### Keywords and Phrases

Convex underestimators;  $\alpha$ BB; Global optimization

### Introduction

In their effort to locate the global solution, deterministic global optimization algorithms, like the  $\alpha$ BB [1,2,6,14], employ a branch and bound framework. During this process, convex underestimation techniques are used to formulate relaxed convex problems that can be solved to optimality with the use of local solvers, thus providing valid lower bounds for the original problem. The tightness of the underestimators used is of fundamental

importance for the computational performance of these algorithms, since a tighter relaxation can lead to faster fathoming and less nodes of the branch and bound tree to be visited [7]. A recent review article on deterministic global optimization approaches can be found in [8].

In the case of arbitrary nonconvex functions that do not exhibit an exploitable mathematical structure, the  $\alpha$ BB general underestimator [3,6] can be used:

$$L(x) = f(x) - \sum_{v=1}^V \alpha_v (x_v - x_v^L)(x_v^U - x_v). \quad (1)$$

Originally introduced in [14], this underestimator derives from the function by subtracting a positive quadratic ( $\alpha_v \geq 0 \forall v$ ). Given sufficiently large values of the  $\alpha_v$  parameters, all nonconvexities in the original function  $f(x)$  can be overpowered, resulting into a convex underestimator  $L(x)$  that is valid for the entire domain  $[x^L, x^U]$ . A number of rigorous methods have been devised in order to select appropriate values for these parameters [2,3,13]. Extensive computational testing of the algorithm [1] showed that the most efficient of those methods is the one based on the scaled Gerschgorin theorem. According to this method, it suffices to select:

$$\alpha_v = \max \left\{ 0, -\frac{1}{2} \left( h_{vv} - \sum_{\substack{u=1 \\ u \neq v}}^V \max \{ |h_{vu}|, \overline{h_{vu}} \} \frac{(x_u^U - x_u^L)}{(x_v^U - x_v^L)} \right) \right\} \quad (2)$$

where  $\underline{h}_{vu}$  and  $\overline{h}_{vu}$  are lower and upper bounds of  $\partial^2 f / \partial x_v \partial x_u$  that can be calculated by interval analysis.

One could use alternatively a new class of general purpose convex underestimators that has been developed by Akrotirianakis and Floudas [4,5]. These underestimators are derived in a similar fashion, by subtracting an exponential term from the original function, that is:

$$L_1(x) = f(x) - \sum_{v=1}^V \left( 1 - e^{\gamma_v(x_v - x_v^L)} \right) \left( 1 - e^{\gamma_v(x_v^U - x_v)} \right). \quad (3)$$

An iterative systematic procedure is used to determine the values of the  $\gamma_v$  parameters so as the underestimating function to be convex. The procedure ensures

also that the resulting underestimator  $L_1(x)$  is tighter than  $L(x)$ , the one that results from the original method. Floudas and Kreinovich [9,10] have in fact shown that these two functional forms (original quadratic and exponential) are the only optimal ones, since they are the only ones to be shift-, sign- and scale-invariant.

Maranas and Floudas [14] showed that the maximum separation distance between the original function  $f(x)$  and the underestimator  $L(x)$  of (1) is a quadratic function of interval length. Because of this, as well as because of potentially less overestimation in the interval extension of the Hessian matrix elements  $h_{vu}$ , the underestimator would become tighter with shrinkage of the domain under consideration. This was firstly exploited in Meyer and Floudas [15], where a piecewise approach was utilized. The method proposed partitioning of the domain into many subdomains and construction of the corresponding  $\alpha$ BB underestimator for each one of them. These underestimators, although not valid for the entire domain, are much tighter in their respective subdomains. A hyperplane is subsequently added to each one of these underestimators and is selected in such a way, so that the combination of all these convex *pieces* results into an overall convex underestimator that is continuous and smooth ( $C^1$ -continuity).

This entry describes the work of [11,12] on the development of tight convex underestimators. The construction of these underestimators is based on a piecewise application of the  $\alpha$ BB underestimator, in a similar fashion with the p- $\alpha$ BB approach [15], but, instead of adding hyperplanes, we identify those supporting line segments that have to be combined with convex parts of the original underestimators so as to form a  $C^1$ -continuous convex underestimator that is valid for the overall domain under consideration. One can also consider only the lines defined by these linear segments, thus coming up with a piecewise linear underestimator that can easily be incorporated in the NLP relaxation as a set of linear constraints.

In their work, Gounaris and Floudas [12] also demonstrated how one can make use of the high quality results of the approach in the univariate case so as to extend its applicability to functions with a higher number of variables. This is achieved by proper projections of the multivariate  $\alpha$ BB underestimators into select two-dimensional planes. Furthermore, since the method utilizes projections into lower-dimensional spaces, they

explored ways to recover some of the information lost in this process. In particular, they apply the method after having transformed the original problem in an orthonormal fashion. This leads to the construction of even tighter underestimators, through the accumulation of additional valid linear cuts in the relaxation.

### Theoretical Results for Univariate Functions

Let  $f(x)$  be a univariate function that needs to be underestimated in  $D = [x^L, x^U]$ . We select an integer  $N > 1$  and partition the complete domain in  $N$  segments of equal length. Thus, the  $i$ -th subdomain would be defined as  $D_i = [x^{i-1}, x^i]$ , where:  $x^i = x^L + \frac{i}{N}(x^U - x^L)$ ,  $i = 0, 1, \dots, N$ .

For every subdomain  $D_i, i = 1, 2, \dots, N$ , we construct the corresponding  $\alpha$ BB underestimator:

$$P_i(x) = f(x) - \alpha^i (x - x^{i-1})(x^i - x) \\ \alpha^i = \max \left\{ 0, -\frac{1}{2} \underline{f''}_{(D_i)} \right\} \quad (4)$$

where  $\underline{f''}_{(D_i)}$  is a lower bound of the second derivative that is valid for the entire subdomain  $D_i$ .

Note that although an underestimator  $P_i(x)$  can be defined outside its respective subdomain, its convexity is only guaranteed for  $x \in [x^{i-1}, x^i]$ .

We define  $P(x), x \in [x^L, x^U]$  to be the following branched function:

$$P(x) = P_i(x), \text{ if } x^{i-1} \leq x \leq x^i. \quad (5)$$

Function  $P(x)$  is a *piecewise* convex valid underestimator of  $f(x)$ . Since it is not convex, a convexification technique has to be employed. The proposed technique involves the identification of those supporting line segments that are required for an overall underestimator  $U(x)$ . The technique is based on two algorithms, called “inner” and “outer”, which are described in detail in [11].

The underestimator  $U(x)$  consists of the identified linear parts, as well as convex parts of the underestimators  $P_i(x)$ , therefore it is a  $C^1$ -continuous branched function. This might pose some computational complications if the lower bounding (relaxation) problem is to be solved by local optimization solvers that require  $C^2$ -continuity. In order to avoid this problem, one can take into account only the lines defined by the line segments. According to this alternative, we first identify

the linear segments needed for the construction of underestimator  $U(x)$ , but we consider those as lines defined in  $[x^L, x^U]$ . Let there be  $K$  such lines denoted as  $T_k(x), k = 1, 2, \dots, K$  and arranged in order of ascending slope. If applicable, this set can be augmented with lines that are tangential to  $P_1$  and  $P_N$  at the respective domain edges  $x^L$  and  $x^U$ .

