal to  $\vartheta(G) - 1$ . Hence, we can obtain a maximum clique of the graph successively selecting a vertex satisfying this condition and repeating the procedure with the subgraph induced by its neighborhood. Moreover, this simple algorithm can be improved [1,17]. Coloring a perfect graph can be also performed in a polynomial time (see, e. g., [7]).

A graph is perfect if and only if its complementary graph is perfect [7,10]. This means that for any vertex-induced subgraph of a perfect graph there is also the equality between the independence number and the clique partition number. The *strong perfect graph theorem*, proved recently [5], states that a graph is perfect if

and only if it does not include an odd hole or an odd antihole as a vertex-induced subgraph. A polynomial-time algorithm for recognizing perfect graphs was also derived on the basis of the strong perfect graph theorem [4].

### Improving Upper Bounds for Independence Number

It is worth to consider how well does  $\vartheta(G)$  approximate the independence number  $\alpha(G)$  for general graphs and whether this approximation can be improved without breaking the polynomial-time computability. It turns out that for random graphs  $\vartheta(G)/\alpha(G)$  grows as  $O(\sqrt{n}/\log n)$  [2,9]. So,  $\vartheta(G)$  does not allow for a fixed approximation guarantee for  $\alpha(G)$ . Moreover, the maximum independent set problem is known to be hard to approximate (see, e. g., [8]). However, there is a number of approaches to formulate increasingly tight approximations of  $\alpha(G)$  based on the  $\vartheta$ -function. The first one is the “lift-and-project” method by Lovász and Shrijver [12]. The second approach is to express  $\alpha(G)$  as a *copositive* program and to use its approximations via semidefinite programming [6]. Finally, we may try to improve the dual bound of (10) and make it closer to the optimum generating *superfluous* quadratic constraints [15,16].

In first two cases one obtains a sequence of semidefinite programs increasing in size, but having non-increasing optimum values, and at some point the optimum value becomes equal to  $\alpha(G)$ . It comes as no surprise that before achieving the value  $\alpha(G)$ , in the general case, the size of the program increases exponentially (otherwise it would imply  $P=NP$ ). What is more surprising is that any provable polynomial-time improvement of  $\vartheta(G)$  (i. e. a polynomial-time computable function of a graph having a value less than  $\vartheta(G)$  whenever  $\alpha(G) < \vartheta(G)$ ) would also imply  $P=NP$  [3]. Hence, unless  $P=NP$ , neither method can deliver, in general case, a value closer to  $\alpha(G)$  than  $\vartheta(G)$  before the size of the program becomes exponential.

## Background

The interval-Newton method is a tool for solving a system of nonlinear algebraic equations. It provides the capability to enclose *all* solutions of the equation system that occur within a specified search interval, and to do so with *mathematical and computational certainty*. In the context of optimization, it is generally applied to the deterministic global optimization of bound-constrained problems:

$$\min_x \phi(\mathbf{x}) \quad (1)$$

$$\mathbf{x} \in \mathbf{X}^{(0)}. \quad (2)$$

The objective  $\phi(\mathbf{x})$  is in general a nonconvex function that may have multiple local minima. The interval vector (box)  $\mathbf{X}^{(0)}$  provides upper and lower bounds on each component of the decision-variable vector  $\mathbf{x}$ . It is assumed here that these bounds are sufficiently wide that the global minimum of  $\phi(\mathbf{x})$  will occur in the interior of  $\mathbf{X}^{(0)}$ . This means that the stationarity condition  $\nabla\phi(\mathbf{x}) = \mathbf{0}$  can be used in the search for the global minimum. The interval-Newton method can then be applied to enclose all stationary points, one of which is the global minimizer. If only the global minimizer is sought, then interval-Newton is typically combined with some branch-and-bound scheme, so that all stationary points need not actually be found. However, in other applications, such as transition state analysis [22,38] and computation of phase equilibrium [13,37], it may be useful to know all of the stationary points, and the interval-Newton approach provides this capability. For situations in which it is possible that the global minimum will lie on a boundary

of  $\mathbf{X}^{(0)}$ , then the “peeling” process described by Kearfott [19], in which interval-Newton is applied to each of the lower dimensional subspaces that constitute the boundary of  $\mathbf{X}^{(0)}$ , can be used. For more general constrained problems, the interval-Newton method can be applied to the solution of the Karush–Kuhn–Tucker (KKT) conditions or the Fritz-John conditions. A thorough discussion of the use of the interval-Newton approach in global optimization has been given by Hansen and Walster [11]. In recent years, this approach has been used in a number of applications, including computation of fluid phase equilibrium from activity coefficient models [27,36,37,40], cubic equation-of-state models [5,12,13,14,40] and statistical associating fluid theory [39], computation of solid-fluid equilibrium [35,41], parameter estimation using standard least squares [7,25] and error-in-variables [8,9], calculation of adsorption in nanoscale pores from a density function theory model [26], transition state analysis [22] and determination of molecular structures [24].

A drawback to the interval-Newton approach, as well as to other approaches for deterministic global optimization, is the potentially high computational cost. One way to improve the efficiency of the interval-Newton method is to more tightly bound the solution set of the linear interval equation system that is at the core of this approach. In this article, we discuss the solution of this linear interval system and describe a bounding strategy [21,23] based on the use of linear programming (LP) techniques. Using this approach it is possible to exactly (within round out) determine the desired bounds on the solution set of the linear interval system. By providing tight interval bounds on the solution set, the goal is to more quickly contract intervals that may contain stationary points, as well as to more quickly identify intervals that contain a unique stationary point or no stationary point, thus leading to an overall improvement in computational efficiency.

## Methods

### Interval-Newton

Several good introductions to interval computations are available [11,17,19,28]. A real interval  $X$  is defined as the set of real numbers lying between (and including) given upper and lower bounds; that is,  $X = [a, b] = \{x \in \mathfrak{R} \mid a \leq x \leq b\}$ . A real interval vector  $\mathbf{X} = (X_1,$

$X_2, \dots, X_n)^T$  has  $n$  real interval components and can be interpreted geometrically as an  $n$ -dimensional rectangle or box. Note that in this context uppercase quantities are intervals, and lowercase quantities are real numbers. Basic arithmetic operations with intervals are defined by  $X \text{ op } Y = \{x \text{ op } y \mid x \in X, y \in Y\}$ , where  $\text{op} \in \{+, -, \times, \div\}$ . Interval versions of the elementary functions can be similarly defined. It should be emphasized that, when machine computations with interval arithmetic operations are done, as in the procedures outlined below, the endpoints of an interval are computed with a directed (outward) rounding. That is, the lower endpoint is rounded down to the next machine-representable number and the upper endpoint is rounded up to the next machine-representable number. In this way, through the use of interval, as opposed to floating-point arithmetic, any potential rounding error problems are avoided and rigorous enclosures are maintained. Implementations of interval arithmetic and elementary functions are readily available, and recent compilers from Sun Microsystems directly support interval arithmetic and an interval data type.

For an arbitrary function  $f(\mathbf{x})$ , the *interval extension*,  $F(\mathbf{X})$ , encloses all values of  $f(\mathbf{x})$  for  $\mathbf{x} \in \mathbf{X}$ ; that is, it encloses the range of  $f(\mathbf{x})$  over  $\mathbf{X}$ . It is often computed by substituting the given interval  $\mathbf{X}$  into the function  $f(\mathbf{x})$  and then evaluating the function using interval arithmetic. This so-called “natural” interval extension may be wider than the actual range of function values, though it always includes the actual range. For the case in which the function is a single-use expression, that is, an expression in which each variable occurs only once, natural interval arithmetic will always yield the true function range. For cases in which such rearrangements are not possible, there are a variety of other approaches that can be used to try to tighten interval extensions [11,17,19,28,29].

Of interest here is the interval-Newton method and its application to the stationarity condition  $\nabla\phi(\mathbf{x}) = \mathbf{0}$ . Given an  $n \times n$  nonlinear equation system  $\mathbf{f}(\mathbf{x}) = \nabla\phi(\mathbf{x}) = \mathbf{0}$  with a finite number of real roots in some initial interval, this technique provides the capability to find tight enclosures of *all* the roots of the system that lie within the given initial interval. An outline of the interval-Newton methodology is given here. More details are available elsewhere [11,19,34]. It should be emphasized that this technique is *not* equivalent to simply

implementing the routine “point” Newton method in interval arithmetic.

Given some initial interval  $X^{(0)}$ , the interval-Newton algorithm is applied to a sequence of subintervals, which arises due to a bisection process. Consider a subinterval  $X^{(k)}$  in the sequence. Before application of interval-Newton, measures are usually taken first to try to eliminate, or at least shrink, this subinterval. For example, one may apply a function range test. An interval extension  $F(X^{(k)})$  of the function  $f(x)$  is calculated. If there is any component of the interval extension  $F(X^{(k)})$  that does not include zero, then the interval can be discarded, since no solution of  $f(x) = 0$  can exist in this interval. The next subinterval in the sequence may then be considered. Otherwise, testing of  $X^{(k)}$  continues. A variety of other interval-based techniques (e.g., constraint propagation) may also be applied to try to shrink  $X^{(k)}$  before proceeding to the interval-Newton procedure.

In the interval-Newton procedure, the linear interval equation system

$$F'(X^{(k)})(N^{(k)} - x^{(k)}) = -f(x^{(k)}), \tag{3}$$

is solved for a new interval  $N^{(k)}$ , where  $F'(X^{(k)})$  is an interval extension of the Jacobian of  $f(x)$ , and  $x^{(k)}$  is an arbitrary point in  $X^{(k)}$ . It has been shown [11,19,28] that any root contained in  $X^{(k)}$  is also contained in the image  $N^{(k)}$ . This implies that if the intersection between  $X^{(k)}$  and  $N^{(k)}$  is empty, then no root exists in  $X^{(k)}$ , and also suggests the iteration scheme  $X^{(k+1)} = X^{(k)} \cap N^{(k)}$ . In addition, it has also been shown [11,19,28] that, if  $N^{(k)}$  is in the interior of  $X^{(k)}$ , then there is a *unique* root contained in  $X^{(k)}$  and thus in  $N^{(k)}$ . Thus, after computation of  $N^{(k)}$  from Eq. (3), there are three possibilities: (1)  $X^{(k)} \cap N^{(k)} = \emptyset$ , meaning there is no root in the current interval  $X^{(k)}$  and it can be discarded; (2)  $N^{(k)}$  is in the interior of  $X^{(k)}$ , meaning that there is *exactly* one root in the current interval  $X^{(k)}$ ; (3) neither of the above, meaning that no conclusion can be drawn. In the last case, if  $X^{(k)} \cap N^{(k)}$  is sufficiently smaller than  $X^{(k)}$ , then the interval-Newton test can be reapplied to the resulting intersection,  $X^{(k+1)} = X^{(k)} \cap N^{(k)}$ . Otherwise, the intersection  $X^{(k)} \cap N^{(k)}$  is bisected, and the resulting two subintervals are added to the sequence of subintervals to be tested. If an interval containing a unique root has been identified, then this root can be tightly enclosed by continuing the interval-Newton it-

eration, which will converge quadratically to a desired tolerance (on the enclosure diameter).

At termination, when the subintervals in the sequence have all been tested, either all the real roots of  $f(x) = 0$  have been tightly enclosed, or it is determined that no root exists. Applied to nonlinear equation solving problems, this can be regarded as a type of branch-and-prune scheme on a binary tree. It should be emphasized that the enclosure, existence, and uniqueness properties discussed above, which are the basis of the method, can be derived without making any strong assumptions about the function  $f(x)$  for which roots are sought. The function must have a *finite* number of roots over the search interval of interest; however, no special properties such as convexity or monotonicity are required, and  $f(x)$  may have transcendental terms.

### Solution of Linear Interval Equation Systems

Clearly, the solution of the linear interval system given by Eq. (3) is essential to the interval-Newton approach. To see the issues involved in solving such a system, consider the general linear interval system  $Az = B$ , where the matrix  $A$  and the right hand side vector  $B$  are interval-valued. The solution set  $S$  of this system is defined by  $S = \{z \mid \tilde{A}z = b, \tilde{A} \in A, b \in B\}$ . However, in general this set is not an interval and may have a very complex polygonal geometry. Thus to “solve” the linear interval system, one instead seeks an interval  $Z$  containing  $S$ . Computing the interval hull (the tightest interval containing  $S$ ) is NP-hard [33], but there are several methods for determining an interval  $Z$  that contains but overestimates  $S$ . Various interval-Newton methods differ in how they solve Eq. (3) for  $N^{(k)}$  and thus in the tightness with which the solution set is enclosed. By obtaining bounds that are as tight as possible, the overall performance of the interval-Newton approach can be improved, since with a smaller  $N^{(k)}$  the volume of  $X^{(k)} \cap N^{(k)}$  is reduced, and it is also more likely either that  $X^{(k)} \cap N^{(k)} = \emptyset$  that  $N^{(k)}$  is in the interior of  $X^{(k)}$  will be satisfied. Thus, intervals that may contain solutions of the nonlinear equation system are more quickly contracted, and intervals that contain no solution or that contain a unique solution may be more quickly identified, all of which leads to a likely reduction in the number of bisections needed.

Frequently,  $N^{(k)}$  is computed component-wise using an interval Gauss–Seidel approach, preconditioned with an inverse-midpoint matrix. Though the inverse-midpoint preconditioner is a good general-purpose preconditioner, it is not always the most effective approach [18,19]. A hybrid preconditioning approach (HP/RP) [10], which combines a simple pivoting preconditioner with the standard inverse-midpoint scheme, has been shown to be significantly more efficient than the inverse-midpoint preconditioner alone on some applications. However, it still may not yield the tightest enclosure of the solution set, which, as noted above, is in general an NP-hard problem. Nevertheless, it is possible, using an LP-based strategy, to compute exact component-wise bounds on the solution set required in the context of the interval-Newton method, while avoiding exponential time complexity. This method is described next.

**LP Strategy for Interval-Newton Method**

Many types of methods have been proposed for bounding the solution set of a system of linear interval equations. One such method is based on the use of LP techniques [1,3,15,17]. Consider again the linear interval system  $Az = B$ . Oettli and Prager [31] showed that the solution set  $S$  is determined by the constraints:

$$|\hat{A}z - \hat{B}| \leq \Delta A |z| + \Delta B, \tag{4}$$

where  $\hat{A}$  is the component-wise midpoint matrix of the interval matrix  $A$ ,  $\Delta A$  is the component-wise half-width (radius) matrix of  $A$ , and similarly  $\hat{B}$  and  $\Delta B$  are the midpoint and radius of  $B$ . Eq. (4) is not directly useful for computing bounds on the solution set because of the absolute value operation on the right-hand side. In general, the solution may lie in all  $2^n$  orthants for an  $n$ -dimensional problem. In each orthant, each component of  $z$  keeps a constant sign, and thus the absolute value can be dropped. For a given orthant, define the diagonal matrix  $D_\alpha$  by

$$(D_\alpha)_{jj} = \begin{cases} 1 & z_j \geq 0 \\ -1 & z_j \leq 0 \end{cases} \quad j = 1, 2, \dots, n. \tag{5}$$

Thus  $|z| = D_\alpha z$  and  $z = D_\alpha |z|$ . Eq. (4) becomes:

$$|\hat{A}z - \hat{B}| \leq \Delta AD_\alpha z + \Delta B. \tag{6}$$

This can be rearranged to the set of linear inequalities

$$\begin{pmatrix} \underline{\hat{A}} - \Delta AD_\alpha \\ -\overline{\hat{A}} - \Delta AD_\alpha \end{pmatrix} z \leq \begin{pmatrix} \underline{\hat{B}} \\ -\overline{\hat{B}} \end{pmatrix}, \tag{7}$$

where the underline and overline denote lower and upper interval bounds, respectively. To determine the tightest interval enclosing the solution set, one can then solve, in each orthant, the set of  $2n$  optimization problems

$$\max_z z_j, \quad j = 1, 2, \dots, n, \tag{8}$$

$$\min_z z_j, \quad j = 1, 2, \dots, n, \tag{9}$$

each with the  $2n$  linear inequality constraints given by Eq. (7). These can be solved using linear programming (LP) techniques. However, in general, there are  $2^n$  orthants and so the solution time complexity will be exponential, as expected since this problem is known to be NP-hard.

In the context of the interval-Newton method, however, the exponential time complexity can be avoided. This is because only that part of the solution set of Eq. (3) that intersects  $X^{(k)}$  needs to be found. Consider the choice of the real point  $x^{(k)}$  in Eq. (3). Here  $x^{(k)}$  is an arbitrary point in  $X^{(k)}$  typically taken to be the midpoint. However, if  $x^{(k)}$  is chosen to be a corner of  $X^{(k)}$  instead, then the part of the solution set for  $N^{(k)} - x^{(k)}$  of Eq. (3) that intersects  $X^{(k)}$  lies in just one orthant. Thus, in the context of interval-Newton, only  $2n$  LP subproblems, each with  $2n$  constraints, needs to be solved. Furthermore, the LP subproblems have properties that can be exploited. First, all the  $2n$  subproblems share the same constraints; that is, they all have the same feasible region. Thus, an initial feasible basis for the LP subproblems needs to be found only once. Second, the objective function of each subproblem consists of just one variable. This makes the problem much simpler since it is not necessary, as it is in the general case, to calculate the gain in objective value when choosing variables to enter and exit the basis.

Lin and Stadtherr [23] have implemented the approach outlined above in the procedure LISS\_LP (Linear Interval System Solver by Linear Programming), and incorporated it in an interval-Newton method for global optimization. Two key aspects of the implementation are:

1. The choice of a corner of  $X^{(k)}$  to be used in the LP problem. For this purpose, a heuristic approach [23] was developed that incorporates ideas from the pivoting preconditioner approach of Gau and Stadtherr [10].
2. Determination of rigorous error bounds on the solution of the LP problems. This is done using a procedure based on primal/dual relationships [16,23,30]. Complete details of the implementation are given by Lin and Stadtherr [23]. We turn next to some examples that demonstrate the performance of the LP-based strategy as implemented in LISS\_LP.

**Cases**

Lin and Stadtherr [21,23] have tested the performance of the LP-based interval-Newton strategy for global optimization on a variety of problems. In this section, we summarize the results on a group of parameter estimation problems. Each parameter estimation case used was formulated using the error-in-variables approach, with complete details given by Gau and Stadtherr [8,9]. Comparisons are made to an interval Gauss–Seidel method with a hybrid preconditioning approach (HP/RP), which has been shown [10] to provide a substantial improvement in computational performance relative to standard implementations of the interval-Newton approach. Comparisons are made in terms of the number of interval-Newton (I-N) tests required, i. e., the number of times Eq. (3) must be solved, and in terms of the CPU time on a Sun Blade 1000 Model 1600 workstation. On a current (early 2007) workstation, these CPU times would be approximately an order of magnitude less.

**Problem 1**

This problem [6,20] involves estimation of binary parameters in the van Laar equation for activity coefficients. These two parameters are estimated from vapor-liquid equilibrium data for the binary system of methanol and 1,2-dichloroethane. Computational performance results are shown in Table 1. When the LP-based strategy (LISS\_LP) is applied, the number of I-N tests is substantially reduced relative to HP/RP, indicating its effectiveness in reducing the number of intervals that must be tested. Essentially, by reducing the size of  $N^{(k)}$ , the LP approach is able to more quickly identify and discard intervals that do not contain a stationary

**LP Strategy for Interval-Newton Method in Deterministic Global Optimization, Table 1**  
**Computational performance of LP-based method (LISS\_LP) and preconditioned interval Gauss–Seidel method (HP/RP) on a Sun Blade 1000 Model 1600**

Problem	Variables (n)	HP/RP		LISS_LP	
		I-N Tests	CPU time (s)	I-N Tests	CPU time (s)
1	12	303589	664.4	156182	496.7
2	264	220	1357.3	81	504.9
3	22	9505	24.0	1258	12.7
4	32	144833	976.2	24817	837.2
5	59	55255	2315.9	9757	1692.4

point. However, the percent reduction in overall CPU time is less than the percent reduction in I-N tests. This occurs due to the overhead in solving the LP subproblems.

**Problem 2**

In this problem [4], the rating parameters are estimated for a steady-state heat exchanger network, which consists of four heat exchangers. The four parameters can be estimated from experimental measurements, including six flow measurements and thirteen temperature measurements. In the version of the problem considered here, 20 data points were considered, leading to an optimization problem involving 264 independent variables. Due to the large number of variables, sparse linear programming routines were implemented in LISS\_LP for this problem. In this case, both I-N tests and CPU time are substantially reduced when the LP-based method is used, as shown in Table 1, indicating that the LP overhead is less significant on this relatively large problem.

**Problems 3 and 4**

Both of these problems involve the estimation of kinetic parameters for an irreversible, first-order reaction  $A \rightarrow B$ . In Problem 3 [6,20], data from an adiabatic continuous-stirred-tank reactor (CSTR) is used, and in Problem 4 [2] data from an isothermal batch reactor is used. In both cases, the reaction rate constant  $k$  is given by an Arrhenius expression

$$k = \theta_1 \exp\left(-\frac{\theta_2}{T}\right), \tag{10}$$

in which two parameters,  $\theta_1$  and  $\theta_2$ , must be determined from experimental measurements. Again, the computational performance results (Table 1) show that use of the LP-based strategy substantially reduces the number of I-N tests required relative to HP/RP, but that a comparable reduction in CPU time is not achieved. For example, on Problem 4, the number of I-N tests is reduced by nearly a factor of 6, but there is only about a 15% reduction in CPU time. This reflects the fact that an I-N test performed using the LP method requires greater computational effort than an I-N test using the HP/RP approach. However, on problems studied by Lin and Stadtherr [21,23], this overhead was always offset by a large reduction in the number of I-N tests, resulting in computational savings on all but very small problems.

### Problem 5

In this problem, parameters are estimated in a model of an isothermal pseudo-differential reactor for the catalytic hydrogenation of phenol on a palladium catalyst [32]. There are 28 experimental kinetic data points of the partial pressure of phenol ( $P_1$ ), the partial pressure of hydrogen ( $P_2$ ), and the initial reaction rate ( $r$ ). It is desired to fit this kinetic data to a semi-empirical model of the form

$$r = \frac{\theta_1 \theta_2^2 \theta_3 P_1 P_2^2}{(1 + \theta_1 P_1 + \theta_2 P_2)^3}, \quad (11)$$

where  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  are the parameters to be estimated. This global optimization problem has 59 independent variables. Due to the relatively large number of variables in this problem, a sparse linear programming routine was used in LISS\_LP. As seen in Table 1, both I-N tests and CPU time are reduced nicely compared to HP/RP when the LP-based method is used. As in the case of Problem 2, on this relatively large problem the impact of the LP overhead appears to be less significant.

### Conclusions

In this article, we have described an LP-based strategy [21,23] for solving the linear interval equation system arising in the context of the interval-Newton approach for deterministic global optimization. The method can obtain tighter bounds on the solution set of the linear interval system than the preconditioned interval Gauss–Seidel approach, and thus leads to a large

reduction in the number of subintervals that must be tested during the interval-Newton procedure. However, the difference between the overhead required to solve the LP subproblems and that required to perform the preconditioned Gauss–Seidel method may lead to relatively smaller or larger improvements in overall computational time, depending on the size of the problem. With sparse linear algebra in the LP subproblems, the method can be successfully applied to deterministic global optimization problems involving over two hundred variables, providing a rigorous guarantee of global optimality.

A *stochastic linear program with recourse* (SLP) is a mathematical program of the form

$$\begin{cases} \min & c \cdot x + Q(x) \\ \text{s.t.} & Ax = b, \quad x \geq 0, \end{cases}$$

where  $Q(x) = E_{\xi} Q(x, \xi)$ ,

$$Q(x, \xi) = \begin{cases} \min & q \cdot y(\xi) \\ \text{s.t.} & W \cdot y(\xi) = h - T \cdot x, \quad y \geq 0, \end{cases}$$

and  $E_{\xi}$  denotes the mathematical expectation with respect to  $\xi$ ,  $x$  is an  $(n_1 \times 1)$  decision vector, and for each  $\xi$ ,  $y$  is  $(n_2 \times 1)$ .  $A$  is  $(m_1 \times n_1)$  and for each  $\xi$ ,  $h$  is  $(m_2 \times 1)$ . All other matrices and vectors have conformable dimensions. Transposes are omitted for simplicity. The random vector  $\xi$  is formed by the random components of  $q, h$  and  $T \cdot Q(x, \xi)$  is the second-stage value function for a given  $\xi$  and  $Q(x)$  the expected value-function or expected recourse.

In the case where random vectors are described by discrete distributions,  $Q(x)$  is a piecewise linear convex function of  $x$ , so that classical decomposition techniques may apply. Let  $k = 1, \dots, K$  index the possible realizations of  $\xi$ , let  $p_k$  be their probabilities and  $y_k$  be the corresponding second stage decision variables. SLP is then equivalent to the *extensive form*

$$(EF) \begin{cases} \min & cx + \sum_{k=1}^K p_k q_k y_k \\ \text{s.t.} & Ax = b, \\ & T_k x + W y_k = h_k, \\ & k = 1, \dots, K, \\ & x, y_k \geq 0. \end{cases}$$

This extensive form possesses a *dual block-angular structure*. It is thus well suited to application of *Benders decomposition*, which in the case of stochastic programming is known as the *L-shaped method*. An abbreviated presentation is as follows. It is restricted to the case where all second stage programs are bounded and feasible for any choice of first-stage decision.

### L-Shaped Method for Two-Stage Stochastic Program with Bounded, Complete Recourse

Consider the master linear program

$$(MLP) \begin{cases} \min & cx + \theta \\ \text{s.t.} & Ax = b, \\ & E_j x + \theta \geq e_j, \quad j = 1, \dots, s, \\ & x \geq 0, \end{cases}$$

with  $s$  *optimality cuts* (initially  $s = 0$ ) and  $\theta$  a lower bound on  $Q(x)$ , ( $\theta$  is omitted when  $s = 0$ ).

Using the solution  $x^s, \theta^s$  of (MLP) at iteration  $s$ , find optimal solutions to the  $K$  subproblems,

$$\begin{cases} \min & w = q_k y \\ \text{s.t.} & W y = h_k - T_k x^s, \\ & y \geq 0, \end{cases}$$

with optimal simplex multipliers  $\pi_k^s, k = 1, \dots, K$ .

Define  $E_{s+1} = \sum_{k=1}^K p_k \pi_k^s T_k$  and  $e_{s+1} = \sum_{k=1}^K p_k \pi_k^s h_k$ .

If  $e_{s+1} - E_{s+1} x^s \leq \theta^s$ , then stop as  $x^s$  is an optimal solution. Otherwise, set  $s = s + 1$  and return to the master program.

Finite convergence of the *L-shaped method* is proved through classical convexity arguments. When the second stage does not have complete recourse, some first stage decisions may imply that no feasible recourse exists for some  $k$ . Then, a number of *feasibility cuts* are also needed. They are obtained through the optimal simplex multipliers of some phase-1 problem. Although these cuts should theoretically be generated for all realizations  $k = 1, \dots, K$ , there are many situations where the search for feasibility cuts can be limited to one selected second-stage only [9].

The *L-shaped method* can be made more efficient by performing some bunching to obtain optimal multipliers for several realizations of  $\xi$  at once (see the experiments in [4]). Efficiency can sometimes be gained by sending disaggregated cuts (also called multicuts) instead of one fully aggregated cut at each iteration [2]. Another way of improving the efficiency of the *L-shaped* is to include a quadratic regularizing term in the first-stage objective function. This additional term is typically the square of the Euclidean distance between

the decision  $x$  and the previous iterate point  $x^s$  [8].  $L$ -shaped methods have also been combined with statistical estimation, in particular to cope with continuous random variables (see [5] and ▶ **Discretely distributed stochastic programs: Descent directions and efficient points**).

A number of alternatives to the  $L$ -shaped techniques have been proposed to solve SLP. One is to use the *Lagrangian finite generation method*, also known as *scenario aggregation* [7]. Another is to use interior points techniques [1]. For a general presentation of stochastic programming, see [3] or [6].

### Abstract

Maritime transportation is a heavily utilized mode when large quantities of bulk products need to be transported over long distances. Often, inventories exist at the loading and/or unloading ports of the sailing legs. When the ship operator has the responsibility for both

the transportation of the fleet and the inventories at the ports, the underlying planning problem is a maritime inventory routing problem. Here we introduce the reader to various applications within maritime inventory routing and present some examples of research contributions. First we consider and present a mathematical model for the basic problem where a single product is transported and denote this problem the *inventory ship routing problem*. There exist a lot of extensions and variants of the problem. These include, among others, problems with inventories at only one end, variable production/consumption rates, multiple products, use of spot charters and problems that combine inventory routing with other planning aspects. Maritime inventory routing problems are very complex and to the authors' knowledge there exist no commercial optimization-based systems for the shipping industry yet. However, it is probably just a question of time before they become available.

### Introduction

In order to survive in a tough global market, many companies have been forced to change their focus from competition between companies to competition between supply chains. Supply chains of companies with foreign sources of raw materials or with overseas customers most often include maritime transportation. Supply chain management and optimization are active fields of research, and we can see applications in almost all industries. So far the focus of such applications has usually not been much on maritime transportation, so there is a great potential and need for research in the area.

A maritime inventory routing problem is defined here as a combined ship routing and scheduling prob-

lem and an inventory management problem. The basic *inventory ship routing problem* (ISRP) concerns the transportation of a single product. The product is produced and stored in inventories at given loading ports and is transported by sea to inventories at unloading or consumption ports. Inventory capacities are defined in all ports. Further, we assume that information about production and consumption rates is given in all ports. To transport the product between the given production and consumption ports, the planners control a heterogeneous fleet of ships. The planning problem is to find routes and schedules for the fleet that minimize the transportation costs without interrupting production or consumption at the storages. Depending on the segment the fleet is operating in, the typical planning period spans from 1 to 2 weeks up to several months.

Most ship scheduling problems studied in the literature are so-called *cargo routing problems* [1]. In cargo routing problems, each cargo is specified by a given loading and unloading port. The quantity of the cargo is given and normally there exist time windows for loading and/or unloading. When planning routes and schedules, the shipping company either seeks to minimize the transportation costs for carrying all contracted cargoes or in addition to maximize profit for optional spot cargoes that may be available. We refer to [4] for a survey on maritime cargo routing problems. The cargo routing problems deviate from the ISPRs in a number of ways. The number of calls at a given port during the planning horizon is not predetermined in the ISRP, neither is the quantity to be loaded or unloaded at each port call. There is also no predefined pickup and delivery pair in the ISRP. The combination of the inventory management and the ship routing and scheduling makes the ISRP a very complex problem.

The inventory routing problem has been focused on in the literature for a couple of decades. Dror and Ball [8] defined the problem as a distribution problem in which each customer maintains a local inventory of a product such as heating oil and consumes a certain amount of that product each day. Given a central supplier (depot), the objective is to minimize the annual delivery costs while attempting to ensure that no customer runs out of the product at any time. The asymmetry between each type of inventory (production

and consumption) with only one central supply node (depot) will often be found in road-based inventory routing problems, and more seldom in maritime transportation (ISRP). In the road-based inventory routing problem, the amount unloaded at each customer is often small compared to the total capacity of the vehicle. This is also in contrast with the ISRP, where the ship is often fully loaded and unloaded.

The objective of this article is to introduce the reader to various real planning problems within maritime inventory routing. The purpose is not to give a comprehensive overview of such problems, but rather to present examples of applications and research in the area.

The rest of the article is organized as follows: The first section defines the basic inventory ship routing problem and the underlying mathematical model. Extensions of the basic ISRP are addressed next. Finally, concluding remarks and future research follow.

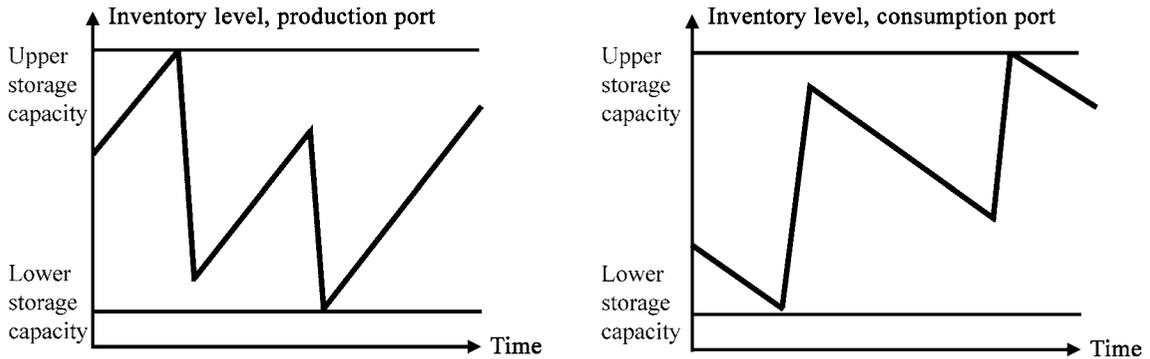

## The Basic ISRP

In order to give an introduction to the various real planning problems within maritime inventory routing, we will start with a basic ISRP. First we describe the planning problem. Then we present an arc-flow formulation of the problem. The final section is devoted to real applications of the basic ISRP.

## Problem Description

The products transported in maritime inventory routing problems are usually bulk products, where large quantities are transported and there are inventories at both the loading and the unloading ports. In these problems, the ship operators have a twofold responsibility: transportation and inventory management at the production and consumption sites. In such planning situations, the routing and scheduling of the fleet have to be synchronized with the inventory management at both production and consumption sites.

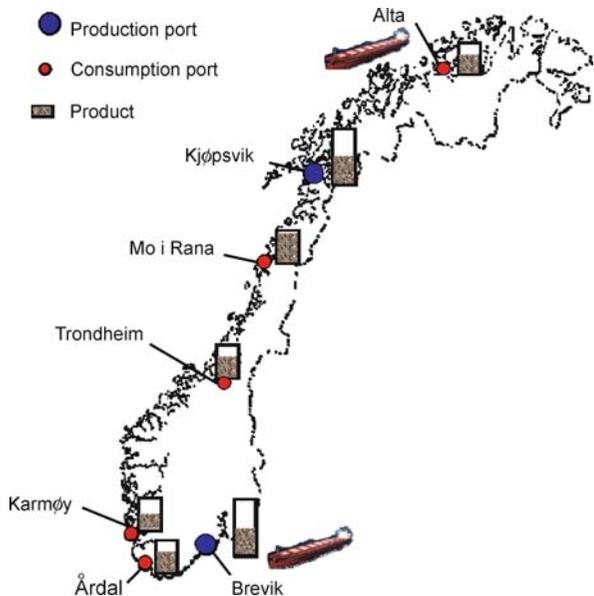

In the basic ISRP a single (homogeneous) product is transported. The product is produced at the sources, called loading ports, and consumed at the destinations, called unloading ports. Inventory storage capacities are given in all ports in addition to the production or consumption rate of the product. Here, the rate is assumed constant during the planning horizon.

**Maritime Inventory Routing Problems, Figure 1**  
Inventory levels during a planning period for a production and a consumption port

The number of calls at a given port during the planning period is not predetermined, nor is the quantity to be loaded or unloaded at each port call. Figure 1 shows an example of a production/consumption and loading/unloading pattern. For both port types, the port is called at twice. However, the quantities loaded or unloaded differ at each call. The reason for this might be that the ports are visited by ships with different capacities loading/unloading full loads, or due to partial loading/unloading. In loading ports, it is important to ensure that the inventory level is not above the maximum inventory level when loading starts and not under the minimum inventory level when the loading has finished. In unloading ports, the opposite has to be ensured. The inventory level at the beginning of the planning period can be at any level, as indicated in Fig. 1.

Therefore, the planning problem is to design routes and schedules that minimize the transportation cost without interrupting production or consumption. We assume no inventory costs because the shipper owns both the producing sources and the consuming destinations. The ship operator controls a heterogeneous fleet of ships. We assume that partial loading and unloading is allowed, such that two ports of the same type (loading or unloading) may be called at in succession. The ship is not necessarily empty at the beginning of the planning horizon, but might have some load onboard. The ship can be either at a port or at sea at the beginning of the planning horizon. Figure 2 shows a simplified illustration of the planning problem for a cement producer in Norway with two production factories and five con-

**Maritime Inventory Routing Problems, Figure 2**  
A simplified planning situation with seven ports and two ships

sumption ports with inventories. The fleet consists of two ships. Each port can be called at several times during the planning period by the same ship or different ships.

### Mathematical Model

The model of the ISRP will be presented in a compact and simplified way. In Sect. “Routing,” we describe the flow network and the objective function. Then, the con-

ditions for the loading and unloading, the time aspects and the inventories are described in Sect. “**Loading and Unloading**”, “**Scheduling**” and “**Inventory Management**,” respectively. We base our notation and model on those of Christiansen et al. [3].

In the upcoming formulation, we have assumed that the ship may be partially loaded/unloaded, meaning that multiple cargoes may be onboard a ship simultaneously. The model could have been simplified if we had assumed full loads only or sailing between different port types (from loading to unloading and vice versa).

**Routing** In the mathematical description of the network each port is represented by an index  $i$  and the set of ports is given by  $\mathcal{N}$ . Let  $\mathcal{V}$ , indexed by  $v$ , be the set of available ships to be routed and scheduled. Not all ships can visit all ports, and  $\mathcal{N}_v = \{\text{feasible ports for ship } v\} \cup \{o(v), d(v)\}$  is the set of ports that can be visited by ship  $v$ . The terms  $o(v)$  and  $d(v)$  represent the artificial origin port and artificial destination port of ship  $v$ , respectively. Each port can be visited several times during the planning horizon, and  $\mathcal{M}_i$  is the set of possible calls at port  $i$ , while  $\mathcal{M}_{iv}$  is the set of calls at port  $i$  that can be made by ship  $v$ . The port call number is represented by an index  $m$ , and  $M_i$  is the last possible call at port  $i$  within the planning period. The set of nodes in the flow network represents the set of port calls, and each port call is specified by  $(i, m)$ ,  $i \in \mathcal{N}$ ,  $m \in \mathcal{M}_i$ . In addition, we specify flow networks for each ship  $v$  with nodes  $(i, m)$ ,  $i \in \mathcal{N}_v$ ,  $m \in \mathcal{M}_{iv}$ .  $\mathcal{A}_v$  contains all feasible arcs for ship  $v$ , which is a subset of  $\{i \in \mathcal{N}_v, m \in \mathcal{M}_{iv}\} \times \{i \in \mathcal{N}_v, m \in \mathcal{M}_{iv}\}$ . Finally,  $C_{ijv}$  represents the variable costs for sailing between port  $i$  and port  $j$  with ship  $v$ . This includes port, channel and fuel costs.

In the network flow part of the formulation we use the following types of variables: the binary flow variable  $x_{imjnv}$ ,  $v \in \mathcal{V}$ ,  $(i, m, j, n) \in \mathcal{A}_v$  equals 1, if ship  $v$  sails from node  $(i, m)$  directly to node  $(j, n)$ , and 0 otherwise, and the slack variable  $w_{im}$ ,  $i \in \mathcal{N}$ ,  $m \in \mathcal{M}_i$  is equal to 1 if no ship takes port call  $(i, m)$ , and 0 otherwise. The routing formulation including the objective function is as follows:

$$\min \sum_{v \in \mathcal{V}} \sum_{(i, m, j, n) \in \mathcal{A}_v} C_{ijv} x_{imjnv}, \quad (1)$$

subject to

$$\sum_{v \in \mathcal{V}} \sum_{j \in \mathcal{N}_v} \sum_{n \in \mathcal{M}_{jv}} x_{imjnv} + w_{im} = 1, \quad \forall i \in \mathcal{N}, m \in \mathcal{M}_i, \quad (2)$$

$$\sum_{j \in \mathcal{N}_v} \sum_{n \in \mathcal{M}_{jv}} x_{o(v)1jnv} = 1, \quad \forall v \in \mathcal{V}, \quad (3)$$

$$\sum_{i \in \mathcal{N}_v} \sum_{m \in \mathcal{M}_{iv}} x_{imjnv} - \sum_{i \in \mathcal{N}_v} \sum_{m \in \mathcal{M}_{iv}} x_{jnimv} = 0, \quad (4)$$

$$\forall v \in \mathcal{V}, j \in \mathcal{N}_v \setminus \{o(v), d(v)\}, n \in \mathcal{M}_{jv},$$

$$\sum_{i \in \mathcal{N}_v} \sum_{m \in \mathcal{M}_{iv}} x_{imd(v)1v} = 1, \quad \forall v \in \mathcal{V}, \quad (5)$$

$$w_{im} - w_{i(m-1)} \geq 0, \quad \forall i \in \mathcal{N}, m \in \mathcal{M}_i, \quad (6)$$

$$x_{imjnv} \in \{0, 1\}, \quad \forall v \in \mathcal{V}, (i, m, j, n) \in \mathcal{A}_v, \quad (7)$$

$$w_{im} \in \{0, 1\}, \quad \forall i \in \mathcal{N}, m \in \mathcal{M}_i. \quad (8)$$

The objective function (1) minimizes the total costs. Constraints (2) ensure that each port call is visited at most once. Constraints (3)–(5) describe the flow on the sailing route used by ship  $v$ . One or several of the calls in a specified port can be made by a dummy ship, and the highest call numbers will be assigned to dummy ships in constraints (6). These constraints reduce the number of symmetrical solutions in the solution approach. For the calls made by a dummy ship, we get artificial starting times and artificial inventory levels within the defined upper and lower limits. Finally, the formulation involves binary requirements (7) and (8) on the flow variables and port call slack variables, respectively.

**Loading and Unloading** The capacity of ship  $v$  is given by  $V_{CAPv}$ . Variable  $l_{imv}$ ,  $v \in \mathcal{V}$ ,  $i \in \mathcal{N}_v \setminus \{d(v)\}$ ,  $m \in \mathcal{M}_{iv}$  gives the total load onboard ship  $v$  just after the service is completed at node  $(i, m)$ , while variable  $q_{imv}$ ,  $v \in \mathcal{V}$ ,  $i \in \mathcal{N}_v \setminus \{d(v)\}$ ,  $m \in \mathcal{M}_{iv}$  represents the quantity loaded or unloaded at port call  $(i, m)$ , when ship  $v$  visits  $(i, m)$ . It is assumed that nothing is loaded or unloaded at the artificial origin  $o(v)$ ;  $q_{o(v)1v} = 0$ . However, the ships may have cargo onboard,  $L_{0v}$ , at the beginning of the planning horizon;  $l_{o(v)1v} = L_{0v}$ . Further, constant  $I_i$  is equal to 1 if port  $i$  is a loading port,  $-1$  if port  $i$  is an unloading port and 0 if port  $i$  is  $o(v)$  or  $d(v)$ . Constraints related to the quantity onboard a ship

can be formulated as follows:

$$x_{imjnv}(l_{imv} + I_j q_{jnv} - l_{jnv}) = 0, \quad (9)$$

$$\forall v \in \mathcal{V}, (i, m, j, n) \in \mathcal{A}_v | j \neq d(v),$$

$$q_{imv} \leq l_{imv} \leq \sum_{j \in \mathcal{N}_v} \sum_{n \in \mathcal{M}_{jv}} V_{CAPv} x_{imjnv}, \quad (10)$$

$$\forall v \in \mathcal{V}, i \in \mathcal{N}_v, m \in \mathcal{M}_{iv} | I_i = 1, \quad (11)$$

$$0 \leq l_{imv} \leq \sum_{j \in \mathcal{N}_v} \sum_{n \in \mathcal{M}_{jv}} V_{CAPv} x_{imjnv} - q_{imv},$$

$$\forall v \in \mathcal{V}, i \in \mathcal{N}_v, m \in \mathcal{M}_{iv} | I_i = -1.$$

Constraints (9) give the relationship between the binary flow variables and the ship load at each port call. Constraints (10) and (11) give the ship capacity intervals at the port calls for loading and unloading ports, respectively.

**Scheduling** The time required to load or unload the ship may constitute a major part of the total time in many maritime transportation applications. It is therefore usual to calculate this as a function of the quantity loaded/unloaded. The time spent loading/unloading one unit of a cargo at port  $i$  is given by  $T_{Qi}$ . The term  $T_{Sijv}$  represents the sailing time from port  $i$  to port  $j$  with ship  $v$ . In some ports, there is a minimum required time,  $T_{Bi}$ , between the departure of one ship and the arrival of the next ship, due to small port area or narrow channels from the port to the pilot station. The time variable  $t_{im}$ , ( $i \in \mathcal{N}$ ,  $m \in \mathcal{M}_i$ )  $\cup$  ( $i \in o(v)$ ,  $\forall v, m = 1$ ) represents the time at which service begins at node  $(i, m)$ . It is assumed that the ship arrives at  $o(v)$  at a given fixed time;  $t_{o(v)1} = T_{0v}$ . Finally, let  $T$  denote the planning horizon. The scheduling constraints can now be written as follows:

$$x_{imjnv}(t_{im} + T_{Qi} q_{imv} + T_{Sijv} - t_{jn}) \leq 0, \quad (12)$$

$$\forall v \in \mathcal{V}, (i, m, j, n) \in \mathcal{A}_v | j \neq d(v),$$

$$t_{im} - t_{i(m-1)} - \sum_{v \in \mathcal{V}} T_{Qi} q_{i(m-1)v} + T_{Bi} w_{im} \geq T_{Bi}, \quad (13)$$

$$\forall i \in \mathcal{N}, m \in \mathcal{M}_i \setminus \{1\}.$$

Constraints (12) take into account the timing or scheduling on the route. Note that waiting at a port is allowed. Constraints (13) prevent service overlap in the ports and ensure the order of real calls at the same port. A ship must complete its service before the next ship starts its service at the same port. If port  $i$  does not have

constraints regarding the minimum time between departure of one ship and arrival of the next,  $T_{Bi} = 0$ . If port  $i$  also allows the service of several ships simultaneously, constraints (13) will simply be  $t_{im} - t_{i(m-1)} \geq 0$ , to ensure the order of calls at the port.

**Inventory Management** The levels of the inventory have to be within a given interval at each port [ $S_{MNi}$ ,  $S_{MXi}$ ]. The production rate  $R_i$  is positive if port  $i$  is producing the product, and negative if port  $i$  is consuming the product. At the beginning of the planning horizon, the inventory level at each port  $i$  is  $S_{0i}$ . Finally,  $s_{im}$ ,  $i \in \mathcal{N}$ ,  $m \in \mathcal{M}_i$  represents the inventory level when service starts at port call  $(i, m)$ . The inventory constraints of the formulation become

$$s_{i1} - R_i t_{i1} = S_{0i}, \quad \forall i \in \mathcal{N}, \quad (14)$$

$$s_{i(m-1)} - \sum_{v \in \mathcal{V}} I_i q_{i(m-1)v} + R_i (t_{im} - t_{i(m-1)}) - s_{im} = 0, \quad \forall i \in \mathcal{N}, m \in \mathcal{M}_i \setminus \{1\}, \quad (15)$$

$$S_{MNi} \leq s_{im} \leq S_{MXi}, \quad \forall i \in \mathcal{N}, m \in \mathcal{M}_i, \quad (16)$$

$$S_{MNi} \leq s_{im} - \sum_{v \in \mathcal{V}} I_i q_{imv} + R_i (T - t_{im}) \leq S_{MXi}, \quad (17)$$

$$\forall i \in \mathcal{N}, m = M_i.$$

The inventory level at the first call at each port is calculated in constraints (14). From constraints (15), we find the inventory level at any port call  $(i, m)$  from the inventory level upon arrival at the port in the previous call  $(i, m-1)$ , adjusted for the loaded/unloaded quantity at the port call and the production/consumption between the two arrivals. The general inventory limit constraints at each port call are given in (16). Constraints (17) ensure that the level of inventory at the end of the planning horizon is within its limits. It can easily be shown by substitution that constraints (17) ensure that the inventory at time  $T$  will be within the bounds even if ports are not visited at their last calls.

**A Real Application** An application that is close to the ISRP is a real ship planning problem for ammonia transportation. Norsk Hydro Agri (now named Yara) produces and consumes ammonia in its factories worldwide. The planners at the company are re-

sponsible for keeping the inventory levels within the predefined upper and lower limits at all Norsk Hydro Agri factories around the world where they produce and consume ammonia. This requires the planners to design routes and schedules for their fleet of heterogeneous ships transporting ammonia from production ports to consumption ports. The problem is described in detail in Christiansen [2]. The overall solution approach is based on a column generation approach with columns for both the ship routes and the inventory management sequences [5], where subproblems are solved by dynamic programming for each port and each ship [6]. Another solution approach to the same problem was developed by Flatberg et al. [9]. They used an iterative improvement heuristic combined with an linear program (LP) solver to solve this problem. The heuristic is used to solve the combinatorial problem of finding the ship routes, and an LP model is used to find the starting time of service at each call and the loading/unloading quantities.

### Extensions of the ISRP

Most of the real applications of maritime inventory routing problems have a more complex structure than the basic ISRP. We present here various extensions of the ISRP that are described in the literature or have been experienced in our research group. In many maritime applications, several of the extensions are combined.

#### One Central Supplier or Consumer

As mentioned in the introduction, the road-based inventory routing problem often has a vehicle routing problem (VRP) structure, where a central supplier (or depot) serves a set of customers with a local inventory and a consumption rate. We can imagine a lot of real planning problems with such a structure, for instance, in the gasoline business, delivering gasoline to gas stations from a refinery or central storage. Milk collection at farms for transport to a dairy has the opposite structure, where the customers are producers and the depot consumes the milk.

In the maritime sector, we can also find this VRP structure for ship operators dealing with maritime inventory routing problems. The Norwegian oil company Statoil will start its production of natural gas from

Snøhvit, Melkøya, north of Norway in 2008. Most of the gas will be cooled down and transported as liquefied natural gas (LNG) by LNG tankers. At the moment the planning problem concerns one source producing the gas and several consumption ports. Frich and Horgen [10] presented a mixed integer program (MIP) model of the planning problem where this special VRP structure is exploited.

Similar maritime inventory routing problems can be found, for instance, with the Arabian Gulf as the source for the transportation of both LNG and heavier oil products.

#### Inventory Constraints in Either Production Ports or Consumption Ports

For the ISRP, the inventory management is considered at both the loading and the unloading ports. However, many real planning problems concern the design of routes and schedules for a fleet of ships with inventory constraints at just one of the port types. There exist for instance ship operators engaged in vendor managed inventory (VMI) contracts. Here, the ship operator monitors its customers' inventories and must ensure that these are kept within predefined limits. Often, the customers are concerned about inventories at only the unloading ports, while the ship operator has entered into a contract to supply the product with given quantities and time windows from the loading ports. The opposite might also be the case, where the customers have inventories at only loading ports. Then, the ship operator must also engage in contracts to deliver these volumes with given quantities and time windows.

#### Variable Production or Consumption Rate

The production and consumption rates are assumed constant for all port inventories during the planning period in the ISRP. However, for many real planning problems this assumption is too coarse, and the production and consumption that may vary from day to day have to be taken into account in the modeling. Including this aspect into the basic ISRP model would result in a more complicated model and it would become harder to solve.

A maritime inventory routing problem for the LNG business was considered by Grønhaug et al. [11]. Here the production of LNG at the liquefaction plants and

the consumption of LNG at the regasification terminals have to be regarded as variable. In order to overcome these complicating factors, a time discretized model was developed, and it was solved by a column generation approach.

Also Ronen [16] used a time discretized model with a variable production and consumption rate for an inventory routing problem for refinery products. The model focuses on the inventory and not the routing part of the problem, as the model solution suggests shipment sizes that are assumed to be an input for a cargo routing problem at a later stage.

### Multiple Products

Here we extend the ISRP to the multiproduct case. In the ISRP several cargoes may be transported simultaneously in one ship, but the product is assumed to be the same. This means that the product does not need to be transported in separated compartments onboard the ship or stored in separate stores at the ports.

The problem with multiple products is frequently encountered by chemical and oil product transport companies. Al-Khayyal and Hwang [1] gave a mathematical formulation for such a problem where the products are assumed to require dedicated compartments in the ship. For this problem there exist inventory limits and production/consumption rates for each product in each port. Hwang [13] used a combined Lagrangian relaxation and heuristic approach to solve test instances of the problem.

The problem described in Ronen [16] also includes multiple products. Sometimes the stowage onboard the ship must also be considered in the inventory routing problem; see, for instance, Haugen and Lund [12] for the transportation of cement products.

### Use of Spot Charters

In some cases the dedicated fleet of ships has insufficient transportation capacity to provide continuous production at all sources and consumption at all destinations. In such a case some of the loads can be serviced by spot charters, which are ships chartered for a single voyage.

The cement company described by Haugen and Lund [12] is faced with limited vessel capacity. In some periods the company makes use of spot charters, while

in peak periods additional road-based transportation is necessary. In their solution approach, the consumption inventories are sorted according to their importance and their location regarding what the cost effects for additional trucks will be. It is ensured that the inventories with highest priority are served by the fleet of ships.

### Combined Inventory Routing and Cargo Routing

The cargo routing problem was introduced in the introduction. For this problem, there exist predefined cargoes with specified quantities and time windows. The cargoes may be contracted or optional spot ones. Often the companies facing an ISRP trade cargoes with other operators in order to better utilize the fleet and to ensure there is product balance at their own plants.

In the real problem described by Christiansen [2], the shipper trades ammonia with other operators. These traded volumes are determined by negotiations. The ship operator undertakes to load or unload ammonia within a determined quantity interval and to arrive at a particular port within a given time window. For these external ports, no inventory management problem exists.

There also exist shipping companies that have VMI contracts with some customers, but apart from that are involved in ordinary cargo routing. This will give these shipping companies a combined inventory and cargo routing planning problem.

### Combining Inventory Routing with Other Planning Aspects

The ISRP concerns parts of a supply chain and focuses on sea transportation and the inventories at both ends of the sailing leg. In many real planning situations, it is sensible to consider larger parts of the supply chain. Persson and Göthe-Lundgren [15] studied a planning problem that integrates both the shipment planning of petroleum products from refineries to depots and the production scheduling at the refineries. Shih [17] and Liu and Sherali [14] presented two other maritime supply chain applications where coal is transported.

Rather than considering a larger part of the supply chain, the ISRP may be combined with other planning aspects. In Sect. “Multiple Products,” we referred to the combined ISRP and stowage of different cement prod-

ucts in various compartments onboard the ships. See Haugen and Lund [12] for more information about the case and solution approach.

### Concluding Remarks

We have described the maritime inventory routing problem, which is a combined inventory management and a ship routing and scheduling problem. The so-called basic ISRP and several extensions to the ISRP were presented. In practice, planners are more often faced with extensions of the ISRP and also the extensions described in combination with each other.

As far as we know, no generic commercial optimization-based decision support system exists for solving maritime inventory routing problems. However, the shipping industry is experiencing an increased need for such systems owing to extended planning responsibility and increased fleet sizes. We expect that such systems will be available on the market in the years to come.

The basic VRP is computationally very hard. The maritime inventory routing problem is even more demanding owing to the additional degrees of freedom. Many of the extensions discussed in this article are barely touched on in the operations research community. This means that there exist a lot of research challenges, in the development of both exact methods and heuristic solution methods.

Maritime transportation is faced with higher uncertainty in its operations compared with many other modes of transportation. This is due to greater dependence on weather conditions and technology. For the maritime inventory routing problem, we have also uncertainties in the production and consumption at the inventories. The consideration of these uncertainty aspects is another interesting topic of research.

### Acknowledgements

This work was carried out with financial support from the Research Council of Norway through the IN-SUMAR project (Integrated supply chain and maritime transportation planning), the OPTIMAR project (Optimization in maritime transportation and logistics) and the DOMinant project (Discrete optimization methods in maritime and road-based transportation).

### Introduction

Progress in digital data acquisition and storage technology has resulted in the growth of huge databases. This has occurred in a variety of scientific and engineering research applications [8] as well as medical domain [19,20]. Making sense out of these rapidly growing massive data sets gave birth to a “new” scientific discipline often referred to as *Data Mining*. Defining a discipline is, however, always a controversial task. The following working definition of the area was recently proposed [9]: Data mining is the analysis of (often large) observational data sets to find unsuspected

relationships and to summarize the data in novel ways that are both understandable and useful to the data owner.

Clearly the term data mining is often used as a synonym for the process of extracting useful information from databases. However, the overall knowledge discovery from databases (KDD) process is far more complicated and convoluted and involves a number of additional pre and post-processing steps [6]. Therefore, in our definition data mining refers to the ensemble of new, and existing, specific algorithms for extracting structure from data [8]. The exact definition of the knowledge extraction process and the expected outcomes are very difficult to characterize. However, a number of specific tasks can be identified and, by and large, define the key subset of deliverables from a data mining activity. Two such critical activities are classification and clustering.

A number of variants for these tasks can be identified and, furthermore, the specific structure of the data involved greatly impacts the methods and algorithms that are to be employed. Before we proceed with the exact definition of the tasks we need to provide working definitions of the nature and structure of the data.

### Basic Definitions

For the purposes of our analysis we will assume that the data are expressed in the form of  $n$ -dimensional feature vectors  $x \in X \subseteq \mathfrak{R}^n$ . Appropriate pre-processing of the data may be required to transform the data into this form. Although in many cases this transformations can be trivial, in other cases transforming the data into a “workable” form is a highly non-trivial task. The goal of data mining is to estimate an explicit, or implicit, function that maps points of the feature vector from the input space,  $X \subseteq \mathfrak{R}^n$ , to an output space,  $C$ , given a finite sample. The concept of the finite sample is important because, in general, what we are given is a finite representative subset of the original space (training set) and we wish to make predictions on new elements of the set (testing set). The data mining tasks can thus be defined based on the nature of the mapping  $C$  and the extent to which the train set is characterized.

If the predicted quantity is a categorical value and if we know the value that corresponds to each elements of the training set then the question becomes how to

identify the mapping that connects the feature vector and the corresponding categorical value (class). This problem is known as the classification problem (supervised learning). If the class assignment is not known and we seek to: (a) identify whether a small, yet unknown, number of classes exist; (b) define the mapping assigning the features to classes then we have a clustering problem (unsupervised learning).

A related problem associated with superfluous information in the feature vector is the so-called feature selection problem. This is a problem closely related to over-fitting in regression. Having a minimal number of features leads to simpler models, better generalization and easier interpretation. One of the fundamental issues in data mining is therefore to identify the least number of features, sub-set of the original set of features, that best address the two issues previously defined. The concept of parsimony (Occam's razor) is often invoked to bias the search [1]: never do with more what can be done with fewer.

Although numerous methods exist for addressing these problems they will not be reviewed here. Nice reviews of classification and were recently presented in [8,9]. In this short introduction we will concentrate on solution methodologies based on reformulating the clustering, and classification questions as optimization problems.

## Mathematical Programming Formulations

Classification and clustering, and for that matter most of the data mining tasks, are fundamentally optimization problems. Mathematical programming methodologies formalize the problem definition and make use of recent advances in optimization theory and applications for the efficient solution of the corresponding formulations. In fact, mathematical programming approaches, particularly linear programming, have long been used in data mining tasks.

The pioneering work presented in [13,14] demonstrated how to formulate the problem of constructing planes to separate linearly separable sets of points.

In this summary we will follow the formalism put forth in [2] since it presented one of the most comprehensive approaches to this problem. One of the major advantages of a formulation based on mathematical programming is the ease in incorporating explicit

problem specific constraints. This will be discussed in greater detail later in this summary.

## Classification

As discussed earlier the main goal in classification is to predict a categorical variable (class) based on the values of the feature vector. The general families of methods for addressing this problem include [9]:

- i) Estimation of the conditional probability of observing class  $C$  given the feature vector  $x$ .
- ii) Analysis of various proximity metrics and based the decision of class assignment based on proximity.
- iii) Recursive input space partitioning to maximize a score of class purity (tree-based methods).

The two-class classification problem can be formulated as the search of a function that assigns a given input vector  $x$  into two disjoint point sets  $A$  and  $B$ . The data are represented in the form of matrices. Assuming that the set  $A$  has  $m$  elements and the set  $B$  has  $k$  elements, then  $A \in \Re^{m \times n}$ ,  $B \in \Re^{k \times n}$ , describe the two sets respectively. The discrimination is based on the derivation of hyperplane

$$P = \{x | x \in \Re^n, x^T \omega = \gamma\}$$

with normal and distance from the origin  $\frac{|\gamma|}{\|\omega\|_2}$ . The optimization problem then becomes to determine  $\omega$  and  $\gamma$  such that the separating hyperplane  $P$  defines two open half spaces

$$\{x | x \in \Re^n, x^T \omega < \gamma\}$$

$$\{x | x \in \Re^n, x^T \omega > \gamma\}$$

containing mostly points in  $A$  and  $B$  respectively. Unless  $A$  and  $B$  are disjoint the separation can only be satisfied within some error. Minimization of the average violations provides a possible approximation of the separating hyperplane [2]:

$$\min_{\omega, \gamma} \frac{1}{m} \|(-A\omega + e\gamma + e)_+\|_1 + \frac{1}{k} \|(-B\omega + e\gamma + e)_+\|_1$$

In [2] a number of linear programming reformulations are discussed exploring the properties of the structure of the optimization problem. In particular an effective

robust linear programming (RLP) reformulation was suggested making possible the solution of large-scale problems:

$$\begin{aligned} \min_{\omega, \gamma, y, z} & \frac{e^T y}{m} + \frac{e^T z}{k} \\ \text{s.t.} & -A\omega + e\gamma + e \leq y \\ & B\omega - e\gamma + e \leq z \\ & y, z \geq 0. \end{aligned}$$

In [17] it was demonstrated how the above formulation can be applied repeatedly to produce complex space partitions similar to those obtained by the application of standard decision tree methods such as C4.5 [21] or CART [4].

### Clustering

The goal of clustering is the segmentation of the raw data into groups that share a common, yet unknown, characteristic property. Similarity is therefore a key property in any clustering task. The difficulty arises from the fact that the process is unsupervised. That is neither the property nor the expected number of groups (clusters) are known ahead of time. The search for the optimal number of clusters is parametric in nature and the optimal point in an “error” vs. “number of clusters” curve is usually identified by a combined objective the weighs appropriately accuracy and number of clusters. Conceptually a number of approaches can be developed for addressing clustering problems:

- i) Distance-based methods, by far the most commonly used, that attempt to identify the best k-way partition of the data by minimizing the distance of the points assigned to cluster k from the center of the cluster.
- ii) Model-based methods assume the functional form of a model that describes each of the clusters and then search for the best parameter fit that models each cluster by minimizing some appropriate likelihood measure.

There are two different types of clustering: (1) hard clustering; (2) fuzzy clustering. The former assigns a data point to *exactly* one cluster while the latter assigns a data point to one of more clusters along with the likelihood of the data point belonging to one of those clusters.

The standard formulation of the hard clustering problem is:

$$\min_c \sum_{i=1}^m \min_l \|x^i - c^l\|_n$$

That is given  $m$  points,  $x$ , in an  $n$ -dimensional space, and a fixed number of cluster,  $k$ , determine the centers of the cluster,  $c$ , such that the sum of the distances of each point to a nearest cluster center is minimized. It was shown in [3] that this general non convex problem can be reformulated such that we minimize a bilinear functions over a polyhedral set by introducing a selection variable  $t_{il}$ :

$$\begin{aligned} \min_{c, d, t} & \sum_{i=1}^m \sum_{l=1}^k t_{il} (e^T d_{il}) \\ \text{s.t.} & -d_{il} \leq x^i - c^l \leq d_{il} \\ & \sum_{l=1}^k t_{il} = 1 \\ & t_{il} \geq 0 \\ & i = 1, \dots, m, l = 1, \dots, k. \end{aligned}$$

$d$  is a dummy variable used to bound the components of the difference  $x - c$ . In the above formulation the 1-norm is selected [3].

The fuzzy clustering problem can be formulated as follows [5]:

$$\begin{aligned} \min_w & \sum_{i=1}^m \sum_{l=1}^k w_{il}^2 \|x^i - c^l\|^2 \\ \text{s.t.} & \sum_{l=1}^k w_{il} = 1 \\ & w_{il} \geq 1, \end{aligned}$$

where  $x^i, i = 1, \dots, m$  is the location descriptor for the data point,  $c^l, l = 1, \dots, k$  is the center of the cluster,  $w_{il}$  is the likelihood of a data point  $i$  being assigned to cluster  $l$ .

### Support Vector Machines

This optimization formalism bares significance resemblance to the Support Vector Machines (SVM) framework [25]. SVM incorporate the concept of structural

risk minimization by determining a separating hyperplane that maximizes not only a quantity measuring the misclassification error but also maximizing the margin separating the two classes. This can be achieved by augmenting the objective of the RLP formulation earlier presented by an appropriately weighted measure of the separation between the two classes as  $(1 - \lambda)(e^T y + e^T z) + \frac{\lambda}{2} \|\omega\|_2^2$ .

In [6] the concept of SVM is extended by introducing the Proximal support vector machines which classify points based on proximity to one of two parallel planes that are pushed as far apart as possible. Non-linear transformations were also introduced in [6] to enable the derivation of non-linear boundaries in classifiers.

### Multi-Class Support Vector Machines

Support vector machines were originally designed for binary classification. Extending to multi-class problems is still an open research area [10].

The earliest multi-class implementation is the *one against all* [22] by constructing  $k$  SVM models, where  $k$  is the number of classes. The  $i$ th SVM classifies the examples of class  $i$  against all the other samples in all other classes. Another alternative builds *one against one* [12] classifiers by building  $\frac{k(k-1)}{2}$  models where each is trained on data from two classes. The emphasis of current research is on novel methods for generating all the decision functions through the solution of a single, but much larger, optimization problem [10].

### Data Mining in the Presence of Constraints

Prior knowledge about a system is often omitted in data mining applications because most algorithms do not have adequate provisions for incorporating explicitly such types of constraints. Prior knowledge can either encode explicit and/or implicit relations among the features or models the existence of “obstacles” in the feature space [24].

One of the major advantages of a mathematical programming framework for performing data mining tasks is that prior knowledge can be incorporated in the definition of the various tasks in the form of (non)linear constraints. Efficient incorporation of prior knowledge in the form of nonlinear inequalities within the SVM framework was recently proposed by [15]. Re-

formulations of the original linear and nonlinear SVM classifiers to accommodate prior knowledge about the problem were presented in [7] in the context of approximation and in [16] in the context of classifiers.

### Data Mining and Integer Optimization

Data mining tasks involve, fundamentally, discrete decisions:

- How many clusters are there?
- Which class does a record belong to?
- Which features are most informative?
- Which samples capture the essential information?

Implicit enumeration techniques such as branch-and-bound were used early on to address the problem of feature selection [18].

Mathematical programming inspired by algorithms for addressing various data mining problems are now being revisited and cast as integer optimization problems. Representative formulations include feature selection using Mixed-Integer Linear Programs [11] and in [23] integer optimization models are used to address the problem of classification and regression.

### Research Challenges

Numerous issues can of course be raised. However, we would like to focus on three critical aspects

- i) Scalability and the curse of dimensionality. Databases are growing extremely fast and problems of practical interest are routinely composed of millions of records and thousands of features. The computational complexity is therefore expected to grow beyond what is currently reasonable and tractable. Hardware advances alone will not address this problem either as the increase in computational complexity outgrows the increase in computational speed. The challenge is therefore two-fold: either improve the algorithms and the implementation of the algorithms or explore sampling and dimensionality reduction techniques.
- ii) Noise and infrequent events. Noise and uncertainty in the data is a given. Therefore, data mining algorithms in general and mathematical programming formulations in particular have to account for the presence of noise. Issues from robustness and uncertainty propagation have to be incorporated.

However, an interesting issue emerges: how do we distinguish between noise and an infrequent, albeit interesting observation? This in fact maybe a question with no answer.

- iii) Interpretation and visualization. The ultimate goal of data mining is understanding the data and developing actionable strategies based on the conclusions. We need to improve not only the interpretation of the derived models but also the knowledge delivery methods based on the derived models. Optimization and mathematical programming needs to provide not just the optimal solution but also some way of interpreting the implications of a particular solution including the quantification of potential crucial sensitivities.

## Introduction

Supply chain management (SCM) is the integration of key business processes from end users through the original suppliers to the customers that provides products, services and information that add value to all parties [13,14,17]. It is therefore concerned with the organization, the planning and the qualitative and quantitative determination of material and information flows both in and between facilities (vendors, plants, sites and distribution centres) and between these and the final consumers. It is a set of important activities in all producing facilities and in many organizations [6].

For some restricted production problems, such as determining an optimal control to a chemical plant, suitable experimental designs can be enacted, such as EVolutionary OPeration (EVOP) [4], Taguchi methods [19], or more complex experimental designs such as Latin squares, Greek squares and block designs [21].

In general, verification procedures, based on experimental replication and design, cannot be used in the applied sciences, as non-reversible and unpredictable changes in the environment occur [18], and the outcome of the plans cannot be imputed to the effect of the decision taken rather than to an environmental change, so there can be no evaluation of the relevance of a formulated supply chain plan.

Thus more complex methodologies than those based on experimental verification, such as intuition experimental design or anecdotal evidence, must be posited. The solution of any SCM problem must be undertaken with respect to a set of principles and procedures to ensure the formulation of expectationally valid

plans, i. e. robust valid feasible policies are determined.

To enable management to formulate good SCM plans, the methodology proposed should be analysed for its logical consistency, its statistical correctness and its adequacy. Essentially, it must be shown that from acceptable premises or axioms, by suitable deductions a policy is formulated (syntactically correctness). Since this policy cannot be tested, but only applied, it must also be shown that in many other historical derivations the policies that were formulated by this methodology turned out to be applicable (semantically adequate).

A dynamic non-linear stochastic system formulation of an SCM model must be estimated and applied. Thus an optimization algorithm must be specified and solved which determines simultaneously the adequate functional form, its parameterization and the optimal control [6].

## Definitions

In this section some fundamental definitions will be given.

A dynamical system is a precise mathematical object [16], and given the flows of the activities of the phenomenon, the input-output relationships must be determined by appropriate estimation methods.

Not every relationship can be modelled by mathematical system theory, since a representation which is non-anticipatory is required [16], while the condition that the functionals be sufficiently smooth which was previously required may be waived.

Dynamical systems have been defined at a high level of generality to refine concepts and perceive unity in a diversity of applications, and by appropriate modelling whole hierarchies of phenomena can be represented as systems defined at different levels.

**Definition 1 ([16])** A dynamical system is a composite mathematical object defined by the following axioms:

1. There is a given time set  $T$ , a state set  $X$ , a set of input values  $U$ , a set of acceptable input functions  $\Omega = \omega: \Omega \rightarrow U$ , a set of output values  $Y$  and a set of output functions  $\Gamma = \gamma: \Gamma \rightarrow Y$ .
2. (Direction of time).  $T$  is an ordered subset of the reals.
3. The input space  $\Omega$  satisfies the following conditions:
  - (a) (Non-triviality).  $\Omega$  is non-empty.

- (b) (Concatenation of inputs). An input segment  $\omega_{(t_1, t_2]}$ ,  $\omega \in \Omega$  restricted to  $(t_1, t_2] \cap T$ . If  $\omega, \omega' \in \Omega$  and  $t_1 < t_2 < t_3$ , there is an  $\omega'' \in \Omega$  such that  $\omega''_{(t_1, t_2]} = \omega_{(t_1, t_2]}$  and  $\omega''_{(t_2, t_3]} = \omega'_{(t_2, t_3]}$ .
4. There is a state transition function  $\phi: T \times T \times X \times \Omega \rightarrow X$  whose value is the state  $x(t) = \phi(t; \tau, x, \omega) \in X$  resulting at time  $t \in T$  from the initial state  $x = x(\tau) \in X$  at the initial time  $\tau \in T$  under the action of the input  $\omega \in \Omega$ .  $\phi$  has the following properties:
- (a) (Direction of time).  $\phi$  is defined for all  $t \geq \tau$ , but not necessarily for all  $t < \tau$ .
- (b) (Consistency).  $\phi(t; t, x, \omega) = x$  for all  $t \in T$ , all  $x \in X$  and all  $\omega \in \Omega$ .
- (c) (Composition property). For any  $t_1 < t_2 < t_3$  there results:

$$\phi(t_3; t_1, x, \omega) = \phi(t_3; t_2, \phi(t_2; t_1, x, \omega), \omega)$$

for all  $x \in X$  and all  $\omega \in \Omega$ .

- (d) (Causality). If  $\omega, \omega' \in \Omega$  and  $\omega_{(\tau, t]} = \omega'_{(\tau, t]}$  then  $\phi(t; \tau, x, \omega) = \phi(t; \tau, x, \omega')$ .
5. There is a given readout map  $\eta: T \times X \rightarrow Y$  which defines the output  $y(t) = \eta(t, x(t))$ . The map  $(\tau, t] \rightarrow Y$  given by  $\sigma \mapsto \eta(\sigma, \phi(\sigma, \tau, x, \omega))$ ,  $\sigma \in (\tau, t]$ , is an output segment, that is the restriction  $\gamma_{(\tau, t]}$  of some  $\gamma \in \Gamma$  to  $(\tau, t]$ .

The following mathematical structures in Definition 1 will be indicated by:

- The pair  $(t, x)$ ,  $t \in T$ ,  $x \in X \forall t$  is called an event;
- The state transition function  $\phi(x_t, u_t)$  is called a trajectory.

Phenomena may also be modelled through dynamical systems in the input/output sense, which reflect an experimental design or a simulative approach, long applied in science.

**Definition 2** A dynamical system in an input/output sense is a composite mathematical object defined as follows:

1. There are given sets  $T, U, \Omega, Y$  and  $\Gamma$  satisfying all the properties required by Definition 1.
2. There is a set  $A$  indexing a family of functions

$$\mathcal{F} = \{f_\alpha: T \times \Omega \rightarrow Y, \alpha \in A\};$$

each member of  $\mathcal{F}$  is written explicitly as  $f_\alpha(t, \omega) = y(t)$ , which is the output resulting at time  $t$  from the

input  $\omega$  under the experiment  $\alpha$ . Each  $f_\alpha$  is called an input/output function and has the following properties:

- (a) (Direction of time). There is a map  $\iota: A \rightarrow T$  such that  $f_\alpha(t, \omega)$  is defined for all  $t \geq \iota(\alpha)$ .
- (b) (Causality). Let  $\tau, t \in T$  and  $\tau < t$ . If  $\omega, \omega' \in \Omega$  and  $\omega_{(\tau, t]} = \omega'_{(\tau, t]}$ , then  $f_\alpha(t, \omega) = f_\alpha(t, \omega')$  for all  $\alpha$  such that  $\tau = \iota(\alpha)$ .

While the input/output approach may determine a family of functions, which generally vary over the time interval of realization and across instances, the state-space approach represents the trajectories in the way indicated, through a unique function. The latter approach is intuitively more appealing, especially in applications.

The representations are equivalent. It is easy to transform a given system from a state space formulation into an input/output formulation and vice versa [2,16], so each may be used as convenience suggests.

It cannot be assumed generally that a dynamical system satisfies the conditions of smoothness, nor that it will meet the necessary and sufficient conditions for an optimal control to exist. Thus in general, the dynamical systems to be dealt with may have an awkward structure, but through the combined estimation and optimization approach a sufficiently good approximation may be obtained with the required characteristics [6].

A sufficiently general representation of a dynamical system may be formulated by applying Definition 1, recalling the equivalence of an input/output system and a system in state form:

$$x_{t+1} = \phi(x_t, u_t), \quad (1)$$

$$y_t = \eta(x_t), \quad (2)$$

where  $x_t \in X \subseteq R^r$  may simply be taken as an  $r$ -dimensional vector in a Euclidean space  $X$ , indicating the state of the system at time  $t$ ,  $u_t \in U \subseteq R^q$  may be taken as a  $q$ -dimensional vector in a Euclidean subspace  $U$  of control variables and  $y_t \in Y \subseteq R^p$  is a  $p$ -dimensional vector in a Euclidean space  $Y$  of output variables, in line with Definitions 1 and 2.

The definition of a dynamical system is based on defining an intermediary set of states and a transition function or a family of functions. Neither of these constructions is unique, so if it is desired to represent

a SCM system by such structures, equivalence of the possible structures must be shown.

**Definition 3** Given two states  $x_{t_0}$  and  $\hat{x}_{t_0}$  belonging to systems  $S$  and  $\hat{S}$  which may not be identical but have a common input space  $\Omega$  and output space  $Y$ , the two states are said to be equivalent if and only if for all input segments  $\omega_{[t_0,t]} \in \Omega$  the response segment of  $S$  starting in state  $x_{t_0}$  is identical with the response segment of  $\hat{S}$  starting in state  $\hat{x}_{t_0}$ ; that is

$$x_{t_0} \cong \hat{x}_{t_0} \Leftrightarrow \eta(t, \varphi(x_{t_0}, \omega_{[t_0,t]})) = \hat{\eta}(t, \hat{\varphi}(\hat{x}_{t_0}, \omega_{[t_0,t]})) \\ \forall t \in T, t_0 \leq t, \forall \omega_{[t_0,t]} \in S, \hat{S}. \quad (3)$$

Systems  $S$  and  $\hat{S}$  may be two models of a SCM system solved with different control policies, or they may be various alternative models of the phenomenon.

**Definition 4** A system is in reduced form if there are no distinct states in its state space which are equivalent to each other.

**Definition 5** Systems  $S$  and  $\hat{S}$  are equivalent  $S \equiv \hat{S}$  if and only if to every state in the state space of  $S$  there corresponds an equivalent state in the state space of  $\hat{S}$  and vice versa.

Some important conditions are required to make the representation of the SCM adequate.

The conditions of the system are:

- Reachability
- Controllability
- Observability
- Stability

These conditions are very important since they allow trajectories to be defined, the initial point of trajectories to be determined and their stability properties to be derived. Moreover they can be applied at any moment in time to determine if the goals of the SCM are still attainable and at what cost. Reachability, controllability and stability are seldom formally examined and yet at every period exogenous events can arise to nullify even the best formulated plan, so these are important instruments for SCM [6].

An important property which distinguishes dynamical systems from their counterparts derived in comparative statics is the distinction between systems which are simply equivalent and those which are multiply

equivalent [6]. This distinction is crucial if dynamical systems are considered, while with comparative static models the distinction does not apply. This is one of the many reasons that one should insist on solving SCM dynamic estimation problems with a data-driven formulation [6].

The dynamical system representation of a SCM system permits one to verify its specification, whether the optimal control which determines the final event is reachable, if the system is controllable throughout the sequence of events comprising the trajectory, if the system is observable and finally if the given solution is stable, so that small perturbations will not give rise to explosive perturbations or to chaotic behaviour. In so doing crucial questions which are important to management can be answered.

If these conditions are not verified, this will suggest strategic changes to the SCM system or profound modification of policies, aspects which are difficult to determine in advance.

Computationally, these aspects are handled by adding appropriate constraints in the mathematical program [6].

## Formulation

Consider the monitoring of a set of activities in time of a supply chain at a given level of aggregation, which may be at the department, plant or firm level, or a hierarchical system developed through all these organizational structures. Although the accuracy of the representation may depend on the sampling strategy and the time interval, these aspects will not be considered here.

Thus a given finite-dimensional estimation and optimization problem will be considered which may well be non-linear and dynamic.

Consider the data set of a phenomenon consisting of measurements  $(y^t, x^t, u^t)$  over  $(t = 1, 2, \dots, T)$  periods, where it is assumed that  $y_t \in R^p$  is a  $p$ -dimensional vector, while  $x_t \in R^r$  is an  $r$ -dimensional vector of explanatory or state variables of the dynamic process of dimension. Also,  $u_t$  is a  $q$ -dimensional vector of control variables. It is desired to determine functional forms  $\varphi: R^{r+q} \rightarrow R^r$  and  $\eta: R^r \rightarrow R^p$  and a set of suitable coefficients  $\Theta \in R^m$  such that:

$$\text{Min } J = \sum_{t=T+1}^T c(x_t, u_t, y_t), \quad (4)$$

$$x^{t+1} = \varphi(x^t, u^t, y^t, w^t) \quad \forall t = T+1, \dots, \mathcal{T}-1, \quad (5)$$

$$y^t = \eta(x^t, u^t, v^t) \quad \forall t = T+1, \dots, \mathcal{T}, \quad (6)$$

where  $w^t$  and  $v^t$  are stochastic processes also to be determined.

Equation (4) is the objective function for the supply chain and (5) and (6) are the system equations in state space formulation and a similar representation may be adopted for the the input-output formulation [16,20].

The system (4)–(6) could be estimated by a maximum likelihood method so as to minimize the random errors, indicated by  $w^t \in R^r$  and  $v^t \in R^p$ , such that they will have minimum variance and zero mean value, and then on the quantified model the optimal control problem could be solved, usually through an appropriate optimization problem.

However, for this type of model with serially correlated disturbances, which are also correlated with the control variables, its estimation will be biased and the necessary least-squares properties to ensure an asymptotically correct estimate may only be fulfilled in exceptional cases. Thus the two-stage approach, indicated above, is inappropriate [15].

It is important to apply a suitable data-driven statistical method to determine the most appropriate statistical form and the most precise values of the parameters, as when implemented correctly with regard to an accurately specified functional form. Such a method will provide estimates of parameters that satisfy the statistical properties [1,18].

Suppose that all the statistical properties that a given estimate must fulfil are set up as constraints to the maximum likelihood problem to be solved; then the parameters are defined implicitly by this optimization problem, which can be inserted into the optimal control system for policy determination, so that statistically correct estimates will always result. Thus the solution yielding the best policy can be chosen, where  $T+1, \dots, \mathcal{T}$  is the forecast period, by solving an optimization formulation of this complex problem. By recursing on the specifications, i. e. by changing the functional form, increasingly better fits can be obtained. At each iteration, the best combination of parameterization and policy is obtained.

The unknowns to be determined are the input and output variables considered and the parameters

of the functional form specified in the current iteration, indicated as  $\Theta = \{\theta_1, \theta_2\} \subset R^m$ , respectively for (5) and (6). Note that  $m$  may be much larger than  $2r + q + p + 1$ , the number of variables present in each system, since the system is non-linear.

The mathematical program will be formulated with respect to the residual variables, but it is immediate that for a given functional form, the unknown parameters will be specified and thus the unknowns of the problem will also be defined and available. Thus the mathematical program is fully specified for each functional form to be considered.

Using the notation given above, the residual terms are given from Eqs. (5) and (6) as:

$$w_i = \hat{x}_{i+1} - \varphi(\hat{x}_i, \hat{u}_i, \hat{y}_i; \theta_1) \quad i = 1, 2, \dots, N, \quad (7)$$

$$v_i = \hat{y}_{i+1} - \eta(\hat{x}_i, \hat{u}_i, \hat{v}_i; \theta_2) \quad i = 1, 2, \dots, N, \quad (8)$$

where  $\hat{\cdot}$ , as usual, indicates the historical values of a variable, and thus suitable values of  $\theta_1$  and  $\theta_2$  must be determined by the mathematical program such that all the constraints expressed in terms of  $w_i, v_i \forall i$  are specified.

### Methods and Applications

Given an experimental data set obtained as a set of measurements of the operation of a phenomenon, it is desired to determine a suitable representation of it in the form of a model, so as to determine a suitable control law for the model which can then be extended to the phenomenon and thus obtain a better performance [3].

Except in some simple cases, the representation assumed by the model and the data that have been collected will condition the results obtainable by enacting the control law. For models that are non-linear in the parameters, the interaction between the estimation of these and the determination of an optimal control is much more complex than the linear case requiring the solution of constrained optimization problems which will determine simultaneously the best estimates and the optimal control.

Consider the availability of a given data set containing a number of sets of time series data or cross-sectional data. To determine from these data a suitable model, a functional form must be selected and a set of suitable parameters must be estimated which will satisfy

all the conditions on the model and permit the determination of a suitable set of control variables, which will define an optimal control with respect to a predefined merit function.

Thus from the data set it is desired to derive a sufficiently accurate model of the phenomenon, which can then be used in control and in prediction.

Statistical estimation methods are important because, when implemented correctly with regard to an accurately specified functional form, they will provide estimates of parameters that have the following properties [1,18]:

1. The parameter estimates are unbiased.
  - As the size of the data set grows larger, the estimated parameters tend to their true values.
2. The parameter estimates are consistent, which will then satisfy the following conditions:
  - The estimated parameters are asymptotically unbiased.
  - The variance of the parameter estimate must tend to zero as the data set tends to infinity.
3. The parameter estimates are asymptotically efficient.
  - The estimated parameters are consistent.
  - The estimated parameters have smaller asymptotic variance as compared to any other consistent estimator.
4. The residuals have minimum variance, which is ensured by the following factors:
  - The variance of the residuals must be minimum.
  - The residuals must be homoscedastic.
  - The residuals must not be serially correlated.
5. The residuals are unbiased (have zero mean).
6. The residuals have a non-informative distribution (usually, a Gaussian distribution).
  - If the distribution of the residuals is informative, the extra information could somehow be obtained, reducing the variance of the residuals, their bias etc., with the result that better estimates are obtained.

In short, through correct implementation of statistical estimation techniques the estimates are as close as possible to their true values, all the information that is available is applied and the uncertainty surrounding the estimates and the data fit is reduced to the maximum extent possible. Thus the estimates of the parameters, which satisfy all these conditions, are the 'best' possible in a 'technical' sense [1].

To ensure that all the statistical properties which the given estimates of the residuals must fulfil are satisfied at every iteration, instead of solving an unconstrained maximum likelihood or least-squares problem [15], the required statistical properties of the estimates are set up as constraints, together with the specification of the model of the phenomenon, and this global optimization problem is solved for all the undetermined variables.

The parameters of this model to be estimated are defined implicitly through those constraints which define the statistical conditions. On solving the global optimization problem, the parameter estimates that result will be defined for the optimal control system for the policy determination so that statistically correct estimates will always result.

The procedure adopted can be specified easily by using the same notation as above and by adding an additional set of constraints which express the statistical conditions that must be satisfied by the estimates.

Let

$$\gamma(x_{i+1}, x_i, u_i, y_{i+1}, y_i, w_i, v_i, \theta_1, \theta_2) \geq 0$$

$$i = 1, 2, \dots, N, N + 1, \dots, \mathcal{T} \quad (9)$$

be the set of conditions to be satisfied to obtain estimates, if they exist, which satisfy the statistical properties indicated above. Then the optimization problem to be solved is:

$$\text{Min } J = \sum_{i=N+1}^{\mathcal{T}} c(x_i, u_i, y_i), \quad (10)$$

$$x_{i+1} = \varphi(x_i, u_i, y_i, w_i; \theta_1) \quad i = 1, 2, \dots, \mathcal{T}, \quad (11)$$

$$y_{i+1} = \eta(x_i, u_i, v_i; \theta_2) \quad i = 1, 2, \dots, \mathcal{T}, \quad (12)$$

$$0 \leq \gamma(x_{i+1}, x_i, u_i, y_{i+1}, y_i, w_i, v_i, \theta_1, \theta_2)$$

$$i = 1, 2, \dots, \mathcal{T}. \quad (13)$$

Thus the solution yielding the best policy can be chosen by solving an optimization formulation of this complex problem. By recursing on the specifications, i. e. by changing the functional form, and increasing the number of independent variables considered, increasingly better fits can be obtained, with regard to both the historical data and the predicted optimal control policy.

## Models

Many models of industrial, extractive and financial activities require the integration of key processes, but the most essential aspect is to formulate precise information where it is most needed [11,12].

Many optimization models solve satisfactorily supply chain problems, but apparently no model except this one integrates information and allocation of goods and operations dynamically.

This algorithm instead solves the combined problem, as has been shown elsewhere [6], while a theory-driven modelling approach to the problem, using models consisting of two stages, an identification stage and an optimization stage, can be shown to be dominated by this data-driven approach.

At present, this seems to be the only viable approach to solving such complex problems.

## Cases

Some non-typical SCM problems are indicated here: dynamical supply chain management problems for perforation oil wells and for finance. Industrial SCM models are given elsewhere [3,8,9,10].

### Dynamic Supply Chain Management Problem for Extraction Activities

The perforation of oil wells consists of a number of operations to drive the bit head lower and lower while ensuring normal functions on the equipment and the operations. To this end complex measurements are executed by software systems indicated as mudlogging systems. These measurements are designed to assist the operator in controlling the perforation rate of the bit head by monitoring a number of crucial operations periodically.

The settings of some of these operations affect the rate of perforation, and therefore it is considered extremely useful to dispose of measurements of these variables and have predictions over the next few periods of the possible advancement of the bit head, or of the rate of perforation, and so enable an optimal control of the process to be formulated [5].

It should be mentioned that periodically the drilling process must be halted so that the boring can be lined with suitable materials. Also, one of the most important

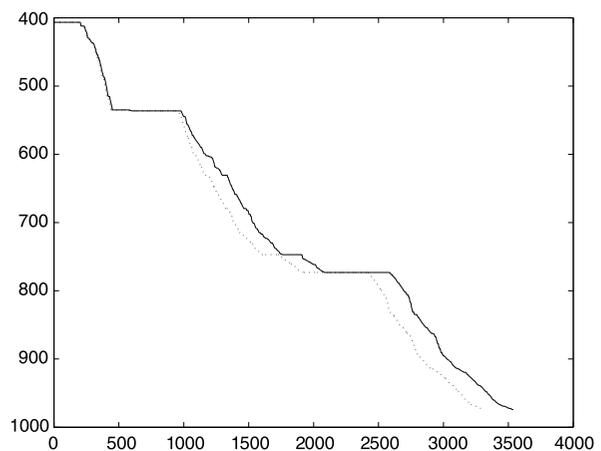

elements of the process is to keep circulating around the bit-head assembly a concentration of mud lubricants, indicated as mud, which gives the name to the measuring process. Recall that all these flows and operations occur in time, so it is considered crucial to specify dynamic models, unless it is desired to determine the steady-state rates of the eventual process.

In fact oil drilling processes can be considered as complex supply chain systems with many phases and many operations.

The determination of optimal control policies in processes for the extraction of oil from underground require that they be formulated as formal procedures, which are syntactically correct and semantically adequate, so as to permit management to make the necessary investments, not on hearsay or clever promotional activities, but on the basis of rational knowledge and confidence in the application.

Figure 1 shows an optimal SCM plan compared to the actual historical plan implemented. The predicted trajectory is superimposed on the actual time path of the perforation process, thus respecting all the interruptions and periods of halting.

In Table 1, six instances to determine optimal controls are indicated, and each entry reflects the drilling experience of the given well for that week with regard to the given period. From the active perforation intervals an initial period was selected randomly and the optimal

Optimal predicted versus actual increment for 6 oil wells over 192 periods (8 h) in metres

Well and week	Optimal increment	Real increment	% difference
FT02D 9	114.0	73.3	35.70
FT02D 16	116.7	83.8	28.19
FT02D 23	73.7	13.45	81.75
GX01 3	94.8	72.2	23.84
GX01 11	57.9	18.8	67.53

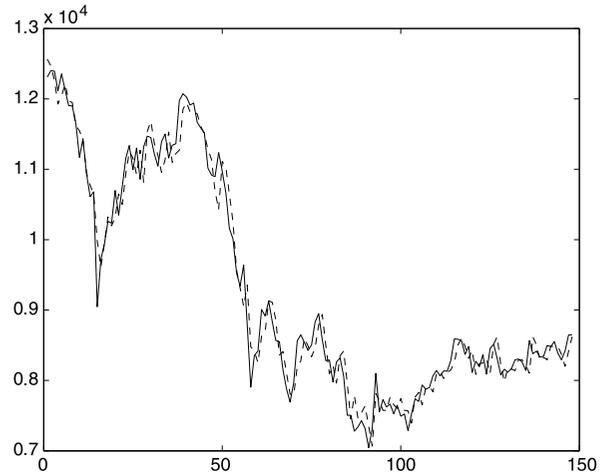

control was defined for the next 192 periods (8 h). The average predicted increment in depth attainable over the actual one was more than 30% on average.

### Dynamic Supply Chain Management Problem for Finance

The prediction of future quotations on stock exchange indices is important and consists of the basic instrument to handle financial supply chain management systems. A financial supply chain system must consider many types of financial intermediaries, many types of stocks and stock indices and many types of operations. Further, there are many possibilities for managing the monetary holdings, so that a full SCM system is envisaged as defined above [7].

Consider the Dow-Jones Industrial Average (DJIA) stock exchange index over a period of 3 years starting in April 2001, as shown in Fig. 2, where the continuous line indicates the actual quotations, week by week over the period, while the 1-week-ahead predictions are given by the dashed line. As can be easily seen, the two curves almost coincide, which implies that the predictions 1 week ahead are very good.

Instead, in Table 2 a period of 5 weeks is considered from April 16, 2004 to May 14, 2004. The quotations are given every Friday evening at closing time, while the predictions are made on Fridays just after closing time. Thus on April 9 predictions were made for the next 5 weeks, as indicated in the second row of the table. After closing on April 16, 2004, predictions were made for 4 weeks only and are depicted in the third row of the table and so on for the subsequent weeks. Finally, in the last row the closing quotations for the week are given.

Results for prediction of the Dow-Jones Industrial Average, 147 periods

Period	16/4	23/4	30/4	7/5	14/5
9/4	8652.86	8568.44	9304.81	13306.5	9958.15
16/4	..	8646.28	8552.54	11514.3	11000.3
23/4	..	..	8820.73	8806.51	4700.47
30/5	..	..	..	8518.12	8361.19
7/5	..	..	..	..	8343.35
Index	8712.88	8855.03	8538.03	8505.54	8432.25

This table allows one to determine with the appropriate portfolio model suitable financial policies to formulate optimal financial SCM plans [7].

### Conclusions

Optimal dynamic SCM policies may be obtained by a correct application of statistical inference and mathematical programming techniques.

It has been indicated that these policies are expectationally valid, which implies that they are syntactically correct and semantically adequate.

Computational evidence has been presented and indicated in the references.

Partial matrix; Completion of matrices

Matrix completion problems are concerned with determining whether partially specified matrices can be completed to fully specified matrices satisfying certain prescribed properties. In this article we survey some results and provide references about these problems for the following matrix properties: positive semidefinite matrices, Euclidean distance matrices, completely positive matrices, contraction matrices, and matrices of given rank. We treat mainly optimization and combinatorial aspects.

## Introduction

A *partial matrix* is a matrix whose entries are specified only on a subset of its positions; a *completion* of a partial matrix is simply a specification of the unspecified entries. *Matrix completion problems* are concerned with determining whether or not a completion of a partial matrix exists which satisfies some prescribed property. We consider here the following matrix properties: positive (semi) definite matrices, distance matrices, completely positive matrices, contraction matrices, and matrices of given rank; definitions are recalled below.

In what follows,  $x^*$ ,  $A^*$  denote the conjugate transpose (in the complex case) or transpose (in the real case) of vector  $x$  and matrix  $A$ . A square real symmetric or complex Hermitian matrix  $A$  is *positive semidefinite* (psd) if  $x^*Ax \geq 0$  for all vectors  $x$  and *positive definite* (pd) if  $x^*Ax > 0$  for all vectors  $x \neq 0$ ; then we write:  $X \succeq 0$  ( $X > 0$ ). Equivalently,  $A$  is psd (respectively, pd) if and only if all its eigenvalues are nonnegative (respectively, positive) and  $A$  is psd if and only if  $A = BB^T$  for some matrix  $B$ . A matrix  $A$  is said to be *completely positive* if  $A = BB^T$  for some nonnegative matrix  $B$ . An  $n \times n$  real symmetric matrix  $D = (d_{ij})$  is a *Euclidean distance matrix* (abbreviated as *distance matrix*) if there exist vectors  $v_1, \dots, v_n \in \mathbf{R}^k$  (for some  $k \geq 1$ ) such that, for all  $i, j = 1, \dots, n$ ,  $d_{ij}$  is equal to the square of the Euclidean distance between  $v_i$  and  $v_j$ . Finally, a (rectangular) matrix  $A$  is a *contraction matrix* if all its singular values (that is, the eigenvalues of  $A^*A$ ) are less than or equal to 1.

The set of positions corresponding to the specified entries of a partial matrix  $A$  is known as the *pattern* of  $A$ . If  $A$  is an  $n \times m$  partial matrix, its pattern can be represented by a bipartite graph with node bipartition  $[1, n] \cup [1, m]$  having an edge between nodes  $i \in [1, n]$  and  $j \in [1, m]$  if and only if entry  $a_{ij}$  is specified.

When asking about existence of a psd completion of a partial  $n \times n$  matrix  $A$ , it is commonly assumed that all diagonal entries of  $A$  are specified (which is no loss of generality if we ask for a pd completion); moreover, it can obviously be assumed that  $A$  is *partial Hermitian*, which means that entry  $a_{ji}$  is specified and equal to  $a_{ij}^*$  whenever  $a_{ij}$  is specified. Hence, in this case, complete information about the pattern of  $A$  is given by the graph  $G = ([1, n], E)$  with node set  $[1, n]$  and whose edge set  $E$  consists of the pairs  $ij$  ( $1 \leq i < j \leq n$ ) for which  $a_{ij}$  is a specified entry of  $A$ . The same holds when dealing

with distance matrix completions (in which case diagonal entries can obviously be assumed to be equal to zero).

An important common feature of the above matrix properties is that they possess an ‘inheritance structure’. Indeed, if a partial matrix  $A$  has a psd (pd, completely positive, distance matrix) completion, then every principal specified submatrix of  $A$  is psd (pd, completely positive, a distance matrix); similarly, if a partial matrix  $A$  admits a completion of rank  $\leq k$ , then every specified submatrix of  $A$  has rank  $\leq k$ . Hence, having a completion of a certain kind imposes certain ‘obvious’ necessary conditions. This leads to asking which are the patterns for the specified entries that insure that if the obvious necessary conditions are met, then there will be a completion of the desired type; therefore, this introduces a combinatorial aspect into matrix completion problems, as opposed to their analytical nature.

In this article we survey some results and provide references for the various matrix completion problems mentioned above, concerning optimization and combinatorial aspects of the problems. See [32,47] for more detailed surveys on some of the topics treated here.

## Positive Semidefinite Completion Problem

We consider here the following *positive (semi) definite completion problem* (PSD): Given a partial Hermitian matrix  $A = (a_{ij})_{ij \in S}$  whose entries are specified on a subset  $S$  of the positions, determine whether  $A$  has a psd (or pd) completion; if, yes, find such a completion. (Here,  $S$  is generally assumed to contain all diagonal positions.)

This problem belongs to the most studied matrix completion problems. This is due, in particular, to its many applications, e. g., in probability and statistics, systems engineering, geophysics, etc., and also to the fact that positive semidefiniteness is a basic property which is closely related to other matrix properties like being a contraction or distance matrix. Equivalently, (PSD) is the problem of testing feasibility of the following system (in variable  $X = (x_{ij})$ ):

$$X \succeq 0, \quad x_{ij} = a_{ij} \quad (ij \in S). \quad (1)$$

Therefore, (PSD) is an instance of the following *semidefinite programming problem* (P): Given Hermitian matrices  $A_1, \dots, A_m$  and scalars  $b_1, \dots, b_m$ , decide

whether the following system is feasible:

$$X \succeq 0, \quad A_j \cdot X = b_j \quad (j = 1, \dots, m) \quad (2)$$

(where  $A \cdot X := \sum_{i,j=1}^n a_{ij} * x_{ij}$  for two Hermitian  $(n \times n)$ -matrices  $A$  and  $X$ ).

The exact complexity status of problems (PSD) and (P) is not known; in particular, it is not known whether they belong to the complexity class  $NP$ . However, it is shown in [60] that (P) is neither  $NP$ -complete nor  $co-NP$ -complete if  $NP \neq co-NP$ . However, the semidefinite programming problem and, thus, problem (PSD) can be solved with an arbitrary precision in polynomial time. This can be done using the ellipsoid method (since one can test in polynomial time whether a rational matrix  $A$  is positive semidefinite and, if not, find a vector  $x$  such that  $x^*Ax < 0$ ; cf. [24]), or interior point methods (cf. [3,27,56]). There has been a growing interest in semidefinite programming in the recent years (1994), which is due, in particular, to its successful application to the approximation of hard combinatorial optimization problems (cf. the survey [20]). This has prompted active research on developing interior point algorithms for solving semidefinite programming problems; the literature is quite large, see [64,65] for extensive information. Numerical tests are reported in [34] where an interior point algorithm is proposed for the approximate psd completion problem; it permits to find exact completions for random instances up to size 110.

Moreover, it is shown in [59] that problem (P) can be solved in polynomial time (for rational input data  $A_j, b_j$ ) if either the number  $m$  of constraints, or the order  $n$  of the matrices  $X, A_j$  in (2) is fixed (cf. also [9]). Moreover, under the same assumption, one can test in polynomial time the existence of an integer solution and find one if it exists [39].

Call a partial Hermitian matrix  $A$  *partial psd* (respectively, *partial pd*) if every principal specified submatrix of  $A$  is psd (respectively, pd). As mentioned in the Introduction, being partial psd (pd) is an obvious necessary condition for  $A$  to have a psd (pd) completion. In general, this condition is not sufficient; for instance, the partial matrix:

$$A = \begin{pmatrix} 1 & 1 & ? & 0 \\ 1 & 1 & 1 & ? \\ ? & 1 & 1 & 1 \\ 0 & ? & 1 & 1 \end{pmatrix}$$

(‘?’ indicates an unspecified entry) is partial psd, yet no psd completion exists; note that the pattern of  $A$  is a circuit of length 4. Call a graph *chordal* if it does not contain any circuit of length  $\geq 4$  as an induced subgraph; chordal graphs occur in particular in connection with the Gaussian elimination process for sparse pd matrices (cf. [21,61]). (An *induced subgraph* of a graph  $G = (V, E)$  being of the form  $H = (U, F)$  where  $U \subseteq V$  and  $F := \{ij \in E: i, j \in U\}$ .) It is shown in [23] that every partial psd matrix with pattern  $G$  has a psd completion if and only if  $G$  is a chordal graph; the same holds for pd completions. This extends an earlier result from [16] which dealt with ‘block-banded’ partial matrices; in the Toeplitz case (all entries equal along a band), one finds the classical Carathéodory–Fejér theorem from function theory.

The proof from [23] is constructive and can be turned into an algorithm with a polynomial running time [48]. Moreover, it is shown in [48] that (PSD) can be solved in polynomial time when restricted to partial rational matrices whose pattern is a graph having a fixed minimum fill-in; the *minimum fill-in* of a graph being the minimum number of edges needed to be added in order to obtain a chordal graph. This result is based on the above mentioned results from [39,59] concerning the polynomial time solvability of (integer) semidefinite programming with a fixed number  $m$  of linear constraints in (2).

The result from [23] on psd completions of partial matrices with a chordal pattern has been generalized in various directions; for instance, considering general inertia possibilities for the completions ([17,35]), or considering completions with entries in a function ring [37].

If  $A$  is a partial matrix having a pd completion, then  $A$  has a unique pd completion with maximum determinant (this unique completion being characterized by the fact that its inverse has zero entries at all unspecified positions of  $A$ ) [23]. In the case when the pattern of  $A$  is chordal, explicit formulas for this maximum determinant are given in [7]. The paper [52] considers the more general problem of finding a maximum determinant psd completion satisfying some additional linear constraints.

Further necessary conditions are known for the existence of psd completions. Namely, it is shown in [8] that if a partial matrix  $A = (a_{ij})$  with pattern  $G$  and di-

agonal entries equal to 1 is completable to a psd matrix, then the associated vector  $x := (\arccos(a_{ij})/\pi)_{ij \in E}$  satisfies the inequalities:

$$\sum_{e \in F} x_e - \sum_{e \in C \setminus F} x_e \leq |F| - 1$$

for all  $F \subseteq C$ ,  $C$  circuit in  $G$ ,  $|F|$  odd. (3)

Moreover, any partial matrix with pattern  $G$  satisfying (3) is completable to a psd matrix if and only if  $G$  does not contain a homeomorph of  $K_4$  as an induced sub-graph (then,  $G$  is also known as *series-parallel graph*) [44]. (Here,  $K_4$  denotes the complete graph on 4 nodes and a *homeomorph* of  $K_4$  is obtained by replacing the edges of  $K_4$  by paths of arbitrary length.) The patterns  $G$  for which every partial psd matrix satisfying (3) has a psd completion are characterized in [6]; they are the graphs  $G$  which can be made chordal by adding a set of edges in such a way that no new clique of size 4 is created. Although (3) can be checked in polynomial time for rational  $x$  [5], the complexity of problem (PSD) for series-parallel graphs (or for the subclass of circuits) is not known. A strengthening of condition (3) (involving cuts in graphs) is formulated in [44].

Another approach to problem (PSD) is considered in [1,28], which is based on the study of the cone

$$\mathcal{P}_G := \left\{ X = (x_{ij})_{i,j \in V} : \begin{array}{l} X \succeq 0, \quad x_{ij} = 0 \\ \forall i \neq j, \quad ij \notin E \end{array} \right\}$$

associated to graph  $G = (V, E)$ . Indeed, it is shown there that a partial matrix  $A$  with pattern  $G$  has a psd completion if and only if

$$\sum_{i \in V} a_{ii} x_{ii} + \sum_{\substack{i \neq j, \\ ij \in E}} a_{ij} x_{ij} \geq 0, \quad \forall X \in \mathcal{P}_G. \quad (4)$$

Obviously, it suffices to check (4) for all  $X$  *extremal* in  $\mathcal{P}_G$  (i. e.,  $X$  lying on an extremal ray of the cone  $\mathcal{P}_G$ ).

Define the *order* of  $G$  as the maximum rank of an extremal matrix in  $\mathcal{P}_G$ . The graphs of order 1 are precisely the chordal graphs [1,58] and the graphs of order 2 have been characterized in [46]. One might reasonably expect that problem (PSD) is easier for graphs having a small order. This is indeed the case for graphs of order 1; the complexity of (PSD) remains however open for the graphs of order 2 (partial results are given in [48]).

### Euclidean Distance Matrix Completion Problem

We consider here the *Euclidean distance matrix completion problem* (abbreviated as *distance matrix completion problem*) (EDM): Given a graph  $G = (V = [1, n], E)$  and a real partial symmetric matrix  $A = (a_{ij})$  with pattern  $G$  and with zero diagonal entries, determine whether  $A$  can be completed to a distance matrix; that is, whether there exist vectors  $v_1, \dots, v_n \in \mathbf{R}^k$  for some  $k \geq 1$  such that

$$a_{ij} = \|v_i - v_j\|^2 \quad \text{for all } ij \in E. \quad (5)$$

(here,  $\|v\| = \sqrt{\sum_{h=1}^k v_h^2}$  denotes the Euclidean norm of  $v \in \mathbf{R}^k$ .) The vectors  $v_1, \dots, v_n$  are then said to form a *realization* of  $A$ . A variant of problem (EDM) is the *graph realization problem* (EDM $k$ ), obtained by letting the dimension  $k$  of the space where one searches for a realization of  $A$  be part of the input data.

Distance matrices are a central notion in the area of distance geometry; their study was initiated by A. Cayley in the 18th century and it was continued in particular by K. Menger and I.J. Schoenberg in the 1930s. They are, in fact, closely related to psd matrices. The following basic connection was established in [63]. Given a symmetric  $(n \times n)$ -matrix  $D = (d_{ij})_{i,j=1}^n$  with zero diagonal entries, consider the symmetric  $((n - 1) \times (n - 1))$ -matrix  $X = (x_{ij})_{i,j=1}^{n-1}$  defined by

$$x_{ij} = \frac{1}{2}(d_{in} + d_{jn} - d_{ij})$$

for all  $i, j = 1, \dots, n - 1$ . (6)

Then,  $D$  is a distance matrix if and only if  $X$  is psd; moreover,  $D$  has a realization in the  $k$ -space if and only if  $X$  has rank  $\leq k$ . Other characterizations are known for distance matrices. As the literature on this topic is quite large, see the monographs [11,13,14], where further references can be found.

Problems (EDM) and (EDM $k$ ) have many important applications; for instance, to multidimensional scaling problems in statistics (cf. [49]) and to position-location problems, i. e., problem (EDM $k$ ) mostly in dimension  $k \leq 3$ . A much studied instance of the latter problem is the molecular conformation problem in chemistry; indeed, nuclear magnetic resonance spectroscopy permits to determine some pairwise interatomic distances, the question being then to reconstruct

the global shape of the molecule from this partial information (cf. [13,41]).

In view of relation (6), problem (EDM) can be formulated as an instance of the semidefinite programming problem (P) and, therefore, it can be solved with an arbitrary precision in polynomial time. Exploiting this fact, some specific algorithms based on interior point methods are presented in [2] together with numerical tests. Moreover, problem (EDM) can be solved in polynomial time when restricted to partial rational matrices whose pattern is a chordal graph or, more generally, a graph with fixed minimum fill-in [48]; as in the psd case, this follows from the fact (mentioned below) that partial matrices that are completable to a distance matrix admit a good characterization when their pattern is a chordal graph.

While the exact complexity of problem (EDM) is not known, it has been shown in [62] that problem (EDM $k$ ) is NP-complete if  $k = 1$  and NP-hard if  $k \geq 2$  (even when restricted to partial matrices with entries in  $\{1, 2\}$ ). Finding  $\epsilon$ -optimal solutions to the graph realization problem is also NP-hard for small  $\epsilon$  ([53]). The graph realization problem (EDM $k$ ) has been much studied, in particular in dimension  $k \leq 3$ , which is the case most relevant to applications. The problem can be formulated as a nonlinear global optimization problem:  $f(v)$  such that  $v = (v_1, \dots, v_n) \in \mathbf{R}^{kn}$ , where the cost function  $f(\cdot)$  can, for instance, be chosen as

$$f(v) = \sum_{ij \in E} (\|v_i - v_j\|^2 - a_{ij})^2.$$

Hence,  $f(\cdot)$  is zero precisely when the  $v_i$ 's provide a realization of the partial matrix  $A$ . This optimization problem is hard to solve (as it may have many local optimum solutions). Several algorithms have been proposed in the literature; see, in particular, [13,19,26,29,31,41,54,57]. They are based on general techniques for global optimization like tabu and pattern search [57], the continuation approach (which consists of transforming the original function  $f(\cdot)$  into a smoother function having fewer local optimizers, [53,54]), or divide-and-conquer strategies aiming to break the problem into a sequence of smaller or easier subproblems [13,29,31]. In [29,31], the basic step consist of finding principal submatrices having a unique realization, treating each of them separately and then trying to combine the solutions. Thus arises the problem

of identifying principal submatrices having a unique realization, which turns out to be NP-hard [62]. However, several necessary conditions for unicity of realization are known, related with connectivity and generic rigidity properties of the graph pattern [30,67]. Generic rigidity of graphs can be characterized and recognized in polynomial time only in dimension  $k \leq 2$  ([42,51]) (cf. the survey [43] for more references).

Call a partial matrix  $A$  a *partial distance matrix* if every specified principal submatrix of  $A$  is a distance matrix. Being a partial distance matrix is obviously a necessary condition for  $A$  to be completable to a distance matrix. It is shown in [4] that every partial distance matrix with pattern  $G$  is completable to a distance matrix if and only if  $G$  is a chordal graph; moreover, if all specified principal submatrices of the partial matrix  $A$  have a realization in the  $k$ -space, then  $A$  admits a completion having a realization in the  $k$ -space.

As noted in [33], if a partial matrix  $A$  with pattern  $G$  is completable to a distance matrix, then the associated vector  $x := (\sqrt{a_{ij}})_{ij \in E}$  must satisfy the inequalities:

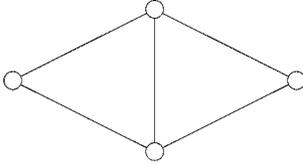

$$x_e - \sum_{f \in C \setminus \{e\}} x_f \leq 0 \quad \text{for all } e \in C, \quad C \text{ circuit in } G. \quad (7)$$

The graphs  $G$  for which every partial matrix (respectively, partial distance matrix)  $A$  with pattern  $G$  for which (7) holds is completable to a distance matrix, are the graphs containing no homeomorph of  $K_4$  as an induced subgraph [45] (respectively, the graphs that can be made chordal by adding edges in such a way that no new clique of size 4 is created [33]). Note the analogy with the corresponding results for the psd completion problem; some connections between the two problems (EDM) and (PSD) are exposed in [38,45].

### Completion to Completely Positive and Contraction Matrices

Call a matrix *doubly nonnegative* if it is psd and entrywise nonnegative. Every completely positive (cp, for short) matrix is obviously doubly nonnegative. The converse implication holds for matrices of order  $n \leq 4$  (cf. [22]) and for certain patterns of the nonzero entries in  $A$  (cf. [40]). The cp property is obviously inherited by principal submatrices; call a partial matrix  $A$  a *partial cp matrix* if every fully specified principal submatrix of  $A$  is cp. It is shown in [15] that every partial cp matrix

with graph pattern  $G$  is completable to a cp matrix if and only if  $G$  is a so-called block-clique graph. A *block-clique graph* being a chordal graph in which any two distinct maximal cliques overlap in at most one node or, equivalently, a chordal graph that does not contain an induced subgraph of the form:

Recall that an  $(n \times m)$ -matrix  $A$  is a contraction matrix if all eigenvalues of  $A^*A$  are less than or equal to 1 or, equivalently, if the matrix

$$\tilde{A} = \begin{pmatrix} I_n & A \\ A^* & I_m \end{pmatrix} \tag{8}$$

is positive semidefinite. Call a partial matrix  $A$  a *partial contraction* if all specified submatrices of  $A$  are contractions. As every submatrix of a contraction is again a contraction, an obvious necessary condition for a partial matrix  $A$  to be completable to a contraction matrix is that  $A$  be a partial contraction. Thus arises the question of characterizing the graph patterns  $G$  for which every partial contraction with pattern  $G$  can be completed to a contraction matrix.

As we now deal with rectangular  $n \times m$  partial matrices  $A$ , their pattern is the bipartite graph  $G$  with node set  $U \cup V$ , where  $U, V$  index the rows and columns of  $A$  and edges of  $G$  correspond to the specified entries of  $A$ . We may clearly assume to be dealing with partial matrices whose pattern is a connected graph (as the partial matrices associated with the connected components can be handled separately). Below is an example of a partial matrix  $A$  which is a partial contraction, but which is not completable to a contraction matrix:

$$A = \begin{pmatrix} ? & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & ? & \frac{1}{\sqrt{2}} \end{pmatrix}.$$

In fact, the graph pattern displayed in this example is in a sense present in every partial contraction which is not completable to a contraction. Namely, it is shown in [36] that the following assertions (i–iii) are equivalent for a connected bipartite graph  $G$  with node bipartition  $U \cup V$ :

- i) Every partial contraction with pattern  $G$  can be completed to a contraction;
  - ii)  $G$  does not contain an induced matching of size 2 (i. e., if  $e := uv, e' := u'v'$  are edges in  $G$  with  $u \neq u' \in U, v \neq v' \in V$ , then at least one of the pairs  $uv', u'v$  is an edge in  $G$ ; that is,  $G$  is nonseparable in the terminology of [21]);
  - iii) The graph  $\tilde{G}$  obtained from  $G$  by adding all edges  $uu' (u \neq u' \in U)$  and  $vv' (v \neq v' \in V)$  is chordal.
- (Note that the implication iii)  $\rightarrow$  i) is a consequence of the result on psd completions from [23] mentioned in the Section on the positive semidefinite completion problem above, as  $\tilde{G}$  is the graph pattern of the matrix  $\tilde{A}$  defined in (8).)

### Rank Completions

In this section, we consider the problem of determining the possible ranks for the completions of a given partial matrix. For a partial matrix  $A$ , let  $\text{mr}(A)$  and  $\text{MR}(A)$  denote, respectively, the minimum and maximum possible ranks for a completion of  $A$ . If  $B, C$  are completions of  $A$  of respective ranks  $\text{mr}(A), \text{MR}(A)$ , then changing  $B$  into  $C$  by changing one entry of  $B$  into the corresponding entry of  $C$  at a time permits to construct completions realizing all ranks in the range  $[\text{mr}(A), \text{MR}(A)]$ . Hence, the question is to determine the two extreme values  $\text{mr}(A)$  and  $\text{MR}(A)$ . As we see below, the value  $\text{MR}(A)$  can, in fact, be expressed in terms of ranks of fully specified submatrices of  $A$  and it can be computed in polynomial time; this constitutes a generalization of the celebrated Frobenius–König theorem (corresponding to the case when specified entries are equal to 0). On the other hand, determining  $\text{mr}(A)$  seems to be a much more difficult task.

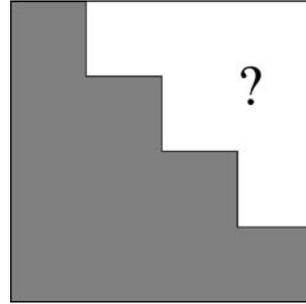

We first deal with the problem of finding *maximum rank completions*. Let  $A$  be an  $n \times m$  partial matrix with graph pattern  $G$ , i. e.,  $G$  is the bipartite graph  $(U \cup V, E)$  where  $U, V$  index respectively the rows and columns of  $A$ , and the edges of  $G$  correspond to the specified entries of  $A$ , and let  $\bar{G}$  denote the complementary bipartite graph whose edges correspond to unspecified entries of  $A$ . Note that computing  $\text{MR}(A)$  amounts to computing the generic rank of  $A$  when viewing the unspecified entries of  $A$  as independent variables over the field containing the specified entries. For a subset  $X \subseteq U \cup V$ , let  $A_X$  denote the submatrix of  $A$  with respective row

and column index sets  $\{i \in [1, n]: u_i \notin X\}$  and  $\{j \in [1, m]: v_j \notin X\}$ . Call  $X$  a *cover* of  $\overline{G}$  if every edge of  $\overline{G}$  has at least one end node in  $X$ ; that is, if  $A_X$  is a fully specified submatrix of  $A$ . Clearly, we have:  $\text{MR}(A) \leq \text{rank}(A_X) + |X|$ . In fact, the following equality holds:

$$\text{MR}(A) = \min_{X \text{ cover of } \overline{G}} \text{rank}(A_X) + |X| \tag{9}$$

as shown in [12]. A determinantal version of the result was given in [25]. In the special case when all specified entries of  $A$  are equal to 0, then  $\text{MR}(A)$  coincides with the maximum cardinality of a matching in  $\overline{G}$  and, therefore, the minimax relation (9) reduces to the Frobenius–König theorem (cf. [50] for details on the latter result). Moreover, one can determine  $\text{MR}(A)$  and construct a maximum rank completion of  $A$  in polynomial time. This was shown in [55] by a reduction to matroid intersection and, more recently, in [18] where a simple greedy procedure is presented that solves the problem by perturbing an arbitrary completion.

We now consider *minimum rank completions*. To start with, note that  $\text{mr}(A)$  may depend, in general, on the actual values of the specified entries of  $A$  (and not only on the ranks of the specified submatrices of  $A$ ). Indeed, consider the partial matrix  $A = \begin{pmatrix} ? & a & b \\ d & ? & c \\ e & f & ? \end{pmatrix}$  where  $a, b, c, d, e, f \neq 0$ . Then,  $\text{mr}(A) = 1$  if  $ace = bdf$  and  $\text{mr}(A) = 2$  otherwise, while all specified submatrices have rank 1 in both cases. Thus arises the question of identifying the bipartite graphs  $G$  for which  $\text{mr}(A)$  depends only on the ranks of the specified submatrices of  $A$  for every partial matrix  $A$  with pattern  $G$ ; such graphs are called *rank determined*. The graph pattern of the above instance  $A$  is the circuit  $C_6$ . Hence,  $C_6$  is not rank determined. Call a bipartite graph  $G$  *bipartite chordal* if it does not contain a circuit of length  $\geq 6$  as an induced subgraph. Then, if a bipartite graph is rank determined, it is necessarily bipartite chordal [12]. It is conjectured there that, conversely, every bipartite chordal graph is rank determined. The conjecture was shown to be true in [66] for the nonseparable bipartite graphs (i. e., the bipartite graphs containing no induced matching of size 2; they are obviously bipartite chordal). Note that a partial matrix  $A$  has a nonseparable pattern if and only if it has (up to row/column permutation) the following ‘triangular’ form:

Then,  $\text{mr}(A)$  can be explicitly formulated in terms of the ranks of the specified submatrices of  $A$ ; in the simplest case, the formula for  $\text{mr}(A)$  reads:

$$\begin{aligned} \text{mr} \begin{pmatrix} B & ? \\ C & D \end{pmatrix} \\ = \text{rank} \begin{pmatrix} B \\ C \end{pmatrix} + \text{rank} \begin{pmatrix} C & D \end{pmatrix} - \text{rank}(C). \end{aligned}$$

It is shown in [12] that the above conjecture holds when the pattern  $G$  is a path, or when  $G$  is obtained by ‘gluing’ a collection of circuits of length 4 along a common edge.

### Keywords

Combinatorial optimization; Greedy technique; Graph optimization

Matroids have been defined in 1935 as generalization of graphs and matrices. Starting from the 1950s they have had increasing interest and the theoretical results obtained have been used for solving several difficult problems in various fields such as civil, electrical, and mechanical engineering, computer science, and mathematics. A comprehensive treatment of matroids can not be contained in few pages or even in only one book. Thus, the scope of this article is to introduce the reader to this theory, providing the definitions of some different types of matroids and their main properties.

**Historical Overview**

In 1935, H. Whitney in [38] studied *linear dependence* and its important application in mathematics. A number of equivalent axiomatic systems for matroids is contained in his pioneering paper, that is considered the first scientific work about matroid theory.

In the 1950s and 1960s, starting from the Whitney’s ideas, W. Tutte in [25,26,27,28,29,30,31,32,33] built a considerable body of theory about the structural properties of matroids, which became popular in the 1960s, when J. Edmonds in [5,6,7,8,9,10,11] introduced matroid theory in combinatorial optimization. From 1965 on, a growing number of researchers became interested in matroids. In 1976, D.J.A. Welsh ([34]) published the first book on matroid theory. In the 1970s, 1980s, and 1990s selected topics have been covered by a huge number of scientific publications, among them [1,2,3,12,13,15,17,18,20,21,23,24,35,36,37]. [16] provides an excellent historical survey, while [21] is a good book for students.

**Definition of a Matroid**

Matroids are combinatorial structures often treated in together with the *greedy technique*, which yields optimal solutions when applied for solving simple problems defined on matroids.

In order to provide the definition of a general matroid, some notation and further definitions are needed.

**Definition 1** An ordered pair  $S = (E, I)$ , where  $E = \{e_1, \dots, e_n\}$  and  $I \subseteq 2^E$ , is an *independent system* (SI) if and only if

$$\forall A, B \subseteq E : B \subset A \in I \Rightarrow B \in I. \tag{1}$$

$E$  is also called *ground set*.

Note that the empty set is necessarily a member of  $I$ .

**Definition 2** The members of  $I$  are called *independent sets*.

**Definition 3** The members of  $D = 2^E \setminus I$  are called *dependent sets*.

**Definition 4** The members of the set

$$B = \{A \subseteq E : A \in I, \forall f \in E \setminus A : B \cup \{f\} \notin I\}$$

are called *maximal independent sets* or *bases*.

In other words, a *basis* is an independent set which is maximal with respect to set inclusion operation.

**Definition 5** The members of the set

$$C = \{C \subseteq E : C \in D, \forall f \in C : C \setminus \{f\} \in I\}$$

are called *minimal dependent sets* or *circuits*. A 1-element circuit is a *loop*.

**Definition 6** A *matroid*  $M$  is an independent system  $(E, I)$  such that if  $A, B \in I, |A| < |B|$ , then there is some element  $x \in B \setminus A$  such that  $A \cup \{x\} \in I$ .

We say that  $M$  satisfies the *exchange property*.

Most combinatorial problems can be viewed as the problem of finding an element in one of the above defined sets corresponding to the optimal objective function value.

The word *matroid* is due to Whitney. He studied *matrix matroids*, in which the elements of  $E$  are the rows of a given matrix and a set of rows is independent if they are linearly independent in the usual sense.

The following theorems express two equivalent axiomatic definitions of matroids in terms of bases and circuits.

**Theorem 7** A nonempty set  $B$  of subsets of  $E$  is the set of bases for a matroid  $M = (E, I)$  if and only if for all  $B_1, B_2 \in B, B_1 \neq B_2$ , and  $x \in B_1 \setminus B_2$ , there exists an element  $y \in B_2 \setminus B_1$  such that

$$B_1 \cup \{y\} \setminus \{x\} \in B.$$

**Theorem 8** A set  $C$  of subsets of  $E$  is the set of circuits for a matroid  $M = (E, I)$  if and only if the following two properties hold:

- 1) for all  $X \neq Y \in C, X \not\subseteq Y$ ;
- 2) for all  $X \neq Y \in C$  and  $z \in X \cap Y$ , there exists  $Z \in C$  such that  $Z \subseteq X \cup Y \setminus \{z\}$ .

Other alternative axiomatic characterizations of a matroid need some further definitions.

Let  $M = (E, I)$  be a matroid.

**Definition 9** For all  $A \subseteq E$ , let  $\rho: 2^E \rightarrow \mathbb{N}$  be a function such that

$$\rho(A) = \max \{|X| : X \subseteq A, X \in I\}.$$

$\rho$  is called *rank* of  $M$ .

Note that the rank of  $M$  is equal to the rank of  $E$ , which is given by the cardinality of the maximal independent subset of  $E$ . The rank is always well-defined, due to the following proposition.

**Proposition 10** *If  $A$  is a subset of  $E$  and  $X$  and  $Y$  are maximal independent subsets of  $A$ , then  $|X| = |Y|$ .*

Proposition 10 claims that the maximal independent subsets contained in  $A \subseteq E$  of a given matroid  $M = (E, I)$  have the same cardinality. Choosing  $A = E$ , the following corollary holds.

**Corollary 11** *The bases of any matroid have the same cardinality.*

**Definition 12** A subset  $A$  of  $E$  is called a *closed* of  $M$  if

$$\rho(A \cup \{x\}) = \rho(A) + 1, \quad \forall x \in E \setminus A,$$

i. e. if it is not possible to add to  $A$  any element without increasing its rank.

**Definition 13** The *closure operator* for  $M$  is a function  $\sigma: 2^E \rightarrow 2^E$  such that for all  $A \subseteq E$   $\sigma(A)$  is the closed of minimum cardinality that contains  $A$ , i. e.

$$\sigma(A) = A \cup \{x \in E \setminus A: \rho(A \cup \{x\}) = \rho(A)\}.$$

**Definition 14** A subset  $A$  of  $E$  *covers*  $M$  if and only if it contains a basis of  $M$ , i. e.

$$\rho(A) = \rho(E).$$

With these further definitions at hand, the following theorems express three other equivalent axiomatic characterizations of a matroid in terms of its rank.

**Theorem 15** *A function  $\rho: 2^E \rightarrow N$  is a rank function of a matroid  $M = (E, I)$  if and only if for all  $X \subseteq E$  and for all  $y, z \in E$  the following three properties hold:*

- 1)  $\rho(\emptyset) = 0$ ;
- 2)  $\rho(X) \leq \rho(X \cup \{y\}) \leq \rho(X) + 1$ ;
- 3)  $\rho(X) = \rho(X \cup \{y\}) = \rho(X \cup \{z\}) \Rightarrow \rho(X \cup \{y, z\}) = \rho(X)$ .

**Theorem 16** *A function  $\rho: 2^E \rightarrow N$  is a rank function of a matroid  $M = (E, I)$  if and only if for all  $X \neq Y \subseteq E$  the following three properties hold:*

- 1)  $0 \leq \rho(X) \leq |X|$ ;
- 2)  $X \subseteq Y \Rightarrow \rho(X) \leq \rho(Y)$ ;

$$3) \rho(X \cup Y) + \rho(X \cap Y) \leq \rho(X) + \rho(Y).$$

Note that the second property of theorem 16 implies that  $\rho$  is a monotonic function, while the third property expresses its submodularity.

**Theorem 17** *A function  $\sigma: 2^E \rightarrow 2^E$  is a closure operator of a matroid  $M = (E, I)$  if and only if for all  $X \neq Y \subseteq E$  and for all  $x, y \in E$  the following four properties hold:*

- 1)  $X \subseteq \sigma(X)$ ;
- 2)  $Y \subseteq X \Rightarrow \sigma(Y) \subseteq \sigma(X)$ ;
- 3)  $\sigma(X) = \sigma(\sigma(X))$ ;
- 4)  $y \notin \sigma(X), y \in \sigma(X \cup \{x\}) \Rightarrow x \in \sigma(X \cup \{y\})$ .

**Definition 18** A matroid  $M = (E, I)$  is *weighted* if there is an associated weight function  $w$  that assigns a strictly positive weight  $w(x)$  to each element  $x \in E$ .

The *weight function*  $w$  extends to subsets  $A$  of  $E$  by summation:

$$w(A) = \sum_{x \in A} w(x).$$

### Minor of Matroids: Restriction and Contraction

A *minor* of a matroid  $M = (E, I)$  is a ‘submatroid’ obtained from *deleting* or *contracting* from the ground set  $E$  one or more elements.

A *loop* is an element  $y$  of a matroid such that  $\{y\}$  is not independent. Equivalently,  $\{y\}$  does not lie in any independent set, nor in maximal independent sets.

**Definition 19** Let  $M = (E, I)$  be a matroid. If an element  $\{x\}$  is not a loop, the matroid  $M/x$ , called a *contraction* of  $M$ , is defined as follows:

- 1) the ground set of  $M/x$  is  $E \setminus \{x\}$ ;
- 2) a set  $A$  is independent in  $M/x$  if and only if  $A \cup \{x\}$  is independent in  $M$ .

The concept of matroid contraction can be dualized. In fact, an element  $y$  is a *coloop* if it is contained in every basis of  $M$ .

**Definition 20** Let  $M = (E, I)$  be a matroid. If an element  $\{x\}$  is not a coloop, the matroid  $M \setminus x$ , called a *restriction* of  $M$ , is defined as follows:

- 1) the ground set of  $M \setminus x$  is  $E \setminus \{x\}$ ;
- 2) a set  $A$  is independent in  $M \setminus x$  if and only if it is independent in  $M$ .

The above definitions have been given in terms of restriction and contraction of only one element, but they

can be easily extended to the restriction and contraction of a set  $X$ . The minors obtained will be denoted  $M \setminus X$  and  $M \setminus X$ , respectively.

### Representability of Matroids

One among the most common canonical examples of matroids is the *vectorial matroid*, whose ground set  $E$  is a finite set of vectors from a vector space, while the independent sets are the linearly independent subsets of vectors of  $E$ . A matroid  $M = (E, I)$  is *representable* on a field  $F$  if there exists some vector space  $V$  over  $F$ , with some finite set  $E$  of vectors of  $V$ , so that  $M$  is isomorphic to the vectorial matroid of the set  $E$ . A *binary matroid* is a matroid representable over  $GF(2)$ , while a *ternary matroid* is representable over  $GF(3)$ .

In recent literature (as of 1999) the problem of classifying all the fields over which a given matroid is representable and the inverse problem of characterizing all the matroids that are representable on a given field have had growing interest. An important result for matroid representability is the following theorem.

**Theorem 21** *A matroid  $M = (E, I)$  is representable over any field if and only if it is representable over  $GF(2)$  and over some field of characteristic other than two.*

A matroid as in the previous theorem is called *regular*.

### Connectivity of Matroids

Connectivity is an important concept in matroid theory.

**Definition 22** A matroid  $M = (E, I)$  admits a *k-separation* if there exists a partition  $(X, Y)$  of the ground set  $E$  such that

- 1)  $|X| \geq k, |Y| \geq k$ ;
- 2)  $\rho(X) + \rho(Y) - \rho(E) \leq k - 1$ .

**Definition 23** The smallest  $k$  such that a matroid  $M = (E, I)$  admits a  $k$ -separation is called the *connectivity* of  $M$ .

If  $k \geq 2$ ,  $M$  is  $n$ -connected for any  $n \leq k$ ; if  $k = 1$ ,  $M$  is *disconnected*; if  $M$  admits any  $k$ -separations for all integers  $k$ ,  $M$  has *infinite connectivity*.

An important result for matroid connectivity is the following theorem.

**Theorem 24** *A matroid  $M = (E, I)$  is disconnected if and only if there exists a partition  $(X, Y)$  of the ground*

*set  $E$  such that every circuit  $C$  of  $M$  is either a subset of  $X$  or a subset of  $Y$ .*

### Examples of Matroids

In this section some of the most popular types of matroids involved in combinatorial optimization will be described.

#### Uniform Matroid

Let  $E$  be a set of  $n$  elements and let  $I$  be the family of subsets  $A$  of  $E$  such that  $|A| \leq k < n$ . Then  $M = (E, I)$  is called the *uniform matroid* of rank  $k$  and is denoted by  $U_{k,n}$ .

The sets of the bases and the circuits of  $U_{k,n}$  are

$$B = \{X \subseteq E : |X| = k\}$$

and

$$C = \{X \subseteq E : |X| = k + 1\},$$

respectively.

Moreover, for all  $A \subseteq E$ ,

$$\rho(A) = \begin{cases} |A| & \text{if } |A| \leq K, \\ K & \text{otherwise,} \end{cases}$$

$$\sigma(A) = \begin{cases} A & \text{if } |A| \leq K, \\ E & \text{otherwise.} \end{cases}$$

#### Graphic Matroid

If  $F$  is the set of forests of a graph  $G = (V, E)$ ,  $M = (E, F)$  is called a *graphic matroid*. The circuits of  $M$  are the graph-theoretic circuits of  $G$ , while the rank of a subset  $E_1$  of  $E$  is given by

$$\rho(E_1) = |V| - c(E_1),$$

where  $c(E_1)$  is the number of connected components of  $G_1 = (V, E_1)$ .

#### Transversal Matroid

Let  $E$  be a finite set,  $C = \{S_1, \dots, S_m\}$  a collection of subsets of  $E$ , and let  $T = \{e_1, \dots, e_t\} \subseteq E$ .

$T$  is called a *transversal* of  $C$  if there exist distinct integers  $j(1), \dots, j(t)$  such that  $e_i \in S_{j(i)}$ ,  $i = 1, \dots, t$ . Let  $I$  be the set of all transversals of  $E$ , then  $M = (E, I)$  is a *transversal matroid*.

**Partition Matroid**

Let  $E$  be a finite set,  $\Pi = \{E_1, \dots, E_p\}$  a partition of  $E$ , that is a collection of disjoint subsets of  $E$  covering  $E$ , and  $d_1, \dots, d_p$   $p$  nonnegative integers. A subset  $A$  of  $E$  is independent, i. e.  $A \in I$ , if and only if  $|A \cap E_j| \leq d_j$ ,  $j = 1, \dots, p$ . The system  $M = (E, I)$  is a matroid, called a partition matroid.

An example of a partition matroid can be obtained by considering any digraph  $G = (V, E)$  and partitioning the edges of the set  $E$  according to which node is the head (or, equivalently, the tail) of each. Suppose that  $d_j = 1, j = 1, \dots, p$ ; then a set  $A$  of edges is independent if no two edges of  $A$  have the same head (or, equivalently, the same tail).

**Dual Matroids**

Let  $M = (E, I)$  be a matroid, and let  $B$  be its set of bases.

The dual matroid  $\bar{M}$  is the matroid on the ground set  $E$ , whose bases are the complements of the bases of  $M$ . Thus, a set  $A$  is independent in  $\bar{M}$  if and only if  $A$  is disjoint from some basis of  $M$ . Note that  $\overline{\bar{M}} = M$ .

For a pair of matroids  $(M, \bar{M})$  and their rank functions, the following propositions hold.

**Proposition 25** Let  $M = (E, I)$  be a matroid, and let  $\rho$  be its rank function. Let  $\bar{M} = (E, \bar{I})$  be the dual matroid of  $M$ ; then

$$\bar{\rho}(A) = |A| + \rho(E \setminus A) - \rho(E),$$

for each  $A \subseteq E$ .

**Proposition 26** Let  $\bar{M}$  be the dual of the matroid  $M = (E, I)$ , let  $A$  be a subset of  $E$  and let  $\bar{A} = E \setminus A$ . If  $\rho$  and  $\bar{\rho}$  are the rank functions of  $M$  and  $\bar{M}$  respectively, then

- 1)  $|\bar{A}| - \bar{\rho}(\bar{A}) = \rho(E) - \rho(A)$ ;
- 2)  $\bar{\rho}(\bar{E}) - \bar{\rho}(\bar{A}) = |A| - \rho(A)$ .

**Proposition 27** Let  $M = (E, I)$  be a matroid, then

- 1)  $x$  is a loop in  $M$  if and only if  $x$  is a coloop in  $\bar{M}$  and vice versa;
- 2) If  $x$  is not a loop in  $M$ , then the dual of  $M/x$  is the matroid  $\bar{M} \setminus x$ ;
- 3) If  $x$  is not a coloop in  $M$ , then the dual of  $M \setminus x$  is the matroid  $\frac{\bar{M}}{x}$ .

As example of the dual of a matroid, let us consider the vectorial matroid. Suppose that the vectors representing  $M$  are the columns of an  $m \times n$  matrix  $A$  and that

these vectors span  $F^m$ . Thus,  $A$  has rank  $m$  and is the matrix of a linear transformation  $T$  from  $F^n$  onto  $F^m$ . Let  $K$  be the kernel of  $T$ , and  $B$  the matrix of a linear embedding of  $U$  into  $F^n$ . Note that  $B$  is a  $n \times (n - m)$  matrix (whose columns are the basis for  $U$ ) and has rank  $n - m$ . Moreover, the columns of the  $(n - m) \times n$  matrix  $B^T$  are indexed by the same set as the columns of  $A$  and  $B^T A = 0$ .  $B^T$  is the dual matroid  $\bar{M}$  of the vectorial matroid  $M$ .

**Greedy Algorithms on Weighted Matroids**

Many combinatorial problems for which the greedy technique gives an optimal solution can be formulated in terms of finding a maximum-weight independent subset in a weighted matroid. In more detail, there is given a weighted matroid  $M = (E, I)$  and the objective is to find an independent set  $A \in I$  such that  $w(A)$  is maximized (also called an optimal subset of  $M$ ). Since the weight  $w(x)$  of any element  $x \in E$  is positive, a maximum-weight independent subset is always a maximal independent subset.

In the minimum spanning tree problem, for example, there are given a connected undirected graph  $G = (V, E)$  and a length function  $w$  such that  $w(e)$  is the positive length of the edge  $e$ . The objective is to find an acyclic subset  $T$  of  $E$  that connects all of the vertices of  $G$  and whose total length

$$w(T) = \sum_{e \in T} w(e)$$

is minimized. This is a classical combinatorial problem and can be formulated as a problem of finding an optimal subset of a matroid. In fact, consider the graphic weighted matroid  $M_G$  with weight function  $w'$  such that  $w'(e) = w_0 - w(e)$ , where  $w_0$  is larger than the maximum length of any edge. It can be easily seen that for each  $e \in E$ ,  $w'(e) \geq 0$  and that an optimal subset of  $M_G$  is a spanning tree of minimum total length in the original graph  $G$ . In more detail, each maximal independent subset  $A$  corresponds to a spanning tree and since

$$w'(A) = (|V| - 1) \cdot w_0 - w(A)$$

for any maximal independent subset  $A$ , the independent subset that maximizes  $w'(A)$  must minimize  $w(A)$ .

J.B. Kruskal in [14] and R.C. Prim in [22] proposed two greedy strategies for solving efficiently the minimum spanning tree, but in the following is reported the

pseudocode of a greedy algorithm that works for any weighted matroid. The algorithm GREEDY takes as input a matroid  $M = (E, I)$  and a weight function  $w$  and returns an optimal subset  $A$ .

```

set  $A = \emptyset$ 
sort  $E[M] = \{x_1, \dots, x_k\}$  into nonincreasing order
by weight  $w$ 
FOR  $i = 1$  to  $t$ 
  IF  $A \cup \{x_i\} \in I[M]$ 
    set  $A = A \cup \{x_i\}$ 
return( $A$ )

```

### Greedy( $M, w$ )

Like any other greedy algorithm, GREEDY always makes the choice that looks best at the moment. In fact, it considers in turn each element  $x_i$  belonging to  $E[M]$ , whose element are sorted into nonincreasing order by weight  $w$  and immediately adds  $x$  to the building set  $A$  if  $A \cup \{x_i\}$  is still independent. Note that the returned set  $A$  is always independent, because it is initialized to the empty set, which is independent by definition of a matroid, and then at each iteration an element  $x_i$  is added to  $A$  while preserving the  $A$ 's independence.  $A$  is also an optimal subset of the matroid  $M$  and therefore, a minimum spanning tree for the original graph  $G$ . To prove its optimality, it is enough to show that weighted matroids exhibit the two ingredients whose existence guarantee that a greedy strategy will solve optimally the given problem: the *greedy-choice property* and the *optimal substructure property*. The proof that matroids exhibit both these properties can be found in [4]. Generally speaking, the proof of the exhibition of the greedy-choice property consists of showing that a globally optimal solution can be obtained by making a locally optimal (greedy) choice. The proof examines a global optimal solution. It shows that the solution can be modified so that a greedy choice is made at the first step and that this choice reduces the original problem into an equivalent problem having smaller size. By induction, it is proved that a greedy choice can be made at each step. To show that making a greedy choice reduces the original problem into a similar but smaller problem reduces the proof of correctness to demonstrating that an optimal solution must exhibit optimal substructure. The optimal substructure property is exhibited by a given

problem, if an optimal solution to the problem contains within it optimal solutions to subproblems. The validity of this property guarantee the applicability of greedy strategies as well as dynamic programming algorithms.

*Maximum constraint satisfaction problems* (MAX-CSPs) generalize *maximum satisfiability* (MAX-SAT) to include cases where the variables are no longer restricted to binary (or Boolean) values.

MAX-CSP is NP-complete even in the special case of *binary CSPs*. Therefore designing procedures to compute upper bounds to the exact (unknown) optimum value (maximum number of satisfied constraints) is a relevant issue. Such bounds may be useful, in particular, to provide estimates of the quality of solutions obtained from various heuristic approaches.

This article describes a systematic way of computing upper bounds for large scale MAX-CSP instances such as those arising from the so-called *radio link frequency assignment problem* (RLFAP). After discussing the general relaxation principle and the basic procedure from which the bounds are derived, we present results of extensive computational experiments on series of 90 instances of RLFAP including both real test problems and randomly generated ‘realistic’ test problems (for sizes ranging from 396 variables and about 1700 constraints to 831 variables and about 4800 constraints).

These results clearly indicate that the proposed approach is practically useful to produce fairly accurate upper bounds for such large MAX-CSP problems.

## Introduction

*Constraint satisfaction problems* (CSPs) may be viewed as a generalization of *satisfiability* (SAT) to include cases where, instead of taking binary values only (0–1 or true–false) the variables may take on a finite number ( $> 2$ ) of given possible values.

For an infeasible CSP, a relevant question, both theoretically and practically, is to determine an assignment of values to variables such that the number of satisfied constraints is the *largest possible*. This is the so-called *maximum constraint satisfaction problem* (MAX-CSP), which generalizes in a natural way *maximum satisfiability* (MAX-SAT).

Since MAX-2SAT is NP-complete (see e. g. [12, pp. 259–260]) even the subclass of MAX-CSP corresponding to *binary CSPs* (those problems with constraints involving pairs of variables only) is NP-complete. Therefore, for very large instances such as those arising from practical applications (e. g. the RLFAP discussed below) one can only hope for approximate solutions using some of the currently available heuristic approaches such as: simulated annealing, tabu search, genetic algorithms, or local search of various kinds.

However, for many applications, getting an approximate solution without any information about the quality of this solution (e. g. measured by the difference between the cost of this solution and the optimal cost) may be of little value.

We address in this paper the problem of computing *upper bounds* to the optimum cost of MAX-CSP problems from which estimates on the quality of heuristic solutions can be derived.

The article is organized as follows. Basic definitions about CSPs and MAX-CSPs are recalled in the second section. Modeling the so-called radio link frequency assignment problem (RLFAP) in terms of CSP and MAX-CSP is addressed in the third section. Then we present a general class of relaxations for MAX-CSP problems and its specialization to the computation of MAX-CSP bounds for RLFAP. Finally results of extensive computational experiments carried out on series of both real test problems and realistic randomly generated test problems are presented. To our knowledge, this is the first time extensive computational results of this kind are reported for such large scale MAX-CSP problems.

## CSP and MAX-CSP

A *constraint satisfaction problem* (CSP) is defined by specifying:

- a set of  $n$  variables  $x_1, \dots, x_n$ ;
- for each variable  $x_i$ ,  $i \in I = \{1, \dots, n\}$  the domain of  $i$ , i. e. the (finite) set  $D_i$  of possible values for  $x_i$ ;
- a set of  $K$  constraints  $\varphi_k$ ,  $k = 1, \dots, K$ . For each  $k \in [1, K]$ , constraint  $\varphi_k$  is defined by its *support set* (i. e. the subset  $S_k = \text{supp}(\varphi_k)$  of indices of the variables involved in the constraint) and an *oracle* which, given any combination  $\bar{x}_{[S_k]}$  of values for variables in  $S_k$ , answers TRUE if  $\varphi_k(\bar{x}_{[S_k]}) = \text{TRUE}$ , i. e. if the combination is allowed, FALSE otherwise. (For any  $S \subset \{1, \dots, n\}$  and  $x \in D_1 \times \dots \times D_n$ ,  $x_{[S]}$  denotes the vector  $x$  restricted to components in  $S$ .)

Given a CSP specified as above, we define a *free assignment* as any  $n$ -tuple  $x \in D = D_1 \times \dots \times D_n$ . A *feasible assignment* (or *solution*) is a free assignment such that  $\varphi_k(x_{[S_k]}) = \text{TRUE}$  for all  $k = 1, \dots, K$ .

For simplicity, we restrict here to the case where each variable takes scalar values only (i. e. real or integer values), but we note that more general CSPs may be defined with variables taking, for instance, vector values.

The *arity* of a constraint  $\varphi_k$  is the cardinality of its support set:  $|S_k| = |\text{supp}(\varphi_k)|$ . A *binary CSP* is a constraint satisfaction problem in which  $|\text{supp}(\varphi_k)| \leq 2$  for all  $k = 1, \dots, K$ .

The constraint hypergraph associated with a given CSP is the hypergraph having vertex set  $I = \{1, \dots, n\}$  and edge set  $\{S_1, \dots, S_K\}$ . In case of a binary CSP this is a graph.

The two examples below are interesting special cases of the general definition and show NP completeness of arbitrary CSPs.

*Example 1 (Satisfiability)* SAT is easily recognized as a special case of CSP where  $\forall i: D_i = \{\text{TRUE}, \text{FALSE}\}$  and where there is a constraint  $\varphi_k$  corresponding to each clause  $C_k$  with  $\varphi_k(x) = \text{TRUE} \Leftrightarrow$  clause  $C_k$  is satisfied under truth assignment  $x$ .

*Example 2 (Hypergraph  $q$ -coloring; see [2, Chap. 19])* Let  $q > 1$  be a given integer and  $H = [V, E]$  an hypergraph with vertex set  $V$  and edge set  $E$ . The problem is to assign one out of  $q$  colors to each vertex of  $H$  so that each edge of  $H$  has vertices of different colors. Clearly this may be formulated as a CSP problem where there is one variable  $x_i$  for each  $v_i \in V$ , with domain  $D_i = \{1,$

$\dots, q\}$ , and one constraint  $\varphi_k$  for each edge  $e_k = \{i_1, \dots, i_p\} \in E$  such that  $\varphi(\bar{x}_{i_1}, \dots, \bar{x}_{i_p}) = \text{TRUE} \Leftrightarrow$  no two values in  $\{\bar{x}_{i_1}, \dots, \bar{x}_{i_p}\}$  are equal. Note that when  $H$  is a *graph* (i. e.  $|e_k| = 2$  for all  $e_k \in E$ ), the resulting CSP is a binary CSP.

For an infeasible CSP, one basic question is to determine a ‘best possible’ or ‘least infeasible’ assignment. If the criterion for quality (or degree of ‘feasibility’) of an assignment  $x$  is taken to be the number  $\sigma(x)$  of constraints satisfied under that assignment, we are led to the so-called *MAX-CSP* problem:

- *Given:* a CSP defined by its variables  $x_1, \dots, x_n$ , domains  $D_1, \dots, D_n$ , and constraints  $\varphi_1, \dots, \varphi_K$ .
- *Find:*  $x \in D_1 \times \dots \times D_n$  such that

$$\sigma(x) = |\{k \in [1, K]: \varphi_k(x_{[S_k]}) = \text{TRUE}\}|$$

is maximized.

*Example 3 (MAX-SAT, MAX-2SAT)* Clearly, MAX-SAT is a special case of MAX-CSP when the given CSP is a satisfiability problem. The associated decision problem is *NP*-complete even for the special case of MAX-2SAT ([13]), showing that MAX-CSP is *NP*-complete even for binary CSPs.

Heuristics for approximately solving the MAX-SAT problem have been proposed by [17,19,23,27]. A branch and bound algorithm for MAX-SAT based on probabilistic bounds is described in [3] with computational results up to 100 binary variables and 1000 clauses. The branch and cut algorithm described in [20] presents computational results for general Max-3SAT problems up to 100 binary variables and 575 clauses. For a recent survey on SAT and MAX-SAT, see [9].

For more general MAX-CSP problems, many heuristic approaches have been investigated such as *tabu search* ([4,7]), *simulated annealing* [5], *genetic algorithms* [18]. Exact Algorithms for random MAX-CSP problems were proposed in [11]. However in the computational experiments reported, the sizes of the problems for which exact optimal solutions were found are rather small (144 variables with domains of cardinality 4 and 646 constraints for the largest problems solved in [11]).

## MAX-CSP and the Radio Link Frequency Assignment Problem

Operating large radio link telecommunication networks gives rise to the so-called *radio link frequency assignment problem* (RLFAP), which is to choose, for each transmission link, a specific operating frequency (among a given list of allowed values) while satisfying a list of noninterference constraints, (most constraints usually involving pairs of links). A CSP formulation of RLFAP is as follows: With  $n$  denoting the number of links, for each link  $i = 1, \dots, n$ , there is an associated variable  $x_i$  representing the frequency to be assigned to link  $i$ . The domain  $D_i$  of  $x_i$  is the (finite) set of allowed frequencies for link  $i$  (frequencies are expressed in Hz, KHz, MHz or any other specified unit).

Any assignment  $x \in S = D_1 \times \dots \times D_n$  is not allowed because a number of constraints, called *noninterference constraints* have to be satisfied.

We will only consider here the case of *binary noninterference constraints* (i. e. involving only pairs of links), which is relevant to many applications of interest (see e. g. [15,16]). For a given pair of links  $i$  and  $j$ , two (exclusive) types of constraints are possible:

- equality constraints of the form

$$(E) \quad |x_i - x_j| = w_{ij};$$

- inequality constraints of the form

$$(I) \quad |x_i - x_j| \geq w_{ij}.$$

The real number  $w_{ij}$  which represents the requested slack or minimum requested slack between the two assigned frequencies will be called the *weight of the constraint*.

An instance of RLFAP is therefore specified by  $n$  (number of links), a list of domains  $D_1, \dots, D_n$  and a list of constraints i. e. a list of quadruples of the form  $(i, j, w_{ij}, T_{ij})$  where:  $i, j$  are the indices of the two links involved,  $w_{ij}$  is the weight of the constraint, and  $T_{ij}$  its type ((E) or (I)). The *constraint graph* associated with an instance of RLFAP is defined as the undirected graph  $G$  with node set  $\{1, \dots, n\}$  and with an edge  $(i, j)$  for each constraint  $(i, j, w_{ij}, T_{ij})$ . We denote  $K$  the total number of constraints in an instance of RLFAP. Benchmarks of the RLFAP involving real instances up to 916 variables and 5744 constraints have been made publicly available in the context of the European Project CALMA

(see [8,15]). In those practical instances, the number of equality constraints (of type (E)) is never more than  $n/2$ , and assignments satisfying all of them can easily be found. We will denote  $S' \subset S = D_1 \times \dots \times D_n$  the set of all such assignments. All assignments  $x \in S \setminus S'$  must be disregarded because they are physically meaningless, therefore, from now on, we will only consider assignments in  $S'$  as possible solution to RLFAP.

An assignment in  $S'$  which satisfies all constraints of type (I) will be called *feasible*. The feasibility version of RLFAP may therefore be stated as the following CSP:

- *Given*: an instance of RLFAP.
- *Question*: does there exist a feasible frequency assignment?
- *Answer*: yes or no and, if yes, output a feasible assignment  $x$ .

Efficient solution methods for RLFAP are of major interest to numerous practical applications in the context of civilian mobile communication networks as well as of military networks. Since the available spectrum is severely limited and the communication needs (traffic requirements) are continuously increasing, a high proportion of the instances of the RLFAP encountered in applications turn out to be *infeasible*.

When faced with an instance which is either infeasible or which is presumably infeasible (e. g. because running a heuristic solution method just failed to produce a feasible solution) a key question for the practitioner becomes to determine a ‘best possible’ or ‘least infeasible’ assignment.

This leads to the ‘optimization version’ of the RLFAP in the form of the following *MAX-CSP*:

- *Given*: an instance of RLFAP with  $n$  variables (links) and  $K$  constraints.
- *Question*: determine  $x^* \in S'$  such that  $\sigma(x^*)$  (number of satisfied constraints) is maximized:

$$\sigma(x^*) = \max_{x \in S'} \{\sigma(x)\}.$$

In view of the *NP*-completeness of *MAX-CSP* for binary CSPs, guaranteed optimal solutions to the above for large scale instances (such as those of the CELAR benchmarks) cannot be reasonably expected from currently available techniques in combinatorial optimization. A less ambitious, though practically relevant objective, addressed in the following section, is to try and obtain good *upper bounds* to an optimal solution value.

We note here that in the case where an upper bound  $\hat{\sigma}$  is found such that  $\hat{\sigma} < K$ , then we can deduce that the given RLFAP has *no feasible solution*. Thus, an interesting by-product of computing bounds will be to produce *proofs of infeasibility* of a given instance of RLFAP. Clearly, such an information may be of considerable importance to the practitioner.

## A General Class of Relaxations for Computing MAX-CSP Bounds

*MAX-CSP* may be reformulated as the discrete optimization problem

$$\left\{ \begin{array}{l} \max \quad z = \sum_{k=1}^K y_k \\ \text{s.t.} \quad g_k(x) \geq y_k, \quad \forall k = 1, \dots, K, \\ \quad \quad y_k = 0 \text{ or } 1, \quad \forall k, \\ \quad \quad x = (x_1, \dots, x_n)^T \in S'. \end{array} \right. \quad (1)$$

In the above, for all  $k = 1, \dots, K$ ,  $g_k(x) \geq 1$  if  $\varphi_k(x_{[S_k]}) = \text{TRUE}$ , and  $g_k(x) < 1$  if  $\varphi_k(x_{[S_k]}) = \text{FALSE}$ . Note that in the case of RLFAP, this specializes to:  $g_k(x) = |x_i - x_j|/w_k$ , where  $x_i$  and  $x_j$  are the two variables involved in constraint  $k$ , and  $w_k$  the weight of constraint  $k$ .

A *relaxation* of an optimization problem such as (1) is obtained by replacing its solution set by a larger solution set. Clearly if the relaxed problem can be solved exactly (i. e. to guaranteed optimality) then its optimal objective function value is an upper bound (in case of maximization) to the optimum objective function value of the original problem.

There exists a number of standard ways of relaxing an optimization problem such as (1), e. g. using Lagrangian relaxation (e. g. [10]) or considering the so-called *continuous relaxation* of some of the variables (e. g. relaxing the constraints on the  $y_k$  variables in (1) to  $0 \leq y_k \leq 1$ ). However, in our treatment of RLFAP, those standard relaxations have not been considered because they do not give rise to easily solvable relaxed problems. We therefore investigated a different approach according to the following general principle.

The relaxations we consider are based on the identification of those parts of the constraint graph or hypergraph which are responsible for the infeasibility of the whole problem. Preliminary computational results obtained in [25] have shown that, at least for *MAX-CSP*

problems deriving from RLFAP, it is most often possible to identify in a given instance an infeasible induced subproblem of sufficiently reduced size to make the corresponding MAX-CSP bound computable in reasonable time.

This suggests to consider relaxations of (1) formed by subproblems induced by properly chosen subsets of constraints. Thus, if  $\mathcal{K}' \subset \mathcal{K} = \{1, \dots, K\}$  is the subset of constraints chosen, the induced relaxation considered is:

$$\begin{cases} \max & z = \sum_{k=1}^K y_k \\ \text{s.t.} & g_k(x) \geq y_k, \forall k \in \mathcal{K}', \\ & y_k = 0 \text{ or } 1, \forall k = 1, \dots, K, \\ & x \in S'. \end{cases} \quad (2)$$

Note that, in an optimal solution to (2)

$$k \in \mathcal{K} \setminus \mathcal{K}' \Rightarrow y_k = 1.$$

Therefore  $\bar{z}$ , the optimum objective function value of (2), may be rewritten as:

$$\bar{z} = K - |\mathcal{K}'| + \bar{z}',$$

where  $\bar{z}'$  is the optimum value of the problem:

$$R[\mathcal{K}'] \begin{cases} \max & z' = \sum_{k \in \mathcal{K}'} y_k \\ \text{s.t.} & g_k(x) \geq y_k, \forall k \in \mathcal{K}', \\ & y_k = 0 \text{ or } 1, \forall k \in \mathcal{K}', \\ & x \in S'. \end{cases}$$

Clearly, the constraint graph or hypergraph  $G'$  corresponding to a relaxation  $R[\mathcal{K}']$  is deduced from the constraint graph or hypergraph  $G$  by deleting all edges associated with the constraints in  $\mathcal{K} \setminus \mathcal{K}'$ . Also observe that if  $G'$  has several distinct connected components, then the solution of  $R[\mathcal{K}']$  decomposes into independent subproblems, one for each connected component.

If the constraint graph or hypergraph  $G'$  is of sufficiently small size, then it is possible to solve  $R[\mathcal{K}']$  exactly, and the optimum solution value obtained clearly leads to an upper bound to the optimum value of the original problem. When  $G'$  is too large to get the exact optimal solution value of  $R[\mathcal{K}']$  then we will content ourselves with getting an upper bound to this exact optimal value (see the procedure SOLVE.RELAX below).

Clearly, any such upper bound still provides a valid upper bound to the original problem. Of course, in the above approach, the quality of the bound derived from  $R[\mathcal{K}']$  essentially depends on how to select the subset  $\mathcal{K}'$ . We now describe the selection procedure which has been used in our computational experiments.

### Building Relaxations for RLFAP Using Maximum Cliques

We now specialize the general relaxation scheme described above to derive bounds for RLFAP. The presentation below improves and extends our preliminary work in [25].

The basic idea of our selection procedure for choosing  $\mathcal{K}' \subset \mathcal{K}$  is that, for RLFAP, infeasibility is more likely to occur on subsets of links which are all mutually constrained, i. e. on subsets of links which induce a *clique* (complete subgraph) in the constraint graph. Since for RLFAP the constraint graphs arising from applications are always very sparse (less than 1% density for the CELAR instances), it is known that finding a clique of maximum cardinality can be efficiently done even using simple approaches such as implicit enumeration.

In [6] an efficient implicit enumeration based algorithm with good computational results for large sparse graphs up to 3000 vertices is described; however, it assumes very small maximum clique sizes (in the computational results presented in [6], *maximum clique* sizes do not exceed 11, and the running times seem to increase extremely fast with this parameter). Unfortunately, in view of the fact that, for our large RLFAP instances, the maximum clique sizes turned out to be commonly in the range [12, 25], the above algorithm could not be used.

We therefore worked out a different implementation of the implicit enumeration technique which allowed us to find guaranteed maximum cliques for all the test problems treated within acceptable computing times (see results at the end of the paper). Using this maximum clique algorithm, the procedure for building a relaxation to MAX-CSP for RFLAP is as follows.

The heuristic solution method used in our experiments to implement step b1) is a variant of *local search* consisting in iteratively improving an initial starting solution; at each iteration an exact tree search is car-

ried out to find an optimal solution to a subproblem involving only a few variables. In our computational experiments we observed that the impact of the quality of the heuristic solutions produced at step b1) on the quality of the relaxation obtained at the end of BUILD.RELAX was practically negligible (the main reason for this is that  $\bar{\sigma}$  is only used as a stopping criterion in the process of successive extraction of maximum cliques). The computational results shown below confirm that bounds of good average quality indeed result from the above construction.

- a Set:  $\bar{G} = [\bar{X}, \bar{U}] \leftarrow G$  (the initial constraint graph),  $i \leftarrow 0$
- b Current step:
  - 1 Apply a heuristic algorithm to get a good approximate solution to MAX-CSP on  $\bar{G}$ . Let  $\bar{\sigma}$  denote the number of constraints satisfied in this solution.  
IF  $\bar{\sigma} = |\bar{U}|$  go to c) (end of the construction),  
ELSE set:  $i \leftarrow i + 1$ .
  - 2 Look for a maximum clique on  $\bar{G}$ . Let  $C_i$  be the clique obtained, with node set  $N(C_i)$  and edge set  $E(C_i)$ .
  - 3 Let  $\bar{G}'$  denote the subgraph of  $\bar{G}$  induced by  $\bar{X} \setminus N(C_i)$  (obtained from  $\bar{G}$  by deleting all edges having at least one endpoint in  $N(C_i)$ ).  
Set  $\bar{G} \leftarrow \bar{G}'$  and return to b).
- c IF  $i = 0$ , the problem is feasible and step b1) produces an assignment satisfying all the constraints. Terminate.  
ELSE the relaxation  $R[\mathcal{K}']$  obtained corresponds to the set  $\mathcal{K}'$  of all constraints in  $\cup_{j=1}^i E(C_j)$ .

#### Procedure BUILD.RELAX

#### Solving the Relaxed Problem $R[\mathcal{K}']$

In order to solve the relaxed problem  $R[\mathcal{K}']$  we use a basic procedure called FIND.SOLUTION( $R[\mathcal{K}']$ ,  $\theta$ ) which, for any integer value  $\theta \in [1, |\mathcal{K}'|]$ , answers YES or NO depending on whether there exists a solution to  $R[\mathcal{K}']$  with objective function value  $z \geq \theta$  or not. In case of a YES answer, the procedure also exhibits the corresponding solution. We assume that this procedure is *ex-*

*act* i. e. always finds the right answer. Clearly, any value of  $\theta$  leading to a NO answer produces an *upper bound* to the optimal solution value of  $R[\mathcal{K}']$ .

The procedure SOLVE.RELAX( $R[\mathcal{K}']$ ) determines a decreasing sequence of upper bounds to the optimal value of  $R[\mathcal{K}']$  until either termination is obtained (at step c)) or the maximum computation time has been reached.

In the former case, the exact optimum solution value to  $R[\mathcal{K}']$  is obtained; in the latter case, only an upper bound to this optimal value is produced.

- a Initialization: Set  $\theta \leftarrow |\mathcal{K}'|$ .
- b Current step:  
Apply FIND.SOLUTION( $R[\mathcal{K}']$ ,  $\theta$ )  
IF the answer is NO,  
THEN set  $\theta \leftarrow \theta - 1$  and return to b).  
ELSE perform step c).
- c A YES answer has been obtained at step b):  $\theta$  is the optimal solution value to  $R[\mathcal{K}']$ . Terminate.

#### Procedure SOLVE.RELAX( $R[\mathcal{K}']$ )

When  $G'$ , the constraint graph of  $R[\mathcal{K}']$  has several distinct connected components corresponding to subsets of constraints,  $\mathcal{K}'_1, \dots, \mathcal{K}'_p$ , then solving  $R[\mathcal{K}']$  decomposes into the solution of several smaller subproblems  $R[\mathcal{K}'_1], \dots, R[\mathcal{K}'_p]$ . In the procedure SOLVE.RELAX, this decomposability may be exploited in various possible ways. In our implementation, this is done by organizing the computation into *phases* numbered  $t = 0, 1, \dots$ . The current upper bound value UB is initialized by:  $UB \leftarrow |\mathcal{K}'|$ . The current phase  $t$  consists in running the procedure FIND.SOLUTION on each of the subproblems  $R[\mathcal{K}'_j]$ ,  $j = 1, \dots, p$ , with the parameter  $\theta = |\mathcal{K}'_j| - t$ . Each time a NO answer is obtained, UB is updated by  $UB \leftarrow UB - 1$ . Clearly with the above process, when a YES answer has been obtained for some subproblem  $R[\mathcal{K}'_j]$  during phase  $t$ , this subproblem should not be considered any more at later phases  $t' > t$ . The computation stops either at the end of a phase during which a YES answer has been obtained for all subproblems; or when a user-specified time limit has been reached.

The basic procedure FIND.SOLUTION has been implemented as a classical depth first tree search process of the implicit enumeration type, (achieved by

means of a recursive  $C$  function). Since getting the exact answer (YES or NO) is essential to the derivation of our bounds, the procedure FIND.SOLUTION is run until full completion of the tree search (i. e. when all the nodes of the tree have been explored implicitly or explicitly).

## Computational Results

In order to validate the above described approach, systematic computational experiments have been carried out on two series of test problems.

The first set was composed of 15 infeasible real problems which arose from actual network engineering studies carried out on three distinct large radio link networks (one in the 2GHz frequency range, one in the 2, 5GHz frequency range and one in the 4GHz frequency range).

The second series concerned a set of  $5 \times 15 = 75$  'realistic' test problems generated by applying some random perturbation to the above 15 real problems. More precisely, each problem of the second series is generated from one problem of the first series by changing the weight  $w_{ij}$  of each inequality constraint of the form:  $|x_i - x_j| \geq w_{ij}$  to:  $\tilde{w}_{ij} = w_{ij} \times (\alpha + \beta\Phi)$  where  $\Phi$  is a pseudorandom number drawn from a uniform dis-

tribution on  $[0, 1]$  and  $\alpha, \beta$  are chosen parameters (of course the pseudorandom drawing is assumed to be independent from one constraint to the next).

Table 1 presents the characteristics of the 15 real test problems treated, numbered 1 to 15 and provides for each problem: number of variables ( $n$ ), number of constraints ( $K$ ), number of distinct frequencies used ( $NF$ ) and the main characteristics of the relaxed subproblem obtained from the procedure BUILD.RELAX: number of variables #var, and number of constraints #const.

Table 3 presents in a similar way the characteristics of the  $5 \times 15 = 75$  test problems deduced from the previous ones by random perturbation. The 5 instances corresponding to each basic problem  $i$  are numbered  $i_1, \dots, i_5$ . For each instance the values of the parameters  $\alpha$  and  $\beta$  used to generate the instance are displayed together with the characteristics (number of variables, number of constraints) of the relaxed subproblem produced by BUILD.RELAX.

The computation times taken to construct the relaxed subproblems (using BUILD.RELAX) on the problems of Tables 1 and 3, are all between 5 minutes to 35 minutes with an average of about 12 minutes.

Table 2 shows the results obtained on the 15 real test problems of Table 1 and Table 4 shows the results for the  $5 \times 15$  problems of Table 3. The computer used

was a PC Pentium 166 workstation with 32Mb RAM. For each problem we provide: HS, the best heuristic solution value obtained (number of satisfied constraints); the best upper bounds obtained after 15 seconds, 5 min-

utes and 1 hour. The results in Table 2 confirm that our approach is practical to consistently produce good bounds for real RLFAP instances within acceptable solution times.

From Tables 2 and 4, it is seen that for all the instances treated, the difference between the heuristic solution values HS and the best upper bounds obtained

are always quite small. More precisely for all the examples treated, the ratio  $R = (UB - HS)/UB$  is most often well below 1% (Problem 14 in Table 2 is the only

one for which  $R > 1\%$ ). We note that since HS is only a *lower bound*,  $R$  is a pessimistic estimate of the relative difference between the best upper bound obtained and the optimal, unknown, solution value.

Also, from Table 4, it is seen that the results obtained appear to be fairly stable, in spite of the importance of the perturbations applied to generate the corresponding 75 instances. In addition to practical applicability, and efficiency, this clearly shows good stability and robustness in the behavior of our algorithms. To our knowledge, this is the first time a systematic way of deriving upper bounds to such large scale MAX-CSP problems has been implemented and fully tested.

To conclude, let us mention that, in view of the results obtained, the techniques described here have been included in an industrial software tool for radio network engineering developed by the French MOD (DGA/CELAR).

### Introduction

The MAXIMUM CUT problem (MAX-CUT) is one of the simplest graph partitioning problems to conceptualize, and yet it is one of the most difficult combinatorial optimization problems to solve. The objective of MAX-CUT is to partition the set of vertices of a graph into two subsets, such that the sum of the weights of the edges having one endpoint in each of the subsets is maximum. This problem is known to be  $\mathcal{NP}$ -complete [18,27];

however, it is interesting to note that the inverse problem, i. e., that of looking for the minimum cut in a graph is solvable in polynomial time using network flow techniques [1]. MAX-CUT is an important combinatorial problem and has applications in many fields including VLSI circuit design [9,32] and statistical physics [5]. For other applications, see [16,21]. For a detailed survey of MAX-CUT, the reader can refer to [33].

### Organization

In this paper, we introduce the MAXIMUM CUT problem and review several heuristic methods which have been applied. In Subsect. “C-GRASP Heuristic” we describe the implementation of a new heuristic based optimizing a quadratic over a hypercube. The heuristic is designed under the C-GRASP (Continuous Greedy Randomized Adaptive Search Procedure) framework. Proposed by Hirsch, Pardalos, and Resende [23], C-GRASP is a new stochastic metaheuristic for continuous global optimization problems. Numerical results are presented and compared with other heuristics from the literature.

### Idiosyncrasies

We conclude this section by introducing the symbols and notations we will employ throughout this paper. Denote a graph  $G = (V, E)$  as a pair consisting of a set of vertices  $V$ , and a set of edges  $E$ . Let the map  $w: E \mapsto \mathbb{R}$  be a weight function defined on the set of edges. We will denote an edge-weighted graph as a pair  $(G, w)$ . Thus we can easily generalize an un-weighted graph  $G = (V, E)$  as an edge-weighted graph  $(G, w)$ , by defining the weight function as

$$w_{ij} := \begin{cases} 1, & \text{if } (i, j) \in E, \\ 0, & \text{if } (i, j) \notin E. \end{cases} \quad (1)$$

We use the symbol “ $b := a$ ” to mean “the expression  $a$  defines the (new) symbol  $b$ ”. Of course, this could be conveniently extended so that a statement like “ $(1 - \epsilon)/2 := 7$ ” means “define the symbol  $\epsilon$  so that  $(1 - \epsilon)/2 = 7$  holds”. We will employ the typical symbol  $S^c$  to denote the complement of the set  $S$ ; further let  $A \setminus B$  denote the set-difference,  $A \cap B^c$ . Agree to let the expression  $x \leftarrow y$  mean that the value of the variable  $y$  is assigned to the variable  $x$ . Finally, to denote the cardinality of a set  $S$ , we use  $|S|$ . We will use **bold** for words

which we define, *italics* for emphasis, and SMALL CAPS for problem names. Any other locally used terms and symbols will be defined in the sections in which they appear.

**Formulation**

Consider an undirected edge-weighted graph  $(G, w)$ , where  $G = (V, E)$  is the graph, and  $w$  is the weight function. A **cut** is defined as a partition of the vertex set into two disjoint subsets  $S$  and  $\bar{S} := V \setminus S$ . The **weight** of the cut  $(S, \bar{S})$  is given by the function  $W: S \times \bar{S} \mapsto \mathbb{R}$  and is defined as

$$W(S, \bar{S}) := \sum_{i \in S, j \in \bar{S}} w_{ij}. \tag{2}$$

For an edge-weighted graph  $(G, w)$ , a **maximum cut** is a cut of maximum weight and is defined as

$$MC(G, w) := \max_{S \subseteq V} W(S, V \setminus S). \tag{3}$$

We can formulate MAX-CUT as the following integer quadratic programming problem:

$$\max \frac{1}{2} \sum_{1 \leq i < j \leq n} w_{ij}(1 - y_i y_j) \tag{4}$$

subject to:

$$y_i \in \{-1, 1\}, \quad \forall i \in V. \tag{5}$$

To see this, notice that each subset  $V \supseteq S := \{i \in V : y_i = 1\}$  induces a cut  $(S, \bar{S})$  with corresponding weight equal to

$$W(S, \bar{S}) = \frac{1}{2} \sum_{1 \leq i < j \leq n} w_{ij}(1 - y_i y_j). \tag{6}$$

An alternative formulation of MAX-CUT based on the optimization of a quadratic over the unit hypercube was given by Deza and Laurent in [12].

**Theorem 1** *Given a graph  $G = (V, E)$  with  $|V| = n$ , the optimal objective function value of the MAXIMUM CUT problem is given by*

$$\max_{x \in \{0,1\}^n} x^T W(e - x), \tag{7}$$

where  $W = [w_{ij}]_{i,j=1}^n$  is the matrix of edge weights, and  $e := [1, 1, \dots, 1]^T$  is the unit vector.

*Proof 1* Let

$$f(x) := x^T W(e - x) \tag{8}$$

denote the objective function from Eq. (7). To begin with, notice that the matrix  $W$  has a zero diagonal, i. e.,  $w_{ii} = 0, \forall i \in 1, 2, \dots, n$ . This implies that  $f(x)$  is linear with respect to each variable, and thus there always exists an optimal solution,  $x^*$  of (7) such that  $x^* \in \{0, 1\}^n$ . Therefore, we have shown that

$$\max_{x \in \{0,1\}^n} x^T W(e - x) = \max_{x \in \{0,1\}^n} x^T W(e - x). \tag{9}$$

The next step is to show that there is a bijection between binary vectors of length  $n$  and cuts in  $G$ . Consider *any* binary vector  $\hat{x} \in \{0, 1\}^n$ . Now suppose we partition the vertex set  $V$  into two disjoint subsets  $V_1 := \{i | \hat{x}_i = 0\}$  and  $V_2 := \{i | \hat{x}_i = 1\}$ . Then, evaluating the objective function we have

$$f(\hat{x}) = \sum_{(i,j) \in V_1 \times V_2} w_{ij}, \tag{10}$$

which is equal to  $W(V_1, V_2)$ , the value of the cut defined by the partition of  $V = V_1 \cup V_2$  (see Eq. (2) above).

Alternatively, consider *any* partition of  $V$  into two disjoint subsets  $V_1, V_2 \subseteq V$ . That is

$$V = V_1 \cup V_2 \quad \text{and} \quad V_1 \cap V_2 = \emptyset.$$

Now, we can construct the vector  $\hat{x}$  as follows:

$$\hat{x}_i = \begin{cases} 1, & \text{if } i \in V_1 \\ 0, & \text{if } i \in V_2. \end{cases} \tag{11}$$

Once again, evaluating the objective function on  $\hat{x}$ , we have

$$f(\hat{x}) = \sum_{(i,j) \in V_1 \times V_2} w_{ij}. \tag{12}$$

Hence  $f(\hat{x}) = W(V_1, V_2)$  and we have the result.<sup>1</sup> Alas, we have shown the bijection between binary  $n$ -vectors

<sup>1</sup>Notice that the result holds even if (without the loss of generality)  $V_1 = V$  and  $V_2 = \emptyset$ . In this case, a cut induced by  $(V_1, V_2)$  will be a maximum cut if  $w_{ij} \leq 0, \forall i, j \in V$ .

and cuts in  $G$ . In summary, we have

$$\begin{aligned} & \max_{x \in \{0,1\}^n} x^T W(e - x) \\ &= \max_{x \in \{0,1\}^n} x^T W(e - x) \\ &= \max_{V=V_1 \cup V_2, V_1 \cap V_2 = \emptyset} \sum_{(i,j) \in V_1 \times V_2} w_{ij}. \end{aligned}$$

□

There are several classes of graphs for which MAX-CUT is solvable in polynomial time [25]. These include planar graphs [11], weakly bipartite graphs with non-negative edge weights [20], and graphs without  $K_5$  minors [4]. The general problem however is known to be  $\mathcal{APX}$ -complete [31]. This implies that unless  $\mathcal{P} = \mathcal{NP}$ , MAX-CUT does not admit a polynomial time approximation scheme [30].

## Methods

The MAXIMUM CUT problem is one of the most well-studied discrete optimization problems [27]. Since the problem is  $\mathcal{NP}$ -hard in general, there has been an incredible amount of research done in which heuristic techniques have been applied. Before we present the new heuristic approach, we review some of the prior work that has been done.

## Review of Solution Approaches

There have been many semidefinite and continuous relaxations based on this formulation. This was first shown by Lovász in [28]. In 1995, Goemans and Williamson [19] used a semidefinite relaxation to achieve an approximation ratio of .87856. This implication of this work is significant for two reasons. The first is of course, the drastic improvement of the best known approximation ratio for MAX-CUT of 0.5 which had not been improved in over 20 years [36]. Secondly, and perhaps more significantly is that until 1995, research on approximation algorithms for nonlinear programming problems did not receive much attention. Motivated by the work of Goemans and Williamson, semidefinite programming techniques were applied to an assortment of combinatorial optimization problems successfully yielding the best known approximation algorithms for GRAPH COLORING [7,26], BETWEEN-

NESS [10], MAXIMUM SATISFIABILITY [13,19], and MAXIMUM STABLE SET [2], to name a few [29].

As noted in [16], the use of interior point methods for solving the semidefinite programming relaxation have proven to be very efficient. This is because methods such as the one proposed by Benson, Ye, and Zhang in [6] exploit the combinatorial structure of the relaxed problem. Other algorithms based on the nonlinear semidefinite relaxation include the work of Helmberg and Rendl [22] and Homer and Peinado [24].