Each of these lines  $T_k$  is a valid underestimator of function  $f(x)$  across the whole domain. We define the function  $V(x)$  to be the pointwise maximum of all these lines.  $V(x)$  is convex, since it is the pointwise maximum of linear functions and it is obviously an underestimator, since it consists of pieces of other underestimators. At the expense of some tightness (in the regions where underestimator  $U(x)$  consisted of convex parts), we now have a piecewise linear underestimator  $V(x)$  that can be incorporated in the relaxation as a set of linear constraints. The whole lower bounding problem can now be formulated as a linear programming problem (LP).

### Tightness of Univariate Underestimator

It is apparent that as the level of partitioning increases, the underestimator  $P(x)$  comes closer to the function, and therefore convex underestimators  $U(x)$  and  $V(x)$  approach the convex envelope of  $f(x)$ . Gounaris and Floudas [11] proved the following two theorems that are relevant with the tightness of the resulting underestimators in the univariate case:

**Theorem 1.** *There is some finite partitioning level  $N$ , for which the convex underestimator  $U(x)$  is the convex envelope of function  $f(x)$ .*

**Theorem 2.** *There is some finite partitioning level  $N$ , for which underestimator  $V(x)$  is  $\epsilon$ -close to underestimator  $U(x)$ , that is:*

$$\max_{x \in D} \{U(x) - V(x)\} < \epsilon \quad (6)$$

where:  $\epsilon > 0$  is an arbitrarily small constant.

Since these univariate underestimators are very tight, the remaining question is whether we can exploit them so as to construct underestimators of functions in higher dimensions. Gounaris and Floudas [12] presented some extensions of the method for application on multivariate functions that involve dimension reduction of the problem through proper projections into

lower-dimensional spaces. These extensions are described in Sect. “**Extension to Multivariate Functions**”.

**Extension to Multivariate Functions**

Let  $f(x)$  be a function of  $V$  variables that needs to be underestimated in a box domain  $D = [x_1^L, x_1^U] \times \dots \times [x_V^L, x_V^U]$ . We choose integers  $N_\nu > 1, \nu = 1, 2, \dots, V$  and partition each range  $[x_\nu^L, x_\nu^U]$  in  $N_\nu$  segments of equal length. Thus, the  $j$ -th segment of the  $\nu$ th set would be defined as  $[x_\nu^{j-1}, x_\nu^j]$ , where:  $x_\nu^j = x_\nu^L + \frac{j}{N_\nu}(x_\nu^U - x_\nu^L), j = 0, 1, \dots, N_\nu$ . The complete  $V$ -dimensional domain  $D$  has now been partitioned into  $N = \prod_{\nu=1}^V N_\nu$  box subdomains of equal measures. Let  $D_i$  be such a  $V$ -dimensional subdomain. It is uniquely defined by a set of indices  $i_\nu, 1 \leq i_\nu \leq N_\nu, \forall \nu = 1, 2, \dots, V$ . Thus, the  $i$ th subdomain would be defined as  $D_i = [x_1^{i_1-1}, x_1^{i_1}] \times \dots \times [x_V^{i_V-1}, x_V^{i_V}]$ .

For every subdomain  $D_i, i = 1, 2, \dots, N$ , we construct the corresponding  $\alpha$ BB underestimator [1,2,3,6,14]:

$$P_i(x) = f(x) - \sum_{\nu=1}^V \alpha_\nu^i (x_\nu - x_\nu^{i_\nu-1})(x_\nu^{i_\nu} - x_\nu)$$

$$\alpha_\nu^i = \max \left\{ 0, -\frac{1}{2} \left( h_{\nu\nu}^{(i)} - \sum_{\substack{u=1 \\ u \neq \nu}}^V \max \left\{ |h_{\nu u}^{(i)}|, \frac{\overline{h_{\nu u}^{(i)}}}{|h_{\nu u}^{(i)}|} \left( \frac{x_u^{i_u} - x_u^{i_u-1}}{x_\nu^{i_\nu} - x_\nu^{i_\nu-1}} \right) \right\} \right) \right\} \quad (7)$$

where  $\underline{h_{\nu u}^{(i)}}$  and  $\overline{h_{\nu u}^{(i)}}$  are respectively lower and upper bounds of  $\partial^2 f / \partial x_\nu x_u$  that are valid for the entire subdomain  $D_i$ .

Note that although an underestimator  $P_i(x)$  can be defined outside its respective subdomain, its convexity is only guaranteed for  $x \in D_i$ .

We select variable  $w, 1 \leq w \leq V$ , which we designate to be the *active* variable, and enumerate all  $M_w = N/N_w$  permutations of indices  $i_\nu, \nu \neq w$ . Every such permutation  $m, 1 \leq m \leq M_w$ , corresponds to a subdomain  $D_{wm} = [x_w^L, x_w^U] \times \prod_{\substack{\nu=1 \\ \nu \neq w}}^V [x_\nu^{i_\nu-1}, x_\nu^{i_\nu}]$ , which can be further divided into  $N_w$  subdomains  $D_{wmj} = [x_w^{j-1}, x_w^j] \times \prod_{\substack{\nu=1 \\ \nu \neq w}}^V [x_\nu^{i_\nu-1}, x_\nu^{i_\nu}], j = 1, 2, \dots, N_w$ . These subdomains, belong to the set of the original subdomains  $D_i$  (for  $i_w = j$ ) and therefore each one has an underestimator  $P_{wmj}(x)$  associated with it,

that is:

$$P_{wmj}(x) = f(x) - \alpha_w^i (x_w - x_w^{j-1})(x_w^j - x_w) - \sum_{\substack{\nu=1 \\ \nu \neq w}}^V \alpha_\nu^i (x_\nu - x_\nu^{i_\nu-1})(x_\nu^{i_\nu} - x_\nu) \quad (8)$$

where index  $i$  satisfies  $D_i = D_{wmj}$  and parameters  $\alpha_\nu^i, \nu = 1, 2, \dots, V$  are calculated according to (7).

For every such subdomain  $D_{wmj}, j = 1, 2, \dots, N_w$ , we define the following univariate function:

$$G_{wmj}(x_w) = \min_{\substack{x_w \\ \forall \nu \neq w}} P_{wmj}(x), \quad x_w^{j-1} \leq x_w \leq x_w^j. \quad (9)$$

Since they correspond to the minimum of a convex function over a subset of its variables, these functions are convex. Furthermore, each one is defined over a different segment of  $[x_w^L, x_w^U]$ . Therefore, each one can be considered as a convex *piece* of an overall *piecewise* convex underestimator. The latter is fully suitable for application of the convex underestimation method for univariate functions which was described in the previous sections.