The work of Burer et al. in [8] describes the implementation of a rank-2 relaxation heuristic dubbed *circut*. This software package was shown to compute better solutions than the randomized heuristic of Goemans and Williamson, in general [16]. In a recent paper dating from 2002, Festa, Pardalos, Resende, and Ribeiro [16] implement and test six randomized heuristics for MAX-CUT. These include variants of Greedy Randomized Adaptive Search Procedures (GRASP), Variable Neighborhood Search, and path-relinking algorithms [35]. Their efforts resulted in improving the best known solutions for several graphs and quickly producing solutions that compare favorably with the method of Goemans and Williamson [19] and *circut* [8]. For several sparse instances, the randomized heuristics presented in [16] outperformed *circut*.

In [25], Butenko et al. derive a “worst-out” heuristic having an approximation ratio of at least 1/3 which they refer to as the *edge contraction method*. They also present a computational analysis of several greedy construction heuristics for MAX-CUT based on variations of the 0.5-approximation algorithm of Sahni and Gonzalez [36]. With this, we now move on and describe the implementation of a new heuristic for MAX-CUT based on the new metaheuristic Continuous GRASP [23].

## C-GRASP Heuristic

The Continuous Greedy Randomized Adaptive Search Procedure (C-GRASP) is a new metaheuristic for continuous global optimization [23]. The method is an extension of the widely known discrete optimization algorithm Greedy Randomized Adaptive Search Procedure (GRASP) [15]. Preliminary results are quite promising, indicating that C-GRASP is able to quickly converge to the global optimum on standard benchmark test func-

```

procedure GRASP(MaxIter, RandomSeed)
1   $f^* \leftarrow 0$ 
2   $X^* \leftarrow \emptyset$ 
3  for  $i = 1$  to MaxIter do
4     $X \leftarrow \text{ConstructionSolution}(G, g, X, \alpha)$ 
5     $X \leftarrow \text{LocalSearch}(X, N(X))$ 
6    if  $f(X) \geq f(X^*)$  then
7       $X^* \leftarrow X$ 
8       $f^* \leftarrow f(X)$ 
9    end
10 end
11 return  $X^*$ 
end procedure GRASP

```

**Maximum Cut Problem, MAX-CUT, Figure 1**  
GRASP for maximization

tions. The traditional GRASP is a two-phase procedure which generates solutions through the controlled use of random sampling, greedy selection, and local search. For a given problem  $\Pi$ , let  $F$  be the set of feasible solutions for  $\Pi$ . Each solution  $X \in F$  is composed of  $k$  discrete components  $a_1, \dots, a_k$ . GRASP constructs a sequence  $\{X\}_i$  of solutions for  $\Pi$ , such that each  $X_i \in F$ . The algorithm returns the best solution found after all iterations. The GRASP procedure can be described as in the pseudo-code provided in Fig. 1. The *construction phase* receives as parameters an instance of the problem  $G$ , a ranking function  $g: A(X) \mapsto \mathbb{R}$  (where  $A(X)$  is the domain of feasible components  $a_1, \dots, a_k$  for a partial solution  $X$ ), and a parameter  $0 < \alpha < 1$ . The construction phase begins with an empty partial solution  $X$ . Assuming that  $|A(X)| = k$ , the algorithm creates a list of the best ranked  $\alpha k$  components in  $A(X)$ , and returns a uniformly chosen element  $x$  from this list. The current partial solution is augmented to include  $x$ , and the procedure is repeated until the solution is feasible, i. e., until  $X \in F$ .

The *intensification phase* consists of the implementation of a hill-climbing procedure. Given a solution  $X \in F$ , let  $N(X)$  be the set of solutions that can be found from  $X$  by changing one of the components  $a \in X$ . Then,  $N(X)$  is called the neighborhood of  $X$ . The improvement algorithm consists of finding, at each step, the element  $X^*$  such that

$$X^* := \arg \max_{X' \in N(X)} f(X'),$$

where  $f: F \mapsto \mathbb{R}$  is the objective function of the problem. At the end of each step we make the assignment  $X^* \leftarrow X$  if  $f(X) > f(X^*)$ . The algorithm will eventually achieve a local optimum, in which case the solution  $X^*$  is such that  $f(X^*) \geq f(X')$  for all  $X' \in N(X^*)$ .  $X^*$  is returned as the best solution from the iteration and the best solution from all iterations is returned as the overall GRASP solution. GRASP has been applied to many discrete problems with excellent results. For an annotated bibliography of GRASP applications, the reader is referred to the work of Festa and Resende in [17].

Like GRASP, the C-GRASP framework is a multi-start procedure consisting of a construction phase and a local search [14]. Specifically, C-GRASP is designed to solve continuous problems subject to box constraints. The feasible domain is given as the  $n$ -dimensional rectangle  $S := \{x = (x_1, x_2, \dots, x_n) \in \mathbb{R}^n : l \leq x \leq u\}$ , where  $l, u \in \mathbb{R}^n$  are such that  $l_i \leq u_i$ , for  $i = 1, 2, \dots, n$ . Pseudo-code for the basic C-GRASP is provided in Fig. 2. Notice that the algorithm takes as input the dimension  $n$ , upper and lower bounds  $l$  and  $u$ , the objective function  $f$ , and parameters `MaxIters`, `MaxNumIterNoImprov`, `NumTimesToRun`, `MaxDirToTry`, and a number  $\alpha \in (0, 1)$ .

To begin with, the optimal objective function value  $f^*$  is initialized to  $-\infty$ . The procedure then enters the main body of the algorithm in the **for** loop from lines 2–21. The value `NumTimesToRun` is the total number of C-GRASP iterations that will be performed. To begin with, more initialization takes place as the current solution  $x$  is initialized as a random point inside the hyperrectangle, which is generated according to a function `UniformRand([l, u])` which is uniform onto  $[l, u]^2$ . Furthermore, the parameter which controls the discretization of the search space,  $h$ , is set to 1. Next, the construction phase and local search phases are entered. In line 9, the new solution is compared to the current best solution. If the objective function value corresponding to the current solution dominates the incumbent, then the current solution replaces the incumbent and `NumIterNoImprov` is set to 0. This parameter

<sup>2</sup>This is the “typical” definition of a *Uniform* distribution. That is,  $P: X \mapsto \mathbb{R}$  is uniform onto  $[A, B]$ , if, for any subinterval  $I \subset [A, B]$ , the measure of  $P^{-1}(I)$  equals the length of  $I$ .

```

procedure C-GRASP( $n, l, u, f(\cdot), \text{MaxIters}, \text{MaxNumIterNoImprov}, \text{NumTimesToRun},$ 
     $\text{MaxDirToTry}, \alpha$ )
1   $f^* \leftarrow -\infty$ 
2  for  $j = 1$  to  $\text{NumTimesToRun}$  do
3     $x \leftarrow \text{UnifRand}([l, u])$ 
4     $h \leftarrow 1$ 
5     $\text{NumIterNoImprov} \leftarrow 0$ 
6    for  $\text{Iter} = 1$  to  $\text{MaxIters}$  do
7       $x \leftarrow \text{ConstructGreedyRandomized}(x, f(\cdot), n, h, l, u, \alpha)$ 
8       $x \leftarrow \text{LocalSearch}(x, f(\cdot), n, h, l, u, \text{MaxDirToTry})$ 
9      if  $f(x) \geq f^*$  then
10        $x^* \leftarrow x$ 
11        $f^* \leftarrow f(x)$ 
12        $\text{NumIterNoImprov} \leftarrow 0$ 
13     else
14        $\text{NumIterNoImprov} \leftarrow \text{NumIterNoImprov} + 1$ 
15     end if
16     if  $\text{NumIterNoImprov} \geq \text{MaxNumIterNoImprov}$  then
17        $h \leftarrow h/2$ 
18        $\text{NumIterNoImprov} \leftarrow 0$ 
19     end if
20   end for
21 end for
22 return  $x^*$ 
end procedure C-GRASP

```

**Maximum Cut Problem, MAX-CUT, Figure 2**  
 C-GRASP pseudo-code adapted from [23]

controls when the discretization measure  $h$  is reduced. That is, after a total of  $\text{MaxNumIterNoImprov}$  iterations occur in which no solution better than the current best solution is found,  $h$  is set to  $h/2$  and the loop returns to line 6. By adjusting the value of  $h$ , the algorithm is able to locate general areas of the search space which contain high quality solutions, and then narrow down the search in those particular regions. The best solution after a total of  $\text{NumTimesToRun}$  iterations is returned as the best solution.

The construction phase of the C-GRASP takes as input the randomly generated solution  $x \in S$  (see Fig. 2, line 3). Beginning with all coordinates unfixed, the method then performs a line search on each unfixed coordinate direction of  $x$  holding the other  $n - 1$  directions constant. The objective function values resulting from the line search solution for each coordinate direction are stored in a vector, say  $V$ . An element  $v_i \in V$  is then selected uniformly at random from the maxi-

mum  $(1 - \alpha)100\%$  elements of  $V$ , and the  $v_i$  coordinate direction is fixed. This process repeats until all  $n$  coordinates of  $x$  have been fixed. The resulting solution is returned as the C-GRASP solution from the current iteration. For a slightly more detailed explanation of this procedure, the reader is referred to [23].

As for the local search phase, this procedure *simulates* the role of calculating the gradient of the objective function  $f(\cdot)$ . As mentioned earlier, gradients are not used in C-GRASP because oftentimes, they are difficult to compute and result in slow computation times. Therefore, the gradient is approximated as follows. Given the construction phase solution  $x$ , the local search generates a set of directions and determines in which direction (if any) the objective function improves.

The directions are calculated according to a bijective function  $T$  which maps the interval of integers  $[1, 3^n) \cap \mathbb{Z}$  onto their balanced ternary representation.

## Maximum Cut Problem, MAX-CUT, Table 1

Parameters used for C-GRASP

$\alpha = 0.4$	MaxDirToTry = 20
NumTimesToRun = 20	MaxIters = 1000
MaxNumIterNoImrpov = 1	

Recall that  $n$  is the dimension of the problem under consideration. That is,  $T: [1, 3^n) \cap \mathbb{Z} \mapsto \{-1, 0, 1\}^{\mathbb{N}}$ . Clearly, as  $n \rightarrow \infty$ , the number of search directions grows exponentially. Therefore, only MaxDirToTry directions are generated<sup>3</sup> and tested on the current solution. For each direction  $d$ , the point  $\hat{x} := x + hd$  is constructed and  $f(\hat{x})$  is computed. Recall that  $h$  is the parameter which controls the density of the search space discretization. If the constructed point  $\hat{x} \in S$  has a more favorable objective value than the current point  $x$ , then  $\hat{x}$  replaces  $x$ , and the process continues. The phase terminates when a locally optimal point  $x^* \in S$  is found. The point  $x^*$  is said to be locally optimal if  $f(x^*) \geq f(x^* + hd) \forall d \in \{1, 2, \dots, \text{MaxDirToTry}\}$ . Again, for a slightly more in depth description of this procedure, the reader should see the paper by Hirsch et al. [23].

**Computational Results** The proposed procedure was implemented in the C++ programming language and compiled using Microsoft® Visual C++ 6.0. It was tested on a PC equipped with a 1700 MHz Intel® Pentium® M processor and 1 GB of RAM operating under the Microsoft® Windows® XP environment. The C-GRASP parameters used are provided in Table 1. First, we tested the C-GRASP on 10 instances produced by the Balasundarm–Butenko problem generator in [3]. Though these problems are relatively small, they have proven themselves to be quite formidable against the Multilevel Coordinate Search (MCS) black-box optimization algorithm. We also tested the C-GRASP on 12 instances from the TSPLIB [34] collection of test problems for the TRAVELING SALESMAN PROBLEM. These problems are also used as benchmark problems for testing MAX-CUT heuristics [19].

For further comparison, all instances were tested using the rank-2 relaxation heuristic *circut* [8], as well as with a simple 2-exchange local search heuristic which

<sup>3</sup>uniformly at random

```

procedure LocalSearch( $G, \text{MaxIter}$ )
1   $f^* \leftarrow -\infty$ 
2   $x^* \leftarrow \emptyset$ 
3  for  $j = 1$  to  $\text{MaxIter}$  do
4     $x \leftarrow \text{KruskalMST}(x, G)$ 
5     $x \leftarrow \text{LocalImprove}(x, G)$ 
6    if  $f(x) \geq f^*$  then
7       $x^* \leftarrow x$ 
8       $f^* \leftarrow f(x)$ 
9    end if
10 end for
11 return  $x^*$ 
end procedure LocalSearch

```

## Maximum Cut Problem, MAX-CUT, Figure 3

The 2-exchange local search routine

is outlined in the pseudo-code provided in Fig. 3. The method receives as input a parameter MaxIter indicating the maximum number of iterations to be performed and  $G = (V, E)$  the instance of the problem whereupon a maximum spanning tree is found using Kruskal's algorithm [1]. The spanning tree, due to its natural bipartite structure provides a feasible solution to which a swap-based local improvement method is applied in line 5. The local improvement works as follows. For all pairs of vertices  $(u, v)$  such that  $u \in S$  and  $v \in \bar{S}$ , a swap is performed. That is, we place  $u \in \bar{S}$  and  $v \in S$ . If the objection function is improved, the swap is kept; otherwise, we undo the swap and examine the next  $(u, v)$  pair. The local search was tested on the same PC as the C-GRASP. The *circut* heuristic was compiled using Compaq® Visual Fortran on a PC equipped with a 3.60 GHz Intel® Xeon® processor and 3.0 GB of RAM operating under the Windows® XP environment.

Table 2 provides computational results of the algorithms on the 10 Balasundarum–Butenko instances from [3]. The first three columns provide the instance name, the number of vertices and the optimal solution. The solutions from the heuristics are provided next. The solutions from the Multilevel Coordinate Search algorithm were provided in [3]. For all of these instances, the time required by the C-GRASP, *circut*, and the local search to find their best solutions was fractions of a second. Computing times were not listed for the MCS algorithm in [3]. Notice that the 2-exchange

**Maximum Cut Problem, MAX-CUT, Table 2**  
Comparative results from the Balasundaram–Butenko instances from [3]

Name	$ V $	Opt	C-GRASP	MCS	<i>circut</i>	LS

G20-2	20	285	285	282	285	285

local search computed optimal solutions for each of these instances, followed closely by *circut* which found optimal cuts for all but one problem. As for the continuous heuristics, the C-GRASP found optimal solutions for 5 of the 10 instances while the MCS procedure produced optimal cuts for only 1 instance. For the 5 instances where C-GRASP produced suboptimal solutions, the average deviation from the optimum was 3.54%.

Table 3 shows results of the C-GRASP, local search, and *circut* heuristics when applied to 12 instances from the TSPLIB collection of test problems for the TRAVELING SALESMAN problem [34]. The first two columns provide the instance name and the size of the

vertex set  $|V|$ . Next the solutions are provided along with the associated computing time required by the respective heuristic. Notice that for all 12 instances, the three heuristics all found the same solutions. Notice that in terms of computation time, the simplest heuristic, the 2-exchange local search seems to be the best performing of the three methods tested. The rank-2 relaxation algorithm *circut* is also very fast requiring only 2.99 s on average to compute the solution. On the other hand, the C-GRASP method did not scale as well as the others. We see that there is a drastic increase in the solution time as the number of vertices increases beyond 48.

This is not particularly surprising. The philosophical reasoning behind the slow computation time of the C-GRASP relative to the discrete heuristics being that the C-GRASP is a *black-box* method and does not take into account any information about the problem other than the objective function. To the contrary, the local search and *circut* specifically exploit the combinatorial structure of the underlying problem. This allows them to quickly calculate high quality solutions.

## Conclusions

In this paper, we implemented a new metaheuristic for the MAXIMUM CUT problem. In particular, we proposed the use of a continuous greedy randomized adaptive search procedure (C-GRASP) [23], for a continuous formulation of the problem. To our knowledge,

this is the first application of C-GRASP to continuous formulations of discrete optimization problems. Numerical results indicate that the procedure is able to compute optimal solutions for problems of relatively small size. However, the method becomes inefficient on problems approaching 100 nodes. The main reason for this is the fact that C-GRASP is a black-box method, in that it does not take advantage of any information about the problem structure. Recall that the only input to the method is some mechanism to compute the objective function. A natural extension of the work presented here is to *enhance* the C-GRASP framework to take advantage of the structure of the problem at hand. Using a priori information about the problem being considered, one could modify the algorithm to include these properties which would presumably reduce the required computation time.

### Abstract

In decision making under uncertainty an important step is uncertainty quantification. Game theory has been traditionally used since it injects robustness into the decision process. Another popular framework is that of maximum entropy. The purpose of this article is to briefly explain the two solution concepts and point out situations in which they are identical.

### Background

Consider the following optimization problem:

$$\inf_{x \in X} F(x) \triangleq \int_{\Omega} f(x, \omega) dP(\omega), \quad (1)$$

where  $x$  is the decision vector,  $\omega$  is a vector representing the random parameters that are distributed according to the probability measure  $P$ . We are not concerned here with the exact properties of  $f(\cdot, \cdot)$  for the problem to be valid, the interested reader is referred to [2] where the properties of this type of problem are made more precise. Instead we give two well known and studied examples of this formulation. The first is the so called two-stage recourse problem and the second is the chance constrained formulation. The former can be formulated as in Eq. (1) with the following definition for the objective function:

$$f(x_1, \omega) \triangleq f_d(x_1) + f_u(x_1, \omega), \quad (2)$$

and where

$$f_u(x_1, \omega) \triangleq \inf_{x_2(\omega)} \{f_2(x_1, x_2(\omega), \omega) \mid x_2(\omega) \in X_2(\omega, x_1)\}. \quad (3)$$

In Eq. (2) the objective function is split into two parts, the deterministic ( $f_d$ ) and the uncertain part ( $f_u$ ) of the problem. The decision to be taken is  $x_1$ . The full consequences of following a particular strategy are not known exactly since the true cost will depend on the

solution of Eq. (3). The objective is therefore to find the decision  $x_1$  that is best on average.

A different decision model is given by chance constrained programming problems. These can be formulated as follows:

$$\inf_x \{f(x) \mid \Pr(g(x, \omega) \geq 0) \geq \alpha\},$$

where we optimize an objective function and impose constraints that need to be satisfied with a probability of above a certain threshold  $\alpha$ .

These two models have been widely studied and have found many applications where traditional optimization is used. It is also evident that their usefulness revolves around our ability to provide a reasonable description of the uncertainties.

In order to provide a description of the uncertainties a technique based on moment matching can be used. Under this framework we assume that the decision maker can not provide an exact description of the distribution but only knows some of its moments. The problem is to recover a meaningful probability measure given this knowledge: suppose a vector of functions  $m(\omega) = [m_1(\omega) \dots m_n(\omega)]$  and a vector of scalars  $\mu = [\mu_1 \dots \mu_n]$  are given, the problem is to find a  $P$  such that:

$$\begin{aligned} \int_{\Omega} m_i(\omega) dP(\omega) &= \mu_i, \quad i = 1, \dots, n \\ \int_{\Omega} dP(\omega) &= 1, \\ P(\omega) &\geq 0, \quad \text{a.e.} \end{aligned} \quad (4)$$

where  $\Omega$  is a compact subset of  $\mathbb{R}^m$ . By  $\mathcal{P}$  we will denote the set of all finite signed measures that are defined on the  $\sigma$ -field  $\mathcal{F}$  of  $\Omega$ . The vector  $m(\omega)$  represents the (generalized) moments of the distribution. The problem in Eq. (4) is the so called generalized Hausdorff moment problem. The aim is to recover a compactly supported distribution from a finite number of its general, not necessarily power, moments. This is a variation of the classical moment problem formulated by Stieltjes. In [4] one can find a comprehensive summary of the main results when  $\Omega = [0, 1]$ . Prekopa [13] provides an excellent summary of results that are especially relevant in stochastic optimization problems.

## Methods

Solving optimization problems where the uncertainty is only known through its moments requires some kind of regularization in order to fix the probability measure with which the optimization is to be done. Two popular frameworks are game theoretic and maximum entropy approaches. Under the game theory framework one selects the distribution with the worst case realization of the uncertainties. When a maximum entropy solution is sought, one optimizes with respect to the distribution with the maximum uncertainty.

### Game Theory Approach

When  $P$  is unknown or not known exactly then the decision maker assumes that if strategy  $x$  is followed then the consequences of following this strategy will be decided by some law of Nature. Motivated by the application oriented requirement for robust decision making, we assume that Nature is antagonistic. If we decide to follow strategy  $x$  then Nature will follow strategy  $P^*$ . The latter is the solution of the following optimization problem:

$$\Phi(x) = \sup_{P \in \mathcal{P}} \int_{\Omega} f(x, \omega) dP(\omega), \quad (5)$$

where  $\Phi(x)$  represents the value (outcome) of the game if strategy  $x$  is followed. Obviously  $\Phi(x) \geq F(x)$  for given  $x \in X$  and for all  $P \in \mathcal{P}$ . Therefore, after we minimize Eq. (5) for  $x$  we will be guaranteed to attain a value which is as good as  $\Phi(x)$  whatever strategy nature decides to follow. The robustness property of the minimax strategy originates from the latter property. We thus reformulate Eq. (1) as follows:

$$\inf_{x \in X} \sup_{P \in \mathcal{P}} \int_{\Omega} f(x, \omega) dP(\omega). \quad (6)$$

This approach has its origins in game theory and has been used extensively in many areas of optimization. See for example [9] for an excellent introduction to game theory, applications of minimax especially in economics and finance can be found in [14]. Numerical algorithms to solve Eq. (6) have been proposed in [5,6]. The general idea of these algorithms is to solve the inner maximization problem using results for general Chebyshev inequalities [4,17]. However these methods require several global optimization steps to be performed

at each iteration in order to identify the support of the measure that maximizes Eq. (5). Moreover it is usually assumed that the max-function is convex. Algorithms based on stochastic quasi-gradient methods were proposed in [4,17]. Recently Shapiro et al. [15] proposed the use of a reference distribution in order to reformulate the minimax problem into a standard stochastic programming problem. Bertsimas et al. [1] and Lassere [11] proposed a semidefinite formulation of the inner maximization problem in Eq. (6).

**Maximum Entropy Formulation**

The formulation of the moment problem using the maximum entropy principle was initiated by Jaynes [8]. The derivations in this Section are more or less standard (see e. g. [12]). We will assume that a multivariate continuous density is postulated, discrete distributions share similar properties. Under these assumptions the maxent formulation is given by:

$$\begin{aligned} \inf_{p \in \mathcal{P}_c} Q(p, h) &= \int_{\Omega} p(\omega) \ln \frac{p(\omega)}{h(\omega)} d\omega \\ \text{s.t } \int_{\Omega} m_i(\omega) p(\omega) d\omega &= \mu_i \quad i = 0 \dots n, \end{aligned} \tag{7}$$

where  $\mathcal{P}_c$  denotes the restriction on  $\mathcal{P}$  to all absolutely continuous measures w.r.t  $d\omega$ , we will write  $\nu \ll \mu$  to mean that  $\nu$  is absolutely continuous w.r.t  $\mu$ . The function in the objective function is the so called Kullback Leibler divergence (see e. g. [3]) and serves as a kind of distance metric between  $h(\omega)$  and  $p(\omega)$ ; the former is a distribution that is assumed to be known. The objective is to find a p.d.f with the prescribed moments that is as close to  $h$  as possible. If such a function is not known then we take  $h(\omega) \equiv 1$  (i. e. the uniform distribution) and the problem becomes the classical maximum entropy formulation. The convex functional defined by  $Q(p, h)$  is always strictly positive and is zero if and only if  $p = h$  a.e. It is also worth mentioning that in general  $Q(p, h) \neq Q(h, p)$ . These properties of  $Q(p, h)$  are well known. We refer the interested reader to [3] for more properties of the entropy function. We assume that  $m_0(\omega) = \mu_0 = 1$ . Note that by considering general moments as opposed to power moments allows us to impose fractile constraints, this property is important in many applications.

While the problem in Eq. (7) is a convex optimization problem it cannot be handled using standard nu-

merical algorithms. For this reason one considers the dual of Eq. (7). The Lagrangian associated with Eq. (7) is given by:

$$\begin{aligned} L(p, \lambda) &= \int_{\Omega} p(\omega) \ln \frac{p(\omega)}{h(\omega)} d\omega \\ &+ \sum_{i=0}^n \lambda_i \left( \int_{\Omega} m_i(\omega) p(\omega) d\omega - \mu_i \right). \end{aligned}$$

The dual problem of Eq. (7) is given by:

$$\sup_{\lambda} D(\lambda) = \inf_{p \in \mathcal{P}_c} L(p, \lambda). \tag{8}$$

It is well known that the inner minimization on Eq. (8) can be done explicitly using functional derivatives [12,16]:

$$\begin{aligned} L(p + \delta p, \lambda) &= \int_{\Omega} (p(\omega) + \delta p(\omega)) \ln \left\{ \frac{p(\omega)}{h(\omega)} \left( 1 + \frac{\delta p(\omega)}{p(\omega)} \right) \right\} d\omega \\ &+ \sum_{i=0}^n \lambda_i \left( \int_{\Omega} m_i(\omega) (p(\omega) + \delta p(\omega)) d\omega - \mu_i \right) \\ &= L(p, \lambda) + \int_{\Omega} \left\{ 1 + \ln \left( \frac{p(\omega)}{h(\omega)} \right) \right\} \delta p(\omega) d\omega \\ &+ \sum_{i=0}^n \int_{\Omega} \lambda_i m_i(\omega) \delta p(\omega) d\omega, \end{aligned}$$

where to get the last equality we assumed that  $\delta p$  is small, used the approximation  $\ln(1 + \epsilon) \approx \epsilon$  (which is valid for small  $\epsilon$ ) and ignored second order terms. The stationary points of the Lagrangian must therefore satisfy:

$$p(\omega) = h(\omega) \exp \left( -1 - \sum_{i=0}^n \lambda_i m_i(\omega) \right). \tag{9}$$

Using the normalization condition we have:

$$Z = \exp(1 + \lambda_0) = \int_{\Omega} h(\omega) \exp \left( - \sum_{i=1}^n \lambda_i m_i(\omega) \right) d\omega.$$

Using the equation above we can write Eq. (9) as follows:

$$p(\omega) = \frac{h(\omega)}{Z} \exp \left( - \sum_{i=1}^n \lambda_i m_i(\omega) \right). \tag{10}$$

Finally, using Eq. (10) and the normalization constraint in Eq. (8) we find the following explicit form for the dual problem:

$$\sup_{\lambda} D(\lambda) = -\ln Z - \sum_{i=1}^n \lambda_i \mu_i. \tag{11}$$

The dual formulation given above is more useful than the primal problem since the dual problem is amenable to conventional optimization algorithms.

**Relationships Between Game Theory and Maximum Entropy**

The minimax approach has proven to be a prudent method for problems where the nature of the uncertainty is not known exactly. We will approach the problem somewhat differently by dispensing the usual assumptions of convexity but allowing the decision maker to adopt mixed strategies. Such an approach (in the context of Stochastic Programming) has been described in Kolbin [10] but has not received much attention. The advantage of allowing mixed strategies is that the problem exhibits a saddle point. Topsøe [18] showed that if the decision problem has a specific structure (will be outlined below) then the solution of the maximum entropy problem and that of zero-sum games are dual to each other. Recently Grünwald et al. [7] has further developed this approach so that it can be applied to more general games. This generalization however has been done at the expense of defining more general entropy functionals; these do not, in general, render themselves to numerical algorithms. We believe this relationship to be very interesting and can under certain conditions be used as an additional motivation for adopting the maximum entropy principle.

Let  $\Omega$  be a compact subset of  $\mathbb{R}^n$  and let  $\mathcal{F}$  be the  $\sigma$ -field generated by  $\Omega$ . We will use  $\omega$  to denote a random vector whose distribution is known to belong to a family  $\mathcal{P}$ . The following meaningless formulation of a stochastic programming problem:

$$\begin{aligned} &\inf_{x \in X} f(x, \omega) \\ &\text{s.t } g_i(x, \omega) \leq 0, \quad i = 1, \dots, k \end{aligned}$$

can be placed into a pertinent form by formulating it as a two-person zero sum game  $G = (x, \omega, q)$ . The first player is the Decision Maker (DM) that selects vectors

$x \in X \subset \mathbb{R}^m$ . The second player is Nature that selects an event  $\omega \in \mathcal{F}$  with probability  $P(\omega)$ , it is further assumed that the exact probability measure of Nature is only known to belong to a certain family  $\mathcal{P}$ . The function  $q$  represents the outcome of the game given the strategies the two players decide to follow. Kolbin [10] suggested the following form:

$$q(x, \omega) = f(x, \omega) + \sum_{i=1}^k \beta_i(g_i(x, \omega)), \tag{12}$$

where  $\beta_i(a)$  is a continuous non-decreasing penalty function that is 0 when  $a \leq 0$ . An example of such a function is the max-penalty function given by:  $c_i \max\{g_i(x, \omega), 0\}$  ( $c_i$  is a penalty parameter).

The DM would like to minimize the outcome of the game given by Eq. (12) whereas Nature being antagonistic would like to maximize this quantity:

$$\inf_{x \in X} \sup_{P \in \mathcal{P}} H(x, P) = \int_{\Omega} q(x, \omega) dP(\omega). \tag{13}$$

For the game above to exhibit a saddle point convexity assumptions need to be imposed on  $q$ . Many problems of interest do not have this property and it is necessary to resort to mixed strategies for the DM. Using our assumptions that  $q$  is continuous, and the compactness of  $\Omega$  and  $X$ , it can be shown [10] that if we allow the DM to follow mixed strategies then the game in Eq. (13) will have a saddle point, i.e:

$$\begin{aligned} &\inf_{K \in \mathcal{K}} \sup_{P \in \mathcal{P}} \int_{\Omega \times X} q(x, \omega) dP(\omega) dK(x) \\ &= \sup_{P \in \mathcal{P}} \inf_{K \in \mathcal{K}} \int_{\Omega \times X} q(x, \omega) dP(\omega) dK(x) \\ &= H(K^*, P^*), \end{aligned} \tag{14}$$

where the set  $\mathcal{K}$  represents the family of randomized strategies of the DM.

Assume that the DM selects a probability measure  $K \in \mathcal{K}$  and Nature selects  $P \in \mathcal{P}$  and both have their support in  $\Omega$  (or  $X$ ). Moreover assume that the objective function of the game has the following functional form:

$$H(K, P) = \int_{\Omega} -p(\omega) \ln k(\omega) d\omega, \tag{15}$$

where  $p(\omega)$  and  $k(\omega)$  are the Radon–Nikodym derivatives w.r.t  $d\omega$  of  $P \in \mathcal{P}$  and  $K \in \mathcal{K}$  respectively.

Topsøe [18] observed that under these conditions the maximum entropy solution and the minimax solution coincide. To see why this is the case, suppose that nature selects a probability measure from the following family:

$$\mathcal{P}_c = \left\{ \frac{dP}{d\omega} \mid P \in \mathcal{P}, \int_{\Omega} m_i(\omega) dP(\omega) = \mu_i, \right. \\ \left. i = 1, \dots, n \ P \ll d\omega \right\},$$

where  $P \ll d\omega$  is used to denote that  $P$  is absolutely continuous w.r.t to  $d\omega$ .  $\mathcal{K}_c$ , the family of admissible strategies for the DM is defined in an analogous manner. If Nature adopts a maximum entropy distribution, then its strategy can be found by solving:

$$\sup_{p \in \mathcal{P}_c} M(p) = \int_{\Omega} -p(\omega) \ln p(\omega) d\omega.$$

The optimal solution will be given by:

$$p^*(\omega) = \exp\{-1 - \lambda_0^* - \sum_{i=1}^n \lambda_i^* m_i(\omega)\}.$$

The optimal strategy of the DM can then be obtained by solving:

$$\inf_{k \in \mathcal{K}_c} \int_{\Omega} -p^*(\omega) \ln k(\omega) d\omega.$$

Using the information inequality [3] we have:

$$\int_{\Omega} -p^*(\omega) \ln k(\omega) d\omega \geq \int_{\Omega} -p^*(\omega) \ln p^*(\omega) d\omega, \tag{16}$$

the above inequality is satisfied as an inequality if and only if  $k(\omega) = p^*(\omega)$  a.e. Consequently the optimal strategy for the DM is the same as Nature's strategy.

Conversely, assuming that the game has the functional form given in Eq. (15), then the minimax solution of the game in Eq. (14) is the same as the maximum entropy solution. Indeed, by using the information inequality we have:

$$\sup_{p \in \mathcal{P}_c} \int_{\Omega} -p(\omega) \ln k(\omega) d\omega \\ \geq \int_{\Omega} -p^*(\omega) \ln k(\omega) d\omega \\ \geq \int_{\Omega} -p^*(\omega) \ln p^*(\omega) d\omega = M(p^*),$$

where  $p^*$  is the distribution of maximum entropy. From the above relationship it follows that:

$$M(p^*) \leq \inf_{k \in \mathcal{K}_c} \sup_{p \in \mathcal{P}_c} \int_{\Omega} -p(\omega) \ln k(\omega) d\omega, \tag{17}$$

if we choose  $k = p^*$  as the minimizer of the left hand side of Eq. (14), then:

$$\sup_{p \in \mathcal{P}_c} \int_{\Omega} -p(\omega) \ln p^*(\omega) d\omega = -\lambda_0^* - \sum_{i=1}^n \lambda_i^* \mu_i \\ = M(p^*),$$

it follows from above that:

$$\inf_{k \in \mathcal{K}} \sup_{p \in \mathcal{P}_c} \int_{\Omega} -p(\omega) \ln k(\omega) d\omega \leq M(p^*), \tag{18}$$

and therefore  $k = p^*$  is indeed the minimizer of the left hand side of Eq. (14). From the well known property of minimax problems:

$$M(p^*) = \inf_{k \in \mathcal{K}} \sup_{p \in \mathcal{P}_c} \int_{\Omega} -p(\omega) \ln k(\omega) d\omega \\ \geq \sup_{p \in \mathcal{P}_c} \inf_{k \in \mathcal{K}} \int_{\Omega} -p(\omega) \ln k(\omega) d\omega,$$

and from:

$$\sup_{p \in \mathcal{P}_c} \inf_{k \in \mathcal{K}} \int_{\Omega} -p(\omega) \ln k(\omega) d\omega \\ \geq \inf_{k \in \mathcal{K}} \int_{\Omega} -p^*(\omega) \ln k(\omega) d\omega = M(p^*),$$

we conclude that the game has a saddle point at  $p = k = p^*$ .

For games in the form of Eq. (15), the relationship between game theory and maximum entropy is most useful both theoretically and practically. For games not in the form described above can still be approached via maximum entropy methods but the definition of the entropy functional is given by a more general functional form. Grünwald et al. [7] defined the generalized entropy function as:

$$M(P) = \inf_{k \in \mathcal{K}} \int_{\Omega \times X} q(x, \omega) dP(\omega) dK(x).$$

The maximum entropy problem becomes:

$$\max_{p \in \mathcal{P}_c} M(P). \tag{19}$$

They showed that using the generalized definition of entropy one could find the same results for both game theory and maximum entropy problems. Even though the formulation in Eq. (19) is very general, unfortunately there is no general way to solve it. However, the relationship between the two principles is worth further investigation.

Entropy optimization; Image reconstruction; Maximum entropy principle; Principle of maximum entropy

*Images* can be used to characterize the underlying distribution of certain physical properties, such as density, shape, and brightness, of an object under investigation. In many applications where an image is required, only a finite number of observations and/or indirect measurements can be made. Image reconstruction is a procedure for processing the measurement data to construct an image of the object. This section introduces the basic concept of *image reconstruction from projection data*. Two types of entropy optimization mod-

els, namely, the finite-dimensional model and vector-space model, and three classes of entropy optimization methodologies, namely, the discretization methods, Banach-space methods (e. g., MENT) and Hilbert-space methods (e. g., *finite element method*) are included. For more details about image reconstruction, the reader is referred to [2,7,13] and the references therein.

A very important scientific application of image reconstruction is in *computerized tomography* (CT) for medical diagnosis. Physicians need to know, for example, the location, shape, and size of a suspected tumor inside a patient's brain in order to plan a suitable course of treatment. With computerized tomography, images of cross-sections of a human body can be constructed from data obtained by measuring the attenuation of  $X$ -rays along a large number of straight lines (or strips) through each cross-section. For ease of introduction, we illustrate the basic ideas about image reconstruction with the example of two-dimensional  $X$ -ray CT, with the understanding that the discussion can be generalized to higher-dimensional settings.

In this example, the distribution to be determined is that of the  $X$ -ray linear attenuation coefficient of human body tissues. The total attenuation of the  $X$ -ray beam between a source and a detector is approximately the integral of the linear attenuation coefficient along the line between the source and the detector. The unknown distribution of the  $X$ -ray linear attenuation coefficient is represented by a density function  $f$  of two variables, which assumes zero-value outside a squared-shape region. The squared region is usually referred to as the support of the image.

Two basic types of entropy optimization models, namely, *finite-dimensional model* and *vector-space model*, are commonly used to decide the density function  $f$ . The finite-dimensional models approximate the density values over the support of the image at a finite number of grid points, while the density is approximated by a real-value function for the entire scanning region in the vector-space models. The latter models were motivated to reconstruct the image with only a small number of available projections.

In the finite-dimensional models, the support of the density  $f$  is represented by  $n$  (given by the users) regularly spaced grid points, and the values of the density function  $f$  at these points are denoted by  $\mathbf{f} \equiv (f_1, \dots,$

$f_n)$ . Assume that  $m$  projections are made and the measurement data  $\mathbf{d} \equiv (d_1, \dots, d_m)$  are obtained.

The relationship between the unknown density values  $\mathbf{f}$  and the observed measurement  $\mathbf{d}$  can be approximated by a linear relation

$$\mathbf{d} \approx \mathbf{A}\mathbf{f}, \quad (1)$$

where  $\mathbf{A} = [a_{ij}]$  is a projection matrix.

Note that the approximation sign in (1) reflects possible errors in modeling and measurement. Also note that, in the classical square pixel model, the image is discretized by partitioning its support into a finite number of equi-sized square regions (called pixels or cells) whose centers are those  $n$  sample points. By assuming that the density function  $f$  is constant in each of the equi-sized pixels, i. e.,  $f = f_j$  throughout pixel  $j$ , the value of  $a_{ij}$  in the projection matrix is simply the length of the intersection of the line corresponding to the  $i$ th projection with the pixel surrounding the  $j$ th sample point.

Once the projection matrix  $\mathbf{A}$  is defined and the measurement  $\mathbf{d}$  is known, the problem is to find an  $\mathbf{f}$  satisfying (1). To cope with the errors mentioned above, G.T. Herman [6] suggested that (1) be replaced by an 'interval constraint' and a nonnegativity constraint be added:

$$\mathbf{d} - \boldsymbol{\epsilon} \leq \mathbf{A}\mathbf{f} \leq \mathbf{d} + \boldsymbol{\epsilon}, \quad (2)$$

$$\mathbf{f} \geq \mathbf{O}, \quad (3)$$

where  $\boldsymbol{\epsilon} = (\epsilon_1, \dots, \epsilon_m)$  is an  $m$ -vector of user-chosen tolerance levels. Note that (2) can be replaced by an equivalent system of inequalities

$$\mathbf{A}'\mathbf{f} \leq \mathbf{d}', \quad (4)$$

with twice as many one-sided inequalities [2,6].

For such an image reconstruction model, we can adopt either the '*feasibility approach*' to find a solution to (2) and (3) directly, or the '*optimization approach*' to find a solution that is not only feasible in the above sense but also optimal with respect to a certain criterion. In the literature, at least three different types of optimization problems have been proposed, namely, the entropy maximization problem, the quadratic minimization problem, and the maximum likelihood problem.

The entropy optimization problem seeks to optimize an entropic objective function subject to (2) and (3) as follows.

Model 1:

$$\begin{cases} \max & -\sum_{j=1}^n f_j \ln f_j \\ \text{s.t.} & \mathbf{d} - \boldsymbol{\epsilon} \leq \mathbf{A}\mathbf{f} \leq \mathbf{d} + \boldsymbol{\epsilon}, \\ & \mathbf{f} \geq \mathbf{O}. \end{cases} \quad (5)$$

Some researchers proposed models in which the  $f_j$ 's are normalized in such a way that  $\sum_{j=1}^n f_j = 1$ , and the projection matrix and the measurement data differ from those of Model 1. See, e.g., [4]. In this way, a solution that is consistent with the measurement data but remains maximally noncommittal can be found. Note that an optimal solution to such models can also be interpreted as the most probable solution that is consistent with the measurement data [3].

Other variations of Model 1 exist. Despite possible modeling and measurement errors, one common practice is to replace (1) and inequalities (2), and (5) by a system of equations:  $\mathbf{A}\mathbf{f} = \mathbf{d}$ .

A different version of the finite-dimensional entropy optimization model begins with the definition of an error vector  $\mathbf{e} = (e_1, \dots, e_m)^T$ , where

$$e_i \equiv d_i - \sum_{j=1}^n a_{ij} f_j, \quad i = 1, \dots, m.$$

Assume that errors  $e_1, \dots, e_m$  exist due to imprecise measurement and are independent noise terms with zero mean and known variance  $\sigma_i^2$ . S.F. Burch et al. [1] observed that the strong law of large numbers implies that

$$Q(\mathbf{f}) \equiv \frac{1}{m} \sum_{i=1}^m \frac{(\sum_{j=1}^n a_{ij} f_j - d_i)^2}{\sigma_i^2} \rightarrow 1,$$

as  $m \rightarrow \infty$ .

Thus, if  $m$  is sufficiently large, the following entropy optimization problem with quadratic constraints can be useful:

Model 2:

$$\begin{cases} \max & -\sum_{j=1}^n f_j \ln f_j \\ \text{s.t.} & \frac{1}{m} (\mathbf{A}\mathbf{f} - \mathbf{d})^T \mathbf{S}^2 (\mathbf{A}\mathbf{f} - \mathbf{d}) = 1, \\ & f_j \geq 0, \quad j = 1, \dots, n, \end{cases}$$

where  $\mathbf{S}$  is a diagonal matrix with  $1/\sigma_i$  being its  $i$ th diagonal element.

Concerns such as the smoothing effect, nonuniformity, peakness, and exactness [14] of a constructed image can also be addressed in this model with proper modification of the objective functions and constraints. So far, we have used the square pixel model to illustrate the idea of entropy optimization for image reconstruction. Other models exist [2].

For an introduction to the concept of *Shannon's entropy* and related entropy optimization principles, i.e., *principle of maximum entropy* and *principle of minimum cross-entropy*, see ► **Entropy optimization: Shannon measure of entropy and its properties**. A large amount of literature has been devoted to developing iterative methods for solving finite-dimensional *entropy optimization* problems with linear and/or quadratic constraints. For details and a unification of such methods, see [3].

The method currently employed in most CT systems is the 'filtered back-projection' method, which is based on a finite-dimensional model. (See [5,10] for details.) Compared to the iterative methods for solving entropy optimization problems, this method provides speed, which enables reconstruction of the image while X-ray transmission data are being collected. Hence the time between scanning and obtaining reconstructed images is reduced. However, there are situations where iterative methods produce comparable or better reconstructed images than the filtered back-projection method, e.g., in image reconstruction with few projections or in high-contrast image reconstruction. The ever increasing computer speed and its companion reduction in cost may increase the desirability of employing iterative methods in CT systems.

In many situations, e.g., conducting diagnostic experiments on plasma in magnetic confinement devices or laser target impositions with measurements on fusion reactor cores, only few projections are available, e.g., less than 10. When the finite-dimensional entropy optimization model is applied, it tends to produce 'streaking' artifacts. This motivated the use of the vector-space model.

Take the two-dimensional X-ray CT problem as an example. By assuming that the unknown density function  $f(x, y)$  is continuous over a compact support  $D$

such that

$$f(x, y) \geq 0 \text{ and } \int \int_D f(x, y) dx dy = 1, \quad (6)$$

G. Minerbo [9] defined the entropy of  $f(x, y)$  as

$$\zeta(f) = - \int \int_D f(x, y) \ln[f(x, y)A] dx dy,$$

where  $A$  is the area of  $D$ . Denote the set of continuous, nonnegative functions with compact support in  $D$  by  $C_+(D)$ .

The scanning area is partitioned into parallel strips, each of which is penetrated by an  $X$ -ray beam. Let  $\theta_j, j = 1, \dots, J$ , be the  $J$  distinct projection angles with respect to the  $X$ -axis of the scanning area. Also let  $M(j)$  be the number of parallel beams associated with the  $j$ th projection or view, and  $S_{j1} < \dots < S_{jM(j)}$  be a set of abscissas for the  $j$ th view. The projection data are assumed to be in the form of the following ‘strip integrals’:

$$P_{jm}(f) \equiv \int_{S_{jm}}^{S_{j(m+1)}} \int_{-\infty}^{\infty} f(s \cos \theta_j - t \sin \theta_j, s \sin \theta_j + t \cos \theta_j) dt ds,$$

where  $m = 1, \dots, M(j)$  and  $j = 1, \dots, J$ . It is assumed that, for  $j = 1, \dots, J$ ,

$$\int_{-\infty}^{\infty} f(s \cos \theta_j - t \sin \theta_j, s \sin \theta_j + t \cos \theta_j) dt = 0, \\ \text{for } s < S_{j1} \text{ or } s > S_{jM(j)}.$$

Let  $G_{jm}$  denote the observed values of  $P_{jm}(f)$ , for  $m = 1, \dots, M(j)$ , and  $j = 1, \dots, J$ . Note that (6) implies  $G_{jm} \geq 0$  and  $\sum_{m=1}^{M(j)} G_{jm} = 1$ .

Then the vector-space model results in the following *optimization problem*:

Model 3:

$$\begin{cases} \sup_{C_+(D)} \zeta(f) \\ \text{s.t.} & P_{jm}(f) = G_{jm}, \\ & m = 1, \dots, M(j); \\ & j = 1, \dots, J. \end{cases} \quad (7)$$

A finite-dimensional unconstrained dual problem can be derived by using the technique of Lagrange multipliers. An algorithm known as MENT [9] was proposed. It was shown that the solutions produced by

MENT converge to a density function  $f^*$  which satisfies the constraint (7) with  $\zeta(f^*) = \sup_{C_+(D)} \zeta(f)$ . However, the limiting density function  $f^*$  is not continuous. Actually, as pointed out in [8],  $f^*$  is piecewise constant and  $f^* \notin C_+(D)$ . When few projections are available and the object being scanned has a simple structure (or close to circular symmetry in density), some preliminary computational results indicated the potential of this approach.

Recognizing the fact that the supremum of Model 3 is not attained by any function  $f \in C_+(D)$ , M. Klaus and R.T. Smith [8] defined an alternative formulation in a richer class of functions than  $C_+(D)$ . More precisely, they replaced  $C_+(D)$  by  $L_+^2(D)$ , the set of all nonnegative square integrable functions on  $D$ , as the setting. Note that all piecewise-constant functions over  $D$  are contained in  $L_+^2(D)$ . Also recognizing that measurements may not be consistent and even be flawed, they considered an optimization problem where the objective function is the original entropy functional  $\zeta(f)$  minus a penalty term corresponding to the residual error in meeting the measurement constraints, and the constraint is that the maximizer lies in a weakly compact set that is determined by known physical information about the density function of the object to be scanned. A corresponding formulation becomes

Model 4:

$$\sup_{f \in \Omega} G(f) \equiv \zeta(f) - \gamma \sum_{j,m} [G_{jm} - P_{jm}(f)]^2,$$

where  $\gamma > 0$  is an adjustable penalty parameter and  $\Omega$  is a convex and weakly (sequentially) compact set of nonnegative functions in  $L_+^2(D)$ , with a compact support in  $D$  and containing physical information known *a priori* about the object to be scanned, e. g., upper and lower bounds on the density function. (A set  $\Omega$  of nonnegative functions in  $L_+^2(D)$  is weakly (sequentially) compact if and only if every sequence in  $\Omega$  has a weakly convergent subsequence whose weak limit lies in  $\Omega$ ; a sequence  $\{f_n(x, y)\}$  converges weakly to  $f(x, y)$  if and only if the sequence  $\{\langle f_n(x, y), g(x, y) \rangle\}$  converges to  $\langle f(x, y), g(x, y) \rangle$  for every  $g(x, y) \in L_+^2(D)$ , where  $\langle h_1, h_2 \rangle \equiv \int \int h_1(x, y) h_2(x, y) dx dy$  denotes the inner product of  $h_1$  and  $h_2$  in the space of  $L_+^2(D)$ .)

With the aid of the theory of Hilbert space, it can be shown [8] that  $G$  has a unique maximizer in  $\Omega$ , for any given data  $G_{jm}, m = 1, \dots, M(j), j = 1, \dots, J$ .

Based on this alternative formulation, the density function  $f(x, y)$  can be approximated by using the *finite element method* [11]. For simplicity, assume that  $D = [-1, 1] \times [-1, 1]$ . First, we superimpose a fixed rectangular mesh on  $D$ , with uniform mesh size  $h = 1/n$  in both the  $x$  and  $y$  directions. We also use the product of piecewise linear functions in  $x$  and  $y$  as the finite element space  $S^h$ . In this way, a basis for  $S^h$  has the form

$$\psi_k(x, y) = \psi_i(x)\psi_l(y), \text{ for } k = 1, \dots, (2n + 1)^2,$$

where

$$l = \left\{ \frac{(k-1) - (k-1) \pmod{2n+1}}{2n+1} \right\} - n,$$

$$i = k - (l + n)(2n + 1) - n - 1,$$

and

$$\psi_j(t) = \begin{cases} 0 & \text{if } t \leq (j-1)h \\ & \text{or } t \geq (j+1)h, \\ \frac{t-(j-1)h}{h}, & \text{if } (j-1)h \leq t \leq jh, \\ \frac{(j+1)h-t}{h}, & \text{if } jh \leq t \leq (j+1)h. \end{cases}$$

It is reasonable to expect that, in practice, one should know a priori the minimum and maximum densities of the object being examined. Hence we focus on a simple constraint set

$$\Omega = \left\{ f \in L_+^2(D): \begin{array}{l} 0 < a \leq f \leq b < \infty \text{ a.e.,} \\ f = 0 \text{ a.e., in } \mathbb{R}^2 \setminus D \end{array} \right\}.$$

The density function  $f(x, y)$  is then approximated in  $S^h$  by

$$f(x, y) = \sum_{k=1}^N c_k \psi_k(x, y),$$

where  $N = (2n + 1)^2$  and  $c_k$ 's are chosen as the optimal solution of the following finite-dimensional optimization problem:

$$\begin{cases} \sup_{c \in \mathbb{R}^N} & G \left( \sum_{k=1}^N c_k \psi_k(x, y) \right) \\ \text{s.t.} & 0 < a \leq \sum_{k=1}^N c_k \psi_k(x, y) \leq b. \end{cases}$$

This problem can be further reduced to

$$\begin{cases} \sup_{c \in \mathbb{R}^N} & \zeta \left( \sum_{k=1}^N c_k \psi_k(x, y) \right) \\ & -\gamma \sum_{j,m} \left[ G_{jm} - \sum_{k=1}^N c_k P_{jm}(\psi_k(x, y)) \right]^2 \\ \text{s.t.} & 0 < a \leq c_k \leq b, \quad k = 1, \dots, N. \end{cases}$$

Preliminary computational results reported in [11, 12] indicate some improvements of this alternative approach over the MENT algorithm when the object under investigation does not have circular symmetry in density and has a high density area near the edge of the scanning region.

Network; Maximum flow problem; Minimum cut problem; Augmenting path algorithm; Preflow-push algorithm; Max-flow min-cut theorem

The *maximum flow problem* seeks the maximum possible flow in a capacitated network from a specified source node  $s$  to a specified sink node  $t$  without exceeding the capacity of any arc. A closely related problem is the *minimum cut problem*, which is to find a set of arcs with the smallest total capacity whose removal separates node  $s$  and node  $t$ . The maximum flow and minimum cut problems arise in a variety of application settings as diverse as manufacturing, communication systems, distribution planning, matrix rounding, and scheduling. These problems also arise as subproblems in the solution of more difficult network optimization problems. In this article, we study the maximum flow and minimum cut problems, briefly introducing the underlying theory and algorithms, and presenting some applications. See [2] for a wealth of additional material that amplifies on this discussion.

Let  $G = (N, A)$  be a *directed network* defined by a set  $N$  of  $n$  nodes and a set  $A$  of  $m$  directed arcs. We refer to nodes  $i$  and  $j$  as *endpoints* of arc  $(i, j)$ . A *directed path*  $i_1 - i_2 - \dots - i_k$  is a set of arcs  $(i_1, i_2), \dots, (i_{k-1}, i_k)$ . Each arc  $(i, j)$  has an associated *capacity*  $u_{ij}$  denoting the maximum amount of flow on this arc. We assume that each arc capacity  $u_{ij}$  is an integer, and let  $U = \max \{u_{ij} : (i, j) \in A\}$ . The network has two distinguished nodes, a *source node*  $s$  and a *sink node*  $t$ . To help in representing a network, we use the arc adjacency list  $A(i)$  of node  $i$ , which is the set of arcs emanating from it, that is,  $A(i) = \{(i, j) \in A : j \in N\}$ .

The maximum flow problem is to find the maximum flow from the source node  $s$  to the sink node  $t$  that satisfies the arc capacities and mass balance constraints at all nodes. We can state the problem formally as follows.

$$\max v \tag{1}$$

subject to

$$\sum_{\{j : (i,j) \in A\}} x_{ij} - \sum_{\{j : (j,i) \in A\}} x_{ji} = \begin{cases} v & \text{for } i = s, \\ 0 & \text{for } i \notin \{s, t\}, \\ -v & \text{for } i = t, \end{cases} \tag{2}$$

$$0 \leq x_{ij} \leq u_{ij} \text{ for all } (i, j) \in A. \tag{3}$$

We refer to a vector  $x = \{x_{ij}\}$  satisfying (2) and (3) as a *flow* and the corresponding value of the scalar variable  $v$  as the *value* of the flow. We refer to the constraints (2) as the *mass balance constraints*, and refer to the constraints (3) as the *flow bound constraints*.

In examining the maximum flow problem, we impose two assumptions:

- i) all arc capacities are integer; and
- ii) whenever the network contains arc  $(i, j)$ , then it also contains arc  $(j, i)$ .

The second assumption is nonrestrictive since we allow arcs with zero capacity.

Sometimes the flow vector  $x$  might be required to satisfy lower bound constraints imposed upon the arc flows; that is, if  $l_{ij} \geq 0$  specifies the lower bound on the flow on arc  $(i, j) \in A$ , we impose the condition  $x_{ij} \geq l_{ij}$ . We refer to this problem as the *maximum flow problem with nonnegative lower bounds*. It is possible to transform a maximum flow problem with nonnegative lower bounds into a maximum flow problem with zero lower bounds.

The minimum cut problem is a close relative of the maximum flow problem. A *cut*  $[S, \bar{S}]$  partitions the node set  $N$  into two subsets  $S$  and  $\bar{S} = N - S$ . It consists of all arcs with one endpoint in  $S$  and the other in  $\bar{S}$ . We refer to the arcs directed from  $S$  to  $\bar{S}$ , denoted by  $(S, \bar{S})$ , as *forward arcs* in the cut and the arcs directed from  $\bar{S}$  to  $S$ , denoted by  $(\bar{S}, S)$ , as *backward arcs* in the cut. The cut  $[S, \bar{S}]$  is called an  $s - t$ -cut if  $s \in S$  and  $t \in \bar{S}$ . We define the *capacity of the cut*  $[S, \bar{S}]$ , denoted as  $u[S, \bar{S}]$ , as  $\sum_{(i,j) \in (S, \bar{S})} u_{ij}$ . A *minimum cut* in  $G$  is an  $s - t$ -cut of minimum capacity. We will show that any algorithm that determines a maximum flow in the network also determines a minimum cut in the network.

The remainder of this article is organized as follows. To help in understanding the importance of the maximum flow problem, we begin by describing several applications. In the next section we present some preliminary results concerning flows and cuts. We next discuss two important classes of algorithms for solving the maximum flow problem: augmenting path algorithms, and preflow-push algorithms. As described in the next section, augmenting path algorithms augment flow along directed paths from the source node to the sink node. The proof of the validity of the augmenting path algorithm yields the well-known max-flow min-cut theorem, which implies that the value of a maxi-

imum flow in a network equals the capacity of a minimum cut in the network. In the next section, we study preflow-push algorithms that ‘flood’ the network so that some nodes have excesses and then incrementally ‘relieve’ the flow from nodes with excesses by sending flow from excess nodes forward toward the sink node or backward toward the source node. In the final section, we study implications of the max-flow min-cut theorem and prove some max-min results in combinatorics.

We would like to design maximum flow algorithms that are guaranteed to be efficient in the sense that their worst-case running times, that is, the total number of multiplications, divisions, additions, subtractions, and comparisons in the worst-case grow slowly in some measure of the problem’s size. We say that a maximum flow algorithm is an  $O(n^3)$  algorithm, or has a worst-case complexity of  $O(n^3)$ , if it is possible to solve any maximum flow problem using a number of computations that is asymptotically bounded by some constant times the term  $n^3$ . We say that an algorithm is a *polynomial time algorithm* if its worst-case running time is bounded by a polynomial function of the input size parameters. For a maximum flow problem, the input size parameters are  $n$ ,  $m$ , and  $\log U$  (the number of bits needed to specify the largest arc capacity). We refer to a maximum flow algorithm as a *pseudopolynomial time algorithm* if its worst-case running time is bounded by a polynomial function of  $n$ ,  $m$ , and  $U$ . For example, an algorithm with worst-case complexity of  $O(nm \log U)$  is a polynomial time algorithm, but an algorithm with worst-case complexity of  $O(nmU)$  is a pseudopolynomial time algorithm.

## Applications

The maximum flow problem arises in a variety of situations and in several forms. Sometimes, it arises directly in combinatorial applications that on the surface might not appear to be maximum flow problems at all; at other times, it occurs as a subproblem in the solution of more difficult network optimization problems. In this section, we describe three applications of the maximum flow problem.

## Capacity of Physical Networks

An oil company needs to ship oil from a refinery to a storage facility using the pipelines of its underlying

distribution network. In this problem context, the refinery corresponds to a particular node  $s$  in the distribution network and the storage facility corresponds to another node  $t$ . The capacity of each arc is the maximum amount of oil per unit time that can flow along it. The value of a maximum  $s$ – $t$  flow determines the maximum flow rate from the source node  $s$  to the sink node  $t$ . Similar applications arise in other settings, for example, determining the transmission capacity between two nodes of a telecommunications network.

### Feasible Flow Problem

The feasible flow problem consists of finding a feasible flow satisfying the following constraints:

$$\sum_{\{j: (i,j) \in A\}} x_{ij} - \sum_{\{j: (j,i) \in A\}} x_{ji} = b(i) \text{ for all } i \in N, \quad (4)$$

$$0 \leq x_{ij} \leq u_{ij} \text{ for all } (i, j) \in A. \quad (5)$$

We assume that  $\sum_{i \in N} b(i) = 0$ . The following distribution scenario illustrates how the feasible flow problem arises in practice. Suppose that merchandise available at several seaports is desired by other ports. We know the stock of merchandise available at the ‘supply’ ports, the amount required at the other ports, and the maximum quantity of merchandise that can be shipped on a particular sea route. We wish to know whether we can satisfy all of the demands by using the available supplies.

We can solve the feasible flow problem by solving a maximum flow problem defined on an augmented network as follows. We introduce two new nodes, a source node  $s$  and a sink node  $t$ . For each node  $i$  with supply (that is, with  $b(i) > 0$ ), we add an arc  $(s, i)$  with capacity  $b(i)$ , and for each node  $i$  with demand (that is, with  $b(i) < 0$ ), we add an arc  $(i, t)$  with capacity  $-b(i)$ . We refer to the new network as the *transformed network*. We then solve a maximum flow problem from node  $s$  to node  $t$  in the transformed network. It is easy to show that the model (4)–(5) has a feasible solution if and only if the maximum flow saturates all the arcs emanating from the source node, that is,  $x_{sj} = u_{sj}$  for all arcs  $(s, j) \in A(s)$ . Moreover, if each  $b(i)$  and  $u_{ij}$  is integer, then model (4)–(5) always has an integer feasible

solution whenever it has a feasible solution (see Theorem 3).

Sometimes in a feasible flow problem arcs have non-negative lower bounds, that is, the flow bound constraints are  $l_{ij} \leq x_{ij} \leq u_{ij}$  instead of  $0 \leq x_{ij} \leq u_{ij}$ , for some constants  $l_{ij} \geq 0$  for each  $(i, j) \in A$ . By substituting  $y_{ij} = x_{ij} - l_{ij}$  for  $x_{ij}$ , we can transform this problem to the formulation (4)–(5). Then (5) reduces to  $0 \leq y_{ij} \leq (u_{ij} - l_{ij})$  and (4) reduces to the same set of equations, but with a different right-hand side vector  $b'$ .

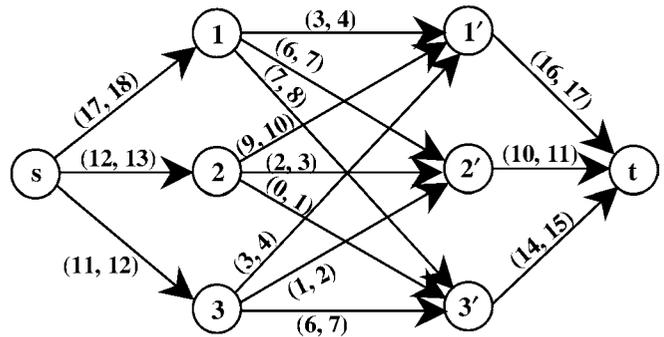

### Matrix Rounding Problem

This application is concerned with consistent rounding of the elements, the row sums, and the column sums of a matrix. We are given a  $p \times q$  matrix of real numbers  $D = \{d_{ij}\}$ , with row sums  $\alpha_i$  and column sums  $\beta_j$ . We can round any real number  $d$  to the next smaller integer  $\lfloor d \rfloor$  or to the next larger integer  $\lceil d \rceil$ , and the decision to round up or round down is entirely up to us. The matrix-rounding problem requires that we round the matrix elements, and the row and column sums of the matrix so that the sum of the rounded elements in each row equals the rounded row sum, and the sum of the rounded elements in each column equals the rounded column sum. We refer to such a rounding as a *consistent rounding*. The matrix-rounding problem arises in several application contexts, for example, the rounding of census data to disguise data on individuals.

Using a numerical example, we will show how to transform a matrix rounding problem into a maximum flow problem. Figure 1a) shows an instance of the matrix rounding problem and Fig. 1b) gives the maximum flow network  $G$  for this problem. The network  $G$  contains a node  $i$  corresponding to each row  $i$  of the matrix  $D$ , a node  $j$  corresponding to each column  $j$  of  $D$ , a source node  $s$ , and a sink node  $t$ . The network contains an arc  $(i, j)$  corresponding to the  $ij$ th element in the matrix, an arc  $(s, i)$  for each row  $i$  (this arc represents the sum of row  $i$ ), an arc  $(j, t)$  for each column  $j$  (this arc represents the sum of column  $j$ ). For any arc  $(i, j)$ , we define its upper bound  $u_{ij} = \lceil d_{ij} \rceil$  and lower bound  $l_{ij} = \lfloor d_{ij} \rfloor$ . Notice that the flow  $x_{ij} = d_{ij}$  is a real-valued feasible flow  $x$  in the network. Since there is a one-to-one correspondence between the consistent roundings of the matrix and feasible integer flows in the corresponding network, we can find a consistent rounding

			<b>Row Sum</b>

by solving a feasible flow problem on the corresponding network. The feasible flow algorithm will produce an integer feasible flow (because of Theorem 3), which corresponds to a consistent rounding.

**Preliminaries**

In this section, we discuss some elementary properties of flows and cuts. We will use these properties to prove the celebrated max-flow min-cut theorem and to establish the correctness of the augmenting path algorithm described in the next section.

**Residual Network**

The concept of residual network plays a central role in the development of maximum flow algorithms. Given a flow  $x$ , the residual capacity  $r_{ij}$  of any arc  $(i, j) \in A$  is the maximum additional flow that can be sent from node  $i$  to node  $j$  using the arcs  $(i, j)$  and  $(j, i)$ . (Recall the assumption from the first Section that whenever the network contains arc  $(i, j)$ , it also contains the arc  $(j, i)$ .) The residual capacity  $r_{ij}$  has two components:

- i)  $u_{ij} - x_{ij}$ , the unused capacity of arc  $(i, j)$ ;
- ii) the current flow  $x_{ji}$  on arc  $(j, i)$ , which we can cancel to increase the flow from node  $i$  to node  $j$ .

Consequently,  $r_{ij} = u_{ij} - x_{ij} + x_{ji}$ . We refer to the network  $G(x)$  consisting of the arcs with positive residual capacities as the *residual network* (with respect to the flow  $x$ ). Figure 2 gives an example of a residual network.

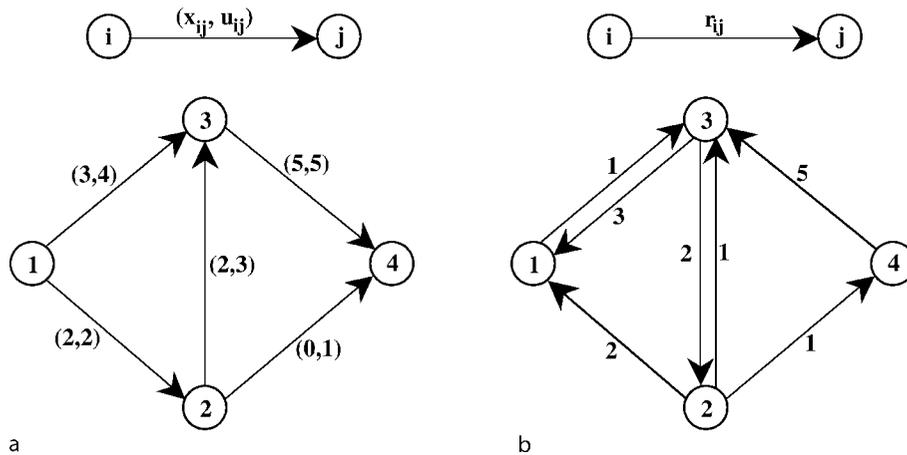

**Flow across an  $s - t$ -Cut**

Let  $x$  be a flow in the network. Adding the mass balance constraint (2) for the nodes in  $S$ , we obtain the equation

$$\begin{aligned}
 v &= \sum_{i \in S} \left[ \sum_{\{j: (i,j) \in A\}} x_{ij} - \sum_{\{j: (j,i) \in A\}} x_{ji} \right] \\
 &= \sum_{(i,j) \in (S, \bar{S})} x_{ij} - \sum_{(i,j) \in (\bar{S}, S)} x_{ij}.
 \end{aligned}
 \tag{6}$$

The second equality uses the fact that whenever both the nodes  $p$  and  $q$  belong to the node set  $S$  and  $(p, q) \in A$ , the variable  $x_{pq}$  in the first term within the bracket (for node  $i = p$ ) cancels the variable  $-x_{pq}$  in the second term within the bracket (for node  $j = q$ ). The first expression in the right-hand side of (6) denotes the amount of flow from the nodes in  $S$  to nodes in  $\bar{S}$ , and the second expression denotes the amount of flow returning from the nodes in  $\bar{S}$  to the nodes in  $S$ . Therefore, the right-hand side denotes the total (net) flow across the cut, and (6) implies that the flow across any  $s - t$ -cut  $[S, \bar{S}]$  equals  $v$ . Substituting  $x_{ij} \leq u_{ij}$  in the first expression of (6) and  $x_{ij} \geq 0$  in the second expression yields:  $v \leq \sum_{(i,j) \in (S, \bar{S})} u_{ij} = u[S, \bar{S}]$  implying that the value of any flow can never exceed the capacity of any cut in the network. We record this result formally for future reference.

**Lemma** *The value of any flow can never exceed the capacity of any cut in the network. Consequently, if the value of some flow  $x$  equals the capacity of some cut*

Maximum Flow Problem, Figure 2

Illustrating the construction of a residual network; a) the original network, with arc capacities and a flow  $x$ ; b) the residual network

$[S, \bar{S}]$ , then  $x$  is a maximum flow and the cut  $[S, \bar{S}]$  is a minimum cut.

The *max-flow min-cut theorem*, to be proved in the next section, states that the value of some flow always equals the capacity of some cut.

### Generic Augmenting Path Algorithm

In this section, we describe one of the simplest and most intuitive algorithms for solving the maximum flow problem, an algorithm known as the *augmenting path algorithm*.

Let  $x$  be a feasible flow in the network  $G$ , and let  $G(x)$  denote the residual network corresponding to the flow  $x$ . We refer to a directed path from the source to the sink in the residual network  $G(x)$  as an augmenting path. We define the residual capacity  $\delta(P)$  of an augmenting path  $P$  as the maximum amount of flow that can be sent along it, that is,  $\delta(P) = \min \{r_{ij} : (i, j) \in P\}$ . Since the residual capacity of each arc in the residual network is strictly positive, the residual capacity of an augmenting path is strictly positive. Therefore, we can always send a positive flow of  $\delta$  units along it. Consequently, whenever the network contains an augmenting path, we can send additional flow from the source to the sink. (Sending an additional  $\delta$  units of flow along an augmenting path decreases the residual capacity of each arc  $(i, j)$  in the path by  $\delta$  units.) The generic augmenting path algorithm is essentially based upon this simple observation.

The algorithm identifies augmenting paths in  $G(x)$  and augments flow on these paths until the network contains no such path. The algorithm below describes the generic augmenting path algorithm.

We can identify an augmenting path  $P$  in  $G(x)$  by using a graph search algorithm. A graph search algorithm starts at node  $s$  and progressively finds all nodes that are reachable from the source node using directed paths. Most search algorithms run in time proportional to the number of arcs in the network, that is,  $O(m)$  time, and either identify an augmenting path or conclude that  $G(x)$  contains no augmenting path; the latter happens when the sink node is not reachable from the source node.

```

BEGIN
   $x := 0$ ;
  WHILE  $G(x)$  contains a directed path from
  node  $s$  to node  $t$  DO
  BEGIN
    identify an augmenting path  $P$  from  $s$  to  $t$ ;
    set  $\delta := \min\{r_{ij} : (i, j) \in P\}$ ;
    augment  $\delta$  units of flow along  $P$ ;
    update  $G(x)$ ;
  END;
END;
```

Generic augmenting path algorithm

For each arc  $(i, j) \in P$ , augmenting  $\delta$  units of flow along  $P$  decreases  $r_{ij}$  by  $\delta$  units and increases  $r_{ji}$  by  $\delta$  units. The final residual capacities  $r_{ij}$  when the algorithm terminates specifies a maximum (arc) flow in the following manner. Since  $r_{ij} = u_{ij} - x_{ij} + x_{ji}$ , the arc flows satisfy the equality  $x_{ij} - x_{ji} = u_{ij} - r_{ij}$ . If  $u_{ij} > r_{ij}$ , we can set  $x_{ij} = u_{ij} - r_{ij}$  and  $x_{ji} = 0$ ; otherwise, we set  $x_{ij} = 0$  and  $x_{ji} = r_{ij} - u_{ij}$ .

We use the maximum flow problem given in Fig. 3) to illustrate the algorithm. Fig 3a) shows the residual network corresponding to the starting flow  $x = 0$ , which is identical to the original network. The residual network contains three augmenting paths:  $1 - 3 - 4$ ,  $1 - 2 - 4$ , and  $1 - 2 - 3 - 4$ . Suppose the algorithm selects the path  $1 - 3 - 4$  for augmentation. The residual capacity of this path is  $\delta = \min\{r_{13}, r_{34}\} = \min\{4, 5\} = 4$ . This augmentation reduces the residual capacity of arc  $(1, 3)$  to zero (thus we delete it from the residual network) and increases the residual capacity of arc  $(3, 1)$  to 4 (so we add this arc to the residual network). The augmentation also decreases the residual capacity of arc  $(3, 4)$  from 5 to 1, and increases the residual capacity of arc  $(4, 3)$  from 0 to 4. Figure 3b) shows the residual network at this stage. In the second iteration, the algorithm selects the path  $1 - 2 - 3 - 4$  and augments 1 unit of flow; Fig. 3c) shows the residual network after the augmentation. In the third iteration, the algorithm augments one unit of flow along the path  $1 - 2 - 4$ . Figure 3d) shows the corresponding residual network. Now the residual network contains no augmenting path and so the algorithm terminates.

Does the augmenting path algorithm always find a maximum flow? The algorithm terminates when the search algorithm fails to identify a directed path in  $G(x)$  from node  $s$  to node  $t$ , indicating that no such path exists (we prove later that the algorithm would terminate finitely). At this stage, let  $S$  denote the set of nodes in  $N$  that are reachable in  $G(x)$  from the source node using directed paths, and  $\bar{S} = N - S$ . Clearly,  $s \in S$  and  $t \notin \bar{S}$ . Since the search algorithm cannot reach any node in  $\bar{S}$  and it can reach each node in  $S$ , we know that  $r_{ij} = 0$  for each  $(i, j) \in (S, \bar{S})$ . Recall that  $r_{ij} = (u_{ij} - x_{ij}) + x_{ji}$ ,  $x_{ij} \leq u_{ij}$ , and  $x_{ji} \geq 0$ . If  $r_{ij} = 0$ , then  $x_{ij} = u_{ij}$  and  $x_{ji} = 0$ . Since  $r_{ij} = 0$  for each  $(i, j) \in (S, \bar{S})$ , by substituting these flow values in expression (6), we find that  $v = u[S, \bar{S}]$ . Therefore, the value of the current flow  $x$  equals the capacity of the cut. Lemma 1 implies that  $x$  is

a maximum flow and  $[S, \bar{S}]$  is a minimum cut. This conclusion establishes the correctness of the generic augmenting path algorithm and, as a byproduct, proves the following *max-flow min-cut theorem*.

**Theorem 2** *The maximum value of the flow from a source node  $s$  to a sink node  $t$  in a capacitated network equals the minimum capacity among all  $s - t$ -cuts.*

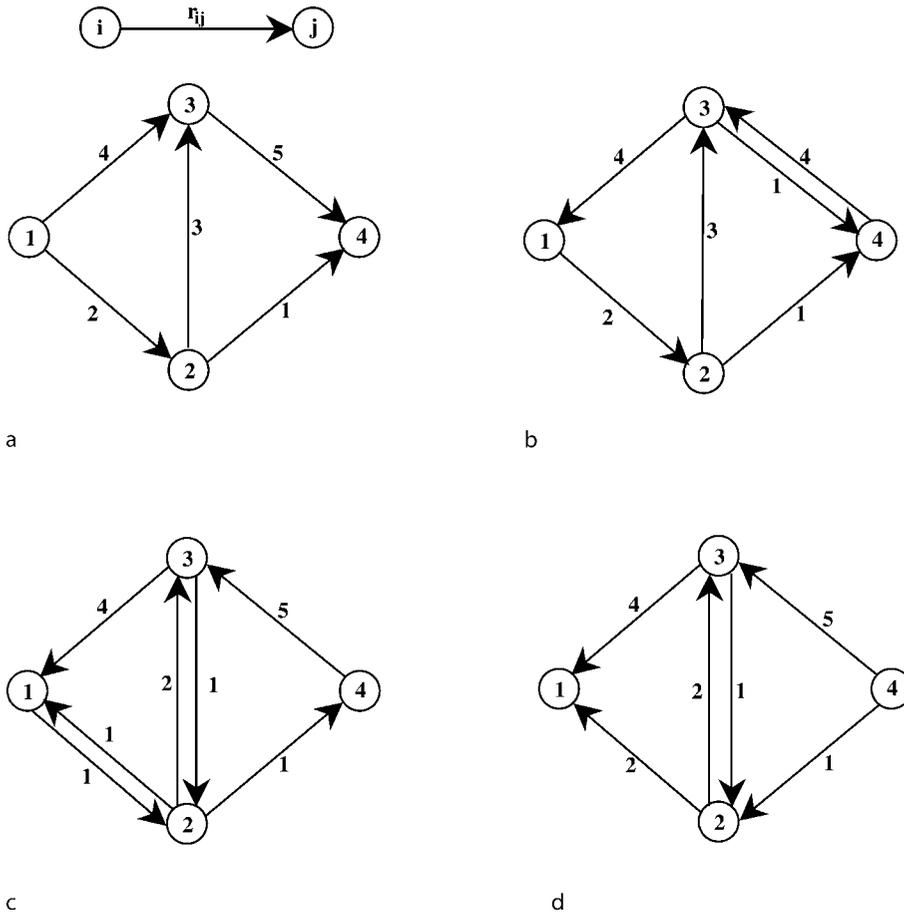

The proof of the max-flow min-cut theorem shows that when the augmenting path algorithm terminates, it also discovers a minimum cut  $[S, \bar{S}]$ , with  $S$  defined as the set of all nodes reachable from the source node in the residual network corresponding to the maximum flow. For our previous numerical example, the algorithm finds the minimum cut in the network, which is  $[S, \bar{S}]$  with  $S = \{1\}$ .

The augmenting path algorithm also establishes another important result, the *integrality theorem*:

**Theorem 3** *If all arc capacities are integer, then the maximum flow problem always has an integer maximum flow.*

This result follows from the facts that the initial (zero) flow is integer and all arc capacities are integer; consequently, all initial residual capacities will be integer. Since subsequently all arc flows change by integer amounts (because residual capacities are integer), the residual capacities remain integer throughout the algorithm. Further, the final integer residual capacities determine an integer maximum flow. The integrality theorem does not imply that every optimal solution of the maximum flow problem is integer. The maximum flow problem might have noninteger solutions and, most often, it has such solutions. The integrality theorem shows that the problem always has at least one integer optimal solution.

What is the worst-case running time of the algorithm? An augmenting path is a directed path in  $G(x)$  from node  $s$  to node  $t$ . We have seen earlier that each iteration of the algorithm requires  $O(m)$  time. In each iteration, the algorithm augments a positive integer amount of flow from the source node to the sink node. To bound the number of iterations, we will determine a bound on the maximum flow value. By definition,  $U$  denotes the largest arc capacity, and so the capacity of the cut  $(\{s\}, S - \{s\})$  is at most  $nU$ . Since the value of any

Maximum Flow Problem, Figure 3

Illustrating the augmented path algorithm: a) the residual network  $G(x)$  for  $x = 0$ ; b) the residual network after augmenting four units along the path  $(1 - 3 - 4)$ ; c) the residual network after augmenting one unit along the path  $(1 - 2 - 3 - 4)$ ; d) the residual network after augmenting one unit along the path  $(1 - 2 - 4)$

flow can never exceed the capacity of any cut in the network, we obtain a bound of  $nU$  on the maximum flow value and also on the number of iterations performed by the algorithm. Consequently, the running time of the algorithm is  $O(nmU)$ , which is a pseudopolynomial time bound. We summarize the preceding discussion with the following theorem.

**Theorem 4** *The generic augmenting path algorithm solves the maximum flow problem in  $O(nmU)$  time.*

The augmenting path algorithm is possibly the simplest algorithm for solving the maximum flow problem. Empirically, the algorithm performs reasonably well. However, the worst-case bound on the number of iterations is poor for large values of  $U$ . For example, if  $U = 2^n$ , the

bound is exponential in the number of nodes. Moreover, as shown by known examples, the algorithm can indeed perform these many iterations. A second drawback of the augmenting path algorithm is that if the capacities are irrational, the algorithm might not terminate. For some pathological instances of the maximum flow problem, the augmenting path algorithm does not terminate in a finite number of iterations and although the successive flow values converge to some value, they might converge to a value strictly less than the maximum flow value. (Note, however, that the max-flow min-cut theorem is valid even if arc capacities are irrational.) Therefore, if the augmenting path algorithm is to be guaranteed to be effective in all situations, it must select augmenting paths carefully.

Researchers have developed specific implementations of the generic augmenting path algorithms that overcome these drawbacks. Of these, the following three implementations are particularly noteworthy:

- i) the maximum capacity augmenting path algorithm which always augments flow along a path in the residual network with the maximum residual capacity and can be implemented to run in  $O(m^2 \log U)$  time;
- ii) the capacity scaling algorithm which uses a scaling technique on arc capacities and can be implemented to run in  $O(nm \log U)$  time;
- iii) the shortest augmenting path algorithm which augments flow along a shortest path (as measured by the number of arcs) in the residual network and runs in  $O(n^2m)$  time.

These algorithms are due to J. Edmonds and R.M. Karp [6], H.N. Gabow [9], and E.A. Dinic [5], respectively. L.R. Ford and D.R. Fulkerson [8] and P. Elias, A. Feinstein and C.E. Shannon [7] independently developed the basic augmenting path algorithm.

### Generic Preflow-Push Algorithm

Another class of algorithms for solving the maximum flow problem, known as *preflow-push algorithms*, is more decentralized than augmenting path algorithms. Augmenting path algorithms send flow by augmenting along a path. This basic operation further decomposes into the more elementary operation of sending flow along individual arcs. Sending a flow of  $\delta$  units along a path of  $k$  arcs decomposes into  $k$  basic operations of sending a flow of  $\delta$  units along each of the arcs of the path. We shall refer to each of these basic operations as a *push*. The preflow-push algorithms push flows on individual arcs instead of on augmenting paths.

A path augmentation has one advantage over a single push: it maintains conservation of flow at all nodes. The preflow-push algorithms violate conservation of flow at all steps except at the very end, and instead maintain a ‘preflow’ at each iteration. A *preflow* is a vector  $x$  satisfying the flow bound constraints and the following relaxation of the mass balance constraints (2):

$$\sum_{\{j: (i,j) \in A\}} x_{ij} - \sum_{\{j: (j,i) \in A\}} x_{ji} \geq 0$$

for all  $i \in N - \{s, t\}$ . (7)

Each element of a preflow vector is either a real number or equals  $+\infty$ . The preflow-push algorithms maintain a preflow at each intermediate stage. For a given preflow  $x$ , we define the excess for each node  $i \in N - \{s, t\}$  as

$$e(i) = \sum_{\{j: (j,i) \in A\}} x_{ji} - \sum_{\{j: (i,j) \in A\}} x_{ij}.$$

We refer to a node with positive excess as an active node. We adopt the convention that the source and sink nodes are never active. In a preflow-push algorithm, the presence of an active node indicates that the solution is infeasible. Consequently, the basic operation in this algorithm is to select an active node  $i$  and try to remove the excess by pushing flow out of it. When we push flow out of an active node, we need to do it carefully. If we just push flow to an adjacent node in an arbitrary manner and the other nodes do the same, then it is conceivable that some nodes keep pushing flow among themselves resulting in an infinite loop, which is not a desirable situation. Since ultimately we want to send the flow to the sink node, it seems reasonable for an active node to push flow to another node that is ‘closer’ to the sink. If all nodes maintain this rule, then the algorithm could never encounter an infinite loop. The concept of distance labels defined next allows us to implement this algorithmic strategy.

The preflow-push algorithms maintain a *distance label*  $d(i)$  with each node in the network. The distance labels are nonnegative (finite) integers defined with respect to the residual network  $G(x)$ . We say that distance labels are valid with respect to a flow  $x$  if they satisfy the following two conditions:

$$d(t) = 0, \tag{8}$$

$$d(i) \leq d(j) + 1 \quad \text{for every arc } (i, j) \text{ in the residual network } G(x). \tag{9}$$

We refer to the conditions (8) and (9) as the *validity conditions*. It is easy to demonstrate that  $d(i)$  is a lower bound on the length of any directed path (as measured by number of arcs) from node  $i$  to node  $t$  in the residual network, and thus is a lower bound on the length of the shortest path between nodes  $i$  and  $j$ . Let  $i = i_1 - \dots - i_k - t$  be any path of length  $k$  in the residual network

from node  $i$  to node  $t$ . The validity conditions (8), (9) imply that  $d(i) = d(i_1) \leq d(i_2) + 1$ ,  $d(i_2) \leq d(i_3) + 1$ ,  $\dots$ ,  $d(i_k) \leq d(t) + 1 = 1$ . Adding these inequalities shows that  $d(i) \leq k$  for any path of length  $k$  in the residual network, and therefore any (shortest) path from node  $i$  to node  $t$  contains at least  $d(i)$  arcs. We say that an arc  $(i, j)$  in the residual network is *admissible* if it satisfies the condition  $d(i) = d(j) + 1$ ; we refer to all other arcs as *inadmissible*.

The basic operation in the preflow-push algorithm is to select an active node  $i$  and try to remove the excess by pushing flow to a node with smaller distance label. (We will use the distance labels as estimates of the length of the shortest path to the sink node.) If node  $i$  has an admissible arc  $(i, j)$ , then  $d(j) = d(i) - 1$  and the algorithm sends flow on admissible arcs to relieve the node's excess. If node  $i$  has no admissible arc, then the algorithm increases the distance label of node  $i$  so that node  $i$  has an admissible arc. The algorithm terminates when the network contains no active nodes, that is, excess resides only at the source and sink nodes. The next algorithm describes the generic preflow-push algorithm.

```
BEGIN
  set  $x := 0$  and  $d(j) := 0$  for all  $j \in \mathbb{N}$ ;
  set  $x_{sj} = u_{sj}$  for each arc  $(s, j) \in A(s)$ ;
   $d(s) := n$ ;
  WHILE residual network  $G(x)$  contains an active node
  DO
    BEGIN
      select an active node  $i$ ;
      push/relabel( $i$ );
    END;
  END;
```

```
procedure push/relabel( $i$ );
BEGIN
  IF network contains an admissible arc  $(i, j)$ 
  THEN push  $\delta := \min\{e(i), r_{i,j}\}$  units of flow
  from node  $i$  to node  $j$ 
  ELSE replace  $d(i)$  by
     $\min\{d(j) + 1 : (i, j) \in A(i), r_{ij} > 0\}$ ;
END;
```

#### The generic preflow-push algorithm

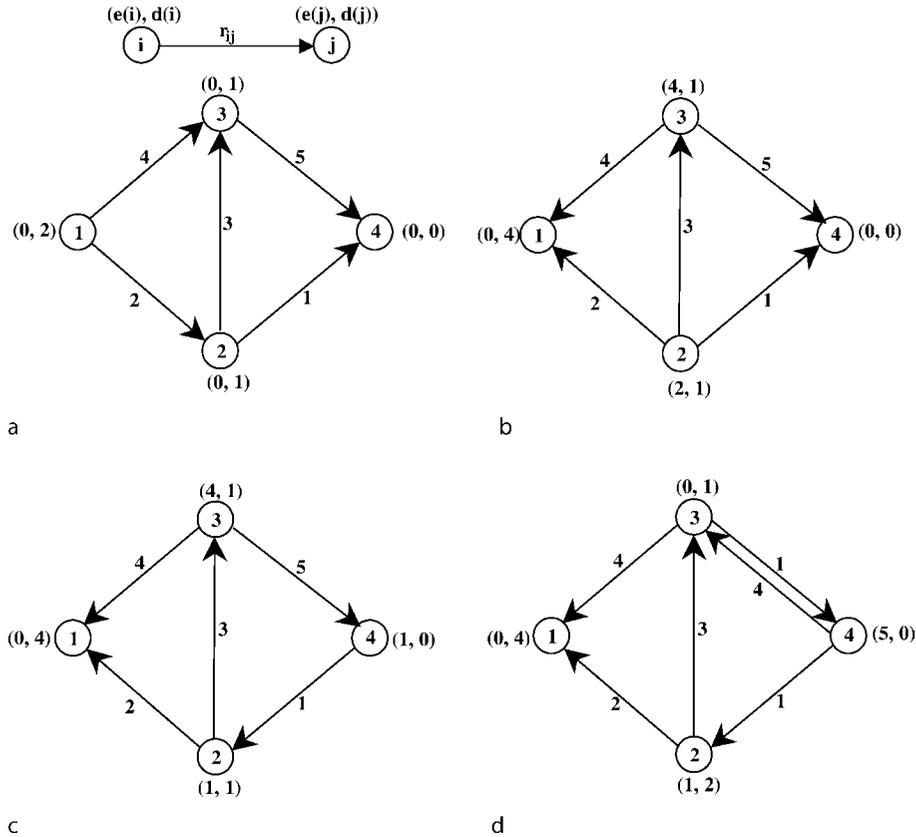

The algorithm first saturates all arcs emanating from the source node; then each node adjacent to node  $s$  has a positive excess, so that the algorithm can begin pushing flow from active nodes. Since the preprocessing operation saturates all the arcs incident to node  $s$ , none of these arcs is admissible and setting  $d(s) = n$  will satisfy the validity condition (8), (9). But then, since  $d(s) = n$ , and a distance label is a lower bound on the length of the shortest path from that node to node  $t$ , the residual network contains no directed path from  $s$  to  $t$ . The subsequent pushes maintain this property and drive the solution toward feasibility. Consequently, when there are no active nodes, the flow is a maximum flow.

A push of  $\delta$  units from node  $i$  to node  $j$  decreases both the excess  $e(i)$  of node  $i$  and the residual  $r_{ij}$  of arc  $(i, j)$  by  $\delta$  units and increases both  $e(j)$  and  $r_{ji}$  by  $\delta$  units. We say that a push of  $\delta$  units of flow on an arc  $(i, j)$  is *saturating* if  $d = r_{ij}$  and is *nonsaturating* otherwise. A nonsaturating push at node  $i$  reduces  $e(i)$  to zero. We refer to the process of increasing the distance label of a node as a *relabel* operation. The purpose of the relabel operation is to create at least one admissible arc on which the algorithm can perform further pushes.

It is instructive to visualize the generic preflow-push algorithm in terms of a physical network: arcs represent flexible water pipes, nodes represent joints, and the distance function measures how far nodes are above the ground. In this network, we wish to send water from the source to the sink. We visualize flow in an admissible arc as water flowing downhill. Initially, we move the source node upward, and water flows to its neighbors. Although we would like water to flow downhill toward the sink, occasionally flow becomes trapped locally at a node that has no downhill neighbors. At this point, we move the node upward, and again water flows downhill toward the sink.

Eventually, no more flow can reach the sink. As we continue to move nodes upward, the remaining excess flow eventually flows back toward the source. The algorithm terminates when all the water flows either into the sink or flows back to the source.

To illustrate the generic preflow-push algorithm, we use the example given in Fig 4. Figure 4a) specifies the initial residual network. We first saturate the arcs emanating from the source node, node 1, and set  $d(1) = n = 4$ . Fig 4b) shows the residual graph at this stage. At

Maximum Flow Problem, Figure 4

Illustrating the preflow-push algorithm: a) the residual network  $G(x)$  for  $x = 0$ ; b) the residual network after saturating arcs emanating from the source; c) the residual network after pushing flow on arc  $(2, 4)$ ; d) the residual network after pushing flow on arc  $(3, 4)$

this point, the network has two active nodes, nodes 2 and 3. Suppose that the algorithm selects node 2 for the push/relabel operation. Arc  $(2, 4)$  is the only admissible arc and the algorithm performs a saturating push of value  $\delta = \min \{e(2), r_{24}\} = \min\{2, 1\} = 1$ . Fig 4c) gives the residual network at this stage. Suppose the algorithm again selects node 2. Since no admissible arc emanates from node 2, the algorithm performs a relabel operation and gives node 2 a new distance label  $d(2) = \min\{d(3)+ 1, d(1)+ 1\} = \min\{2, 5\} = 2$ . The new residual network is the same as the one shown in Fig 4c) except that  $d(2) = 2$  instead of 1. Suppose this time the algorithm selects node 3. Arc  $(3, 4)$  is the only admissible arc emanating from node 3, and so the algorithm performs a nonsaturating push of value  $\delta = \min\{e(3), r_{34}\} = \min\{4, 5\} = 4$ . Fig 4d) specifies the residual network at the end of this iteration. Using this process for a few

more iterations, the algorithm will determine a maximum flow.

The analysis of the computational (worst-case) complexity of the generic preflow-push algorithm is somewhat complicated. Without examining the details, we might summarize the analysis as follows. It is possible to show that the preflow-push algorithm maintains valid distance labels at all steps of the algorithm and increases the distance label of any node at most  $2n$  times. The algorithm performs  $O(nm)$  saturating pushes and  $O(n^2m)$  nonsaturating pushes. The nonsaturating pushes are the limiting computational operation of the algorithm and so it runs in  $O(n^2m)$  time.

The preflow-push algorithm has several attractive features, particularly its flexibility and its potential for further improvements. Different rules for selecting active nodes for the push/relabel operations create many

different versions of the generic algorithm, each with different worst-case complexity. As we have noted, the bottleneck operation in the generic preflow-push algorithm is the number of nonsaturating pushes and many specific rules for examining active nodes can produce substantial reductions in the number of nonsaturating pushes. The following specific implementations of the generic preflow-push algorithms are noteworthy:

- i) the FIFO preflow-push algorithm examines the active nodes in the first-in, first-out (FIFO) order and runs in  $O(n^3)$  time;
- ii) the highest label preflow-push algorithm pushes flow from an active node with the highest value of a distance label and runs in  $O(n^2 m^{1/2})$  time; and
- iii) the excess-scaling algorithm uses the scaling of arc capacities to attain a time bound of  $O(nm + n^2 \log U)$ .

These algorithms are due to A.V. Goldberg and R.J. Tarjan [10], J. Cheriyan and S.N. Maheshwari [4], and R.K. Ahuja and J.B. Orlin [3], respectively. These preflow-push algorithms are more general, more powerful, and more flexible than augmenting path algorithms. The best preflow-push algorithms currently outperform the best augmenting path algorithms in theory as well as in practice (see, for example, [1]).

### Combinatorial Implications of the Max-Flow Min-Cut Theorem

The max-flow min-cut theorem has far reaching consequences. It can be used to prove several important results in combinatorics that appear to be difficult to prove using other means. We will illustrate the use of the max-flow min-cut theorem to prove two such important results.

#### Network Connectivity

Given a directed network  $G = (N, A)$  and two specified nodes  $s$  and  $t$ , we are interested in the following two questions:

- i) what is the maximum number of arc-disjoint (directed) paths from node  $s$  to node  $t$ ; and
- ii) what is the minimum number of arcs that we should remove from the network so that it contains no directed paths from node  $s$  to node  $t$ .

We will show that these two questions are closely related. The second question shows how robust a net-

work, for example, a telecommunications network, is to the failure of its arcs.

In the network  $G$ , let us define the capacity of each arc as equal to one. Consider any feasible flow  $x$  of value  $v$  in the resulting unit capacity network. We can decompose the flow  $x$  into flows along  $v$  directed paths from node  $s$  to node  $t$ , each path carrying a unit flow. Now consider any  $s - t$ -cut  $[S, \bar{S}]$  in the network. The capacity of this cut is  $|E(S, \bar{S})|$  that is, equals the number of forward arcs in the cut. Since each path joining nodes  $s$  and  $t$  contains at least one arc in the set  $(S, \bar{S})$ , the removal of all the arcs in  $(S, \bar{S})$  disconnects all paths from node  $s$  to node  $t$ . Consequently, the network contains a disconnecting set of arcs of cardinality equal to the capacity of any  $s - t$ -cut  $[S, \bar{S}]$ . The max-flow min-cut theorem immediately implies the following result:

**Corollary 5** *The maximum number of arc-disjoint paths from  $s$  to  $t$  in a directed network equals the minimum number of arcs whose removal will disconnect all paths from node  $s$  to node  $t$ .*

#### Matchings and Covers

The max-flow min-cut theorem also implies a max-min result concerning matchings and node covers in a directed bipartite network  $G = (N_1 \cup N_2, A)$ , with arc set  $A \subseteq N_1 \times N_2$ . In the network  $G$ , a subset  $M \subseteq A$  is a *matching* if no two arcs in  $M$  have an endpoint in common. A subset  $C \subseteq N_1 \cup N_2$  is a *node cover* of  $G$  if every arc in  $A$  has at least one endpoint in the node set  $C$ . Suppose we create the network  $G'$  from  $G$  by adding two new nodes  $s$  and  $t$ , as well as arcs  $(s, i)$  of capacity 1 for each  $i \in N_1$  and arcs  $(j, t)$  of capacity 1 for each  $j \in N_2$ . All other arcs in  $G'$  correspond to the arcs in  $G$  and have infinite capacity. It is possible to show that each matching of cardinality  $v$  defines a flow of value  $v$  in  $G'$ , and each  $s - t$  cut of capacity  $v$  induces a corresponding node cover with  $v$  nodes. Consequently, the max-flow min-cut theorem establishes the following result:

**Corollary 6** *In a bipartite network  $G = (N_1 \cup N_2, A)$ , the maximum cardinality of any matching equals the minimum cardinality of any node cover of  $G$ .*

These two examples illustrate important relationships between maximum flows, minimum cuts, and many other problems in the field of combinatorics. The maximum flow problem is of interest because it provides

a unifying tool for viewing many such results, because it arises directly in many applications, and because it has been a rich arena for developing new results concerning the design and analysis of algorithms.

### Abstract

Maximum-likelihood detection is a generic NP-hard problem in digital communications which requires efficient solution in practice. Some existing quasi-maximum-likelihood detectors achieve polynomial complexity with significant bit-error-rate performance degradation (e.g. LMMSE Detector), while others exhibit near-maximum-likelihood bit-error-rate performance with exponential complexity (e.g. Sphere Decoder and its variants). We present an efficient suboptimal detector based on a semidefinite relaxation, called SDR Detector, which enjoys near-maximum-likelihood bit-error-rate with worst-case polynomial complexity.

SDR Detector can be implemented with recently developed Interior-Point methods for convex optimization problems. For large systems SDR Detector provides a constant factor approximation for the maximum-likelihood detection problem. In high signal-to-noise ratio region SDR Detector can solve the maximum-likelihood detection problem exactly. Efficient implementations of SDR Detector empirically deliver a near-optimal bit-error-rate with running time that scales well to large problems and in any signal-to-noise ratio region.

Maximum-likelihood detection; Multiple-input multiple-output systems; Multiuser detection; Semidefinite relaxation

### Introduction

Maximum-Likelihood (ML) detection is a fundamental problem in digital communications. Under the mild assumption of equiprobable transmitted signals ML Detector achieves the best Bit-Error-Rate (BER). In general, the ML detection problem is NP-hard due to the discrete nature of a signal constellation. The exhaustive search can be applied for small problem sizes, however this strategy is not practical for large systems. Large communication systems often arise in schemes with efficient rate and diversity utilization, e.g. the systems based on Linear Dispersion Codes [6]. Various suboptimal detectors that have been developed to approximate ML Detector can be divided into two major categories:

- Accelerated versions of ML Detector with exponential complexity (e.g. versions of Sphere Decoder [3,16]),
- Polynomial complexity detectors with significant degradation in the BER performance (e.g. Linear Minimum Mean Square Error (LMMSE) Detector, Matched Filter, Decorrelator, etc.).

We focus on an alternative detector which is based on a semidefinite relaxation of the ML detection problem. This detector, called SDR Detector hereafter, enjoys a worst-case polynomial complexity while delivering a near-optimal BER performance. In the next subsection we will introduce notations and a system model used throughout the text.

### Formulation

#### System Model

Consider a vector communication channel with  $n$  transmit and  $m$  receive antennas. In wireless communications a Rayleigh fading model is widely used in scenarios with significantly attenuated line-of-sight signal component. An abundant research is based on this model which is used in profound theoretical results on channel capacity, diversity and multiplexing gain. Define a fading coefficient from the  $i$ th transmit antenna to the  $k$ th receive antenna to be a Gaussian zero-mean unit-variance,  $\mathcal{N}(0, 1)$ , variable  $H_{ki}$ , with a Rayleigh distributed amplitude  $|H_{ki}|$  and a uniformly distributed phase  $\phi(H_{ki})$ . The coefficients  $H_{ki}$  are assumed to be spatially and temporarily independent and identically distributed (i.i.d.). The transmitted signals  $\mathbf{s} = [s_1, \dots, s_n]^T$  are drawn from a discrete  $n$ -dimensional complex set  $C^n$ . The communication system is operating at an average Signal-to-Noise Ratio (SNR) denoted by  $\rho$ . Noise samples at each receive antenna,  $v_k, k = 1, \dots, m$ , are modelled as i.i.d.  $\mathcal{N}(0, 1)$  random variables. With these notations a Rayleigh memoryless vector channel can be represented by:

$$\mathbf{y} = \sqrt{\rho/n} \mathbf{H} \mathbf{s} + \mathbf{v}. \quad (1)$$

The coefficient  $\sqrt{\rho/n}$  ensures that the expected value of SNR at each receive antenna is equal to  $\rho$  independent of problem dimension  $n$ . Channel model (1) is quite generic and can be used to describe other communication systems, for example, a synchronous CDMA multi-access channel, where  $n$  denotes the number of users in the system.

In the sequel, we will assume that the receiver has perfect information of the fading matrix  $\mathbf{H}$ . In practice  $\mathbf{H}$  is estimated by sending training signals which are known to the receiver. Given the vector of received signals  $\mathbf{y}$  and the channel state  $\mathbf{H}$ , the optimal detector computes an estimate of transmitted signals such that the probability of an erroneous decision is minimized. For equiprobable input signals the minimal error probability is achieved by ML Detector given by:

$$\mathbf{s}_{\text{ML}} = \arg \max_{\mathbf{s} \in C^n} p(\mathbf{y}|\mathbf{s}, \mathbf{H}),$$

where  $p(\cdot|\cdot)$  is a conditional probability density function and  $\mathbf{s}_{\text{ML}}$  denotes the ML estimate of transmitted

signals. For Gaussian noise this optimization problem can be stated in the form of the Integer Least Squares (ILS) problem:

$$\mathbf{s}_{\text{ML}} = \arg \min_{\mathbf{s} \in C^n} \|\mathbf{y} - \sqrt{\rho/n} \mathbf{H} \mathbf{s}\|^2. \quad (2)$$

In general, this optimization problem is NP-hard and the discrete constraint set  $C^n$  of dimension  $n$  is the source of intractability. We are interested in an efficient polynomial time approximation algorithm for (2) with theoretical performance guarantees. In the next section we will briefly discuss common approaches to solving problem (2).

### Connection with Unconstrained Optimization

Several strategies have been developed to overcome high computational complexity of ML Detector. Some detectors achieve polynomial complexity by relaxing the integer constraint in the ML detection problem (2), e. g. LMMSE Detector, Decorrelator, and Matched Filter [5]. From the perspective of optimization theory these detectors can be jointly treated by dropping the discrete constraint in (2) and imposing a penalty function instead. For the BPSK constellation the relaxed problem can be written as:

$$\hat{\mathbf{s}} = \arg \min_{\mathbf{s} \in \mathbb{R}^n} \|\mathbf{y} - \sqrt{\rho/n} \mathbf{H} \mathbf{s}\|^2 + \gamma \|\mathbf{s}\|^2. \quad (3)$$

The modified optimization problem is usually followed by a rounding procedure which projects the optimal solution of the relaxed problem onto set  $C^n$ . Selecting proper values for  $\gamma$ , we can specialize (3) to LMMSE Detector, Decorrelator, or Matched Filter. An appealing advantage of this approach is that it can be solved analytically:

$$\hat{\mathbf{s}} = \text{sign} \left( \left( \frac{\rho}{n} \mathbf{H}^T \mathbf{H} + \gamma \mathbf{I} \right)^{-1} \mathbf{H}^T \mathbf{y} \right). \quad (4)$$

This strategy achieves complexity  $\mathcal{O}(n^3)$  while sacrificing the BER performance.

Another type of detectors preserves the near-ML BER while reducing the high complexity of the exhaustive search. The work originates in [3,16] with the algorithm to find the shortest vector on a lattice, known as the so-called Sphere Decoder. The algorithm reduces the exhaustive search to an ellipse centered at the zero-forcing estimate of the transmitted signals:

$$\mathbf{s}_{ZF} = \sqrt{n/\rho} (\mathbf{H}^T \mathbf{H})^{-1} \mathbf{H}^T \mathbf{y}.$$

Different variants of this approach use various intelligent strategies of the radius selection and ordering of points to be searched inside the ellipse. In high SNR region for small problem sizes Sphere Decoder empirically demonstrates fast running time [7]. However, a thorough theoretical analysis [9,10] has shown that both the worst-case and expected complexity of this algorithm is still exponential.

### Semidefinite Relaxation Strategy

We consider an alternative approach to solve (2) which is based on a convex relaxation of the ML detection problem. Convexity of an optimization problem is a good indicator of problem tractability. Efficient and powerful algorithms with complexity  $\mathcal{O}(n^{3.5})$  have recently been developed to solve convex optimization problems (e. g. Interior-Point methods). These algorithms make efficient use of theoretically computable stopping criteria, enjoy robustness, and offer the certificate of infeasibility when no solution exists. All these properties render convex optimization methods a primary tool for various fields of engineering.

There are several generic types of convex problems, the simplest one being a Linear Program (LP), i. e. the optimization problem with a linear objective function and linear constraints. An LP allows natural generalization of the notion of an inequality constraint to a so-called Linear Matrix Inequality (LMI). Instead of the regular componentwise meaning of the inequality in LP, LMI  $\mathbf{X} \succeq 0$  implies that  $\mathbf{X}$  belongs to the cone of symmetric positive semidefinite matrices, i. e. all eigenvalues of  $\mathbf{X}$  are non-negative. Such generalization leads us to a generic class of Semi-Definite Programs (SDP), which can be written in the standard form as follows:

$$\begin{aligned} \min \quad & \mathbf{Q} \bullet \mathbf{X} \\ \text{s.t.} \quad & \mathbf{A}_k \bullet \mathbf{X} = b_k, \quad k = 1, \dots, K, \\ & \mathbf{X} \succeq 0, \end{aligned} \quad (5)$$

where  $(\bullet)$  denotes inner product in the matrix space:  $\mathbf{Q} \bullet \mathbf{X} = \text{Tr}(\mathbf{Q}\mathbf{X})$ . The class of SDP problems (5) includes Linear Programs as well as Second Order Cone Programs as special cases. It is quite remarkable that any problem (5) in the broad class of SDP problems can be solved in polynomial time, which makes it a valuable asset for solving engineering problems, includ-

ing filter design, control, VLSI circuit layout design, etc. [2].

In addition to application in numerical solvers, SDP formulation (5) is widely used for analysis and design of approximation algorithms for NP-hard problems. Traditional approaches involve relaxation of an NP-hard problem to an LP, which can be easily solved in polynomial time. With the invent of Interior-Point methods for non-linear convex optimization problems some approximation algorithms have been significantly improved [4]. Such advanced non-linear approximation algorithms use weaker relaxations, thereby preserving most of the structure of the original NP-hard problem. The class of SDP problems represents a perfect candidate for design of approximation algorithms since the SDP form is quite generic. The solution to the original NP-hard problem is generated from the solution of the relaxed SDP problem by a randomized or deterministic rounding procedure. For example, as will be shown later, the ML detection problem can be formulated as

$$\begin{aligned} f_{\text{ML}} := \min \quad & \mathbf{Q} \bullet \mathbf{X} \\ \text{s.t.} \quad & X_{i,i} = 1, \quad i = 1, \dots, n+1 \\ & \mathbf{X} \succeq 0 \\ & \mathbf{X} \text{ is rank-1.} \end{aligned} \quad (6)$$

Relaxing the rank constraint of  $\mathbf{X}$  reduces the problem to the standard SDP form (5):

$$\begin{aligned} f_{\text{SDP}} := \min \quad & \mathbf{Q} \bullet \mathbf{X} \\ \text{s.t.} \quad & X_{i,i} = 1, \quad i = 1, \dots, n+1 \\ & \mathbf{X} \succeq 0. \end{aligned} \quad (7)$$

A subsequent rounding procedure generates an estimate of the transmitted signals with an objective value denoted  $f_{\text{SDR}}$  based on the optimal solution  $\mathbf{X}_{\text{opt}}$  of this SDP problem.

Since SDR Detector outputs an estimate that belongs to the feasible set of the ML detection problem, the optimal objective value  $f_{\text{SDR}}$  of SDR Detector satisfies  $f_{\text{ML}} \leq f_{\text{SDR}}$ . Let  $f_{\text{opt}}$  ( $f_{\text{apr}}$ ) denote the optimal objective value of an NP-hard problem (approximation algorithm) in minimization form, then the approximation algorithm with ratio  $c \geq 1$  guarantees to provide a solution with objective value  $f_{\text{apr}}$  such that  $f_{\text{apr}} \leq c f_{\text{opt}}$ . The quality of SDR Detector can be measured in terms

of approximation ratio  $c$  such that:

$$f_{\text{ML}} \leq f_{\text{SDR}} \leq c f_{\text{ML}}, \quad c \geq 1,$$

where  $c$  is independent of problem size.

Relaxation (5) was first applied to combinatorial optimization in [4] where the authors relaxed MAX-CUT problem to an SDP problem in the standard form (5). This strategy resulted in a substantial improvement of the approximation ratio for MAX-CUT problem, as compared to the classical relaxation to an LP. Unfortunately, we can not pursue this approach because the ML detection problem involves minimization instead of maximization (for a positive semidefinite matrix  $\mathbf{Q}$ ) used in the formulation of MAX-CUT problem. Moreover, the ML detection problem does not allow a constant factor approximation algorithm for the worst case realizations of  $\mathbf{H}$  and  $\mathbf{v}$ . However, from the perspective of digital communications we are interested in the average performance of SDR Detector over many channel and noise realizations. It turns out that SDR Detector allows a probabilistic approximation ratio for the random channel model (1). In high SNR region a typical behavior of the detection error probability is

$$P_e \simeq e^{-\gamma(\rho)},$$

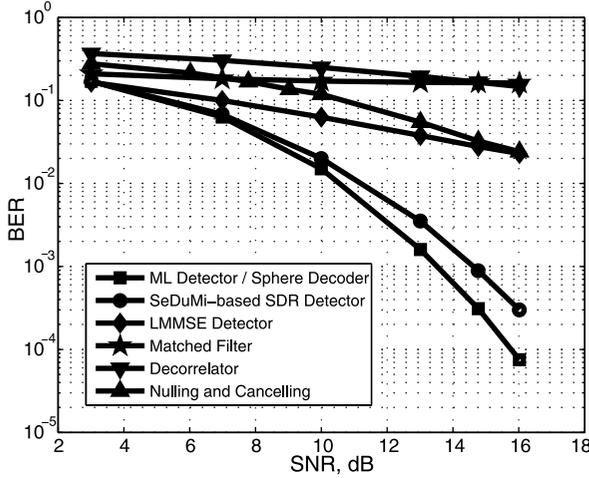

where function  $\gamma(\rho)$  varies for different detectors. For example,  $\gamma_{\text{ml}}(\rho) = \mathcal{O}(\rho)$  for ML Detector, and  $\gamma_{\text{lmmse}}(\rho) = \mathcal{O}(\sqrt{\rho})$  for LMMSE Detector [5]. When a suboptimal detector is deployed instead of ML Detector, the incurred BER deterioration can be expressed in terms of the log-likelihood ratio:

$$\frac{\log(P_e(\text{sdr}))}{\log(P_e(\text{ml}))} = \frac{\gamma_{\text{sdr}}(\rho)}{\gamma_{\text{ml}}(\rho)} \leq c(\rho).$$

Therefore, the approximation ratio  $c(\rho)$  is an essential step in bounding the SNR gap between two detectors. Before we proceed with the probabilistic analysis of the performance, let us consider the empirical BER performance of SDR Detector in numerical simulations for channel model (1).

### Bit-Error-Rate Performance

The detector based on a semidefinite relaxation (SDR) consists of two parts: a solver of relaxation (7) and a randomized rounding procedure. The SDP in (7) can

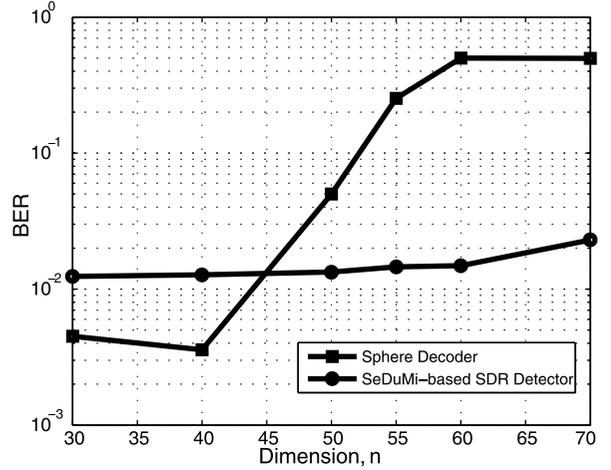

Maximum Likelihood Detection via Semidefinite Programming, Figure 1

Bit-Error-Rate as a function of Signal-to-Noise Ratio for different detectors

be efficiently solved using Interior Point (IP) methods with complexity  $\mathcal{O}(n^{3.5})$ . For this purpose we use SeDuMi optimization toolbox for Matlab. The randomized rounding procedure projects the solution of the SDP (7) onto the original discrete constraint set and will be discussed in details in the next section.

Figure 1 shows a comparison of the BER performance of the SeDuMi-based SDR Detector [13], LMMSE Detector, Matched Filter, Decorrelator, Nulling and Cancelling strategy, Sphere Decoder, and ML Detector. We observe a significant BER improvement of SDR Detector compared to other polynomial complexity detectors. Sphere Decoder with adjustable radius search [16] delivers the BER performance of ML Detector (with probability 1) with running time that scales exponentially [9] with problem size.

In many real-time/embedded applications a detection latency is upper bounded and, in general, premature decisions cause significant BER degradation. For simulation purposes we suppose that an engineering system is designed with BPSK modulation, operates at SNR = 10 dB and allows 6.3 ms per bit detection latency. Figure 2 demonstrates the BER performance of this system under the upper bound on the detection latency. The exponential complexity of Sphere Decoder reveals itself between dimensions 40 and 60 where we observe a rapid BER degradation because the running time of Sphere Decoder exceeds the fixed detection time

Maximum Likelihood Detection via Semidefinite Programming, Figure 2

BER degradation due to the limit on detection time. Simulation parameters: BPSK modulation, SNR = 10 dB and time limit per bit = 6.3 ms

threshold for most channel realizations. At the same time, the running time of SDR Detector scales gracefully with problem size and, in most cases, the detector completes detection in time. As a result, SDR Detector does not suffer any significant BER degradation even for large problem sizes. In fact, the number of late detections for SDR Detector does not exceed 1% for all dimensions shown in Fig. 2. For different values of SNR and latency per bit we obtain essentially similar curves for both detectors. Such behavior is indicative of the exponentially growing computational effort of Sphere Decoder and comparably modest computational power required by SDR Detector.

In the next section we will discuss the details of the SDP relaxation (11) and the randomized rounding procedure. After that we present theoretical guarantees that substantiate the observed empirical behavior of SDR Detector.

## Method

SDR Detector consists of two components: an SDP solver and a randomized rounding procedure.

### SDP Solver

A transformation of the original ML detection problem (2) into the standard SDP form (5) will help

us localize the place in (2) that makes the problem NP-hard. We start with homogenizing the objective function:

$$\begin{aligned} & \|\mathbf{y} - \sqrt{\rho/n} \mathbf{H}\mathbf{s}\|^2 \\ &= [\mathbf{s} \ 1]^T \begin{bmatrix} (\rho/n) \mathbf{H}^T \mathbf{H} & -\sqrt{\rho/n} \mathbf{H}^T \mathbf{y} \\ -\sqrt{\rho/n} \mathbf{y}^T \mathbf{H} & \|\mathbf{y}\|^2 \end{bmatrix} \begin{bmatrix} \mathbf{s} \\ 1 \end{bmatrix} \\ &= \rho \operatorname{Tr}(\mathbf{Q}\mathbf{x}\mathbf{x}^T), \end{aligned}$$

where matrix  $\mathbf{Q} \in \mathbb{R}^{(n+1) \times (n+1)}$  and vector  $\mathbf{x} \in \mathbb{R}^{n+1}$  are defined as

$$\mathbf{Q} = \begin{bmatrix} (1/n) \mathbf{H}^T \mathbf{H} & -\sqrt{1/n\rho} \mathbf{H}^T \mathbf{y} \\ -\sqrt{1/n\rho} \mathbf{y}^T \mathbf{H} & \|\mathbf{y}\|^2/\rho \end{bmatrix}, \mathbf{x} = \begin{bmatrix} \mathbf{s} \\ 1 \end{bmatrix} \quad (8)$$

Notice, that matrix  $\mathbf{Q}$  is composed of the parameters that are known at the receiver. We linearize the objective function by introducing a variable matrix  $\mathbf{X}$  to comply with the standard SDP form (5):

$$\begin{aligned} f_{\text{ML}} &:= \min \operatorname{Tr}(\mathbf{Q}\mathbf{X}) \\ \text{s.t.} \quad & \mathbf{X} = \mathbf{x}\mathbf{x}^T \\ & X_{i,i} = 1, \quad i = 1, \dots, n+1. \end{aligned} \quad (9)$$

In this problem formulation we discarded constraint  $x_{n+1} = 1$  on the last entry of vector  $\mathbf{x}$  because the problem is not sensitive to the sign of vector  $\mathbf{x}$ . If  $\hat{x}_{n+1} = -1$  we output  $-\hat{\mathbf{x}}$  as the solution to (9). Constraint  $\mathbf{X} = \mathbf{x}\mathbf{x}^T$  is equivalent to the set  $\{\mathbf{X} \succeq 0, \operatorname{rank}(\mathbf{X}) = 1\}$ , where notation  $\mathbf{X} \succeq 0$  implies that matrix  $\mathbf{X}$  is symmetric positive semidefinite. Thus, we complete the transformation of the original ML Detection problem over BPSK constellation to the equivalent form stated in (6):

$$\begin{aligned} f_{\text{ML}} &:= \min \operatorname{Tr}(\mathbf{Q}\mathbf{X}) \\ \text{s.t.} \quad & X_{i,i} = 1, \quad i = 1, \dots, n+1 \\ & \mathbf{X} \succeq 0 \\ & \mathbf{X} \text{ is rank-1.} \end{aligned} \quad (10)$$

The rank-1 constraint is the only non-convex constraint in (10) which makes the above problem intractable. SDR Detector relaxes the rank constraint and solves the following convex optimization problem:

$$\begin{aligned} f_{\text{SDP}} &:= \min \operatorname{Tr}(\mathbf{Q}\mathbf{X}) \\ \text{s.t.} \quad & X_{i,i} = 1, \quad i = 1, \dots, n+1 \\ & \mathbf{X} \succeq 0. \end{aligned} \quad (11)$$

To reveal the difference between this relaxation and the one in (3) we can take one step further by relaxing the set of constraints  $\{X_{i,i} = 1, i = 1, \dots, n+1\}$  into  $\{\operatorname{Tr}(\mathbf{X}) = n+1\}$  while keeping constraint  $\mathbf{X} \succeq 0$  intact. This extra relaxed problem can be solved analytically and leads to the solution

$$\hat{\mathbf{s}} = \frac{\rho}{n} \left( \frac{\rho}{n} \mathbf{H}^T \mathbf{H} \right)^{-1} \mathbf{H}^T \mathbf{y},$$

which is exactly the soft output of Decorrelator (4) with  $\gamma = 0$ . The relaxation in (11) compares favorably to the relaxations in (3) because it requires less modifications of the ML problem, although complexity  $\mathcal{O}(n^{3.5})$  of (11) is higher than  $\mathcal{O}(n^3)$  for the detectors in (3).

Since we dropped the rank constraint in (11), a solution  $\mathbf{X}_{\text{opt}}$  of (11) is no longer rank-1, hence, we need to project  $\mathbf{X}_{\text{opt}}$  onto the feasible set of the original ML detection problem. Such projection is usually done by a rounding procedure which can be either deterministic like in (4) or randomized [13]. It can also vary depending on the processing power available for the algorithm. In the next section we will consider a randomized rounding procedure based on the principal eigenvector of matrix  $\mathbf{X}_{\text{opt}}$ .

### Randomized Rounding Procedure

There are various rounding procedures that can be used to extract a rank-1 approximation of  $\mathbf{X}_{\text{opt}}$ . Widely used approaches and their analysis can be found in [4,13,14]. For our purposes we consider the randomized strategy based on the principal eigenvector of matrix  $\mathbf{X}_{\text{opt}}$ . Notice that in the noise-free case, we have  $\mathbf{v} = \mathbf{0}$  and a transmitted vector  $\mathbf{s}$  belongs to the kernel of matrix  $\mathbf{Q}$  which is defined in (8). The optimal objective function is 0 and is achieved by the vector of transmitted signals  $\mathbf{s}$ . Thus, in the noise-free case, the optimal solution of problem (11) is a rank-1 matrix:

$$\mathbf{X}_{\text{opt}} = \begin{bmatrix} \mathbf{s} \\ 1 \end{bmatrix} [\mathbf{s}^T \ 1].$$

The structure of the optimal matrix  $\mathbf{X}_{\text{opt}}$  in the noise-free case suggests that the principal component of the eigen-decomposition contains most reliable information on the transmitted signals in high SNR region. It turns out that the optimal matrix  $\mathbf{X}_{\text{opt}}$  has a strong

principal component even in low SNR region, justifying the randomized rounding procedure presented below:

- *INPUT*: Solution  $\mathbf{X}_{\text{opt}}$  of (11), and number  $D$  of randomized rounding tries.
- *OUTPUT*: Quasi-ML estimate  $\mathbf{s}_{\text{SDR}}$  and the best achieved objective value  $f_{\text{SDR}}$ .
- *RANDOMIZED ROUNDING PROCEDURE*:

1. Take a spectral decomposition  $\mathbf{X}_{\text{opt}} = \sum_{i=1}^{n+1} \lambda_i \mathbf{u}_i \mathbf{u}_i^T$  and set  $\mathbf{v}_i = \sqrt{\lambda_i} \mathbf{u}_i$ ,  $i = 1, \dots, n+1$ .
2. Pick  $\mathbf{v}_i$  corresponding to the principal eigenvector  $\mathbf{v}^{\text{max}} = \arg \max_{1 \leq i \leq n+1} \{\|\mathbf{v}_i\|\}$ .
3. For each entry  $x_i$  define Bernoulli distribution:

$$\begin{aligned} \Pr\{x_i = +1\} &= (1 + v_i^{\text{max}})/2, \\ \Pr\{x_i = -1\} &= (1 - v_i^{\text{max}})/2, \end{aligned} \quad (12)$$

where  $v_i^{\text{max}}$  denotes the  $i$ th entry of vector  $\mathbf{v}^{\text{max}}$ .

4. Generate a fixed number  $D$  of i.i.d.  $(n+1)$ -dimensional vector samples  $\tilde{\mathbf{x}}_d$ ,  $d = 1, \dots, D$ , such that each entry of  $(\tilde{\mathbf{x}}_d)_i$ ,  $i = 1, \dots, n+1$ , is drawn from distribution (12).
5. For all  $D$  samples, set  $\bar{\mathbf{x}}_d := -\tilde{\mathbf{x}}_d$  if  $(n+1)$ -st entry of  $\tilde{\mathbf{x}}_d$  is equal to  $-1$ .
6. Pick  $\mathbf{x}_{\text{SDR}} := \arg \min_d \tilde{\mathbf{x}}_d^T \mathbf{Q} \tilde{\mathbf{x}}_d$  and set the best achieved objective value  $f_{\text{SDR}} := \mathbf{x}_{\text{SDR}}^T \mathbf{Q} \mathbf{x}_{\text{SDR}}$ .
7. Return  $f_{\text{SDR}}$  and  $\mathbf{s}_{\text{SDR}}$  which is given by vector  $\mathbf{x}_{\text{SDR}}$  with the last bit discarded.

This randomized rounding procedure is designed to ensure that output  $\mathbf{s}_{\text{SDR}}$  is equal to the vector of transmitted signals with high probability. Whenever there is an error, the procedure selects  $\mathbf{s}_{\text{SDR}}$  to reduce the number of bits in error.

## Cases

### Performance of SDR Detector

**Constant Factor Optimality of SDR Detector** The core component of SDR Detector is an approximation algorithm based on the convex relaxation (11) of the original ML detection problem. In this section we analyze the approximation ratio of this algorithm.

A technique pioneered in [4] is widely used in optimization literature to derive a constant factor optimality for SDP-based relaxations. After the optimal solution  $\mathbf{X}_{\text{opt}}$  of problem (11) has been obtained

the randomized rounding procedure used in [4] defines Gaussian distribution  $\mathcal{N}(\mathbf{0}, \mathbf{X}_{\text{opt}})$  (compare with (12)) and implements the  $n$ -dimensional  $\text{sign}(\cdot)$  operator with uniformly generated cutting hyperplanes:

- Generate  $D$  i.i.d. samples  $\tilde{\mathbf{x}}_1, \dots, \tilde{\mathbf{x}}_D$  from Gaussian distribution  $\mathcal{N}(\mathbf{0}, \mathbf{X}_{\text{opt}})$ .
- Let  $\mathbf{x}_i = \text{sign}(\tilde{\mathbf{x}}_i)$  and set the solution  $\mathbf{x}_{\text{SDR}}$  that achieves minimum:

$$f_{\text{SDR}} := \mathbf{x}_{\text{SDR}}^T \mathbf{Q} \mathbf{x}_{\text{SDR}} = \min_i \mathbf{x}_i^T \mathbf{Q} \mathbf{x}_i .$$

The best objective value  $f_{\text{SDR}}$  achieved with this randomized rounding procedure can be upper bounded as follows [4]:

$$\begin{aligned} E\{f_{\text{SDR}}\} &= E\{\mathbf{x}_{\text{SDR}}^T \mathbf{Q} \mathbf{x}_{\text{SDR}}\} \\ &\leq^P E\{\mathbf{x}_i^T \mathbf{Q} \mathbf{x}_i\} \\ &= \text{Tr}(\mathbf{Q} E\{\mathbf{x}_i \mathbf{x}_i^T\}) \\ &= \frac{2}{\pi} \text{Tr}(\mathbf{Q} \arcsin(\mathbf{X}_{\text{opt}})) , \end{aligned} \quad (13)$$

where the inequality above holds in probability for sufficiently many samples  $D$ , and the last equality follows from that fact that for any scalar random samples  $\tilde{x}_i$  and  $\tilde{x}_j$  drawn from  $\mathcal{N}(0, 1)$  we have:

$$E\{\text{sign}(\tilde{x}_i) \text{sign}(\tilde{x}_j)\} = \frac{2}{\pi} \arcsin(E\{\tilde{x}_i \tilde{x}_j\}) .$$

By taking Taylor expansion of  $\arcsin(\mathbf{Y})$ , we can see that for any matrix  $\mathbf{Y}$ , such that  $\mathbf{Y} \succeq 0$ ,  $Y_{ii} = 1$  the following inequality holds:

$$\arcsin(\mathbf{Y}) \succeq \mathbf{Y} . \quad (14)$$

Suppose that  $\mathbf{Q} \preceq 0$ , then we have the following upper bound:

$$\text{Tr}(\mathbf{Q} \arcsin(\mathbf{X}_{\text{opt}})) \leq \text{Tr}(\mathbf{Q} \mathbf{X}_{\text{opt}}) , \quad (15)$$

which allows us to bound  $f_{\text{SDR}}$  as a constant factor away from  $f_{\text{ML}}$ :

$$\begin{aligned} f_{\text{ML}} &\leq E\{f_{\text{SDR}}\} \leq^P \frac{2}{\pi} \text{Tr}(\mathbf{Q} \mathbf{X}_{\text{opt}}) \\ &= \frac{2}{\pi} f_{\text{SDP}} \leq \frac{2}{\pi} f_{\text{ML}} , \end{aligned}$$

where the first inequality holds because an output of SDR Detector belongs to the feasible set of the ML problem (10), the second inequality follows from (13)

combined with (15), the third equality is the definition of  $f_{SDP}$ , and the last inequality holds because the SDP problem (11) is a relaxation of the ML problem (10). Therefore, given  $\mathbf{Q} \succeq 0$ , we obtain a  $2/\pi$ -approximation ratio for the algorithm. Unfortunately, for ML detection problem the reverse inequality takes place (8):

$$\mathbf{Q} = \begin{bmatrix} (1/n) \mathbf{H}^T \mathbf{H} & -\sqrt{1/n\rho} \mathbf{H}^T \mathbf{y} \\ -\sqrt{1/n\rho} \mathbf{y}^T \mathbf{H} & \|\mathbf{y}\|^2/\rho \end{bmatrix} \succeq 0.$$

We can attempt to cure the problem with inequality similar to (14) in the reverse direction for some constant  $c$ :

$$\arcsin(\mathbf{Y}) \leq c\mathbf{Y}, \text{ for all } \mathbf{Y} \succeq 0, \text{ with } Y_{ii} = 1.$$

For this inequality to hold,  $c$  must be growing linearly with problem dimension  $n$ . Hence, in the limit  $n \rightarrow \infty$  the constant  $c$  together with the approximation ratio of the algorithm grow unbounded. That is, we can not obtain a constant factor approximation by applying the standard technique of [4] to the analysis of the SDP relaxation in (11).

The technique presented above applies to any negative semidefinite matrix  $\mathbf{Q}$ , hence, in the context of suboptimal detection it attempts to obtain a constant factor optimality for the worst-case channel realization. However, from the perspective of digital communications, we are interested in the average performance of SDR Detector over many channel realizations. Unlike the technique we have discussed above, a probabilistic analysis of Karush–Kuhn–Tucker (KKT) optimality conditions of the semidefinite problem (11) allows us to claim a constant factor optimality for SDR Detector in probability [11].

The optimal objective value  $f_{SDR}$  achieved by SDR Detector is within a constant factor  $c(\rho, \gamma)$  away from the optimal ML objective value in probability:

$$\lim_{\substack{n, m \rightarrow \infty \\ m/n \rightarrow \gamma \geq 1}} P \left\{ \frac{f_{SDR}}{f_{ML}} \leq c(\rho, \gamma) \right\} = 1, \quad (16)$$

$$\text{where } c(\rho, \gamma) = 1 + \frac{2(1 + \sqrt{\gamma})^2 \beta}{\gamma \rho^\alpha - 1},$$

and  $\{\alpha, \beta\}$  are given by

$$\alpha = \begin{cases} \frac{1}{3}, & \text{if } \gamma = 1 \\ \frac{1}{2}, & \text{if } \gamma > 1 \end{cases} \quad \beta = \begin{cases} 4\sqrt[3]{4}, & \text{if } \gamma = 1 \\ 4\sqrt{\frac{\gamma}{\gamma-1}}, & \text{if } \gamma > 1 \end{cases}$$

The statement implies that the log-likelihood ratio of SDR and ML Detectors is bounded in probability by a constant which is fully specified by SNR only.

### Performance of SDR Detector in High SNR Region

We have argued in Sect. “Randomized Rounding Procedure” that the selected randomized rounding procedure provides the optimal solution in the noise-free case. The optimality condition can be extended to the case of large finite SNR: for sufficiently high SNR SDR Detector solves ML detection problem in polynomial time.

For given system dimension  $n$  and SNR  $\rho$  (both finite), the solution  $\mathbf{X}_{\text{opt}}$  of the relaxed problem (11) is rank-1 if channel matrix  $\mathbf{H}$  and noise  $\mathbf{v}$  realizations satisfy:

$$\lambda_{\min}(\mathbf{H}^T \mathbf{H}) > \sqrt{\frac{n}{\rho}} \|\mathbf{H}^T \mathbf{v}\|_1. \quad (18)$$

Since random matrix  $\mathbf{H}^T \mathbf{H}$  is full rank with probability 1, this claim can also be interpreted as follows: for any given  $n$  there exists a sufficiently high (finite) SNR level such that (18) holds and  $\mathbf{X}_{\text{opt}}$  is rank-1. In general, if (18) does not hold  $\mathbf{X}_{\text{opt}}$  may still be rank-1. Notice that if condition (18) is satisfied the solution of the SDP problem (11) belongs to the feasible set of (10), thus,  $\mathbf{X}_{\text{opt}}$  is also the solution of the ML detection problem. Hence, under the specified conditions SDR Detector solves the original ML detection problem.

The asymptotic performance of SDR Detector for fixed problem size and  $\rho \rightarrow \infty$  has been analyzed in [8], where it is shown that for Rayleigh fading  $\mathbf{H}$  SDR Detector achieves maximum diversity, i. e.

$$\lim_{\rho \rightarrow \infty} \frac{\log P\{\mathbf{s}_{\text{sdr}} \neq \mathbf{s}\}}{\log \rho} = \lim_{\rho \rightarrow \infty} \frac{\log P\{\mathbf{s}_{\text{ml}} \neq \mathbf{s}\}}{\log \rho} = -\frac{n}{2}.$$

### Simulation Results

In this section we compare the running time and the BER performance of various implementations of the detectors based on the semidefinite relaxation (11) and that of Sphere Decoder:

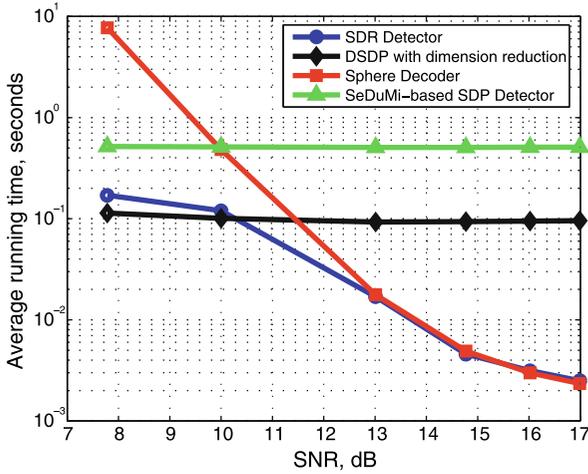

- SDP detector [13] implemented with SeDuMi toolbox [15] for convex optimization problems.
- SDR Detector that is based on a dual-scaling interior-point method (DSDP implementation [1]) and a dimension reduction strategy [12].

- SDR Detector [12], implemented with a dual-scaling interior-point method, a dimension reduction strategy, and warm start with a truncated version of Sphere Decoder.
- Sphere Decoder [16].

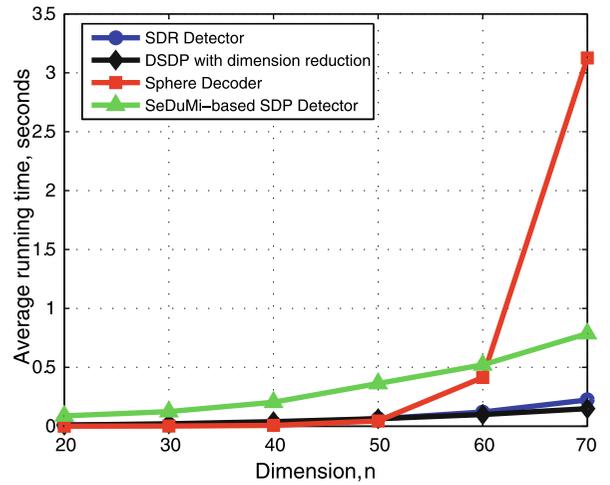

Figures 3 and 4 demonstrate the average running time and the BER performance achieved by the above detectors for problem size  $n = 60$ . Notice, the running time of DSDP-based (SeDuMi-based) detector is insensitive to SNR, and the BER performance shows 1 dB (2-dB)

SNR loss. Sphere Decoder is faster than the semidefinite relaxation-based detectors in high SNR regime but becomes significantly slower for SNR lower than 10 dB. SDR Detector matches the speed of Sphere Decoder in high SNR region, matches the running time of other semidefinite relaxation-based detectors in low SNR regime, and enjoys the near-ML BER performance.

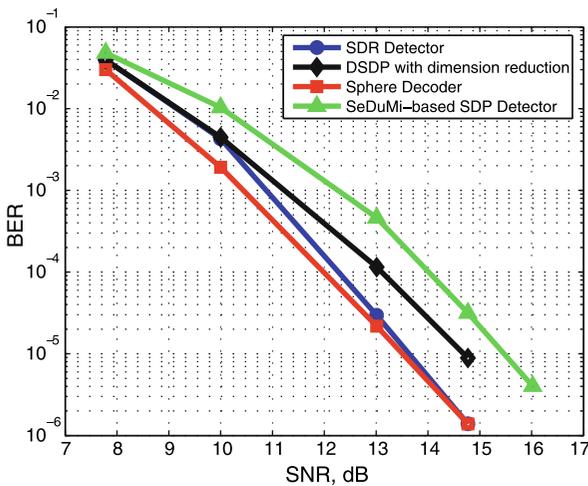

Figures 5 and 6 compare the average running time for large problems and in low SNR region. The running time of polynomial complexity detectors (SDR

Running time in low SNR regime,  $n = 40$

Detector, SeDuMi and DSDP-based) scales well in both regimes, remaining in the sub-second region, while the running time of Sphere Decoder deteriorates in both scenarios.

## Conclusions

We have considered the maximum likelihood detection problem. Among various quasi-ML detectors SDR Detector offers a near-optimal BER performance with the worst-case polynomial complexity. We have analyzed the underlying structure of the SDP relaxation which is the core of SDR Detector. For a given SNR SDR Detector delivers a constant factor approximation of the log-likelihood ratio for the original ML detection problem in probability, where the constant factor is independent of problem size. SDR Detector solves ML detection problem exactly in high SNR region. Numerical simulations of BER and running time empirically demonstrate the advantages of SDR Detector as compared to the computationally expensive ML Detector.

### Keywords

Maximum matching; Greedy algorithm; Star network; Parallel routing algorithm

The maximum partition matching problem was introduced recently in the study of routing schemes on interconnection networks [2]. In this article, we study the basic properties of the problem. An efficient algorithm for the maximum partition matching problem is presented.

## Definitions and Motivation

Let  $\mathbf{S} = \{C_1, \dots, C_k\}$  be a collection of subsets of the universal set  $U = \{1, \dots, n\}$  such that  $\cup_{i=1}^k C_i = U$ , and  $C_i \cap C_j = \emptyset$  for all  $i \neq j$ . A partition  $(\mathbf{A}, \mathbf{B})$  of  $\mathbf{S}$  pairs two elements  $a$  and  $b$  in  $U$  if  $a$  is contained in a subset in  $\mathbf{A}$  and  $b$  is contained in a subset in  $\mathbf{B}$ . A *partition matching* (of order  $m$ ) of  $\mathbf{S}$  consists of two ordered subsets  $L = \{a_1, \dots, a_m\}$  and  $R = \{b_1, \dots, b_m\}$  of  $m$  elements of  $U$  (the subsets  $L$  and  $R$  may not be disjoint), together with a sequence of  $m$  distinct partitions of  $\mathbf{S}$ :  $(\mathbf{A}_1, \mathbf{B}_1), \dots, (\mathbf{A}_m, \mathbf{B}_m)$  such that for all  $i = 1, \dots, m$ , the partition  $(\mathbf{A}_i, \mathbf{B}_i)$  pairs the elements  $a_i$  and  $b_i$ . The *maximum partition matching problem* is to construct a partition matching of order  $m$  for a given collection  $\mathbf{S}$  with  $m$  maximized.

The maximum partition matching problem arises in connection with the parallel routing problem in interconnection networks. In particular, in the study of the star networks [1], which are attractive alternatives to the popular hypercubes networks. It can be shown that constructing an optimal parallel routing scheme in the star networks can be effectively reduced to the maximum partition matching problem. Readers interested in this connection are referred to [2] for a detailed discussion.

The maximum partition matching problem can be formulated in terms of the *3-dimensional matching problem* as follows: given an instance  $\mathbf{S} = \{C_1, \dots, C_k\}$  of the maximum partition matching problem, we construct an instance  $M$  for the 3-dimensional matching problem such that a triple  $(a, b, P)$  is contained in  $M$  if and only if the partition  $P$  of  $\mathbf{S}$  pairs the elements  $a$  and  $b$ . However, since the number of partitions of the collection  $\mathbf{S}$  can be as large as  $2^n$  and the 3-dimensional matching problem is *NP-hard* [4], this reduction does not hint a polynomial time algorithm for the maximum partition matching problem.

In the rest of this article, we study the basic properties for the maximum partition matching problem, and present an algorithm of running time  $O(n^2 \log n)$  for the problem. We first introduce necessary terminologies that will be used in our discussion.

Let  $\pi = \langle L, R, (\mathbf{A}_1, \mathbf{B}_1), \dots, (\mathbf{A}_m, \mathbf{B}_m) \rangle$  be a partition matching of the collection  $\mathbf{S}$ , where  $L = \{a_1, \dots, a_m\}$  and  $R = \{b_1, \dots, b_m\}$ . We will say that the partition  $(\mathbf{A}_i, \mathbf{B}_i)$  *left-pairs* the element  $a_i$  and *right-pairs* the element  $b_i$ . An element  $a$  is said to be *left-paired* if it is in the set

$L$ . Otherwise, the element  $a$  is *left-unpaired*. Similarly we define *right-paired* and *right-unpaired* elements. The collections  $\mathbf{A}_i$  and  $\mathbf{B}_i$  are called the *left-collection* and *right-collection* of the partition  $(\mathbf{A}_i, \mathbf{B}_i)$ . The partition matching  $\pi$  may also be written as  $\pi[(a_1, b_1), \dots, (a_m, b_m)]$  if the corresponding partitions are implied.

For the rest of this paper, we assume that  $U = \{1, \dots, n\}$  and that  $\mathbf{S} = \{C_1, \dots, C_k\}$  is a collection of pairwise disjoint subsets of  $U$  such that  $\cup_{i=1}^k C_i = U$ .

## Case I. Via Pre-Matching when $\|\mathbf{S}\|$ is Large

A necessary condition for two ordered subsets  $L = \{a_1, \dots, a_m\}$  and  $R = \{b_1, \dots, b_m\}$  of  $U$  to form a partition matching for the collection  $\mathbf{S}$  is that  $a_i$  and  $b_i$  belong to different subsets in the collection  $\mathbf{S}$ , for all  $i = 1, \dots, m$ . We say that the two ordered subsets  $L$  and  $R$  of  $U$  form a *pre-matching*  $\sigma = \{(a_i, b_i) : 1 \leq i \leq m\}$  if  $a_i$  and  $b_i$  do not belong to the same subset in the collection  $\mathbf{S}$ , for all  $i = 1, \dots, m$ . The pre-matching  $\sigma$  is *maximum* if  $m$  is the largest among all pre-matchings of  $\mathbf{S}$ .

A maximum pre-matching can be constructed efficiently by the *algorithm pre-matching* given below, where we say that a set is *singular* if it consists of a single element. See [3] for a proof for the correctness of the algorithm.

```

Input :   the collection  $\mathbf{S} = \{C_1, \dots, C_k\}$  of subsets
          of  $U$ 
Output :  a maximum pre-matching  $\sigma$  in  $\mathbf{S}$ 
1.        $\mathbf{T} = \mathbf{S}; \sigma = \emptyset;$ 
2.       WHILE  $\mathbf{T}$  contains more than one set but
          does not consist of exactly three singular
          sets
          DO
2.1.     pick two sets  $C$  and  $C'$  of largest cardinal-
          ity in  $\mathbf{T}$ ;
2.2.     pick an element  $a$  in  $C$  and an element  $b$ 
          in  $C'$ ;
2.3.      $\sigma = \sigma \cup \{(a, b), (b, a)\};$ 
2.4.      $C = C - \{a\}; C' = C' - \{b\};$ 
2.5.     if  $C$  or  $C'$  is empty now, delete it from  $\mathbf{T}$ ;
3.       IF  $\mathbf{T}$  consists of exactly three singular sets
           $C_1 = \{a_1\}, C_2 = \{a_2\},$  and  $C_3 = \{a_3\}$ 
          THEN
           $\sigma = \sigma \cup \{(a_1, a_2), (a_2, a_3), (a_3, a_1)\}.$ 

```

## Algorithm pre-matching

In the following, we show that when the cardinality of the collection  $\mathbf{S}$  is large enough, a maximum partition matching of  $\mathbf{S}$  can be constructed from the maximum pre-matching  $\sigma$  produced by the algorithm pre-matching.

Suppose that the collection  $\mathbf{S}$  consists of  $k$  subsets  $C_1, \dots, C_k$  and  $2^k \geq 4n$ . The pre-matching  $\sigma$  contains at most  $n$  pairs. Let  $(a, b)$  be a pair in  $\sigma$  and let  $C$  and  $C'$  be two arbitrary subsets in  $\mathbf{S}$  such that  $C$  contains  $a$  and  $C'$  contains  $b$ . Note that the number of partitions  $(\mathbf{A}, \mathbf{B})$  of  $\mathbf{S}$  such that  $C$  is in  $\mathbf{A}$  and  $C'$  is in  $\mathbf{B}$  is equal to  $2^{k-2} \geq n$ . Therefore, at least one such partition can be used to left-pair  $a$  and right-pair  $b$ . This observation results in the following theorem.

**Theorem 1** *Let  $\mathbf{S} = \{C_1, \dots, C_k\}$  be a collection of nonempty subsets of the universal set  $U = \{1, \dots, n\}$  such that  $\cup_{i=1}^k C_i = U$  and  $C_i \cap C_j = \emptyset$ , for  $i \neq j$ . If  $2^k \geq 4n$ , then a maximum partition matching in  $\mathbf{S}$  can be constructed in time  $O(n^2)$ .*

*Proof* Consider the following algorithm partition-matching-I.

Input: the collection  $\mathbf{S} = \{C_1, \dots, C_k\}$  of subsets of  $U$

Output: a partition matching  $\pi$  in  $\mathbf{S}$

1. construct a maximum pre-matching  $\sigma$  of  $\mathbf{S}$ ;
2. FOR each pair  $(a, b)$  in  $\sigma$  DO  
use an unused partition of  $\mathbf{S}$  to pair  $a$  and  $b$ .

**Algorithm partition-matching-I**

Suppose the pre-matching  $\sigma$  constructed in step 1 is  $\sigma = \{(a_1, b_1), \dots, (a_m, b_m)\}$ . According to the above discussion, for each pair  $(a_i, b_i)$  in  $\sigma$ , there is always an unused partition of  $\mathbf{S}$  that left-pairs  $a$  and right-pairs  $b$ . Therefore, step 2 of the algorithm partition-matching-I is valid and constructs a partition matching  $\pi$  for the collection  $\mathbf{S}$ . Since each partition matching for  $\mathbf{S}$  induces a pre-matching in  $\mathbf{S}$  and  $\sigma$  is a maximum pre-matching, we conclude that the partition matching  $\pi$  is a maximum partition matching for the collection  $\mathbf{S}$ .

By carefully organizing the elements in  $U$  and the partitions of  $\mathbf{S}$ , we can show that the algorithm partition-matching-I runs in time  $O(n^2)$ . See [3].

**Case II. Via Greedy Method when  $\|\mathbf{S}\|$  is Small**

Now we consider the case  $2^k < 4n$ . Since the number  $2^k$  of partitions of the collection  $\mathbf{S}$  is small, we can apply a greedy strategy that expands a current partition matching by trying to add each of the unused partitions to the partition matching. We show in this section that a careful use of this greedy method constructs a maximum partition matching for the given collection.

Suppose we have a partition matching  $\pi = \pi[(a_1, b_1), \dots, (a_h, b_h)]$  and want to expand it. The partitions of the collection  $\mathbf{S}$  then can be classified into two classes:  $h$  of the partitions are used to pair the  $h$  pairs  $(a_i, b_i)$ ,  $i = 1, \dots, h$ , and the rest  $2^k - h$  partitions are unused. Now if there is an unused partition  $P = (\mathbf{A}, \mathbf{B})$  such that there is a left-unpaired element  $a$  in  $\mathbf{A}$  and a right-unpaired element  $b$  in  $\mathbf{B}$ , then we simply pair the element  $a$  with the element  $b$  using the partition  $P$ , thus expanding the partition matching  $\pi$ .

Now suppose that there is no such unused partition, i. e., for all unused partitions  $(\mathbf{A}, \mathbf{B})$ , either  $\mathbf{A}$  contains no left-unpaired elements or  $\mathbf{B}$  contains no right-unpaired elements. This case may not necessarily imply that the current partition matching is the maximum. For example, suppose that  $(\mathbf{A}, \mathbf{B})$  is an unused partition such that there is a left-unpaired element  $a$  in  $\mathbf{A}$  but no right-unpaired elements in  $\mathbf{B}$ . Assume further that there is a used partition  $(\mathbf{A}', \mathbf{B}')$  that pairs elements  $(a', b')$ , such that the element  $b'$  is in  $\mathbf{B}$  and there is a right-unpaired element  $b$  in  $\mathbf{B}'$ . Then we can let the partition  $(\mathbf{A}', \mathbf{B}')$  pair the elements  $(a', b)$ , and then let the partition  $(\mathbf{A}, \mathbf{B})$  pair the elements  $(a, b')$ , thus expanding the partition matching  $\pi$ . An explanation of this process is that the used partitions have been incorrectly used to pair elements, thus in order to construct a maximum partition matching, we must re-pair some of the elements. To further investigate this relation, we need to introduce a few notations.

For a used partition  $P$  of  $\mathbf{S}$ , we put an underline on a set in the left-collection (resp. the right-collection) of  $P$  to indicate that an element in the set is left-paired (resp. right-paired) by the partition  $P$ . The sets will be called the *left-paired set* and the *right-paired set* of the partition  $P$ , respectively.

**Definition 2** A used partition  $P$  is *directly left-reachable* from a partition  $P_1 = (\mathbf{A}_1, \mathbf{B}_1)$  if the left-paired set of  $P$  is contained in  $\mathbf{A}_1$  (the partition  $P_1$

can be either used or unused). The partition  $P$  is *directly right-reachable* from a partition  $P_2 = (\mathbf{A}_2, \mathbf{B}_2)$  if the right-paired set of  $P$  is contained in  $\mathbf{B}_2$ . A partition  $P_s$  is *left-reachable* (resp. *right-reachable*) from a partition  $P_1$  if there are partitions  $P_2, \dots, P_{s-1}$  such that  $P_i$  is directly left-reachable (resp. directly right-reachable) from  $P_{i-1}$ , for all  $i = 2, \dots, s$ .

The left-reachability and the right-reachability are transitive relations.

Let  $P_1 = (\mathbf{A}_1, \mathbf{B}_1)$  be an unused partition such that there are no left-unpaired elements in  $\mathbf{A}_1$ , and let  $P_s = (\mathbf{A}_s, \mathbf{B}_s)$  be a partition left-reachable from  $P_1$  and there is a left-unpaired element  $a_s$  in  $\mathbf{A}_s$ . We show how we can use a *chain justification* to make a left-unpaired element for the collection  $\mathbf{A}_1$ .

By the definition, there are used partitions  $P_2, \dots, P_{s-1}$  such that  $P_i$  is directly left-reachable from  $P_{i-1}$ , for  $i = 2, \dots, s$ . We can further assume that  $P_i$  is not directly left-reachable from  $P_{i-2}$  for  $i = 3, \dots, s$  (otherwise we simply delete the partition  $P_{i-1}$  from the sequence). Thus, these partitions can be written as

$$\begin{aligned} P_1 &= (\{\underline{C}_1\} \cup \mathbf{A}'_1, \mathbf{B}_1), \\ P_2 &= (\{\underline{C}_1, \underline{C}_2\} \cup \mathbf{A}'_2, \mathbf{B}_2), \\ P_3 &= (\{\underline{C}_2, \underline{C}_3\} \cup \mathbf{A}'_3, \mathbf{B}_3), \\ &\vdots \\ P_{s-1} &= (\{\underline{C}_{s-2}, \underline{C}_{s-1}\} \cup \mathbf{A}'_{s-1}, \mathbf{B}_{s-1}), \\ P_s &= (\{\underline{C}_{s-1}, \underline{C}_s\} \cup \mathbf{A}'_s, \mathbf{B}_s), \end{aligned}$$

where  $\mathbf{A}'_1, \dots, \mathbf{A}'_s$  are subcollections of  $\mathbf{S}$  without an underlined set.

We can assume that the left-unpaired element  $a_s$  in  $\mathbf{A}_s = \{\underline{C}_{s-1}, \underline{C}_s\} \cup \mathbf{A}'_s$  is in a nonunderlined set  $C_s$  in  $\mathbf{A}_s$  (otherwise we consider the sequence  $P_1, \dots, P_{s-1}$  instead). We modify the partition sequence into

$$\begin{aligned} P_1 &= (\{\underline{C}_1\} \cup \mathbf{A}'_1, \mathbf{B}_1), \\ P_2 &= (\{\underline{C}_1, \underline{C}_2\} \cup \mathbf{A}'_2, \mathbf{B}_2), \\ P_3 &= (\{\underline{C}_2, \underline{C}_3\} \cup \mathbf{A}'_3, \mathbf{B}_3), \\ &\vdots \\ P_{s-1} &= (\{\underline{C}_{s-2}, \underline{C}_{s-1}\} \cup \mathbf{A}'_{s-1}, \mathbf{B}_{s-1}), \\ P_s &= (\{\underline{C}_{s-1}, \underline{C}_s\} \cup \mathbf{A}'_s, \mathbf{B}_s). \end{aligned}$$

The interpretation is as follows: we use the partition  $P_s$  to left-pair the left-unpaired element  $a_s$  (the right-

paired element in the right-collection  $\mathbf{B}_s$  is unchanged). Thus, the element  $a_{s-1}$  in the set  $C_{s-1}$  of the partition  $P_s$  used to left-pair becomes left-unpaired. We then use the partition  $P_{s-1}$  to left-pair the element  $a_{s-1}$  and leave an element  $a_{s-2}$  in the set  $C_{s-2}$  left-unpaired, then we use the partition  $P_{s-2}$  to left-pair  $a_{s-2}$ , etc. At the end, we use the partition  $P_2$  to left-pair an element  $a_2$  in the set  $C_2$  and leave an element  $a_1$  in the set  $C_1$  left-unpaired. Therefore, this process makes an element in the left-collection  $\mathbf{A}_1 = \{C_1\} \cup \mathbf{A}'_1$  of the partition  $P_1$  left-unpaired.

The above process will be called a *left-chain justification*. Thus, given an unused partition  $P_1 = (\mathbf{A}_1, \mathbf{B}_1)$  in which the left-collection  $\mathbf{A}_1$  has no left-unpaired elements and given a used partition  $P_s = (\mathbf{A}_s, \mathbf{B}_s)$  left-reachable from  $P_1$  such that the left-collection  $\mathbf{A}_s$  of  $P_s$  has a left-unpaired element, we can apply the left-chain justification that keeps all used partitions in the partition matching  $\pi$  and makes a left-unpaired element for the partition  $P_1$ . A process called *right-chain justification* for right-collections of the partitions can be described similarly.

A greedy method based on the left-chain and right-chain justifications is presented in the following *algorithm greedy-expanding*.

Input: the collection  $\mathbf{S} = \{C_1, \dots, C_k\}$  of subsets of  $U$

Output: a partition matching  $\pi_{\text{exp}}$  in  $\mathbf{S}$

1.  $\pi_{\text{exp}} = \emptyset$ ;
2. repeat until no more changes  
 IF there is an unused partition  $P = (\mathbf{A}, \mathbf{B})$  that has a left-unpaired element  $a$  in  $\mathbf{A}$  and a right-unpaired element  $b$  in  $\mathbf{B}$   
 THEN pair the elements  $(a, b)$  by the partition  $P$  and add  $P$  to the matching  $\pi_{\text{exp}}$   
 ELSE IF a left-chain justification or a right-chain justification (or both) is applicable to make an unused partition  $P = (\mathbf{A}, \mathbf{B})$  to have a left-unpaired element in  $\mathbf{A}$  and a right-unpaired element in  $\mathbf{B}$   
 THEN apply the left-chain justification and/or the right-chain justification

#### Algorithm greedy-expanding

In case  $2^k < 4n$ , a careful organization of the elements and the partitions can make the running time

of the algorithm greedy-expanding bounded by  $O(n^2 \log n)$ . Briefly speaking, we construct a graph  $G$  of  $2^k$  vertices in which each vertex represents a partition of  $\mathcal{S}$ . The direct left- and right- reachabilities of partitions are given by the edges in the graph  $G$ , so that checking left- and right- reachabilities and performing left- and right- chain justifications can be done efficiently. Interested readers are referred to [3] for a detailed description.

After execution of the algorithm greedy-expanding, we obtain a partition matching  $\pi_{\text{exp}}$ . For each partition  $P = (\mathbf{A}, \mathbf{B})$  not included in  $\pi_{\text{exp}}$ , either  $\mathbf{A}$  has no left-unpaired elements and no used partition left-reachable from  $P$  has a left-unpaired element in its left-collection, or  $\mathbf{B}$  has no right-unpaired elements and no used partition right-reachable from  $P$  has a right-unpaired element in its right-collection.

**Definition 3** Define  $L_{\text{free}}$  to be the set of partitions  $P$  not used by  $\pi_{\text{exp}}$  such that the left-collection of  $P$  has no left-unpaired elements and no used partition left-reachable from  $P$  has a left-unpaired element in its left-collection, and define  $R_{\text{free}}$  to be the set of partitions  $P'$  not used by  $\pi_{\text{exp}}$  such that the right-collection of  $P'$  has no right-unpaired elements and no used partition right-reachable from  $P'$  has a right-unpaired element in its right-collection.

According to the algorithm greedy-matching, each partition not used by  $\pi_{\text{exp}}$  is either in the set  $L_{\text{free}}$  or in the set  $R_{\text{free}}$ . The sets  $L_{\text{free}}$  and  $R_{\text{free}}$  may not be disjoint.

**Definition 4**  $L_{\text{reac}}$  to be the set of partitions in  $\pi_{\text{exp}}$  that are left-reachable from a partition in  $L_{\text{free}}$ , and define  $R_{\text{reac}}$  to be the set of partitions in  $\pi_{\text{exp}}$  that are right-reachable from a partition in  $R_{\text{free}}$ .

According to the definitions, if a used partition  $P$  is in the set  $L_{\text{reac}}$ , then all elements in its left-collection are left-paired, and if a used partition  $P$  is in the set  $R_{\text{reac}}$ , then all elements in its right-collection are right-paired.

We first show that if  $L_{\text{reac}}$  and  $R_{\text{reac}}$  are not disjoint, then we can construct a maximum partition matching from the partition matching  $\pi_{\text{exp}}$  constructed by the algorithm greedy-expanding. For this, we need the following technical lemma.

**Lemma 5** *If the sets  $L_{\text{reac}}$  and  $R_{\text{reac}}$  contain a common partition and the partition matching  $\pi_{\text{exp}}$  has less than  $n$  pairs, then there is a set  $C_0$  in  $\mathcal{S}$ ,  $|C_0| \leq n/2$ , such that either all elements in each set  $C \neq C_0$  are left-paired and every used partition whose left-paired set is not  $C_0$  is contained in  $L_{\text{reac}}$ , or all elements in each set  $C \neq C_0$  are right-paired and every used partition whose right-paired set is not  $C_0$  is contained in  $R_{\text{reac}}$ .*

For a proof, see [3].

**Theorem 6** *If  $L_{\text{reac}}$  and  $R_{\text{reac}}$  have a common partition, then the collection  $\mathcal{S}$  has a maximum partition matching of  $n$  pairs, which can be constructed in linear time from the partition matching  $\pi_{\text{exp}}$ .*

*Proof* If  $\pi_{\text{exp}}$  has  $n$  pairs, then  $\pi_{\text{exp}}$  is already a maximum partition matching. Thus we assume that  $\pi_{\text{exp}}$  has less than  $n$  pairs. According to the above lemma, we can assume, without loss of generality, that all elements in each set  $C_i$ ,  $i = 2, \dots, k$ , are left-paired, and that every used partition whose left-paired set is not  $C_1$  is in  $L_{\text{reac}}$ . Moreover,  $|C_1| \leq \sum_{i=2}^k |C_i|$ .

Let  $t = \sum_{i=2}^k |C_i|$  and  $d = |C_1|$ . Then we can assume that the partition matching  $\pi_{\text{exp}}$  consists of the partitions

$$P_1, \dots, P_t, P_{t+1}, \dots, P_{t+h}$$

where  $P_1, \dots, P_t$  are used by  $\pi_{\text{exp}}$  to left-pair the elements in  $\cup_{i=2}^k C_i$ , and  $P_{t+1}, \dots, P_{t+h}$  are used by  $\pi_{\text{exp}}$  to left-pair the elements in  $C_1$ ,  $h < d$ . Moreover, all partitions  $P_1, \dots, P_t$  are in the set  $L_{\text{reac}}$ . Thus, the set  $C_1$  must be contained in the right-collection in each of the partitions  $P_1, \dots, P_t$ .

We ignore the partitions  $P_{t+1}, \dots, P_{t+h}$  and use the partitions  $P_1, \dots, P_t$  to construct a maximum partition matching of  $n$  pairs. Note that  $\{P_1, \dots, P_t\}$  also forms a partition matching in the collection  $\mathcal{S}$ .

For a partition  $(\mathbf{A}, \mathbf{B})$  of  $\mathcal{S}$ , we say that the partition  $(\mathbf{B}, \mathbf{A})$  is obtained by *flipping* the partition  $(\mathbf{A}, \mathbf{B})$ . In the following *algorithm partition-flipping*, we show that a maximum partition matching of  $n$  pairs can be constructed by flipping  $d$  partitions in the partitions  $P_1, \dots, P_t$ .

- Input:** a partition matching  $\{P_1, \dots, P_t\}$  that left-pairs all elements in  $\cup_{i=2}^k C_i$ ,  $t = \sum_{i=2}^k |C_i|$ , and the set  $C_1$  is contained in the right-collection of each partition  $P_i$ ,  $i = 1, \dots, t$ ,  $d = |C_1| \leq t$
- Output:** a maximum partition matching in  $\mathbf{S}$  with  $n$  pairs.
1. if not all elements in the set  $C_1$  are right-paired by  $P_1, \dots, P_t$ , replace a proper number of right-paired elements in  $\cup_{i=2}^k C_i$  by the right-unpaired elements in  $C_1$  so that all elements in  $C_1$  are right-paired by  $P_1, \dots, P_t$ ;
  2. suppose that the partitions  $P_1, \dots, P_{t-d}$  right-pair  $t-d$  elements  $b_1, \dots, b_{t-d}$  in  $\cup_{i=2}^k C_i$ , and that  $P_{t-d+1}, \dots, P_t$  right-pair the  $d$  elements in  $C_1$ ;
  3. suppose that  $\bar{P}_1, \dots, \bar{P}_{t-d}$  are the  $t-d$  partitions in  $\{P_1, \dots, P_t\}$  that left-pair the elements  $b_1, \dots, b_{t-d}$ ;
  4. flip each of the  $d$  partitions in  $\{P_1, \dots, P_t\} - \{\bar{P}_1, \dots, \bar{P}_{t-d}\}$  to get  $d$  partitions  $P'_1, \dots, P'_d$  to left-pair the  $d$  elements in  $C_1$ . The right paired element of each  $P'_i$  is the left-paired element before the flipping;
  5.  $\{P_1, \dots, P_t, P'_1, \dots, P'_d\}$  is a partition matching of  $n$  pairs.

### Algorithm partition-flipping

Step 1 of the algorithm is always possible: since  $C_1$  is contained in the right-collection of each partition  $P_i$ ,  $i = 1, \dots, t$ , and  $t \geq d$ , for each right-unpaired element  $b$  in  $C_1$ , we can always pick a partition  $P_i$  that right-pairs an element in  $\cup_{i=2}^k C_i$ , and let  $P_i$  right-pair the element  $b$ . We keep doing this replacement until all  $d$  elements in  $C_1$  get right-paired. At this point, the number of partitions in  $\{P_1, \dots, P_t\}$  that right-pair elements in  $\cup_{i=2}^k C_i$  is exactly  $t-d$ . Step 3 is always possible since the partitions  $P_1, \dots, P_t$  left-pair all elements in  $\cup_{i=2}^k C_i$ .

Now we verify that the constructed sequence  $\{P_1, \dots, P_t, P'_1, \dots, P'_d\}$  is a partition matching in  $\mathbf{S}$ . No two partitions  $P_i$  and  $P_j$  can be identical since  $\{P_1, \dots, P_t\}$  is supposed to be a partition matching in  $\mathbf{S}$ . No two partitions  $P'_i$  and  $P'_j$  can be identical since they are obtained by flipping two different partitions in  $\{P_1, \dots, P_t\}$ . No partition  $P_i$  is identical to a partition  $P'_j$  because

$P_i$  has  $C_1$  in its right-collection while  $P'_j$  has  $C_1$  in its left-collection. Therefore, the partitions  $P_1, \dots, P_t, P'_1, \dots, P'_d$  are all distinct.

Each of the partitions  $P_1, \dots, P_t$  left-pairs an element in  $\cup_{i=2}^k C_i$ , and each of the partitions  $P'_1, \dots, P'_d$  left-pairs an element in  $C_1$ . Thus, all elements in the universal set  $U$  get left-paired in  $\{P_1, \dots, P_t, P'_1, \dots, P'_d\}$ .

Finally, the partitions  $P_1, \dots, P_t$  right-pair all elements in  $C_1$  and the elements  $b_1, \dots, b_{t-d}$  in  $\cup_{i=2}^k C_i$ . Now by our selection of the partitions, the partitions  $P'_1, \dots, P'_d$  precisely right-pair all the elements in  $\cup_{i=2}^k C_i - \{b_1, \dots, b_{t-d}\}$ . Thus, all elements in  $U$  also get right-paired in  $\{P_1, \dots, P_t, P'_1, \dots, P'_d\}$ .

This concludes that the constructed sequence  $\{P_1, \dots, P_t, P'_1, \dots, P'_d\}$  is a maximum partition matching in the collection  $\mathbf{S}$ . The running time of the algorithm partition-flipping is obviously linear.

Now we consider the case when the sets  $L_{\text{reac}}$  and  $R_{\text{reac}}$  have no common partitions.

**Theorem 7** *If  $L_{\text{reac}}$  and  $R_{\text{reac}}$  have no common partitions, then the partition matching  $\pi_{\text{exp}}$  is a maximum partition matching.*

*Proof* Let  $W_{\text{other}}$  be the set of used partitions in  $\pi_{\text{exp}}$  that belong to neither  $L_{\text{reac}}$  nor  $R_{\text{reac}}$ . Then  $L_{\text{free}} \cup R_{\text{free}} \cup L_{\text{reac}} \cup R_{\text{reac}} \cup W_{\text{other}}$  is the set of all partitions of the collection  $\mathbf{S}$ , and  $L_{\text{reac}} \cup R_{\text{reac}} \cup W_{\text{other}}$  is the set of partitions contained in the partition matching  $\pi_{\text{exp}}$ . Since all sets  $L_{\text{reac}}$ ,  $R_{\text{reac}}$ , and  $W_{\text{other}}$  are pairwise disjoint, the number of partitions in  $\pi_{\text{exp}}$  is precisely  $|L_{\text{reac}}| + |R_{\text{reac}}| + |W_{\text{other}}|$ .

Now consider the set  $W_L = L_{\text{free}} \cup L_{\text{reac}}$ . Let  $U_L$  be the set of elements that appears in the left-collection of a partition in  $W_L$ . We have

- Every  $P \in L_{\text{reac}}$  left-pairs an element in  $U_L$ ;
- Every element in  $U_L$  is left-paired;
- If an element  $a$  in  $U_L$  is left-paired by a partition  $P$ , then  $P \in L_{\text{reac}}$ .

Therefore, the partitions in  $L_{\text{reac}}$  precisely left-pair the elements in  $U_L$ . This gives  $|L_{\text{reac}}| = |U_L|$ . Since there are only  $|U_L|$  elements that appear in the left-collections in partitions in  $L_{\text{free}} \cup L_{\text{reac}}$ , we conclude that the partitions in  $W_L = L_{\text{free}} \cup L_{\text{reac}}$  can be used to left-pair at most  $|U_L| = |L_{\text{reac}}|$  elements in any partition matching in  $\mathbf{S}$ .

Similarly, the partitions in the set  $W_R = R_{\text{free}} \cup R_{\text{reac}}$  can be used to right-pair at most  $|R_{\text{reac}}|$  elements in any partition matching in  $\mathbf{S}$ .

Therefore, any partition matching in the collection  $\mathbf{S}$  can include at most  $|L_{\text{reac}}|$  partitions in the set  $W_L$ , at most  $|R_{\text{reac}}|$  partitions in the set  $W_R$ , and at most all partitions in the set  $W_{\text{other}}$ . Consequently, a maximum partition matching in  $\mathbf{S}$  consists of at most  $|L_{\text{reac}}| + |R_{\text{reac}}| + |W_{\text{other}}|$  partitions. Since the partition matching  $\pi_{\text{exp}}$  constructed by the algorithm greedy-expanding contains just this many partitions,  $\pi_{\text{exp}}$  is a maximum partition matching in the collection  $\mathbf{S}$ .

Now it is clear how the maximum partition matching problem is solved.

**Theorem 8** *The maximum partition matching problem is solvable in time  $O(n^2 \log n)$ .*

*Proof* Suppose that we are given a collection  $\mathbf{S} = \{C_1, \dots, C_k\}$  of pairwise disjoint subsets of  $U = \{1, \dots, n\}$ .

In case  $2^k \geq 4n$ , we can call the algorithm partition-matching-I to construct a maximum partition matching in time  $O(n^2)$ .

In case  $2^k < 4n$ , we first call the algorithm greedy-expanding to construct a partition matching  $\pi_{\text{exp}}$  and compute the sets  $L_{\text{reac}}$  and  $R_{\text{reac}}$ . If  $L_{\text{reac}}$  and  $R_{\text{reac}}$  have no common partition, then according to the previous theorem,  $\pi_{\text{exp}}$  is already a maximum partition matching. Otherwise, we call the algorithm partition-flipping to construct a maximum partition matching. All these can be done in time  $O(n^2 \log n)$ . A detailed analysis of this algorithm can be found in [3].

### Keywords

Maximum satisfiability; Local search; Approximation algorithms; History-sensitive heuristics

In the maximum satisfiability (MAX-SAT) problem one is given a *Boolean formula in conjunctive normal form*, i. e., as a conjunction of clauses, each clause being a disjunction. The task is to find an assignment of truth values to the variables that satisfies the maximum number of clauses.

Let  $n$  be the number of variables and  $m$  the number of clauses, so that a formula has the following form:

$$\bigwedge_{1 \leq i \leq m} \left( \bigvee_{1 \leq k \leq |C_i|} l_{ik} \right),$$

where  $|C_i|$  is the number of literals in clause  $C_i$  and  $l_{ik}$  is a *literal*, i. e., a propositional variable  $u_j$  or its negation  $\bar{u}_j$ , for  $1 \leq j \leq n$ . The set of clauses in the formula is denoted by  $\mathcal{C}$ . If one associates a weight  $w_i$  to each clause  $C_i$  one obtains the *weighted MAX-SAT problem*, denoted as MAX W-SAT: one is to determine the assignment of truth values to the  $n$  variables that maximizes the sum of the weights of the satisfied clauses. In

the literature one often considers problems with different numbers  $k$  of literals per clause, defined as MAX- $k$ -SAT, or MAX  $W$ - $k$ -SAT in the weighted case. In some papers MAX- $k$ -SAT instances contain up to  $k$  literals per clause, while in other papers they contain exactly  $k$  literals per clause. We consider the second option unless otherwise stated.

MAX-SAT is of considerable interest not only from the theoretical side but also from the practical one. On one hand, the decision version SAT was the first example of an NP-complete problem [16], moreover MAX-SAT and related variants play an important role in the characterization of different approximation classes like APX and PTAS [5]. On the other hand, many issues in mathematical logic and artificial intelligence can be expressed in the form of satisfiability or some of its variants, like constraint satisfaction. Some exemplary problems are consistency in expert system knowledge bases [46], integrity constraints in databases [4,23], approaches to inductive inference [35,40], asynchronous circuit synthesis [32]. An extensive review of algorithms for MAX-SAT appeared in [9].

M. Davis and H. Putnam [19] started in 1960 the investigation of useful strategies for handling resolution in the satisfiability problem. Davis, G. Logemann and D. Loveland [18] avoid the memory explosion of the original DP algorithm by replacing the resolution rule with the *splitting rule*. A recent review of advanced techniques for resolution and splitting is presented in [31].

The MAX  $W$ -SAT problem has a natural integer linear programming formulation. Let  $y_j = 1$  if Boolean variable  $u_j$  is ‘true’,  $y_j = 0$  if it is ‘false’, and let the Boolean variable  $z_i = 1$  if clause  $C_i$  is satisfied,  $z_i = 0$  otherwise. The integer linear program is:

$$\max \sum_{i=1}^m w_i z_i$$

subject to the constraints:

$$\begin{cases} \sum_{j \in U_i^+} y_j + \sum_{j \in U_i^-} (1 - y_j) \geq z_i, \\ i = 1, \dots, m, \\ y_j \in \{0, 1\}, & j = 1, \dots, n, \\ z_i \in \{0, 1\}, & i = 1, \dots, m, \end{cases}$$

where  $U_i^+$  and  $U_i^-$  denote the set of indices of variables that appear unnegated and negated in clause  $C_i$ , respectively. If one neglects the objective function and sets all  $z_i$  variables to 1, one obtains an integer programming feasibility problem associated to the SAT problem [11].

The integer linear programming formulation of MAX-SAT suggests that this problem could be solved by a branch and bound method (cf. also ► **Integer programming: Branch and bound methods**). A usable method uses Chvátal cuts. In [35] it is shown that the resolvents in the propositional calculus correspond to certain *cutting planes* in the integer programming model of inference problems.

*Linear programming relaxations* of integer linear programming formulations of MAX-SAT have been used to obtain upper bounds in [27,33,55]. A linear programming and rounding approach for MAX-2-SAT is presented in [13]. A method for strengthening the generalized set covering formulation is presented in [47], where Lagrangian multipliers guide the generation of cutting planes.

The first approximation algorithms with a ‘guaranteed’ quality of approximation [5] were proposed by D.S. Johnson [38] and use greedy construction strategies. The original paper [38] demonstrated for both of them a performance ratio 1/2. In detail, let  $k$  be the minimum number of variables occurring in any clause of the formula,  $m(x, y)$  the number of clauses satisfied by the feasible solution  $y$  on instance  $x$ , and  $m^*(x)$  the maximum number of clauses that can be satisfied.

For any integer  $k \geq 1$ , the first algorithm achieves a feasible solution  $y$  of an instance  $x$  such that

$$\frac{m(x, y)}{m^*(x)} \geq 1 - \frac{1}{k+1},$$

while the second algorithm obtains

$$\frac{m(x, y)}{m^*(x)} \geq 1 - \frac{1}{2^k}.$$

Recently (1997) it has been proved [12] that the second algorithm reaches a performance ratio 2/3. There are formulas for which the second algorithm finds a truth assignment such that the ratio is 2/3. Therefore this bound cannot be improved [12].

One of the most interesting approaches in the design of new algorithms is the use of *randomization*.

During the computation, random bits are generated and used to influence the algorithm process. In many cases randomization allows to obtain better (expected) performance or to simplify the construction of the algorithm. Two randomized algorithms that achieve a performance ratio of  $3/4$  have been proposed in [27] and [55]. Moreover, it is possible to derandomize these algorithms, that is, to obtain deterministic algorithms that preserve the same bound  $3/4$  for every instance. The approximation ratio  $3/4$  can be slightly improved [28]. T. Asano [2] (following [3]) has improved the bound to  $0.77$ . For the restricted case of MAX-2-SAT, one can obtain a more substantial improvement (performance ratio  $0.931$ ) with the technique in [21]. If one considers only satisfiable MAX W-SAT instances, L. Trevisan [54] obtains a  $0.8$  approximation factor, while H. Karloff and U. Zwick [41] claim a  $0.875$  performance ratio for satisfiable instances of MAX W-3-SAT. A strong negative result about the approximability can be found in [36]: Unless  $P = NP$  MAX W-SAT cannot be approximated in polynomial time within a performance ratio greater than  $7/8$ .

MAX-SAT is among the problems for which local search has been very successful: in practice, local search and its variations are the only efficient and effective method to address large and complex real-world instances. Different variations of local search with randomness techniques have been proposed for SAT and MAX-SAT starting from the late 1980s, see for example [30,52], motivated by previous applications of ‘min-conflicts’ heuristics in the area of artificial intelligence [44].

The general scheme is based on generating a starting point in the set of admissible solution and trying to improve it through the application of basic moves. The search space is given by all possible truth assignments. Let us consider the elementary changes to the current assignment obtained by changing a single truth value. The definitions are as follows.

Let  $U$  be the discrete search space:  $U = \{0, 1\}^n$ , and let  $f$  be the number of satisfied clauses. In addition, let  $U^{(t)} \in U$  be the current configuration along the *search trajectory* at iteration  $t$ , and  $N(U^{(t)})$  the neighborhood of point  $U^{(t)}$ , obtained by applying a set of basic moves  $\mu_i$  ( $1 \leq i \leq n$ ), where  $\mu_i$  complements the  $i$ th bit  $u_i$  of the string:  $\mu_i(u_1, \dots, u_i, \dots, u_n) = (u_1, \dots, 1 - u_i, \dots,$

$u_n)$ :

$$N(U^{(t)}) = \left\{ U \in U : U = \mu_i, U^{(t)}, i = 1, \dots, n \right\}.$$

The version of local search that we consider starts from a random initial configuration  $U^{(0)} \in U$  and generates a search trajectory as follows:

$$V = \text{BESTNEIGHBOR}(N(U^{(t)})), \quad (1)$$

$$U^{(t+1)} = \begin{cases} V & \text{if } f(V) > f(U^{(t)}), \\ U^{(t)} & \text{if } f(V) \leq f(U^{(t)}) \end{cases} \quad (2)$$

where BESTNEIGHBOR selects  $V \in N(U^{(t)})$  with the best  $f$  value and ties are broken randomly.  $V$  in turn becomes the new current configuration if  $f$  improves. Other versions are satisfied with an improving (or nonworsening) neighbor, not necessarily the best one. Clearly, local search stops as soon as the first *local optimum* point is encountered, when no improving moves are available, see (2). Let us define as  $LS^+$  a modification of LS where a specified number of iterations are executed and the candidate move obtained by BESTNEIGHBOR is always accepted even if the  $f$  value remains equal or worsens.

Properties about the number of clauses satisfied at a *local optimum* have been demonstrated. Let  $m^*$  be the best value and  $k$  the minimum number of literals contained in the problem clauses. Let  $m_{\text{loc}}$  be the number of satisfied clauses at a local optimum of any instance of MAX-SAT with at least  $k$  literals per clause.  $m_{\text{loc}}$  satisfies the following bound [34]:

$$m_{\text{loc}} \geq \frac{k}{k+1} m$$

and the bound is sharp. Therefore, if  $m_{\text{loc}}$  is the number of satisfied clauses at a local optimum, then:

$$m_{\text{loc}} \geq \frac{k}{k+1} m^*. \quad (3)$$

State-of-the-art heuristics for MAX-SAT are obtained by complementing local search with schemes that are capable of producing better approximations beyond the locally optimal points. In some cases, these schemes generate a sequence of points in the set of admissible solutions in a way that is fixed before the search

starts. An example is given by *multiple runs* of local search starting from different random points. The algorithm does not take into account the *history* of the previous phase of the search when the next points are generated. The term ‘memory-less’ denotes this lack of feedback from the search history.

In addition to the cited multiple-run local search, these techniques are based on Markov processes (simulated annealing; cf. also ► [Simulated annealing methods in protein folding](#)), ‘plateau’ search and ‘random noise’ strategies, or combinations of randomized constructions and local search. The use of a Markov process to generate a stochastic search trajectory is adopted, for example in [53].

The *Gsat algorithm* was proposed in [52] as a *model-finding procedure*, i. e., to find an interpretation of the variables under which the formula comes out ‘true’. Gsat consists of multiple runs of  $LS^+$ , each run consisting of a number of iterations that is typically proportional to the problem dimension  $n$ . An empirical analysis of Gsat is presented in [24,25]. Different ‘noise’ strategies to escape from attraction basins are added to Gsat in [50,51].

A hybrid algorithm that combines a randomized greedy construction phase to generate initial candidate solutions, followed by a local improvement phase is the *GRASP* scheme proposed in [48] for the SAT and generalized for the MAX W-SAT problem in [49]. GRASP is an iterative process, with each iteration consisting of two phases, a construction phase and a local search phase.

Different *history-sensitive heuristics* have been proposed to continue local search schemes beyond local optimality. These schemes aim at intensifying the search in promising regions and at diversifying the search into uncharted territories by using the information collected from the previous phase (the history) of the search. Because of the internal feedback mechanism, some algorithm parameters can be modified and tuned in an *on-line* manner, to reflect the characteristics of the *task* to be solved and the *local* properties of the configuration space in the neighborhood of the current point. This tuning has to be contrasted with the *off-line* tuning of an algorithm, where some parameters or choices are determined for a given problem in a preliminary phase and they remain fixed when the algorithm runs on a specific instance.

*Tabu search* is a *history-sensitive heuristic* proposed by F. Glover [26] and, independently, by P. Hansen and B. Jaumard, that used the term ‘SAMd’ (steepest ascent mildest descent) and applied it to the MAX-SAT problem in [34]. The main mechanism by which the history influences the search in tabu search is that, at a given iteration, some neighbors are *prohibited*, only a nonempty subset  $N_A(U^{(t)}) \subset N(U^{(t)})$  of them is *allowed*. The general way of generating the search trajectory that we consider is given by:

$$N_A(U^{(t)}) = \text{allow}(N(U^{(t)}), \dots, U^{(t)}), \quad (4)$$

$$U^{(t+1)} = \text{BESTNEIGHBOR}(N_A(U^{(t)})). \quad (5)$$

The set-valued function *allow* selects a nonempty subset of  $N(U^{(t)})$  in a manner that depends on the entire previous history of the search  $U^{(0)}, \dots, U^{(t)}$ . A specialized tabu search heuristic is used in [37] to speed up the search for a solution (if the problem is satisfiable) as part of a branch and bound algorithm for SAT, that adopts both a relaxation and a decomposition scheme by using polynomial instances, i. e., 2-SAT and Horn-SAT.

Different methods to generate prohibitions produce *discrete dynamical systems* with qualitatively different *search trajectories*. In particular, prohibitions based on a list of *moves* lead to a faster escape from a locally optimal point than prohibitions based on a list of visited *configurations* [6]. In detail, the function *allow* can be specified by introducing a *prohibition parameter*  $T$  (also called *list size*) that determines how long a move will remain prohibited after its execution. The *fixed tabu search* algorithm is obtained by fixing  $T$  throughout the search [26]. A neighbor is allowed if and only if it is obtained from the current point by applying a move that has not been used during the last  $T$  iterations. In detail, if  $LU(\mu)$  is the last usage time of move  $\mu$  ( $LU(\mu) = -\infty$  at the beginning):

$$N_A(U^{(t)}) = \left\{ U = \mu U^{(t)} : LU(\mu) < (t - T) \right\}.$$

The *reactive tabu search* algorithm of [10], defines simple rules to determine the prohibition parameter by reacting to the repetition of previously-visited configurations. One has a repetition if  $U^{(t+R)} = U^{(t)}$  for  $R \geq 1$ . The prohibition period  $T$  depends on the iteration  $t$  and

a *reaction equation* is added to the dynamical system:

$$T^{(t)} = \text{react}(T^{(t-1)}, U^{(0)}, \dots, U^{(t)}).$$

An algorithm that combines local search and *nonoblivious local search* [8], the use of prohibitions, and a reactive scheme to determine the prohibition parameter is the *Hamming-reactive tabu search* algorithm proposed in [7], which contains also a detailed experimental analysis.

Given the hardness of the problem and the relevancy for applications in different fields, the emphasis on the experimental analysis of algorithms for the MAX-SAT problem has been growing in recent years (as of 2000).

In some cases the experimental comparisons have been executed in the framework of ‘challenges,’ with support of electronic collection and distribution of software, problem generators and test instances. An example is the the Second DIMACS algorithm implementation challenge on cliques, coloring and satisfiability, whose results have been published in [39]. Practical and industrial MAX-SAT problems and benchmarks, with significant case studies are also presented in [20]. Some basic problem models that are considered both in theoretical and in experimental studies of MAX-SAT algorithms are described in [31].

Different algorithms demonstrate a different degree of effort, measured by number of elementary steps or CPU time, when solving different kinds of instances. For example, in [45] it is found that some distributions used in past experiments are of little interest because the generated formulas are almost always very easy to satisfy. It also reports that one can generate very hard instances of  $k$ -SAT, for  $k \geq 3$ . In addition, it reports the following observed behavior for random fixed length 3-SAT formulas: if  $r$  is the ratio  $r$  of clauses to variables ( $r = m/n$ ), almost all formulas are satisfiable if  $r < 4$ , almost all formulas are unsatisfiable if  $r > 4.5$ . A rapid transition seems to appear for  $r \approx 4.2$ , the same point where the computational complexity for solving the generated instances is maximized, see [17,42] for reviews of experimental results.

Let  $\kappa$  be the least real number such that, if  $r$  is larger than  $\kappa$ , then the probability of  $\mathcal{C}$  being satisfiable converges to 0 as  $n$  tends to infinity. A notable result found independently by many people, including [22] and [14]

is that

$$\kappa \leq \log_{\frac{8}{7}} 2 = 5.191.$$

A series of theoretical analyses aim at approximating the *unsatisfiability threshold* of random formulas [1,15,29,43].

### Introduction

In multiproduct and multipurpose batch plants, different products can be manufactured via the same or a similar sequence of operations by sharing available pieces of equipment, intermediate materials, and other production resources. They are ideally suited to manufacture products that are produced in small quantities or for which the production recipe or the customer demand pattern is likely to change. The inherent operational flexibility of this type of plant provides the opportunity for increased savings through the realization of an efficient production schedule which can reduce inventories, production and transition costs, and production shortfalls.

The problem of production scheduling and planning for multiproduct and multipurpose batch plants has received a considerable amount of attention during the last two decades. Extensive reviews have been written by Reklaitis [10], Pantelides [9], Shah [11] and more recently by Floudas and Lin [4,5]. Most of the work in the area of multiproduct batch plants has dealt with either the long-term planning problem or the short-term scheduling problem. Both planning and scheduling deal with the allocation of available resources over time to perform a set of tasks required to manufacture one or more products. However, long-term planning problems deal with longer time horizons (e.g., several months or years) and are focused on higher level decisions such as timing and location of additional facilities and levels of production. In contrast, short-term scheduling models address shorter time horizons (e.g., several days) and are focused on determining detailed sequencing of various operational tasks. The area of medium-term scheduling, however, which involves medium time horizons (e.g. several weeks) and still aims to determine detailed production schedules, can result in very large-scale problems and has received much less attention in the literature.

For medium-term scheduling, relatively little work has been presented in the literature. Medium-term

scheduling can be quite computationally complex, thus it is common for mathematical programming techniques to be used in their solution. The most widely employed strategy to overcome the computational difficulty is based on the idea of decomposition. The decomposition approach divides a large and complex problem, which may be computationally expensive or even intractable when formulated and solved directly as a single MILP model, to smaller subproblems, which can be solved much more efficiently. There have been a wide variety of decomposition approaches proposed in the literature. In addition to decomposition techniques developed for general forms of MILP problems, various approaches that exploit the characteristics of specific process scheduling problems have also been proposed. In most cases, the decomposition approaches only lead to suboptimal solutions, however, they substantially reduce the problem complexity and the solution time, making MILP based techniques applicable for large, real-world problems.

In this chapter, we propose an enhanced State-Task Network MILP model for the medium-term production scheduling of a multipurpose, multiproduct industrial batch plant. The proposed approach extends the work of Ierapetritou and Floudas [6] and Lin et al. [8] to consider a large-scale production facility and account for various storage policies (UIS, NIS, ZW), variable batch sizes and processing times, batch mixing and splitting, sequence-dependent changeover times, intermediate due dates, products used as raw materials, and several modes of operation. The methodology consists of the decomposition of the whole scheduling period into successive short horizons of a few days. A decomposition model is implemented to determine each short horizon and the corresponding products to be included. Then, a novel continuous-time formulation for short-term scheduling of batch processes with multiple intermediate due dates is applied to each short horizon selected, leading to a large-scale mixed-integer linear programming (MILP) problem. The scheduling model includes over 80 pieces of equipment and can take into account the processing recipes of hundreds of different products. Several characteristics of the production plant are incorporated into the scheduling model and actual plant data are used to model all parameters.

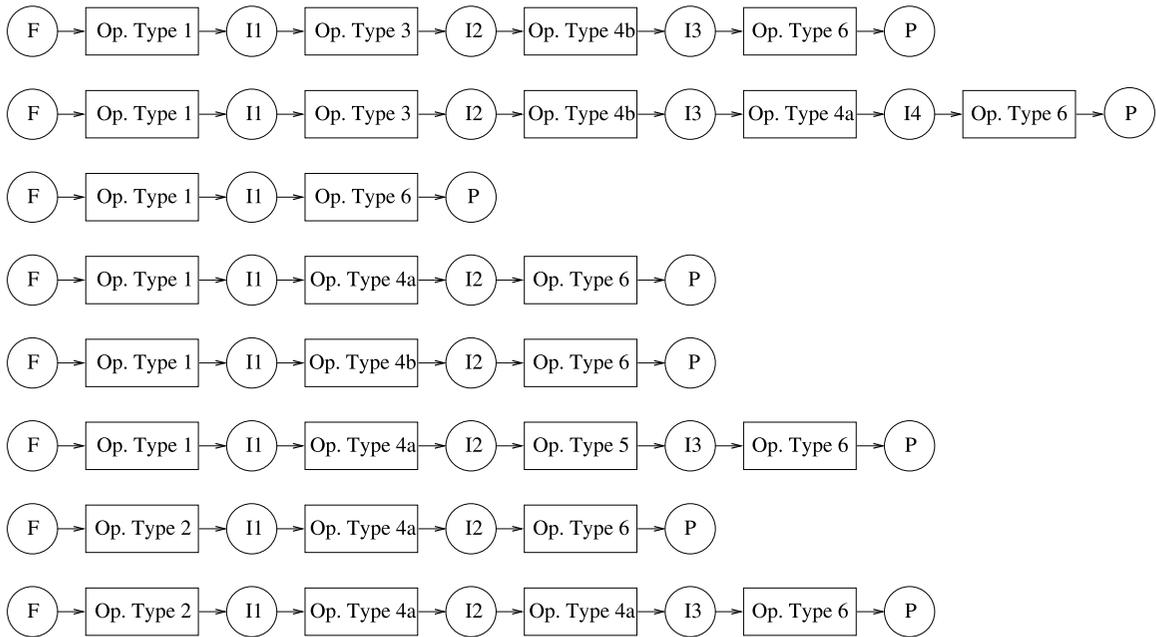

## Problem Statement

In the multiproduct batch plant investigated, there are several different types of operations (or tasks) termed operation type 1 to operation type 6. The plant has many different types of units and over 80 are modeled explicitly. Hundreds of different products can be produced and for each of them, one of the processing recipes shown in Fig. 1 or a slight variation is applied. The recipes are represented in the form of State-Task Network (STN), in which the *state* node is denoted by a circle and the *task* node by a rectangle. The STN representation provides the flow of material through various tasks in the production facility to produce different types of final products and does not represent the actual connectivity of equipment in the plant.

For the first type of STN shown in Fig. 1, raw materials (or state F) are fed into a type 1 unit and undergo operation type 1 to produce an intermediate (or state I1). This intermediate then undergoes operation type 3 in a type 3 unit to produce another intermediate (or state I2). This second intermediate is then sent to a type 4b unit before the resulting intermediate material (or state I3) is sent to a type 6 unit to undergo an operation type 6 task to produce a final product (or state P). The information on which units are suitable for each product is given. All the units are utilized in a batch mode with the exception of the type 5 and 6 units, which operate in a continuous mode. The capacity limits of the type 1, type 2, and type 3 units vary from one product to another, while the capacity limits of the types 4a, 4b, 5 and 6 units are the same for all suitable products. The processing time or processing rate of each task in the suitable units is also specified. Also, some products require other products as their raw materials, creating very complicated state-task networks.

The time horizon considered for production scheduling is a few weeks or longer. Customer orders are fixed throughout the time horizon with specified amounts and due dates. There is no limitation on external raw materials and we apply the zero-wait storage condition or limited intermediate storage capacity for all materials based on actual plant data. There are two different types of products produced, category 1 and 2.

The sixth STN shown in Fig. 1 shows a special type of product, denoted as a campaign product. For this

**Medium-Term Scheduling of Batch Processes, Figure 1**  
**State-task network (STN) representation of plant**

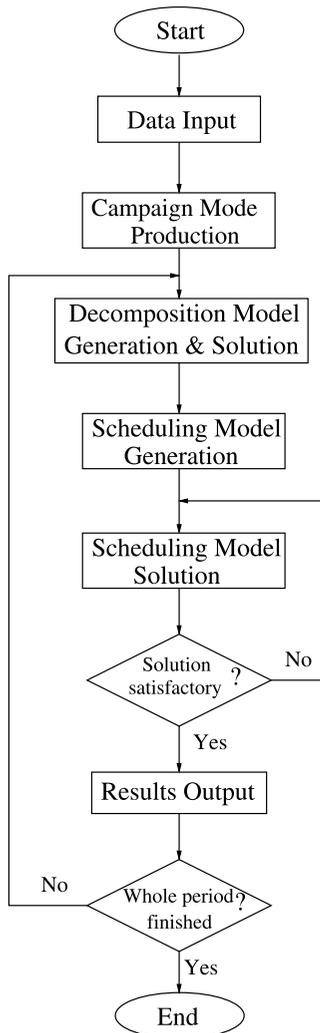

type of product, raw materials are fed into up to three type 1 units and undergo operation type 1 to produce an intermediate, or state I1. This intermediate is then sent to one of two type 4a units before being processed in the type 5 unit, which is a continuous unit. Finally, the intermediate material (or state I3) is sent to a type 6 unit, producing a final campaign product (or state P). Because product changeovers in the type 5 unit can be undesirable, there was a need to introduce the ability to fix campaigns for continuous production of a single product in the type 5 unit, called campaign mode production.

**Formulation**

The overall methodology for solving the medium-range production scheduling problem is to decompose the large and complex problem into smaller short-term scheduling subproblems in successive time horizons [8]. The flowchart for this rolling horizon approach is shown in Fig. 2. The first step is to input relevant data into the formulation. Then, if necessary, campaign mode production is determined. Next, the overall medium-term scheduling problem is considered. A decomposition model is formulated and solved

to determine the current time horizon and corresponding products that should be included in the current subproblem. According to the solution of the decomposition model, a short-term scheduling model is formulated using the information on customer orders, inventory levels, and processing recipes. The resulting MILP problem is a large-scale, complex problem which requires a large computational effort for its solution. When a satisfactory solution is determined, the relevant data is output and the next time horizon is considered. The above procedure is applied iteratively in an automatic fashion until the whole time horizon under consideration has been scheduled.

Note that the decomposition model determines how many days and products to consider in the shorter scheduling horizon subject to an upper limit on the complexity of the resulting mathematical model. Products are selected for the scheduling horizon if there is an order for the product, if the product has an order within a set amount of time into the future, if the product is used as a raw material for another product which is included, if the product was still processing in the previous scheduling horizon, or if the product is a campaign product and is included in a campaign for the current horizon.

Medium-Term Scheduling of Batch Processes, Figure 2  
Flowchart of the rolling horizon approach

### Models

A key component of the rolling horizon approach is the determination of the time horizon and the products which should be included for each short-term scheduling subproblem. We extend the two-level decomposition formulation of Lin et al. [8] which partitions the entire scheduling horizon into shorter subhorizons by taking into account the trade-off between demand satisfaction, unit utilization, and model complexity. In the first level, the number of days in the time horizon and the main products which should be included are determined. In the second level, additional products are

added to the horizon so that each of the first-stage units, or type 1 units, are fully utilized.

### Short-Term Scheduling Model

Once the decomposition model has determined the days in the time horizon and the products to be included, a novel continuous-time formulation for short-term scheduling with multiple intermediate due dates is applied to determine the detailed production schedule. This formulation is based on the models of Floudas and coworkers [6,7,8] and is expanded and enhanced in this work to take into account specific aspects of the problem under consideration. The proposed short-term scheduling formulation requires the following indices, sets, parameters and variables:

#### Indices:

- $d$  days;
- $i$  processing tasks;
- $j$  units;
- $k$  orders;
- $n$  event points representing the beginning of a task;
- $s$  states;

#### Sets:

- $D$  days in the overall scheduling horizon;
- $D^{\text{in}}$  days in the current scheduling horizon;
- $I$  processing tasks;
- $I_j$  tasks which can be performed in unit ( $j$ );
- $I_k$  tasks which process order ( $k$ );
- $I_s^c$  tasks which consume state ( $s$ );
- $I_s^p$  tasks which produce state ( $s$ );
- $I^{\text{in}}$  tasks which are included in the current scheduling horizon;
- $I^{\text{T5}}$  tasks which are used to determine the type 5 unit campaign;
- $I^{\text{T6b}}$  tasks which are used to perform operation type 6 for category 1 products;
- $J$  units;
- $J_i$  units which are suitable for performing task ( $i$ );
- $J^p$  units which are suitable for performing only processing tasks, or operation type 1, 2, 3, and 5 tasks;
- $J^{\text{T1}}$  units which are suitable for performing only operation type 1 tasks;

$J^{T4}$	units which are suitable for performing only operation type 4a and 4b tasks;	$dem_s^{tot}$	total demand for state ( $s$ ) in the overall horizon;
$J^{T5}$	units are which used to determine the type 5 unit campaign;	$duek_{ksd}$	due date of order ( $k$ ) for state ( $s$ ) on day ( $d$ );
$J^{T6}$	units which are suitable for performing only operation type 6 tasks;	$ExtraTime_i$	amount of time needed for operation type 3 task after processing task ( $i$ );
$K$	orders;	$FixedTime_{ij}$	constant term of processing time for task ( $i$ ) in unit ( $j$ );
$K_i$	orders which are processed by task ( $i$ );	$H$	time horizon;
$K_s$	orders which produce state ( $s$ );	$mintasks$	the minimum number of tasks that must occur in the first-stage processing units, $J^{T1}$ ;
$K^{in}$	orders which are included in the current scheduling horizon;	$N^{max}$	the maximum number of event points in the scheduling horizon;
$N$	event points within the time horizon;	$praw_{ss'}$	0-1 parameter to relate final product ( $s$ ) to its raw material product ( $s'$ );
$S$	states;	$price_s$	price of state ( $s$ );
$S_k$	states which are used to satisfy order ( $k$ );	$prior_s$	priority of product state ( $s$ );
$S^{cat1}$	states which are category 1 final products;	$prior_s^{raw}$	priority of raw material state ( $s$ );
$S^{cat2}$	states which are category 2 final products;	$RateCT_{ij}$	variable term of processing time for task ( $i$ ) in unit ( $j$ );
$S^{cpm}$	states which have minimum or maximum storage limitations;	$rk_{ksd}$	amount of order ( $k$ ) for state ( $s$ ) on day ( $d$ );
$S^f$	states which are final products, after operation type 6;	$start_j$	the time at which unit ( $j$ ) first becomes available in the current scheduling horizon;
$S^i$	states which are intermediate products, before operation type 6;	$stcap_s^{max}$	maximum capacity for storage of state ( $s$ );
$S^{in}$	states which are included in the current scheduling horizon;	$stcap_s^{min}$	minimum capacity for storage of state ( $s$ );
$S^P$	states which are either final or intermediate products;	$\alpha$	coefficient for the demand satisfaction of individual orders term;
$S^{rw}$	states which are products and are used as raw materials for other products;	$\beta$	coefficient for the due date satisfaction of individual orders term;
$S^{st}$	states which have no intermediate storage;	$\gamma$	coefficient for the overall demand satisfaction slack variable term;
$S^{T5}$	states which are used to determine the type 5 unit campaign;	$\delta$	coefficient for the minimum inventory requirement in dedicated units term;
$S^{unl}$	states which have unlimited intermediate storage;	$\eta$	coefficient for the artificial demands on raw material states term;
$S^0$	states which are external raw materials;	$\kappa$	coefficient for the minimizing of binary variables term;
<i>Parameters:</i>		$\lambda$	coefficient for the minimizing of active start times term;
$B_s^{max}$	the maximum suitable batch size used to produce product state ( $s$ );	$\mu$	a small constant (e. g., 0.01);
$B_s^{min}$	the minimum suitable batch size used to produce product state ( $s$ );	$\rho_{is}^c$	proportion of state ( $s$ ) consumed by task ( $i$ );
$C$	a large constant (e. g., 10000);	$\rho_{is}^p$	proportion of state ( $s$ ) produced by task ( $i$ );
$cap_{ij}^{max}$	maximum capacity for task ( $i$ ) in unit ( $j$ );		
$cap_{ij}^{min}$	minimum capacity for task ( $i$ ) in unit ( $j$ );		
$dem_s$	demand for state ( $s$ ) in the current scheduling horizon;		
$dem_s^{rw}$	demand for raw material product state ( $s$ );		

$\tau_{ii'}$	sequence-dependent setup time between tasks ( $i$ ) and ( $i'$ );	$tt^s(i, j, n)$	starting time of the active task ( $i$ ) in unit ( $j$ ) at event point ( $n$ );
$\phi$	coefficient for the satisfaction of orders term;	<i>Binary Variables:</i>	
$\omega$	coefficient for the overall production term;	$wv(i, j, n)$	assigns the beginning of task ( $i$ ) in unit ( $j$ ) at event point ( $n$ );
<i>Continuous Variables:</i>		$y(i, k, n)$	assigns the delivery of order ( $k$ ) through task ( $i$ ) at event point ( $n$ );
$B(i, j, n)$	amount of material undertaking task ( $i$ ) in unit ( $j$ ) at event point ( $n$ );	On the basis of this notation, the mathematical model for the short-term scheduling of an industrial batch plant with intermediate due dates involves the following constraints:	
$D(s, n)$	amount of state ( $s$ ) delivered at event point ( $n$ );	$\sum_{i \in I^{in}, I_j} wv(i, j, n) \leq 1, \quad (1)$	
$Df(s, n)$	amount of state ( $s$ ) delivered after the last event point;	$\forall j \in J, n \in N, n \leq N^{\max}$	
$kD(k, s, n)$	amount of state ( $s$ ) delivered at event point ( $n$ ) for order ( $k$ );	$cap_{ij}^{\min} \cdot wv(i, j, n) \leq B(i, j, n) \leq cap_{ij}^{\max} \cdot wv(i, j, n), \quad (2)$	
$kDf(k, s, n)$	amount of state ( $s$ ) delivered after the last event point for order ( $k$ );	$\forall i \in I^{in}, j \in J_i, n \in N, n \leq N^{\max}$	
$sla1(k, s, d)$	amount of state ( $s$ ) due on day ( $d$ ) for order ( $k$ ) that is not delivered;	$st(s, n) = 0, \quad \forall s \in S^{in}, S^{st}, \quad (3)$	
$sla2(k, s, d)$	amount of state ( $s$ ) due on day ( $d$ ) for order ( $k$ ) that is over delivered;	$s \notin S^{cpm}, S^{unl}, \quad n \in N, n \leq N^{\max}$	
$slcap(s, n)$	amount of state ( $s$ ) that is deficient in its dedicated storage unit at event point ( $n$ );	$st(s, n) \geq stcap_s^{\min} - slcap(s), \quad (4)$	
$sll(s)$	amount of state ( $s$ ) due in the current time horizon but not made;	$\forall s \in S^{in}, S^{cpm}, n \in N, n \leq N^{\max}$	
$sll^{raw}(s)$	amount of raw material product state ( $s$ ) artificially due in the current time horizon but not made;	$st(s, n) \leq stcap_s^{\max}, \quad (5)$	
$slorder(k)$	0-1 variable indicating if order ( $k$ ) was met;	$\forall s \in S^{in}, S^{cpm}, n \in N, n \leq N^{\max}$	
$slt1(k, s, d)$	amount of time state ( $s$ ) due on day ( $d$ ) for order ( $k$ ) is late;	$ST(s, n) = ST(s, n-1) - D(s, n) + \sum_{i \in I_s^p} \rho_{is}^p \sum_{j \in J_i} B(i, j, n-1) - \sum_{i \in I_s^c} \rho_{is}^c \sum_{j \in J_i} B(i, j, n), \quad (6)$	
$slt2(k, s, d)$	amount of time state ( $s$ ) due on day ( $d$ ) for order ( $k$ ) is early;	$\forall s \in S^{in}, n \in N, n > 1, n \leq N^{\max}$	
$ST(s, n)$	amount of state ( $s$ ) at event point ( $n$ );	$ST(s, n) = STO(s) - D(s, n) - \sum_{i \in I_s^c} \rho_{is}^c \sum_{j \in J_i} B(i, j, n), \quad (7)$	
$STF(s)$	final amount of state ( $s$ ) at the end of the current time horizon;	$\forall s \in S^{in}, n \in N, n = 1$	
$STO(s)$	initial amount of state ( $s$ ) at the beginning of the current time horizon;	$STF(s) = ST(s, n) - Df(s, n) + \sum_{i \in I_s^p} \rho_{is}^p \sum_{j \in J_i} B(i, j, n), \quad (8)$	
$T^f(i, j, n)$	time at which task ( $i$ ) finishes in unit ( $j$ ) at event point ( $n$ );	$\forall s \in S^{in}, n \in N, n = N^{\max}$	
$T^s(i, j, n)$	time at which task ( $i$ ) starts in unit ( $j$ ) at event point ( $n$ );		
$tot(s)$	total amount of state ( $s$ ) made in the current time horizon;		

$$T^f(i, j, n) = T^s(i, j, n) + \text{FixedTime}_{ij} \cdot wv(i, j, n) \\ + \text{RateCT}_{ij} \cdot B(i, j, n), \quad (9)$$

$$\forall i \in I^{\text{in}}, j \in J^{\text{P}} \cup J^{\text{T6}}, J_i, n \in N, n \leq N^{\text{max}}$$

$$T^f(i, j, n) \geq T^s(i, j, n), \\ \forall i \in I^{\text{in}}, j \in J^{\text{T4}}, J_i, n \in N, n \leq N^{\text{max}} \quad (10)$$

$$T^f(i, j, n) = H, \quad \forall s \in S^{\text{in}}, S^{\text{st}}, s \notin S^{\text{unl}}, \\ i \in I^{\text{in}}, I_s^{\text{P}}, j \in J^{\text{T4}}, J_i, n \in N, n = N^{\text{max}} \quad (11)$$

$$T^s(i, j, n+1) \geq T^f(i, j, n) \\ + \text{ExtraTime}_i \cdot wv(i, j, n), \quad (12) \\ \forall i \in I^{\text{in}}, j \in J_i, n \in N, n < N^{\text{max}}$$

$$T^s(i, j, n+1) \geq T^f(i', j, n) + (\tau_{i'} + \text{ExtraTime}_{i'}) \\ \cdot wv(i', j, n) - H[1 - w(i', j, n)], \\ \forall j \in J, i, i' \in I^{\text{in}}, I_j, i \neq i', n \in N, n < N^{\text{max}} \quad (13)$$

$$T^s(i, j, n+1) \geq T^f(i', j', n) \\ - H[1 - wv(i', j', n)], \quad (14) \\ \forall s \in S^{\text{in}}, i \in I^{\text{in}}, I_s^{\text{c}}, i' \in I^{\text{in}}, I_s^{\text{P}}, \\ j \in J_i, j' \in J_{i'}, j \neq j', n \in N, n < N^{\text{max}}$$

$$T^s(i, j, n+1) \leq T^f(i', j', n) + H[2 - wv(i', j', n) \\ - wv(i, j, n+1)], \\ \forall s \in S^{\text{in}}, S^{\text{st}}, s \notin S^{\text{unl}}, i \in I^{\text{in}}, I_s^{\text{c}}, i' \in I^{\text{in}}, I_s^{\text{P}}, \\ j \in J_i, j' \in J_{i'}, j \neq j', n \in N, n < N^{\text{max}} \quad (15)$$

The allocation constraints in (1) express the requirement that for each unit ( $j$ ) and at each event point ( $n$ ), only one of the tasks that can be performed in the unit (i. e.,  $i \in I_j$ ) should take place. The capacity constraints in (2) express the requirement for the batch-size of a task ( $i$ ) processing in a unit ( $j$ ) at event point ( $n$ ),  $B(i, j, n)$ , to be greater than the minimum amount of material,  $cap_{ij}^{\text{min}}$ , and less than the maximum amount of material,  $cap_{ij}^{\text{max}}$ , that can be processed by task ( $i$ ) in unit ( $j$ ). The storage constraints in (3) enforce that those states with no intermediate storage have to be consumed by some processing task or storage task immediately after they are produced. Constraints (4) represent

the minimum required storage for state ( $s$ ) in a dedicated storage tank where this amount can be violated, if necessary, by an amount  $slcap(s)$  which is penalized in the objective function. Constraints (5) represent the maximum available storage capacity for state ( $s$ ) based on the maximum storage capacity of the dedicated storage tank. According to the material balance constraints in (6), the amount of material of state ( $s$ ) at event point ( $n$ ) is equal to that at event point ( $n-1$ ) increased by any amounts produced at event point ( $n-1$ ), decreased by any amounts consumed at event point ( $n$ ), and decreased by the amount required by the market at event point ( $n$ ),  $D(s, n)$ . Constraints (7)–(8) represent the material balance on state ( $s$ ) at the first and last event points, respectively. The duration constraints in (9) represent the relationship between the starting and finishing times of task ( $i$ ) in unit ( $j$ ) at event point ( $n$ ) for all processing tasks (i. e.,  $J^{\text{P}}$ ) and all operation type 6 tasks (i. e.,  $J^{\text{T6}}$ ) where  $\text{FixedTime}_{ij}$  are the fixed processing times for batch tasks and zero for continuous tasks and  $\text{RateCT}_{ij}$  are the inverse of processing rates for continuous tasks and zero for batch tasks, respectively. Constraints (10) also represent the relationship between the starting and finishing times of task ( $i$ ) in unit ( $j$ ) at event point ( $n$ ), but for operation type 4a and 4b tasks (i. e.,  $J^{\text{T4}}$ ). They do not impose exact durations for tasks in these units but just enforce that all tasks must end after they start. Constraints (11) are written only for tasks in units which are processing a nonstorable state (i. e.,  $S^{\text{st}}$  and not  $S^{\text{unl}}$ ) and enforce that task ( $i$ ) taking place at the last event point ( $n$ ) must finish at the end of the horizon.

The sequence constraints in (12) state that task ( $i$ ) starting at event point ( $n+1$ ) should start after the end of the same task performed in the same unit ( $j$ ) which has finished at the previous event point, ( $n$ ) where extra time is added after task ( $i$ ) at event point ( $n$ ), if necessary. The constraints in (13) are written for tasks ( $i$ ) and ( $i'$ ) that are performed in the same unit ( $j$ ) at event points ( $n+1$ ) and ( $n$ ), respectively. If both tasks take place in the same unit, they should be at most consecutive. The third set of sequence constraints in (14) relate tasks ( $i$ ) and ( $i'$ ) which are performed in different units ( $j$ ) and ( $j'$ ) but take place consecutively according to the production recipe. The zero-wait constraints in (15) are written for different tasks ( $i$ ) and ( $i'$ ) that take place consecutively with the intermediate state ( $s$ )

having no possible intermediate storage and thus subject to the zero-wait condition.

$$\sum_{\substack{i \in I^{\text{in}}, \\ I_k, I^{\text{T6b}}}} \sum_{\substack{n \in N \\ n \leq N^{\text{max}}}} y(i, k, n) + \text{slorder}(k) \geq 1, \quad (16)$$

$$\forall s \in S^{\text{in}}, S^{\text{cat1}}, \quad k \in K^{\text{in}}, K_s, \quad i \in I^{\text{in}}, I_k, I^{\text{T6b}},$$

$$j \in J_i, \quad n \in N, \quad n \leq N^{\text{max}}, \quad d \in D^{\text{in}}, rk_{ksd} > 0$$

$$T^f(i, j, n) + \text{slt2}(k, s, d, n) \geq (\text{duek}(k, s, d) - 24) - H \cdot (2 - wv(i, j, n) - y(i, k, n)),$$

$$\forall s \in S^{\text{in}}, S^{\text{cat1}}, \quad k \in K^{\text{in}}, K_s, \quad i \in I^{\text{in}}, I_k, I^{\text{T6b}},$$

$$j \in J_i, \quad n \in N, \quad n \leq N^{\text{max}}, \quad d \in D^{\text{in}}, rk_{ksd} > 0 \quad (26)$$

The order satisfaction constraints in (16)–(23) are written to ensure that all orders for category 1 products are met on-time and with the required amount. Both under and overproduction as well as early and late production are represented with slack variables that are penalized in the objective function. Note that these constraints can be modified to represent different requirements for production, if desired. Constraints (16) try to ensure that each order ( $k$ ) is met at least one time with an operation type 6 task ( $i$ ), where task ( $i$ ) is suitable for order ( $k$ ) if  $i \in I_k$  and is a operation type 6 task for a category 1 product if  $i \in I^{\text{T6b}}$ . Similarly, constraints (17) enforce the condition that each order ( $k$ ) for category 1 product state ( $s$ ) on day ( $d$ ) can be met with at most  $\lceil rk_{ksd} / B_s^{\text{min}} \rceil$  tasks. Constraints (18) and (19) link the delivery of order ( $k$ ) through task ( $i$ ) at event point ( $n$ ) to the beginning of task ( $i$ ) in any suitable unit ( $j$ ) at event point ( $n$ ) so that every category 1 operation type 6 task must be linked to at least one order delivery and vice versa. Thus, constraint (18) enforces that if a binary variable is activated for operation type 6 task ( $i$ ), then at least one order delivery must be activated. Similarly, constraint (19) ensures that if no binary variables are activated for operation type 6 task ( $i$ ) at event point ( $n$ ), then no delivery variables can be activated. Constraints (20) relate the individual order delivery variables to the batch-size of the operation type 6 task used to satisfy the order. If an order ( $k$ ) is met by task ( $i$ ) at event point ( $n$ ) (i. e.,  $y(i, k, n) = 1$ ), then at least one

operation type 6 task is active for task ( $i$ ) at event point ( $n$ ) and thus at least one  $B(i, j, n)$  variable is greater than zero. Constraints (21) and (22) relate the individual order delivery variables to the overall delivery variables used in the material balance constraints.

Constraints (23) and (24) determine the under and overproduction, respectively, of order ( $k$ ) for state ( $s$ ) on day ( $d$ ). Constraints (23) try to enforce the individual order delivery variables to exceed the amount due for order ( $k$ ) (i.e.,  $rk_{ksd}$ ) where slack variables  $sla1(k, s, d)$  are activated in the case of underproduction. Similarly, constraints (24) try to enforce the individual order delivery variables plus any amount of the product state left at the end of the horizon not to exceed the amount due for order ( $k$ ) where slack variables  $sla2(k, s, d)$  are activated in the case of overproduction. Constraints (25) and (26) determine the late and early production, respectively, of order ( $k$ ) for state ( $s$ ) on day ( $d$ ). Constraints (25) try to enforce the finishing time of task ( $i$ ) used to satisfy order ( $k$ ) at event point ( $n$ ) to be less than the due date of order ( $k$ ) where slack variables  $slt1(k, s, d, n)$  are activated in the case of late production. Similarly, constraints (26) try to enforce the finishing time of task ( $i$ ) used to fulfill order ( $k$ ) at event point ( $n$ ) to be greater than the beginning of the day ( $d$ ) on which the order is due (i.e.,  $duek(k, s, d) - 24$ ). Otherwise, slack variables  $slt2(k, s, d, n)$  are activated indicating early production.

$$tot(s) = stf(s) + \sum_{\substack{n \in N \\ n \leq N^{\max}}} [D(s, n) + Df(s, n)], \quad (27)$$

$$\forall s \in S^{\text{in}}$$

$$\sum_{\substack{n \in N \\ n \leq N^{\max}}} [D(s, n) + Df(s, n)] + sll(s) \geq dem_s, \quad (28)$$

$$\forall s \in S^{\text{in}}, S^{\text{cat1}}$$

$$tot(s) + sll(s) \geq dem_s, \quad \forall s \in S^{\text{in}}, S^{\text{cat2}} \quad (29)$$

$$\sum_{i \in I^{\text{in}}, I_s^{\text{p}}} \sum_{j \in J_i} \sum_{\substack{n \in N \\ n \leq N^{\max}}} B(i, j, n) + sll^{\text{raw}}(s) \geq dem_s^{\text{raw}}, \quad (30)$$

$$\forall s \in S^{\text{in}}, S^{\text{rw}}, s' \in S^{\text{in}}, S^{\text{f}}, praw_{s',s} > 0,$$

$$dem_{s'} > 0, dem_s^{\text{raw}} > 0$$

Constraints (27)–(29) are used to determine the overall underproduction for both category 1 and 2

products in the current time horizon. First, constraints (27) determine the total production for all product states ( $s$ ) (i.e.,  $tot(s)$ ) in the current horizon. Then, constraints (28) sum the overall delivery variables for category 1 products and activate the slack variables  $sll(s)$  if the sum does not exceed the demand for category 1 product state ( $s$ ). Similarly, constraints (29) calculate the amount of underproduction (i.e.,  $sll(s)$ ) for category 2 product state ( $s$ ) based on its overall demand in the time horizon. The slack variable  $sll(s)$  is then penalized in the objective function where category 1 and 2 products can be penalized at different weights. Constraints (30) determine the amount of underproduction for intermediate product states ( $s$ ) that are needed as raw materials for final product states ( $s'$ ).

The bound constraints are used to impose lower and upper bounds on the continuous variables including slack variables. They are also used to fix some binary and continuous variables to be zero when necessary.

$$T^{\text{f}}(i, j, n) \geq start_j, \quad \forall i \in I, j \in J_i, n \in N$$

\end{aligned}$$

There are several different objective functions that can be employed with a general short-term scheduling problem. In this work, we maximize the sale of final products while penalizing several other terms including the slack variables introduced previously. The overall objective function is as follows:

$$\begin{aligned}
Max \quad & \omega \cdot \sum_{s \in S^{in}, S^P} price_s \cdot tot(s) \\
& - \lambda \cdot \sum_{i \in I^{in}} \sum_{j \in J_i} \sum_{\substack{n \in N \\ n \leq N^{max}}} tts(i, j, n) \\
& - \kappa \cdot \left[ \sum_{i \in I^{in}} \sum_{j \in J_i} \sum_{\substack{n \in N \\ n \leq N^{max}}} wv(i, j, n) \right. \\
& \quad \left. + \sum_{k \in K^{in}} \sum_{i \in I_k} \sum_{\substack{n \in N \\ n \leq N^{max}}} y(i, k, n) \right] \\
& - \gamma \cdot \sum_{s \in S^f} prior_s \cdot sll(s) - \phi \cdot \sum_{k \in K^{in}} slorder(k) \\
& - \alpha \cdot \left[ \sum_{k \in K^{in}} \sum_{s \in S^{cat1}} \sum_{d \in D^{in}} sla1(k, s, d) \right. \\
& \quad \left. + \mu \cdot sla2(k, s, d) \right]
\end{aligned}$$

$$\begin{aligned}
& - \beta \cdot \left[ \sum_{k \in K^{in}} \sum_{s \in S^{cat1}} \sum_{d \in D^{in}} \sum_{\substack{n \in N \\ n \leq N^{max}}} \mu \cdot slt1(k, s, d, n) \right. \\
& \quad \left. + slt2(k, s, d, n) \right] \\
& - \eta \cdot \sum_{s \in S^{rw}} prior_s^{raw} \cdot sll^{raw}(s) \\
& - \delta \cdot \sum_{s \in S^{cpm}} \sum_{\substack{n \in N \\ n \leq N^{max}}} slcap(s, n)
\end{aligned} \quad (32)$$

where each of the coefficients is used to balance the relative weight of each term in the overall objective function. The first term is the maximization of the value of the final products and is the main term of the objective function. The second term seeks to minimize the sum of the starting times of all active processing tasks. This is done to encourage all tasks to start as early as possible in the scheduling horizon. Note that this results in a bilinear term which can be replaced with an equivalent linear term and set of constraints [3]. The third term seeks to minimize the number of active binary variables in the final production schedule. The fourth term seeks to minimize the slack variable that is activated when product state ( $s$ ) does not meet its overall demand for the time horizon. Coefficient  $prior_s$  allows the ability to assign different weights to different product states. The fifth term minimizes the number of category 1 orders ( $k$ ) that are not filled in the time horizon. The sixth term minimizes the amount of over and underproduction of orders for category 1 products in the time horizon where the coefficient  $\mu$  allows over and underproduction to be penalized by different amounts. The seventh term seeks to minimize the amount of early and late production of orders for category 1 products due in the time horizon where the coefficient  $\mu$  allows early and late production to be penalized to different degrees. The eighth term minimizes the slack variables activated when insufficient raw material state ( $s$ ) is produced during the time horizon where  $prior_s^{raw}$  allows different states to be penalized by different amounts. The ninth, and final, term seeks to minimize the slack variables activated when insufficient intermediate state ( $s$ ) is stored in its dedicated storage tank at each event point. Typical

values for each of the coefficients are as follows:  $\omega = 1$ ,  $\lambda = 1$ ,  $\kappa = 10$ ,  $\gamma = 1000$ ,  $\phi = 1000$ ,  $\alpha = 2000$ ,  $\beta = 500$ ,  $\mu = 0.01$ ,  $\eta = 50$ ,  $\delta = 10$ .

**Cases**

In this section, an example problem is presented to demonstrate the effectiveness of the rolling horizon framework. The example utilizes the proposed framework to determine the medium range production schedule of an industrial batch plant for a two-week time period which satisfies customer orders for various products distributed throughout the time period. The example is implemented with GAMS 2.50 [1] and solved using CPLEX 9.0 [2] with a 3.20 GHz Linux workstation. The dual simplex method is used with best-bound search and strong branching. A relative optimality tolerance equal to 0.001% was used as the termination criterion along with a three hour time limit and an integer solution limit of 40.

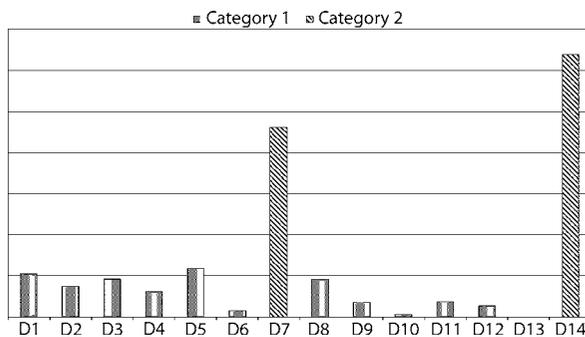

The distribution of demands for the entire two-week time period is shown in Fig. 3 where the amounts are shown in relative terms. There are two categories of products, category 1 and 2, and a total of 67 different products have demands. There are two different campaign products that can be scheduled for campaign mode production and an additional eight intermediate products are used to make final products, even though they do not have demands. It is assumed that no final products are available at the beginning of the time horizon although some intermediate materials are available. Also, we assume no limitation on external raw materials and the zero-wait condition is applied to all intermediate materials unless they are used as raw materials for

other final products. In this case, unlimited intermediate storage is allowed. Note that finite intermediate storage is effectively modeled for those intermediates that have a dedicated storage task with a given capacity limit. In addition, there are two types of connections made between each consecutive short-term scheduling horizon in the rolling horizon framework: the initial available time for each unit and the inventory of intermediate materials.

**Case 1: Nominal Run without Campaign Mode Production**

The example problem considers the production scheduling of an industrial batch plant where no type 5 unit campaign is imposed. Instead, demands for both campaign products are created throughout the time horizon with a total demand for each product equal to the production that would be imposed by a campaign. The total time period is 19 days, from D0 to D18. The rolling horizon framework decomposes the time horizon into 8 individual subhorizons, each with its own products and demands. The results of the decomposition for each time horizon can be seen in Table 1.

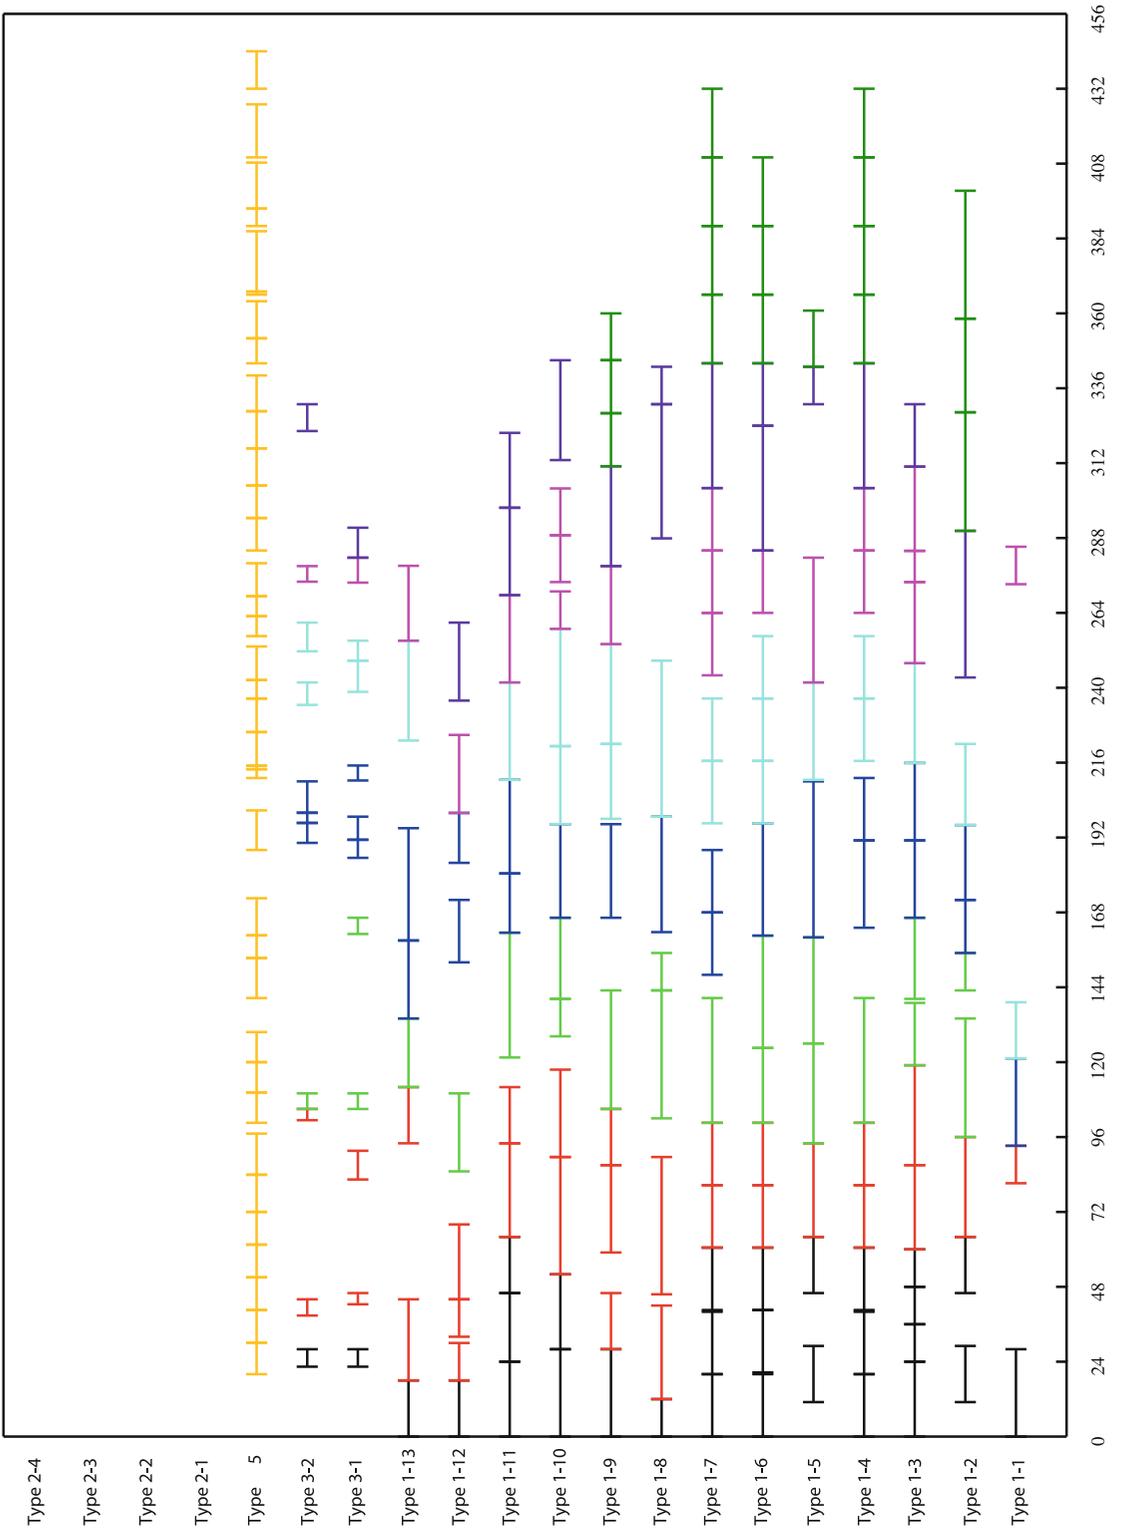

The final production schedule for the entire time period can be seen in Fig. 4 and 5 where the processing units (operation type 1, 2, 3, and 5) are shown in the first figure and the other units (operation type 4a, 4b, and 6) are shown in the second. Each short-term scheduling horizon is represented with a different color beginning with black for the first horizon, red for the second horizon, green for the third horizon, etc. The model and solution statistics for each short-term

scheduling horizon can be seen in Table 2 where each horizon runs for the time limit of three hours.

The total demand for the entire 14-day period is 2323.545 and the total production is 2744.005, where 51.674 of the demands are not met. The production schedules obtained satisfy demands for almost all the products, though some due dates are relaxed, and also produce 18.10% more material than the demands require. Many of the processing units are not fully utilized, as shown in Table 3, indicating the potential for even more production in the given time period. Also, note that the processing units become more idle towards the end of the overall time horizon. This is because no demands are specified for the days following day D14 including days D15 to D18. Additional demands at the end of the overall time horizon or in the following days would generate a more heavily utilized production schedule.

## Conclusions

In this paper, a *unit-specific* event-based continuous-time formulation is presented for the medium-term production scheduling of a large-scale, multipurpose industrial batch plant. The proposed formulation takes into account a large number of processing recipes and units and incorporates several features including various storage policies (UIS, NIS, ZW), variable batch sizes and processing times, batch mixing and splitting, sequence-dependent changeover times, intermediate due dates, products used as raw materials, and several modes of operation. The scheduling horizon is several weeks or longer, however longer time periods can be addressed with the proposed framework. A key feature of the proposed formulation is the use of a de-

Type 5	362.04	93.96	79.39%

composition model to split the overall scheduling horizon into smaller subhorizons which are scheduled in a sequential fashion. Also, new constraints are added to the short-term scheduling model in order to model the delivery of orders at intermediate due dates. The effectiveness of the proposed approach is demonstrated with an industrial case study. Results indicate that the rolling horizon approach is effective at solving large-scale, medium-term production scheduling problems.

### Introduction

The **vehicle routing problem (VRP)** or the **capacitated vehicle routing problem (CVRP)** is often described as a problem in which vehicles based at a central depot are required to visit geographically dispersed customers in order to fulfill known customer demands. Let  $G = (V, E)$  be a graph where  $V = \{i_0, i_1, i_2, \dots, i_n\}$  is the vertex set ( $i_0 = i_0$  refers to the depot and the customers are indexed  $i_i = i_1, \dots, i_n$ ) and  $E = \{(i_l, i_{l_1}) : i_l, i_{l_1} \in V\}$  is the edge set. Each customer must be assigned to exactly one of the  $k$  vehicles and the total size of deliveries for customers assigned to each vehicle must not exceed the vehicle capacity ( $Q_k$ ). If the vehicles are homogeneous, the capacity for all vehicles is equal and denoted by  $Q$ . A demand  $q_{i_l}$  and a service time  $st_{i_l}$  are associated with each customer node  $i_l$ . The travel cost between customers  $i_l$  and  $i_{l_1}$  is  $c_{i_l i_{l_1}}$ . The problem is to construct a low cost, feasible set of routes – one for each vehicle. A route is a sequence of locations that a vehicle must visit along with the indication of the service it provides. The vehicle must start and finish its tour at the depot. The most important variants of the vehicle routing problem can be found in [12,13,39,54,84].

The vehicle routing problem was first introduced by Dantzig and Ramser [21]. As it is an NP-hard problem, the instances with a large number of customers cannot be solved in optimality within reasonable time. Due to the general inefficiency of the exact methods and their inability to solve large scale VRP instances, a large number of approximation techniques have been proposed. These techniques are classified into two main categories, the classical heuristics that were developed mostly between 1960 and 1990 and the metaheuristics that were developed in the last fifteen years.

In the 1960s and 1970s the first attempts to solve the vehicle routing problem focused on route building, route improvement and two-phase heuristics. In the 1980s a number of mathematical programming procedures were proposed for the solution of the problem. The most important of them can be found in [6,18,19,22,28,29,33,62,88].

### Metaheuristic Algorithms for the Vehicle Routing Problem

The last fifteen years an incremental amount of metaheuristic algorithms have been proposed. Simulated

annealing, genetic algorithms, neural networks, tabu search, ant algorithms, together with a number of hybrid techniques are the main categories of the metaheuristic procedures. These algorithms have the ability to find their way out of local optima. Surveys in metaheuristic algorithms have been published by [27,31,32,49,50,79].

A number of metaheuristic algorithms have been proposed for the solution of the Capacitated Vehicle Routing Problem. The most important algorithms published for each metaheuristic algorithm are given in the following:

- **Simulated Annealing (SA)** [1,3,47,72] plays a special role within local search for two reasons. First, they appear to be quite successful when applied to a broad range of practical problems. Second, some threshold accepting algorithms such as SA have a stochastic component, which facilitates a theoretical analysis of their asymptotic convergence. Simulated Annealing [2] is a stochastic algorithm that allows random uphill jumps in a controlled fashion in order to provide possible escapes from poor local optima. Gradually the probability allowing the objective function value to increase is lowered until no more transformations are possible. Simulated Annealing owes its name to an analogy with the annealing process in condensed matter physics, where a solid is heated to a maximum temperature at which all particles of the solid randomly arrange themselves in the liquid phase, followed by cooling through careful and slow reduction of the temperature until the liquid is frozen with the particles arranged in a highly structured lattice and minimal system energy. This ground state is reachable only if the maximum temperature is sufficiently high and the cooling sufficiently slow. Otherwise a meta-stable state is reached. The meta-stable state is also reached with a process known as quenching, in which the temperature is instantaneously lowered. Its predecessor is the so-called Metropolis filter. Simulated Annealing algorithms for the VRP are presented in [14,31,63].
- **Threshold Accepting Method** is a modification of the Simulated Annealing, which together with **record to record travel** [25,26] are known as **Deterministic Annealing** methods. These methods leave out the stochastic element in accepting worse solutions by introducing a deterministic threshold denoted by  $Th_m > 0$ , and accept a worse solution if  $\sigma = c(S') - c(S) \leq Th_m$ , where  $c$  is the cost of the solution. This is the move acceptance criterion and the subscript  $m$  is an iteration index. Dueck and Scheurer [26] were the first to propose the Threshold Accepting Method for the VRP. Tarantilis et al. [81,82] proposed two very efficient algorithms belonging to this class: the **Backtracking Adaptive Threshold Accepting (BATA)** and the **List-Based Threshold Accepting (LBTA)**. Other Deterministic Annealing methods were proposed by Golden et al. [40], the **Record-to-Record Travel Method** and by Li et al. [51].
- **Tabu search (TS)** was introduced by Glover [34,35] as a general iterative metaheuristic for solving combinatorial optimization problems. Computational experience has shown that TS is a well established approximation technique, which can compete with almost all known techniques and which, by its flexibility, can beat many classic procedures. It is a form of local neighbor search. Each solution  $S$  has an associated set of neighbors  $N(S)$ . A solution  $S' \in N(S)$  can be reached from  $S$  by an operation called a *move*. TS can be viewed as an iterative technique which explores a set of problem solutions, by repeatedly making moves from one solution  $S$  to another solution  $S'$  located in the neighborhood  $N(S)$  of  $S$  [37]. TS moves from a solution to its best admissible neighbor, even if this causes the objective function to deteriorate. To avoid cycling, solutions that have been recently explored are declared *forbidden or tabu* for a number of iterations. The tabu status of a solution is overridden when certain criteria (*aspiration criteria*) are satisfied. Sometimes, *intensification* and *diversification* strategies are used to improve the search. In the first case, the search is accentuated in the promising regions of the feasible domain. In the second case, an attempt is made to consider solutions in a broad area of the search space. Tabu Search algorithms for the VRP are presented in [7,9,20,30,63,70,71,77,85,89,90].
- **Genetic Algorithms (GAs)** are search procedures based on the mechanics of natural selection and natural genetics. The first GA was developed by John H. Holland in the 1960s to allow computers to evolve solutions to difficult search and combinatorial prob-

lems, such as function optimization and machine learning [44]. Genetic algorithms offer a particularly attractive approach for problems like vehicle routing problem since they are generally quite effective for rapid global search of large, non-linear and poorly understood spaces. Moreover, genetic algorithms are very effective in solving large-scale problems. Genetic algorithms [38,72] mimic the evolution process in nature. GAs are based on an imitation of the biological process in which new and better populations among different species are developed during evolution. Thus, unlike most standard heuristics, GAs use information about a population of solutions, called individuals, when they search for better solutions. A GA is a stochastic iterative procedure that maintains the population size constant in each iteration, called a generation. Their basic operation is the mating of two solutions in order to form a new solution. To form a new population, a binary operator called crossover, and a unary operator, called mutation, are applied [65,66]. Crossover takes two individuals, called parents, and produces two new individuals, called offsprings, by swapping parts of the parents. Genetic Algorithms for the VRP are presented in [4,5,8,11,45,56,53,60,64].

- **Greedy Randomized Adaptive Search Procedure – GRASP [73]** is an iterative two phase search method which has gained considerable popularity in combinatorial optimization. Each iteration consists of two phases, a construction phase and a local search procedure. In the construction phase, a randomized greedy function is used to build up an initial solution. This randomized technique provides a feasible solution within each iteration. This solution is then exposed for improvement attempts in the local search phase. The final result is simply the best solution found over all iterations. Greedy Randomized Adaptive Search Procedure algorithms for the VRP are presented in [17,42,55].
- The use of **Artificial Neural Networks** to find good solutions to combinatorial optimization problems has recently caught some attention. A neural network consists of a network [76] of elementary nodes (neurons) that are linked through weighted connections. The nodes represent computational units, which are capable of performing a simple computation, consisting of a summation of the

weighted inputs, followed by the addition of a constant called the threshold or bias, and the application of a nonlinear response (activation) function. The result of the computation of a unit constitutes its output. This output is used as an input for the nodes to which it is linked through an outgoing connection. The overall task of the network is to achieve a certain network configuration, for instance a required input–output relation, by means of the collective computation of the nodes. This process is often called *self-organization*. Neural Networks algorithm for the VRP are presented in [61,83].

- The **Ant Colony Optimization (ACO)** metaheuristic is a relatively new technique for solving combinatorial optimization problems (COPs). Based strongly on the Ant System (AS) metaheuristic developed by Dorigo, Maniezzo and Colormi [24], ant colony optimization is derived from the foraging behaviour of real ants in nature. The main idea of ACO is to model the problem as the search for a minimum cost path in a graph. Artificial ants walk through this graph, looking for good paths. Each ant has a rather simple behavior so that it will typically only find rather poor-quality paths on its own. Better paths are found as the emergent result of the global cooperation among ants in the colony. An ACO algorithm consists of a number of cycles (iterations) of solution construction. During each iteration a number of ants (which is a parameter) construct complete solutions using heuristic information and the collected experiences of previous groups of ants. These collected experiences are represented by a digital analogue of trail pheromone which is deposited on the constituent elements of a solution. Small quantities are deposited during the construction phase while larger amounts are deposited at the end of each iteration in proportion to solution quality. Pheromone can be deposited on the components and/or the connections used in a solution depending on the problem. Ant Colony Optimization algorithms for the VRP are presented in [10,15,16,23,57,67,68,69].
- **Path Relinking** This approach generates new solutions by exploring trajectories that connect high-quality solutions – by starting from one of these solutions, called the *starting solution* and generating a path in the neighborhood space that leads

towards the other solution, called the *target solution* [36]. Two new metaheuristic algorithms using the path relinking strategy as a part first of Tabu Search Metaheuristic is proposed in [43] and second as a part of a Particle Swarm Optimization Metaheuristic is proposed in [52].

- **Guided Local Search (GLS)**, originally proposed by Voudouris and Chang [86,87], is a general optimization technique suitable for a wide range of combinatorial optimization problems. The main focus is on the exploitation of problem and search-related information to effectively guide local search heuristics in the vast search spaces of NP-hard optimization problems. This is achieved by augmenting the objective function of the problem to be minimized with a set of penalty terms which are dynamically manipulated during the search process to steer the heuristic to be guided. GLS augments the cost function of the problem to include a set of penalty terms and passes this, instead of the original one, for minimization by the local search procedure. Local search is confined by the penalty terms and focuses attention on promising regions of the search space. Iterative calls are made to local search. Each time local search gets caught in a local minimum, the penalties are modified and local search is called again to minimize the modification cost function. Guided Local Search algorithms for the VRP are presented in [58,59].
- **Particle Swarm Optimization (PSO)** is a population-based swarm intelligence algorithm. It was originally proposed by Kennedy and Eberhart as a simulation of the social behavior of social organisms such as bird flocking and fish schooling [46]. PSO uses the physical movements of the individuals in the swarm and has a flexible and well-balanced mechanism to enhance and adapt to the global and local exploration abilities. The first algorithm for the solution of the Vehicle Routing Problem was proposed by [52].
- One of the most interesting developments that have occurred in the area of TS in recent years is the concept of **Adaptive Memory** developed by Rochat and Taillard [74]. It is, mostly, used in TS, but its applicability is not limited to this type of metaheuristic. An adaptive memory is a pool of good solutions that is dynamically updated throughout the search process.

Periodically, some elements of these solutions are extracted from the pool and combined differently to produce new good solutions. Very interesting and efficient algorithms based on the concept of Adaptive Memory have been proposed [74,78,79,80].

- **Variable Neighborhood Search (VNS)** is a metaheuristic for solving combinatorial optimization problems whose basic idea is systematic change of neighborhood within a local search [41]. Variable Neighborhood Search algorithms for the VRP are presented in [48].

### Introduction

Many decision problems in various areas such as business, engineering, economics, and science, including those in manufacturing, location, routing, and scheduling, may be formulated as optimization problems. Owing to the complexity of many of these optimization problems, particularly those of large sizes encountered in most practical settings, exact algorithms often perform very poorly, in some cases taking days or more to find moderately decent, let alone optimal, solutions even to fairly small instances. As a result, heuristic algorithms are conspicuously preferable in practical applications.

As an extension of simple heuristics, a large number of local search approaches have been developed to improve given feasible solutions. The main drawback of these approaches is their inability to continue the search upon becoming trapped in local optima. This leads to consideration of techniques for guiding known heuristics to overcome local optimality. Following this theme metaheuristics have become a most important class of approaches for solving optimization problems. They support managers in decision-making with robust tools that provide high-quality solutions to important applications in reasonable time horizons.

We describe metaheuristics mainly from an operations research perspective. Earlier survey papers on metaheuristics include those of Blum and Roli [14] and Voß [95]. Here we occasionally rely on the latter. The general concepts have not become obsolete, and many changes are mainly based upon an update to most recent references. A handbook on metaheuristics is available describing a great variety of concepts by various authors in a comprehensive manner [44].

## Definitions

The basic concept of heuristic search as an aid to problem solving was first introduced in [76]. A *heuristic* is a technique (consisting of a rule or a set of rules) which seeks (and hopefully finds) *good* solutions at a reasonable computational cost. A heuristic is *approximate* in the sense that it provides (hopefully) a good solution for relatively little effort, but it does not guarantee optimality.

Heuristics provide simple means of indicating which among several alternatives seems to be best. That is, “Heuristics are criteria, methods, or principles for deciding which among several alternative courses of action promises to be the most effective in order to achieve some goal. They represent compromises between two requirements: the need to make such criteria simple and, at the same time, the desire to see them discriminate correctly between good and bad choices. A heuristic may be a *rule of thumb* that is used to guide one’s action” [73].

*Greedy heuristics* are simple iterative approaches available for any kind of (e. g., combinatorial) optimization problem. A good characterization is their *myopic* behavior. A greedy heuristic starts with a given feasible or infeasible solution. In each iteration there are a number of alternative choices (*moves*) that can be made to transform the solution. From these alternatives which consist in fixing (or changing) one or more variables, a *greedy choice* is made, i. e., the best alternative according to a given measure is chosen until no such transformations are possible any longer.

Usually, a greedy *construction heuristic* starts with an incomplete solution and completes it stepwise. Savings and dual algorithms follow the same iterative scheme: dual heuristics change an infeasible low-cost solution until reaching feasibility; savings algorithms start with a high-cost solution and realize the highest savings as long as possible. Moreover, in all three cases, once an element has been chosen this decision is (usually) not reversed throughout the algorithm, it is kept.

As each alternative has to be measured, in general we may define some sort of *heuristic measure* (providing, e. g., some priority values or some ranking information) which is iteratively followed until a complete solution is built. Usually this heuristic measure is applied in a greedy fashion.

For heuristics we usually have the distinction between finding initial feasible solutions and improving them. In that sense we first discuss local search before characterizing metaheuristics.

## Local Search

The basic principle of local search is to successively alter solutions *locally*. Related transformations are defined by neighborhoods which for a given solution include all solutions that can be reached by one move. That is, neighborhood search usually is assumed to correspond to the process of iteratively moving from one solution to another one by performing some sort of operation. More formally, each solution of a problem has an associated set of neighbors called its *neighborhood*, i. e., solutions that can be obtained by a single operation called transformation or move. Most common ideas for transformations are, e. g., to add or drop some problem-specific individual components. Other options are to exchange two components simultaneously, or to swap them. Furthermore, components may be shifted from a certain position into other positions. All components involved within a specific move are called its elements or attributes.

Moves must be evaluated by some *heuristic measure* to guide the search. Often one uses the implied change of the objective function value, which may provide reasonable information about the (local) advantage of moves. Following a greedy strategy, *steepest descent* (SD) corresponds to selecting and performing in each iteration the best move until the search stops at a local optimum. Obviously, savings algorithms correspond to SD.

As the solution quality of local optima may be unsatisfactory, we need mechanisms which guide the search to overcome local optimality. A simple strategy called iterated local search is to iterate/restart the local search process after a local optimum has been obtained, which requires some perturbation scheme to generate a new initial solution (e. g., performing some random moves). Of course, more structured ways to overcome local optimality may be advantageous.

A general survey of local search can be found in [1] and the references from [2]. A simple template is provided in [90].

Starting in the 1970s (see Lin and Kernighan [66]), a variable way of handling neighborhoods is still a topic within local search. Consider an arbitrary neighborhood structure  $N$ , which defines for any solution  $s$  a set of neighbor solutions  $N_1(s)$  as a neighborhood of depth  $d = 1$ . In a straightforward way, a neighborhood  $N_{d+1}(s)$  of depth  $d + 1$  is defined as the set  $N_d(s) \cup \{s' | \exists s'' \in N_d(s) : s' \in N_1(s'')\}$ . In general, a large  $d$  might be unreasonable, as the neighborhood size may grow exponentially. However, depths of two or three may be appropriate. Furthermore, temporarily increasing the neighborhood depth has been found to be a reasonable mechanism to overcome *basins of attraction*, e.g., when a large number of neighbors with equal quality exist.

*Large-scale neighborhoods* have become an important topic (see, e.g., [5] for a survey), especially when efficient ways are at hand for exploring them. Related research can also be found under various names; see, e.g., [75] for the idea of ejection chains.

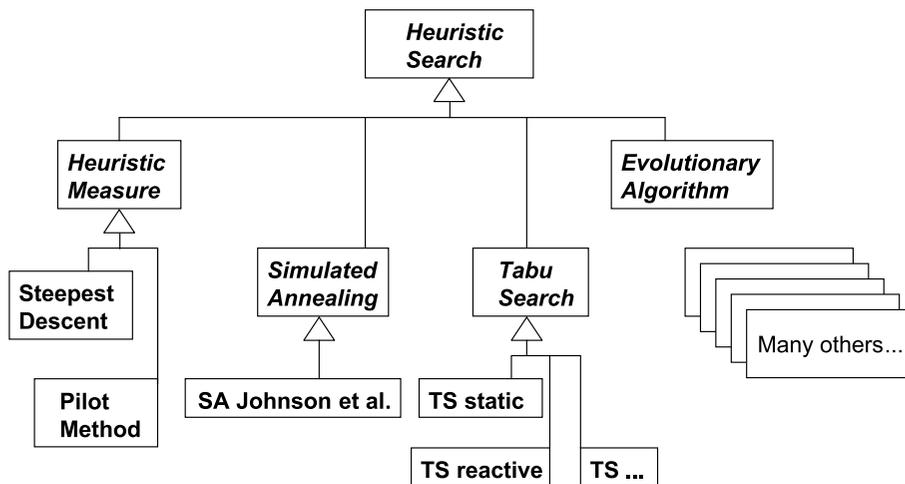

*Stochastic local search* is pretty much all we know about local search but is enhanced by randomizing choices. That is, a stochastic local search algorithm is a local search algorithm making use of randomized choices in generating or selecting candidate solutions for given instances of optimization problems. Randomness may be used for search initialization as well as the computation of search steps. A comprehensive treatment of stochastic local search is given in [58].

**Metaheuristics**

The formal definition of metaheuristics is based on a variety of definitions from different authors based on [39]. Basically, a metaheuristic is a top-level strategy that guides an underlying heuristic solving a given problem. In that sense we distinguish between a *guiding process* and an *application process*. The guiding process decides upon possible (local) moves and forwards its decision to the application process, which then executes the move chosen. In addition, it provides information for the guiding process (depending on the requirements of the respective metaheuristic) like the recomputed set of possible moves.

According to [43], “metaheuristics in their modern forms are based on a variety of interpretations of what constitutes *intelligent search*”, where the term “intelligent search” has been made prominent by Pearl [73] (regarding heuristics in an artificial intelligence context; see also [92] regarding an operations research context). In that sense we may also consider the following definition: “A metaheuristic is an iterative generation process which guides a subordinate heuristic by combining intelligently different concepts for exploring and exploiting the search spaces using learning strategies to structure information in order to find efficiently near-optimal solutions” [72].

To summarize, the following definition seems to be most appropriate: “A metaheuristic is an iterative

Metaheuristics, Figure 1  
Simplified metaheuristics inheritance tree

master process that guides and modifies the operations of subordinate heuristics to efficiently produce high-quality solutions. It may manipulate a complete (or incomplete) single solution or a collection of solutions at each iteration. The subordinate heuristics may be high (or low) level procedures, or a simple local search, or just a construction method. The family of metaheuristics includes, but is not limited to, adaptive memory procedures, tabu search, ant systems, greedy randomized adaptive search, variable neighborhood search, evolutionary methods, genetic algorithms, scatter search, neural networks, simulated annealing, and their hybrids” (p. ix in [97]).

We describe the ingredients and basic concepts of various metaheuristic strategies like *tabu search* (TS), *simulated annealing* (SA), and *scatter search*. This is based on a simplified view of a possible inheritance tree for heuristic search methods, illustrating the relationships between some of the most important methods discussed below, as shown in Fig. 1.

We also emphasize advances including the important incorporation of exact methods into intelligent search. Furthermore, general frames are sketched that may subsume various approaches within the metaheuristics field.

## Metaheuristic Methods

We survey the basic concepts of some of the most important metaheuristics. We shall see that adaptive processes originating from different settings such as psychology (“learning”), biology (“evolution”), physics (“annealing”), and neurology (“nerve impulses”) have served as interesting starting points.

### Simple Local Search Based Metaheuristics

To improve the efficiency of greedy heuristics, one may apply generic strategies to be used alone or in combination with each other, namely, changing the definition of alternative choices, look ahead evaluation, candidate lists, and randomized selection criteria bound up with *repetition*, as well as combinations with local search or other methods.

**Greedy Randomized Adaptive Search** Omitting a greedy choice criterion for a random strategy, one can run the algorithm several times and obtain a large

number of different solutions. A combination of best and random choice seems to be appropriate: We define a *candidate list* as a list consisting of a number of (best, i. e., first best, second best, third best, etc.) alternatives. Out of this list one alternative is chosen randomly. The length of the candidate list is given either as an absolute value, a percentage of all feasible alternatives, or implicitly by defining an allowed quality gap (to the best alternative), which also may be an absolute value or a percentage.

Replicating a search procedure to determine a local optimum multiple times with different starting points has been given the acronym GRASP and investigated with respect to different applications. A comprehensive survey of GRASP and its applications is given in [32]. It should be noted that GRASP goes back to older approaches [52], which is frequently overlooked in many applications. The different initial solutions or starting points are found by a greedy procedure incorporating a probabilistic component. That is, given a candidate list to choose from, GRASP randomly chooses one of the best candidates from this list in a greedy fashion, but not necessarily the best possible choice.

The underlying principle is to investigate many good starting points through the greedy procedure and thereby to increase the possibility of finding a good local optimum on at least one replication. The method is said to be adaptive as the greedy function takes into account previous decisions when performing the next choice.

**The Pilot Method** Building on a simple greedy algorithm such as, e. g., a construction heuristic, the *pilot method* [29,30] is a metaheuristic not necessarily based on a local search in combination with an improvement procedure. It primarily *looks ahead* for each possible local choice (by computing a so-called “pilot” solution), memorizing the best result, and performing the respective move. (Very similar ideas have been investigated under the name *rollout method* [13].) One may apply this strategy by successively performing a greedy heuristic for all possible local steps (i. e., starting with all incomplete solutions resulting from adding some not yet included element at some position to the current incomplete solution). The look ahead mechanism of the pilot method is related to increased neighborhood depths as the pilot method exploits the evaluation

of neighbors at larger depths to guide the neighbor selection at depth one.

In most applications, it is reasonable to restrict the pilot process to some *evaluation depth*. That is, the method is performed up to an incomplete solution (e. g., partial assignment) based on this evaluation depth and is then completed by continuing with a conventional heuristic. For a recent study applying the pilot method to several combinatorial optimization problems obtaining very good results see [96]. Additional applications can be found, e. g., in [18,68].

**Variable Neighborhood Search** The basic idea of variable neighborhood search (VNS) is to change the neighborhood during the search in a systematic way. VNS usually explores increasingly distant neighborhoods of a given solution, and jumps from this solution to a new one if and only if an improvement has been made. In this way often favorable characteristics of incumbent solutions, e. g., that many variables are already at their appropriate value, will be kept and used to obtain promising neighboring solutions.

Moreover, a local search routine is applied repeatedly to get from these neighboring solutions to local optima. This routine may also use several neighborhoods. Therefore, to construct different neighborhood structures and to perform a systematic search, one needs to have a way for finding the distance between any two solutions, i. e., one needs to supply the solution space with some metric (or quasi-metric) and then induce neighborhoods from it. For an excellent treatment of various aspects of VNS see [51].

### Simulated Annealing

*Simulated annealing* (SA) extends basic local search by allowing moves to inferior solutions [26,64]. A basic SA algorithm may be described as follows: Successively, a candidate move is randomly selected; this move is accepted if it leads to a solution with an improved objective function value compared to the current solution, otherwise, the move is accepted with a probability depending on the deterioration  $\Delta$  of the objective function value. The acceptance probability is computed as  $e^{-\Delta/T}$ , using a temperature  $T$  as a control parameter. Usually,  $T$  is reduced over time for diversification at an earlier stage of the search and to intensify later.

Various authors have described a robust concretization of this general SA approach [60,62]. An interesting variant of SA is to strategically reheat the process, i. e., to perform a nonmonotonic acceptance function.

*Threshold accepting* [28] is a modification (or simplification) of SA accepting every move that leads to a new solution which is “not much worse” (i. e., deteriorates not more than a certain threshold which reduces with temperature) than the older one.

### Tabu Search

The basic paradigm of *tabu search* (TS) is to use information about the search history to guide local search approaches to overcome local optimality (see [43] for a survey on TS). In general, this is done by a dynamic transformation of the local neighborhood. Based on some sort of memory, certain moves may be forbidden; we say they are set tabu. As for SA, the search may lead to performing deteriorating moves when no improving moves exist or when all improving moves of the current neighborhood are set tabu. At each iteration a best admissible neighbor may be selected. A neighbor, or a corresponding move, is called admissible if it is not tabu or if an aspiration criterion is fulfilled. An aspiration criterion is a rule to eventually override a possibly unreasonable tabu status of a move. For example, a move that leads to a neighbor with a better objective function value than encountered so far should be considered as admissible.

We briefly describe some TS methods that differ especially in the way in which tabu criteria are defined, taking into consideration the information about the search history (performed moves, traversed solutions).

The most commonly used TS method is based on a *recency-based* memory that stores moves, or attributes characterizing respective moves, of the recent past (*static TS*). The basic idea of such approaches is to prohibit an appropriately defined inversion of performed moves for a given period. For example, one may store the solution attributes that have been created by a performed move in a tabu list. To obtain the current tabu status of a move to a neighbor, one may check whether (or how many of) the solution attributes that would be destroyed by this move are contained in the tabu list.

*Strict TS* embodies the idea of preventing cycling to formerly traversed solutions. The goal is to provide ne-

cessity and sufficiency with respect to the idea of not revisiting any solution. Accordingly, a move is classified as tabu if and only if it leads to a neighbor that has already been visited during the previous search. There are two primary mechanisms to accomplish the tabu criterion: First, we may exploit logical interdependencies between the sequence of moves performed throughout the search process, as realized by, e. g., the reverse elimination method and the cancellation sequence method [40,94]. Second, we may store information about all solutions visited so far. This may be carried out either exactly or, for reasons of efficiency, approximately (e. g., by using hash codes).

*Reactive TS* aims at the automatic adaptation of the tabu list length of static TS [12]. The idea is to increase the tabu list length when the tabu memory indicates that the search is revisiting formerly traversed solutions. A possible specification can be described as follows: Starting with a tabu list length  $l$  of 1 it is increased every time a solution has been repeated. If there has been no repetition for some iterations, we decrease it appropriately. To accomplish the detection of a repetition of a solution, one may apply a trajectory-based memory using hash codes as for strict TS.

For reactive TS [12], it is appropriate to include means for diversifying moves whenever the tabu memory indicates that we are trapped in a certain region of the search space. As a trigger mechanism one may use, e. g., the combination of at least two solutions each having been traversed three times. A very simple escape strategy is to perform a number of random moves (depending on the average of the number of iterations between solution repetitions); more advanced strategies may take into account some long-term memory information (like the frequencies of appearance of specific solution attributes in the search history).

Of course there are a great variety of additional ingredients that may make TS work successfully, e. g., restricting the number of neighbor solutions to be evaluated (using candidate list strategies).

## Evolutionary Algorithms

*Evolutionary algorithms* comprise a great variety of different concepts and paradigms, including genetic algorithms (GAs) [45,56], evolutionary strategies [55,83], evolutionary programs [36], scatter search [38,41], and

memetic algorithms [71]. For surveys and references on evolutionary algorithms see also [9,37,69,78].

GAs are a class of adaptive search procedures based on principles derived from the dynamics of natural population genetics. One of the most crucial ideas for a successful implementation of a GA is the representation of an underlying problem by a suitable scheme. A GA starts, e. g., with a randomly created initial population of artificial creatures (strings), a set of solutions. These strings in whole and in part are the base set for all subsequent populations. They are copied and information is exchanged between the strings in order to find new solutions of the underlying problem. The mechanisms of a simple GA essentially consist of copying strings and exchanging partial strings. A simple GA uses three operators which are named according to the corresponding biological mechanisms: reproduction, crossover, and mutation. Performing an operator may depend on a *fitness function* or its value (fitness), respectively. As some sort of heuristic measure, this function defines a means of measurement for the profit or the quality of the coded solution for the underlying problem and often depends on the objective function of the given problem.

GAs are closely related to *evolutionary strategies*. Whereas the mutation operator in a GA serves to protect the search from premature loss of information, evolution strategies may incorporate some sort of local search procedure (such as SD) with self-adapting parameters involved in the procedure. On a simplified scale many algorithms may be coined evolutionary once they are reduced to the following frame [54]:

1. Generate an initial population of individuals.
2. While no stopping condition is met do.
3. Co-operation.
4. Self-adaptation.

Self-adaptation refers to the fact that individuals (solutions) evolve independently while co-operation refers to an information exchange among individuals.

*Scatter search* ideas established a link between early ideas from various sides – evolutionary strategies, TS, and GAs. As an evolutionary approach, scatter search originated from strategies for creating composite decision rules and surrogate constraints [38]. Scatter search is designed to operate on a set of points, called reference points, that constitute good solutions obtained

from previous solution efforts. The approach systematically generates linear combinations of the reference points to create new points, each of which is mapped into an associated point that yields integer values for discrete variables. Scatter search contrasts with other evolutionary procedures, such as GAs, by providing unifying principles for joining solutions based on generalized path constructions in Euclidean space and by utilizing strategic designs where other approaches resort to randomization. For a very comprehensive treatment of scatter search see [65].

### Swarm Intelligence

Swarm intelligence is a relatively novel discipline interested in the study of self-organizing processes in nature and human artifacts [15,63]. While researchers in ethology and animal behavior have proposed many models to explain various aspects of social insect behavior such as self-organization and shape formation, algorithms inspired by these models have been proposed to solve optimization problems. Successful examples are the so-called *ant system* or *ant colony* paradigm, the bee system, and swarm robotics, where the focus is on applying swarm intelligence techniques to the control of large groups of cooperating autonomous robots.

The *ant system* is a dynamic optimization process reflecting the natural interaction between ants searching for food [23]. The ants' ways are influenced by two different kinds of search criteria. The first one is the local visibility of food, i. e., the attractiveness of food in each ant's neighborhood. Additionally, each ant's way through its food space is affected by the other ants' trails as indicators for possibly good directions. The intensity of trails itself is time-dependent: With time passing, parts of the trails are diminishing, while the intensity may increase by new and fresh trails. With the quantities of these trails changing dynamically, an autocatalytic optimization process is started forcing the ants' search into most promising regions. This process of interactive learning can easily be modeled for most kinds of optimization problems by using simultaneously and interactively processed search trajectories.

A comprehensive treatment of the ant system paradigm can be found in [24]. To achieve enhanced performance of the ant system it is useful to hybridize it at least with a local search component.

### Miscellaneous

*Target analysis* may be viewed as a general learning approach. Given a problem we first explore a set of sample instances and an extensive effort is made to obtain a solution which is optimal or close to optimality. The best solutions obtained provide *targets* to be sought within the next part of the approach. For instance, a TS algorithm may resolve the problems with the aim of finding what are the right choices to come to the already known solution (or as close to it as possible). This may give some information on how to choose parameters for other problem instances.

A different method in this context is *path relinking* (PR), which provides a useful means of intensification and diversification. Here new solutions are generated by exploring search trajectories that combine elite solutions, i. e., solutions that have proven to be better than others throughout the search. For references on target analysis and PR see [43].

Recalling local search based on *data perturbation* the *noising method* may be related to the following approach too. Given an initial feasible solution, the method performs some data perturbation [87] in order to change the values taken by the objective function of a respective problem to be solved. On the perturbed data a local search may be performed (e. g., following a SD approach). The amount of data perturbation (the noise added) is successively reduced until it reaches zero. The noising method is applied, e. g., in [19] for the clique partitioning problem.

The key issue in designing *parallel algorithms* is to decompose the execution of the various ingredients of a procedure into processes executable by parallel processors. In contrast to ant systems or GAs, metaheuristics like TS or SA, at first glance, have an intrinsic sequential nature owing to the idea of performing the neighborhood search from one solution to the next. However, some effort has been undertaken to define templates for parallel local search [20,90,91,93]. A comprehensive treatment with successful applications is provided in [6]. The discussion of parallel metaheuristics has also led to interesting hybrids such as the combination of a population of individual processes, agents, in a cooperative and competitive nature (see, e. g., the discussion of *memetic algorithms* in [71]) with TS.

*Neural networks* may be considered as metaheuristics, although we have not considered them here; see [85] for a comprehensive survey of these techniques for combinatorial optimization. In contrast, one may use metaheuristics to speed up the learning process regarding artificial neural networks; see [7] for a comprehensive consideration.

Furthermore, recent efforts on problems with multiple objectives and corresponding metaheuristic approaches can be found in [61]. See [82] for some ideas regarding GAs and fuzzy multiobjective optimization.

### General Frames

An important avenue of metaheuristics research refers to general frames (to explain the behavior and the relationship between various methods) as well as the development of software systems incorporating metaheuristics (eventually in combination with other methods). Besides other aspects, this takes into consideration that in metaheuristics it has very often been appropriate to incorporate a certain means of diversification vs. intensification to lead the search into new regions of the search space. This requires a meaningful mechanism to detect situations when the search might be trapped in a certain area of the solution space. Therefore, within intelligent search the exploration of memory plays a most important role.

### Adaptive Memory Programming

Adaptive memory programming (AMP) coins a general approach (or even thinking) within heuristic search focusing on exploiting a collection of memory components [42,89]. An AMP process iteratively constructs (new) solutions based on the exploitation of some memory, especially when combined with learning mechanisms supporting the collection and use of the memory. Based on the idea of initializing the memory and then iteratively generating new solutions (utilizing the given memory) while updating the memory based on the search, we may subsume various of the above-described metaheuristics as AMP approaches. This also includes exploiting provisional solutions that are improved by a local search approach.

The performance as well as the efficiency of a heuristic scheme strongly depends on its ability to use AMP techniques providing flexible and variable

strategies for types of problems (or special instances of a given problem type) where standard methods fail. Such AMP techniques could be, e. g., dynamic handling of operational restrictions, dynamic move selection formulas, and flexible function evaluations.

Consider, as an example, adaptive memory within TS concepts. Realizing AMP principles depends on which specific TS application is used. For example, the reverse elimination method observes logical interdependencies between moves and infers corresponding tabu restrictions, and therefore makes fuller use of AMP than simple static approaches do.

To discuss the use of AMP in intelligent agent systems, one may use the simple model of ant systems as an illustrative starting point. Ant systems are based on combining local search criteria with information derived from the trails. This follows the AMP requirement for using flexible (dynamic) move selection rules (formulas). However, the basic ant system exhibits some structural inefficiencies when viewed from the perspective of general intelligent agent systems, as no distinction is made between successful and less successful agents, no time-dependent distinction is made, and there is no explicit handling of restrictions providing protection against cycling and duplication. Furthermore, there are possible conflicts between the information held in the adaptive memory (*diverging trails*).

### A Pool Template

In [48] a *pool template* (PT) is proposed as can be seen in Fig. 2. The following notation is used. A pool of  $p \geq 1$  solutions is denoted by  $P$ . Its input and output transfer is managed by two functions which are called  $IF$  and  $OF$ , respectively.  $S$  is a set of solutions with cardinality  $s \geq 1$ . A solution combination method (procedure  $SCM$ ) constructs a solution from a given set  $S$ , and  $IM$  is an improvement method.

Depending on the method used, in step 1 a pool is either completely (or partially) built by a (randomized) diversification generator or filled with a single solution which has been provided, e. g., by a simple greedy approach. Note that a crucial parameter that deserves careful elaboration is the cardinality  $p$  of the pool. The main loop, executed until a termination criterion holds, consists of steps 2–5. Step 2 is the call of the output

```

1. Initialize  $P$  by an external procedure
WHILE termination=FALSE DO BEGIN
  2.  $S := OF(P)$ 
  3. IF  $s > 1$  THEN  $S' := SCM(S)$ 
     ELSE  $S' := S$ 
  4.  $S'' := IM(S')$ 
  5.  $P := IF(S'')$ 
END
6. Apply a post-optimizing procedure to  $P$ 

```

### Metaheuristics, Figure 2

#### Pool template

function which selects a set of solutions,  $S$ , from the pool. Depending on the kind of method represented in the PT, these solutions may be assembled (step 3) to a working solution  $S'$  which is the starting point for the improvement phase of step 4. The outcome of the improvement phase,  $S''$ , is then evaluated by means of the input function, which possibly feeds the new solution into the pool. Note that a post-optimization procedure in step 6 is for facultative use. It may be a straightforward greedy improvement procedure if used for single-solution heuristics or a pool method on its own. As an example we quote a *sequential* pool method, the TS with PR in [11]. Here a PR phase is added *after* the pool has been initialized by a TS. A *parallel* pool method on the other hand uses a pool of solutions *while* it is constructed by the guiding process (e. g., a GA or scatter search).

Several heuristic and metaheuristic paradigms, whether they are obviously pool-oriented or not, can be summarized under the common PT frame. We provide the following examples:

- a) Local search/SD: PT with  $p = s = 1$ .
- b) SA:  $p = 2, s = 1$  incorporating its probabilistic acceptance criterion in *IM*. (It should be noted that  $p = 2$  and  $s = 1$  seems to be unusual at first glance. For SA we always have a current solution in the pool for which one or more neighbors are evaluated and eventually a neighbor is found which replaces the current solution. Furthermore, at all iterations throughout the search the so far best solution is stored too (even if no real interaction between those two stored solutions takes place). The same is also valid for a simple TS. As for local search the current

solution corresponds to the best solution of the specific search, we have  $p = 1$ .)

- c) Standard TS:  $p = 2, s = 1$  incorporating adaptive memory in *IM*.
- d) GAs:  $p > 1$  and  $s > 1$  with population mechanism (crossover, reproduction, and mutation) in *SCM* of step 3 and without the use of step 4.
- e) Scatter search:  $p > 1$  and  $s > 1$  with subset generation in *OF* of step 2, linear combination of elite solutions by means of *SCM* in step 3, e. g., a TS for procedure *IM* and a reference set update method in *IF* of step 5.
- f) PR (as a parallel pool method):  $p > 1$  and  $s = 2$  with a PR neighborhood in *SCM*. Facultative use of step 4.

### Partial Optimization Metaheuristic Under Special Intensification Conditions

A natural way to solve large optimization problems is to decompose them into independent subproblems that are solved with an appropriate procedure. However, such approaches may lead to solutions of moderate quality since the subproblems might have been created in a somewhat arbitrary fashion. Of course, it is not easy to find an appropriate way to decompose a problem a priori. The basic idea of POPMUSIC conditions is to locally optimize subparts of a solution, a posteriori, once a solution to the problem is available. These local optimizations are repeated until a local optimum is found. Therefore, POPMUSIC may be viewed as a local search working with a special, large neighborhood. While the acronym POPMUSIC was given by Taillard and Voß [88] other metaheuristics may be incorporated into the same framework too [84].

For large optimization problems, it is often possible to see the solutions as composed of parts (or chunks [102], cf. the term “vocabulary building”). Considering the vehicle routing problem, a part may be a tour (or even a customer). Suppose that a solution can be represented as a set of parts. Moreover, some parts are more in relation with some other parts, so a corresponding heuristic measure can be defined between two parts. The central idea of POPMUSIC is to select a so-called *seed part* and a set  $P$  of parts that are mostly related to the seed part to form a subproblem.

Then it is possible to state a local search optimization frame that consists of trying to improve all sub-

problems that can be defined, until the solution does not contain a subproblem that can be improved. In the POPMUSIC frame of [88],  $P$  corresponds precisely to seed parts that have been used to define subproblems that have been unsuccessfully optimized. Once  $P$  contains all the parts of the complete solution, all subproblems have been examined without success and the process stops.

Basically, the technique is a gradient method that starts from a given initial solution and stops in a local optimum relative to a large neighborhood structure. To summarize, both POPMUSIC as well as AMP may serve as a general frame encompassing various other approaches.

### Hybrids with Exact Methods

Often a new idea or a new paradigm in metaheuristics is claimed to be *the* idea by the inventor, while others see it as useless in the first instance. However, once it has been hybridized, things begin to *fly*. Especially in population-based metaheuristics, many researchers have followed this trend. That is, we now see many hybrid approaches where the successful ingredients of various metaheuristics have been combined. The term “hybridization”, however, goes further, as it also refers to combining metaheuristics with exact methods.

Traditionally, the structure of neighborhoods is determined by local transformations or moves. This usually refers to relatively small homogeneous neighborhoods. Different types of moves have been used in the construction of very large and diverse neighborhoods. In contrast, as a hybrid one may deploy neighborhoods that are *method-based*. By this we mean that the basic structure of a neighborhood is determined by the needs and requirements of a given (say, exact) optimization method used to search the neighborhood. That is, given an incumbent solution one may define the neighborhood so that an exact method can be efficiently used rather than defining a neighborhood and trying to find an appropriate method to explore it. This approach was called *corridor method* by Sniedovich and Voß [86] as it literally defines a neighborhood as a sufficiently sized corridor around a given solution so that a given exact method behaves well. Iteratively the corridor is moved through the search space for exploration.

*Constraint programming* (CP) is a paradigm for representing and solving a wide variety of problems expressed by means of variables, their domains, and constraints on the variables. Usually CP models are solved using depth-first search and branch and bound. Naturally, these concepts can be complemented by local search concepts and metaheuristics. This idea is followed by several authors; see [21] for TS and guided local search hybrids. Commonalities with the POPMUSIC approach can be deduced from [74].

Of course, the treatment of this topic is by no means complete and various ideas have been developed. One idea is to transform a greedy heuristic into a search algorithm by branching only in a few (i. e., limited number) cases when the choice criterion of the heuristic observes some borderline case or where the choice is least compelling, respectively. This approach may be called *limited discrepancy search* [17,53].

Independent from the CP concept, one may investigate hybrids of branch and bound and metaheuristics, e. g., for deciding upon branching variables or search paths to be followed within a branch and bound tree (see [103] for an application of reactive TS). Here we may also use the term “cooperative solver.” Somewhat related is the local branching concept for solving mixed integer programs (MIP), which seeks to explore neighborhoods defined through (invalid) linear cuts. The neighborhoods are searched by means of a general purpose MIP solver [35].

Correspondingly, one of the current research issues refers to exploiting mathematical programming (MP) techniques in a (meta)heuristic framework or, correspondingly, granting to MP approaches the cross-problem robustness and computation time effectiveness which characterize metaheuristics. Discriminating landmark is some form of exploitation of a MP formulation, e. g., by means of MIP. In this respect various efforts have been made towards developing strategies for making a heuristic sequence of roundings to obtain feasible solutions for problems represented by means of appropriate MIP [3,34].

### Optimization Software Libraries

Besides some well-known approaches for reusable software in the field of exact optimization (e. g., CPLEX or ABACUS; see <http://www.ilog.com> and

[informatik.uni-koeln.de/abacus](http://informatik.uni-koeln.de/abacus)) some ready-to-use and well-documented component libraries in the field of local search based heuristics and metaheuristics have been developed; see especially the contributions in [98].

The most successful approaches documented in the literature are the heuristic optimization framework HOTFRAME of [33] and EASYLOCAL++ of [22]. HOTFRAME, as an example, is implemented in C++, which provides adaptable components incorporating different metaheuristics and an architectural description of the collaboration among these components and problem-specific complements. Typical application-specific concepts are treated as objects or classes: problems, solutions, neighbors, solution attributes, and move attributes. On the other hand, metaheuristic concepts such as the different methods described above and their building blocks such as tabu criteria or diversification strategies are also treated as objects. HOTFRAME uses genericity as the primary mechanism to make these objects adaptable. That is, common behavior of metaheuristics is factored out and grouped in generic classes, applying static type variation. Metaheuristics template classes are parameterized by aspects such as solution spaces and neighborhood structures.

## Applications

Applications of metaheuristics are almost uncountable and appear in various journals (e. g., *Journal of Heuristics*), books, and technical reports every day. A helpful source for a subset of successful applications may be special issues of journals or compilations such as [25, 77, 79, 97], just to mention some.

Specialized conferences like the Metaheuristics International Conference are devoted to the topic [25, 59, 72, 80, 81, 97] and even more general conferences reveal that metaheuristics have become part of necessary prerequisites for successfully solving optimization problems [46]. Moreover, ready-to-use systems such as class libraries and frameworks have been developed, although they are usually restricted to application by the *knowledgeable* user.

Specialized applications also reveal research needs, e. g., in dynamic environments. One example refers to the application of metaheuristics for online optimization [49].

## Conclusions

Over the last few decades metaheuristics have become a substantial part of the optimization stockroom with various applications in science and, even more important, in practice. Metaheuristics have been considered in textbooks, e. g., in operations research, and a wealth of monographs [27, 43, 70, 92] are available. Most important in our view are general frames. AMP, an intelligent interplay of intensification and diversification (such as ideas from POPMUSIC), and the connection to powerful exact algorithms as subroutines for handable subproblems are avenues to be followed.

From a theoretical point of view, the use of most metaheuristics has not yet been fully justified. While convergence results regarding solution quality exist for most metaheuristics, once appropriate probabilistic assumptions are made [8, 31, 50] these turn out not to be very helpful in practice as usually a disproportionate computation time is required to achieve these results (usually convergence is achieved for a computation time tending to infinity, with a few exceptions, e. g., for the reverse elimination method within TS or the pilot method where optimality can be achieved with a finite, but exponential number of steps in the worst case). Furthermore, we have to admit that theoretically one may argue that none of the metaheuristics described are *on average* better than any other; there is *no free lunch* [101]. Basically this leaves the choice of a best possible heuristic or related ingredients to the ingenuity of the user/researcher. Some researchers related the term “hyperheuristics” to the question of which (heuristic) method among a given set of methods to choose for a given problem [16].

Moreover, despite the widespread success of various metaheuristics, researchers occasionally still have a poor understanding of many key theoretical aspects of these algorithms, including models of the high-level run-time dynamics and identification of search space features that influence problem difficulty [99]. Moreover, fitness landscape evaluations are considered to be in their infancy too.

From an empirical standpoint it would be most interesting to know which algorithms perform best under various criteria for different classes of problems. Unfortunately, this theme is out of reach as long as we do not

have any well-accepted standards regarding the testing and comparison of different methods.

While most papers on metaheuristics claim to provide “high-quality” results based on some sort of measure, we still believe that there is a great deal of room for improvement in testing existing as well as new approaches from an empirical point of view [10,57,67]. In a dynamic research process numerical results provide the basis for systematically developing efficient algorithms. The essential conclusions of finished research and development processes should always be substantiated (i. e., empirically and, if necessary, statistically proven) by numerical results based on an appropriate empirical test cycle. Furthermore, even when excellent numerical results are obtained, it may still be possible to compare with a simple random restart procedure and obtain better results in some cases [47]. However, this comparison is usually neglected.

Usually the ways of preparing, performing, and presenting experiments and their results are significantly different. The failing of a generally accepted standard for testing and reporting on the testing, or at least a corresponding guideline for designing experiments, unfortunately implies the following observation: Some results can be used only in a restricted way, e. g., because relevant data are missing, wrong environmental settings are used, or simply results are glossed over. In the worst case nonsufficiently prepared experiments provide results that are unfit for further use, i. e., any generalized conclusion is out of reach. Future algorithm research needs to provide effective methods for analyzing the performance of, e. g., heuristics in a more scientifically founded way (see [4,100] for some steps into this direction).

A final aspect that deserves special consideration is to investigate the use of information within different metaheuristics. While the AMP frame provides a very good entry into this area, this still provides an interesting opportunity to link artificial intelligence with operations research concepts.

Metropolis; Simulated annealing; Monte-Carlo method

Nicholas Constantine Metropolis was born in Chicago on June 11, 1915 and died on October 17, 1999 in Los Alamos. At Los Alamos, Metropolis was the main driving force behind the development of the MANIAC series of electronic computers. He was the first to code a problem for the ENIAC in 1945–1946 (together with S. Frankel), a task which consumed approximately 1,000,000 IBM punched cards.

Metropolis received his PhD in physics from the University of Chicago in 1941. He went to Los Alamos in 1943 as a member of the initial staff of fifty scientists of the Manhattan Project. He spent his entire career at Los Alamos, except for two periods (1946–1948 and 1957–1965), during which he was professor of Physics at the University of Chicago.

Metropolis is best known for the development (joint with S. Ulam and J. von Neumann) of the *Monte-Carlo method*. The Monte-Carlo method provides approximate solutions to a variety of mathematical problems by performing statistical sampling experiments on a computer. However, the real use of Monte-Carlo methods as a research tool stems from work on the atomic bomb during the second world war. This work involved

a direct simulation of the probabilistic problems concerned with random neutron diffusion in fissile material. Metropolis and his collaborators, obtained Monte-Carlo estimates for the eigenvalues of Schrodinger equation.

In 1953, Metropolis co-authored the first paper on the technique that came to be known as *simulated annealing* [3,8]. Simulated annealing is a method for solving optimization problems. The name of the algorithm derives from an analogy between the simulation of the annealing of solids. Annealing refers to a process of cooling material slowly until it reaches a stable state.

Metropolis also made several early contributions to the use of computers in the exploration of nonlinear dynamics. In the Sixties and Seventies he collaborated with G.-C. Rota and others on significance arithmetic. Another contribution of Metropolis to numerical analysis is an early paper on the use of *Chebyshev's iterative method* for solving large scale linear systems [1].

Minimax problem; Max-function; Maxmin function; Directional derivative; Higher-order derivatives; Hypodifferentiability; Support function

Minimax is a principle of optimal choice (of some parameters or functions). If applied, this principle requires to find extremal values of some max-type function. Since the operation of taking the pointwise maximum (of a finite or infinite number of functions) generates, in general, a nonsmooth function, it is important to study properties of such a function. Fortunately enough, though a max-function is not differentiable, in many cases it is still directionally differentiable. The directional differentiability provides a tool for formulating necessary (and sometimes sufficient) conditions for a minimum or maximum and for constructing numerical algorithms.

Recall that a function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  is called *Hadamard directionally differentiable* (H.d.d.) at a point  $x \in \mathbf{R}^n$  if for any  $g \in \mathbf{R}^n$  there exists the finite limit

$$f'_H(x, g) = \lim_{\alpha \rightarrow 0} \lim_{g' \rightarrow g} \frac{f(x + \alpha g') - f(x)}{\alpha}.$$

A function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  is called *Dini directionally differentiable* (D.d.d.) at a point  $x \in \mathbf{R}^n$  if for any  $g \in \mathbf{R}^n$  there exists the finite limit

$$f'_D(x, g) = \lim_{\alpha \downarrow 0} \frac{f(x + \alpha g) - f(x)}{\alpha}.$$

If  $f$  is H.d.d., then it is D.d.d. as well and  $f'_H(x, g) = f'_D(x, g)$ .

Let  $\Omega \subset \mathbf{R}^n$  be a convex compact set,  $x \in \Omega$ . The cone

$$N_x(\Omega) = \{v \in \mathbf{R}^n: (v, x) = \rho_\Omega(x)\}$$

is called *normal* to  $\Omega$  at  $x$ . Here

$$\rho_\Omega(x) = \max_{y \in \Omega} (v, y)$$

is the *support function* of  $\Omega$  at  $x$ .

## A max-function

Let

$$f(x) = \max_{y \in G} \varphi(x, y), \quad (1)$$

where  $\varphi: S \times G \rightarrow \mathbf{R}$  is continuous jointly in  $x, y$  on  $S \times G$  and continuously differentiable in  $x$  there,  $S \subset \mathbf{R}^n$  is an open set,  $G$  is a compact set of some space. Under the conditions stated, the function  $f$  is continuous on  $S$ .

**Proposition 1** *The function  $f$  is H.d.d. at any point  $x \in S$  and*

$$f'_H(x, g) = \max_{y \in R(x)} (\varphi'_x(x, y), g) = \max_{v \in \partial f(x)} (v, g), \quad (2)$$

where

$$R(x) = \{y \in G: f(x) = \varphi(x, y)\},$$

$\varphi'_x(x, g)$  is the gradient of  $\varphi$  with respect to  $x$  for a fixed  $y$ ,  $(a, b)$  is the scalar product of vectors  $a$  and  $b$ ,

$$\partial f(x) = \text{co} \{ \varphi'_x(x, g): y \in R(x) \} \subset \mathbf{R}^n.$$

The set  $\partial f(x)$  is called the *subdifferential* of  $f$  at  $x$ . It is convex and compact. The mapping  $\partial f$  is, in general, discontinuous.

**Remark 2** It turns out that a convex function can also be represented in the form (1) with  $\varphi$  being *affine* in  $x$ . For this special (convex) case the set  $\partial f(x)$  is

$$\begin{aligned} \partial f(x) \\ = \{v \in \mathbf{R}^n: f(z) - f(x) \geq (v, z - x), \forall z \in S\}. \end{aligned}$$

The discovery of the directional differentiability of max-functions ([1,2,6]) and convex functions [10] was a breakthrough and led to the development of *minimax theory* and convex analysis ([4,9,10]).

**A Maximum Function with Dependent Constraints**

Let  $x \in \mathbf{R}^n$ ,  $Y \subset \mathbf{R}^m$  be open sets and let

$$f(x) = \max_{y \in a(x)} \varphi(x, y), \tag{3}$$

where  $a(x)$  is a multivalued mapping with compact images,  $\varphi: X \times Y \rightarrow \mathbf{R}$  is Hadamard differentiable as a function of two variables, i. e. there exists the limit

$$\varphi'_H([x, y], [g, v]) = \lim_{[\alpha, g', v'] \rightarrow [0, g, v]} \frac{1}{\alpha} \cdot [\varphi(x + \alpha g', y + \alpha v') - \varphi(x, y)].$$

Then  $\varphi$  is continuous and  $\varphi'_H$  is continuous as a function of direction  $[g, v]$ .

The function  $f$  is called a *maximum function with dependent constraints*. Such functions are of great importance and have widely been studied (see [3,5,7,8]). To illustrate the results let us formulate one of them [5, Thm. I, 6.3].

**Proposition 3** *Let a mapping  $a$  be closed and bounded, its images be convex and compact, the support function  $a(x, l) = \max_{v \in a(x)} (v, l)$  be uniformly differentiable with respect to parameter  $l$ . Let, further,  $x \in X$  and a function  $\varphi$  be concave in some convex neighborhood of the set  $\{[x, y]: y \in R(x)\}$  (where  $R(x) = \{y \in a(x): \varphi(x, y) = f(x)\}$ ). Then  $f$  (see (3)) is H.d.d. and*

$$f'(x, g) = \sup_{y \in R(x)} \min_{[l_1, l_2] \in V(x, y)} [(l_1, g) + a'(x, l_2; g)], \tag{4}$$

where

$$V(x, y) = \{l = [l_1, l_2] \in \bar{\partial}\varphi(x, y): l_2 \in N_{x, y}\},$$

$\bar{\partial}\varphi(x, y)$  is the superdifferential of  $\varphi$  at the point  $[x, y]$ , and  $N_{x, y}$  is the cone normal to  $a(x)$  at  $y$ .

Recall that if a function  $F: \mathbf{R}^s \rightarrow \mathbf{R}$  is concave,  $Z \subset \mathbf{R}^s$  is open,  $z \in Z$ , then the set

$$\bar{\partial}F(z) = \left\{ v \in \mathbf{R}^s: \begin{matrix} F(z') - F(z) \leq (v, z' - z), \\ \forall z' \in Z \end{matrix} \right\}$$

is called the *superdifferential* of  $F$  at  $z \in Z$ . It is convex and compact.

**A Maxmin Function**

Let  $\varphi(x, y, z): S \times G_1 \times G_2 \rightarrow \mathbf{R}$  be continuous jointly in all variables,  $S \subset \mathbf{R}^n$  be an open set,  $G_1 \subset \mathbf{R}^m$ ,  $G_2 \subset \mathbf{R}^p$  be compact. Put

$$f(x) = \max_{y \in G_1} \min_{z \in G_2} \varphi(x, y, z). \tag{5}$$

The function  $f$  is continuous on  $S$ .

Let

$$\Phi(x, y) = \min_{z \in G_2} \varphi(x, y, z),$$

$$R(x) = \{y \in G_1: \Phi(x, y) = f(x)\},$$

$$Q(x, y) = \{z \in G_2: \varphi(x, y, z) = \Phi(x, y)\}.$$

Fix  $x \in S$ , let  $D_\varepsilon (\varepsilon > 0)$  be an  $\varepsilon$ -neighborhood of the set  $\{x\} \times R(x) \times \cup_{y \in R(x)} Q(x, y)$ . Assume that the derivatives

$$\frac{\partial \varphi}{\partial x}, \frac{\partial \varphi}{\partial y}, \frac{\partial^2 \varphi}{\partial x^2}, \frac{\partial^2 \varphi}{\partial x \partial y}, \frac{\partial^2 \varphi}{\partial y^2}$$

exist and are continuous jointly in all variables on  $D_\varepsilon(x)$  and that

$$\left( \frac{\partial^2 \varphi(\bar{x}, y, z)}{\partial y^2} v, v \right) \leq 0,$$

$$\forall [\bar{x}, y, z] \in D_\varepsilon(x), \quad v \in \mathbf{R}^m.$$

Assume also that  $G_1$  is convex. Let  $y \in G_1$ . Put

$$\gamma(y) = \{v = \lambda(y' - y): \lambda > 0, y' \in G_1\},$$

$$\Gamma(y) = \text{cl } \gamma(y).$$

**Proposition 4 [3, Thm. 5.2]** *Under the above assumptions the function  $f$  (see (5)) is Hadamard directionally differentiable and*

$$f'_H(x, g) = \sup_{y \in R(x)} \sup_{y \in \Gamma(y)} \min_{z \in Q(x, y)}$$

$$\left[ \left( \frac{\partial \varphi(x, y, z)}{\partial y}, v \right) + \left( \frac{\partial \varphi(x, y, z)}{\partial x}, g \right) \right].$$

*Remark 5* More sophisticated results on the directional differentiability of max- and maxmin functions can be found, e. g., in [8].

**Higher-Order Directional Derivatives**

The results above are related to the first order directional derivatives. Using these derivatives, it is possible

to construct the following first order expansion:

$$f(x + \alpha g) = f(x) + \alpha f'(x, g) + o_{x,g}(\alpha), \quad (6)$$

where  $f'$  is either  $f_H'$  or  $f_D'$ .

In some cases it is possible to get 'higher-order' expansions.

Let

$$f(x) = \max_{i \in I} f_i(x), \quad (7)$$

where  $I = 1 : N$ ,  $x = (x_1, \dots, x_n) \in \mathbf{R}^n$ , the  $f_i$ 's are continuous and continuously differentiable up to the  $l$ th order on an open set  $S \subset \mathbf{R}^r$ . Fix  $x \in S$ . Then for sufficiently small  $\alpha > 0$

$$\begin{aligned} f_i(x + \alpha g) \\ = f_i(x) + \sum_{k=1}^l \frac{\alpha^k}{k!} f_i^{(k)}(x, g) + o_i(g, \alpha^l), \end{aligned} \quad (8)$$

where

$$\begin{aligned} f_i^{(k)}(x, g) = \sum_{j_1, \dots, j_k=1}^n \frac{\partial^k f_i(x)}{\partial x_{j_1} \dots \partial x_{j_k}} g_{j_1}, \dots, g_{j_k}, \\ k \in 1, \dots, l, \frac{o_i(g, \alpha^l)}{\alpha^l} \xrightarrow{\alpha \downarrow 0} 0 \end{aligned} \quad (9)$$

uniformly with respect to  $g$ ,  $\|g\| = 1$ .

Let us use the following notation

$$f_i^0(x, g) = f_i(x),$$

$$\forall i \in I, \quad R_0(x, g) = I,$$

$$R_k(x, g) = \{i \in R_{k-1}(x, g) :$$

$$f_i^{(k-1)}(x, g) = \max_{j \in R_{k-1}(x, g)} f_j^{(k-1)}(x, g)\},$$

$$k \in 1, \dots, l.$$

Clearly

$$R_0(x, g) \supset R_1(x, g) \supset R_2(x, g) \supset \dots$$

Note that  $R_0(x, g)$  does not depend on  $x$  and  $g$ , and  $R_1(x, g)$  does not depend on  $g$ .

**Proposition 6 [3, Thm. 9.1]** *The following expansion holds:*

$$\begin{aligned} f(x + \alpha g) = f(x) + \sum_{k=1}^l \frac{\alpha^k}{k!} f^{(k)}(x, g) + o(g, \alpha^l), \\ \forall g \in \mathbf{R}^n, \end{aligned} \quad (10)$$

where

$$\begin{aligned} f^{(k)}(x, g) = \max_{i \in R_k(x, g)} f_i^{(k)}(x, g), \\ \frac{o(g, \alpha^l)}{\alpha^l} \xrightarrow{\alpha \downarrow 0} 0 \end{aligned} \quad (11)$$

uniformly with respect to  $g$ ,  $\|g\| = 1$ .

The value  $\partial^k f(x) / \partial g^k = f^{(k)}(x, g)$  is called the  $k$ th derivative of  $f$  at  $x$  in a direction  $g$ .

*Remark 7* The mapping  $R_1(x, g)$  is not continuous in  $x$ , while the mappings  $R_k(x, g)$  ( $k \geq 2$ ) are not continuous in  $x$  as well as in  $g$ . Therefore the functions  $f^{(k)}(x, g)$  in (11) are not continuous in  $x$  and (if  $k \geq 2$ ) in  $g$  and, as a result, expansion (6) is also not 'stable' in  $x$ .

To overcome this difficulty we shall employ another tool.

### Hypodifferentiability of a Max Function

Let us again consider the case where  $f$  is defined by (7). It follows from (8) that, for  $\Delta = (\Delta_1, \dots, \Delta_n) \in \mathbf{R}^n$ ,

$$\begin{aligned} f(x + \Delta) \\ = \max_{i \in I} \left[ f_i(x) + \sum_{k=1}^l \frac{1}{k!} f_i^{(k)}(x, \Delta) \right] + o(\|\Delta\|^k). \end{aligned} \quad (12)$$

Let us use the notation (see (9))

$$f_i^{(k)}(x, \Delta) = A_{ik} \Delta^k.$$

The function  $f_i^{(k)}(x, \Delta)$  is a  $k$ th order form of coordinates  $\Delta_1, \dots, \Delta_n$ ;  $A_{ik}$  being the set of coefficients of this form. Then (12) can be rewritten as

$$\begin{aligned} f(x + \Delta) \\ = \max_{i \in I} \left[ f_i(x) + \sum_{k=1}^l \frac{1}{k!} A_{ik} \Delta^k \right] + o(\|\Delta\|^k) \\ = f(x) + \max_{A \in d^l f(x)} \left[ \sum_{k=1}^l \frac{1}{k!} A_k \Delta^k \right] + o(\|\Delta\|^k), \end{aligned} \quad (13)$$

where

$$d^l f(x) = \text{co} \left\{ A^{(i)} = (A_{i0}, \dots, A_{il}) : i \in I \right\},$$

$$A_{i0} = f_i(x) - f(x), \quad A = (A_0, \dots, A_l),$$

$$A_0 \in \mathbb{R}, \quad A_1 \in \mathbb{R}^n,$$

$$A_2 \in \mathbb{R}^{n \times n}, \dots, A_k \in \overbrace{\mathbb{R}^{n \times \dots \times n}}^{k \text{ times}}.$$

Here,  $\overbrace{\mathbb{R}^{n \times \dots \times n}}^{k \text{ times}}$  is the space of  $k$ th order real forms, e. g.  $\mathbb{R}^{n \times n}$  is the space of real  $(n \times n)$ -matrices.

The set  $d^l f(x)$  is called the  $k$ th order hypodifferential of  $f$  at  $x$ . It is an element of the space  $\mathbb{R} \times \mathbb{R}^n \times \dots \times \underbrace{\mathbb{R}^{n \times \dots \times n}}_l$ . The mapping  $d^l f$  is continuous in  $x$ .

*Remark 8* Expansion (13) can be extended to the case where  $f$  is given by (1) and  $\varphi$  is  $l$  times continuously differentiable in  $x$ .

Max functions represent a special case of the class of quasidifferentiable functions (see [5]).

Algorithms; Games; Minimax; Searching

With the introduction of computers, also started the interest in having machines play games. Programming a computer such that it could play, for example chess, was seen as giving it some kind of intelligence. Starting in the mid fifties, a theory on how to play two player zero sum perfect information games, like chess or go, was developed. This theory is essentially based on traversing a tree called minimax or game tree. An edge in the tree represents a move by either of the players and a node a configuration of the game.

Two major algorithms have emerged to compute the best sequence of moves in such a minimax tree. On one hand, there is the alpha-beta algorithm suggested around 1956 by I. McCarthy and first published in [27]. On the other hand, G.C. Stockman [29] introduced the SSS\* algorithm. Both methods try to minimize the number of nodes explored in the game tree using special traversal strategies and cut conditions.

### Minimax Trees

A *two-player zero-sum perfect-information game*, also called *minimax game*, is a game which involves exactly two players who alternatively make moves. No information is hidden from the adversary. No coins are tossed, that is, the game is completely deterministic, and there is perfect symmetry in the quality of the moves allowed. Go, checker and chess are such minimax games whereas backgammon (the outcome of a die determines the moves available) or card games (cards are hidden from the adversary) are not.

A *minimax tree* or *game tree* is a tree where each node represents a state of the game and each edge a possible move. Nodes are alternatively labeled 'max' and 'min' representing either player's turn. A node having no descendants represents a final outcome of the game. The goal of a game is to find a winning sequence of moves, given that the opponent always plays his best move.

The quality of a node  $t$  in the minimax game tree, representing a configuration, is given by its value  $e(t)$ . The value  $e(t)$ , also called *minimax value*, is defined recursively as

$$e(t) = \begin{cases} f(t) & \text{if } t \text{ is a leave node,} \\ \max_{s \in \text{sons}(t)} e(s) & \text{if } t \text{ is labeled 'max',} \\ \min_{s \in \text{sons}(t)} e(s) & \text{if } t \text{ is labeled 'min'.} \end{cases}$$

If the considered minimax tree represents a *complete game*, that is, all possible board configurations, the function  $f$  may be defined as follows:

$$f(t) = \begin{cases} +1 & \text{if } t \text{ leads to a winning position,} \\ 0 & \text{if } t \text{ leads to a tie position,} \\ -1 & \text{if } t \text{ leads to a losing position;} \end{cases}$$

otherwise  $f(t)$  represents an evaluation of the quality of a board position.

The relation between minimax trees and games is detailed in the following table.

Minimax tree notion	Minimax game notion
Minimax tree	All board configurations
Node in the tree	Board configuration
Edge from "max" to "min" node	Move by player "max"
Edge from "min" to "max" node	Move by player "min"
Node value	Quality of board position
Leave node	Outcome of a game
Solution path	Sequence of moves leading the best outcome

### Sequential Minimax Game Tree Algorithms

Let  $t$  be a node of a minimax tree. Then the function  $\text{first\_son}(t)$  returns the first son node  $s_1$  of  $t$  and  $\text{next\_son}(s_i, t)$  returns the  $i + 1$ th son of node  $t$ . The function  $\text{no\_more\_sons}(s, t)$  returns true if  $s$  is the last son of  $t$ . Otherwise it returns false. The ordering of the sons introduced by these functions is arbitrary. In practice it is given by some heuristic function. The function  $\text{father}(t)$  returns the father node of  $t$ ,  $\text{is\_leave}(t)$  whether or not  $t$  is a leave node and  $\text{node\_type}(t)$  the type of node  $t$ .

#### Minimax Algorithm

The most basic minimax algorithm is called the *minimax algorithm*. It systematically traverses, in a depth first, left to right fashion, the complete minimax tree. All nodes are visited exactly once.

#### Alpha-Beta Algorithm

The first nontrivial algorithm introduced to compute the minimax value of a game tree was the

*alpha-beta algorithm*. According to D. Knuth and R. Moore, McCarthy's comments at the Dartmouth summer research conference on artificial intelligence led to the use of alpha-beta pruning in game playing programs since the late 1950s. The first published discussion of an algorithm for minimax tree pruning appeared in 1958 (see [11, p. 56]). Two early extensive studies of the algorithm may be found in [18] and [27].

The idea behind the alpha-beta algorithm is to traverse the minimax tree in a depth first, left to right fashion. It tries to prune sub-trees that can not influence the minimax value of the tree. The conditions used to prune sub-trees are called *cut conditions*. The idea behind the suggested cut conditions is to associate to each node a lower and an upper bound, called  $\alpha$  and  $\beta$  bounds. The bounds of a node are passed to its sons and tightened during the execution of the algorithm. It is easy to see that if the lower bound of a node  $t$  of type 'max' is larger than its upper bound then all not visited sons of node  $t$  can be pruned, and similar for nodes of type 'min'.

```

FUNCTION AlphaBeta( $n, \alpha, \beta$ ) IS
BEGIN
  IF is_leave( $n$ ) THEN RETURN  $f(n)$ 
   $s \leftarrow$  first_son( $n$ )
  IF node_type( $n$ )=max THEN
    LOOP
       $\alpha \leftarrow$  max{ $\alpha, \text{AlphaBeta}(s, \alpha, \beta)$ }
      IF  $\alpha \geq \beta$  THEN RETURN  $\beta$ 
      EXIT LOOP WHEN no_more_sons( $s, n$ )
       $s \leftarrow$  next_son( $s, n$ )
    END LOOP
    RETURN  $\alpha$ 
  ELSE
    LOOP
       $\beta \leftarrow$  max{ $\alpha, \text{AlphaBeta}(s, \alpha, \beta)$ }
      IF  $\beta \leq \alpha$  THEN RETURN  $\alpha$ 
      EXIT LOOP WHEN no_more_sons( $s, n$ )
       $s \leftarrow$  next_sons( $s, n$ )
    END LOOP
    RETURN  $\beta$ 
  END IF
END AlphaBeta

```

Pseudocode for the alpha-beta algorithm

It has been proved in [18] that the alpha-beta algorithm correctly calculates the minimax value of a tree. The above pseudocode describes the alpha-beta algorithm.

The minimax value of a tree  $T$  is computed as follows.

$$e(\text{root}(T)) \leftarrow \text{AlphaBeta}(\text{root}(T), -\infty, +\infty).$$

### Optimal State Space Search Algorithm SSS\*

It has been introduced by Stockman in 1979, [29]. It originates not in game playing but in systematic pattern recognition. The algorithm was first analyzed and criticized in [26].

The idea behind the SSS\* algorithm is to use a tree traversal strategy that is, better than the depth first and left to right strategy found in the alpha-beta algorithm. The criteria used to order the nodes yet to visit is an upper bound of their value. Nodes are stored in non increasing order of their upper bound in a list called 'open'.

The SSS\* algorithm first traverses the minimax tree from top to bottom. Nodes whose sons have not yet been visited and which cannot yet be pruned are marked 'live'. Nodes marked 'solved' have already been visited once and have therefore their best upper bound associated.

The operation  $\text{purge}(t, \text{open})$  removes all nodes from the open list for which the node  $t$  is an ancestor. Due to the fact that the nodes in the open list are sorted in nonincreasing order of their associated upper bound, the pruning operation only eliminates nodes that need no further consideration.

The SSS\* algorithm is described by the following pseudocode.

```

FUNCTION SSS* IS
BEGIN
  open  $\leftarrow$   $\emptyset$ 
  insert (root, live,  $+\infty$ , open)
  LOOP
    ( $s, t, m$ )  $\leftarrow$  remove (open)
    IF  $s = \text{root}$  AND  $t = \text{solved}$  THEN RETURN  $m$ 
    ( Apply the  $\Gamma$  operator to node  $s$  )
  END LOOP
END SSS*

```

Pseudocode for the SSS\* algorithm

The operator  $\Gamma(s)$  is applied to each node  $s$  extracted from the 'open' list.

It is possible to define a dual version of the SSS\*, which may be called SSS\* -*dual*, in which the computation of upper bounds is replaced by the computation of lower bounds. The SSS\* -dual algorithm has been suggested in [21].

Stockman has shown that if the SSS\* algorithm explores a node, then this node is also explored by the alpha-beta algorithm. In fact, the alpha-beta algorithm loses efficiency (in the number of nodes visited) against the SSS\* algorithm when the value of the minimax tree is found towards the right of the tree. If the SSS\* algorithm is applied to win-lose trees then it visits exactly the same nodes in the same order as would the alpha-beta algorithm.

```

⟨Apply the  $\Gamma$  operator to node  $s$ ⟩  $\equiv$ 
  IF  $t = \text{live}$  AND  $\text{node\_type} = \text{max}$ 
    AND NOT  $\text{is\_leave}(t)$  THEN
     $s \leftarrow \text{first\_son}(t)$ 
    LOOP
      insert( $s, \text{live}, m, \text{open}$ )
      EXIT LOOP WHEN  $\text{no\_more\_sons}(s, t)$ 
       $s \leftarrow \text{next\_son}(s, t)$ 
    END LOOP
  END IF
  IF  $t = \text{live}$  AND  $\text{node\_type} = \text{min}$ 
    AND NOT  $\text{is\_leave}(t)$  THEN
    insert( $\text{first\_son}(t), \text{live}, m, \text{open}$ )
  END IF
  IF  $t = \text{live}$  AND  $\text{is\_leave}(t)$  THEN
    insert( $t, \text{solved}, \text{min}\{f(t), m\}, \text{open}$ )
  END IF
  IF  $t = \text{solved}$  AND  $\text{node\_type} = \text{max}$ 
    AND NOT  $\text{no\_more\_sons}(t, \text{father}(t))$  THEN
    insert( $\text{next\_son}(t, \text{father}(t)), \text{live}, m, \text{open}$ )
  END IF
  IF  $t = \text{solved}$  AND  $\text{node\_type} = \text{max}$ 
    AND  $\text{no\_more\_sons}(t, \text{father}(t))$  THEN
    insert( $\text{father}(t), \text{solved}, m, \text{open}$ )
  END IF
  IF  $t = \text{solved}$  AND  $\text{node\_type} = \text{min}$  THEN
    insert( $\text{father}(t), \text{solved}, m, \text{open}$ )
    purge( $\text{father}(t), \text{open}$ )
  END IF

```

### SCOUT: Minimax Algorithm of Theoretical Interest

In the previous sections, we have described the most common minimax algorithms. While trying to show the optimality of the alpha-beta algorithm, J. Pearl [23] introduced the SCOUT algorithm. His idea was to show that the SCOUT algorithm is dominated by the alpha-beta algorithm and to prove that SCOUT achieves an optimal performance. But counterexamples showed that the alpha-beta algorithm does not dominate the SCOUT algorithm because the conservative testing approach of the SCOUT algorithm may sometimes cut off nodes that would have been explored by the alpha-beta algorithm.

The SCOUT algorithm itself recursively computes the value of the first of its sons. Then it tests to see if the value of the first son is better than the value of the other sons. In case of a negative result, the son that failed the test is completely evaluated by recursively calling SCOUT.

Although the SCOUT algorithm is more of theoretical interest, there are some problem instances where it outperforms all other minimax algorithms. A last advantage of the SCOUT algorithm versus one of its major competitors, the SSS\* algorithm, is that its storage requirements are similar to those of the alpha-beta algorithm.

### GSEARCH: Generalized Game Tree Search Algorithm

In 1986, T. Ibaraki [16] proposed a generalization of the previously known algorithms to compute the minimax value of a game tree. His idea was to use a branch and bound like approach. Nodes of the considered tree which have not yet been evaluated are stored in a list which is ordered according to a given criteria. Different orderings give different traversal strategies. A lower and upper bound is associated to each node. These bounds generalize the  $\alpha$  and  $\beta$  values found in the alpha-beta algorithm.

Finally Ibaraki showed how the algorithm GS}CH is related to other minimax algorithms like alpha-beta or SSS\*, and proved that his algorithm always surpasses the alpha-beta algorithm.

## SSS-2: Recursive State Space Search Algorithm

The SSS-2 algorithm has been proposed by W. Pijls and A. de Bruin [24]. It is based on the idea of computing an upper bound for the root node and then repeatedly transforming this upper bound into a tighter one. They have shown that the SSS-2 algorithm exactly expands the same nodes as those to which the SSS\* algorithm applies the  $\Gamma$  operator.

### Some Variations On The Subject

Computing the minimax value of a game tree may be seen as aspiring the solution value from a leaf node through the whole tree up to the root node. While moving closer to the root node, more and more useless subtrees will be eliminated, as we have already stated for the alpha-beta algorithm. The better the  $\alpha$  and  $\beta$  bounds, the more subtrees may be pruned. If, for instance, one knows that the minimax value will, with high probability, be found in the subset  $]a, b[$ , then it may be worth calling the alpha-beta algorithm as

$$e \leftarrow \text{AlphaBeta}(\text{root}(T), a, b)$$

If, indeed, the minimax value  $e(\text{root}(T))$  belongs to the set  $]a, b[$ , then the algorithm will correctly return that value. If the minimax value does not belong to the set  $]a, b[$ , then the value returned will be either  $a$  or  $b$ , depending on whether the minimax value belongs to  $] -\infty, a[$  or  $]b, +\infty[$ . We then say that the alpha-beta algorithm *failed low*, respectively *high*. In the case where the algorithm failed low, the call

$$e \leftarrow \text{AlphaBeta}(\text{root}(T), -\infty, a + 1)$$

will return the correct value. But it would also be possible to reiterate this procedure on a subset  $]a_1, a + 1[$ .

The technique of limiting the interval in which the solution may be found is called *aspiration search*. If the minimax value belongs to the specified interval, then a much larger number of cut conditions are verified and the tree actually traversed is much smaller than the one traversed by the alpha-beta algorithm without initial alpha and beta bounds.

Furthermore it is interesting to note that aspiration search is at the bases of a technique called *iterative deepening* which is used in many game playing programs.

I. Althöfer [5] suggested an *incremental negamax algorithm* which uses estimates of all nodes in the mini-

max tree, rather than only those of the leaf nodes, to determine the value of the root node. This algorithm is useful when dealing with erroneous leaf evaluation functions. Under the assumption of independently occurring and sufficiently small errors, the proposed algorithm is shown to have exponentially reduced error probabilities with respect to the depth of the tree.

R.L. Rivest [25] proposed an algorithm for searching minimax trees based on the idea of approximating the min and the max operators by generalized mean value operators. The approximation is used to guide the selection of the next leaf node to expand, since the approximation allows to select efficiently that leaf node upon whose value the minimax value most highly depends. B.W. Ballard [6] proposed a similar algorithm where the value of some nodes (the chance node as he calls them) is a, possibly weighted, average of the values of its sons. In fact he considers one additional type of nodes called chance nodes.

*Conspiracy numbers* have been introduced by D.A. McAllester in [22] as a measurement of the accuracy of the minimax value of an incomplete tree. They measure the number of leaf nodes whose value must change in order to change the minimax value of the root node by a given amount.

### Parallel Minimax Tree Algorithms

Parallelizing the minimax algorithm is trivial over uniform trees. Even on irregular trees, the parallelization remains easy. The only additional problem arises from the fact that the size of the subtrees to explore may now vary. Different processors will be attributed problems of varying computational volume. All what is needed then to achieve excellent speedups, is a load-balancing scheme, that is, a mechanism by means of which processors may, during run-time, exchange problems so as to keep all processors busy all the time.

The parallelization of the alpha-beta and the SSS\* algorithms are much more interesting than the more theoretical minimax algorithm. There exist basically two approaches or techniques to parallelize the alpha-beta algorithm. In the first approach, which has been one of the first techniques used, all processors explore the entire tree but using different search-intervals. This approach is at the basic of the algorithm called *parallel aspiration search* by G. Baudet [7]. The second one

consists in exploring simultaneously different parts of the minimax tree.

### A Simple Way to Parallelize the Exploration of Minimax Trees

Exploring a minimax tree in parallel can very simply be obtained by generating the sons of the root node, and their sons and so on up to the point where one has as many son nodes waiting to be explored as there are processors. At this point, each processor explores the subtree rooted at one of these nodes, using any given sequential minimax algorithm. When all processors have completed their exploration, the solution for the entire tree is computed by using the partial results obtained from each of the processors.

In practice the sons of a node may be ordered in such a way that any son has a probability of yielding the locally optimal path that is no smaller than the corresponding probabilities for its right neighbors. The probability to find the optimum in the subtree rooted at a given son then always decreases when traversing the sons in a left to right order. Such ordering information is generally available in game-playing programs, the ordering function being a heuristic function based on the knowledge of the game to be played.

### A Mandatory Work First Algorithm

R. Hewett and G. Krishnamurthy [15] proposed an algorithm that achieves an efficiency of roughly 50% for an number of processors in the range of 2 to 25. All the nodes that still need to be explored are maintained in a list called 'open' list. This list is ordered with respect to how the nodes have been reached. More precisely, the algorithm maintains two lists called 'open' and 'closed', and a tree called 'cut'. The 'open' list contains all the nodes yet to be explored, the 'closed' list contains the expanded nodes not yet pruned and the 'cut' tree contains the pruned nodes. The 'open' list initially contains only the root node. All processors fetch nodes from the 'open' list and process them if they cannot be discarded, that is, they do not have any of their ancestors in the 'cut' tree. Leave nodes are evaluated and their result is returned to the parent which may update its value and check for possible pruning by traversing the 'cut' tree up to the root node applying the usual alpha and beta cutoffs. If the node selected is not a leave node, it is ex-

panded and its sons are inserted into the 'open' list and itself into the 'closed' list.

S.G. Akl et al. [1,2] proposed an algorithm that uses the same approach for exploring the minimax tree. Their priority function is computed as

$$p(n_i) = p(\text{father}(n_i)) - (b_{n_i} + 1 - i) \cdot 10^{(h-f-1)},$$

where  $n_i$  is the  $i$ th son of node  $\text{father}(n_i)$ ,  $b_{n_i}$  the branching of node  $\text{father}(n_i)$ ,  $h$  the search depth (the maximal depth of the minimax tree) and  $f$  the depth of node  $\text{father}(n_i)$  in the minimax tree.

K. Almquist et al. [3] also developed an algorithm based on the idea of having two categories of unexplored nodes which are ordered according to a given priority function. Furthermore they add to this concept parallel aspiration search as well as a novel scheduling algorithm.

In the same direction, V.-D. Cung and C. Roucairol [9] have proposed a shared memory parallel minimax algorithm which distinguishes between critical and non critical nodes. In their algorithm one processor is assigned to each node.

In the algorithm by I.R. Steinberg and M. Solomon [28], which is also a mandatory work first type algorithm, the list containing the speculative work or non critical nodes is dynamically ordered.

### Aspiration Search

The parallel algorithm called *aspiration search* has been introduced by Baudet in 1978 [7]. In this algorithm the search interval  $] -\infty, +\infty [$  used by the sequential alpha-beta algorithm is divided into a certain number of subintervals that cover the entire range  $] -\infty, +\infty [$ . Now, every processor explores the entire minimax tree using one subinterval, different processors being assigned different intervals. Any processor searching an interval  $]a_i, a_{i+1} [$  may either fail low or high. The principle is the same as in the sequential version of the algorithm. Exactly one processor will neither fail low, nor fail high. The value computed by this processor is the value of the minimax tree to explore.

The implementation of the aspiration search algorithm is really simple. Furthermore, there is no information exchange needed between processors. If the nodes in the to explore minimax tree are ordered in such a way that the alpha-beta algorithm has to explore

the whole tree, then the speedup obtained by using the aspiration search algorithm is maximal. But, when the aspiration search algorithm is applied to randomly generated trees then Baudet has shown that the speedup is limited to about six and is independent of the number of processors used.

### Tree-Splitting Algorithm

Among the early parallel minimax algorithms is the *tree-splitting algorithm* by R.A. Finkel and J.P. Fishburn [14]. This algorithm is based on the idea to look at the available processors as a tree of processors. Each processor, except for the ones representing leaves in the processor tree, have a fixed number  $p_b$  of son or slave processors. During the execution of the algorithm a non leaf processor associated with a node  $n$  in the minimax tree spawns the exploration of the sons  $s_i$  of  $n$  to its  $p_b$  slaves. As soon as one slave returns the next unexplored son  $s_j$  is spawned to that slave or the current value is returned to the father processor if the cut condition is satisfied. If all the sons of a node have been spawned to its slaves, the father processor waits for the results of all its slaves. Leave processors simply compute the value of their associated node using the sequential alpha-beta algorithm.

An important advantage of the tree-splitting algorithm over other more elaborated algorithms is that it may be simply implemented as well on a shared memory parallel machine as on a distributed memories parallel machine.

The tree-splitting algorithm has been implemented and its execution has been simulated. On a 27 processor simulated machine, in which each processor has tree slave sons associated, the average speedup was 5.31 for trees of depth eight and a branching of three.

### PVSPLIT: Principal Variation Splitting Algorithm

It has been proposed by T.A. Marsland and M.S. Campbell [19] and is by far the most often implemented algorithm, especially in chess playing programs. The algorithm is based on the structure of the sequential alpha-beta algorithm. The idea is to first explore in a sequential fashion a path from the root node to its leftmost leaf. This path is called the *principal variation path*. The traversal is done to obtain alpha and beta bounds. If the minimax tree to explore is of type best first, then

the explored principal variation path represents the solution path. In a second phase, for each level of the minimax tree all the yet to be visited sons are explored in parallel by using the bounds computed during the principal variation path computation and the traversal of the lower levels of the minimax tree.

The PVSPLIT algorithm is completely described by the following pseudocode using the negamax notation.

The PVSPLIT algorithm has been implemented in [20] on a network of Sun workstations. An acceleration of 3.06 has been measured on 4 processors when traversing minimax trees representing real chess games. The main problem of the PVSPLIT algorithm is that, during the second phase, the subtrees explored in parallel are not necessarily of the same size.

The PVSPLIT algorithm is most efficient when the iterative deepening technique is used, because with each iteration is increasingly likely that the first move tried, that is, the one on the principal variation path, is the best one.

```

FUNCTION PVSplit( $b, \alpha, \beta$ ) IS
BEGIN
  IF is_leave( $n$ ) THEN RETURN  $f(n)$ 
   $s \leftarrow$  first_son( $n$ )
   $\alpha \leftarrow$  -PVSplit( $s, -\beta, -\alpha$ )
  IF  $\alpha \geq \beta$  THEN RETURN  $\alpha$ 
  FOR  $s' \in$  sons( $n$ ) - { $s$ } LOOP IN PARALLEL
    (wait until a slave node is idle)
     $v_i \leftarrow$  -TreeSplit( $s', -\beta, -\alpha$ )
    IF  $v_i > \alpha$  THEN
       $\alpha \leftarrow v_i$ 
      (Update the bounds according to  $\alpha$  on all slaves)
    END IF
  IF  $\alpha > \beta$  THEN
    (Terminate all slave processors)
    RETURN  $\alpha$ 
  END IF
END LOOP
RETURN  $\alpha$ 
END PVSplit

```

### Pseudocode for the PVSPLIT algorithm

### Synchronized Distributed State Space Search

A completely different approach to parallelizing the SSS\* algorithm has been taken by C.G. Diderich and

M. Gengler [10]. The algorithm proposed is called synchronized distributed state space search (SDSSS). It is an alternation of computation and synchronization phases. The algorithm has been designed for a distributed memory multiprocessor machine. Each processor manages its own local ‘open’ list of unvisited nodes.

The synchronization phase may be subdivided in three major parts. First, the processors exchange information about which nodes can be removed from the local ‘open’ lists. This corresponds to each processor sending the nodes for which the ‘purge’ operation may be applied by all the other processors. Next, all the processors agree on the globally lowest upper bound  $m^*$  for which nodes exist in some of the ‘open’ lists. Finally all the nodes having the same upper bound  $m^*$  are evenly distributed among all the processors. This operation concludes the synchronization phase.

The computation phase of the SDSSS algorithm may be described by the following pseudocode.

```

(Computation phase) ≡
  WHILE (there exists a node in the open list
  having an upper bound of  $m^*$ )
    LOOP
      ( $s, t, m^*$ ) ← remove(open)
      IF  $s = \text{root}$  AND  $t = \text{solved}$  THEN
        BROADCAST ‘the solution has been
        found’
        RETURN  $m^*$ 
      END IF
      (Apply the  $\Gamma$  operator to node  $s$ )
    END LOOP
  
```

**Pseudocode for the computation phase of the SDSSS algorithm**

Experiments executing the SDSSS algorithm on an Intel iPSC/2 parallel machine have been conducted. Speedups of up to 11.4 have been measured for 32 processors.

### Distributed Game Tree Search Algorithm

R. Feldman [12] parallelized the alpha-beta algorithm for massively parallel distributed memory machines. Different subtrees are searched in parallel by different processors. The allocation of processors to trees is done by imposing certain conditions on the nodes which are

be selectable. They introduce the concept of *younger brother waits*. This concept essentially says that in the case of a subtree rooted at  $s_1$ , where  $s_1$  is the first son node of a node  $n$ , is not yet evaluated, then the other sons  $s_2, \dots, s_b$  of node  $n$  are not selectable. Younger brothers may only be considered after their elder brothers, which has as a consequence that the value of the elder brothers may be used to give a tight search window to the younger brothers.

This concept is nevertheless not sufficient to achieve the same good search window as the alpha-beta algorithm achieves. Indeed when node  $s_1$  is computed, then the younger brothers may all be explored in parallel using the value of node  $s_1$ . Thus the node  $s_2$  has the same search window as it would have in the sequential alpha-beta algorithm, but this is not true anymore for  $s_i$ , where  $i \geq 3$ . Indeed if nodes  $s_2$  and  $s_3$  are processed in parallel, they only know the value of node  $s_1$ , while in the sequential alpha-beta algorithm, the node  $s_3$  would have known the value of both  $s_1$  and  $s_2$ . This fact forces the parallel algorithm to provide an information dissemination protocol.

In case the nodes  $s_2$  and  $s_3$  are evaluated on processors  $P$  and  $P'$ , and processor  $P$  finishes its work before  $P'$ , producing a better value than node  $s_1$  did, then processor  $P$  will inform processor  $P'$  of this value, allowing it to continue with better information on the rest of its subtree or to terminate its work if the new value allows  $P'$  to conclude that its computation becomes useless. The load distribution is realized by means of a dynamic load balancing scheme, where idle processors ask other processors for work.

Speedups as high as 100 have been obtained on a 256 processor machines. In [13], a speedup of 344 on a 1024 transputer network interconnected as a grid and a speedup of 142 on a 256 processor transputer de Bruijn interconnected network have been shown.

### Parallel Minimax Algorithm with Linear Speedup

In 1988, Althöfer [4] proved that it is possible, to develop a parallel minimax algorithm which achieves linear speedup in the average case. With the assumption that all minimax trees are binary win-loss trees, he exhibited such a parallel minimax algorithm.

M. Böhm and E. Speckenmeyer [8] also suggested an algorithm which uses the same basic ideas as Althöf-

fer. Their algorithm is more general in the sense that it needs only to know the distribution of the leaf values and is independent of the branching of the tree explored.

In 1989, R.M. Karp and Y. Zhang [17] proved that it is possible to obtain linear speedup on every instance of a random uniform minimax tree if the number of processors is close to the height of the tree.

## Keywords

Minimax theorem; Fixed point theorem; Hahn–Banach theorem; Connectedness

We suppose that  $X$  and  $Y$  are nonempty sets and  $f: X \times Y \rightarrow \mathbf{R}$ . A *minimax theorem* is a theorem that asserts that, under certain conditions,

$$\inf_Y \sup_X f = \sup_X \inf_Y f,$$

that is to say,

$$\inf_{y \in Y} \sup_{x \in X} f(x, y) = \sup_{x \in X} \inf_{y \in Y} f(x, y).$$

The purpose of this article is to give the reader the flavor of the different kind of minimax theorems, and of the techniques that have been used to prove them. This is a very large area, and it would be impossible to touch on all the work that has been done in it in the space that we have at our disposal. The choice that we have made is to give the historical roots of the subject, and then go directly to the most recent results. The reader who is interested in a more complete narrative can refer to the 1974 survey article [35] by E.B. Yanovskaya, the 1981 survey article [8] by A. Irle and the 1995 survey article [31] by S. Simons.

## Von Neumann's Results

In his investigation of *games of strategy*, J. von Neumann realized that, even though a two-person zero-sum game did not necessarily have a solution in *pure* strategies, it did have to have one in *mixed* strategies. Here is a statement of that seminal result ([19], translated into English in [21]):

**Theorem 1** (1928) *Let  $A$  be an  $m \times n$  matrix, and  $X$  and  $Y$  be the sets of nonnegative row and column vectors with unit sum. Then*

$$\min_{y \in Y} \max_{x \in X} xAy = \max_{x \in X} \min_{y \in Y} xAy.$$

Despite the fact that the statement of this result is quite elementary, the proof was quite sophisticated, and depended on an extremely ingenious induction argument. Nine years later, in [20], von Neumann showed that the bilinear character of Theorem 1 was not needed when he extended it as follows, using *Brouwer's fixed point theorem*:

**Theorem 2** (1937) *Let  $X$  and  $Y$  be nonempty compact, convex subsets of Euclidean spaces, and  $f: X \times Y \rightarrow \mathbf{R}$  be jointly continuous. Suppose that  $f$  is quasiconcave on  $X$  and quasiconvex on  $Y$  (see below). Then*

$$\min_Y \max_X f = \max_X \min_Y f.$$

When we say that  $f$  is *quasiconcave* on  $X$ , we mean that

- for all  $y \in Y$  and  $\lambda \in \mathbf{R}$ ,  $GT(\lambda, y)$  is convex, and when we say that  $f$  is *quasiconvex* on  $Y$ , we mean that

- for all  $x \in X$  and  $\lambda \in \mathbf{R}$ ,  $LE(x, \lambda)$  is convex.

Here,  $GT(\lambda, y)$  and  $LE(x, \lambda)$  are 'level sets' associated with the function  $f$ . Specifically,

$$GT(\lambda, y) := \{x \in X: f(x, y) > \lambda\}$$

and

$$LE(x, \lambda) := \{y \in Y: f(x, y) \leq \lambda\}.$$

In 1941, S. Kakutani [10] analyzed von Neumann's proof and, as a result, discovered the fixed point theorem that bears his name.

## Infinite-Dimensional Results for Convex Sets

The first infinite-dimensional minimax theorem was proved in 1952 by K. Fan ([1]), who generalized Theorem 2 to the case when  $X$  and  $Y$  are compact, convex subsets of infinite-dimensional locally convex spaces, and the quasiconcave and quasiconvex conditions are somewhat relaxed. The result in this general line that has the simplest statement is that of M. Sion, who proved the following ([33]):

**Theorem 3** (1958) *Let  $X$  be a convex subset of a linear topological space,  $Y$  be a compact convex subset of a linear topological space, and  $f: X \times Y \rightarrow \mathbf{R}$  be upper semicontinuous on  $X$  and lower semicontinuous on  $Y$ . Suppose that  $f$  is quasiconcave on  $X$  and quasiconvex on  $Y$ . Then*

$$\min_Y \sup_X f = \sup_X \min_Y f.$$

When we say that  $f$  is ‘upper semicontinuous on  $X$ ’ and ‘lower semicontinuous on  $Y$ ’ we mean that, for all  $y \in Y$ , the map  $x \mapsto f(x, y)$  is *upper semicontinuous* and, for all  $x \in X$ , the map  $y \mapsto f(x, y)$  is *lower semicontinuous*. The importance of Sion’s weakening of continuity to semicontinuity was that it indicated that many kinds of minimax problems have equivalent formulations in terms of subsets of  $X$  and  $Y$ , and led to Fan’s 1972 work ([4]) on sets with convex sections and minimax inequalities, which has since found many applications in economic theory. Like Theorem 2, all these result relied ultimately on Brouwer’s fixed point theorem (or the related *Knaster–Kuratowski–Mazurkiewicz lemma* (KKM lemma) on closed subsets of a finite-dimensional simplex).

### Functional-Analytic Minimax Theorems

The first person to take minimax theorems out of the context of convex subsets of vector spaces, and their proofs (other than that of the matrix case discussed in Theorem 1) out of the context of fixed point theorems was Fan in 1953 ([2]). We present here a generalization of Fan’s result due to H. König ([15]). König’s proof depended on the Mazur–Orlicz version of the Hahn–Banach theorem (see Theorem 5 below).

**Theorem 4** (1968) *Let  $X$  be a nonempty set and  $Y$  be a nonempty compact topological space. Let  $f: X \times Y \rightarrow \mathbf{R}$  be lower semicontinuous on  $Y$ . Suppose that:*

- for all  $x_1, x_2 \in X$ , there exists  $x_3 \in X$  such that

$$f(x_3, \cdot) \geq \frac{f(x_1, \cdot) + f(x_2, \cdot)}{2} \quad \text{on } Y;$$

- for all  $y_1, y_2 \in Y$ , there exists  $y_3 \in Y$  such that

$$f(\cdot, y_3) \leq \frac{f(\cdot, y_1) + f(\cdot, y_2)}{2} \quad \text{on } X.$$

Then

$$\min_Y \sup_X f = \sup_X \min_Y f.$$

We give here the statement of the *Mazur–Orlicz version of the Hahn–Banach theorem*, since it is a very useful result and it not as well-known as it deserves to be.

**Theorem 5 (Mazur–Orlicz theorem)** *Let  $S$  be a sublinear functional on a real vector space  $E$ , and  $C$  be a nonempty convex subset of  $E$ . Then there exists a linear functional  $L$  on  $E$  such that  $L \leq S$  on  $E$  and  $\inf_C L = \inf_C S$ .*

See [16,22] and [23] for applications of the Mazur–Orlicz theorem and the related ‘sandwich theorem’ to measure theory, Hardy algebra theory and the theory of flows in infinite networks.

The kind of minimax theorem discussed in this section (where  $X$  is not topologized) has turned out to be extremely useful in functional analysis, in particular in *convex analysis* and also in the theory of *monotone operators on a Banach space*. (See [32] for more details of these kinds of applications.)

### Minimax Theorems that Depend on Connectedness

It was believed for some time that proofs of minimax theorems required either the fixed point machinery of algebraic topology, or the functional-analytic machinery of convexity. However, in 1959, W.-T. Wu proved the first minimax theorem in which the conditions of convexity were totally replaced by conditions related to *connectedness*. This line of research was continued by H. Tuy, L.L. Stachó, M.A. Geraghty with B.-L. Lin, and J. Kindler with R. Trost, whose results were all subsumed by a family of general topological minimax theorem established by König in [17]. Here is a typical result from [17]. In order to simplify the statements of this and some of our later results, we shall write  $f_* := \sup_X \inf_Y f$ .  $f_*$  is the ‘lower value’ of  $f$ . If  $\lambda \in \mathbf{R}$ ,  $V \subset Y$  and  $W \subset X$ , we write  $GT(\lambda, V) := \bigcap_{y \in V} GT(\lambda, y)$  and  $LE(W, \lambda) := \bigcap_{x \in W} LE(x, \lambda)$ .

**Theorem 6** (1992) *Let  $X$  be a connected topological space,  $Y$  be a compact topological space, and  $f: X \times Y \rightarrow \mathbf{R}$  be upper semicontinuous on  $X$  and lower semicontinuous on  $Y$ . Let  $\Lambda$  be a nonempty subset of  $(f_*, \infty)$*

such that  $\inf \Lambda = f_*$  and suppose that, for all  $\lambda \in \Lambda$ , for all nonempty subsets  $V$  of  $Y$ , and for all nonempty finite subsets  $W$  of  $X$ ,

$$GT(\lambda, V) \text{ is connected in } X,$$

and

$$LE(W, \lambda) \text{ is connected in } Y.$$

Then

$$\min_Y \sup_X f = \sup_X \min_Y f.$$

**Mixed Minimax Theorems**

In [34], F. Terkelsen proved the first *mixed minimax theorem*. We describe Terkelsen’s result as ‘mixed’ since one of the conditions in it is taken from Theorem 4, and the other from Theorem 6:

**Theorem 7 (1972)** *Let  $X$  be a nonempty set and  $Y$  be a nonempty compact topological space. Let  $f: X \times Y \rightarrow \mathbf{R}$  be lower semicontinuous on  $Y$ . Suppose that,*

- *for all  $x_1, x_2 \in X$  there exists  $x_3 \in X$  such that*

$$f(x_3, \cdot) \geq \frac{f(x_1, \cdot) + f(x_2, \cdot)}{2} \text{ on } Y.$$

*Suppose also that, for all  $\lambda \in \mathbf{R}$  and, for all nonempty finite subsets  $W$  of  $X$ ,*

$$LE(W, \lambda) \text{ is connected in } Y.$$

Then

$$\min_Y \sup_X f = \sup_X \min_Y f.$$

**A Metaminimax Theorem**

It was believed for some time that Brouwer’s fixed point theorem or the Knaster–Kuratowski–Mazurkiewicz lemma was required to order to prove Sion’s theorem, Theorem 3. However, in 1966, M.A. Ghouila-Houri ([7]) proved Theorem 3 using a simple combinatorial property of convex sets in finite-dimensional space. This was probably the first indication of the breakdown of the classification of minimax theorems as either of ‘topological’ or ‘functional-analytic’ type. Further indi-

cation of this breakdown was provided by Terkelsen’s result, Theorem 7, and the subsequent 1982 results of I. Joó and Stachó ([9]), the 1985 and 1986 results of Geraghty and Lin ([5] and [6]), and the 1989 results of H. Komiya ([18]).

Kindler ([11]) was the first to realize (in 1990) that some abstract concept akin to connectedness might be involved in minimax theorems, even when the topological condition of connectedness was not explicitly assumed. This idea was pursued by Simons with the introduction in 1992 of the concept of *pseudoconnectedness*, which we will now describe. We say that sets  $H_0$  and  $H_1$  are *joined* by a set  $H$  if

$$H \subset H_0 \cup H_1, \quad H \cap H_0 \neq \emptyset$$

and

$$H \cap H_1 \neq \emptyset.$$

We say that a family  $\mathcal{H}$  of sets is *pseudoconnected* if

$$\begin{aligned} H_0, H_1, H \in \mathcal{H} \quad \text{and} \quad H_0 \text{ and } H_1 \text{ joined by } H \\ \Downarrow \\ H_0 \cap H_1 \neq \emptyset. \end{aligned}$$

Any family of closed connected subsets of a topological space is pseudoconnected. So also is any family of open connected subsets. However, pseudoconnectedness can be defined in the absence of any topological structure and, as we shall see in Theorem 8, is closely related to minimax theorems. Theorem 8 is the improvement of the result of [29] due to König (see [30]). We shall say that a subset  $W$  of  $X$  is *good* if

- $W$  is finite; and
- for all  $x \in X$ ,  $LE(x, f_*) \cap LE(W, f_*) \neq \emptyset$ .

**Theorem 8 (1995)** *Let  $Y$  be a topological space, and  $\Lambda$  be a nonempty subset of  $\mathbf{R}$  such that  $\inf \Lambda = f_*$ . Suppose that, for all  $\lambda \in \Lambda$  and for all good subsets  $W$  of  $X$ ,*

- *for all  $x \in X$ ,  $LE(x, \lambda)$  is closed and compact;  $\{LE(x, \lambda) \cap LE(W, \lambda)\}_{x \in X}$  is pseudoconnected; and*
- *for all  $x_0, x_1 \in X$ , there exists  $x \in X$  such that  $LE(x_0, \lambda)$  and  $LE(x_1, \lambda)$  are joined by  $LE(x, \lambda) \cap LE(W, \lambda)$ .*

Then

$$\min_Y \sup_X f = \sup_X \min_Y f.$$

Theorem 8 is proved by induction on the cardinality of the good subsets of  $W$ . Given the obvious topological motivation behind the concept of pseudoconnectedness, it is hardly surprising that Theorem 8 implies Theorem 6. What is more unexpected is that Theorem 8 implies Theorems 4 and 7 also. We prefer to describe Theorem 8 as a *metaminimax theorem* rather than a *minimax theorem*, since it is frequently harder to prove that the conditions of Theorem 8 are satisfied in any particular case than it is to prove Theorem 8 itself. So Theorem 8 is really a device for obtaining minimax theorems rather than a minimax theorem in its own right.

More recent work by Kindler ([12,13] and [14]) on abstract intersection theorems has been at the interface between minimax theory and abstract set theory.

### Minimax Theorems and Weak Compactness

There are close connections between minimax theorems and *weak compactness*. The following ‘converse minimax theorem’ was proved by Simons in [25]; this result also shows that there are limitations on the extent to which one can totally remove the assumption of compactness from minimax theorems.

**Theorem 9 (1971)** *Suppose that  $X$  is a nonempty bounded, convex, complete subset of a locally convex space  $E$  with dual space  $E^*$ , and*

$$\inf_{y \in Y} \sup_{x \in X} \langle x, y \rangle = \sup_{x \in X} \inf_{y \in Y} \langle x, y \rangle$$

*whenever  $Y$  is a nonempty convex, equicontinuous, subset of  $E^*$ . Then  $X$  is weakly compact.*

No compactness is assumed in the following, much harder, result (see [26]):

**Theorem 10 (1972)** *If  $X$  is a nonempty bounded, convex subset of a locally convex space  $E$  such that every element of the dual space  $E^*$  attains its supremum on  $X$ , and  $Y$  is any nonempty convex equicontinuous subset of  $E^*$ , then*

$$\inf_{y \in Y} \sup_{x \in X} \langle x, y \rangle = \sup_{x \in X} \inf_{y \in Y} \langle x, y \rangle.$$

If one now combines the results of Theorems 9 and 10, one can obtain a proof of the ‘sup theorem’ of R.C.

James, one of the most beautiful results in functional analysis:

**Theorem 11 (James sup theorem)** *If  $C$  is a nonempty bounded closed convex subset of  $E$ , then  $C$  is  $w(E, E^*)$ -compact if and only if, for all  $x^* \in E^*$ , there exists  $x \in C$  such that  $\langle x, x^* \rangle = \max_C x^*$ .*

James’s theorem is not easy - the standard proof can be found in the paper [24] by J.D. Pryce.

See [31] for more details of the connections between minimax theorems and weak compactness.

### Minimax Inequalities for Two or More Functions

Motivated by *Nash equilibrium* and the theory of *non-cooperative games*, Fan generalized Theorem 2 to the case of more than one function. In particular, he proved in [3] the following two-function minimax inequality (since the compactness of  $X$  is not needed, this result can in fact be strengthened to include Sion’s theorem, Theorem 3, by taking  $g = f$ ):

**Theorem 12 (1964)** *Let  $X$  and  $Y$  be nonempty compact, convex subsets of topological vector spaces and  $f, g: X \times Y \rightarrow \mathbf{R}$ . Suppose that  $f$  is lower semicontinuous on  $Y$  and quasiconcave on  $X$ ,  $g$  is upper semicontinuous on  $X$  and quasiconvex on  $Y$ , and*

$$f \leq g \quad \text{on } X \times Y.$$

*Then*

$$\min_Y \sup_X f \leq \sup_X \inf_Y g.$$

Fan (unpublished) and Simons (see [27]) generalized König’s theorem, Theorem 4, with the following two-function minimax inequality:

**Theorem 13 (1981)** *Let  $X$  be a nonempty set,  $Y$  be a compact topological space and  $f, g: X \times Y \rightarrow \mathbf{R}$ . Suppose that  $f$  is lower semicontinuous on  $Y$ , and*

- *for all  $y_1, y_2 \in Y$  there exists  $y_3 \in Y$  such that*

$$f(\cdot, y_3) \leq \frac{f(\cdot, y_1) + f(\cdot, y_2)}{2} \quad \text{on } X;$$

- for all  $x_1, x_2 \in X$  there exists  $x_3 \in X$  such that

$$g(x_3, \cdot) \geq \frac{g(x_1, \cdot) + g(x_2, \cdot)}{2} \quad \text{on } Y;$$

and

- $f \leq g$  on  $X \times Y$ .

Then

$$\min_Y \sup_X f \leq \sup_X \inf_Y g.$$

Theorems 12 and 13 both unify the theory of minimax theorems and the theory of *variational inequalities*. The curious feature about these two results is that they have ‘opposite geometric pictures’. This question is discussed in [27] and [28]. The relationship between Theorem 12 and Brouwer’s fixed point theorem is quite interesting. As we have already pointed out, Sion’s theorem, Theorem 3, can be proved in an elementary fashion without recourse to fixed point related concepts. On the other hand, Theorem 12 can, in fact, be used to prove *Tychonoff’s fixed point theorem*, which is itself a generalization of Brouwer’s fixed point theorem. (See [3] for more details of this.)

A number of authors have proved minimax inequalities for more than two functions. See [31] for more details of these results.

### Coincidence Theorems

A *coincidence theorem* is a theorem that asserts that if  $S: X \rightarrow 2^Y$  and  $T: Y \rightarrow 2^X$  have nonempty values and satisfy certain other conditions, then there exist  $x_0 \in X$  and  $y_0 \in Y$  such that  $y_0 \in Sx_0$  and  $x_0 \in Ty_0$ . The connection with minimax theorems is as follows: Suppose that  $\inf_Y \sup_X f \neq \sup_X \inf_Y f$ . Then there exists  $\lambda \in \mathbf{R}$  such that

$$\sup_X \inf_Y f < \lambda < \inf_Y \sup_X f.$$

Hence,

- for all  $x \in X$  there exists  $y \in Y$  such that  $f(x, y) < \lambda$ ;  
and
- for all  $y \in Y$  there exists  $x \in X$  such that  $f(x, y) > \lambda$ .

Define  $S: X \rightarrow 2^Y$  and  $T: Y \rightarrow 2^X$  by

$$Sx := \{y \in Y: f(x, y) < \lambda\} \neq \emptyset$$

and

$$Tx := \{x \in X: f(x, y) > \lambda\} \neq \emptyset.$$

If  $S$  and  $T$  were to satisfy a coincidence theorem, then we would have  $x_0 \in X$  and  $y_0 \in Y$  such that

$$f(x_0, y_0) < \lambda \quad \text{and} \quad f(x_0, y_0) > \lambda,$$

which is clearly impossible. Thus this coincidence theorem would imply that

$$\inf_Y \sup_X f = \sup_X \inf_Y f.$$

The coincidence theorems known in algebraic topology consequently give rise to corresponding minimax theorems. There is a very extensive literature about coincidence theorems. See [31] for more details about this.

### Keywords

Flows in networks; Global optimization; Nonconvex programming; Fixed charge transportation problem

The minimum concave transportation problem MCTP concerns the least cost method of carrying flow on a bipartite network in which the marginal cost for an arc is a nonincreasing function of the flow on that arc. A *bipartite network* contains source nodes and sink nodes, but no transshipment (i. e., intermediate) nodes. The MCTP can be formulated as

$$\min \sum_{(i,j) \in A} \phi_{ij}(x_{ij}) \quad (1)$$

subject to:

$$\sum_{j \in N} x_{ij} = s_i, \quad \forall i \in M, \quad (2)$$

$$\sum_{i \in M} x_{ij} = d_j, \quad \forall j \in N, \quad (3)$$

$$x_{ij} \geq 0, \quad \forall (i, j) \in A, \quad (4)$$

where  $M$  is the set of source nodes;  $N$  is the set of sink nodes;  $s_i$  is the supply at source node  $i$ ,  $d_j$  is the demand at sink node  $j$ ;  $A = \{(i, j) : i \in M, j \in N\}$  is the (directed) arc set;  $x_{ij}$  is the flow carried on arc  $(i, j)$ ; and  $\phi_{ij}(x_{ij})$  is the concave cost function for arc  $(i, j)$ . Objective function (1) minimizes total costs; constraints (2) balance flow at the source nodes; and constraints (3) balance flow at the sink nodes. If  $\sum_{i \in M} s_i$  is less (greater) than  $\sum_{j \in N} d_j$ , then a dummy source (sink) node can be added to set  $M$  ( $N$ ).

MCTPs arise naturally in distribution problems involving shipments sent directly from supply points to demand points in which the transportation costs exhibit economies of scale [21]. However, the MCTP is not limited to this class of problems. Specifically, any network flow problem with arc cost functions that are not concave can be converted to a network flow problem on an expanded network whose arc cost functions are all concave [16]. Then, the expanded network can be converted to a bipartite network by replacing each transshipment node with a source node and a sink node. Arc flow capacities can be removed by adding additional source nodes, one for each capacitated arc [19,23].

The fixed charge transportation problem FCTP is a type of MCTP in which the cost function  $\phi_{ij}(x_{ij})$  for each arc  $(i, j) \in A$  is of the form

$$\phi_{ij}(x_{ij}) = \begin{cases} 0 & \text{if } x_{ij} = 0, \\ f_{ij} + g_{ij} \cdot x_{ij} & \text{if } x_{ij} > 0, \end{cases} \quad (5)$$

where  $f_{ij}$  and  $g_{ij}$  are coefficients with  $f_{ij} \geq 0$ . FCTPs are commonly used to model network flow problems involving setup costs [9]. Furthermore, a variety of combinatorial problems can be converted to FCTPs. For instance, consider the 0–1 knapsack problem KP. The KP is formulated as

$$\max \sum_{k=1}^n c_k \cdot y_k \quad (6)$$

subject to:

$$\sum_{k=1}^n a_k \cdot y_k \leq b, \quad (7)$$

$$y_k \in \{0, 1\}, \quad \text{for } k = 1, \dots, n, \quad (8)$$

with  $a_k \geq 0$  and  $c_k \geq 0$  for  $k = 1, \dots, n$ . The KP can be converted to a FCTP with two source nodes and  $n +$

1 sink nodes. Define  $a_{n+1} = b$  and  $c_{n+1} = 0$ . Then, the network is specified as  $M = \{1, 2\}$ ,  $N = \{1, \dots, n + 1\}$ ,  $s_1 = b$ ,  $s_2 = \sum_{k=1}^n a_k$ , and  $d_j = a_j$  for  $j = 1, \dots, n + 1$ ; and the cost function is of the form of (5) where, for each arc  $(i, j) \in A$ , the coefficients  $f_{ij}$  and  $g_{ij}$  are given by

$$f_{ij} = \begin{cases} \sum_{k=1}^n c_k & \text{if } j = 1, \dots, n, \\ 0 & \text{if } j = n + 1, \end{cases} \quad (9)$$

$$g_{ij} = \begin{cases} -\frac{c_j}{a_j} & \text{if } i = 1, \\ 0 & \text{if } i = 2. \end{cases} \quad (10)$$

For  $j = 1, \dots, n$  sink node  $j$  has two incoming arcs, exactly one of which will have nonzero flow in the optimal solution to the FCTP. If  $x_{1j}^* > 0$  in the FCTP, then  $y_j^* = 1$  in the KP. If  $x_{2j}^* > 0$  in the FCTP, then  $y_j^* = 0$  in the KP.

One consequence of this result is that any integer programming problem with integer coefficients can (in principle) be formulated and solved as a FCTP by first converting the integer program to a KP [10].

Exact solution methods for the MCTP are predominately branch and bound enumeration procedures [2,3,4,6,8,11,12,15]. Binary partitioning is used for the FCTP; and interval partitioning is used for the MCTP with arbitrary concave arc cost functions. Finite convergence of the method was shown by R.M. Soland [22]. The convex envelope of the cost function  $\phi_{ij}(x_{ij})$  is an affine function. Hence, a subproblem in the branch and bound procedure can be solved efficiently as a linear transportation problem (LTP) [1]. Fathoming techniques (such as ‘up and down penalties’ and ‘capacity improvement’) based on post-optimality analysis of the LTP facilitate the branch and bound procedure for the MCTP [2,3,18,20]. The LTP is also used in approximate solution methods for the MCTP which rely on successive linearizations of the concave cost function,  $\phi_{ij}(x_{ij})$  [5,13,14].

Test problems for the MCTP are given in [7,8,12,17,20].

## Keywords

Network; Minimum cost flow problem; Cycle-canceling algorithm; Successive shortest path algorithm; Network simplex algorithm

The *minimum cost flow problem* seeks a least cost shipment of a commodity through a network to satisfy demands at certain nodes by available supplies at other nodes. This problem has many, varied applications: the distribution of a product from manufacturing plants to warehouses, or from warehouses to retailers; the flow of raw material and intermediate goods through various machining stations in a production line; the routing of automobiles through an urban street network; and the routing of calls through the telephone system. The minimum cost flow problem also has many less direct applications. In this article, we briefly introduce the theory, algorithms and applications of the minimum cost flow problem. [1] contains much additional material on this topic.

Let  $G = (N, A)$  be a *directed network* defined by a set  $N$  of  $n$  nodes and a set  $A$  of  $m$  directed arcs. Each arc  $(i, j) \in A$  has an associated *cost*  $c_{ij}$  that denotes the cost per unit flow on that arc. We assume that the flow cost varies linearly with the amount of flow. Each arc  $(i, j) \in A$  has an associated *capacity*  $u_{ij}$  denoting the maximum amount that can flow on this arc, and a lower bound  $l_{ij}$  that denotes the minimum amount that must flow on the arc. We assume that the capacity and flow lower bound for each arc  $(i, j)$  are integers. We associate with each node  $i \in N$  an integer  $b(i)$  representing its supply/demand. If  $b(i) > 0$ , node  $i$  is a *supply node*; if  $b(i) < 0$ , then node  $i$  is a *demand node* with a demand of  $-b(i)$ ; and if  $b(i) = 0$ , then node  $i$  is a *transshipment node*. We assume that  $\sum_{i \in N} b(i) = 0$ . The decision variables  $x_{ij}$  are arc flows defined for each arc  $(i, j) \in A$ .

The minimum cost flow problem is an optimization model formulated as follows:

$$\text{Minimize } \sum_{(i,j) \in A} c_{ij} x_{ij} \quad (1)$$

subject to

$$\sum_{\{j: (i,j) \in A\}} x_{ij} - \sum_{\{j: (j,i) \in A\}} x_{ji} = b(i), \quad \text{for all } i \in N, \quad (2)$$

$$l_{ij} \leq x_{ij} \leq u_{ij}, \quad \text{for all } (i, j) \in A. \quad (3)$$

We refer to the constraints (2) as the *mass balance constraints*. For a fixed node  $i$ , the first term in the constraint (2) represents the total outflow of node  $i$  and the second term represents the total inflow of node  $i$ . The mass balance constraints state that outflow minus inflow must equal the supply/demand of each node. The flow must also satisfy the lower bound and capacity constraints (3), which we refer to as *flow bound constraints*.

This article is organized as follows. To help in understanding the applicability of the minimum cost flow problem, we begin in Section 2 by describing several applications. In Section 3, we present preliminary material needed in the subsequent sections. We next discuss algorithms for the minimum cost flow problem, describing the cycle-canceling algorithm in Section 4 and the successive shortest path algorithm in Section 5. The cycle-canceling algorithm identifies negative cost cycles in the network and augments flows along them. The successive shortest path algorithm augments flow along shortest cost augmenting paths from the supply nodes to the demand nodes. In Section 6, we describe the network simplex algorithm.

## Applications

Minimum cost flow problems arise in almost all industries, including agriculture, communications, defense, education, energy, health care, manufacturing, medicine, retailing, and transportation. Indeed, minimum cost flow problems are pervasive in practice. In this section, by considering a few selected applications that arise in distribution systems planning, capacity planning, and vehicle routing, we give a passing glimpse of these applications.

## Distribution Problems

A large class of network flow problems center around distribution applications. One core model is often described in terms of shipments from plants to warehouses (or, alternatively, from warehouses to retailers). Suppose a firm has  $p$  plants with known supplies and  $q$  warehouses with known demands. It wishes to identify a flow that satisfies the demands at the warehouses from the available supplies at the plants and that minimizes

its shipping costs. This problem is a well-known special case of the minimum cost flow problem, known as the *transportation problem*. We next describe in more detail a slight generalization of this model that also incorporates manufacturing costs at the plants.

A car manufacturer has several manufacturing plants and produces several car models at each plant that it then ships to geographically dispersed retail centers throughout the country. Each retail center requests a specific number of cars of each model. The firm must determine the production plan of each model at each plant and a shipping pattern that satisfies the demand of each retail center while minimizing the overall cost of production and transportation.

We describe this formulation through an example. Figure 1 illustrates a situation with two manufacturing plants, two retailers, and three car models. This model has four types of nodes:

- i) *plant nodes*, representing various plants;
- ii) *plant/model nodes*, corresponding to each model made at a plant;
- iii) *retailer/model nodes*, corresponding to the models required by each retailer; and
- iv) *retailer nodes* corresponding to each retailer.

The network contains three types of arcs:

- i) production arcs;
- ii) transportation arcs; and
- iii) demand arcs.

The production arcs connect a plant node to a plant/model node; the cost of this arc is the cost of producing the model at that plant. We might place lower and upper bounds on production arcs to control for the minimum and maximum production of each particular car model at the plants. Transportation arcs connect plant/model nodes to retailer/model nodes; the cost of any such arc is the total cost of shipping one car from the manufacturing plant to the retail center. The transportation arcs might have lower or upper bounds imposed upon their flows to model contractual agreements with shippers or capacities imposed upon any distribution channel. Finally, demand arcs connect retailer/model nodes to the retailer nodes. These arcs have zero costs and positive lower bounds that equal the demand of that model at that retail center.

The production and shipping schedules for the automobile company correspond in a one-to-one fashion with the feasible flows in this network model. Conse-

quently, a minimum cost flow provides an optimal production and shipping schedule.

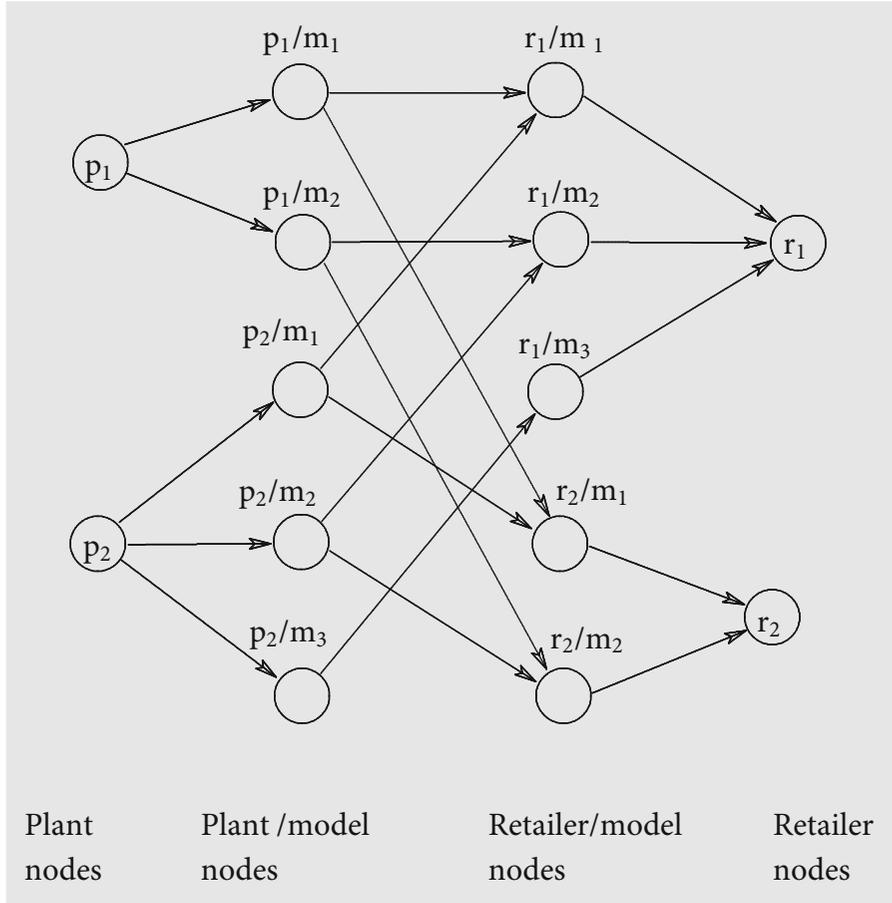

### Airplane Hopping Problem

A small commuter airline uses a plane, with a capacity to carry at most  $p$  passengers, on a 'hopping flight' as shown in Fig. 2a). The hopping flight visits the cities  $1, \dots, n$ , in a fixed sequence. The plane can pick up passengers at any node and drop them off at any other node. Let  $b_{ij}$  denote the number of passengers available at node  $i$  who want to go to node  $j$ , and let  $f_{ij}$  denote the fare per passenger from node  $i$  to node  $j$ . The airline would like to determine the number of passengers that the plane should carry between the various origins to destinations in order to maximize the total fare per trip while never exceeding the plane's capacity.