Let  $V_{wm}(x_w)$  be the piecewise linear underestimator obtained by the univariate method, and let it be the pointwise maximum of  $K_{wm}$  associated lines, that is:

$$V_{wm}(x_w) = \max \{ T_{wmk}(x_w), \forall k = 1, 2, \dots, K_{wm} \}, \quad x_w^L \leq x_w \leq x_w^U \quad (10)$$

Without loss of generality, let us assume that the lines  $T_{wmk}$  are arranged in order of ascending slope, that is,  $slope(T_{wm(k-1)}) < slope(T_{wmk}), k = 2, 3, \dots, K_{wm}$ , and that the set already includes the potential augmented tangents at the domain edges, designated earlier as  $T_0$  and  $T_{K+1}$ .

Univariate underestimator  $V_{wm}(x_w)$  could, in principle, be considered as a multivariate function that is dependent to only one variable,  $x_w$ , and defined over the whole multidimensional (dimension  $V$ ) subdomain  $D_{wm}$ . That is:

$$V_{wm}(x_w) \rightarrow V_{wm}(x), \quad x \in D_{wm} \quad (11)$$

Function  $V_{wm}(x)$  is piecewise affine and consists of segments of  $V$ -dimensional hyperplanes. Since these hyperplanes depend only on the  $w$ th variable, they are

parallel to all standard basis vectors  $e_v$  with the exception of  $e_w$  (to which they are parallel only if the slope of the corresponding line  $T_{wmk}$  is zero). This function is a valid underestimator for the original function  $f(x)$  across the whole subdomain  $D_{wm}$ .

Applying the aforementioned procedure for every permutation  $m = 1, 2, \dots, M_w$ , we come up with a collection of such underestimating segments, each of which is a valid underestimator for the function  $f(x)$  across a subset of its original domain  $D$ . In order to develop a convex underestimator that would be valid for the whole domain, we have to *combine* all these segments. Let  $m = 0$  denote the combination of all permutations  $m = 1, 2, \dots, M_w$ . This combination can be achieved back in the projection space, by computing the lower hull of the set of all underestimators  $V_{wm}(x_w)$ . In fact, one needs to consider only the vertex points of each underestimator  $V_{wm}(x_k)$  (that is the points of intersection between two lines  $T_{wm(k-1)}$  and  $T_{wmk}$ ), as well as their end points  $(x_w^L, T_{wm1}(x_w^L))$  and  $(x_w^U, T_{wm(K_{wm})}(x_w^U))$ . Any standard 2d convex hull algorithm (e. g., *Graham-Scan*) can be used for this purpose. The lower hull is a convex piecewise linear function  $V_{w0}(x_w)$ , and it is the pointwise maximum of  $K_{w0}$  lines, that is:

$$V_{w0}(x_w) = \max \{ T_{w0k}(x_w), \forall k = 1, 2, \dots, K_{w0} \}, \quad (12)$$

$$x_w^L \leq x_w \leq x_w^U .$$

By construction, this function is a convex underestimator of all pieces  $G_{w mj}(x_w)$  for all permutations, that is:

$$V_{w0}(x_w) \leq G_{w mj}(x_w), x_w \in [x_w^{j-1}, x_w^j],$$

$$\forall j = 1, 2, \dots, N_w, \forall m = 1, 2, \dots, M_w . \quad (13)$$

Therefore, function  $V_{w0}(x_w)$ , if considered as  $V_{w0}(x)$ , is a valid underestimator for function  $f(x)$  across its whole original domain  $D$ .

For any selection of the active variable  $w$ , the method will yield a convex (piecewise affine) underestimator which would be valid for the whole domain of interest,  $D$ . However, the method can be independently applied for every variable being active (one at a time),

leading to a collection of valid underestimators. The pointwise maximum of all these is itself a valid convex underestimator, and is tighter (or equally tight) to the original function than any of its predecessors. Thus, the resulting underestimator is:

$$V(x) = \max \{ V_{w0}(x), \forall w = 1, 2, \dots, V \}, x \in D . \quad (14)$$

Note that the underestimator  $V(x)$  is also piecewise hyperplanar, and can be represented in the problem relaxation as a set of linear constraints. Since we do not know explicitly which hyperplanes  $T_{w0k}(x_w) \rightarrow T_{w0k}(x), k = 1, 2, \dots, K_{w0}, w = 1, 2, \dots, V$  contribute some part of theirs to the overall underestimator  $V(x)$ , all of them should be included in this relaxation, despite the fact that some may end up being redundant.

Since our method produces piecewise affine underestimators  $L \equiv V$ , the resulting convex relaxation is just a linear programming problem (LP), which takes the form of (15).

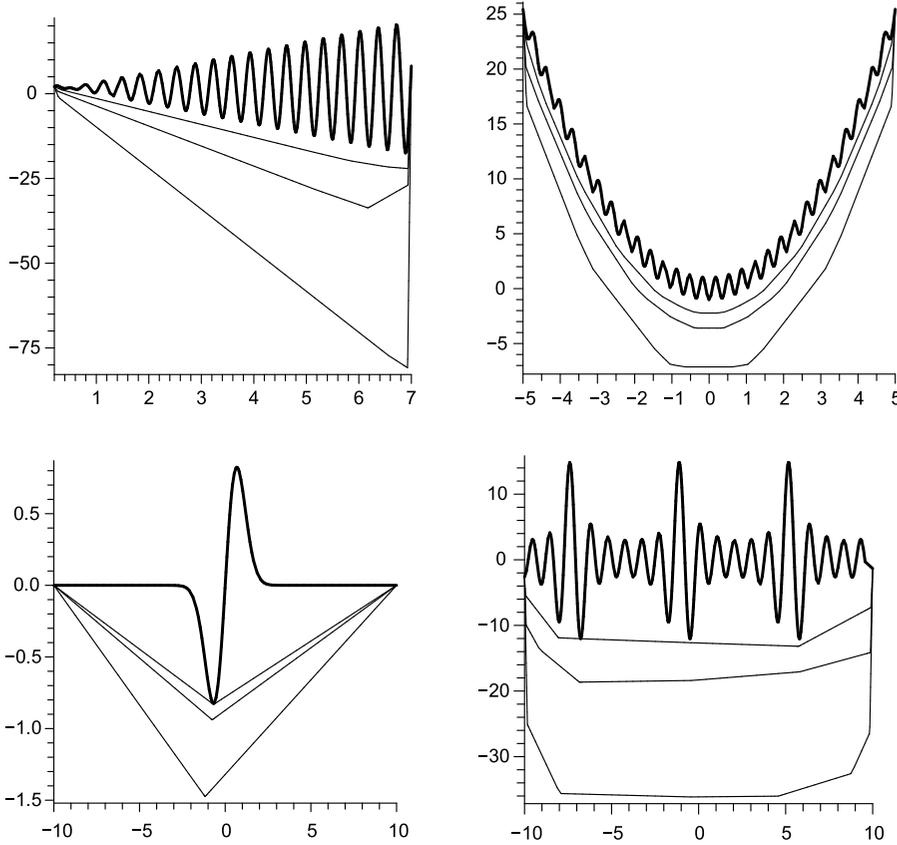

$$\min_{\mu, x} \mu$$

$$s.t. \quad \mu \geq T_{w0k}^{(0)}(x_w) \left\{ \begin{array}{l} \forall k = 1, 2, \dots, K_{w0}^{(0)} \\ \forall w = 1, 2, \dots, V \end{array} \right\} \quad (15)$$

$$T_{w0k}^{(q)}(x_w) \leq 0 \left\{ \begin{array}{l} \forall k = 1, 2, \dots, K_{w0}^{(q)} \\ \forall w = 1, 2, \dots, V \\ \forall q = 1, 2, \dots, Q \end{array} \right\}$$