Figure 2b) shows a minimum cost flow formulation of this hopping plane flight problem. The network contains data for only those arcs with nonzero costs and with finite capacities: any arc listed without an associated cost has a zero cost; any arc listed without an associated capacity has an infinite capacity. Consider, for example, node 1. Three types of passengers are available at node 1: those whose destination is node 2, node 3 or node 4. We represent these three types of passengers in a new derived network by the nodes  $1-2$ ,  $1-3$  and  $1-4$  with supplies  $b_{12}$ ,  $b_{13}$  and  $b_{14}$ . A passenger available at any such node, say  $1-3$ , could board the plane at its origin node represented by flowing through the arc  $(1-3, 1)$  and incurring a cost of  $-f_{13}$  units (or profit of  $f_{13}$  units). Or, the passenger might never board the plane, which we represent by the flow through the arc  $(1-3, 3)$ . It is easy to establish a one-to-one correspondence between feasible flows in Fig. 2b) and feasible loading of the plane with passengers. Consequently, a minimum cost flow in Fig. 2b) will prescribe a most profitable loading of the plane.

### Directed Chinese Postman Problem

The *directed Chinese postman problem* is a generic routing problem that can be stated as follows. In a directed network  $G = (N, A)$  in which each arc  $(i, j)$  has an associated cost  $c_{ij}$ , we wish to identify a walk of minimum cost that starts at some node (the post office), visits each arc of the network at least once, and returns to the starting point (see the next Section for the def-

**Minimum Cost Flow Problem, Figure 1**  
**Formulating the production-distribution problem**

initiation of a walk). This problem has become known as the Chinese postman problem because a Chinese mathematician, K. Mei-Ko, first discussed it. The Chinese postman problem arises in other settings as well; for instance, patrolling streets by police, routing street sweepers and household refuse collection vehicles, fuel oil delivery to households, and spraying roads with sand during snowstorms. The directed Chinese postman problem assumes that all arcs are directed, that is, the postal carrier can traverse an arc in only one direction (like one-way streets).

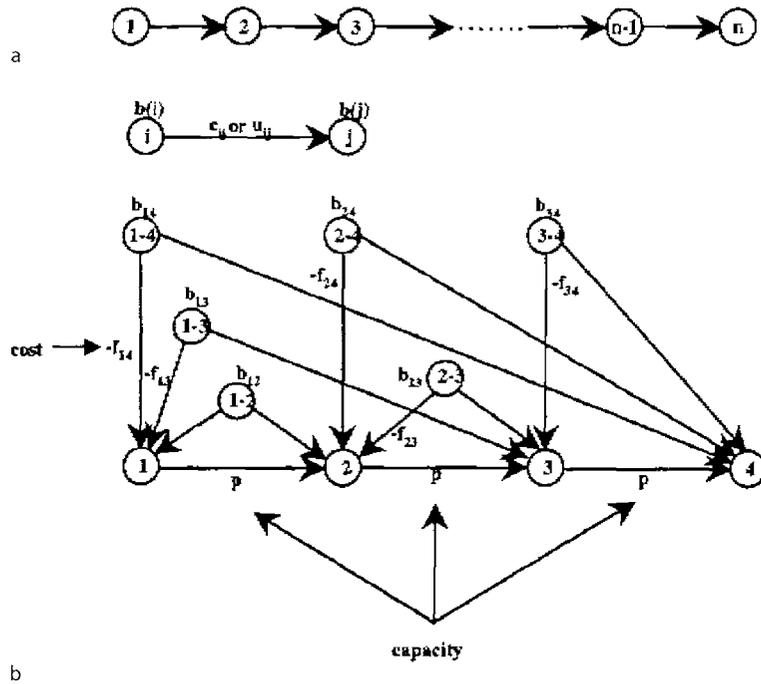

In the directed Chinese postman problem, we are interested in a closed (directed) walk that traverses each arc of the network at least once. The network might not contain any such walk. It is easy to show that a network contains a desired walk if and only if the net-

work is *strongly connected*, that is, every node in the network is reachable from every other node via a directed path. Simple graph search algorithms are able to determine whether the network is strongly connected, and we shall therefore assume that the network is strongly connected.

In an optimal walk, a postal carrier might traverse arcs more than once. The minimum length walk minimizes the sum of lengths of the repeated arcs. Let  $x_{ij}$  denote the number of times the postal carrier traverses arc  $(i, j)$  in a walk. Any carrier walk must satisfy the following conditions:

$$\sum_{\{j: (i,j) \in A\}} x_{ij} - \sum_{\{j: (j,i) \in A\}} x_{ji} = 0 \quad \text{for all } i \in N, \quad (4)$$

$$x_{ij} \geq 1 \quad \text{for all } (i, j) \in A. \quad (5)$$

**Minimum Cost Flow Problem, Figure 2**  
**Formulation of the hopping plane flight problem as a minimum cost flow problem**

The constraints (4) state that the carrier enters a node the same number of times that he or she leaves it. The constraints (5) state that the carrier must visit each arc at least once. Any solution  $x$  satisfying the system (4)–(5) defines a carrier’s walk. We can construct a walk in the following manner. Given a flow  $x_{ij}$ , we replace each arc  $(i, j)$  with  $x_{ij}$  copies of the arc, each arc carrying a unit flow. In the resulting network, say  $G' = (N, A')$ , each node has the same number of outgoing arcs as it has the incoming arcs. It is possible to decompose this network into at most  $m/2$  arc-disjoint directed cycles (by walking along an arc  $(i, j)$  from some node  $i$  with  $x_{ij} > 0$ , leaving an node each time we enter it until we repeat a node). We can connect these cycles together to form a closed walk of the carrier.

The preceding discussion shows that the solution  $x$  defined by a feasible walk for the carrier satisfies conditions (4)–(5), and, conversely, every feasible solution of system (4)–(5) defines a walk of the postman. The length of a walk defined by the solution  $x$  equals  $\sum_{(i,j) \in A} c_{ij}x_{ij}$ . This problem is an instance of the minimum cost flow problem.

**Preliminaries**

In this Section, we discuss some preliminary material required in the following sections.

**Assumptions**

We consider the minimum cost flow problem subject to the following six assumptions:

- 1)  $l_{ij} = 0$  for each  $(i, j) \in A$ ;
- 2) all data (cost, supply/demand, and capacity) are integral;
- 3) all arc costs are nonnegative;
- 4) for any pair of nodes  $i$  and  $j$ , the network does not contain both the arcs  $(i, j)$  and  $(j, i)$ ;
- 5) the minimum cost flow problem has a feasible solution; and
- 6) the network contains a directed path of sufficiently large capacity between every pair of nodes.

It is possible to show that none of these assumptions, except 2), restricts the generality of our development. We impose them just to simplify our discussion.

### Graph Notation

We use standard graph notation. A directed graph  $G = (N, A)$  consists of a set  $N$  of nodes and a set  $A$  of arcs. A directed arc  $(i, j)$  has two *endpoints*,  $i$  and  $j$ . An arc  $(i, j)$  is *incident* to nodes  $i$  and  $j$ . The arc  $(i, j)$  is an *outgoing arc* of node  $i$  and an *incoming arc* of node  $j$ . A *walk* in a directed graph  $G = (N, A)$  is a sequence of nodes and arcs  $i_1, a_1, i_2, a_2, \dots, i_r$  satisfying the property that for all  $1 \leq k \leq r-1$ , either  $a_k = (i_k, i_{k+1}) \in A$  or  $a_k = (i_{k+1}, i_k) \in A$ . We sometimes refer to a walk as a *sequence of arcs* (or nodes) without any explicit mention of the nodes (or arcs). A *directed walk* is an oriented version of the walk in the sense that for any two consecutive nodes  $i_k$  and  $i_{k+1}$  on the walk,  $a_k = (i_k, i_{k+1}) \in A$ . A *path* is a walk without any repetition of nodes, and a *directed path* is a directed walk without any repetition of nodes. A *cycle* is a path  $i_1, i_2, \dots, i_r$  together with the arc  $(i_r, i_1)$  or  $(i_1, i_r)$ . A *directed cycle* is a directed path  $i_1, i_2, \dots, i_r$  together with the arc  $(i_r, i_1)$ . A *spanning tree* of a directed graph  $G$  is a subgraph  $G' = (N, A')$  with  $A' \subseteq A$  that is connected (that is, contains a path between every pair of nodes) and contains no cycle.

### Residual Network

The algorithms described in this article rely on the concept of a *residual network*  $G(x)$  corresponding to a flow  $x$ . For each arc  $(i, j) \in A$ , the residual network contains two arcs  $(i, j)$  and  $(j, i)$ . The arc  $(i, j)$  has cost  $c_{ij}$  and *residual capacity*  $r_{ij} = u_{ij} - x_{ij}$ , and the arc  $(j, i)$  has cost  $c_{ji} = -c_{ij}$  and residual capacity  $r_{ji} = x_{ij}$ . The residual network consists of arcs with positive residual capacity. If  $(i, j) \in A$ , then sending flow on arc  $(j, i)$  in  $G(x)$  corresponds to decreasing flow on arc  $(i, j)$ ; for this reason, the cost of arc  $(j, i)$  is the negative of the cost of arc  $(i, j)$ . These conventions show how to determine the residual network  $G(x)$  corresponding to any flow  $x$ . We can also determine a flow  $x$  from the residual network  $G(x)$  as follows. If  $r_{ij} > 0$ , then using the definition of residual capacities and Assumption 4), we set  $x_{ij} = u_{ij} - r_{ij}$  if  $(i, j) \in A$ , and  $x_{ji} = r_{ij}$  otherwise. We define the *cost of a directed cycle*  $W$  in the residual network  $G(x)$  as  $\sum_{(i,j) \in W} c_{ij}$ .

### Order Notation

In our discussion, we will use some well-known notation from the field of complexity theory. We say that

an algorithm for a problem  $\mathcal{P}$  is an  $O(n^3)$  algorithm, or has a *worst-case complexity* of  $O(n^3)$ , if it is possible to solve any instance of  $\mathcal{P}$  using a number of computations that is asymptotically bounded by some constant times the term  $n^3$ . We refer to an algorithm as a *polynomial time algorithm* if its worst-case running time is bounded by a polynomial function of the input size parameters, which for a minimum cost flow problem, are  $n, m, \log C$  (the number of bits needed to specify the largest arc cost), and  $\log U$  (the number of bits needed to specify the largest arc capacity). A *polynomial time algorithm* is either a *strongly polynomial time algorithm* (when the complexity terms involves only  $n$  and  $m$ , but not  $\log C$  or  $\log U$ ), or is a *weakly polynomial time algorithm* (when the complexity terms include  $\log C$  or  $\log U$  or both). We say that an algorithm is a *pseudopolynomial time algorithm* if its worst-case running time is bounded by a polynomial function of  $n, m$  and  $U$ . For example, an algorithm with worst-case complexity of  $O(nm^2 \log n)$  is a strongly polynomial time algorithm, an algorithm with worst-case complexity  $O(nm^2 \log U)$  is a weakly polynomial time algorithm, and an algorithm with worst-case complexity of  $O(n^2 mU)$  is a pseudopolynomial time algorithm.

### Cycle-Canceling Algorithm

In this Section, we describe the cycle-canceling algorithm, one of the more popular algorithms for solving the minimum cost flow problem. The algorithm sends flows (called *augmenting flows*) along directed cycles with negative cost (called *negative cycles*). The algorithm rests upon the following negative cycle optimality condition stated as follows.

**Theorem 1 (Negative cycle optimality condition)** A feasible solution  $x^*$  is an optimal solution of the minimum cost flow problem if and only if the residual network  $G(x^*)$  contains no negative cost (directed) cycle.

It is easy to see the necessity of these conditions. If the residual network  $G(x^*)$  contains a negative cycle (that is, a negative cost directed cycle), then by augmenting positive flow along this cycle, we can decrease the cost of the flow. Conversely, it is possible to show that if the residual network  $G(x^*)$  does not contain any negative cost cycle, then  $x^*$  must be an optimal flow.

The negative cycle optimality condition suggests one simple algorithmic approach for solving the min-

```

BEGIN
  establish a feasible flow  $x$  in the network;
  WHILE  $G(x)$  contains a negative cycle DO
  BEGIN
    identify a negative cycle  $W$ ;
     $\delta := \min\{r_{ij} : (i, j) \in W\}$ ;
    augment  $\delta$  units of flow in the cycle  $W$ 
    and update  $G(x)$ ;
  END;
END
    
```

**Minimum Cost Flow Problem, Figure 3**  
**Cycle-canceling algorithm**

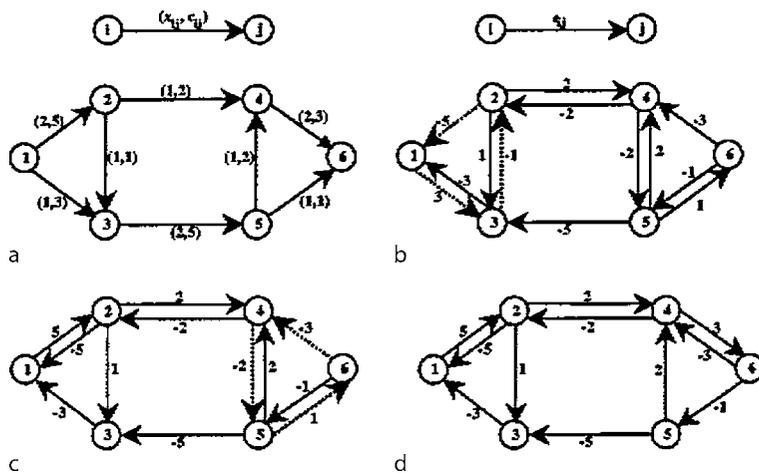

imum cost flow problem, which we call the *cycle-canceling algorithm*. This algorithm maintains a feasible solution and at every iteration improves the objective function value. The algorithm first establishes a feasible flow  $x$  in the network by solving a related (and easily solved) problem known as the maximum flow problem. Then it iteratively finds negative cycles in the residual network and augments flows on these cycles. The algorithm terminates when the residual network contains no negative cost directed cycle. Theorem 1 implies that when the algorithm terminates, it has found a minimum cost flow. Figure 3a specifies this generic version of the cycle-canceling algorithm.

The numerical example shown in Fig. 4a) illustrates the cycle-canceling algorithm. This figure shows the arc

costs and the starting feasible flow in the network. Each arc in the network has a capacity of 2 units. Figure 4b) shows the residual network corresponding to the initial flow. We do not show the residual capacities of the arcs in Fig. 4b) since they are implicit in the network structure. If the residual network contains both arcs  $(i, j)$  and  $(j, i)$  for any pair  $i$  and  $j$  of nodes, then both have residual capacity equal to 1; and if the residual network contains only one arc, then its capacity is 2 (this observation uses the fact that each arc capacity equals 2). The residual network shown in Fig. 4b) contains a negative cycle  $1 - 3 - 2 - 1$  with cost  $-3$ . By augmenting a unit flow along this cycle, we obtain the residual network shown in Fig. 4c). The residual network shown in Fig. 4c) contains a negative cycle  $6 - 4 - 5 - 6$  with cost  $-4$ . We augment unit flow along this cycle, producing the residual network shown in Fig. 4d), which contain no negative cycle. Given the optimal residual network, we can determine optimal flow using the method described in the previous Section.

A byproduct of the cycle-canceling algorithm is the following important result.

**Theorem 2 (Integrity property)** *If all arc capacities and supply/demands of nodes are integer, then the minimum cost flow problem always has an integer minimum cost flow.*

**Minimum Cost Flow Problem, Figure 4**

Illustration of the cycle-canceling algorithm. a) the original network with flow  $x$  and arc costs; b) the residual network  $G(x)$ ; c) the residual network after augmenting a unit of flow along the cycle  $2 - 1 - 3 - 2$ ; d) the residual network after augmenting a unit of flow along the cycle  $4 - 5 - 6 - 4$

This result follows from the fact that for problems with integer arc capacities and integer node supplies/demand, the cycle-canceling algorithm starts with an integer solution (which is provided by the maximum flow algorithm used to obtain the initial feasible flow) and at each iteration augments flow by an integral amount.

What is the worst-case computational requirement (complexity) of the cycle-canceling algorithm? The algorithm must repeatedly identify negative cycles in the residual network. We can identify a negative cycle in the residual network in  $O(nm)$  time using a shortest path label-correcting algorithm [1]. How many times must the generic cycle-canceling algorithm perform this computation? For the minimum cost flow problem,  $mCU$  is an upper bound on the initial flow cost (since  $c_{ij} \leq C$  and  $x_{ij} \leq U$  for all  $(i, j) \in A$ ) and  $-mCU$  is a lower bound on the optimal flow cost (since  $c_{ij} \geq -C$  and  $x_{ij} \leq U$  for all  $(i, j) \in A$ ). Any iteration of the cycle-canceling algorithm changes the objective function value by an amount  $\sum_{(i,j) \in W} c_{i,j} \delta$ , which is strictly negative. Since we have assumed that the problem has integral data, the algorithm terminates within  $O(mCU)$  iterations and runs in  $O(nm^2 CU)$  time, which is a pseudopolynomial running time.

The generic version of the cycle-canceling algorithm does not specify the order for selecting negative cycles from the network. Different rules for selecting negative cycles produce different versions of the algorithm, each with different worst-case and theoretical behavior. Two versions of the cycle-canceling algorithm are polynomial time implementations:

- i) a version that augments flow in arc-disjoint negative cycles with the maximum improvement [2]; and
- ii) a version that augments flow along a negative cycle with minimum mean cost, that is, the average cost per arc in the cycle [4]).

### Successive Shortest Path Algorithm

The cycle-canceling algorithm maintains feasibility of the solution at every step and attempts to achieve optimality. In contrast, the successive shortest path algorithm maintains optimality of the solution at every step (that is, the condition that the residual network  $G(x)$  contains no negative cost cycle) and strives to attain feasibility. It maintains a solution  $x$ , called a pseudoflow

(see below), that is nonnegative and satisfies the arcs' flow capacity restrictions, but violates the mass balance constraints of the nodes. At each step, the algorithm selects a node  $k$  with excess supply (i. e., supply not yet sent to some demand node), a node  $l$  with unfulfilled demand, and sends flow from node  $k$  to node  $l$  along a shortest path in the residual network. The algorithm terminates when the current solution satisfies all the mass balance constraints.

To be more precise, a *pseudoflow* is a vector  $x$  satisfying only the capacity and nonnegativity constraints; it need not satisfy the mass balance constraints. For any pseudoflow  $x$ , we define the *imbalance* of node  $i$  as

$$e(i) = b(i) + \sum_{\{j,i\} \in A} x_{ji} - \sum_{\{(i,j)\} \in A} x_{ij} \quad \text{for all } i \in N. \quad (6)$$

If  $e(i) > 0$  for some node  $i$ , then we refer to  $e(i)$  as the *excess* of node  $i$ ; if  $e(i) < 0$ , then we refer to  $-e(i)$  as the node's *deficit*. We refer to a node  $i$  with  $e(i) = 0$  as *balanced*. Let  $E$  and  $D$  denote the sets of excess and deficit nodes in the network. Notice that  $\sum_{i \in N} e(i) = \sum_{i \in N} b(i) = 0$ , which implies that  $\sum_{i \in E} e(i) = -\sum_{i \in D} e(i)$ . Consequently, if the network contains an excess node, then it must also contain a deficit node. The residual network corresponding to a pseudoflow is defined in the same way that we define the residual network for a flow. The successive shortest path algorithm uses the following result.

**Theorem 3 (Shortest augmenting path theorem)**  
*Suppose a pseudoflow (or a flow)  $x$  satisfies the optimality conditions and we obtain  $x'$  from  $x$  by sending flow along a shortest path from node  $k$  to some other node  $l$  in the residual network, then  $x'$  also satisfies the optimality conditions.*

To prove this Theorem, we would show that if the residual network  $G(x)$  contain no negative cycle, then augmenting flow along any shortest path does not introduce any negative cycle (we will not establish this result in this discussion). Figure 5 gives a formal description of the successive shortest path algorithm.

The numerical example shown in Fig. 6a) illustrates the successive shortest path algorithm. The algorithm starts with  $x = 0$ , and at this value of flow, the residual network is identical to the starting network. Just as we

```

BEGIN
  x := 0;
  e(i) = b(i) for all i ∈ N;
  initialize the sets E and D;
  WHILE E ≠ ∅ DO
  BEGIN
    select a node k ∈ E and a node l ∈ D;
    identify a shortest path P in G(x) from
    node k to node l;
    δ := min[e(s), -e(t), min{rij : (i, j) ∈ P}];
    augment δ units of flow along the path P and
    update x and G(x);
  END
END
    
```

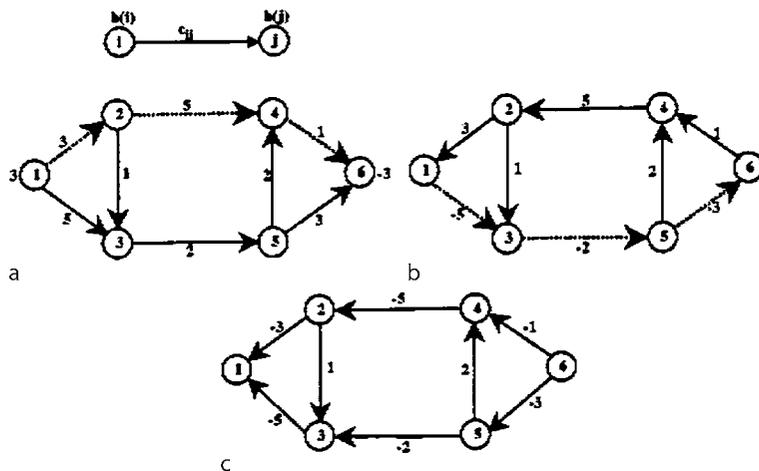

**Minimum Cost Flow Problem, Figure 5**  
**Successive shortest path algorithm**

observed in Fig. 4, whenever the residual network contains both the arcs  $(i, j)$  and  $(j, i)$ , the residual capacity of each arc is 1. If the residual network contains only one arc,  $(i, j)$  or  $(j, i)$ , then its residual capacity is 2 units. For this problem,  $E = \{1\}$  and  $D = \{6\}$ . In the residual network shown in Fig. 6a), the shortest path from node 1 to node 6 is  $1 - 2 - 4 - 6$  with cost equal to 9. The residual capacity of this path equals 2. Augmenting two units of flow along this path produces the residual network shown in Fig. 6b), and the next shortest path from

node 1 to node 6 is  $1 - 3 - 5 - 6$  with cost equal to 10. The residual capacity of this path is 2 and we augment two unit of flow on it. At this point, the sets  $E = D = \emptyset$ , and the current solution solves the minimum cost flow problem.

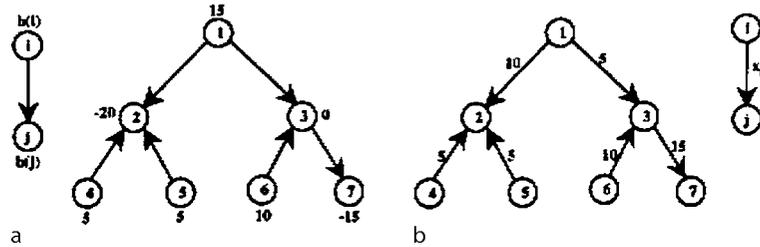

To show that the algorithm correctly solves the minimum cost flow problem, we argue as follows. The algorithm starts with a flow  $x = 0$  and the residual network  $G(x)$  is identical to the original network. Assumption 3) implies that all arc costs are nonnegative. Consequently, the residual network  $G(x)$  contains no negative cycle and so the flow vector  $x$  satisfies the negative cycle optimality conditions. Since the algorithm augments flow along a shortest path from excess nodes to deficit nodes, Theorem 3 implies that the pseudoflow maintained by the algorithm always satisfies the optimality conditions. Eventually, node excesses and deficits become zero; at this point, the solution maintained by the algorithm is an optimal flow.

What is the worst-case complexity of this algorithm? In each iteration, the algorithm reduces the excess of some node. Consequently, if  $U$  is an upper bound on the largest supply of any node, then the algorithm would terminate in at most  $nU$  iterations. We can determine a shortest path in  $G(x)$  in  $O(nm)$  time using a label-correcting shortest path algorithm [1]. Consequently, the running time of the successive shortest path algorithm is  $n^2mU$ .

**Minimum Cost Flow Problem, Figure 6**

Illustration of the successive shortest path algorithm. a) the residual network corresponding to  $x = 0$ ; b) the residual network after augmenting 2 units of flow along the path  $1 - 2 - 4 - 6$ ; c) the residual network after augmenting 2 units of flow along the path  $1 - 3 - 5 - 6$

Minimum Cost Flow Problem, Figure 7  
Computing flows for a spanning tree

The successive shortest path algorithm requires pseudopolynomial time to solve the minimum cost flow problem since it is polynomial in  $n$ ,  $m$  and the largest supply  $U$ . This algorithm is, however, polynomial time for some special cases of the minimum cost flow problem (such as the assignment problem for which  $U = 1$ ). Researchers have developed weakly polynomial time and strongly polynomial time versions of the successive shortest path algorithm; some notable implementations are due to [3] and [5].

### Network Simplex Algorithm

The network simplex algorithm for solving the minimum cost flow problem is an adaptation of the well-known simplex method for general linear programs. Because the minimum cost flow problem is a highly structured linear programming problem, when applied to it, the computations of the simplex method become considerably streamlined. In fact, we need not explicitly maintain the matrix representation (known as the simplex tableau) of the linear program and can perform all of the computations directly on the network. Rather than presenting the network simplex algorithm as a special case of the linear programming simplex method, we will develop it as a special case of the cycle-canceling algorithm described above. The primary advantage of our approach is that it permits the network simplex algorithm to be understood without relying on linear programming theory.

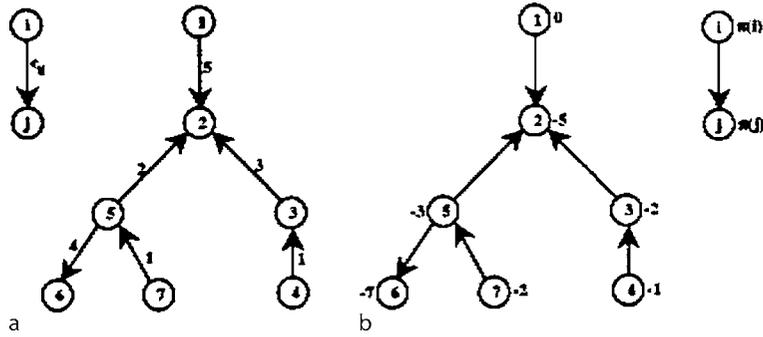

The network simplex algorithm maintains solutions called spanning tree solutions. A *spanning tree solution* partitions the arc set  $A$  into three subsets:

- i)  $T$ , the arcs in the spanning tree;
- ii)  $L$ , the nontree arcs whose flows are restricted to value zero;

- iii)  $U$ , the nontree arcs whose flow values are restricted in value to the arcs' flow capacities.

We refer to the triple  $(T, L, U)$  as a *spanning tree structure*. Each spanning tree structure  $(T, L, U)$  has a unique solution that satisfies the mass balance constraints (2). To determine this solution, we set  $x_{ij} = 0$  for all arcs  $(i, j) \in L$ ,  $x_{ij} = u_{ij}$  for all arcs  $(i, j) \in U$ , and then solve the mass balance equations (2) to determine the flow values for arcs in  $T$ .

To show that the flows on spanning tree arcs are unique, we use a numerical example. Consider the spanning tree  $T$  shown in Fig. 7a). Assume that  $U = \varnothing$ , that is, all nontree arcs are at their lower bounds. Consider the leaf node 4 (a leaf node is a node with exactly one arc incident to it). Node 4 has a supply of 5 units and has only one arc  $(4, 2)$  incident to it. Consequently, arc  $(4, 2)$  must carry 5 units of flow. So we set  $x_{42} = 5$ , add 5 units to  $b(2)$  (because it receives 5 units of flow sent from node 4), and delete arc  $(4, 2)$  from the tree. We now have a tree with one fewer node and next select another leaf node, node 5 with the supply of 5 units and the single arc  $(5, 2)$  incident to it. We set  $x_{52} = 5$ , again add 5 units to  $b(2)$ , and delete the arc  $(5, 2)$  from the tree. Now node 2 becomes a leaf node with modified supply/demand of  $b(2) = -10$ , implying that node 2 has an unfulfilled demand of 10 units. Node 2 has exactly one incoming arc  $(1, 2)$  and to meet the demand of 10 units of node 2, we must send 10 units of flow on this arc. We set  $x_{12} = 10$ , subtract 10 units from  $b(1)$  (since node 1 sends 10 units), and delete the arc  $(1, 2)$  from the tree. We repeat this process until we have identified flow on all arcs in the tree. Figure 7b) shows the corresponding flow. Our discussion assumed that  $U$  is empty. If  $U$  were nonempty, we would first set  $x_{ij} = u_{ij}$ , add  $u_{ij}$  to  $b(j)$ , and subtract  $u_{ij}$  from  $b(i)$  for each arc  $(i, j) \in U$ , and then apply the preceding method.

Minimum Cost Flow Problem, Figure 8  
Computing node potentials for a spanning tree

We say a spanning tree structure is *feasible* if its associated spanning tree solution satisfies all of the arcs' flow bounds. We refer to a spanning tree structure as *optimal* if its associated spanning tree solution is an optimal solution of the minimum cost flow problem. We will now derive the optimality conditions for a spanning tree structure  $(T, L, U)$ .

The network simplex algorithm augments flow along negative cycles. To identify negative cycles quickly, we use the concept of *node potentials*. We define node potentials  $\pi(i)$  so that the reduced cost for any arc in the spanning tree  $T$  is zero. That is, that is,  $c_{ij}^\pi = c_{ij} - \pi(i) + \pi(j) = 0$  for each  $(i, j) \in T$ . With the help of an example, we show how to compute the vector  $\pi$  of node potentials. Consider the spanning tree shown in Fig. 8a) with arc costs as shown. The vector  $\pi$  has  $n$  variables and must satisfy  $n - 1$  equations, one for each arc in the spanning tree. Therefore, we can assign one potential value arbitrary. We assume that  $\pi(1) = 0$ . Consider arc  $(1, 2)$  incident to node 1. The condition  $c_{12}^\pi = c_{12} - \pi(1) + \pi(2) = 0$  yields  $\pi(2) = -5$ . We next consider arcs incident to node 2. Using the condition  $c_{52}^\pi = c_{52} - \pi(5) + \pi(2) = 0$ , we see that  $\pi(5) = -3$ , and the condition  $c_{32}^\pi = c_{32} - \pi(3) + \pi(2) = 0$  shows that  $\pi(3) = -2$ . We repeat this process until we have identified potentials of all nodes in the tree  $T$ . Figure 8b) shows the corresponding node potentials.

Consider any nontree arc  $(k, l)$ . Adding this arc to the tree  $T$  creates a unique cycle, which we denote as  $W_{kl}$ . We refer to  $W_{kl}$  as the *fundamental cycle* induced by the nontree arc  $(k, l)$ . If  $(k, l) \in L$ , then we define the orientation of the fundamental cycle as in the direction of  $(k, l)$ , and if  $(k, l) \in U$ , then we define the orienta-

tion opposite to that of  $(k, l)$ . In other words, we define the orientation of the cycle in the direction of flow change permitted by the arc  $(k, l)$ . We let  $c(W_{kl})$  denote the change in the cost if we send one unit of flow on the cycle  $W_{kl}$  along its orientation. (Notice that because of flow bounds, we might not always be able to send flow along the cycle  $W_{kl}$ .) Let  $\overline{W}_{kl}$  denote the set of forward arcs in  $W_{kl}$  (that is, those with the same orientation as  $(k, l)$ ), and let  $\underline{W}_{kl}$  denote the set of backward arcs in  $W_{kl}$  (that is, those with an opposite the orientation to arc  $(k, l)$ ). Then, if we send one unit of flow along  $W_{kl}$ , then the flow on arcs in  $\overline{W}_{kl}$  increases by one unit and the flow on arcs in  $\underline{W}_{kl}$  decreases by one unit. Therefore,

$$c(W_{kl}) = \sum_{(i,j) \in \overline{W}_{kl}} c_{ij} - \sum_{(i,j) \in \underline{W}_{kl}} c_{ij}.$$

Let  $c^\pi(W_{kl})$  denote the change in the reduced costs if we send one unit of flow in the cycle  $W_{kl}$  along its orientation, that is,

$$c^\pi(W_{kl}) = \sum_{(i,j) \in \overline{W}_{kl}} c_{ij}^\pi - \sum_{(i,j) \in \underline{W}_{kl}} c_{ij}^\pi.$$

It is easy to show that  $c^\pi(W_{kl}) = c(W_{kl})$ . This result follows from the fact that when we substitute  $c_{kl}^\pi = c_{kl} - \pi(k) + \pi(l)$  and add the reduced costs around any cycle, then the node potentials  $\pi(i)$  cancel one another. Next notice that the manner we defined node potentials ensures that each arc in the fundamental cycle  $W_{kl}$  except the arc  $(k, l)$  has zero reduced cost. Consequently, if arc  $(k, l) \in L$ , then

$$c(W_{kl}) = c^\pi(W_{kl}) = c_{kl}^\pi,$$

and if arc  $(k, l) \in U$ , then

$$c(W_{kl}) = c^\pi(W_{kl}) = -c_{kl}^\pi.$$

This observation and the negative cycle optimality condition (Theorem 1) implies that for a spanning tree solution to be optimal, it must satisfy the following necessary conditions:

$$c_{kl}^\pi \geq 0 \quad \text{for every arc } (i, j) \in L, \quad (7)$$

$$c_{kl}^\pi \leq 0 \quad \text{for every arc } (i, j) \in U. \quad (8)$$

It is possible to show that these conditions are also sufficient for optimality; that is, if any spanning tree solution satisfies the conditions (7)–(8), then it solves the minimum cost flow problem.

We now have all the necessary ingredients to describe the network simplex algorithm. The algorithm maintains a feasible spanning tree structure at each iteration, which it successively transforms it into an improved spanning tree structure until the solution becomes optimal. The algorithm first obtains an initial spanning tree structure. If an initial spanning tree structure is not easily available, then we could use the following method to construct one: for each node  $i$  with  $b(i) \geq 0$ , we connect node  $i$  to node 1 with an (artificial) arc of sufficiently large cost and large capacity; and for each node  $i$  with  $b(i) < 0$ , we connect node 1 to node  $i$  with an (artificial) arc of sufficiently large cost and capacity. These arcs define the initial tree  $T$ , all arcs in  $A$  define the set  $L$ , and  $U = \emptyset$ . Since these artificial arcs have large costs, subsequent iterations will drive the flow on these arcs to zero.

Given a spanning tree structure  $(T, L, U)$ , we first check whether it satisfies the optimality conditions (7) and (8). If yes, we stop; otherwise, we select an arc  $(k, l) \in L$  or  $(k, l) \in U$  violating its optimality condition as an *entering arc* to be added to the tree  $T$ , obtain the fundamental cycle  $W_{kl}$  induced by this arc, and augment the maximum possible flow in the cycle  $W_{kl}$  without violating the flow bounds of the tree arcs. At this value of augmentation, the flow on some tree arc, say arc  $(p, q)$ , reaches its lower or upper bound; we select this arc as an arc to leave the spanning tree  $T$ , adding it added to  $L$  or  $U$  depending upon its flow value. We next add arc  $(k, l)$  to  $T$ , giving us a new spanning tree structure. We repeat this process until the spanning tree structure

```

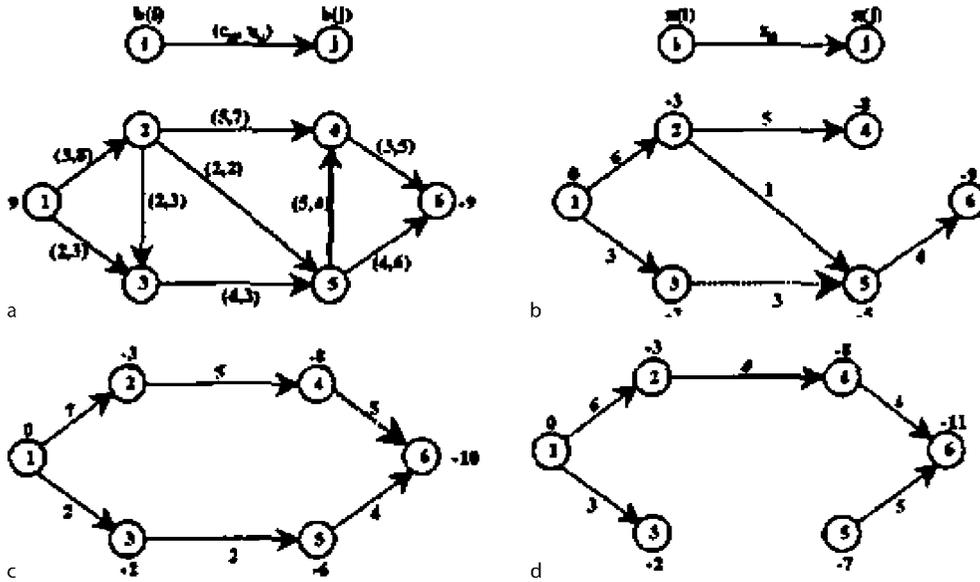

BEGIN
  determine an initial feasible tree structure
   $(T, L, U)$ ;
  let  $x$  be the flow and let  $\pi$  be the corresponding
  node potentials;
  WHILE (some nontree arc violates its opti-
  mality condition) DO
    BEGIN
      select an entering arc  $(k, l)$  violating the opti-
      mality conditions;
      add arc  $(k, l)$  to the spanning tree  $T$ , thus
      forming a unique cycle  $W_{kl}$ ;
      augment the maximum possible flow  $\delta$  in the
      cycle  $W_{kl}$  and
      identify a leaving arc  $(p, q)$  that reaches its
      lower or upper flow bound;
      update the flow  $x$ , the spanning tree struc-
      ture  $(T, L, U)$  and the potentials  $\pi$ ;
    END;
  END

```

#### Minimum Cost Flow Problem, Figure 9 The network simplex algorithm

satisfies the optimality conditions. Figure 9 specifies the essential steps of the algorithm.

To illustrate the network simplex algorithm, we use the numerical example shown in Fig. 10a). Figure 10b) shows a feasible spanning tree solution for the problem. For this solution,  $T = \{(1, 2), (1, 3), (2, 4), (2, 5), (5, 6)\}$ ,  $L = \{(2, 3), (5, 4)\}$  and  $U = \{(3, 5), (4, 6)\}$ . We next compute  $c_{35}^\pi = 1$ . We introduce the arc  $(3, 5)$  into the tree, creating a cycle. Since  $(3, 5)$  is at its upper bound, the orientation of the cycle is opposite to that of  $(3, 5)$ . The arcs  $(1, 2)$  and  $(2, 5)$  are forward arcs in the cycle and arcs  $(3, 5)$  and  $(1, 3)$  are backward arcs. The maximum increase in flow permitted by the arcs  $(3, 5)$ ,  $(1, 3)$ ,  $(1, 2)$ , and  $(2, 5)$  without violating their upper and lower bounds is, respectively, 3, 3, 2, and 1 units. Thus, we augment 1 unit of flow along the cycle. The augmentation increases the flow on arcs  $(1, 2)$  and  $(2, 5)$  by one unit and decreases the flow on arcs  $(1, 3)$  and  $(3, 5)$  by one unit. Arc  $(2, 5)$  reaches its upper bound and we select it as the leaving arc. We update the spanning tree structure; Fig. 10c) shows the new spanning tree  $T$  and the new node potentials. The sets  $L$  and  $U$  become  $L = \{(2, 3), (5, 4)\}$  and  $U = \{(2, 5), (4, 6)\}$ . In the next iter-

Minimum Cost Flow Problem, Figure 10  
 Numerical example for the network simplex algorithm

ation, we select arc (4, 6) since this arc violates the arc optimality condition. We augment one unit flow along the cycle 6 – 4 – 2 – 1 – 3 – 5 – 6 and arc (3, 5) leaves the spanning tree. Figure 10d) shows the next spanning tree and the updated node potentials. All nontree arcs satisfy the optimality conditions and the algorithm terminates with an optimal solution of the minimum cost flow problem.

The network simplex algorithm can select any nontree arc that violates its optimality condition as an entering arc. Many different rules, called pivot rules, are possible for choosing the entering arc, and these rules have different empirical and theoretical behavior. [1] describes some popular pivot rules. We call the process of moving from one spanning tree structure to another as a *pivot operation*. By choosing the right data structures for representing the tree  $T$ , it is possible to perform a pivot operation in  $O(m)$  time.

To determine the number of iterations performed by the network simplex algorithm, we distinguish two cases. We refer to a pivot operation as *nondegenerate* if it augments a positive amount of flow in the cycle  $W_{kl}$  (that is,  $\delta > 0$ ), and *degenerate* otherwise (that is,  $\delta = 0$ ). During a degenerate pivot, the cost of the spanning tree solution decreases by  $|c_{kl}^\pi| \delta$ . When combined with the integrality of data assumption (Assumption 2)

above), this result yields a pseudopolynomial bound on the number of nondegenerate iterations. However, degenerate pivots do not decrease the cost of flow and so are difficult to bound. There are methods to bound the number of degenerate pivots. Obtaining a polynomial bound on the number of iterations remained an open problem for quite some time; [6] suggested an implementation of the network simplex algorithm that runs in polynomial time. In any event, the empirical performance of the network simplex algorithm is very attractive. Empirically, it is one of the fastest known algorithms for solving the minimum cost flow problem.

MINLP; Facility location-allocation

The *location-allocation problem* may be stated in the following general way: Given the location or distribution of a set of customers which could be probabilistic and their associated demands for a given product or service, determine the optimal locations for a number of service facilities and the allocation of their products or services to the costumers, so as to minimize total (expected) location and transportation costs. This problem finds a variety of applications involving the location of warehouses, distribution centers, service and production facilities and emergency service facilities. In the last section we are going to consider the development of an offshore oil field as a real-world application of the location-allocation problem. This problem involves the location of the oil platforms and the allocation of the oil wells to platforms.

It was shown in [25] that the joint location-allocation problem is *NP*-hard even with all the demand points located along a straight line. In the next section alternative location-allocation models will be presented based on different objectives and the incorporation of consumer behavior, price elasticity and system dynamics within the location-allocation decision framework.

## Location-allocation Models

In developing location-allocation models different objectives alternatives are examined. One possibility is to follow the approach in [5], to minimize the number of centers required to serve the population. This objective is appropriate when the demand is exogenously fixed. A more general objective is to maximize demand by optimally locating the centers as proposed in [10]. The demand maximization requires the incorporation of *price elasticity* representing the dependence of the customer preference to the distance from the center. The cost of establishing the centers can also be incorporated in the

model as proposed in [13]. An alternative objective towards the implementation of customer preference towards the nearest center is the minimization of an aggregated weighted distance which is called the *median location-allocation* problem.

The simplest type of location-allocation problem is the *Weber problem*, as posed in [9], which involves locating a production center so as to minimize aggregate weighted distance from the different raw material sources. The extension of the Weber problem is the *p-median location-allocation problem*, which involves the optimal location of a set of *p uncapacitated centers* to minimize the total weighted distance between them and *n* demand locations. Here, each source is assumed to have infinite capacity. In continuous space, the *p*-median problem can be formulated as follows:

$$\left\{ \begin{array}{l} \min \quad C = \sum_{i=1}^n \sum_{j=1}^p O_i \lambda_{ij} c_{ij} \\ \text{s.t.} \quad \sum_{j=1}^p \lambda_{ij} = 1, \quad i = 1, \dots, n, \\ \lambda_{ij} = 0, 1, \quad i = 1, \dots, n, \quad j = 1, \dots, p, \end{array} \right.$$

where  $O_i$  is the quantity demanded at location  $i$  whose coordinates are  $(x_i, y_i)$ ; and  $\lambda_{ij}$  is the binary variables that is assigned the value of 1 if demand point  $i$  is located to center  $j$  and zero otherwise. The above formulation allocate the consumers to their nearest center while ensuring that only one center will serve each customer. This however, can lead to disproportionately sized facilities. In the more realistic situation where the capacities of the facilities are limited to supplies of  $s_1, \dots, s_n$  for  $i = 1, \dots, n$  facilities then the location-allocation problem takes the following form [24]:

$$\left\{ \begin{array}{l} \min \quad C = \sum_{i=1}^n \sum_{j=1}^p w_{ij} c_{ij} \\ \text{s.t.} \quad \sum_{j=1}^p w_{ij} = s_i, \quad i = 1, \dots, n, \\ \sum_{i=1}^n w_{ij} = d_j, \quad j = 1, \dots, p, \\ \lambda_{ij} = 0, 1, \quad i = 1, \dots, n, \quad j = 1, \dots, p, \end{array} \right.$$

where  $w_{ij}$  is the amount shipped from facility  $i$  located at  $(x_i, y_i)$  to destination  $j$ . In the above formulations the distance (or the generalized transport cost, which is assumed to be proportional to distance) between the demand point  $i$  and the supply point  $j$  is represented by  $c_{ij}$ . The Euclidean metric:

$$c_{ij} = \sqrt{(x_i - \alpha_j)^2 + (y_i - \beta_j)^2}$$

or the rectilinear metric:

$$c_{ij} = |x_i - \alpha_j| + |y_i - \beta_j|.$$

The rectilinear metric is appropriate when the transportation is occurring along a grid of city streets (Manhattan norm) or along the aisles of a floor shop [8].

The aforementioned location-allocation models are based on the assumption that the consumers always prefer the nearest center to obtain service. In reality however, as reported in the literature from several empirical studies [11] there exist several services for which consumers choose their service facility center. The travel patterns of the consumers for example can produce a variety of allocations that differ from the nearest center rule. In order to accommodate such behavior a *spatial-interaction model* is incorporated within the uncapacitated *p*-median location-allocation model in the following manner:

$$\left\{ \begin{array}{l} \min \quad \frac{1}{\beta} \sum_j Y_j \sum_i S_{ij} \log(S_{ij} - 1) \\ \quad \quad \quad + \sum_j \sum_i Y_j S_{ij} c_{ij} \\ \text{s.t.} \quad \sum_j Y_j S_{ij} = O_i, \quad i = 1, \dots, n, \\ \sum_j Y_j = p \\ S_{ij} \leq Y_j, \quad i = 1, \dots, n, \quad j = 1, \dots, p, \\ Y_j = 0, 1, \quad j = 1, \dots, p, \end{array} \right.$$

where the decision variables include  $Y_j$  which takes the value of one if the facility is located at  $J$  models. and zero otherwise;

$$S_{ij} = A_i O_i Y_j \exp(-\beta c_{ij})$$

that defines the interaction of facility  $i$  and consumer  $j$ .

$$A_i = \frac{1}{\sum_l Y_l \exp(-\beta c_{il})}, \quad i = 1, \dots, m,$$

that ensures that the sum of all outflows from the origin  $i$  add up to the amount of demand at that location;  $\beta$  is either calibrated to match some known interaction data or is defined exogenously. The following relationship holds between the original  $p$ -median model and the spatial-interaction model as shown in [17]. The value of the optimal objective function at the solution of the  $p$ -median problem is given by:

$$\sum_i \sum_j O_i X_{ij} c_{ij},$$

where  $X_{ij}$  allocates demand to the nearest of  $p$  available centers. Turning to spatial-interaction model, as the impedance parameter  $\beta$  increases the term:

$$\frac{Y_j \exp(-\beta c_{ij})}{\sum_l Y_l \exp(-\beta c_{il})}$$

of the  $S_{ij}$  tends to  $X_{ij}$ , where  $X_{ij} = 1$  if the travel time from  $i$  to  $j$  is smaller than the travel time from  $i$  to any other facility and zero otherwise. Therefore, the  $S_{ij}$  tends to  $O_i X_{ij}$  and this model allocates the demand to the nearest facility as the original  $p$ -median problem.

All the models mentioned above consider the static location-allocation problem where all the activities take place at one instance. These formulations are sufficient if neither the level nor the location of demand alters over time. An important factor however, in any location-allocation problem is the dynamics of the system involving demand changes over time. Particularly, in the competitive environment, an optimal center location could become undesirable as new competing centers develop. Potential directions include the literature on *decision making under uncertainty*, [12]. A.J. Scott [18] proposed a general framework for the integration of the spatial and discrete temporal dimensions in the location-allocation models. He proposed a modification of the location-allocation so as to minimize an aggregate weighted transport cost over  $T$  time periods, during which time the number  $n_t$ , level  $O_{it}$  and the location  $(x_{it}, y_{it})$  of the demand points change. If the lo-

cations were greatly different the center would be likely to relocate at some time and costs of relocation are included in the model. It was assumed that when a center relocates it incurs a fixed cost,  $\alpha$ . Based on these ideas the formulation proposed for the uncapacitated location-allocation problem has the following form:

$$\left\{ \begin{array}{l} \min \quad \alpha_1 + \sum_{i=1}^{n_1} O_{i1} c_{ij1} \\ \quad + \sum_{t=2}^T \left( \alpha \lambda_t + \sum_{i=1}^{n_t} O_{it} c_{ijt} \right) \\ \text{s.t.} \quad \lambda_t = 0, 1, \quad t = 2, \dots, T, \end{array} \right.$$

where the subscript  $t$  refers to different time periods,  $\alpha_1$  is the cost of establishing the center in the first time period. The problem as formulated above is to locate in the first period one center that takes into account future variations. Extending the aspects of this model allows the replacement of a truly dynamic model by a series of static problems as proposed in [3], thus outlining a multilayer approach, where the objective is to sequentially locate each period's facility given the previous period's facility locations in order to minimize the present period cost. This strategy is appropriate whenever the period durations are sufficiently long or under uncertainty regarding future data or decisions. An alternative approach proposed in [24] is a discounted present worth strategy which is appropriate whenever the foregoing conditions do not hold. In this case the facilities are being located one per period and the decisions are made in a rolling horizon framework.

## Solution Approaches

For the uncapacitated location-allocation problem using Euclidean metric for the distances between each facility and the different demand points, R.F. Love and H. Juel [15] showed that this problem is equivalent to a concave minimization problem for which they used several heuristic procedures. For the capacitated problems assuming that the costs are proportional to  $l_p^q$  using  $l_p$  distances where  $p \geq 1$  and  $q \geq 1$  are integers, M. Avriel [1] developed a geometric programming approach. H.D. Sherali and C.M. Shetty [22] proposed a polar cutting plane algorithm for the case  $p = q = 1$ . For the case  $p = q = 2$ , Sherali and C.H. Tunc-

bilek [23] proposed a branch and bound algorithm (cf. ► **MINLP: Branch and bound methods**; ► **MINLP: Branch and bound global optimization algorithm**) that utilizes a specialized tight, linear programming representation to calculate strong upper bounds via a Lagrangian relaxation scheme. They exploit the special structure of the transportation constraints to derive a partitioning scheme. Additional cut-set inequalities are also incorporated to preserve partial solution.

For the uncapacitated location-allocation model using rectilinear distance metric Love and J.G. Morris [16] have developed an exact two-stage algorithm. R.E. Kuenne and R.M. Soland [14], have developed a branch and bound algorithm based on a constructive assignment of customers to sources. The capacitated problem has been addressed in [19,21] and utilize the discrete equivalence of the capacitated location-allocation problem. In particular, [8], and [26] showed that

- a) the optimal values of  $x_i$  and  $y_i$  for each  $i$  must satisfy  $x_i = \alpha_j$  for some  $j$  and  $y_i = \beta_j$  for some  $j$ , which means that the rectilinear distance location problem always has an optimal solution with the sources located at the grid points of the vertical and horizontal lines drawn through the existing customer locations; and
- b) the optimal source locations lie in the convex hull of the existing facility locations.

Based on these ideas and by denoting  $k = 1, \dots, K$  the intersection grid points that also belong to the convex hull of the existing facility locations, [21], introduced the decision binary variables  $z_{ik}$  that take the value of 1 if source  $i$  is located at point  $k$  and zero otherwise. This leads to the following discrete location-allocation problem:

$$\left\{ \begin{array}{l} \min \quad \sum_{i=1}^n \sum_{j=1}^p \sum_{k=1}^K c_{ijk} w_{ij} z_{ik} \\ \text{s.t.} \quad \sum_{k=1}^K z_{ik} = 1, \quad i = 1, \dots, n, \\ \sum_{j=1}^p w_{ij} = s_i, \quad i = 1, \dots, n, \\ \sum_{i=1}^n w_{ij} = d_j, \quad j = 1, \dots, p, \\ w_{ij} \geq 0, \quad i = 1, \dots, n, \quad j = 1, \dots, p, \\ z_{ik} = 0, 1, \quad i = 1, \dots, n, \end{array} \right.$$

where  $c_{ijk} = c_{ij} [|\alpha_k - \alpha_j| + |\beta_k - \beta_j|]$ . The above model corresponds to a mixed integer bilinear programming problem. See [19] for a related version of this discrete-site location-allocation problem involving one-to-one assignment restriction and fixed charges. See [20] for the solution of the problem as a bilinear programming problem, since the binary variables  $z$  can be treated as positive variables because of the problem structure that preserves the binariness of  $z$  at optimality. However, in [21] it is proved that it is more useful to exploit the binary nature of  $z$  variables for the efficient solution of the above model. Before giving more details of this proposed branch and bound based approach we should mention the heuristic approach proposed in [4], which is very widely used. This so-called *alternating procedure* exploited the fundamental concepts of the location-allocation problem and simply involves allocating demand to centers and relocating centers until some convergence criterion is achieved. For the uncapacitated  $p$ -median problem, the alternating procedure involves iterating through the following equations:

$$x_j = \frac{\sum_{i=1}^n \frac{O_i \lambda_{ij} x_i}{c_{ij}}}{\sum_{i=1}^n \frac{O_i \lambda_{ij}}{c_{ij}}},$$

$$y_j = \frac{\sum_{i=1}^n \frac{O_i \lambda_{ij} y_i}{c_{ij}}}{\sum_{i=1}^n \frac{O_i \lambda_{ij}}{c_{ij}}},$$

which are derived from differentiating the objective function with respect to  $x_j$  and  $y_j$  and setting the partial derivatives to zero. The major drawback of this procedure is that it does not guarantee global optimality. This is in fact a concern because the spatial configuration of the local and the global optimum may be very different. As a rule, repeated runs using numerous starting values should be undertaken, although there is no guarantee that the repeatedly found solution would be the global optimum. Note however that the procedure is general to all different models of the location-allocation problem.

Returning to the approach proposed in [21] for the case of rectilinear capacitated location-allocation problem, the following linear reformulation of the problem

is used:

$$\left\{ \begin{array}{l} \min \quad \sum_{i=1}^n \sum_{j=1}^p \sum_{k=1}^K c_{ijk} X_{ijk} \\ \text{s.t.} \quad \sum_{k=1}^K X_{ijk} - w_{ij} = 0, \quad \forall(i, j), \\ \sum_{j=1}^p X_{ijk} - s_i z_{ik} = 0, \quad \forall(i, k), \\ -X_{ijk} + u_{ij} z_{ik} \geq 0, \quad \forall(i, j), \\ \sum_{k=1}^K z_{ik} = 1, \quad \forall i, \\ \sum_{j=1}^p w_{ij} = s_i, \quad \forall i, \\ \sum_{i=1}^n w_{ij} = d_j, \quad \forall j, \\ w_{ij} \geq 0, \quad \forall(i, j), \\ z_{ik} = 0, 1, \quad \forall i, \\ X_{ijk} \geq 0, \quad \forall(i, j, k), \end{array} \right.$$

where  $u_{ij} = \min\{s_i, d_j\}$ . The above model corresponds to a mixed integer linear programming problem for which a special branch and bound algorithm is applied based on the derivation of tight lower bounds via a suitable Lagrangian dual formulation.

Briefly, for the location-allocation problems that have embedded spatial-interaction equations dual-based exact methods, [17], and heuristic approaches, [2], have been developed.

### Application: Development of Offshore Oil Fields

In this section a real world application of the location-allocation problem is presented considering the minimum-cost development of offshore oil fields, [6]. The facilities to be located are the platforms and the demands to be allocated are the oil wells. For the initial information about an oil field, locations are decided upon the production wells which are specified by two map coordinates and a depth coordinate. The drilling is performed directionally from fixed platforms. The cost of drilling depends on the length and angle of the well from the platform. The platform cost depends on the water depth and on the number of wells to be drilled from the platform. Consequently for a large number of wells (25 to 300) an optimization problem that arises is

to find the number, size and location of the platforms and the allocation of wells to platforms so as to minimize the sum of platform and drilling costs.

In order to formulate this problem the following indices, parameters and variables are introduced. Let  $m$  denote the number of wells and  $i$  the index of well,  $n$  the number of platforms and  $j$  the index for platform,  $z_{ij}$  are then the binary variables that represent the allocation of the well  $i$  to platform  $j$  if it takes the value of 1, otherwise it becomes 0,  $S_j$  the capacity of the platform  $j$  representing the number of wells drilled from this platform,  $(a_i, b_i)$  denote the location coordinates of well  $i$  and  $(x_j, y_j)$  the location of platform  $j$ ,  $d_{ij} = \sqrt{[(x_j - a_i)^2 + (y_j - b_i)^2]}$  is the horizontal Euclidean distance between well  $i$  and platform  $j$ ,  $g(d_{ij})$  denotes the drilling cost function that depends on distance  $d_{ij}$ ,  $P(S_j, x_j, y_j)$  is the platform cost which is a function of platform size  $S_j$  and its location. Based on this notation the location-allocation problem can be formulated as follows:

$$\left\{ \begin{array}{l} \min \quad \sum_{i=1}^m \sum_{j=1}^n z_{ij} g(d_{ij}) + \sum_{j=1}^n P(S_j, x_j, y_j) \\ \text{s.t.} \quad \sum_{j=1}^n z_{ij} = 1, \quad \forall(i), \\ \sum_{i=1}^m z_{ij} = S_j, \quad \forall j, \\ z_{ij} = 0, 1, \quad \forall(i, j), \end{array} \right.$$

where the first set of constraints guarantee that each well is assigned to exactly one platform and the second set guarantee that exactly  $S_j$  wells are assigned to each platform. Note that  $n$  is fixed in the problem and is usually small in the size of 3 to 5. The nature of the problem depends upon the form of the cost of the drilling function and the platform cost function. The approach taken in [6] is the alternating location-allocation method presented in the previous section. For the specific problem the approach involves the following steps:

- given fixed platform locations find a minimum cost allocation of wells to platforms;
- given fixed allocation of wells to platforms find the minimum total cost location for each platform.

The procedure alternates between steps a) and b) until convergence is achieved. The convergence criterion is the following: From the solution of step a) a set of

n subproblems are generated for each one of the platforms, the solution of these problems result in the re-location of the platforms. The iterations continue until no changes are possible. As mentioned above, the solution obtained from this algorithmic procedure is locally optimum in the sense that for a given assignment of wells to platforms the solution cannot be improved by changing locations and for given locations, the solution cannot be improved by altering the assignment of wells to platforms. The mathematical formulation of problem a), the *allocation subproblem* is the following:

$$\left\{ \begin{array}{l} \min \sum_{i=1}^m \sum_{j=1}^n z_{ij} g(d_{ij}) + \sum_{j=1}^n P(S_j) \\ \text{s.t.} \sum_{j=1}^n z_{ij} = 1, \quad \forall(i), \\ \sum_{i=1}^m z_{ij} = S_j, \quad \forall j, \\ z_{ij} = 0, 1, \quad \forall(i, j), \end{array} \right.$$

note that the platform cost now depends only on  $S_j$  since the location of the platforms are known. The solution procedure for this problem depends on the form of the platform cost  $P(S_j)$ . Five different forms are discussed in [6]:

- 1) *Single fixed cost with no capacity constraints:*  $P(S_j) = a_j$  In this case the total cost for platforms is fixed and the optimal allocation corresponds to the assignment of the wells to the closest platform.
- 2) *Single fixed cost with capacity constraints:*  $P(S_j) = a_j$  and capacity constraints are introduced as inequalities  $\sum_{i=1}^m z_{ij} \leq S_j, \forall j$ . In this case the problem corresponds to a linear programming model.
- 3) *Linear platform cost:*  $P(S_j) = a_j + b_j S_j$  By considering the following transformation  $c_{ij}' = c_{ij} + b_j$  the problem takes the form of case 1).
- 4) *Piecewise linear function.* In this case the problem has the structure of 'transshipment problem' which can be solved network flow techniques.
- 5) *Step function:*  $P(S_j) = \sum_{k=1}^{K_j} r_j^k z_{ij}^k$ , where  $K_j$  are the number of different size platforms available and  $r_j^k$  is the cost of  $k$ th size of platform  $j$ . The problem in this case is a mixed integer linear programming problem.

The mathematical formulation for problem b), the location problem, is the following. Assuming that  $A_j$  is

the set of indices for the wells assigned to platform  $j$ , then  $z_{ij} = 1$ , for  $i \in A_j$ ,  $z_{ij} = 0$  otherwise and the problem for platform  $j$  takes the form:

$$\min \sum_{i=1}^m \sum_{i \in A_j} g(d_{ij}) + P(x_j, y_j).$$

Note that the platform cost is a function of platform location only since the size is assumed known. Since the drilling cost function is convex, if the platform cost is also convex then the problem corresponds to the minimization of a convex function that can be achieved through a local minimization algorithm. Of course if the platform cost is nonconvex then global optimality cannot be guaranteed and global optimization techniques should be considered, [7].

Finally, M.D. Devine and W.G. Lesso, [6], applied the aforementioned procedure to two test problems one involving 60 wells and 7 platforms and a second one involving 102 wells and 3 platforms. In both cases they reported large economic savings in the field development.

Pooling and blending is inherent in many manufacturing plants with limited tankage available to store the intermediate streams produced by various processes. Also, chemical products often need to be transported as a mixture, either in a pipeline, a tank car or a tanker. In each case, blended or pooled streams are then used in further downstream processing. In modeling these processes, it is necessary to model not only product

**MINLP: Applications in Blending and Pooling Problems, Figure 1**  
 General pooling and blending problem

flows but the properties of intermediate streams as well. The presence of these pools can introduce nonlinearities and nonconvexities in the model of the process, resulting in difficult problems with multiple local optima.

Given a set of components  $i$ , a set of products  $j$ , a set of pools  $k$  and a set of qualities  $l$ , let  $x_{il}$  be the amount of component  $i$  allocated to pool  $l$ ,  $y_{lj}$  be the amount going from pool  $l$  to product  $j$ ,  $z_{ij}$  be the amount of component  $i$  going directly to product  $j$  and  $p_{lk}$  be the level of quality  $k$  in pool  $l$ . Furthermore, let  $A_i$ ,  $D_j$  and  $S_l$  be upper bounds for component availabilities, product demands and pool sizes respectively, let  $C_{ik}$  be the level of quality  $k$  in component  $i$ ,  $P_{jk}$  be upper bounds on product qualities,  $c_i$  be the unit price of component  $i$  and  $d_j$  be the unit price of product  $j$ . The general pooling and blending model can then be written as [1]:

$$\left\{ \begin{array}{l} \max \quad - \sum_{i,l} c_i x_{il} + \sum_{l,j} d_j y_{lj} + \sum_{i,j} (d_j - c_i) z_{ij} \\ \text{s.t.} \quad \sum_l x_{il} + \sum_j z_{ij} \leq A_i \\ \sum_l y_{lj} + \sum_i z_{ij} \leq D_j \\ \sum_i x_{il} - \sum_j y_{lj} = 0 \\ \sum_i x_{il} \leq S_l \\ - \sum_i C_{ik} x_{il} + p_{lk} \sum_j y_{lj} = 0 \\ \sum_l (p_{lk} - P_{jk}) y_{lj} \\ \quad + \sum_i (C_{ij} - P_{jk}) z_{ij} \leq 0 \\ x_{il}, y_{lj}, z_{ij}, p_{lk} \geq 0. \end{array} \right.$$

The first two sets of constraints ensure that the amount of components used and products made do not exceed the respective availabilities or demands. The third and fourth set of constraints are material balance constraints around each pool, which ensure that there is no accumulation or overflow of material in the pools. The fifth set of constraints relates the quality of each pool to the quality of the components going into the pool (in this case, the qualities are assumed to blend linearly, that is, the pool quality is an average of the qualities of the components). Finally, the sixth set of equations ensures that any upper bound specifications on product qualities are met. These last two sets of equations are

bilinear, and can cause significant problems in solving these models.

The general blending problem has a similar formulation as above, except that the pools need not be present; the components can be blended directly to make various products. It should also be noted that there are various other formulations possible, involving multiple time periods, tanks and inventories for components and products, and costs for pooling. Moreover, not all the components need go through all pools. One example of a simplified pooling model, due to C.A. Haverly [8,9], is given in Fig. 2, where three components with varying sulfur contents are to be blended to form two products. There is a maximum sulfur restriction on each product. The components have values of 6, 13 and 10, respectively, while the products have values of 9 and 15, respectively. The mathematical model for the problem consists of writing mass and sulfur balances for the various streams, and can be formulated as

$$\left\{ \begin{array}{l} \max \quad 9 \cdot (y_{11} + z_{31}) + 15 \cdot (y_{12} + z_{32}) \\ \quad \quad -6x_{11} - 13x_{21} - 10 \cdot (z_{31} + z_{32}) \\ \text{s.t.} \quad x_{11} + x_{21} - y_{11} - y_{12} = 0 \\ \quad \quad p \cdot y_{11} + 2z_{31} - 2.5(y_{11} + z_{31}) \leq 0 \\ \quad \quad p \cdot y_{12} + 2z_{32} - 1.5(y_{12} + z_{32}) \leq 0 \\ \quad \quad p \cdot (y_{11} + y_{12}) - 3x_{11} - x_{21} = 0 \\ \quad \quad y_{11} + z_{31} \leq 100 \\ \quad \quad y_{12} + z_{32} \leq 200. \end{array} \right.$$

The variable  $p$  represents the sulfur content of the pool (and of  $y_{11}$  and  $y_{12}$ ) and is determined as an average of the sulfur contents of  $x_{11}$  and  $x_{21}$ .

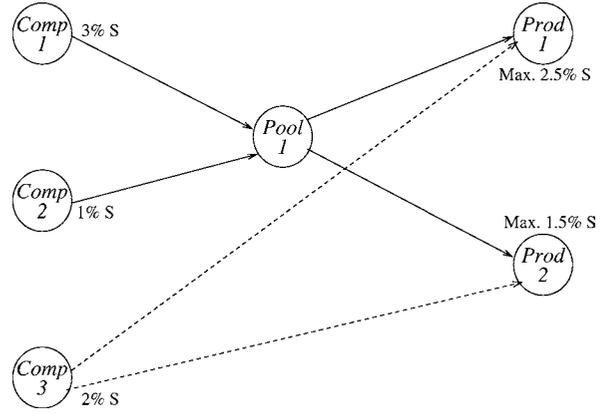

**Characteristics of Pooling and Blending Problems**

**Multiple Solutions**

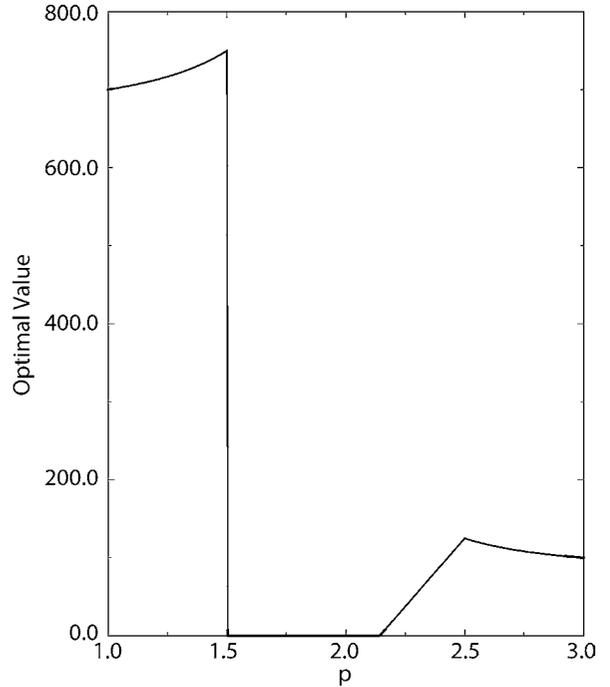

The presence of nonconvex constraints needed to define pool and product qualities often results in multiple local solutions in these models. For example, consider the optimal solution of the Haverly pooling problem as a function of the pool quality  $p$ , as shown in Fig. 3.

It can be seen that the problem has three solutions:

- 1) A local maximum of 125 at  $p = 2.5$  with  $x_{11} = 75, x_{21} = 25, y_{11} = 100$  and all other variables zero;
- 2) a saddle point region with  $1 < p < 2$ , all flows zero and profit of zero; and

**MINLP: Applications in Blending and Pooling Problems, Figure 2**  
Haverly pooling problem

**MINLP: Applications in Blending and Pooling Problems, Figure 3**  
Optimal solution to Haverly pooling problem

- 3) a global maximum of 750 at  $p = 1.5$  with  $x_{11} = 50, x_{21} = 150, y_{12} = 200$  and all other variables zero.

It is not uncommon for a large pooling problem to have many dozen local optima, with the objective function varying by small amounts but with all the flow and quality variables taking on vastly different values.

## Nonlinear Blending

For the sake of simplicity, it is often assumed in formulating these models that the qualities to be tracked blend linearly by volume or weight of each component. In practice, however, this is rarely the case. For example, one of the properties commonly tracked in refinery blends is the *Reid vapor pressure* (RVP), which measures the volatility of a blend. The most commonly used blending rule for RVP is the *Chevron method*:

$$\left( \sum_i x_i \right) R^{1.25} = \sum_i x_i r_i^{1.25},$$

where  $r_i$  is the RVP of component  $i$ ,  $x_i$  is its volume, and  $R$  is the RVP of the blend. Including such a nonlinear equation in the model can cause difficulty in its solution. Fortunately, this can be avoided by introducing a *blending index*, defined as

$$\bar{r}_i = r_i^{1.25}, \quad \bar{R} = R^{1.25}.$$

Then, all specifications on the blend RVP can be converted using the same index. For example, if there is a lower bound  $R^L$  on the blend RVP, then using the blending index results in the constraints as:

$$\left( \sum_i x_i \right) \bar{R} = \sum_i x_i \bar{r}_i, \quad \bar{R} \geq (R^L)^{1.25}.$$

In some cases, the properties (such as octane number or pour point) can require complex blending rules which cannot be simplified using the blending index, and the full nonlinear blending equation must be included in the model as is.

### Single versus Multiperiod Models

Since components are pooled or blended in the plants on a regular basis, it is often advantageous to model these processes using multiple periods. With *multiperiod models*, it is possible to accumulate material in the pools or blend tanks, thereby facilitating the allocation of stocks ahead of time in anticipation of a future lifting of a valuable product. This requires the model to incorporate inventories (carry-over stock) in each tank or pool, resulting in more complex models. It is important to note that each period does not need to be of the same duration. Often, the results of the multiperiod models will only be implemented for the first

period, with results for future periods being used for planning purposes. Therefore, initial periods are typically of shorter duration (say a day each) while later periods might be as long as a month. This way, the same multiperiod model can be used as an operating tool for the present and a planning tool for the future.

Another important consideration in multiperiod models is the disposition of stocks at the end of the final period. If the final inventories/stocks are included simply as variables, the optimal solution will almost always set them to zero. In practice, however, this is unrealistic since it is not desired to run down stocks. This can be dealt with in several ways:

- set the final inventory levels to reasonable values (say the same as inventory levels at the beginning of the first period);
- assign a value to final inventory; this way the model can decide if it is worthwhile to produce stock to sell at the end of the final period.

### Logical Constraints and MINLP Formulations

It is often necessary to impose additional logical constraints that dictate how various components are to be blended in relation to each other. Modeling such constraints often requires the addition of integer variables, as discussed below.

- If a component is to be used in a particular blend, then it must be present in at least a certain amount in the blend. This arises from the fact that it is usually not practical to blend in infinitesimally small quantities.

If  $x$  represents the volume of such a component, then introducing a new binary variable  $\delta$  (i. e.  $\delta$  is either 0 or 1) and the constraints

$$\begin{aligned} x - M\delta &\leq 0, \\ x - m\delta &\geq 0 \end{aligned}$$

are sufficient to ensure this condition is satisfied. Here,  $M$  is a sufficiently large number, while  $m$  represents the threshold value below which a component should not be blended in.

- Each product can have at most  $k$  components in its blend. This is typically imposed by limitations on how many streams can be physically blended in a reasonable amount of time. Again, introducing the

new variables and constraints as below:

$$\begin{aligned}x_1 - m\delta_1 &\geq 0, \\ \dots \\ x_n - m\delta_n &\geq 0, \\ \delta_1 + \dots + \delta_n &\leq k, \\ \delta_1, \dots, \delta_n &\in \{0 - 1\}^n,\end{aligned}$$

ensures this condition is met.

- c) If component *A* is to be present in the blend, then component *B* must also be present:

$$\begin{aligned}x_A - m\delta_A &\geq 0, \\ x_B - m\delta_B &\geq 0, \\ \delta_B &\geq \delta_A.\end{aligned}$$

Each of these logical constraints results in a mixed integer nonlinear programming (MINLP) model (cf. also ► **Mixed integer nonlinear programming**). To date (2000), such models have not been used extensively in the practical solution of these problems in industry.

### Complexity of Models

With the various options of single versus multiperiod and linear versus nonlinear blending, the models for pooling and blending can vary significantly in complexity. This is shown pictorially in Fig. 4.

### Solution Methods

Pooling problems can be solved using a variety of solution algorithms. These can be broadly classified as local and global solution methods.

#### Local Optimization Approaches

Traditionally, pooling and blending problems have been solved using various recursion and successive linear programming (SLP) techniques. The first published approach for solving the pooling problem was due to Haverly [8], who proposed the following recursion approach for solving the problem given in Fig. 2:

- 1 Start with a guess for the pool quality  $p$ .
- 2 Solve the remaining linear problem for all other variables.
- 3 Calculate a new value for  $p$  from the solution in 2).

Unfortunately, this rather simple recursion will converge to a suboptimal solution regardless of the starting value for  $p$ . This can be partially addressed by using a ‘distributed recursion’ approach, where an additional recursion coefficient  $f$  and two additional ‘correction vectors’ are introduced, modifying the inequalities in the model as follows:

$$\begin{aligned}p \cdot y_{11} + 2z_{31} - 2.5(y_{11} + z_{31}) \\ + f(\text{over} - \text{under}) &\leq 0, \\ p \cdot y_{12} + 2z_{32} - 1.5(y_{12} + z_{32}) \\ + (1 - f)(\text{over} - \text{under}) &\leq 0.\end{aligned}$$

This formulation serves to distribute the error made in estimating the pool quality to the two pool destinations. Recursing on both  $p$  and  $f$  has a better likelihood of identifying the optimal solution.

*SLP algorithms* solve nonlinear models through a sequence of linear programs (LPs), each of which is a linearized version of the model around some base point. These methods consist of replacing nonlinear constraints of the form

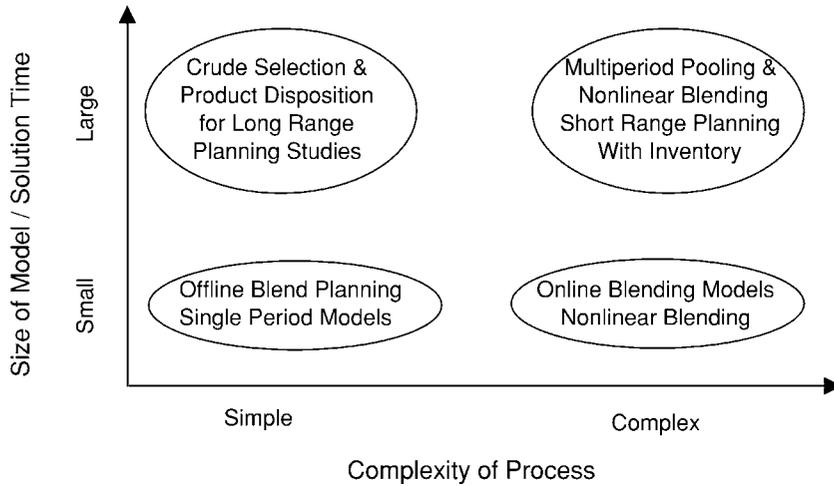

$$g(x) \leq 0, \quad h(x) = 0,$$

with the linearizations

$$\begin{aligned}g(\bar{x}^k) + \nabla g(\bar{x}^k) \cdot (x - \bar{x}^k) &\leq 0, \\ h(\bar{x}^k) + \nabla h(\bar{x}^k) \cdot (x - \bar{x}^k) &= 0\end{aligned}$$

around a base point  $\bar{x}^k$  at the  $k$ th iteration. The linearized problems can be solved using standard LP methods. The solution to the problem is used to provide a value for  $\bar{x}^{k+1}$ . As long as there is an improvement in the objective function value as well as the feasibility of the original constraints, these methods can be shown to converge to a local optimum. They work well for largely linear problems and have therefore found widespread use in the refining industry for solving pooling, blending and general refinery planning problems [4,11]. However, when there are nonlinear blending constraints, the linearization in the SLP is often a bad approximation of the original problem, leading to poor convergence rates and large solution times.

Pooling and blending problems can also be solved using other nonlinear programming (NLP) methods such as generalized reduced gradient, successive quadratic programming or penalty function methods.

**MINLP: Applications in Blending and Pooling Problems, Figure 4**  
Types of pooling problems

In general, these methods have not found large acceptance in solving these problems, mainly due to difficulties with convergence and stability.

**Global Optimization Approaches**

The recursive, SLP and conventional NLP techniques all suffer from the drawback that the solution found is highly dependent on the starting point, and in general cannot guarantee convergence to the global solution. In the last dozen years, numerous approaches have been proposed for the solution of quadratically constrained optimization problems (such as the pooling/blending problem). Surveys of these algorithms can be found in [10,12]. These approaches can generally be classified as either decomposition-based or branch and bound algorithms.

One of the common approaches to dealing with the nonconvexities in the pooling problem is to reduce the bilinear terms to linear terms over a convex envelope [2]. Noting that for any bilinear term  $p \cdot y$ ,

$$\begin{aligned} (p - p^L) \cdot (y - y^L) &\geq 0, \\ (p - p^U) \cdot (y - y^U) &\geq 0, \\ (p - p^L) \cdot (y - y^U) &\leq 0, \\ (p - p^U) \cdot (y - y^L) &\leq 0, \end{aligned}$$

where  $[p^L, p^U]$  and  $[y^L, y^U]$  define the ranges for the variables  $p$  and  $y$ . This allows the term  $p \cdot y$  to be replaced by a set of linear inequalities in the model, re-

sulting in a linearized problem which provides an upper bound on the global solution to the original problem. After solving this problem, the rectangle defined by the bounds on  $p$  and  $y$  can be subdivided into smaller rectangles, and a new linearized problem can be solved over each of these subrectangles. By continuously subdividing these rectangles, the upper bound can be made to asymptotically approach the global solution. See [7] for the solution of several pooling problems using this approach.

Note that the pooling problem is a partially linear problem. That is, it can be formulated as

$$\begin{cases} \min_{x,p} & c^T x \\ \text{s.t.} & A(p)x \leq b, \end{cases} \tag{1}$$

where  $p$  represents the pool quality and  $x$  represents all component flow rates. For such problems, decomposition approaches provide a natural solution mechanism. For a fixed value of  $p$ , this problem is linear, and provides an upper bound on the global solution. The solution to this linear problem (called the ‘primal’ problem) can be used to generate a *Lagrange function* of the form

$$L(x, p) = c^T x + \lambda \cdot (A(p)x - b)$$

where  $\lambda$  represents the multipliers or marginal values for the constraints from the primal problem. Then, the

‘dual’ problem

$$\begin{cases} \min_{x,p,\mu} & \mu \\ \text{s.t.} & \mu \geq L(x,p) \end{cases} \quad (2)$$

provides an upper bound on the global solution. Problem (2) contains bilinear terms of the form  $A(p)x$ , which can be underestimated in a variety of ways. C.A. Floudas and V. Visweswaran [5,6] have developed the GOP algorithm based on this approach. By alternating between the primal problem and a series of relaxed dual problems (developed by successively partitioning the feasible region), the GOP algorithm guarantees convergence to the global solution. In [13,14], they show that it is possible to develop properties that reduce the number of relaxed dual problems that need to be solved, thus speeding up the overall algorithm. They also report the solution of numerous pooling and blending problems using this approach.

Instead of fixing  $p$  for the primal problem, it is possible to solve (1) directly using local optimization techniques. For example, nonsmooth optimization techniques can be effective in finding local solutions to these problems [1]. The dual problem can also be solved this way, with the region for  $p$  being refined by partitioning. See [1] for the solution of several pooling problems using this approach.

It is important to note that these global optimization approaches (and others) for solving the pooling problem can be computationally intensive. Invariably, a large number of subproblems need to be solved before convergence to a global solution can be guaranteed. Because the subproblems are usually of the same structure, varying only slightly in the data for the problems, they can be solved in parallel. See [3] for an implementation of a distributed parallel version of the GOP algorithm and a successful application to solve pooling problems of medium size.

## Applications

The most common application of pooling and blending models is in the *refining* and *petrochemical industries*. Crude oil from various sources is often brought into the refinery and stored in common tanks before being processed downstream. Similarly, intermediate streams from various refinery processes (alkylation, reforming,

cracking) are usually sent to common pools from which finished products such as gasoline and diesel oil are made. In both cases, it is important to know various qualities of the stream coming out of the pool (such as chemical compositions like sulfur or physical properties such as vapor pressure).

In addition to refinery processes, blending is a feature of various other manufacturing processes. These include

- *agriculture*, where blending livestock feeds or fertilizers at minimum cost is very important;
- *mining*, where different ores are often mixed to achieve a desired quality;
- various aspects of *food manufacturing*; and
- *pulp and paper*, involving blending of raw materials used to produce paper.

Mixed integer nonlinear optimization; Parametric optimal control; Interaction of design and control

In the development of a process, the steady state design aspects and dynamic operability issues are usually handled sequentially. First, the design engineers develop and synthesize the structure of the flowsheet and determine the operating parameters and steady-state operating conditions. Then, the control engineer takes the fixed design and develops a control system to maintain the system at the desired specifications. During the first step, the dynamic operation of the process is generally not considered, and in the second step, changes to the flowsheet and operating conditions generally can not be made.

*Process design* seeks to determine the arrangement of processing units that will convert the given raw materials into the desired products. The idea is to develop a process flowsheet from the large number of possible design alternatives. Numerous process design methods and techniques exist for determining the best process flowsheet and operating conditions. This best design is determined by optimizing some economic criteria and the quality of the design is based on its economic value. Hence, the process is designed to operate at steady state and issues relating to the *process dynamics*, *operability*, and *controllability* are usually not considered.

Once the process has been designed, the plans are handed over to the *process control* engineer whose task is to ensure the stable dynamic performance of the process. The control engineer is concerned with developing a control system which maintains the operation of the process at the desired steady state in the presence ever-changing external influences. Issues such as disturbances, uncertainty, and changes in production rates must be addressed so as to maintain product quality and safe operation. By addressing the design and control sequentially, the inherent connection between the two is neglected. For instance, the steady-state design of

a process may appear to produce great economic profits. However, unfavorable dynamic operation may lead to a product which does not meet the required specifications. This may result in an economic loss due to disposal or reworking costs. Thus, a process design with good controllability aspects may have better economic value than an economically optimal steady state design when the dynamic operation is considered. This trade-off between the steady state design and the dynamic controllability motivates the treatment of the issues simultaneously.

There are additional incentives for employing a simultaneous approach. Due to economic and environmental reasons, the recent trend in process design has been towards more highly integrated process in terms of both material and energy flows. Processes are also required to operate under much tighter operating conditions due to environmental and safety issues. Both of these lead to designs with increased dynamic interactions and processes which are generally more difficult to control. Thus, the dynamic operation of the process must be considered at the early stages of the design.

A systematic method for analyzing the *interaction of design and control* requires quantitative *controllability measures* of the process. Such measures have been derived to quantify certain qualitative concepts about the controllability of the process such as inversion, interaction effects, and directionality problems. A common measure for controllability is the integral squared error (ISE) between outputs and their desired levels. Although it is easy to measure, it is not of direct interest in practice. Other performance criteria such as maximum deviation of output variables, maximum magnitude of control variables, or time to return to steady state can also be used.

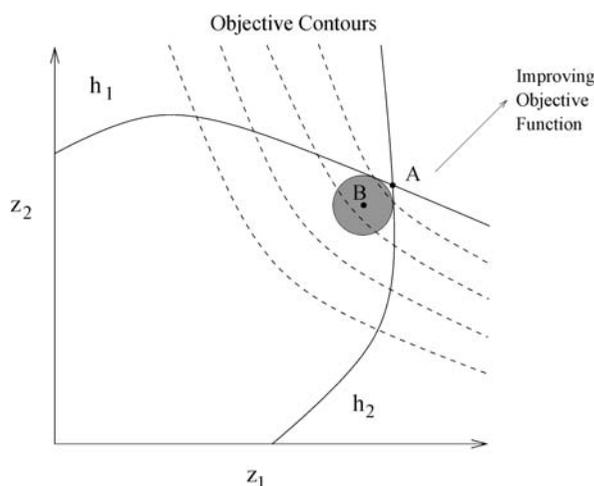

Most of the work in the development of controllability measures has focused on linear dynamic models. The control objective is the robust performance of the process without any restrictions on the controller structure [15]. One such measure is the structured singular value,  $\sigma$ , which indicates the performance in the presence of uncertainty. The condition number,  $\gamma$ , has been developed as an indicator of closed-loop sensitivity to model error while the disturbance conditions number,  $\gamma_d$ , indicates the sensitivity of the process to disturbances. The relative gain array (RGA),  $\Lambda$ , is used as an indicator of the relationship between control error

and set point changes while the closed-loop disturbance gain (CLDG) is used to measure the relation between control error and disturbances. These measures have been used extensively in applications for controllability assessment; however, they can be misleading. While these indicators give ideas as to the closed loop performance of the process, their impact on the economics of the process is not clear.

### Previous Work

In comparison to the amount of research on the controllability measures, relatively little work has been placed on methods for systematically determining the *trade-offs* between steady-state economics and dynamic controllability. Although economics continues to be the driving force in the design of a process, there is no straightforward method for evaluating the economics of the dynamic operation of the process. Several methods have been proposed to address these issues. M. Morari and J.D. Perkins [14] discuss the concept of controllability and emphasize that the design of a control system for a process is part of the overall design of the process. Noting that a great amount of effort has been placed on the assessment of controllability, particularly for linear dynamic models, they indicate that very little has been published on algorithmic approaches for determination of process designs where economics and controllability are traded off systematically.

In order to deal with the controllability issues on a economic level, a *back-off* method was presented in [18] to determine the economic impact of disturbances on the system. The basic idea is to determine the optimal steady-state operating point such that the feasible operation is maintained with respect to all constraints in the presence of uncertainties and disturbances. This operating point is compared to the optimal steady-state operating point determined in the absence of disturbances. The economic penalty incurred by backing away from the disturbances-free operating point to the feasible operating point can be determined and thus the cost of the disturbance can be evaluated. This concept is illustrated in Fig. 1. Point A indicates the nominal steady-state design, and point B is the back-off point which corresponds to the design which will not violate the constraints  $h_1$  and  $h_2$  in the presence of uncertainties and disturbances.

MINLP: Applications in the Interaction of Design and Control, Figure 1

### Illustration of the back-off approach

The method is further developed in [17], where the control structure selection problem is analyzed. Perfect control assumptions are used along with a linearized model to formulate a mixed integer linear program (MILP) where the integer variables indicate the pairings between the manipulated and controlled variables. The back-off approach incorporated the dynamic operation of the process into the design, but it only ensures the feasible operation of the process and does not directly address controllability aspects.

An approach for determining process designs which are both steady-state and operationally optimal was presented in [2]. The controllability of potential designs is evaluated along with their economic performance by incorporating a model predictive control algorithm into the process design optimization algorithm. This coordinated approach uses an objective function which is a weighted sum of economic and controllability measures.

A multi-objective approach was proposed in [9,10] to simultaneously consider both controllability and economic aspects of the design. This approach incorporates both design and control aspects into a process synthesis framework where the trade-offs between various open-loop controllability measures and the economics of the process can be observed. The problem is formulated as a *mixed integer nonlinear program (MINLP)*, where integer variables are utilized for structural al-

ternatives in the process flowsheet. Through the application of multi-objective techniques, a process design which is both economic and controllable is determined.

A screening approach was proposed in [4], where the variability in the product quality is used to compare different steady-state process designs. The dynamic controllability is measured economically by calculating the amount of material produced that is off-specification and on-specification. The on-specification material leads to profits while the off-spec material results in costs for reworking or disposal.

A back-off technique was also developed in [1] for the design of steady-state and open-loop dynamic processes. Both uncertainties and disturbances are considered for determining the amount of back-off. In order to address the fact that back-off approaches address the feasible operation and do not address controllability aspects, [5] introduces a recovery factor which is defined as the ratio of the amount of penalty recovered with control to the penalty with no control. This ratio is then used to rank different control strategies.

The advantage of the back-off approaches is that they determine the cost increase associated with moving to the back-off position which is attributed to the uncertainties and disturbances. A limitation of this approach is that it can lead to rather conservative designs since the worst-case uncertainty scenario is considered. Although the probability of the worst-case uncertainty occurring may not be high, this is the basis for the final design. Also, the method has not been applied to the design/synthesis problem. A fixed design is considered and then the back-off is considered as a modification of this design.

The optimal design of dynamic systems under uncertainty was addressed in [13]. Flexibility aspects as well as the control design were considered simultaneously with the process design. The algorithm is used to find the economic optimum which satisfies all of the constraints for a given set of uncertainties and disturbances when the control system is included.

S. Walsh and Perkins [23] outline the use of optimization as a tool for the design/control problem. They note that the advances in computational hardware and optimization tools have made it possible to solve the complex problems that arise in design/control. Their assessment focuses on the control structure selection

problem where the economic cost of a disturbance is balanced against the performance of the controller.

The increasing importance of design and control issues had led to more and more discussion on the topic. One contribution to the area has been [11]. The fundamental design and control concepts are described and several quantitative examples are given which illustrate the interaction of design and control.

Most of the previous work does not address synthesis issues and does not treat the problem quantitatively. Two methods employ the optimization approach in process synthesis to arrive at mathematical programming formulations which are solved to determine the trade-offs between the steady-state design and dynamic controllability. The first method [9,10] uses steady state linear controllability measures while the second method [20] uses full nonlinear dynamic models of the process.

### Process Synthesis

Mathematical programming has been found to be a very useful tool for process synthesis. Its application in analyzing the interaction of design and control has followed directly along the process synthesis methodology.

The goal in process synthesis to determine the structure and operating conditions of the process flowsheet. The optimization approach to the synthesis problem involves three steps:

- 1) The representation of process design alternatives of interest through a process *superstructure*.
- 2) The *mathematical modeling* of the superstructure.
- 3) The *algorithmic development* of solution procedure to extract the optimal process flowsheet from the superstructure and solution of the optimization problem.

The key aspect is the postulation of a superstructure which contains all possible design alternatives of interest. The superstructure must be sufficiently rich so as to include the numerous design possibilities yet succinct enough to eliminate redundancies and reduce complexities.

The mathematical model is characterized by the variables and equations used in the model. Continuous variables are used to represent flowrates, compositions, temperatures, etc. Binary variables are used to

represent structural alternatives such as the existence of process units. The modeling of steady-state processes leads to algebraic equations and constraints and results in an MINLP. When dynamic models are to be used, the continuous variables are partitioned into dynamic state variables, control variables, and time invariant variables, and the resulting formulation is classified as a *mixed integer optimal control problem* (MIOCP).

### Steady-State Modeling Approach

This approach was outlined in [9,10] and follows the optimization approach for process synthesis. A systematic procedure is presented for incorporating open-loop steady-state controllability measures into the process synthesis problem. The problem is formulated mathematically as a MINLP and a *multi-objective optimization* problem is solved to quantitatively determine the best-compromise solution among the economic and control objectives. The  $\epsilon$ -constraint method is used to determine the *noninferior solution set* where one objective can be improved only at the expense of another, and the best-compromise solution is determined using a *cutting plane algorithm*.

In order to apply the process synthesis approach, the controllability measure must be expressed as a function of the unknown design parameters. Steady-state controllability measures are used to simplify the problem and reduce implementation difficulties that arise when considering controllability measures as functions of frequency. The steady-state gains of the process can be written in an analytical form thus allowing for an algebraic representation.

The starting point for the controllability analysis is the linear multiple input/multiple output system written in the Laplace domain as

$$\mathbf{z}(s) = \mathbf{G}(s)\mathbf{u}(s) + \mathbf{G}_d(s)\mathbf{d}(s),$$

where  $\mathbf{z}$  are the output variables,  $\mathbf{u}$  are the control variables,  $\mathbf{G}(s)$  is the process transfer function matrix, and  $\mathbf{G}_d(s)$  is the disturbance transfer function matrix.

Closed-loop control can be considered by expressing the control variable  $\mathbf{u}(s)$  as

$$\mathbf{u}(s) = \mathbf{G}_c(s)(\mathbf{z}^*(s) - \mathbf{z}(s)),$$

where  $\mathbf{G}_c(s)$  is the controller transfer function and  $\mathbf{z}^*$  is the desired set-point. This requires that the form of

controller transfer function be known as well as the method for calculating the parameters. Since this causes problems in the formulation of the optimization problem, the controllability is viewed as a property inherent to the process and independent of the particular control system design. The analysis thus considers only the open-loop controllability measures which depend only on the process itself.

Since both the process design and controllability measures can be expressed as functions of the unknown design parameters, the synthesis problem can be expressed as a multi-objective MINLP:

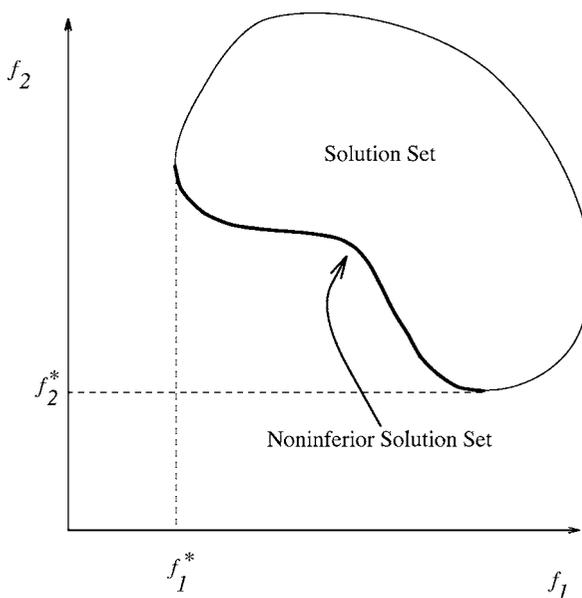

$$\left\{ \begin{array}{l} \min \quad \mathbf{J}(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} \quad \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \quad \quad \mathbf{g}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \quad \quad \boldsymbol{\eta} = \bar{\mathbf{h}}(\mathbf{x}, \mathbf{y}) \\ \quad \quad \mathbf{x} \in \mathbf{X} \subseteq \mathbb{R}^p \\ \quad \quad \mathbf{y} \in \{0, 1\}^q. \end{array} \right.$$

In this formulation,  $\mathbf{J}$  is a vector of objectives which includes both the economic objectives and controllability objectives. The expressions  $\mathbf{h}$  and  $\mathbf{g}$  represent material and energy balances, thermodynamic relations, and other constraints. The controllability measures are included in the formulation as  $\boldsymbol{\eta}$ . The variables in this problem are partitioned as continuous  $\mathbf{x}$  and binary  $\mathbf{y}$ .

The problem is posed with multiple objectives representing the competing economic and open-loop controllability measures. Different techniques have been developed in order to assess the trade-offs among the objectives quantitatively. In this approach, the noninferior solution set is generated to determine the set of solutions in which one objective can be improved only at the expense of the other(s). The noninferior solution set for a two objective problem is visually depicted in Fig. 2.

This noninferior solution set is generated using an  $\epsilon$ -constraint method where one objective is optimized and the others are included as constraints less than a parameter  $\epsilon$ . The problem is reduced to a single objective optimization problem which is iteratively solved for varying values of  $\epsilon$  to generate the noninferior solution set.

By reducing the problem to a single objective problem, MINLP optimization techniques can be applied

MINLP: Applications in the Interaction of Design and Control, Figure 2  
Noninferior solution set for a problem with two objectives

to solve the problem. These MINLP techniques include *generalized Benders decomposition* (GBD) [7,19], outer approximation (OA) [3], outer approximation with equality relaxation (OA/ER) [8], and outer approximation with equality relaxation and augmented penalty [22]. These are discussed in detail in [6].

Once the noninferior solution set is determined, the best compromise solution is determined by applying a *cutting plane algorithm*. The trade-offs among the objectives are quantitatively assessed using weight factors which come from the slope of the noninferior solution set.

### Dynamic Modeling Approach

The major limitation of the above approach is that it does not consider the dynamic behavior of the process. This approach considers the full dynamic model of the process and a dynamic controllability measure. An optimization approach is applied which involves a dynamic optimization problem.

One of the initial difficulties with this method is defining a controllability measure for nonlinear dynamic systems. As in the previous method, the controllability measure must be capable of being expressed as

a function of the unknown design parameters. One possible choice for the controllability measure is the integral square error (ISE). The benefit of this measure is that it is easy to calculate and does reflect the dynamics of the process albeit only in the outputs of the process. One downside of this measure is that there is no one to one correspondence between the the control structure and the ISE measure. Thus, different dynamic characteristics of the process may not be reflected in the ISE.

The superstructure is the same as in the previous approach, but a dynamic model is used instead of a steady-state model. The dynamic modeling of the superstructure leads to a problem that includes *differential and algebraic equations* (DAEs) and the formulation is a multi-objective MIOCP. New algorithmic techniques must be developed for the solution of the formulation.

The general formulation for the multi-objective MIOCP is as follows:

$$\left\{ \begin{array}{l} \min \quad J(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{u}(t_i), \mathbf{x}, \mathbf{y}) \\ \text{s.t.} \quad \mathbf{f}_1(\dot{\mathbf{z}}_1(t), \mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{u}(t), \mathbf{x}, \mathbf{y}, t) = \mathbf{0} \\ \quad \mathbf{f}_2(\mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{u}(t), \mathbf{x}, \mathbf{y}, t) = \mathbf{0} \\ \quad \mathbf{z}_1(t_0) = \mathbf{z}_1^0 \\ \quad \mathbf{z}_2(t_0) = \mathbf{z}_2^0 \\ \quad \mathbf{h}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{u}(t_i), \mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \quad \mathbf{g}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{u}(t_i), \mathbf{x}, \mathbf{y}) \leq \mathbf{0} \quad (1) \\ \quad \mathbf{h}''(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \quad \mathbf{g}''(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \quad \mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^p \\ \quad \mathbf{y} \in \{0, 1\}^q \\ \quad t_i \in [t_0, t_N] \\ \quad i = 0, \dots, N. \end{array} \right.$$

Here,  $\mathbf{z}_1(t)$  is a vector of  $n$  dynamic variables whose time derivatives,  $\dot{\mathbf{z}}_1(t)$ , appear explicitly, and  $\mathbf{z}_2(t)$  is a vector of  $m$  dynamic variables whose time derivatives do not appear explicitly,  $\mathbf{x}$  is a vector of  $p$  time invariant continuous variables,  $\mathbf{y}$  is a vector of  $q$  binary variables, and  $\mathbf{u}(t)$  is a vector of  $r$  control variables. Time  $t$  is the independent variable for the DAE system where  $t_0$  is the fixed initial time,  $t_i$  are time instances, and  $t_N$  is the final time. The DAE system is represented by  $\mathbf{f}_1$ , the  $n$  differential equations, and  $\mathbf{f}_2$ , the  $m$  dynamic algebraic

equations. The constraints  $\mathbf{h}'$  and  $\mathbf{g}'$  are point constraints where  $t_i$  represents the time instance at which the constraint is enforced and  $\mathbf{h}''$  and  $\mathbf{g}''$  are general constraints. The objective functions for the economic and controllability measures are represented by the vector  $\mathbf{J}$ .

The initial condition for the above system is determined by specifying  $n$  of the  $2n + m$  variables  $\mathbf{z}_1(t_0)$ ,  $\dot{\mathbf{z}}_1(t_0)$ ,  $\mathbf{z}_2(t_0)$ . For DAE systems with index 0 or 1, the remaining  $n + m$  values can be determined. In this work, DAE systems of index 0 or 1 are considered and the initial conditions for  $\mathbf{z}_1(t)$  and  $\mathbf{z}_2(t)$  are  $\mathbf{z}_1^0$  and  $\mathbf{z}_2^0$  respectively.

Note that in this general formulation, the  $\mathbf{y}$  variables appear in the DAE system as well as in the point constraints and general constraints. This has implications on the solution strategy.

A similar approach to that of the previous approach is applied to address the multi-objective nature of the problem. An  $\epsilon$ -constraint method is applied to reduce to problem to an iterative solution of single objective MIOCPs.

### MIOCP Solution Algorithm

The strategy for solving the MIOCP is to apply iterative decomposition strategies similar to existing MINLP algorithms with extensions for handling the DAE system. The algorithm developed for the solution of the MIOCP closely parallels existing algorithms for MINLP optimization (GBD, OA, OA/ER, OA/ER/AP). The presence of the  $\mathbf{y}$  variables in DAE system for the general case prohibits the use of Outer Approximation and its variants. For the special cases where the  $\mathbf{y}$  variables do not appear in the DAEs and do participate in a linear and separable fashion, outer approximation and its variants can be applied to the problem. The GBD algorithm can be applied to the solution of the general problem, and the algorithmic development closely follows those of GBD.

The GBD algorithm is an iterative procedure which generates upper and lower bounds on the solution of the MINLP formulation. The upper bound results from the solution of an NLP primal problem and the lower bound from an MILP master problem. The bounds on the solution converge in a finite number of iterations to yield the solution to the MINLP model. A similar

methodology is applied to the MIOCP problem, but the forms of the primal and master problems have to be altered.

### Primal Problem

The primal problem is obtained by fixing the  $\mathbf{y}$  variables which leads to an optimal control problem. For fixed values of  $\mathbf{y} = \mathbf{y}^k$ , the MIOCP has the following form:

$$\left\{ \begin{array}{l} \min \quad J(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{u}(t_i), \mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} \quad \mathbf{f}_1(\dot{\mathbf{z}}_1(t), \mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{u}(t), \mathbf{x}, \mathbf{y}^k, t) = \mathbf{0} \\ \quad \mathbf{f}_2(\mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{u}(t), \mathbf{x}, \mathbf{y}^k, t) = \mathbf{0} \\ \quad \mathbf{z}_1(t_0) = \mathbf{z}_1^0 \\ \quad \mathbf{z}_2(t_0) = \mathbf{z}_2^0 \\ \quad \mathbf{h}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{u}(t_i), \mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ \quad \mathbf{g}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{u}(t_i), \mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ \quad \mathbf{h}''(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ \quad \mathbf{g}''(\mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ \quad \mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^p \\ \quad t_i \in [t_0, t_N] \\ \quad i = 0, \dots, N. \end{array} \right. \quad (2)$$

The solution of this optimal control problem can be handled in several ways: complete discretization, solution of the necessary conditions, dynamic programming, and *control parameterization*. This work focuses on the control parameterization techniques which parameterize only the control variables  $\mathbf{u}(t)$  in terms of time invariant parameters. At each step of the optimization procedure, the DAEs are solved for given values of the decision variables and a feasible path for  $\mathbf{z}(t)$  is obtained. This solution is used to evaluate the objective function and remaining constraints. The control parameterization can either be open loop as described in [21] or closed-loop such as that described in [17] and [16] which also includes the control structure selection.

The basic idea behind the control parameterization is to express the control variables  $\mathbf{u}(t)$  as functions of time invariant parameters. This parameterization can be done in terms of the independent variable  $t$  (open loop):

$$\mathbf{u}(t) = \phi(\mathbf{w}, t).$$

Alternatively, the parameterization can be done in terms of the state variables  $\mathbf{z}(t)$  (closed-loop):

$$\mathbf{u}(t) = \psi(\mathbf{w}, \dot{\mathbf{z}}(t), \mathbf{z}(t)).$$

In both cases,  $\mathbf{w}$  are the time invariant control parameters. The set of time invariant parameters,  $\mathbf{x}$ , is now expanded to include the control parameters:

$$\mathbf{x} = \{\mathbf{x}, \mathbf{w}\}.$$

The set of DAEs ( $\mathbf{f}$ ) is expanded to include parameterization functions

$$\mathbf{f}(\cdot) = \{\mathbf{f}(\cdot), \phi(\cdot), \psi(\cdot)\}$$

and the control variables are converted to dynamic state variables:

$$\mathbf{z} = \{\mathbf{z}, \mathbf{u}\}.$$

Through the application of the control parameterization, the control variables are effectively removed from the problem and the following problem results:

$$\left\{ \begin{array}{l} \min \quad J(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} \quad \mathbf{f}_1(\dot{\mathbf{z}}_1(t), \mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{x}, \mathbf{y}^k, t) = \mathbf{0} \\ \quad \mathbf{f}_2(\mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{x}, \mathbf{y}^k, t) = \mathbf{0} \\ \quad \mathbf{z}_1(t_0) = \mathbf{z}_1^0 \\ \quad \mathbf{z}_2(t_0) = \mathbf{z}_2^0 \\ \quad \mathbf{h}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ \quad \mathbf{g}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ \quad \mathbf{h}''(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ \quad \mathbf{g}''(\mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ \quad \mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^p \\ \quad t_i \in [t_0, t_N] \\ \quad i = 0, \dots, N. \end{array} \right. \quad (3)$$

This problem is a nonlinear program with differential and algebraic constraints (NLP/DAE). This problem is solved using a parametric method where the DAE system is solved as a function of the  $\mathbf{x}$  variables. The solution of the DAE system is achieved through an integration routine which returns the values of the  $\mathbf{z}$  variables at the time instances,  $\mathbf{z}(t_i)$ , along with their sensitivities with respect to the parameters,  $d\mathbf{z}/d\mathbf{x}(t_i)$ . The resulting problem is an NLP optimization over the space

of  $\mathbf{x}$  variables which has the form:

$$\left\{ \begin{array}{l} \min J(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{x}, \mathbf{y}^k) \\ \text{s.t. } \mathbf{h}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ \mathbf{g}'(\dot{\mathbf{z}}_1(t_i), \mathbf{z}_1(t_i), \mathbf{z}_2(t_i), \mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ \mathbf{h}''(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ \mathbf{g}''(\mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ \mathbf{x} \in \mathcal{X} \\ t_i \in [t_0, \dots, t_N] \\ i = 0, \dots, N, \end{array} \right. \quad (4)$$

where the variables  $\dot{\mathbf{z}}_1(t_i)$ ,  $\mathbf{z}_1(t_i)$ , and  $\mathbf{z}_2(t_i)$  are determined through the solution of the DAE system by integration:

$$\left\{ \begin{array}{l} \mathbf{f}_1(\dot{\mathbf{z}}_1(t), \mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{x}, \mathbf{y}^k, t) = \mathbf{0}, \\ \mathbf{f}_2(\mathbf{z}_1(t), \mathbf{z}_2(t), \mathbf{x}, \mathbf{y}^k, t) = \mathbf{0}, \\ \mathbf{z}_1(t_0) = \mathbf{z}_1^0, \\ \mathbf{z}_2(t_0) = \mathbf{z}_2^0. \end{array} \right. \quad (5)$$

The functions  $J(\cdot)$ ,  $\mathbf{g}'(\cdot)$ , and  $\mathbf{h}'(\cdot)$  are functions of  $\mathbf{z}(t_i)$  which are implicit functions of the  $\mathbf{x}$  variables through the integration of the DAE system. For the solution of the NLP the objective and constraints evaluations, along with their gradients with respect to  $\mathbf{x}$ , are required. These are evaluated directly for the constraints  $\mathbf{g}''(\mathbf{x})$  and  $\mathbf{h}''(\mathbf{x})$ . However, for the functions  $J(\cdot)$ ,  $\mathbf{g}'(\cdot)$ , and  $\mathbf{h}'(\cdot)$ , the values  $\mathbf{z}(t_i)$ , and the gradients  $d\mathbf{z}/d\mathbf{x}(t_i)$ , as returned from the integration, are used. The functions  $J(\cdot)$ ,  $\mathbf{g}'(\cdot)$ , and  $\mathbf{h}'(\cdot)$  are evaluated directly and the gradients  $dJ/d\mathbf{x}$ ,  $d\mathbf{g}'/d\mathbf{x}$ , and  $d\mathbf{h}'/d\mathbf{x}$  are evaluated by using the chain rule:

$$\left\{ \begin{array}{l} \frac{dJ}{d\mathbf{x}} = \left( \frac{\partial J}{\partial \mathbf{z}} \right) \left( \frac{\partial \mathbf{z}}{\partial \mathbf{x}} \right) + \left( \frac{\partial J}{\partial \mathbf{x}} \right), \\ \frac{d\mathbf{h}'_i}{d\mathbf{x}} = \left( \frac{\partial \mathbf{h}'_i}{\partial \mathbf{z}} \right) \left( \frac{\partial \mathbf{z}}{\partial \mathbf{x}} \right) + \left( \frac{\partial \mathbf{h}'_i}{\partial \mathbf{x}} \right), \\ \frac{d\mathbf{g}'_i}{d\mathbf{x}} = \left( \frac{\partial \mathbf{g}'_i}{\partial \mathbf{z}} \right) \left( \frac{\partial \mathbf{z}}{\partial \mathbf{x}} \right) + \left( \frac{\partial \mathbf{g}'_i}{\partial \mathbf{x}} \right). \end{array} \right. \quad (6)$$

Standard gradient based optimization techniques can be applied to solve this problem as an NLP. The solution of this problem provides values of the  $\mathbf{x}$  variables and trajectories for  $\mathbf{z}(t)$ .

The master problem is formulated using *dual information* and the solution of the primal problem. Provided that the  $\mathbf{y}$  variables participate linearly, the problem is an MILP whose solution provides a lower bound

**MINLP: Applications in the Interaction of Design and Control, Table 1**  
Constraints and their corresponding dual variables

constraint	dual variable
$\mathbf{f}_1$	$\mathbf{v}_1(t)$
$\mathbf{f}_2$	$\mathbf{v}_2(t)$
$\mathbf{g}'$	$\boldsymbol{\mu}'$
$\mathbf{h}'$	$\boldsymbol{\lambda}'$
$\mathbf{g}''$	$\boldsymbol{\mu}''$
$\mathbf{h}''$	$\boldsymbol{\lambda}''$

and  $\mathbf{y}$  variables for the next primal problem. Dual information is required from all of the constraints including the DAEs whose dual variables, or adjoint variables, are dynamic. The constraints and their corresponding dual variables are listed in Table 1.

The dual variables  $\boldsymbol{\mu}'$ ,  $\boldsymbol{\lambda}'$ ,  $\boldsymbol{\mu}''$ , and  $\boldsymbol{\lambda}''$  are generally obtained from the solution technique for the primal problem. Dual information from the DAE system is obtained by solving the *adjoint problem* for the DAE system which has the following formulation:

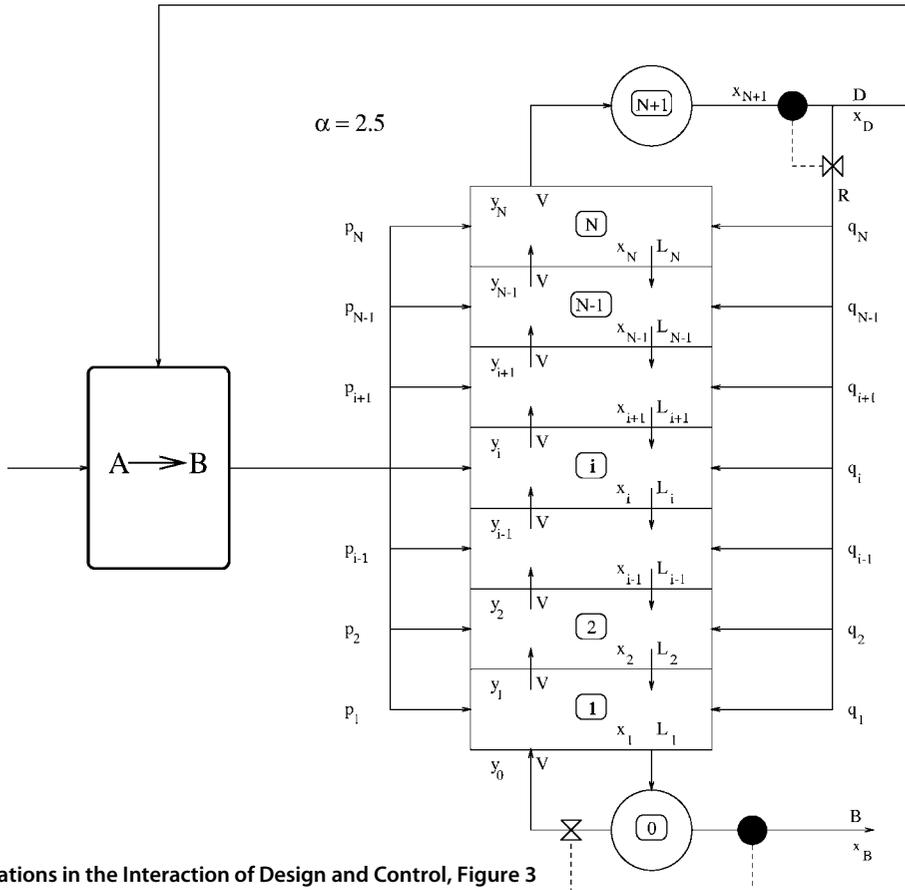

$$\left\{ \begin{array}{l} \mathbf{p} = \mathbf{v}_1^\top \frac{d\mathbf{f}_1}{dz_1}, \\ \dot{\mathbf{p}} = \mathbf{v}_1^\top \frac{d\mathbf{f}_1}{dz_1} + \mathbf{v}_2^\top \frac{d\mathbf{f}_2}{dz_1}, \\ \mathbf{0} = \mathbf{v}_1^\top \frac{d\mathbf{f}_1}{dz_2} + \mathbf{v}_2^\top \frac{d\mathbf{f}_2}{dz_2}. \end{array} \right. \quad (7)$$

This is a set of DAEs where the solutions for  $d\mathbf{f}_1/d\dot{\mathbf{z}}_1$ ,  $d\mathbf{f}_1/dz_1$ ,  $d\mathbf{f}_2/dz_1$ ,  $d\mathbf{f}_1/dz_2$ , and  $d\mathbf{f}_2/dz_2$  are known functions of time obtained from the solution of the primal problem. The variables  $\mathbf{v}_1(t)$  and  $\mathbf{v}_2(t)$  are the adjoint variables and the solution of this problem is a backward integration in time with the following final time conditions:

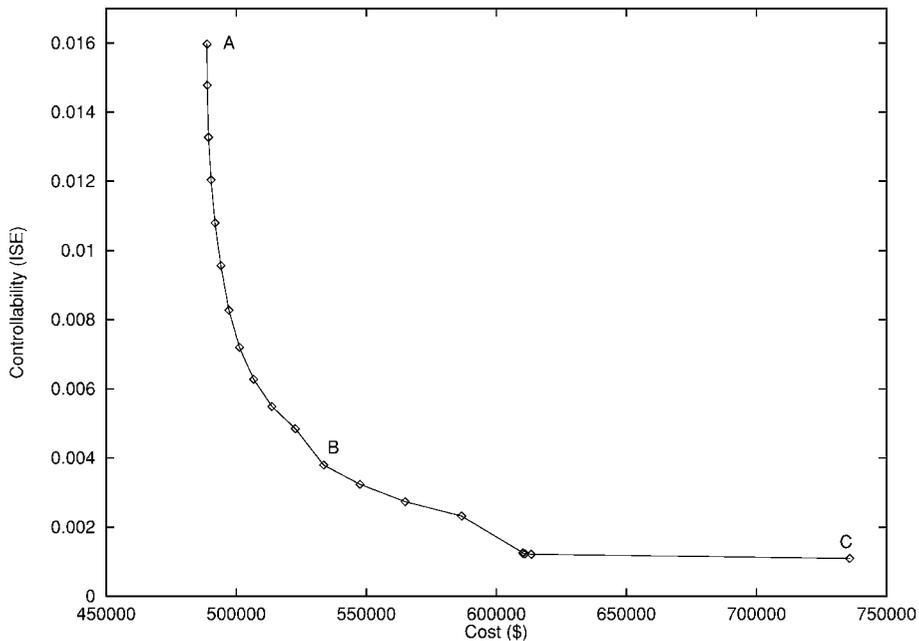

$$\frac{dJ}{dz_1} + \boldsymbol{\lambda}' \frac{d\mathbf{h}'}{dz_1} + \boldsymbol{\mu}' \frac{d\mathbf{g}'}{dz_1} + \mathbf{v}_1^\top \frac{d\mathbf{f}_1}{d\dot{\mathbf{z}}_1} = 0.$$

Thus, the Lagrange multipliers for the end-time constraints are used as the final time conditions for the adjoint problem and are not included in the master problem formulation.

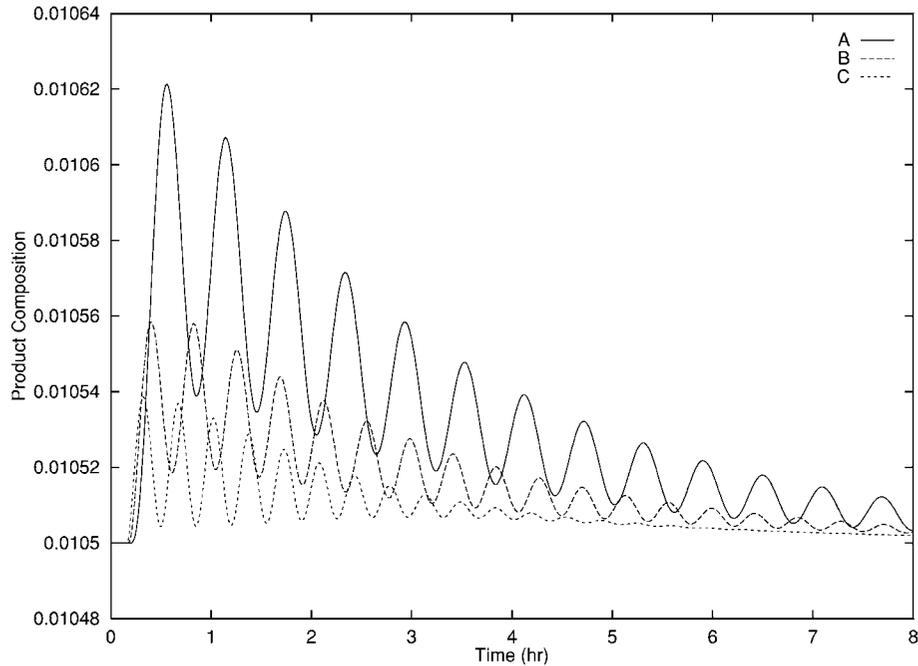

The master problem is formulated using the solution of the primal problem,  $\mathbf{x}^k$  and  $\mathbf{z}^k(t)$ , along with

the dual information,  $\mu''^k$ ,  $\lambda''^k$ , and  $v^k(t)$ . The master problem has the following form:

$$\left\{ \begin{array}{l} \min_{\mathbf{y}, \mu_b} \quad \mu_b \\ \text{s.t.} \quad \mu_b \geq J(\mathbf{x}^k, \mathbf{y}) \\ \quad + \int_{t_0}^{t_N} v_1^k(t) \mathbf{f}_1(\mathbf{z}_1^k(t), \mathbf{z}_1^k(t), \mathbf{z}_2^k(t), \mathbf{x}^k, \mathbf{y}, t) dt \\ \quad + \int_{t_0}^{t_N} v_2^k(t) \\ \quad \quad \mathbf{f}_2(\mathbf{z}_1^k(t), \mathbf{z}_2^k(t), \mathbf{x}^k, \mathbf{y}, t) dt \\ \quad + \mu''^k \mathbf{g}''(\mathbf{x}^k, \mathbf{y}) + \lambda''^k \mathbf{h}''(\mathbf{x}^k, \mathbf{y}), \\ \quad \quad k \in K_{\text{feas}}, \\ \mathbf{0} \geq \int_{t_0}^{t_N} v_1^k(t) \\ \quad \quad \mathbf{f}_1(\mathbf{z}_1^k(t), \mathbf{z}_1^k(t), \mathbf{z}_2^k(t), \mathbf{x}^k, \mathbf{y}, t) dt \\ \quad + \int_{t_0}^{t_N} v_2^k(t) \mathbf{f}_2(\mathbf{z}_1^k(t), \mathbf{z}_2^k(t), \mathbf{x}^k, \mathbf{y}, t) dt \\ \quad + \mu''^k \mathbf{g}''(\mathbf{x}^k, \mathbf{y}) + \lambda''^k \mathbf{h}''(\mathbf{x}^k, \mathbf{y}), \\ \quad \quad k \in K_{\text{infeas}}, \\ \mathbf{y} \in \{0, 1\}^q. \end{array} \right.$$

The integral term can be evaluated since the profiles for  $\mathbf{z}^k(t)$  and  $v^k(t)$  both are fixed and known. Note that this formulation has no restrictions on whether or not  $\mathbf{y}$  variables participate in the the DAE system.

### Example: Reactor-Separator-Recycle System

The example problem considered here is the design of a process involving a reaction step, a separation step, and a recycle loop. Fresh feed containing A and B flow into a an isothermal reactor where the first order irreversible reaction  $A \rightarrow B$  takes place. The product from the reactor is sent to a distillation column where the unreacted A is separated from the product B and sent back to the reactor. The superstructure is shown in Fig. 3.

The model equations for the reactor (CSTR) and the separator (ideal binary distillation column) can be found in [12]. The specific problem design follows the work in [10].

For this problem, the single output is the product composition. The bottoms (product) composition is controlled by the vapor boil-up and the distillate composition is controlled by the reflux rate. Since only the product composition is specified, the distillate compo-

(8)

sition set-point is free and left to be determined through the optimization.

The cost function includes column and reactor capital and utility costs.

$$\begin{aligned} \text{cost}_{\text{reactor}} &= 17639D_r^{1.066}(2D_r)^{0.802}, \\ \text{cost}_{\text{column}} &= 6802D_c^{1.066}(2.4N_t)^{0.802} \\ &\quad + 548.8D_c^{1.55}N_t, \\ \text{cost}_{\text{exchangers}} &= 193023V_{ss}^{0.65}, \\ \text{cost}_{\text{utilities}} &= 72420V_{ss}, \\ \text{cost}_{\text{total}} &= \frac{\text{cost}_{\text{reactor}} + \text{cost}_{\text{column}} + \text{cost}_{\text{exchangers}}}{\beta_{\text{pay}}} \\ &\quad + \beta_{\text{tax}}[\text{cost}_{\text{utilities}}]. \end{aligned}$$

The controllability measure is the time weighted ISE for the product composition:

$$\frac{d\mu}{dt} = t(x_B - x_B^*)^2.$$

The noninferior solution set is shown in Fig. 4, and Table 2 lists the solution information for three of the designs in the noninferior solution set. The dynamic profile for these three designs are shown in Fig. 5.

All of the designs in the noninferior solution set are strippers. Since the feed enters at the top of the column, there is no reflux and thus no control loop for the distillate composition. The controllability of the process is increased by increasing the size of the reactor and decreasing the size of the column. The most controllable design has a large reactor and a single flash unit.

### Keywords

Mixed integer nonlinear programming; Global optimization; Branch and bound algorithms

A wide range of nonlinear optimization problems involve integer or discrete variables in addition to continuous ones. These problems are denoted as *mixed integer nonlinear programming* (MINLP) problems. Integer variables correspond to logical decisions describing whether certain actions do or do not take place, or modeling the sequence according to which those decisions take place. The nonlinear nature of the MINLP models may arise from:

- nonlinear relations in the integer domain only
- nonlinear relations in the continuous domain only
- nonlinear relations in the joint domain, i. e., products of continuous and binary/integer variables.

The general mathematical formulation of the MINLP problems can be stated as follows:

$$\left\{ \begin{array}{l} \min_{x,y} \quad f(x, y) \\ \text{s.t.} \quad h(x, y) = 0 \\ \quad \quad g(x, y) \leq 0 \\ \quad \quad x \in X \subset \mathbb{R}^n \\ \quad \quad y \in Y \quad (\text{integer}). \end{array} \right.$$

Here,  $x$  represents a vector of  $n$  continuous variables,  $y$  is a vector of integer variables,  $f(x, y)$ ,  $h(x, y)$ ,  $g(x, y)$  represent the objective function, equality and inequality constraints, respectively. It should be noted, that every problem of the form just presented, can be transformed into one where all integer variables have been transformed into binary, i. e., 0–1, variables, by realizing that every integer  $y^L \leq y \leq y^U$  can be expressed through 0–1 variables,  $z = (z_1, \dots, z_N)$ , as:

$$y = y^L + z_1 + 2z_2 + 4z_3 + \dots + 2^{N-1}z_N,$$

$$N = 1 + \text{INT} \left\{ \frac{\log(y^U - y^L)}{\log 2} \right\}.$$

Therefore, any MINLP problem can be written as:

$$\left\{ \begin{array}{l} \min_{x,y} \quad f(x, y) \\ \text{s.t.} \quad h(x, y) = 0 \\ \quad \quad g(x, y) \leq 0 \\ \quad \quad x \in X \subset \mathbb{R}^n \\ \quad \quad y \in Y = \{0, 1\}^m. \end{array} \right.$$

In the analysis of MINLP problems two issues are of paramount importance:

- combinatorial explosion of computational requirements as the number of binary variables increases
- NP-hard nature of the problem of determining the *global minimum solution* of general nonconvex MINLP problems.

A complexity analysis of the former is presented in [16], while the complexity of determining global minimum solutions of MINLPs is discussed in [15].

Various methods exist for identifying a locally optimum solution of MINLP problems. These are discussed in great detail in [9] and in a recent thorough review paper, [6], which presents a comprehensive account of the various approaches for addressing issues related to the

solution of mixed integer nonlinear optimization problems.

The main objective in a general branch and bound algorithm is to perform an enumeration of the alternatives without examining all 0–1 combinations of the binary variables. A key element in such an enumeration is the representation of alternatives via a *binary tree*. The basic ideas in a branch and bound algorithm are the following. First, a reasonable effort is made in solving the original problem, by considering for instance the continuous relaxation of it. If the relaxation does not result in an integer-feasible solution, i. e., one in which the binary variables achieve 0–1 at the optimal point, then the root node is separated into two candidate subproblems which are subsequently solved. The separation aims at creating simpler instances of the original problem. Until the problem is successfully solved this process of generating candidate subproblems is repeated. Branch and bound algorithms are also known as *divide-and-conquer* for that very reason. A basic principle common to all branch and bound algorithms is that the solution of the subproblems aims at generating *valid lower bounds* on the original MINLP through its relaxation to a continuous problem. The relaxation, in the case of MINLP, results in a nonlinear programming problem (NLP) which, in the general case, is nonconvex and needs to be solved to global optimality so as to provide a valid lower bound. If the NLP relaxation renders an integer solution, then this solution is referred to as *valid upper bound*. The generation of the sequence of valid upper and lower bounds is called *bounding step*. The way subproblems are created is by forcing some of the binary variables to take on a value of 0 or 1. This is known as the *branching step*. Nodes in the tree are pruned when the corresponding valid lower bound exceeds the valid upper bound, this stage is known as the *fathoming step*. The selection of the branching node, the branching variable and the generation of the lower bound are very crucial steps whose importance becomes even more pronounced when addressing nonconvex MINLP problems. Two basic strategies exist regarding the selection of the branching node depending on whether one designs a branch and bound based on a *depth-first* or a *breadth-first* approach. In the former, the last node created is selected for branching, in the latter the node that generated the best lower bound is selected. It is not clear which strategy is the

best and it is often that the one that minimizes the computational requirement is selected, [13]. Another alternative is to select nodes based on the deviation of the solution from integrality, [12]. The most common strategy for selecting a branching variable is to select the variable whose value at the solution of some relaxed problem is the farthest from integer, i. e., the most fractional variable, [17]. In [12] a method based on the concept of *pseudocosts* which quantifies the effect of binary variables is also proposed, which assigns essentially priorities on the order of branching variables. Finally, one of the most important computational step is the generation of the lower bound, in other words the solution of the relaxed problem. The effectiveness of a branch and bound depends of the quality of the lower bound that is generated. At every node of the branch and bound tree a nonlinear-nonconvex NLP is solved. Two issues are important: the lower bound must be valid, in other words the relaxation at a particular node must underestimate the solution of the original problem for this node, and the lower bounds must be tight so as to enhance the fathoming step. The key complexity when dealing with nonconvex MINLPs is that the relaxation solved at each node is, of course, a non-convex NLP that has to be solved to global optimality. With the exception of problems which are convex in the  $x$  and relaxed  $y$ -space for which variants of the branch and bound algorithms will lead the correct solution, [18], in all other cases *global optimization* algorithms have to be employed for the generation of valid lower bounds.

In [19] the scope of branch and bound algorithms was extended to problems for which valid convex underestimating NLPs can be constructed for the convex relaxations. The problems included bilinear and separable problems for which convex underestimators can be build [14]. A number of very useful tests were proposed to accelerate the reduction of solution space. Namely:

1) Optimality based range reduction tests: For the first set of tests, an upper bound  $U$  on the nonconvex MINLP must be computed and a convex lower bounding NLP must be solved to obtain a lower bound  $L$ . If a bound constraint for variable  $x_i$ , with  $x_i^L \leq x_i \leq x_i^U$ , is active at the solution of the convex NLP and has multiplier  $\lambda_i^* > 0$ , the bounds on  $x_i$  can be updated as follows:

- a) If  $x_i - x_i^U = 0$  at the solution of the convex NLP and  $\kappa_i = x_i^U - (U - L)/\lambda_i^*$  is such that  $\kappa_i > x_i^L$ , then  $x_i^L = \kappa_i$ .
- b) If  $x_i - x_i^L = 0$  at the solution of the convex NLP and  $\kappa_i = x_i^L + (U - L)/\lambda_i^*$  is such that  $\kappa_i < x_i^U$ , then  $x_i^U = \kappa_i$ .

If neither bound constraint is active at the solution of the convex NLP for some variable  $x_j$ , the problem can be solved by setting  $x_j = x_j^U$  or  $x_j = x_j^L$ . Tests similar to those presented above are then used to update the bounds on  $x_j$ .

2) Feasibility based range reduction tests: In addition to ensuring that tight bounds are available for the variables, the constraint underestimators are used to generate new constraints for the problem. Consider the constraint  $g_i(x, y) \leq 0$ . If its underestimating function  $\underline{g}_i(x, y) = 0$  at the solution of the convex NLP and its multiplier is  $\mu_i^* > 0$ , the constraint

$$\underline{g}_i(x, y) \geq -\frac{U - L}{\mu_i^*}$$

can be included in subsequent problems.

A global optimization algorithm branch and bound algorithm has been proposed in [20]. It can be applied to problems in which the objective and constraints are functions involving any combination of binary arithmetic operations (addition, subtraction, multiplication and division) and functions that are either concave over the entire solution space (such as ln) or convex over this domain (such as exp).

The algorithm starts with an automatic reformulation of the original nonlinear problem into a problem that involves only linear, bilinear, linear fractional, simple exponentiation, univariate concave and univariate convex terms. This is achieved through the introduction of new constraints and variables. The reformulated problem is then solved to global optimality using a branch and bound approach. Its special structure allows the construction of a convex relaxation at each node of the tree. The integer variables can be handled in two ways during the generation of the convex lower bounding problem. The integrality condition on the variables can be relaxed to yield a convex NLP which can then be solved globally. Alternatively, the integer variables can be treated directly and the convex lower bounding MINLP can be solved using a branch and bound algorithm as described earlier. This second ap-

proach is more computationally intensive but is likely to result in tighter lower bounds on the global optimum solution. In order to obtain an upper bound for the optimum solution, several methods have been suggested. The MINLP can be transformed to an equivalent nonconvex NLP by relaxing the integer variables. For example, a variable  $y \in \{0, 1\}$  can be replaced by a continuous variable  $z \in [0, 1]$  by including the constraint  $z - z \cdot z = 0$ . The nonconvex NLP is then solved locally to provide an upper bound. Finally, the discrete variables could be fixed to some arbitrary value and the nonconvex NLP solved locally.

In [1] *SMIN* was proposed which is designed to address the following class of problems to global optimality:

$$\begin{cases} \min & f(x) + x^\top A_0 y + c_0^\top y \\ \text{s.t.} & h(x) + x^\top A_1 y + c_1^\top y = 0 \\ & g(x) + x^\top A_2 y + c_2^\top y \leq 0 \\ & x \in X \subset \mathbb{R}^n \\ & y \in Y \text{ (integer),} \end{cases}$$

where  $c_0^\top$ ,  $c_1^\top$  and  $c_2^\top$  are constant vectors,  $A_0$ ,  $A_1$  and  $A_2$  are constant matrices and  $f(x)$ ,  $h(x)$  and  $g(x)$  are functions with continuous second order derivatives. The solution strategy is an extension of the  $\alpha$ BB algorithm for twice-differentiable NLPs [4,5,7]. It is based on the generation of two converging sequences of upper and lower bounds on the global optimum solution. A rigorous underestimation and convexification strategy for functions with continuous second order derivatives allows the construction of a lower bounding MINLP problem with convex functions in the continuous variables. If no mixed-bilinear terms are present ( $A_i = 0$ ,  $\forall i$ ), the resulting MINLP can be solved to global optimality using the *outer approximation algorithm* (OA), [8]. Otherwise, the *generalized Benders decomposition* (GBD) can be used, [10], or the Glover transformations [11] can be applied to remove these bilinearities and permit the use of the OA algorithm. This convex MINLP provides a valid lower bound on the original MINLP. An upper bound on the problem can be obtained by applying the OA algorithm or the GBD to find a local solution. This bound generation strategy is incorporated within a branch and bound scheme: a lower and upper bound on the global solution are first obtained for the entire solution space. Subsequently, the domain

is subdivided by branching on a binary or a continuous variable, thus creating new nodes for which upper and lower bounds can be computed. At each iteration, the node with the lowest lower bound is selected for branching. If the lower bounding MINLP for a node is infeasible or if its lower bound is greater than the best upper bound, this node is fathomed. The algorithm is terminated when the best lower and upper bound are within a pre-specified tolerance of each other.

Before presenting the algorithmic procedure, an overview of the underestimation and convexification strategy is given, and some of the options available within the algorithm are discussed.

In order to transform the MINLP problem of the form just described into a convex problem which can be solved to global optimality with the OA or GBD algorithm, the functions  $f(x)$ ,  $h(x)$  and  $g(x)$  must be convexified. The underestimation and convexification strategy used in the  $\alpha$ BB algorithm has previously been described in detail [3,4,5]. Its main features are exposed here.

In order to construct as tight an underestimator as possible, the nonconvex functions are decomposed into a sum of convex, bilinear, univariate concave and general nonconvex terms. The overall function underestimator can then be built by summing up the convex underestimators for all terms, according to their type. In particular, a new variable is introduced to replace each bilinear term, and is bounded by its convex envelope. The univariate concave terms are linearized. For each nonconvex term  $nt(x)$  with Hessian matrix  $H_{nt}(x)$ , a convex underestimator  $L(x)$  is defined as

$$L(x) = nt(x) - \sum_i \alpha_i (x_i^U - x_i)(x_i - x_i^L), \quad (1)$$

where  $x_i^U$  and  $x_i^L$  are the upper and lower bounds on variable  $x_i$ , respectively, and the  $\alpha$  parameters are non-negative scalars such that  $H_{nt}(x) + 2 \text{diag}(\alpha_i)$  is positive semidefinite over the domain  $[x^L, x^U]$ . The rigorous computation of the  $\alpha$  parameters using interval Hessian matrices is described in [3,4,5].

The underestimators are updated at each node of the branch and bound tree as their quality strongly depends on the bounds on the variables. An unusual feature of the *SMIN- $\alpha$ BB* algorithm is the strategy used to select branching variables. It follows a hybrid approach where branching may occur both on the integer and the

continuous variables in order to fully exploit the structure of the problem being solved. After the node with the lowest lower bound has been identified for branching, the type of branching variable must be determined according to one of the following two criteria:

- 1) Branch on the binary variables first.
- 2) Solve a continuous relaxation of the nonconvex MINLP locally. Branch on a binary variable with a low degree of fractionality at the solution. If there is no such variable, branch on a continuous variable.

The first criterion results in the creation of an integer tree for the first  $q$  levels of the branch and bound tree, where  $q$  is the number of binary variables. At the lowest level of this integer tree, each node corresponds to a nonconvex NLP and the lower and upper bounding problems at subsequent levels of the tree are NLP problems. The efficiency of this strategy lies in the minimization of the number of MINLPs that need to be solved. The combinatorial nature of the problem and its nonconvexities are handled sequentially. If branching occurs on a binary variable, the selection of that variable can be done randomly or by solving a relaxation of the nonconvex MINLP and choosing the most fractional variable at the solution.

The second criterion selects a binary variable for branching only if it appears that the two newly created nodes will have significantly different lower bounds. Thus, if a variable is close to integrality at the solution of the relaxed problem, forcing it to take on a fixed value may lead to the infeasibility of one of the nodes or the generation of a high value for a lower bound, and therefore the fathoming of a branch of the tree. If no binary variable is close to integrality, a continuous variable is selected for branching.

A number of rules have been developed for the selection of a continuous branching variable. Their aim is to determine which variable is responsible for the largest separation distances between the convex underestimating functions and the original nonconvex functions. These efficient rules are exposed in [2]. Variable bound updates performed before the generation of the convex MINLP have been found to greatly enhance the speed of convergence of the  $\alpha$ BB algorithm for continuous problems [2]. For continuous variables, the variable bounds are updated by minimizing or maximizing the chosen variable subject to the convexified constraints being satisfied. In spite of its computational

cost, this procedure often leads to significant improvements in the quality of the underestimators and hence a noticeable reduction in the number of iterations required.

In addition to the update of continuous variable bounds, the SMIN- $\alpha$ BB algorithm also relies on binary variable bound updates. Through simple computations, an entire branch of the branch and bound tree may be eliminated when a binary variable is found to be restricted to 0 or 1. The bound update procedure for a given binary variable is as follows:

- 1) Set the variable to be updated to one of its bounds  $y = y_B$ .
- 2) Perform interval evaluations of all the constraints in the nonconvex MINLP, using the bounds on the solution space for the current node.
- 3) If any of the constraints are found infeasible, fix the variable to  $y = 1 - y_B$ .
- 4) If both bounds have been tested, repeat this procedure for the next variable to be updated. Otherwise, try the second bound.

In [1] *GMIN*, which operates within a classical branch and bound framework, was proposed. The main difference with similar branch and bound algorithms [12,17] is its ability to identify the global optimum solution of a much larger class of problems of the form

$$\begin{cases} \min_{x,y} & f(x, y) \\ \text{s.t.} & h(x, y) = 0 \\ & g(x, y) \leq 0 \\ & x \in X \subset \mathbb{R}^n \\ & y \in N^q, \end{cases}$$

where  $N$  is the set of nonnegative integers and the only condition imposed on the functions  $f(x, y)$ ,  $g(x, y)$  and  $h(x, y)$  is that their continuous relaxations possess continuous second order derivatives. This increased applicability results from the use of the  $\alpha$ BB global optimization algorithm for continuous twice-differentiable NLPs [4,5,7].

At each node of the branch and bound tree, the nonconvex MINLP is relaxed to give a nonconvex NLP, which is then solved with the  $\alpha$ BB algorithm. This allows the identification of rigorously valid lower bounds and therefore ensures convergence to the global optimum. In general, it is not necessary to let the  $\alpha$ BB al-

gorithm run to completion as each one of its iterations generates a lower bound on global solution of the NLP being solved. A strategy of early termination leads to a reduction in the computational requirements of each node of the binary branch and bound tree and faster overall convergence.

The GMIN- $\alpha$ BB algorithm selects the node with the lowest lower bound for branching at every iteration. The branching variable selection strategy combines several approaches: branching priorities can be specified for some of the integer variables. When no variable has a priority greater than all other variables, the solution of the continuous relaxation is used to identify either the most fractional variable or the least fractional variable for branching.

Other strategies have been implemented to ensure a satisfactory convergence rate. In particular, bound updates on the integer variables can be performed at each level of the branch and bound tree. These can be carried out through the use of interval analysis. An integer variable,  $y^*$ , is fixed at its lower (or upper) bound and the range of the constraints is evaluated with interval arithmetic, using the bounds on all other variables. If the range of any constraint is such that this constraint is violated, the lower (or upper) bound on variable  $y^*$  can be increased (or decreased) by one. Another strategy for bound updates is to relax the integer variables, to convexify and underestimate the nonconvex constraints and to minimize (or maximize) a variable  $y^*$  in this convexified feasible region. The resulting lower (or upper) bound on relaxed variable  $y^*$  can then be rounded up (or down) to the nearest integer to provide an updated bound for  $y^*$ .

### Keywords

Mixed integer programming; Branch and bound; MINLP

A general *mixed integer nonlinear programming problem (MINLP)* can be written as

$$\text{(MINLP)} \quad \left\{ \begin{array}{l} \min \quad f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} \quad \mathbf{h}(\mathbf{x}, \mathbf{y}) = 0 \\ \quad \quad \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq 0 \\ \quad \quad \mathbf{x} \in \mathbb{R}^n \\ \quad \quad \mathbf{y} \in \mathbb{Z}^m. \end{array} \right.$$

Here  $\mathbf{x}$  is a vector of  $n$  continuous variables and  $\mathbf{y}$  is a vector of  $m$  integer variables. In many cases, the integer variables  $\mathbf{y}$  are restricted to the values 0 and 1. Such variables are called *binary variables*. The function  $f$  is a scalar valued objective function, while the vector functions  $\mathbf{h}$  and  $\mathbf{g}$  express linear or nonlinear constraints. Problems of this form have a wide variety of applications, in areas as diverse as IR spectroscopy [6], finance [3], chemical process synthesis [9], topological design of transportation networks [12], and marketing [10].

The earliest work on *branch and bound* algorithms for mixed integer linear programming dates back to the early 1960s [7,13,15]. Although the possibility of applying branch and bound methods to mixed integer nonlinear programming problems was apparent from the beginning, actual work on such problems did not begin until later. Early papers on branch and bound algorithms for mixed integer nonlinear programming include [11,14].

A branch and bound algorithm for solving (MINLP) requires the following data structures. The algorithm maintains a list  $L$  of unsolved subproblems. The algorithm also maintains a record of the best integer solution that has been found. This solution,  $(\mathbf{x}^*, \mathbf{y}^*)$ , is called the incumbent solution. The incumbent solution provides an upper bound,  $ub$ , on the objective value of an optimal solution to (MINLP).

The basic branch and bound procedure is as follows.

- 1) *Initialize*: Create the list  $L$  with (MINLP) as the initial subproblem. If a good integer solution is known,

then initialize  $\mathbf{x}^*$ ,  $\mathbf{y}^*$ , and  $ub$  to this solution. If there is no incumbent solution, then initialize  $ub$  to  $+\infty$ .

- 2) *Select*: Select an unsolved subproblem,  $S$ , from the list  $L$ . If  $L$  is empty, then stop: If there is an incumbent solution, then that solution is optimal; If there is no incumbent solution, then (MINLP) is infeasible.
- 3) *Solve*: Relax the integrality constraints in  $S$  and solve the resulting nonlinear programming relaxation. Obtain a solution  $\hat{\mathbf{x}}$ ,  $\hat{\mathbf{y}}$ , and a lower bound,  $lb$ , on the optimal value of the subproblem.
- 4) *Fathom*: If the relaxed subproblem was infeasible, then  $S$  will clearly not yield a better solution to (MINLP) than the incumbent solution. Similarly, if  $lb \geq ub$ , then the current subproblem cannot yield a better solution to (MINLP) than the incumbent solution. Remove  $S$  from  $L$ , and return to step 2.
- 5) *Integer Solution*: If  $\hat{\mathbf{y}}$  is integer, then a new incumbent integer solution has been obtained. Update  $\mathbf{x}^*$ ,  $\mathbf{y}^*$ , and  $ub$ . Remove  $S$  from  $L$  and return to step 2.
- 6) *Branch*: At least one of the integer variables  $y_k$  takes on a fractional value in the solution to the current subproblem. Create a new subproblem,  $S_1$  by adding the constraint

$$y_k \leq \lfloor \hat{y}_k \rfloor.$$

Create a second new subproblem,  $S_2$  by adding the constraint

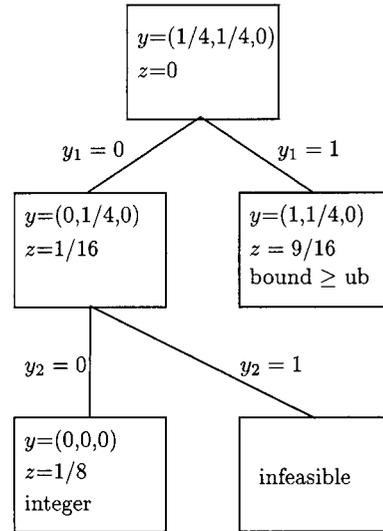

$$y_k \geq \lceil \hat{y}_k \rceil.$$

Remove  $S$  from  $L$ , add  $S_1$  and  $S_2$  to  $L$ , and return to step 2.

The following example demonstrates how the branch and bound algorithm solves a simple (MINLP):

$$\begin{cases} \min & (y_1 - \frac{1}{4})^2 + (y_2 - \frac{1}{4})^2 + y_3^2 \\ & -2y_1 + 2y_2 \leq 1 \\ & \mathbf{y} \text{ binary.} \end{cases}$$

The optimal solution to the initial nonlinear programming relaxation is  $y = (1/4, 1/4, 0)$ , with an objective value of  $z = 0$ . Both  $y_1$  and  $y_2$  take on fractional values in this solution, so it is necessary to select a branching variable. The algorithm arbitrarily selects  $y_1$  as the

MINLP: Branch and Bound Methods, Figure 1  
Branch and bound tree for a sample problem

branching variable, and creates two new subproblems in which  $y_1$  is fixed at 0 or 1. In the subproblem with  $y_1$  fixed at 0, the optimal solution is  $y = (0, 1/4, 0)$ , with  $z = 1/16$ . Since the optimal value of  $y_2$  is fractional, the algorithm again creates two new subproblems, with  $y_2$  fixed at 0 and 1. The optimal solution to the subproblem with  $y_1 = 0$  and  $y_2 = 0$  is  $y = (0, 0, 0)$ , with  $z = 1/8$ . This establishes an incumbent integer solution. The subproblem with  $y_1 = 0$  and  $y_2 = 1$  is infeasible and can be eliminated from consideration. The subproblem with  $y_1 = 1$  has an optimal solution with  $y = (1, 1/4, 0)$  and objective value  $z = 9/16$ . Since  $9/16$  is larger than the objective value of the incumbent solution, this subproblem can be eliminated from consideration. Thus the optimal solution to the example problem is  $y^* = (0, 0, 0)$  with objective value  $z^* = 1/8$ .

Since each subproblem  $S$  creates at most two new subproblems, the set of subproblems considered by the branch and bound algorithm can be represented as a binary tree. The above figure shows the branch and bound tree for the example problem.

There are a number of important issues in the implementation of a branch and bound algorithm for (MINLP).

The first important issue is how to solve the nonlinear programming relaxations of the subproblems in step 3. If the objective function  $f$  and the constraint

functions  $\mathbf{g}$  are convex, while the constraint functions  $\mathbf{h}$  are linear, then the nonlinear programming subproblems in step 3 are convex and thus relatively easy to solve. A variety of methods have been used to solve these subproblems including generalized reduced gradient (GRG) methods [11], sequential quadratic programming (SQP) [4], active set methods for quadratic programming [8], and interior point methods [16].

However, if the nonlinear programming subproblems are nonconvex, then it can be extremely difficult to solve the nonlinear programming relaxation of  $S$  or even obtain a lower bound on the optimal objective function value. For some specialized classes of nonconvex optimization problems, including *indefinite quadratic programming*, *bilinear programming*, and *fractional linear programming*, convex functions which underestimate the nonconvex objective function are known. These *convex underestimators* are widely used in branch and bound algorithms for nonconvex nonlinear programming problems. Branch and bound techniques for nonconvex continuous optimization problems can also be used within a branch and bound algorithm for nonconvex mixed integer nonlinear programming problems. For instance, the *BARON* system uses this approach to solve a variety of nonconvex mixed integer nonlinear programming problems [17,18]. This approach is also used in the *GMIN- $\alpha$ BB* algorithm to solve nonconvex 0 – 1 mixed integer nonlinear programming problems with twice differentiable objective and constraint functions [1].

The choice of the next subproblem to be solved in step 2 can have a significant influence on the performance of the branch and bound algorithm. In mixed integer linear programming, a variety of heuristics are employed to select the next subproblem [2]. One popular heuristic used in branch and bound algorithms for MILP is the *best bound rule*, in which the subproblem with the smallest lower bound is selected. The best bound rule is widely used within branch and bound algorithms for (MINLP) [4,11,18]

In step 6, there may be a choice of several variables with fractional values to be the branching variable. A simple approach is to select the variable whose value  $\hat{y}_k$  is furthest from being an integer [4,11]. In mixed integer linear programming, estimates of the increase in the objective function that will result from forcing a variable to an integer value are often made. These es-

timates, called *'pseudocosts'* or *'penalties'*, are used to select the branching variable. Penalties have also been used in branch and bound algorithms for mixed integer nonlinear programming problems [11,18].

The performance of the branch and bound algorithm can be improved by computing lower bounds on the optimal value of a subproblem without actually solving the subproblem. In [8], lower bounds on the optimal objective value of a subproblem are derived from an optimal dual solution to the subproblem's parent problem. If this lower bound is larger than the objective value of the incumbent solution, then the subproblem can be eliminated from consideration. In [4], Lagrangian duality is used to compute lower bounds during the solution of a subproblem. When the lower bound exceeds the value of the incumbent solution, the current subproblem can be discarded.

Another way to improve the performance of a branch and bound algorithm for (MINLP) is to tighten the formulation of the nonlinear programming subproblems before solving them. In the *BARON* package, dual information from the solution to a nonlinear programming subproblem is used to restrict the ranges of variables and constraints in the children of the subproblem [17,18].

In *branch and cut* approaches, constraints called cutting planes are added to the nonlinear programming subproblems [3,19]. These additional constraints are selected so that they reduce the size of the feasible region of nonlinear programming subproblems without eliminating any integer solutions from consideration. This tightens the formulations of the subproblems and thus increases the probability that a subproblem can be fathomed by bound. Furthermore, the use of cutting planes can make it more likely that an integer solution will be obtained early in the branch and bound process. A variety of cutting planes developed for use in branch and cut algorithms for integer linear programming have been adapted for use in branch and cut algorithms for nonlinear integer programming. These include *mixed integer rounding cuts* [3], *knapsack cuts* [3], *intersection cuts* [3], and *lift-and-project cuts* [19].

To date, little work has been done to compare the performance of branch and bound methods for (MINLP) with other approaches such as *outer approximation* and *generalized Benders decomposition*. B. Borchers and J.E. Mitchell (1997) compared an ex-

perimental branch and bound code with a commercially available outer approximation code on a number of test problems [5]. This study found that the branch and bound code and outer approximation code were roughly comparable in speed and robustness. R. Fletcher and S. Leyffer (1998) compared the performance of their branch and bound code for mixed integer convex quadratic programming problems with their implementations of outer approximation, generalized Benders decomposition, and an algorithm that combines branch and bound and outer approximation approaches [8]. Fletcher and Leyffer found that their branch and bound solver was consistently faster than the other codes by about an order of magnitude.

### Keywords

Batch process; Design; Scheduling; Continuous and discrete time models

The design of batch processes has been a major area of research for the past several decades. In conjunction with the design of batch plants, many different approaches have been proposed for the determination of an optimal schedule for the plant. It has been recognized for some time that in order to increase the efficiency of batch processes, the two tasks of design and scheduling should be considered simultaneously.

The problem is to design a batch process consisting of  $M$  processing steps, in which  $N$  products are made, where all materials follow the same path through the process. This is commonly known as a *multiproduct batch plant*, or a *flow-shop*.

There are two predominant methods for formulating the batch process design and scheduling problem. The first is a *continuous-time formulation* in which the scheduling information is incorporated through a *planning horizon* constraint. This problem can be formulated as a NLP or MINLP depending on whether the number of parallel units is fixed or variable. The solution of this problem does not give the actual schedule, but does guarantee that a feasible schedule exists. A separate problem, typically a MILP, must be solved to find the actual schedule.

The second method for formulating the batch process design and scheduling problem is based on a *state-task-network* (STN) representation. In this approach, the planning horizon is discretized into time steps. Each task must be assigned to both a unit and a time slot. The formulation results in a large MINLP whose solution provides both the plant design and the actual schedule.

### Continuous-Time Formulations

The early work of [10] was based on the *single product campaign* (SPC) scheduling policy. In a single product campaign, all batches of one product are processed one after the other, followed by all of the batches of the next product, and so on.

In this approach, the scheduling information is incorporated by way of a planning horizon constraint. This constraint requires that all products must be completed before the planning horizon,  $H$ , is reached. In a single product campaign, the time between batches of product  $i$  is based on the maximum processing time over all of the stages,

$$t_{Li} = \max_j(t_{ij}),$$

where  $t_{Li}$  is the ‘limiting’ time for product  $i$ . The planning horizon constraint can be written as the sum over all of the products of the limiting time multiplied by the number of batches of each product

$$\sum_i \frac{Q_i}{B_i} T_{Li} \leq H,$$

where  $Q_i$  is the total production of  $i$  and  $B_i$  is the batch size for  $i$ . Because  $Q_i$  and  $B_i$  are variables, this results in a NLP.

In [4] the authors formulated the batch process design and scheduling problem as a MINLP. Their model was based on the SPC model of [10]. In this problem, more than one piece of equipment per stage is available for use in parallel. Rather than solve the MINLP rigorously, they relaxed the number of units per stage to be continuous and solved the resulting NLP. [5] formulated the MINLP using binary 0-1 variables and solved it with an outer approximation method. In addition to the combinatorial nature of the problem due to integer variables, the solution of the problem is complicated by the nonconvex form of the planning horizon constraint.

[2] developed extensions of the SPC formulation to allow more efficient utilization of the batch process equipment. They considered two *mixed-product campaign* (MPC) scheduling policies,

- i) the *unlimited intermediate storage* (UIS) policy; and
- ii) the *zero-wait* (ZW) policy.

As its name implies, a mixed product campaign allows batches of different products to be processed sequentially. For example, a SPC schedule for three batches each of two products A and B would be, AAABBB, while a MPC schedule could be ABABAB. In the zero-wait policy, when a product has completed processing in one stage, it must immediately begin processing in the next stage. Conversely, the UIS policy allows a product to be stored for a period of time before beginning the next processing step. [7] showed that for the case of zero cleanup times, the UIS policy is the most efficient mixed-product campaign policy, while the ZW policy is the most conservative. [2] incorporated the new scheduling policies into the batch process design problem by considering the characteristic cycle time for each policy. The cycle time becomes the basis upon which the planning horizon constraint is imposed.

[3] used the batch design formulation with mixed-product campaign schedules to formulate the batch synthesis, design and scheduling problem. In this formulation the number of stages,  $M$ , in the batch process is not fixed. Instead, each product is required to undergo the same sequence,  $T$ , of processing tasks. Units that each can perform one of the tasks are given, and in addition, 'superunits' are postulated that can combine two or more tasks. The problem is to assign tasks to units, size the units, and determine the number of parallel units in the batch process.

## Problem Formulation

### 1) Binary variables

$$YEX_j = \begin{cases} 1 & \text{if unit } j \text{ exists} \\ 0 & \text{otherwise,} \end{cases}$$

$$YC_{cj} = \begin{cases} 1 & \text{if unit } j \text{ contains} \\ & c \text{ parallel units} \\ 0 & \text{otherwise,} \end{cases}$$

$$Y_{tj} = \begin{cases} 1 & \text{if task } t \text{ is assigned} \\ & \text{to unit } j \\ 0 & \text{otherwise,} \end{cases}$$

$$YF_{tj} = \begin{cases} 1 & \text{if } t \text{ is the first task} \\ & \text{processed in unit } j \\ 0 & \text{otherwise.} \end{cases}$$

### 2) Design constraints

- Task volume requirement,  $V_t^T$ , depends on batch size,  $B_i$ , of each product and size factor,  $S_{it}$ , for each product in each task.

$$V_t^T \geq B_i S_{it}.$$

- The volume of a processing unit  $j$  must be large enough to accommodate task  $t$  if task  $t$  is assigned to unit  $j$ , ( $Y_{tj} = 1$ ).

$$V_j \geq V_t^T - V_j^U (1 - Y_{tj}).$$

- The processing time,  $pt_{ij}$ , for each product in each unit is given by the corresponding time factor,  $t_{it}$ , for each product in task  $t$  if task  $t$  is assigned to unit  $j$ , ( $Y_{tj} = 1$ ).

$$pt_{ij} \geq \sum_t t_{it} Y_{tj}.$$

- The number of batches,  $n_i$ , multiplied by the batch size must satisfy the production requirement,  $Q_i$ , for each product.

$$n_i B_i \geq Q_i.$$

### 3) Parallel equipment constraints

- The number of parallel units in each stage  $j$  is determined by the binary variable  $YC_{cj}$  multiplied by the number  $c$ ,

$$N_j = \sum_c c \cdot YC_{cj}.$$

## 4) Scheduling constraint

- For the UIS policy with zero cleanup times, the planning horizon constraint derived by [2] is used,

$$\sum_i n_i p t_{ij} \leq H \cdot N_j.$$

## 5) Logical constraints

- If a stage  $j$  exists, then at least one processing task must be assigned to it,

$$\sum_t Y_{tj} \geq YEX_j.$$

- If a stage  $j$  does not exist, there can be no tasks assigned to it,

$$Y_{tj} \leq YEX_j.$$

- If a stage  $j$  exists, then one of the tasks assigned to it must be the first task assigned to stage  $j$ ,

$$\sum_t YF_{tj} = YEX_j.$$

- There cannot be more than one first task assigned to each stage,

$$\sum_t YF_{tj} \leq 1.$$

- A task can be the first task assigned to a stage only if the task is among those assigned to the stage,

$$YF_{tj} \leq Y_{tj}.$$

- No tasks that occur before the first task assigned to stage  $j$  can be among those assigned to the stage,

$$Y_{t'j} \leq 1 - YF_{tj} \quad \text{for } t' < t.$$

- If multiple tasks are assigned to a unit, they must be consecutive tasks,

$$Y_{tj} \leq YF_{tj} + Y_{t-1,j}.$$

- One and only one binary variable that determines the number of parallel units in stage  $j$  must be active,

$$\sum_c YC_{cj} = 1.$$

## 6) Objective function

- The objective is to minimize the cost of the plant. [3] used a fixed-charge cost for each unit,  $\gamma_j$ , plus a nonlinear cost function on the size of the unit,

$$\text{Cost} = \sum_j N_j [\gamma_j + \alpha_j V_j^{\beta_j}].$$

This formulation is a MINLP where all binary variables participate linearly and separably. However, it is a non-convex problem due to the cost function, and the *bi-linear* terms in the batch size constraints and the planning horizon constraints. [3] used the *outer approximation* method implemented in DICOPT ([11]) to solve a number of example problems. Due to the nonconvexities in the formulation, there is no guarantee of global optimality with the outer approximation method, but they report good results for the examples presented in the paper.

Two examples are briefly discussed to illustrate the proposed approach for multiproduct batch plants with a variety of scheduling policies. The first example consists of three products with four processing tasks and five potential units and superunits. The MINLP formulation with the SPC policy contains 33 binary variables and 54 continuous variables. With the ZW policy, the number of binary variables drops to 8, with 98 continuous variables. For the UIS policy, the formulation has 33 binary variables with 51 continuous variables.

The second example is larger and contains 6 products with 7 potential units and superunits. The SPC policy formulation contains 46 binary variables and 101 continuous variables. The MINLP formulation for the ZW policy has 11 binary and 374 continuous variables. The UIS policy formulation has 46 binary and 95 continuous variables. In all cases the examples were solved in less than 50 minutes using GAMS/DICOPT ++ on Microvax II.

### Discrete-Time Formulations

A.P.F.D. Barbosa-Póvoa and S. Macchietto, [1], proposed a MILP formulation to address the problem of optimal batch design by simultaneously considering optimizing production schedule. They based their formulation on

- an extended state-task-network (mSTN) representation of the batch plant; and

b) the discrete time representation using *uniform time discretization*.

In the STN representation, proposed in [6], all the materials are represented as states processed through a set of processing steps ('tasks'). In order to incorporate connectivity constraints the extended state-task-network (mSTN) is proposed involving the alternative design configurations considering all permitted equipment and connections allocations. Single campaign is assumed with a cyclic schedule of cycle time  $T$  repeated over a planning horizon  $H$ . A cycle represents a sequence of operations involving the production of all products and the utilization of all resources. The operational characteristics such as the allocation of equipments to tasks, batch sizes, task timings, transport of material and storage profiles are identical in each cycle. The mathematical formulation they proposed involves:

- allocation constraints for the assignment of the tasks to the units
- capacity constraints expressing the limiting equipment capability
- connectivity constraints for determining the connection of different units
- dedicated storage constraints
- mass balances
- production requirement constraints
- an objective function, which is chosen to be either the minimization of the capital cost or the maximization of plant profit.

The main variables of the formulation are:

- a) binary structural variables representing the existence of an equipment;
- b) binary allocation variables for the assignment of a task to a unit at the beginning of a time period;
- c) continuous variables representing the capacity of a unit;
- d) continuous variables corresponding to the batch size of a task to a unit at each time period;
- e) amount of material delivered and received at each time period;
- f) the amount of material transferred at each time period; and
- g) the amount of material stored at each time period.

The proposed formulation correspond to a mixed integer linear programming (MILP) problem since they used linear cost functions to express the capital cost of equipments and time discretization to represent time.

Three examples were solved illustrating:

- a) the effect of limited connectivity and connection cost in the optimal design;
- b) the advantages of considering simultaneously the plant design and plant connectivity rather than optimizing first the equipment sizes and then optimizing plant connectivity.

In later work, Barbosa-Póvoa and C.C. Pantelides, [1], proposed a new mathematical formulation for the optimization of batch plant design considering detailed operation characteristics (i.e., short term scheduling). This formulation also considers a uniform time discretization, the only difference lies in the plant representation. The resource-state-task (RTN) plant representation, [9], was used which corresponds to a more general and uniform description of all available production resources. However, the new formulation shares the main characteristics of the previous presented one with the same basic variables, and constraints.

Both formulations share the limitations of the discrete time formulations, which are that:

- i) they correspond to an approximation of the time horizon; and
- ii) they result in an unnecessary increase of the number of binary variables in particular, and in the overall size of the mathematical model.

A continuous-time formulation was proposed in [12], based on the STN representation and the scheduling formulation proposed in [13]. It gives rise to a mixed integer nonlinear programming problem which is solved using a stochastic MINLP optimizer based on an *evolutionary algorithm* (EA) with *simulated annealing* (SA) presented in [12]. The method is based on a guided stochastic generation of alternative vectors of decision variables, which explore promising areas of the search space through selection, crossover, and mutation operations applied to individuals in a population of solution candidates. It can be used to deal with nonconvex, nondifferentiable functions although it has no guarantee of convergence to even a local optimal solution. The proposed formulation involves the following basic variables:

- Main design variables representing the discrete decisions of selecting a unit ( $j$ ),  $E_j$ , or a storage ( $s$ ),  $E_s$ , or continuous decisions corresponding to the capacity of unit storage or utility,  $V_j$ ,  $V_s$ , and  $U_u$ , respectively.

- Main operation variables corresponding to the discrete decision of allocation of task ( $i$ ) in unit ( $j$ ) at time  $T_l$ ,  $W_{ijl}$ , and the decision of assigning task ( $i$ ) in unit ( $j$ ) between starting time  $T_l$  and end time  $T_{l'}$ , and continuous variables, the time of event ( $l$ ),  $T_l$ , the batch size, the processing time and utility requirement of task ( $i$ ) allocated to unit ( $j$ ) starting at  $T_l$ ,  $B_{ijl}$ ,  $\tau_{ijl}$ ,  $U_{ijl}^u$ , respectively,

Based on these variables the proposed formulation involves:

- 1) Processing task models:

$$U_{ijl}^u = \alpha_{ijl}^u + \beta_{ij}^u B_{ijl}^{\gamma_{ij}^u},$$

expressing the consumption-generation of utilities as a function of batch size;

$$\tau_{ijl} = \alpha_{ijl} + \beta_{ij} B_{ijl}^{\gamma_{ij}} + \sum_u \mu_{ij}^u U_{ijl}^u + \sum_\alpha \mu_{ij}^\alpha A_{jl}^\alpha,$$

expressing the dependence of processing time,  $\tau_{ijl}$ , of batch size,  $B_{ijl}$ , utilities,  $U_{ijl}^u$ , and unit availabilities,  $A_{jl}^\alpha$ .

- 2) Batch size constraints:

$$\phi_{ij}^{\min} V_j W_{ijl} \leq B_{ijl} \leq \phi_{ij}^{\max} V_j W_{ijl}$$

imposing the maximum and minimum capability of unit ( $j$ ) when task ( $i$ ) is performed.

- 3) Timing constraints:

$$W_{ijl}(\tau_{ijl} + T_l) = \sum_{l' > l} X_{ijll'} T_{l'},$$

which establish the relationship between processing time,  $\tau_{ijl}$ , and time of event ( $l$ ),  $T_l$ .

$$0 \leq T_1 \leq T_2 \leq \dots \leq T_{l_{\max}} \leq H,$$

expressing the monotonic increase in event times.

- 4) Allocation constraints:

$$0 \leq \sum_{i \in I_j} \sum_{l'' \leq l'} W_{ijl''} - \sum_{i \in I_j} \sum_{l < l''} \sum_{l'' \leq l'} X_{ijll''} \leq E_j,$$

$$\sum_{i \in I_j} \sum_{l'' \leq l_{\max}} W_{ijl''} = \sum_{i \in I_j} \sum_{l < l''} \sum_{l'' \leq l_{\max}} X_{ijll''},$$

$$W_{ijl} = \sum_{l' > l} X_{ijll'},$$

expressing the relationship between  $W_{ijl}$  and  $X_{ijll'}$  operation variables, [13].

- 5) Material balances written for state  $s$  at event time  $T_l$ :

$$\begin{aligned} C_{sl'} &= C_{sl'-1} \\ &+ \sum_{i \in I_s} \sum_{j \in J_i} \rho_{sij}^{in} \sum_{l < l'} B_{ijl} X_{ijll'} \\ &- \sum_{i \in I_s} \sum_{j \in J_i} \rho_{sij}^{out} B_{ijl'}, \\ 0 &\leq C_{sl'} \leq V_{s0} + V_s. \end{aligned}$$

- 6) Utility constraints written for utility ( $u$ ) at event time  $T_l$ :

$$\begin{aligned} U_{ul'} &= U_{ul'-1} \\ &+ \sum_{i \in I_u} \sum_{j \in J_i} \sum_{l < l'} U_{ijl}^u X_{ijll'} \\ &- \sum_{i \in I_u} \sum_{j \in J_i} U_{ijl'}^u W_{ijl'}, \\ 0 &\leq U_{ul'} \leq U_u, \\ U_{uc} &= \sum_{i \in I_u} \sum_{j \in J_i} \sum_l U_{ijl}^u T_{ijl} W_{ijl}. \end{aligned}$$

- 7) Availability constraints written for unit ( $j$ ) at event time  $T_l$ :

$$\begin{aligned} A_{jl'+1}^\alpha &= \sum_{i \in I_j} A_{jl'}^\alpha \alpha_{ij}^\alpha W_{ijl'} - \sum_{i \in I_j} \beta_{ij}^\alpha W_{ijl'}, \\ A_{jl'}^\alpha &\leq \sum_{i \in I_j} \gamma_{ij}^\alpha W_{ijl'}. \end{aligned}$$

- 8) Existence constraints:

$$\begin{aligned} \sum_{i \in I_j} W_{ijl} &\leq E_j, \\ V_j^{\min} E_j &\leq V_j \leq V_j^{\max} E_j, \\ V_s^{\min} E_s &\leq V_s \leq V_s^{\max} E_s, \end{aligned}$$

that correspond to logical restrictions on production unit and storage tank size if this unit-storage tank is present at the optimal design.

- 9) Production constraints:

$$C_{sl_{\max}} \geq R_s,$$

expressing the requirement of producing at least as much as the market demands for state ( $s$ ).

10) Objective function:

$$\begin{aligned} \text{Profit} = & \sum_{s \in S_p} p_s C_{sI\max} \\ & + \sum_{s \in S_i} p_s (C_{sI\max} - C_{s0}) \\ & - \sum_{s \in S_f} p_s C_{s0} - \sum_u c_u U_{uc}; \end{aligned}$$

the first two terms represent the revenue due to product and intermediate state production, respectively, whereas the last two terms express the cost of raw materials and utilities, respectively,

$$\begin{aligned} \text{Cost} = & \sum_j (E_j \tilde{\alpha}_j + \tilde{\beta}_j V_j^{\gamma_j}) \\ & + \sum_s (E_s \tilde{\alpha}_s + \tilde{\beta}_s V_s^{\gamma_s}); \end{aligned}$$

the first term represent the cost of installing production unit ( $j$ ), whereas the second term correspond to the cost of storage tank ( $s$ ).

$$\text{Objective} = \text{Cost} - \text{Profit}.$$

This above formulation correspond to a MINLP problem with decision variables:  $W_{ijl}, X_{ijl}, B_{ijl}, U_{ijl}^u, T_l$  that correspond to plant operation and  $E_j, E_s, V_j, V_s, U_u$  that represent design decisions. Nonconvexities appear in the timing constraints, material balances, utility constraints as bilinear products of binary and continuous variables and in the objective function in power form of the type  $V_j^{\gamma_j}$  and  $V_s^{\gamma_s}$ . The authors proposed an evolutionary algorithm (EA) with simulated annealing (SA), [12], to solve this problem. They utilized simulated annealing to improve the poor local search ability of EA. A suitable encoding procedure is proposed which results in reduction in the number of constraints and variables by up to 50%. In particular, they explored the mathematical structure of the problem in the following sense. If  $W_{ijl} = 1$  and  $X_{ijl} = 1$ , unit  $j$  exists, it executes operation  $k$  which starts at  $ST^j = l$  finishes at  $FT_k^j = l'$  involving task  $TS_k^j = i$  with batch size  $BS_k^j = B_{ijl}$  and utility usage  $U_{uk}^j = U_{ijl}^u$ . So they proposed to replace  $W_{ijl}, X_{ijl}, B_{ijl}$  and  $U_{ijl}^u$  by the operation sequence of tasks in units: task sequence  $TS^j = (i_1, \dots, i_{N_j})$ , task batch size  $BS^j = (B_1, \dots, B_{N_j})$ , task utility

usage  $U_u^j = (U_1^u, \dots, U_{N_j}^u)$ , start time  $ST^j = (l_1, \dots, l_{N_j})$ , finish time  $FT^j = (l'_1, \dots, l'_{N_j})$ . In this way the decision variables become  $(E_j, V_j, E_s, V_s, U_u, T_l, TS^j, BS^j, U_u^j, ST^j, FT^j)$ . The algorithm starts with an initial guess and evolves a number of candidate instances for these variables. The allocation and the capacity constraints are automatically satisfied by each candidate solution and  $T_l$  are chosen so that the timing constraints are also satisfied. Two examples are presented to illustrate the applicability of the proposed approach to solve batch design problem involving detailed scheduling constraints. Linear and nonlinear task processing times and unit cost models are considered for both the examples. For the first example considering linear functions for processing times and unit cost models the results obtained are compared with a discrete time formulation, [8], and found to outperform it in terms of number of variables which is expected since the formulation is based on the continuous time description and the computational requirement for the solution of their model. Considering nonlinear models for processing times and unit costs, the resulting model for a problem with 4 production units, 4 storage tanks, 5 tasks and 4 states, involves 62 integer and 34 continuous variables and 122 constraints. This example was the largest presented in this work, and required considerable computational effort, 7849.23 CPU seconds on a SUN ULTRASTATION-1.

### Keywords

Decomposition; Primal-dual; Nonlinear; Mixed integer

Decomposition methods, such as the classical Benders decomposition (cf. ▶ [Generalized Benders decomposition](#)), [1], and Dantzig–Wolfe decomposition, [3], have been used to solve many different large structured optimization problems, by decomposing them with the help of relaxation of constraints or fixation of variables. The success of such an approach depends very much on the structure of the problem. In some cases these methods are very efficient, but in other cases they are not competitive with other techniques.

However, the simple elegance of these basic principles has inspired many researchers to propose modifications of the basic methods, mostly aimed at improving the efficiency of the methods, but also aimed at extending the applicability of the approaches.

Dantzig–Wolfe decomposition, originally for linear programming problems, [3], has been extended to convex nonlinear programming problems, [2], under several names, for example generalized linear programming. We will here simply use the term ‘nonlinear Dantzig–Wolfe decomposition’.

Benders decomposition, originally for linear mixed integer programming problems, [1], has been extended to partly convex nonlinear programming problems, [5], under the name ‘generalized Benders decomposition’.

On the other hand, among the numerous suggestions for modifications to increase the efficiency, there is one which in a way shares the simplicity and clear principle of the basic methods, namely *cross decomposition*, [11]. Usually described as a combination of Benders decomposition and Dantzig–Wolfe decomposition, simultaneously using the two methods in an iterative manner, the method borrows its basic convergence properties from these two methods. However, one can also view cross decomposition as the more general method, and Benders and Dantzig–Wolfe decomposition as modifications of cross decomposition, obtained by excluding one of the subproblems and one of the master problems.

Cross decomposition was originally developed for linear mixed integer programming problems, [11], but the approach is more general and not restricted to such problems. The first application of cross decomposition was to the capacitated facility location problem, [12], and produced a solution method which is recognized as one of the most efficient existing methods for that problem. However, another early application was to the stochastic transportation problem (a convex problem with linear parts), [10].

Here we will describe ‘generalized cross decomposition’, which was first proposed in [6], and more thoroughly treated in [7]. The generalization of the procedure, parallel to that in [5] for generalized Benders decomposition, enables the solving of nonlinear programming problems with convex parts, for example nonlinear mixed integer programming problems, see for example [4].

**The Problem**

Consider the following general optimization problem.

$$(P) \begin{cases} v^* = \min f(x, y) \\ \text{s.t.} & G_1(x, y) \leq 0 \\ & G_2(x, y) \leq 0 \\ & x \in X \\ & y \in Y \end{cases}$$

where  $X$  and  $Y$  are compact, nonempty sets. Assume that  $X$  is convex and  $f, G_1$  and  $G_2$  are proper convex functions in  $x$  for any fixed  $y \in Y$ , i. e. that the problem is convex in  $x$ . Also assume that that  $f, G_1$  and  $G_2$  are bounded and Lipschitzian on  $(X, Y)$ . Note that we do not assume any convexity in the  $y$ -variables. An important case is when  $Y$  is a (finite) set of integers.

Furthermore we assume the following (as was done in [5] for generalized Benders decomposition). The optimization with respect to  $x$  of the Lagrangian functions must be possible to do ‘essentially independent’ of  $y$  (called property P by A.M. Geoffrion). We therefore assume that the functions  $q_1, q_2, q_3$  and  $q_4$  exist, such that  $f(x, y) + u_1^\top G_1(x, y) + u_2^\top G_2(x, y) = q_1(q_3(x, u), y, u), \forall x, y, u$ , and  $\tilde{u}_1^\top G_1(x, y) + \tilde{u}_2^\top G_2(x, y) = q_2(q_4(x, \tilde{u}), y, \tilde{u}), \forall x, y, \tilde{u}$ , where  $q_3$  and  $q_4$  are scalar functions,  $q_1$  and  $q_2$  are increasing in their first argument, and  $\tilde{u}$  is assumed to belong to the set of all possible nonnegative, normalized directions  $C = \{\tilde{u} \geq 0: e^\top \tilde{u} = 1\}$ , where  $e$  is a vector of ones. Since  $f, G_1$  and  $G_2$  are convex in  $x$  and bounded and Lipschitzian on  $(X, Y)$ , the same applies to  $q_1$  for any fixed  $u \geq 0$ , and to  $q_2$  for any fixed  $\tilde{u} \in C$ .

The optimal solution of P is denoted by  $(x^*, y^*)$ . We will also mention the case when P is convex, i. e. where  $f, G_1$  and  $G_2$  are convex functions (in  $y$  too) and  $Y$  is a convex set. Lagrangian duality can be used to get a dual solution (the optimal Lagrange multipliers), denoted by  $u^* = (u_1^*, u_2^*)$ .

Let us for convenience introduce the following notation.

$$\begin{aligned} L(x, y, u) &= f(x, y) + u_1^\top G_1(x, y) + u_2^\top G_2(x, y), \\ \tilde{L}(x, y, \tilde{u}) &= \tilde{u}_1^\top G_1(x, y) + \tilde{u}_2^\top G_2(x, y), \\ L_1(x, y, u_1) &= f(x, y) + u_1^\top G_1(x, y), \\ \tilde{L}_1(x, y, \tilde{u}_1) &= \tilde{u}_1^\top G_1(x, y). \end{aligned}$$

**The Primal Master Problem**

Using the primal structure of (P) we can rewrite it as

$$v^* = \min_{y \in Y} h(y),$$

where  $\forall y \in V$ ,

$$\begin{cases} h(y) = \min f(x, y) \\ \text{s.t.} & G_1(x, y) \leq 0 \\ & G_2(x, y) \leq 0 \\ & x \in X \end{cases}$$

and

$$V = \left\{ y \in Y : \exists x \in X : \begin{array}{l} G_1(x, y) \leq 0, \\ G_2(x, y) \leq 0 \end{array} \right\}.$$

The problem is convex in  $x$ , so we can use Lagrangian duality to get,  $\forall y \in V$ ,

$$h(y) = \max_{u \geq 0} \min_{x \in X} L(x, y, u).$$

A similar expression can be obtained for  $V$ :

$$V = \left\{ y \in Y : \left( \max_{u \in C} \min_{x \in X} \tilde{L}(x, y, \tilde{u}) \right) \leq 0 \right\}.$$

The full primal master problem is given below:

$$\begin{cases} v^* = \min q \\ \text{s.t.} & q \geq \min_{x \in X} L(x, y, u), \quad \forall u \geq 0, \\ & 0 \geq \min_{x \in X} \tilde{L}(x, y, \tilde{u}), \quad \forall \tilde{u} \in C, \\ & y \in Y. \end{cases}$$

This problem has an infinite number of constraints, one for each nonnegative dual point and one for each nonnegative dual direction. Each constraint contains an optimization problem (minimization with respect to  $x$ ), which should in theory be solved for all  $y \in Y$  before the main problem,  $\min_{y \in Y} h(y)$ , can be solved. However, we have

$$\min_{x \in X} L(x, y, u) = q_1 \left( \min_{x \in X} q_3(x, u), y, u \right)$$

and

$$\min_{x \in X} \tilde{L}(x, y, \tilde{u}) = q_2 \left( \min_{x \in X} q_4(x, \tilde{u}), y, \tilde{u} \right).$$

Since  $q_1$  and  $q_2$  are proper, convex, bounded and Lipschitzian on  $X$ , and  $X$  is compact and convex, the optima in  $x$  (for fixed  $u$  and  $\tilde{u}$ ) will be attained.  $q_1$  and  $q_2$  are increasing in their first argument, so the minimization in  $x$  can be made in  $q_3$  and  $q_4$  instead, and the value of  $y$  will thus not influence the result of this minimization. The minimization over  $x$  can be made once (for any  $y$ ) and the result will then be true for all  $y \in Y$ .

The *relaxed primal master problem* only contains a finite number of cuts (with index sets  $P_U$  and  $R_U$ ) which gives an approximate description of  $h(y)$  and  $V$ , and an optimal objective function value,  $v_{PM} \leq v^*$ . Since the part of the problem that is described by the constraints is convex in  $x$ ,  $v_{PM}$  will converge asymptotically towards  $v^*$  as the sets of constraints grow.

The constraints can now be expressed as

$$\begin{aligned} q &\geq q_1 \left( \min_{x \in X} q_3(x, u^{(k)}), y, u^{(k)} \right), \quad \forall k \in P_U, \\ 0 &\geq q_2 \left( \min_{x \in X} q_4(x, \tilde{u}^{(k)}), y, \tilde{u}^{(k)} \right), \quad \forall k \in R_U. \end{aligned}$$

The minimization in  $x$  can now be made independently in each constraint, since the other arguments in  $q_3$  and  $q_4$ , namely  $u$  and  $\tilde{u}$ , are fixed. Since the minima are attained, we use the notation  $x^{(k)}$ ,  $\forall k \in P_U$ , and  $\tilde{x}^{(k)}$ ,  $\forall k \in R_U$ , for the minimizers of  $q_3$  and  $q_4$ .

Inserting this, we obtain the final form of the relaxed primal master problem.

$$(PM) \quad \begin{cases} v_{PM} = \min q \\ \text{s.t.} & q \geq L(x^{(k)}, y, u^{(k)}), \quad \forall k \in P_U, \\ & 0 \geq \tilde{L}(\tilde{x}^{(k)}, y, \tilde{u}^{(k)}), \quad \forall k \in R_U, \\ & y \in Y. \end{cases}$$

The constraints in the first set are called *value cuts*, and those in the second set are called *feasibility cuts*.

### The Dual Master Problem

Using Lagrangian duality on (P) yields a relaxation and a lower bound,  $v_L$ , on  $v^*$ :

$$v_L = \max_{u_1 \geq 0} g(u_1)$$

where,  $\forall u_1 \geq 0$ ,

$$\begin{cases} g(u_1) = \min L_1(x, y, u_1) \\ \text{s.t.} & G_2(x, y) \leq 0 \\ & x \in X \\ & y \in Y. \end{cases}$$

This leads to a dual master problem, which is a convexification of the problem. If (P) is not convex a duality gap might occur. We denote the subset of the solutions that are included by  $(x^{(k)}, y^{(k)})$ ,  $\forall k \in P_X$ , and obtain the restricted dual master problem as

$$(DM) \begin{cases} v_{DM} = \max q \\ \text{s.t.} & q \leq L_1(x^{(k)}, y^{(k)}, u_1), \\ & \forall k \in P_X, \\ & u_1 \geq 0. \end{cases}$$

**The Subproblems**

The primal subproblem is a convex problem in  $x$ , obtained by fixing  $y$  to  $\bar{y}$ .

$$(PS) \begin{cases} h(\bar{y}) = \min f(x, \bar{y}) \\ \text{s.t.} & G_1(x, \bar{y}) \leq 0 \\ & G_2(x, \bar{y}) \leq 0 \\ & x \in X. \end{cases}$$

A solution to (PS) is assumed to consist of both a primal solution,  $x^{(k)}$ , and a dual solution,  $(u_1^{(k)}, u_2^{(k)})$ . Due to the convexity we can use Lagrangian duality without creating a duality gap.

$$(PSL) \quad h(\bar{y}) = \sup_{u \geq 0} \min_{x \in X} L(x, \bar{y}, u).$$

If (PS) is infeasible, (PSL) will be unbounded in  $u$ , and a solution is represented by a direction,  $\tilde{u}^{(k)}$ . A valid cut for the primal master problem also requires a corresponding primal solution,  $\hat{x}^{(k)}$ , obtained by solving

$$\min_{x \in X} \tilde{L}(x, \bar{y}, \tilde{u}^{(k)}).$$

(Note that  $\hat{x}^{(k)}$  is not feasible in (PS).)

The dual subproblem is the following (nonconvex) problem, obtained by relaxing the first set of constraints in (P) and fixing the Lagrange multipliers  $u_1$  to  $\bar{u}_1$ :

$$(DS) \begin{cases} g(\bar{u}_1) = \min L_1(x, y, \bar{u}_1) \\ \text{s.t.} & G_2(x, y) \leq 0 \\ & x \in X \\ & y \in Y \end{cases}$$

To handle unbounded dual solutions,  $\tilde{u}_1$ , we can use the following subproblem:

$$(UDS) \begin{cases} \tilde{v}(\tilde{u}_1) = \min \tilde{L}_1(x, y, \tilde{u}_1) \\ \text{s.t.} & G_2(x, y) \leq 0 \\ & x \in X \\ & y \in Y. \end{cases}$$

(UDS) does not produce a bound on  $v^*$ , but if  $\tilde{v}(\tilde{u}_1) \leq 0$  it yields a dual cut that will eliminate  $\tilde{u}_1$ .

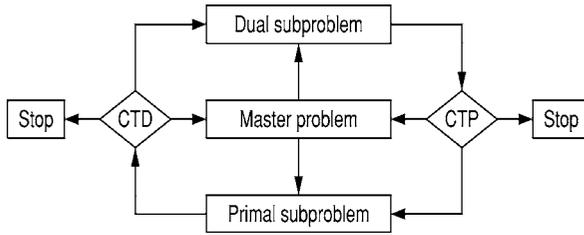

**The Cross Decomposition Algorithm**

In the subproblem phase of the cross decomposition method we iterate between the primal subproblem (PS) and the dual subproblem (DS) (or (UDS)).

The primal subproblem, (PS), supplies an upper bound,  $h(\bar{y})$ , on  $v^*$ , and  $\bar{u}_1$  for the dual subproblem. The dual subproblem, (DS), supplies a lower bound,  $g(\bar{u}_1)$ , on  $v^*$ , and  $\bar{y}$  for the primal subproblem. If (PS) has an unbounded solution,  $\tilde{u}_1$ , we use (UDS) (instead of (DS)) to get  $\bar{y}$ .

Unfortunately, the lack of controllability for the important parts of the solutions,  $y$  and  $u_1$ , which occurs unless the problem is strictly convex, implies that this procedure alone cannot be expected to converge to the optimal solution.

We therefore need to use the master problems to ensure convergence. (PM) or (DM) can be solved with all the constraints generated by the subproblem solutions. We have all the known results for generalized Benders or nonlinear Dantzig–Wolfe decomposition to fall back on, so this technique is well known. After the solution of one master problem, the subproblem phase is reentered. (We do not switch to Benders or Dantzig–Wolfe decomposition completely.)

MINLP: Generalized Cross Decomposition, Figure 1

We will later describe convergence tests that tell us exactly when to use a master problem. The existence of such convergence tests is a very important aspect of cross decomposition. Let us, before getting any further, give below a short algorithm for cross decomposition algorithm.

Let us denote the convergence test in step 3 (before (PS)) by CTP and the convergence test in step 6 (before (DS)) by CTD. The optimality tests (step 2 and step 5) are included in the convergence tests, and the decision about where to go is based on the results of both tests. The algorithm is pictured in Fig. 1.

0	Get a starting $\bar{u}$ .
1	Solve (DS) (or (UDS)).
2	IF optimal go to 8.
3	IF not convergence, go to 7A (or 7B).
4	Solve (PS).
5	IF optimal go to 8.
6	IF not convergence go to 7B (or 7A). ELSE go to 1.
7A	Solve (PM). Go to 4.
7B	Solve (DM). Go to 1.
8	Stop. The solution from (PS) is optimal.

We can start with either one of the subproblems, so a good primal starting solution can also be utilized.

If CTP indicates that (PS) will not give further convergence, we use (PM). If CTD indicates failure of convergence for (DS), we can use (DM) (which however gives certain convergence only if (P) is convex). After (PM) we go to (PS) and after (DM) we go to (DS), in order to make use of the output of the master problems. In the general nonconvex case, it is not necessary to use (DM). It is even possible to omit the convergence tests CTD if only (DM) is used.

## The Convergence Tests

Returning to the question of convergence in the subproblem phase, we make the following definitions of  $\varepsilon$ -improvements.

‘ $\varepsilon$ -bound-improvement’ is an improvement of at least  $\varepsilon$  of the upper or lower bound.

‘ $\varepsilon$ -cut-improvement’ is a generation of a new, so far unknown cut, that is at least  $\varepsilon$  better (i. e. has a value of at least  $\varepsilon$  higher or lower) than all known cuts at some point.

Discussing *linear mixed integer problems*, as in [11], one can let  $\varepsilon = 0$ . In such a case we simply omit  $\varepsilon$  from the above notation.

Cut-improvement thus means that a new cut will be included in one of the restricted master problems and that the description of the functions  $h(y)$  or  $g(u_1)$  or the set  $Y$  is refined. By ‘improvement’ we will, in the rest of this paper mean bound-improvement and/or cut-improvement. When using unbounded solutions as input no finite bounds are obtained, so bound-improvement can not appear. Also, a cut giving a cut-improvement can be a value cut or a feasibility cut, i. e. generated by output in the form of unbounded as well as bounded solutions.

Let us by *primal cut-improvement* denote generation of a primal cut (for (PM)) and by *dual cut-improvement* denote generation of a dual cut (for (DM)). We also use the notation ‘primal’ or ‘dual bound-improvement’ to indicate which of the two subproblems that gave the improvement, i. e. *primal bound-improvement* means that  $h(\bar{y}) < \bar{v}$  and *dual bound-improvement* means that  $g(\bar{u}_1) > \underline{v}$ . ( $\bar{v}$  is the least upper bound known and  $\underline{v}$  the largest lower bound known.)

The convergence tests are originally formulated to give the answers to the following questions.

- Can  $\bar{y}$  give a bound-improvement in (PS)?
- Can  $\bar{u}_1$  give a bound-improvement in (DS)?

Testing extreme rays,  $\bar{u}_1$ , for convergence, we note that the subproblem (UDS) can not give bound-improvement. We call the test of unbounded solutions CTDU.

We now give the convergence tests, CT, with strict inequalities, following [11]:

CTP	If $L(x^{(k)}, \bar{y}, u^{(k)}) < \bar{v}$ , $\forall k \in P_U$ , and $\tilde{L}(\hat{x}^{(k)}, \bar{y}, \tilde{u}^{(k)}) < 0$ , $\forall k \in R_U$ , then $\bar{y}$ will give primal improvement. If not, use a master problem.
CTD	If $L_1(x^{(k)}, y^{(k)}, \bar{u}_1) > \underline{v}$ , $\forall k \in P_X$ , then $\bar{u}_1$ will give dual improvement. If not, use a master problem.
CTDU	If $\tilde{L}_1(x^{(k)}, y^{(k)}, \tilde{u}_1) > 0$ , $\forall k \in P_X$ , then $\tilde{u}_1$ will give dual cut-improvement. If not, use a master problem.

We call CTD and the first part of CTP *value convergence tests* and CTDU and the second part of CTP *feasibility convergence tests*. This conforms to the notation of value and feasibility cuts in the master problems.

One can show that the convergence tests CTP and CTD are necessary for bound-improvement and sufficient for cut- or bound-improvement, see [7]. The convergence tests CTDU are sufficient for cut-improvement.

However, there can be an infinite number of primal and/or dual improvements, so one can not be certain that CT will fail within a finite number of steps. For this reason it is necessary to consider  $\varepsilon$ -improvements.

We need the following  $\varepsilon$ -convergence tests, CT  $\varepsilon$ :

CTP $\varepsilon$	If $L(x^{(k)}, \bar{y}, u^{(k)}) \leq \bar{v} - \varepsilon$ , $\forall k \in P_U$ , and $\tilde{L}(\hat{x}^{(k)}, \bar{y}, \tilde{u}^{(k)}) \leq -\varepsilon$ , $\forall k \in R_U$ , then $\bar{y}$ will give primal $\varepsilon$ -improvement. If not, use a master problem.
CTD $\varepsilon$	If $L_1(x^{(k)}, y^{(k)}, \bar{u}_1) \geq \underline{v} + \varepsilon$ , $\forall k \in P_X$ , then $\bar{u}_1$ will give dual $\varepsilon$ -improvement. If not, use a master problem.
CTDU $\varepsilon$	If $\tilde{L}_1(x^{(k)}, y^{(k)}, \tilde{u}_1) \geq \varepsilon$ , $\forall k \in P_X$ , then $\tilde{u}_1$ will give dual $\varepsilon$ -cut-improvement. If not, use a master problem.

The  $\varepsilon$ -value convergence tests correspond to the value cuts of the master problems, and the  $\varepsilon$  used corresponds directly to a change of  $\varepsilon$  of the bounds ( $\varepsilon$ -bound-improvement). The  $\varepsilon$ -feasibility convergence tests, on the other hand, correspond to feasibility cuts of the master problems, and the  $\varepsilon$  used corresponds to the ‘infeasibility’ it gives some previously feasible points, which is what we call  $\varepsilon$ -cut-improvement for feasibility cuts. While these  $\varepsilon$ -tests are sufficient for  $\varepsilon$ -

improvement, they are not necessary. To prove necessity would require an inverse Lipschitz assumption, namely that for points a certain distance apart, the value of a function (the feasibility cut) should differ by at least a certain amount. The following result is proved in [7].

The  $\varepsilon$ -value convergence tests of CTP  $\varepsilon$ , the feasibility convergence tests of CTP and the  $\varepsilon$ -convergence tests CTD  $\varepsilon$  are necessary for  $\varepsilon$ -bound-improvement. The  $\varepsilon$ -convergence tests CT  $\varepsilon$  are sufficient for  $\varepsilon$ -bound- or  $\varepsilon$ -cut-improvement, in the sense that they are sufficient for one of the following.

- I)  $\varepsilon$ -bound-improvement.
- II)  $\varepsilon$ -cut-improvement.
- III)  $\varepsilon_1$ -bound-improvement and  $\varepsilon_2$ -cut-improvement, where  $\varepsilon_1 + \varepsilon_2 = \varepsilon$ .

Now it is possible to verify finiteness of the convergence tests. A formal proof for this can be found in [7]. The following reasoning is used.

When the bounded set  $Y$  is completely described with an accuracy better than  $\varepsilon$  by either value cuts or feasibility cuts, the  $\varepsilon$ -convergence tests will fail (if not earlier). Each time the  $\varepsilon$ -convergence tests do not fail, we will get improvement according to one of the three cases mentioned above.

A finite number of  $\varepsilon$ -bound-improvements is obviously sufficient to decrease the finite distance between  $\bar{v}$  and  $v^*$  to less than  $\varepsilon$ . After an  $\varepsilon$ -cut-improvement, the new cut describes  $h(y)$  with an accuracy better than  $\varepsilon$  in the area around  $\bar{y}$  where  $h(y) < L(x^{(l)}, y, u^{(l)}) + \varepsilon$ . Due to the Lipschitzian property of the functions  $f$ ,  $G_1$  and  $G_2$ , there is a least distance,  $\delta$ , proportional to  $\varepsilon$ , from  $\bar{y}$  to any point  $y$  violating this inequality, and the  $\varepsilon$ -convergence tests will fail for any point with a distance to  $\bar{y}$  less than  $\delta$ . The bounded set  $V$  can be completely covered by a finite number of such areas.

In the third case, an  $\varepsilon_1$ -bound-improvement together with an  $\varepsilon_2$ -cut-improvement, where  $\varepsilon_1 + \varepsilon_2 = \varepsilon$ , we can ignore the least of  $\varepsilon_1$  and  $\varepsilon_2$ , leaving us with the other one greater or equal to  $\varepsilon/2$ . This yields one of the two cases above, so exchanging  $\varepsilon$  for  $\varepsilon/2$  finiteness is still assured.

For unbounded solutions to (PS), any  $y$  satisfying  $\tilde{L}(\hat{x}^{(l)}, y, \tilde{u}^{(l)}) > -\varepsilon$  will make the  $\varepsilon$ -convergence tests fail, and because of the Lipschitzian property of  $G_1$  and  $G_2$  there is a least distance,  $\delta$  (proportional to  $\varepsilon$ ), from  $\bar{y}$  to any  $y$  not making the  $\varepsilon$ -convergence tests fail. Thus an area of a certain least size is made ‘infeasible’, and

the bounded set  $Y \setminus V$  can be covered by a finite set of such areas. Thus CTP  $\varepsilon$  will fail within a finite number of steps.

Note that it is enough that CTP  $\varepsilon$  fails. To obtain finiteness we do not need to use CTD  $\varepsilon$ , even if it might be useful in practice. We cannot show that CTD  $\varepsilon$  will fail within a finite number of steps. Dual  $\varepsilon$ -bound-improvement can only occur a finite number of times, but dual  $\varepsilon$ -cut-improvement can occur an infinite number of times, since the area to be covered by the cuts is the nonnegative orthant of  $u_1$ .

We therefore require that (PM) is used regularly. (One could even skip (DM) completely.) The following is our main result.

**Theorem 1** *The generalized cross decomposition algorithm equipped with  $\varepsilon$ -convergence tests CT  $\varepsilon$  finds an  $\varepsilon$ -optimal solution to (P) in a finite number of steps, if the generalized Benders decomposition algorithm does.*

All the results for generalized Benders decomposition can be directly used for generalized cross decomposition, especially the following two.

In [5] it is shown that generalized Benders decomposition has finite exact convergence if  $Y$  is a finite discrete set. The worst case is solving the primal subproblem with each possible  $y \in Y$ , which will give a perfect description of  $h(y)$  and  $V$  on  $Y$ .

Therefore we know that if  $Y$  is a finite discrete set, the generalized cross decomposition algorithm will solve P exactly in a finite number of steps.

It is also shown in [5] that generalized Benders decomposition terminates in a finite number of steps to an  $\varepsilon$ -optimal solution, i. e. where  $\bar{v} - \underline{v} \leq \varepsilon$  for any given  $\varepsilon > 0$ , if the set of interesting  $(u_1, u_2)$ -solutions (possible optimal solutions to the primal subproblem) is bounded and  $Y \subseteq V$ . This makes the primal feasibility cuts (and the corresponding convergence tests) unnecessary. So for generalized cross decomposition, we know the following.

If  $h(y)$  is bounded from above for all  $y \in Y$ , i. e. (PS) has a feasible solution for every  $y \in Y$ , then the cross decomposition algorithm (without UDS and the  $\varepsilon$ -feasibility convergence tests of CT  $\varepsilon$ ) will yield finite  $\varepsilon$ -convergence, i. e. yield  $\bar{v} - \underline{v} \leq \varepsilon$  in a finite number of steps, for any given  $\varepsilon > 0$ .

If  $Y \not\subseteq V$  one might get asymptotic convergence of the feasibility cuts, i. e. solutions getting closer and

closer to the feasible set, but never actually becomes feasible. If one is reluctant to base a stopping criterion on  $\varepsilon$ -feasible solutions, one could use penalty functions, which transforms feasibility cuts to value cuts and gives better possibilities of handling cases where  $Y \not\subseteq V$ . One could also use artificial variables for this purpose. As for nonlinear penalty function techniques, one should not forget the Lipschitzian assumption made.

The practical motivation behind cross decomposition is to replace the hard primal master problem with the easier dual subproblem to the largest possible extent. Therefore the theoretical result that generalized cross decomposition equipped with  $\varepsilon$ -convergence tests does not have asymptotically weaker convergence than generalized Benders decomposition, is quite satisfactory.

Finally one might mention that these approaches also has been applied to pure (not mixed) integer programming problems in [8] (nonlinear) and [9] (linear). In such cases, various duality gaps appear, and exact solution is not possible. However, the approach may be useful for obtaining good bounds on the objective function value, which are to be used in branch and bound methods.

Global optimization; Twice-differentiable MINLPs; Branch and bound;  $\alpha$ BB algorithm

The  $\alpha$ BB global optimization algorithm for continuous twice-differentiable NLPs (cf. ▶  **$\alpha$ BB algorithm**) [2,4,5,6,8,18] can be used to design global optimization algorithms for *mixed integer nonconvex problems* [1,3,7]. One such algorithm, the *special structure mixed integer  $\alpha$ BB algorithm* (SMIN- $\alpha$ BB) is designed to address the class of *MINLPs* in which all the integer variables are binary variables that participate in linear or mixed-bilinear terms and in which the nonconvex functions in the continuous variables have continuous second order derivatives. This algorithm is an extension of the  $\alpha$ BB algorithm and branching is performed on both the continuous and the binary variables. A second algorithm, the *general structure mixed integer  $\alpha$ BB algorithm* (GMIN- $\alpha$ BB), guarantees convergence to the global optimum of a much broader class of problems. The integer variables may participate in the problem in a very general way, provided that the continuous relaxation of the MINLP is  $C^2$  continuous. This article describes both algorithms.

## The SMIN- $\alpha$ BB Algorithm

The *SMIN- $\alpha$ BB algorithm* [1,3,7] guarantees finite  $\epsilon$ -convergence to the global solution of MINLPs belong-

ing to the class

$$\left\{ \begin{array}{l} \min_{\mathbf{x}, \mathbf{y}} \quad f(\mathbf{x}) + \mathbf{x}^\top A_f \mathbf{y} + c_f^\top \mathbf{y} \\ \text{s.t.} \quad g_i(\mathbf{x}) + \mathbf{x}^\top A_{g,i} \mathbf{y} + c_{g,i}^\top \mathbf{y} \leq 0, \\ \quad \quad i = 1, \dots, m, \\ \quad \quad h(\mathbf{x}) + \mathbf{x}^\top A_{h,i} \mathbf{y} + c_{h,i}^\top \mathbf{y} = 0, \\ \quad \quad i = 1, \dots, p, \\ \mathbf{x} \in [\mathbf{x}^L, \mathbf{x}^U] \\ \mathbf{y} \in \{0, 1\}^q \end{array} \right. \quad (1)$$

where  $f(\mathbf{x})$ ,  $g(\mathbf{x})$ , and  $h(\mathbf{x})$ , are continuous, twice-differentiable functions,  $m$  is the number of inequality constraints,  $p$  is the number of equality constraints,  $q$  is the dimension of the binary variable vector,  $A_f$ ,  $A_{g,i}$  and  $A_{h,i}$  are  $n \times q$  matrices, and  $c_f$ ,  $c_{g,i}$  and  $c_{h,i}$  are  $q$ -dimensional vectors.

The main features of any *branch and bound algorithm* are the strategy used to generate valid lower and upper bounds for the problem and the selection criteria for the branching node and the branching variable. Optionally, a procedure to tighten the variable bounds may be considered. Each one of these issues is examined in the context of the SMIN- $\alpha$ BB algorithm.

### Generation of Valid Upper and Lower Bounds

A local solution of the nonconvex MINLP (1) using one of the algorithms described in [13] constitutes a valid upper bound on the global optimum solution of that problem. The *generalized Benders decomposition* (GBD) [10,14] or a standard MINLP branch and bound algorithm (B&B) [9,11,15,19,20] may be used to obtain such a solution. When there are no mixed-bilinear terms, the *outer approximation with equality relaxation* (OA/ER) [12,16] may also be used. Alternatively, the binary variables may be fixed to a combination of 0 and 1 values and the resulting nonconvex NLP may be solved locally.

A relaxed problem which can be solved to global optimality must be constructed from problem (1) in order to obtain a valid lower bound. The class of MINLPs in which the continuous functions  $f(\mathbf{x})$ ,  $g_i(\mathbf{x})$ , and  $h_i(\mathbf{x})$ , are convex can be solved to global optimality using the GBD or B & B algorithms, and, when

there are no mixed-bilinear terms, the OA/ER algorithm. To identify a *guaranteed lower bound* on the solution of the problem, it therefore suffices to construct convex underestimators for the nonconvex functions  $f(\mathbf{x})$ ,  $g_i(\mathbf{x})$ , and  $h_i(\mathbf{x})$ , and to solve the resulting problem with one of these algorithms. The rigorous *convexification/relaxation strategy* used in the  $\alpha$ BB algorithm for nonconvex continuous problem [2,4,5,6] allows the construction of the desired lower bounding MINLP. This scheme is based on a decomposition of the functions into a sum of terms with special mathematical structure, such as linear, convex, bilinear, trilinear, fractional, fractional trilinear, univariate concave and general nonconvex terms. A different convex relaxation technique is then applied for each class of term. The fact that a summation of convex functions is itself a convex function is then used to construct overall function underestimators and arrive at a convex lower bounding MINLP.

### Selection of Branching Node

A list of the lower bounds on all the nodes that have not yet been explored during the branch and bound procedure is maintained. A number of approaches can be used to select the next branching node, such as depth-first, breadth-first or smallest lower bound first. Since the purpose of the algorithm is to identify the global solution of the problem, all promising regions, that is, all regions for which the lower bound is less than or equal to the best upper bound on the solution, must be explored. The strategy that usually minimizes the number of nodes to be examined and therefore the CPU requirements of the algorithm is used to choose the next branching node in the SMIN- $\alpha$ BB algorithm. Thus, the node with the smallest lower bound is selected.

### Selection of Branching Variable

Several strategies can be used to select the next variable to be branched on. If a continuous variable is judiciously chosen, the partition results in an improvement of the lower bound on the problem through a tightening of the convex relaxation of the nonconvex continuous functions. Binary variables have an indirect effect

on the quality of the convex underestimators as they influence the range of values that the continuous variables can take on.

A first branching variable selection scheme exploits the direct relationship between the range of the continuous variables and the quality of the lower bounds and therefore branches only on these variables. One of the rules available for the  $\alpha$ BB algorithm [2] is used for the selection. These are based on the size of the variable ranges, or on a measure of the quality of the underestimator for each term, or on a measure of each variable's overall contribution to the quality of the underestimators.

A second approach aims to first tackle the combinatorial aspects of the problem by branching only on binary variables for the first  $q$  levels of the branch and bound tree, where  $q$  is the number of binary variables. The nonconvexities are dealt with on subsequent levels of the tree, by branching on the continuous variables. The specific binary variable used for branching is chosen randomly or from a priority assigned on the basis of its effect on the structure of the problem. In particular, the binary variables that influence the bounds on the greatest number of variables are given the highest priorities. Once all the binary variables have been fixed, the problems that must be considered are *continuous* nonconvex and convex problems for the upper and lower bound respectively. The bounding of the nodes below level  $q$  is therefore less computationally intensive than above that level.

A third approach also involves branching on the continuous and binary variables although the choice is no longer based on the level in the tree. To increase the impact of binary variable branching on the quality of the lower bound, such a variable is selected when a continuous relaxation of the problem indicates that the two children node will have significantly different lower bounds, and that one of them may even be infeasible. Thus, if one of the binary variables is close to 0 or 1 at a local solution of the continuous relaxation, it is branched on. The degree of closeness is an arbitrary parameter which can typically be set to 0.1 or 0.2. If no 'almost-integer' binary variable is found, a continuous variable is selected for branching. In general, this hybrid strategy results in a faster im-

provement in the lower bounds than the second approach, but it is more computationally intensive because a continuous relaxation must be solved before selecting a branching variable and a larger number of MINLP nodes may be encountered during the branch and bound search.

### Variable Bound Updates

The tightening of variable bounds is a very important step because of its impact on the quality of the underestimators. For continuous variables, the strategies developed for the  $\alpha$ BB algorithm may be used [2]. For the SMIN- $\alpha$ BB algorithm, they rely on the solution of several convex MINLPs in the optimization-based approach, or the iterative interval evaluation of the constraints in the interval-based approach. In this latter case, the binary variables are relaxed during the interval computation.

```

PROCEDURE binary variable bound update()
  Consider  $R = \{(\mathbf{x}, \mathbf{y}) \in F : y_i = 0\}$ ;
  Test interval feasibility of  $R$ ;
  IF infeasible, set  $y_i^L = 1$ ;
  Consider  $R = \{(\mathbf{x}, \mathbf{y}) \in F : y_i = 1\}$ ;
  Test interval feasibility of  $R$ ;
  IF infeasible,
    IF  $y_i^L = 1$ , RETURN(infeasible node);
    ELSE, set  $y_i^U = 0$ ;
  RETURN(new bounds  $y_i^L$  and  $y_i^U$ );
END binary variable bound update;

```

### Procedure for binary variable bound updates

In the case of binary variables, successful bound updates are beneficial in two ways. First, they indirectly lead to the construction of tighter underestimators as they affect the continuous variable bounds. Second, they allow a binary variable to be fixed and therefore decrease the number of combinations that potentially need to be explored. An interval-based strategy can be used to carry out binary variable bound updates. Given the current upper bound  $\bar{f}^*$  on the global optimum solution, the feasible region  $F$  is defined by the constraints appearing in the nonconvex problem, a new

constraint  $f(\mathbf{x}) + \mathbf{x}^\top A_f \mathbf{y} + \mathbf{c}_f^\top \mathbf{y} \leq \bar{f}^*$ , and the box  $(\mathbf{x}, \mathbf{y}) \in [\mathbf{x}^L, \mathbf{x}^U] \times [\mathbf{y}^L, \mathbf{y}^U]$ . Consider a variable  $y_i \in \{0, 1\}$  whose bounds are being updated. The procedure above is used.

### Algorithmic Procedure

The algorithmic procedure for the SMIN- $\alpha$ BB algorithm is as follows:

```

PROCEDURE SMIN- $\alpha$ BB algorithm()
  Decompose functions in problem;
  Set tolerance  $\epsilon$ ;
  Set  $\underline{f}^* = \underline{f}^0 = -\infty$  and  $\bar{f}^* = \bar{f}^0 = +\infty$ ;
  Initialize list of lower bounds  $\{\underline{f}^0\}$ ;
  DO  $\bar{f}^* - \underline{f}^* > \epsilon$ 
    Select node  $k$  with smallest lower bound,  $\underline{f}^k$ ,
    from list of lower bounds;
    Set  $\underline{f}^* = \underline{f}^k$ ;
    (Optional) Update binary and continuous variable
    bounds;
    Select binary or continuous branching variable
    Partition to create new nodes;
    DO for each new node  $i$ 
      Generate convex lower bounding MINLP;
      Find solution  $\underline{f}^i$  of convex lower bounding
      MINLP;
      IF infeasible or  $\underline{f}^i > \bar{f}^* + \epsilon$ 
        Fathom node;
      ELSE
        Add  $\underline{f}^i$  to list of lower bounds;
        Find a solution  $\bar{f}^i$  of nonconvex MINLP;
        IF  $\bar{f}^i < \bar{f}^*$  THEN Set  $\bar{f}^* = \bar{f}^i$ ;
    OD;
  OD;
  RETURN( $\bar{f}^*$  and variables values at corresponding
  node);
END SMIN- $\alpha$ BB algorithm;

```

### Pseudocode for the SMIN- $\alpha$ BB algorithm

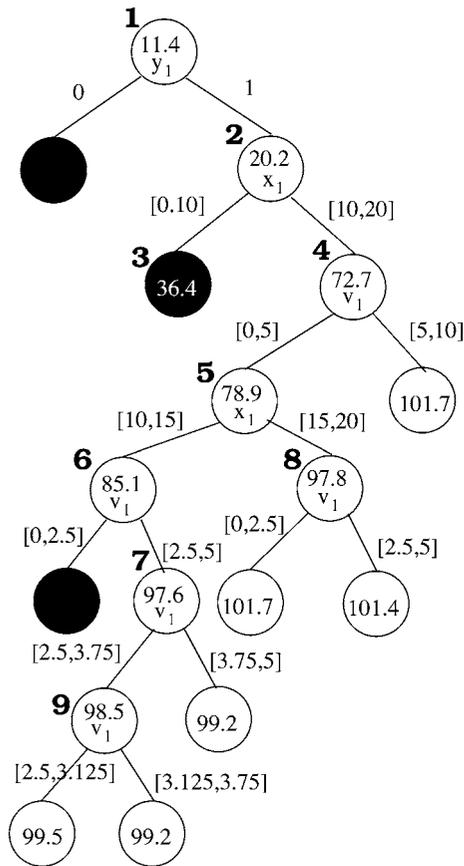

In order to illustrate the algorithmic procedure, a small example proposed in [17] is used. It is a simple design problem where one of two reactors must be chosen to produce a given product at the lowest possible cost. It involves two binary variables, one for each reactor, and seven continuous variables. The formula-

tion is:

$$\begin{cases}
 \min & 7.5y_1 + 5.5y_2 + 7v_1 + 6v_2 + 5x \\
 \text{s.t.} & z_1 - 0.9(1 - e^{-0.5v_1})x_1 = 0 \\
 & z_2 - 0.8(1 - e^{-0.5v_2})x_2 = 0 \\
 & x_1 + x_2 - x = 0 \\
 & z_1 + z_2 = 10 \\
 & v_1 - 10y_1 \leq 0 \\
 & v_2 - 10y_2 \leq 0 \\
 & x_1 - 20y_1 \leq 0 \\
 & x_2 - 20y_2 \leq 0 \\
 & y_1 + y_2 = 1 \\
 & 0 \leq x_1, x_2 \leq 20; \quad 0 \leq z_1, z_2 \leq 30 \\
 & 0 \leq v_1, v_2 \leq 10; \quad 0 \leq x \leq 20 \\
 & (y_1, y_2) \in \{0, 1\}^2
 \end{cases}$$

Because of the linear participation of the binary variables, the SMIN- $\alpha$ BB algorithm is well-suited to solve this nonconvex MINLP. It identifies the global solution of 99.2 after nine iterations, when bound updates are performed at every iteration and branching takes place on the binary variables first. Branching variable selection takes place randomly for the binary variables and according to the term measures for the continuous variables. At the global solution, the binary variable values are  $y_1 = 1$  and  $y_2 = 0$ . The steps of the algorithm are shown in Fig. 1. The boldface numbers next to the nodes indicate the order in which the nodes were explored. The lower bound is computed by solving a convex relaxation of the nonconvex problem is indicated inside each node, and the branching variable selected for the node is also specified. The domain to which this branching variable is restricted is displayed along each branch. A black node indicates the lower bounding problem was found infeasible and a shaded node is fathomed because its lower bound is greater than the current upper bound on the solution.

At the first node, the initial lower bound is 11.4 and an upper bound of 99.2 is found. The binary variable  $y_1$  is selected as a branching variable. The region  $y_1 = 0$  is infeasible and can therefore be fathomed (black node), while an improved lower bound is found for  $y_1 = 1$ . This latter region is therefore chosen for exploration at the second iteration. Variable bound updates reveal that  $y_2 = 1$  is infeasible so that  $y_2$  can be fixed to zero. Branch-

MINLP: Global Optimization with  $\alpha$ BB, Figure 1  
SMIN- $\alpha$ BB branch and bound tree

ing on the continuous variables may now begin. The first selected variable is  $x_1$  and regions  $0 \leq x_1 \leq 10$  and  $10 \leq x_1 \leq 20$  are created. Since the left region has the lowest lower bound (36.4), it is examined at iteration 3. Variable bound updates show that this region is in fact infeasible and it is therefore eliminated without further processing. The algorithm proceeds to node 4 for which  $v_1$  is selected as a branching variable. The right region,  $5 \leq v_1 \leq 10$ , is fathomed since it has a lower bound greater than 99.2. The algorithm progresses along the branch and bound until, at iteration 9, two nodes are left open with lower bounds of 99.2. This is within the accuracy required for this run so the procedure is terminated. One more iteration would reveal that the only global optimum lies in the right child of node 9.

The SMIN- $\alpha$ BB algorithm is especially effective for chemical process synthesis problem such as distillation network or heat exchanger network synthesis [1,3].

## The GMIN- $\alpha$ BB Algorithm

The GMIN- $\alpha$ BB algorithm is designed to address the broad class of problems represented by

$$\begin{cases} \min_{\mathbf{x}, \mathbf{y}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq 0 \\ & \mathbf{h}(\mathbf{x}, \mathbf{y}) = 0 \\ & \mathbf{x} \in [\mathbf{x}^L, \mathbf{x}^U] \\ & \mathbf{y} \in [\mathbf{y}^L, \mathbf{y}^U] \cap \mathbb{N}^q \end{cases} \quad (2)$$

where  $f(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$ , and  $\mathbf{h}(\mathbf{x}, \mathbf{y})$ , are functions whose continuous relaxation is twice continuously differentiable.

The GMIN- $\alpha$ BB algorithm [2,3,7] extends the applicability of the standard branch and bound approaches for MINLPs [9,11,13,15,19,20] by making use of the  $\alpha$ BB-algorithm. The most crucial characteristics of the algorithm are the branching strategy, the derivation of a valid lower bound on problem (2), and the variable bound update strategies.

## Branching Variable Selection

Branching in the GMIN- $\alpha$ BB algorithm is carried out on the integer variables only. When it is a bisection, the partition takes place either at the midpoint of the range of the selected variable, or at the value of that variable at the solution of the lower bounding problem. It is also possible to branch on more than one variable at a given node, or to perform  $k$ -section on one of the variables. More than two children node may be created from a parent node when the structure of the problem is such that the bounds on a small fraction of the integer variables affect the bounds on many of the other variables in the problem. As in the SMIN- $\alpha$ BB algorithm, an integer variable is chosen randomly or according to branching priorities. An additional rule consists of selecting the most or least fractional variable at the solution of a continuous relaxation of the problem.

## Generation of a Valid Lower Bound

A guaranteed lower bound on the global solution of the current node of the branch and bound tree is obtained by solving a continuous relaxation of the non-convex MINLP at that node. When the integer variables

that have not yet been fixed are allowed to vary continuously between their bounds, the problem becomes a nonconvex NLP. The validity of the lower bound can only be ensured if the global solution of this nonconvex NLP is identified or if a lower bound on this solution is found. On the other hand, when all integer variables have been fixed to integer values at a node, no additional partitioning of this node can take place and the global optimum solution of the nonconvex NLP is required to guarantee convergence of the GMIN- $\alpha$ BB. Based on these conditions, the  $\alpha$ BB algorithm can be used as a subroutine to generate valid lower bounds:

- If at least one integer variable can be relaxed at the current node, run the  $\alpha$ BB algorithm for a few iterations to obtain a valid lower bound on the global solution of the continuous relaxation *or* run the  $\alpha$ BB algorithm to completion to obtain the global solution of the continuous relaxation.
- Otherwise, run the  $\alpha$ BB algorithm to completion to obtain the global solution for the current node.

This strategy makes use of the convergence characteristics of the  $\alpha$ BB algorithm to improve the performance of the GMIN- $\alpha$ BB algorithm. The rate of improvement of the lower bound on the global solution of a nonconvex NLP is usually very high at early iterations and then gradually tapers off. At later stages of an  $\alpha$ BB run, the computationally expensive reduction of the gap between the bounds on the solution of the continuous relaxation does not result in a sufficiently significant increase in the lower bound to affect the performance of the GMIN- $\alpha$ BB algorithm and can therefore be bypassed.

### Generation of a Valid Upper Bound

Because of the finite size of the branch and bound tree, it is not necessary to generate an upper bound on the nonconvex MINLP at each node in order to guarantee convergence of the GMIN- $\alpha$ BB algorithm. In the worst case, the integer variables are fixed at every node of the last level of the tree, and the solutions of the corresponding NLPs provide the upper bounds needed to identify the global optimum solution. However, upper bounds play a significant role in improving the convergence rate of the algorithm by allowing the fathoming of nodes whose lower bound is greater than the smallest upper bound and therefore reducing the final size of the

branch and bound tree. An upper bound on the solution of a given node can be obtained in several ways. For example, if the solution of the continuous relaxation is integer-feasible, that is, all the relaxed integer variables have integer values at the solution, this solution is both a lower and an upper bound on the current node. If the  $\alpha$ BB algorithm was run for only a few iterations and the relaxed integer variables are integer at the lower bound, they can be fixed to these integer values and the resulting nonconvex NLP can be solved locally to yield an upper bound on the solution of the node. Finally, a set of integer values satisfying the integer constraints can be used to construct a nonconvex NLP whose local solutions are upper bounds on the current node solution.

### Variable Bound Updates

If the bounds on the integer variables at any given node can be tightened, the solution space can be significantly reduced due to the combinatorial nature of the problem. The allocation of computational resources for this purpose is therefore a potentially worthwhile investment. An optimization-based approach or an interval-based approach may be used to update the variable bounds. These approaches are similar to those developed for the  $\alpha$ BB algorithm but they take advantage of the integrality of the variables. Thus, in the optimization approach, the lower or upper bound on variable  $y_i$  is improved by first relaxing the integer variables, and then solving the convex NLP

$$y^* = \begin{cases} \min \text{ or } \max_{\mathbf{x}, \mathbf{y}, \mathbf{w}} & y_i \\ \text{s.t.} & \check{f}(\mathbf{x}, \mathbf{y}, \mathbf{w}) \leq \bar{f}^* \\ & \mathbf{C}(\mathbf{x}, \mathbf{y}, \mathbf{w}) \\ & \mathbf{x} \in [\mathbf{x}^L, \mathbf{x}^U] \\ & \mathbf{y} \in [\mathbf{y}^L, \mathbf{y}^U] \\ & \mathbf{w} \in [\mathbf{w}^L, \mathbf{w}^U] \end{cases} \quad (3)$$

where  $\check{f}(\mathbf{x}, \mathbf{y}, \mathbf{w})$  denotes the convex underestimator of objective function,  $\bar{f}^*$  denotes the current best upper bound on the global optimum solution,  $\mathbf{C}(\mathbf{x}, \mathbf{y}, \mathbf{w})$  denotes the set of convexified constraints, and  $\mathbf{w}$  is the set of new variables introduced during the convexification/relaxation procedure. Finally, the improved lower or upper bound is obtained by setting  $y_i^L = \lceil y_i^* \rceil$  or  $y_i^U = \lfloor y_i^* \rfloor$ .

In the interval-based approach, an iterative procedure is followed based on an interval test which provides sufficient conditions for the infeasibility of the original constraints and the 'bound improvement constraint'  $f(\mathbf{x}, \mathbf{y}) \leq \bar{f}^*$ , given the relaxed region  $(\mathbf{x}, \mathbf{y}) \in [\mathbf{x}^L, \mathbf{x}^U] \times [\mathbf{y}^L, \mathbf{y}^U]$ . This set of constraints defines a region denoted by  $F$ . The procedure to improve the lower (upper) bound on variable  $y_i$  is as follows:

```

PROCEDURE interval-based bound update()
  Set initial bounds  $L = y_i^L$  and  $U = y_i^U$ ;
  Set iteration counter  $k = 0$ ;
  Set maximum number of iterations  $K$ ;
  DO  $k < K$  and  $L \neq U$ 
    Compute 'midpoint'  $M = \lfloor (U + L)/2 \rfloor$ ;
    Set left region
       $\{(\mathbf{x}, \mathbf{y}) \in F : y_i \in [L, M]\}$ ;
    Set right region
       $\{(\mathbf{x}, \mathbf{y}) \in F : y_i \in [M + 1, U]\}$ ;
    Test interval feasibility of left(right) region;
    IF feasible,
      Set  $U = M$  ( $L = M$ );
    ELSE
      Test interval feasibility of right(left)
      region;
      IF feasible,
        Set  $L = M$  ( $U = M$ );
      ELSE
        IF  $k = 0$ ,
          RETURN(infeasible node);
        ELSE
          Set  $L = U$  ( $U = L$ );
          Set  $U = y_i^U$  ( $L = y_i^L$ );
        Set  $k = k + 1$ ;
    OD;
  RETURN( $y_i^L = L$  ( $y_i^U = U$ ));
END interval-based bound update;

```

#### Interval-based bound update procedure

The variable bound tightening is performed before calling the  $\alpha$ BB algorithm to obtain a lower bound on the solution of the current node. In many cases, during an  $\alpha$ BB run, variable bound updates are also used to improve the quality of the generated lower bounds. Although the  $\alpha$ BB algorithm treats the  $\mathbf{y}$  variables as continuous, the bound update strategy within the  $\alpha$ BB al-

gorithm may be modified to account for the true nature of these variables. A larger reduction in the solution space can be achieved by adopting one of the *integer* bound update strategies described here for the relaxed  $\mathbf{y}$  variables. This more stringent approach leads to a lower bound which is not necessarily a valid lower bound on the continuous relaxation, but which is always a lower bound on the global solution of the nonconvex MINLP.

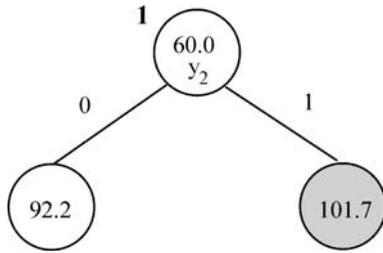

The overall algorithmic procedure for the GMIN- $\alpha$ BB algorithm is shown below:

```

PROCEDURE GMIN- $\alpha$ BB algorithm()
  Set tolerance  $\epsilon$ ;
  Set  $\underline{f}^* = \underline{f}^0 = -\infty$  and  $\bar{f}^* = \bar{f}^0 = +\infty$ ;
  Initialize list of lower bounds  $\{\underline{f}^0\}$ ;
  DO  $\bar{f}^* - \underline{f}^* > \epsilon$ 
    Select node  $k$  with smallest lower bound,  $\underline{f}^k$ ,
    from list of lower bounds;
    Set  $\underline{f}^* = \underline{f}^k$ ;
    (Optional) Update  $\mathbf{y}$  variable bounds;
    Select integer branching variable(s);
    Create new nodes by branching;
    DO for each new node  $i$ 
      Obtain lower bound  $\underline{f}^i$  on node
      IF all integer variables are fixed,
        Find global solution  $\underline{f}^i$  of nonconvex
        NLP with  $\alpha$ BB algorithm;
      ELSE
        Relax integer variables;
        Run  $\alpha$ BB algorithm to completion or
        for a few iterations to get  $\underline{f}^i$ 
        (Optional) Use integer bound
        updates on  $\mathbf{y}$  variables;
      IF  $\underline{f}^i > \bar{f}^i + \epsilon$ , THEN Fathom node;
      ELSE
        Add  $\underline{f}^i$  to list of lower bounds;
        (Optional) Obtain upper bound  $\bar{f}^i$  on
        nonconvex MINLP;
        IF  $\bar{f}^i < \bar{f}^*$  THEN Set  $\bar{f}^* = \bar{f}^i$ ;
      OD;
    OD;
  RETURN( $\bar{f}^*$  and variables values at corres-
  ponding node);
END GMIN- $\alpha$ BB algorithm;

```

#### Pseudocode for the GMIN- $\alpha$ BB algorithm

**MINLP: Global Optimization with  $\alpha$ BB, Figure 2**  
GMIN- $\alpha$ BB branch and bound tree

The algorithmic procedure for the GMIN- $\alpha$ BB algorithm is illustrated using the same example as for the SMIN- $\alpha$ BB algorithm. The branch and bound tree is shown in Fig. 2, using the same notation as previously.

At the first node, the continuous relaxation of the nonconvex MINLP is solved for 10  $\alpha$ BB iterations to yield a lower bound of 60. No upper bound is found. Next, the binary variable  $y_2$  is chosen for branching and the continuous relaxation of the problem with  $y_2 = 0$  is solved. A lower bound of 92.2 is found as the global solution to this nonconvex NLP. In addition, this solution is integer feasible and therefore provides an upper bound on the global optimum solution of the nonconvex MINLP. The region  $y_2 = 1$  is then examined and the global solution of the NLP is found to be 101.7 after 10  $\alpha$ BB iterations. This node can therefore be fathomed and the procedure terminated.

The GMIN- $\alpha$ BB algorithm has been used to solve nonconvex MINLPs involving nonconvex terms in the integer variables and some mixed nonconvex terms. Branching priorities combined with variable bound updates and a small number of  $\alpha$ BB iterations for relaxed nodes allow the identification of the global optimum solution after the exploration of a small fraction of the maximum number of nodes and with small CPU requirements. In particular, the algorithm has been used on a pump network synthesis problem [2,3]. Some nonconvex integer problems have also been tackled by the same approach. For instance, the minimization of trim loss, a problem taken from the paper cutting industry, has also been addressed for medium order sizes [3].

## Conclusions

The  $\alpha$ BB algorithm for nonconvex NLPs can be incorporated within more general frameworks to address

broad classes of nonconvex MINLPs. One extension of the algorithm is the SMIN- $\alpha$ BB algorithm which identifies the global optimum solution of problems in which binary variables participate in linear or mixed-bilinear terms and continuous variables appear in twice continuously differentiable functions. The partitioning of the solution space takes place in both the continuous and binary domains. The GMIN- $\alpha$ BB algorithm is designed to locate the global optimum solution of problems involving integer and continuous variables in functions whose continuous relaxation is twice continuously differentiable. The algorithm is similar to traditional branch and bound algorithms for mixed integer problems in that branching occurs on the integer variables only and a continuous relaxation of the problem is constructed during the bounding step. It uses the  $\alpha$ BB algorithm for the efficient and rigorous generation of lower bounds. Both algorithms are widely applicable and have been successfully tested on a variety of medium-size nonconvex MINLPs.

MINLP; HEN synthesis; Network synthesis

Heat exchanger network synthesis problems arise in chemical process design when the heat released by hot process streams is used to satisfy the demands of cold process streams. These problems have been the subject of an intensive research effort, and over 400 publications have been written in the area. See [7,8,9] for reviews of the area, and [1,3] for detailed analysis of HEN synthesis.

The discovery by T. Umeda et al. [11] of a thermodynamic pinch point that limits heat integration in a heat exchanger network led to much of this research effort. They showed that setting minimum temperature approach,  $\Delta T_{\min}$ , places a lower bound on the utility consumption in a heat exchanger network and decomposed a heat exchanger network into independent subnetworks. This enables the heat exchanger network synthesis problem to be decomposed into four subproblems. The first subproblem finds the appropriate minimum temperature approach, the second subproblem minimizes the utility consumption, the third subproblem finds the minimum number of matches and identifies the matches and their heat duty, and the fourth finds and optimizes the actual network structure.

See [5] for a systematic scheme for solving these problems sequentially. First, the utility consumption is minimized using the linear programming (LP) transshipment model approach of [10]. Second, a set of process matches and their heat duties that minimize the total number of units is found with the mixed integer linear programming (MILP) strategy of [10]. Then, the network structure is found [5] by optimizing a superstructure that contains all possible network configurations embedded within it using a nonlinear programming (NLP) problem. When there is more than one combination of matches and heat duties that satisfies the minimum unit criterion, the best combination is found by exhaustive enumeration. The minimum temperature approach is optimized with a golden section search that solves all three of these optimization problems at each iteration.

In the late 1980s it was found, [4,12], that better network designs could be obtained by solving some of the heat exchanger network design subproblems simultaneously. C.A. Floudas and A.R. Ciric [4] combined the MILP stream matching problem with the NLP superstructure optimization problem formulated in [5], creating a mixed integer nonlinear programming problem (MINLP) that avoided the exhaustive search through all combinations of matches that minimize the number of units. In 1990, they [2] formulated the entire heat exchanger network design problem as a MINLP. The solution of this problem yields the optimal temperature approach, utility level, process matches, heat duties, and network structure, eliminating the need for a global section search for the optimum minimum temperature approach.

T.F. Yee and I.E. Grossmann [12] used a smaller superstructure proposed in [6] that embodies a sequential-parallel network structure to formulate an alternative MINLP for heat exchanger network synthesis. The solution of this MINLP yielded the utility consumption, matches and network structure and heat exchanger areas.

## Problem Statement

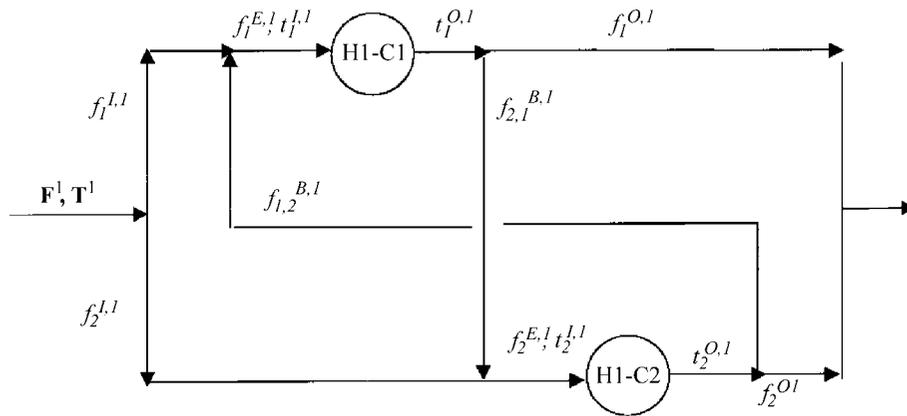

This article will explore two mixed integer nonlinear programming problems in heat exchanger network synthesis: combined match-network optimization and heat exchanger network synthesis without decomposition. The synthesis without decomposition problem can be stated as follows:

Given:

- 1) A set of hot process streams and hot utilities  $i \in H$ , their inlet and outlet temperatures  $T^i$ ,  $T^{O,i}$ , and heat capacity flow rates  $F^i$ ;
- 2) A set of cold process streams and cold utilities  $j \in C$ , their inlet and outlet temperatures  $T^j$ ,  $T^{O,j}$ , and heat capacity flow rates  $F^j$ ; and
- 3) Overall heat transfer coefficients  $U_{ij}$ .

Determine:

- A) The stream matches ( $ij$ ), the heat duty  $Q_{ij}$  of match ( $ij$ ), and the heat exchanger area  $A_{ij}$  of match ( $ij$ );
- B) the piping structure for each stream in the network; and
- C) the temperature and flowrate within each pipe of the network.

**MINLP: Heat Exchanger Network Synthesis, Figure 1**  
 A superstructure for one hot stream exchanging heat with two cold streams

In the match-network problem, one is also given

- the level of each utility; and
- a minimum temperature approach  $\Delta T_{\min}$ .

These problems can be solved using mixed integer nonlinear programming. The development and application of these approaches is described in more detail below.

### Heat Exchanger Network Superstructures

Mixed integer nonlinear programming approaches to these problems begin with a superstructure that contains many alternative designs embedded within it. Two superstructures are particularly interesting.

Figure 1 shows a superstructure of a hot stream, above the thermodynamic pinch point, that may exchange heat with two cold streams [5]. Notice that the stream can be piped in series, in parallel, and in split-mix-bypass configurations, as shown in Fig. 2. As we shall see, this richness leads to nonconvex constraints in the MINLP. The first network superstructure is created by constructing similar structures for every other stream above the pinch point.

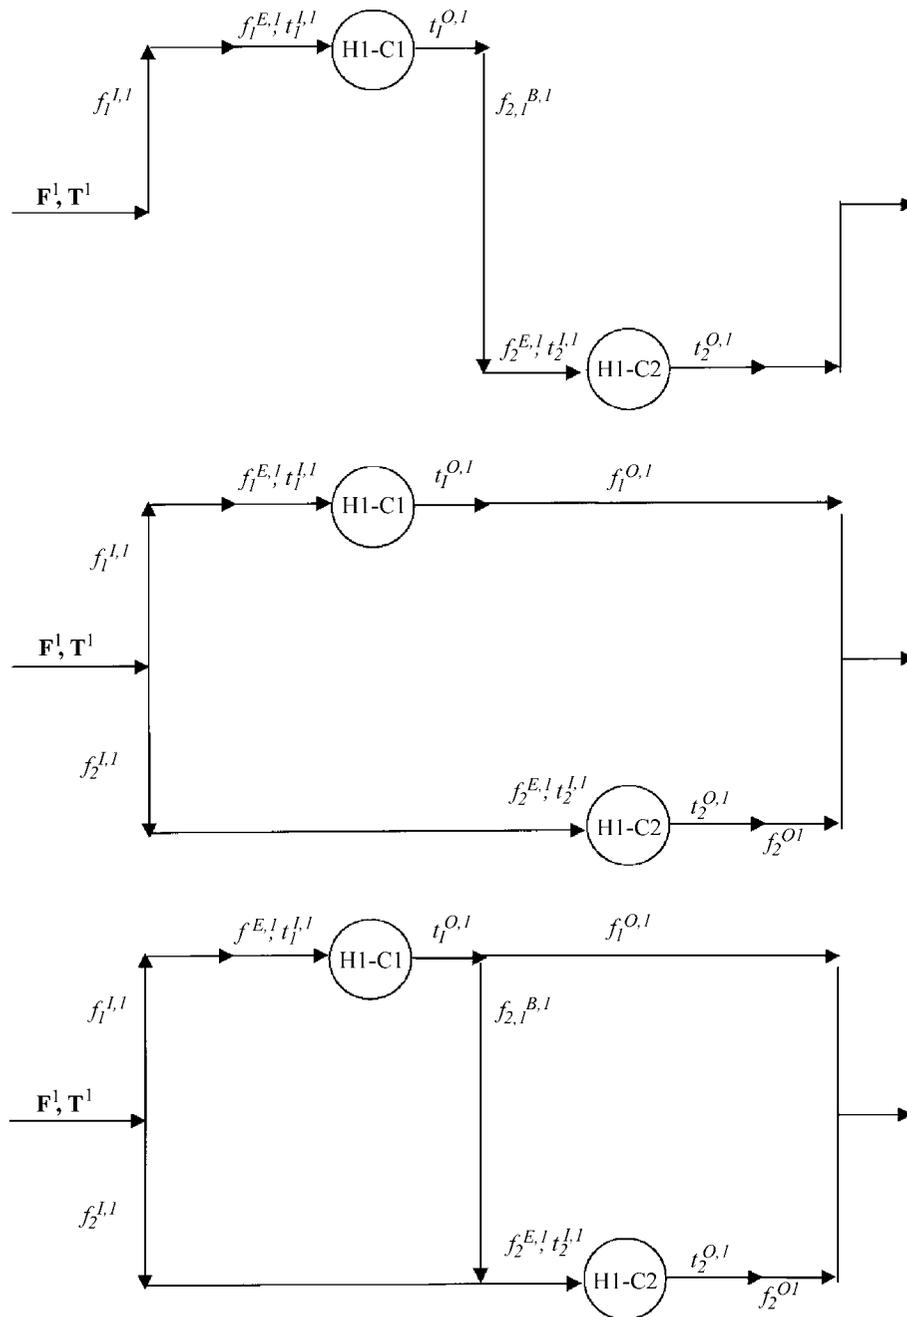

Notice that in this subnetwork, streams H1 and C1, and all other pairs of hot and cold streams, can exchange heat no more than once. H1 and C1 may exchange heat again in the subnetwork below the thermodynamic pinch point. The thermodynamic pinch point has partitioned the temperature range into two intervals, and in each interval, individual process streams can only exchange heat once.

One could increase the number of times two streams can exchange heat by partitioning the temper-

ature range further. This is the basic strategy behind the second superstructure [6,12] shown in Fig. 3. Here, the temperature range has been partitioned into many intervals, or stages. Within any particular stage, each hot stream may exchange heat with each cold stream; multiple intervals allow any particular match to take place many times in the network. Unlike the first superstructure, each stream in each stage is piped in a parallel configuration, and the inlet and outlet temperature of each parallel line is fixed by the temperature interval. Series piping structures arise when a stream exchanges heat only once per interval. The superstructure does not contain split-mix-bypass or series-parallel structures, but as we shall see that in exchange the nonconvex constraints that arise from the first superstructure have been eliminated.

### Mathematical Models for HEN Synthesis using MINLPs

MINLP models of heat exchanger network synthesis arise when the process stream matches are selected while simultaneously optimizing the heat exchanger network; the former is a discrete decision modeled with integer variables, the latter, a nonlinear optimization problem. In this paper, we refer to this as the *match-network problem*. MINLPs may also be used to formulate an optimization problem that simultaneously minimizes the utility consumption, selects the stream matches, and optimizes the network layout, in *heat exchanger network synthesis without decomposition*.

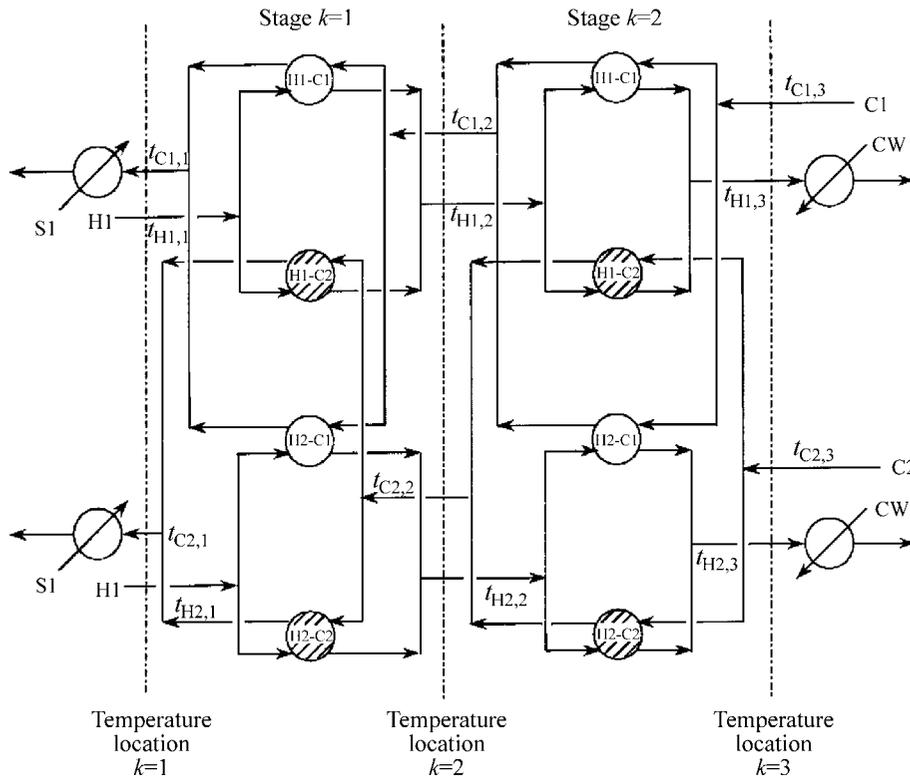

MINLP: Heat Exchanger Network Synthesis, Figure 2  
Stream piping configurations embedded in the superstructure shown in Fig. 1

### Match-Network Problem

The MINLP model of the match-network problem has three components: a *transshipment model* [10] that identifies feasible process stream matches and their heat

duties, a *superstructure model* of all possible network structures, and an *objective function*.

The transshipment model partitions the temperature range into  $t = 1, \dots, T$  temperature intervals, using the inlet and outlet temperatures of the streams and

MINLP: Heat Exchanger Network Synthesis, Figure 3  
Two-stage superstructure

the temperature interval approach temperature (TIAT). Hot streams release heat into the temperature intervals, where it either flows to the cold streams in the same interval or cascades down to the next colder interval. The binary variable  $Y_{ij}$  denotes the existence of a match between hot stream  $i$  and cold stream  $j$ , where heat loads are  $q_{ij}$  and  $Q_{ij}$ , and heat residuals are  $R_k$ . The model is composed by the following constraints:

$$\left\{ \begin{array}{l} \sum_{j \in C_t} q_{ijt} + R_{i,t} - R_{i,t-1} = Q_{it}^H, \quad i \in H, \quad j \in C_i, \\ \sum_{i \in R_j} q_{ijt} = Q_{jt}^C, \quad j \in C, \quad t = 1, \dots, T, \\ \sum_{t=1}^T q_{ijt} = Q_{ij}, \quad i \in H, \quad j \in C_i, \\ Q_{ij} - UY_{ij} \leq 0, \quad i \in H, \quad j \in C_i, \\ \sum_{i \in H} \sum_{j \in C_i} Y_{ij} \leq N_{\max}. \end{array} \right.$$

The first two constraints in the transshipment model are the energy balances for each temperature interval.

The total heat load in a match is given by the third constraint. The fourth constraint bounds the heat load using the binary variable  $Y_{ij}$  and a large fixed constant  $U$ . The last constraint in the above model puts an upper bound on the number of existing matches, which is the maximum number of units.

The second part of the match-network synthesis model is the hyperstructure topology model, which consists of mass and energy balances for the mixers and splitters, feasibility constraints, utility load constraint and bounds on the flow rate heat-capacities.

Mass balances for the splitters at the inlet of the superstructure:

$$\sum_{k'} f_{k'}^{I,k} = F^k, \quad k \in \text{HCT}.$$

Here, HCT is the set of all process streams and utilities. Mass balances for the mixers at the inlets of the exchangers:

$$f_{k'}^{I,k} + \sum_{k''} f_{k',k''}^{B,k} - f_{k'}^{E,k} = 0, \quad k', k \in \text{HCT}.$$

Mass balances for the splitters at the outlets of the exchangers:

$$f_{k'}^{O,k} + \sum_{k''} f_{k'',k'}^{B,k} - f_{k'}^{E,k} = 0, \quad k', k \in \text{HCT}.$$

Energy balances for the mixers at the inlets of the exchangers:

$$T^k f_{k'}^{I,k} + \sum_{k''} f_{k'',k'}^{B,k} t_{k''}^{O,k} - f_{k'}^{E,k} t_{k'}^{I,k} = 0,$$

$$k', k \in \text{HCT}.$$

Energy balances over the heat exchangers:

$$Q_{ij} - f_j^{E,i} (t_j^{I,i} - t_j^{O,i}) = 0, \quad i \in H, \quad j \in C,$$

$$Q_{ij} - f_i^{E,j} (t_i^{O,j} - t_i^{I,j}) = 0.$$

The minimum temperature approach between a hot stream and a cold stream:

$$t_j^{I,i} - t_i^{O,j} \geq \Delta T_{\min},$$

$$t_j^{O,i} - t_i^{I,j} \geq \Delta T_{\min}.$$

Logical relations between the heat-capacity flow rates and the existence of a match:

$$f_j^{E,i} - F^i Y_{ij} \leq 0,$$

$$f_i^{E,j} - F^j Y_{ij} \leq 0.$$

Lower bounds on the heat-capacity flow rates through the exchanger:

$$f_j^{E,i} - \frac{Q_{ij}}{\Delta T_{ij,\max}} \geq 0,$$

$$f_i^{E,j} - \frac{Q_{ij}}{\Delta T_{ij,\max}} \geq 0,$$

where  $\Delta T_{ij,\max}$  equals  $T^i - T^j$ . Lastly, the objective function minimizes the total investment cost:

$$\min \sum_{i \in H} \sum_{j \in C} \alpha \left( \frac{Q_{ij}}{U_{ij} \frac{t_j^{I,i} - t_j^{O,j} - t_j^{O,i} + t_j^{I,j}}{\ln \frac{t_j^{I,i} - t_i^{O,j}}{t_j^{O,i} - t_i^{I,j}}}} \right)^{\beta} Y_{ij}.$$

The model is a mixed integer nonlinear programming (MINLP) problem, as the objective function and the energy balances are nonlinear, and the decision variables  $Y_{ij}$  are binary. Notice that the energy balances are bilinear, creating a nonconvex feasible region.

## Heat Exchanger Network Synthesis Without Decomposition

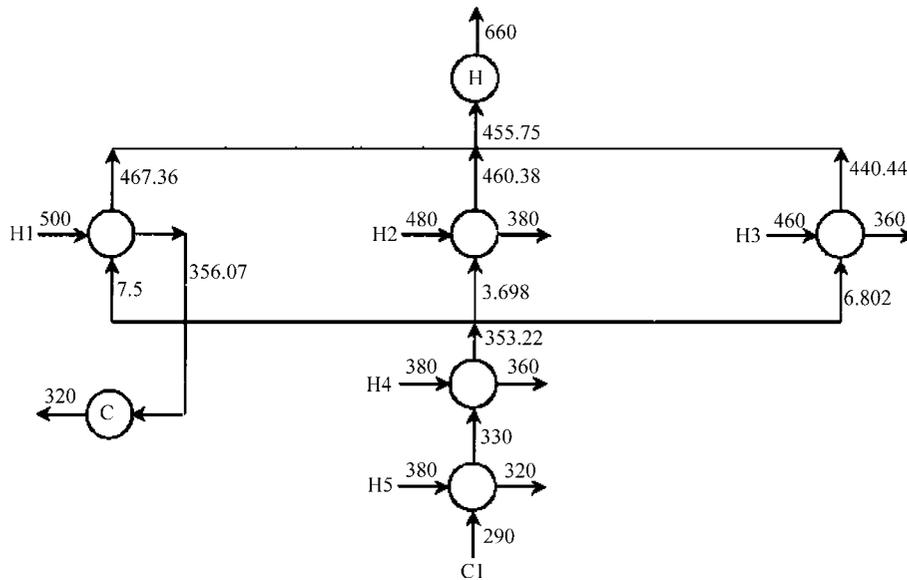

MINLP models that optimize utility consumption as well as process matches, heat duties, and network configurations can also be formulated. See [2] and [12] for pseudopinch approaches that set the TIAT to a small value and lets heat flow across the pinch. A strict decomposition at the pinch can also be maintained by letting TIAT vary, and using integer variables to model the changing structure of the temperature cascade.

*Example 1* These techniques are demonstrated with a problem given in both [12] and [2]. The problem consists of two hot streams, two cold streams, one hot utility (steam), and one cold utility (cooling water). The stream data is given in Table 1.

Using the pseudopinch method with  $TIAT = 1C$  and  $\Delta T_{\min} = 0.5C$ , and allowing HRAT to vary between  $1C$

MINLP: Heat Exchanger Network Synthesis, Figure 4  
Optimal network configuration for example problem; pseudopinch [2]

MINLP: Heat Exchanger Network Synthesis, Figure 5  
Optimal network configuration for example problem; simultaneous approach [12]

and 30C, Ciric and Floudas [2] formulated the problem as a MINLP problem and solved it using the generalized Benders decomposition algorithm. The optimal network configuration is pictured in Fig. 3. The network consumes 3592.4kW of steam and 1312.4kW of cooling water, the HRAT is 8.42C. The annual cost of the network is \$571,080. The match data of this solution is given in Table 2. Yee and Grossmann [12] used the same problem to demonstrate the simultaneous optimization approach. The problem is again formulated

as a MINLP problem. The optimal network configuration is given in Fig. 4. The annual cost of this network is \$576,640. HRAT is 13.1C. The match data of this network is given in Table 3.

## Conclusions

Mixed integer nonlinear programming offer a powerful approach to heat exchanger network synthesis. Using these techniques, stream matching, the combina-

Generalized disjunctive programming; Disjunctive programming; Outer approximation method; generalized Benders decomposition; Mixed integer programming

There has been an increasing trend to representing linear and nonlinear discrete optimization problems by models consisting of algebraic constraints, logic disjunctions and logic relations ([1,7,8]). For instance, a mixed integer program can be formulated as a generalized disjunctive program as has been shown in [5]:

$$(DP1) \left\{ \begin{array}{l} \min \quad Z = \sum_k c_k + f(x) \\ \text{s.t.} \quad g(x) \leq 0 \\ \quad \quad \forall_{i \in D_k} \begin{bmatrix} Y_{ik} \\ h_{ik}(x) \leq 0 \\ c_k = \gamma_{ik} \end{bmatrix}, \\ \quad \quad k \in SD, \\ \quad \quad \Omega(Y) = \text{true} \\ \quad \quad x \in \mathbb{R}^n, \quad c \in \mathbb{R}^m, \\ \quad \quad Y \in \{\text{true}, \text{false}\}^m, \end{array} \right.$$

in which  $Y_{ik}$  are the boolean variables that establish whether a given term in a disjunction is true ( $h_{ik}(x) \leq 0$ ), while  $\Omega(Y)$  are logical relations assumed to be in the form of propositional logic involving only the boolean variables.  $Y_{ik}$  are auxiliary variables that control the part of the feasible space in which the continuous variables,  $x$ , lie, and the variables  $c_{ik}$  represent fixed charges which are set to a value  $\gamma_{ik}$  if the corresponding term of the disjunction is true. Finally, the logical conditions,  $\Omega(Y)$ , express relationships between the disjunctive sets. In the context of optimal synthesis of process networks, the disjunctions in (DP1) typically arise for each unit  $i$  in the following form:

$$\begin{bmatrix} Y_i \\ h_i(x) \leq 0 \\ c_i = \gamma_i \end{bmatrix} \bigvee \begin{bmatrix} \neg Y_i \\ B^i x = 0 \\ c_i = 0 \end{bmatrix}, \quad i \in I, \quad (1)$$

in which the inequalities  $h_i$  apply and a fixed cost  $\gamma_i$  is incurred if the unit is selected ( $Y_i$ ); otherwise ( $\neg Y_i$ ) there is no fixed cost and a subset of the  $x$  variables is set to zero with the matrix  $B^i$ . An important advantage of

the above modeling framework is that there is no need to introduce artificial parameters for the ‘big-M’ constraints that are normally used in MINLP to model disjunctions.

M. Turkay and I.E. Grossmann [9] proposed a logic version of the outer approximation algorithm for MINLP [3] for solving problem (DP1), and in which the disjunctions are given as in equation (1), and all the functions are assumed to be convex. The algorithm consists of solving a sequence of NLP subproblems and master problems, which are as follows.

For fixed values of the boolean variables,  $Y_{ik} = \text{true}$  and  $Y_{ik} = \text{false}$  for  $\hat{i} \neq i$ , the corresponding NLP subproblem is as follows:

$$(NLPD) \left\{ \begin{array}{l} \min \quad Z = \sum_k c_k + f(x) \\ \text{s.t.} \quad g(x) \leq 0 \\ \quad \quad \text{for } Y_{ik} = \text{true} : \begin{cases} h_{ik}(x) \leq 0 \\ c_k = \gamma_{ik} \end{cases} \\ \quad \quad \text{for } Y_{ik} = \text{false} : \begin{cases} B^i x = 0 \\ c_k = 0 \end{cases} \\ \quad \quad k \in SD, \\ \quad \quad x \in \mathbb{R}^n, \quad c_i \in \mathbb{R}^1. \end{array} \right.$$

Note that for every disjunction  $k \in SD$  only constraints corresponding to the boolean variable  $Y_{ik}$  that is true are imposed. Also, fixed charges  $\gamma_{ik}$  are only applied to these terms. Assuming that  $K$  subproblems (NLPD) are solved in which sets of linearizations  $l = 1, \dots, K$  are generated for subsets of disjunction terms  $L(ik) = \{l: Y_{ik}^l = \text{true}\}$ , one can define the following *disjunctive OA master problem*:

$$(MDP1) \quad \min Z = \sum_k c_k + f(x)$$

such that

$$\begin{aligned} \alpha &\geq f(x^l) + \nabla f(x^l)^T (x - x^l), \\ g(x^l) + \nabla g(x^l)^T (x - x^l) &\leq 0, \\ l &= 1, \dots, L, \end{aligned}$$

$$\bigvee_{i \in D_k} \begin{bmatrix} Y_{ik} \\ h_{ik}(x^l) + \nabla h_{ik}(x^l)^T (x - x^l) \leq 0 \\ c_k = \gamma_{ik} \end{bmatrix},$$

$$\begin{aligned}
 k &\in SD, \\
 \Omega(Y) &= \text{true}, \\
 \alpha &\in \mathbb{R}, \quad x \in \mathbb{R}^n, \quad c \in \mathbb{R}^m, \\
 Y &\in \{\text{true}, \text{false}\}^m.
 \end{aligned}$$

It should be noted that before applying the above master problem it is necessary to solve various subproblems (NLPD) so as to produce at least one linear approximation of each of the terms in the disjunctions. Selecting the smallest number of subproblems amounts to the solution of a set covering problem, which is of small size and easy to solve [9].

The above problem (MDP1) can be solved by the methods described in [1] and [7]. It is also interesting to note that for the case of process networks Turkay and Grossmann [9] have shown that if the convex hull representation of the disjunctions in (1) is used in (MDP1), then assuming  $B^l = I$  and converting the logic relations  $\Omega(Y)$  into the inequalities  $Ay \leq a$ , leads to the MILP problem,

$$(\text{MIPDF}) \quad \min Z = \sum_k c_k + f(x)$$

such that

$$\begin{aligned}
 \alpha &\geq f(x^l) + \nabla f(x^l)^\top (x - x^l), \\
 g(x^l) + \nabla g(x^l)^\top (x - x^l) &\leq 0, \\
 l &= 1, \dots, L, \\
 \nabla_{x_{z_i}} h_i(x^l)^\top x_{z_i} + \nabla_{x_{N_i}} h_i(x^l)^\top x_{N_i}^1 & \\
 &\leq \left[ -h_i(x^\ell) + \nabla_x h_i(x^\ell)^\top x^\ell \right] y_i, \\
 \ell &\in K_L^i, \quad i \in I, \\
 x_{N_i} &= x_{N_i}^1 + x_{N_i}^2, \\
 0 &\leq x_{N_i}^1 \leq x_{N_i}^U y_i, \\
 0 &\leq x_{N_i}^2 \leq x_{N_i}^U (1 - y_i), \\
 Ay &\leq a, \\
 x &\in \mathbb{R}^n, \quad x_{N_i}^1 \geq 0, x_{N_i}^2 \geq 0, \\
 y &\in \{0, 1\}^m,
 \end{aligned}$$

where the vector  $x$  is partitioned into the variables for each disjunction  $i$  according to the definition of the matrix  $B^i$ . The linearization set is given by  $K_L^i = \{\ell: Y\ell_i = \text{true}, \ell = 1, \dots, L\}$  that denotes the fact that only a subset of inequalities were enforced for a given subproblem  $\ell$ . It is interesting to note that the logic-based outer approximation algorithm represents a generalization of

the modeling/decomposition strategy [5] for the synthesis of process flowsheets.

Turkay and Grossmann [9] have also shown that while a logic-based *generalized Benders method* [4] cannot be derived as in the case of the OA algorithm, one can exploit the property for MINLP problems that performing one Benders iteration [2] on the MILP master problem of the OA algorithm, is equivalent to generating a generalized Benders cut. Therefore, a logic-based version of the generalized Benders method consists of performing one Benders iteration on the MILP master problem (MIPDF). It should also be noted that slacks can be introduced to (MDP1) and to (MIPDF) to reduce the effect of nonconvexities as in the augmented-penalty MILP master problem [10].

Finally, it should be noted that S. Lee and Grossmann [6] have developed a new branch and bound method and a MINLP reformulation that is based on the convex hull of each of the disjunctions in (DP1) with nonlinear inequalities.

MINLP; Mass and heat exchange; Separation

Mass integration in the form of *mass exchanger networks*, MEN, appears in the chemical industries as an economic alternative in waste treatment, feed preparation, product separation, recovery of valuable materials, etc. The MEN involves a set of rich streams, wherefrom one or more components are removed by means of lean streams (mass separating agents) in mass transfer operations that do not require energy (constant pressure and temperature).

The MEN synthesis/design problem is posed as a combinatorial problem, involving discrete and continuous decisions (e.g. the mass exchange operations/matches and the unit sizes, respectively), that both affect the overall mass integration cost.

When the mass transfer operations can take place at different temperatures, heat integration of the rich and

MINLP: Mass and Heat Exchanger Networks, Figure 1

lean streams is also considered within a combined *mass and heat exchanger network*, MHEN, synthesis problem.

In isothermal MEN synthesis, the simultaneous optimization of the mass exchange operations, the mass separating agent flows and the network configuration has been formulated by K.P. Papalexandri, E.N. Pistikopoulos and C.A. Floudas [9] as an MINLP problem based on:

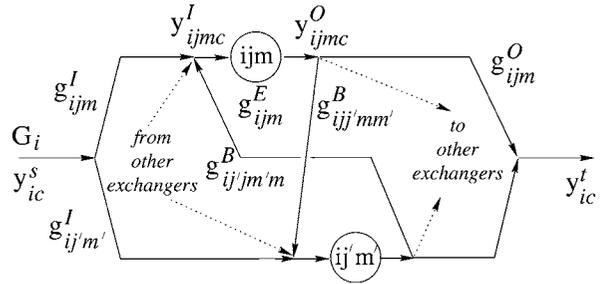

- the MEN superstructure of synthesis/design alternatives;
- modeling of mass exchange in each mass exchanger; and,
- minimization of a total annualized network cost.

Details are given below

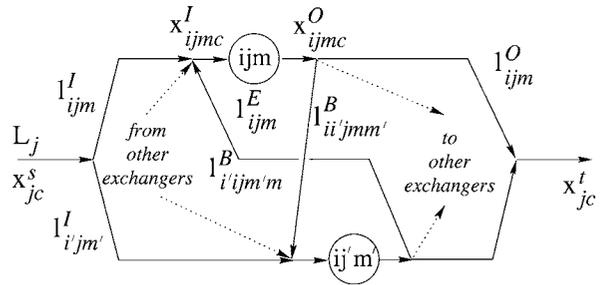

### MEN Superstructure

The *MEN superstructure* for a given set of rich and lean streams includes all possible mass exchange operations (*mass exchange matches*) between the network streams in all possible network configurations. Its main features are:

- Each potential match between a rich and a lean stream corresponds to a potential mass exchanger (one-to-one correspondence). Multiple mass exchange matches between two streams may be considered (i. e. streams integrated at different points in the network), increasing thus the considered MEN structures and the combinatorial complexity of the synthesis problem. Note that, this is not similar to an a priori decomposition of the network into separable subnetworks.
- Each stream entering the network is split towards all its potential mass exchanger units.
- After each mass exchanger, a splitter is considered for each stream, where the stream is split towards its final mixer and all the other potential stream exchangers.
- Prior to each potential mass exchanger, a mixer is considered for each participating stream, where the flow from the initial splitter and connecting (bypass) flows from all the other exchangers of the stream are merged into the flow towards the exchanger.
- A mixer is considered at the network outlet of each stream, where flows from all the potential stream exchangers are merged into the outlet flow.

MINLP: Mass and Heat Exchanger Networks, Figure 2  
Rich stream superstructure

MINLP: Mass and Heat Exchanger Networks, Figure 3  
Lean stream superstructure

For example, for a rich stream  $i$  and its  $m$ th and  $m'$ th possible exchangers with lean streams  $j$  and  $j'$  respectively, we have Fig. 2

In Fig. 2,  $c = 1, \dots, C$  are the transferable components. All possible configurations for the two exchangers ( $(ijm)$  and  $(ij'm')$  in series, or in parallel), result by 'deleting' appropriate connecting streams. Stream deletion corresponds to zero stream flows (e. g.  $g_{ijm'}^I = g_{ijm}^O = 0$  and  $g_{ijj'mm'}^B = 0$  results in the exchangers in series).

For a lean stream  $j$  and its  $m$ th and  $m'$ th exchangers with rich streams  $i$  and  $i'$ , we have Fig. 3.

The MEN superstructure is described by mass balances for the overall streams and each transferable component at the exchangers, splitters and mixers of the superstructure:

$$\begin{cases} g_{ijm}^E (y_{ijmc}^I - y_{ijmc}^O) = M_{ijmc}, \\ i \in R, c = 1, \dots, C, \\ l_{ijm}^E (x_{ijmc}^O - x_{ijmc}^I) = M_{ijmc}, \\ i \in S, c = 1, \dots, C, \end{cases} \quad (1)$$

$$\begin{cases} \sum_{j \in S, m} g_{ijm}^I - G_i = 0, & i \in R, \\ \sum_{i \in R, m} l_{ijm}^I - L_j = 0, & i \in S, \end{cases} \quad (2)$$

$$\begin{cases} g_{ijm}^O + \sum_{j' \in S, m'} g_{ij'jm'm'}^B - g_{ijm}^E = 0, \\ l_{ijm}^O + \sum_{i' \in S, m'} l_{i'ijm'm'}^B - l_{ijm}^E = 0, \\ i \in R, j \in S, m = 1, \dots, M, \end{cases} \quad (3)$$

$$\begin{cases} g_{ijm}^I + \sum_{j' \in S, m'} g_{ij'jm'm'}^B - g_{ijm}^E = 0, \\ l_{ijm}^I + \sum_{i' \in S, m'} l_{i'ijm'm'}^B - l_{ijm}^E = 0, \\ i \in R, j \in S, m = 1, \dots, M, \end{cases} \quad (4)$$

$$\begin{cases} g_{ijm}^I y_{ic}^s + \sum_{j' \in S, m'} g_{ij'jm'm'}^B y_{ij'm'c}^O - g_{ijm}^E y_{ijmc}^I = 0, \\ l_{ijm}^I x_{jc}^s + \sum_{i' \in S, m'} l_{i'ijm'm'}^B x_{i'ijm'c}^O - l_{ijm}^E x_{ijmc}^I = 0, \\ i \in R, j \in S, \\ c = 1, \dots, C, m = 1, \dots, M, \end{cases} \quad (5)$$

$$\begin{cases} \sum_{j \in S, m} g_{ijm}^O y_{ijmc}^O - G_i y_{ic}^t = 0, \\ i \in R, c = 1, \dots, C, \\ \sum_{i \in R, m} l_{ijm}^O x_{ijmc}^O - L_j x_{jc}^t = 0, \\ i \in S, c = 1, \dots, C, \end{cases} \quad (6)$$

where the inlet, outlet, exchanger and exchanger-connecting flows of the rich and lean streams ( $g^I, g^O, g^E, g^B$  and  $l^I, l^O, l^E, l^B$ , respectively) and the intermediate compositions of components (molar fractions  $x^I, x^O, y^I, y^O$ ) are illustrated in the corresponding superstructure figures.

### Modeling Mass Exchange

The existence of each potential mass exchanger in the network is denoted by a binary variable:

$$E_{ijm} = \begin{cases} 1, & \text{when the } m\text{th exchanger} \\ & \text{between streams } i \text{ and } j \text{ exists,} \\ 0, & \text{otherwise,} \end{cases}$$

and defined by

$$\begin{cases} g_{ijm}^E - E_{ijm} U \leq 0, \\ l_{ijm}^E - E_{ijm} U \leq 0, \\ M_{ijmc} - E_{ijm} U \leq 0, \\ g_{ijm}^E, l_{ijm}^E, M_{ijmc} \geq 0, \end{cases} \quad (7)$$

where  $M_{ijmc}$  is the mass exchange load of component  $c$  in mass exchanger ( $ijm$ ), and  $U$  a large positive number.

In each potential mass exchanger a component  $c$  is transferred from the rich to the lean stream when the rich composition is greater than the equilibrium composition with respect to the lean stream:

$$y_c \geq f(x_c),$$

where  $f(x_c)$  is the mass transfer equilibrium relation, that may account for reactive mass transfer also.

Feasibility of mass transfer is ensured imposing the above constraint at the inlet and outlet of the streams, i. e. (for counter-current flows):

$$\begin{cases} -y_{ijmc}^I + f(x_{ijmc}^O) + \epsilon_{ijc} - (1 - E_{ijm})U \leq 0, \\ -y_{ijmc}^O + f(x_{ijmc}^I) + \epsilon_{ijc} - (1 - E_{ijm})U \leq 0, \end{cases} \quad (8)$$

where  $\epsilon_{ijc}$  is a *minimum composition difference* that is required for feasible mass exchange in a unit of finite size (e. g. imposed from mechanical constraints). When  $f(x_c)$  is not convex the constraints in (8) cannot guarantee feasible mass transfer throughout the exchanger. In this case  $f(x_c)$  can be approximated by a set of convex functions and feasible mass transfer be ensured considering the constraints in (8) also for intermediate exchanger points, that define the convex parts. Note that, the mass-transfer feasibility or driving-force constraints in (8) are activated only when the corresponding exchanger exists ( $E_{ijm} = 1$ ).

The size of each potential mass exchanger (number of mass transfer stages,  $N^{st}$ , etc.) is calculated as a function of the variable mass transfer, through appropriate design equations (e. g. for perforated-plate columns the *Kremser equation*):

$$N_{ijm}^{st} = N^{st}(g_{ijm}^E, l_{ijm}^E, x_{ijmc}^I, x_{ijmc}^O, y_{ijmc}^I, y_{ijmc}^O). \quad (9)$$

### Minimizing Network Cost

The total network cost comprises

- the annualized capital cost of the mass exchangers, that may be discontinuous (involve a fixed charge cost factor), and
- the annualized operating cost, i. e. the cost of the mass separating agents.

Consequently, the MEN MINLP synthesis model is formulated as follows:

(P1) min

$$\sum_{ijm} \left( AC_{ijm}^1 E_{ijm} + AC_{ijm}^2 (N_{ijm}^{st}) \right) + \sum_j AC_j^3 L_j$$

such that

(2) – (9)

$$g_{ijm}^I, g_{ijm}^E, g_{ijj'mm'}^B, g_{ijm}^O \geq 0,$$

$$y_{ijmc}^I, y_{ijmc}^O \geq 0,$$

$$i \in R, j, j' \in S,$$

$$m, m' = 1, \dots, M,$$

$$c = 1, \dots, C,$$

$$l_{ijm}^I, l_{ijm}^E, l_{ii'jmm'}^B, l_{ijm}^O \geq 0,$$

$$x_{ijmc}^I, x_{ijmc}^O \geq 0,$$

$$i \in R, j, j' \in S,$$

$$m, m' = 1, \dots, M,$$

$$c = 1, \dots, C,$$

$$E_{ijm} = 0, 1,$$

$$i \in R, j, j' \in S,$$

$$m, m' = 1, \dots, M.$$

(P1) is a nonconvex MINLP problem and global optimization methods are required to guarantee global optimal solutions.

The main advantage of the simultaneous MEN synthesis model (P1), as opposed to the sequential MEN synthesis method, is that the trade-off between the capital and operating costs is systematically considered. Also,

- (P1) derives the optimal network with respect to all the transferable components, considering the mass transfer of each component separately within the calculated mass-transfer stages of each exchanger.
- Forbidden mass exchange matches, limited mass exchange and/or forbidden exchanger connections can be explicitly considered in (P1).

- Variable target compositions are straightforwardly handled.

When the mass exchange matches and mass exchange loads are fixed (e. g. when these are determined within a sequential MEN synthesis framework), (P1) reduces to an NLP and can be solved to derive a network configuration and unit sizes with minimum capital cost.

Extending the concept of cost optimality of the mass exchanger network, two special cases have been studied:

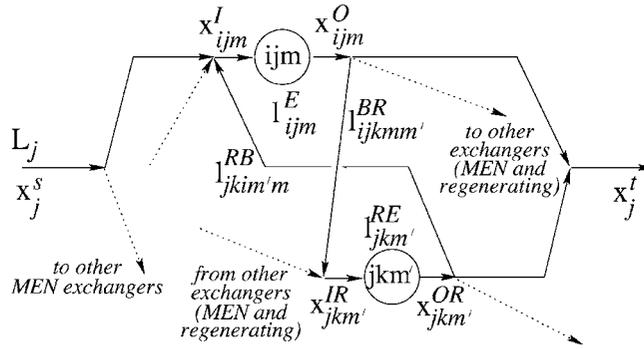

- MEN and *regeneration networks*.

When regenerating agents are available for some (or all) lean streams, the total mass integration cost involves also the regeneration cost. The regeneration network can be considered simultaneously within the MINLP MEN synthesis model [9], accounting for all the regeneration alternatives of the lean streams and employing binary variables to denote the existence of the regenerating exchangers. In this case, the mass separating agents behave as lean streams in the mass exchangers of the main MEN and as rich streams in the regenerating mass exchangers. The regeneration network is not necessarily separable from the main MEN, as a lean stream may be partly regenerated before being used as a separating agent in another mass exchanger. Thus, the lean stream superstructures involve all the possible interconnections between the exchangers of the main MEN and the regenerating exchangers. For example, for a lean stream  $j$  and its  $m$ th and  $m'$ th exchangers with rich stream  $i$  and regenerant  $k$  we have Fig. 4.

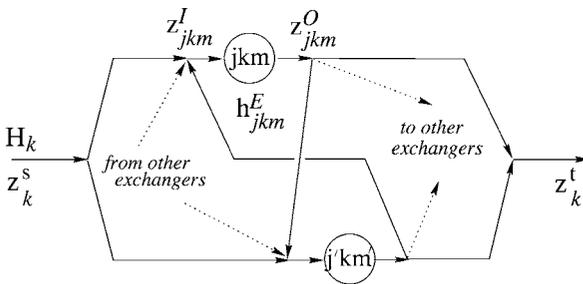

The overall superstructure of mass exchange and regeneration alternatives involves also the superstructures of the regenerating agents, that have variable flows, while the overall network cost includes the main MEN and the regeneration cost (capital and operating cost).

- *Flexible mass exchange networks*.

The ability of MEN to accommodate variations in the rich stream flows and inlet compositions in an efficient manner affects cost optimality. A *multi-period MINLP MEN synthesis model* has been suggested in [7], to derive mass exchange networks, flexible to accommodate in an optimal manner different mass integration requirements. In the multiperiod MINLP model a weighted operating cost is optimized simultaneously with the capital cost

MINLP: Mass and Heat Exchanger Networks, Figure 4  
Regenerable lean stream superstructure

MINLP: Mass and Heat Exchanger Networks, Figure 5  
Regenerating stream superstructure

for mass exchangers that can operate feasibly under the different conditions. The MEN superstructure is extended to include control variables that enhance flexibility (as exchanger-bypassing streams and overall bypass streams that are accordingly penalized).

When the alternative mass transfer operations take place at different and/or variable temperatures, heat integration between the network streams can be simultaneously considered within a combined MEN and HEN synthesis problem [7]. The available rich and lean streams define hot, cold or hot-and-cold streams in the heat integration problem, depending on whether their supply and target compositions are above or below the mass exchange temperatures. Thus, their heat exchange alternatives include both hot- and cold-side matching. Inlet and outlet temperatures and compositions in mass and heat exchangers are variables. The combined mass and heat exchanger superstructure involves all the possible mass and heat exchangers of a stream and all the possible interconnections between them, Fig. 6.

The combined MEN and HEN superstructure is described by

- mass balances at the superstructure splitters (i. e. the initial stream splitters and the splitters after each side of the possible mass and heat exchangers), similar to (2) and (3), and considering all the connecting flows;
- mass balances for overall flows and transferable components at the superstructure mixers (i. e. the final stream mixers and the mixers prior to each side of the potential mass and heat exchangers), similar to (4), (5) and (6), and considering all the connecting flows;

- energy balances at the superstructure mixers;
- mass balances at the mass exchangers, similar to (1), and

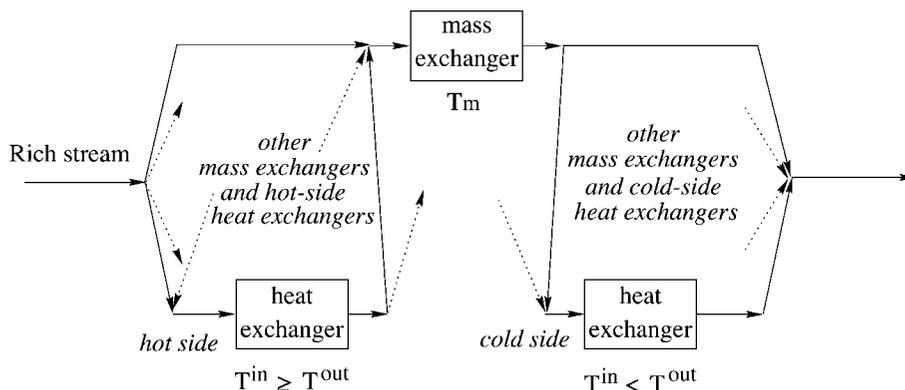

- energy balances at the heat exchangers.

The MHEN synthesis model also involves

- binary variables, to denote the existence of mass and heat exchangers, and their definition (mixed integer constraints),
- driving force constraints for mass exchange (8) at the potential mass exchangers, and for heat exchange at the potential heat exchangers (based on  $\Delta T_{\min}$ ),
- design equations for the potential mass and heat exchangers, and
- a total annualized network cost.

and is formulated as a (nonconvex) MINLP.

The simultaneous MHEN synthesis model addresses systematically the trade-off between capital and operating cost of mass and heat integration. The MEN and HEN are not assumed separable. Thus, better integration can be achieved, as it is allowed for a stream to be partly heated for a particular mass exchange operation and then heated further for final purification.

MINLP: Mass and Heat Exchanger Networks, Figure 6  
Combined MEN and HEN superstructure

In the simple case when the temperatures of the mass exchange operations are given or can be pre-postulated, the rich and lean streams define hot (or cold) streams before participating to mass exchangers and cold (or hot) streams afterwards [11].

The final mass and heat exchanger network structure results from the flows of the superstructure substreams. Alternatively, the use of binary variables has been suggested in [7] to denote the existence of exchanger connections. This, although increasing the combinatorial complexity of the MINLP synthesis model, allows for:

- i) explicit piping cost considerations,
- ii) structural constraints to be easily modeled, and
- iii) the solution of simple NLP subproblems within a decomposition-based MINLP solution method.

Mass exchange networks have been introduced as an end-of-pipe treatment alternative. However, the extent of mass recovery and the corresponding cost are closely related to the reactive and mixing operations in a process. A. Lakshmanan and L.T. Biegler [6] have suggested a MINLP model for the synthesis of optimal reactor networks, where the thermodynamic feasibility of mass integration and its implications are taken simultaneously into account, applying the first and second thermodynamic laws for mass exchange, i. e.

- Total mass balance for the mass integrated streams (resulting process and available rich and lean streams);

$$\sum_{i \in R} G_i (y_{ic}^s - y_{ic}^t) = \sum_{j \in S} L_j (x_{jc}^t - x_{jc}^s) \quad (10)$$

and

- feasibility of mass exchange above (and below) each candidate mass exchange pinch:

$$\left\{ \begin{array}{l} \text{Mass lost by all the rich} \\ \text{streams below each pinch} \\ \text{point candidate} \end{array} \right\} - \left\{ \begin{array}{l} \text{Mass gained by all the lean} \\ \text{streams below each pinch} \\ \text{point candidate} \end{array} \right\} \leq 0$$

i. e.

$$\begin{aligned} & \sum_{i \in R} G_i \\ & \times [\max(0, y_p - y_{ic}^t) - \max(0, y_p - y_{ic}^s)] \\ & - \sum_{j \in S} L_j \\ & \times [\max(0, x_p - x_{jc}^s) - \max(0, x_p - x_{jc}^t)] \\ & \leq 0 \end{aligned} \quad (11)$$

Note that the thermodynamic feasibility requirements in (11) involve nondifferentiable terms if inlet and outlet compositions are variables (position of streams with respect to candidate pinch points). These can be handled either employing differentiable approximation functions [6], or introducing binary variables [2,3,5].

The main assumption in MEN is that mass transfer operations are isothermal. In the general case these can be followed (or caused) by heat transfer, as in distillation. Assuming constant counter-current molar flows, M.J. Bagajewicz and V. Manousiouthakis showed in [1] that distillation columns can be handled as pure

mass transfer operations and derived targets for energy consumption and separation of a 'key' component, employing the first and second thermodynamic laws in (10) and (11), within an MINLP-based MHEN sequential synthesis framework. The problem of energy-induced separations has been addressed by M.M. El-Halwagi, B.K. Srinivas and R.F. Dunn in [4], translating the energy-based separation tasks into simple energy-requiring operations (heating and cooling tasks) and deriving targets for energy consumption and the corresponding mass recovery, based on thermodynamic feasibility constraints.

Extending the concept of mass exchange to non-isothermal mass transfer operations Papalexandri and Pistikopoulos introduced a *mass/heat transfer module* [8], where mass is transferred between different phases or reacting species if that is thermodynamically feasible, i. e. if that decreases the total Gibbs free energy of the system. Mass and energy balances, taking into account possible reactions, and mass-transfer driving-force constraints based on total Gibbs free energy are employed to model the mass/heat transfer module as an aggregate of differential mass and energy transfer phenomena. Considering a superstructure of mass/heat and heat exchange modules in a process and all possible interconnections between them, process synthesis tasks can be formulated as mass/heat and heat exchange superstructure MINLP problems, where binary variables are employed to denote the existence of mass/heat and heat exchangers. Then, process operations (conventional and/or hybrid) and networks are derived as combinations of mass/heat and heat exchange phenomena [8,10].

Mixed integer nonlinear programming; Outer approximation method; Generalized Benders decomposition; Extended cutting plane method

The *outer approximation algorithm* (OA algorithm) ([1,2,9]) addresses mixed integer nonlinear programs of the form:

$$(P) \quad \begin{cases} \min & Z = f(x, y) \\ \text{s.t.} & g_j(x, y) \leq 0, \quad j \in J, \\ & x \in X, y \in Y, \end{cases}$$

where  $f(\cdot), g(\cdot)$  are convex, differentiable functions,  $J$  is the index set of inequalities, and  $x$  and  $y$  are the continuous and discrete variables, respectively. The set  $X$  is commonly assumed to be a convex compact set, e. g.  $X = \{x: x \in \mathbf{R}^n, Dx \leq d, x^L \leq x \leq x^U\}$ ; the discrete set  $Y$  corresponds to a polyhedral set of integer points,  $Y = \{y: y \in \mathbf{Z}^m, Ay \leq a\}$ , and in most cases is restricted to 0–1 values,  $y \in \{0, 1\}^m$ . In most applications of interest the objective and constraint functions  $f(\cdot), g(\cdot)$  are linear in  $y$  (e. g. fixed cost charges and logic constraints).

The OA algorithm is based on the following theorem [1]:

**Theorem 1** *Problem (P) and the following mixed-integer linear program (MILP) master problem (M-OA) have the same optimal solution  $(x^*, y^*)$ ,*

$$(M - OA) \quad \min Z_L = \alpha$$

such that

$$\begin{aligned} \alpha &\geq f(x^k, y^k) + \nabla f(x^k, y^k) \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix}, \\ g_j(x^k, y^k) + \nabla g_j(x^k, y^k) \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix} &\leq 0, \\ j &\in J, \quad k \in K^*, \\ x &\in X, \quad y \in Y, \end{aligned}$$

where

$$K^* = \left\{ k: \begin{array}{l} (x^k, y^k) \text{ is the optimal} \\ \text{solution to (NLP1)} \\ \text{for all feasible } y^k \in Y \end{array} \right\},$$

$$(NLP1) \quad \begin{cases} \min & Z_U^k = f(x, y^k) \\ \text{s.t.} & g_j(x, y^k) \leq 0, \quad j \in J, \\ & x \in X, \end{cases}$$

where  $Z_U^k$  is an upper bound to the optimum of problem (P).

Note that since the functions  $f(x, y)$  and  $g(x, y)$  are convex, the linearizations in (M-OA) correspond to outer approximations of the nonlinear feasible region in problem (P). Also, since the master problem (M-OA) requires the solution of all feasible discrete variables  $y^k$ , the following MILP relaxation is considered, assuming that the solution of  $K$  NLP subproblems is available:

$$(RM - OA) \quad \min Z_L^K = \alpha$$

such that

$$\begin{aligned} \alpha &\geq f(x^k, y^k) + \nabla f(x^k, y^k) \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix}, \\ g_j(x^k, y^k) + \nabla g_j(x^k, y^k) \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix} &\leq 0, \\ j &\in J, \quad k = 1, \dots, K, \\ x &\in X, \quad y \in Y. \end{aligned}$$

Given the assumption on convexity of the functions  $f(x, y)$  and  $g(x, y)$ , the following property can be easily be established,

*Property 2* The solution of problem (RM-OA), corresponds to a lower bound to the solution of problem (P).

Note that since function linearizations are accumulated as iterations proceed, the master problems (RM-OA) yield a nondecreasing sequence of lower bounds,  $Z_L^1 \leq \dots \leq Z_L^K$ , since linearizations are accumulated as iterations  $k$  proceed.

The OA algorithm as proposed by M.A. Duran and I.E. Grossmann [1] consists of performing a cycle of major iterations,  $k = 1, \dots, K$ , in which (NLP1) is solved for the corresponding  $y^k$ , and the relaxed MILP master problem (RM-OA) is updated and solved with the corresponding function linearizations at the point  $(x^k, y^k)$ . The (NLP1) subproblems yield an upper bound that is used to define the best current solution,  $UB^K = \min(Z_U^k)$ . The cycle of iterations is continued until this upper bound and the lower bound of the relaxed master problem, are within a specified tolerance.

It should be noted that for the case when the problem (NLP1) has no feasible solution, there are two major ways to handle this problem. The more general option is to consider the solution of the feasibility prob-

lem,

$$(NLFP) \quad \begin{cases} \min & u \\ \text{s.t.} & g_j(x, y^k) \leq u, \quad j \in J, \\ & x \in X, \quad u \in \mathbb{R}^1. \end{cases}$$

R. Fletcher and S. Leyffer [2] have shown that for infeasible NLP subproblems, if the linearization at the solution of problem (NLFP) is included, this will guarantee convergence to the optimal solution.

For the case when the discrete set  $Y$  is given by 0–1 values in problem (P), the other option to ensure convergence of the OA algorithm without solving the feasibility subproblems (NLFP), is to introduce the following integer cut whose objective is to make infeasible the choice of the previous 0–1 values generated at the  $K$  previous iterations [1]:

$$(ICUT) \quad \begin{cases} \sum_{i \in B^k} y_i - \sum_{i \in N^k} y_i \leq |B^k| - 1, \\ k = 1, \dots, K, \end{cases}$$

where  $B^k = \{i: y_i^k = 1\}$ ,  $N^k = \{i: y_i^k = 0\}$ ,  $k = 1, \dots, K$ . This cut becomes very weak as the dimensionality of the 0–1 variables increases. However, it has the useful feature of ensuring that new 0–1 values are generated at each major iteration. In this way the algorithm will not return to a previous integer point when convergence is achieved. Using the above integer cut the termination takes place as soon as  $Z_L^K \geq UB^K$ .

The OA method generally requires relatively few cycles or major iterations. One reason for this behavior is given by the following property:

*Property 3* The OA algorithm trivially converges in one iteration if  $f(x, y)$  and  $g(x, y)$  are linear.

The proof simply follows from the fact that if  $f(x, y)$  and  $g(x, y)$  are linear in  $x$  and  $y$  the MILP master problem (RM-OA) is identical to the original problem (P).

It is also important to note that the MILP master problem need not be solved to optimality. In fact given the upper bound  $UB^K$  and a tolerance  $\varepsilon$  it is sufficient to generate the new  $(y^K, x^K)$  by solving,

$$(M - OAF) \quad \min Z_L^K = 0\alpha$$

such that

$$\begin{aligned} \alpha &\geq UB^K - \varepsilon, \\ \alpha &\geq f(x^k, y^k) + \nabla f(x^k, y^k) \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix}, \\ g_j(x^k, y^k) + \nabla g_j(x^k, y^k) \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix} &\leq 0, \\ j &\in J, \quad k = 1, \dots, K, \\ x &\in X, \quad y \in Y. \end{aligned}$$

While in (M-OA) the interpretation of the new point  $y^K$  is that it represents the best integer solution to the approximating master problem, in (M-OAF) it represents an integer solution whose lower bounding objective does not exceed the current upper bound  $UB^K$ ; in other words it is a feasible solution to (M-OA) with an objective below the current estimate. Note that in this case the OA iterations are terminated when (M-OAF) is infeasible.

Another interesting point about the OA algorithm is the relationship of its master problem with the one of the *generalized Benders decomposition* method [3], which is given by:

$$(RM - GBD) \quad \min Z_L^K = \alpha$$

such that

$$\begin{aligned} \alpha &\geq f(x^k, y^k) + \nabla_y f(x^k, y^k)^\top (y - y^k) \\ &\quad + (\mu^k)^\top \left[ g(x^k, y^k) + \nabla g(x^k, y^k)(y - y^k) \right], \\ k &\in KFS, \\ (\lambda^k)^\top \left[ g(x^k, y^k) + \nabla g(x^k, y^k)(y - y^k) \right] &\leq 0, \\ k &\in KIS, \\ x &\in X, \quad \alpha \in \mathbb{R}^1, \end{aligned}$$

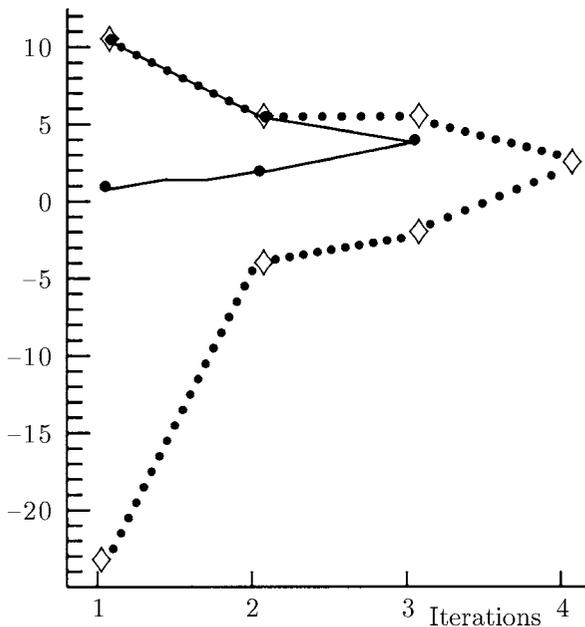

where  $KFS$  is the set of feasible subproblems (NLP1) and  $KIS$  the set of infeasible subproblems whose solution is given by (NLFP). Also  $|KFS \cup KIS| = K$ . The following property, holds between the two methods [1]:

*Property 4* Given the same set of  $K$  subproblems, the lower bounds predicted by the relaxed master problem (RM-OA) are greater or equal to the ones predicted by the relaxed master problem (RM-GBD).

The above proof follows from the fact that the Lagrangian and feasibility cuts in (RM-GBD) are surrogates of the outer approximations in the master problem (M-OA). Given the fact that the lower bounds of

**MINLP: Outer Approximation Algorithm, Table 1**  
Summary of computational results

ECP	—	5 (M-MIP)	18LPs

**MINLP: Outer Approximation Algorithm, Figure 1**  
Progress of iterations of OA and GBD for MINLP in MIP-EX

GBD are generally weaker, this method commonly requires a larger number of cycles or major iterations. As the number of 0–1 variables increases this difference becomes more pronounced. This is to be expected since only one new cut is generated per iteration. Therefore user-supplied constraints must often be added to the master problem to strengthen the bounds. As for the OA algorithm, the trade-off is that while it generally predicts stronger lower bounds than GBD, the computational cost for solving the master problem (M-OA) is greater since the number of constraints added per iteration is equal to the number of nonlinear constraints plus the nonlinear objective.

The OA algorithm is also closely related to the *extended cutting plane* (ECP) method by T. Westerlund

and F. Peterssen [8]. The main difference lies that in the ECP method no NLP subproblem is solved, and that linearization simply takes place over the predicted continuous points from the MILP master problem, which in turn will normally only include linearizations of the most violated constraints.

Extension of the OA algorithm [4] include the LP/NLP based branch and bound [6], which avoids the complete solution of the MILP master problem (M-OA) at each major iteration. The method starts by solving an initial NLP subproblem which is linearized as in (M-OA). The basic idea consists then of performing an LP-based branch and bound method for (M-OA) in which NLP subproblems (NLP1) are solved at those nodes in which feasible integer solutions are found. By updating the representation of the master problem in the current open nodes of the tree with the addition of the corresponding linearizations, the need of restarting the tree search is avoided. Another important extension has been the method by Fletcher and Leyffer [2] who included a quadratic approximation based on the Hessian of the Lagrangian to the master problem (M-OAF) in order to capture nonlinearities in the 0–1 variables. Note that in this case the optimal solution of the mixed integer quadratic program (MIQP),  $Z^K$ , does not predict valid lower bounds in this case, and hence the constraint  $\alpha \leq \text{UBK} - \varepsilon$  is added, with which the search is terminated when no feasible solution can be found in the MIQP master.

Finally, in order to handle equations in problem (P), G.R. Kocis and Grossmann [5] proposed the equality relaxation strategy, in which linearizations of equations are converted into inequalities for the MIP master problem according to the sign of the Lagrange multipliers of the corresponding NLP subproblem. J. Viswanathan and Grossmann [7], further proposed to add slack variables to this MILP master problem, and an augmented penalty function. Since in this generally nonconvex case the bounding properties do not apply, the algorithm was modified so as to start with the NLP relaxation of problem (P). If no integer solution is found, iterations between the MILP and NLP subproblems take place until there is no improvement in the objective function. This idea was precisely implemented in the commercial code DICOPT, which can also be modified to the original OA algorithm, if the user knows that the functions  $f(x, y)$  and  $g(x, y)$  are convex.

*Example 5* In order to illustrate the performance of the OA algorithm, a simple numerical MINLP example is considered.

$$\begin{array}{l}
 \text{(MIP - EX)} \quad \left\{ \begin{array}{l}
 \min \quad Z = y_1 + 1.5y_2 + 0.5y_3 \\
 \quad \quad + x_1^2 + x_2^2 \\
 \text{s.t.} \quad (x_1 - 2)^2 - x_2 \leq 0 \\
 \quad \quad x_1 - 2y_1 \geq 0 \\
 \quad \quad x_1 - x_2 - 4(1 - y_2) \leq 0 \\
 \quad \quad x_1 - (1 - y_1) \geq 0 \\
 \quad \quad x_2 - y_2 \geq 0 \\
 \quad \quad x_1 + x_2 \geq 3y_3 \\
 \quad \quad y_1 + y_2 + y_3 \geq 1 \\
 \quad \quad 0 \leq x_1 \leq 4, \quad 0 \leq x_2 \leq 4 \\
 \quad \quad y_1, y_2, y_3 = 0, 1.
 \end{array} \right.
 \end{array}$$

The optimum solution to this problem corresponds to  $y_1 = 0$ ,  $y_2 = 1$ ,  $y_3 = 0$ ,  $x_1 = 1$ ,  $x_2 = 1$ ,  $Z = 3.5$ . Figure 1 shows the progress of the iterations of the OA and GBD algorithm with the starting point  $y_1 = y_2 = y_3 = 1$ . As can be seen the lower bounds predicted by the OA algorithm are considerably stronger than the ones predicted by GBD. In particular at iteration 1, the lower bound of OA is 1.0 while the one of GBD is  $-23.5$ . Nevertheless, since this is a very small problem GBD requires only one more iteration than OA (4 versus 3). It is interesting to note that the NLP relaxation of this problem is 2.53, which is significantly lower than the optimal mixed integer solution. Also, as can be seen in Table 1, an NLP-based branch and bound method requires the solution of 5 NLP subproblems, while the ECP method requires 5 successive MILP problems.

Reactive distillation; Bilevel programming; MINLP

*Reactive distillation* (RD) occurs when a reaction takes place in the liquid holdup on the trays, in the reboiler, or in the condenser of a distillation column. Reactive distillation can increase the conversion of equilibrium limited reactions by continuously separating products and reactants, improve the selectivity in some kinetically limited reaction systems, and separate azeotropic and isomeric mixtures by converting one species into another that is easy to remove. It can also create a natural heat integration that uses an exothermic heat of reaction to create vapor boilup in a distillation column, and reduce capital costs by completing several processing steps in a single vessel. Reactive distillation is used commercially to produce methyl tert-butyl ether [13], esters including methyl acetate [1], and nylon 6, 6 [9]. It has also been proposed for hydrolysis reactions [7], ethylene glycol synthesis [11], and cumene production [12]. See [7] for a review of the area.

As a result of increasing interest in the reactive distillation technique, systematic reactive distillation design methods have gained much importance. See [2,3,4,5] for residue curve maps, a powerful tool for visualizing distillation problems, to reactive distillation. In [7] this work was extended by including kinetic effects when the Damkohler number is fixed. In [14] synthesis of reactive distillation with multiple reactions is studied.

Reactive distillation poses a challenging problem for optimization based design techniques. Unlike in conventional distillation, holdup volume is an important design variable in reactive distillation, since the reaction generally takes place in the liquid body on the tray. The constant molar overflow assumption of conventional distillation design is not valid unless the re-

action has thermal neutrality and is stoichiometrically balanced. For an optimal solution one should take into account that the feed to the column may be distributed. This, in addition to the holdup volume, liquid and vapor flows, composition and temperature profiles, number of trays and feed location(s) become major variables of an optimization problem which searches for a minimum of a cost function. The constraints of this optimization problem are material and energy balances, vapor-liquid equilibria, mole fraction summations, kinetic and thermodynamic relationships, and logical relationships between the variables. The resulting optimization model is a mixed integer nonlinear programming problem since it involves the optimum number of trays and feed tray locations which are integer variables. The cost function and the material and energy balances cause the nonlinearity of the problem.

There are two approaches to RD design via MINLP methods. One addresses reactive distillation through heat and mass exchanger networks [10], and the other addresses it through distillation column superstructures [6,8].

## Problem Statement

The general problem of the reactive distillation column synthesis problem can be stated formally as follows.

Given:

- the chemical species,  $i = 1, \dots, I$ , involved in the distillation; desired products,  $i \in P$ , and their production rates  $P_j$ ;
- the set of chemical reactions,  $j = 1, \dots, J$ ;
- rate expressions  $r_j$  or an equilibrium constant  $K_j$  for each reaction  $j$ ;
- heat of vaporization and vapor-liquid equilibrium data;
- cost of downstream separations;
- cost  $c_s$  and composition  $x_{is}$  of all feedstocks,  $s = 1 \dots S$ ;
- the cost of the column as a function of the number of trays and the internal vapor flow rate,  $C(V, N)$ ;
- the form of the catalyst.

Determine:

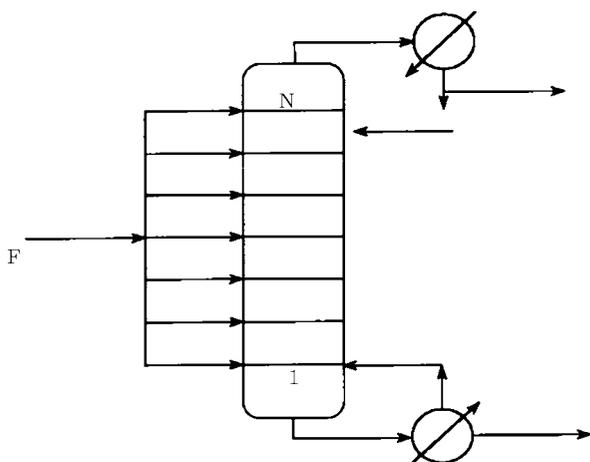

- the optimum number of trays;
- the trays where reactions take place;
- the holdup on each tray where a kinetically limited reaction takes place;

- the reflux ratio;
- the condenser and reboiler duties; and
- the feed location(s).

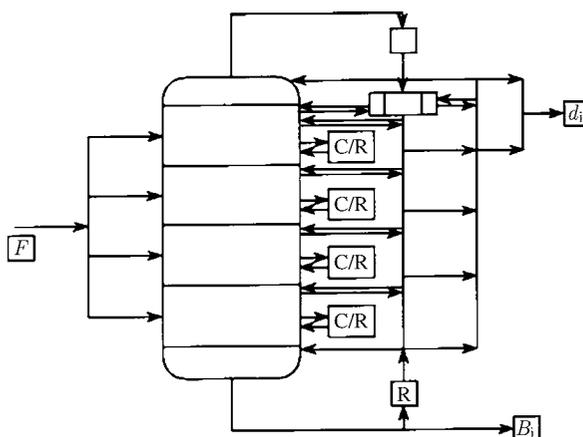

Such that the total cost is minimized while producing the correct amount of product.

### Distillation Based Superstructure Approaches

One approach to MINLP based reactive distillation column design uses a superstructure that contains many different alternative designs embedded within it. Two different superstructures have been proposed; they differ in their treatment of the liquid reflux and vapor boilup, and in their heat management. See [6] for a structure that varies the number of trays and always recycles the liquid reflux to the top tray and the vapor boilup to the bottom tray (Fig. 1). More recently (1997), Z.H. Gumus and A.R. Ciric [8] modified the superstructure presented in [15] recycling vapor boilup and liquid reflux to each tray by adding a decanter to the distillate stream and side heaters and coolers to each tray (Fig. 2). In both of these superstructures, the number of trays may vary between 1 and some upper bound  $K$ . Each feed stream is split, and a portion is sent to each tray in the superstructure. In kinetically limited reactions, the hold-up volume may vary, and, in reactions systems with a solid catalyst, some trays will have reaction while others do not.

MINLP: Reactive Distillation Column Synthesis, Figure 1 Superstructure for optimum feed location(s) and number of trays [6]

MINLP: Reactive Distillation Column Synthesis, Figure 2 Tray-by-tray superstructure of [8]

The structure shown in Fig. 1 is appropriate for reactive distillation processes with a single liquid phase and kinetically limited reactions that are catalyzed with a solid catalyst. Representing the existence of each tray with an integer variable  $Y_k$  leads to a mixed integer nonlinear programming problem whose solution extracts a design with the number of trays, feed tray locations, reactive trays, holdup volumes, reflux ratio and boilup ratio that minimize the total cost. Assumed vapor liquid equilibrium on each tray, no reaction in the vapor phase, homogeneous liquid phase, negligible enthalpy of liquid streams, constant heat of vaporization leads to the MINLP shown below [6]:

$$\begin{aligned} \min Z = & c_o + \sum_{sk} c_s F_{sk} + c_R Q_B + c_C Q_C \\ & + c_T D^{1.55} \times \sum \left( 2Y_k + 1.27 \frac{W_k}{D^2} \right) \\ & + c_{SH} D \sum_k \left( H_o + \sum_{k' \leq k} 2 + 1.27 \frac{W_{k'}}{D^2} \right)^{0.802} \\ & \times (Y_k - Y_{k+1}) \end{aligned}$$

subject to

$$\begin{aligned} \sum_s x_{is} F_{s1} - L_1 x_{i1} (1 - \beta) \\ + L_2 x_{i,2} - V_1 K_{i1} x_{i1} + \sum_j v_{ij} \xi_{1j} = 0, \quad (1) \end{aligned}$$

$$\left[ \sum_s x_{is} F_{sk} + V_{k-1} K_{i,k-1} x_{ik-1} + L_{k+1} x_{i,k+1} - L_k x_{ik} - V_k K_{ik} x_{ik} + \sum_j v_{ij} \xi_{jk} \right] Y_k = 0, \quad k = 2, \dots, K, \quad (2)$$

$$\left[ \lambda V_{k-1} - \lambda V_k - \sum_j \Delta H_j \xi_{jk} \right] Y_k = 0, \quad (3)$$

$$D_{ist} = \sum_k (V_k - L_{k+1})(Y_k - Y_{k+1}), \quad (4)$$

$$x_{i,k+1} - x d_i - 1 + y_k - y_{k+1} \leq 0, \quad (10)$$

$$\sum_i x d_i = 1, \quad (11)$$

$$\xi_{jk} = W_k f_j(x_{ik}, T_k), \quad (12)$$

$$K_{ik} = K_{ik}(x_{ik}, T_k), \quad (13)$$

$$V_k - F_{\max} Y_k \leq 0, \quad (14)$$

$$\sum_s F_{sk} - F_{\max} Y_k \leq 0, \quad (15)$$

$$L_{k+1} - F_{\max} Y_k \leq 0, \quad (16)$$

$$W_k - W_{\max} Y_k \leq 0, \quad (17)$$

$$Q_B = \beta \lambda L_1, \quad (18)$$

$$Q_C = \sum_k \lambda V_k (Y_k - Y_{k+1}), \quad (19)$$

$$D^4 \geq C_D \beta^2 L_1^2, \quad (20)$$

$$D \geq D_{\min}, \quad (21)$$

$$Y_{k+1} \leq Y_k. \quad (22)$$

In this model, constraints (1) and (2) are the component balances of species  $i$  over the bottom tray and the remaining trays  $k$ ; constraint (3) is the energy balance around tray  $k$ . The distillate flow is found with constraint (4). Distillate flow is calculated as the difference between the vapor flow leaving the top tray and the liquid flow entering it. Note that the term  $Y_k - Y_{k+1}$  will be nonzero only for top tray, and zero for all others. Constraint (5) calculates the bottoms flow rate and constraint (6) specifies the production rate. Summation equations for the mole fractions are given in constraints (7) and (8). Constraints (9)–(11) identify the top tray and set the distillate and liquid reflux composition equal to the composition of the vapor leaving the top tray. Reaction rates are given in constraint (12), and the vapor liquid equilibrium constant is found by constraint (13). Constraints (14)–(17) ensure that when  $Y_k$  equals zero and tray  $k$  does not exist, the flows onto and off of the tray are zero. Constraints (18) and (19) calculate the reboiler and condenser duties, while constraints (20) and (21) find the column diameter. The last constraint ensures that tray  $k + 1$  does not exist if tray  $k$  does not exist.

In [6] this technique is demonstrated with the synthesis of a reactive distillation column that makes ethylene glycol from ethylene oxide and water. The main reaction is

Further reaction of ethylene glycol gives the undesired byproduct diethylene glycol:

Ethylene glycol is produced using reactive distillation because the large volatility difference between the product and the reactants allows the continuous removal of EG from the reaction zone and absorption of the heat of reaction by the separation results in cost cuts.

The problem is solved using the reaction, physical property and cost data given in Table 1. The production rate is taken as 25 kg.mol/h of ethylene glycol. When the problem is solved without specifying the number of feed trays or their locations the solution obtained using GAMS is a 10-tray distillation column with a total

annualized cost of  $15.69 \times 10^6$ /yr. The reaction zone is above tray 4 and the feed is distributed to each tray in the reaction zone. When the problem is slightly modified by adding constraints on the feed tray number, the solution changes to a 10-tray column with a total annualized cost of  $15.73 \times 10^6$ /yr. The reaction zone is between trays 4 and 10 and water is fed to tray 10 while ethylene glycol enters the column at tray 4. The selectivity reached by both columns is the same. (Fig. 3) shows the solutions. The column specifications are given in Table 2.

### Heat and Mass Exchange Networks

In this approach, process units are defined as combinations of heat and mass exchanger blocks, and the alternatives for the synthesis are explored simultaneously in a superstructure. A reactive distillation column can be described as a combination of mass/heat exchanger units with a condenser and a reboiler [10]. Heat and mass transfer takes place between the contacting vapor

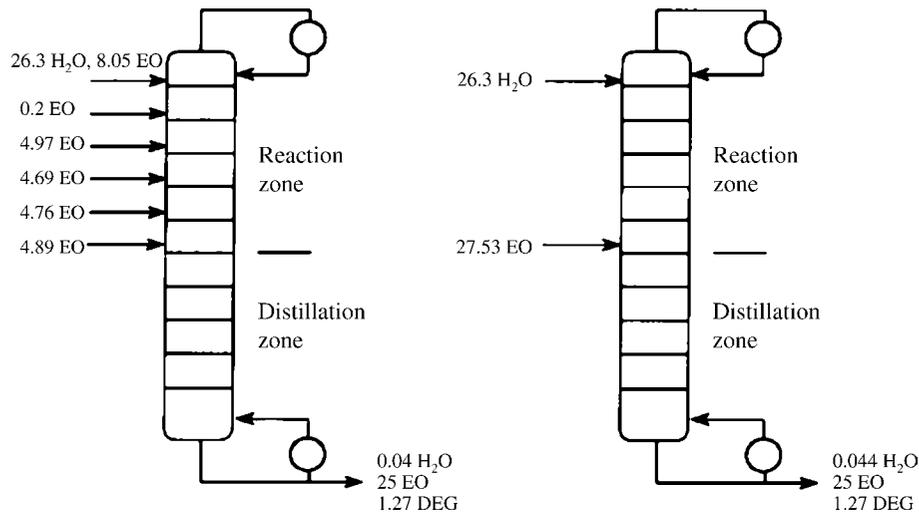

and liquid phases and from reactants to products. Multiple feeds and products and side heating and cooling tasks can be included in the description in the form of multiple mass and heat exchanger blocks between liquid and vapor streams. Its phase and quality define each stream. The quality indicator describes the leanness or richness of a stream in different components. Heat and mass transfer occurs between vapor and liquid streams of the same quality or between liquid and liquid (reactant and product) streams. For example, consider the reaction

Then there are liquid and vapor streams LABCD and VABCD in general notation. The streams lean in a component, for example in A, have that letter in parentheses, e.g. L(A)BCD or V(A)BCD. All possibilities of such streams, i.e. LAB(CD), VAB(CD), L(ABC)D, V(ABC)D, L(AB)C(D), V(AB)C(D), etc., and all the possible matches between them are considered within the structure. The possible matches are liquid-vapor matches of the same stream and all liquid-liquid matches.

This model describes exchangers with simple mass and energy balances and constraints defining phase and feasibility. Mass and heat generated or consumed by chemical reactions are included in the balances. Mass transfer is driven by a minimum concentration approach while a minimum temperature approach is the driving force for heat transfer. Concentration and temperature approach constraints are considered at each end of the exchanger. Equilibrium can be represented by a zero concentration approach, which means no driving force for mass transfer.

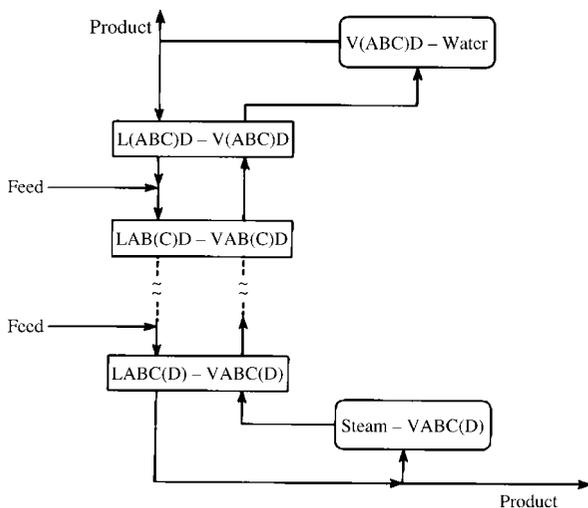

In the synthesis framework for an optimal process network, one should start with the construction of the stream sets containing all the initial, intermediate, and final process streams. The key is the availability of the physical and chemical property information on the streams. When the information is not enough to identify the individual streams, especially the intermediate streams, a general set of one vapor and one liquid stream is constructed, which contain all components involved in the process. The second step is to list all the possible stream matches. Engineering knowledge plays an important role in this step. One should be careful about not listing redundant or meaningless stream

Distr.	1.3	12	0.958	6.7	7.31
Two-feed	1.3	12	0.96	6.9	7.5

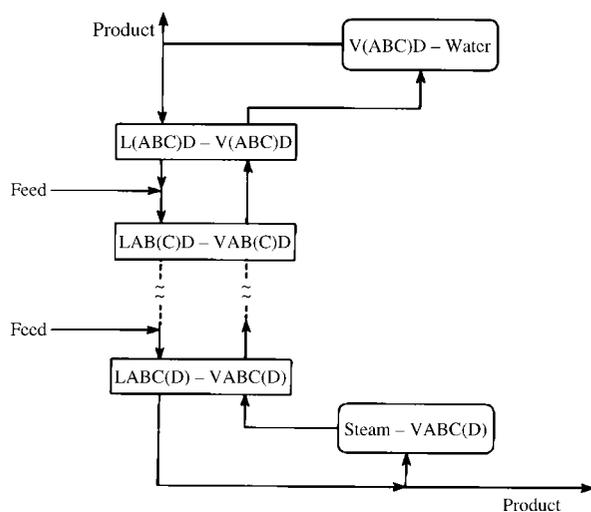

**MINLP: Reactive Distillation Column Synthesis, Figure 4**  
Mass/heat exchange network representation of a multifeed reactive distillation column

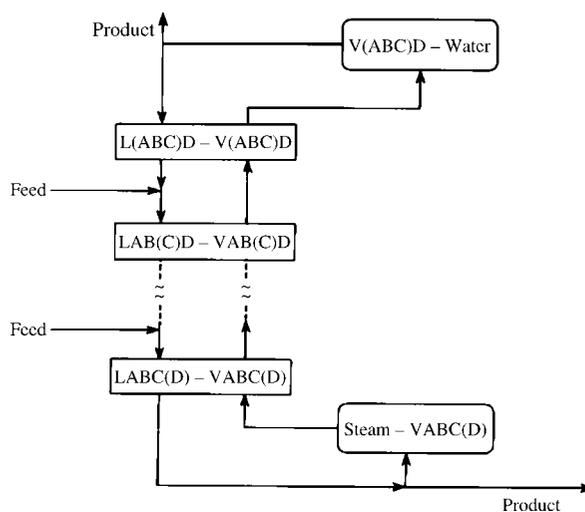

matches since these will only make the problem more complex. Knowledge about the system is the key in this screening stage. Developing the mass/heat exchange

network superstructure is the next step in the framework. All possible interconnections between the stream splitters and mixers should be taken into consideration. The last step is the optimization of the superstructure. Usually, the objective function of the optimization problem is a cost function. If the cost function includes only operating cost, which depends on the raw material and utility consumption, the objective function can be easily formulated from the superstructure. If, however, capital investment costs are involved in the objective cost function, the formulation is not straightforward from the superstructure, since process unit specifications are not considered in the superstructure. In this case, capital cost is to be approximated using cost functions that take operating conditions into account. Separation difficulty can be used in evaluating the capital cost of a distillation tray.

K.P. Papalexandri and E.N. Pistikopoulos [10] used the production of ethylene glycol from ethylene oxide and water to demonstrate this approach. The reactions involved in this production were given before. Physical properties, cost and reaction data are

MINLP: Reactive Distillation Column Synthesis, Figure 5  
Steps of the synthesis framework

MINLP: Reactive Distillation Column Synthesis, Figure 6  
Optimal reactive distillation column for ethylene glycol production

the same as given earlier in Table 1. The difference from the example problem studied in [6] is the objective, which is the minimization of operating cost only. The set of streams include the intermediate streams  $L\{EO, H_2O, EG, DEG\}$  and  $V\{EO, H_2O, EG, DEG\}$  and the product streams  $L(EG)$  and  $L(DEG)$ . Five liquid-liquid mass/heat exchange matches and 15 liquid-vapor mass/heat exchange matches are considered. Representing each match with a binary variable, and considering all possible interactions between units, the problem is formulated as a mixed integer nonlinear programming problem with the objective of minimizing operating cost, which includes raw material cost, purification, and utility cost. The optimal reactive distillation column obtained is pictured in Fig. 6. The column has two reaction zones and multiple feeds, and the operating cost is  $1.17 \times 10^6$  \$/yr.

## Conclusions

This paper discussed the MINLP applications in reactive distillation design problems. Two main approaches are studied: distillation based superstructure approach that uses rigorous tray-by-tray method to model reactive distillation, and heat and mass exchanger network superstructure approach that realizes reactive distillation processes as combinations of several mass/heat exchangers with a condenser and a reboiler. Examples are included to demonstrate the approaches.

Scheduling; Paper converting; Trim-loss problem;  
Bilinear; Convex transformation

The trim-loss problem is one of the most demanding optimization problems in the paper-converting industry. It appears when an order specified by a customer is to be satisfied by cutting out a set of product reels from a wider raw paper reel.

The products in the order are characterized by width and quality. In a paper-converting mill the raw paper can be printed, coated and cut. In a typical paper-converting mill, there may be hundreds of different products to be produced. When considering the trim-loss problem, width is the most important property while the main problem is to determine such cutting patterns that minimize waste production, the *trim loss*.

In the optimization problem, beyond the number of cutting patterns needed, the appearance of each cutting pattern needs to be determined at the same time as having to decide how many times the cutting patterns ought to be repeated.

The customer widths and the raw paper widths are often more or less independent of each other. This makes it combinatorially very demanding to produce a cutting plan that minimizes the trim loss. Even if the trim-loss problem is in its basic form an integer problem, it has often been solved by linear programming (LP) methods [3] or some heuristic algorithms

**MINLP: Trim-loss Problem, Figure 1**  
**The cutting procedure**

[4]. A good survey of widely used solution methods for trim-loss and assortment problems is given in [7].

When using an LP-approach to solve an integer problem the biggest difficulty is to convert the continuous solution such that the integer variables obtain integer values. The rounding methods are heuristic [8] and often fail to give the optimal integer solution even though the solution may be fairly good.

**Problem Formulation**

The trim-loss problem is a bilinear nonconvex integer nonlinear programming (INLP) problem. The appearance of a cutting pattern needs to be determined by integer variables and the bilinearity comes from the demand constraints.

A cutting pattern tells how many times a certain product is cut out from the raw paper. Let a cutting pattern have the index  $j$  and a product the index  $i$ . Assume a customer demand with  $I$  different products and further assume that the maximum allowed number of different cutting patterns is  $J$ . Further let  $m_j$  be the number of times a certain cutting pattern is repeated and  $n_{ij}$  be the number of times a product  $i$  appears in cutting pattern  $j$ . If the demand of a product  $i$  is expressed by  $n_{i, \text{order}}$ , the demand constraints can be written as

$$\begin{aligned}
 n_{i, \text{order}} - \sum_{j=1}^J m_j \cdot n_{ij} &\leq 0, \\
 i &= 1, \dots, I, \\
 m_j, n_{ij} &\in \mathbb{Z}^+.
 \end{aligned}
 \tag{1}$$

The negative bilinear terms make the problem nonconvex. Both of the variables in the term are integer variables and consequently the problem is a bilinear inte-

ger optimization problem. It is not possible to replace one of the variables  $n_{ij}$  with a continuous variable because this would violate the product specification. In theory it is possible to replace the  $m_j$  with a continuous variable but this may easily dissatisfy the desired product reel length and diameter requirements. Therefore, in the following study it is preferable to keep both  $m_j$  and  $n_{ij}$  as integers.

While raw paper reels of the same width are often glued together to form a continuous raw paper reel the problem can be simplified by omitting the raw paper length and assuming that the pattern lengths are equal.

Besides the demand constraint, certain constraints are needed to keep the problem feasible. Let the width of a product  $i$  be expressed by  $b_i$  and the width of the raw paper used for cutting pattern  $j$  by  $B_{j, \text{max}}$ . The trim-loss width cannot exceed, for instance, 200mm owing to the machinery. This limit is represented by  $\Delta_j$ . Furthermore, the maximum number of products that can be cut out from a pattern often has a physical restriction. The outcoming product reels have to form an angle big enough so that the reels do not attach together, yet with too big an angle between the outermost reels the paper may be torn off. Let this upper limit be  $N_{j, \text{max}}$ .

Besides the total number of patterns, the pattern changes are also of interest when doing the optimization. This is due to the fact that the machinery normally needs to be stopped for a knife change which causes a production stop. Let therefore the variable  $y_j$  be 1 if the cutting pattern  $j$  exists and 0 if not. The sum of  $y_j$  variables then indicates how many different cutting patterns are needed to satisfy the production and the sum of  $m_j$  indicates the total number of all patterns which are related to the running metres of the raw material.

Now the basic formulation can be written in mathematical form. The objective is to minimize the total number of patterns and the number of pattern changes.

$$\min_{m_j, n_{ij}, y_j} \left\{ \sum_{j=1}^J c_j \cdot m_j + C_j \cdot y_j \right\}
 \tag{2}$$

subject to

$$\sum_{i=1}^I b_i \cdot n_{ij} - B_{j, \text{max}} \leq 0,
 \tag{3}$$

$$-\sum_{i=1}^I b_i \cdot n_{ij} + B_{j,\max} - \Delta_j \leq 0, \quad (4)$$

$$\sum_{i=1}^I n_{ij} - N_{j,\max} \leq 0, \quad (5)$$

$$y_j - m_j \leq 0, \quad (6)$$

$$\begin{aligned} m_j - M_j \cdot y_j &\leq 0, \\ j &= 1, \dots, J, \end{aligned} \quad (7)$$

$$n_{i,\text{order}} - \sum_{j=1}^J m_j \cdot n_{ij} \leq 0, \quad (8)$$

$$\begin{aligned} i &= 1, \dots, I, \\ m_j, n_{ij} &\in \mathbb{Z}, \quad y_j \in \{0, 1\}. \end{aligned}$$

The  $M_j$  gives the upper bound for corresponding  $m_j$  variables. When using an objective as in (2) the constraint (6) becomes irrelevant. The width constraints are given in (3)–(4) and the constraint (5) restricts the number of cuts in a pattern. The binary variables,  $y_j$ , are defined in (6)–(7).

The functionality of the variables are demonstrated in the following figure where the raw-paper width is  $B_{j,\max}$ . Note that the pattern length may typically be e. g. 6500m.

The last constraint, the demand constraint (8), is an integer bilinear constraint where both variables in bilinear terms are pure integers. This makes the problem a nonconvex MINLP problem where the nonconvexity appears in the integer variables.

There are very few methods available that are capable of solving similar nonconvex MINLP problems. Some heuristic methods such as simulated annealing [9] may find the global optimal solution within infinite time but algorithmic methods have not been proven to converge with such types of problems. Only recently (1999) some advancements have been reported in [1] and [11].

However, it is fully possible to transform the trim-loss problem into convex or linear form and use some established MINLP or MILP solver to solve the resulting problem to global optimality. Some linear transformations are presented in [6] and methods to transform the nonconvex problem into a convex form can be found in [10] and [5].

## Linear Transformations

As can be seen from (2)–(8), all constraints but the last demand constraint are linear. This means that the problem should be fairly well bounded already by the linear part of the problem and thus a linear formulation strategy seems to be fully possible.

However, this linear transformation requires new variables and constraints that may complicate the problem. Using a standard approach, by rewriting one of the integer variables in the bilinear term by binary variables, the following is obtained.

$$\begin{aligned} m_j &= \sum_{k=1}^K 2^{k-1} \cdot \beta_{jk}, \\ m_j &\in \mathbb{R}, \quad \beta_{jk} \in \{0, 1\}. \end{aligned} \quad (9)$$

$K$  is the number of binary variables needed. By defining  $L_{ij}$  to be the upper bound for respective  $n_{ij}$  variables and introducing a new slack-variable  $s_{ijk}$  the following constraints will create a necessary link between the  $n_{ij}$  and  $s_{ijk}$  variables:

$$s_{ijk} - n_{ij} \leq 0, \quad (10)$$

$$-s_{ijk} + n_{ij} - L_{ij} \cdot (1 - \beta_{jk}) \leq 0, \quad (11)$$

$$s_{ijk} - L_{ij} \cdot \beta_{jk} \leq 0. \quad (12)$$

Using the above constraints the bilinear demand constraint can be written in linear form

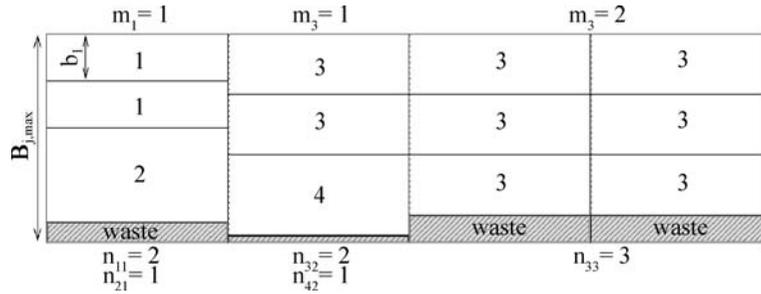

$$n_{i,\text{order}} - \sum_{j=1}^J \sum_{k=1}^K 2^{k-1} \cdot s_{ijk} \leq 0. \quad (13)$$

The  $m_j$  could also be represented by special ordered sets (SOS) where at most, one of the binary variables are allowed to be nonzero.

$$m_j = \sum_{k=1}^K k \cdot \beta_{jk}, \quad \sum_{k=1}^K \beta_{jk} \leq 1. \quad (14)$$

It should be noted that the usage of this kind of transformation may enlarge the integrality gap unless for instance the  $n_{ij}$  variables in equations (3)–(5) are replaced with corresponding variables  $s_{ijk}$ .

The same transformation can be modified such that  $n_{ij}$  is replaced by a binary representation and  $m_j$  is defined through the slack-variables  $s_{ijk}$ .

MINLP: Trim-loss Problem, Figure 2  
The integer variables

**Parameterization Methods**

Beyond the linear transformation, the problem can be written in linear form by simply parameterizing one of the variables in the bilinear term. This method though may lead to global optimality only in such cases where all the possible combinations have been considered. This strategy may be good for smaller problems but it may also generate far too many integer variables in solving larger trim-loss problems.

It is quite easy to generate all the possible combinations of  $n_{ij}$  variables satisfying the constraints (3)–(5). This strategy results in a problem where these constraints can be removed and where the  $n_{ij}$  variables in the resulting linear demand constraint are parameters:

$$n_{i,\text{order}} - m_j \cdot n'_{ij} \leq 0, \quad m_j \in \mathbb{Z}. \quad (15)$$

The same type of parameterization strategy may also be applied to the other variable  $m_j$  but in this case it may be more difficult to define the exact values of the parameters. One strategy is to use the upper bounds  $M_j$  or define all the  $m_j$  variables to be equal to one and make sure that a sufficient amount of the variables  $m_j$  are considered.

Another alternative is to combine the parameterization and transformation methods so that a proper amount of parameterized variables are combined with original variables. This strategy may be very efficient but often requires such information that may be difficult to obtain from a larger problem without any knowledge of the solution.

**Convex Transformations**

In the previous sections a number of methods were presented where the nonconvex problem can be trans-

formed or parameterized into linear form. The main drawback for this linear transformation strategy is the large number of extra constraints and continuous variables. The parameterization strategy results in a formulation with a few constraints but many extra integer variables.

In the following a number of convexification methods are presented. Generally, the convex formulations need fewer extra constraints and continuous variables as the linear strategies and no extra integer variables as is the case with the parameterization methods. Thus, the convex transformation could be expected to result in formulations which are easier to solve especially for larger-scale orders. This creates an interesting problem, where the integer search space is reduced at the expense of more complex nonlinear functions, which could, in principle, be used as benchmarks for the performance of MINLP algorithms.

The basic principle for the convex transformation is to first expand the bilinearity in the demand constraint

$$m_j \cdot n_{ij} = (m_j + \tau)(n_{ij} + \tau) - \tau \cdot (m_j + n_{ij}) - \tau^2. \quad (16)$$

In the following text, the translation constant  $\tau = 1$  is used for simplicity. The second step is to substitute the bilinear term in the original demand constraint

$$n_{i,\text{order}} - \sum_{j=1}^J (m_j + 1)(n_{ij} + 1) + \sum_{j=1}^J (m_j + n_{ij}) + J \leq 0. \quad (17)$$

It should be noted that the transformations that follow need to consider the whole problem not only individual

functions, which makes the transformation techniques more demanding. A transformation of a single function may cause linear constraints to become nonlinear if one is unaware of this fact.

### Exponential Transformation

The demand constraint is originally a negative bilinear constraint. The exponential transformation can only be applied to a positive bilinear constraint. Therefore, one of the variables in the bilinear term needs to be substituted with its reversed value.

$$r_{ij} = N_{j,\max} - n_{ij} \quad (18)$$

and the demand constraint is modified to

$$n_{i,\text{order}} - \sum_{j=1}^J m_j \cdot N_{j,\max} + \sum_{j=1}^J m_j \cdot r_{ij}. \quad (19)$$

Now the exponential transformation can be applied. The transformation is of the form

$$m_j + 1 = e^{M_j}, \quad r_{ij} + 1 = e^{R_{ij}} \quad (20)$$

and the variables are defined as

$$m_j = \sum_{l=1}^{L_j} \beta_{jl} \cdot l, \quad (21)$$

$$M_j = \sum_{l=1}^{L_j} \beta_{jl} \cdot \ln(l + 1), \quad (22)$$

$$r_{ij} = \sum_{k=1}^{K_i} \beta_{ijk} \cdot k, \quad (23)$$

$$R_{ij} = \sum_{k=1}^{K_i} \beta_{ijk} \cdot \ln(k + 1), \quad (24)$$

$$\sum_{l=1}^{L_j} \beta_{jl} \leq 1, \quad \sum_{k=1}^{K_i} \beta_{ijk} \leq 1, \quad (25)$$

$$\beta_{jl}, \beta_{ijk} \in \{0, 1\}, \quad M_j, R_{ij} \in \mathbb{R}.$$

When combining these definitions, the demand constraint can be written in convex form

$$n_{i,\text{order}} - J + \sum_{j=1}^J e^{M_j + R_{ij}} - \sum_{j=1}^J \left( (N_{j,\max} + 1) \cdot \sum_{l=1}^{L_j} \beta_{jl} \cdot l + \sum_{k=1}^{K_i} \beta_{ijk} \cdot k \right) \leq 0. \quad (26)$$

This transformation can also be achieved in slightly another way but using this strategy also requires updating some of the constraints in (3)–(7).

### Square-Root Transformation

This transformation is almost equivalent to the previous one. A main difference is that it can be applied straight to the negative bilinear constraint and thus no  $r_{ij}$  variables need to be defined. The constraint (21) is valid but the constraint (23) needs to be modified to

$$n_{ij} = \sum_{k=1}^{K_i} \beta_{ijk} \cdot k. \quad (27)$$

Note that the equations in (25) are valid. The transformation is of the form

$$m_j + 1 = \sqrt{M_j}, \quad n_{ij} + 1 = \sqrt{N_{ij}}. \quad (28)$$

The transformation variables  $M_j$  and  $N_{ij}$  are defined as

$$M_j = 1 + \sum_{l=1}^{L_j} \beta_{jl} \cdot l(l + 2), \quad (29)$$

$$N_{ij} = 1 + \sum_{k=1}^{K_i} \beta_{ijk} \cdot k(k + 2), \quad (30)$$

$$\beta_{jk}, \beta_{ijk} \in \{0, 1\}, \quad M_j, N_{ij} \in \mathbb{R}.$$

and the resulting convex demand constraint is

$$n_{i,\text{order}} + J - \sum_{j=1}^J \sqrt{M_j \cdot N_{ij}} + \sum_{j=1}^J \left( \sum_{l=1}^{L_j} \beta_{jl} \cdot l + \sum_{k=1}^{K_i} \beta_{ijk} \cdot k \right) \leq 0. \quad (31)$$

### Logarithmic and Square-Root Transformation

The square-root and the logarithmic functions can be combined, resulting in a third convex transformation. It is directly applicable to the negative bilinear function and the transformation can be written as

$$m_j + 1 = \sqrt{M_j}, \quad n_{ij} + 1 = \ln N_{ij}. \quad (32)$$

The  $m_j$ ,  $n_{ij}$  and  $M_j$  variables are defined as in the square-root transformation and the  $N_{ij}$  is defined as

$$N_{ij} = e + \sum_{k=1}^{K_i} \beta_{ijk} \cdot (e^{k+1} - e) \quad (33)$$

and the following convex demand constraint is obtained

$$n_{i,\text{order}} + J - \sum_{j=1}^J \sqrt{M_j} \cdot \ln N_{ij} + \sum_{j=1}^J \left( \sum_{l=1}^{L_j} \beta_{jl} \cdot l + \sum_{k=1}^{K_i} \beta_{ijk} \cdot k \right) \leq 0. \quad (34)$$

It can be noted in equation (34) that the only difference to the former transformation is the third term of the demand constraint.

### Inverted Transformation

The following transformation can be applied to a positive bilinear constraint. Thus the same definition of  $r_{ij}$  has to be done as for the exponential transformation. The transformation has the form

$$m_j + 1 = \frac{1}{M_j}, \quad r_{ij} + 1 = \frac{1}{R_{ij}}. \quad (35)$$

The definitions of the transformation variables follow:

$$M_j = 1 + \sum_{l=1}^{L_j} \beta_{jl} \cdot \left( \frac{1}{l+1} - 1 \right), \quad (36)$$

$$R_{ij} = 1 + \sum_{k=1}^{K_i} \beta_{ijk} \cdot \left( \frac{1}{k+1} - 1 \right). \quad (37)$$

The demand constraint is obtained exactly in the same way as before

$$n_{i,\text{order}} - J + \sum_{j=1}^J \frac{1}{M_j \cdot R_{ij}} - \sum_{j=1}^J \left( (N_{\max} + 1) \cdot \sum_{l=1}^{L_j} \beta_{jl} \cdot l + \sum_{k=1}^{K_i} \beta_{ijk} \cdot k \right) \leq 0. \quad (38)$$

### Modified Square-Root Transformation

As the last transformation, a modification to the previously presented square-root transformation is introduced. In such cases where the variable  $m_j$  may take large values, it may be more efficient to use another type of binary representation.

$$m_j = \sum_{l=1}^{L'_j} 2^{l-1} \cdot \beta_{jl}, \quad (39)$$

where  $L'_j = \lceil \log_2(m_{j,\max}) \rceil + 1$  if  $m_{j,\max}$  is the upper bound for the respective  $m_j$  variable. This modification reduces the required number of binary variables and the transformation variable  $M_j$  needs to be redefined. The definition also requires additional slack-variables and constraints. In the following, the square-root transformation is used:

$$M_j = 1 + \sum_{l=1}^{L'_j} (s^{2l-2} + 2^l) \cdot \beta_{jl} + \sum_{l,m=1; m < l}^{L'_j} 2^{l+m-1} \cdot s_{jlm}, \quad (40)$$

$$-s_{jlm} - 1 + \beta_{jl} + \beta_{jm} \leq 0, \quad (41)$$

$$2 \cdot s_{jlm} - \beta_{jl} - \beta_{jm} \leq 0, \quad l, m = 1, \dots, L'_j; \quad m < l. \quad (42)$$

By adding the extra constraints and defining  $N_{ij}$  as in the square-root strategy, the demand constraint can be

written in convex form as follows

$$n_{i,\text{order}} + J - \sum_{j=1}^J \sqrt{M_j \cdot N_{ij}} + \sum_{j=1}^J \left( \sum_{l=1}^{L_j} \beta_{jl} \cdot 2^{l-1} + \sum_{k=1}^{K_i} \beta_{ijk} \cdot k \right) \leq 0. \quad (43)$$

Five methods for transforming the originally nonconvex trim-loss problem into convex form have been discussed. Three of them were directly applicable to a negative bilinear function but for two methods some operations were needed to change the demand constraint into a positive bilinear constraint.

### Example: A Numerical Problem

In this last section a numerical example is solved with all of the presented methods. To improve the performance of the solution procedure some extra linear constraints need to be defined. They are, however, not specified here.

In the following example order an upper limit for products  $n_{i,\text{max}}$  that are allowed to be produced also has been defined. Here, the maximal possible overproduction of any product is 2. This limit is somewhat unnatural and is therefore not used as a constraint. However, the use of this type of upper bounds makes it possible to efficiently reduce the combinatorial space.

$i$	$b_i(\text{mm})$	$n_{i,\text{order}}$	$n_{i,\text{max}}$
1	330	8	10
2	360	16	18
3	380	12	14
4	430	7	9
5	490	14	16
6	530	16	18

#### Example order

The example demand is a mid-size customer order with a total weight of 27.5tons. Some important parameters need to be defined before optimization. The raw paper

width of 2200mm is chosen and a maximal trim loss of 100mm is tolerated. At most 5 products may be cut out from a cutting pattern. Among the following parameters, the parameter  $M_j$  refers to the upper bound of the respective  $m_j$  variable and the parameter  $N_i$  to the  $n_{ij}$  variables. Note, that since the raw paper width is equal for every pattern the latter upper bound is independent of the index  $j$ .

$$\begin{aligned} J = I = 6 & & N_{j,\text{max}} = 5 \\ c_j = 1 & & M_j = \{14, 12, 8, 7, 4, 2\} \\ C_j = 0.1 & & N_i = \{2, 3, 3, 5, 3, 4\} \\ B_{j,\text{max}} = 2200\text{mm} & & M_{\text{min}} = 15 \\ \Delta_j = 100\text{mm} & & \end{aligned}$$

#### The problem parameters

The parameter  $M_{\text{min}}$  is the lower bound for the sum of the variables  $m_j$ . This sum can easily be calculated in advance and significantly enhances the optimization performance.

Before doing the actual optimization it should be pointed out that the results are not comparable. The main purpose for showing the numerical results is to demonstrate that the above presented strategies are fully usable and result in quite efficient solvable formulations. The transformation strategies can be directly applied to any problem where the bilinear terms contain integer variables.

The methods are divided into three groups of which the linear transformation and the parameterization strategies result into MILP formulations. The third group, the convex transformation strategy produces MINLP formulations that have in this case been solved using the extended cutting plane (ECP) algorithm by T. Westerlund and F. Peterssen [12].

In the parameterization strategies the problem is redefined by parameterizing certain variables which means that the resulting problem has already been partly solved. This may, however, not always be a benefit, especially in such problems where a huge number of parameters increases the integer search space for other variables.

The strategies are numbered as follows:

1.	binary representation of $m_j$
2.	binary representation of $n_{ij}$
3.	parameterization of $n_{ij}$
4.	parameterization of $m_j$
5.	exponential transformation
6.	square-root transformation
7.	logarithmic and square-root transformation
8.	inverted transformation
9.	modified square-root transformation

The strategies enlarge the problem both in terms of variables and constraints. In the following the number of variables and constraints are given. All the constraints are linear except in the convex transformation strategies where six of the constraints are nonlinear.

The strategies 1–4 are linear formulations of which 3–4 use the parameterization strategy to overcome the bilinearity. Strategies 5–9 are convex transformations. The field with combinations gives simply the number of unconstrained discrete variable combinations as a function of number of binary variables. This information is more informative than just the number of variables.

Strategy	Constraints	Variables (I/B/C)	Comb. $2^n$
1.	408	36/23/120	$2^{98}$
2.	366	6/88/144	$2^{105}$
3.	59	51/51/–	$2^{140}$
4.	201	282/47/–	$2^{634}$
5.	199	–/169/84	$2^{96}$
6.	199	–/169/84	$2^{96}$
7.	185	–/169/84	$2^{96}$
8.	185	–/169/84	$2^{96}$
9.	225	–/208/84	$2^{118}$

The MILP problems 1–4 were solved with CPLEX-5.0 using default settings and the MINLP problems 5–

9 were solved by ‘mittlp’, an ECP application written by H. Skrifvars. The optimization was done on a Pentium Pro 200MHz running the Linux operating system.

The optimization results can be seen in the following table.

Strategy	Nodes (MILP)	ECP-iter. (MINLP)	CPU-time (s)
1.	265	-	7.6
2.	51	-	0.51
3.	2174	-	3.2
4.	265	-	7.7
5.	-	4	8.6
6.	-	7	66.6
7.	-	9	138.6
8.	-	10	736.4
9.	-	6	49.9

The optimal result has two cutting patterns with the widths  $B_1 = 2110$  mm and  $B_2 = 2170$  mm and multiples  $m_1 = 8$ ,  $m_2 = 7$ . The appearances of the patterns are given by the following variables:  $n_{1,1} = 1$ ,  $n_{2,1} = 2$ ,  $n_{6,1} = 2$ ,  $n_{3,2} = 2$ ,  $n_{4,2} = 1$ ,  $n_{5,2} = 2$

## Conclusions

The study above is not a fair comparison. Experience has shown that the performance order is highly dependent on the specific problem. In order to get an idea of which of the methods is, in average the most efficient one, tens of problems of different sizes need to be solved. However, the study illustrates that it is fully possible to apply the transformation methods to a well explored real industrial problem.

In the present study the trim-loss problem was used as an example case but the transformation methods are general and can be applied to any problem with similar type of bilinear constraints.

**Notation**

$i$	product index
$j$	cutting pattern index
$l$	number of products in the order
$J$	number of possible cutting patterns
$m_j$	number of times the pattern $j$ is used
$n_{ij}$	number of product $i$ in pattern $j$
$r_{ij}$	reversed value of $n_{ij}$
$n_{i, \text{order}}$	number of product $i$ ordered
$b_i$	width of product $i$
$B_{j, \text{max}}$	width of raw paper of pattern $j$
$\Delta_j$	max. trim-loss width
$N_{j, \text{max}}$	max. number of products in pattern $j$
$y_j$	binary variable that is one if $m_j > 0$
$c_j, C_j$	cost coefficients
$M_j$	upper bound / transformation variable
$\beta_{jl}, \beta_{jk}$	binary variables for defining $m_j$
$L_{ij}$	upper bound
$s_{ijk}$	slack-variable for linear transformations
$\beta_{ijk}$	binary variables for defining $n_{ij}$ or $r_{ij}$
$n_{ij}'$	fixed $n_{ij}$ values
$\tau$	translation constant
$N_{ij}$	transformation variable
$R_{ij}$	transformation variable
$l, k, m$	indices of binary variables
$L_j, K_i$	number of binary variables needed

### Introduction/Background

In the past two decades, biologists have sequenced more and more complete genome sets for various species. To reveal secrets of life hiding in enormous genome data, the mechanism which conducts gene expression is continuously researched and discussed. Gene transcription, a primary gateway to gene function, is controlled by a complex regulatory mechanism. In this mechanism, many specific regulatory proteins bind to local regions of a gene upstream, called transcription factor binding sites (TFBS) or motifs, to control the gene expression. Therefore, the discrimination of TFBSs becomes an essential task for genome function analysis. Finding TFBSs is a challenging issue because motifs are mostly orientation- and position- independent to transcription starting points, and usually with some degree of ambiguity. Experimental methods like DNA microarray (DeRisi et al., 1997; Lockhart et al., 1996) and

SAGE (Velculescu et al., 2000) are capable of precisely elucidating motifs, but too laborious and time consuming to analyze enormous genome data. More and more computer based methods - such as enumeration methods, probability models and heuristics - are being developed to help motif finding. The modeling of in silico motif finding has two parts: scoring function and algorithm. The simplest scoring function is given by summing up the number of base matches in a regulatory region. Generally it needs a predefined shared pattern for accuracy. Another scoring criterion is position-specific scoring matrices (PSSM) or its variant, information content (IC, Schneider et al., 1986), [44]. Though more computing is required, PSSM and IC are the most popular scoring functions, owing to their pattern-free property.

Current motif finding algorithms can generally be categorized as the probabilistic approaches and the deterministic approaches. Popular probabilistic algorithms are the expectation maximization [22], Gibbs sampling [21] and hidden Markov model (HMM). These are used to develop various sample-driven tools like MEME [3], CONSENSUS [17], AlignACE [19], ANN-spec [54], BioProspector [24], MotifSampler [48], GLAM [13], The Improbizer [1], QuickScore [38], SesiMCMC [11] and TFBSfinder [51].

There are many discrepancies among deterministic methods. A representative one is the consensus-based approach, [45] which tests all  $4^m$   $m$ -wide patterns and promises an optimal solution, but is very time consuming and impractical for large  $m$  [33,49]. Many heuristics are developed to prune the huge searching space, including testing only the substrings in the sequences [15,26], specifying a shared pattern to restrict the locations of mismatches [5,7,38,41], constructing suffix tree with fixed mismatches [30,31] and clustering approaches [6,23,34].

The methods for determining a consensus pattern can be split into two parts. The first part is the model for describing the shared pattern, and the second part is the algorithm for identifying the optimal consensus sequence according to its shared pattern. This study belongs to the second part. A consensus based motif finding problem is, given a set of sequences known to contain binding sites for a common factor but not knowing where the site are, to discover the location of the sites in each sequence [45].

Ecker et al. (2002) utilized optimization techniques to reformulate the maximum likelihood approach for motif finding problems. They adopted a probabilistic model and formulated a well-designed nonlinear model with reference to the expectation maximization algorithm of Lawrence and Reilly [22]. Their method, however, occasionally only finds a feasible solution or a local optimum, which means the best solution may not be found. Additionally, no further structural feature in the target motif can be embedded conveniently in their model.

### Definitions

This study introduces a linear programming method for solving a motif finding problem to reach the globally optimal consensus sequence. Two examples of searching for CRP-binding sites and for FNR-binding sites in the *Escherichia coli* genome are used to illustrate the proposed method. The motif finding problem is firstly formulated as a nonlinear mixed 0-1 program for the alignment of DNA sequences; each of the four bases are coded with two binary variables and a matching score is designed. This nonlinear mixed 0-1 program is then converted into a linear mixed 0-1 program by linearization techniques. Owing to some special features of the binary relationships, this linear 0-1 program includes  $2m$  binary variables where  $m$  is the number of active letters in the consensus. This method makes the number of binary variables independent of the number of sequences and the size of each sequence. That means the proposed method is computationally efficient in solving a motif finding problem with a large data size. Secondly, the proposed method is guaranteed to find the global optimum instead of a local optimum. Thirdly, many kinds of specific features accompanied with the target motif can be formulated as logical constraints and embedded into the linear program.

An example of searching CRP-binding sites, as discussed in Stormo et al. [44] and Ecker et al. (Ecker et al., 2002), is described as follows. Given eighteen letter sequences, each 105 positions long, where each position contains a letter from the set  $\{A, T, C, G\}$ , find a consensus sequence of length 16 with the pattern

$$L_1L_2L_3L_4L_5 * * * * * L_6L_7L_8L_9L_{10}$$

where  $L_i \in \{A, T, C, G\}$  and  $*$ 's mean the positions of ignored letters.

Restated, the problem is to specify

- (i) the  $L_i$ 's of the consensus sequence pattern, and
- (ii) the location of the site in each given sequence which can fit most closely the consensus sequence.

### Formulation

This study firstly formulates a motif finding problem as a nonlinear mixed 0-1 program. This nonlinear mixed 0-1 program is then converted into a linear mixed 0-1 program using linearization techniques. To reduce the computational burden, many 0-1 variables in this linear mixed 0-1 program can actually be solved as continuous variables by an all or nothing assignment technique which greatly improves the computational efficiency of this program.

Here we use the example data in [44], as listed in Appendix, to describe the proposed method. First, we represent the data in Appendix as an  $18 \times 105$  data matrix  $D$ :

$$D = \begin{bmatrix} b_{1,1} & b_{1,2} & \cdots & b_{1,105} \\ b_{2,1} & b_{2,2} & \cdots & b_{2,105} \\ \vdots & \vdots & \ddots & \vdots \\ b_{18,1} & b_{18,2} & \cdots & b_{18,105} \end{bmatrix} \quad (1)$$

where  $b_{l,p}$  is the letter in the position  $p$  of the sequence  $l$ .

Recall the example discussed in previous section: the consensus sequence we want to find has 16 positions (ten  $L_i$ 's and six ignored letters). A sequence has 90 corresponding sites, so an  $18 \times 900$  data matrix  $D'$  is generated from  $D$ .

$$D' = \begin{bmatrix} d_{1,1}^1 & \cdots & d_{1,1}^{10} & d_{1,2}^1 & \cdots & d_{1,2}^{10} & \cdots & d_{1,90}^1 & \cdots & d_{1,90}^{10} \\ d_{2,1}^1 & \cdots & d_{2,1}^{10} & d_{2,2}^1 & \cdots & d_{2,2}^{10} & \cdots & d_{2,90}^1 & \cdots & d_{2,90}^{10} \\ \vdots & & \vdots & & & \vdots & \ddots & \vdots & & \vdots \\ d_{18,1}^1 & \cdots & d_{18,1}^{10} & d_{18,2}^1 & \cdots & d_{18,2}^{10} & \cdots & d_{18,90}^1 & \cdots & d_{18,90}^{10} \end{bmatrix} \quad (2)$$

where

$$d_{i,s}^i = \begin{cases} b_{l,i+s-1} & (\text{for } i = 1, 2, \dots, 5) \\ b_{l,i+s+5} & (\text{for } i = 6, 7, \dots, 10), \end{cases}$$

and  $s = 1 \dots 90$  is the starting position of each candidate site.

**Mixed 0-1 Linear Programming Approach for DNA Transcription Element Identification, Table 1**  
Base code in the determined consensus sequence

Base	$u_i$	$v_i$	$a_i$	$t_i$	$c_i$	$g_i$
A	0	0	1	0	0	0
T	1	1	0	1	0	0
C	0	1	0	0	1	0
G	1	0	0	0	0	1

For  $L_i \in \{A, T, C, G\}$ , two binary variables  $u_i$  and  $v_i$  can be used to express  $L_i$ , an element of the consensus sequence, as shown in Table 1.

Table 1 indicates that if  $L_i$  is A, T, C, or G respectively, then  $a_i = 1$ ,  $t_i = 1$ ,  $c_i = 1$  or  $g_i = 1$ , which implies following conditions.

$$\begin{aligned} a_i &= (1 - u_i)(1 - v_i) \\ t_i &= u_i v_i \\ c_i &= (1 - u_i)v_i \\ g_i &= u_i(1 - v_i) \end{aligned} \quad (3)$$

Now we let  $\text{Score}_l$  be the degree of fitting to the found consensus sequence, specified as

$$\text{Score}_l = \sum_{s=1}^{90} z_{l,s} (\theta_{l,s}^1 + \theta_{l,s}^2 + \dots + \theta_{l,s}^{10}) \quad (4)$$

where  $\theta_{l,s}^i$  is the element of candidate sites extracted from  $D'$ . The constraints associated with (4) are below:

$$\sum_{s=1}^{90} z_{l,s} = 1, \quad z_{l,s} \in \{0, 1\} \text{ for all } l \text{ and } s. \quad (5)$$

(ii)

$$\theta_{l,s}^i = \begin{cases} a_i & \text{if } d_{l,s}^i = A \\ t_i & \text{if } d_{l,s}^i = T \\ c_i & \text{if } d_{l,s}^i = C \\ g_i & \text{if } d_{l,s}^i = G. \end{cases} \quad (6)$$

Clearly,  $0 \leq \text{Score}_l \leq 10$ , and the objective is to maximize the total sum of  $\text{Score}_l$ .

## Methods/Applications

Consider the sample data in Fig. 1 for instance:

$$\begin{aligned} \text{Score}_1 &= \\ z_{1,1}(a_1 + a_2 + g_3 + a_4 + c_5 + t_6 + t_7 + t_8 \\ &\quad + g_9 + a_{10}) \\ &\quad + z_{1,2}(a_1 + g_2 + a_3 + c_4 + t_5 + t_6 + t_7 + g_8 \\ &\quad + a_9 + t_{10}) \\ z_{1,3}(g_1 + a_2 + c_3 + t_4 + g_5 + t_6 + g_7 + a_8 \\ &\quad + t_9 + c_{10}) \end{aligned} \quad (7)$$

$$\begin{aligned} \text{Score}_2 &= \\ z_{2,1}(g_1 + a_2 + t_3 + t_4 + a_5 + c_6 + g_7 + g_8 \\ &\quad + c_9 + g_{10}) \\ &\quad + z_{2,2}(a_1 + t_2 + t_3 + a_4 + t_5 + g_6 + g_7 + c_8 \\ &\quad + g_9 + t_{10}) \\ &\quad + z_{2,3}(t_1 + t_2 + a_3 + t_4 + t_5 + g_6 + c_7 + g_8 \\ &\quad + t_9 + c_{10}) \end{aligned} \quad (8)$$

All  $z_{l,s}$  in (4) are binary variables. Equation (5) implies that for a sequence  $l$ , only one site is chosen to contribute to  $\text{Score}_l$ . Suppose the  $k$ th site is selected, then  $z_{l,k} = 1$  and  $z_{l,s} = 0$  for all  $s \in \{1, 2, \dots, 90\}$ ,  $s \neq k$ . Since a huge amount of  $z_{l,s}$  (i. e.,  $|l| * |s|$ ) are involved, to treat  $z_{l,s}$  as binary variables would cause a heavy computational burden. Therefore  $z_{l,s}$  should be resolved as continuous variables rather than binary variables. An important proposition is introduced below:

**Proposition 1 (All or nothing assignment)** Let  $z_{l,s} \geq 0$  be continuous variables instead of binary variables. If there is a  $k$ ,  $k \in \{1, 2, \dots, 90\}$ , such that  $\sum_{i=1}^{10} \theta_{l,k}^i = \max \left\{ \sum_{i=1}^{10} \theta_{l,s}^i \text{ for } s = 1, 2, \dots, 90 \right\}$ , then assigning  $z_{l,k} = 1$  and  $z_{l,s} = 0$  for all  $s \neq k$ ,  $s \in \{1, 2, \dots, 90\}$ , can maximize the value of  $\text{Score}_l$ .

*Proof* Since  $\sum_s z_{l,s} = 1$  and  $z_{l,s} \geq 0$ , it is true that  $\max \left\{ \sum_s (z_{l,s} \sum_i \theta_{l,s}^i) \right\} \leq \max \left\{ \sum_i \theta_{l,s}^i \text{ for } s = 1, 2, \dots, 90 \right\} = \sum_i \theta_{l,k}^i$ .  $\square$

*Remark 1* The objective function  $\sum_l \text{Score}_l$  can be rewritten as

$$f(x) = \sum_{i=1}^{10} \left\{ a_i \sum_{(l,s) \in SA_i} z_{l,s} + t_i \sum_{(l,s) \in ST_i} z_{l,s} + c_i \sum_{(l,s) \in SC_i} z_{l,s} + g_i \sum_{(l,s) \in SG_i} z_{l,s} \right\} \quad (9)$$

where  $SA_i = \{(l, s) | d_{l,s}^i = A\}$ ,  $ST_i = \{(l, s) | d_{l,s}^i = T\}$ ,  $SC_i = \{(l, s) | d_{l,s}^i = C\}$ , and  $SG_i = \{(l, s) | d_{l,s}^i = G\}$  for  $i = 1, 2, \dots, 10$ .

This result implies that  $SA_i$  (or  $ST_i$ ,  $SC_i$ ,  $SG_i$ ) is a set composed of  $(l, s)$  in which the product term  $z_{l,s} a_i$  (or  $z_{l,s} t_i$ ,  $z_{l,s} c_i$ ,  $z_{l,s} g_i$  respectively) appears on the right hand side of (4) because  $\theta_{l,s}^i = a_i$ .

For instance, the sum of  $\text{Score}_1$  and  $\text{Score}_2$  in (7) and (8) becomes

$$\begin{aligned} \text{Score}_1 + \text{Score}_2 &= a_1(z_{1,1} + z_{1,2} + z_{2,2}) + \dots \\ &+ a_{10}z_{1,1} + \dots + g_1(z_{1,3} + z_{2,1}) + \dots + g_{10}z_{2,1}. \end{aligned} \quad (10)$$

Some logical constraints can be conveniently expressed by binary variables. For instance, the constraint that a CRP dimer binds a symmetrical site requires that

$$\text{if } L_i = \begin{cases} A & \text{then } L_{11-i} = T, \\ C & \text{then } L_{11-i} = G. \end{cases}$$

Such a logical structure can be conveniently formulated with the following constraints:

$$\left. \begin{aligned} u_i + u_{11-i} &= 1 \\ v_i + v_{11-i} &= 1 \end{aligned} \right\} \text{for } i = 1, 2, 3, 4, 5 \quad (11)$$

where  $u_i, v_i, u_{11-i}, v_{11-i} \in \{0, 1\}$ .

With reference to Table 1, clearly if  $L_i = A$  (i. e.,  $u_i = 0$  and  $v_i = 0$ ) then  $L_{11-i} = T$  (i. e.,  $u_{11-i} = 1$  and  $v_{11-i} = 1$ ) and vice versa; (ii) if  $L_i = C$  (i. e.,  $u_i = 0$  and  $v_i = 1$ ) then  $L_{11-i} = G$  (i. e.,  $u_{11-i} = 1$  and  $v_{11-i} = 0$ ) and vice versa.