### Domain Rotation

The methodology presented in Section 4 involves the minimization of underestimators  $P_{w mj}(x)$ , over all their variables with the exception of one, variable  $x_w$ , which is designated as “active”. Whenever such a projection into spaces of lower dimensionality is involved, there is the possibility that some useful information is lost. Some of this lost information will be recovered if we opt to apply the methodology for every variable being “active”, one at a time, which basically calls for projecting into  $V$  different two-dimensional planes, each one being parallel to a different basis vector  $e_v, v = 1, 2, \dots, V$ . However, since there is a finite number of variables in our problem, there is a limited number of planes to which we can project. If we want to enhance further the col-

**Global Optimization: Tight Convex Underestimators, Figure 1**  
 Univariate functions  $f_{1-4}$  with underestimators  $V(x)$  for three different partitioning levels ( $N = 24, 36$  and  $48$ )

lection of underestimators that we will eventually accumulate in the relaxation (thus improve our chances for better tightness/lower bound), we will have to project into additional planes, that do not correspond to some variable that is “natural” to the problem, rather than to some linear combination of theirs.

This can be achieved by applying an orthonormal transformation to the problem’s variable space, that is:

$$x \rightarrow x' = R \cdot x . \tag{16}$$

This transformation has to be orthogonal, which means that it should preserve the lengths of vectors and the angles between vectors. Furthermore, it should be an orientation-preserving transformation. A  $V \times V$  matrix  $R$  that could provide such a transformation is called a *rotation matrix* and has to be a member of the

special orthogonal group, that is:

$$R \in SO(V) \Leftrightarrow \begin{cases} R^{-1} = R^T \\ |R| = +1 . \end{cases} \tag{17}$$

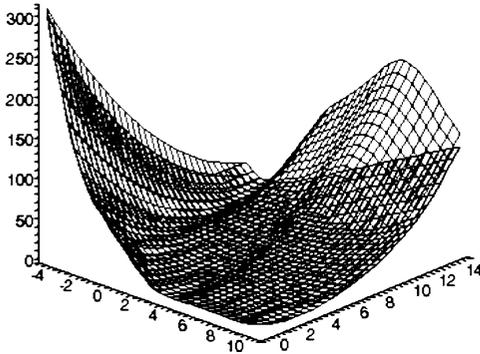

In their work, Gounaris and Floudas [12] discuss the selection of a suitable such matrix. They rigorously address the issue of selecting a suitable “rotated” domain and some suitable level of partitioning, and they also present a method to calculate appropriate values for the  $\alpha$  parameters in the transformed counterpart of the problem.

**Examples**

Figure 1 depicts the plots for four nonlinear univariate functions. In particular, for functions:  $f_1(x) = (3x - 1.4)\sin(18x) + 1.7$ ,  $f_2(x) = x^2 - \cos(18x)$ ,  $f_3(x) = (x + \sin x)e^{-x}$  and  $f_4(x) = -\sum_{k=1}^5 k\sin[(k + 1)x + k]$ .

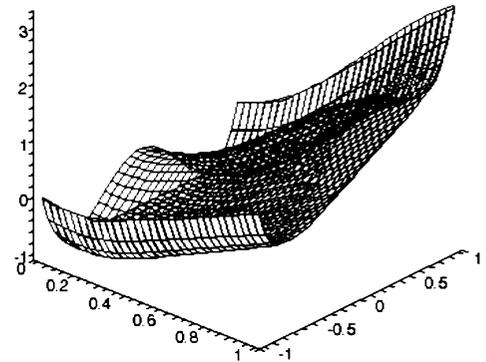

$$f(x_1, x_2) = \left( x_2 - \frac{5.1x_1^2}{4\pi^2} + \frac{5x_1}{\pi} - 6 \right)^2 + 10 \left( 1 - \frac{1}{8\pi} \right) \cos x_1 + 10$$

$$f(x_1, x_2) = 4x_1^2 - 2.1x_1^4 + \frac{x_1^6}{3} + x_1x_2 - 4x_2^2 + 4x_2^4$$

$N = (32 \times 32) \quad \Delta\phi = \pi / 8$

**Total Linear Cuts = 162**  
**Global minimum = 0.398**  
**Lower Bound = 0.316**  
 **$\alpha$ BB Lower Bound = - 884**

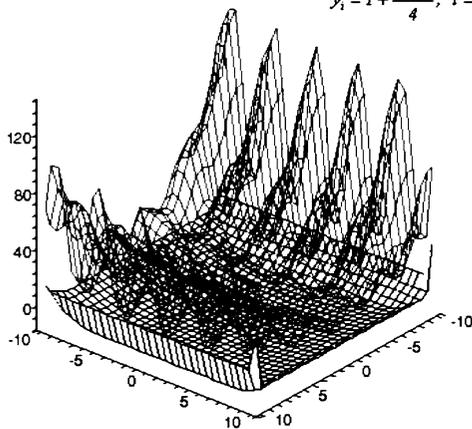

$N = (32 \times 32) \quad \Delta\phi = \pi / 16$

**Total Linear Cuts = 309**  
**Global minimum = -1.03163**  
**Lower Bound = -1.03164**  
 **$\alpha$ BB Lower Bound = - 6.04**

$$f(x_1, x_2) = \frac{\pi}{2} \left\{ 10 \sin^2(\gamma_1) + (y_1 - 1)^2 \left[ 1 + 10 \sin^2(\gamma_2) \right] + (y_2 - 1)^2 \right\}$$

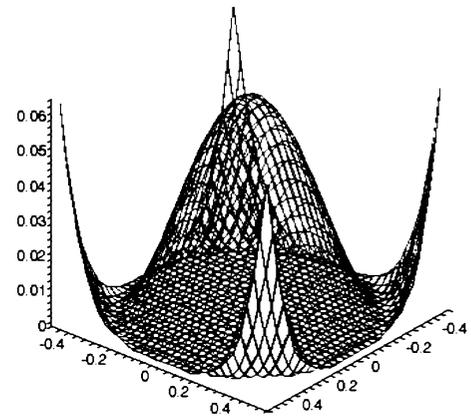

$$y_i = 1 + \frac{x_i - 1}{4}, \quad i = 1, 2$$

$$f(x_1, x_2) = 1\sigma^5(x_1 - 1)^2 + 1\sigma^5(x_2 - 1)^2 + \left( x_1^2 - x_2^2 - \frac{1}{4} \right)^2$$

$N = (8 \times 24) \quad \Delta\phi = \pi / 8$

**Total Linear Cuts = 49**  
**Global minimum = 0**  
**Lower Bound = - 14**  
 **$\alpha$ BB Lower Bound = - 8441**

$N = (32 \times 32) \quad \Delta\phi = \pi / 8$

**Total Linear Cuts = 191**  
**Global minimum =  $3 \times 10^6$**   
**Lower Bound =  $-7 \times 10^6$**   
 **$\alpha$ BB Lower Bound = - 0.69**

Global Optimization: Tight Convex Underestimators, Figure 2  
 Piecewise planar underestimators of bivariate functions

The underestimators presented correspond to partitioning in  $N = 24, 36$  and  $48$  subdomains (increasing tightness).

Figure 2 depicts plots for four nonlinear bivariate functions. For each case,  $N_1 \times N_2$  is the level of partitioning used and  $\Delta\phi$  is the resolution of domain

rotation. Some additional information regarding the improvement of lower bound, as well as the number of linear cuts that have to be accumulated in the relaxation, is also included.

A large number of decision problems in the world of applications may be formulated as searching for a *constrained global optimum* (minimum, for certainty)

$$\begin{aligned}\varphi^* &= \varphi(y^*) \\ &= \min \{ \varphi(y) : y \in D, g_i(y) \leq 0, 1 \leq i \leq m \},\end{aligned}$$

where the *domain of search* (DS)

$$D = \{ y \in \mathbf{R}^N : -2^{-1} \leq y_j \leq 2^{-1}, 1 \leq j \leq N \},$$

$\mathbf{R}^N$  is the  $N$ -dimensional Euclidian space and the *objective function*  $\varphi(y)$  (henceforth denoted  $g_{m+1}(y)$ ) and the left-hand sides  $g_i(y)$ ,  $1 \leq i \leq m$ , of the *constraints* are *Lipschitzian* (with respective constants  $L_i$ ,  $1 \leq i \leq m + 1$ ) and may be multi-extremal.

If DS is set defined by the hyperparallelepiped

$$S = \{ w \in \mathbf{R}^N : a_j \leq w_j \leq b_j, 1 \leq j \leq N \},$$

then, by introducing the transformation

$$y_j = \frac{w_j - (a_j + b_j)/2}{\rho},$$

$$\rho = \max \{b_j - a_j : 1 \leq j \leq N\},$$

and the extra constraint

$$g_0(y) = \max \left\{ \left| y_j - \frac{b_j - a_j}{2\rho} \right| : 1 \leq j \leq N \right\} \leq 0,$$

it is possible to keep up the initial presentation  $D$  for DS (which is assumed to be the standard one) not altering the relations of Lipschitzian properties in dimensions.

The assumption of the divided functions  $g_i$ ,  $0 \leq i \leq m + 1$ , differences being bounded by the respective constants  $L_i$  (Lipschitzian property), which may be interpreted as a mathematical description of a limited power of change in real systems, provides a basis for estimating  $\varphi^*$  and  $y^*$ ; by exploring DS with finite number of trials depending on the desired accuracy of search. This Lipschitzian approach ([2,5,9,20]) requires, in general, substantially less trials than the plain *uniform grid technique* owing to the thorough selection of each subsequent trial with the account of all the previously computed functions' values.

Such a selection turns into solving some auxiliary multidimensional optimization problem (MOP) of increasing multi-extremality (along with the accumulation of trial outcomes) at each step of the search process. But the case  $N = 1$  is effectively solvable and, therefore, it is of interest to present MOP by its one-dimensional equivalent.

A possible way to do so ([1,7,11,12,14,15,18]) is to employ single-valued *Peano curves*  $y(x)$  continuously mapping the unit interval  $[0, 1]$  on the  $x$ -axis onto the hypercube  $D$  and, thus, yielding the equality

$$\varphi^* = \varphi(x^*)$$

$$= \min \left\{ \varphi(y(x)) : \begin{array}{l} x \in [0, 1], \\ g_i(y(x)) \leq 0, 0 \leq i \leq m \end{array} \right\}. \quad (1)$$

These curves, first introduced in [4,8], are 'filling' the cube, i. e. they pass through every point of  $D$ , and this gave rise to the term *space filling curves* (SFC); see survey [10].

The construction of SFC can be explained by following the scheme from [4]. Divide  $D$  into  $2^N$  equal hypercubes of 'first-partition' by cutting  $D$  with the set of

$N$  mutually orthogonal hyperplanes (each plain is parallel to one of the coordinate ones and passes through the middle points of  $D$  edges orthogonal to this hyperplane). Then divide (in the above manner) each of the obtained first-partition cubes into  $2^N$  second-partition cubes. Continuing this process, i. e. consequently cutting each cube of a current partition into  $2^N$  cubes of the subsequent partition, yields hypercubes of any  $M$ th partition with the edge-length equal  $2^{-M}$ . The total number of cubes in the  $M$ th partition is equal  $2^{MN}$ .

Next, cut the interval  $[0, 1]$  into  $2^N$  equal parts. Then, once again, cut each of these parts into  $2^N$  smaller (equal) parts, etc. Designate  $d(M, \nu)$  the subinterval of  $M$ th partition, where  $\nu$  is the coordinate of the left endpoint of this interval. The length of  $d(M, \nu)$  is equal  $2^{-MN}$ . Assume that  $\nu \in d(M, \nu)$ , but the right endpoint of this subinterval (if it is not equal 1) does not belong to it.

Establish a mutually single-valued correspondence between all subintervals of any particular  $M$ th partition and all subcubes of  $M$ th partition. Henceforth, the notation  $D(M, \nu)$  will stay for the subcube corresponding to the subinterval  $d(M, \nu)$  and vice versa. Assume this correspondence to satisfy the following conditions:

- $D(M + 1, \nu') \subset D(M, \nu'')$  if and only if  $d(M + 1, \nu') \subset d(M, \nu'')$ .
- $d(M, \nu')$  and  $d(M, \nu'')$  have a common endpoint (which is either  $\nu'$  or  $\nu''$ ) if and only if  $D(M, \nu')$  and  $D(M, \nu'')$  have a common face (i. e. these subcubes are contiguous).

Now, a single-valued continuous map  $y(x)$  is set by introducing the third requirement

- If  $x \in d(M, \nu)$ , then  $y(x) \in D(M, \nu)$ , for  $M \geq 1$ .

Note that for any integer  $M \geq 1$  and any given  $x \in [0, 1]$  there is just one subinterval meeting the condition  $x \in d(M, \nu)$ ; the continuity is the consequence of the first two conditions.

### Approximation of SFC

The center  $y^c(x)$  of the subcube  $D(M, \nu)$  containing  $y(x)$  may be interpreted as an approximation to  $y(x)$ ; the inequalities

$$\max \left\{ \left| y_j^c(x) - y_j(x) \right| : 1 \leq j \leq N \right\} \leq 2^{-(M+1)},$$

$$x \in [0, 1],$$

reflect the accuracy attainable for any particular preset value of  $M$ .