## Models

A motif finding problem can be formulated as a nonlinear mixed 0-1 program based on these constraints:

## Program 1 (Nonlinear Mixed 0-1 Program)

Maximize

$$\begin{aligned} \sum_{l=1}^{18} \text{Score}_l &= \sum_{i=1}^{10} \left\{ a_i \sum_{(l,s) \in SA_i} z_{l,s} + t_i \sum_{(l,s) \in ST_i} z_{l,s} + c_i \sum_{(l,s) \in SC_i} z_{l,s} + g_i \sum_{(l,s) \in SG_i} z_{l,s} \right\} \end{aligned} \quad (12)$$

subject to  $\sum_{s=1}^{90} z_{l,s} = 1$ ,  $z_{l,s} \geq 0$  for all  $l, s$

$$\left. \begin{aligned} a_i &= (1 - u_i)(1 - v_i) \\ t_i &= u_i v_i \\ c_i &= (1 - u_i)v_i \\ g_i &= u_i(1 - v_i) \end{aligned} \right\} \text{Conservative constraints for } i = 1, 2, \dots, 10$$

$$\left. \begin{aligned} u_i + u_{11-i} &= 1 \\ v_i + v_{11-i} &= 1 \end{aligned} \right\} \text{Logical constraints for } i = 1, 2, \dots, 5$$

$$u_i, v_i \in \{0, 1\}$$

$$\text{for } i = 1, 2, \dots, 5$$

$$0 \leq u_i, v_i \leq 1$$

$$\text{for } i = 6, 7, \dots, 10$$

$$0 \leq a_i, t_i, c_i, g_i \leq 1$$

$$\text{for } i = 1, 2, \dots, 10.$$

This program intends to solve  $\{a_i, t_i, c_i, g_i\}$  for  $i = 1, 2, \dots, 10$  thus to maximize the total degree of fitting to the consensus sequence for the given 18 sequences, subjected to a possible logical constraint. A very important feature of Program 1 is that we can treat  $z_{l,s}$  as continuous variables rather than binary variables, which can improve the computational efficiency dramatically. We can ensure all found  $z_{l,s}$  still have binary values as discussed in the next section.

**Linearization of Program 1** Program 1 is a mixed nonlinear 0-1 program where  $q_i \sum z_{l,s}$  for  $q_i \in \{a_i, t_i, c_i, g_i\}$  and  $u_i v_i$  are product terms. These product terms can be linearized directly by the following propositions:

**Proposition 2** *The product term  $\lambda_i = q_i \sum z_{l,s}$ , where  $\lambda_i$  is to be maximized and  $q_i \in \{0, 1\}$ , can be linearized*

as follows:

$$\begin{aligned} \lambda_i &\geq \sum z_{l,s} + M(q_i - 1) \\ \lambda_i &\geq 0 \\ \lambda_i &\leq \sum z_{l,s} \\ \lambda_i &\leq M q_i \end{aligned} \quad (13)$$

where  $M$  is a big constant larger than or equal to the number of sequences.

*Proof* If  $q_i = 1$  then  $\lambda_i = \sum z_{l,s}$ ; and otherwise  $\lambda_i = 0$ .  $\square$

**Proposition 3** The product term  $w_i = u_i v_i$ , where  $u_i, v_i \in \{0, 1\}$ , can be linearized as follows:

$$\begin{aligned} w_i &\leq u_i \\ w_i &\leq v_i \\ w_i &\geq 0 \\ w_i &\geq u_i + v_i - 1. \end{aligned} \quad (14)$$

Denote  $Z(a_i) = a_i \sum_{(l,s) \in SA_i} z_{l,s}$ ,  $Z(t_i) = t_i \sum_{(l,s) \in ST_i} z_{l,s}$ ,  $Z(c_i) = c_i \sum_{(l,s) \in SC_i} z_{l,s}$ , and  $Z(g_i) = g_i \sum_{(l,s) \in SG_i} z_{l,s}$ . Program 1 is then linearized into Program 2 based on Proposition 2 and Proposition 3.

### Program 2 (Linear Mixed 0-1 Program)

$$\begin{aligned} \text{Maximize} \quad & \sum_{l=1}^{18} \text{Score}_l \\ &= \sum_{i=1}^{10} (Z(a_i) + Z(t_i) + Z(c_i) \\ &+ Z(g_i)) \end{aligned} \quad (15)$$

subject to

$$\sum_{s=1}^{90} z_{l,s} = 1, \quad z_{l,s} \geq 0 \quad \text{for all } l, s$$

$$\left. \begin{aligned} a_i &= 1 - u_i - v_i + w_i \\ t_i &= w_i \\ c_i &= v_i - w_i \\ g_i &= u_i - w_i \\ w_i &\leq u_i \\ w_i &\leq v_i \\ w_i &\geq 0 \\ w_i &\geq u_i + v_i - 1 \end{aligned} \right\} \text{Conservative constraints} \\ \text{for } i = 1, 2, \dots, 10$$

$$\left. \begin{aligned} u_i + u_{11-i} &= 1 \\ v_i + v_{11-i} &= 1 \end{aligned} \right\} \text{Logical constraints} \\ \text{for } i = 1, 2, \dots, 5$$

$$\left. \begin{aligned} \sum_{(l,s) \in SA_i} z_{l,s} + M(a_i - 1) &\leq Z(a_i) \leq \sum_{(l,s) \in SA_i} z_{l,s} \\ 0 &\leq Z(a_i) \leq M a_i \\ \sum_{(l,s) \in ST_i} z_{l,s} + M(t_i - 1) &\leq Z(t_i) \leq \sum_{(l,s) \in ST_i} z_{l,s} \\ 0 &\leq Z(t_i) \leq M t_i \\ \sum_{(l,s) \in SC_i} z_{l,s} + M(c_i - 1) &\leq Z(c_i) \leq \sum_{(l,s) \in SC_i} z_{l,s} \\ 0 &\leq Z(c_i) \leq M c_i \\ \sum_{(l,s) \in SG_i} z_{l,s} + M(g_i - 1) &\leq Z(g_i) \leq \sum_{(l,s) \in SG_i} z_{l,s} \\ 0 &\leq Z(g_i) \leq M g_i \end{aligned} \right\} \text{Constraints for linearizing product terms}$$

$$u_i, v_i \in \{0, 1\} \quad \text{for } i = 1, 2, \dots, 5$$

$$0 \leq u_i, v_i \leq 1 \quad \text{for } i = 6, 7, \dots, 10$$

$$0 \leq a_i, t_i, c_i, g_i \leq 1 \quad \text{for } i = 1, 2, \dots, 10$$

$z_{l,s}$ 's are treated as non-negative continuous variables for  $l = 1, 2, \dots, 18$  and  $s = 1, 2, \dots, 90$  where  $M$  can be any value greater than or equal to 18.

In Program 2, since  $u_i$  and  $v_i$  are binary variables,  $a_i$ ,  $t_i$ ,  $c_i$ , and  $g_i$  should have binary values following (3). Although  $z_{l,s}$  are treated as continuous variables, the values of  $z_{l,s}$  should be 0 or 1. This is because the optimal solution of a linear program should be a vertex point satisfying  $\sum_s z_{l,s} = 1$  for all  $l$ .

Consider the following proposition.

**Proposition 4** Let the optimal solution of Program 2 be  $x^* = (Z^*, u^*, v^*)$  and  $\sum_s z_{l,s} = 1$ . Assume that a sequence  $l$  contains sites  $s_1, s_2, \dots, s_k$  such that

$0 < z_{l,s_j}^* < 1$  for  $j = 1, 2, \dots, k$ , then,

$$\sum_i \theta_{l,s_1}^i = \sum_i \theta_{l,s_2}^i = \dots = \sum_i \theta_{l,s_k}^i = \max \left\{ \sum_i \theta_{l,s}^i \right\},$$

where  $\theta_{l,s_j}^i$  are specified in (6).

*Proof* For  $\sum_s z_{l,s} = 1$ , if  $s_p, s_q \in \{s_1, s_2, \dots, s_k\}$  where  $\sum_i \theta_{l,s_p}^i > \sum_i \theta_{l,s_q}^i$ , then to maximize  $\text{Score}_l = \sum_{l,j} z_{l,s_j} \sum_i \theta_{l,s_j}^i$  requires  $z_{l,s_q} = 0$ . This conflicts with the observation that  $0 < z_{l,s_q} < 1$ , therefore  $\sum_i \theta_{l,s_1}^i = \sum_i \theta_{l,s_2}^i = \dots = \sum_i \theta_{l,s_k}^i$ .  $\square$

After solving Program 2 we can obtain the globally optimum solution “TGTGA\*\*\*\*\*TCACA” with objective value 147. The related nonzero  $z_{l,s}$  values indicate the starting positions of the binding sites in the 18 sequences, as listed below:

$$\begin{aligned} z_{1,64} = z_{2,58} = z_{3,79} = z_{4,66} = z_{5,53} = z_{6,63} = z_{7,27} \\ = z_{8,42} = z_{9,12} = z_{10,17} = z_{11,64} = z_{12,44} = z_{13,51} \\ = z_{14,74} = z_{15,20} = z_{16,56} = z_{17,87} = z_{18,81} = 1 \end{aligned}$$

All other  $z_{l,s}$ 's have value 0.

In Program 2 the total number of 0-1 variables is  $2m$  and the total number of the continuous variables is  $20m + |l| * |s|$ . Since the number of 0-1 variables is independent of the lengths of  $l$  and  $s$ , a motif finding problem with many long sequences can be solved effectively.

**Suboptimal Consensus Sequences** Program 2 can find the exact global optimum solution. Sometimes the second best and the third best solution may also be useful. It is very convenient for the proposed method to find a complete set of consensus sequences by adding some extra constraints. For instance, the second best solution of Program 2 can be obtained conveniently by solving the following program:

$$\begin{aligned} \text{Maximize } & \sum_{l=1}^{18} \text{Score}_l \quad (16) \\ \text{subject to } & \text{(i) The same constraints in Model 1} \\ & \text{(ii) } t_1 + g_2 + t_3 + g_4 + a_5 + t_6 + c_7 + \\ & \quad a_8 + c_9 + a_{10} \leq 9 \text{ (new constraint)} \end{aligned}$$

c

**Mixed 0-1 Linear Programming Approach for DNA Transcription Element Identification, Figure 1**

**A small example of finding consensus sequence: a two sequences to be compared; b Schematic representation of the candidate sites; c The associated  $D'$  matrix**

The new constraint is used to force the program to find a new solution different from the solution of Program 2. The found second best consensus sequence is “TTTGA\*\*\*\*\*TCAAA” with score 129. Similarly we can find another solution by adding following constraint into (16).

$$t_1 + t_2 + t_3 + g_4 + a_5 + t_6 + c_7 + a_8 + a_9 + a_{10} \leq 9$$

The found third best consensus sequence is “AAATT\*\*\*\*\*AATTT” with score 129.

**Extend to Find Unknown Binding Sites** A more complicated motif finding problem is to search for the consensus sequence with an uncertain pattern format where the number of ignored letters between the two half sites is unknown. An example is to find a consensus sequence of length  $2 * 5 + k$  with the pattern

$$L_1L_2L_3L_4L_5 * \dots * L_6L_7L_8L_9L_{10}$$

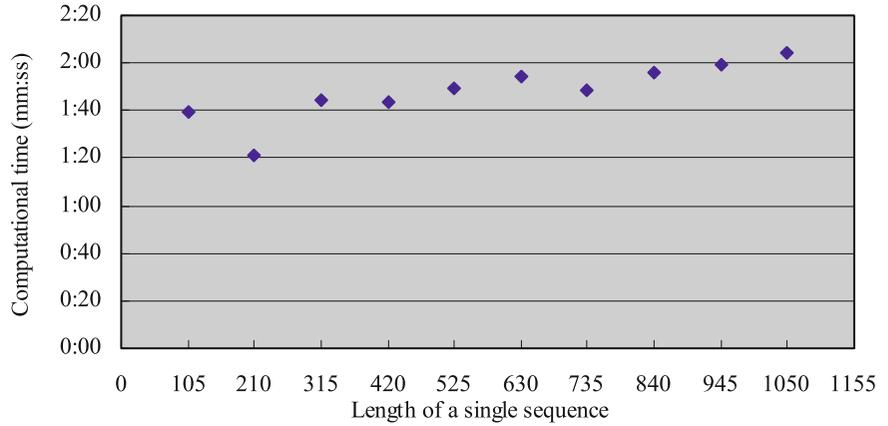

where  $k$ , the number of  $*$ 's, is an unknown integer between 0 and 10.

Program 2 can be modified slightly to treat this type of motif finding problem. Firstly we expand  $D$  in (1) as  $D'$  below:

$$D' = [D'(0)D'(1)D'(2) \dots D'(10)]$$

Computational time of Program 3 with various numbers of possible  $k$ 's. The number enclosed in the common site is the solution of  $k$

in which

$$D'(k) = \begin{bmatrix} d_{1,1,k}^1 & \cdots & d_{1,1,k}^{10} & d_{1,2,k}^1 & \cdots & d_{1,2,k}^{10} & \cdots & d_{1,90,k}^1 & \cdots & d_{1,90,k}^{10} \\ d_{2,1,k}^1 & \cdots & d_{2,1,k}^{10} & d_{2,2,k}^1 & \cdots & d_{2,2,k}^{10} & \cdots & d_{2,90,k}^1 & \cdots & d_{2,90,k}^{10} \\ \vdots & & \vdots & & \vdots & & \ddots & & \vdots & \\ d_{18,1,k}^1 & \cdots & d_{18,1,k}^{10} & d_{18,2,k}^1 & \cdots & d_{18,2,k}^{10} & \cdots & d_{18,90,k}^1 & \cdots & d_{18,90,k}^{10} \end{bmatrix}$$

where  $k \in \{0, 1, \dots, 10\}$ .

$$d_{l,s,k}^i = \begin{cases} b_{l,i+s-1} & (\text{for } i = 1, 2, 3, 4, 5) \\ b_{l,i+s+k-1} & (\text{for } i = 6, 7, 8, 9, 10) \end{cases}$$

$\theta_{l,s,k}^i = a_i, t_i, c_i$  or  $g_i$  when  $d_{l,s,k}^i = \text{'A'}, \text{'T'}, \text{'C'},$  or  $\text{'G'}$  respectively.

The cases with  $k$  larger than 10 are not considered since they are relatively rare. A linear mixed 0-1 program for solving this example is formulated below:

**Program 3**

Maximize  $\sum_{i=1}^{2m} (Z(a_i) + Z(t_i) + Z(c_i) + Z(g_i))$  (15)

subject to (i)  $\sum_{k=0}^{10} \sum_{s=1}^{96-k} z_{l,s,k} = 1,$   
 $z_{l,s,k} \geq 0$  for all  $l, s, k$

(ii)  $\sum_s z_{1,s,k} = \sum_s z_{2,s,k} = \dots = \sum_s z_{18,s,k}$  for  $k \in \{0, 1, \dots, 10\}$

(iii) the same conservative and logical constraints in Program 2

(iv) the same constraints for linearizing product terms in Program 2 but replace  $z_{l,s}$  by  $z_{l,s,k}$ .

Constraints (i) and (ii) are used to ensure that when a specific  $k$  is chosen then  $\sum_s z_{l,s,k} = 1$  and  $\sum_s z_{l,s,k'} = 0$  for  $k' \neq k$ .

\* For visualizing the comparison, the letters in uppercase represent the binding site listed in RegulonDB; the letter in bold face is the center of the site sequence; and the encompassed letters represent the exact binding site obtained by Program 3.

\*\* The second site listed in RegulonDB is not contained in the sequence data, which is only 96 bases long, from GenBank.

## Cases

### Finding CRP Binding Sites with a Given Pattern

Several experiments are tested here, using the example in the Appendix, to analyze the effect of sequence length and number of sequences on the computational time. All examples are solved by LINGO [40], a widely used optimization software, on a personal computer with a Pentium 4 2.0G CPU. A software package named “Global Site Seer” is developed based on Program 2 for finding DNA motifs. This software is available from <http://www.iim.nctu.edu.tw/~cjfu/gss.htm>.

Figure 2 illustrates the experimental results for analyzing the time complexity. Figure 2a is the computational time given various sequence lengths, where the number of sequences is fixed at 18. The results show that the computational time changes only slightly even if the sequence length is increased from 105 to 1050.

Figure 2b is the computational time with various numbers of sequences. It shows that the solving time is roughly proportional to the number of sequences. The proposed model is quite promising for finding DNA motifs in a dataset with a large sequence length and a large number of sequences. Figure 2c shows that the computational time rises exponentially as the number of independent positions increases.

Using Program 3 to search CRP binding sites, we obtain the globally optimal solution “TGTGA\*\*\*\*\*TCACA” with score 147, which is exactly the same solution found in Program 2. The second best solution is “GTGAA\*\*\*\*\*TTCAC” with score 134. The relationship between the computational time and the number of possible  $k$ 's (i. e.  $|k|$ ) is linear, as shown in the experiment result listed in Fig. 3. The number of ignored letters  $k$  is between 0 and  $\bar{k}$ , the upper bound of  $k$ , and thus we have  $|k| = \bar{k} + 1$  in this experiment.

### Finding FNR-binding Sites with an Ambiguous Shared Pattern

Program 3 is also applied to solve an example of searching for binding sites of fumarate and nitrate reduction regulatory protein (FNR) in *E. coli*. Both CRP and FNR belong to the CRP/FNR helix-turn-helix transcription factor superfamily [47]. The sequence data, which is taken from GenBank, contains 12 DNA sequences with lengths varied from 96 to 781. Owing to the dimer structure of the binding protein, the consensus sequence in this example also has a constraint of inverse symmetry. The RegulonDB database [18] lists the found regulatory binding sites for eight of these twelve sequences while the exact positions of the other four sequences are not listed yet. Solving this example by Program 3 we obtained the global optimal consensus sequence as “TTGAT\*\*\*\*ATCAA” with score 107, which is the same consensus sequence as indicated by [47]. Table 2 illustrates the result including the consensus sequence and the predicted binding sites for all of the 12 sequences. Some sites downstream of the transcription start (i. e. with positive indices) are also listed because there are a few known cases in which regulatory sites appear within transcription units [47]. The proposed method has found some sites not listed in RegulonDB, but which have scores higher than those listed in RegulonDB (e. g. the third solution in the Operon *ansB* row of Table 2). The best predicted sites in the four undetermined sequences are also listed in Table 2.

### Conclusions

This study proposes a linear mixed 0-1 programming approach for finding DNA motifs. Compared to the widely used maximum likelihood methods, the proposed method can reach a global optimum rather than finding a local optimum or a feasible solution. Additionally, by utilizing binary variables, some logical constraints can be embedded into the models. It is also convenient to find the complete set of the second, third, etc. best consensus sequences. Since the number of binary variables is fully independent of the number of sequences and the length of a sequence, the proposed method can treat motif finding problems with many long sequences. For finding motifs with many independent positions in an acceptable time, this study also proposes a method for distributed computing.

The proposed method can also be conveniently extended to treat more complicated motif finding problems. In this study an extension of the linear program is designed to find DNA motifs with an unknown number of ignored letters between the two half sites. The result of searching for FNR-binding sites shows that the extended model can find not only the locations of known binding sites listed in the RegulonDB database but also those not yet delimited.

## Introduction

The *G*-group classification problem, also known as the *G*-group discriminant problem, involves a population partitioned into *G* distinct (and predefined) groups. The object is to construct a scalar- or vector- valued scoring function  $f : \mathfrak{R}^P \rightarrow \mathfrak{R}$  so that the group to which a population member with observed attributes  $\mathbf{x} \in \mathfrak{R}^P$  belongs can be determined, with best possible accuracy, from its score  $f(\mathbf{x})$ . The scoring function  $f$  is usually restricted to a particular class (most commonly, linear). By a wide margin, the majority of studies have focused on the two-group case. Construction of  $f$  is based on training samples from the various groups. The most reasonable criterion for choosing  $f$  may be expected misclassification cost, but many studies make the simplifying assumptions that all misclassifications are equally expensive and that groups are represented in the training samples in proportion to their prior probability of being encountered, in which case the criterion reduces

Mixed Integer Classification Problems, Figure 1  
Optimal linear classifier (□ = misclassified)

to minimizing the number of misclassifications in the combined training samples. Figure 1 illustrates an optimal choice of linear classifier  $f$  in a two-group problem.

Classical discriminant analysis relies on distributional assumptions. In the two-group case with normally distributed attributes, the scalar-valued discriminant function that minimizes expected misclassification cost is known to be linear if the two groups have identical covariance structures and quadratic if not. In both cases, direct estimation of  $f$  is straightforward. Nonparametric approaches, making no distributional assumptions, have utilized an eclectic assortment of techniques, among them neural networks, metaheuristics, and mathematical programming. Although some consideration has been given to nonlinear programming methods, the bulk of the work involving mathematical programming has utilized either linear or mixed integer linear programming models, or support vector machines (quadratic programs) [8]. See [10] and ► [linear programming models for classification](#) (elsewhere in this volume) for an overview of the subject.

When  $f$  is linear, the problem of minimizing the number of misclassifications is a special case of the slightly more general problem of dropping the smallest (or least costly) set of constraints necessary to render an inconsistent set of linear inequalities consistent. This problem crops up in a variety of contexts, including pattern recognition [18], machine learning/data mining [5] and the analysis of infeasible linear programs [6]. Thus methods from those areas may be applicable to discriminant problems. For instance, Soltysik and Yarnold [15] applied the algorithm of Warmack and Gonzalez [18] to the two-group linear discriminant problem.

## Formulation

The following is a typical mixed integer programming model for the two-group case, using a scalar linear discriminant function:

$$\begin{aligned} \min \quad & \sum_{g=1}^2 \frac{\pi_g C_g}{N_g} \sum_{n=1}^{N_g} z_{gn} \\ \text{s.t.} \quad & \mathbf{X}_1 \mathbf{w} + w_0 \cdot \mathbf{1} - M \cdot \mathbf{z}_1 \leq \mathbf{0} \\ & \mathbf{X}_2 \mathbf{w} + w_0 \cdot \mathbf{1} + M \cdot \mathbf{z}_2 \geq \mathbf{0} \\ & \mathbf{w}, w_0 \text{ free}; \mathbf{z}_g \in \{0, 1\}^{N_g}. \end{aligned} \quad (1)$$

Matrix  $\mathbf{X}_g$  is an  $N_g \times p$  training sample from group  $g$ , while  $\pi_g$  and  $C_g$  are respectively the prior probability of group  $g$  and the cost of misclassifying a member of that group.  $M$  is a sufficiently large positive constant, and  $\mathbf{0}$  and  $\mathbf{1}$  denote vectors, all of whose entries are respectively 0 or 1. The discriminant function  $f(\mathbf{x}) = \mathbf{w}'\mathbf{x} + w_0$  is intended to produce negative scores for members of the first group and positive scores for members of the second group. Bivalent indicator variable  $z_{gn}$  takes value 1 if the  $n$ th training observation from group  $g$  is classified incorrectly and 0 if it is classified correctly.

The discriminant function is linear as written, but various nonlinear functions can be generated by embedding the attribute space  $\mathfrak{R}^p$  in a higher-dimensional space. Support vector machines are particularly adept at this. Polynomial functions, for instance, are easily accommodated in (1) by expanding the sample matrices to include powers and products of attributes.

A score of zero results in an ambiguous classification. Some authors deal with this by changing the first two constraints of (1) to

$$\begin{aligned} \mathbf{X}_1 \mathbf{w} + w_0 \cdot \mathbf{1} - M \cdot \mathbf{z}_1 &\leq -\varepsilon \cdot \mathbf{1} \\ \mathbf{X}_2 \mathbf{w} + w_0 \cdot \mathbf{1} + M \cdot \mathbf{z}_2 &\geq +\varepsilon \cdot \mathbf{1}, \end{aligned}$$

where  $\varepsilon$  is a small positive constant. This formulation is nearly as general, although it is mathematically possible that infelicitous choices of  $\varepsilon$  and  $M$  could rule out an otherwise desirable solution.

Problem (1) is known to be NP-hard [1]. At the same time, using the finite VC-dimension of linear classifiers [16,17], it can be shown that the error rate of the solution to (1) converges in probability to the optimal error rate as sample size grows [2]. Assuming availability of sufficient data, a key question is whether the problem remains tractable when the training sample is large enough to provide a suitably accurate solution. There is grounds for (cautious) optimism, in that progress in hardware, software and algorithms advances the boundaries of what is tractable, while for a given problem instance the sample size needed for accuracy is static.

While there will often be a unique best choice of training observations to misclassify (i. e., unique optimal values of  $\mathbf{z}_1$  and  $\mathbf{z}_2$ ), there commonly will be infinitely many choices for the coefficients  $\mathbf{w}$ ,  $w_0$  of a discriminant function that misclassifies those observations

only. To select from among those coefficient solutions, authors often introduce additional terms in the objective function. As an example, Bajgier and Hill [4] used a formulation similar to the following:

$$\begin{aligned} \min \quad & \sum_{g=1}^2 \frac{\pi_g}{N_g} \sum_{n=1}^{N_g} \left[ C_g z_{gn} + \varepsilon_1 d_{gn}^- - \varepsilon_2 d_{gn}^+ \right] \\ \text{s.t.} \quad & \mathbf{X}_1 \mathbf{w} + w_0 \cdot \mathbf{1} + \mathbf{d}_1^+ - \mathbf{d}_1^- - M \cdot \mathbf{z}_1 \leq \mathbf{0} \\ & \mathbf{X}_2 \mathbf{w} + w_0 \cdot \mathbf{1} - \mathbf{d}_2^+ + \mathbf{d}_2^- + M \cdot \mathbf{z}_2 \geq \mathbf{0} \\ & w, w_0 \text{ free; } \mathbf{d}_g^+, \mathbf{d}_g^- \geq \mathbf{0}; \mathbf{z}_g \in \{0, 1\}^{N_g}. \end{aligned}$$

The deviation variables  $\mathbf{d}_g^+$  and  $\mathbf{d}_g^-$  measure the amount by which each score falls on the correct and incorrect side of the zero cutoff, respectively. The objective functions rewards the former and penalizes the latter, using small positive objective coefficients  $\varepsilon_1$  and  $\varepsilon_2$  to prevent improvements in these terms from inducing unnecessary misclassifications.

The motivation for formulation (1) is simple: if the training samples are representative of the overall population, the discriminant function that minimizes misclassification costs on the training samples should come close to minimizing expected misclassification cost on the overall population. Models like (1) tend to be computationally expensive, however. As is typical with mixed integer programming models, computation time increases modestly with the number of attributes ( $p$ ) but more dramatically with the number of zero-one variables ( $N_1 + N_2$ , the combined sample size). Moreover, the constant  $M$  must be chosen large enough that the best choice of  $\mathbf{w}$  and  $w_0$  is not rendered infeasible by a misclassified observation with score larger than  $M$  in magnitude; but the larger  $M$  is, the weaker the bounds in a branch-and-bound solution of the problem, and thus the longer the solution time. Codato and Fischetti [7] reported success using a form of Benders cut to eliminate  $M$ .

In the special case where all attribute variables are discrete, it is likely that some observation vectors will appear more than once in the training samples. When that occurs, the number of zero-one variables can be reduced from one per observation to one per *distinguishable* observation, yielding a variation of (1) in which the objective function is replaced with

$$\min \quad \sum_{g=1}^2 \frac{\pi_g C_g}{N_g} \sum_{k=1}^{K_g} N_{gk} z_{gk}.$$

In this formulation [3],  $K_g$  is the number of distinct attribute vectors  $\mathbf{x}$  in the training sample from group  $g$ ,  $N_{gk}$  is the number of repetitions of the  $k$ th distinct observation from group  $g$ , and the matrices  $\mathbf{X}_g$  contain only one copy of each such observation.

### Multiple Groups

When  $G > 2$  groups are involved, the problem becomes considerably more complicated. In a practical application with multiple groups, it is plausible that misclassification costs would depend not only on the group to which a misclassified point belonged but also the one into which it was classified. Thus an appropriate objective function might look like

$$\sum_{g=1}^G \frac{\pi_g}{N_g} \sum_{\substack{h=1 \\ h \neq g}}^G C_{gh} \sum_{n=1}^{N_g} z_{ghn},$$

where  $C_{gh}$  is the cost of classifying a point from group  $g$  into group  $h$  and  $z_{ghn}$  is 1 if the  $n$ th observation of group  $g$  is classified into group  $h$  and 0 otherwise. This represents a substantial escalation of the number of indicator variables. As a consequence, most research on the multiple group problem assumes that misclassification costs depend only on the correct group.

Few models, and fewer computational results, have been published for the multiple group problem. Gehrlein [9] presented one of the earliest scalar-valued mixed integer models for the case  $G > 2$ . The range of his discriminant function is partitioned into separate intervals corresponding to the groups. His model, adapted to the preceding notation, is

$$\begin{aligned} \min \quad & \sum_{g=1}^G \frac{\pi_g C_g}{N_g} \sum_{n=1}^{N_g} z_{gn} \\ \text{s.t.} \quad & \mathbf{X}_g \mathbf{w} + w_0 \cdot \mathbf{1} - M \cdot \mathbf{z}_g - U_g \cdot \mathbf{1} \leq \mathbf{0} \\ & \mathbf{X}_g \mathbf{w} + w_0 \cdot \mathbf{1} + M \cdot \mathbf{z}_g - L_g \cdot \mathbf{1} \geq \mathbf{0} \\ & U_g - L_g \geq 0 \\ & L_h - U_g + M y_{hg} \geq \varepsilon \\ & y_{gh} + y_{hg} = 1 \\ & \mathbf{w}, w_0, \mathbf{L}, \mathbf{U} \text{ free;} \\ & \mathbf{z}_g \in \{0, 1\}^{N_g}; \mathbf{y} \in \{0, 1\}^{G(G-1)}. \end{aligned}$$

The first three constraints are repeated for  $g = 1, \dots, G$  while the next two are repeated for all pairs  $g,$

$h = 1, \dots, G$  such that  $g \neq h$ . Observations are classified into group  $g$  if their scores fall in the interval  $[L_g, U_g]$ . Variable  $y_{gh} = 1$  if the scoring interval for group  $g$  precedes that for group  $h$ . Parameter  $\varepsilon > 0$  dictates a minimum separation between intervals.

Using a single scalar-valued discriminant function with  $G > 2$  groups is restrictive; it assumes that the groups project onto some line in an orderly manner. In [9], Gehrlein also suggested a model using a vector-valued discriminant function  $f(\cdot)$  of dimension  $G$ . Observation  $\mathbf{x}$  would be classified into the group corresponding to the largest component of  $\mathbf{f}(\mathbf{x})$ . The model increases the number of coefficient variables and the number of constraints but not the number of 0-1 variables, the primary determinant of execution time. The model is:

$$\begin{aligned} \min \quad & \sum_{g=1}^G \frac{\pi_g C_g}{N_g} \sum_{n=1}^{N_g} z_{gn} \\ \text{s.t.} \quad & \mathbf{X}_g \mathbf{w}_g + w_{g0} \cdot \mathbf{1} - \mathbf{X}_g \mathbf{w}_h - w_{h0} \cdot \mathbf{1} + M \cdot \mathbf{z}_g \\ & \geq \varepsilon \cdot \mathbf{1} \\ & \mathbf{w}_g, w_{g0} \text{ free; } \mathbf{z}_g \in \{0, 1\}^{N_g}. \end{aligned}$$

Here  $\mathbf{w}'_g \mathbf{x} + w_{g0}$  is the  $g$ th component of  $\mathbf{f}(\mathbf{x})$  and  $\varepsilon > 0$  is the minimum acceptable difference between the correct component of the scoring function and the largest incorrect component. The sole constraint is repeated once for each pair  $g, h = 1, \dots, G$  such that  $g \neq h$ .

## Methods

Advances in computer hardware, optimization software and algorithms for the mixed integer classification problem have allowed progressively larger training samples to be employed: where Koehler and Erenuguc [11] were restricted to combined training samples of 100 in 1990 (on a mainframe), Rubin [13] was able to handle over 600 observations in 1997 (on a personal computer). Nonetheless, a variety of heuristics have been developed to find near optimal solutions to the problem. Several revolve around this property of the problem: if the training samples can be classified with perfect accuracy by a linear function, then problem (1) can be solved as a linear program, with the  $z_{gn}$  deleted, to obtain a discriminant function. Deletion of the  $z_{gn}$  reduces the objective function to a constant

0. Although this is perfectly acceptable, heuristics may substitute an objective function from one of the linear programming classification models, to encourage the chosen discriminant function to separate scores of the two groups as much as possible. This often also necessitates inclusion of a normalization constraint, to keep the resulting linear program from being unbounded. Alternatively, (1) may be solved heuristically to determine which training observations to misclassify, and then a linear programming model using the remaining observations may be employed to select the final discriminant function.

The BPMM heuristic of [11] solves the linear program dual to a relaxation of the mixed integer problem, notes which observations would be misclassified by the resulting discriminant function, and then solves the dual of each linear relaxation obtainable by deleting one of those observations. Solving the dual problem tends to be more efficient than solving the primal, since there will typically be more observations than attributes ( $N_1 + N_2 \gg p$ ). The heuristics presented in [14] also operate on the dual of the linear relaxation of the mixed integer problem, restricting basis entry to force certain dual variables to take value zero (equivalent to relaxing the corresponding primal constraints, thus allowing the associated observations to be misclassified).

As noted earlier, comparatively few computational studies involve mixed integer models for multiple groups. Pavur proposed a sequential mixed integer method to handle multiple groups [12], constructing a vector-valued scoring function from a sequence of scalar functions. An initial mixed integer model similar to Gehrlein's is solved to obtain the first scalar function. Thereafter, a sequence of similar mixed integer models is solved, with each model bearing additional constraints compelling the scores produced by the next scoring function to have sample covariance zero with the scores of each of the preceding functions. The covariance constraints impose a sort of probabilistic "orthogonality" on the dimensions of the composite (vector-valued) scoring function.

Heat exchanger networks use the waste heat released by hot process streams to heat the cold process streams of a chemical manufacturing plant, reducing utility costs by as much as 80%. *Heat exchanger network synthesis* has been an active area of process research ever since the energy crisis of the 1970s, and over 400 research papers have been published in the area. See [1,2,4,5,6], for recent reviews.

In 1979, T. Umeda et al. [8] discovered a thermodynamic pinch point that limits the energy savings of a heat exchanger network, establishes minimum utility levels, and partitions the heat exchanger network into two independent subnetworks. This discovery revolutionized heat exchanger network synthesis: with it, designers could compute utility levels a priori, then seek the heat exchanger network structure that uses the minimum utility consumption while also minimizing the total investment cost. This remaining problem requires matching the hot utilities and process streams that release heat with the cold process streams and utilities that require heat, choosing the network structure of each stream, and designing the individual heat exchanger networks. In general, this is a *mixed integer nonlinear programming problem* (MINLP), but can be decomposed into two smaller problems by first selecting the matches between hot and cold process streams

and utilities by minimizing the total number of units, then optimizing the network structure. The first problem is a mixed integer linear programming problem that will be discussed in detail here.

### Using MILP Models to Find the Minimum Number of Units

Stated formally, the *minimum-units problem* is:

Given

- 1) A set of hot process streams and utilities  $i \in H$ , and for each hot stream  $i$ :
  - a) the inlet and outlet temperatures  $T_i^I$  and  $T_i^O$ ;
  - b) either the heat capacity flow rate  $FC_{Pi}$  or the heat duty  $Q_i$ .
- 2) A set of cold process streams  $j \in C$ , and for each cold stream  $j$ :
  - a) the inlet and outlet temperatures  $T_j^I$  and  $T_j^O$ ;
  - b) either the heat capacity flow rate  $FC_{pj}$  or the heat duty  $Q_j$ ,
- 3) The minimum temperature difference between hot and cold streams exchanging heat,  $\Delta T_{\min}$ .

Identify a set of stream matches ( $ij$ ) and their heat duties  $Q_{ij}$  that

- a) meets the heating and cooling needs of each stream; and
- b) minimizes the total number of matches.

S.A. Papoulias and I.E. Grossmann [7] formulated this as a mixed integer programming problem using a *transshipment model*, by making an analogy between heat exchanger networks and transportation networks. In the transshipment analogy, hot process streams, the sources of heat, are similar to manufacturing plants, the sources of goods, while cold process streams, the heat sinks, are akin to stores and shopping malls, the sinks of manufactured goods.

The analogy is not perfect, as heat only flows from a high temperature to a lower one, in obedience to the second law of thermodynamics. Partitioning the temperature range of the heat exchanger network into intervals can capture this heat flow pattern. Each interval sends excess, or residual, heat to the interval below it, just as excess manufactured goods are sent to a discount warehouse.

The hot side of this *temperature cascade* is created by ordering  $T_i^I$  and  $T_j^I + \Delta T_{\min}$  from the highest to the lowest value, creating  $t = 1, \dots, TI$  temperature in-

### Mixed Integer Linear Programming: Heat Exchanger Network Synthesis, Table 1

Stream data.  $Q_{CW} = 8395.2 \text{ kW}$ ,  $\Delta T_{\min} = 10^\circ\text{C}$

Stream	$T^{\text{in}}(^{\circ})$	$T^{\text{out}}(^{\circ})$	$FC_p(\text{kW/K})$
H1	159	77	228.5
H2	159	88	20.4
H3	159	90	53.8
C1	26	127	93.3
C2	118	149	196.1

tervals. Temperatures on the cold side of the cascade equal the temperature on the hot side minus  $\Delta T_{\min}$ . Hot stream  $i$  releases  $Q_{it}^H$  units of heat to temperature interval  $t$ .  $Q_{it}^H$  is equal to

$$Q_{it}^H = \begin{cases} FCP_i(T_{t-1} - T_i) & \text{if } T_i^I \geq T_{t-1} \text{ and } T_i^O \leq T_t, \\ FCP_i(T_{t-1} - T_i^O) & \text{if } T_i^I \geq T_{t-1} \text{ and } T_i^O \geq T_t, \\ Q & \text{if } T_i^I = T_i^O \text{ and } T_{t-1} = T_i^I. \end{cases}$$

Cold stream  $j$  absorbs  $Q_{jt}^C$  units of heat from temperature interval  $t$ .  $Q_{jt}^C$  equals

$$Q_{jt}^C = \begin{cases} FCP_j(T_{t-1} - T_j) & \text{if } T_j^I \leq T_t - \Delta T_{\min} \text{ and } \\ & T_j^O \geq T_{t-1} - \Delta T_{\min}, \\ FCP_j(T_j^O - T_{t-1}) & \text{if } T_j^I \leq T_t - \Delta T_{\min} \text{ and } \\ & T_j^O \leq T_{t-1} - \Delta T_{\min}, \\ Q_j & \text{if } T_j^I = T_j^O \text{ and } T_j^I = T_{t-1} - \Delta T_{\min}. \end{cases}$$

Any excess heat sent to interval  $t$  from hot stream  $i$  cascades down to interval  $t+1$  through the residual flow  $R_{it}$ . Process utilities may be treated as process streams, or may be placed at the top or bottom of the cascade.

This transshipment model of heat flow leads to the following mixed integer linear programming problem:

$$\min \sum_{i,j} y_{ij}$$

subject to

$$R_{i,t} - R_{i,t-1} + \sum_j q_{ijt} = Q_{it}^H, \quad (1)$$

$$i = 1, \dots, H, \quad t = 1, \dots, TI,$$

$$\sum_i q_{ijt} = Q_{jt}^C, \quad j = 1, \dots, C, \quad t = 1, \dots, TI, \quad (2)$$

$$Q_{ij} = \sum_{t \in TI} q_{ijt}, \quad i = 1, \dots, H, \quad j = 1, \dots, C, \quad (3)$$

$$Q_{ij} \leq U_{ij} y_{ij}, \quad i = 1, \dots, H, \quad j = 1, \dots, C, \quad (4)$$

$$\begin{cases} q_{ijt} \geq 0, \\ R_t \geq 0, \end{cases} \quad (5)$$

$$i = 1, \dots, H, \quad j = 1, \dots, C, \quad t = 1, \dots, TI,$$

$$R_0 = R_T = 0, \quad (6)$$

$$y_{ij} = \{0, 1\}, \quad i = 1, \dots, H, \quad j = 1, \dots, C. \quad (7)$$

In this formulation,  $y_{ij}$  is a binary variable which is one if a match between hot process stream  $i$  and cold process stream  $j$  occurs, and zero otherwise;  $q_{ijt}$  is the amount of heat exchanged between hot stream  $i$  and cold stream  $j$  in temperature interval  $t$ ,  $R_{it}$  is the residual heat flow associated with hot stream  $i$  that cascades down from temperature interval  $t$  to temperature interval  $t+1$ , and  $Q_{ij}$  is the heat duty of match  $(i, j)$ . The overall objective function minimizes the total number of units. Constraint (1) is the energy balance for hot stream  $i$  around temperature interval  $t$  and constraint (2) is the energy balance for cold stream  $j$  around temperature interval  $t$ . Constraint (3) finds the overall heat duty of match  $(ij)$ . Constraint (4) sets this heat duty to zero when match  $(ij)$  does not exist. The nonnegativity constraints prevents heat flow from a low temperature to a higher one. Note that the residual heat flows into the first temperature interval and out of the last temperature interval are zero when there are no utilities above or below the cascade. The objective function and the constraints are linear, and the formulation involves both continuous and integer variables, making this a mixed integer linear programming problem.

Lower bounds on the solution of this problem are given by linear programming problems where some integer variables are fixed to either zero or one and the remainder are treated as continuous variables. The accuracy of these bounds depends upon the parameters  $U_{ij}$  is the fourth constraint. When these parameters are very large, the lower bounds will be quite far from the solution of the MILP.

The smallest acceptable value of  $U_{ij}$  is the minimum of the cooling requirements of stream  $i$  and the heating requirements of stream  $j$ :

$$U_{ij} = \min \left\{ \sum_{t \in TI} Q_{it}^H, \sum_{t \in TI} Q_{jt}^C \right\}.$$

*Example 1* This example is from [3] and features three hot streams, two cold streams, and a cold utility. Table 1 gives the inlet and outlet stream temperatures and the flowrate heat capacities of each process stream and the cooling water duty.

Temperatures on the hot side of the cascade are 159°C, 128°C, and 36°C, while temperatures on the cold side are 149°C, 118°C and 26°C. There are two temperature intervals. Table 2 gives the heat released from hot streams to the temperature intervals, while Table 3 gives the heat absorbed by the cold streams from the temperature intervals.

**Mixed Integer Linear Programming: Heat Exchanger Network Synthesis, Table 2**

$Q_{it}^H$ , heat released from hot stream  $i$  to temperature interval  $t$

Stream	Temperature Interval	
	TI-1	TI-2
H1	7083.5	11635.5
H2	632.4	816.0
H3	1667.8	2044.4

**Mixed Integer Linear Programming: Heat Exchanger Network Synthesis, Table 3**

$Q_{it}^C$ , heat absorbed by cold stream  $i$  from temperature interval  $t$

Stream	Temperature Interval	
	TI-1	TI-2
C1	839.7	8583.6
C2	6079.1	
CW		8395.2

**Mixed Integer Linear Programming: Heat Exchanger Network Synthesis, Table 4**  
Four solutions which satisfy minimum number of matches

Solution 1		Solution 2		Solution 3		Solution 4	
Match Duty ( $Q_{ij}$ )		Match Duty ( $Q_{ij}$ )		Match Duty ( $Q_{ij}$ )		Match Duty ( $Q_{ij}$ )	
H1–C1	9423.3	H1–C1	7974.9	H1–C1	5711.1	H1–C1	4262.7
H1–C2	6079.1	H1–C2	6079.1	H1–C2	6079.1	H1–C2	6079.1
H1–CW	3234.6	H1–CW	4683.0	H1–CW	6946.8	H1–CW	8395.2
H2–CW	1448.4	H2–C1	1448.4	H2–CW	1448.4	H2–C1	1448.4
H3–W	3712.2	H3–CW	3712.2	H3–C1	3712.2	H3–C1	3712.2

In this example, the minimum number of units is 5, and there are four solutions to this MILP that meet this minimum (cf. Table 4).

## Conclusions

Mixed integer linear programs are used in heat exchanger network synthesis to identify the minimum number of units, and a set of matches and their heat loads meeting the minimum. These MILPs are based upon a transshipment model of heat flow.

## Keywords

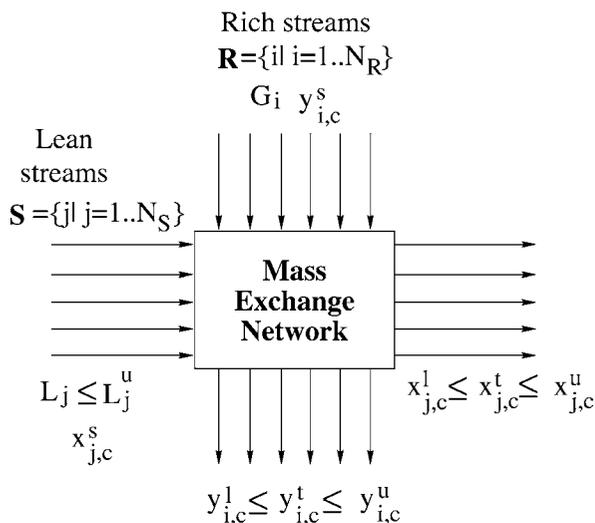

MILP; Mass and heat exchange; Separation

Separation networks involving mass transfer operations that do not require energy (e.g. absorption, liquid-liquid extraction, ion-exchange etc.) are characterized as mass exchange networks (MEN). These appear in the chemical industries mostly in waste treatment, but also, in feed preparation, product separation, recovery of valuable materials, etc. A *mass exchanger*, in this context, is any counter-current, direct-contact mass transfer unit, where one or more components are transferred at constant temperature and pressure from one process stream, which is characterized as *rich stream*, to another process or utility stream, characterized as *lean stream*. Mass integration aims to the purification of the rich streams and the recovery of valuable or hazardous materials at the minimum total cost (investment and operating cost of auxiliary streams). In the specific case, when the mass transfer operations take place at the same temperature, or heating/cooling requirements are negligible, the integration problem is limited to the synthesis of a mass exchanger network (MEN) only. When mass exchange operations at different temperature levels are encountered, mass and heat exchanger networks (MHEN) may be considered simultaneously.

MEN synthesis involves a set of rich streams, in terms of one or more components,  $\mathbf{R} = \{i: i = 1, \dots, N_R\}$ , with known flowrates,  $G_i$ , inlet and outlet compositions for the components of interest,  $y_{i,c}^s, y_{i,c}^t$  (exact values or bounds) respectively, and a set of process or auxiliary lean streams (*mass separating agents*, MSAs),  $\mathbf{S} = \{j: j = 1, \dots, N_S\}$  with known cost, inlet and outlet compositions for the same components,  $x_{j,c}^s, x_{j,c}^t$  (exact values or bounds), as shown in Fig. 1.

The *synthesis problem* refers to the selection of the appropriate lean streams and their flowrates,  $L_j$ , the mass exchange operations (*mass exchange matches*), the mass transfer load for each separator and its required size, and the configuration of the overall network.

Mass transfer in each mass exchanger is governed by the first and second thermodynamic laws, as is heat transfer in heat exchangers. Mass transfer of a component  $c$  from a rich to a lean stream is feasible if the composition of  $c$  in the rich phase is greater than the equi-

Mixed Integer Linear Programming: Mass and Heat Exchanger Networks, Figure 1

librium composition with respect to the lean phase:

$$y_c \geq f(x_c) + \epsilon, \quad (1)$$

where  $f(x_c)$  is the equilibrium relation and  $\epsilon$  is a *minimum composition difference* that ensures feasible mass transfer in a separator of finite size, in analogy to  $\Delta T_{\min}$  in heat exchangers. This analogy led to the development of synthesis methods for mass exchanger networks employing mixed integer optimization techniques, similar to heat exchanger networks (cf. Mixed Integer Linear Programming: Mass and Heat Exchanger Networks; ► **MINLP: Mass and Heat Exchanger Networks**), that are categorized into the *sequential synthesis* and the *simultaneous synthesis* methods.

The *sequential MEN synthesis method*, introduced in [3] and [4] involves the following steps:

- 1) Minimum cost of mass separating agents (minimum utility problem), to determine the optimal flows of the mass separating agents.
- 2) Minimum number of mass exchanger units, for fixed MSA flows, to determine the mass exchange matches.
- 3) Network configuration and separator sizes for fixed mass exchange operations.

The first two synthesis steps involve the solution of linear and mixed integer linear problems.

A useful tool of the sequential MEN synthesis method is the *composition interval diagram*, CID,

where thermodynamic feasibility of mass transfer is explored mapping the rich and the lean streams on equivalent composition scales, that are derived from the mass transfer feasibility requirements in (1). In general, the composition equivalent scales and the minimum composition difference,  $\epsilon$ , are defined for each component of interest and each pair of rich and lean streams. In the simple case of a single component, where mass transfer is independent of the presence of other components in the rich streams, the CID is constructed as illustrated in Fig. 2.

Feasible rich-to-lean mass transfer is guaranteed within a composition interval when the equilibrium relation  $f(x_c)$  is convex within the interval. When  $f(x_c)$  is convex in the whole composition range, only inlet compositions are required to construct the CID [8].

The minimum cost of mass separating agents is found employing a *transshipment model*, where the components of interest are the transferred commodities, the rich and the lean streams are considered as sources and sinks respectively, and the composition intervals define the intermediate nodes [4]. The model involves energy balances around the temperature intervals (intermediate nodes):

$$(TP1) \quad \left\{ \begin{array}{l} \min \quad \sum_j c_j L_j \\ \text{s.t.} \quad \delta_{k-1} + \sum_{i \in R_k} WR_k^i \\ \quad \quad = \delta_k + \sum_{j \in S_k} WS_k^j \\ 0 \leq L_j \leq L_j^{\text{up}}, \quad j \in S, \\ \delta_0 = \delta_{N_{\text{int}}} = 0; \\ \delta_k \geq 0, \quad k = 1, \dots, N_{\text{int}} - 1, \end{array} \right.$$

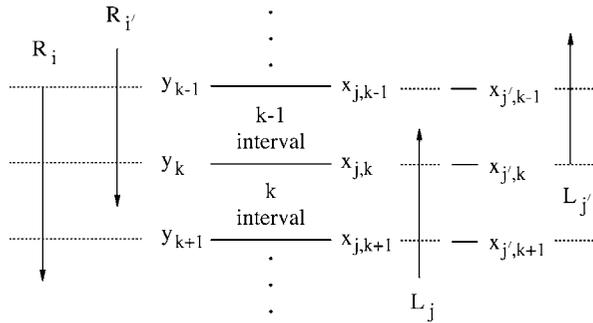

where

- $R_k$  is the set of rich streams, present in interval  $k$ ;
- $S_k$  is the set of lean streams, present in interval  $k$ ;
- $N_{\text{int}}$  is the number of composition intervals;
- $WR_k^i$  is the mass exchange load of rich stream  $i$  in interval  $k$ ,

$$WR_k^i = G_i(y_k - \max(y_{k+1}, y_i^t));$$

- $WS_k^j$  is the mass exchange load of lean stream  $j$  in interval  $k$ ,

$$WS_k^j = L_j(\min(x_j^t, x_{jk}) - x_{jk+1});$$

**Mixed Integer Linear Programming: Mass and Heat Exchanger Networks, Figure 2**  
Composition interval diagram

- $\delta_k$  is the residual mass exchange load in interval  $k$ . Problem (TP1) results in the optimal flows of the mass separating agents and the identification of the *pinch points*, i.e. the thermodynamic bottlenecks in mass transfer. The pinch points are defined by zero residual flows and divide the mass exchange network into subnetworks. Mass transfer between different subnetworks (i.e. across the pinch) increases the cost of mass separating agents.

An assumption in (TP1) is that molar flows of the rich and the lean streams are constant. If significant flowrate variations take place, compositions and mass exchange loads are calculated based on nontransferable components.

The following cases are distinguished:

- Fixed inlet and outlet compositions. Then, (TP1) is an LP problem. When multiple components are considered, the CID is defined for all the components of interest and (TP1) corresponds to the multicommodity transshipment model. The pinch points are then determined by the component that requires the greater MSA flows.
- Variable outlet compositions. Then, the mass exchange loads of the rich and lean streams in their final intervals (defined by the upper and lower bounds on their outlet compositions) are variables. Problem (TP1) can still be solved as an LP [9], considering the variable mass exchange loads explicitly in the model.

Variable inlet compositions usually require flexible mass exchange networks to accommodate the variations and define a different problem. For a single com-

ponent it has been shown that the minimum MSA cost corresponds to the lower bounds of the inlet compositions [8].

For nonconvex equilibrium relations, (TP1) cannot guarantee feasible mass transfer throughout the composition range, while the predicted MSA cost is a lower bound to the actual minimum one. B.K. Srinivas and M.M. El-Halwagi suggested in [14] an iterative procedure to calculate the minimum required MSA cost, that involves two major steps:

- i) a 'feasibility problem', where 'critical' composition levels are identified and included in the CID (non-convex NLP step, that requires global optimization methods), and
  - ii) (TP1) with updated intervals, which calculates increasing lower bounds to the minimum MSA cost.
- Instead of target outlet compositions for the rich streams, it may be of interest to remove a certain total mass load of pollutants. Then, (TP1) is solved with variable rich outlets and a fixed total mass exchange load [10]:

$$M_c = \sum_i G_i (y_i^s - y_i^t)$$

The minimum-utility-cost problem has been alternatively formulated as an LP or MINLP problem, based on total mass balances and the following property:

$$\left\{ \begin{array}{l} \text{Mass lost by all the rich} \\ \text{streams below each} \\ \text{pinch point candidate} \end{array} \right\} - \left\{ \begin{array}{l} \text{Mass gained by all the lean} \\ \text{streams below each} \\ \text{pinch point candidate} \end{array} \right\} \leq 0 \quad (2)$$

and employing binary variables to denote the relative position of variable outlet compositions with respect to each pinch point candidate in the CID [5,6,8,9].

The minimum number of mass exchange operations (units) for fixed MSA cost is determined in each subnetwork in a second step, in an attempt to minimize the fixed cost of the separators. The minimum number of mass exchangers is found employing the *expanded transshipment model*, where the existence of a mass exchange match-separator in a subnetwork is denoted by

a binary variable:

$$E_{ijm} = \begin{cases} 1, & \text{when streams } i, j \\ & \text{exchange mass} \\ & \text{in subnetwork } m \\ 0, & \text{otherwise.} \end{cases}$$

For a single component, the minimum number of mass exchanger units is given by the following MILP problem [4]:

$$(TP2) \quad \left\{ \begin{array}{l} \min \sum_m \sum_{i \in R_m} \sum_{j \in S_m} E_{ijm} \\ \text{s.t. } \delta_{ik} - \delta_{ik-1} + \sum_{j \in S_{mk}} M_{ijk} = WR_k^i, \\ k \in I_m, i \in R_{mk}, m \in M, \\ \sum_{i \in R_{mk}} M_{ijk} = WS_k^j, \\ k \in I_m, j \in S_{mk}, m \in M \\ \sum_{k \in I_m} M_{ijk} - E_{ijm} U_{ijm} \leq 0 \\ \delta_{ik} \geq 0, k \in I_m, i \in R_m, \\ M_{ijk} \geq 0, k \in I_m, \\ i \in R_{km}, j \in S_{km} \\ E_{ijk} = 0, 1, k \in I_m, \\ i \in R_{km}, j \in S_{km}, \end{array} \right.$$

where

- $R_m$  is the set of rich streams, present in subnetwork  $m$ ,
- $S_m$  is the set of lean streams, present in subnetwork  $m$ ,
- $I_m$  is the set of intervals in subnetwork  $m$ ,
- $R_{km}$  is the set of rich streams, present in interval  $k$  of subnetwork  $m$ , or above,
- $S_{km}$  is the set of lean streams, present in interval  $k$  of subnetwork  $m$ ,
- $WR_k^i$  is the mass exchange load of rich stream  $i$  in interval  $k$ ,
- $\delta_{ik}$  is the residual mass exchange load of rich stream  $i$  in interval  $k$ ,
- $WS_k^j$  is the mass exchange load of lean stream  $j$  in interval  $k$ , as determined by (TP1),
- $M_{ijk}$  is the mass exchange load between  $i$  and  $j$  in interval  $k$ ,

- $U_{ijm}$  is an upper bound to the possible mass exchange load between  $i$  and  $j$  in subnetwork  $m$ ,

$$U_{ijm} = \min \left( \sum_{k \in I_m} WR_k^i, \sum_{k \in I_m} WS_k^j \right).$$

Srinivas and El-Halwagi have shown [14] that, when the equilibrium relations around a pinch point are not convex, a mass exchanger can straddle the pinch and still be thermodynamically feasible. To account for such cases, exchangers across the pinch points can be considered introducing extra binary variables:

$$\begin{aligned} I_{ijp} &\leq M_{ijp}, \\ I_{ijp+1} &\leq M_{ijp+1}, \\ I_{ijp} + I_{ijp+1} &\geq 2B_{ijp}, \\ I_{ijp}, I_{ijp+1} &\in \{0, 1\}, \\ B_{ijp} &\in \{0, 1\}, \end{aligned}$$

where

- $I_{ijp}$  denotes that streams  $i$  and  $j$  exchange mass at the interval directly above pinch point  $p$ ,
- $I_{ijp+1}$  denotes that streams  $i$  and  $j$  exchange mass at the interval directly below pinch point  $p$ ,
- $B_{ijp}$  denotes the existence of an exchanger between streams  $i$  and  $j$ , across the pinch  $p$ .

Then, the number of required units to minimize is given by:

$$\sum_m \left( \sum_{i \in R_m} \sum_{j \in S_m} E_{ijm} - \sum_p B_{ijp} \right).$$

Note, that  $I_{ijp}$ -variables can be relaxed to continuous, due to total unimodularity of the model with respect to these variables:

$$0 \leq I_{ijp}, I_{ijp+1} \leq 1$$

Problem (TP2) may not have a unique solution. Alternative combinations of mass exchange matches, featuring the minimum MSA cost, may be generated by solving (TP2) iteratively and including integer cuts. These do not necessarily correspond to networks of the same overall cost.

The expanded transshipment model can also be employed to determine the minimum MSA cost, considering variable mass loads for the lean streams. Then, forbidden or restricted mass exchange operations can be explicitly accounted for.

Although (TP2) does not determine the network structure, stream splitting and exchanger connectivity may be guided by the resulting mass exchange load distribution in each composition interval [4]. The actual network configuration is found in a next step, employing heuristic methods [3,5] or superstructure methods (NLP models).

Special cases of mass exchange networks have been studied:

- MEN and *regeneration networks* [5,11].

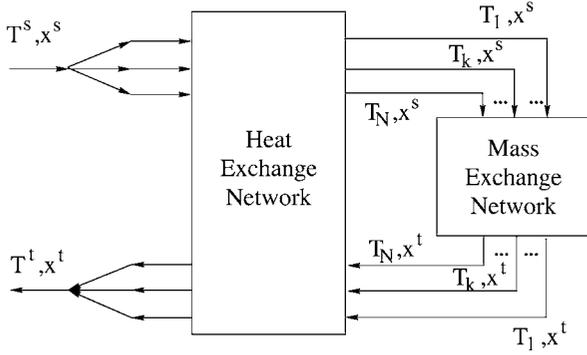

The regeneration of mass separating agents by auxiliary streams can be considered simultaneously with the main MEN, in another mass exchanger network, where the MSAs behave as the rich streams. In this case, the CID is extended to include the equivalent composition scales of the regenerating agents. The inlet and outlet compositions of the lean streams in the main MEN are in general variables.

- Reactive mass exchange networks [6,11,14]

Rich-to-lean mass transfer may involve interphase mass transfer and chemical reaction in the lean phase, at constant temperature. Mass exchange operations of this kind are considered deriving the equilibrium relations based on chemical equilibrium.

The main advantage of the sequential synthesis method for mass exchange networks is that simple optimization models are solved. However, unless the MSA cost is dominant, as synthesis decisions are fixed from one step to the next, important trade-offs between operating and capital cost are not exploited and overall cost optimality cannot be guaranteed. Furthermore, the minimum composition difference,  $\epsilon$  that defines the mass recovery levels in (TP1) and (TP2), is in general, an optimization variable for each mass exchanger separately. In the sequential synthesis method this is fixed arbitrarily to a possibly conservative value for the construction of the CID. El-Halwagi and V. Manousiouthakis [4] suggested a two-level optimization procedure to select a unique  $\epsilon$  for all mass exchange operations, based on the impact of  $\epsilon$  on the final MEN cost, still, not exploiting the overall cost trade-offs.

When isothermal mass exchange operations take place at different temperature levels, the operating and overall mass integration costs are affected by the heating and cooling requirements of the system. Energy integration between the rich and lean streams can be

**Mixed Integer Linear Programming: Mass and Heat Exchanger Networks, Figure 3**

considered within a mass and heat exchanger network synthesis problem (MHEN) to reduce the total cost. The overall problem is addressed combining MEN and HEN synthesis tools. The optimal temperature of mass exchange is defined for each pair of rich and lean streams by the equilibrium relations that limit mass transfer

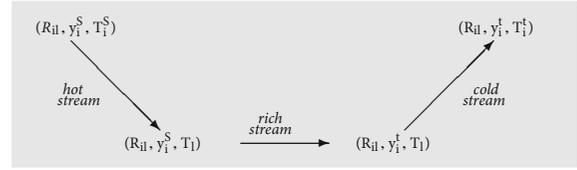

$$y_i \geq K_{ij}(T)x_j,$$

where  $K_{ij}(T)$  is a known function of temperature.

In the sequential synthesis framework, the overall minimum operating cost for the network (cost of mass separating agents and heating/cooling utilities) may be calculated from a combined mass and heat transshipment model. Each stream is considered to consist of substreams, of the same inlet and outlet composition and temperature, each of which participates to isothermal mass exchange operations at a different temperatures. Srinivas and El-Halwagi proved [13], that, for monotonic dependence of the equilibrium constant on temperature, the overall utility cost of the combined MHEN is independent of such a stream decomposition, see Fig. 3.

Although the mass exchange temperatures ( $T_1, \dots, T_N$ ) are variables, their relative position with respect to inlet and outlet stream temperatures (greater or less) can be prepostulated. Thus, the rich and lean substreams define hot (or cold) streams before their mass exchange operations and cold (or hot) streams afterwards, cf. Fig. 4.

A CID is constructed, similarly to the simple MEN case, involving the several substreams with variable flows, and thus, variable mass loads in each composi-

**Mixed Integer Linear Programming: Mass and Heat Exchanger Networks, Figure 4**

Rich substream with  $T_i^s \leq T_l \leq T_i^t$

tion interval. Mass exchange is permitted between substreams of the same temperature. A *temperature interval diagram*, TID, is also constructed, involving the hot and cold substreams and the available heating and cooling utilities, with variable heat loads per interval, due to the variable substream flows. In order to avoid discrete decisions (i. e. presence or not of streams in temperature intervals with variable limits), the temperature range for each mass transfer operation is discretized and a substream is associated with each candidate temperature [13].

The minimum utility cost is found from the solution of the combined LP transshipment model, which, for a single component is as follows:

$$(TP3) \quad \left\{ \begin{array}{l} \min \left( \sum_{j \in S} c_j L_j \right. \\ \quad \left. + \sum_{n \in TI} \sum_{h \in HU_n} c_h Q H U_{hn} \right. \\ \quad \left. + \sum_{n \in TI} \sum_{c \in CU_n} c_c Q C U_{cn} \right) \end{array} \right.$$

such that

$$\delta_{l_i k} - \delta_{l_i k-1} + \sum_{j \in S} \sum_{l'_j \in SS_{jk}} M_{l_i l'_j k} = W R_k^{l_i},$$

$$k \in CI, \quad i \in R, \quad l_i \in RS_{ik},$$

$$\theta_{hn}^h \geq 0, n \in TI, h \in HU_n,$$

$$M_{l_i l'_j k} \geq 0,$$

$$k \in CI, i \in R, j \in S,$$

$$l_i \in RS_{ik}, l'_j \in SS_{jk},$$

$$M_{l_i l'_j k} = 0,$$

$$k \in CI, i \in R, j \in S,$$

$$l_i \in RS_{ik}, l'_j \in SS_{jk},$$

$$(l_i l'_j) \in FM,$$

$$\delta_{l_i 0} = \delta_{l_i N_{CI}} = 0,$$

$$i \in R, l_i \in RS_i,$$

$$\theta_{l_s 0} = \theta_{l_s N_{TI}} = 0,$$

$$s \in R \cup S, l_s \in HS_s,$$

$$\theta_{h0}^h = \theta_{h N_{TI}}^h = 0,$$

$$h \in HU,$$

where

- $CI$  is the set of composition intervals  $k$ ,
- $TI$  is the set of temperature intervals  $n$ ,

- $RS_{ik}$  is the set of substreams of rich stream  $i$ , of variable flow,  $G_{l_i}$ , such that

$$\sum_l G_{l_i} = G_i,$$

present in interval  $k$ , or above,

- $SS_{jk}$  is the set of substreams of lean stream  $j$ , of variable flow,  $L_{l_j}$ , such that

$$\sum_l L_{l_j} = L_j,$$

present in interval  $k$ ,

- $HS_{sn}$  is the set of hot substreams of stream  $s$ , present in interval  $n$ , or above,
- $CS_{sn}$  is the set of cold substreams of stream  $s$ , present in interval  $n$ ,
- $HU_n$  is the set of hot utilities, present in interval  $n$ , or above,
- $CU_n$  is the set of cold utilities, present in interval  $n$ ,
- $WR_{ik}^{l_i}$  is the mass exchange load of substream  $l_i$ , in interval  $k$ ,

$$WR_{ik}^{l_i} = G_{l_i}(y_k - \max(y_{k+1}, y_i spt)),$$

- $WS_{kj}^{l_j}$  is the mass exchange load of substream  $l_j$ , in interval  $k$ ,

$$WS_{kj}^{l_j} = L_{l_j}(\min(x_j^t, x_{jk}) - x_{jk+1}),$$

- $\delta_{l_i k}$  is the residual mass load of substream  $l_i$  in interval  $k$ ,
- $M_{l_i l'_j k}$  is the mass exchange load between  $l_i$  and  $l'_j$ , in  $k$ ,
- $FM$  is the set of mass exchanging substreams that are at different temperatures,
- $QS_{l_s n}$  is the heat load of substream  $l_s$  in interval  $n$ ,
- $Q_{l_s l'_s n}$  is the heat exchange load between  $l_s$  and  $l'_s$  in interval  $n$ ,
- $\theta_{l_s n}$  is the residual heat load of hot substream  $l_s$  in interval  $n$ ,
- $QHU_{hn}$  is the heat load of hot utility  $h$  in interval  $n$ ,
- $QCU_{cn}$  is the heat load of cold utility  $c$  in interval  $n$ ,
- $QH_{hl_s n}$  is the heat exchange load between hot utility  $h$  and  $l_s$  in interval  $n$ ,
- $\theta_{hn}^h$  is the residual heat load of hot utility  $h$  in interval  $n$ ,
- $QC_{l_s c n}$  is the heat exchange load between  $l_s$  and cold utility  $c$  in interval  $n$ .

Problem (TP3) results in the minimum utility cost and the corresponding flows of separating agents and heating/cooling utility streams, the optimal decomposition of each stream into substreams of fixed mass exchange temperature and the mass and heat exchange pinch points and corresponding subnetworks.

The minimum operating cost of the combined MHEN can alternatively be found applying the first and second thermodynamic laws (property in (2)) on the composition and temperature interval diagrams [13].

The minimum number of mass and heat exchangers is determined in a second step through the expanded MILP transshipment model, separately in each mass and heat exchanger subnetwork. The final network configurations and unit sizes are determined in a final step, applying heuristic rules or superstructure models.

Additional disadvantages of the sequential MHEN synthesis method, compared to the synthesis of simple MEN, are that:

- i) the mass and heat exchange networks are assumed separable and
- ii) the intermediate mass exchange temperatures are decided in the first step; this forbids full exploitation of the mass/heat integration trade-offs, as capital cost implications of such decision is not accounted for.

Modeling concepts from the sequential mass and heat exchanger network synthesis methods, employing LP and MILP optimization models, have been extended to explore distillation networks [1], pervaporation systems [12] and other energy-requiring separation networks [2,7].

### Keywords and Phrases

Bilevel programming; Bilevel nonlinear; Bilevel optimization; Mixed integer optimization; Global optimization; Two-level optimization; Mixed integer nonlinear

### Introduction

The global optimization of classes of mixed integer nonlinear bilevel optimization problems is addressed. For problems where the integer variables participate in both the inner and the outer problems, the outer level

may involve general mixed-integer nonlinear functions. The inner level may involve functions that are mixed-integer nonlinear in outer variables, linear, polynomial, or multilinear in inner integer variables and linear in inner continuous variables. The technique is based on reformulating the mixed-integer inner problem as continuous by its convex hull representation [11,12] and solving the resulting nonlinear bilevel optimization problem by a novel deterministic global optimization framework.

### Formulation

The general mixed-integer nonlinear Bilevel Programming Problem (BLP) formulation is:

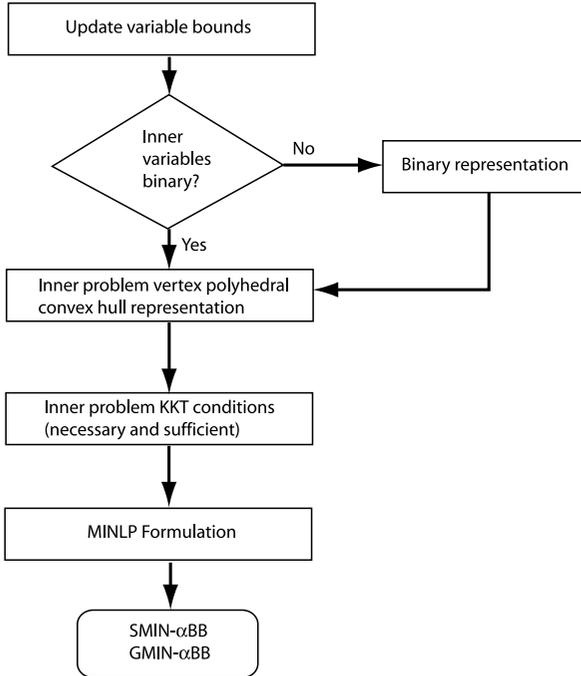

$$\begin{aligned} \min_{\mathbf{x}} F(\mathbf{x}, \mathbf{y}) \\ \text{s.t. } \mathbf{G}(\mathbf{x}, \mathbf{y}) \geq 0 \\ \mathbf{H}(\mathbf{x}, \mathbf{y}) = 0 \\ \min_{\mathbf{y}} f(\mathbf{x}, \mathbf{y}) \\ \text{s.t. } \mathbf{g}(\mathbf{x}, \mathbf{y}) \geq 0 \\ \mathbf{h}(\mathbf{x}, \mathbf{y}) = 0 \\ x_1, \dots, x_i \in \mathfrak{R}^{n_1}, y_1, \dots, y_j \in \mathfrak{R}^{n_2}, \\ x_{i+1}, \dots, x_{n_1} \in Z^+, y_{j+1}, \dots, y_{n_2} \in Y_{\text{IN}} \subseteq Z^+ . \end{aligned} \quad (1)$$

where  $\mathbf{x}$  is a vector of outer problem variables, of which  $i$  are continuous and  $n_1 - i$  are integer,  $\mathbf{y}$  is a vector of inner problem variables, of which  $j$  are continuous and  $n_2 - j$  are integer,  $F(\mathbf{x}, \mathbf{y})$  is the outer objective function,  $\mathbf{H}(\mathbf{x}, \mathbf{y})$  are outer equality constraints,  $\mathbf{G}(\mathbf{x}, \mathbf{y})$  are outer inequality constraints,  $f(\mathbf{x}, \mathbf{y})$  is the inner objective function,  $\mathbf{h}(\mathbf{x}, \mathbf{y})$  are inner equality constraints, and  $\mathbf{g}(\mathbf{x}, \mathbf{y})$  are inner inequality constraints. The applications of BLP are many and diverse [4,6,7]; if these problems involve discrete decisions in addition to continuous ones, then the mixed-integer BLP models arise.

### Classes

The nonlinear mixed integer BLP can be classified into four different categories, depending on the existence of integer variables in the outer or the inner problems:

- (I). Integer Upper, Continuous Lower BLP;
- (II). Purely Integer BLP;
- (III). Continuous Upper, Integer Lower BLP;
- (IV). Mixed-Integer Upper and Lower BLP.

**Mixed Integer Nonlinear Bilevel Programming: Deterministic Global Optimization, Figure 1**  
Algorithm flowsheet for type II, III, IV BLPs

The existence of both integer and nonlinear terms in the above problem classes require special solution techniques. The specific mathematical structure of the mixed integer nonlinear BLP is of great import in developing corresponding solution strategies. Problems of Type I can be addressed with existing BLP solution approaches. For problems of Type II, enumeration methods can be applied. However, BLPs of Type III and IV are the most difficult to solve.

### BLPs with Inner Integer Variables

The conventional solution method of the continuous BLP is to transform it into a single level problem by replacing the inner problem with the set of equations that define its Karush–Kuhn–Tucker (KKT) optimality conditions. However, the KKT optimality conditions use gradient information, so the conventional approach is not applicable when integer inner variables exist. Furthermore, if the integrality constraint is relaxed on the inner integer variables, the solution of this relaxed BLP does not provide a valid lower bound on the solution of the mixed-integer BLP [9]. Note that even if the optimal

solution of the relaxed BLP is integral in  $y$ , this may not be a globally optimal solution of the original BLP [9]. Thus, the conventional KKT-based methods inherently fail in locating the global optimum.

The BLP with inner mixed-integer variables can be transformed into an equivalent BLP with inner mixed-binary (0-1) variables as follows. Every inner problem integer variable  $y_j$ , with upper and lower bounds  $y_j^L \leq y_j \leq y_j^U$  is converted into a set of binary variables using the formula [2]:

$$y_j = y_j^L + z_{j1} + 2z_{j2} + 4z_{j3} + \dots + 2^{(N_j-1)}z_{jN} \quad (2)$$

where  $z_j$  is a vector of (0-1) variables and  $N_j$  is the minimum number of (0-1) variables needed:

$$N_j = 1 + \text{INT} \left( \frac{\log(y_j^U - y_j^L)}{\log(2)} \right) \quad (3)$$

such that INT truncates its real argument to an integer.

The only time that the KKT optimality conditions are applicable to solve the BLP with mixed-binary  $y$  is when the following property is satisfied [8]:

**Property 1** *If the inner problem constraint set,  $Y_{\text{IN}}$ , defines a vertex polyhedral convex hull and all the vertices of the convex hull lie in  $Y_{\text{IN}}$ , then the optimal inner problem integer solution is equivalent to its linear programming relaxation. As a result, the Karush–Kuhn–Tucker, KKT, conditions of relaxed inner linear problem are necessary and sufficient to define the optimal inner problem integer solution.*

The property is also satisfied when outer variables exist in the inner problem constraints, such that the inner problem vertex polyhedral convex envelope is defined *parametrically in  $x$* . Hence, the integer solution of the inner problem lies at a vertex of the inner solution set and the KKT optimality conditions locate the true optimal solution [8].

Here, a global optimization procedure is presented for BLPs of Type II, III and IV that is based on a reformulation/linearization scheme combined with a global optimization framework. The idea is that if the inner problem constraint set has a vertex polyhedral convex envelope, then *Property 1* is satisfied and the mixed-integer inner problem can be converted into a continuous problem of equivalent form. The application of the reformulation/linearization technique results in the

convex hull representation for several classes of inner problems.

### Reformulation/Linearization

The mixed-binary inner problem constraint set is transformed into the continuous domain by converting it into a polynomial programming problem and then relinearizing it into an extended linear problem by a method based on [11]. First, a polynomial factor is defined as follows:

$$F_n(J_1, J_2) = \left\{ \begin{array}{l} \left( \prod_{j \in J_1} y_j \right) \left( \prod_{i \in J_2} (1 - y_i) \right), \\ J_1, J_2 \subseteq N_y \equiv 1, \dots, n_y, \\ \text{s.t. } J_1 \cap J_2 = \emptyset, |J_1 \cup J_2| = n_y \end{array} \right\}. \quad (4)$$

Using this polynomial factor, the convex hull of the inner problem,  $Y_{\text{IN}}$ , is obtained. If the inner optimization problem is linear, then the 2-step process is as follows:

**Step 1 Reformulation.** Multiply every constraint, including  $0 \leq y \leq 1$ , with every factor defined as above and use the relationship  $y_j^2 = y_j, \forall j = 1, \dots, n_y$  to linearize terms polynomial in  $y$ . Include in the inner problem constraint set the nonnegativities on all possible factors of degree  $n_y$  (i. e.  $F_n(J_1, J_2) \geq 0$  for all  $(J_1, J_2)$  of order  $n_y$ ).

**Step 2 Linearization.** Linearize the inner constraints that are multilinear in  $y$ , such as  $\prod_{j \in J} y_j$  by substituting a  $z_J$  for each set  $J$  with  $|J| \geq 2$ , with the elements of  $J$  in increasing order. (i. e. a new variable  $z_{ij}$  is introduced to substitute for a bilinear term ( $y_i y_j = z_{ij}$ ) and further substitution is performed for multilinear terms). At constant  $x$ , the resulting inner constraint set describes a polytope with all vertices defined by binary values and characterizes the convex hull of feasible solutions for any inner problem that is linear or polynomial binary in  $y$ -variables.

If the inner optimization problem is mixed-binary linear or polynomial, the problem constraints are again multiplied by  $n_y$ -degree polynomial factors composed of the  $n_y$  binary variables and their complements and the resulting nonlinear problem is linearized by a substitution of new variables. Additional nonlinear terms arise from the multiplication of the  $n_y$ -degree polynomial factors with the inner problem linear continuous

terms in  $y$ , that are also linearized through a redefinition [8,12]. This transformation is applicable when in the mixed-binary inner problem, the continuous  $y$  are  $0 \leq y \leq 1$ . Note that there are no such restrictions on the outer problem  $x$ -variables in both inner and outer problems.

### Inner Problem KKT Conditions and Complementarity

After reformulation/relinearization, the inner problem is replaced by the set of equations that define its necessary and sufficient KKT optimality conditions:

$$\begin{aligned} h_i^r(x, y^*) &= 0, \quad i \in I, \\ \frac{\partial f(x, y^*)}{\partial y^*} &+ \sum_{j=1}^J \lambda_j \frac{\partial g_j^r}{\partial y^*} + \sum_{j=1}^J \mu_j^* \frac{\partial h_j^r}{\partial y^*} = 0, \\ g_j^r(x, y^*) + s_j^* &= 0, \quad j \in J \\ \lambda_j^* s_j^* &= 0, \quad j \in J \quad (\text{CS}) \\ \lambda_j^* s_j^* &\geq 0, \quad j \in J \end{aligned} \quad (5)$$

where  $f^r$ ,  $h^r$  and  $g^r$  are the reformulated inner objective, equality and inequality constraints,  $\lambda$  and  $\mu$  are the Lagrange multipliers of the inner inequality and equality constraints, and  $s$  are the slack variables associated with the complementarity constraints.

### Active Set Strategy

The complementarity condition constraints, (CS) involve discrete decisions on the choice of the inner problem active constraint set. The set changes when at least one inequality function and its Lagrange multiplier are equal to zero. This imposes a major difficulty in the solution of the transformed problem. To overcome this difficulty, the Active Set Strategy [5,8] is employed, such that the complementarity constraints are reformulated as:

$$\begin{aligned} \lambda_j - U Y_j &\leq 0, \quad j \in J \\ s_j - U(1 - Y_j) &\leq 0, \quad j \in J \\ \lambda_j, s_j &\geq 0, \quad j \in J \\ Y_j &\in \{0, 1\}. \end{aligned} \quad (6)$$

where  $U$  is an upper bound on the slack variables  $s$  and  $Y$  are the additional binary variables introduced. If constraint  $j$  is active, ( $Y_j = 1$ ), and if inactive, ( $Y_j = 0$ ). Note that now the integer variable set includes the binary variables  $Y$  in addition to the outer problem integer variables.

### Transformed BLPP Global Optimization

The problem that results after the reformulated/linearized inner problem is replaced with its KKT optimality conditions and active set strategy is applied can still have nonlinear terms due to complementarity and stationarity conditions. Further, nonlinear terms in the outer problem variables may exist in either the inner or outer problem constraints. Hence, the resulting problem is a mixed-integer (nonlinear) optimization problem and should be solved by a global optimization procedure. If the integer variables are all binary and only appear in linear or mixed-bilinear terms, the Special structure MINLP- $\alpha$ BB, SMIN- $\alpha$ BB [1,3] approach is employed. If the outer integer variables are not restricted to binary and/or participate in nonlinear terms, the General structure MINLP- $\alpha$ BB, GMIN- $\alpha$ BB [1,3] approach is employed. The steps of the proposed framework are given below.

### Global Optimization Algorithm

**Step 1** Establish variable bounds by solving the problems:

$y^L, y^U = \min y, -y$  s.t. inner problem constraint setprotect

to obtain simple lower and upper bounds on  $y$ ,

$$y^L \leq y \leq y^U.$$

**Step 2** If the inner integer variables are integer, convert into a set of binary variables by Eq. (2) and Eq. (3).

**Step 3** Obtain the vertex polyhedral convex envelope of the inner problem feasible region via the reformulation/linearization [11]. The inner problem is now linear in both inner binary and continuous variables and parametric in outer problem variables,  $x$ .

**Step 4** Replace the inner problem with the set of equations that define its necessary and sufficient KKT optimality conditions. The resulting problem is single level.

**Step 5** Solve the resulting single level optimization

problem to global optimality. The inner integer variables are all separable, linear and binary at the beginning of this step. If the final problem is a Mixed Integer Linear Problem, (MILP), then use CPLEX. Notice that the problem will be an MILP only for the simplest cases. If there are nonlinear continuous variables, but the integer variables are all binary, linear and separable, use SMIN- $\alpha$ BB [1,3] global optimization procedure. If the outer problem has nonlinear integer terms, then use GMIN- $\alpha$ BB [1,3] global optimization procedure.

### Illustrative Example

The following problem [10] can not be solved to global optimality using current deterministic solution approaches for integer bilevel programming problems in the literature.

$$\begin{aligned} \min & - \left( -\frac{2}{5}x_1^2x_2 + 4x_2^2 \right) y_1y_2 \\ & - (-x_2^3 + 3x_1^2x_2)(1-y_1)y_2 - (2x_2^2 - x_1)(1-y_2) \\ \text{s.t.} & \min - (x_1x_2^2 + 8x_2^3 - 14x_1^2 - 5x_1) y_1y_2 \\ & - (-x_1x_2^2 + 5x_1x_2 + 4x_2)(1-y_1)y_2 \\ & - 8x_1y_1(1-y_2) \\ \text{s.t.} & y_1 + y_2 \geq 1 \\ & 0 \leq x_1 \leq 10 \\ & 0 \leq x_2 \leq 10 \\ & y_1, y_2 \in \{0, 1\}^2, \quad x \in \Re. \end{aligned} \tag{7}$$

**Steps 1-2** Variable bounds are already given in this problem, with  $0 \leq x \leq 10$ , and  $y_1$  and  $y_2$  are defined as binary.

**Step 3** Determination of the vertex polyhedral convex hull: The inner problem is  $Ny = 2$  degrees, second degree factors  $y_1y_2$ ,  $y_1(1-y_2)$ ,  $(1-y_1)y_2$ ,  $(1-y_1)(1-y_2)$  multiply the inner problem constraint  $y_1 + y_2 - 1 \geq 0$  and result in:

$$\begin{aligned} y_1y_2 & \geq 0 \\ y_1 + y_2 - y_1y_2 - 1 & \geq 0. \end{aligned} \tag{8}$$

Linearization: Assign a new variable for the bilinear term  $z_{12} = y_1y_2$  that leads to the additional constraints:

$$\begin{aligned}
 z_{12} &\geq 0 \\
 y_1 - z_{12} &\geq 0 \\
 y_2 - z_{12} &\geq 0 \\
 -y_1 - y_2 + z_{12} &\geq -1.
 \end{aligned} \tag{9}$$

From Eqs. (8) and (9),  $y_1 + y_2 - z_{12} - 1 = 0$ . Substituting the definition of  $z_{12}$  into Eq. (8), a linear relaxation of the inner problem constraint set leads to the original set of constraints:

$$\begin{aligned}
 y_1 + y_2 - 1 &\geq 0 \\
 1 - y_2 &\geq 0 \\
 1 - y_1 &\geq 0.
 \end{aligned} \tag{10}$$

Hence, the continuous relaxation of the original problem constraints define the convex hull and no additional constraints are necessary. The inner problem is continuous and linear in  $y_1$  and  $y_2$ , and parametric in the outer problem variables  $x$ .

**Step 4** Replace the relaxed inner problem with the equivalent set of equations that define its necessary and sufficient KKT optimality conditions:

$$\begin{aligned}
 \min &\left( \frac{17}{5}x_1^2x_2 - 4x_2^2 - x_2^3 \right) y_1 + \left( \frac{2}{5}x_1^2x_2 - 2x_2^2 - x_1 \right) \\
 &\cdot y_2 \left( -\frac{17}{5}x_1^2x_2 + 2x_2^2 + x_2^3 + x_1 \right) \\
 0 &\leq x_1 \leq 10 \\
 0 &\leq x_2 \leq 10 \\
 -x_1^2x_2^2 - 8x_2^3 + 14x_1^2 + 5x_1 - x_1x_2^2 + 5x_1x_2 + 4x_2 \\
 &- \lambda_1 + \lambda_2 = 0 \\
 -\lambda_1 - x_1^2x_2^2 - 8x_2^3 + 14x_1^2 + 13x_1 + \lambda_3 &= 0 \\
 -y_1 - y_2 + 1 + s_1 &= 0 \\
 y_1 + s_2 &= 1 \\
 y_2 + s_3 &= 1 \\
 \lambda_1 - UY &\leq 0 \\
 s_1 + UY &\leq U \\
 Y \in \{0, 1\}; \quad s_1, \lambda_1, y_1, y_2 &\geq 0; \\
 x_1, x_2 \in \mathfrak{R}; \quad y_1, y_2 &\leq 1.
 \end{aligned} \tag{11}$$

**Step 5** The single level problem constraint contains the following nonlinear terms:  $x_1^2x_2y_1$ ,  $x_2^2y_1$ ,  $x_1^2x_2y_2$ ,  $x_2^2y_2$ ,  $x_1y_2$ ,  $x_1^2x_2$ ,  $x_2^2$ ,  $x_2^3$ ,  $x_1x_2^2$ ,  $x_1x_2$ ,  $x_1^2x_2^2$  that should be underestimated. All integer variables are binary, linear and separable. Solve the resulting single level prob-

lem to global optimality using SMIN- $\alpha$ BB [1,3]. The global optimal solution reported in [10] is at  $(x_1^*, x_2^*, y_1^*, y_2^*) = (6.038, 2.957, 0, 1)$ . We identify the lower global solution at  $(0, 10, 1, 1)$ . Note that the solution of this problem by enumeration methods could be labor intensive due to the presence of continuous variables.

## Conclusions

The global optimization framework addresses the solution of several classes of mixed integer nonlinear bilevel optimization problems. The outer problem may be mixed-integer nonlinear in both inner and outer variables; the inner problem may be mixed-integer nonlinear in outer variables, linear, polynomial or multilinear in inner integer variables and linear in inner continuous variables. This is based on the reformulation of the mixed-integer inner problem feasible space to generate its convex hull, where the vertices correspond to binary solutions. This allows the equivalence of the inner optimization problem to the set of equations that define its KKT optimality conditions, with which it is replaced. The resulting single level optimization problem is solved to global optimality. This is arguably the first deterministic global optimization technique that can solve several classes of mixed-integer nonlinear bilevel optimization problems. Note that if the central decision maker wants to locate the second-best inner or outer integer solutions, simple integer cuts [2] can be added prior to applying the relevant solution strategy.

### Introduction

The mixed-integer nonlinear programming (MINLP) approach was widely used to model and solve the process synthesis problems in chemical engineering filed during the last two decades within the superstructure framework that always involves discrete and continuous variables [3,4,5,6,10]. Recently, the successful employment of the branch-and-cut method for 0-1 integer programming [7,8] and 0-1 mixed-integer linear programming [1,2] has spurred great interest in its application for 0-1 mixed-integer nonlinear optimization due to the significant progress of interior point algorithm for convex optimization problems. Stubbs and Mehrotra [9] generalized the lift-and-project cut or the disjunctive cut for 0-1 integer or mixed-integer linear programming proposed in [1,2,7,8], and extended their method into a branch-and-cut algorithm for the 0-1 mixed-integer nonlinear optimization problem. The disjunctive cutting plane presented by Stubbs and Mehrotra [9] is obtained by solving a convex projection problem, so it is computationally expensive. In [11], a valid disjunctive cutting plane for mixed-integer nonlinear optimization problems was constructed by solving a linear programming problem implemented in an algorithmic package named MINO, i. e., Mixed-Integer Nonlinear Optimizer.

### Formulation

The general 0-1 mixed-integer nonlinear optimization problems can be formulated as

$$(P) \begin{cases} \min_{x,y} & dx \\ \text{s.t.} & Ax + Gy \leq b \\ & g_i(x, y) \leq 0, \quad i = 1, \dots, l \\ & x \in \mathfrak{R}^n, \quad y \in \{0, 1\}^q \end{cases}$$

where the constant vectors and matrices are defined as  $d \in \mathfrak{R}^n, A \in \mathfrak{R}^{m \times n}, G \in \mathfrak{R}^{m \times q}, b \in \mathfrak{R}^m$ . Let the feasible region of the standard continuous relaxation of problem (P) be defined as

$$C = \left\{ (x, y) \in \mathfrak{R}^{n+q} \mid \begin{cases} Ax + Gy \leq b, \\ g_i(x, y) \leq 0, \quad i = 1, \dots, l, \\ 0 \leq y \leq 1, \end{cases} \right\}$$

Hence, the feasible set of (P) can be formulated as

$$C^0 = \{(x, y) \in C : y_j \in \{0, 1\}, \quad j = 1, \dots, q\}.$$

At a generic step of the branch-and-cut algorithm, let  $(\bar{x}, \bar{y})$  be a solution to the current NLP relaxation of (P). If any of the components of the binary variables  $\bar{y}$  are not in  $\{0, 1\}$ , we can add a valid inequality into the current feasible set such that this inequality is violated by  $(\bar{x}, \bar{y})$ . We denote by  $c$  the family of inequalities to describe the current feasible set and the newly incorporated inequalities. We denote by  $F_0, F_1 \subseteq \{1, \dots, q\}$  the sets of binary variables that have been fixed at 0 and 1, respectively. Let

$$K(C, F_0, F_1) = \left\{ (x, y) \in C \mid \begin{array}{l} y_j = 0 \text{ for } j \in F_0 \\ y_j = 1 \text{ for } j \in F_1 \end{array} \right\}$$

And let  $NLP(C, F_0, F_1)$  denote the nonlinear program

$$\begin{array}{ll} \min_{x,y} & dx \\ \text{s.t.} & (x, y) \in K(C, F_0, F_1) \end{array}$$

The active nodes of the enumeration tree are represented by a list of  $S$  with ordered pairs  $(F_0, F_1)$ . Let  $UBD$  represent the current upper bound, i. e., the value of the best-known solution to problem (P).

**Branch-And-Cut Procedure**

Input of  $d, n, q, A, G, b, g_i$  ( $i = 1, \dots, l$ ):

- (1) Initialization. Set  $S = \{(F_0 = \phi, F_1 = \phi)\}$ , and let  $C$  consist of the nonlinear programming relaxation of (P) and  $UBD = \infty$ .
- (2) Node Selection. If  $S = \phi$ , stop. Otherwise, choose an ordered pair  $(F_0, F_1) \in S$  and remove it from  $S$ .
- (3) Lower Bounding Step. Solve the nonlinear program  $NLP(C, F_0, F_1)$ . If the problem is infeasible, go to Step 2. Otherwise, let  $(\bar{x}, \bar{y})$  denote its optimal solution. If  $d\bar{x} \geq UBD$ , go to Step 2. If  $\bar{y}_j \in \{0, 1\}, j = 1, \dots, q$ , let  $(x^*, y^*) = (\bar{x}, \bar{y}), UBD = d\bar{x}$ , and go to Step 2.
- (4) Branching versus cutting decision. Should cutting planes be generated? If yes, go to Step 5, else go to Step 6.
- (5) Cut generation. Generate cutting plane  $\alpha x + \beta y \leq \gamma$  valid for (P) but violated by  $(\bar{x}, \bar{y})$ . Add the cuts into  $C$  and go to Step 3.
- (6) Branching Step. Pick an index  $j \in \{1, \dots, q\}$  such that  $0 < \bar{y}_j < 1$ . Generate the subproblems corresponding to  $(F_0 \cup \{j\}, F_1)$  and  $(F_0, F_1 \cup \{j\})$ , add them into the node set  $S$ . Go to Step 2.

When the algorithm terminates, if  $UBD < \infty, (x^*, y^*)$  is an optimal solution to (P), otherwise (P) is infeasible.

**Linear Approximation of NLP Relaxation**

The continuous relaxation of problem (P) at some node in an enumeration tree can be described by

$$(NLP) \quad \begin{array}{l} \min_{x,y} dx \\ \text{s.t. } \tilde{A}x + \tilde{G}y \leq \tilde{b}, \\ g_i(x, y) \leq 0, \quad i = 1, \dots, l, \\ y_j = 0, \quad j \in F_0, \\ y_j = 1, \quad j \in F_1, \\ (x, y) \in \mathfrak{R}^{n+q}, \end{array}$$

where the reformulated linear constraint set consists of the original linear constraint set and the upper and lower bound constraints for binary variables, so we have  $\tilde{A} \in \mathfrak{R}^{(m+2q) \times n}, \tilde{G} \in \mathfrak{R}^{(m+2q) \times q}, \tilde{b} \in \mathfrak{R}^{m+2q}$ . Assume that the above NLP continuous problem is feasible and has a finite minimum at  $(\bar{x}, \bar{y})$ , since otherwise the node is done. A linear approximation problem at  $(\bar{x}, \bar{y})$  for the above NLP problem can be obtained by

$$(LP) \quad \begin{array}{l} \min_{x,y} dx \\ \text{s.t. } \tilde{A}x + \tilde{G}y \leq \tilde{b}, \\ g_i(\bar{x}, \bar{y}) + \nabla g_i(\bar{x}, \bar{y}) \begin{pmatrix} x - \bar{x} \\ y - \bar{y} \end{pmatrix} \leq 0, \\ i = 1, \dots, l, \\ y_j = 0, \quad j \in F_0, \\ y_j = 1, \quad j \in F_1, \\ (x, y) \in \mathfrak{R}^{n+q}, \end{array}$$

where the original convex and differentiable functions are replaced by their first-order Taylor approximation at  $(\bar{x}, \bar{y})$ . Accordingly, a MILP problem corresponding to the MINLP problem at the current node can be described by

$$(MILP) \quad \begin{array}{l} \min_{x,y} dx \\ \text{s.t. } \tilde{A}x + \tilde{G}y \leq \tilde{b}, \\ g_i(\bar{x}, \bar{y}) + \nabla g_i(\bar{x}, \bar{y}) \begin{pmatrix} x - \bar{x} \\ y - \bar{y} \end{pmatrix} \leq 0, \\ i = 1, \dots, l, \\ y_j = 0, \quad j \in F_0, \\ y_j = 1, \quad j \in F_1, \\ x \in \mathfrak{R}^n, y \in \{0, 1\}^q, \end{array}$$

[11] proved that if the above NLP achieves its optimal solution at  $(\bar{x}, \bar{y})$ . Then,  $(\bar{x}, \bar{y})$  is also an optimal solution to the aforementioned LP. The geometrical explanation of the above linear approximation is presented in Fig. 1, and it is obvious that the mixed-integer set is expanded after linear approximation.

**Disjunctive Cut Generation**

For problem (P), it is very attractive to construct the lift-and-project cut in terms of the approximated LP instead of the NLP, but the cut still can cut away the fraction point  $(\bar{x}, \bar{y})$ . Such cut can be derived by imposing the 0–1 integral condition on a binary variable  $y_j$  while  $0 < \bar{y}_j < 1$ . In Fig. 1, the short dashed line represents the cut generated directly by using the convex hull of the mixed-integer convex set presented by [9], and the long dashed line stands for the cut to be generated in [11] based on the linear approximation. For cut generation, the node sets  $F_0$  and  $F_1$  can be expanded to include additional binary variables whose optimal solutions are taken at 0 or 1 for the NLP problem at the current node. Then, we redefine these two sets as  $\bar{F}_0 = \{i : \bar{y}_i = 0\}$  and  $\bar{F}_1 = \{i : \bar{y}_i = 1\}$ . It is not difficult to verify that the above NLP and LP problems have the same optimal solutions if we change the original node sets to be the expanded ones. Let the feasible region of the above LP be defined as

$$K = K(C, \bar{F}_0, \bar{F}_1) = \left\{ (x, y) \in \mathfrak{R}^{n+q} \left| \begin{array}{l} \bar{A}x + \bar{G}y \leq \bar{b} \\ y_i = 0, i \in \bar{F}_0 \\ y_i = 1, i \in \bar{F}_1 \end{array} \right. \right\}$$

where  $\bar{A} \in \mathfrak{R}^{(m+2q+l) \times n}$ ,  $\bar{G} \in \mathfrak{R}^{(m+2q+l) \times q}$ ,  $\bar{b} \in \mathfrak{R}^{m+2q+l}$ , i. e., the newly reformulated linear constraint set consists of the linear approximation set besides the original one, as

$$\bar{A}x + \bar{G}y \leq \bar{b} \equiv \begin{cases} Ax + Gy \leq b, \\ \nabla g^x(\bar{x}, \bar{y})x + \nabla g^y(\bar{x}, \bar{y})y \\ \leq \nabla g(\bar{x}, \bar{y}) \begin{pmatrix} \bar{x} \\ \bar{y} \end{pmatrix} - g(\bar{x}, \bar{y}), \\ -y_i \leq 0 \quad i = 1, \dots, q, \\ y_i \leq 1 \quad i = 1, \dots, q, \end{cases}$$

It should be noted that the node sets have already been changed to the expanded ones in the above for-

mulation. If we impose the integrality condition on a binary variable  $y_j$  for which  $0 < \bar{y}_j < 1$ , the disjunctive cut can be obtained by choosing a valid inequality for

$$P_j(K) = \text{conv} \left( K \cap \left\{ (x, y) \in \mathfrak{R}^{n+q} : y_j \in \{0, 1\} \right\} \right),$$

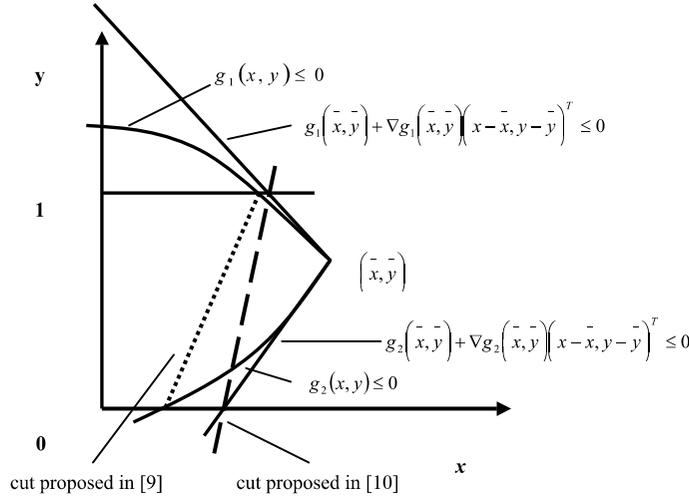

The convex hull of this union set can be further described by its disjunctive form as

$$P_j(K) = \text{conv} \left( \left\{ K \cap \left\{ (x, y) \in \mathfrak{R}^{n+q} : y_j \leq 0 \right\} \right\} \cup \left\{ K \cap \left\{ (x, y) \in \mathfrak{R}^{n+q} : -y_j \leq -1 \right\} \right\} \right),$$

Let  $F = \{1, \dots, q\} \setminus (\bar{F}_0 \cup \bar{F}_1)$  denote the set of free variables at node  $(\bar{F}_0, \bar{F}_1)$ , and the vector corresponding to those free variables can be defined as  $y^F = y \setminus \{y_i : i \in (\bar{F}_0 \cup \bar{F}_1)\}$ . The columns of matrix  $\bar{G}$  corresponding to the fixed binary variables can be removed from the constraint set by defining  $\bar{G}^F = \bar{G} \setminus \{\bar{G}_i : i \in (\bar{F}_0 \cup \bar{F}_1)\}$ , and the right-hand side can be calculated accordingly as  $\bar{b}^F = \bar{b} - \sum_{i \in \bar{F}_1} \bar{G}_i$ . Finally, the rows in matrices  $\bar{A}$  and  $\bar{G}^F$ , and vector  $\bar{b}^F$  that correspond to the upper and lower bounds of the fixed binary variables are removed. After doing the above operations, we can assume without loss of generality, that  $F_1 = \phi$ . Since if  $F_1 \neq \phi$ , all the variables  $y_k$  in  $F_1$  can be complemented by  $1-y_k$  which amounts replacing the columns  $G_k$  and the right-hand side with  $-G_k$  and  $b - G_k$ , respectively. The reduced LP constraint set after removing the fixed binary variables becomes

$$\bar{A}^F x + \bar{G}^F y^F \leq \bar{b}^F \equiv \begin{cases} Ax + \sum_{i \in F} G_j y_j \leq b \\ - \sum_{i \in F_1} G_j, \\ \nabla g^x(\bar{x}, \bar{y})x \\ + \sum_{i \in F} \nabla g_i^y(\bar{x}, \bar{y})y_j \\ \leq \nabla g(\bar{x}, \bar{y}) \begin{pmatrix} \bar{x} \\ \bar{y} \end{pmatrix} \\ -g(\bar{x}, \bar{y}) \\ - \sum_{i \in F_1} \nabla g_i^y(\bar{x}, \bar{y}), \\ -y_i \leq 0 \quad i \in F, \\ y_i \leq 1 \quad i \in F, \end{cases}$$

where  $\bar{A}^F \in \mathfrak{R}^{(m+2|F|+l) \times n}$ ,  $\bar{G}^F \in \mathfrak{R}^{(m+2|F|+l) \times |F|}$ ,  $\bar{b}^F \in \mathfrak{R}^{m+2|F|+l}$ . Then, the feasible region of the above

Mixed-Integer Nonlinear Optimization: A Disjunctive Cutting Plane Approach, Figure 1

Linear approximation of the mixed-integer nonlinear optimization problem, where the mixed-integer convex set is described by a continuous variable and a binary variable

LP can be reformulated as

$$K = \left\{ (x, y^F) \in \mathbb{R}^{n+|F|} \mid \overline{A}^F x + \overline{G}^F y^F \leq \overline{b}^F \right\}$$

Let  $(\bar{x}, \bar{y})$  be the optimal solution when solving  $NLP(C, \overline{F}_0, \overline{F}_1)$ . First, we assume that  $(\bar{x}, \bar{y})$  is not feasible to problem (P), and let  $j$  be the binary variable index such that  $0 < \bar{y}_j < 1$ . In [11], a disjunctive cut generation linear programming is given by

$$(LP(F)) \quad \left\{ \begin{array}{l} \min \sum_{i \in N} z_i + \sum_{i \in F} w_i \\ \text{s.t. } x = u_0 + u_1, \quad y^F = v_0 + v_1, \\ \overline{A}^F u_0 + \overline{G}^F v_0 - \overline{b}^F \lambda_0 \leq 0, \\ v_{0,j} \leq 0, \\ \overline{A}^F u_1 + \overline{G}^F v_1 - \overline{b}^F \lambda_1 \leq 0, \\ -v_{1,j} \leq -\lambda_1, \\ \lambda_0 + \lambda_1 = 1; \\ -z + x \leq \bar{x}, \quad -z - x \leq -\bar{x}, \\ -w + y^F \leq \bar{y}^F, \quad -w - y^F \leq -\bar{y}^F, \\ \lambda_0, \lambda_1 \geq 0, \quad x, u_0, u_1, z \in \mathbb{R}^n, \\ y^F, v_0, v_1, w \in \mathbb{R}^{|F|}. \end{array} \right.$$

This linear program has  $4n + 4|F| + 2$  variables with  $2m + 3n + 7|F| + 2l + 3$  equality or inequality constraints. After solving this linear program, we get its solutions denoted by  $(\tilde{x}, \tilde{y}^F, \tilde{u}_0, \tilde{v}_0, \tilde{u}_1, \tilde{v}_1, \tilde{z}, \tilde{w}, \tilde{\lambda}_0, \tilde{\lambda}_1)$  as well as the dual multipliers. Denote by  $\pi_x^F, \pi_y^F, \delta_\lambda^F$  the multipliers for the equality constraints,  $\delta_0^F, \delta_1^F$  for

the disjunctive inequality constraints,  $\mu_0^F, \mu_1^F$  for the inequality original constraints, and  $\varepsilon_+^F, \varepsilon_-^F, \varphi_+^F, \varphi_-^F$  for the additional constraints in LP(F), the cut generated in Theorem 2, i. e.  $\alpha x + \beta^F y^F \leq \gamma$ , can be reformulated by the dual multipliers and the primal solutions to LP(F), as  $\pi_x^F x + \pi_y^F y^F \leq \pi_x^F \tilde{x} + \pi_y^F \tilde{y}^F$ . Since the feasible set of problem (P) at the node  $(F_0, F_1)$  is contained in the feasible set of the MILP at that node. Therefore, the inequality  $\alpha x + \beta^F y^F \leq \gamma$  is valid and proper for problem (P) at the current node denoted by  $(F_0, F_1)$ , and its descendants where the variables in  $(F_0, F_1)$  remain fixed.

**Cut Lifting**

An important advantage of the cut generated by the lift-and-project technology is that the multipliers, i. e.,  $\mu_0^F, \delta_0^F, \mu_1^F, \delta_1^F$ , obtained along with the solution  $(\tilde{x}, \tilde{y}^F)$  by solving LP(F) can be used to calculate the closed form expressions of the coefficients  $\beta_i$  for the binary variables in the index set  $F_0 \cup F_1$ . First, we lift the inequality obtained at the current node into the complemented original space of the MILP problem, that is

$$\left\{ (x, y) \in \mathbb{R}^{n+q} : \begin{array}{l} \overline{A}x + \overline{G}^Q y \leq \overline{b}^Q, \\ y \in \{0, 1\}^q \end{array} \right\}$$

Let  $j \in \{1, \dots, q\}$  be an index such that  $0 < \bar{y}_j < 1$  and consider the inequality  $\alpha^q x + \beta^q y \leq \gamma^q$  generated over the complemented original space of the MILP

problem, this is to solve the linear program LP(Q), as

$$(LP(Q)) \quad \begin{cases} \min & \sum_{i \in N} z_i + \sum_{i \in Q} w_i \\ \text{s.t.} & x = u_0 + u_1, \quad y = v_0 + v_1, \\ & \bar{A}u_0 + \bar{G}^Q v_0 - \bar{b}^Q \lambda_0 \leq 0, \\ & v_{0,j} \leq 0, \\ & \bar{A}u_1 + \bar{G}^Q v_1 - \bar{b}^Q \lambda_1 \leq 0, \\ & -v_{1,j} \leq -\lambda_1, \\ & \lambda_0 + \lambda_1 = 1, \\ & -z + x \leq -\bar{x}, \quad -z - x \leq -\bar{x}, \\ & -w + y \leq \bar{y}, \quad -w - y \leq -\bar{y}, \\ & \lambda_0, \lambda_1 \geq 0, \\ & x, u_0, u_1, z \in \mathfrak{N}^n, y, v_0, v_1, w \in \mathfrak{N}^q. \end{cases}$$

Note that more variables and constraints are added into this linear program compared with LP(F). But, by using the solutions to LP(F) and its multipliers, we can obtain the optimal solution to the above LP(Q). Let  $(\hat{x}, \hat{y}, \hat{u}_0, \hat{v}_0, \hat{u}_1, \hat{v}_1, \hat{z}, \hat{w}, \hat{\lambda}_0, \hat{\lambda}_1)$  be the solution to the linear program LP(Q), which can be constructed by the solution to the LP(F), as  $\bar{x} = \hat{x}$ ,  $\hat{y} = (\hat{y}^F, 0)$ ,  $\hat{u}_0 = \hat{u}_0$ ,  $\hat{u}_1 = \hat{u}_1$ ,  $\hat{v}_0 = (\hat{v}_0, 0)$ ,  $\hat{v}_1 = (\hat{v}_1, 0)$ ,  $\hat{\lambda}_0 = \hat{\lambda}_0$ ,  $\hat{\lambda}_1 = \hat{\lambda}_1$ ,  $\hat{z} = \hat{z}$ , and  $\hat{w} = (\hat{w}, 0)$ . Then, the corresponding dual multipliers of LP(Q) denoted by  $(\hat{\pi}_x^Q, \hat{\pi}_y^Q, \hat{\mu}_0^Q, \hat{\delta}_0^Q, \hat{\mu}_1^Q, \hat{\delta}_1^Q, \hat{\delta}_\lambda^Q, \hat{\varepsilon}_+^Q, \hat{\varepsilon}_-^Q, \hat{\varphi}_+^Q, \hat{\varphi}_-^Q)$ , which is also the solution to the dual linear program DLP(Q), can be constructed by those to DLP(F), as  $\hat{\pi}^Q = \hat{\pi}^F$ ,  $\hat{\pi}_{y,i}^Q = \hat{\pi}_{y,i}^F$  for  $i \in F$ ,  $\hat{\pi}_{y,i}^Q = \min\{\hat{\mu}_0^F \bar{G}_i^Q, \hat{\mu}_1^F \bar{G}_i^Q\}$  for  $i \in F_0 \cup F_1$ ,  $\hat{\delta}_0^Q = \hat{\delta}_0^F$ ,  $\hat{\delta}_1^Q = \hat{\delta}_1^F$ ,  $\hat{\delta}_\lambda^Q = \hat{\delta}_\lambda^F$ ,  $\hat{\mu}_0^Q = (\hat{\mu}_0^F, 0)$ ,  $\hat{\mu}_1^Q = (\hat{\mu}_1^F, 0)$ ,  $\hat{\varepsilon}_+^Q = \hat{\varepsilon}_+^F$ ,  $\hat{\varepsilon}_-^Q = \hat{\varepsilon}_-^F$ ,  $\hat{\varphi}_+^Q = (\hat{\varphi}_+^F, 0)$ , and  $\hat{\varphi}_-^Q = (\hat{\varphi}_-^F, 0)$ . The inequality  $\alpha^q x + \beta^q y \leq \gamma^q$  described by  $\hat{\pi}_x^Q x + \hat{\pi}_y^Q y \leq \hat{\pi}_x^Q \hat{x} + \hat{\pi}_y^Q \hat{y}$  is valid for the entire enumeration tree, and cuts away  $(\bar{x}, \bar{y})$ .

## Conclusion

A branch-and-cut algorithm is introduced in this section to solve 0–1 mixed-integer nonlinear optimization problem where the disjunctive cuts are generated and incorporated into an enumeration process. The lift-and-project cut generation is performed via linear programming, as opposed to the convex nonlinear approach used in [9]. This new approach has the advantage of making the cut generation computationally cheaper and overcoming the nondifferential problems.

A wide range of nonlinear optimization problems involve integer or discrete variables in addition to the continuous variables. These classes of optimization problems arise from a variety of applications and are denoted as *mixed integer nonlinear programming* MINLP problems.

The integer variables can be used to model, for instance, sequences of events, alternative candidates, existence or non-existence of units (in their zero-one representation), while discrete variables can model, for instance, different equipment sizes. The continuous variables are used to model the input-output and interaction relationships among individual units/operations and different interconnected systems.

The nonlinear nature of these mixed integer optimization problems may arise from:

- i) nonlinear relations in the integer domain exclusively (e.g., products of binary variables in the quadratic assignment model);
- ii) nonlinear relations in the continuous domain only (e.g., complex nonlinear input-output model in a distillation column or reactor unit);
- iii) nonlinear relations in the joint integer-continuous domain (e.g., products of continuous and binary

variables in the scheduling/planning of batch processes and retrofit of heat recovery systems).

The book [88] studies mixed integer linear optimization and combinatorial optimization, while the [40] studies mixed integer nonlinear optimization problems.

The coupling of the integer domain and the continuous domain with their associated nonlinearities make the class of MINLP problems very challenging from the theoretical, algorithmic, and computational point of view. Mixed integer nonlinear optimization problems are encountered in a variety of applications in all branches of engineering and applied science, applied mathematics, and operations research. These represent very important and active research areas that include:

- *process synthesis*
  - heat exchanger networks
  - retrofit of heat recovery systems
  - distillation sequencing
  - mass exchange networks
  - reactor-based systems
  - reactor-separator-recycle systems
  - utility systems
  - total process systems
  - metabolic engineering
- *process design*
  - reactive distillation
  - design of dynamic systems
  - plant layout
  - environmental design
- process synthesis and *design under uncertainty*
  - uncertainty analysis
  - dynamic systems
  - batch plant design
- *molecular design*
  - solvent selection
  - design of polymers and refrigerants
  - property prediction under uncertainty
- *interaction of design, synthesis and control*
  - steady state operation
  - dynamic operation
- *process operations*
  - scheduling of multiproduct plants
  - design and retrofit of multiproduct plants
  - synthesis, design and scheduling of multipurpose plants

- planning under uncertainty
- *facility location and allocation*
- *facility planning and scheduling*
- *topology of transportation networks*

The applications in the area of *process synthesis* in chemical engineering include:

- i) the synthesis of grassroots heat recovery networks [24,25,43,138,139,140];
- ii) the retrofit of heat exchanger systems [25,95];
- iii) the synthesis of distillation-based separation systems [8,9,90,102,104,131];
- iv) the synthesis of mass exchange networks [54,99];
- v) the synthesis of complex reactor networks [71,73,74,119];
- vi) the synthesis of reactor-separator-recycle systems [72];
- vii) the synthesis of utility systems [65];
- viii) the synthesis of total process systems [28,29,68,69,75,76,98]; and
- ix) the analysis and synthesis of metabolic pathways [30,58,59,107].

Reviews of the mixed integer nonlinear optimization frameworks and applications in Process Synthesis are provided in [40,49,50], and [7], while algorithmic advances for logic and global optimization in Process Synthesis are reviewed in [44].

The MINLP applications in the area of *process design* include:

- i) reactive distillation processes [26];
- ii) design of dynamic systems [11,14,117,118];
- iii) plant layout systems [47,105]; and
- iv) environmentally benign systems [27,123].

The MINLP applications in the area of *process synthesis and design under uncertainty* include:

- i) deterministic and stochastic uncertainty analysis [1,33,51];
- ii) design of dynamic systems under uncertainty [31,85]; and
- iii) design of batch processes under uncertainty [57,63,108,109].

In the area of *molecular design*, the MINLP applications include:

- i) the computer-aided molecular design aspects of selecting the best solvents [91];
- ii) design of polymers and refrigerants [21,22,23,35,80,111,126]; and
- iii) property prediction under uncertainty [81].

The MINLP applications in the area of *interaction of design, synthesis and control* include:

- i) studies under steady state operation of chemical processes [78,79,96,97]; and
- ii) studies under dynamic operation [85,86,118].

Applications of MINLP approaches have also emerged in the area of *process operations* and include:

- i) short term scheduling of batch and semicontinuous processes [85,143];
- ii) the design of multiproduct plants [17,18,53];
- iii) the synthesis, design and scheduling of multipurpose plants [13,36,37,93,94,116,127,128,132,133,137]; and
- iv) planning under uncertainty [62,63,64,77,106].

Reviews of the advances in the design, scheduling and planning of batch plants can be found in [52,113], while a collection of recent contributions can be found in the proceedings of the 1998 FOCAPO meeting.

MINLP applications received significant attention in other engineering disciplines. These include

- i) the facility location in a multi-attribute space [45];
- ii) the optimal unit allocation in an electric power system [16];
- iii) the facility planning of an electric power generation [19,114];
- iv) the chip layout and compaction [32];
- v) the topology optimization of transportation networks [60]; and
- vi) the optimal scheduling of thermal generating units [48].

## Mathematical Description

The general algebraic MINLP formulation can be stated as:

$$\left\{ \begin{array}{ll} \min_{\mathbf{x}, \mathbf{y}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X} \subseteq \mathbb{R}^n \\ & \mathbf{y} \in \mathbf{Y} \text{ integer.} \end{array} \right. \quad (1)$$

Here  $\mathbf{x}$  represents a vector of  $n$  continuous variables (e.g., flows, pressures, compositions, temperatures, sizes of units), and  $\mathbf{y}$  is a vector of integer variables (e.g., alternative solvents or materials);  $\mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}$  denote the  $m$  equality constraints (e.g., mass, energy

balances, equilibrium relationships);  $\mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0}$  are the  $p$  inequality constraints (e. g., specifications on purity of distillation products, environmental regulations, feasibility constraints in heat recovery systems, logical constraints); and  $f(\mathbf{x}, \mathbf{y})$  is the objective function (e. g., annualized total cost, profit, thermodynamic criteria).

*Remark 1* The integer variables  $\mathbf{y}$  with given lower and upper bounds

$$\mathbf{y}^L \leq \mathbf{y} \leq \mathbf{y}^U$$

can be expressed through 0–1 variables (i. e., binary), denoted as  $\mathbf{z}$ , by the following formula:

$$y = y^L + z_1 + 2z_2 + 4z_3 + \dots + 2^{N-1}z_N,$$

where  $N$  is the minimum number of 0–1 variables needed. This minimum number is given by:

$$N = 1 + \text{INT} \left\{ \frac{\log(y^U - y^L)}{\log 2} \right\},$$

where the INT function truncates its real argument to an integer value.

Then, formulation (1) can be written in terms of 0–1 variables:

$$\begin{cases} \min_{\mathbf{x}, \mathbf{y}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X} \subseteq \mathbb{R}^n \\ & \mathbf{y} \in \{0, 1\}^q, \end{cases} \quad (2)$$

where  $\mathbf{y}$  now is a vector of  $q$  0–1 variables (e. g., existence of a process unit ( $y_i = 1$ ) or nonexistence ( $y_i = 0$ )).

### Challenges in MINLP

Dealing with *mixed integer nonlinear optimization* models of the form (1) or (2) present two major challenges. These difficulties are associated with the nature of the problem, namely, the combinatorial domain ( $\mathbf{y}$ -domain) and the continuous domain ( $\mathbf{x}$ -domain).

As the number of binary variables  $\mathbf{y}$  in (2) increase, one is faced with a large combinatorial problem, and the complexity analysis results characterize MINLP problems as NP-complete [88]. At the same time, due to the nonlinearities the MINLP problems

are in general nonconvex which implies the potential existence of multiple local solutions. The determination of a global solution of the *nonconvex MINLP* problems is also NP-hard, since even the global optimization of constrained nonlinear programming problems can be NP-hard [100], and even quadratic problems with one negative eigenvalue are NP-hard [101]. An excellent book on complexity issues for nonlinear optimization is [129].

Despite the aforementioned discouraging results from complexity analysis, which are worst-case results, significant progress has been achieved in the MINLP area from the theoretical, algorithmic, and computational perspective. As a result, several algorithms have been proposed for convex and nonconvex MINLP models, their convergence properties have been investigated, and a large number of applications now exist that cross the boundaries of several disciplines. In the sequel, we will discuss these developments.

### Overview of Local Optimization Approaches for Convex MINLP Models

A representative collection of *local MINLP* algorithms developed for solving *convex MINLP* models of the form (1) or restricted classes of (2) includes the following:

- 1) *generalized Benders decomposition*, GBD, [42,46,103];
- 2) *outer approximation*, OA, [34];
- 3) *outer approximation with equality relaxation*, OA/ER, [67];
- 4) *outer approximation with equality relaxation and augmented penalty*, OA/ER/AP, [131];
- 5) *generalized outer approximation*, GOA, [38];
- 6) *generalized cross decomposition*, GCD, [61];
- 7) *branch and bound*, BB, [15,20,39,55,92,110];
- 8) *feasibility approach*, FA, [82];
- 9) *extended cutting plane*, ECP, [134,135];
- 10) *logic-based approaches*, [124,130].

In the pioneering work [46] on the generalized benders decomposition, GBD, two sequences of updated upper(nonincreasing) and lower (nondecreasing) bounds are created that converge within  $\epsilon$  in a finite number of iterations. The upper bounds correspond to solving subproblems in the  $\mathbf{x}$  variables by fixing the  $\mathbf{y}$  variables, while the lower bounds are based on duality theory.

The outer approximation, OA, addresses problems with nonlinear inequalities, and creates sequences of upper and lower bounds as the GBD, but it has the distinct feature of using primal information, that is the solution of the upper bound problems, so as to linearize the objective and constraints around that point. The lower bounds in OA are based upon the accumulation of the linearized objective function and constraints, around the generated primal solution points.

The OA/ER algorithm extends the OA to handle nonlinear equality constraints by relaxing them into inequalities according to the sign of their associated multipliers.

The OA/ER/AP algorithm introduces an augmented penalty function in the lower bound subproblems of the OA/ER approach.

The generalized outer approximation, GOA, extends the OA to the MINLP problems that the GBD addresses and introduces exact penalty functions.

The generalized cross decomposition, GCD, simultaneously utilizes primal and dual information by exploiting the advantages of Dantzig–Wolfe and generalized Benders decomposition.

An overview of these local MINLP algorithms and extensive theoretical, algorithmic, and applications of GBD, OA, OA/ER, OA/ER/AP, GOA, and GCD algorithms can be found in [40].

The branch and bound, BB, approaches start by solving the continuous relaxation of the MINLP and subsequently perform an implicit enumeration where a subset of the 0–1 variables is fixed at each node. The lower bound corresponds to the NLP solution at each node and it is used to expand on the node with the lowest lower bound or it is used to eliminate nodes if the lower bound exceeds the current upper bound. If the continuous relaxation, NLP in most cases with the exception of the algorithm of [110] where an LP problem is obtained, of the MINLP has a 0–1 solution for the  $y$  variables, then the BB algorithm will terminate at that node. With a similar argument, if a tight NLP relaxation results in the first node of the tree, then the number of nodes that would need to be eliminated can be low. However, loose NLP relaxations may result in having a large number of NLP subproblems to be solved. The algorithm terminates when the lowest lower bound is within a prespecified tolerance of the best upper bound.

The feasibility approach, FA, rounds the relaxed NLP solution to an integer solution with the least local degradation by successively forcing the superbasic variables to become nonbasic based on the reduced cost information. The premise of this approach is that the problems to be treated are sufficiently large so that techniques requiring the solution of several NLP relaxations, such as the branch and bound approach, have prohibitively large costs. They therefore wish to account for the presence of the integer variables in the formulation and solve the mixed integer problem directly. This is achieved by fixing most of the integer variables to one of their bounds (the *nonbasic variables*) and allowing the remaining small subset (the *basic variables*) to take discrete values in order to identify feasible solutions. After each iteration, the reduced costs of the variables in the nonbasic set are computed to measure their effect on the objective function. If a change causes the objective function to decrease, the appropriate variables are removed from the nonbasic set and allowed to vary for the next iteration. When no more improvement in the objective function is possible, the algorithm is terminated. This strategy leads to the identification of a local solution.

The *cutting plane* algorithm proposed in [66] for NLP problems has been extended to MINLPs [134,135]. The ECP algorithm relies on the linearization of one of the nonlinear constraints at each iteration and the solution of the increasingly tight MILP made up of these linearizations. The solution of the MILP problem provides a new point on which to base the choice of the constraint to be linearized for the next iteration of the algorithm. The ECP does not require the solution of any NLP problems for the generation of an upper bound. As a result, a large number of linearizations are required for the approximation of highly nonlinear problems and the algorithm does not perform well in such cases. Due to the use of linearizations, convergence to the global optimum solution is guaranteed only for problems involving inequality constraints which are convex in the  $x$  and relaxed  $y$ -space.

An alternative to the direct solution of the MINLP problem was proposed by [124]. Their approach stems from the work of [70] on a modeling/decomposition strategy which avoids the zero-flows generated by the nonexistence of a unit in a process network. The first stage of the algorithm is the reformulation of the

MINLP into a generalized disjunctive program. A vector of Boolean variables indicate the status of a disjunction (True or False) and are associated with the alternatives. The set of disjunctions allows the representation of several alternatives. A set of logical relationships between the Boolean variables is introduced. Instead of resorting to binary variables within a single model, the disjunctions are used to generate a different model for each alternative. Since all continuous variables associated with the nonexisting alternatives are set to zero, this representation helps to reduce the size of the problems to be solved. Two algorithms are suggested by [124]. They are logic-based variants of the outer approximation and generalized Benders decomposition. [130] introduced LOGMIP, a computer code for disjunctive programming and MINLP problems, and studied modeling alternatives and process synthesis applications.

### Overview of Global Optimization Approaches for Nonconvex MINLP Models

In the previous Section we discussed local MINLP algorithms which are applicable to convex MINLP models. While identification of the global solution for convex problems can be guaranteed, a local solution is often obtained for nonconvex problems. The recent book by [41] discusses the theoretical, algorithmic and applications oriented advances in the global optimization of mixed integer nonlinear models. A number of *global MINLP* algorithms that have been developed to address different types of nonconvex MINLPs are presented in this section. These include:

- 1) *Branch and reduce* approach, [115];
- 2) *interval analysis* based approach, [125];
- 3) *extended cutting plane* approach, [135,136];
- 4) *reformulation/spatial branch and bound* approach, [121,122];
- 5) *hybrid branch and bound and outer approximation* approach, [141,142];
- 6) The *SMIN- $\alpha$ BB* approach, [2,4];
- 7) The *GMIN- $\alpha$ BB* approach, [2,4].

In the sequel, we will briefly discuss the approaches 1)–7).

### Branch and Reduce Algorithm

[115] extended the scope of branch and bound algorithms to problems for which valid convex underesti-

mating NLPs can be constructed for the nonconvex relaxations. The range of application of the proposed algorithm encompasses bilinear problems and separable problems involving functions for which convex underestimators can be built [10,83]. Because the nonconvex NLPs must be underestimated at each node, convergence can only be achieved if the continuous variables are branched on. A number of tests are suggested to accelerate the reduction of the solution space. They are summarized in the following.

### Optimality Based Range Reduction Tests

For the first set of tests, an upper bound  $U$  on the nonconvex MINLP must be computed and a convex lower bounding NLP must be solved to obtain a lower bound  $L$ . If a bound constraint for variable  $x_i$ , with  $x_i^L \leq x_i \leq x_i^U$ , is active at the solution of the convex NLP and has multiplier  $\lambda_i^* > 0$ , the bounds on  $x_i$  can be updated as follows:

- 1) If  $x_i - x_i^U = 0$  at the solution of the convex NLP and  $\kappa_i = x_i^U - (U - L)/\lambda_i^*$  is such that  $\kappa_i > x_i^L$ , then  $x_i^L = \kappa_i$ .
- 2) If  $x_i - x_i^L = 0$  at the solution of the convex NLP and  $\kappa_i = x_i^L + (U - L)/\lambda_i^*$  is such that  $\kappa_i < x_i^U$ , then  $x_i^U = \kappa_i$ .

If neither bound constraint is active at the solution of the convex NLP for some variable  $x_j$ , the problem can be solved by setting  $x_j = x_j^U$  or  $x_j = x_j^L$ . Tests similar to those presented above are then used to update the bounds on  $x_j$ .

### Feasibility Based Range Reduction Tests

In addition to ensuring that tight bounds are available for the variables, the underestimators of the constraints are used to generate new constraints for the problem. Consider the constraint  $g_i(\mathbf{x}, \mathbf{y}) \leq 0$ . If its underestimating function  $\underline{g}_i(\mathbf{x}, \mathbf{y}) = 0$  at the solution of the convex NLP and its multiplier is  $\mu_i^* > 0$ , the constraint

$$\underline{g}_i(\mathbf{x}, \mathbf{y}) \geq -\frac{U - L}{\mu_i^*}$$

can be included in subsequent problems.

The branch and reduce algorithm has been tested on a set of small problems.

### Interval Analysis Based Approach

An approach based on interval analysis was proposed by [125] to solve to global optimality problems with a twice-differentiable objective function and once-differentiable constraints. Interval arithmetic allows the computation of guaranteed ranges for these functions [87,89,112]. The approach relies on the same concepts of successive partitioning of the domain and bounding of the objective function, while the branching takes place on the discrete and continuous variables. The main difference with the branch and bound algorithms is that bounds on the problem solution in a given domain are not obtained through optimization. Instead, they are based on the range of the objective function in the domain under consideration, as computed with interval arithmetic. As a consequence, these bounds may be quite loose and efficient fathoming techniques are required in order to enhance convergence. [125] suggested node fathoming tests and branching strategies which are outlined in the sequel. Convergence is declared when best upper and lower bounds are within a prespecified tolerance and when the width of the corresponding region is below a prespecified tolerance.

### Node Fathoming Tests

The *upper-bound test* is a classical criterion used in all branch and bound schemes: If the lower bound for a node is greater than the best upper bound for the MINLP, the node can be fathomed.

The *infeasibility test* is also used by all branch and bound algorithms. However, the identification of infeasibility using interval arithmetic differs from its identification using optimization schemes. An inequality constraint  $g_i(\mathbf{x}, \mathbf{y}) \leq 0$  is declared infeasible if its interval inclusion over the current domain, is positive. If a constraint is found to be infeasible, the current node is fathomed.

The *monotonicity test* is used in interval-based approaches. If a region is feasible, the monotonicity properties of the objective function can be tested. For this purpose, the inclusions of the gradients of the objective with respect to each variable are evaluated. If all the gradients have a constant sign for the current region, the objective function is monotonic and only one point needs to be retained from the current node.

The *nonconvexity test* is used to test the existence of a solution (local or global) within a region. If such a point exists, the Hessian matrix of the objective function at this point must be positive semidefinite. A sufficient condition is the nonnegativity of at least one of the diagonal elements of its interval Hessian matrix.

[125] suggested two additional tests to accelerate the fathoming process. The first is denoted as *lower bound test*. It requires the computation of a valid lower bound on the objective function through a method other than interval arithmetic. If the upper bound at a node is less than this lower bound, the region can be eliminated. The second test, the *distrust region method*, aims to help the algorithm identify infeasible regions so that they can be removed from consideration. Based on the knowledge of an infeasible point, interval arithmetic is used to identify an infeasible hypercube centered on that point.

### Branching Strategies

The variable with the widest range is selected for branching. It can be a continuous or a discrete variable. In order to determine where to split the chosen variable, a relaxation of the MINLP is solved locally.

- **Continuous Branching Variable:** If the optimal value of the continuous branching variable,  $x^*$ , is equal to one of the variable bounds, branch at the midpoint of the interval. Otherwise, branch at  $x^* - \beta$ , where  $\beta$  is a very small scalar.
- **Discrete Branching Variable:** If the optimal value of the discrete branching variable,  $y^*$ , is equal to the upper bound on the variable, define a region with  $y = y^*$  and one with  $y^L \leq y \leq y^* - 1$ , where  $y^L$  is the lower bound on  $y$ . Otherwise, create two regions  $y^L \leq y \leq \text{int}(y^*)$  and  $\text{int}(y^*) + 1 \leq y \leq y^U$ , where  $y^U$  is the upper bound on  $y$ .

This algorithm has been tested on a small example problem and a molecular design problem [125].

### Extended Cutting Plane for Pseudoconvex MINLPs

The use of the ECP algorithm for nonconvex MINLP problems was suggested in [135], using a modified algorithmic procedure as described in [136]. The main changes occur in the generation of new constraints for the MILP at each iteration (Step 4). In addition to the

construction of the linear function  $l_k(\mathbf{x}, \mathbf{y})$  at iteration  $k$ , the following steps are taken:

- 1) Remove all constraints for which  $l_i(\mathbf{x}^k, \mathbf{y}^k) > g_{ji}(\mathbf{x}^k, \mathbf{y}^k)$ . These correspond to linearizations which did not underestimate the corresponding nonlinear constraint at all points due to the presence of non-convexities.
- 2) Replace all constraints for which  $l_i(\mathbf{x}^k, \mathbf{y}^k) = g_{ji}(\mathbf{x}^k, \mathbf{y}^k) = 0$  by their linearization around  $(\mathbf{x}^k, \mathbf{y}^k)$ .
- 3) If constraint  $i$  is such that  $g_i(\mathbf{x}^k, \mathbf{y}^k) > 0$ , add its linearization around  $(\mathbf{x}^k, \mathbf{y}^k)$ .

The convergence criterion is also modified. In addition to the test used in Step 3, the following two conditions must be met:

- 1)  $(\mathbf{x}^k - \mathbf{x}^{k-1})^\top (\mathbf{x}^k - \mathbf{x}^{k-1}) \leq \delta$ , a pre-specified tolerance.
- 2)  $\mathbf{y}^k - \mathbf{y}^{k-1} = 0$ .

The ECP algorithm for pseudoconvex MINLPs has been used to address a trim loss problem arising in the paper industry [136]. A comparative study between the outer approximation, the generalized Benders decomposition and the extended cutting plane algorithm for convex MINLPs was presented in [120].

### Reformulation/Spatial Branch and Bound Algorithm

A global optimization algorithm of the branch and bound type was proposed in [121]. It can be applied to problems in which the objective and constraints are functions involving any combination of binary arithmetic operations (addition, subtraction, multiplication and division) and functions that are either concave over the entire solution space (such as  $\ln$ ) or convex over this domain (such as  $\exp$ ).

The algorithm starts with an automatic reformulation of the original nonlinear problem into a problem that involves only linear, bilinear, linear fractional, simple exponentiation, univariate concave and univariate convex terms. This is achieved through the introduction of new constraints and variables. The reformulated problem is then solved to global optimality using a branch and bound approach. Its special structure allows the construction of a convex relaxation at each node of the tree. It should be noted that due to the introduction of many new constraints and variables the size of the convex relaxation of the reformulated

problem increases substantially even for modest size problems. The integer variables can be handled in two ways during the generation of the convex lower bounding problem. The integrality condition on the variables can be relaxed to yield a convex NLP which can then be solved globally. Alternatively, the integer variables can be treated directly and the convex lower bounding MINLP can be solved using a branch and bound algorithm. This second approach is more computationally intensive but is likely to result in tighter lower bounds on the global optimum solution.

In order to obtain an upper bound on the optimum solution, a local MINLP algorithm can be used. Alternatively, the MINLP can be transformed to an equivalent nonconvex NLP by relaxing the integer variables. For example, a variable  $y \in \{0, 1\}$  can be replaced by a continuous variable  $z \in [0, 1]$  by including the constraint  $z - z \cdot z = 0$ .

This algorithm has been applied to reactor selection, distillation column design, nuclear waste blending, heat exchanger network design and multilevel pump configuration problems.

### Hybrid Branch and Bound and Outer Approximation

[142] proposed a global optimization MINLP approach for the synthesis of heat exchanger networks without stream splitting. This approach is a hybrid branch and bound with outer approximation. It is based on two alternative convex underestimators for the heat transfer area. The first type of these convex underestimators along with the variable bounds and techniques for the bound contraction are based on a thermodynamic analysis. The second type is based on a relaxation and transformation so as to employ specific underestimation schemes. These convex underestimators result in a convex MINLP that is solved using the Outer Approximation approach and which provides valid lower bounds on the global solution. This approach has been applied to five heat exchanger network examples that employ the MINLP model of [138] that contains linear constraints and nonconvex objective function.

[141] introduced a deterministic branch and contract approach for structured process systems that have univariate concave, bilinear and linear fractional terms.

They proposed properties of the contraction operation and studied their effect on several applications.

### The SMIN- $\alpha$ BB Algorithm

The SMIN- $\alpha$ BB global optimization algorithm, proposed by [2] is designed to solve to global optimality mathematical models where the binary/integer variables appear linearly and hence separably from the continuous variables and/or appear in at most bilinear terms, while nonlinear terms in the continuous variables appear separably from the binary/integer variables. These mathematical models become:

$$\left\{ \begin{array}{l} \min_{\mathbf{x}, \mathbf{y}} \quad f(\mathbf{x}) + \mathbf{x}^\top A_0 \mathbf{y} + \mathbf{c}_0^\top \mathbf{y} \\ \text{s.t.} \quad \mathbf{h}(\mathbf{x}) + \mathbf{x}^\top A_1 \mathbf{y} + \mathbf{c}_1^\top \mathbf{y} = \mathbf{0} \\ \quad \quad \mathbf{g}(\mathbf{x}) + \mathbf{x}^\top A_2 \mathbf{y} + \mathbf{c}_2^\top \mathbf{y} \leq \mathbf{0} \\ \quad \quad \mathbf{x} \in \mathbf{X} \subseteq \mathbb{R}^n \\ \quad \quad \mathbf{y} \in \mathbf{Y} \quad \text{integer,} \end{array} \right. \quad (3)$$

where  $\mathbf{c}_0^\top$ ,  $\mathbf{c}_1^\top$  and  $\mathbf{c}_2^\top$  are constant vectors,  $A_0$ ,  $A_1$  and  $A_2$  are constant matrices and  $f(\mathbf{x})$ ,  $\mathbf{h}(\mathbf{x})$  and  $\mathbf{g}(\mathbf{x})$  are functions with continuous second order derivatives.

The theoretical, algorithmic and computational studies of the SMIN- $\alpha$ BB algorithm are presented in detail in [41].

### The GMIN- $\alpha$ BB Algorithm

The GMIN- $\alpha$ BB global optimization algorithm proposed in [2] operates within a branch and bound framework. The main difference with the algorithms of [56,92] and [20] is its ability to identify the global optimum solution of a much larger class of problems of the form

$$\left\{ \begin{array}{l} \min_{\mathbf{x}, \mathbf{y}} \quad f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} \quad \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \quad \quad \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \quad \quad \mathbf{x} \in \mathbf{X} \subseteq \mathbb{R}^n \\ \quad \quad \mathbf{y} \in \mathbb{N}^q, \end{array} \right.$$

where  $\mathbb{N}$  is the set of nonnegative integers and the only condition imposed on the functions  $f(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$  and  $\mathbf{h}(\mathbf{x}, \mathbf{y})$  is that their continuous relaxations possess con-

tinuous second order derivatives. This increased applicability results from the use of the  $\alpha$ BB global optimization algorithm for continuous twice-differentiable NLPs [3,5,6,12].

The theoretical, algorithmic and computational studies of the GMIN- $\alpha$ BB Algorithm are presented in detail in [41].

### Abstract

This Chapter presents a novel, mixed integer nonlinear programming (MINLP) model for the well scheduling problem, where the nonlinear behavior of the reservoir, wells, pipelines and surface facilities has been incorporated into the mathematical formulation. The well scheduling problem is formulated as a snapshot optimization problem with an objective function that expresses the maximization of an economic index. Discrete decisions here include the operational status of the wells, the allocation of wells to manifold or separators and the allocation of surface flowlines to separators. Continuous decisions include the well oil flowrates, and the allocation of gas-to-gas lift wells.

A three-step solution strategy is proposed for the solution of this problem, where logic based relations and piecewise linear approximations of oil field wells are integrated in the MINLP formulation. The model is solved following an Outer Approximation (OA) class algorithm. A number of examples are presented to illustrate the performance and business value of the proposed strategy; a remarkable increase in oil production of up to 10% is demonstrated, compared to results obtained via widespread heuristic methods. A further increase of 2.9% can be achieved by dynamic optimization based on explicit consideration of the multiphase flow within the reservoirs of a particular oil field.

### Introduction

In an era of globalized business operations, large and small oil and gas producers alike strive to foster profitability by improving the agility of exploration endeavors and the efficiency of oil production, storage and transport operations [7]. Consequently, they all face acute challenges: ever-increasing international production, intensified global competition, price volatility, operational cost reduction policies, aggressive financial goals (market share, revenue, cash flow and profitability) and strict environmental constraints (offshore extraction, low sulphur): all these necessitate a high level of oilfield modeling accuracy, so as to maximize recovery from certified reserves. Straightforward translation

of all considerations to explicit mathematical objectives and constraints can yield optimal oilfield network design, planning and operation policies. Therefore, the foregoing goals and constraints should be explicitly incorporated and easily revised if the generality of production optimization algorithms is to be preserved. This Chapter provides a summary of a new, efficient MINLP optimization formulation for well scheduling, and a novel strategy towards integration of equation-oriented process modeling and multiphase reservoir computational fluid dynamics (CFD), in order to include the dynamic behavior of reservoirs into oil and gas production models.

The problem of fuel production optimization subject to explicit oilfield constraints has attracted significant attention, documented in many petroleum engineering publications. A comprehensive literature review by Kosmidis [18] classifies previous algorithms in 3 broad categories (simulation, heuristic, and mathematical programming methods) and underlines that most are applied either to simple pipeline networks of modest size, relying on heuristic rules of limited applicability, or are suitable for special structures. Reducing the computational burden (focus on natural-flow wells or gas-lift wells only, or reducing well network connectivity discrete variables) is a crucial underlying pattern.

Dynamic oil and gas production systems simulation and optimization is a research trend which has the clear potential to meet the foregoing challenges of the international oil and gas industry and assist producers in achieving business goals and energy needs. Previous work [8,19,20,23] has addressed successfully research challenges in this field, using appropriate simplifying correlations [25] for two-phase flow of oil and gas in production wells and pipelines. A series of assumptions are routinely adopted to achieve manageable computational complexity: the fundamental one is the steady-state assumption for the reservoir model, based on the enormous timescale difference between different spatial levels (oil and gas reservoir dynamics evolve in the order of weeks, the respective timescales of pipeline networks are in the order of minutes, and the production optimization horizon is in the order of days). The decoupling of reservoir simulation from surface facilities optimization is based on these timescale differences among production elements [2,25]. While the surface and pipeline facilities are in principle no different from

those found in any petrochemical plant, sub-surface elements (reservoirs, wells) induce complexity which must be addressed via a systematic strategy that has not been hitherto proposed.

In some petroleum fields, such as the Prudhoe Bay [22], a production well can be connected to different manifolds that lead to different separators. In such fields, switching a well from one manifold to another could be an effective way to increase oil production and/or reduce production cost by making optimal use of the existing resources such as the capacity of separators [9]. However, for best results, the well connection must be optimized simultaneously with the well oil rate and gas lift rate. The corresponding optimization problem is known as well scheduling problem.

### Problem Statement

The well scheduling problem in integrated oil and gas production can be stated as follows: given are (i) a *set of wells*, which could be closed (shut in) or connected to manifolds or separators, (ii) a *set of flowlines* which could be connected to separators. The goal is to determine: (i) the *operational status of the wells*, i. e. closed or open, (ii) the *connection of wells* to manifolds or separators, (iii) the *connection of flow lines* to separators, (iv) the *well oil flowrate* and the (v) the *allocation of gas* to gas lift wells, which maximize the net revenue (oil sales minus the cost of gas compression), while satisfying physical laws and operational constraints such as: (i) a *well bore model*, (ii) *mass, energy and momentum balances* throughout the production network, (iii) *upper and lower well oil rate constraints* and minimum pressure constraints at the inlet and outlet of the flowlines, (iv) *maximum oil, gas and water capacity constraints* in the separators, (v) an *upper bound on gas lift availability* and (vi) a *maximum number of well switches*. The first step in order to determine the optimal well configuration that maximizes the revenue is to develop a suitable superstructure that includes all the possible pipeline network configurations. Such a production network superstructure is shown in Fig. 1 and includes the *reservoir (R)*, the *wells (W)*, the *manifolds (M)*, and the *separators (S)* nodes as well as the potential connection of wells to manifolds or separators and flowlines to separators. Two types of wells are considered: (i) *type A wells* that can be connected only

to manifolds, and (ii) *type B wells* that can be connected to separators. It must be noted that a feasible production network should satisfy the following requirements: (i) a *type A well* should be either shut in or else connected to one manifold, (ii) a *type B well* should be either shut in or else connected to one separator, and (iii) a manifold flowline must be connected to one separator.

### Optimization Model

This section presents the MINLP optimization model for the well scheduling problem, based on the following assumptions:

- the system is under steady state conditions,
- a homogeneous slip model which is applied to determine the pressure drop in the pipelines,
- the temperature of the reservoir is known,
- the operating pressures of the separators are constant, and
- the thermodynamic description of the fluid is based on the *black oil model*.

For the development of the MINLP optimization model, the following sets, variables and parameters are defined:

#### Sets

- $I$  set of wells
- $I_A$  set of wells of type A
- $I_B$  set of wells of type B
- $M$  set of manifolds
- $S$  set of separators

#### Indices

- $i, i_A, i_B$  well in set  $I, I_A, I_B$  respectively
- $m$  manifold in set  $M$
- $s$  separator in set  $S$

#### Binary decision variables

$$y_i = \begin{cases} 1 & \text{if well } i \text{ is open} \\ 0 & \text{otherwise} \end{cases}$$

$$y_{i,m} = \begin{cases} 1 & \text{if well } i \text{ is connected to manifold } m \\ 0 & \text{otherwise} \end{cases}$$

$$y_{m,s} = \begin{cases} 1 & \text{if manifold } m \text{ is connected to} \\ & \text{separator } s \\ 0 & \text{otherwise} \end{cases}$$

$$y_{i,s} = \begin{cases} 1 & \text{if well } i \text{ is connected to separator } s \\ 0 & \text{otherwise} \end{cases}$$

#### Continuous variables

- $q_{p,i}$  flowrate in stock tank conditions of phase  $p$  from well  $i$
- $q_{p,i,m}$  flowrate in stock tank condition of phase  $p$  from well  $i$  to manifold  $m$
- $q_{p,m,s}$  flowrate in stock tank condition of phase  $p$  from manifold  $m$  to separator  $s$
- $q_{p,s}$  flowrate in stock tank condition of phase  $p$  in separator  $s$
- $P_{i,m}$  pressure of well  $i$  at the manifold level
- $P_m$  manifold pressure
- $H_{i,m}$  total enthalpy of well  $i$  at the manifold level
- $H_m$  manifold enthalpy

The proposed model includes the following elements: (i) the well bore model, (ii) the mass, momentum and energy balances in well, manifold and separator nodes, (iii) the network logic constraints, (iv) the well and flowline momentum and energy balances, (v) the maximum number of allowable well switches, and (vi) the objective function.

#### Wellbore Model

The wellbore model describes the multiphase fluid flow from the reservoir to the wellbore and comprises the following equations:

$$q_{o,i} = PI_i(P_{R,i} - P_i^{\text{wf}}), \quad \forall i \in I \quad (1)$$

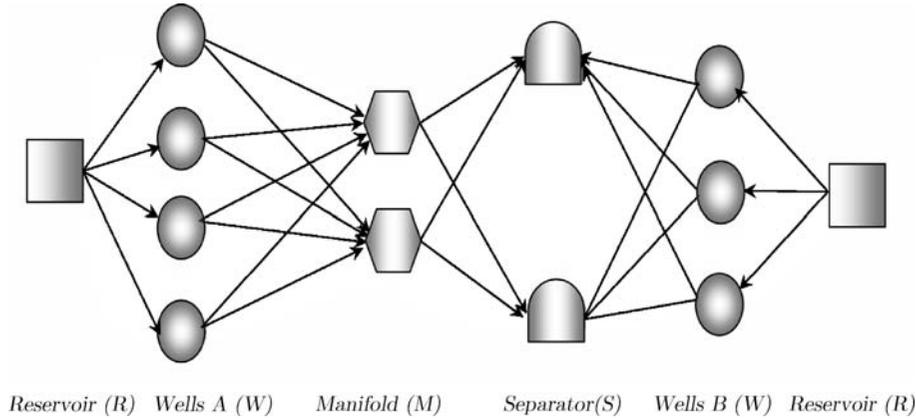

$$q_{g,i}^f = f_o(q_{o,i}), \quad \forall i \in I \quad (2)$$

$$q_{w,i} = f_w(q_{o,i}), \quad \forall i \in I \quad (3)$$

$$T_i = T_R, \quad \forall i \in I \quad (4)$$

$$H_i = f_H(P_i^{\text{wf}}, T_i, q_{o,i}, q_{w,i}, q_{g,i}^f), \quad \forall i \in I \quad (5)$$

where  $P_i^{\text{wf}}$  is the bottomhole pressure and  $q_{g,i}^f$  is the formation gas flowrate in stock tank conditions. Equations (2) and (3) can be nonlinear in order to model the case of gas and water coning wells. These nonlinear relations are generated either by using Addington's correlations [1] or by repetitively solving a well coning model for different values of well oil rate  $q_{o,i}$ , in order to calculate the corresponding water  $q_{w,i}$  and gas

Mixed Integer Optimization in Well Scheduling, Figure 1  
Production network superstructure for the well scheduling problem

flowrates  $q_{g,i}^f$ . In the latter case, Eq. (2) and (3) are constructed via curve fitting to the data series  $(q_{o,i}, q_{o,i})$  and  $(q_{o,i}, q_{g,i}^f)$  respectively. For naturally flowing wells, the total gas flowrate is given by:

$$q_{g,i} = q_{g,i}^f, \forall i \in D = \{i \in I \mid \text{natural flow}\} \quad (6)$$

while for gas lift wells the total gas flowrate is equal to:

$$q_{g,i} = q_{g,i}^f + q_{g,i}^{\text{inj}}, \forall i \in F = \{i \in I \mid \text{gas lift}\}. \quad (7)$$

**Mass, Momentum and Energy Balances in Well, Manifold and Separator Nodes**

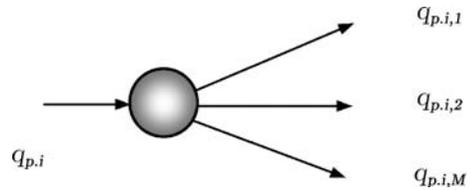

A well node of type A can be modeled as a splitter  $i \in I_A$ , which consists of an inlet stream that represents the fluid flow from the reservoir, and a set of outlet streams that represents the potential connections of a well to manifolds as shown in Fig. 2. The mass balances around the splitter for each phase are given by the following relations:

$$q_{p,i} = \sum_m q_{p,i,m}, \forall p \in \{o, w, g\}, i \in I_A. \quad (8)$$

Similarly, the mass balances around a well node of type B are given by:

$$q_{p,i} = \sum_s q_{p,i,s}, \forall p \in \{o, w, g\}, i \in I_B. \quad (9)$$

There is also an upper and a lower bound in the well oil flowrates. The upper bound is enforced to prevent

Mixed Integer Optimization in Well Scheduling, Figure 2  
Splitter node

sand production [4], while the lower bound is imposed to satisfy stable flow [27]:

$$y_i q_{o,i}^L \leq q_{o,i} \leq q_{o,i}^U y_i, \forall i \in I. \quad (10)$$

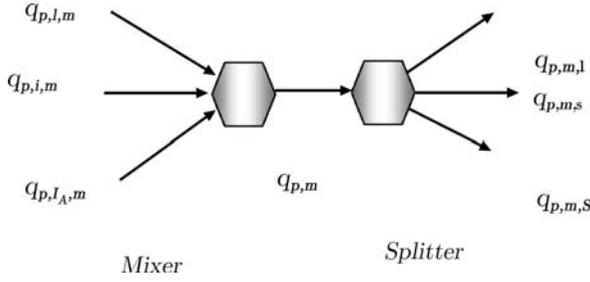

Equation (10) states that if well  $i$  is open ( $y_i = 1$ ), then the well oil flowrate  $q_{o,i}$  is constraint by an upper and a lower bound, while if well  $i$  is shut in ( $y_i = 0$ ), then the well oil flowrate  $q_{o,i}$  is zero.

**Manifold Node** A manifold node is shown in Fig. 3 and performs two tasks: (i) mixing and (ii) splitting. The mass balance of the mixer for each phase is given by:

$$\sum_{i \in I_A} q_{p,i,m} = q_{p,m}, \forall p \in \{o, w, g\}, m \in M. \quad (11)$$

The splitter allocates the manifold fluid  $q_{p,m}$  to one separator  $s$ . The mass balances for each phase around the splitter are given by:

$$q_{p,m} = \sum_s q_{p,m,s}, \forall p, m \in M. \quad (12)$$

Mixed Integer Optimization in Well Scheduling, Figure 3  
Manifold node

All wells that are connected to manifold  $m$  must operate at the same pressure ( $P_m$ ):

$$L^P(1 - y_{i,m}) \leq P_i^m - P_m \leq U^P(1 - y_{i,m}), \quad (13)$$

$$\forall i \in I_A, m \in M$$

where  $P_{i,m}$  is the pressure of well  $i$  at manifold level  $m$ , and  $L^P$ ,  $U^P$  are the corresponding upper and lower bounds, respectively. Moreover, if manifold  $m$  is connected to separator  $s$ , then its inlet pressure must be greater than the separator pressure:

$$P_s y_{m,s} \leq P_m, \quad \forall m \in M, s \in S. \quad (14)$$

The pressure of the flowline at the separator level  $P_{m,s}$  is equal to the separator pressure:

$$P_{m,s} = \sum_s y_{m,s} P_s. \quad (15)$$

The energy balance in the manifold is given by:

$$\sum_{i \in I_A} H_i^m = H_m, \quad \forall m \in M \quad (16)$$

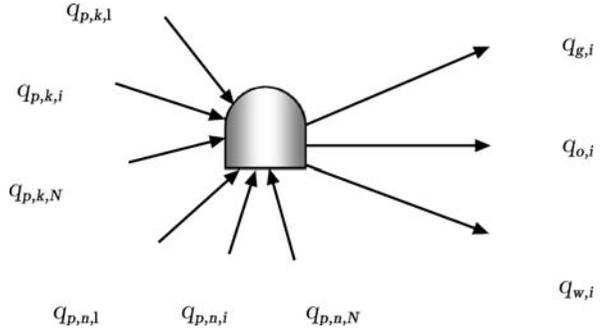

where  $H_i^m$  is the enthalpy of well  $i$  at manifold level  $m$ .

**Separator Node** Each separator  $s$  has a set of inlet streams coming from the flowlines and type B wells, as shown in Fig. 4. The mass balances for each phase are given by the following relation:

$$\sum_m q_{p,m,s} + \sum_{i \in I_B} q_{p,i,s} = q_{p,s}, \quad \forall p, s \in S \quad (17)$$

while the separator capacity constraints must also be satisfied:

$$q_{p,s} \leq C_{p,s}, \quad \forall p, s \in S. \quad (18)$$

Mixed Integer Optimization in Well Scheduling, Figure 4  
Separation node

Finally, the total amount of gas available for gas lift is restricted by the compressor capacity ( $C_C$ ):

$$\sum_i q_{g,i}^{\text{inj}} \leq C_c. \quad (19)$$

### Network Logic Constraints

A well of type A could either be shut in, or else connected to one manifold:

$$\sum_m y_{i,m} = y_i, \quad \forall i \in I_A \quad (20)$$

$$y_{i,m} \leq y_i, \quad \forall i \in I_A, m \in M. \quad (21)$$

The integer Eq. (20) states that if the well is open ( $y_i = 1$ ) then it should be connected to one manifold, while Eq. (21) states that if the well is shut in ( $y_i = 0$ ) then all binary variables  $y_{i,m}$  which represent the connection of well  $i$  to manifold  $m$  are zero.

Similarly, a well of type B could either be shut in, or else connected to one separator:

$$\sum_s y_{s,i} = y_i, \quad \forall i \in I_B \quad (22)$$

$$y_{s,i} \leq y_i, \quad \forall i \in I_B, s \in S. \quad (23)$$

Furthermore, it is also necessary to enforce the condition that each manifold flowline is connected to one separator:

$$\sum_s y_{m,s} = 1, \quad \forall m \in M. \quad (24)$$

Moreover, if the connection of well  $i$  to manifold  $m$  or separator  $s$  does not exist, then its corresponding flowrates and enthalpies must be zero:

$$0 \leq H_i^m \leq H^U y_{i,m}, \quad \forall i \in I_A \quad (25)$$

$$0 \leq q_{p,i,m} \leq q_{p,i,m}^U y_{i,m}, \quad \forall p, i \in I_A, m \in M \quad (26a)$$

$$0 \leq q_{p,i,s} \leq q_{p,i,s}^U y_{i,s}, \quad \forall p, i \in I_B, s \in S \quad (26b)$$

### Well and Flowline Momentum and Energy Balances

1. *Naturally flowing wells of type A.* Kosmidis [18] discusses how naturally flowing wells of type A can be accurately approximated by piecewise linear functions:

$$q_{o,i}^{\max} = \sum_j \eta_{i,j} q_{o,i,j}^{d,\max}, \quad \forall i \in I_A \quad (27a)$$

$$P_i^m = \sum_j \eta_{i,j} P_{i,j}^d, \quad \forall i \in I_A \quad (27b)$$

$$H_i^m = \sum_j \sum_k \lambda_{i,j,k} H_{i,j,k}^d, \quad \forall i \in I_A \quad (27c)$$

$$q_{o,i} = \sum_j \sum_k \lambda_{i,j,k} q_{o,i,j,k}^d, \quad \forall i \in I_A \quad (27d)$$

$$q_{o,i} \leq q_{o,i}^{\max}, \quad \forall i \in I_A \quad (27e)$$

$$\sum_j \sum_k \lambda_{i,j,k} = y_i, \quad \forall i \in I_A \quad (27f)$$

$$\eta_{i,j} = \sum_k \lambda_{i,j,k}, \quad \xi_{i,k} = \sum_j \lambda_{i,j,k}, \quad (27g)$$

$$\zeta_{i,t} = \sum_j \lambda_{i,j,j+t}, \quad \forall i \in I_A \quad (27h)$$

$$\eta_{i,j}, \xi_{i,k}, \zeta_{i,t} \geq 0, \text{ SOS}, \quad \forall i \in I_A. \quad (27h)$$

It must be noted that if well  $i$  is shut in ( $y_i = 0$ ), then all continuous variables in constraint (27) are set equal to zero, as it can be observed from constraint (27f). The piecewise linear approximation of the well model is constructed in a pre-processing step by discretizing:

- (i) the manifold pressure between the valid lower ( $L^P$ ) and upper ( $U^P$ ) bound, and
- (ii) the well oil rate in the interval  $[q_{o,i}^L, q_{o,i}^U]$ .

The lower bound ( $L^P$ ) is equal to the lowest operating pressure of the separators, while the upper bound ( $U^P$ ) must be greater than the highest operating pressure of the separators.

2. *Naturally flowing wells of type B.* For the case of naturally flowing wells of type B, the oil flowrate  $q_{o,i,s}$  of well  $i$  in separator  $s$  is given by:

$$q_{o,i,s} \leq q_{o,i,s}^{d,\max} y_{i,s}, \quad \forall i \in I_B \quad (28)$$

where  $q_{o,i,s}^{d,\max}$  is calculated in a pre-processing step for each fixed pressure separator  $s$  by setting the choke fully open.

3. *Gas lift wells of type A.* These can be accurately approximated by the following set of mixed integer linear relations:

$$q_{o,i} = \sum_j \sum_k \lambda_{i,j,k} q_{o,i,j,k}^d, \quad \forall i \in I_B \quad (29a)$$

$$q_{g,i}^{\text{inj}} = \sum_j \sum_k \lambda_{i,j,k} q_{g,i,k}^{d,\text{inj}}, \quad \forall i \in I_B \quad (29b)$$

$$P_i^m = \sum_j \sum_k \lambda_{i,j,k} P_{i,j}^d, \quad \forall i \in I_B \quad (29c)$$

$$H_i^m = \sum_j \sum_k \lambda_{i,j,k} H_{i,j,k}^d, \quad \forall i \in I_B \quad (29d)$$

$$\sum_j \sum_k \lambda_{i,j,k} = y_i, \quad \forall i \in I_B \quad (29e)$$

$$\eta_{i,j} = \sum_k \lambda_{i,j,k}, \quad \xi_{i,k} = \sum_j \lambda_{i,j,k}, \quad (29f)$$

$$\zeta_{i,t} = \sum_j \mu_{i,j,j+t}, \quad \forall i \in I_B$$

$$\eta_{i,j}, \xi_{i,k}, \zeta_{i,t} \geq 0 \text{ (SOS)}, \quad \forall i \in I_B. \quad (29g)$$

These relations are constructed in a pre-processing step by discretizing:

- (iii) the manifold pressure in the interval  $[L^P, U^P]$ , and
- (iv) the well gas injection rate in the interval  $[0, q_{g,i}^{\text{inj},U}]$ , where  $q_{g,i}^{\text{inj},U}$  is the gas injection rate at the upper bound pressure ( $U^P$ ), where the well oil flowrate is reduced despite the increase in gas injection rate.

4. *Gas lift wells of type B.* These are connected to a fixed pressure separator and they can be accurately approximated as follows:

$$q_{o,i,s} = \sum_j \lambda_{i,j,s} q_{o,i,j,s}^d, \quad \forall i \in I_B, s \in S \quad (30a)$$

$$q_{g,i,s}^{\text{inj}} = \sum_j \lambda_{i,j,s} q_{g,i,j,s}^{d,\text{inj}}, \quad \forall i \in I_B, s \in S \quad (30b)$$

$$\sum_j \lambda_{i,j,s} = y_{i,s}, \quad \forall i \in I_B, s \in S \quad (30c)$$

$$\lambda_{i,j,s} \geq 0, \text{ SOS.} \quad (30d)$$

**Flowline Momentum Balance** The momentum balance in the manifold flowlines is given by:

$$P_{m,s} - f_P(P_m, H_m, q_{o,m}, q_{g,m}, q_{w,m}) = 0, \quad \forall m \in M, s \in S \quad (31)$$

where  $P_{m,s}$  is the pressure of flowline  $m$  at separator level  $s$ .

*Remark* During construction of the piecewise linear approximations or calculation of  $q_{o,i,s}^{\text{max}}$ , it is possible to identify naturally flowing wells of type A or type B which are unable to flow towards certain manifolds or separators. To exclude these infeasible connections, the following logic constraints are incorporated in the mathematical formulation:

$$y_{i,m} \leq 1 - y_{m,s}, \quad \forall i \in I_A \quad (32)$$

$$y_{i,s} \leq 0, \quad \forall i \in I_B. \quad (33)$$

Constraint (32) states that if flowline  $m$  is connected to separator  $s$  ( $y_{m,s} = 1$ ), then well  $i$  cannot be connected to manifold  $m$ .

**Maximum Number of Well Switches**

There is an upper bound on the number of well switches (for wells of both types A and B) that can be performed within a day. This is an operational constraint and is applied to avoid huge flow variations which may eventually lead to a surface facility shut down. To consider and model this requirement, the following binary variables and parameters are introduced:

**Binary variables**

$$c_i^f = \begin{cases} 1 & \text{if the well } i \text{ is open and in the} \\ & \text{previous day was closed} \\ 0 & \text{otherwise} \end{cases}$$

$$c_i^{\text{nf}} = \begin{cases} 1 & \text{if the well } i \text{ is closed and in the} \\ & \text{previous day was open} \\ 0 & \text{otherwise} \end{cases}$$

$$c_{i,m} = \begin{cases} 1 & \text{if the well } i \text{ of type A is connected} \\ & \text{to a new manifold } m \text{ on this day} \\ 0 & \text{otherwise} \end{cases}$$

$$c_{i,s} = \begin{cases} 1 & \text{if the well } i \text{ of type B is connected to} \\ & \text{a new separator } s \text{ on this day} \\ 0 & \text{otherwise} \end{cases}$$

$$c_{m,s} = \begin{cases} 1 & \text{if the flowline } m \text{ is connected to} \\ & \text{a new separator } s \text{ on this day} \\ 0 & \text{otherwise.} \end{cases}$$

**Parameters**

$NC_A^{\text{max}}$  maximum number of switches for the wells of type A.

$NC_B^{\text{max}}$  maximum number of switches for the wells of type B.

$y^b$  binary parameters representing the well structure of the previous day.

One switch is accounted for in the following cases:

(i) *A well  $i$  was closed and is currently open.* This case is modeled by incorporating the following constraint in the formulation:

$$y_i - y_i^b \leq c_i^f, \quad \forall i \in I. \quad (34)$$

Thus, if well  $i$  is open ( $y_i = 1$ ) while it was previously closed ( $y_i^b = 0$ ), then one well switch is accounted for by forcing the binary variable  $c_i^f$  to be 1.

(ii) *A well  $i$  was open and is currently closed.* To incorporate this well switch in the formulation, the following constraint is used:

$$y_i^b - y_i \leq c_i^{\text{nf}}, \quad \forall i \in I. \quad (35)$$

(iii) *A well of type A switches manifold.* If well  $i$  is currently connected to manifold  $m$  ( $y_{i,m} = 1$ ) and it was previously connected to manifold  $m' \neq m$

(that implies  $y_{i,m}^b = 0$ ), then there is one well switch, which is modeled by the following constraint in the formulation:

$$y_{i,m} - y_{i,m}^b \leq c_{i,m}, \quad \forall i \in B, m \in M \quad (36)$$

where the set  $B = \{i \in I_A \mid y_i^b \neq 0\}$  is the set of wells of type A that were open during the previous day. Constraint (36) is applicable only for wells of type A that were previously open ( $y_i^b \neq 0$ ), to avoid double counting a well switch; the case of a well that was closed ( $y_i^b = 0$ ) and is currently open ( $y_i = 1$ ) is considered by constraint (34).

- (iv) *A well of type B switches to a new separator.* If well  $i$  is currently connected to separator  $s$  ( $y_{i,s} = 1$ ) and was previously connected to separator  $s' \neq s$  ( $y_{i,s'}^b = 0$ ), then there is one well switch, which is modeled by the following constraint in the formulation:

$$y_{i,s} - y_{i,s'}^b \leq c_{i,s}, \quad \forall i \in C, s \in S \quad (37)$$

where the set  $C = \{i \in I_B \mid y_i^b \neq 0\}$  is the set of wells of type B that were open during the previous day.

- (v) *A manifold flowline switches to a new separator.* If a manifold flowline  $m$  is currently connected to a separator  $s$  ( $y_{m,s} = 1$ ) and was previously connected to separator  $s' \neq s$  ( $y_{m,s'}^b = 0$ ), then there is one switch, which is accounted for by forcing the binary variable  $c_{m,s}$  to be 1:

$$y_{m,s} - y_{m,s'}^b \leq c_{m,s}, \quad \forall m \in M, s \in S. \quad (38)$$

The sum of switches for the wells of type A and B must be less than an upper bound:

$$\sum_{i \in I_A} (c_i^f + c_i^{nf}) + \sum_{i \in B} \sum_{m \in M} c_{i,m} + \sum_{m \in M} \sum_{s \in S} c_{m,s} \leq NC_A^{\max} \quad (39)$$

$$\sum_{i \in I_A} (c_i^f + c_i^{nf}) + \sum_{i \in C} \sum_{s \in S} c_{i,s} \leq NC_B^{\max}. \quad (40)$$

### Objective Function

The objective function is the maximization of daily revenue:

$$\max w_o \sum_{i \in I} q_{o,i} - w_g \sum_{i \in I} q_{g,i}^{\text{inj}} \quad (41)$$

The control variables are:

- (i) the well operational status (open or close),
- (ii) the well connections to manifolds and separators,
- (iii) the flowline connections to separators,
- (iv) the well oil flowrates, and
- (v) the gas injection rates into gas lift wells.

### An MINLP Formulation for the Well Scheduling Problem

By defining the vectors  $\mathbf{x} = [P, H]$ ,  $\mathbf{q}_p = [q_o, q_g, q_w, q_g^{\text{inj}}]$ ,  $\mathbf{y}^s = [y_i, y_{i,m}, y_{m,s}, y_{i,s}]$ ,  $\mathbf{c} = [c_i^f, c_i^{nf}, c_{i,m}, c_{i,s}, c_{m,s}]$ ,  $\boldsymbol{\phi} = [\lambda_{i,j}, \xi_{i,k}, \zeta_{i,t}]$  and  $\mathbf{y}^a$  (the vector of binary variables that are used to impose the adjacency condition in SOS-type variables), the mathematical programming formulation (P) for the well scheduling problem can be concisely expressed as:

$$P: \max \psi(q_{o,i}, q_{g,i}^{\text{inj}}) \quad (42)$$

subject to

$$m_1(\mathbf{x}_i, \mathbf{q}_{p,i}) = 0 \quad (43)$$

$$m_2(\mathbf{q}_{p,i}, \mathbf{q}_{p,i,m}, \mathbf{q}_{p,i,s}, \mathbf{q}_{p,s}, \mathbf{x}_i, \mathbf{x}_{i,m}, \mathbf{y}^s) \leq 0 \quad (44)$$

$$m_3(\mathbf{q}_{p,i,m}, \mathbf{q}_{p,i,s}, \mathbf{y}^s) \leq 0 \quad (45)$$

$$m_4(q_{o,i}, q_{g,i}^{\text{inj}}, q_{o,i,s}, q_{o,i,s}^{\max}, q_{g,i,s}^{\text{inj}}, \mathbf{x}_{i,m}, \boldsymbol{\phi}, \mathbf{y}^s, \mathbf{y}^a) = 0 \quad (46)$$

$$m_5(\mathbf{x}_m, \mathbf{q}_{p,m}) = 0 \quad (47)$$

$$m_6(\mathbf{y}^s, \mathbf{c}) \leq 0. \quad (48)$$

The equivalence of the equations within the above model (P) is explained as follows. Equation (42) is equivalent to the linear objective function (41). Equation (43) represents the nonlinear wellbore model Eq. (1)–(7). Equation (44) represents the mixed integer linear mass, momentum and energy balances in the wells, manifold and separator nodes and is equivalent to Eq. (8)–(19). Equation (45) represents the mixed integer linear network logic constraints and is equivalent to Eq. (20)–(26). Equation (46) represents the well piecewise linear approximation and is equivalent to Eq. (27)–(30). Equation (47) represents the nonlinear momentum balance in the flowlines and is equivalent

to Eq. (31). Finally, Eq. (48) represents the integer logic relations associated with the ability of naturally flowing wells to flow and with the relevant well switches, and is equivalent to Eq. (32)–(40).

The mathematical programming formulation  $P$  includes: (i) binary variables, and (ii) nonlinear equations. Therefore, it belongs to the class of mixed integer nonlinear programming (MINLP) problems. There are two categories of binary variables: the one that is associated with the structure of the production network and the well switches ( $\mathbf{y}^s$ ,  $\mathbf{c}$ ), and a second that is used to impose the adjacency condition on SOS-type variables ( $\mathbf{y}^a$ ). Moreover, the number of nonlinear equations is equal to the number of coning wells plus the number of flowlines.

The most popular methods for solving MINLP problems are those that proceed by solving a sequence of nonlinear (NLP) and mixed integer linear programs (MILP) problems. These include Generalized Benders decomposition (GBD, Geoffrion [3]) and Outer Approximation (OA, Kocis and Grossmann [5]). The disadvantage of GBD is that it may require a significant number of major iterations of the NLP subproblem and the MILP master problem. The major advantage of OA is that it typically requires fewer iterations to achieve a solution, since its MILP master problem contains more information than the GBD formulation. Conversely, because the OA master problem is richer, it is also more time-consuming to solve. A detailed review of the various MINLP algorithms has been published by Floudas [10].

This Chapter considers an approach based on Outer Approximation (OA), since it typically requires fewer iterations when compared to other MINLP techniques. Also, its modified version (Outer Approximation/Augmented Penalty (OA/AP), (Viswanathan and Grossmann, 1990)) has been found to be capable of handling mild nonconvexities present in the MINLP problems.

### Optimization Strategy

The first NLP subproblem of the OA/AP algorithm involves solving an optimization problem where the structure of the pipeline network is the one of the previous day. The  $l$ th NLP subproblem ( $l > 1$ ) involves fixing the discrete decisions  $\mathbf{y}^s$  and  $\mathbf{c}$  to a given set of values

( $\mathbf{y}^{s(l)}$ ,  $\mathbf{c}^{(l)}$ ). Therefore, there is no need to introduce the logic constraints (45), (48) and hence the NLP subproblem ( $P$ ) is equivalent to the well operation and gas lift allocation problem. It must be noted that the solution of the NLP subproblem provides a lower bound on the solution of the MINLP problem since the binary variables  $\mathbf{y}^s$  and  $\mathbf{c}$  are fixed to values that are not necessarily optimal.

The master problem is formulated from the linearization of the nonlinear constraints (43) and (47) at the solution points of the subproblems ( $l = 1, \dots, L$ ) and relaxation of them to inequalities using the sign of the Lagrange multipliers [17]. It is therefore, a MILP problem. The master problem provides (i) an upper bound to the MINLP problem and (ii) a new set of binary variables  $\mathbf{y}^s$  and  $\mathbf{c}$ . The master MILP problem is as follows:

$$PM: \max \psi(q_{o,i}, q_{g,i}^{\text{inj}}) - (\mathbf{w}_l^p)^T \mathbf{p}_l - (\mathbf{w}_l^q)^T \mathbf{q}_l \quad (49)$$

subject to

$$\mathbf{T}^l \left\{ \begin{array}{l} [\nabla_{\mathbf{x}_i} m_1(\mathbf{x}_i^l, \mathbf{q}_{p,i}^l) \nabla_{\mathbf{q}_{p,i}} m_1(\mathbf{x}_i^l, \mathbf{q}_{p,i}^l)] \\ \left[ \begin{array}{l} (\mathbf{x}_i - \mathbf{x}_i^l) \\ (\mathbf{q}_{p,i} - \mathbf{q}_{p,i}^l) \end{array} \right] \end{array} \right\} \leq \mathbf{p}_l, \quad \forall l = 1, \dots, L \quad (50)$$

$$m_2(\mathbf{q}_{p,i}, \mathbf{q}_{p,i,m}, \mathbf{q}_{p,i,s}, \mathbf{q}_{p,s}, \mathbf{x}_i, \mathbf{x}_{i,m}, \mathbf{y}^s) \leq 0 \quad (51)$$

$$m_3(\mathbf{q}_{p,i,m}, \mathbf{q}_{p,i,s}, \mathbf{y}^s) \leq 0 \quad (52)$$

$$m_4(q_{o,i}, q_{g,i}^{\text{inj}}, q_{o,i,s}, q_{o,i,s}^{\text{max}}, q_{g,i,s}^{\text{inj}}, \mathbf{x}_{i,m}, \phi, \mathbf{y}^s, \mathbf{y}^a) = 0 \quad (53)$$

$$\mathbf{T}^l \left\{ \begin{array}{l} [\nabla_{\mathbf{x}_m} m_5(\mathbf{x}_m^l, \mathbf{q}_{p,m}^l) \nabla_{\mathbf{q}_{p,m}} m_5(\mathbf{x}_m^l, \mathbf{q}_{p,m}^l)] \\ \left[ \begin{array}{l} \mathbf{x}_m - \mathbf{x}_m^l \\ \mathbf{q}_{p,m} - \mathbf{q}_{p,m}^l \end{array} \right] \end{array} \right\} \leq \mathbf{q}_l, \quad l = 1, \dots, L \quad (54)$$

$$m_6(\mathbf{y}^s, \mathbf{c}) \leq 0 \quad (55)$$

$$\sum_{n \in G^l} y_n^s - \sum_{n \in NG^l} y_n^s \leq |G^l|, \quad \forall l = 1, \dots, L \quad (56)$$

where  $\mathbf{w}_l^p$  and  $\mathbf{w}_l^q$  are both vectors whose dimension is equal to the number of equations in (50) and (54), respectively. Each element of these vectors is a positive

scalar which is greater than the absolute value of the Lagrange multiplier  $v_j^l$  associated with the  $j$ th constraint in (50) and (54) at the  $l$ th iteration. Moreover,  $\mathbf{T}^l$  is a diagonal matrix whose elements are defined as follows:

$$t_{jj}^l = \begin{cases} -1 & \text{if } v_j^l < 0 \\ 1 & \text{if } v_j^l > 0 \\ 0 & \text{if } v_j^l = 0. \end{cases} \quad (57)$$

Furthermore,  $\mathbf{p}^l$  and  $\mathbf{q}^l$  are vectors whose elements are positive slack variables associated with each of the constraints in Eq. (50) and (54), respectively. Finally, the constraint (56) is known as an *integer cut* and is applied to ensure that any pipeline configuration that has already been considered is not selected again. The notion  $|G^l|$  denotes the cardinality of the set  $G^l$  whose elements are all the structural binary variables  $y_n^s$  that have a value of 1 at the  $l$ th iteration, while  $NG^l$  is the set of structural binary variables that have a value of zero at  $l$ th iteration.

The MINLP problem terminates when the difference of the best lower bound from the NLP subproblems ( $\max_l LB^l$ ) and the current upper bound from the MILP problem ( $UB^l$ ) are within a prespecified tolerance  $\varepsilon$ :

$$\frac{\max_l LB^l - UB^l}{UB^l} \leq \varepsilon \quad (58)$$

or when the MILP problem is integer-infeasible. The optimal solution is the one given by the best NLP subproblem.

However, the solution of the MILP problem on the full space of both structural and interpolation binary variables is computationally intensive, since the number of interpolation binary variables becomes very large as the number of wells increases. For instance, a problem with 10 gas lift wells involves about 300 interpolation binary variables. This motivates the need to reformulate the MILP problem ( $PM$ ), so as to involve only structural and switching binary variables  $\mathbf{y}^s$  and  $\mathbf{c}$ . As mentioned, the master MILP problem is constructed from (i) linearization of the nonlinear constraints, and (ii) relaxation of the nonlinear equality constraints using the sign of Lagrange multipliers. Fortunately, information for both is available from the solution of the NLP subproblem. Consider for instance the case of a gas lift well of type A (29), where the subscript  $i$  has

been dropped for simplicity. At the optimal point, three adjacent  $\mu$  coefficients are active (Williams, 1990). The active triplet is assumed to be  $(\mu_{j,k}, \mu_{j+1,k}, \mu_{j,k+1})$ , without loss of generality. Then the gas lift model (29) can be written as:

$$q_o = \mu_{j,k} q_{o,j,k}^d + \mu_{j+1,k} q_{o,j+1,k}^d + \mu_{j,k+1} q_{o,j,k+1}^d \quad (59a)$$

$$q_g^{\text{inj}} = \mu_{j,k} q_{g,k}^{d,\text{inj}} + \mu_{j+1,k} q_{g,k}^{d,\text{inj}} + \mu_{j,k+1} q_{g,k+1}^{d,\text{inj}} \quad (59b)$$

$$P_m = \mu_{j,k} P_j^{d,m} + \mu_{j+1,k} P_{j+1}^{d,m} + \mu_{j,k+1} P_j^{d,m} \quad (59c)$$

$$\mu_{j,k} + \mu_{j+1,k} + \mu_{j,k+1} = 1 \quad (59d)$$

By substituting Eq. (59d) into (59b) and (59c), both  $\mu_{j+1,k}$  and  $\mu_{j,k+1}$  are given by:

$$\mu_{j+1,k} = \frac{P_m - P_j^{d,m}}{P_{j+1}^{d,m} - P_j^{d,m}} \quad (60a)$$

$$\mu_{j,k} = \frac{q_g^{\text{inj}} - q_{g,k}^{d,\text{inj}}}{q_{g,k+1}^{d,\text{inj}} - q_{g,k}^{d,\text{inj}}}. \quad (60b)$$

Substituting Eq. (60a) and (60b) into (59a), the following equation is obtained:

$$q_o = q_{o,j,k} + \frac{q_{o,j+1,k}^d - q_{o,j,k}^d}{P_{j+1}^{d,m} - P_j^{d,m}} (P_m - P_j^{d,m}) + \frac{q_{o,j,k+1}^d - q_{o,j,k}^d}{q_{g,k+1}^{d,\text{inj}} - q_{g,k}^{d,\text{inj}}} (q_g^{\text{inj}} - q_{g,k}^{\text{inj}}). \quad (61)$$

Equation (61) is the linearization of the nonlinear gas lift well model, where the derivatives are calculated by forward finite difference formulae. If Eq. (61) replaces Eq. (59), a new NLP subproblem is obtained; then, by applying KKT conditions to both NLP subproblems, it is easy to prove that the Lagrange multiplier of Eq. (59a) is equal to the Lagrange multiplier of Eq. (61). Consequently, the active triplet of  $\mu$ 's is obtained from the solution of the NLP subproblem, along with the Lagrange multiplier; moreover, the new MILP master problem ( $PM'$ ) is formulated:

$$PM': \max \psi(q_{o,i}, q_{g,i}^{\text{inj}}) - (\mathbf{w}_i^p)^T \mathbf{p}_i - (\mathbf{w}_i^q)^T \mathbf{q}_i - (\mathbf{w}_i^r)^T \mathbf{r}_i \quad (62)$$

subject to

$$\mathbf{T}^l \left\{ \begin{array}{l} [\nabla_{\mathbf{x}_i} m_1(\mathbf{x}_i^l, \mathbf{q}_{p,i}^l), \nabla_{\mathbf{q}_{p,i}} m_1(\mathbf{x}_i^l, \mathbf{q}_{p,i}^l)] \\ \left[ \begin{array}{l} (\mathbf{x}_i - \mathbf{x}_i^l) \\ (\mathbf{q}_{p,i} - \mathbf{q}_{p,i}^l) \end{array} \right] \end{array} \right\} \leq \mathbf{p}_l, \quad \forall l = 1, \dots, L \quad (63)$$

$$m_2(\mathbf{q}_{p,i}, \mathbf{q}_{p,i,m}, \mathbf{q}_{p,i,s}, \mathbf{q}_{p,s}, \mathbf{x}_i, \mathbf{x}_{i,m}, \mathbf{y}^s) \leq 0 \quad (64)$$

$$m_3(\mathbf{q}_{p,i,m}, \mathbf{q}_{p,i,s}, \mathbf{y}^s) \leq 0 \quad (65)$$

$$\mathbf{T}^l \left\{ \begin{array}{l} [\nabla_{\mathbf{x}_i} m_4(\mathbf{x}_i^l, \mathbf{q}_{p,i}^l), \nabla_{\mathbf{q}_{p,i}} m_4(\mathbf{x}_i^l, \mathbf{q}_{p,i}^l)] \\ \left[ \begin{array}{l} (\mathbf{x}_i - \mathbf{x}_i^l) \\ (\mathbf{q}_{p,i} - \mathbf{q}_{p,i}^l) \end{array} \right] \end{array} \right\} \leq \mathbf{r}_l, \quad \forall l = 1, \dots, L \quad (66)$$

$$\mathbf{T}^l \left\{ \begin{array}{l} [\nabla_{\mathbf{x}_m} m_5(\mathbf{x}_m^l, \mathbf{q}_{p,s}^l), \nabla_{\mathbf{q}_{p,s}} m_5(\mathbf{x}_m^l, \mathbf{q}_{p,s}^l)] \\ \left[ \begin{array}{l} \mathbf{x}_m - \mathbf{x}_m^l \\ \mathbf{q}_{p,s} - \mathbf{q}_{p,s}^l \end{array} \right] \end{array} \right\} \leq \mathbf{q}_l, \quad l = 1, \dots, L \quad (67)$$

$$m_6(\mathbf{y}^s, \mathbf{c}) \leq 0 \quad (68)$$

$$\sum_{n \in G^l} y_n^s - \sum_{n \in NG^l} y_n^s \leq |G^l|, \quad \forall l = 1, \dots, L. \quad (69)$$

The MILP problem ( $PM'$ ) involves only structural ( $\mathbf{y}^s$ ) and switching ( $\mathbf{c}$ ) binary variables. Figure 5 depicts the linearization of the nonlinear gas lift model, according to the foregoing analysis.

### Solution Procedure

Based on the foregoing sections, the steps of the proposed MINLP optimization strategy for the well scheduling problem are formally presented as follows:

#### (1) Pre-processing step

1. The reservoir information (productivity index, GOR and WOR) is updated, using a reservoir simulator.
2. For each naturally flowing well, the manifold pressure and the well oil rate are discretized between a lower and an upper bound. Then, the well model is simulated for each pair of discrete

points, and the momentum and energy balances are approximated with piecewise linear functions.

3. For each gas lift well, the manifold pressure and the gas injection rate are discretized between a lower and an upper bound. Then, the well model is simulated for each pair of discrete points, and the momentum and energy balances are approximated with piecewise linear functions.
4. If a naturally flowing well cannot flow towards a separator, then the corresponding logic constraint is incorporated into the formulation.
5. If Vertical Flowing Tables are used, then the approximation of momentum and energy balances in the wells is simpler: there is no need for well simulation using each pair of discrete points, and simple interpolation calculations are used to approximate the momentum and energy balances in the wells.

#### (2) Processing step

This step involves the solution of the MINLP problem:

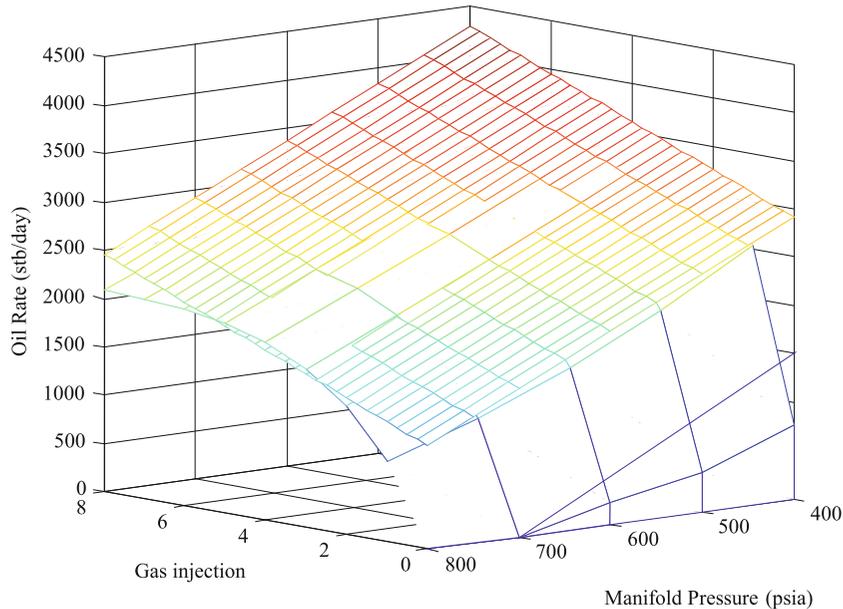

1. Set the iteration counter at  $l = 0$ , and the upper bound at  $UB^0 = +\infty$ .
2. Solve the NLP subproblem as a sequence of MILP problems, following the algorithm described by Kosmidis [18] 4 to obtain a lower bound ( $LB^l$ ).
3. Add linearizations and integer cuts cumulatively, and solve the MILP master problem ( $PM'$ ) and update the upper bound ( $UB^l$ ).
4. If  $(UB^l - \max_l LB^l)/(LB^l) \leq \varepsilon$  or the MILP problem is integer-infeasible, then STOP. The optimal structure is the one which corresponds to the best lower bound  $\max_l LB^l$ . Else, set  $l = l + 1$  and go to step (2).2.

#### (3) Post-processing step

For each well, fix the manifold pressure and the well oil flowrate and perform a well simulation (based on the system of well equations) to calculate the precise well choke settings.

### Example Problems

This section illustrates the performance of the proposed MINLP algorithm in two different example problems.

**Mixed Integer Optimization in Well Scheduling, Figure 5**  
**Linearization of a gas lift well model**

The first example is a small production network which involves three wells connected to a manifold, and it is used to illustrate the economic impact of incorporating discrete decisions in the well scheduling problem. In the second example, the proposed MINLP optimization strategy is applied to a field consisting of 3 separators, 2 manifolds and 11 naturally flowing wells. To evaluate the economic benefits of the proposed MINLP optimization strategy, heuristic rules are also applied to the same problem for comparison. Finally, the proposed method is applied to an oil field, which consists of 22 (both naturally flowing and gas lift) wells.

### Example 1

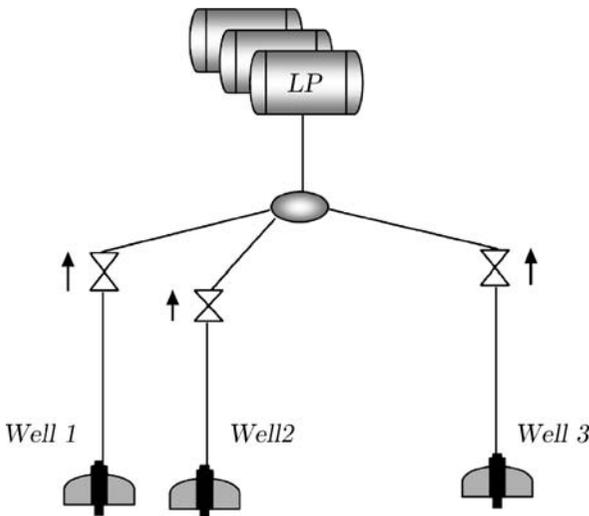

The mathematical formulation and the solution procedure developed in this Chapter has been applied to the production network presented in Fig. 6. The well characteristics, separator pressures and capacities are given in Table 1 and 2, respectively. The problem has been formulated as an MINLP problem, where binary variables are used to model the operational status of each (closed or open) well. The MILP problems have been implemented in GAMS [5] and solved using CPLEX® as the MIP solver. The problem involves 3 binary variables, 26 interpolation binary variables and 81 con-

straints. Initially, the manifold pressure and the well oil flowrate are discretized to construct a piecewise linear approximation of the well model. Then, the initial structure (all wells tied to the manifold) has been evaluated by solving the corresponding NLP subproblem: the optimal solution has thus been determined equal to  $LB^1 = 12010$  STB/day. The master MILP problem is then formulated and solved: the MILP problem solution generates a new production network structure, where well 1 is shut in. The new structure has then been evaluated in the NLP subproblem, and a new lower bound equal to  $LB^2 = 12104.2$  STB/day has been determined. The algorithm terminates, since the MILP master problem is found to be integer-infeasible. Therefore, the optimal structure involves only wells 2 and 3 connected to the manifold, with their chokes fully open.

A typical heuristic rule for maximization of oil production states that the well chokes must be fully open for oil maximization. The application of this heuristic rule to this particular production network yields an oil production level equal to 11929.2 STB/day. The results from the application of heuristic rules and the proposed strategy are summarized in Table 3 and suggest that: (i) these heuristic rules may lead to suboptimal solutions, and (ii) an increase in oil production of 175 STB/day is observed when the proposed formal

Oil Capacity (STB/day)	17000
Gas Capacity (MSCF/day)	33000
Water Capacity (STB/day)	22000

MINLP optimization technique is applied to the well scheduling problem. The above result can be explained by considering the interaction of wells that share a common flowline. This particular three-well network problem has a well with a very high water cut (well 1), as can

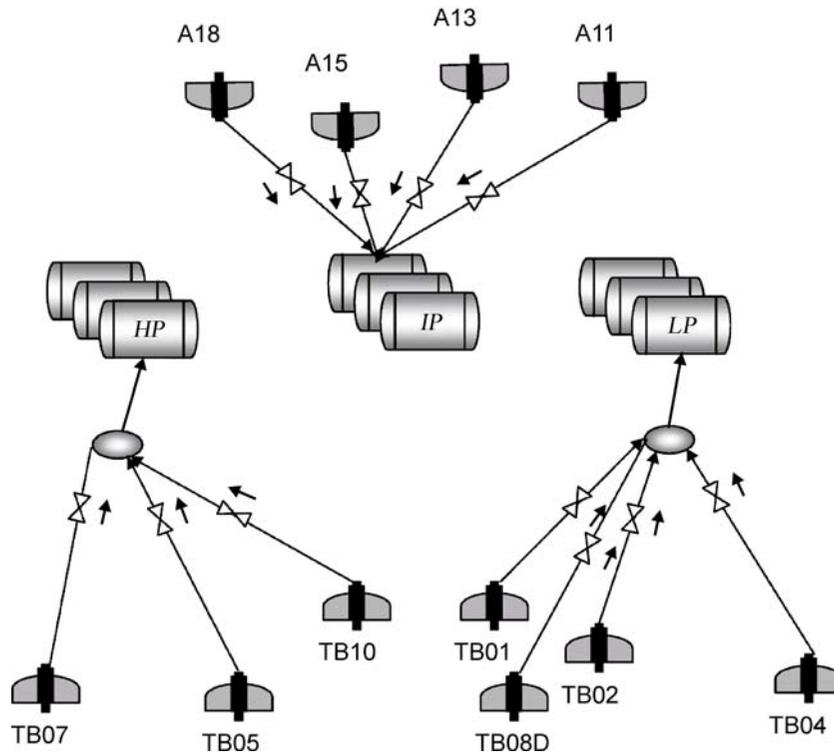

**Mixed Integer Optimization in Well Scheduling, Table 3**  
Comparison of structure and oil production results: heuristics vs. optimization

Structure	Objective function (STB/day)
$(y_1, y_2, y_3) = (1, 1, 1)$	11929.2 (Heuristics)
$(y_1, y_2, y_3) = (0, 1, 1)$	12104.2 (Optimization)

be seen from Table 1: this results in increased back pressure in the manifold flowline, which restricts oil production from wells 2 and 3. By shutting in well 1, the pressure drop in the flowline is reduced: the increased production from wells 2 and 3 thus compensates losses in oil production by shutting in well 1.

### Example 2

The proposed MINLP optimization strategy is also applied to an oil field that comprises 11 naturally flowing wells, 2 manifolds and 3 separators: this production network is depicted in Fig. 7. Two types of wells are considered: (i) *type A wells*, designated as TB01, TB02, TB04, TB05, TB07, TB08D and TB10, and (ii) *type B wells*, designated as A11, A13, A15 and A18. All these are naturally flowing wells and their well oil flowrate upper bounds are given in Table 4. The surface facilities consist of a high (HP), an intermediate (IP) and a low (LP) pressure separator, and the respective operating pressures and capacities are summarized in Table 5. Two case studies are considered: the first is a gas coning oil field, while the second is a water coning oil field. The well bore model is generated from a reservoir

simulator using a coning model. Details about this second example (oil flowrate as a function of bottomhole pressure, GOR and WC for both cases) are presented by Kosmidis [18].

*Example 2a (gas coning problem)* The initial structure of the production network is shown in Fig. 7, and five (5) well interconnection changes are allowed for wells of type A and type B. The MINLP optimization problem involves 89 binary variables, 260 interpolation binary variables, 924 continuous variables, 1082 constraints and the objective is the maximization of oil production. The optimization requires 5 OA/AP iterations and the total oil production is 29317.2 STB/day; the optimal production network structure is presented in Fig. 8. Table 5 summarizes the amount of oil, gas and water in the separators and the convergence history of the MINLP algorithm; the individual well fluid flowrates are reported in Table 6. A remarkable observation is that the gas capacity of all separators is fully utilized at the optimal operating point, as can be observed from the results of Table 5.

*Example 2b (water coning problem)* This problem is again solved following the proposed MINLP optimization strategy. The initial structure of the field is presented in Fig. 8; the maximum number of allowable well interconnection changes is seven (7) for wells of type A and type B. The MINLP problem converges in 6 OA/AP iterations and the optimal structure is depicted in Fig. 9. Table 7 presents the amount of oil, gas

and water in the separators and the convergence history of the MINLP problem, while well fluid flowrates are reported in Table 8. The results of Table 7 suggest that the production bottleneck of the oil field is the water separator capacity, and the proposed MINLP optimization method manages to allocate and operate the wells in such a way that the available water separator capacity is almost fully utilized. The manifold flowline that is connected to the HP separator in the initial structure (Fig. 7) is reallocated to the IP separator, since the latter has a larger water capacity compared to the HP separator (Table 7).

**Heuristic Rules vs. Optimization** Examples 2a and 2b are also both solved with heuristic rules, by applying the following procedure:

*STEP 0.* Consider an initial pipeline structure identical to that of the previous day.

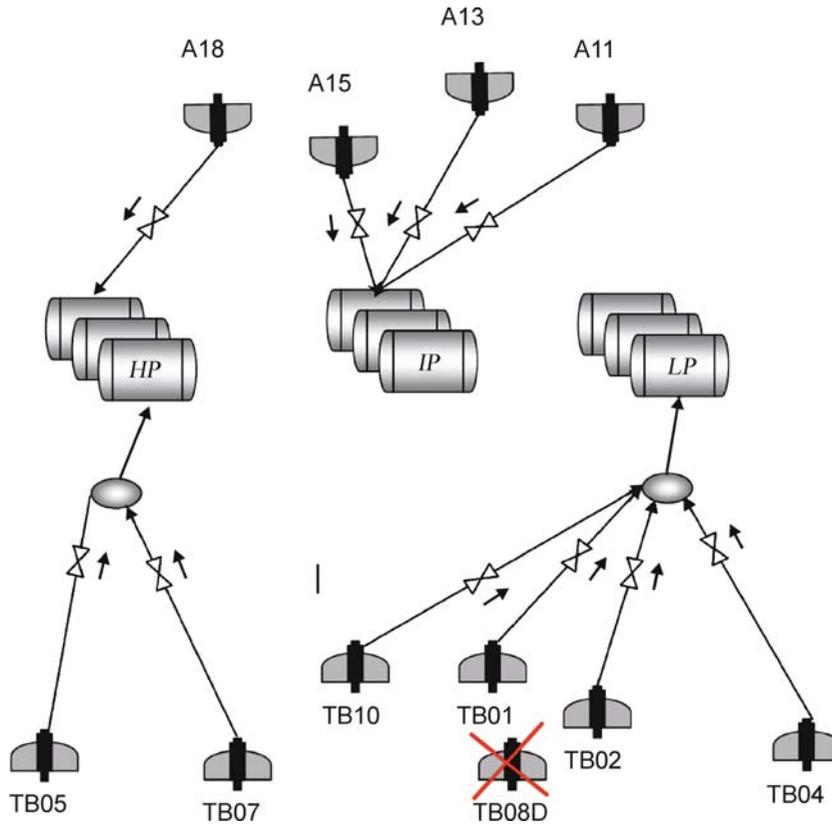

*STEP 1.* Set the chokes fully open and solve the corresponding production network problem.

*STEP 2.* If some of the resulting well flowrates from Step 1 violate their upper bounds, then choke back these wells until the respective upper bounds are satisfied.

*STEP 3.* The following two heuristic rules are applied sequentially (one well at a time):

- (i) Choke back the well according to the following heuristic rule: if gas and/or water capacity constraints are violated, then choke back the well with the highest GOR and/or WC, respectively, until the capacity constraints are satisfied. Terminate or else go to Step 3 (ii).
- (ii) Allocate high GOR wells to the HP separator and high WC wells to the LP separator, and go back to Step 1.

It must be noted that: (i) the heuristic rules are applied sequentially, and (ii) the termination criterion is based on the satisfaction of the operator. The results from the application of heuristic rules are based on repetitively applying the procedure described, until the maximum number of allowable interconnection changes is reached. The production network structures resulting from the application of heuristic rules in Examples 2a and 2b are depicted in Fig. 10 and 11, respectively. Tables 9 and 10 summarize the results derived from both MINLP optimization and heuristic strategies. The comparison clearly demonstrates the economic bene-

fits from the application of the proposed MINLP optimization strategy, which in both examples achieves of up to 10% in oil production. There are many reasons which can explain these superior results: (i) the simplistic nature of heuristic rules, which consider only the individual well *GOR* and *WC*, and neglect other param-

eters (e.g. productivity index, pipeline length and diameter), (ii) heuristic strategies do not account directly for system interactions, which become important when the wells share a common flowline, and (iii) heuristic methods often have ad hoc or unclear termination criteria.

**Integration of Reservoir Multiphase Flow Simulation and Optimization**

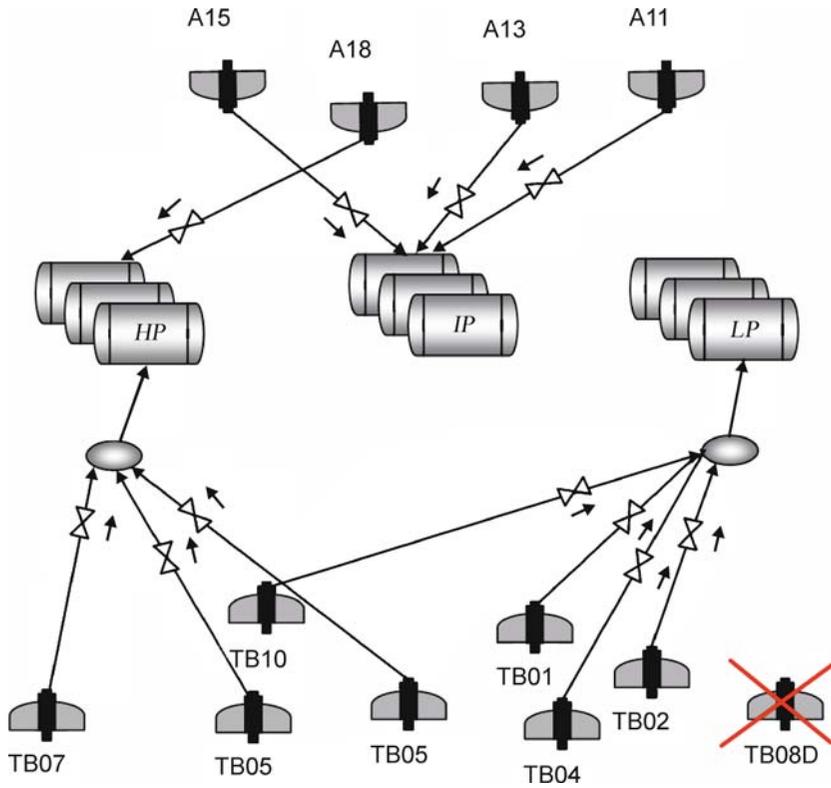

Dynamic oil and gas production systems simulation and optimization is a research trend with a potential

to meet the challenges faced by the international oil and gas industry, as has been already demonstrated in a wide variety of publications in the open literature. The multiphase flow in reservoirs and wells governs fuel transport and production, but is mostly handled by algebraic approximations in modern optimization applications: true reservoir state variable profiles (initial/boundary conditions) are generally not known. Nevertheless, oil reservoirs, wells, pipelines, manifolds and surface facilities are all equally important elements of a spatially and temporally distributed complex system, and the potential contribution of CFD methods has not been fully explored so far, even though it is generally recognized that computing accurate reservoir and well state variable profiles can be extremely useful for optimization. This section discusses a strategy for interfacing reservoir simulation (ECLIPSE®) with equation-oriented process optimization (gPROMS®) and presents a relevant application [13].

The complex multiphase flow in oil production fields is of paramount importance. Despite intensive

experimentation and extensive CFD simulations towards improved understanding of flow and phase distribution, commercial optimization applications have not benefited adequately from accurate sub-surface multiphase CFD modeling, and knowledge from field data is not readily implementable in commercial software. Model integration can enable the employment of two-phase reservoir CFD simulation, towards enhanced oil or gas production from depleted or gas-rich reserves, respectively.

The concept of integrated modeling and optimization of oil and gas production treats oil reservoirs, wells and surface facilities as a single (albeit multiscale) system, and focuses on computing accurate reservoir state variable profiles (as initial/boundary conditions). The upper-level optimization can thus benefit from the low-level reservoir simulation of oil and gas flow, yielding flow control settings and production resource allocations. The components of this system are tightly interconnected (well operation, allocation of wells to headers and manifolds, gas lift allocation, control of un-

stable gas lift wells). These are only some of the problems that can be addressed via this unified framework. Figure 12 presents the concept of integrated modeling of oil and gas production systems.

### Literature Review and Challenges for Integrated Modeling and Optimization

A number of scientific publications address modeling and simulation of oil extraction: they either focus on accurate reservoir simulation, without optimization considerations [15,22], or on optimal well planning and operations, with reduced [8,23,29,32] or absent [28,30] reservoir models. A recent paper [16] is the only considering a three-dimensional field topology (without additional flow constraints) for well placement optimization. Computational Field Dynamics (CFD) is a powerful technology, suitable for studying the dynamic behavior of reservoirs for efficient field operation [2]. The MINLP formulation for oilfield production optimization of Kosmidis [19] uses detailed well

Mixed Integer Optimization in Well Scheduling, Figure 12

Integrated modeling concept for oil and gas production systems optimization: illustration of the hierarchy of levels and all production circuit elements

models and serves as a starting point in the case examined in this section. Therein, the nonlinear reservoir behavior, the multiphase flow in pipelines, and surface capacity constraints are *all* considered (multiphase flow is handled by DAE systems, which in turn comprise ODEs for flow equations and algebraics for phys. properties). The model uses a degrees-of-freedom analysis and well bounding, but most importantly approximates each well model with piecewise linear functions (via data preprocessing).

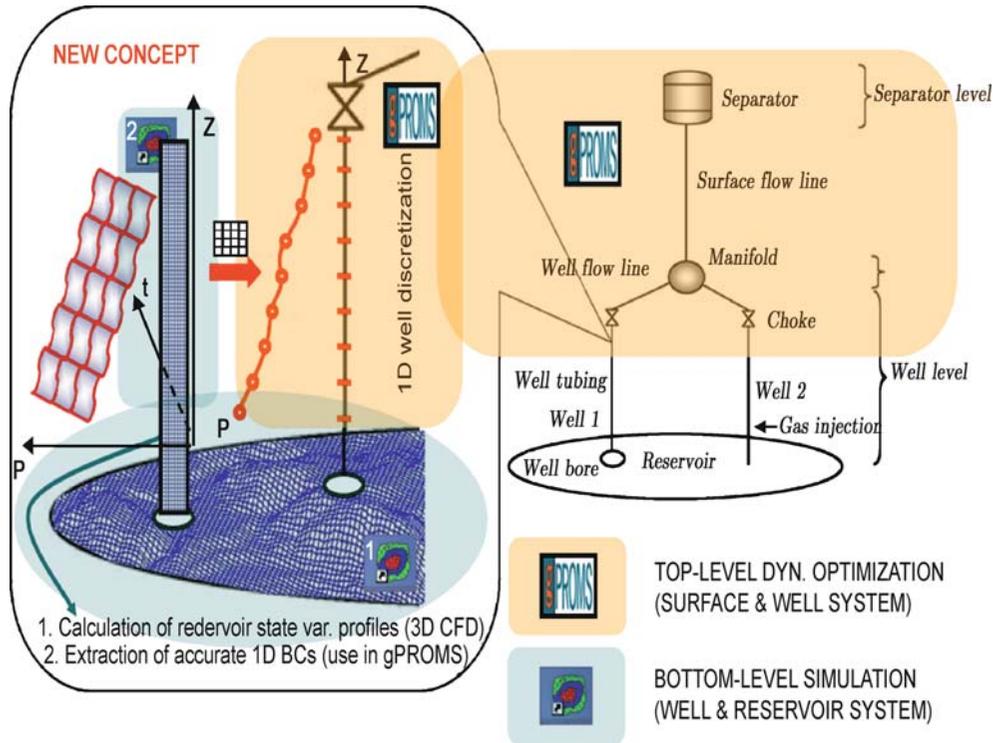

Here, explicit reservoir flow simulation via a dynamic reservoir simulator (ECLIPSE<sup>®</sup>) is combined with an equation-oriented process optimizer (gPROMS<sup>®</sup>), towards integrated modeling and optimization of a literature problem 13. An asynchronous fashion is employed: the first step is the calculation of state variable profiles from a detailed description of the production system (reservoir) via ECLIPSE<sup>®</sup>. This is possible by rigorously simulating the multiphase flow within the reservoir, with real-world physical properties (whose extraction is laborious [7]). These dynamic state variable profiles (pressure, oil, gas and water sat-

uration, flows) are a lot more accurate than piecewise linear approximations [18], serving as initial conditions for the higher-level dynamic optimization model (within gPROMS<sup>®</sup>). Crucially, these profiles constitute major sources of uncertainty in simplified models. Considering the oil and gas pressure drop evolution within the reservoir and along the wells, one can solve single-period or multi-period dynamic optimization problems that yield superior optima, because piecewise linear pressure underestimation is avoided. While integrating different levels (sub-surface elements and surface facilities – Fig. 12) is vital, interfacing CFD simulation with MINLP optimization is here pursued in an asynchronous fashion (given the computational burden for CFD nested within MINLP).

The concept of integrated modeling and optimization is illustrated in Fig. 13.

### Problem Definition and Model Formulation

Dynamic CFD modeling for explicit multiphase flow simulation in reservoirs and wells comprises a large

Mixed Integer Optimization in Well Scheduling, Figure 13

Integrated modeling and optimization of oil and gas production systems: illustration of the explicit consideration of multi-phase flow within reservoirs and wells

number of conservation laws and constitutive equations for closure: Table 1 presents only the most important ones, which are implemented in ECLIPSE®. The *black-oil model* [25] is adopted in this study, to manage complexity. More complicated, *compositional models* are widely applied [2], accounting explicitly for different hydrocarbon real- or pseudo-species concentrations. A black-oil model allows for multiphase simulation via only 3 phases (oil, water, gas):

Multiphase flow CFD model equations (Nomenclature [19]):

Oil:

$$\nabla \left[ \frac{k k_{ro}}{\mu_o B_o} \nabla (P_o + \rho g h) \right] + q_o = \frac{\partial}{\partial t} \left( \phi \frac{S_o}{B_o} \right) \quad (70)$$

Water:

$$\nabla \left[ \frac{k k_{rw}}{\mu_w B_w} \nabla (P_w + \rho g h) \right] + q_w = \frac{\partial}{\partial t} \left( \phi \frac{S_w}{B_w} \right) \quad (71)$$

Gas:

$$\begin{aligned} & \nabla \left[ \frac{k k_{rg}}{\mu_g B_g} \nabla (P_g + \rho g h) \right] \\ & + \nabla \left[ R_s \frac{k k_{ro}}{\mu_o B_o} \times \nabla (P_o + \rho g h) \right] + q_g \\ & = \frac{\partial}{\partial t} \left( \phi \frac{S_g}{B_g} + R_s \frac{\phi S_o}{B_o} \right) \quad (72) \end{aligned}$$

Total pressure gradient:

$$\frac{dP}{dx} = -g \rho_m(x) \sin(\theta) - \frac{\tau_w(x) S}{A} \quad (73)$$

Capillary pressure (oil/gas):

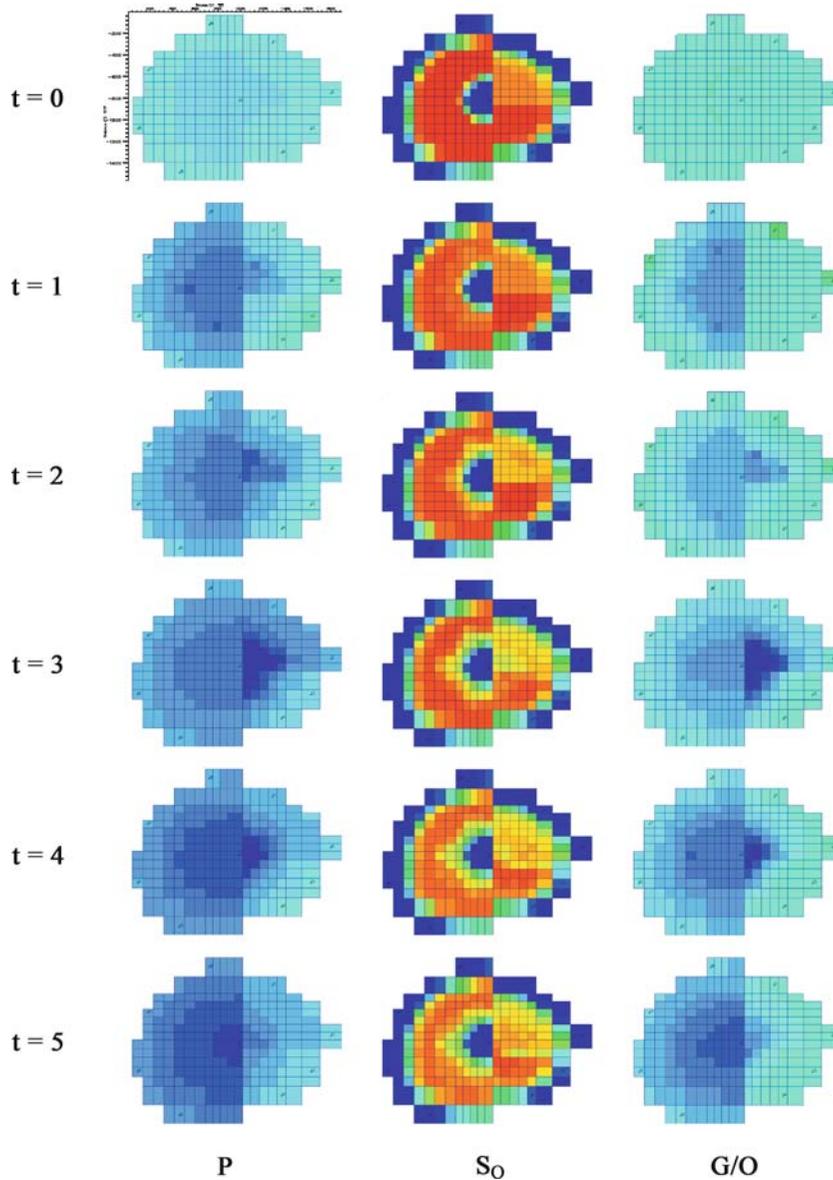

$$P_{cog}(S_o, S_g) = P_o - P_g \quad (74)$$

Capillary pressure (oil/water):

$$P_{cow}(S_o, S_w) = P_o - P_w \quad (75)$$

Multiphase mixture saturation:

$$S_o + S_w + S_g = 1 \quad (76)$$

Mixed Integer Optimization in Well Scheduling, Figure 14

Temporal evolution of pressure, oil saturation and gas/oil ratio in an oilfield: the gradual depletion of oil in reservoirs is explicitly considered for optimization (t:yr)

Multiphase mixture density:

$$\rho_m(x) = \rho_l(x)E_l(x) + \rho_g(x)E_g(x) \quad (77)$$

Multiphase mixture viscosity:

$$\mu_m(x) = \mu_l(x)E_l(x) + \mu_g(x)E_g(x) \quad (78)$$

Multiphase mixture sup. velocity:

$$U_m(x) = \frac{\rho_l(x)}{\rho_m(x)}U_{sl}(x) + \frac{\rho_g(x)}{\rho_m(x)}U_{sg}(x) \quad (79)$$

Multiphase mixture holdup closure:

$$E_g(x) + E_l(x) = 1 \quad (80)$$

Drift flux model (gas holdup):

$$E_g = f_d(U_{sl}, U_{sg}, \text{mixture properties}) \quad (81)$$

Choke model (for well & valve  $i$ ):

$$q_{L,i} = f_c(d_i, P_i(x_{ch}^-), P_i(x_{ch}^+), c_i, q_{g,i}, q_{w,i}) \quad (82)$$

**Mixed Integer Optimization in Well Scheduling, Table 11**  
Oil production optimization by explicit CFD simulation boundary conditions

Example 2a, Kosmidis et al. [20]	Total capacity	Via performance indices	With explicit reservoir simulation
Oil production (STB/day)	35000	29317.2	30193.7 (+2.9%)
Gas production (MSCF/day)	60000	60000	60000
Water production (STB/day)	14000	11294.3	11720.1 (+3.8%)

Choke setting (for well & valve  $i$ ):

$$c_i = \max(c_c, P_i(x_{ch}^-), P_i(x_{ch}^+)) \quad (83)$$

Performance (flow vs. pressure):

$$q_{j,i} = f_j(P_{wf,j,i}), \forall i \in I, \forall j \in \{o, w, g\}. \quad (84)$$

Reduced (1D) multiphase flow balances were solved using a fully implicit formulation and Newton's method, but only for the wells and not for the reservoir [18]. The present section uses: (a) explicit reservoir and well 3D multiphase flow simulation, (b) elimination of Eq. (84) (performance relations/preprocessing obsolete due to CFD), (c) CFD profiles as initial conditions (asynchronous fashion) for dynamic optimization. The MINLP optimization objective (maximize oil production) and model structure is adopted from the literature [20] via a gPROMS<sup>®</sup>-SLP implementation. Adopting an SQP strategy can increase robustness as well as computational complexity.

### Reservoir Multiphase Flow Simulation Results

Dynamic multiphase flow simulation results (ECLIPSE<sup>®</sup>) are presented in Fig. 14.

### Oil Production Optimization Results

Dynamic optimization via explicit CFD simulation of a particular oil field problem can improve on results from MINLP optimization: the comparison is presented in Table 11.

### Conclusions

A novel MINLP optimization formulation for the well scheduling problem has been proposed in this Chapter: the optimal connectivity of wells to manifolds and separators is treated simultaneously with the optimal well operation and gas lift allocation. The algorithm avoids examining infeasible connections of wells to manifolds or separators by incorporating appropriate integer cuts

in the formulation: these, along with the incorporation of operational logic constraints pertinent to the maximum number of well switches, lead to satisfactory computational performance: convergence has been achieved in less than 6 iterations in all cases examined. The business value of the new MINLP formulation has been investigated by comparing the proposed method with established heuristic rules, and an increase of up to 10% in oil production has been observed for the cases studied [18].

The combination of dynamic multiphase CFD simulation and MINLP optimization has the potential to yield improved solutions towards efficiently maximizing oil production. This Chapter also addresses integrated oilfield modeling and optimization, treating the oil reservoirs, wells and surface facilities as a combined system: most importantly, it stresses the benefit of computing accurate state variable profiles for reservoirs via CFD. Explicit CFD simulations via a dynamic reservoir simulator (ECLIPSE<sup>®</sup>, Schlumberger) are combined with equation-oriented process optimization software (gPROMS<sup>®</sup>, PSE): the key idea is to use reduced-order copies of CFD profiles for dynamic optimization. The literature problem solved shows that explicit use of CFD results in optimization yields improved optima at additional cost (CPU cost *and* cost for efficient separation of the additional water; the percentage difference is due to accurate reservoir simulation). These can also be evaluated systematically for larger case studies under various conditions [14].

## Background

### Mixed-Integer Programming

Mixed-Integer Programming (MIP) [5] emerged in the mid 1950s as an extension of Linear Programming (LP) to include both integer and continuous variables. It was developed to address a variety of problems (facility location, scheduling, design of plants and networks, etc.) where discrete decisions needed to be made. There are two main algorithms used to solve MIP models: branch-and-bound [5,31] and cutting planes. When the two solution methods are combined we have the branch-and-cut algorithm, where cutting planes are added until either an integral solution is found or it becomes impossible or too expensive to find another cutting plane. In the latter case, a traditional branch operation is performed and the search for cutting planes continues for the subproblems. Balas developed an algorithm for 0–1 problems to obtain dual bounds and check primal feasibility [3]. The idea of cutting planes was originally proposed by Gomory in [17], and a cutting plane algorithm was presented by Gomory in [18]. A general procedure for bounded programs was proposed by Chvatal in [13].

The results of Edmonds and Fulkerson in the late 1960s led several authors to propose other, specific types of cutting planes: cover inequalities [4,5], flow cover inequalities [4], and GUB constraints [51]. Due to the incorporation of these theoretical results, the efficiency of the commercial solvers has greatly been enhanced during the last decade. Advances in preprocessing, more sophisticated branching and node selection rules, as well as the use of primal heuristics have also contributed to the improvement of MIP solvers. Special techniques have also been used extensively for the solution of MIP problems, when the set of constraints exhibits a special structure. The most popular of these schemes are Benders decomposition [9] and Lagrangean relaxation [16,19]. More information on MIP can be found in [38], and [52], while an exposition in recent progress in solution techniques for MIP models can be found in [30].

### Constraint Programming

Constraint Programming [24,47] is a relatively new modeling and solution paradigm that was originally developed to solve feasibility problems, but it has been extended to solve optimization problems as well. Constraint Programming (CP) has emerged as a very interesting sub-field of logic programming that aims at combining the declarative aspect of logic programming and constraint solving in an efficient problem solving environment [29]. Optimization problems in Constraint Programming are solved as Constraint Satisfaction Problems (CSP), where we have a set of variables, a set of possible values for each variable (domain) and a set of constraints among the variables. Constraints are solved with methods and advanced techniques originating in various areas, from Artificial Intelligence, Operations Research and Discrete Mathematics. The computation domains handled by CP solvers are quite diverse, including Boolean algebra, linear programming, finite domains, and list and set handling. Successful industrial applications were implemented with CP solvers over finite domains in production planning, scheduling and resource applications [44]. Finite domain constraints are expressed over variables, which range over a finite set of possible values. Constraints may be arithmetic, symbolic or global constraints [1] that have been developed to efficiently model and solve complex problems. A CP program is usually structured as follows: (1) declaration of decision variables, (2) constraints and (3) the enumeration/optimization. The question to be answered is as follows: Is there an assignment of values to variables that satisfy all constraints? Constraint Programming is very expressive as continuous, integer, as well as boolean variables are permitted and moreover, variables can be indexed by other variables. A CP problem can be seen as a network of constraints. As soon as some information becomes available at some points in this network, constraints are invoked to check consistency and to remove inconsistent values by applying efficient handling methods. The new domain reductions are propagated through the network. The solution of CP models is based on performing constraint propagation at each node by reducing the domains of the variables. If an empty domain is found the node is pruned. Branching is performed whenever a domain of an integer, binary or boolean variable has more than one ele-

ment, or when the bounds of the domain of a continuous variable do not lie within a tolerance. Whenever a solution is found, or a domain of a variable is reduced, new constraints are added. The search terminates when no further nodes must be examined.

The effectiveness of CP depends on the propagation mechanism behind the constraints. Thus, even though many constructs and constraints are available, not all of them have efficient propagation mechanisms. For some problems, such as scheduling, propagation mechanisms have been proven to be very effective. Some of the most common propagation rules for scheduling are the “time-table” constraint [32], the “disjunctive-constraint” propagation [6,45], the “edge-finding” [12,39] and the “not-first, not-last” [7]. Constrained-based scheduling algorithms can be found in [8]. General information on CP can be found in [24,27,36,47].

## Methods

Several authors have compared MIP and CP based approaches for solving a variety of problems [21,26], and the main findings are as follows:

- MIP based techniques are very efficient when the LP relaxation is tight and the models have a structure that can be effectively exploited.
- CP based techniques are better for highly constrained discrete optimization problems.

Since the two approaches appear to have complementary strengths, in order to solve difficult problems that are not effectively solved by either of the two, several researchers have proposed models that integrate the two paradigms. The integration between MIP and CP can be achieved in two ways [26,48]:

- 1 By combining MIP and CP constraints into one hybrid model. In this case a hybrid algorithm that integrates constraint propagation with linear programming in a single search tree is also needed for the solution of the model (e. g. see [21,42]).
- 2 By decomposing the original problem into two subproblems: one MIP and one CP subproblem. Each model is solved separately and information obtained while solving one subproblem is used for the solution of the other subproblem [11,28].

Bockmayr and Kasper [10] have presented a unifying framework, called *Branch and Infer*, which can

be used for the development of various integration schemes. Hooker et al. [25] have proposed a new modeling paradigm to perform efficient integration of MIP and CP techniques. In general, it is not clear whether an integration strategy performs better than a standalone MIP or CP approach, especially when the problem at hand is solved effectively by one of the two approaches. For some problems, however, the integration of the two approaches has led to significant computational improvements. Common integration schemes include the derivation of cuts for MIP formulations using CP techniques, the use of CP to accelerate column generation, and the use of CP local search to solve MIP scheduling problems. Integration schemes are described in [21,23,26,27,37], and [48].

MIP/CP Hybrid Schemes are particularly successful for scheduling problems that often arise in manufacturing, chemical and food industry, in transportation industries and in computing environments. To solve a scheduling problem one has to (i) allocate limited resources to tasks, and (ii) sequence the tasks allocated to a single resource. We will refer to the first set of decisions as the *assignment* problem, and the second set of decisions as the *sequencing* problem.

While heuristic methods are widely used, rigorous optimization methods have also been studied. To solve some hard scheduling problems to optimality, several authors have proposed MIP/CP hybrid schemes that exploit the complementary strengths of Mathematical and Constraint Programming. The main idea behind these approaches is to solve a relaxed MIP model to determine the allocation of machines to tasks, and use CP to check the feasibility of a given assignment and to generate cuts that are added in the relaxed MIP model. Thus, the complementary strengths of the two methods are combined: Mathematical Programming is used for optimization (i. e. identify potentially good assignments) and Constraint Programming to check feasibility.

## Applications

A scheduling problem that has been widely studied using hybrid schemes is the Multi-Machine Assignment Scheduling Problem (MMASP) with Release and Due Times. In this problem a set  $I$  of  $N$  jobs have to be processed on a set  $J$  of  $M$  machines; the processing of job

$i \in I = \{1, \dots, N\}$  on any machine  $j \in J = \{1, \dots, M\}$ , must start after its release time  $r_i$  and must be completed before its due time  $d_i$ ; the processing time and processing cost of job  $i \in I$  on machine  $j \in J$  are  $P_{ij}$ , and  $C_{ij}$  respectively. The objective is to minimize the total processing cost. The MMSAP was first studied by Hooker et al. [22] in a hybrid optimization framework.

A MIP model (M) for the MMASP consists of constraints (1)–(6):

$$\min Z = \sum_{i \in I} \sum_{j \in J} C_{ij} x_{ij} \quad (1)$$

$$\sum_{j \in J} x_{ij} = 1 \quad \forall i \in I \quad (2)$$

$$s_i \geq r_i \quad \forall i \in I \quad (3)$$

$$s_i + \sum_{j \in J} P_{ij} x_{ij} \leq d_i \quad \forall i \in I \quad (4)$$

$$y_{ii'} + y_{i'i} \geq x_{ij} + x_{i'j} - 1 \\ \forall j \in J, \forall i \in I, \forall i' \in I | i < i' \quad (5)$$

$$s_i + \sum_{j \in J} P_{ij} x_{ij} \leq s_{i'} + M(1 - y_{ii'}) \\ \forall i \in I, \forall i' \in I | i \neq i' \quad (6)$$

where binary  $x_{ij}$  is 1 if job  $i$  is assigned to machine  $j$ , binary  $y_{ii'}$  is 1 if job  $i$  is scheduled before job  $i'$  in the same machine, and  $s_i$  is the start time of processing of job  $i$ .

Constraint (2) ensures that each job is processed on exactly one machine. Constraints (3) and (4) restrict each job to start after its release, and finish before its due time, respectively. Constraint (5) imposes the condition that if both jobs  $i$  and  $i'$  are assigned to the same machine  $j$  (i. e.  $x_{ij} + x_{i'j} - 1 = 1$ ), then jobs  $i$  and  $i'$  must be sequenced (i. e.  $y_{ii'} = 1$  or  $y_{i'i} = 1$ ). Constraint (6) is a big-M sequencing constraint that is active when  $y_{ii'}$  is 1.

Hooker et al. [22] and Jain and Grossmann [28] showed that model (M) is not efficient, due to the poor LP relaxation caused by the big-M sequencing constraint (6). Furthermore, they showed that standalone CP models are not efficient either, due to the large number of different assignments. To overcome this, the authors proposed a scheme where an IP master problem

and a CP subproblem are solved iteratively. The IP master problem is a relaxation of model (M) and it is used to determine an assignment. The CP subproblem is used to check feasibility of the current assignment; if infeasible, integer cuts are added and the IP master problem is re-solved; if feasible, the subproblem gives a feasible sequence, and the algorithm terminates. The IP master problem consists of constraints (1)–(2), (7) and the integer cuts that are added at each iteration. Constraint (7) is used to eliminate infeasible assignments:

$$\sum_{i \in I} P_{ij} x_{ij} \leq \max_{i \in I} \{d_i\} - \min_{i \in I} \{r_i\} \quad \forall j \in J \quad (7)$$

The IP master problem does not include the sequencing binary variables  $y_{ii'}$  and big-M constraint (6), it is solved fast, and at iteration  $k$ , yields a complete job-machine assignment  $\mathbf{x}^k$ . The CP subproblem is then used to check whether the current assignment  $\mathbf{x}^k$  is feasible. At each iteration  $k$ , the set  $I_j^k$  of jobs assigned on machine  $j \in J$ , the processing time  $\bar{P}_i^k$  of each job, and the domain  $D_i^k$  for the start time of job  $i$  (i. e.  $s_i \in D_i^k$ ) are given by (8)–(10), respectively:

$$I_j^k = \{i | x_{ij}^k = 1\} \quad \forall j \in J \quad (8)$$

$$\bar{P}_i^k = \sum_{j \in J} P_{ij} x_{ij}^k \quad \forall i \in I \quad (9)$$

$$D_i^k = [r_i, d_i - \bar{P}_i^k] \quad \forall i \in I \quad (10)$$

Thus, the CP subproblem reduces to  $|J|$  one-machine independent problems, and for each one of these problems we try to find a sequence of jobs in  $I_j^k$  that satisfies constraint (10) and the non-overlapping of jobs assigned to machine  $k$  (see (5) and (6)). This problem can be solved using the global constraint *cumulative* [1], and various propagation techniques (time-table, disjunctive, edge-finding, etc.).

$$\text{cumulative}_{i \in O} ((s_i, d_i, r_i), l, e) \quad (11)$$

The basic version of *cumulative*, (see detailed examples in [2]) takes 3 arguments, argument 1 is the set of operations  $O$  where each operation is characterized by three parameters, which can be either domain variables or values; the starting time  $s_i$ , the duration  $d_i$ , and the amount of some resource  $r_i$  used by the operation. The second argument  $l$  is the upper bound on the resource

consumption. The third argument  $e$  is the completion time. In this case, Eq. (11) can be written as follows:

$$\text{cumulative}_{i \in I_j} \left( (s_i, \bar{P}_i^k, 1), 1, \max_{i \in I_j} \{d_i\} \right) \quad (12)$$

The global cumulative constraint is satisfied if the following conditions hold:

$$\sum_{i \in O: s_i \leq t \leq s_i + d_i, t \in 1..l} r_i \leq l \quad \text{AND} \quad \max_{i \in O} (s_i + d_i) \leq e \quad (13)$$

If there is no sequence for machine  $j$  that satisfies constraint (12), then the current assignment  $\mathbf{x}^k$  is infeasible. For every infeasible one-machine problem we add the following integer cut in the cut-pool of the master problem:

$$\sum_{i \in I_j^k} x_{ij} \leq |I_j^k| - 1 \quad (14)$$

If the IP master problem is solved to optimality, the lower bound provided by the optimal solution  $Z^k$  of the IP is non-decreasing, and the first feasible assignment is the assignment that yields the optimal solution with a minimum assignment cost. A schematic of the proposed algorithm is given in Fig. 1. The hybrid iterative approach was shown to be considerably faster than standalone MIP and CP models.

The above hybrid decomposition can also be implemented in a branch-and-cut framework (B&C), where the IP master problem is not solved to optimality before adding cuts. In the B&C framework, cuts are added either at a (possibly suboptimal) integer solution to the master problem or a *partially* feasible node, i. e. a node with integer assignments for a subset of machines.

Bockmayr and Pizaruk [11] proposed a hybrid branch-and-cut scheme where the master problem is solved using an IP solver and the CP solver is called at a node of the tree, in order to generate integer cuts. The advantage of this method is that the IP model is not solved from scratch every time an integer solution (i. e. an assignment) is found. Furthermore, the authors were able to obtain cuts that are stronger than the ones proposed by Jain and Grossmann [28]. They were also able to generate cuts from fractional LP solutions of the IP model. The computational performance

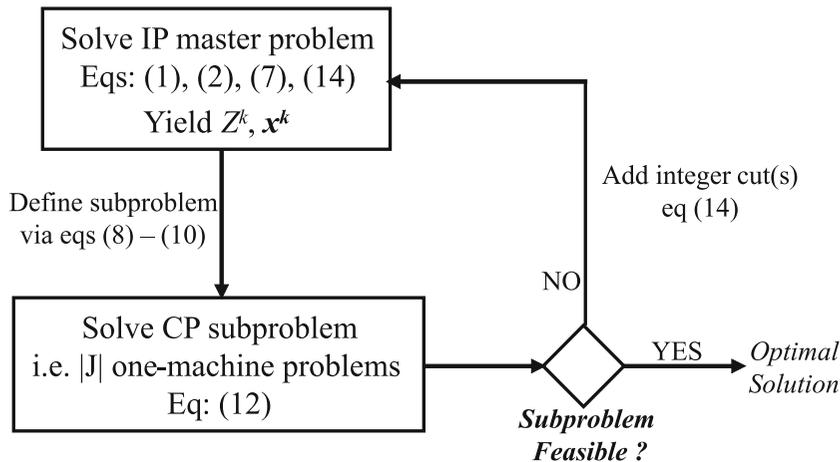

of the proposed hybrid branch-and-cut approach is better than the iterative IP/CP approach. Vazacopoulos and Verma [49] proposed certain Disjunctive and preemptive cuts to a priori forbid infeasible assignments and developed two hybrid MIP/CP algorithms for the MMASP. Sadykov and Wolsey [43] studied several hybrid approaches and developed two IP/CP hybrid schemes that appear to be better than those previously proposed. In the first, the authors were able to develop two classes of tightening inequalities, in the space of  $x_{ij}$  variables, which exclude many infeasible assignments and thus lead to smaller trees. The tightening inequalities are knapsack constraints, similar to constraint (7), but for subsets of set  $I$ . They also proposed a column generation algorithm using the tightening inequalities.

While the MMASP has been extensively studied due to its simple structure, hybrid schemes have also been developed for more complex scheduling problems. Harjunkoski and Grossmann [20], Timpe [46] and Constantino [14] presented hybrid schemes for complex chemical plants. Maravelias and Grossmann [33,34] proposed a general framework for integrating Mathematical and Constraint Programming methods for the solution of scheduling problems, while Maravelias [35] proposed the integration of MIP methods with heuristic algorithms. Hybrid methods that combine Mathematical and Constraint Programming have also been applied to transportation, inventory management and resource allocation problems.

## Conclusions

While the computational efficiency of MIP/CP methods varies significantly, there is evidence that for some classes of problems they outperform existing methods. In general, if the structure of the problem at hand is exploited by efficient preprocessing and the generation of strong cuts, it is expected that hybrid schemes will be more effective because they combine the complementary strengths of two solution techniques.

The computational performance of hybrid methods relies on (i) the quality of the decomposition, (ii) the solution efficiency of the two subproblems, and (iii) the number of subproblems needed to be solved to prove optimality. Ideally, the original problem should be decomposed/reformulated into a tight MIP subproblem that is easily solved yielding potentially good feasible

**Mixed Integer Programming/Constraint Programming Hybrid Methods, Figure 1**  
Iterative hybrid IP/CP scheme of Jain and Grossmann [28]

solutions, and a feasibility CP subproblem that is used to check feasibility and generate cuts.

In particular, MIP/CP methods have been shown to be very effective in tackling scheduling problems where both assignment and sequencing decisions have to be made. The key idea in these methods is the decomposition of the original problem into two sub problems; Mathematical Programming is used for the assignment of tasks to resources, while Constraint Programming is used for the sequencing of tasks on resources.

## Abstract

This chapter presents model based controllers for two drug delivery systems: (i) surgery under anesthesia and (ii) insulin delivery for type 1 diabetes. For anesthesia, a compartmental model is presented and then used for deriving model predictive controller for simultaneous control of mean arterial pressure (MAP), cardiac output (CO) and hypnosis. For type 1 diabetes, parametric control techniques are used for obtaining insulin delivery rate as an explicit function of the state of the patient. This reduces the implementation of the model based controller to function evaluations that can be carried out on a portable computational hardware.

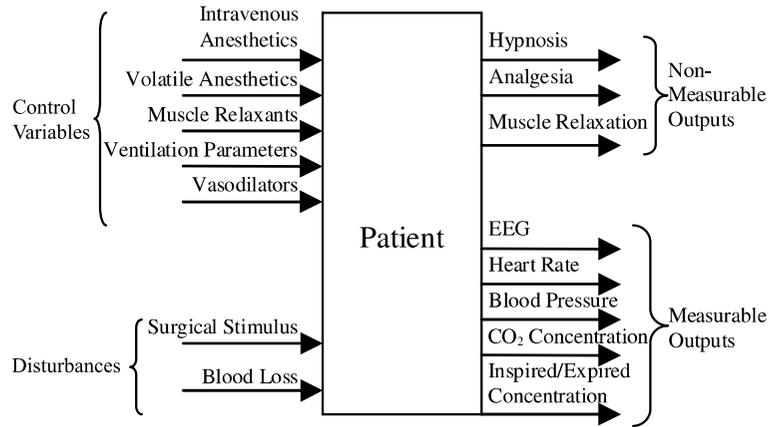

## Introduction

Drug delivery systems aim to provide effective therapy by minimizing side effects, reducing deviations from the desired state of the patient and increasing patient compliance and safety. Automation of a drug delivery system relies on the mathematical model of the patient that can take into account the pharmacokinetic and pharmacodynamic effects of the drugs on various organs of the body. To reduce the complexity of the mathematical model, some of the organs are lumped

and then represented as interconnected compartments. This reduction in complexity is quite important especially for models that are used for controlling the amount of drugs to be infused. In this chapter, models and advanced model based controllers for two drug delivery systems are presented. In Sect. “Surgery Under Anesthesia”, the first system which is concerned with the delivery of anesthetics for patients undergoing surgery is discussed. A compartmental model is presented that considers a choice of three drugs, isoflurane, dopamine and sodium nitroprusside, and therefore allows simultaneous control of mean arterial pressure, cardiac output and hypnosis. This model is then used for designing model predictive controller and the performance of the controller is tested for its set-point tracking capabilities. In Sect. “Blood Glucose Control for Type 1 Diabetes” model based parametric controller for the regulation of the blood glucose concentration for people with type 1 diabetes is derived. The key advantage of this controller is that the optimal drug infusion rate is obtained as an explicit function of the state of the patient and therefore requires simple function evaluations for its implementation. Concluding remarks are presented in Sect. “Concluding Remarks”.

## Surgery Under Anesthesia

Anesthesia is defined as the absence or loss of sensation. In order to provide safe and adequate anesthesia, the anesthesiologist must guarantee analgesia, provide hypnosis, muscle relaxation and maintain vital functions of the patient. Anesthesiologists administer anesthetics and monitor a wide range of vital functions, such as mean arterial pressure (MAP), heart rate, cardiac output (CO). These vital functions need to be monitored and maintained within tolerable operating ranges by infusing various drugs and/or intravenous fluids as shown in Fig. 1. Automation of anesthesia is desirable as it will provide more time and flexibility to the anesthesiologist to focus on critical issues, monitor the conditions that cannot be easily measured and overall improve patient's safety. Also, the cost of the drugs will be reduced and shorter time will be spent in the post-operative care unit. There is a significant amount of research in the area of developing models and control strategies for anesthesia [10,14,15,17]. Gentilini et

Model Based Control for Drug Delivery Systems, Figure 1  
Anesthesia control system (adapted from [6])

al. [6] proposed a model for the regulation of MAP and hypnosis with isoflurane. It was observed that controlling both MAP and hypnosis simultaneously with isoflurane was difficult. Yu et al. [16] proposed a model for regulating MAP and CO using dopamine (DP) and sodium nitroprusside (SNP), but the control of hypnosis was not considered.

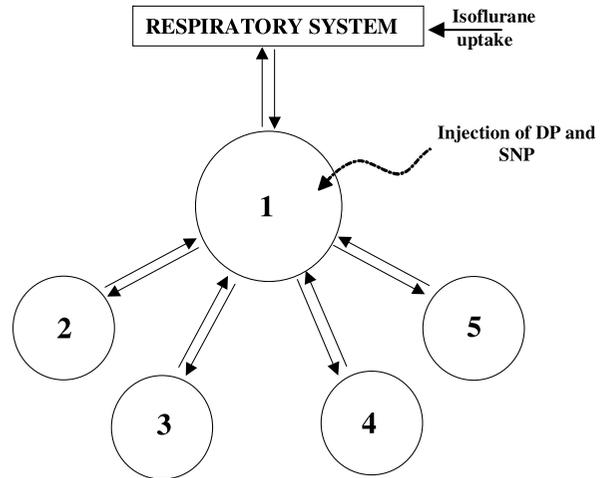

In the next section, a compartmental model is presented, which allows the simultaneous regulation of the MAP and the unconsciousness of the patients. The model is characterized by: (i) pharmacokinetics for the uptake and distribution of the drugs, (ii) pharmacodynamics which describes the effect of the drugs on the vital functions and (iii) baroreflex for the reaction of the central nervous system to changes in the blood pressure. The model involves choice of three drugs, isoflurane, DP and SNP. This combination of drugs allows simultaneous regulation of MAP and hypnosis.

### Modeling Anesthesia

The model is based on the distribution of isoflurane in the human body [15]. It consists of five compartments organized as shown in Fig. 2.

The compartments 1–5 represent lungs, vessel rich organs (e.g. liver), muscles, other organs and tissues and fat tissues respectively.

The distribution of the drugs occurs from the central compartment to the peripheral compartments by the arteries and from the peripheral to the central by the veins. The first compartment in Fig. 2 is the central

Model Based Control for Drug Delivery Systems, Figure 2  
Compartmental model

compartment and heart can be considered to be belonging to the central compartment, whereas compartments 2–5 are the peripheral compartments.

**Pharmacokinetic Modeling** The uptake of isoflurane in central compartment via the respiratory system is modeled as:

$$V \frac{dC_{\text{insp}}}{dT} = Q_{\text{in}} C_{\text{in}} - (Q_{\text{in}} - \Delta Q) C_{\text{insp}} - f_R (V_T - \Delta) (C_{\text{insp}} - C_{\text{out}}),$$

where  $C_{\text{insp}}$  is the concentration of isoflurane inspired by the patient (g/ml),  $C_{\text{in}}$  is the concentration of isoflu-

rane in the inlet stream (g/ml),  $C_{out}$  is the concentration of isoflurane in the outlet stream (g/ml),  $Q_{in}$  is the inlet flow rate (ml/min),  $\Delta Q$  is the losses (ml/min),  $V$  is the volume of the respiratory system (l),  $f_R$  is the respiratory frequency (l/min),  $V_T$  is the tidal volume (l) and  $\Delta$  is the physiological dead space (ml). For the central compartment, the concentration of isoflurane is given by:

$$V_1 \frac{dC_1}{dt} = \sum_{i=2}^5 \left( Q_i \left( \frac{C_i}{R_i} - C_1 \right) \right) + f_R (V_T \Delta) (C_{insp} C_1),$$

where  $C_i$  is the concentration of the drug in compartment  $i$  (g/ml),  $R_i$  is the partition coefficient between blood and tissues in compartment  $i$ ,  $Q_i$  is the blood flow in compartment  $i$  (ml/min). The concentration of DP and SNP in the central compartment is modeled as follows:

$$V_1 \frac{dC_1}{dt} = \sum_{i=2}^5 \left( Q_i \left( \frac{C_i}{R_i} - C_1 \right) \right) + C_{inf} - \frac{1}{\tau_{1/2}} C_1 V_1,$$

where  $C_{inf}$  is the concentration of the drug infused (g/min),  $V_i$  is the volume of compartment  $i$  (ml) and  $\tau_{1/2}$  is the half-life of the drug (min). Isoflurane is eliminated by exhalation and metabolism in liver, the 2nd compartment, as follows:

$$V_2 \frac{dC_2}{dt} = Q_2 \left( C_1 - \frac{C_2}{R_2} \right) - k_{20} C_2 V_2,$$

where  $k_{20}$  is the rate of elimination of isoflurane in the 2nd compartment ( $\text{min}^{-1}$ ). The distribution of isoflurane in compartments 3 to 5 is given by:

$$V_i \frac{dC_i}{dt} = Q_i \left( C_1 - \frac{C_i}{R_i} \right), \quad i = 3, \dots, 5.$$

The natural decay of DP and SNP in the body, for compartment 2 to 5, is given by:

$$V_i \frac{dC_i}{dt} = Q_i \left( C_1 - \frac{C_i}{R_i} \right) - \frac{1}{\tau_{1/2}} C_i V_i, \quad i = 2, \dots, 5.$$

**Pharmacodynamic Modeling** The effect of DP and SNP on two of the heart's characteristic parameters:

maximum elastance ( $E_{max}$ ) and systemic resistance ( $R_{sys}$ ) is given by:

$$\begin{aligned} \frac{d\text{Eff}}{dt} &= k_1 C_1^N (\text{Eff}_{max} - \text{Eff}) - k_2 \text{Eff} \\ E_{max} &= E_{max,0} (1 + \text{Eff}_{DP-E_{max}}) \\ R_{sys} &= R_{sys,0} (1 - \text{Eff}_{DP-R_{sys}} - \text{Eff}_{SNP-R_{sys}}), \end{aligned}$$

where Eff is the measure of the effect of drug on the parameters of interest,  $R_{sys}$  is the systemic resistance (mmHg/(ml/min)),  $E_{max}$  is the maximum elastance (mmHg/ml),  $E_{max,0}$  is nominal maximum elastance,  $R_{sys,0}$  is nominal systemic resistance,  $\text{Eff}_{DP-E_{max}}$  is effect of DP on  $E_{max}$ ,  $\text{Eff}_{DP-R_{sys}}$  is effect of DP on  $R_{sys}$ ,  $\text{Eff}_{SNP-R_{sys}}$  is the effect of SNP on  $R_{sys}$ ,  $k_1$ ,  $k_2$  are the rate constants and  $N$  is the non-linearity constant. MAP can then be expressed as a function of  $E_{max}$  and  $R_{sys}$  as:

$$\text{MAP}^2 \frac{1}{R_{sys}^2} + 2K^2 \text{MAP} - 2K^2 V_{LV} E_{max} = 0$$

$$K = \frac{A_{aorta} A_{LV}}{\sqrt{\rho} \sqrt{A_{LV}^2 - A_{aorta}^2}},$$

where MAP is the mean arterial pressure (mmHg),  $A_{aorta}$  is the cross sectional area of the aorta ( $\text{cm}^2$ ),  $A_{LV}$  is the cross sectional area of the left ventricle ( $\text{cm}^2$ ),  $V_{LV}$  is the mean volume of the left ventricle (ml) and  $\rho$  is the blood density (g/ml). Isoflurane affects MAP as follows:

$$\text{MAP} = \frac{Q_1}{\sum_{i=2}^5 (g_{i,0} (1 + b_i C_i))},$$

where,  $g_{i,0}$  is the baseline conductivities (ml/(min.mmHg)) and  $b_i$  is the variation coefficient of conductivity (ml/g). There is experimental evidence that a transportation delay exists between the lungs and the site of effect of isoflurane on the unconsciousness of the patient. In order to model this, an effect compartment is linked to the central compartment. The concentration of isoflurane within this compartment is related to the central compartment, which is given by:

$$\frac{dC_e}{dt} = k_{e0} (C_1 - C_e),$$

where  $C_e$  is the concentration of isoflurane in the effect compartment (g/ml), and  $k_{e0}$  is the kinetics in the effect compartment ( $\text{min}^{-1}$ ). The action of isoflurane can be

then expressed as follows:

$$\begin{aligned}\Delta \text{BIS} &= \Delta \text{BIS}_{\text{MAX}} \frac{C_e^\gamma}{C_e^\gamma + \text{EC}_{50}^\gamma} \\ \Delta \text{BIS} &= \text{BIS} - \text{BIS}_0 \\ \Delta \text{BIS}_{\text{MAX}} &= \text{BIS}_{\text{MAX}} - \text{BIS}_0,\end{aligned}$$

where  $\text{BIS}_0$  is the baseline value of BIS (assumed to be 100),  $\text{BIS}_{\text{MAX}}$  is the maximum value of BIS (assumed to be 0),  $\text{EC}_{50}$  is the patient's sensitivity to the drug and  $\gamma$  is the measure of the degree of non-linearity.

**Baroreflex** Baroreflex is obtained from a set of transfer functions relating the mean arterial pressure to the maximum elastance and the systemic resistance and is given by:

$$\text{bfc} = \frac{e^{c(\text{MAP}-\text{MAP}_0)}}{1 + e^{c(\text{MAP}-\text{MAP}_0)}},$$

where  $c$  is the empirical constant (mmHg).

### Control of Anesthesia

The model presented in the previous section was validated by carrying out a number of dynamic simulations for different amounts of drug dosages and disturbances using gPROMS [7]. For designing controllers, this model was linearized at the nominal values of inputs: 0.6% vol. of isoflurane, 2  $\mu\text{g}/\text{kg}/\text{min}$  of DP and 4  $\mu\text{g}/\text{kg}/\text{min}$  of SNP and outputs: 57.38 mmHg of MAP, 61.1 BIS and 1.21 l/min of CO, to obtain a state-space model of the following form:

$$\begin{aligned}x_{t+1} &= Ax_t + Bu_t \\ y_t &= Cx_t + Du_t,\end{aligned}\quad (1)$$

subject to the following constraints:

$$\begin{aligned}x_{\min} &\leq x_t \leq x_{\max} \\ y_{\min} &\leq y_t \leq y_{\max} \\ u_{\min} &\leq u_t \leq u_{\max},\end{aligned}\quad (2)$$

where  $x_t \in R^n$ ,  $y_t \in R^l$ ,  $u_t \in R^m$ , are the state, output and input vectors respectively and the subscripts min and max denote lower and upper bounds respectively.

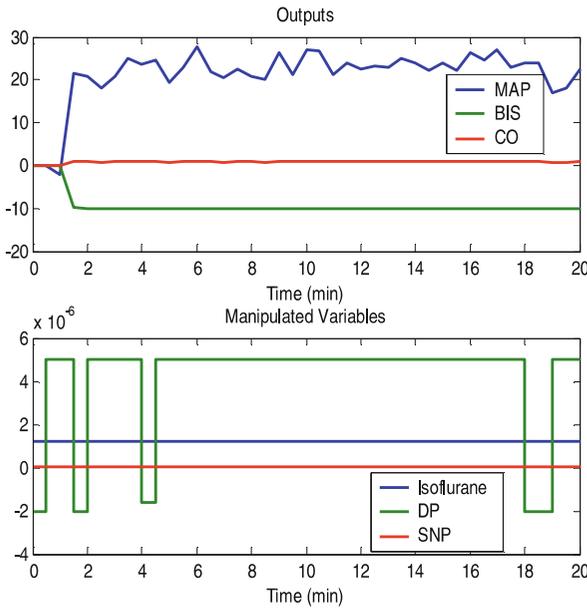

Model predictive control (MPC) [5] problem can then be posed as the following optimization problem:

$$\begin{aligned}\min_U J(U, x(t)) &= x_{t+N_y|t}^T P x_{t+N_y|t} \\ &+ \sum_{k=0}^{N_y-1} \left[ x_{t+k|t}^T Q x_{t+k|t} + u_{t+k}^T R u_{t+k} \right] \\ \text{s.t. } x_{\min} &\leq x_{t+k|t} \leq x_{\max}, \quad k = 1, \dots, N_c \\ y_{\min} &\leq y_{t+k|t} \leq y_{\max}, \quad k = 1, \dots, N_c \\ u_{\min} &\leq u_{t+k} \leq u_{\max}, \quad k = 1, \dots, N_c \\ x_{t+k+1|t} &= Ax_{t+k|t} + Bu_{t+k}, \quad k \geq 0 \\ y_{t+k|t} &= Cx_{t+k} + Du_{t+k}, \quad k \geq 0 \\ u_{t+k} &= Ku_{t+k|t}, \quad N_u \leq k \leq N_y,\end{aligned}\quad (3)$$

where  $U = [u_t^T, \dots, u_{t+N_u-1}^T]^T$ ,  $Q$  and  $R$  are constant, symmetric and positive definite matrices,  $P$  is given by the solution of the Riccati or Lyapunov equation,  $N_y$ ,  $N_u$  and  $N_c$  are the prediction, control and constraint horizons respectively and the superscript  $T$  denotes transpose of the vector. Problem (3) is solved at each time  $t$  for the current state  $x_t$  and the vector of predicted state variables,  $x_{t+1|t}, \dots, x_{t+N_y|t}$  at time  $t+1, \dots, t+k$  respectively and corresponding control actions  $u_t, \dots, u_{t+k}$  are obtained.

### Results

The model for anesthesia consists of 23 states, 3 outputs and 3 inputs. This state-space form of the model is then adapted for designing model predictive controller by using the MATLAB Model Predictive Control Toolbox™ [11]. For designing the MPC controller, the following input:  $0 \leq \text{DP} \leq 7 \mu\text{g}/\text{kg}.\text{min}$ ,  $0 \leq \text{SNP} \leq 10 \mu\text{g}/\text{kg}.\text{min}$ ,  $0 \leq \text{Isoflurane} \leq 5\% \text{vol.}$ , and output constraints:  $40 \leq \text{MAP} \leq 150 \text{mmHg}$ ,  $40 \leq \text{BIS} \leq 65$ ,  $1 \leq \text{CO} \leq 6.5 \text{l}/\text{min}$  are used. A prediction horizon of 5, control horizon of 3 and sampling time of 0.5 minutes are considered. A set point of [20–10 1]' deviation from the nominal point of the output variables is given and the performance of the controller is shown in Fig. 3. It is observed that the MPC tracks the set point quite well. The performance of the MPC was also tested by reducing the model to 15 states and was observed to be very good. From the above results it can be inferred that the model based control technology provides a promising platform for the automation of anesthesia.

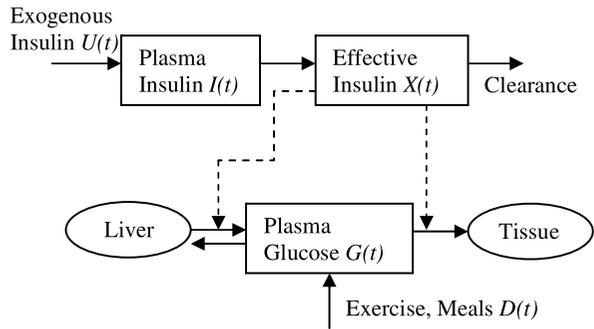

**Model Based Control for Drug Delivery Systems, Figure 3**  
MPC performance for anesthesia

Note that MPC solves a quadratic program at regular time intervals. In the next section a parametric programming approach for control of blood glucose for type 1 diabetes is presented that does not require repetitively solving quadratic programs.

**Blood Glucose Control for Type 1 Diabetes**

Diabetes is a disease that affects the body’s ability to regulate glucose. In Type 1 diabetes, the pancreas produces insufficient insulin, and exogenous insulin is required to be infused at an appropriate rate to maintain blood sugar levels within the range of 60–120 mg/dl [2]. If insulin is supplied in excess, the blood glucose level can go well below normal (< 60 mg/dl), a condition known as *hypoglycemia*. On the other hand, if insulin is not supplied sufficiently, the blood glucose level is elevated above normal (> 120 mg/dl), a condition known as *hyperglycemia*. Both hypo- and hyperglycemia can be harmful to an individual’s health. Hence, it is very important to control the level of blood glucose in the body to within a reasonable range [9,12]. In the following sections, advanced model based controllers for regulating the blood glucose concentration for type 1 diabetes are presented.

**Model Based Control for Drug Delivery Systems, Figure 4**  
Schematic representation of the Bergman model

**Model for Type 1 Diabetes**

The Bergman model [1] is used in this study, which presents a ‘minimal’ model comprising 3 equations to describe the dynamics of the system. The schematic representation of the model is shown in Fig. 4. The modeling equations are:

$$\frac{dG}{dt} = -P_1G - X(G + G_b) + D(t) \tag{4}$$

$$\frac{dI}{dt} = -n(I + I_b) + U(t)/V_1 \tag{5}$$

$$\frac{dX}{dt} = -P_2X + P_3I. \tag{6}$$

The states in this model are:  $G$ , plasma glucose concentration (mg/dl) relative to basal value,  $I$ , plasma insulin concentration (mU/l) relative to basal value, and  $X$ , proportional to  $I$  in remote compartment ( $\text{min}^{-1}$ ). The inputs are:  $D(t)$ , meal glucose disturbance (mg/dl/min),  $U(t)$ , manipulated insulin infusion rate (mU/min) and  $G_b, I_b$ , nominal values of glucose and insulin concentration (81 mg/dl; 15 mU/l). The parameter values for a Type 1 diabetes are:  $P_1 = 0 \text{ min}^{-1}$ ,  $P_2 = 0.025 \text{ min}^{-1}$ ,  $P_3 = 0.000013 \text{ l/mUmin}^2$ ,  $V_1 = 12 \text{ l}$  and  $n = 5/54 \text{ min}$  [4].

The model, (4)–(6) is linearized about the steady-state values of  $G_b = 81 \text{ mg/dl}$ ,  $I_b = 15 \text{ mU/l}$ ,  $X_b = 0$  and  $U_b = 16.66667 \text{ mU/min}$  to obtain the state space model of the form:  $x_{t+1} = Ax_t + Bu_t + B_d d_t$  where the term  $d_t$  represents the input disturbance glucose meal. The sampling time considered is 5 minutes, which is reasonable for the current glucose sensor technology. The discrete state-space matrices  $A, B, C$  and  $B_d$

are as follows:

$$A = \begin{bmatrix} 1 & -0.000604 & -21.1506 \\ 0 & 0.6294 & 0 \\ 0 & 0.00004875 & 0.8825 \end{bmatrix}$$

$$B = \begin{bmatrix} -0.000088 \\ 0.3335 \\ 0.0000112 \end{bmatrix},$$

$$C = [1 \ 0 \ 0], \quad B_d = \begin{bmatrix} 5 \\ 0 \\ 0 \end{bmatrix}$$

The constraints imposed are  $60 \leq G + G_b \leq 180$  and  $0 \leq U + U_b \leq 100$ .

### Parametric Controller

Parametric programming can be used in the MPC framework to obtain  $U$  as a function of  $x_t$  by treating  $U$  as optimization variables and  $x_t$  as parameters as described next [3,13]. For simplicity in presentation assume that  $N_y = N_u = N_c$ , the theory presented is however valid for the case when  $N_y$ ,  $N_u$  and  $N_c$  are not equal. The equalities in formulation (3) are eliminated by making the following substitution:

$$x_{t+k|t} = A^k x_t + \sum_{j=0}^{k-1} A^j B u_{t+k-1-j} \quad (7)$$

to obtain the following Quadratic Program (QP):

$$\min_U \frac{1}{2} U^T H U + x_t^T F U + \frac{1}{2} x_t^T Y x_t \quad (8)$$

$$s.t. G U \leq W + E x_t,$$

where,  $U = [u_t^T, \dots, u_{t+N_u-1}^T]^T \in R^s$ , is the vector of optimization variables,  $s = m N_u$ ,  $H$  is a constant, symmetric and positive definite matrix and  $H, F, Y, G, W, E$  are obtained from  $Q, R$  and (1) and (2).

The QP problem in (8) can now be reformulated as a multi-parametric quadratic program (mp-QP):

$$V_z(x) = \min_z \frac{1}{2} z^T H z \quad (9)$$

$$s.t. G z \leq W + S x_t,$$

where,  $z = U + H^{-1} F^T x_t$ ,  $z \in R^s$ , and  $S = E + G H^{-1} F^T$ .

This mp-QP is solved by treating  $z$  as the vector of optimization variables and  $x_t$  as the vector of parameters to obtain  $z$  as an explicit function of  $x_t$ .  $U$  is then obtained as an explicit function of  $x_t$  by using  $U = z - H^{-1} F^T x_t$ .

### Results

A prediction horizon  $N_y = 5$  and  $Q/R$  ratio of 1000 is considered for deriving the control law – this results in partitioning of the state-space into 31 polyhedral regions. These regions are known as Critical Regions (CR). Associated with each CR is a control law that is an affine function of the state of the patient. For example, one of the CRs is given by the following state inequalities:

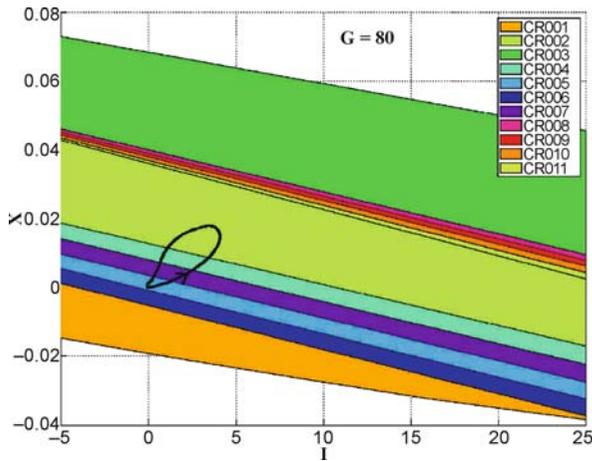

$$\begin{aligned} -5 &\leq I \leq 25 \\ 0.0478972G - 0.0002712I - X &\leq 0.104055 \\ 0.0261386G - 0.0004641I - X &\leq 0.0576751 \\ -0.00808846G + 0.00119685I + X &\leq 0 \\ -0.00660123G + 0.00130239I + X &\leq 0 \\ 0.00609435G - 0.00134362I - X &\leq 0 \end{aligned} \quad (10)$$

where the insulin infusion rate as a function of the state variables for the next five time intervals is given as follows:

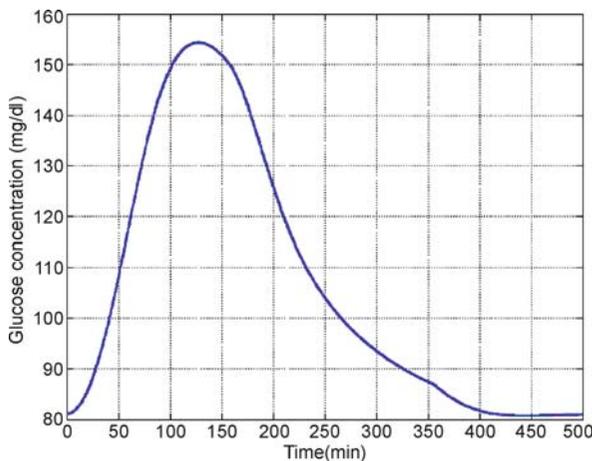

$$\begin{aligned} U(1) &= 30.139G - 0.44597I - 3726.2X \\ U(2) &= 24.874G - 0.40326I - 3280.4X \\ U(3) &= 20.16G - 0.35946I - 2842.8X \\ U(4) &= 16.002G - 0.31571I - 2424.1X \\ U(5) &= 0 \end{aligned} \quad (11)$$

The complete partitioning of the state-space for  $G = 80$  mg/dl into CRs is shown in Fig. 5. The performance of the parametric controller for a 50 mg meal disturbance [8] is as shown in Figs. 6 and 7. The corresponding trajectory of the state variables is also shown in Fig. 5.

The model based parametric controller of the form given in (10) and (11) can be stored and implemented on a simple computational hardware and therefore can provide effective therapy at low on-line computational costs.

Critical regions for type 1 diabetes

Model Based Control for Drug Delivery Systems, Figure 6  
Glucose concentration vs. time

### Concluding Remarks

Automation of drug delivery systems aims at reducing patient inconvenience by providing better and personalized healthcare. The automation can be achieved by developing detailed models and by deriving advanced controllers that can take into account the model as well as the constraints on state and control variables. In this chapter, a compartmental model incorporating pharmacokinetic and pharmacodynamic aspects for delivery of anesthetic agents has been presented. This model was then used for the derivation of model predictive controller. For type 1 diabetes, implementation of advanced model based controllers through a simple com-

Model Based Control for Drug Delivery Systems, Figure 7  
Insulin infusion vs. time

putational hardware was demonstrated by deriving insulin delivery rate as an explicit function of the state of patient. The developments presented in this chapter highlight the importance of modeling and control techniques for biomedical systems.

### Introduction

We define difficult optimization problems as problems that cannot be solved to optimality or to any guaranteed bound by any standard solver within a reasonable time limit. The problem class we have in mind are mixed-integer programming (MIP) problems. Optimization, and especially MIP, is often appropriate and frequently used to model real-world optimization problems. While it started in the 1950s, models have become larger and more complicated.

A reasonable general framework is mixed-integer nonlinear programming (MINLP) problems. They are specified by the augmented vector  $\mathbf{x}_{\oplus}^T = \mathbf{x}^T \oplus \mathbf{y}^T$  established by the vectors  $\mathbf{x}^T = (x_1, \dots, x_{n_c})$  and  $\mathbf{y}^T = (y_1, \dots, y_{n_d})$  of  $n_c$  continuous and  $n_d$  discrete variables, an objective function  $f(\mathbf{x}, \mathbf{y})$ ,  $n_e$  equality constraints  $\mathbf{h}(\mathbf{x}, \mathbf{y})$ , and  $n_i$  inequality constraints  $\mathbf{g}(\mathbf{x}, \mathbf{y})$ . The problem

$$\min \left\{ f(\mathbf{x}, \mathbf{y}) \left| \begin{array}{l} \mathbf{h}(\mathbf{x}, \mathbf{y}) = 0, \mathbf{h} : X \times U \rightarrow \mathbb{R}^{n_e}, \\ \mathbf{x} \in X \subseteq \mathbb{R}^{n_c} \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \geq 0, \mathbf{g} : X \times U \rightarrow \mathbb{R}^{n_i}, \\ \mathbf{y} \in U \subseteq \mathbb{Z}^{n_d} \end{array} \right. \right\} \quad (1)$$

is called a *mixed-integer nonlinear programming* (MINLP) problem if at least one of the functions  $f(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$ , or  $\mathbf{h}(\mathbf{x}, \mathbf{y})$  is nonlinear. The vector inequality,  $\mathbf{g}(\mathbf{x}, \mathbf{y}) \geq 0$ , is to be read componentwise. Any vector  $\mathbf{x}_{\oplus}^T$  satisfying the constraints of (1) is called a *feasible point* of (1). Any feasible point whose objective function value is less than or equal to that of all other feasible points is called an *optimal solution*. From this

definition it follows that the problem might not have a unique optimal solution.

Depending on the functions  $f(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$ , and  $\mathbf{h}(\mathbf{x}, \mathbf{y})$  in (1) we get the following structured problems known as

Acronym	Type of optimization	$f(\mathbf{x}, \mathbf{y})$	$\mathbf{h}(\mathbf{x}, \mathbf{y})$	$\mathbf{g}(\mathbf{x}, \mathbf{y})$	$n_d$
LP	Linear programming	$\mathbf{c}^T \mathbf{x}$	$\mathbf{A}\mathbf{x} - \mathbf{b}$	$\mathbf{x}$	0
QP	Quadratic programming	$\mathbf{x}^T \mathbf{Q}\mathbf{x} + \mathbf{c}^T \mathbf{x}$	$\mathbf{A}\mathbf{x} - \mathbf{b}$	$\mathbf{x}$	0

MILP	Mixed-integer LP	$\mathbf{c}^T \mathbf{x}_\oplus$	$\mathbf{A}\mathbf{x}_\oplus - \mathbf{b}$	$\mathbf{x}_\oplus$	$\geq 1$
MIQP	Mixed-integer QP	$\mathbf{x}_\oplus^T \mathbf{Q}\mathbf{x}_\oplus + \mathbf{c}^T \mathbf{x}_\oplus$	$\mathbf{A}\mathbf{x}_\oplus - \mathbf{b}$	$\mathbf{x}_\oplus$	$\geq 1$
MINLP	Mixed-integer NLP				$\geq 1$

with a matrix  $\mathbf{A}$  of  $m$  rows and  $n$  columns, i.e.,  $\mathbf{A} \in \mathcal{M}(m \times n, \mathbb{R})$ ,  $\mathbf{b} \in \mathbb{R}^m$ ,  $\mathbf{c} \in \mathbb{R}^n$ , and  $n = n_c + n_d$ . Real-world problems lead much more frequently to LP and MILP than to NLP or MINLP problems. QP refers to quadratic programming problems. They have a quadratic objective function but only linear constraints. QP and MIQP problems often occur in applications of the financial services industry.

While LP problems as described in [31] or [1] can be solved relatively easily (the number of iterations, and thus the effort to solve LP problems with  $m$  constraints, grows approximately linearly in  $m$ ), the computational complexity of MILP and MINLP grows exponentially with  $n_d$  but depends strongly on the structure of the problem. Numerical methods to solve NLP problems work iteratively, and the computational problems are related to questions of convergence, getting stuck in bad local optima and availability of good initial solutions. Global optimization techniques can be applied to

both NLP and MINLP problems, and its complexity increases exponentially in the number of all variables entering nonlinearly into the model.

While the word *optimization*, in nontechnical or colloquial language, is often used in the sense of *improving*, the mathematical optimization community sticks to the original meaning of the word related to finding the *best value* either globally or at least in a local neighborhood. For an algorithm being considered as a (mathematical, strict, or exact) optimization algorithm in the mathematical optimization community there is consensus that such an algorithm computes feasible points proven globally (or locally) optimal for linear (nonlinear) optimization problems. Note that this is a definition of a mathematical optimization algorithm and *not* a statement saying that computing a local optimum is sufficient for nonlinear optimization problems. In the context of mixed-integer linear problems an optimization algorithm [12] and [13] is expected to compute a proven optimal solution or to generate feasible points and, for a maximization problem, to derive a reasonably tight, nontrivial upper bound. The quality of such bounds is quantified by the integrality gap – the difference between the upper and lower bound. What one considers to be a good-quality solution depends on the problem, the purpose of the model, and the accuracy of the data. A few percent, say 2 to 3%, might be acceptable for the example discussed by Kallrath (2007, Encyclopedia: Planning). However, discussion based on percentage gaps become complicated when the objective function includes penalty terms containing coefficients without a strict economic interpretation. In such cases scaling is problematic. Goal programming as discussed in ([23], p. 294) might help in such situations to avoid penalty terms in the model. The problem is first solved with respect to the highest-priority goal, then one is concerned with the next level goal, and so on.

For practical purposes it is also relevant to observe that solving mixed-integer linear problems and the problem of finding appropriate bounds is often  $\mathcal{NP}$ -complete, which makes these problems hard to solve. A consequence of this structural property is that these problems scale badly. If the problem can be solved to optimality for a given instance, this might not be so if the size is increased slightly. While tailor-made optimization algorithms such as column generation and branch-and-price techniques can often cope with this

situation for individual problems, it is very difficult for standard software.

We define difficult optimization problems as problems that cannot be solved to optimality or within a reasonable integrality gap by any standard MIP solver within a reasonable time limit. Problem structure, size, or both could lead to such behavior. However, in many cases these problems (typically MIP or nonconvex optimization problems fall into this class) can be solved if they are individually treated, and we resort to the art of modeling.

The art of modeling includes choosing the right level of detail implemented in the model. On the one hand, this needs to satisfy the expectations of the owner of the real-world problem. On the other hand, we are limited by the available computational resources. We give reasons why strict optimality or at least safe bounds are essential when dealing with real-world problems and why we do not accept methods that do not generate both upper and lower bounds.

Mapping the reality also forces us to discuss whether deterministic optimization is sufficient or whether we need to resort to optimization under uncertainty. Another issue is to check whether one objective function suffices or whether multiple-criterion optimization techniques need to be applied.

Instead of solving such difficult problems directly as, for example, a standalone MILP problem, we discuss how problems can be solved equivalently by solving a sequence of models.

Efficient approaches are as follows:

- Column generation with a master and subproblem structure,
- Branch-and-price,
- Exploiting a decomposition structure with a rolling time horizon,
- Exploiting auxiliary problems to generate safe bounds for the original problem, which then makes the original problems more tractable,
- Exhaustion approaches,
- Hybrid methods, i. e., constructive heuristics and local search on subsets of the difficult discrete variables leaving the remaining variables and constraints in tractable MILP or MINLP problems that can be solved.

We illustrate various ideas using real-world planning, scheduling, and cutting-stock problems.

## Models and the Art of Modeling

We are here concerned with two aspects of modeling and models. The first one is to obtain a reasonable representation of the reality and mapping it onto a mathematical model, i. e., an optimization problem in the form of (1). The second one is to reformulate the model or problem in such equivalent forms that is numerically tractable.

**Models** The terms *modeling* and *model building* are derived from the word *model*. Its etymological roots are the Latin word *modellus* (scale, [diminutive of *modus*, measure]) and what was to be in the 16th century the new word *modello*. Nowadays, in a scientific context the term is used to refer to a simplified, abstract, or well-structured part of the reality one is interested in. The idea itself and the associated concept is, however, much older. Classical geometry, and especially Pythagoras around 600 B.C., distinguish between wheel and circle and field and rectangle. Around A.D. 1100 a wooden model of the later Speyer cathedral was produced; the model served to build the real cathedral. Astrolabs and celestial globes have been used as models to visualize the movement of the moon, planets, and stars on the celestial sphere and to compute the times of rises and settings. Until the 19th century mechanical models were understood as pictures of reality. Following the principles of classical mechanics the key idea was to reduce all phenomena to the movement of small particles. Nowadays, in physics and other mathematical sciences one will talk about models if

- For reasons of simplification, one restricts oneself to certain aspects of the problem (*example*: if we consider the movement of the planets, in a first approximation the planets are treated as point masses);
- For reasons of didactic presentation, one develops a simplified picture for more complicated reality (*example*: the planetary model is used to explain the situation inside atoms);
- One uses the properties in one area to study the situation in an analogous problem.

A model is referred to as a mathematical model of a process or a problem if it contains typical mathematical objects (variables, terms, relations). Thus, a (mathematical) model represents a real-world problem in

the language of mathematics using mathematical symbols, variables, equations, inequalities, and other relations.

It is very important when building a model to define and state precisely the purpose of the model. In science, we often encounter epistemological arguments. In engineering, a model might be used to construct some machines. In operations research and optimization, models are often used to support strategic or operative decisions. All models enable us to

- Learn and understand situations that do not allow easy access (very slow or fast processes, processes involving a very small or very large region);
- Avoid difficult, expensive, or dangerous experiments; and
- Analyze case studies and *what-if-when scenarios*.

Tailored optimization models can be used to support decisions (that is, the overall purpose of the model). It is essential to have a clear objective describing what a good decision is. The optimization model should produce, for instance, optimal solutions in the following sense:

- To avoid unwanted byproducts as much as possible,
- To minimize costs, or
- to maximize profit, earnings before interest and taxes (EBIT), or contribution margin.

The purpose of a model may change over time.

To solve a real-world problem by mathematical optimization, at first we need to represent our problem by a *mathematical model*, that is, a set of mathematical relationships (e.g., equalities, inequalities, logical conditions) representing an abstraction of our real-world problem. This translation is part of the model-building phase (which is part of the whole modeling process) and is not trivial at all because there is nothing we could consider an exact model. Each model is an acceptable candidate as long as it fulfills its purpose and approximates the real world accurately enough. Usually, a model in mathematical optimization consists of four key objects:

- Data, also called the *constants* of a model;
- Variables (continuous, semicontinuous, binary, integer), also called decision variables;
- Constraints (equalities, inequalities), also called *restrictions*; and
- Objective function (sometimes even several of them).

The data may represent costs or demands, fixed operation conditions of a reactor, capacities of plants, and so on. The variables represent the degrees of freedom, i.e., what we want to decide: how much of a certain product is to be produced, whether a depot is closed or not, or how much material we will store in the inventory for later use. Classical optimization (calculus, variational calculus, optimal control) treats those cases in which the variables represent continuous degrees of freedom, e.g., the temperature in a chemical reactor or the amount of a product to be produced. Mixed-integer optimization involves variables restricted to integer values, for example counts (numbers of containers, ships), decisions (yes-no), or logical relations (if product *A* is produced, then product *B* also needs to be produced). The constraints can be a wide range of mathematical relationships: algebraic, analytic, differential, or integral. They may represent mass balances, quality relations, capacity limits, and so on. The objective function expresses our goal: minimize costs, maximize utilization rate, minimize waste, and so on. Mathematical models for optimization usually lead to structured problems such as:

- *Linear programming* (LP) problems,
- *Mixed-integer linear programming* (MILP) problems,
- *Quadratic* (QP) and *mixed-integer quadratic programming* (MIQP),
- *Nonlinear programming* (NLP) problems, and
- *Mixed-integer nonlinear programming* (MINLP) problems.

**The Art of Modeling** How do we get from a given problem to its mathematical representation? This is a difficult, nonunique process. It is a compromise between the degree of detail required to model a problem and the complexity, which is tractable. However, simplifications should not only be seen as an unavoidable evil. They could be useful for developing understanding or serve as a platform with the client, as the following three examples show.

1. At the beginning of the modeling process it can be useful to start with a “down-scaled” version to develop a feeling for the structure and dependencies of the model. This enable a constructive dialog between the modeler and the client. A vehicle fleet with 100 vehicles and 12 depots could be analyzed with

only 10 vehicles and 2 depots to let the *model world* and the *real world* find each other in a sequence of discussions.

2. In partial or submodels the modeler can develop a deep understanding of certain aspects of the problem which can be relevant to solve the whole problem.
3. Some aspects of the real world problem could be too complicated to model them complete or exactly. During the modeling process it can be clarified, using a smaller version, whether partial aspects of the model could be neglected or whether they are essential.

In any case it is essential that the simplifications be well understood and documented.

### Tricks of the Trade for Monolithic Models

Using state-of-the-art commercial solvers, e.g., XPressMP [XPressMP is by Dash Optimization, <http://www.dashoptimization.com>] or CPLEX [CPLEX is by ILOG, <http://www.ilog.com>], MILP problems can be solved quite efficiently. In the case of MINLP and using global optimization techniques, the solution efficiency depends strongly on the individual problem and the model formulation. However, as stressed in [21] for both MILP and MINLP problem, it is recommended that the full mathematical structure of a problem be exploited, that appropriate reformulations of models be made, and that problem-specific valid inequalities or cuts be used. Software packages may also differ with respect to the ability of *presolving techniques*, *default strategies* for the branch-and-bound algorithm, *cut generation* within the branch-and-cut algorithm, and, last but not least, *diagnosing and tracing infeasibilities*, which is an important issue in practice.

Here we collect a list of recommendation tricks that help to improve the solution procedure of monolithic MIP problems, i. e., standalone models that are solved by one call to a MILP or MINLP solver. Among them are:

- Use bounds instead of constraints if the dual values are not necessarily required.
- Apply one's own presolving techniques. Consider, for instance, a set of inequalities

$$B_{ijk}\delta_{ijk} \leq A_{ijk}; \quad \forall\{i, j, k\} \quad (2)$$

on binary variables  $\delta_{ijk}$ . They can be replaced by the bounds

$$\delta_{ijk} = 0; \quad \forall\{(i, j, k) \mid A_{ijk} < B_{ijk}\}$$

or, if one does not trust the  $<$  in a modeling language, the bounds

$$\delta_{ijk} = 0; \quad \forall\{(i, j, k) \mid A_{ijk} \leq B_{ijk} - \varepsilon\}$$

where  $\varepsilon > 0$  is a small number, say, of the order of  $10^{-6}$ . If  $A_{ijk} \geq B_{ijk}$ , then (2) is redundant. Note that, due to the fact that we have three indices, the number of inequalities can be very large.

- Exploit the *presolving techniques* embedded in the solver; cf. [28].
- Exploit or eliminate symmetry: sometimes, symmetry can lead to degenerate scenarios. There are situations, for instance, in scheduling where orders can be allocated to identical production units. Another example is the capacity design problem of a set of production units to be added to a production network. In that case, symmetry can be broken by requesting that the capacities of the units be sorted in descending order, i. e.,  $c_u \geq c_{u+1}$ . [29] exploit symmetry in order allocation for stock cutting in the paper industry; this is a very enjoyable paper to read.
- Use special types of variables for which tailor-made branching rules exist (this applies to semicontinuous and partial-integer variables as well as special ordered sets).
- Experiment with the various *strategies* offered by the commercial branch-and-bound solvers for the branch-and-bound algorithm.
- Experiment with the *cut generation* within the commercial branch-and-cut algorithm, among them Gomory cuts, knapsack cuts, or flow cuts; cf. [28].
- Construct one's own valid inequalities for certain substructures of problems at hand. Those inequalities may be added a priori to a model, and in the extreme case they would describe the complete convex hull. As an example we consider the mixed-integer inequality

$$x \leq C\lambda, \quad 0 \leq x \leq X; \quad x \in \mathbb{R}_0^+, \quad \lambda \in \mathbb{N} \quad (3)$$

which has the valid inequality

$$x \leq X - G(K - \lambda) \quad \text{where} \quad (4)$$

$$K := \left\lceil \frac{X}{C} \right\rceil \quad \text{and} \quad G := X - C(K - 1).$$

This valid inequality (4) is the more useful, the more  $K$  and  $X/C$  deviate. A special case arising is often the situation  $\lambda \in \{0, 1\}$ . Another example, taken from [39], p. 129 is

$$A_1\alpha_1 + A_2\alpha_2 \leq B + x \quad x \in \mathbb{R}_0^+ \quad \alpha_1, \alpha_2 \in \mathbb{N} \tag{5}$$

which for  $B \notin \mathbb{N}$  leads to the valid inequality

$$\lfloor A_1 \rfloor \alpha_1 + \left( \lfloor A_2 \rfloor \alpha_2 + \frac{f_2 - f}{1 - f} \right) \leq \lfloor B \rfloor + \frac{x}{1 - f} \tag{6}$$

where the following abbreviations are used:

$$f := B - \lfloor B \rfloor, \quad f_1 := A_1 - \lfloor A_1 \rfloor, \quad f_2 := A_2 - \lfloor A_2 \rfloor. \tag{7}$$

The dynamic counterpart of valid inequalities added a priori to a model leads to cutting-plane algorithms that avoid adding a large number of inequalities a priori to the model (note, this can be equivalent to finding the complete convex hull). Instead, only those useful in the vicinity of the optimal solution are added dynamically. For the topics of valid inequalities and cutting-plane algorithms the reader is referred to books by Nemhauser and Wolsey [30], Wolsey [39], and Pochet and Wolsey [32].

- Try disaggregation in MINLP problems. Global optimization techniques are often based on convex underestimators. Univariate functions can be treated easier than multivariate terms. Therefore, it helps to represent bilinear or multilinear terms by their disaggregated equivalences. As an example we consider  $x_1x_2$  with given lower and upper bounds  $X_i^-$  and  $X_i^+$  for  $x_i$ ;  $i = 1, 2$ . Wherever we encounter  $x_1x_2$  in our model we can replace it by

$$x_1x_2 = \frac{1}{2}(x_{12}^2 - x_1^2 - x_2^2)$$

and

$$x_{12} = x_1 + x_2.$$

The auxiliary variable is subject to the bounds  $X_{12}^- := X_1^- + X_2^-$  and

$$X_{12}^- \leq x_{12} \leq X_{12}^+, \quad X_{12}^+ := X_1^+ + X_2^+.$$

This formulation has another advantage. It allows us to construct easily a relaxed problem which can be used to derive a useful lower bound. Imagine a problem  $\mathcal{P}$  with the inequality

$$x_1x_2 \leq A. \tag{8}$$

Then

$$x_{12}^2 - X_1^-x_1 - X_2^-x_2 \leq 2A \tag{9}$$

is a relaxation of  $\mathcal{P}$  as each point  $(x_1, x_2)$  satisfying (8) also fulfills (9). Note that an alternative disaggregation avoiding an additional variable is given by

$$x_1x_2 = \frac{1}{4} [(x_1 + x_2)^2 - (x_1 - x_2)^2].$$

However, all of the creative attempts listed above may not suffice to solve the MIP using one monolithic model. That is when we should start looking at solving the problem by a sequence of problems. We have to keep in mind that to solve a MIP problem we need to derive tight lower and upper bounds with the gap between them approaching zero.

### Decomposition Techniques

Decomposition techniques decompose a problem into a set of smaller problems that can be solved in sequence or in any combination. Ideally, the approach can still compute the global optimum. There are standardized techniques such as Benders Decomposition [cf. Floudas ([9], Chap. 6)]. But often one should exploit the structure of an optimization to construct tailor-made decompositions. This is outlined in the following subsections.

### Column Generation

In linear programming parlance, the term *column* usually refers to variables. In the context of column-generation techniques it has wider meaning and stands for any kind of objects involved in an optimization problem. In vehicle routing problems a column might, for instance, represent a subset of orders assigned to a vehicle. In network flow problems a column might represent a feasible path through the network. Finally, in cutting-stock problems [10,11] a column represents a pattern to be cut.

The basic idea of column generation is to decompose a given problem into a master and subproblem. Problems that might otherwise be nonlinear can be completely solved by solving only linear problems. The critical issue is to generate master and subproblems that can both be solved efficiently. One of the most famous examples is the elegant column-generation approach of Gilmore and Gomory [10] for computing the minimal number of rolls to satisfy a requested demand for smaller sized rolls. This problem, if formulated as one monolithic problem, leads to a MINLP problem with a large number of integer variables. In simple cases, such as those described by Schrage ([35], Sect. 11.7), it is possible to generate all columns explicitly, even within a modeling language. Often the decomposition has a natural interpretation. If not all columns can be generated, the columns are added dynamically to the problem. Barnhart et al. [2] give a good overview on such techniques. A more recent review focusing on selected topics of column generation is [25]. In the context of vehicle routing problems, feasible tours contain additional columns as needed by solving a shortest-path problem with time windows and capacity constraints using dynamic programming [7].

More generally, column-generation techniques are used to solve well-structured MILP problems involving a huge number, say, several hundred thousand or millions, of variables, i. e., columns. Such problems lead to large LP problems if the integrality constraints of the integer variables are relaxed. If the LP problem contains so many variables (columns) that it cannot be solved with a direct LP solver (revised simplex, interior point method), one starts solving this so-called *master problem* with a small subset of variables yielding the *restricted master problem*. After the restricted master problem has been solved, a pricing problem is solved to identify new variables. This step corresponds to the identification of a nonbasic variable to be taken into the basis of the simplex algorithm and the term *column generation*. The restricted master problem is solved with the new number of variables. The method terminates when the pricing problems cannot identify any new variables. The simplest version of column generation is found in the Dantzig–Wolfe decomposition [6].

Gilmore and Gomory [10,11] were the first to generalize the idea of dynamic column generation to an integer programming (IP) problem: the cutting-stock

problem. In this case, the pricing problem, i. e., the subproblem, is an IP problem itself – and one refers to this as a *column-generation algorithm*. This problem is special as the columns generated when solving the relaxed master problem are sufficient to get the optimal integer feasible solution of the overall problem. In general this is not so. If not only the subproblem, but also the master problem involves integer variables, then the column-generation part is embedded into a branch-and-bound method; this is called *branch-and-price*. Thus, branch-and-price is integer programming with column generation. Note that during the branching process new columns are generated; therefore the name *branch-and-price*.

**Column Generation in cutting-stock Problems** This section describes the mathematical model for minimizing the number of roles or trimloss and illustrates the idea of column generation.

*Indices* used in this model:

$p \in \mathcal{P} := \{p_1, \dots, p_{N^p}\}$  for cutting patterns (formats).

Either the patterns are directly generated according to a complete enumeration or they are generated by column generation.

$i \in \mathcal{I} := \{i_1, \dots, i_{N^i}\}$  given orders or widths.

*Input Data* We arrange the relevant input data size here:

$B$  [L] width of the rolls (raw material roles)

$D_i$  [-] number of orders for the width  $i$

$W_i$  [L] width of order type  $i$

*Integer Variables* used in the different model variants:

$\mu_p \in \mathbb{N}_0 := \{0, 1, 2, 3, \dots\}$  [-] indicates how often pattern  $p$  is used.

If cutting pattern  $p$  is not used, then we have  $\mu_p = 0$ .

$\alpha_{ip} \in \mathbb{N}_0$  [-] indicates how often width  $i$  is contained in pattern  $p$ .

This variable can take values between 0 and  $D_i$  depending on the order situation.

*Model* The model contains a suitable object function

$$\min f(\alpha_{ip}, \mu_p),$$

as well as the boundary condition (fulfillment of the demand)

$$\sum_p \alpha_{ip} \mu_p = D_i, \quad \forall i \tag{10}$$

and the integrality constraints

$$\begin{aligned} \alpha_{ip} &\in \mathbb{N}_0, \quad \forall \{ip\}, \\ \mu_p &\in \mathbb{N}_0, \quad \forall \{p\}. \end{aligned} \tag{11}$$

**General Structure of the Problem** In this form it is a mixed-integer nonlinear optimization problem (MINLP). This problem class is difficult in itself. More serious is the fact that we may easily encounter several million variables  $\alpha_{ip}$ . Therefore the problem cannot be solved in this form.

*Solution Method* The idea of dynamic column generation is based on the fact that one must decide in a master problem for a predefined set of patterns how often every pattern must be used as well as calculate suitable input data for a subproblem. In this subproblem new patterns are calculated.

The master problem solves for the multiplicities of existing patterns and has the shape

$$\min \sum_p \mu_p,$$

with the demand-fulfill inequality (note that it is allowed to produce more than requested)

$$\sum_i N_{ip} \mu_p \geq D_i, \quad \forall i \tag{12}$$

and the integrality constraints

$$\mu_p \in \mathbb{N}_0, \quad \forall \{p\}. \tag{13}$$

The subproblem generates new patterns. Structurally it is a knapsack problem with object function

$$\min_{\alpha_i} 1 - \sum_p P_i \alpha_i,$$

where  $P_i$  are the dual values (pricing information) of the master problem (pricing problem) associated with

(12) and  $\alpha_i$  is an integer variable specifying how often width  $i$  occurs in the new pattern. We add the knapsack constraint with respect to the width of the rolls

$$\sum_i W_i \alpha_i \leq B, \quad \forall i \tag{14}$$

and the integrality constraints

$$\alpha_i \in \mathbb{N}_0, \quad \forall \{i\}. \tag{15}$$

In some cases,  $\alpha_i$  could be additionally bounded by the number,  $K$ , of knives.

**Implementation Issues** The critical issues in this method, in which we alternate in solving the master problem and the subproblem, are the initialization of the procedure (a feasible starting point is to have one requested width in each initial pattern, but this is not necessarily a good one), excluding the generation of the existing pattern by applying integer cuts, and the termination.

### Column Enumeration

Column enumeration is a special variant of column generation and is applicable when a small number of columns is sufficient. This is, for instance, the case in real-world cutting-stock problems when it is known that the optimal solution has only a small amount of trimloss. This usually eliminates most of the pattern. Column enumeration naturally leads to a type of selecting columns or partitioning models. A collection of illustrative examples contained in ([35], Sect. 11.7) covers several problems of grouping, matching, covering, partitioning, and packing in which a set of given objects has to be grouped into subsets to maximize or minimize some objective function. Despite the limitations with respect to the number of columns, column enumeration has some advantages:

- No pricing problem,
- Easily applied to MIP problems,
- Column enumeration is much easier to implement.

In the online version of the vehicle routing problem described in [22] it is possible to generate the complete set,  $C_r$ , of all columns, i.e., subsets of orders  $i \in \mathcal{O}$ ,  $r = |\mathcal{O}|$ , assigned to a fleet of  $n$  vehicles,  $v \in \mathcal{V}$ . Let  $C_r$  be the union of the sets,  $C_{rv}$ , i.e.,  $C_r = \cup_{v=1 \dots n} C_{rv}$  with  $C_r = |C_r| = 2^r n$ , where  $C_{rv}$

contains the subsets of orders assigned to vehicle  $v$ . Note that  $C_{rv}$  contains all subsets containing 1, 2, or  $r$  orders assigned to vehicle  $v$ . The relevant steps of the algorithm are:

1. Explicitly generate all columns  $C_{rv}$ , followed by a simple feasibility test *w.r.t.* the availability of the cars.
2. Solve the routing-scheduling problem for all columns  $C_{rv}$  using a tailor-made branch-and-bound approach (the optimal objective function values,  $Z(\tau_c)$  or  $Z(\tau_{cv})$ , respectively, and the associated routing-scheduling plan are stored).
3. Solve the partitioning model:

$$\min_{\gamma_{cv}} \sum_{c=1}^{C_{rv}} \sum_{v=1}^{N^V} Z(\tau_{cv})\gamma_{cv}, \tag{16}$$

s.t.

$$\sum_{c=1}^{C_r} \sum_{v=1}^{N^V} I_i(\tau_{cv})\gamma_{cv} = 1, \quad \forall i = 1, \dots, r \tag{17}$$

ensures that each order is contained exactly once, the inequality

$$\sum_{c=1}^{C_r} \gamma_{cv} \leq 1, \quad \forall v \in \mathcal{V}, \tag{18}$$

ensuring that at most one column can exist for each vehicle, and the integrality conditions

$$\gamma_{cv} \in \{0, 1\}, \quad \forall c = 1, \dots, C_r. \tag{19}$$

Note that not all combinations of index pairs  $\{c, v\}$  exist; each  $c$  corresponds to exactly one  $v$ , and vice versa. This formulation allows us to find optimal solutions with the defined columns for a smaller number of vehicles. The objective function and the partitioning constraints are just modified by substituting

$$\sum_{v=1|v \in \mathcal{V}}^{N^V} \rightarrow \sum_{v=1|v \in \mathcal{V}_*}^{N^V},$$

the equations

$$\sum_{c=1}^{C_{rv}} \sum_{v=1|v \in \mathcal{V}_*}^{N^V} I_i(\tau_{cv})\gamma_{cv} = 1, \quad \forall i = 1, \dots, r,$$

and the inequality

$$\sum_{c=1}^{C_{rv}} \gamma_{cv} \leq 1, \quad \forall v \in \mathcal{V}_*,$$

where  $\mathcal{V}_* \subset \mathcal{V}$  is a subset of the set  $\mathcal{V}$  of all vehicles. Alternatively, if it is not prespecified which vehicles should be used but it is only required that not more than  $N_*^V$  vehicles be used, then the inequality

$$\sum_{c=1}^{C_r} \sum_{v=1|v \in \mathcal{V}}^{N^V} \gamma_{cv} \leq N_*^V \tag{20}$$

is imposed.

4. Reconstruct the complete solution and extract the complete solution from the stored optimal solutions for the individual columns.

**Branch-and-Price**

Branch-and-price (often coupled with branch-and-cut) refers to a tailor-made algorithm exploiting the decomposition structure of the problem to be solved. This efficient method for solving MIP problems with column generation has been well described by Barnhart et al. [2] and has been covered by Savelsbergh [34] in the first edition of the *Encyclopedia of Optimization*. Here, we give a list of more recent successful applications in various fields.

- *Cutting stock*: [3,38]
- *Engine routing and industrial in-plant railroads*: [26]
- *Network design*: [16]
- *Lot sizing*: [38]
- *Scheduling (staff planning)*: [8]
- *Scheduling of switching engines*: [24]
- *Supply chain optimization* (pulp industry): [5]
- *Vehicle routing*: [7,15]

**Rolling Time Decomposition**

The overall methodology for solving the medium-range production scheduling problem is to decompose the large and complex problem into smaller short-term scheduling subproblems in successive time horizons, i.e., we decompose according to time. Large-scale industrial problems have been solved by Janak et al. [18,19]. A decomposition model is formulated and solved to determine the current horizon and

corresponding products that should be included in the current subproblem. According to the solution of the decomposition model, a short-term scheduling model is formulated using the information on customer orders, inventory levels, and processing recipes. The resulting MILP problem is a large-scale complex problem that requires a large computational effort for its solution. When a satisfactory solution is determined, the relevant data are output and the next time horizon is considered. The above procedure is applied iteratively in an automatic fashion until the whole scheduling period under consideration is finished.

Note that the decomposition model determines automatically how many days and products to consider in the small scheduling horizon subject to an upper limit on the complexity of the resulting mathematical model.

### An Exhaustion Method

This method combines aspects of a constructive heuristics and of exact model solving. We illustrate the exhausting method by the cutting-stock problem described in Sect. “[Column Generation in cutting-stock Problems](#)”; assigning orders in a scheduling problem would be another example. The elegant column generation approach by Gilmore and Gomory [10] is known for producing minimal trimloss solutions with *many* patterns. Often this corresponds to setup changes on the machine and therefore is not desirable. A solution with a minimal number of patterns minimizes the machine setup costs of the cutter. Minimizing simultaneously trimloss and the number of patterns is possible for a small case of a few orders only exploiting the MILP model by Johnston and Salinlija [20]. It contains two conflicting objective functions. Therefore one could resort to goal programming. Alternatively, we could produce several parameterized solutions leading to different numbers of rolls to be used and patterns to be cut from which the user would extract the one he likes best.

As the table above indicates, we compute tight lower bounds on both trimloss and the number of patterns. Even for up to 50 feasible orders, near-optimal solutions are constructed in less than a minute.

Note that it would be possible to use the branch-and-price algorithm described in [38] or [3] to solve the one-dimensional cutting-stock problem with minimal numbers of patterns. However, these methods are

not easy to implement. Therefore, we use the following approaches, which are much easier to program:

- V1: Direct usage of the model by Johnston and Salinlija [20] for a small number, say,  $N^I \leq 14$ , of orders and  $D_{\max} \leq 10$ . In a preprocessing step we compute valid inequalities as well as tight lower and upper bounds on the variables.
- V2: Exhaustion procedure in which we generate successively new patterns with maximal multiplicities. This method is parameterized by the permissible percentage waste  $W_{\max}$ ,  $1 \leq W_{\max} \leq 99$ . After a few patterns have been generated with this parameterization, it could happen that it is not possible to generate any more patterns with waste restriction. In this case the remaining unsatisfied orders are generated by V1 without the  $W_{\max}$  restriction.

### Indices and Sets

In this model we use the indices listed in Johnston and Salinlija [20]:

$i \in \mathcal{I} := \{i_1, \dots, i_{N^I}\}$  denotes the sets of width.

$j \in \mathcal{J} := \{j_1, \dots, j_{N^J}\}$  denotes the pattern;  $N^J \leq N^I$ .

The patterns are generated by V1, or dynamically by maximizing the multiplicities of a used pattern.

$k \in \mathcal{K} := \{k_1, \dots, k_{N^P}\}$  denotes the multiplicity index to indicate how often a width is used in a pattern.

The multiplicity index can be restricted by the ratio of the width of the orders and the width of the given rolls.

### Variables

The following integer or binary variables are used:

$a_{ijk} \in \mathbb{N}$  [–] specifies the multiplicity of pattern  $j$ .

The multiplicity can vary between 0 and  $D_{\max} := \max\{D_i\}$ . If pattern  $j$  is not used, we have  $r_j = p_j = 0$ .

$p_j \in \{0, 1\}$  [–] indicates whether pattern  $j$  is used at all.

$r_j \in \mathbb{N}$  [–] specifies how often pattern  $j$  is used.

The multiplicity can vary between 0 and  $D_{\max} := \max\{D_i\}$ . If pattern  $j$  is not used, we have  $r_j = p_j = 0$ .

$\alpha_{ip} \in \mathbb{N}$  [–] specifies how often width  $i$  occurs in pattern  $p$ .

```

# of #  output file  flag Wmax          comment
rolls pat
-----
 0   5                8  99  lower bound: minimal # of patterns
30  10  pat00.out     9  99  lower bound: minimal # of rolls
34   7  pat01.out     0  20
31   9  pat02.out     1  15
30   8  pat03.out     0  10  minimal number of rolls
32   9  pat04.out     1   8
30   8  pat05.out     0   6  minimal number of rolls
31   8  pat06.out     1   4

The best solution found contains 7 patterns!
The solution with minimal trimloss contain 30 rolls!

Improvement in the lower bound of pattern: 6!
Solutions with 6 patterns are minimal w.r.t.
to the number of patterns.

A new solution was found with only 6 patterns and 36 rolls: patnew.out
36   6  patnew.out    0  99

```

This width-multiplicity variable can take all values between 0 and  $D_i$ .

$x_{ijk} \in \{0, 1\}$  [–] indicates whether width  $i$  appears in pattern  $j$  at level  $k$ .

Note that  $x_{ijk} = 0$  implies  $a_{ijk} = 0$ .

### The Idea of the Exhaustion Method

In each iteration we generate  $m$  at most two or three new patterns by maximizing the multiplicities of these patterns, allowing no more than a maximum waste,  $W_{\max}$ . The solution generated in iteration  $m$  is preserved in iteration  $m + 1$  by fixing the appropriate variables. If the problem turns out to be infeasible (this may happen if  $W_{\max}$  turns out to be restrictive), then we switch to a model variant in which we minimize the number of patterns subject to satisfying the remaining unsatisfied orders.

The model is based on the inequalities (2,3,5,6,7,8,9) in [20], but we add a few more additional ones or modify the existing ones. We exploit two objective functions: maximizing the multiplicities of the patterns generated

$$\max \sum_{j=1}^{\pi_u} r_j,$$

where  $\pi_u$  specifies the maximal number of patterns ( $\pi_u$  could be taken from the solution of the column-generation approach, for instance), or minimizing the number of patterns generated

$$\min \sum_{j=1}^{\pi_u} p_j.$$

The model is completed by the integrality conditions

$$r_j, a_{ijk} \in \{0, 1, 2, 3, \dots\} \quad (21)$$

$$p_j, x_{ijk}, y_{jk} \in \{0, 1\}. \quad (22)$$

The model is applied several times with  $a_{ijk} \leq \tilde{D}_i$ , where  $\tilde{D}_i$  is the number of remaining orders of width  $i$ . In particular, the model has to fulfill the relationships

$$ka_{ijk} > \tilde{D}_i \implies a_{ijk} = 0, \quad x_{ijk} = 0$$

and

$$a_{ijk} \leq \left\lceil \frac{\tilde{D}_i}{k} \right\rceil \quad \text{or} \quad a_{ijk} \leq \left\lceil \frac{\tilde{D}_i + S_i}{k} \right\rceil,$$

where  $S_i$  denotes the permissible overproduction.

The constructive method described so far provides an improved upper bound,  $\pi'_u$ , on the number of pattern.

## Computing Lower Bounds

To compute a lower bound we apply two methods. The first method is to solve a bin-packing problem, which is equivalent to minimizing the number of rolls in the original cutting-stock problem described in the Sect. “[Column Generation in Cutting-Stock Problems](#)” for equal demands  $D_i = 1$ . If solved with the column-generation approach, this method is fast and cheap, but the lower bound,  $\pi'_l$ , is often weak. The second method is to exploit the upper bound,  $\pi'_u$ , on the number of patterns obtained and to call the exact model as in V1. It is impressive how quickly the commercial solvers CPLEX and XpressMP improve the lower bound yielding  $\pi''_l$ . For most examples with up to 50 orders we obtain  $\pi'_u - \pi'_l \leq 2$ , but in many cases  $\pi'_u - \pi'_l = 1$  or even  $\pi'_u = \pi'_l$ .

## Primal Feasible Solutions and Hybrid Methods

We define hybrid methods as methods based on any combination of exact MIP methods with constructive heuristics, local search, metaheuristics, or constraint programming that produces primal feasible solutions. Dive-and-fix, near-integer-fix, and fix-and-relax are such hybrid methods. They are user-developed heuristics exploiting the problem structure. In their kernel they use a declarative model solved, for instance, by CPLEX and XpressMP.

In constructive heuristics we exploit the structure of the problem and compute a feasible point. Once we have a feasible point we can derive safe bounds on the optimum and assign initial values to the critical discrete variable, which could be exploited by the GAMS/CPLEX *mipstart* option. Feasible points can sometimes be generated by appropriate sequences of relaxed models. For instance, in a scheduling problem  $\mathcal{P}$  with due times one might relax these due times obtaining the relaxed model  $\mathcal{R}$ . The optimal solution, or even any feasible point of  $\mathcal{R}$ , is a feasible point of  $\mathcal{P}$  if the due times are models with appropriate unbounded slack variables.

Constructive heuristics can also be established by systematic approaches of fixing critical discrete variables. Such approaches are *dive-and-fix* and *relax-and-fix*. In *dive-and-fix* the LP relaxation of an integer problem is to be solved followed by fixing a subset of fractional variables to suitable bounds. *Near-integer-fix* is

a variant of *dive-and-fix* that fixes variables with fractional values to the nearest integer point. Note that these heuristics are subject to the risk of becoming infeasible.

The probability of becoming infeasible is less likely in *relax-and-fix*. In *relax-and-fix*, following Pochet and Wolsey ([32], pp. 109) we suppose that the binary variables  $\delta$  of a MIP problem  $\mathcal{P}$  can be partitioned into  $R$  disjoint sets  $S^1; \dots; S^R$  of decreasing importance. Within these subsets  $U^r$  with  $U \subseteq \bigcup_{u=r+1}^R S^u$  for  $r = 1; \dots; R - 1$  can be chosen to allow for somewhat more generality. Based on these partitions,  $R$  MIP problems are solved, denoted  $\mathcal{P}^r$  with  $1 \leq r \leq R$  to find a heuristic solution to  $\mathcal{P}$ . For instance in a production planning problem,  $S^1$  might be all the  $\delta$  variables associated with time periods in  $\{1, \dots, t_1\}$ ,  $S^u$  those associated with periods in  $\{t_u + 1, \dots, t_{u+1}\}$ , whereas  $U^r$  would be the  $\delta$  variables associated with the periods in some set  $\{t_r + 1, \dots, u_r\}$ .

In the first problem,  $\mathcal{P}^1$ , one only imposes the integrality of the important variables in  $S^1 \cup U^1$  and relaxes the integrality on all the other variables in  $S$ . As  $\mathcal{P}^1$  is a relaxation of  $\mathcal{P}$ , for a minimization problem, the solution of  $\mathcal{P}^1$  provides a lower bound of  $\mathcal{P}$ . The solution values,  $\delta^1$ , of the discrete variables are kept fixed when solving  $\mathcal{P}^r$ . This continues and in the subsequent  $\mathcal{P}^r$ , for  $2 \leq r \leq R$ , we additionally fix the values of the  $\delta$  variables with index in  $S^{r-1}$  at their optimal values from  $\mathcal{P}^{r-1}$  and add the integrality restriction for the variables in  $S^r \cup U^r$ .

Either  $\mathcal{P}^r$  is infeasible for some  $r \in \{1, \dots, R\}$ , and the heuristic failed, or else  $(x^R, \delta^R)$  is a *relax-and-fix* solution. To avoid infeasibilities one might apply a smoothed form of this heuristic that allows for some overlap of  $U^{r-1}$  and  $U^r$ . Additional free binary variables in horizon  $r - 1$  allow one to link the current horizon  $r$  with the previous one. Usually this suffices to ensure feasibility. *Relax-and-fix* comes in various flavors exploiting time-decomposition or time-partitioning structures. Other decompositions, for instance plants, products, or customers, are possible as well.

A local search can be used to improve the solution obtained by the *relax-and-fix* heuristic. The main idea is to solve repeatedly the subproblem on a small number of binary variables reoptimizing, for instance, the production of some products. The binary variables for resolving could be chosen randomly or by a metaheuristic

such as simulated annealing. All binary variables related to them are released; the others are fixed to the previous best values.

Another class of MIP hybrid method is established by algorithms that combine a MIP solver with another algorithmic method. A hybrid method obtained by the combination of mixed-integer and constraint logic programming strategies has been developed and applied by Harjunkoski et al. [14] as well as Jain and Grossmann [17] for solving scheduling and combinatorial optimization problems. Timpe [37] solved mixed planning and scheduling problems with mixed MILP branch-and-bound and constraint programming. Maravelias and Grossmann [27] proposed a hybrid/decomposition algorithm for the short-term scheduling of batch plants, and Roe et al. [33] presented a hybrid MILP/CLP algorithm for multipurpose batch process scheduling in which MILP is used to solve an aggregated planning problem while CP is used to solve a sequencing problem. Other hybrid algorithms combine evolutionary and mathematical programming methods; see, for instance, the heuristics by Till et al. [36] for stochastic scheduling problems and by Borisovsky et al. [4] for supply management problems.

Finally, one should not forget to add some algorithmic component that, for the minimization problem at hand, would generate some reasonable bounds to be provided in addition to the hybrid method. The hybrid methods discussed above provide upper bounds by constructing feasible points. In favorite cases, the MIP part of the hybrid solver provides lower bounds. In other case, lower bounds can be derived from auxiliary problems, which are relaxations of the original problem, and which are easier to solve.

## Summary

If a given MIP problem cannot be solved by an available MIP solver exploiting all its internal presolving techniques, one might reformulate the problem and obtain an equivalent or closely related representation of reality. Another approach is to construct MIP solutions and bounds by solving a sequence of models. Alternatively, individual tailor-made exact decomposition techniques could help as well as primal heuristics such as relax-and-fix or local search techniques on top of a MIP model.

Algorithmic language; Declarative language; Modeling language; Solver

In this paper, modeling languages are identified as a new computer language paradigm and their applications for representing optimization problems is illustrated by examples.

Programming languages can be classified into three paradigms: imperative, functional, and logic programming [14]. The *imperative programming paradigm* is closely related to the physical way of how (the von Neumann) computer works: Given a set of memory locations, a program is a sequence of well defined instructions on retrieving, storing and transforming the content of these locations. The *functional paradigm* of computation is based on the evaluation of functions. Every program can be viewed as a function which translates an input into a unique output. Functions are first-class values, that is, they must be viewed as values themselves. The computational model is based on the  $\lambda$ -calculus invented by A. Church (1936) as a mathematical formalism for expressing the concept of a computation. The *paradigm of logic programming* is based on the insight that a computation can be viewed as a kind of (constructive) proof. Hence, a program is a notation for writing logical statements together with specified algorithms for implementing inference rules.

All three programming paradigms concentrate on problem representation as a *computation*, that is, the problem is stated in a way that describes the process of solving it. The computation on how to solve a problem ‘is’ its representation. One may call such a notational system an *algorithmic language*.

**Definition 1** An *algorithmic language* describes (explicitly or implicitly) the computation of solving a problem, that is, ‘how’ a problem can be processed using a machine. The computation consists of a sequence of well-defined instructions which can be executed in a finite time by a Turing machine. The information of a problem which is captured by an algorithmic language is called *algorithmic knowledge* of the problem.

Algorithmic knowledge to describe a problem is very common in our everyday life – one only need to look at cookery-books, or technical maintenance manuals – that one may ask whether the human brain is ‘predisposed’ to preferably present a problem in describing its solution recipe.

However, there exists at least one different way to capture knowledge about a problem; it is the method

which describes ‘what’ the problem is by defining its properties, rather than saying ‘how’ to solve it. Mathematically, this can be expressed by a set  $\{x \in X: R(x)\}$ , where  $X$  is a continuous or discrete state space and  $R(x)$  is a Boolean relation, defining the properties or the *constraints* of the problem;  $x$  is called the *variable(s)*. A notational system that represents a problem in this way is called a *declarative language*.

**Definition 2** A *declarative language* describes the problem as a set using mathematical variables and constraints defined over a given state space. This space can be finite or infinite, countable or noncountable. The information of a problem which is captured by a declarative language is called *declarative knowledge* of the problem.

The declarative representation, in general, does not give any indication on how to solve the problem. It only states what the problem is. Of course, there exists a trivial algorithm to solve a declaratively stated problem, which is to enumerate the state space and to check whether a given  $x \in X$  violates the constraint  $R(x)$ . The algorithm breaks down, however, whenever the state space is infinite. But even if the state space is finite, it is – for most nontrivial problems – so large that a full enumeration is practically impossible.

Algorithmic and declarative representations are two fundamentally different kinds of modeling and representing knowledge. Declarative knowledge answers the question ‘what is?’, whereas algorithmic knowledge asks ‘how to?’ [4]. An algorithm gives an exact recipe of how to solve a problem. A mathematical model, i. e. its declarative representation, on the other hand, (only) defines the problem as a subspace of the state space. No algorithm is given to find all or a single element of the feasible subspace.

### Why Declarative Representation

The question arises, therefore, why to present a problem using a declarative way, since one must solve it anyway and, hence, represent as an algorithm? The reasons are, first of all, *conciseness*, *insight*, and *documentation*. Many problems can be represented declaratively in a very concise way, while the representation of their computation is long and complex. Concise writings favor also the insight of a problem. Furthermore, in many scientific papers a problem is stated in a declarative

way using mathematical equations and inequalities for documentational purposes. This gives a clear statement of the problem and is an efficient way to communicate it to other scientists. However, documentation is by no means limited to human beings. One can imagine declarative languages implemented on a computer like algorithmic languages, which are parsed and interpreted by a compiler. In this way, an interpretative system can *analyse the structure* of a declarative program, can *pretty-print* it on a printer or a screen, can *classify* it, or *symbolically transform* it in order to view it as a diagram or in another textual form.

Of course, the most interesting question is whether the declarative way of representing a problem could be of any help in *solving* the problem.

Indeed, for certain classes of problems the computation can be obtained directly from a declarative formulation. This is true for all recursive definitions. A classical example is the algorithm of Euclid to find the greatest common divisor (gcd) of two integers. One can prove that

$$\text{gcd}(a, b) = \begin{cases} \text{gcd}(b, a \bmod b), & b > 0 \\ a, & b = 0, \end{cases}$$

which is clearly a declarative statement of the problem. In *Scheme*, a functional language, this formula can be implemented directly as a function in the following way:

```
(define (gcd a b)
  (if (= b 0) a
      (gcd b (remainder a b))))
```

Similar formulations can be given for any other language which includes recursion as a basic control structure. This class of problems is surprisingly rich. The whole paradigm of dynamic programming can be subsumed under this class.

A class of problems of a very different kind are linear programs, which can be represented declaratively in the following way:

$$\{\min cx: Ax \geq b\}$$

From this formulation – in contrast to the class of recursive definitions – nothing can be deduced that would be useful in solving the problem. However, there

exists well-known methods, for example the simplex method, which solves almost all instances in a very efficient way. Hence, to make the declarative formulation of a linear program useful for solving it, one only needs to translate it into a form, the simplex algorithm accepts as input. The translation from the declarative formulation  $\{\min cx: Ax \geq b\}$  to such an input-form can be automated. This concept can be extended to nonlinear and discrete problems.

### Algebraic Modeling Languages

The idea to state the mathematical problem in a declarative way and to translate it into an ‘algorithmic’ form by a standard procedure led to a new language paradigm emerged basically in the community of operations research at the end of the 1980s, the *algebraic modeling languages* (AIMMS [1], AMPL [7], GAMS [2], LINGO [18], and LPL [12] and others). These languages are becoming increasingly popular even outside the community of operations research. Algebraic modeling languages represent a problem in a purely declarative way, although most of them include computational facilities to manipulate the data as well as certain control structures.

One of their strength is the complete separation of the problem formulation as a declarative model from finding a solution, which is supposed to be computed by an external program called a *solver*. This allows the modeler not only to separate the two main tasks of model formulation and model solution, but also to switch easily between several solvers. This is an invaluable benefit for many difficult problems, since it is not uncommon that a model instance can be solved using one method, and another instance is solvable only using another method. Another advantage of such languages is to separate clearly between model structure, which only contains parameters (place-holder for data) but no data, and model instance, in which the parameters are replaced by a specific data set. This leads to a natural separation between model formulation and data gathering stored in databases. Hence, the main features of these algebraic modeling languages are:

- purely declarative representation of the problem;
- clear separation between formulation and solution;
- clear separation between model structure and model data.

It is, however, naive to think that one only needs to formulate a problem in a concise declarative form and to link it somehow to a solver in order to solve it. First of all, the ‘linking process’ is not so straightforward as it seems initially. Second, a solver may not exist which could solve the problem at hand in an efficient way. One only needs to look at Fermat’s last conjecture which can be stated in a declarative way as  $\{a, b, c, n \in \mathbf{N}^+ : a^n + b^n = c^n, a, b, c \geq 1, n > 2\}$  to convince oneself of this fact. Even worse, one can state a problem declaratively for which no solver can exist. This is true already for the rather limited declarative language of first order logic, for which no algorithm exists which decides whether a formula is true or false in general (see [5]).

In this sense, efforts are under way actually in the design of such languages which focus on flexibly linking the declarative formulation to a specific solver to make this paradigm of purely declarative formulation more powerful. This language-solver-interface problem has different aspects and research goes in many directions. A main effort is to integrate symbolic model transformation rules into the declarative language in order to generate formulations which are more useful for a solver. AMPL, for example, automatically detects partially separable structure and computes second derivatives [8]. This information are also handed over to a nonlinear solver. LPL, to cite a very different undertaking, has integrated a set of rules to translate *symbolically* logical constraints into 0–1 constraint [11]. To do this in an intelligent way is all but easy, because the resulting 0–1 formulation should be as sharp as possible. This translation is useful for large mathematical models which must be extended by a few logical conditions. For many applications the original model becomes straightforward while the transformed is complicated but still relatively easy to solve (examples were given in [11]). Even if the resulting formulation is not solvable efficiently, the modeler can gain more insights into the structure of the model from such a symbolic translation procedure, and eventually modify the original formulation.

## Second Generation Modeling Languages

Another research activity, actually under way, goes in the direction of extending the algebraic modeling languages in order to express also algorithmic knowledge.

This is necessary, because even if one could link an purely declarative language to any solver, it remains doubtful of whether this can be done efficiently in all cases. Furthermore, for many problems it is not useful to formulate them in a declarative way: the algorithmic way is more straightforward and easier to understand. For still other problems a mixture of declarative and algorithmic knowledge leads to a superior formulation in terms of understandability as well as in terms of efficiency, (examples are given below to confirm this findings).

Therefore, AIMMS integrates control structures and procedure definitions. GAMS, AMPL and LPL also allow the modeler to write algorithms powerful enough to solves models repeatedly.

A theoretical effort was undertaken in [10] to specify a modeling language which allows the modeler (or the programmer) to combine algorithmic and declarative knowledge within the same language framework without intermingle them. The overall syntax structure of a model (or a program) in this framework is as follows:

```
MODEL ModelName
    (declarative part of the model)
BEGIN
    (algorithmic part of the model)
END ModelName.
```

Declarative and algorithmic knowledge are clearly separated. Either part can be empty, meaning that the problem is represented in a purely declarative or in a purely algorithmic form. The declarative part consists of the basic building blocks of declarative knowledge: variables, parameters, constraints, model checking facilities, and sets (that is a way to ‘multiply’ basic building blocks). This part may also contain ‘ordinary declarations’ of an algorithmic language (e. g., type and function declarations). Furthermore, one can declare whole models within this part, leading to nested model structures, which is very useful in decomposing a complex problem into smaller parts. The algorithmic part, on the other hand, consists of all control structures which make the language Turing complete. One may imagine his or her favorite programming language being implemented in this part. A language which combines declar-

ative and algorithmic knowledge in this way is called *modeling language*.

**Definition 3** A *modeling language* is a notational system which allows one to combine (not to merge) declarative and algorithmic knowledge in the same language framework. The content captured by such a notation is called a *model*.

Such a language framework is very flexible. Purely declarative models are linked to external solvers to be solved; purely algorithmic models are programs, that is algorithms + data structures, in the ordinary sense.

### Modeling Language and Constraint Logic Programming

Merging declarative and algorithmic knowledge is not new, although it is not very common in language design. The only existing language paradigm doing it is *constraint logic programming* (CLP), a refinement of logic programming [13]. There are, however, important differences between the CLP paradigm and the paradigm of modeling language as defined above.

- 1) In CLP the algorithmic part – normally a search mechanism – is behind the scene and the computation is intrinsically coupled with the declarative language itself. This could be a strength because the programmer does not have to be aware of how the computation is taking place, he or she only writes the rules in a descriptive, that is declarative, way and triggers the computation by a request. In reality, however, it is an important drawback, because – for most nontrivial problem – the programmer ‘must’ be aware on how the computation is taking place. Therefore, to guide the computation in CLP, the declarative program is interspersed with additional rules which have nothing to do with the description of the original problem. In a modeling language, the user either links the declarative part to an external solver or writes the solver within the language. In either case, both parts are strictly separated. Why is this separation so important? Because it allows the modeler to ‘plug in’ different solvers without touching the overall model formulation.
- 2) The second difference is that the modeling language paradigm lead automatically to modular design. This is probably to hottest topic in software

engineering: building components. Software engineering teaches us that a complex structure can be only managed efficiently by break it down into many relatively independent components. The CLP approach leads more likely to programs that are difficult to survey and hard to debug and to maintain, because such considerations are entirely absent within the CLP paradigm.

- 3) On the other hand, the community of CLP has developed methods to solve specific classes of combinatorial problems which seems to be superior to other methods. This is because they rely on propagation, simplification of constraints, and various consistency techniques. In this sense, CLP solvers could be used and linked with modeling languages. Such a project is actually under way between the AMPL language and the ILOG solver [6,17].

Hence, while the *representation of models* is probably best done in the language framework of modeling languages, the solution process can taken place in a CLP solver for certain problems.

### Modeling Examples

Five modeling examples are chosen from very different problem domains to illustrate the highlights of the presented paradigm of modeling language. The first two examples show that certain problems are best formulated using algorithmic knowledge, the next two examples show the power of a declarative formulation, and a last example indicates that mixing both paradigms is sometimes more advantageous.

#### Sorting

Sorting is a problem which is preferably expressed in an algorithmic way. Declaratively, the problem could be formulated as follows: Find a permutation  $\pi$  such that  $A_{\pi i} \leq A_{\pi i+1}$  for all  $i \in \{1, \dots, n-1\}$  where  $A_1, \dots, A_n$  is an array of objects on which an order is defined. It is difficult to imagine a ‘solver’ that could solve this problem as efficiently as the best known sorting algorithms such as Quicksort, of which the implementation is straightforward.

The reason why the sorting problem is best formulated as an algorithm is probably that the state space is exponential in the number of items, however, the best algorithm only has complexity  $O(n \log n)$ .

### The $n$ -Queens Problem

The  $n$ -queens problem is to place  $n$  queens on a chessboard of dimension  $n \times n$  in such a way, that they cannot beat each other. This problem can be formulated declarative as follows:  $\{x_i, x_j \in \{1, \dots, n\}: x_i \neq x_j, x_i + i \neq x_j + j, x_i - i \neq x_j - j\}$ , where  $x_i$  is the column position of the  $i$ th queen (i. e. the queen in row  $i$ ).

Using the LPL [12] formulation:

```
MODEL nQueens;
  PARAMETER n; SET i ALIAS j ::= {1, ..., n};
  DISTINCT VARIABLE x{i}[1, ..., n];
  CONSTRAINT S{i, j : i < j}:
    x[i] + i <> x[j] + j AND x[i] - i <> x[j] - j;
END
```

the author was able to solve problems for  $n \leq 8$  using a general MIP solver. The problem is automatically translated into a 0–1 problem by LPL. Replacing the MIP-solver by a tabu search heuristic, problems with  $n \leq 50$  were solvable within the LPL framework. Using the constraint language OZ [19] problems of  $n \leq 200$  are efficiently solvable using techniques of propagation and variable domain reductions. However, the success of all these methods seems to be limited compared to the best we can attain. In [20,21], Sosic Rok and Gu Jun presented a polynomial time local heuristic that can solve problems of  $n \leq 3\,000\,000$  in less than one minute. The presented algorithm is very simple. The conclusion seems to be for the  $n$ -queens problem that an algorithmic formulation is advantageous.

### A Two-Person Game

Two players choose at random a positive number and note it on a piece of paper. They then compare them. If both numbers are equal, then neither player gets a payoff. If the difference between the two numbers is one, then the player who has chosen the higher number obtains the sum of both; otherwise the player who has chosen the smaller number obtains the sum of both. What is the optimal strategy for a player, i. e. which numbers should be chosen with what frequencies to get the maximal payoff? This problem was presented in [9] and is

a typical two-person zero-sum game. In LPL, it can be formulated as follows:

```
ODEL Game 'finite two-person zero-sum game';
  SET i ALIAS j := /1 : 50/;
  PARAMETER p{i, j} := IF(j > i, IF(j = i + 1,
    -i - j, MIN(i, j)), IF(j < i, -p[j, i], 0));
  VARIABLE x{i};
  CONSTRAINT R : SUM{i} x[i] = 1;
  MAXIMIZE gain: MIN{j}(SUM{i} p[j, i] * x[i]);
END Game.
```

This is an very compact way to declaratively formulate the problem and it is difficult to imagine how this could be achieved using algorithmic knowledge alone. It is also an efficient way to state the problem, because large instances can be solved by an linear programming solver. LPL automatically transforms it into an linear program. (By the way, the problem has an interesting solution: Each player should only choose number smaller than six.)

### Equal Circles in a Square

The problem is to find the maximum diameter of  $n$  equal mutually disjoint circles packed inside a unit square.

In LPL, this problem can be compactly formulated as follows:

```
MODEL circles 'pack equal circles in a square';
  PARAMETER n 'number of circles';
  SET i ALIAS j = 1, ..., n;
  VARIABLE
    t 'diameter of the circles';
    x{i}[0, 1] 'x-position of the center';
    y{i}[0, 1] 'y-position of the center';
  CONSTRAINT
    R{i, j : i < j} 'circles must be disjoint':
      (x[i] - x[j])2 + (y[i] - y[j])2 ≥ t;
  MAXIMIZE obj 'maximize diameter': t;
END
```

C.D. Maranas et al. [15] obtained the best known solutions for all  $n \leq 30$  and, for  $n = 15$ , an even better one

using an equivalent formulation in GAMS and linking it to MINOS [16], an well-known nonlinear solver.

### The (Fractional) Cutting-Stock Problem

Paper is manufactured in rolls of width  $B$ . A set of customers  $W$  orders  $d_w$  rolls of width  $b_w$  (with  $w \in W$ ). Rolls can be cut in many ways, every subset  $P' \subseteq W$  such that  $\sum_{i \in P'} y_i b_i \leq B$  is a possible cut-pattern, where  $y_i$  is a positive integer. The question is how the initial roll of width  $B$  should be cut, that is, which patterns should be used, in order to minimize the overall paper waste. A straightforward formulation of this problem is to enumerate all patterns, each giving a variable, then to minimize the number of used patterns while fulfilling the demands. The resulting model is a very large linear program which cannot be solved.

A well-known method in operations research to solve such kind of problems is to use a column generation method (see [3] for details), that is, a small instance with only a few patterns is solved and a rewarding column – a pattern – is added repeatedly to the problem. The new problem is then solved again. This process is repeated, until no pattern can be added. To find a rewarding pattern, another problem – named a knapsack problem – must be solved.

The problem can be formulated partially be algorithmic partially by declarative knowledge. It consists of two declaratively formulated problems (a linear program and an knapsack problem), which are both repeatedly solved. In a pseudocode one could formulate the algorithmic knowledge as follows:

```
SOLVE the small cutting-stock problem
SOLVE the knapsack problem
WHILE a rewarding pattern was found DO
  add pattern to the cutting-stock problem
  SOLVE the cutting-stock problem again
  SOLVE the knapsack problem again
ENDWHILE
```

The two models (the cutting-stock problem and the knapsack problem) can be formulated declaratively. In the proposed framework of modeling language, the complete problem can now be expressed as in the program below.

```
MODEL CuttingStock;
  MODEL Knapsack(i, w, p, K, x, obj);
    SET i;
    PARAMETER w{i}; p{i}; K;
    INTEGER VARIABLE x{i};
    CONSTRAINT R: SUM{i} w * x ≤ K;
    MAXIMIZE obj: SUM{i} p * x;
  END Knapsack.
SET
  w ‘rolls ordered’; p ‘possible patterns’;
PARAMETER
  a{w, p} ‘pattern table’;
  d{w} ‘demands’;
  b{w} ‘widths of ordered rolls’;
  B ‘initial width’;
  INTEGER y{w} ‘new added pattern’;
  C ‘contribution of a cut’;
VARIABLE
  X{p} ‘number of rolls cut according to p’;
CONSTRAINT
  Dem{w}: SUM{p} a * X ≥ d;
MINIMIZE obj: SUM{p} X;
BEGIN
  SOLVE;
  SOLVE Knapsack(w, b, Dem.dual, B, y, C);
  WHILE (C > 1) DO
    p := p + {‘pattern_’ + str(#p)};
    a{w, #p} := y[w];
    SOLVE;
    SOLVE Knapsack(w, b, Dem.dual, B, y, C);
  END;
END CuttingStock.
```

This formulation has several remarkable properties:

- 1) It is short and readable. The declarative part consists of the (small) linear cutting-stock problem, it also contains, as a submodel, a knapsack problem. The algorithmic part implements the column generation method. Both parts are entirely separated.
- 2) It is a complete formulation, except from the data. No other code is needed; both models can be solved using a standard MIP solver (since the knapsack problem is small in general).
- 3) It has a modular structure. The knapsack problem is an independent component with its own name space; there is no interference with the surrounding model. It could even be declared outside the cutting-stock problem.

- 4) The cutting-stock problem is only one problem of a large class of relevant problems which are solved using a column generation or, alternatively, a row-cut generation.

## Conclusion

It has been shown that certain problems are best formulated as algorithms, others in a declarative way, still others need both paradigms to be stated concisely. Computer science made available many algorithmic languages; they can be contrasted to the algebraic modeling languages which are purely declarative. A language, called modeling language, which combines both paradigms was defined in this paper and examples were given showing clear advantages of doing so. Its is more powerful than both paradigms separated.

However, the integration of algorithmic and declarative knowledge cannot be done in an arbitrary way. The language design must follow certain criteria well-known in computer science. The main criteria are: *reliability* and *transparency*. Reliability can be achieved by a unique notation to code models, that is, by a modeling language, and by various checking mechanisms (type checking, unit checking, data integrity checking and others). Transparency can be obtained by flexible decomposition techniques, like modular structure as well as access and protection mechanisms of these structure, well-known techniques in language design and software engineering.

Solving efficiently and relevant optimization problems using present desktop machine not only asks for fast machines and sophisticated solvers, but also for formulation techniques that allow the modeler to communicate the model easily and to build it in a readable and maintainable way.

### Introduction

This article presents a general overview of some of the most recent approaches for solving the molecular distance geometry problem, namely, the ABBIE algorithm, the Global Continuation Algorithm, d.c. optimization algorithms, the geometric build-up algorithm, and the BP algorithm.

The determination of the three-dimensional structure of a molecule, especially in the protein folding framework, is one of the most important problems in computational biology. That structure is very important because it is associated to the chemical and biological properties of the molecule [7,11,46]. Basically, this problem can be tackled in two ways: experimentally, via nuclear magnetic resonance (NMR) spectroscopy and X-ray crystallography [8], or theoretically, through potential energy minimization [19].

The Molecular Distance Geometry Problem (MDGP) arises in NMR analysis. This experimental technique provides a set of inter-atomic distances  $d_{ij}$  for certain pairs of atoms  $(i,j)$  of a given protein [23,24,33,56,57]. The MDGP can be formulated as follows:

Given a set  $S$  of atom pairs  $(i,j)$  on a set of  $m$  atoms and distances  $d_{ij}$  defined over  $S$ , find positions  $x_1, \dots, x_m \in \mathbb{R}^3$  of the atoms in the molecule such that

$$\|x_i - x_j\| = d_{ij}, \quad \forall (i, j) \in S. \quad (1)$$

When the distances between all pairs of atoms of a molecule are given, a unique three-dimensional structure can be determined by a linear time algorithm [16]. However, because of errors in the given distances, a solution may not exist or may not be unique. In addition to this, because of the large scale of problems that arise in practice, the MDGP becomes very hard to solve in general. Saxe [51] showed that the MDGP is NP-complete even in one spatial dimension.

The exact MDGP can be naturally formulated as a nonlinear global minimization problem, where the objective function is given by

$$f(x_1, \dots, x_m) = \sum_{(i,j) \in S} (\|x_i - x_j\|^2 - d_{ij}^2)^2. \quad (2)$$

This function is everywhere infinitely differentiable and has an exponential number of local minimizers. Assuming that all the distances are correctly given,  $x \in \mathbb{R}^{3m}$  solves the problem if and only if  $f(x) = 0$ .

Formulations (1) and (2) correspond to the exact MDGP. Since experimental errors may prevent solution existence (e. g. when the triangle inequality

$$d_{ij} \leq d_{ik} + d_{kj}$$

is violated for atoms  $i, j, k$ ), we sometimes consider an  $\epsilon$ -optimum solution of (1), i. e. a solution  $x_1, \dots, x_m$  satisfying

$$|\|x_i - x_j\| - d_{ij}| \leq \epsilon, \quad \forall (i, j) \in S. \quad (3)$$

Moré and Wu [41] showed that even obtaining such an  $\epsilon$ -optimum solution is NP-hard for  $\epsilon$  small enough.

In practice, it is often just possible to obtain lower and upper bounds on the distances [4]. Hence a more practical definition of the MDGP is to find positions  $x_1, \dots, x_m \in \mathbb{R}^3$  such that

$$l_{ij} \leq \|x_i - x_j\| \leq u_{ij}, \quad \forall (i, j) \in S, \quad (4)$$

where  $l_{ij}$  and  $u_{ij}$  are lower and upper bounds on the distance constraints, respectively.

The MDGP is a particular case of a more general problem, called the distance geometry problem [6,13,14,15], which is intimately related to the Euclidean distance matrix completion problem [1,28,38].

Several methods have been developed to solve the MDGP, including the EMBED algorithm by Crippen and Havel [12,25], the alternating projection algorithm by Glunt et al. [20], spectral gradient methods by Glunt et al. [21,22], the multi-scaling algorithm by Trosset et al. [29,52], a stochastic/perturbation algorithm by Zou, Byrd, and Schnabel [58], variable neighborhood search-based algorithms by Liberti, Lavor, and Maculan [35,39], the ABBIE algorithm by Hendrickson [26,27], the Global Continuation Algorithm by Moré and Wu [41,42,43,44,45], the d.c. optimization algorithms by An and Tao [2,3], the geometric build-up algorithm by Dong, Wu, and Wu [16,17,54], and the BP algorithm by Lavor, Liberti, and Maculan [37]. Two completely different approaches for solving the MDGP are given in [34] (based on quantum computation) and [53] (based on algebraic geometry).

The wireless network sensor positioning problem is closely related to the MDGP, the main difference being the presence of fixed anchor points with known positions: results derived for this problem can often be applied to the MDGP. Amongst the most notable, [18] shows that the MDGP associated to a trilateration graph (a graph with an order on the vertices such that each vertex is adjacent to the preceding 4 vertices) can be solved in polynomial time; [40] provides a detailed study of Semi Definite Programming (SDP) relaxations applied to distance geometry problems.

### ABBIE Algorithm

In [26,27], Hendrickson describes an approach to the exact MDGP that replaces a large optimization problem, given by (2), by a sequence of smaller ones. He exploits some combinatorial structure inherent in the MDGP, which allows him to develop a divide-and-conquer algorithm based on a graph-theoretic viewpoint.

If the atoms and the distances are considered as nodes and edges of a graph, respectively, the MDGP can be described by a distance graph and the solution to the problem is an embedding of the distance graph in an Euclidean space. When some of the atoms can be

moved without violating any distance constraints, there may be many embeddings. The graph is then called flexible or otherwise rigid.

If the graph is rigid or does not have partial reflections, for example, then the graph has a unique embedding. These necessary conditions can be used to find subgraphs that have unique embeddings. The problem can then be solved by decomposing the graph into such subgraphs, in which the minimization problems associated to the function (2) are solved. The solutions found for the subgraphs can then be combined into a solution for the whole graph.

This approach to the MDGP has been implemented in a code named ABBIE and tested on simulated data provided by the bovine pancreatic ribonuclease A, a typical small protein consisting of 124 amino acids, whose three-dimensional structure is known [47]. The data set consists of all distances between pairs of atoms in the same amino acid, along with 1167 additional distances corresponding to pairs of hydrogen atoms that were within 3.5 Å of each other. It was used fragments of the protein consisting of the first 20, 40, 60, 80 and 100 amino acids as well as the full protein, with two sets of distance constraints for each size corresponding to the largest unique subgraphs and the reduced graphs. These problems have from 63 up to 777 atoms.

### Global Continuation Algorithm

In [43], Moré and Wu formulated the exact MDGP in terms of finding the global minimum of a similar function to (2),

$$f(x_1, \dots, x_m) = \sum_{(i,j) \in S} w_{ij} (||x_i - x_j||^2 - d_{ij}^2)^2, \quad (5)$$

where  $w_{ij}$  are positive weights (in numerical results  $w_{ij} = 1$  was used).

Following the ideas described in [55], Moré and Wu proposed an algorithm, called Global Continuation Algorithm, based on a continuation approach for global optimization. The idea is gradually transform the function (5) into a smoother function with fewer local minimizers, where an optimization algorithm is then applied to the transformed function, tracing their minimizers back to the original function. For other works based on continuation approach, see [9,10,30,31,32,49].

The transformed function  $\langle f \rangle_\lambda$ , called the Gaussian transform, of a function  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  is defined by

$$\langle f \rangle_\lambda(x) = \frac{1}{\pi^{n/2} \lambda^n} \int_{\mathbb{R}^n} f(y) \exp\left(-\frac{\|y-x\|^2}{\lambda^2}\right) dy, \quad (6)$$

where the parameter  $\lambda$  controls the degree of smoothing. The value  $\langle f \rangle_\lambda(x)$  is a weighted average of  $f(x)$  in a neighborhood of  $x$ , where the size of the neighborhood decreases as  $\lambda$  decreases: as  $\lambda \rightarrow 0$ , the average is carried out on the singleton set  $\{x\}$ , thus recovering the original function in the limit. Smoother functions are obtained as  $\lambda$  increases.

This approach to the MDGP has been implemented and tested on two artificial models of problems, where the molecule has  $m = s^3$  atoms located in the three-dimensional lattice

$$\{(i_1, i_2, i_3): 0 \leq i_1 < s, 0 \leq i_2 < s, 0 \leq i_3 < s\}$$

for an integer  $s \geq 1$ . In numerical results, it was considered  $m = 27, 64, 125, 216$ .

In the first model, the ordering for the atoms is specified by letting  $i$  be the atom at the position  $(i_1, i_2, i_3)$ ,

$$i = 1 + i_1 + s i_2 + s^2 i_3,$$

and the set of atom pairs whose distances are known,  $S$ , is given by

$$S = \{(i, j) : |i - j| \leq r\}, \quad (7)$$

where  $r = s^2$ . In the second model, the set  $S$  is specified by

$$S = \{(i, j) : \|x_i - x_j\| \leq \sqrt{r}\}, \quad (8)$$

where  $x_i = (i_1, i_2, i_3)$  and  $r = s^2$ . For both models,  $s$  is considered in the interval  $3 \leq s \leq 6$ .

In (7),  $S$  includes all nearby atoms, while in (8),  $S$  includes some of nearby atoms and some relatively distant atoms.

It was shown that the Global Continuation Algorithm usually finds a solution from any given starting point, whereas the local minimization algorithm used in the multistart methods is unreliable as a method for determining global solutions. It was also showed that the continuation approach determines a global solution with less computational effort that is required by the multistart approach.

## D.C. Optimization Algorithms

In [2,3], An and Tao proposed an approach for solving the exact MDGP, based on the d.c. (difference of convex functions) optimization algorithms. They worked in  $\mathcal{M}_{m,3}(\mathbb{R})$ , the space of real matrices of order  $m \times 3$ , where for  $X \in \mathcal{M}_{m,3}(\mathbb{R})$ ,  $X_i$  (resp.,  $X^i$ ) is its  $i$ th row (resp.,  $i$ th column). By identifying a set of positions of atoms  $x_1, \dots, x_m$  with the matrix  $X$ ,  $X_i^T = x_i$  for  $i = 1, \dots, m$ , they expressed the MDGP by

$$0 = \min \left\{ \sigma(X) := \frac{1}{2} \sum_{(i,j) \in S, i < j} w_{ij} \theta_{ij}(X) : X \in \mathcal{M}_{m,3}(\mathbb{R}) \right\}, \quad (9)$$

where  $w_{ij} > 0$  for  $i \neq j$  and  $w_{ii} = 0$  for all  $i$ . The pairwise potential  $\theta_{ij}: \mathcal{M}_{m,3}(\mathbb{R}) \rightarrow \mathbb{R}$  is defined for problem (1) by either

$$\theta_{ij}(X) = \left( d_{ij}^2 - \|X_i^T - X_j^T\|^2 \right)^2 \quad (10)$$

or

$$\theta_{ij}(X) = \left( d_{ij} - \|X_i^T - X_j^T\| \right)^2, \quad (11)$$

and for problem (4) by

$$\theta_{ij}(X) = \min^2 \left\{ \frac{\|X_i^T - X_j^T\|^2 - l_{ij}^2}{l_{ij}^2}, 0 \right\} + \max^2 \left\{ \frac{\|X_i^T - X_j^T\|^2 - u_{ij}^2}{u_{ij}^2}, 0 \right\}. \quad (12)$$

Similarly to (2),  $X$  is a solution if and only if it is a global minimizer of problem (9) and  $\sigma(X) = 0$ .

While the problem (9) with  $\theta_{ij}$  given by (9) or (12) is a nondifferentiable optimization problem, it is a d.c. optimization problem.

An and Tao demonstrated that the d.c. algorithms can be adapted for developing efficient algorithms for solving large-scale exact MDGPs. They proposed various versions of d.c. algorithms that are based on different formulations for the problem. Due its local character, the global optimality cannot be guaranteed for a general d.c. problem. However, the fact that the global optimality can be obtained with a suitable starting point

motivated them to investigate a technique for computing good starting points for the d.c. algorithms in the solution of (9), with  $\theta_{ij}$  defined by (11).

The algorithms have been tested on three sets of data: the artificial data from Moré and Wu [43] (with up to 4096 atoms), 16 proteins in the PDB [5] (from 146 up to 4189 atoms), and the data from Hendrickson [27] (from 63 up to 777 atoms). Using these data, they showed that the d.c. algorithms can efficiently solve large-scale exact MDGPs.

### Geometric Build-up Algorithm

In [17], Dong and Wu proposed the solution of the exact MDGP by an algorithm, called the geometric build-up algorithm, based on a geometric relationship between coordinates and distances associated to the atoms of a molecule. It is assumed that it is possible to determine the coordinates of at least four atoms, which are marked as fixed; the remaining ones are non-fixed. The coordinates of a non-fixed atom  $a$  can be calculated by using the coordinates of four non-coplanar fixed atoms such that the distances between any of these four atoms and the atom  $a$  are known. If such four atoms are found, the atom  $a$  changes its status to fixed. More specifically, let  $b_1, b_2, b_3, b_4$  be the four fixed atoms whose Cartesian coordinates are already known. Now suppose that the Euclidean distances among the atom  $a$  and the atoms  $b_1, b_2, b_3, b_4$ , namely  $d_{a,b_i}$ , for  $i = 1, 2, 3, 4$ , are known. That is,

$$\|a - b_1\| = d_{a,b_1},$$

$$\|a - b_2\| = d_{a,b_2},$$

$$\|a - b_3\| = d_{a,b_3},$$

$$\|a - b_4\| = d_{a,b_4}.$$

Squaring both sides of these equations, we have:

$$\|a\|^2 - 2a^T b_1 + \|b_1\|^2 = d_{a,b_1}^2,$$

$$\|a\|^2 - 2a^T b_2 + \|b_2\|^2 = d_{a,b_2}^2,$$

$$\|a\|^2 - 2a^T b_3 + \|b_3\|^2 = d_{a,b_3}^2,$$

$$\|a\|^2 - 2a^T b_4 + \|b_4\|^2 = d_{a,b_4}^2.$$

By subtracting one of these equations from the others, it is obtained a linear system that can be used to determine the coordinates of the atom  $a$ . For example, subtracting the first equation from the others, we obtain

$$Ax = b, \quad (13)$$

where

$$A = -2 \begin{bmatrix} (b_1 - b_2)^T \\ (b_1 - b_3)^T \\ (b_1 - b_4)^T \end{bmatrix}, \quad x = a,$$

and

$$b = \begin{bmatrix} \left( d_{a,b_1}^2 - d_{a,b_2}^2 \right) - (\|b_1\|^2 - \|b_2\|^2) \\ \left( d_{a,b_1}^2 - d_{a,b_3}^2 \right) - (\|b_1\|^2 - \|b_3\|^2) \\ \left( d_{a,b_1}^2 - d_{a,b_4}^2 \right) - (\|b_1\|^2 - \|b_4\|^2) \end{bmatrix}.$$

Since  $b_1, b_2, b_3, b_4$  are non-coplanar atoms, the system (13) has a unique solution. If the exact distances between all pairs of atoms are given, this approach can determine the coordinates of all atoms of the molecule in linear time [16].

Dong and Wu implemented such an algorithm, but they verified that it is very sensitive to the numerical errors introduced in calculating the coordinates of the atoms. In [54], Wu and Wu proposed the updated geometric build-up algorithm showing that, in this algorithm, the accumulation of the errors in calculating the coordinates of the atoms can be controlled and prevented. They have been tested the algorithm with a set of problems generated using the known structures of 10 proteins downloaded from the PDB data bank [5], with problems from 404 up to 4201 atoms.

### BP Algorithm

In [37], Lavor, Liberti, and Maculan propose an algorithm, called branch-and-prune (BP), based on a discrete formulation of the exact MDGP. They observe that the particular structures of proteins makes it possible to formulate the MDGP applied to protein backbones as a discrete search problem. They formalize this by introducing the discretizable molecular distance geometry problem (DMDGP), which consists of a certain subset of MDGP instances (to which most protein backbones belong) for which a discrete formulation can be supplied. This approach requires that the bond lengths and angles, as well as the distances between atoms separated by three consecutive bond lengths are known.

In order to describe a backbone of a protein with  $m$  atoms, in addition to the bond lengths  $d_{i-1,i}$ , for  $i = 2, \dots, m$ , and the bond angles  $\theta_{i-2,i}$ , for  $i = 3, \dots, m$ ,

Protein folding; Molecular structure determination;  
Convex global underestimation

An important class of difficult global minimization problems arise as an essential feature of molecular structure calculations. The determination of a stable molecular structure can often be formulated in terms of calculating the global (or approximate global) minimum of a potential energy function (see [6]). Computing the global minimum of this function is very difficult because it typically has a very large number of local

minima which may grow exponentially with molecule size.

One such application is the well known protein folding problem. It is widely accepted that the folded state of a protein is completely dependent on the one-dimensional linear sequence (i. e., 'primary' sequence) of amino acids from which the protein is constructed: external factors, such as enzymes, present at the time of folding have no effect on the final, or native, state of the protein. This led to the formulation of the *protein folding problem*: given a known primary sequence of amino acids, what would be its native, or folded, state in three-dimensional space.

Several successful predictions of folded protein structures have been made and announced before the experimental structures were known (see [3,9]). While most of these have been made with a blend of a human expert's abilities and computer assistance, fully automated methods have shown promise for producing previously unattainable accuracy [2].

These machine based prediction strategies attempt to lessen the reliance on experts by developing a completely computational method. Such approaches are generally based on two assumptions. First, that there exists a potential energy function for the protein; and second that the folded state corresponds to the structure with the lowest potential energy (minimum of the potential energy function) and is thus in a state of thermodynamic equilibrium. This view is supported by in vitro observations that proteins can successfully refold from a variety of denatured states. Evolutionary theory also supports a folded state at a global energy minimum. Protein sequences have evolved under pressure to perform certain functions, which for most known occurrences requires a stable, unique, and compact structure. Unless specifically required for a certain function, there was no biochemical need for proteins to hide their global minimum behind a large kinetic energy barrier. While kinetic blocks may occur, they should be limited to special proteins developed for certain functions (see [1]).

### Molecular Model

Unfortunately, finding the 'true' energy function of a molecular structure, if one even exists, is virtually impossible. For example, with proteins ranging in size

up to 1, 053 amino acids (a collagen found in tendons), exhaustive conformational searches will never be tractable. Practical search strategies for the protein folding problem currently require a simplified, yet sufficiently realistic, molecular model with an associated potential energy function representing the dominant forces involved in protein folding [4]. In a one such simplified model, each residue in the primary sequence of a protein is characterized by its backbone components  $\text{NH} - \text{C}_\alpha\text{H} - \text{C}'\text{O}$  and one of 20 possible amino acid sidechains attached to the central  $\text{C}_\alpha$  atom. The three-dimensional structure of the chain is determined by internal molecular coordinates consisting of bond lengths  $l$ , bond angles  $\theta$ , sidechain torsion angles  $\chi$ , and the backbone dihedral angles  $\phi$ ,  $\psi$ , and  $\omega$ . Fortunately, these  $10r - 6$  parameters (for an  $r$ -residue structure) do not all vary independently. Some of these ( $7r - 4$  of them) are regarded as fixed since they are found to vary within only a very small neighborhood of an experimentally determined value. Among these are the  $3r - 1$  backbone bond lengths  $l$ , the  $3r - 2$  backbone bond angles  $\theta$ , and the  $r - 1$  peptide bond dihedral angles  $\omega$  (fixed in the trans conformation). This leaves only the  $r$  sidechain torsion angles  $\chi$ , and the  $r - 1$  backbone dihedral angle pairs  $(\phi, \psi)$ . In the reduced representation model presented here, the sidechain angles  $\chi$  are also fixed since sidechains are treated as united atoms (see below) with their respective torsion angles  $\chi$  fixed at an 'average' value taken from the Brookhaven Protein Databank. Remaining are the  $r - 1$  backbone dihedral angles pairs. These also are not completely independent; they are severely constrained by known chemical data (the Ramachandran plot) for each of the 20 amino acid residues. Furthermore, since the atoms from one  $\text{C}_\alpha$  to the next  $\text{C}_\alpha$  along the backbone can be grouped into rigid planar peptide units, there are no extra parameters required to express the three-dimensional position of the attached O and H peptide atoms. Hence, these bond lengths and bond angles are also known and fixed.

Another key element of this simplified polypeptide model is that each sidechain is classified as either hydrophobic or polar, and is represented by only a single 'virtual' center of mass atom. Since each sidechain is represented by only the single center of mass 'virtual atom'  $\text{C}_s$ , no extra parameters are needed to define the position of each sidechain with respect to the backbone

mainchain. The twenty amino acids are thus classified into two groups, hydrophobic and polar, according to the scale given by S. Miyazawa and R.L. Jernigan [7].

Corresponding to this simplified polypeptide model is a simple energy function. This function includes four components: a contact energy term favoring pairwise hydrophobic residues, a second contact term favoring hydrogen bond formation between donor NH and acceptor  $C' = O$  pairs, a steric repulsive term which rejects any conformation that would permit unreasonably small interatomic distances, and a main chain torsional term that allows only certain preset values for the backbone dihedral angle pairs  $(\phi, \psi)$ . Since the residues in this model come in only two forms, hydrophobic and polar, where the hydrophobic monomers exhibit a strong pairwise attraction, the lowest free energy state involves those conformations with the greatest number of hydrophobic ‘contacts’ [4] and intrastrand hydrogen bonds. Simplified potential functions have been successful in [10,11], and [12]. Here we use a simple modification of the energy function from [11].

### The Convex Global Underestimator

One practical means for finding the global minimum of the polypeptide’s potential energy function is to use a convex global underestimator to localize the search in the region of the global minimum. The idea is to fit all known local minima with a convex function which underestimates all of them, but which differs from them by the minimum possible amount in the discrete L1 norm. The minimum of this underestimator is used to predict the global minimum for the function, allowing a more localized conformer search to be performed based on the predicted minimum.

More precisely, given an  $r$ -residue structure with  $n = 2r - 2$  backbone dihedral angles, denote a conformation of this simplified model by  $\phi \in \mathbf{R}^n$ , and the corresponding simplified potential energy function value by  $F(\phi)$ . Then, assuming that  $k \geq 2n + 1$  local minimum conformations  $\phi^{(j)}$ , for  $j = 1, \dots, k$ , have been computed, a convex quadratic underestimating function  $U(\phi)$  is fitted to these local minima so that it underestimates all the local minima, and normally interpolates  $F(\phi^{(j)})$  at  $2n + 1$  points. This is accomplished by determining the coefficients in the function  $U(\phi)$  so that

$$\delta_j = F(\phi^{(j)}) - U(\phi^{(j)}) \geq 0 \quad (1)$$

for  $j = 1, \dots, k$ , and where  $\sum_{j=1}^n \delta_j$  is minimized. That is, the difference between  $F(\phi)$  and  $U(\phi)$  is minimized in the discrete  $L_1$  norm over the set of  $k$  local minima  $\phi^{(j)}$ ,  $j = 1, \dots, k$ . Of course, this ‘underestimator’ only underestimates known local minima. The specific underestimating function  $U(\phi)$  used in this convex global underestimator (CGU) method is given by

$$U(\phi) = c_0 + \sum_{i=1}^n \left( c_i \phi_i + \frac{1}{2} d_i \phi_i^2 \right). \quad (2)$$

Note that  $c_i$  and  $d_i$  appear linearly in the constraints of (1) for each local minimum  $\phi^{(j)}$ . Convexity of this quadratic function is guaranteed by requiring that  $d_i \geq 0$  for  $i = 1, \dots, n$ . Other linear combinations of convex functions could also be used, but this quadratic function is the simplest.

Additionally, in order to guarantee that  $U(\phi)$  attains its global minimum  $U_{\min}$  in the hyperrectangle  $H\phi = \{\phi_i: 0 \leq \underline{\phi}_i \leq \phi_i \leq \overline{\phi}_i \leq 2\pi\}$ , an additional set of constraints are imposed on the coefficients of  $U(\phi)$ :

$$\begin{cases} c_i + \underline{\phi}_i d_i \leq 0, \\ c_i + \overline{\phi}_i d_i \geq 0, \end{cases} \quad i = 1, \dots, n. \quad (3)$$

Note that the satisfaction of (3) implies that  $c_i \leq 0$  and  $d_i \geq 0$  for  $i = 1, \dots, n$ .

The unknown coefficients  $c_i$ ,  $i = 0, \dots, n$ , and  $d_i$ ,  $i = 1, \dots, n$ , can be determined by a linear program which may be considered to be in the dual form. For reasons of efficiency, the equivalent primal of this problem is actually solved, as described below. The solution to this primal linear program provides an optimal dual vector, which immediately gives the underestimating function coefficients  $c_i$  and  $d_i$ . Since the convex quadratic function  $U(\phi)$  gives a global approximation to the local minima of  $F(\phi)$ , then its easily computed global minimum function value  $U_{\min}$  is a good candidate for an approximation to the global minimum of the correct energy function  $F(\phi)$ .

An efficient linear programming formulation and solution satisfying (1)–(3) will now be summarized. Let  $f^{(j)} = F(\phi^{(j)})$ , for  $j = 1, \dots, k$ , and let  $f \in \mathbf{R}^k$  be the vector with elements  $f^{(j)}$ . Also let  $\omega^{(j)} \in \mathbf{R}^n$  be the vector with elements  $\frac{1}{2}(\phi_i^{(j)})^2$ ,  $i = 1, \dots, n$ , and let  $e_k \in \mathbf{R}^k$  be the vector of ones. Now define the following two matrices

$\Phi \in \mathbf{R}^{(n+1) \times k}$  and  $\Omega \in \mathbf{R}^{n \times k}$ :

$$\begin{cases} \Phi = \begin{pmatrix} e_k^\top \\ \phi^{(1)} \dots \phi^{(k)} \end{pmatrix}, \\ \Omega = \begin{pmatrix} \omega^{(1)} \dots \omega^{(k)} \end{pmatrix}. \end{cases} \quad (4)$$

Finally, let  $c \in \mathbf{R}^{n+1}$ ,  $d \in \mathbf{R}^n$ , and  $\delta \in \mathbf{R}^k$  be the vectors with elements  $c_i$ ,  $d_i$ , and  $\delta_i$ , respectively. Then (1)–(3) can be restated as the linear program (with free variables  $c$ ,  $d$ , and  $\delta$ ):

- minimize  $e_k^\top \delta$
- such that

$$\begin{pmatrix} \Phi^\top & \Omega^\top & 0 \\ -\Phi^\top & -\Omega^\top & -I_k \\ I'_n & \underline{D} & 0 \\ -I'_n & -\bar{D} & 0 \end{pmatrix} \begin{pmatrix} c \\ d \\ \delta \end{pmatrix} \leq \begin{pmatrix} f \\ -f \\ 0 \\ 0 \end{pmatrix}, \quad (5)$$

where  $\underline{D} = \text{diag}(\underline{\phi}_1, \dots, \underline{\phi}_n)$ ,  $\bar{D} = \text{diag}(\bar{\phi}_1, \dots, \bar{\phi}_n)$ ,  $I_k$  is the identity matrix of order  $k$ , and  $I'_n$  is the  $n \times (n+1)$  ‘augmented’ matrix  $(0 : I_n$  where  $I_n$  is the identity matrix of order  $n$ .