A constructive way to establishing the above correspondence is described and substantiated in [3,12,15,19] and, in short, can be presented as follows. Introduce the auxiliary hypercube

$$\Delta = \{y \in \mathbf{R}^N: -0.5 \leq y_i \leq 1.5, 1 \leq i \leq N\}$$

and designate  $\Delta(s), 0 \leq s \leq 2^N - 1$ , the subcubes of the first partition of  $\Delta$ . The centers of  $\Delta(s)$  (to be referred as  $u(s)$ ) are  $N$ -dimensional binary vectors defined by the relations

$$\begin{aligned} u_i(s) &= (\beta_i + \beta_{i-1}) \pmod 2, \\ 1 \leq i < N, \quad u_N &= \beta_{N-1}, \end{aligned} \tag{2}$$

where  $\beta_i, 0 \leq i < N$ , are digits in binary presentation of  $s$ :

$$s = \beta_{N-1}2^{N-1} + \dots + \beta_02^0. \tag{3}$$

Owing to this numeration, any two centers  $u(s)$  and  $u(s + 1), 0 \leq s < 2^N - 1$ , have just one different coordinate, which means that the corresponding subcubes  $\Delta(s)$  and  $\Delta(s + 1)$  are contiguous.

Next, let the binary form of  $v$  in  $d(M, v)$  be

$$0 \leq v = \sum_{i=1}^{MN} \alpha_i 2^{-i} < 1.$$

Then the identity  $d(M, v) = d(z_1, \dots, z_M)$ , where

$$z_j = \sum_{i=1}^N \alpha_{(j-1)N+i} 2^i, \quad 1 \leq j \leq M, \tag{4}$$

provides the possibility to interpret  $d(z_1, \dots, z_M)$ , as the  $z_M$ th subinterval of the interval  $d(z_1, \dots, z_{M-1})$  divided into  $2^N$  equal parts (the numeration streams from left to right along the  $x$ -axis). Note that the above identity implies  $D(M, v) = D(z_1, \dots, z_M)$ .

Now, mapping  $\Delta$  onto  $D$  by the linear transformation and assuming that  $D(z_1) = D(s)$  if  $D(s)$  is the image of  $\Delta(s)$ , we obtain the numeration (in the first partition of  $D$ ) satisfying the above conditions. Then by mapping  $\Delta$  onto each subcube  $D(z_1)$  of the first partition, we get the desired numeration in the second partition of  $D$ , where  $D(z_1, z_2) = D(z_1, s)$  if  $D(z_1, s)$  is the image of  $\Delta(s)$ , and so on. To ensure that  $D(z_1, 2^N - 1)$  and  $D(z_1 + 1, 0)$

would also have a common face (and, in general, the last subcube in the first partition of  $D(z_1, \dots, z_M)$  and the first subcube in the first partition of  $D(z_1, \dots, z_M + 1)$  would also be contiguous) we add some mechanism in the above numeration procedure to provide the necessary juxtapositioning.

Introduce the integer  $l = l(z_1, \dots, z_M)$  indicating the number of the only coordinate which has to be different for the center of the initial subcube  $D(z_1, \dots, z_M, 0)$  and the last subcube  $D(z_1, \dots, z_M, 2^N - 1)$  of the next partition of  $D(z_1, \dots, z_M)$  and the binary vector  $w = w(z_1, \dots, z_M)$  indicating the position of the center of the subcube  $D(z_1, \dots, z_M, 0)$ . To do so we employ the integer function

$$l(s) = \begin{cases} 1 & \text{if } s = 0 \text{ or } s = 2^N - 1, \\ \min \left\{ j: 2 \leq j \leq N, \beta_{j-1} = 1 \right\} & \text{otherwise,} \end{cases} \tag{5}$$

where  $\beta_{j-1}$  is from (3), and the binary vector-function

$$w_i(s + 1) = w_i(s) = \begin{cases} \bar{u}_i(s), & i = 1, \\ u_i(s), & 2 \leq i \leq N, \end{cases} \tag{6}$$

where  $s$  is supposed to be the odd number,  $\bar{u}_i$  stays for logical negation of  $u_i$ , and  $w(0) = u(0)$ . The amended procedure for successive numeration in subsequent partitions includes the operations:

- permutation of  $u_N$  and  $u_t$  in  $u(z_j)$  from (2) and of  $w_N$  and  $w_t$  in  $w(z_j)$  from (6) with  $t = l(z_{j-1})$ , where  $z_{j-1}$  is from (4),  $1 < j \leq M$ , and  $l(z_{j-1})$  is from (5);  $t = N$  if  $j = 1$ . New vectors are to be referred as  $u^t(z_j)$  and  $w^t(z_j)$ ;
- addition

$$\begin{aligned} u_i^{tq}(z_j) &= (u_i^t(z_j) + q_i) \pmod 2, \quad 1 \leq i \leq N, \\ w_i^{tq}(z_j) &= (w_i^t(z_j) + q_i) \pmod 2, \quad 1 \leq i \leq N, \end{aligned}$$

where  $q = w(z_{j-1}), 1 < j \leq M$ , and  $q = (0, \dots, 0) \in \mathbf{R}^N$  if  $j = 1$ ;

- transformation

$$l^t(z_j) = \begin{cases} N, & l(z_j) = t, \\ t, & l(z_j) = N, \\ l(z_j), & l(z_j) \neq N \text{ and } l(z_j) \neq t, \end{cases}$$

where  $t$  is from the above permutation.

The successively computed values  $u^{tq}(z_j)$ ,  $w^{tq}(z_j)$ ,  $l^t(z_j)$  are used instead of the initial values  $u(z_j)$ ,  $w(z_j)$ ,  $l(z_j)$ ,  $1 \leq j \leq M$ , to obtain the approximation

$$y^c(x) = \sum_{j=1}^M (u^{tq}(z_j) - p)2^{-j}, \quad x \in d(M, v),$$

with  $p = (2^{-1}, \dots, 2^{-1}) \in \mathbf{R}^N$ .

The important property of reducing dimensionality through SFC is that functions  $g_i(y(x))$ ,  $0 \leq i \leq m + 1$ , from (1) corresponding to Lipschitzian functions from the initial MOP satisfy the *uniform Hölder conditions* ([7,11,15,19])

$$|g_i(y(x')) - g_i(y(x''))| \leq K_i(|x' - x''|)^{\frac{1}{N}},$$

$$x', x'' \in [0, 1],$$

with respective coefficients  $K_i = 4L_i\sqrt{N}$ ,  $0 \leq i \leq m + 1$ .

Problem (1) can further be reduced to an unconstrained case by employing the *index approach* (IA) ([7,13,17,18]) which makes no use of *penalties* and, thus, does not require any adjustments of penalty coefficients. Within IA functions  $g_i(y(x))$  from (1) may not be defined throughout  $[0, 1]$ ; they have to be computable only at the points  $x \in [0, 1]$  meeting the conditions  $g_k(y(x)) \leq 0$ ,  $1 \leq k < i$  (this property is to be referred as *partial computability* of problem functionals). Therefore, within IA the *outcome* of each trial is given by a dyad

$$f(x) = g_v(y(x)), \quad v = v(x) = v(y(x)), \quad (7)$$

where  $v$  is the number of the first constraint violated at the point  $x$ ; this number is to be referred as the *index* of the corresponding point.

The unconstrained equivalent of (1) is

$$\psi(x^*) = \min \{ \psi(x) : x \in [0, 1] \},$$

where

$$\psi(x) = \frac{g_v(y(x))}{K_v}$$

$$- \begin{cases} 0, & v = v(x) \leq m, \\ \frac{\varphi^*}{K_v}, & v = v(x) = m + 1, \end{cases}$$

and  $x^*$  is a solution to (1). The algorithm presented below solves (1) by minimizing  $\psi(x)$ . It substitutes the unknown values  $\varphi^*$  and  $K_i$ ,  $0 \leq i \leq m+1$ , by their running estimates; it also surmounts the discontinuity inherent to  $\psi(x)$ .

### Algorithm

The first trial is to be executed at an arbitrary interior point  $x^1 \in (0, 1)$ . The choice of any subsequent point  $x^{k+1}$ ,  $k \geq 1$ , is due to the rules:

- 1) Renumber the points  $x^1, \dots, x^k$  of the previous trials by subscripts in the increasing order of the coordinate, i. e.

$$0 = x_0 < \dots < x_k < x_{k+1} = 1,$$

and associate them with the computed values  $z_i = f(x_i)$ ,  $1 \leq i \leq k$ , from (7); values  $z_0$  and  $z_{k+1}$  are undefined.

- 2) Collect in the sets

$$I_v = \{i : 1 \leq i \leq k, v = v(x_i)\},$$

$$0 \leq v \leq m + 1,$$

all subscripts corresponding to the points with equal indices; it is assumed that  $v(x_0) = v(x_{k+1}) = -1$  and  $I_{-1} = \{0, k + 1\}$ .

- 3) Construct the unions

$$S_v = I_{-1} \cup \dots \cup I_{v-1}, \quad 0 \leq v \leq m + 1,$$

and

$$T_v = I_{v+1} \cup \dots \cup I_{m+1} \cup I_{m+2},$$

$$0 \leq v \leq m + 1,$$

of subscripts corresponding to the trial points with the indices less than  $v$  and exceeding  $v$  respectively;  $I_{m+2} = \emptyset$  by the definition.

- 4) Compute the running lower bounds

$$\mu_v = \max \left\{ \begin{array}{l} |z_j - z_i| \\ (x_j - x_i)^{\frac{1}{N}} \end{array} : \begin{array}{l} i, j \in I_v, \\ i < j \end{array} \right\} \quad (8)$$

for respective Hölder coefficients of the functions  $g_v(y(x))$ ,  $0 \leq v \leq m + 1$ . If  $I_v$  contains less than two elements or if  $\mu_v$  from (8) is equal zero, assume that  $\mu_v = 1$ .

- 5) Find the values

$$z_v^* = \begin{cases} -\varepsilon_v, & T_v \neq \emptyset, \\ \min \{z_i : i \in I_v\}, & T_v = \emptyset, \end{cases}$$

for all nonempty sets  $I_v$ ,  $0 \leq v \leq m + 1$ ; vector  $\varepsilon = (\varepsilon_0, \dots, \varepsilon_m)$  is the input of the algorithm.

6) Compute characteristics  $R(i), 1 \leq i \leq k + 1$ , where

$$R(i) = \Delta_i + \frac{(z_i - z_{i-1})^2}{r^2 \mu_v^2 \Delta_i} - \frac{2(z_i + z_{i-1} - 2z_v^*)}{r \mu_v},$$

$$i - 1, \quad i \in I_v,$$

$$R(i) = 2\Delta_i - \frac{4(z_i - z_v^*)}{r \mu_v},$$

$$i \in I_v, \quad i - 1 \in S_v,$$

$$R(i) = 2\Delta_i - \frac{4(z_{i-1} - z_v^*)}{r \mu_v},$$

$$i - 1 \in I_v, \quad i \in S_v,$$

$$\Delta_i = (x_i - x_{i-1})^{\frac{1}{N}}.$$

Proper choice of the parameter  $r > 1$  allows to use the product  $r\mu_v$  as an upper bound for  $K_v$ .

7) Select integer  $t$  from

$$R(t) = \max \{R(i): 1 \leq i \leq k + 1\}$$

and execute the subsequent trial at the point

$$x^{k+1} = \frac{x_t + x_{t-1}}{2} - \text{sign}(z_t - z_{t-1}) \left[ \frac{|z_t - z_{t-1}|}{\mu_v} \right]^N \cdot \frac{1}{2r}$$

if  $v(x_t) = v(x_{t-1})$ ; otherwise, i. e. if  $v(x_{t-1}) \neq v(x_t)$ , the second term is omitted.

The concept of  $\varepsilon$ -reserved solution  $y_\varepsilon$ , where

$$\varphi(y_\varepsilon) = \min \left\{ \varphi(y): \begin{array}{l} y \in D, \\ g_i(y) \leq -\varepsilon_i, \\ 0 \leq i \leq m \end{array} \right\}$$

and  $\varepsilon_i > 0, 0 \leq i \leq m$ , provides interpretation for  $\varepsilon$  from Step 5). The sequence of points  $\{x^k\}$  selected by the Steps 1)–7) in the interval  $[0, 1]$  generates the corresponding sequence  $\{y^k\} = \{y(x^k)\}$  in  $D$ .

### Convergence Conditions

([15,16,17] [18]). Assume that the following is true:

- the problem (1) has an  $\varepsilon$ -reserved solution;
- functions  $g_i(y), 0 \leq i \leq m + 1$ , admit Lipschitzian continuations throughout  $D$ ;
- from some Step onwards, the values  $\mu_v, 0 \leq v \leq m + 1$ , from (8) satisfy the inequalities

$$r\mu_v > 16L_v \sqrt{N}, \quad 0 \leq v \leq m + 1.$$

Then any limit point  $\bar{y}$  of the sequence  $\{y^k\}$  generated by the above algorithm satisfies the conditions:

$$\varphi(\bar{y}) = \inf \left\{ \varphi(y^k): \begin{array}{l} k \in N_1, \\ g_i(y^k) \leq 0, \\ 0 \leq i \leq m \end{array} \right\} \leq \varphi(y_\varepsilon),$$

where  $N_1$  is the set of positive integers.

As long as in applications SFC  $y(x)$  is to be approximated by  $y^c(x)$  corresponding to some  $M$ th partition, it is important to notice that the substantiation of the above convergence conditions implies the relation

$$2^{-M} \ll \frac{1}{\sqrt{N}} \min_{0 \leq v \leq m} \left( \frac{\varepsilon_v}{L_v} \right),$$

which means that the existence of an  $\varepsilon$ -reserved solution may be interpreted as some kind of the *regularity conditions* (cf. [6]).

Dimensionality reduction through SFC causes some loss of the information on the closeness of trial points in the initial multidimensional space. Two close points in  $D$  may have substantially nonclose pre-images in  $[0, 1]$ . To overcome this obstacle, it is possible either to store all pre-images of each trial point (close points in  $D$  always have some close pre-images; see [12]) or to use some sets of shifted SFC to provide the better transfer of metric information (see [17]).