Since the matrix in (5) has more rows than columns ( $2(k+n)$  rows and  $k+2n+1$  columns, where  $k \geq 2n+1$ ), it is computationally more efficient to consider it as a dual problem, and to solve the equivalent primal. After some simple transformations, this primal problem reduces to:

$$\begin{cases} \min & f^\top y_1 - f^\top e_k \\ \text{s.t.} & \begin{pmatrix} \Phi & I_n^\top & -I_n^\top \\ \Omega & \underline{D} & -\bar{D} \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \begin{pmatrix} \Phi e_k \\ \Omega e_k \end{pmatrix} \\ & y_1, y_2, y_3 \geq 0 \end{cases} \quad (6)$$

which has only  $2n+1$  rows and  $k+2n \geq 4n+1$  columns, and the obvious initial feasible solution  $y_1 = e_k$  and  $y_2 = y_3 = 0$ . Furthermore, since the first of the  $2n+1$  constraints in (6) in fact requires that  $e_k^\top y_1 = 1$ , then the function  $f^\top y_1 - f^\top e_k$  is also bounded below, and so this primal linear program always has an optimal solution. This optimal solution gives the values of  $c$ ,  $d$ , and  $\delta$  via the dual vectors, and also determines which values of  $f^{(j)}$  are interpolated by the potential function  $U(\phi)$ . That is, the basic columns in the optimal solution to (6) correspond to the conformations  $\phi^{(j)}$  for which  $F(\phi^{(j)}) = U(\phi^{(j)})$ .

Note that once an optimal solution to (6) has been obtained, the addition of new local minima is very easy. It is done by simply adding new columns to  $\Phi$  and  $\Omega$ , and therefore to the constraint matrix in (6). The number of primal rows remains fixed at  $2n+1$ , independent of the number  $k$  of local minima.

The convex quadratic underestimating function  $U(\phi)$  determined by the values  $c \in \mathbf{R}^{n+1}$  and  $d \in \mathbf{R}^n$  now provides a global approximation to the local minima of  $F(\phi)$ , and its easily computed global minimum point  $\phi_{\min}$  is given by  $(\phi_{\min})_i = -c_i/d_i$ ,  $i = 1, \dots, n$ , with corresponding function value  $U_{\min}$  given by  $U_{\min} = c_0 - \sum_{i=1}^n c_i^2/d_i$ . The value  $U_{\min}$  is a good candidate for an approximation to the global minimum of the correct energy function  $F(\phi)$ , and so  $\phi_{\min}$  can be used as an initial starting point around which additional configurations (i.e., local minima) should be generated. These local minima are added to the constraint matrix in (6) and the process is repeated. Before each iteration of this process, it is necessary to reduce the volume of the hyperrectangle  $H\phi$  over which the new configurations are produced so that a tighter fit of  $U(\phi)$  to the local minima ‘near’  $\phi_{\min}$  is constructed.

The rate and method by which the hyperrectangle size is decreased, and the number of additional local minima computed at each iteration must be determined by computational testing. But clearly the method depends most heavily on computing local minima quickly and on solving the resulting linear program efficiently to determine the approximating function  $U(\phi)$  over the current hyperrectangle.

If  $E_c$  is a cutoff energy, then one means for decreasing the size of the hyperrectangle  $H\phi$  at any step is to let  $H\phi = \{\phi : U(\phi) \leq E_c\}$ . To get the bounds of  $H\phi$ , consider  $U(\phi) \leq E_c$  where  $U(\phi)$  satisfies (2). Then limiting  $\phi_i$  requires that

$$\sum_{i=1}^n \left( c_i \phi_i + \frac{1}{2} d_i \phi_i^2 \right) \leq E_c - c_0. \quad (7)$$

As before, the minimum value of  $U(\phi)$  is attained when  $\phi_i = -c_i/d_i$ ,  $i = 1, \dots, n$ . Assigning this minimum value to each  $\phi_i$ , except  $\phi_k$ , then results in

$$c_k \phi_k + \frac{1}{2} d_k \phi_k^2 \leq E_c - c_0 + \frac{1}{2} \sum_{i \neq k} \frac{c_i^2}{d_i} \equiv \beta_k. \quad (8)$$

The lower and upper bounds on  $\phi_k$ ,  $k = 1, \dots, n$ , are given by the roots of the quadratic equation

$$c_k \phi_k + \frac{1}{2} d_k \phi_k^2 = \beta_k. \quad (9)$$

Hence, these bounds can be used to define the new hyperrectangle  $H\phi$  in which to generate new configurations.

Clearly, if  $E_c$  is reduced, the size of  $H\phi$  is also reduced. At every iteration the predicted global minimum value  $U_{\min}$  satisfies  $U_{\min} \leq F(\phi^*)$ , where  $\phi^*$  is the smallest known local minimum conformation. Therefore,  $E_c = F(\phi^*)$  is often a good choice. If at least one improved point  $\phi$ , with  $F(\phi) < F(\phi^*)$ , is obtained in each iteration, then the search domain  $H\phi$  will strictly decrease at each iteration, and may decrease substantially in some iterations.

### The CGU Algorithm

Based on the preceding description, a general method for computing the global, or near global, energy minimum of the potential energy function  $F(\phi)$  can now be described.

- 1) Compute  $k \geq 2n + 1$  distinct local minima  $\phi^{(j)}$ , for  $j = 1, \dots, k$ , of the function  $F(\phi)$ .
- 2) Compute the convex quadratic underestimator function given in (2) by solving the linear program given in (6). The optimal solution to this linear program gives the values of  $c$  and  $d$  via the dual vectors.
- 3) Compute the predicted global minimum point  $\phi_{\min}$  given by  $(\phi_{\min})_i = -c_i/d_i$ ,  $i = 1, \dots, n$ , with corresponding function value  $U_{\min}$  given by  $U_{\min} = c_0 - \sum_{i=1}^n c_i^2/(2d_i)$ .
- 4) If  $\phi_{\min} = \phi^*$ , where  $\phi^* = \operatorname{argmin}\{F(\phi^{(j)}): j = 1, 2, \dots\}$  is the best local minimum found so far, then stop and report  $\phi^*$  as the approximate global minimum conformation.
- 5) Reduce the volume of the hyperrectangle  $H\phi$  over which the new configurations will be produced, and remove all columns from  $\Phi$  and  $\Omega$  which correspond to the conformations which are excluded from  $H\phi$ .
- 6) Use  $\phi_{\min}$  as an initial starting point around which additional local minima  $\phi^{(j)}$  of  $F(\phi)$  (restricted to the hyperrectangle  $H\phi$ ) are generated. Add these

new local minimum conformations as columns to the matrices  $\Phi$  and  $\Omega$ .

7) Return to step 2.

The number of new local minima to be generated in step 6 is unspecified since there is currently no theory to guide this choice. In general, a value exceeding  $2n + 1$  would be required for the construction of another convex quadratic underestimator in the next iteration (step 2). In addition, the means by which the volume of the hyperrectangle  $H\phi$  is reduced in step 5 may vary. One could use the two roots of (7) to define the new bounds of  $H\phi$ . Another method would be simply to use  $H\phi = \{\phi_i: (\phi_{\min})_i - \delta_i \leq \phi_i \leq (\phi_{\min})_i + \delta_i\}$  where  $\delta_i = |(\phi_{\min})_i - (\phi^*)_i|$ ,  $i = 1, \dots, n$ .

For complete details of the CGU method and its computational results, see [5,8].

### Introduction

The role of convexity in optimization theory has increased significantly over the last few decades. Despite this fact, a wide variety of global optimization problems

are usually encountered in applications in which non-convex models need to be tackled. For this reason, developing solution methods for specially structured non-convex problems has become one of the most active areas in recent years. Although these problems are difficult by their nature, promising progress is achieved for some special mathematical structures. Among the solution methods developed for these special structures, *monotonic optimization*, first proposed by Tuy [9], is presented in this study.

Problems of optimizing monotonic functions of  $n$  variables under monotonic constraints arise in the mathematical modeling of a broad range of real-world systems, including in economics and engineering. The original difficulties of these problems can be reduced by a number of principles derived from their monotonicity properties. For example, in nonconvex problems in general, a solution which is known to be feasible or even locally optimal, does not provide any information about global optimality and the search should be continued on the entire feasible space, while for an increasing objective function, a feasible solution like  $z$ , would exclude the cone  $z + R_+^n$  from the search procedure (for a minimization objective function). In a similar way, if  $g(x)$  in a constraint like  $g(x) \leq 0$  is increasing, then by knowing that  $z$  is infeasible for this constraint, the whole cone  $z + R_+^n$  can be discarded from further consideration. This kind of information would obviously restrict the search space and may result in more efficient solution methods.

To formally present the general framework of the monotonic optimization problem, consider two vectors  $x, x' \in R^n$ . We say  $x' \geq x$  ( $x'$  dominates  $x$ ) if  $x'_i \geq x_i \forall i = 1, \dots, n$ . We say  $x' > x$  ( $x'$  strictly dominates  $x$ ) if  $x'_i > x_i \forall i = 1, \dots, n$ . Let  $R_+^n = \{x \in R^n | x \geq 0\}$  and  $R_{++}^n = \{x \in R^n | x > 0\}$ . If  $a, b \in R^n$  and  $a \leq b$ , we define the box  $[a, b]$  as the set of all  $x \in R^n$  such that  $a \leq x \leq b$ . Similarly, let  $[a, b) = \{x | a \leq x < b\}$  and  $(a, b] = \{x | a < x \leq b\}$ . A function  $f : R^n \rightarrow R$  is called *increasing* on a box  $[a, b] \in R^n$  if  $f(x) \leq f(x')$  for  $a \leq x \leq x' \leq b$ . A function  $f$  is called *decreasing* if  $-f$  is increasing. Any increasing or decreasing function is referred to as *monotonic*. It can be easily shown that the pointwise supremum of a bounded-above family of increasing functions and the pointwise infimum of a bounded-below family of increasing functions are increasing.

In monotonic optimization, the following problem is considered:

$$\begin{aligned}
 & \text{Maximize (minimize)} && f(x) \\
 & \text{subject to} && g_i(x) \leq 1 \quad \forall i = 1, \dots, m_1, \\
 & && h_j(x) \geq 1 \quad \forall j = 1, \dots, m_2, \\
 & && x \in R_+^n,
 \end{aligned} \tag{1}$$

in which  $f(x)$ ,  $g_i(x)$ , and  $h_j(x)$  are increasing functions on  $R^n$ . A more general definition of this problem is presented in Sect. “Normal Sets and Polyblocks”. Heuristically,  $f(x)$  may be a cost function (profit function for the maximize problem),  $g_i(x)$  may express some resource availability constraints, while  $h_j(x)$  may be a family of utility functions which have to take a value at least as big as a goal.

The remainder of this article is organized as follows. We first describe the theory of normal sets and polyblocks in Sect. “Normal Sets and Polyblocks”. Monotonic optimization algorithms are presented in Sect. “Solution Method”. Section “Generalizations” contains two generalizations of monotonic optimization. Different class of applications for which monotonic optimization is adapted are discussed in Sect. 5 and finally conclusions are made in Sect. “Conclusions”.

### Normal Sets and Polyblocks

The theory of normal sets and polyblocks is the underlying principle for monotonic optimization. In this section, the definitions are presented as well as the main concepts and properties to help the reader to understand the upcoming algorithms. For more details and proofs see [5,9,10].

#### Normal Sets

A set  $G \subset R_+^n$  is called *normal* if for any two points  $x, x' \in R_+^n$  such that  $x \leq x' > x' \in G$  implies  $x \in G$ . Given any set  $D \subset R_+^n$ , the set  $N[D]$ , which is called the *normal hull* of  $D$ , is the smallest normal set containing  $D$ . In other words,  $N[D]$  can be interpreted as the intersection of all normal sets that contain  $D$ . The intersection and the union of a family of normal sets are normal. If the normal set contains a point  $u \in R_{++}^n$  we say it has a *nonempty interior*. Suppose that  $g(x)$  is an increasing function over  $R_+^n$ . Define the *level set* of  $g(x)$

as the set  $G = \{x \in R_+^n | g(x) \leq 1\}$ . It can be shown that the level set of an increasing function is a normal set and it is closed if the function is lower semicontinuous.

Define  $I(x) = \{i | x_i = 0\}$ ,  $K_x = \{x' \in R_+^n | x'_i > x_i \forall i \notin I(x)\}$ , and  $clK_x = \{x' \in R_+^n | x' \geq x\}$ . Then a point  $y \in R_+^n$  is called an *upper boundary point* of a bounded normal set  $G$  if  $y \in clG$  while  $K_y \subset R_+^n \setminus G$ . The set of upper boundary points of  $G$  is called the *upper boundary* of  $G$  and is denoted by  $\partial^+G$ .

For a compact normal set  $G \subset [0, b]$  with nonempty interior and for every point  $z \in R_+^n \setminus \{0\}$ , the half line from 0 through  $z$  meets  $\partial^+G$  at a unique point denoted by  $\pi_G(z)$ , which is defined as  $\pi_G(z) = \lambda z$ ,  $\lambda = \max \{\alpha > 0 | \alpha z \in G\}$ .

A set  $H \subset R_+^n$  is called a *reverse normal set* (also known as *conormal*) if  $x' \geq x$  and  $x \in H$  implies  $x' \in H$ . A reverse normal set in a box  $[0, b]$  is defined as a set like  $H \in R_+^n$  for which  $0 \leq x \leq x' \leq b$  and  $x \in H$  implies  $x' \in H$ . As before,  $rN[D]$  is the smallest reverse normal set containing  $D \subset R_+^n$  and is called a *reverse normal hull* of set  $D$ . Define  $H = \{x \in R_+^n | h(x) \geq 1\}$  for the increasing function  $h(x)$ . Then it can be shown that  $H$  is reverse normal and it is closed if  $h(x)$  is upper semicontinuous.

A point  $y \in R_+^n$  is called a *lower boundary point* of a reverse normal set  $H$  if  $y \in clH$  and  $x \notin H \forall x < y$ . The set of lower boundary points of  $H$  is called the *lower boundary* of  $H$  and is denoted by  $\partial^-H$ .

For the closed reverse normal set  $H$  and  $b \in \text{int}H$  and every point  $z \in [0, b] \setminus H$ , the half line from  $b$  through  $z$  meets  $\partial^-H$  at a unique point  $\rho_H(z)$ , which is defined as  $\rho_H(z) = b + \mu(z - b)$ ,  $\mu = \max \{\alpha > 0 | b + \alpha(z - b) \in H\}$ .

Now consider the set of constraints imposed by increasing functions  $g_i(x)$  and  $h_j(x)$  in problem (1). The feasible space characterized by these sets of constraints can properly be presented by normal sets and reverse normal sets. Define the sets  $G, H \subset R_+^n$  as  $G = \{x \in R_+^n | g_i(x) \leq 1 \forall i = 1, \dots, m_1\}$  and  $H = \{x \in R_+^n | h_j(x) \geq 1 \forall j = 1, \dots, m_2\}$ . Then by the basic properties of normal and reverse normal sets which were described above,  $G$  is the intersection of a finite number of normal sets which is normal. In a similar way,  $H$  is the intersection of a finite number of reverse normal sets which is reverse normal. Now we can redefine the fundamental problem of monotonic optimization, also called the *canonical monotonic optimization*

problem, as optimizing a monotonic function on the intersection of a family of normal and reverse normal sets as follows:

$$\begin{aligned} & \text{Maximize (minimize)} && f(x) \\ & \text{subject to} && x \in G \cap H, \end{aligned} \quad (2)$$

in which  $G \subset [0, b] \subset R_+^n$  is a compact normal set,  $H$  is a close reverse normal set, and  $f(x)$  is an increasing function on  $[0, b]$ . Tuy [9] proved that if  $G$  has a nonempty interior (if  $b \in \text{int}H$ ), then the maximum (minimum) of  $f(x)$  over  $G \cap H$ , if it exists, is attained on  $\partial^+ G \cap H$  ( $G \cap \partial^- H$ ). On the basis of this essential result, it can be shown that for every arbitrary compact set  $D \subset R_+^n$ ,  $\max\{f(x)|x \in D\} = \max\{f(x)|x \in N[D]\}$ . Analogously, for the minimization version of the objective function, for any arbitrary set  $E \subset R_+^n$ , we have  $\min\{f(x)|x \in E\} = \min\{f(x)|x \in rN[E]\}$ .

It is worth mentioning that the minimization problem can be converted to the maximization case by making a simple set of transformations. So it can be either transformed to the maximization problem or treated separately.

### Polyblocks

The role of *polyblocks* in monotonic optimization is the same as that of the polytope in convex optimization. As the polytope is the convex hull of finitely many points in  $R^n$ , a polyblock is the normal hull of finitely many points in  $R_+^n$ . A set  $P \subset R_+^n$  is a polyblock in  $[a, b] \subset R_+^n$  if it is the union of a finite number of boxes  $[a, z], z \in T \subset [a, b]$ . The set  $T$  is called the *vertex set* of the polyblock. We call the vertex  $z \in T$  a *proper* vertex if  $z \notin [0, z'] \forall z' \in T \setminus \{z\}$ , i. e., by removing the vertex  $z$  from  $T$ , the new polyblock created by  $T$  is not equivalent to  $P$ . A vertex which is not proper is called an *improper* vertex. A polyblock can be defined by the set of its proper vertices.

A polyblock is a closed normal set and the intersection of a set of polyblocks is again a polyblock. Now suppose that  $x \in [a, b]$  and consider the set  $P = [a, b] \setminus (x, b]$ . Then it is easy to verify that  $P$  is a polyblock with vertices  $z^i = b + (x - b)e^i, \forall i = 1, \dots, n$  in which  $e^i$  is the  $i$ th unit vector. Using this property, we can approximate an arbitrary compact normal set  $\Omega \subset R_+^n$  (with any desired accuracy) by

a nested sequence of polyblock approximation. At each iteration, a point  $x \notin \Omega$  is found and a new polyblock is constructed based on that which is a subset of the previous polyblock but still contains the set  $\Omega$ .

To present the main idea of the *polyblock approximation method* in monotonic optimization, we need one more result on optimizing an increasing function over a polyblock. Tuy [9] proved that the increasing function  $f(x)$  achieves its maximum over a polyblock at a proper vertex.

Now consider the problem of maximizing the increasing function  $f(x)$  over the arbitrary compact set  $\Omega \subset R_+^n$ . As mentioned before, we can substitute  $\Omega$  by its normal hull. So without loss of generality, we assume that  $\Omega$  is normal. The idea is to construct a nested sequence of polyblock outer approximation  $P_1 \supset P_2 \supset \dots \supset \Omega$  in such a way that  $\max\{f(x)|x \in P_k\} \searrow \max\{f(x)|x \in \Omega\}$ .

At iteration  $k$ , assume  $z^k$  is the proper vertex of  $P_k$  which maximizes  $f(x)$ , i. e.,  $z^k = \arg \max\{f(z)|z \in T_k\}$ , where  $T_k$  is the set of proper vertices of  $P_k$ . Then if  $z^k$  is feasible in  $\Omega$ , the initial feasible space, it also solves the problem. Otherwise, we are interested in a new polyblock  $P_{k+1} \subset P_k \setminus \{z^k\}$  which still contains  $\Omega$  as a subset.

To obtain  $P_{k+1}$  from  $P_k$ , the box  $[0, z^k]$  is replaced by  $[0, z^k] \setminus K_{x^k}$ , in which  $x^k$  is defined as  $\pi(z^k)$ . Mathematically,  $P_{k+1} = ([0, z^k] \setminus K_{x^k}) \cup_{z \in T_k \setminus \{z^k\}} [0, z]$ , which clearly satisfies the desired property of  $\Omega \subset P_{k+1} \subset P_k \setminus \{z^k\}$ .

The vertex set of the established polyblock  $P_{k+1}$ , denoted by  $V_{k+1}$ , contains the proper vertices of  $P_k$  excluding  $z^k$  and a set of  $n$  new vertices,  $z^{k,1}, z^{k,2}, \dots, z^{k,n}$ , defined as  $z^{k,i} = z^k + (x_i^k - z_i^k)e^i$ . This result is directly followed by the earlier-mentioned property of polyblocks about the vertices of  $[a, b] \setminus (x, b]$ . Finally, the proper vertex set of  $P_{k+1}$ ,  $T_{k+1}$ , is obtained from  $V_{k+1}$  by removing its improper vertices [9,10].

A set  $P \subset R_+^n$  is called a *reverse polyblock* in  $[0, b]$  if it is the union of a finite number of boxes  $[z, b], z \in T, T \subset [0, b]$ . The set  $T$  is called the *vertex set* of the reverse polyblock. As before,  $z$  is a *proper* vertex if by removing it from  $T$ , the new reverse polyblock created by  $T$  is not equivalent to  $P$ . A reverse polyblock can be defined by the set of its proper vertices. An increasing function  $f(x)$  achieves its minimum over a re-

verse polyblock at a proper vertex. Similar results to what we had for polyblocks can be developed for reverse polyblocks in the very same way. For more details see [9,10].

### Solution Method

Consider problem (2) (in the maximization form) as discussed in Sect. “Normal Sets and Polyblocks” with the additional assumptions that  $f(x)$  is semicontinuous on  $H$  and  $G \cap H \subset R_{++}^n$ . The latter assumption implies the existence of a vector  $a$  such that  $0 < a \leq x, \forall x \in G \cap H$ . Let  $H_a = \{x \in H | x \geq a\}$ . For  $\epsilon \geq 0$  as a given tolerance, the solution  $x'$  is called  $\epsilon$ -optimal if  $f(x') \geq f(x) - \epsilon, \forall x \in G \cap H$ . We attempt to design an algorithm which is capable of finding an  $\epsilon$ -optimal solution for any given  $\epsilon$ .

Obviously,  $b \in H$  because otherwise the problem is infeasible. Let  $P_1 = [0, b]$  be the initial polyblock and  $T_1 = \{b\}$  its corresponding proper vertex set. If we apply the polyblock approximation method described in Sect. “Normal Sets and Polyblocks” to this problem, at each iteration  $k$ ,  $P_k$  and its proper vertex set,  $T_k$ , are obtained from the last iteration. We should notice that every vertex  $z \in T_k \setminus H_a$  can be removed since they do not belong to the initial feasible space. Also suppose that  $f(x^k)$  is the best value found for the objective function so far. Then any vertex  $z$  for which  $f(z) \leq f(x^k) + \epsilon$  is discarded because no  $\epsilon$ -optimal solution happens to be in box  $[0, z]$ . These two rules can be applied at each iteration to refine the proper vertex set  $T_k$  and delete some of the vertices from further consideration.

If  $T_k = \emptyset$  in some iteration  $k$ , it means there is no solution  $x$  for which  $f(x) > f(x^k) + \epsilon$ . So,  $x^k$ , the best solution found so far, is  $\epsilon$ -optimal and the procedure terminates. Otherwise, let  $z^k = \arg \max \{f(z) | z \in T_k\}$ . If  $z^k$  is feasible in  $G \cap H$ , it solves the problem. Since  $z^k \in H$  is always true, it is feasible if it belongs to  $G$  and infeasible otherwise. In the case of infeasibility, we find  $x^k = \pi_G(z^k)$  and construct the polyblock  $P_{k+1}$  as described in Sect. “Normal Sets and Polyblocks” which excludes  $z^k$  while still containing a global optimal solution of the problem. This procedure is repeated until the termination criteria are satisfied or the problem is known to be infeasible. This procedure, first proposed by Tuy [9], is called the *polyblock algorithm*. Tuy [9] discussed the convergence of this method and showed that

as  $k \rightarrow \infty$ , the sequence  $x^k$  converges to a global optimal solution of the problem.

Now consider the minimization case of problem (2) in Sect. “Normal Sets and Polyblocks” with additional assumptions that  $f(x)$  is semicontinuous on  $G$  and there exists a vector  $c$  such that  $0 < c < b$  and  $0 \leq x \leq c, \forall x \in G \cap H$ . A nested sequence of reverse polyblock outer approximation of  $G \cap H$  (or a subset of  $G \cap H$  in which the existence of at least one optimal solution is guaranteed) is called the *reverse polyblock algorithm* (*copolyblock algorithm*) which is devised to solve this problem [9].

The polyblock approximation algorithm works properly for relatively small dimension  $n$ , typically  $n = 10$ . However, the algorithm converges slowly as it gets closer to the global optimal solution and needs a large number of iterations even for a value of  $n$  as small as 5. Tuy et al. [12] presented two main reasons for this drawback of the algorithm. First, the speed of convergence depends on the way in which we construct the current polyblock from the previous one. Obviously, we prefer to remove a larger portion of the previous polyblock to have a smaller search space and a higher speed of convergence. This goal is achieved by employing more complex rules of constructing the polyblocks, which imposes some additional computational effort. The second source of the slowness of the algorithm is how it selects the solution  $x_k$  in each iteration. These solutions are basically derived from the monotonicity properties of the problem, while sometimes there may exist some amount of convexity which can be used to speed up the algorithm.

Tuy and Al-Khayyal [11] introduced the concept of *reduced box* and *reduced polyblock*. It involves tightening the box in which we are interested to find the upper bound of  $f(x)$ , in such a way that the reduced box still contains an optimal solution of the problem. Then based on that, a new procedure is developed to produce tighter polyblocks. They also redefined the proper vertex set of polyblocks in the algorithm and suggested that instead of selecting  $x^k$  as the last point of  $G$  on the halfline from  $a$  through  $z^k$ , as the original algorithm does, a more complex way can be implemented by incorporating some of the convexity properties of the problem. This is by solving the convex relaxation of the problem  $\max \{f(x) | x \in G \cap H, x \in [a, z^k]\}$  which gives us an upper bound of  $f(x)$  over the feasible solu-

tion  $x$  in box  $[a, x^k]$ . Similar ideas were applied to the reverse polyblock algorithm as well. Using these two new modifications and improvements, they developed new algorithms and discussed their convergence properties, namely, the *revised polyblock algorithm* and the *revised reverse polyblock (copolyblock) algorithm*.

Most of the outer approximation procedures, including the polyblock algorithm, encounter storage and numerical problems while solving problems in high dimensions. By using branch-and-bound strategies, one can tackle these difficulties. Bounding is performed on the basis of the polyblock approximation. As before, monotonicity cuts and convex relaxation can be combined to enhance the quality of the bounds in the corresponding portion of the feasible space. In this branch-and-bound approach, branching is performed as partitioning the feasible space into cones pairwise having no common interior point. The logic behind using conical partitioning instead of rectangular partitioning is the fact that the optimal solution of the monotonic optimization problem, as discussed before, is always achieved on the upper boundary of the feasible normal set. Using conical partitioning is more efficient and less expensive in terms of the computational time.

The algorithm starts with initial cone  $R_+^n$  and partitions it into subcones. For each of these subcones, an upper bound for the value of the objective function over the feasible solutions contained in it is derived. Those cones which are known to not contain an optimal solution are fathomed and the remaining ones are subdivided again and the procedure is repeated until the termination criteria are satisfied. Among the remaining cones, the one having the maximal bound is the first candidate for branching. This algorithm, suggested by Tuy and Al-Khayyal [11], is called the *conical algorithm*.

For those problems having partial monotonicity and partial convexity, this branch-and-bound scheme can be extended to devise a more general method. In this method, branching is performed on the nonconvex variables and bounds are computed by Lagrangian or convex relaxation [6].

To further exploit the monotonic structure of the problem, *reduction cuts* are combined with original monotonicity cuts and a more efficient method is developed [13]. This method creates branch-and-cut algorithms to solve monotonic optimization problems by systematic use of these cuts.

Finally, it is worth mentioning that a new concept of the *essential  $\epsilon$ -optimal solution* can be applied to monotonic optimization problems. The advantage of the method developed on the basis of this concept is the finding of an approximate optimal solution which is more appropriate and more stable than that which is found by the  $\epsilon$ -optimal method. For details see [8].

## Generalizations

The essential approach used in monotonic optimization can be further generalized to cover a wider class of non-convex general optimization problems. Among these generalizations, optimization of the difference of monotonic functions and discrete monotonic optimization are presented here.

### Optimization of the Difference of Monotonic Functions

The underlying idea of monotonic optimization can be extended to deal with problems including the *difference of monotonic functions*. A function  $f : R_+^n \rightarrow R$  is said to be a difference of monotonic functions if it is representable as the difference of two increasing functions:  $f_1 : R_+^n \rightarrow R$  and  $f_2 : R_+^n \rightarrow R$ . Similar to functions presented as the difference of convex functions, the class of difference of monotonic functions is a linear space. The pointwise minimum and pointwise maximum of a family of difference of monotonic functions (difference of convex functions) is still a difference of monotonic functions (difference of convex functions). The linear combination of a set of difference of monotonic functions is a difference of monotonic functions. Obviously, any polynomial function can be presented as the difference of two increasing functions, the first one includes all terms having positive coefficients and the second one includes all terms having negative coefficients.

Consider the problem:

$$\begin{aligned} & \text{Maximize (minimize)} && f(x) - g(x) \\ & \text{subject to} && x \in G \cap H, \end{aligned} \quad (3)$$

in which  $G$  and  $H$  are as before and  $f(x)$  and  $g(x)$  are increasing functions on  $[0, b]$ . Tuy [9] extended the original polyblock algorithm to solve this problem. By introducing  $t$  as the difference between  $g(b)$

and  $g(x)$  for  $x \in [0, b]$  and regarding the fact that  $t$  is always positive owing the function  $g(x)$  being increasing, we rewrite the model as (maximization case)  $\max\{f(x) + t - g(b) | x \in G \cap H, t = g(b) - g(x)\}$ . Now  $g(b)$  is a constant and can be removed from the objective function. In the resulting problem,  $\max\{f(x) + t | x \in G \cap H, 0 \leq t \leq g(b) - g(x)\}$ , consider the set of constraints. By incrementing the dimension of the problem by one, the feasible space can be presented as  $D \cap E$  such that  $D = \{(x, t) | x \in G, t + g(x) \leq g(b), 0 \leq t \leq g(b) - g(0)\}$  and  $E = \{(x, t) | x \in H, 0 \leq t \leq g(b) - g(0)\}$ . It is easy to verify that  $D$  is a normal set and  $H$  is a reverse normal set in the box  $[0, b] \times [0, g(b) - g(0)]$ . Also the function  $F(x, t) = f(x) + t$  is an increasing function on  $[0, b] \times [0, g(b) - g(0)]$ . So problem (3) is reduced to problem (2) in Sect. “Normal Sets and Polyblocks” and can be treated by the original polyblock algorithm. The additional cost that the presence of difference of monotonic functions has incurred is the dimension of the problem incremented by one.

For the minimization case of problem (3), a similar transformation can be applied to convert this problem to the minimization case of problem (2).

To make the problem even more general, suppose that all constraints are also difference of monotonic functions. Specifically, consider the problem:

$$\begin{aligned} \text{Maximize (minimize)} \quad & f_1(x) - f_2(x) \\ \text{subject to} \quad & g_i(x) - h_i(x) \leq 0 \\ & \forall i = 1, \dots, m, \\ & x \in \Omega \subset [0, b] \subset \mathbb{R}_+^n, \end{aligned} \tag{4}$$

in which  $f_1(x)$ ,  $f_2(x)$ ,  $g_i(x)$ , and  $h_i(x)$  are increasing functions and  $\Omega$  is a normal set. By the above argument, first we can make a proper transformation and convert the objective function to an increasing function. So without loss of generality, let us assume that  $f_2(x) = 0$ . Now consider the set of  $m$  constraints. This set of constraints can be rewritten as  $\max_i \{g_i(x) - h_i(x)\} \leq 0$ . Since the pointwise maximum of a family of difference of monotonic functions is still a difference of monotonic functions, we can represent the space imposed by these constraints by  $g(x) - h(x) \leq 0$ , where both  $g(x)$  and  $h(x)$  are increasing. By introducing the new variable  $t \geq 0$  and assuming  $g(b) \geq 0$  (this assumption is not restrictive), the set

of the following two constraints fully defines the space mentioned:  $g(x) + t \leq g(b)$ ,  $h(x) + t \geq g(b)$ . The first constraint gives us the upper bound of  $g(b) - g(0)$  for  $t$ .

Finally the problem reduces to (maximization case):  $\max\{f_1(x) | g(x) + t \leq g(b), h(x) + t \geq g(b), x \in \Omega, 0 \leq t \leq g(b) - g(0)\}$ . This problem is the same as problem (2) by defining  $G = \{(x, t) | x \in \Omega, g(x) + t \leq g(b), 0 \leq t \leq g(b) - g(0)\}$ , which is a subset of the box  $[0, b] \times [0, g(b) - g(0)]$  and  $H = \{(x, t) | h(x) + t \geq g(b)\}$  is defined in  $\mathbb{R}_+^{n+1}$ .

Increasing the dimension of the problem is the main drawback of the above mentioned approach. Tuy and Al-Khayyal [11] presented a direct approach for the difference of monotonic functions optimization problem requiring no additional dimension. This method is referred to as the branch-reduce-and-bound (BRB) algorithm. As the name of the algorithm suggests, it contains three main steps, which are branching upon nonconvex variables, reducing any partition set before bounding, and bounding over each partition set.

The branching phase is performed by rectangular subdivision. Every box is divided into two subboxes by a hyperplane. The reduction phase contains a set of operations by which the box  $[p, q]$  is tightened without losing any feasible solution. This is called a *proper reduction* of  $[p, q]$ . This approach takes advantage of the monotonicity properties of the problem and increases the rate of convergence in the algorithm. In the bounding phase, for a properly reduced box  $[p, q]$ , an upper bound like  $\beta$  is obtained such that  $\beta \geq \max\{f_1(x) - f_2(x) | g_i(x) - h_i(x) \leq 0, \forall i = 1, \dots, m; x \in [p, q]\}$ . As mentioned before, stronger bounds are obtained by a sequence of polyblock approximations or by combining monotonicity with convexity present in the problem. Furthermore, more complex methods can be applied to improve the quality of the bounds in the bounding phase.

### Discrete Monotonic Optimization

A class of monotonic optimization problems containing the additional discrete constraints are called *discrete monotonic optimization problems*. Specifically, given a finite set  $S$  of points in the box  $[a, b]$ , the constraint  $x \in S$  is added to the model. So the problem can be represented as  $\max\{f(x) | x \in G \cap H \cap S\}$  (all the assumptions are as in problem (2)).

The original polyblock algorithm is not practical for these problems. Since the polyblock algorithm is an iterative procedure, it does not have the capability to produce the optimal solution in a finite number of iterations. However, by making suitable modifications, one can use this algorithm to obtain the exact optimal solution of the problem in a finite number of steps [1,14]. In the new method, monotonicity cuts are adjusted on the basis of a special procedure to cope with discrete requirements. This adjustment consists in updating the vertex of the monotonicity cut by pushing it deeper inside the polyblock to obtain a tighter space while keeping all discrete points which are not proven to be nonoptimal, unaffected.

The algorithm first constructs the normal hull of  $G \cap S$ , denoted by  $\tilde{G}$ , and then tries to solve the problem  $\max \{f(x) | x \in \tilde{G} \cap H\}$  in continuous space. This method is called the *discrete polyblock algorithm*. For large-scale instances, a similar BRB algorithm was developed by Tuy et al. [14].

## Applications

Although monotonic optimization is a new approach in global optimization and there is not a broad literature on its applications, it can be applied to numerous problems. In most of these applications, first some transformations are performed and the problems are reformulated in the proper way. Then monotonic optimization is applied and other approaches are employed to enhance the quality of the bounds. Some of these applications are briefly introduced in this section.

**Polynomial programming:** The problem of minimizing or maximizing a polynomial function under a set of polynomial constraints, which is encountered in a multitude of applications, is called *polynomial programming*. Tuy [9] reformulated this problem as a difference of monotonic functions problem which can be solved by the methods described before. Tuy [7] proposed a robust solution approach for polynomial programming based on a monotonic optimization scheme. He developed a BRB procedure to tackle the polynomial optimization problems of higher dimensions.

Polynomial optimization contains nonconvex quadratic programming as a special case. So every polynomial optimization method can be applied to solve this important class of problems [4,16].

**Fractional programming:** In *fractional programming*, we are dealing with functions which are represented by ratios of other functions. Phuong and Tuy [3] considered a generalized linear fractional programming problem. In this problem, the objective function consists of an arbitrary continuous increasing function of  $m$  linear fractional functions and the feasible set is the polytope  $D$ . Linear fractional functions are defined as the ratio of two linear affine functions. They proposed a new unified approach which reformulates the problem and solves it as a monotonic optimization problem.

Tuy [17] considered a more general class of fractional programming problems which is optimizing a polynomial fractional function (the ratio of two polynomial functions) under polynomial constraints. His method to solve the problem is again based on reformulating the problem as a monotonic optimization problem. A branch-and-bound scheme was presented for problems of higher ranks. Clearly, polynomial programming is a special case of this class of problems.

**Multiplicative programming:** *Multiplicative programming* problems are optimization problems containing products of a number of convex or concave functions in the objective function or constraints. Tuy [9] showed that these classes of problems are essentially monotonic optimization problems. Tuy and Nghia [15] devised a new approach based on the reverse polyblock approximation method for a broad class of problems including generalized linear multiplicative and linear fractional programming as special cases.

For more applications, including *Lipschitz optimization*, *optimization under network constraints*, the *Fekete points problem*, and the *Lennard-Jones potential energy function*, see [9].

## Conclusions

We have discussed the recently developed theory of monotonic optimization as well as its generalizations and applications. This noble scheme which is capable of solving a wide range of nonconvex problems is based on an polyblock outer approximation procedure.

The approach that monotonic optimization uses to deal with optimization problems is analogous to convex optimization in several respects. Just as we approx-

imate convex sets by polyhedrons, normal sets, defined as the level sets of increasing functions, can be approximated by a set of polyblocks in monotonic optimization. As the difference of convex functions plays an essential role in convex analysis (because any arbitrary continuous function can be represented as the difference of two convex functions), optimization problems representable as the difference of monotonic functions can be treated in monotonic optimization.

The performance of this method can be significantly improved by incorporating some other techniques like convex relaxation to exploit other properties present in the problem. In high dimensions, branch-and-bound or branch-and-cut extensions of the algorithm can be applied to overcome storage difficulties and increase the convergence speed.

We review uses of Monte-Carlo simulated annealing in the protein folding problem. We will discuss the strategy for tackling the protein folding problem based on all-atom models. Our approach consists of two elements: the inclusion of accurate solvent effects and the development of powerful simulation algorithms that can avoid getting trapped in states of energy local minima. For the former, we discuss several models varying in nature from crude (distance-dependent dielectric function) to rigorous (reference interaction site model).

For the latter, we show the effectiveness of Monte-Carlo simulated annealing.

## Introduction

Proteins under their native physiological conditions spontaneously fold into unique three-dimensional structures (tertiary structures) in the time scale of milliseconds to minutes. Although protein structures appear to be dependent on various environmental factors within the cell where they are synthesized, it was inferred by experiments 'in vitro' that the three-dimensional structure of a protein is determined solely by its amino-acid sequence information [12]. Hence, it has been hoped that once the correct Hamiltonian of the system is given, one can predict the native protein tertiary structure from the first principles by computer simulations. However, this has yet to be accomplished. There are two reasons for the difficulty. One reason is that the inclusion of accurate solvent effects is nontrivial, because the number of solvent molecules that have to be considered is very large. The other reason for the difficulty comes from the fact that the number of possible conformations for each protein is astronomically large [30,60]. Simulations by conventional methods such as Monte-Carlo or molecular dynamics algorithms in canonical ensemble will necessarily be trapped in one of many local-minimum states in the energy function. In this article, I will discuss a possible strategy to alleviate these difficulties. The outline of the article is as follows. In Sect. "Energy Functions of Protein Systems" we summarize the energy functions of protein systems that we used in our simulations. In Sect. "Methods" we briefly review our simulation methods. In Sect. "Results" we present the results of our protein folding simulations. Section "Conclusions" is devoted to conclusions.

## Energy Functions of Protein Systems

The energy function for the protein systems is given by the sum of two terms: the conformational energy  $E_P$  for the protein molecule itself and the solvation free energy  $E_S$  for the interaction of protein with the surrounding solvent. The conformational energy function  $E_P$  (in kcal/mol) for the protein molecule that we used is one of the standard ones. Namely, it is given by the sum of the electrostatic term  $E_C$ , 12-6 Lennard-Jones term  $E_{LJ}$ ,

and hydrogen-bond term  $E_{HB}$  for all pairs of atoms in the molecule together with the torsion term  $E_{tor}$  for all torsion angles:

$$\begin{cases} E_P = E_C + E_{LJ} + E_{HB} + E_{tor}, \\ E_C = \sum_{(i,j)} \frac{332q_i q_j}{\epsilon r_{ij}}, \\ E_{LJ} = \sum_{(i,j)} \left( \frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^6} \right), \\ E_{HB} = \sum_{(i,j)} \left( \frac{C_{ij}}{r_{ij}^{12}} - \frac{D_{ij}}{r_{ij}^{10}} \right), \\ E_{tor} = \sum_i U_i (1 \pm \cos(n_i \chi^i)). \end{cases} \quad (1)$$

Here,  $r_{ij}$  is the distance (in Å) between atoms  $i$  and  $j$ ,  $\epsilon$  is the dielectric constant, and  $\chi^i$  is the torsion angle for the chemical bond  $i$ . Each atom is expressed by a point at its center of mass, and the partial charge  $q_i$  (in units of electronic charges) is assumed to be concentrated at that point. The factor 332 in  $E_C$  is a constant to express energy in units of kcal/mol. These parameters in the energy function as well as the molecular geometry were adopted from ECEPP/2 [37,41,57]. The computer code KONF90 [23,46] was used for all the Monte-Carlo simulations. For gas phase simulations, we set the dielectric constant  $\epsilon$  equal to 2. The peptide-bond dihedral angles  $\omega$  were fixed at the value  $180^\circ$  for simplicity. So, the remaining dihedral angles  $\phi$  and  $\psi$  in the main chain and  $\chi$  in the side chains constitute the variables to be updated in the simulations. One Monte-Carlo (MC) sweep consists of updating all these angles once with Metropolis evaluation [36] for each update.

Solvation free energy of interactions between a solute molecule and solvent molecules, in general, can be divided into three contributions: hydrophobic term that corresponds to the work required to create a cavity of the shape of the solute molecule in solution (the term 'hydrophobic' used in this article is different from a more standard one; see [11] for clarification on various definitions), the electrostatic term (including the hydrogen-bond energy) between solute and solvent molecules, and the Lennard-Jones term between solute and solvent molecules.

One of the simplest ways to represent solvent effects is by the sigmoidal, distance-dependent dielectric function [20,54]. The explicit form of the function we used

is given by [43]

$$\epsilon(r) = D - \frac{D-2}{2} [(sr)^2 + 2sr + 2] e^{-sr}, \quad (2)$$

which is a slight modification of the one used in [9]. Here, we use  $s = 0.3$  and  $D = 78$ . It approaches 2 (the value inside a protein) in the limit the distance  $r$  going to zero and 78 (the value for bulk water) in the limit  $r$  going to infinity. The distance-dependent dielectric function is simple and also computationally only slightly more demanding than the gas-phase case. But it only involves the electrostatic interactions. Other solvent contributions are hydrophobic interactions and Lennard–Jones interactions between protein and solvent.

Another commonly used term that represents solvent contributions is the term proportional to the solvent-accessible surface area of protein molecule. The solvation free energy  $E_S$  in this approximation is given by

$$E_S = \sum_i \sigma_i A_i, \quad (3)$$

where  $A_i$  is the solvent-accessible surface area of  $i$ th functional group, and  $\sigma_i$  is the proportionality constant. There are several versions of the set of the proportionality constants and functional groups. Five parameter sets were compared for the systems of peptides and a small protein, and we found that the parameter sets of [52,59] are valid ones [33]. The term in (3) includes all the contributions from solvent (namely, hydrophobic, electrostatic, and Lennard–Jones interactions), and it is therefore more accurate than the distance-dependent dielectric function. It is, however, an empirical representation, and its validity has to be eventually tested with a rigorous solvation theory.

The most widely-used and rigorous method of inclusion of solvent effects is probably the one that deals with the explicit solvent molecules with all-atom representations. Many molecular dynamics simulations of protein systems now directly include these explicit solvent molecules (for a review, see, for instance, [4]). Another rigorous method is based on the statistical mechanical theory of liquid and solution and is called the reference interaction site model (RISM) [7,21]. The RISM integral equation for solute-solvent ( $p$ - $s$ ) correla-

tion functions in Fourier  $k$ -space is given by

$$\tilde{\mathbf{h}}^{\text{ps}} = \tilde{\mathbf{w}}^{\text{pp}} \tilde{\mathbf{c}}^{\text{ps}} (\tilde{\mathbf{w}}^{\text{ss}} + \rho \tilde{\mathbf{h}}^{\text{ss}}), \quad (4)$$

where  $\tilde{\mathbf{h}}^{\text{ps}}$  and  $\tilde{\mathbf{h}}^{\text{ss}}$  are the matrices of the solute-solvent and the solvent-solvent total correlation functions, respectively,  $\tilde{\mathbf{c}}^{\text{ps}}$  is the matrix of the solute-solvent direct correlation functions,  $\tilde{\mathbf{w}}^{\text{pp}}$  and  $\tilde{\mathbf{w}}^{\text{ss}}$  are the intramolecular correlation matrices for solute and solvent, respectively, and  $\rho$  is the number density matrix of the solvent. The solvation free energy is given by

$$E_S = 4\pi\rho k_B T \int_0^\infty r^2 F(r) dr, \quad (5)$$

where  $F(r)$  is defined by

$$F(r) \equiv \sum_{a,b} \left\{ \frac{1}{2} h_{ab}^{\text{ps}}(r)^2 - c_{ab}^{\text{ps}}(r) - \frac{1}{2} h_{ab}^{\text{ps}}(r) c_{ab}^{\text{ps}}(r) \right\}. \quad (6)$$

Here, the summation indices  $a$  and  $b$  run over the solute and the solvent sites, respectively. A robust and fast algorithm for solving RISM equations was recently (as of 1999) developed [24], which made folding simulations of peptides a feasible possibility [25]. Although this method is computationally much more time-consuming than the first two methods (terms with distance-dependent dielectric function and those proportional to surface area), it gives the most accurate representation of the solvation free energy.

## Methods

Once the appropriate energy function of the protein system is given, we have to employ a simulation method that does not get trapped in states of energy local minima. We have been advocating the use of Monte-Carlo simulated annealing [27].

In the regular canonical ensemble with a given inverse temperature  $\beta \equiv 1/k_B T$ , the probability weight of each state with energy  $E$  is given by the Boltzmann factor:

$$W_B(E) = \exp(-\beta E). \quad (7)$$

The probability distribution in energy is then given by

$$P_B(T, E) \propto n(E) W_B(E), \quad (8)$$

where  $n(E)$  is the number of states with energy  $E$ . Since the number of states  $n(E)$  is an increasing function of energy and the Boltzmann factor  $W_B(E)$  decreases exponentially with  $E$ , the probability distribution  $P_B(T, E)$  has a bell-like shape in general. When the temperature is high,  $\beta$  is small, and  $W_B(E)$  decreases slowly with  $E$ . So,  $P_B(T, E)$  has a wide bell-shape. On the other hand, at low temperature  $\beta$  is large, and  $W_B(E)$  decreases rapidly with  $E$ . So,  $P_B(T, E)$  has a narrow bell-shape (and in the limit  $T \rightarrow 0$  K,  $P_B(T, E) \propto \delta(E - E_{GS})$ , where  $E_{GS}$  is the global-minimum energy). However, it is very difficult to obtain canonical distributions at low temperatures with conventional simulation methods. This is because the thermal fluctuations at low temperatures are small and the simulation will certainly get trapped in states of energy local minima. Simulated annealing [27] is based on the process of crystal making. Namely, by starting a simulation at a sufficiently high temperature (much above the melting temperature), one lowers the temperature gradually during the simulation until it reaches the global-minimum-energy state (crystal). If the rate of temperature decrease is sufficiently slow so that thermal equilibrium may be maintained throughout the simulation, only the state with the global energy minimum is obtained (when the final temperature is 0 K). However, if the temperature decrease is rapid (quenching), the simulation will get trapped in a state of energy local minimum in the vicinity of the initial state.

Simulated annealing was first successfully used to predict the global-minimum-energy conformations of polypeptides and proteins [22,61,63] and to refine protein structures from X-ray and NMR data [5,42] almost a decade ago. Since then this method has been extensively used in the protein folding and structure refinement problems (for reviews, see [45,62]). Our group has been testing the effectiveness of the method mainly in oligopeptide systems. The procedure of our approach is as follows. While the initial conformations in the protein simulations are usually taken from the structures inferred by the experiments, our initial conformations are *randomly generated*. Each Monte-Carlo sweep updates every dihedral angle (in both the main chain and side chains) once. Our annealing schedule is as follows: The temperature is lowered exponentially from  $T_I = 1000$  K to  $T_F = 250$  K (the final temperature  $T_F$  was sometimes set equal to 100 K, 50 K, or 1 K) [23,46]. The

temperature for the  $n$ th MC sweep is given by

$$T_n = T_I \gamma^{n-1}, \quad (9)$$

where  $\gamma$  is a constant which is determined by  $T_I$ ,  $T_F$ , and the total number of MC sweeps of the run. Each run consists of  $10^4 \sim 10^6$  MC sweeps, and we usually made 10 to 20 runs from different initial conformations.

## Results

We now present the results of our simulations based on Monte-Carlo simulated annealing. All the simulations were started from randomly-generated conformations.

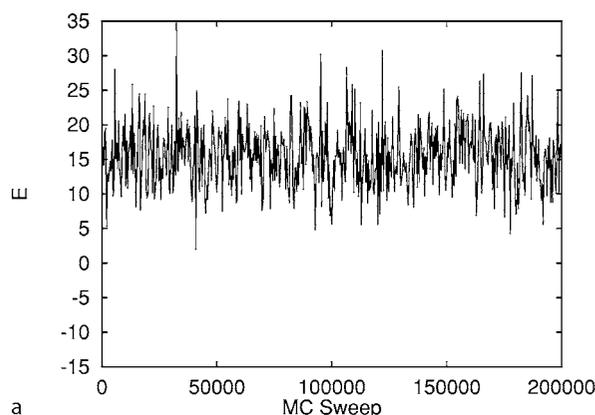

The first example is Met-enkephalin. This brain neuro peptide consists of 5 amino acids with the amino-acid sequence: Tyr-Gly-Gly-Phe-Met. Because it is one of the smallest peptides that have biological functions, it has served as a bench mark for testing a new simulation method. The global minimum conformation of this peptide for ECEPP/2 energy function in gas phase ( $\epsilon = 2$ ) is known [31,49]. For KONF90 realization of ECEPP/2 energy, the peptide is essentially in the ground state for  $E_p \leq -11$  kcal/mol [15,49] and the lowest value is  $-12.2$  kcal/mol [16,17].

In Fig. 1, we show the ‘time series’ of the total conformational energy  $E_p$  (in (1)) obtained by conventional canonical Monte-Carlo simulations at  $T = 1000$ , 300, and 50 K.

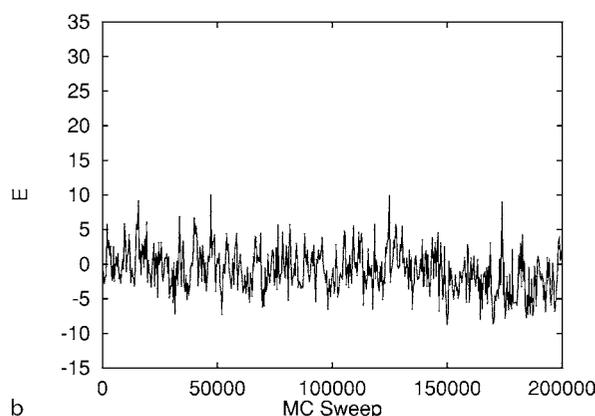

The thermal fluctuations for the run at  $T = 50$  K in Fig. 1c are very small and this run has apparently gotten trapped in states of energy local minima (because the average energy at 50 K is about  $-11$  kcal/mol [15,16]). In Fig. 2 we display the time series of energy obtained by a Monte-Carlo simulated annealing simulation.

This run reaches the global minimum region ( $E_p \leq -11$  kcal/mol) as the temperature is decreased during the simulation from 1000 K to 50 K.

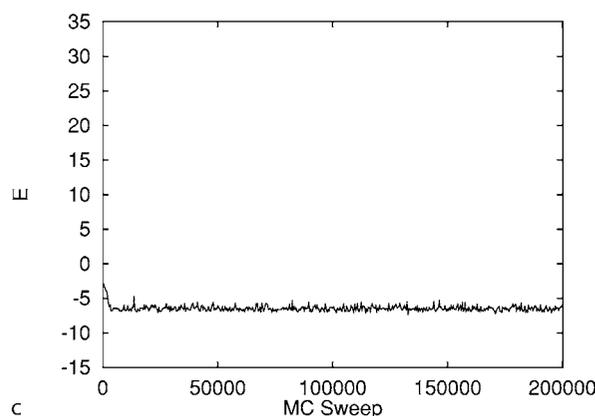

We have up to now presented the results in gas phase ( $\epsilon = 2$ ). In Fig. 3 we compare the superposed structures of lowest-energy conformations from 8 Monte-Carlo simulated annealing runs in gas phase, simple-repulsive solvent, and water (the latter two contributions were calculated by the RISM theory) [26] with those of 5 structures inferred from NMR experiments ([13, Fig. 2]). The figures were created with RasMol [55].

We see a striking similarity between simulation results in water Fig. 3c and those of NMR experiments (Fig. 3d). The simulation results in Fig. 3 are from the same number of MC sweeps. It seems that the presence of water speeds up the convergence of the backbone structures in the sense that it requires less number of MC sweeps for convergence [26].

The solvation free energy based on the RISM theory is very accurate, but it is also computationally very demanding. We are currently trying to solve this problem making the algorithm more efficient and robust [24]. Hereafter, we discuss how well other solvation theories can still describe the effects of solvent in the prediction of three-dimensional structures of oligopeptides and small proteins.

Next systems we discuss are those of homooligomers with length of 10 amino acids. From the structural data base of X-ray experiments of protein structures [8] and CD experiments [6], it is known that certain amino acids have more tendency of  $\alpha$ -helix formation than others. For instance, alanine is a helix former and glycine is a helix breaker, while phenylalanine has intermediate helix-forming tendency. We have performed 20 Monte-Carlo simulated annealing runs of 10,000 MC sweeps in gas phase ( $\epsilon = 2$ ) with each of  $(\text{Ala})_{10}$ ,  $(\text{Leu})_{10}$ ,  $(\text{Met})_{10}$ ,  $(\text{Phe})_{10}$ ,  $(\text{Ile})_{10}$ ,  $(\text{Val})_{10}$ , and  $(\text{Gly})_{10}$  [44]. These amino acids are nonpolar and we can avoid the complications of electrostatic and

hydrogen-bond interactions of side chains with each other, with main chain, and with the solvent.

In order to analyze how much  $\alpha$ -helix formation is obtained by simulations, we first define  $\alpha$ -helix state of a residue. We consider that a residue is in the  $\alpha$ -helix state when the dihedral angles  $(\phi, \psi)$  fall in the range  $(-60 \pm 45^\circ, -50 \pm 45^\circ)$  (Definition I) [23,46]. The length  $\ell$  of a helical segment is then defined by the number of successive residues that are in the  $\alpha$ -helix state. The number  $n$  of helical residues in a conformation is defined by the sum of  $\ell$  over all helical segments in the conformation. Note that  $\ell = 3$  corresponds to roughly one turn of  $\alpha$ -helix. We therefore consider a conformation as helical if it has a segment with helix length  $\ell \geq 3$ .

The average values of the dihedral angles  $\phi$  and  $\psi$  for the helical segments based on Definition I (with helix length  $\ell \geq 3$ ) are  $-70^\circ$  and  $-37^\circ$ , respectively, and the standard deviation is  $\sim 10^\circ$  for ECEPP/2 energy function [44,46]. Hence, for detailed analyses of the data we adopt a more stringent criterion for  $\alpha$ -helix state (Definition II): The range is  $(\phi, \psi) = (-70 \pm 20^\circ, -37 \pm 20^\circ)$  [44].

We likewise consider that a residue is in the  $\beta$ -strand state when the dihedral angles  $(\phi, \psi)$  fall in the range  $(-130 \pm 50^\circ, 135 \pm 45^\circ)$  [44]. The  $\beta$ -strand length  $m$  is then defined to be the number of successive residues that are in the  $\beta$ -strand state. We consider a conformation as  $\beta$ -stranded if it has a segment with  $\beta$ -strand length  $m \geq 3$ .

In Table 1 we summarize the  $\alpha$ -helix formation in the 20 Monte-Carlo simulated annealing runs [44]. The results are for Definition II of the  $\alpha$ -helix state.

We see that  $(\text{Met})_{10}$ ,  $(\text{Ala})_{10}$ , and  $(\text{Leu})_{10}$  gave many helical conformations: 15, 9, and 9 (out of 20), respectively. In particular,  $(\text{Met})_{10}$  and  $(\text{Ala})_{10}$  produced long helices, some conformations being almost entirely helical ( $\ell \geq 8$ ). On the other hand,  $(\text{Val})_{10}$ ,  $(\text{Ile})_{10}$ , and  $(\text{Gly})_{10}$  gave few helical conformations: 2, 2, and 1 (out of 20), respectively. We obtained not only a smaller number of helices but also shorter helices for these homo-oligomers than the above three homo-oligomers. Finally, the results for  $(\text{Phe})_{10}$  indicate that Phe has intermediate helix-forming tendency between these two groups. We thus have the following rank order of helix-forming tendency for the seven amino acids [44]:

$$\text{Met} > \text{Ala} > \text{Leu} > \text{Phe} > \text{Val} > \text{Ile} > \text{Gly}. \quad (10)$$

This can be compared with the experimentally determined helix propensities [6,8]. Our rank order (10) is in good agreement with the experimental data.

We then analyzed the relation between helix-forming tendency and energy. We found that the differences  $\Delta E = E_{\text{NH}} - E_{\text{H}}$  between minimum energies for nonhelical (NH) and helical (H) conformations is large for homo-oligomers with high helix-forming tendency (9.7, 10.2, 21.5 kcal/mol for (Met)<sub>10</sub>, (Ala)<sub>10</sub>, (Leu)<sub>10</sub>, respectively) and small for those with low helix-forming tendency (0.5, 1.6, -3.2 kcal/mol for (Val)<sub>10</sub>, (Ile)<sub>10</sub>, (Gly)<sub>10</sub>, respectively). Moreover, we found that the large  $\Delta E$  for the former homo-oligomers are caused by the Lennard-Jones term  $\Delta E_{\text{LJ}}$  (13.3, 8.0, 17.5 kcal/mol for (Met)<sub>10</sub>, (Ala)<sub>10</sub>, (Leu)<sub>10</sub>, respectively). Hence, we conjecture that the differences in helix-forming tendencies are determined by the following factors [44]. A helical conformation is energetically favored in general because of the Lennard-Jones term  $E_{\text{LJ}}$ . For amino acids with low helix-forming tendency except for Gly, however, the steric hindrance of side chains raises  $E_{\text{LJ}}$  of helical conformations so that the difference  $\Delta E_{\text{LJ}}$  between nonhelical and helical conformations are reduced significantly. The small  $\Delta E_{\text{LJ}}$  for these amino acids can be easily overcome by the entropic effects and their helix-forming tendencies are small. Note that such amino acids (Val and Ile here) have two large side-chain branches at  $C^\beta$ , while the helix forming amino acids such as Met and Leu have only one branch at  $C^\beta$  and Ala has a small side chain.

We now study the  $\beta$ -strand forming tendencies of these seven homo-oligomers. In Table 2 we summarize

the  $\beta$ -strand formation in 20 Monte-Carlo simulated annealing runs [44].

The implications of the results are not as obvious as in the  $\alpha$ -helix case. This is presumably because a short, isolated  $\beta$ -strand is not very stable by itself, since hydrogen bonds between  $\beta$ -strands are needed to stabilize them. However, we can still give a rough estimate for the rank order of strand-forming tendency for the seven amino acids [44]:

$$\text{Val} > \text{Ile} > \text{Phe} > \text{Leu} > \text{Ala} > \text{Met} > \text{Gly}. \quad (11)$$

Here, we considered Val as more strand-forming than Ile, since the longer the strand segment is, the harder it is to form by simulation. Our rank order (11) is again in good agreement with the experimental data [8].

By comparing (11) with (10), we find that the helix-forming group is the strand-breaking group and vice versa, except for Gly. Gly is both helix and strand breaking. This reflects the fact that Gly, having no side chain, has a much larger (backbone) conformational space than other amino acids.

The helix-coil transitions of homo-oligomer systems were further analyzed by multicanonical algorithms [3] in [47,48]. The obtained results gave quantitative support to those by Monte-Carlo simulated annealing described above [44].

We have so far studied peptides with nonpolar amino acids each of which is electrically neutral as a whole. We now discuss the helix-forming tendencies of peptides with polar amino acids where side chains are charged by protonation or deprotonation. One example is the C-peptide, residues 1–13 of ribonuclease A.

It is known from the *X*-ray diffraction data of the whole enzyme that the segment from Ala-4 to Gln-11 exhibits a nearly 3-turn  $\alpha$ -helix [58,64]. It was also found by CD [56] and NMR [53] experiments that the isolated C-peptide also has significant  $\alpha$ -helix formation in aqueous solution at temperatures near 0°C.

Furthermore, the CD experiment of the isolated C-peptide showed that the side-chain charges of residues Glu-2<sup>-</sup> and His-12<sup>+</sup> enhance the stability of the  $\alpha$ -helix, while the rest of the charges of other side chains do not [56]. The NMR experiment [53] of the isolated C-peptide further observed the formation of the characteristic salt bridge between Glu-2<sup>-</sup> and Arg-10<sup>+</sup> that exists in the native structure determined by the *X*-ray experiments of the whole protein [58,64].

In order to test whether our simulations can reproduce these experimental results, we made 20 Monte-Carlo simulated annealing runs of 10,000 MC sweeps with several C-peptide analogues [23,46]. The amino-acid sequences of four of the analogues are listed in Table 3.

The simulations were performed in gas phase ( $\epsilon = 2$ ). The temperature was decreased exponentially from 1000 K to 250 K for each run. As usual, all the simulations were started from random conformations.

In Table 4 we summarize the helix formation of all the runs [46]. Here, the number of conformations with segments of helix length  $\ell \geq 3$  are given with Definition I of the  $\alpha$ -helix state. From this table one sees that  $\alpha$ -helix was hardly formed for Peptide IV where Glu-2 and His-12 are neutral, while many helical conformations were obtained for the other peptides. This is in

accord with the experimental results that the charges of Glu-2<sup>-</sup> and His-12<sup>+</sup> are necessary for the  $\alpha$ -helix stability [56].

Peptides II and III had conformations with the longest  $\alpha$ -helix ( $\ell = 7$ ). These conformations turned out to have the lowest energy in 20 simulation runs for each peptide. They both exhibit an  $\alpha$ -helix from Ala-5 to Gln-11, while the structure from the X-ray data has an  $\alpha$ -helix from Ala-4 to Gln-11. These three conformations are compared in Fig. 4.

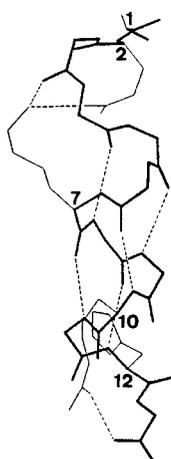

As mentioned above, the agreement of the backbone structures is conspicuous, but the side-chain

c

**Monte-Carlo Simulated Annealing in Protein Folding, Figure 4**

The lowest-energy conformations of Peptide II (a) and Peptide III (b) of C-peptide analogues obtained from 20 Monte-Carlo simulated annealing runs in gas phase, and the corresponding X-ray structure (c)

structures are not quite similar. In particular, while the X-ray [58,64] and NMR [53] experiments imply the formation of the salt bridge between the side chains of Glu-2<sup>-</sup> and Arg-10<sup>+</sup>, the lowest-energy conformations of Peptides II and III obtained from the simulations do not have this salt bridge.

The disagreement is presumably caused by the lack of solvent in our simulations. We have therefore made multicannonical Monte-Carlo simulations of Peptide II with the inclusion of solvent effects by the distance-dependent dielectric function (see (2)) [18,19]. It was found that the lowest-energy conformation obtained has an  $\alpha$ -helix from Ala-4 to Gln-11 and does have the characteristic salt bridge between Glu-2<sup>-</sup> and Arg-10<sup>+</sup> [18,19].

Similar dependence of  $\alpha$ -helix stability on side-chain charges was observed in Monte-Carlo simulated annealing runs of a 17-residue synthetic peptide [43]. The pH difference in the experimental conditions was represented by the corresponding difference in charge assignment of the side chains, and the agreement with the experimental results (stable  $\alpha$ -helix formation at low pH and low helix content at high pH) was observed in the simulations by Monte-Carlo simulated annealing with the distance-dependent dielectric function [43].

Considering our simulation results on homooligomers of nonpolar amino acids, C-peptide, and the synthetic peptide, we conjecture that the helix-forming tendencies of oligopeptide systems are controlled by the following factors [43]. An  $\alpha$ -helix structure is generally favored energetically (especially, the Lennard-Jones term). When side chains are uncharged, the steric hindrance of side chains is the key factor for the difference in helix-forming tendency. When some of the

side chains are charged, however, these charges play an important role in the helix stability in addition to the above factor: Some charges enhance helix stability, while others reduce it.

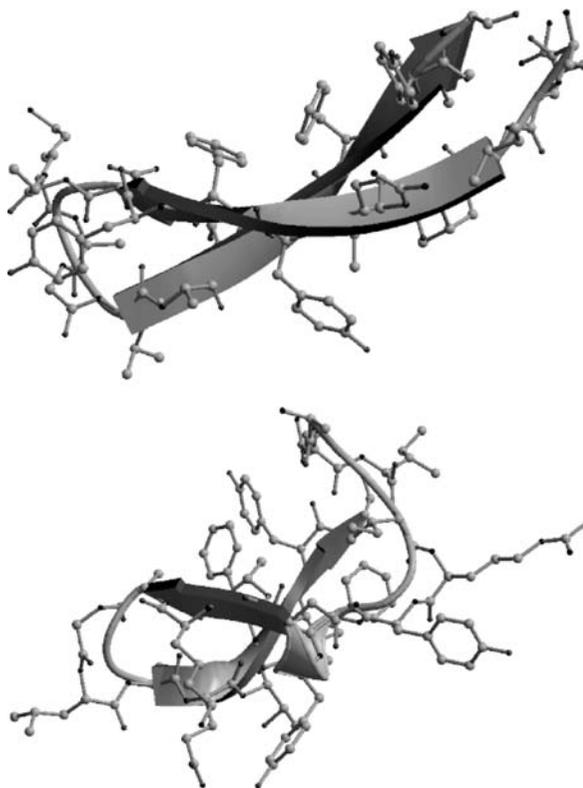

We have up to now discussed  $\alpha$ -helix formations in our simulations of oligopeptide systems. We have also studied  $\beta$ -sheet formations by Monte-Carlo simulated annealing [38,39,51]. The peptide that we studied is the fragment corresponding to residues 16–36 of bovine pancreatic trypsin inhibitor (BPTI) and has the amino-acid sequence: Ala<sup>16</sup>-Arg<sup>+</sup>-Ile-Ile-Arg<sup>+</sup>-Tyr-Phe-Tyr-Asn-Ala-Lys<sup>+</sup>-Ala-Gly-Leu-Cys-Gln-Thr-Phe-Val-Tyr-Gly<sup>36</sup>. An antiparallel  $\beta$ -sheet structure in residues 18–35 is observed in X-ray crystallographic data of the whole protein [10].

We first performed 20 Monte-Carlo simulated annealing runs of 10,000 MC sweeps in gas phase ( $\epsilon = 2$ ) with the same protocol as in the previous simulations [38]. Namely, the temperature was decreased exponentially from 1000 K to 250 K for each run, and all the simulations were started from random conformations. The difference of the present simulation and the previous ones comes only from that of the amino-acid sequences.

The most notable feature of the obtained results is that  $\alpha$ -helices, which were the dominant motif in previous simulations of C-peptide and other peptides, are absent in the present simulation. Most of the conformations obtained consist of stretched strands and a 'turn' which connects them. The lowest-energy structure indeed exhibits an antiparallel  $\beta$ -sheet [38].

We next made 10 Monte-Carlo simulated annealing runs of 100,000 MC sweeps for BPTI(16–36) with two dielectric functions:  $\epsilon = 2$  and the sigmoidal, distance-dependent dielectric function of (2) [39]. The results with  $\epsilon = 2$  reproduced our previous results: Most of the obtained conformations have  $\beta$ -strand structures and no extended  $\alpha$ -helix is observed. Those with the sigmoidal dielectric function, on the other hand, indicated formation of  $\alpha$ -helices. One of the low-energy conformations, for instance, exhibited about a four-turn  $\alpha$ -helix from Ala-16 to Gly-28 [39]. This presents an example in which a peptide with the same amino-acid sequence can form both  $\alpha$ -helix and  $\beta$ -sheet structures, depending on its electrostatic environment.

NMR experiments suggest that this peptide actually forms a  $\beta$ -sheet structure [40]. The representation of

Monte-Carlo Simulated Annealing in Protein Folding, Figure 5

The structure of BPTI(16–36) deduced from X-ray experiments (a) and the lowest-energy conformation of BPTI(16–36) obtained from 20 Monte-Carlo simulated annealing runs in aqueous solution represented by solvent-accessible surface area (b)

solvent by the sigmoidal dielectric function (which gave  $\alpha$ -helices instead) is therefore not sufficient. Hence, the same peptide fragment, BPTI(16–36), was further studied in aqueous solution that is represented by solvent-accessible surface area of (3) by Monte-Carlo simulated annealing [51]. Twenty simulation runs of 100,000 MC sweeps were made. It was indeed found that the lowest-energy structure obtained has a  $\beta$ -sheet structure (actually, type II'  $\beta$ -turn) at the very location suggested by the NMR experiments [40]. This structure and that deduced from the X-ray experiments [10] are compared in Fig. 5. The figures were created with Molscrip [29] and Raster3D [2,35].

Although both conformations are  $\beta$ -sheet structures, there are important differences between the two: The positions and types of the turns are different. Since

the X-ray structure is taken from the experiments on the whole BPTI molecule, it does not have to agree with that of the isolated BPTI(16–36) fragment. It was found [51] that the simulated results in Fig. 5b have remarkable agreement with those in the NMR experiments of the isolated fragment [40].

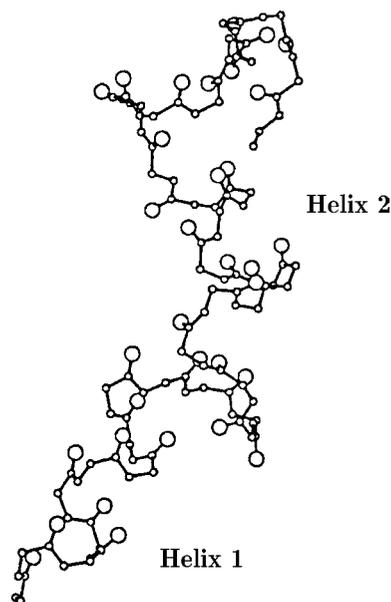

We have so far dealt with peptides with small number of amino acids (up to 21) with simple secondary structural elements: a single  $\alpha$ -helix or  $\beta$ -sheet. The native proteins usually have more than one secondary structural elements. We now discuss our attempts on the first-principles tertiary structure predictions of larger and more complicated systems.

The first example is the fragment corresponding to residues 1–34 of human parathyroid hormone (PTH). An NMR experiment of PTH(1–34) suggested the existence of two  $\alpha$ -helices around residues from Ser-3 to His-9 and from Ser-17 to Leu-28 [28]. Another NMR experiment of a slightly longer fragment, PTH(1–37), in aqueous solution also suggested the existence of the two helices [32]. One of the determined structures, for instance, has  $\alpha$ -helices in residues from Gln-6 to His-9 and from Ser-17 to Lys-27 [32].

For PTH(1–34) we performed 20 Monte-Carlo simulated annealing runs of 10,000 MC sweeps in gas phase ( $\epsilon = 2$ ) with the same protocol as in the previous simulations [50]. Many conformations among the 20 final conformations obtained exhibited  $\alpha$ -helix structures (especially in the N-terminus area). In Fig. 6 we show the lowest-energy conformation of PTH(1–34) [50].

This conformation indeed has two  $\alpha$ -helices around residues from Val-2 to Asn-10 (Helix 1) and from Met-18 to Glu-22 (Helix 2), which are precisely the same locations as suggested by experiment [28], although Helix 2 is somewhat shorter (5 residues long) than the corresponding one (12 residues long) in the experimental data.

A slightly larger peptide fragment, PTH(1–37), was also studied by Monte-Carlo simulated annealing [34] to compare with the results of the recent NMR experiment in aqueous solution [32]. Ten simulation runs of 100,000 MC sweeps were made in gas phase ( $\epsilon = 2$ ) and in aqueous solution that is represented by the terms proportional to the solvent-accessible surface area (see (3)). Although the results are preliminary, the simulations in gas phase did not produce two helices this time in contrast to the previous work [50], where a short

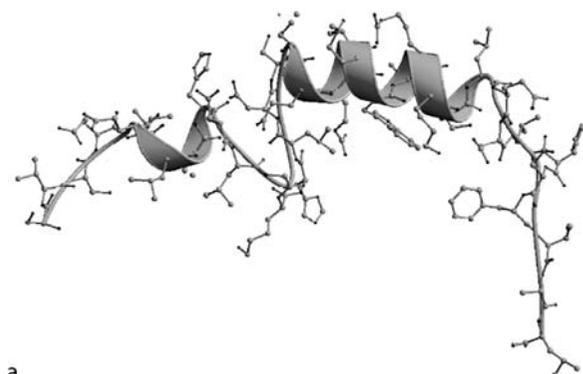

Monte-Carlo Simulated Annealing in Protein Folding, Figure 6

Lowest-energy conformation of PTH(1–34) obtained from 20 Monte-Carlo simulated annealing runs in gas phase

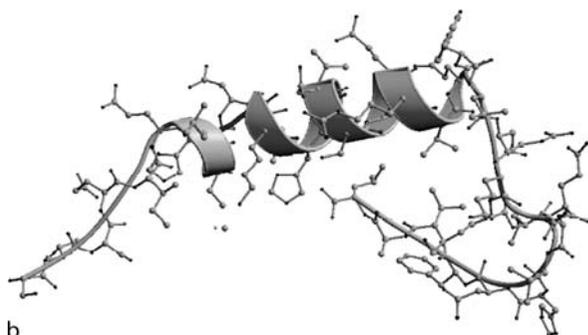

second helix was observed, as discussed in the previous paragraph. The lowest-energy conformation has an  $\alpha$ -helix from Val-2 to Asn-10. The simulations in aqueous solution, on the other hand, did observe the two  $\alpha$ -helices. The lowest-energy conformation obtained has  $\alpha$ -helices from Gln-6 to His-9 and from Gly-12 to Glu-22. Note that the second helix is now more extended than the first one in agreement with experiments. This structure together with one of the NMR structure [32] is shown in Fig. 7. The figures were again created with Molscrip [29] and Raster3D [2,35].

Generalized-ensemble simulations of PTH(1–37) are now in progress in order to obtain more quantitative information such as average helicity as a function of residue number, etc.

The second example of more complicated system is the immunoglobulin-binding domain of streptococcal protein G. This protein is composed of 56 amino acids and the structure determined by an NMR experiment [14] and an X-ray diffraction experiment [1] has an  $\alpha$ -helix and a  $\beta$ -sheet. The  $\alpha$ -helix extends from residue Ala-23 to residue Asp-36. The  $\beta$ -sheet is made of four  $\beta$ -strands: from Met-1 to Gly-9, from Leu-12 to Ala-20, from Glu-42 to Asp-46, and from Lys-50 to Glu-56.

A structure of PTH(1–37) deduced from NMR experiments (a) and the lowest-energy conformation of PTH(1–37) obtained from 10 Monte-Carlo simulated annealing runs in aqueous solution represented by solvent-accessible surface area (b)

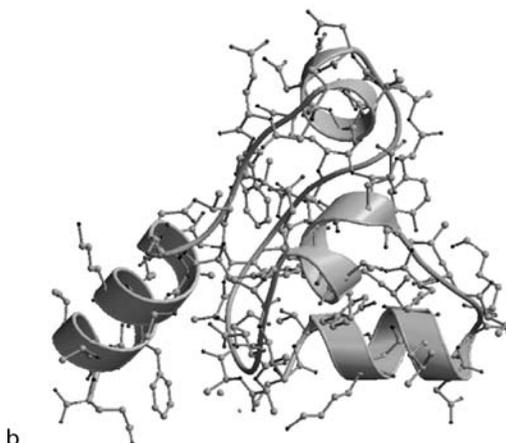

This structure is shown in Fig. 8a). The figures in Fig. 8 were again created with Molscript [29] and Raster3D [2,35].

We have performed eight Monte-Carlo simulated annealing runs of 50,000 to 400,000 MC sweeps with the sigmoidal, distance-dependent dielectric function of (2). The lowest-energy conformation so far obtained has four  $\alpha$ -helices and no  $\beta$ -sheet in disagreement with the X-ray structure. This structure is shown in Fig. 8b).

The disagreement of the lowest-energy structure (Fig. 8b) so far obtained with the X-ray structure (Fig. 8a) is presumably caused by the poor representation of the solvent effects. As can be seen in Fig. 8a), the X-ray structure has both interior where a well-defined hydrophobic core is formed and exterior where it is exposed to the solvent. The distance-dependent dielectric function, which mimics the solvent effects only

in electrostatic interactions, is therefore not sufficient to represent the effects of the solvent here.

## Conclusions

In this article we have reviewed theoretical aspects of the protein folding problem. Our strategy in tackling this problem consists of two elements: 1) inclusion of accurate solvent effects, and 2) development of powerful simulation algorithms that can avoid getting trapped in states of energy local minima.

We have shown the effectiveness of Monte-Carlo simulated annealing by showing that direct folding of  $\alpha$ -helix and  $\beta$ -sheet structures from randomly-generated initial conformations are possible.

As for the solvent effects, we considered several methods: a distance-dependent dielectric function, a term proportional to solvent-accessible surface area, and the reference interaction site model (RISM). These methods vary in nature from crude but computationally inexpensive (distance-dependent dielectric function) to accurate but computationally demanding (RISM theory). In the present article, we have shown that the inclusion of some solvent effects is very important for a successful prediction of the tertiary structures of small peptides and proteins.

Stochastic programming; Simulation-based optimization; Monte-Carlo method

Many important real-world problems contain stochastic elements and require optimization. *Stochastic programming* and *simulation-based optimization* are two approaches used to address this issue. We do not explicitly discuss other related areas including stochastic control, stochastic dynamic programming, and Markov decision processes. We consider a stochastic optimization problem of the form

$$(SP) \quad z^* = \min_{x \in X} \text{E}f(x, \xi),$$

where  $x$  is a vector of decision variables with deterministic feasible region  $X \subset \mathbf{R}^d$ ,  $\xi$  is a random vector, and  $f$  is a real-valued function with finite expectation,  $\text{E}f(x, \xi)$ , for all  $x \in X$ . We use  $x^*$  to denote an optimal solution to (SP). Note that the decision  $x$  must be made prior to observing the realization of  $\xi$ .

A wide variety of types of problems can be expressed as (SP) depending on the definitions of  $f$  and  $X$ . Two of the most commonly-used approaches are rooted in mathematical programming and in discrete-event simulation modeling.

In a two-stage stochastic linear program with recourse [6,14],  $X$  is a polyhedral set and  $f$  is defined as the optimal value of a linear program, given  $x$  and  $\xi$ , i. e.,

$$f(x, \xi) = cx + \begin{cases} \min_{y \geq 0} & qy \\ \text{s.t.} & Wy = Tx + h. \end{cases} \quad (1)$$

Here,  $\xi$  is the vector of random elements from  $h$ ,  $q$ ,  $T$ , and  $W$ . A prototypical problem of this nature is a capacity allocation model under uncertain demand and/or

capacity availabilities.  $x$  is a strategic decision allocating resources while  $y$  represents an operational recourse decision that is made *after* observing the demand and availabilities. Example applications of this type include capacity expansion planning in an electric power system [16] and in a telecommunications network [61]. The two-stage model generalizes to a more dynamic, multistage model (see, e. g., [10]) in which decisions are made, and random events unfold, over time. For multistage applications in asset-liability management see [13] and in hydro-electric scheduling see [39].

In the context of a simulation model,  $f(x, \xi)$  could represent a performance measure under a design specified by  $x$ . For example,  $f(x, \xi)$  might represent the number of hours in a workday that a critical machine is blocked in a queueing network model of a manufacturing system in which buffer sizes are determined by  $x$ . In another application, E.L. Plambeck et al. [53] allocate constrained processing rates to unreliable machines with buffers in a fluid serial queueing network in order to maximize steady-state throughput. In non-terminating simulations, the expectation in  $Ef(x, \xi)$  is typically with respect to a steady-state distribution.

Note that  $Ef(x, \xi)$  can capture objectives not usually thought of as a ‘mean’. For example, if  $c$  represents random rates of return and  $x$  investment amounts, we might want to maximize the probability of exceeding a return threshold,  $T$ . We can write  $P(cx \geq T) = EI(cx \geq T)$  where  $I(\cdot)$  is the *indicator function* that takes value one if its argument is true and zero otherwise. For more on probability maximization models (and generalizations of (SP) in which  $X$  contains probabilistic constraints) see [54]. See [45] for a discussion of risk modeling in stochastic optimization.

A more general model than (SP) allows the distribution of  $\xi$  to depend on  $x$ . Some simple types of dependencies can effectively be captured in (SP) via modeling tricks, such as the  $x$  scaling random elements of  $T$  in (1). General dependencies, however, are difficult to handle. For work on decision-dependent distributions when there are a finite number of possibilities see [26,40].

Regardless of whether it is defined as the expected value of a mathematical program or as a long-run average performance measure of a discrete-event simulation model, it is usually impossible to calculate  $Ef(x, \xi)$  exactly- even for a fixed value of  $x$ . When the dimension

of the random vector  $\xi$  is relatively low, one approach is to obtain deterministic approximations of  $Ef(x, \xi)$  using numerical quadrature or related ideas. In stochastic programming, this corresponds to generating and refining bounds on  $Ef(x, \xi)$  within a sequential approximation algorithm [20,24,43]. For problems in which  $\xi$  is of moderate-to-high dimension and is continuous or has a large number of realizations, *Monte-Carlo simulation* is widely regarded as the method of choice for estimating  $Ef(x, \xi)$ . As a result, it is not surprising that Monte-Carlo techniques play a fundamental role in solving (SP).

In recent years (1999), considerable progress has been made in solving realistically-sized problems with a significant number of stochastic parameters and decision variables. The telecommunications model considered in [61] has 86 random point-to-point demand pairs and 89 links on which capacity may be installed. In [53] queueing networks with up to 50 nodes are studied. Each node represents a machine with random failures and has a decision variable denoting its assigned cycle time. [53] also solves a stochastic PERT (program evaluation and review technique) problem with 70 nodes and 110 stochastic arcs. The arcs model the times required to complete activities and a decision variable associated with each arc influences (parameterizes) the distribution of the random activity duration. These problems contain objectives with high-dimensional expectations and all were solved using Monte-Carlo methods.

In this article we discuss:

- i) several types of Monte-Carlo-based solution procedures that can be used for solving (SP);
- ii) methods for testing the quality of a candidate solution  $\hat{x} \in X$ ;
- iii) variance reduction techniques used in stochastic optimization; and
- iv) theoretical justification for using sampling.

## Solution Procedures

Monte-Carlo methods for approximately solving stochastic optimization problems can typically be classified on the basis of whether the sampling is external to, or internal to, the optimization algorithm. Solution procedures of both types are driven by estimates of objective function values and/or gradients. Before turn-

ing to solution procedures we briefly discuss *gradient estimation*.

In stochastic programming, gradient (or subgradient) estimates of  $Ef(x, \xi)$  are typically available via duality. In simulation-based optimization, the primary methods for obtaining gradient estimates are finite differences, the *likelihood ratio* (LR) method (also called the *score function method*) [29,57], and *infinitesimal perturbation analysis* (IPA) [27,35]. *Finite-difference approximations* require minimal structure, needing only estimates of  $Ef(x, \xi)$ ; however, they result in solution procedures that can converge slowly. The LR method is more widely applicable than IPA, but when both apply the IPA approach tends to produce estimators with lower variance. See, for example, [28] for a discussion of these issues.

In the simplest form of ‘external sampling’ (also called ‘*sample-path optimization*’ [55] and the ‘*stochastic counterpart*’ method [57]) we generate independent and identically distributed (i.i.d.) replicates  $\xi^1, \dots, \xi^n$  from the distribution of  $\xi$  and form the approximating problem

$$(SP_n) \quad z_n^* = \min_{x \in X} \frac{1}{n} \sum_{i=1}^n f(x, \xi^i).$$

Even when it is possible to construct  $(SP_n)$  using i.i.d. variates, it may be preferable to use another sampling scheme in order to reduce the variance of the resulting estimators. Moreover, in nonterminating simulation models, generating i.i.d. replicates from a stationary distribution is often impossible (for exceptions see recent work on *exact sampling*, e. g., [3,22]), but under appropriate conditions we may run the simulation for a length  $n$  and replace the objective function in  $(SP_n)$  with a consistent estimate of the desired long-run average performance measure.

After constructing an instance of  $(SP_n)$  we employ a (deterministic) optimization algorithm to obtain a solution  $x_n^*$ . In the case of stochastic linear programming,  $(SP_n)$  is a large scale linear program. The cutting plane algorithm of R.M. Van Slyke and R.J-B. Wets [64], its variant with a quadratic proximal term [58], and its multistage version [7,9] are powerful tools for solving such problems. A cutting plane algorithm with a proximal term and IPA-based gradients is used in an external sampling method for solving the queueing network

problem in [53]. See [8] for a recent survey of computational methods for stochastic programming instances of  $(SP_n)$ .

Intuitively, we might expect solutions of  $(SP_n)$  to more accurately approximate solutions of (SP) as  $n$  increases. We discuss results supporting this in Sect. “**Theoretical Justification for Sampling**”. In addition, after having solved  $(SP_n)$  to obtain  $x_n^*$  it would be desirable to know whether  $n$  was ‘large enough’. More generally, we would like to be able to test the quality of a candidate solution (such as  $x_n^*$ ). This is discussed in the next section.

We now turn to solution procedures based on internal sampling. These algorithms adapt deterministic optimization algorithms by replacing exact function and gradient evaluations with Monte-Carlo estimates. The sampling is internal because new observations of  $\xi$  are generated on an as-needed basis at each iteration of the algorithm. We briefly discuss stochastic adaptations of steepest descent and cutting plane methods.

A deterministic *steepest descent algorithm* for (SP) forms iterates  $\{x^\ell\}$  using the recursion

$$x^{\ell+1} \leftarrow \Pi_X \left[ x^\ell - \rho^\ell \nabla Ef(x^\ell, \xi) \right].$$

$\Pi_X$  performs a projection onto  $X$  and  $\{\rho^\ell\}$  are steplengths. It is usually impossible to calculate  $\nabla Ef(x, \xi)$  exactly and it must be estimated. *Stochastic approximation* (SA) and *stochastic quasigradient* (SQG) algorithms are stochastic variants of a steepest descent search. The *Keifer-Wolfowitz* SA method uses unbiased estimates of  $Ef(x, \xi)$  to form finite-difference approximations of the gradient. The *Robbins-Monro* SA procedure requires unbiased estimates of  $\nabla Ef(x, \xi)$ . SQG methods do not require that  $Ef(x, \xi)$  be differentiable and work under more general assumptions concerning the estimates of (sub)gradients of  $Ef(x, \xi)$ . In particular, the estimates need not be unbiased but the bias must effectively shrink to zero as the algorithm proceeds. For convergence properties of SA methods see [49] and for SQG procedures see [23].

*Cutting plane methods* are applicable when  $Ef(x, \xi)$  is convex. The iterates  $\{x^\ell\}$  are found by solving a sequence of optimization problems of the form

$$\min_{x \in X} \max_{\ell=1, \dots, L} Ef(x^\ell, \xi) + \nabla Ef(x^\ell, \xi)(x - x^\ell),$$

where  $L$  grows as the algorithm proceeds. At each iteration a first order Taylor approximation of  $Ef(x, \xi)$ , i. e., a cutting plane, is computed at the current iterate  $x^\ell$  and is used to refine the piecewise-linear outer approximation of  $Ef(x, \xi)$ . The key idea is that this approximation need only be accurate in the neighborhood of an optimal solution. For stochastic linear programs, G.B. Dantzig, P.W. Glynn [15], and G. Infanger [37,38] and J.L. Higle and S. Sen [32,34] have developed Monte-Carlo-based cutting plane methods by using statistical estimates for the cut intercepts and gradients. Dantzig, Glynn, and Infanger use separate streams of observations of  $\xi$  to estimate each cut. The *stochastic decomposition* algorithm of Higle and Sen uses common random number streams to calculate each cut and employs an updating procedure to ensure that the statistical cuts are asymptotically valid (i. e., lie below  $Ef(x, \xi)$ ). Relative to SA and SQG methods, cutting plane procedures avoid potentially difficult projections and, in practice, have a reputation for converging more quickly, particularly when  $X$  is high dimensional.

*Grid search* and optimization of *metamodels* are two common approaches to optimizing system performance in discrete-event simulation models. In grid search,  $X$  is replaced by a ‘grid’ of points  $X_m = \{x^1, \dots, x^m\}$  and sample-mean estimates

$$\bar{f}_n(x) = 1/n \sum_{i=1}^n f(x, \xi^i)$$

are formed at each  $x \in X_m$ . (SP) is then approximately solved by  $z_n^* = \min_{x \in X_m} \bar{f}_n(x)$  with  $x_n^*$  being the associated minimizer. Grid search is attractive because it requires minimal structure, but in implementing this procedure, we must exercise care in selecting  $m$  and  $n$ . With independent sampling at each grid point, K.B.ENSOR and Glynn [21] consider the rate at which  $n$  must grow relative to  $m$  in order to achieve consistency and they also discuss the method’s limiting behavior when the rate of growth is at (and slower than) the critical rate.

A metamodel can be used to approximate a more complex simulation model which, in turn, is an approximation of the real system. In such a metamodel, estimates of  $Ef(x, \xi)$  are formed at each point in a set specified by an experimental design, and the parameters of the postulated *response surface* are fit to these observed values. The resulting function is then optimized

with respect to  $x$ . For more on metamodels see, e. g., [11,47]. The review in [25] includes optimization using response surfaces, and metamodeling has also been applied in stochastic programming [5].

The grid-search and metamodel approaches are classified as external sampling procedures if the procedure is executed once. However, it may be desirable to refine the grid (or the region covered by the experimental design) in the neighborhood of promising values of  $x$  and repeat the methodology. When it is adaptively repeated in this fashion the procedure is classified as an internal sampling method.

We have not explicitly discussed approaches for when  $X$  is discrete. These range from methods for selecting the best design in simulation to those for solving stochastic integer programming models. Finally, sampling-based procedures for multistage stochastic programs have been proposed in [17].

### Establishing Solution Quality

Establishing solution quality is a key concept when using an approximation scheme to solve an optimization problem. When applying Monte-Carlo techniques to (SP), the best we can expect are probabilistic quality statements. In the context of external sampling, there has been significant work on studying the behavior of solutions to  $(SP_n)$  for large sample sizes (see the last section). There are analogous convergence results for algorithms based on internal sampling. Such results take a number of forms but perhaps the most fundamental is to show that limit points of the sequence of solutions are, say, almost surely optimal to (SP). Next, it is desirable to have a statement regarding the rate of convergence and an associated asymptotic distribution. These consistency and limiting distribution results are aimed at justifying sampling-based methods and may be viewed as establishing solution quality. However, the approach discussed in this section centers on the question: Given a candidate solution  $\hat{x} \in X$ , what can be said regarding its quality? Because candidate solutions may be obtained by internal or external sampling schemes or via another, heuristic, method, procedures that can directly test the quality of  $\hat{x}$ , regardless of its origin, are very attractive.

One natural way of defining solution quality is by the optimality gap,  $Ef(\hat{x}, \xi) - z^*$ . An optimal solution

has an optimality gap of zero, but in our setting we hope to make probabilistic statements such as

$$P\{Ef(\hat{x}, \xi) - z^* \leq \epsilon\} \geq \alpha, \tag{2}$$

where  $\epsilon$  is a random confidence interval width and  $\alpha$  is a confidence level, e. g.,  $\alpha = 0.95$ . Unfortunately, exact confidence intervals such as (2) can be difficult to obtain even in relatively simple statistical settings so we attempt to construct approximate confidence intervals

$$P\{Ef(\hat{x}, \xi) - z^* \leq \epsilon\} \approx \alpha. \tag{3}$$

To form a *confidence interval* (3) for  $Ef(\hat{x}, \xi) - z^*$  we estimate the mean of a gap random variable  $G_n = U_n - L_n$  that is expressed as the difference between upper and lower bound estimators and satisfies  $EG_n \geq Ef(\hat{x}, \xi) - z^*$ .

In many problems it is relatively straightforward to estimate the performance of a suboptimal decision  $\hat{x}$  via simulation. For example, the standard sample mean estimator,  $U_n = 1/n \sum_{i=1}^n f(\hat{x}, \xi^i)$ , provides an unbiased estimate of the expected cost of using decision  $\hat{x}$ , i. e.,  $Ef(\hat{x}, \xi)$ .

To construct a confidence interval for the optimality gap we also want an estimate of  $z^*$ . However, unbiased estimates of  $z^*$  are difficult to obtain so an estimator  $L_n$  that satisfies  $EL_n \leq z^*$  is used. In [51] it is shown that if the objective in (SP<sub>n</sub>) is an unbiased estimate of  $Ef(x, \xi)$  then  $Ez_n^* \leq z^*$ , i. e.,  $z_n^*$  is one possible lower bound estimator  $L_n$ . Higle and Sen [33] perform a Lagrangian relaxation of a reformulation of (SP<sub>n</sub>) which uses explicit ‘nonanticipativity’ constraints. The resulting lower bound is weaker in expectation than  $z_n^*$  but has the computational advantage that the optimization problem separates by scenario.

Once observations of  $G_n$  can be formed, we can appeal to the batch means method and use the central limit theorem [51], or a nonparametric approach [31,33], to construct approximate confidence intervals (3). Another approach to examining solution quality is to test the null hypothesis that the (generalized) Karush-Kuhn-Tucker (KKT) optimality conditions are satisfied; see [63]. Higle and Sen [31] also consider the KKT conditions but use them to derive bounds on the optimality gap.

### Variance Reduction Techniques

When applying the ‘crude’ Monte-Carlo method to estimate  $Ef(x, \xi)$  for fixed  $x$ , we use the standard sample mean estimator based on i.i.d. terms,

$$\frac{1}{n} \sum_{i=1}^n f(x, \xi^i).$$

The error associated with this estimate is proportional to

$$\left[ \frac{\text{var } f(x, \xi)}{n} \right]^{1/2}. \tag{4}$$

This error can be decreased by increasing the sample size. However, obtaining an additional digit of accuracy requires increasing the sample size by a factor of 100. If  $f$  is defined as the optimal value of a mathematical program or as the performance measure of a simulation model, increasing the number of evaluations of  $f$  in this fashion can be prohibitively expensive. *Variance reduction techniques* (VRTs) effectively decrease the numerator in (4) instead of increasing the denominator. Many problems for which crude Monte-Carlo would yield useless results are instead made computationally tractable via VRTs. As described in Sect. “**Solution Procedures**”, sampling is also used to estimate  $\nabla Ef(x, \xi)$ , but for simplicity we primarily restrict our attention to VRTs for estimating  $Ef(x, \xi)$ .

Some VRTs, including *control variates* (CVs) and *importance sampling* (IS), exploit special structures of  $f(x, \xi)$ . Suppose that we have  $\Gamma_x(\xi)$ , with known mean  $\mu_\Gamma$ , which is believed to approximate (be positively correlated with)  $f(x, \xi)$ . In CVs we attempt to ‘subtract out’ variation by generating observations of  $[f(x, \xi) - \Gamma_x(\xi)] + \mu_\Gamma$ , which has the same expectation as  $f(x, \xi)$ . (It is common to incorporate a multiplicative factor with the control variate  $\Gamma_x(\xi)$  and also possible to use multiple controls.) In IS we attempt to reduce variance by generating observations of  $\mu_\Gamma [f(x, \xi) / \Gamma_x(\xi)]$ . In CVs observations of  $\xi$  are generated from its original distribution. However, in IS the expected value of the ratio is not the ratio of expectations and, as a result, there is a change of measure induced by  $\Gamma_x$  that is required to yield an unbiased estimate. Under the new IS distribution, we are more likely to sample  $\xi$  where  $\Gamma_x(\xi)$  is large, i. e., scenarios that our approximation function predicts have high cost. In an IS scheme for

stochastic linear programs, [15,37] use an approximation function that is separable in the components of  $\xi$  while [48] utilizes a piecewise-linear approximation. See [12] for the solution of a stochastic optimization problem to price American-style financial options using the simpler European option as a control variate. These papers report significant variance reduction in computational results.

Other VRTs exploit correlation structures in the solution methodology. *Common random numbers* (CRNs) are often used in simulation when comparing the performance of two systems. The use of CRNs has been suggested in a stochastic approximation method with finite differences where the same stream is used for the forward and backward point estimates [50]. The upper and lower bounds used to determine solution quality (see the previous section) may be viewed as two ‘systems’ and the use of CRNs in estimating their difference has been advocated in [34,51]. In order to reduce the error in the resulting response surface, various methods have been proposed for generating the streams of observations of  $\xi$  at each point in the experimental design. The *Schruben–Margolin* scheme [59] uses a mixture of CRNs and antithetic variates and an extension [65] also incorporates CVs.

Another group of VRTs attempts to more regularly spread the sampled observations over the support of  $\xi$ . Such techniques include stratified sampling and Latin hypercube sampling as well as quasi-Monte-Carlo techniques in which the sequence of observations is deterministic. Empirical results in [30] for two-stage stochastic linear programming compare the variance reduction obtained by stratified sampling, antithetic variates, IS, and CVs and suggest that a CV procedure performs relatively well, particularly on high-variance problems.

### Theoretical Justification for Sampling

In Sect. “**Solution Procedures**” we formed an approximating problem for external sampling procedures by using the sample mean estimator of  $Ef(x, \xi)$ . Here we redefine  $(SP_n)$  as

$$(SP_n) \quad z_n^* = \min_{x \in X} E_n f(x, \xi),$$

with  $x_n^*$  again denoting an optimal solution. In (SP) the expected value operator  $E$  is with respect to the ‘true’

probability measure  $P$  while in  $(SP_n)$ ,  $E_n$  is with respect to a measure  $P_n$  that is a statistical estimate of  $P$ . If Monte-Carlo methods are used to generate i.i.d. replicates from  $P$  then  $P_n$  is the associated (random) *empirical measure*.

Since  $z_n^*$  is an estimator of  $z^*$  and  $x_n^*$  an estimator of an optimal solution to (SP), it is natural to study the behavior of these estimators for large sample sizes. For example, under what conditions do we obtain consistency and what can be said concerning rates of convergence? Positive answers to such questions provide theoretical justification for employing external Monte-Carlo sampling techniques to solve (SP).

In general,  $(SP_n)$  and (SP) may have multiple optimal solutions and so we cannot expect  $\{x_n^*\}$  to converge. Instead, establishing consistency of  $x_n^*$  amounts to showing that the accumulation points of the sequence are almost surely optimal to (SP). If, for example, the samples are i.i.d. then by the strong law of large numbers we have  $E_n f(x, \xi) \rightarrow Ef(x, \xi)$ , a.s., for all  $x$ . Unfortunately, this does not ensure that  $\{x_n^*\}$  has accumulation points that are optimal to (SP) and that  $z_n^* \rightarrow z^*$ , a.s. [4].

The notion of *epiconvergence* plays a fundamental role in establishing consistency results for  $x_n^*$  and  $z_n^*$ ; see [4]. A sequence of functions  $\{\phi_n\}$  is said to *epi-converge* to  $\phi$  (written  $\phi_n \xrightarrow{\text{epi}} \phi$ ) if the *epigraphs* of  $\phi_n$ ,  $\{(x, \beta): \beta \geq \phi_n(x)\}$ , converge to that of  $\phi$ . Epiconvergence is weaker than classical uniform convergence. P. Kall [41] provides an excellent review of various types of convergence, their relations, and their implications for approximations of optimization models. Epiconvergence is a valuable property because of the following result:

**Theorem 1** *Suppose  $\phi_n \xrightarrow{\text{epi}} \phi$ . If  $\hat{x}$  is an accumulation point of  $\{x_n^*\}$ , where  $x_n^* \in \text{argmin } \phi_n(x)$ , then  $\hat{x} \in \text{argmin } \phi(x)$ .*

Constrained optimization is captured in this result because  $\phi_n$  and  $\phi$  are defined to be extended-real-valued functions that take value  $+\infty$  at infeasible points. While it is possible that the sequence of optimizers  $\{x_n^*\}$  has no accumulation points, this potential difficulty is avoided if the feasible region  $X$  is compact (i. e., closed and bounded).

Because of the implications of epiconvergence, there is considerable interest in determining sufficient

conditions on  $f$ ,  $P_n$ , and  $P$  under which  $E_n f(x, \xi) \xrightarrow{\text{epi}} E f(x, \xi)$ , a.s. Note that because  $\{P_n\}$  are random measures, the epiconvergence of the approximating functions is with probability one (also called *epiconsistency*). Under this hypothesis the accumulation points of  $\{x_n^*\}$  are almost surely optimal to (SP); see [19].

Sufficient conditions for achieving  $E_n f(x, \xi) \xrightarrow{\text{epi}} E f(x, \xi)$ , a.s. are examined in [19,42,55], and [56]. Roughly speaking, we will obtain epiconsistency if  $f$  is sufficiently smooth,  $P_n$  converges weakly to  $P$  with probability one, and the tails of the distributions are well-behaved relative to  $f$ . See [2,60] for results when  $f$  is discontinuous.

For two-stage stochastic programming in which the recourse matrix  $W$  in (1) is deterministic and  $P_n$  is the empirical measure, [46] contains consistency results under modest assumptions. We note that it is possible to develop consistency results using other (stronger) types of convergence of  $E_n f(x, \xi)$  to  $E f(x, \xi)$ ; see, for example, [52].

There is a large literature on consistency, stability, and rates of convergence for solutions of (SP<sub>n</sub>). Much of this work may be viewed as generalizing earlier results on constrained *maximum likelihood estimation* in [1] and [36]. Under restrictive assumptions, asymptotic normality for  $\sqrt{n}(z_n^* - z^*)$  and  $\sqrt{n}(x_n^* - x^*)$  may be obtained, e. g., [19]. However, when inequality constraints in  $X$  play a nontrivial role we cannot, in general, expect to obtain limiting distributions that are normal [18,44,62]. See [44] for a limiting distribution for  $\sqrt{n}(x_n^* - x^*)$  that is the solution of a (random) quadratic program.

### Keywords

Inequality systems; Duality; Certificate; Transposition theorem

Motzkin’s transposition theorem (MTT) [1] is a so-called *theorem of the alternative* (cf. ► [Linear Optimization: Theorems of the Alternative](#)). It deals with the question whether or not a given system of *linear inequalities* has a solution. In the most general case such a system has the form

$$(S) \quad Ax \geq a, \quad Bx > b,$$

where  $A$  and  $B$  are matrices of size  $m \times n$  and  $p \times n$ , respectively, and where  $Ax \geq a$  contains the ‘larger than or equal’ inequalities and  $Bx > b$  the ‘larger than’ inequalities. Note that inequalities of the opposite type (‘smaller than or equal’ or ‘smaller than’) can be turned into the appropriate form by multiplying them by  $-1$ .

The Motzkin transposition theorem states that the system (S) has no solution if and only if at least one of the systems (T1) and (T2) has a solution, where the latter systems are given by

$$(T1) \quad \begin{cases} y^T A + v^T B = 0, & y^T a + v^T b > 0, \\ y \geq 0, & v \geq 0, \end{cases}$$

and

$$(T2) \quad \begin{cases} y^T A + v^T B = 0, & y^T a + v^T b \geq 0, \\ y \geq 0, & v \geq 0, \quad v \neq 0, \end{cases}$$

respectively.

In other words, when one has a solution of (T1) or of (T2) this solution is a *certificate* for the fact that the given system (S) is *infeasible*, i. e., has no solution.

It makes sense to formulate two most useful principles following from the theorem.

**Theorem 1 (Principle A)** *The system (S) is infeasible if and only if one can combine the inequalities in (S) in a linear fashion (i. e., multiply each inequality with a nonnegative number and add the results) to get the contradictory inequality  $0 > 0$  (or  $0 \geq 1$ ).*

To see that this is exactly what the MTT says, let  $y$  and  $v$  denote nonnegative vectors of appropriate sizes. Then the inequality

$$(y^T A + v^T B) x \geq y^T a + v^T b \tag{1}$$

is a consequence of the inequalities in (S), and if the vector  $v$  is not the zero vector, then also the stronger inequality

$$(y^T A + v^T B) x > y^T a + v^T b \tag{2}$$

is a consequence of (S). The inequalities (1) and (2) have certainly solutions if  $y^T A + v^T B \neq 0$ . But if  $y^T A + v^T B = 0$  then (1) yields a contradiction if  $y^T a + v^T b > 0$  and (2) if  $y^T a + v^T b \geq 0$ . The first case occurs if (T1) has a solution and the second case if (T2) has a solution.

The second principle is:

**Theorem 2 (Principle B)** *If (S) is feasible, then a linear inequality is a consequence of the inequalities in (S) if and only if it can be obtained by combining, in a linear fashion, the inequalities in (S) and the trivial inequality  $0 \geq -1$ .*

This principle can be understood in a similar way: If (S) is feasible, then  $c^T x \geq z$  is an implied inequality if and only if

$$Ax \geq a, Bx > b \quad \Rightarrow \quad c^T x \geq z,$$

which is equivalent to the system

$$Ax \geq a, \quad Bx > b, \quad -c^T x > -z$$

being infeasible. By Principle A this happens if and only if there exist nonnegative vectors  $y$  and  $v$  and a nonnegative scalar  $\lambda$  such that

$$(y^T A + v^T B - \lambda c) x \geq y^T a + v^T b - \lambda z$$

is a contradictory inequality. Hence  $y^T A + v^T B - \lambda c = 0$  and  $y^T a + v^T b - \lambda z > 0$ . Since (S) is feasible, we must have  $\lambda > 0$ . Without loss of generality we may assume  $\lambda = 1$ . Then  $c = y^T A + v^T B$  and  $z \geq y^T a + v^T b$ . This proves the claim.

The above principles are highly nontrivial and very deep. Consider, e. g., the following system of 4 inequalities with two variables  $u, v$ :

$$\begin{aligned} -1 &\leq u \leq 1, \\ -1 &\leq v \leq 1. \end{aligned}$$

From these inequalities it follows that

$$u^2 + v^2 \leq 2,$$

which in turn implies, by the *Cauchy inequality*, the inequality  $u + v \leq 2$ :

$$u + v = 1 \cdot u + 1 \cdot v \leq \sqrt{1^2 + 1^2} \sqrt{u^2 + v^2} \leq 2.$$

The concluding inequality is linear, and is a consequence of the original system, but the above derivation is 'highly nonlinear'. It is absolutely unclear a priori why the same inequality can also be obtained from the given system in a linear manner as well, as stated by Principle B. Of course, it can – it suffices to add the inequalities  $u \leq 1$  and  $v \leq 1$ .

The MTT is one of the deepest result in the part of mathematics dealing with linear inequalities and, in fact, is logically equivalent to other deep results in this discipline. For example, it is equivalent to the duality theorem for linear optimization (cf. ► **Linear Programming**). To demonstrate this, consider the *linear optimization problem*

$$(P) \quad \min \{c^T x : Ax \geq b\}.$$

Let  $z^*$  denote the optimal value of (P), where we take  $z^* = -\infty$  if (P) is unbounded and  $z^* = \infty$  if (P) is infeasible. Now, a real  $z$  is a lower bound on the optimal value of (P) if and only if  $c^T x \geq z$  is a consequence of  $Ax \geq b$ , or, which is the same, if and only if the system of linear inequalities

$$(S_z) \quad Ax \geq b, \quad -c^T x > -z$$

has no solutions. By the MTT this is the case if and only if at least one of the systems

$$(T1_z) \quad \begin{cases} y^T A - y_0 c = 0, & y^T b - y_0 z > 0, \\ y \geq 0, & y_0 \geq 0 \end{cases}$$

and

$$(T2_z) \quad \begin{cases} y^T A - y_0 c = 0, & y^T b - y_0 z \geq 0, \\ y \geq 0, & y_0 > 0 \end{cases}$$

has a solution. Note that the only difference between these two systems is that  $(T1_z)$  requires  $y_0 \geq 0$  whereas  $(T2_z)$  requires  $y_0 > 0$ . Also, since the system  $(T2_z)$  is homogeneous, without loss of generality we may take  $y_0 = 1$ . Thus it follows that  $z$  is a lower bound on the optimal value of (P) if and only if one of the following two systems

$$(T1'_z) \quad y^T A = 0, \quad y^T b > 0, \quad y \geq 0$$

and

$$(T2'_z) \quad y^T A = c, \quad y^T b \geq z, \quad y \geq 0$$

has a solution. Observe that  $z$  does not appear in  $(T1'_z)$ . Therefore, if this system has a solution then each real  $z$  is a lower bound on the optimal value of (P), but this occurs if and only if the problem (P) is infeasible. Assuming that (P) is feasible, it follows that  $z$  is a lower bound on the optimal value of (P) if and only if the system  $(T2'_z)$

has a solution. Given a solution  $y$  of  $(T2'_z)$  any  $z$  satisfying  $y^T b \geq z$  is a lower bound and the largest lower bound provided in this way is  $y^T b$ . Hence, the largest possible lower bound on the optimal value of (P) is the optimal value of the problem

$$(D) \quad \max \{b^T y: y^T A = c, y \geq 0\}.$$

If the problem (P) is unbounded, i. e., if there does not exist a lower bound on the optimal value of (P), then the problem (D) must be infeasible. Otherwise the optimal value of (D) must coincide with the optimal value of (P).

The problem (D) is called the *dual problem* of the *primal problem* (P). The above findings can be summarized as follows:

if one of the two problems (P) and (D) is unbounded then the other is infeasible; if both problems are feasible then they have both an optimal solution and the optimal values are the same.

This is the *duality theorem for linear optimization*. Note that one other case may occur, namely that both problems are infeasible. It became clear above that (P) is infeasible if and only if  $(T1'_z)$  has a solution, so

the primal problem (P) is infeasible if and only if there exists a *dual ray*  $y$ , i. e., a vector  $y$  such that

$$y^T A = 0, \quad y^T b > 0, \quad y \geq 0. \quad (3)$$

In fact, the latter statement is equivalent to the statement that (3) and  $Ax \geq b$  are *alternative systems*, which is the special case of the MTT occurring when  $B$  is vacuous and which is known as *Farkas' lemma*. (See ► **Linear Optimization: Theorems of the Alternative** and ► **Farkas Lemma**.) In just the same way it can be derived from a variant of Farkas' lemma that:

the dual problem (D) is infeasible if and only if there exists a *primal ray*  $x$ , i. e., a vector  $x$  such that

$$Ax \geq 0, \quad c^T x < 0. \quad (4)$$

It has been shown above that the MTT implies the duality theorem for linear optimization. The converse

is also true: Assuming the duality theorem for linear optimization, the MTT easily can be proved, showing that the two results are logically equivalent. This goes in two steps. Assuming the duality theorem for linear optimization, first one derives Farkas' lemma and then it is shown that the MTT follows. To derive Farkas' lemma, consider the problem

$$\min \{0^T x: Ax \geq b\}.$$

Clearly, the system  $Ax \geq b$  has a solution if and only if the optimal value of this problem is zero. By the duality theorem this holds if and only if the optimal value of the dual problem

$$\max \{b^T y: y^T A = 0, y \geq 0\}$$

is also zero. This holds if and only

$$y^T A = 0, y \geq 0 \quad \Rightarrow \quad b^T y \leq 0,$$

which is true if and only if the system

$$y^T A = 0, \quad y \geq 0, \quad b^T y > 0$$

has no solution, proving Farkas' lemma.

To prove the MTT, one derives from Farkas' lemma that the 'weaker' system

$$(S1) \quad Ax \geq a, \quad Bx \geq b$$

is infeasible if and only if the system (T1) has a solution. If (S1) is feasible then one easily verifies that (S) has no solution if and only if the optimal value of the problem

$$(P1) \quad \min \{v: Ax \geq a, Bx + ve \geq b\}$$

is a nonnegative real. Here  $e$  denotes the all-one vector. Since (P1) is feasible and below bounded, by the duality theorem this happens if and only if the optimal value of the dual problem

$$(D1) \quad \max \left\{ a^T y + b^T v: \begin{array}{l} y^T A + v^T B = 0, \\ e^T v = 1, \\ y \geq 0, \quad v \geq 0 \end{array} \right\}$$

is a nonnegative real and, finally, this occurs if and only if (T2) has a solution. Thus it has been shown that the MTT is logically equivalent to the duality theorem for linear optimization.

So far the issue of how to prove the MTT has not been touched. One possible approach is to prove the duality theorem for linear optimization and then derive the MTT in the above described way. This approach is now quite popular in text books. For a recent example see, e. g., [2]. The easiest way for a direct proof is to prove first the Farkas' lemma and then derive the MTT from this lemma. The latter step uses the easy to verify statement that (S) has no solution if and only if the system

$$\begin{aligned} Ax - ta &\geq 0, \\ Bx - tb - se &\geq 0, \\ t - s &\geq 0, \\ -s &< 0 \end{aligned}$$

has no solution. Application of a suitable variant of Farkas' lemma to this system yields the MTT. Farkas' lemma and its proof have a rich history; for a nice and detailed survey one might consult [3].

### Introduction

Data classification is a supervised learning strategy that analyzes the organization and categorization of data in distinct classes [14]. Generally, a training set, in which all objects are already associated with known class labels, is used by classification methods. The data classification algorithm works on this set by using input attributes and builds a model to classify new objects. In other words, the algorithm predicts output attribute values. Output attribute of the developed model is categorical [4]. There are many applications of data classification in finance [6,14], health care [14], sports [14], engineering [10,14] and science [10]. Data classification is an important problem that has applications in a diverse set of areas ranging from finance to bioinformatics.

A broad range of methods exists for data classification problem including Decision Tree Induction [14], Bayesian Classifier [14], Neural Networks (NN) [10], Support Vector Machines (SVM) [10] and Mathematical Programming (MP) [1]. An overall view of classification methods is published by Weiss and Kulikowski [21]. A neural network is a data structure that attempts to simulate the behavior of neurons in a biological brain [14]. A major shortcoming of the neural network approach is a lack of explanation of the constructed model. The possibility of obtaining a non-convergent solution due to the wrong choice of initial weights and the possibility of resulting in a non-optimal solution due to the local minima problem are important handicaps of neural network-based methods. SVM approach operates by finding a hyper surface that will split the classes so that the distance between the hyper surface and the nearest of the points in the groups has the largest value [19]. The main goal is to generate a separating hyper surface which maximizes the margin and produces good generalization ability [10]. In recent years, SVM has been considered one of the most effi-

Koç University, Istanbul, Turkey

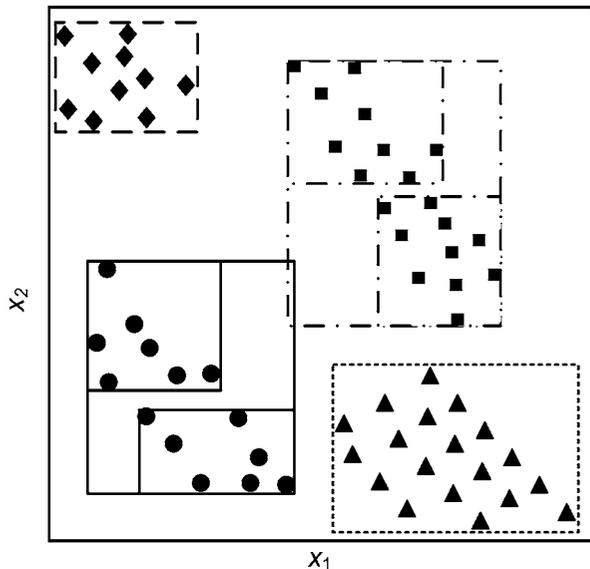

cient methods for two-class classification problems [5]. SVM method has two important drawbacks in multi-class classification problems; a combination of SVM has to be used in order to solve the multi-class classification problems and some approximation algorithms are used in order to reduce the computational time for SVM while learning the large scale of data.

There have been numerous attempts to solve classification problems using mathematical programming. A survey of classification methods using mathematical programming is published by Joachimsthaler and Stam [11]. The mathematical programming approach to data classification was first introduced in early 1980's. Since then, numerous mathematical programming models have appeared in the literature. As an extension of complement to these, Erenguc and Koehler provide a comprehensive review [7]. Many distinct mathematical programming methods with different objective functions are developed in the literature. These include; minimizing the maximum exterior deviation, minimizing the weighted sum of exterior deviations, minimizing a measure of exterior deviations while maximizing a measure of interior deviations, minimizing the number of misclassifications, and minimizing a generalized distance measure. Most of these methods modeled data classification as linear programming (LP) problems to optimize a distance function. Contrary to LP problems, mixed-integer linear programming (MILP) problems that minimize the misclassifications on the design data set are also widely studied [7]. Mathematical programming methods have certain advantages over the parametric ones. For instance, they are free from parametric assumptions and weights to be adjusted. Moreover, varied objectives and more complex problem formulations can easily be accommodated. On the other hand, obtaining a solution without any discriminating power, unbounded solutions and excessive computational effort requirement are some of the problems in mathematical programming based methods. Koehler [12] surveys the potential problems in mathematical programming formulations. There have been several attempts to formulate data classification problems as MILP problems [2,8,13,15]. Since MILP methods suffer from computational difficulties, the efforts are mainly focused on efficient solutions for two-group supervised classification problems. Although ways to solve a multi-class data classification problem exist by

means of solving several two-group problems, such approaches also have drawbacks including computational complexity resulting in long computational times [16].

### MILP Formulation

The objective in data classification is to assign data points that are described by several attributes into a pre-defined number of classes. The use of hyper-boxes for defining boundaries of the sets that include all or some of the points in that set as shown in Fig. 1 can be very accurate on multi-class problems. If it is necessary, more than one hyper-box could be used in order to represent a class as shown in Fig. 1. When the classes that are indicated by square and circle data points are both represented by a single hyper-box respectively, the boundaries of these hyper-boxes will overlap. Thus, two boxes are constructed in order to eliminate this overlapping. A very important consideration in using hyper-boxes is the number of boxes used to define a class. If the total number of hyper-boxes is equal to the number of classes, then the data classification is very efficient. On the other hand; if there are as many hyper-boxes of a class as the number of data points in a class, then the data classification is inefficient.

Multi-Class Data Classification via Mixed-Integer Optimization, Figure 1  
Schematic representation of multi-class data classification using hyper-boxes

The data classification problem based on this new idea is built in two parts: training and testing. Determination of the characteristics of the data points that belong to a certain class and differentiation them from the data points that belong to other classes are the targets done during the training part. Thus, boundaries of the classes are formed by the construction of hyper-boxes in the training step. After the distinguishing characteristics of the classes are determined, then the effectiveness of the classification must be tested. Predictive accuracy of the developed model is performed on a test data set during the test part.

### Training Problem Formulation

Training part studies are performed on a training data set composed of a number of instances  $i$ . The data points are represented by the parameter  $a_{im}$  that denotes the value of attribute  $m$  for the instance  $i$ . The class  $k$  that the data point  $i$  belongs to are given by the set  $D_{ik}$ . Each existing hyper-box  $l$  encloses a number of data points belonging to the class  $k$ . Moreover, bounds  $n$  (lower, upper) of each hyper-box is determined by solving the training problem.

Given these parameters and the sets, the following variables are sufficient to model the data classification problem with hyper-boxes. The binary variable  $y_{b_l}$  is indicates whether the box  $l$  is used or not. The position (inside or outside) of the data point  $i$  with regard to box  $l$  is represented by  $y_{pb_{il}}$ . The assigned class  $k$  of box  $l$  and data point  $i$  is symbolized by  $y_{bc_{lk}}$  and  $y_{pc_{ik}}$ , respectively. If the data point  $i$  is within the bound  $n$  with respect to attribute  $m$  of box  $l$ , then the binary variable  $y_{pb_{ilmn}}$  takes the value of 1, otherwise 0. Similarly,  $y_{pb_{ilm}}$  indicates whether the data point  $i$  is within the bounds of attribute  $m$  of box  $l$  or not. Finally,  $y_{p_{ik}}$  indicate the misclassification of data points. In order to define the boundaries of hyper-boxes, two continuous variables are required:  $X_{lmn}$  is the one that models bounds  $n$  for box  $l$  on attribute  $m$ . Correspondingly, bounds  $n$  for box  $l$  of class  $k$  on attribute  $m$  are defined with the continuous variable  $XD_{l,k,m,n}$ .

The following MILP problem models the training part of data classification method using hyper-boxes:

$$\min z = \sum_i \sum_k y_{p_{ik}} + c \sum_l y_{b_l} \quad (1)$$

subject to

$$XD_{lkmn} \leq a_{im} y_{pb_{il}} \quad \forall i, k, l, m, n | n = lo \quad (2)$$

$$XD_{lkmn} \geq a_{im} y_{pb_{il}} \quad \forall i, k, l, m, n | n = up \quad (3)$$

$$XD_{lkmn} \leq Q y_{bc_{lk}} \quad \forall k, l, m, n \quad (4)$$

$$\sum_k XD_{lkmn} = X_{lmn} \quad \forall l, m, n \quad (5)$$

$$y_{pb_{ilmn}} \geq (1/Q)(X_{lmn} - a_{im}) \quad \forall i, l, m, n | n = up \quad (6)$$

$$y_{pb_{ilmn}} \geq (1/Q)(a_{im} - X_{lmn}) \quad \forall i, l, m, n | n = lo \quad (7)$$

$$\sum_l y_{pb_{il}} = 1 \quad \forall i \quad (8)$$

$$\sum_k y_{pc_{ik}} = 1 \quad \forall i \quad (9)$$

$$\sum_l y_{pb_{il}} = \sum_k y_{pc_{ik}} \quad \forall i \quad (10)$$

$$\sum_k y_{bc_{lk}} \leq y_{b_l} \quad \forall l \quad (11)$$

$$y_{bc_{lk}} - \sum_i y_{pb_{il}} \leq 0 \quad \forall l, k \quad (12)$$

$$y_{bc_{lk}} - \sum_i y_{pc_{ik}} \leq 0 \quad \forall l, k \quad (13)$$

$$\sum_n y_{pb_{ilmn}} - y_{pb_{ilm}} \leq N - 1 \quad \forall i, l, m \quad (14)$$

$$\sum_m y_{pb_{ilm}} - y_{pb_{il}} \leq M - 1 \quad \forall i, l \quad (15)$$

$$y_{pc_{ik}} - y_{p_{ik}} \leq 0 \quad \forall i, k \notin D_{ik} \quad (16)$$

$$X_{lmn}, XD_{lkmn} \geq 0, y_{b_l}, y_{bc_{lk}}, y_{pb_{il}}, y_{pc_{ik}}, y_{pb_{ilmn}}, y_{pb_{ilm}}, y_{p_{ik}} \in \{0, 1\} \quad (17)$$

The objective function of the MILP problem (Eq. (1)) is to minimize the misclassifications in the data set with the minimum number of hyper-boxes. In order to eliminate unnecessary use of hyper-boxes, the unnecessary existence of a box is penalized with a small scalar  $c$  in

the objective function. The lower and upper bounds of the boxes are given in Eqs. (2) and (3), respectively. The lower and upper bounds for the hyper-boxes are determined by the data points that are enclosed within the hyper-box. Eq. (4) enforces the bounds of hyper-boxes exist if and only if this hyper-box is assigned to a class. Eq. (5) is used to relate the two continuous variables that represent the bounds of the hyper-boxes. The position of a data point with respect to the bounds on attribute  $m$  for a hyper-box is given in Eqs. (6) and (7). The binary variable  $y_{pbni_{lmn}}$  helps to identify whether the data point  $i$  is within the hyper-box  $l$ . Two constraints, one for the lower bound and one for the upper bound, are needed for this purpose (Eqs. (6) and (7)). Since these constraints establish a relation between continuous and binary variables, an arbitrarily large parameter,  $Q$ , is included in these constraints. The Eqs. (8) and (9) state that every data point must be assigned to a single hyper-box,  $l$ , and a single class,  $k$ , respectively. The equivalence between Eqs. (8) and (9) is given in Eq. (10); indicating that if there is a data point in the class  $k$ , then there must be a hyper-box  $l$  to represent the class  $k$  and vice versa. The existence of a hyper-box implies the assignment of that hyper-box to a class as shown in Eq. (11). If a class is represented by a hyper-box, there must be at least one data point within that hyper-box as in Eq. (12). In the same manner, if a hyper-box represents a class, there must be at least a data point within that class as given in Eq. (13). The Eq. (14) represents the condition of a data point being within the bounds of a box in attribute  $m$ . If a data point is within the bounds of all attributes of a box, then it must be in the box as shown in Eq. (15). When a data point is assigned to a class that it is not a member of, a penalty applies as indicated in Eq. (16). Finally, last constraint gives non-negativity and integrality of decision variables. By using this MILP formulation, a training set can be studied and the bounds of the classes are determined for a data classification problem.

### Testing Problem Formulation

The testing problem for multi-class data classification using hyper-boxes is straight forward. If a new data point whose membership to a class is not known arrives, it is necessary to assign this data point to one of the classes. There are three possibilities for a new data

point when determining its class:

- i. the new data point is within the boundaries of a single hyper-box,
- ii. the new data point is within the boundaries of more than one hyper-box,
- iii. the new data point is not enclosed in any of the hyper-boxes determined in the training problem.

When the first possibility is realized for the new data point, the classification is made by directly assigning this data to the class that was represented by the hyper-box enclosing the data point. Since eliminating the shared areas between the constructed hyper-boxes introduces new constraints into the training problem that makes it computationally very difficult to be solved, there exists a possibility for a new data point to be within the boundaries of more than one hyper-box. In that case, the data point is assigned to the classes of the hyper-boxes that enclose this specific data point. The proportion of the number of correct classes to the number of total assigned classes to that data point determines the effect of that data point to the accuracy of the model. In the case when the third possibility applies, the assignment of the new data point to a class requires some analysis. If the data point is within the lower and upper bounds of all but not one of the attributes (i. e.,  $m'$ ) defining the box, then the shortest distance between the new point and the hyper-box is calculated using the minimum distance between hyper-planes defining the hyper-box and the new data point. The minimum distance between the new data point  $j$  and the hyper-box is calculated using Eq. (18) considering the fact that the minimum distance is given by the normal of the hyper-plane.

$$\min_{l,m,n} \{|(a_{jm} - X_{lmn})|\} \quad (18)$$

When the data point is between the bounds of smaller than or equal to  $M-2$  attributes, then the smallest distance between the point and the hyper-box is obtained by calculating the minimum distance between edges of the hyper-box and the new point. An edge is a finite segment consists of the points of a line that are between two extreme points  $X_{lmn}$  and  $X_{lm'n}$ . The data point  $j$  is represented by the vector  $\vec{A}_j$  which is composed of  $a_{jm}$  values and  $P0_{lmn}$  and  $P1_{lmn}$  are the vector forms of two extreme points. The minimum distance between the new data point  $j$  and one of the segments of the

hyper-box determined by two extreme points is calculated using Eq. (25) where  $(\cdot)$  indicates the dot product of the matrices in Eq. (22) and (23).

$$\vec{W}_{jlmn} = \vec{A}_j - P0_{lmn} \tag{19}$$

$$\vec{V}_{jlmn} = \vec{P1}_{lmn} - \vec{P0}_{lmn} \tag{20}$$

$$C1_{jlmn} = \frac{(W_{jlmn} \cdot V_{jlmn})}{\|W_{jlmn}\| \|V_{jlmn}\|} \tag{21}$$

$$C2_{jlmn} = \frac{(V_{jlmn} \cdot V_{jlmn})}{\|V_{jlmn}\| \|V_{jlmn}\|} \tag{22}$$

$$b_{jlmn} = \frac{C1_{jlmn}}{C2_{jlmn}} \tag{23}$$

$$Pb_{jlmn} = P0_{jlmn} + b_{jlmn} V_{jlmn} \tag{24}$$

$$\min_{l,n} \left\{ \sqrt{\sum_m (a_{jm} - pb_{jlmn})^2} \right\} \tag{25}$$

When data point is not within the lower and upper bounds of any attributes defining the box, then the shortest distance between the new point and the hyper-box is calculated using the minimum distance between extreme points of the hyper-box and the new data. The minimum distance between the new data point  $j$  and one of the extreme points of the hyper-box is calculated using Eq. (26).

$$\min_{l,n} \left\{ \sqrt{\sum_m (a_{jm} - X_{lmn})^2} \right\} \tag{26}$$

The following algorithm assign a new data point  $j$  with attribute values  $a_{jm}$  to class  $k$ :

**Step 0:** Initialize  $inAtt(l,m) = 0$ .

**Step 1:** For each  $l$  and  $m$ , if

$$X_{lmn} \leq a_{jm} \leq X_{lmn'} \quad \forall n = lo, n' = up \tag{27}$$

Set  $inAtt(l,m) = inAtt(l,m) + 1$ .

**Step 2:** If  $inAtt(l,m) = M$ , then go to Step 3. Otherwise, continue. If  $inAtt(l,m) \leq M - 1$ , then go to Step 4.

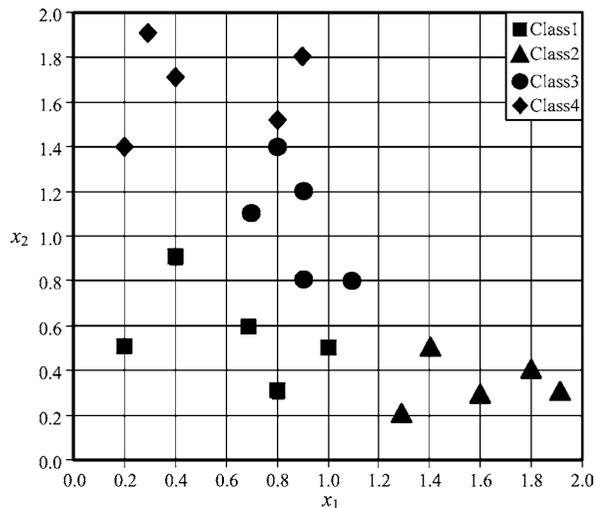

**Step 3:** Assign the new data point to class  $k$  where  $yc_{lk}$  is equal to 1 for the hyper-box in Step 2. Stop.

**Step 4:** Calculate the minimum given by Eq. (18) and set the minimum as  $min1(l)$ . Calculate the minimum given by Eq. (25) and set the minimum as  $min2(l)$ . Calculate the minimum given by Eq. (26) and set the minimum as  $min3(l)$ . Select the minimum between  $min1(l)$ ,  $min2(l)$  and  $min3(l)$  to determine the hyper-box  $l$  that is closest to the new data point  $j$ . Assign the new data point to class  $k$  where  $yc_{lk}$  is equal to 1 for the hyper-box  $l$ . Stop.

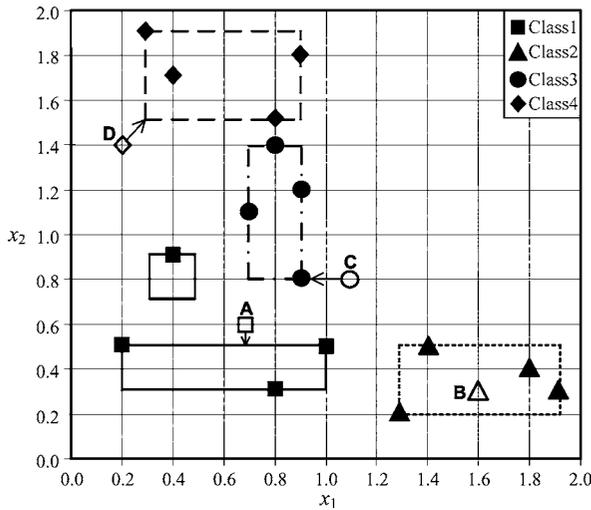

**Application**

We applied the mathematical programming method on a set of 16 data points in 4 different classes given in Fig. 2. The data points can be represented by two attributes, 1 and 2.

There are a total of 20 data points; 16 of these points were used in training and 4 of them used in testing. The training problem classified the data into 4 four classes using 5 hyper-boxes as shown in Fig. 3. It is interesting to note that Class1 requires two hyper-boxes while the other classes are represented with a single hyper-box only. The reason for having two hyper-boxes for Class1 is due to the fact that a single hyper-box for this

**Multi-Class Data Classification via Mixed-Integer Optimization, Figure 2**  
Data points in the illustrative example and their graphical representation

**Multi-Class Data Classification via Mixed-Integer Optimization, Figure 3**

**Hyper-boxes that classify the data points in the illustrative example**

class would include one of the data points that belong to Class3. In order to eliminate inconsistencies in training data set, the method included one more box for Class1.

After the training is successfully completed, the test data is processed to assign them to hyper-boxes that classify the data perfectly. The assignment of the test data point B to Class2 is straightforward since it is included in the hyper-box that classifies Class2 (i.e.,  $inAtt(l,m) = M$  for this data point). The test data in Class1 is assigned to one of the hyper-boxes that classify Class1. Similarly, the test data in Class3 is also assigned to the hyper-box that classifies Class3. Since the test data in these classes are included within the bounds of one of the two attributes, the minimum distance is calculated as the normal to the closest hyper-plane to these data points. In the case of data point that belongs to Class4, it is assigned to its correct class since the closest extreme point of a hyper-box classifies Class4. This extreme point of the hyper-box 5 classifying Class4 is given by  $(X_{5,1,10}, X_{5,2,10})$ . The test problem also classified the data points with 100% accuracy as shown in Fig. 3.

This illustrative example is also tested by different data classification models existing in the literature in order to compare the results and to measure the performance of the proposed model. Table 1 shows the ex-

amined models and their outcomes for this small illustrative example.

Neural Networks, Support Vector Machines, Bayesian, K-nearest Neighbor and Statistical Regression classifiers have only one misclassified instance which leads to 75% accuracy value as shown in Table 1. Neural Networks and K-nearest Neighbor classifier predicts the class of test sample A as Class3. Support Vector Machine method misclassifies test sample D and assigns it to Class1 while Bayesian and Statistical Regression classifier classifies test sample C as belonging to Class2. On the other hand, Decision Tree classifier gives the lowest accuracy value (50%) with two misclassifications. Sample A and sample C is classified as Class3 and Class2, respectively. Consequently, MILP approach in this thesis classifies all of the test samples accurately and achieves 100% accuracy. As a result, the MILP approach performs better than other data classification methods that are listed in Table 1 for the illustrative example. The accuracy of the MILP approach is tested on IRIS dataset and protein folding type dataset. The results indicate that the MILP approach has better accuracy than other methods on these datasets [17,18].

## Conclusion

Multi-class data classification problem can be very effectively modeled as an MILP problem. One of the

most important characteristics of the MILP approach is allowing the use of hyper-boxes for defining the boundaries of the classes that enclose all or some of the points in that set. In other words, if necessary, more than one hyper-box is constructed for a specific class through the training part studies. Moreover, well-construction of the boundaries of each class provides the lack of misclassifications in the training set and indirectly improves the accuracy of the model. The model does not require the underlying distribution of the training data set and learns from the training set in a reasonable time. With only one parameter ( $c$ : the penalty parameter to minimize the total number of hyper-boxes), the suggested model is simple and very effective. Furthermore, the proposed model can be used for both binary and multi-class data classification problems without any modifications. Hence, the performance of the model does not depend on the class related changes.

Multicommodity network flows; Column generation; Decomposition; Transportation

Linear multicommodity flow problems (MCF) are linear programs (LPs) that can be characterized by a set of commodities and an underlying network. A *commodity* is a good that must be transported from one or more origin nodes to one or more destination nodes in the network. In practice these commodities might be telephone calls in a telecommunications network, packages in a distribution network, or airplanes in an airline flight network. Each commodity has a unique set of characteristics and the commodities are not interchangeable. That is, you cannot satisfy demand for one commodity with another commodity. The objective of the MCF problem is to flow the commodities through the network at minimum cost without exceeding arc capacities. A comprehensive survey of linear multicommodity flow models and solution procedures are presented in [2].

Integer multicommodity flow (IMCF) problems, a constrained version of the linear multicommodity flow problem in which flow of a commodity (specified in this case by an origin-destination pair) may use only one path from origin to destination.

MCF and IMCF problems are prevalent in a number of application contexts, including transportation, communication and production.

## MCF Example Applications

- *Routing vehicles in traffic networks (dynamic traffic assignment)*. This involves the determination of minimum delay routes for vehicles from their origins to their respective destinations over the traffic network. The allowable congestion levels determine the arc capacities. Alternatively, there are no capacities but the cost on an arc is a function of the amount of flow on the arc. In the former case, the objective function is linear while in the latter it is nonlinear.
- *Distribution systems planning*. In this problem there are different products (or, commodities) produced at several plants with known production capacities. Each commodity has a certain demand in each customer zone. The demand is satisfied by shipping via regional distribution centers with finite storage capacities. A.M. Geoffrion and G.W. Graves [28] model this problem of routing the commodities from the manufacturing plants to the customer zones through the distribution centers as a MCF problem.
- *Import and export models*. One of the factors that may affect export is handling capacity at ports. D. Barnett, J. Binkley and B. McCarl [8] use a MCF model to analyze the effect of US port capacities on the export of wheat, corn and soybean.
- *Optimization of freight operations*. T. Crainic, J.A. Ferland and J.M. Rousseau [20] develop a MCF-based routing and scheduling optimization model that considers the planning issues for the railroad industry. More recently, H.N. Newton [48] and C. Barnhart, H. Jin and P.H. Vance [13] study the railroad blocking problem using multicommodity based formulations.
- *Freight Assignment in the Less-than-Truckload (LTL) industry*. An LTL carrier has to consolidate many shipments to make economic use of the vehicles. This requires the establishment of a large number of terminals to sort freight. Trucking companies use forecasted demands to define routes for each vehicle to carry freight to and from the terminals. Once the routes are fixed, the problem is to deliver all the shipments with minimum total service time or cost. This problem is formulated as a MCF problem in [17] and [24].
- *Express Shipment Delivery*. D. Kim [40] models the shipment delivery problem faced by express carriers like Federal Express, United States Postal Service, United Parcel Service, etc. as a MCF problem on a network in space and time.
- *Routing messages in a telecommunications or computer network*. The network consists of transmission lines. Each message request is a commodity. The problem is to route the messages from origins to the respective destinations at a minimum cost. T.L. Magnanti et al. [42] and others provide MCF-based formulations for this problem.

- Long-term *hydro-generation* optimization. The task in this case is to determine the amount of hydro-generation at a reservoir in an interval of time, that minimizes the expected cost of power generation over a period of time, divided into several intervals. N. Nabonna [47] showed that this problem can be modeled as a MCF problem with inflows given as probabilistic density functions.
- *Forest management*. For each planning period, forest managers have to make decisions concerning the land areas to be harvested, the volume of timber to be harvested from these areas, the land areas to be developed for recreation and the road network to be built and maintained in order to support both the timber haulers and recreationists. This problem has been formulated as a MCF problem in [33].
- *Street planning*. L.R. Foulds [26] introduced this problem and modeled it as a MCF problem. The objective is to identify a set of two-way streets such that making these streets one-way minimizes the total congestion cost in the network.
- *Spatial price equilibrium (SPE)* problem. This problem requires modeling consumer flows within a general network. The SPE problem determines the optimum levels of production and consumption at each market and the optimal flows satisfy the equilibrium property. R.S. Segall [59] models and solves the SPE problem as a MCF problem.

For a more comprehensive description of MCF applications, see [2,37,57].

### IMCF Example Applications

- *Airline fleet assignment*. Given a time table of flight arrivals and departures, the expected demand on the flights and a set of aircraft, the objective is to arrive at a minimum cost assignment of aircraft to the flights. This problem has been extensively studied in [1,31].
- *Airline crew scheduling*. This problem deals with the minimum cost scheduling of crews. Factors such as hours of work limitations and Federal Aviation Administration regulations must be taken into account while solving the problem. For an in-depth study see [5,14].
- *Airline maintenance routing problems* require that single aircraft be routed such that maintenance requirements are satisfied and each flight is assigned to exactly one aircraft. This problem has been studied in [10,19,25].
- *Bandwidth packing problems* require that bandwidth be allocated in telecommunications networks to maximize total revenue. The demands, or calls, on the networks are the commodities and the objective is to route the calls from their origin to their destination. In the case of video teleconferencing, since call splitting is not allowed, each call must be routed on exactly one network path. This IMCF problem is described in [49].
- *Package flow problems*, such as those arising in express package delivery operations, require that shipments, each with a specific origin and destination, be routed over a transportation network. Each set of packages with a common origin-destination pair can be considered as a commodity and often, to facilitate operations and ensure customer satisfaction, must be assigned to a single network path. These problems are cast as IMCF problems in [12].

### Formulations

Multicommodity flow problems can be modeled in a number of ways depending how one defines a commodity. There are three major options: a commodity may originate at a subset of nodes in the network and be destined for another subset of nodes, or it may originate at a single node and be destined for a subset of the nodes, or finally it may originate at a single node and be destined for a single node. K.L. Jones et al. [34] present models for each of these different cases. In the interest of space, we will only consider models for the last case. The other cases can also be modeled using variants of the models presented here.

We present two different formulations of the MCF problem: the *node-arc* or *conventional* formulation and the *path* or *column generation formulation*. The MCF is defined over the network  $G$  comprised of node set  $N$  and arc set  $A$ . MCF contains decision variables  $x$ , where  $x_{ij}^k$  is the fraction of the total quantity (denoted  $q^k$ ) of commodity  $k$  assigned to arc  $ij$ . In the IMCF problem these variables are restricted to be binary. The cost of assigning commodity  $k$  in its entirety to arc  $ij$  equals  $q^k$  times the unit flow cost for arc  $ij$ , denoted  $c_{ij}^k$ . Arc  $ij$  has capacity  $d_{ij}$ , for all  $ij \in A$ . Node  $i$  has supply of

commodity  $k$ , denoted  $b_i^k$ , equal to 1 if  $i$  is the origin node for  $k$ , equal to  $-1$  if  $i$  is the destination node for  $k$ , and equal to 0 otherwise.

The node-arc MCF formulation is:

$$\text{minimize } \sum_{k \in K} \sum_{ij \in A} c_{ij}^k q^k x_{ij}^k \quad (1)$$

such that

$$\sum_{ij \in A} x_{ij}^k - \sum_{ji \in A} x_{ji}^k = b_i^k, \quad \forall i \in N, \forall k \in K, \quad (2)$$

$$\sum_{k \in K} q^k x_{ij}^k \leq d_{ij}, \quad \forall ij \in A, \quad (3)$$

$$x_{ij}^k \geq 0, \quad \forall ij \in A, \quad \forall k \in K. \quad (4)$$

Note that without restricting generality of the problem, we model the arc flow variables  $x$  having values between 0 and 1. To do this, we scale the demand for each commodity to 1 and accordingly adjust the coefficients in the objective function (1) and in constraints (3). Also note the block-angular structure of this model. The conservation of flow constraints (2) form nonoverlapping blocks, one for each commodity. Only the arc capacity constraints (3) link the values of the flow variables of different commodities.

To contrast, the path-based or column generation MCF formulation has fewer constraints, and far more variables. Again, the underlying network  $G$  is comprised of node set  $N$  and arc set  $A$ , with  $q^k$  representing the quantity of commodity  $k$ .  $P(k)$  represents the set of all origin-destination paths in  $G$  for  $k$ , for all  $k \in K$ . In the column generation model, the binary decision variables are denoted  $y_p^k$ , where  $y_p^k$  is the fraction of the total flow of commodity  $k$  assigned to path  $p \in P(k)$ . The cost of assigning commodity  $k$  in its entirety to path  $p$  equals  $q^k$  times the unit flow cost for path  $p$ , denoted  $c_p^k$ .  $c_p^k$  represents the sum of the  $c_{ij}^k$  costs for all arcs  $ij$  contained in path  $p$ . As before, arc  $ij$  has capacity  $d_{ij}$ , for all  $ij \in A$ . Finally,  $\delta_{ij}^p$  is equal to 1 if arc  $ij$  is contained in path  $p \in P(k)$ , for all  $k \in K$ ; and is equal to 0 otherwise.

The path or column generation IMCF formulation is then:

$$\text{minimize } \sum_{k \in K} \sum_{p \in P(k)} c_p^k q^k y_p^k \quad (5)$$

such that

$$\sum_{k \in K} \sum_{p \in P(k)} q^k y_p^k \delta_{ij}^p \leq d_{ij}, \quad \forall ij \in A, \quad (6)$$

$$\sum_{p \in P(k)} y_p^k = 1, \quad \forall k \in K, \quad (7)$$

$$y_p^k \geq 0, \quad \forall p \in P(k), \quad \forall k \in K. \quad (8)$$

## LP Solution Methods

Comprehensive surveys of the available multicommodity network flow solution techniques are provided in [6,37]. Descriptions of these approaches are also provided in [2,38].

*Price-directive decomposition* techniques use the path-based MCF model. To limit the number of variables considered in finding an optimal solution, *column generation* techniques are used. Further details of price-directive decomposition and column generation are provided in [18,22,41,45,61].

*Resource-directive decomposition* techniques attempt to solve MCF problems by allocating arc capacity by commodity and solving the resulting decoupled minimum cost flow problems for each commodity. Additional descriptions of this technique can be found in [27,30,35,37,39,41,52,60,61].

Computational comparisons of the performance of price- and resource-directive decomposition methods can be found in [3,4]. A. Ali, R.V. Helgason, J.L. Kennington, and H. Lall [4] report that specialized decomposition codes can be expected to run from three to ten times faster than a general linear programming package. Furthermore, A.A. Assad [7] reports that resource-directive algorithms converge quickly for small problems but are outperformed by the price-directive method for larger MCF problems.

G. Saviozzi [56] uses *subgradient* techniques on the *Lagrangian relaxation* of the bundle constraints and proposes a method of arriving at an advanced starting basis for the minimum cost multicommodity flow problem.

*Partitioning methods* specialize the simplex method by partitioning the current basis to exploit the underlying network structure. Experiences with primal partitioning techniques have been reported in [24,32,

[36,43,51,53,54,55], among others. J.B. Rosen [53] develops a partitioning strategy for angular problems. J.K. Hartman and L.S. Lasdon [32] develop a generalized upper bounding algorithm for multicommodity network flow problems in which the special structure of the MCF problem is exploited. Their primal partitioning procedure, a specialization of the generalized upper bounding procedure developed by G.B. Dantzig and R.M. Van Slyke [21], involves the determination at each iteration of the inverse of a basis containing only one row for each saturated arc. Similarly, C.J. McCallum [44] developed a generalized upper bounding algorithm for a communications network planning problem. All of these procedures exploit the block-diagonal problem structure and perform all steps of the simplex method on a reduced working basis of dimension  $m$ , where  $m$  represents the size of set  $A$ .

Interior point methods and parallel computing techniques have also been applied to MCF problems. Interior point methods provide polynomial time algorithms for the MCF problems. The best time bound is due to P.M. Vaidya [62]. G.L. Schultz and R.R. Meyer [58] provide an interior point method with massive parallel computing to solve multicommodity flow problems.

Development of new heuristic procedures for MCF problems include the primal and dual-ascent heuristics described in [17] and [9], respectively. A. Gershk and A. Shulman [29] use a barrier-penalty method to find nearly optimal solutions for multicommodity problems, while R. Schneur [62] describes a scaling algorithm to determine nearly feasible MCF solutions.

Recently, price-directive decomposition or column generation approaches, such as those presented in [2,11,23,34] have been the most extensively used method for solving large versions of the linear MCF problem. The general idea of column generation is that optimal solutions to large LP's can be obtained without explicitly including all columns (i. e., variables) in the constraint matrix (called the *Master Problem* or MP). In fact, only a very small subset of all columns will be in an optimal solution and all other (nonbasic) columns can be ignored. In a minimization problem, this implies that all columns with positive reduced cost can be ignored. The multicommodity flow column generation strategy, then, is:

- 0) RMP Construction. Include a subset of columns in a restricted MP, called the *Restricted Master Problem*, or RMP;
- 1) RMP Solution. Solve the RMP LP;
- 2) Pricing Problem Solution. Use the dual variables obtained in solving the RMP to solve the pricing problem. The pricing problem either identifies one or more columns with negative reduced cost (i. e., columns that price out) or determines that no such column exists.
- 3) Optimality Test. If one or more columns price out, add the columns (or a subset of them) to the RMP and return to Step 1; otherwise stop, the MP is solved.

For any RMP in Step 1, let  $-\pi_{ij}$  represent the non-negative dual variables associated with constraints (6) and  $\sigma^k$  represent the unrestricted dual variables associated with constraints (7). Since  $c_p^k$  can be represented as  $\sum_{ij \in A} c_{ij}^k \delta_{ij}^p$ , the reduced cost of column  $p$  for commodity  $k$ , denoted  $\bar{c}_p^k q^k$ , is:

$$\bar{c}_p^k q^k = \sum_{ij \in A} q^k (c_{ij}^k + \pi_{ij}) \delta_{ij}^p - \sigma^k, \quad \forall p \in P(k), \forall k \in K. \quad (9)$$

For each RMP solution generated in Step 1, the pricing problem in Step 2 can be solved efficiently. Columns that price out can be identified by solving one shortest path problem for each commodity  $k \in K$  over a network with arc costs equal to  $c_{ij}^k + \pi_{ij}$ , for each  $ij \in A$ . Let  $p^*$  represent a resulting shortest path  $p^*$  for commodity  $k$ . Then, if for all  $k \in K$ ,

$$c_{p^*}^k q^k \geq 0,$$

the MP is solved. Otherwise, the MP is not solved and, for each  $k \in K$  with

$$c_{p^*}^k q^k < 0,$$

path  $p^* \in P(k)$  is added to the RMP in Step 3.

## IP Solution Methods

The ability to solve large MCF LP's enables the solution of large IMCF problems. Successful approaches for solving large IMCF problems use the path-based or

column generation formulation of the problem. Column generation IP's can be solved to optimality using a procedure known as *branch and price*, detailed in [15,23,64]. Branch and price, a generalization of branch and bound with LP relaxations, allows column generation to be applied at each node of the branch and bound tree. Branching occurs when no columns price out to enter the basis and the LP solution does not satisfy the integrality conditions.

Applying a standard branch and bound procedure to the final restricted master problem with its existing columns will not guarantee an optimal (or feasible) solution. After the branching decision modifies RMP, it may be the case that there exists a column for MP that prices out favorably, but is not present in RMP. Therefore, to find an optimal solution we must maintain the ability to solve the pricing problem after branching. The importance of generating columns after the initial LP has been solved is demonstrated for airline crew scheduling applications in [63]. Although they were unable to find even feasible IP solutions using just the columns generated to solve the initial LP relaxation, they were able to find quality solutions using a branch and price approach for crew scheduling problems in which they generated additional columns whenever the LP bound at a node exceeded a preset IP target objective value.

The difficulty of performing column generation with branch and bound is that conventional integer programming branching on variables may not be effective because fixing variables can destroy the structure of the pricing problem. For the multicommodity flow application, a branching rule is needed that ensures that the pricing problem for the LP with the branching decisions included can be solved efficiently with a shortest path procedure. To illustrate, consider branching based on variable dichotomy in which one branch forces commodity  $k$  to be assigned to path  $p$ , i. e.,  $y_p^k = 1$ , and the other branch does not allow commodity  $k$  to use path  $p$ , i. e.,  $y_p^k = 0$ . The first branch is easy to enforce since no additional paths need to be generated once  $k$  is assigned to path  $p$ . The latter branch, however, cannot be enforced if the pricing problem is solved as a shortest path problem. There is no guarantee that the solution to the shortest path problem is not path  $p$ . In fact, it is likely that the shortest path for  $k$  is indeed path  $p$ . As a result, to enforce a branching decision, the pricing

problem solution must be achieved using a *next shortest path procedure*. In general, for a subproblem, involving a set of a branching decisions, the pricing problem solution must be achieved using a  $k$ th shortest path procedure.

The key to developing a branch and price procedure is to identify a branching rule that eliminates the current fractional solution without compromising the tractability of the pricing problem. In general, J. Desrosiers et al [23] argue this can be achieved by basing branching rules on variables in the original formulation, and not on variables in the column generation formulation. This means that branching rules should be based on the arc flow variables  $x_{ij}^k$  from the node-arc formulation of the problem. Barnhart et al. [15] develop branching rules for a number of different master problem structures. They also survey specialized algorithms that have appeared in the literature for a broad range of applications.

M. Parker and J. Ryan [49] present a branch and price algorithm for the bandwidth packing problem. in which the objective is to choose which of a set of commodities to send in order to maximize revenue. They use a path-based formulation. Their branching scheme selects a fractional path and creates a number of new subproblems equal to the length of the path (measured in the number of arcs it contains) plus one. On one branch, the path is fixed into the solution and on each other branch, one of the arcs on the path is forbidden. To limit time spent searching the tree they use a dynamic optimality tolerance. They report the solution of 14 problems with as many as 93 commodities on networks with up to 29 nodes and 42 arcs. All but two of the instances are solved to within 95% of optimality.

K. Ziarati et al. [16] consider the problem of assigning railway locomotives to trains. They model the problem as an integer multicommodity flow problem with side constraints and solve using a Dantzig–Wolfe decomposition technique, where subproblems are formulated as constrained or unconstrained shortest path problems.

P. Raghavan and C.D. Thompson [50] illustrate the use of randomized algorithms to solve some integer multicommodity flow problems. They use randomized rounding procedures that give provably good solutions in the sense that they have a very high probability of being close to optimality.

Barnhart et al. [12] present a *branch and price and cut* algorithm for general IMCF problems where each commodity is represented by an origin-destination pair and flow volume. *Branch and cut*, another variant of branch and bound, allows valid inequalities, or cuts, to be added throughout the branch and bound tree. *Branch and price and cut* combines column and row generation to yield very strong LP relaxations at nodes of the branch and bound tree.

### Introduction

References to Financial Statements Fraud (FSF) and earnings manipulation have attracted the attention of

market participants, academics, and regulators all over the world especially in recent years and following the collapse of Enron. During these years there have also been several cases of financial statement fraud which have been undetected by the auditors.

Using normal audit procedures, the detection of falsified financial statements is a difficult task [18,73]). There are numerous reasons for these difficulties such as a shortage of knowledge concerning the characteristics of management fraud, the efforts of managers to deceive auditors, and difficulties in collecting, analyzing and synthesizing large quantities of data from several different sources.

Models of audit reporting have several uses (i. e. prediction, determination, bankruptcy), as described by Dopuch et al. [26]. For example, they can provide a benchmark representing the probability that an auditor would issue a modified audit report on a given company. Furthermore, these models can be imperative in an auditing system that enables the users to take preventive or corrective actions [30,57,80]).

Most of the earlier studies of FSF have used discrete choice models in which the dependent variable was dichotomous. Mutchler [66] and Levitan and Knoblett [60] used discriminant analysis, Dopuch et al. [26] and Lennox [59] used probit models, Keasey et al. [48], Bell and Tabor [9], Monroe and Teh [65], Louwers [62], DeFond et al. [25], Citron and Taffler [17], Menon and Schwartz [63], and Spathis [80] used logit models, Krishnan [55] used an ordered probit model, Spathis et al. [79,81]), and Pasiouras et al. [71] used multicriteria decision aid (UTADIS) and multivariate statistical techniques (e. g. discriminant and logit analysis), Gaganis and Pasiouras [35] used discriminant and logit models, Gaganis et al. [36] used probabilistic neural network models, Gaganis et al. [33] used nearest neighbor models, Fanning et al. [31] and Fanning and Cogger [30] used artificial neural networks, and Doumpos et al. [27] used support vector machines.

In the present study, a multicriteria approach was followed through the application of the nonparametric Multi-group Hierarchical DIScrimination (MHDIS) method with the aim of developing a sorting model to detect those firms that issue FSF in Greece. The MHDIS model was compared with logit analysis in order to test its efficiency against a benchmark that has been com-

monly used in previous studies. MHDIS is not based on statistical assumptions, which often cause problems during the application of statistical methods (logit and probit analysis), and furthermore, it can easily incorporate qualitative data.

Although there have recently been a few attempts to develop models to detect falsified audit statements in Greece [15,51,79,81]. The present study differs in several respects. First, we have used a more recent and larger dataset than in previous studies, which contains more detailed information. The data used corresponds to the fiscal years 2001–2004 and covers 398 companies. Spathis et al. [79,81] and Kirkos et al. [51] examined the same random sample of 76 manufacturing companies covering the period 1997–1999, and Caramanis and Spathis [15] examined a sample of 182 companies. Second, we examined both listed and unlisted companies from the manufacturing, trade, and services sectors in contrast to Spathis et al. [79,81] and Kirkos et al. [51] who examined only manufacturing listed companies and Caramanis and Spathis [15] who considered only listed companies. Third, we used out-of-time and out-of-sample testing samples. When evaluating the classification ability of a model, it is important to ensure that it has not been over-fitted to the training (estimation) dataset. As Stein [83] mentions “a model without sufficient validation may only be a hypothesis”. Previous research has shown that when classification models are used to reclassify the observations of the training sample, the classification accuracies are biased upward. Thus, it is necessary to classify a set of observations which were not used during the development of the model, using some kind of testing sample.

The rest of the paper is organized as follows: Section “**Sample**” describes the sample used in this study. Section “**Method**” describes the methodology. Section “**Empirical Results**” presents the empirical results, and the Sect. “**Conclusions and Further Research**” discusses the concluding remarks and suggests some possible future research directions.

## Sample

The data used in the study consisted of financial statement information (i.e. balance sheet, income statement, auditors’ opinions, and the notes to financial

statements) of a sample of companies obtained from ICAP<sup>1</sup> database and Athens Stock Exchange (ASE). Our analysis was restricted to Greek limited (société anonyme) and limited liability companies, which are obliged by law to have their financial statements audited, and we focused on the period between 2001 and 2004.

We obtained 199 qualified cases which were distributed over various sectors<sup>2</sup>. The next step was to select unqualified firms. We used a pair-matching method by sector. Matching of firms is common practice when conducting classification studies in auditing as well as in other areas of finance, such as bankruptcy or acquisitions prediction (e.g. [11,34,50,58,71]). There are two primary reasons for following this procedure, which is known as choice-based sampling. The first is the lower cost of collecting data in comparison with an unmatched sample [6,46,90]. The second and most important is that a choice-based sample provides greater information content than a random sample [19,45,69]. Hence, our sample consisted of the same number of qualified and unqualified cases.

Most of the previous studies concerning the development of models to replicate (or predict) auditors’ opinion used training and testing samples from the same period, or re-sampling techniques such as jackknife and bootstrap (e.g. [57,79,81]). However, as Espahbodi and Espahbodi [29] point out, the real test of a classification model and its practical usefulness is its ability to classify objects correctly in the future. The main reason, as stated by Barnes [5], is that given inflationary effects, technological and other reasons, such as accounting policies, it is not reasonable to expect financial ratios to be stable over time. To account for this *population drifting*, in the present study, we split our sample of 398 companies into two distinct samples. The training sample, used for the development of the models, consisted of 234 companies and covered the period 2001–2003. The validation sample consisted of the remaining 164 companies and used data from 2004.

<sup>1</sup>ICAP is the largest company providing Business Information and Consulting Services in Greece.

<sup>2</sup>The sample for this study consists of 164 manufacturing, 122 trade and 110 services companies.

## Financial Variables

Similar to previous studies we used financial ratios as the indicators of FSF. One of the problems with the selection of suitable ratios is that not only are there many financial variables which could be potential candidates for inclusion in the model, but also that previous studies have, in general, failed to select variables that reflect theoretical models of FFS as well. We therefore selected variables that were regarded as important in previous studies, such as Albrecht and Romney [1], Palmrose [70], Dopouch et al. [26], Loebbecke et al. [61], Green [38], Stice [84], Davia et al. [23], Bell et al. [10], Schilit [75], Arens and Loebbecke [3], Beasley [7], Bologna et al. [12], Krishnan and Krishnan [54], Green and Choi [39], Hoffman [42], Hollman and Patton [43], Zimbelman [89], Laitinen and Laitinen [57], Spathis et al. [79,81], Spathis [80], Doumpos et al. [27], Gaganis et al. [33,36], Gaganis and Pasiouras [35], and Pasiouras et al. [71]. Table 1 present a full list of the variables considered in this study. There are 28 financial variables covering all aspects of the performance of the selected companies, such as liquidity, leverage, profitability, managerial activity, and annual changes in basic accounts [20].

An examination of previous research indicates that the prediction variables range between 6 and 20. Most of these studies selected the effective independent variables using a statistical method, in an attempt to reduce the number of independent variables and the impact of potential multicollinearity. There is, however, little relevant theory about the selection of independent variables for the nonlinear methods. From a practical point of view, developing a model that considers a large number of variables poses problems for the applicability of the model on a daily basis by the auditor. This is because any application of the model requires that the auditor collects all necessary data, which leads to increased time and cost for data collection and management [79]. In the present study, we used a combination of two statistical analysis methods to examine whether there was an association between our variables and auditors' opinions and hence to select our final set.

First, we used the Kruskal–Wallis non-parametric test to examine the differences between qualified and unqualified companies. Table 1 present the results of the Kruskal–Wallis test for the training sample. Only

three variables:  $365 \times \text{Stock}/\text{Cost of Sales}$ ;  $\text{Logarithm of Debt}$ ; and  $\text{Inventories}/\text{Total Assets}$  were not statistically significant at the 10% level. We then reduced the number of variables to a manageable size using factor analysis.

This approach can be used to uncover the latent structure of a set of variables by reducing the attribute space from a larger number of variables to a smaller number of factors. The factor loadings were then used to select a limited set of financial variables.

Finally, seven financial variables were selected, each being the variable with the highest loading in each factor. These were:  $\text{Receivable}/\text{Sales}$ ;  $\text{Current Assets}/\text{Current Liabilities}$ ;  $\text{Current Assets}/\text{Total Assets}$ ;  $\text{Cash}/\text{Total Assets}$ ;  $\text{Profit before tax}/\text{Total Assets}$ ;  $\text{Inventories}/\text{Total Assets}$ ; and  $\text{Annual Change in Sales}$ .

## Non-financial Variables

In addition to the seven financial variables discussed above, six non-financial ones were also used. Dopouch et al. [26] presented a predictive model of audit opinion qualifications in which the variables with greatest predictive power were categorical ones.

Previous studies mainly dealt with the construction of bankruptcy models for making audit opinions relative to going concern (e.g. [44,52,53]). Prior research (e.g. [17,30,41,61,74,79,84]) suggests that financial distress is very important in the issuing of an audit qualification. Although most of the previous studies used Altman's  $z$ -score [2] or credit risk assessment of a rating agency [71] as a proxy of default, such an approach may not be appropriate in our case. The reason is that Altman's  $z$ -score was developed for a particular industry (i.e. manufacturing), under different economic conditions (i.e. in the 1960s) and for a specific country (i.e. USA). In the present study, we used a score (UTADISCR) estimated from the UTADIS bankruptcy prediction model of Zopounidis et al. [92]. We anticipated that the use of this measure, which indicates the likelihood of default of Greek firms over the 12 months following the date of its calculation, might provide more accurate results.

Spathis [80] found that audit qualification decision was positively associated with company litigation. In this study, the client litigation variable was coded as zero if a company had litigation in the year preceding

the audit opinion and as one otherwise. Skinner [77] considered companies having litigation in the following cases: (a) a lawsuit had been filed in a Greek court; (b) there had been an allegation of common stock price fraud; or (c) there had been an allegation of stock exchange violation under Greek law.

The most consistent result in all previous research has been that auditor size can explain the supply of a higher level of audit quality, defined as the joint probability of detecting and reporting material financial errors (i. e., [4,8,22,24,25,28,47,48,64,72]). The evidence concerning the relationship between audit firms and audit report is mixed. Whereas Warren [88] did find a significant association between large audit firms and qualified audit reports, Shank and Murdock [76] found otherwise.

Previous studies also examined whether the auditor is one of the Big Four (namely PricewaterhouseCoopers, Deloitte and Touche, KPMG, Ernst and Young) or not [35]. We use a dummy variable set to zero (Domestic = 0) if the auditor was one of the domestic audit firms and one if the auditor was one of the foreign audit firms in Greece (Foreign = 1). In Greece the auditing profession was liberalized in 1992 by enabling legislation [37], see Caramanis [13,14]. The competition between the local Greek and foreign audit companies has increased since 1992. Nowadays, Greek companies audit a greater percentage of companies than foreign audit companies. It is possible that smaller companies avoid paying the premium price levied by the large audit companies, since Krishnan et al. [54] found that smaller firms in the US are less likely to be audited by the 'Big Four' companies. Furthermore, it is possible that the partners of domestic audit companies are more likely to develop close personal relationships with the directors of Greek client companies. On the other hand, there is a chance that the domestic audit companies will be more familiar with the 'small acceptable standards of control' in Greece.

Various papers examine the relationship between the audit opinion before and after the chance of auditors (switching). Chow and Rice [16], Craswell [21], Gul et al. [40], and Krishnan et al. [56] found a significant positive association between qualified opinions and subsequent auditor switching. As Nieves [68] points out, two effects may obscure the influence of the audit report in motivating a change: (a) many auditor

changes may be unrelated to audit opinion; and (b) the reasons for auditor changes are an internal state which is not directly observable. We tested the importance of auditor changes to detection of FFS over a 3-year period. The 3-year period included the first year of the financial statements and auditors' opinions and the 2 years before this first year. We used a dummy variable (Prior 2 year auditor) that takes a value of one (yes = 1) if the auditor had been retained and a value of zero if the firm had switched auditors (no = 0).

Finally, we used two other variables, LOSS and STOCK. LOSS is an indicator variable whose value is zero if an auditee experienced a loss in the year of audit opinion and one (profit) otherwise. Spathis [80] found a significant difference between qualified and non-qualified audit reports for this variable. STOCK is a dummy variable that takes a value of zero (yes = 0) for companies listed in the Athens Stock Exchange and one for unlisted companies (no = 1). Ireland [46] reported that whether a company is listed or unlisted may influence the auditor's independence. Listed companies may have greater supervision and training of their stock exchange authority. Furthermore, as Ireland [46] points out, large companies are more likely to have good accounting systems and internal controls, thus reducing disagreements and limitations on scope while, at the same time, auditors are more likely to waive earnings management attempts (resulting in mis-statements) in large clients, even after controlling for the materiality of such attempts [67].

## Method

Multicriteria decision making (MCDM) provides the methodological basis for the combination of qualitative and quantitative data. MCDA has been applied in finance as a sophisticated tool to improve the decision-taking in the turbulent and complex financial environment that exists nowadays. Spronk et al. [82] thoroughly investigated the application of this technique in the financial field. In the present study we used the MHDIS method [91].

The problem considered in this case study falls within the classification problematic that in general involves the assignment of a finite set of alternatives  $A = \{a_1, a_2, \dots, a_n\}$  to a set of  $q$  ordered classes  $C_1 > C_2 > \dots > C_q$ . Each alternative was evaluated

along a set of  $m$  criteria  $g_1, g_2, \dots, g_m$ . In the present case study the alternatives involved the companies in the sample, the criteria correspond to the set of seven financial variables, and six non-financial variables and there were two classes, the unqualified financial statements (class  $C_1$ ) and the qualified financial statements (class  $C_2$ ).

MHDIS distinguishes the groups progressively, starting by discriminating the first group from the others, and then proceeds to the discrimination between the alternatives belonging to the other group. To accomplish this task two additive utility functions are developed in each one of the  $q - 1$  steps, where  $q$  is the number of groups. The first function  $U_k(a)$  describes the alternatives of group  $C_1$ , and the second function  $U_{\sim k}(a)$  describes the remaining alternatives that are classified in lower groups  $C_{k+1}, \dots, C_q$ .

$$U_k(a) = \sum_{i=1}^m p_{ki} u_{ki}(g_i)$$

$$\text{and } U_{\sim k}(a) = \sum_{i=1}^m p_{\sim ki} u_{\sim ki}(g_i),$$

$$k = 1, 2, \dots, q - 1.$$

The corresponding marginal utility functions for each criterion  $g_i$  are denoted as  $u_{ki}(g_i)$  and  $u_{\sim ki}(g_i)$  which are normalized between 0 and 1, while the criteria weights  $p_{ki}$  and  $p_{\sim ki}$  sum up to 1. As mentioned above, the model is developed in  $q - 1$  steps. In the first step, the method develops a pair of additive utility functions  $U_1(a)$  and  $U_{\sim 1}(a)$  to discriminate between the alternatives of group  $C_1$  and the alternatives of the other groups  $C_2, \dots, C_q$ . On the basis of the above function forms the rule to decide upon the classification of any alternative has the following form:

If  $U_1(a) \geq U_{\sim 1}(a)$  then  $a$  belongs in  $C_1$ .

Else if  $U_1(a) \leq U_{\sim 1}(a)$  then  $a$  belongs in  $(C_2, C_3, \dots, C_q)$ .

The alternatives that are found to belong in class  $C_1$  (correctly or incorrectly) are excluded from further analysis. In the next step, another pair of utility functions  $U_2(a)$  and  $U_{\sim 2}(a)$  is developed to discriminate between the alternatives of group  $C_2$  and the alternatives of the groups  $C_3, \dots, C_q$ . Similarly to step 1, the alternatives that are found to belong in group  $C_2$  are excluded from further analysis. This pro-

cedure is repeated up to the last stage ( $q - 1$ ), when all groups have been considered. The estimation of the weights of the criteria in the utility functions as well as the marginal utility functions is accomplished through mathematical programming techniques. More specifically, at each stage of the hierarchical discrimination procedure, two linear programs and a mixed-integer one are solved to estimate the two additive utility functions optimally and to minimize the classification error. Further details of the mathematical programming formulations used in MHDIS can be found in Zopounidis and Doumpos [91].

### Empirical Results

Table 1 presents descriptive statistics which indicate the magnitude of the difference in the independent variables between the qualified and unqualified reports over the period 2001–2003. A comparison between the mean value of UTADISCR for the qualified and unqualified companies in the training sample shows that the former had a lower average value, which was statistically significant at the 1% level. Hence, many companies that had manipulated their financial statements were in financial distress [30,36,78]). Statistically significant differences at the 1% level were also found for two others variables, namely Inventories/Sales and Sales Annual Change, between the two groups in the training sample. Thus, companies with lower sales are more likely to receive a qualified report than other companies in Greece.

Furthermore, the variable Profits before tax/Total Assets (ROA) had lower means for the qualified companies, which was consistent with most of the previous studies, indicating that firms which receive qualified opinions made less profit [7,61,78,81,86]).

Table 2 illustrates the contribution of each of the financial and non-financial criteria in our auditing model. As our study involved two groups (unqualified and qualified) the hierarchical discrimination process of MHDIS consisted of only one stage, during which two additive utility functions were developed. The utility function  $U_1$  characterizes the unqualified companies whereas the utility function  $U_{\sim 1}$  characterizes those that were qualified.

ROA is indicated as one of the important criteria in most cases. Particularly in the case of unquali-

Average weights for the criteria in the 2 models

	MHDIS financial		MHDIS No financial	
	U1	U~1	U1	U~1
REC / SAL	2.28%	3.82%	0.02%	0.02%
CA / CL	7.17%	25.18%	3.99%	16.41%
CA / TA	21.49%	5.02%	15.04%	10.14%
CASH / TA	4.39%	11.23%	16.87%	1.11%
ROA	44.75%	25.71%	28.09%	11.57%
INV / SAL	12.54%	13.74%	10.55%	0.02%
SALCH	7.38%	15.30%	1.50%	3.94%
Profit or Loss in the year			0.00%	0.00%
Stock Exchange			0.00%	17.49%
Auditor			0.00%	0.00%
Prior 2 years Auditor			9.93%	0.00%
Litigation			0.00%	22.37%
UTADISCR			14.01%	16.94%

**Notes:** REC / SAL: Receivable / Sales, CA / CL: Current Assets / Current Liabilities, CA / TA: Current Assets / Total Assets, CASH / TA: Cash / Total Assets, ROA: Profit before Tax  $\times$  100 / Total Assets, INV / SAL: Inventories / Total Assets, SALCH: (Sales in year  $t$  – Sales in year  $t - 1$ )  $\times$  100 / Sales in year  $t - 1$

fied firms, it has a weight that is as high as 44.75% in the financial model and 28.09% in the non-financial one. Similar findings were observed in previous studies [7,61,71,78,81,86]).

The most important criteria that characterized the qualified firms in the case of the financial model are ROA and Current Assets/Current Liabilities (CA/CL) followed by Sales in year  $t$  – Sales in year  $t - 1$  (SALCH) with weights of 25.71, 25.18 and 15.30%, respectively. Pasiouras et al. [71] also found ROA to be statistically significant at the 1% level and one of the most important criteria for the models. In addition, Ireland [46] reported that companies with high liquidity (CA/CL) might increase the likelihood of a qualified audit opinion as assets may have been overstated.

From the non-financial criteria, litigation, STOCK, UTADISCR and CA/CL were the most important criteria with 22.37, 17.49, 16.94 and 16.41%, respectively, for qualified companies. A comparison with the results of previous studies showed that the results were similar. In particular, Spathis [80] found that litigation and financial distress were among the most important vari-

**Multicriteria Decision Support Methodologies for Auditing Decisions, Table 3**  
Classification results (accuracies in %) for the MHDIS and Logit models

	Unqualified	Qualified	Average
<b>Panel A: Financial Variables</b>			
<b>Training (2001-2003)</b>			
MHDIS	94.87	95.73	95.30
LA	95.7	95.7	95.7
<b>Holdout (2004)</b>			
MHDIS	80.49	87.80	84.15
LA	78.00	86.6	82.3
<b>Panel B: Non-financial Variables</b>			
<b>Training (2001-2003)</b>			
MHDIS	98.29	98.29	98.29
LA	97.43	95.73	96.58
<b>Holdout (2004)</b>			
MHDIS	84.15	91.46	87.81
LA	74.39	93.90	84.15

ables, and Spathis et al. [79] found CA/CL to be among the most important factors.

Table 3 presents the classification results obtained from the financial and non financial models. The classification ability of the models was tested further using the out-of-time and out-of-sample companies. The results indicated that the MHDIS models developed with the selected variables were able to provide a satisfactory distinction between qualified and unqualified statements.

The overall correct classifications at the training and holdout stages were 95.3 and 84.15%, respectively. The differences between the financial and the non-financial MHDIS models were significant. Overall, the non-financial MHDIS model provided higher overall classification accuracy in both the training (92.3%) and holdout samples (87.81%). This means that the inclusion of non-financial variables in the model yielded a more accurate distinction between qualified and unqualified companies than the inclusion of financial variables alone.

For benchmarking purposes, we developed additional models with logit analysis (LA). These models were developed with the same input variables. In the case of the financial model, the classification accuracy in the training sample was 78%, and the correspond-

ing figure for the holdout sample was 74.3%. In the case of the non-financial model, however, the classification accuracies were 82.3 and 84.15% in the training and holdout samples, respectively. It is therefore clear that MHDIS was more efficient than LA during both the training and holdout stages (for both financial and non-financial models).

MHDIS achieves more balanced results in terms of type I and type II errors in the holdout sample. Whereas Bell and Tabory [9] reported that type II errors are more costly than type I errors, Kida [49] argued that type I errors might result in: (a) a company changing its audit firm (switching), which means loss in audit firm revenue; (b) a lawsuit by a client against the accounting firm; (c) a negative effect on the auditor's reputation in the business community; (d) a deterioration in relations with the client; or (e) the so-called self-fulfilling prophecy – the qualification itself jeopardizes client survival, which in turn increases the probability of that consequence.

## Conclusions and Further Research

This study investigated the extent to which MHDIS models based on financial and non-financial variables could predict auditors' decisions to issue qualified opinions in the Greek market.

The sample consisted of 199 companies operating in the Greek manufacturing, trade and service sectors with FSF between 2001 and 2004, matched by industry and total assets with 199 non-FSF ones, yielding a total of 398 companies. We used out-of-time and out-of-sample testing samples to evaluate the classification ability of the model and ensure that they were not over-fitted to the training dataset. The sample was split into a training dataset of 234 companies using data from the period 2001–2003 and a validation dataset of 164 companies using data from the year 2004.