GOSF based on the reduction to one dimension by using SFC and on the reduction to unconstrained problems by employing IA admits effective parallelization (see [16,19]).

### Keywords

Weber problem; Facility location; Global optimization

Weber's problem and all its variations with positive weights is clearly one of the most extensively studied problems in the area of continuous location theory. It frequently arises in planning situations where a single central facility must be located so as to minimize the total cost associated with serving a number of demand centers. In all these cases, the underlying assumption, that the associated service costs are directly proportional to the Euclidean distance of the demand center from the central facility, has been adopted.

*Weber's problem with attraction and repulsion* can be stated as follows: Given a number of 'attractive' or 'repulsive' points located on a 2D-plane, find the position of a single facility inside an arbitrary region  $P$  such that the sum of the weighted distances of all points from the single facility is at its global minimum.

This problem can be formulated as the following nonlinear optimization problem:

$$\min_{(x,y) \in P} \sum_{i \in I^+} w_i \sqrt{(x - x_i)^2 + (y - y_i)^2} - \sum_{i \in I^-} w_i \sqrt{(x - x_i)^2 + (y - y_i)^2},$$

where  $I^+$ ,  $I^-$  are the sets of attractive (users) and repulsive (residents) points, respectively;  $w_i$ ,  $i \in I^+$  the positive weight of the  $i$ th attractive point and  $-w_i$ ,  $i \in I^-$  the negative weight of the  $i$ th repulsive point;  $(x_i, y_i)$  are the coordinates of the  $i$ th attractive or repulsive point;

and  $P$  is the region where where the single facility must be situated.

The unconstrained version of this problem has been shown to involve a number of important properties. The first property provides a sufficient condition for having finite solutions or solutions at infinity. Z. Drezner and G.O. Wesolowsky [6] by using the well-known triangle inequality relation proved the following:

*Property 1* For the unconstrained problem, if  $W > 0$  then the global optimum location is finite; if  $W < 0$  then the global optimum location is at infinity, where

$$W = \sum_{i \in I^+} w_i - \sum_{i \in I^-} w_i.$$

The second property deals with the localization of all local minimum solutions. Let  $R$  be the radius of the smallest circle enclosing all points. The square of this radius  $R$  can be obtained through the solution of the following nonlinear optimization problem:

$$\begin{cases} \min_{x^c, y^c, R^2} & R^2 \\ \text{s.t.} & (x^c - x_i)^2 + (y^c - y_i)^2 \leq R^2, \\ & \forall i \in I^+ \cup I^-, \end{cases}$$

which is convex in the combined space of the coordinates of the center of the circle  $(x^c, y^c)$  and the square of the radius of the circle  $R^2$  enclosing all points. Drezner and Wesolowsky [6] proved the following localization property, which generalizes the *majority theorem* [24] for Weber’s problem.

*Property 2* For the unconstrained problem, all local minima and therefore the global minimum are inside a disc with a radius equal to

$$\rho = \frac{R}{\sqrt{1 - \alpha^2}}$$

where

$$\alpha = \frac{W^-}{W^+}, \quad W^+ = \sum_{i \in I^+} w_i, \quad W^- = \sum_{i \in I^-} w_i.$$

Note that the boundary of this disc is attainable.

The case  $\alpha = 1$  or, equivalently,  $W = 0$  is accounted for by finding the optimal solution at infinity and comparing it with the best finite solution. Drezner and Wesolowsky [6] by using asymptotic analysis showed the following:

*Property 3* For the unconstrained problem, if  $W = 0$  the best solution at infinity is  $-(A^2 + B^2)^{1/2}$  where:

$$A = \sum_{i \in I^+} w_i x_i - \sum_{i \in I^-} w_i x_i, \\ B = \sum_{i \in I^+} w_i y_i - \sum_{i \in I^-} w_i y_i.$$

The following property examines whether a demand point corresponds to a local minimum [6].

*Property 4* For the unconstrained problem, if there is a point  $i$  such that

$$w_i - (W_x + W_y)^{1/2} \begin{cases} > 0, & \text{then point } i \text{ is a local minimum,} \\ < 0, & \text{then point } i \text{ is not a local minimum,} \\ = 0, & \text{then both possibilities are open,} \end{cases}$$

where

$$W_x = \sum_{i, j \in I^+, i \neq j} \frac{w_i(x_i - x_j)}{\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}} - \sum_{i, j \in I^-, i \neq j} \frac{w_i(x_i - x_j)}{\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}}, \\ W_y = \sum_{i, j \in I^+, i \neq j} \frac{w_i(y_i - y_j)}{\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}} - \sum_{i, j \in I^-, i \neq j} \frac{w_i(y_i - y_j)}{\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}}.$$

P.-C. Chen and others [5] and F. Plastria [14] derived independently the following sufficient condition for a demand point to be the global minimum solution.

*Property 5* For the unconstrained problem, if there is a point  $i^* \in I^+$  such that

$$w_{i^*} \geq \sum_{i \in I^+ \cup I^-, i \neq i^*} w_i,$$

then  $(x_{i^*}, y_{i^*})$  is the global optimum location.

It is quite straightforward to show that if all weights are positive then the expression for the weighted sum of the Euclidean distances is convex [13] and therefore the single local minimum corresponds to the global minimum. This means that the total expression for the sum of weighted Euclidean distances is a difference of two convex functions. As it has been noted earlier the presence of negative weights greatly complicates the location of the global minimum solution by introducing concave contributions in the objective function. This special class of difference of two convex functions (DC) optimization problems has recently (1990) received considerable attention [7]. The next theorem introduces a set of conditions for convexity of  $F(x, y)$  at some point  $(x, y)$ .

*Property 6*  $F(x, y)$  is convex at  $(x, y)$  if

$$\sum_{i \in I^+ \cup I^-} \frac{W_i}{r_i} \geq 0,$$

and

$$\sum_{i \in I^+ \cup I^-} \sum_{\substack{j \in I^+ \cup I^- \\ j > i}} \frac{W_i W_j}{r_i^3 r_j^3} \times [(x - x_i)(y - y_j) + (x - x_j)(y - x_i)]^2 \geq 0,$$

where  $r_i = \sqrt{(x - x_i)^2 + (y - y_i)^2}$ ,  $i \in I^+ \cup I^-$  and

$$W_i = \begin{cases} w_i, & i \in I^+, \\ -w_i, & i \in I^-. \end{cases}$$

A proof of this property can be found in [11].

A special case of this problem, involving three points with weights equal to one, was first posed by P. Fermat in the seventeenth century and it was solved geometrically by E. Toricelli. E. Weiszfeld [23] first proposed a simple iterative algorithm but with no convergence proof. Later, H.W. Kuhn [8,9,10] proved that Weiszfeld's algorithm was convergent assuming no iterate coincided with any of the demand points. L.M. Ostresh [12] and E. Balas and others [1] proposed modifications of the Weiszfeld algorithm where by perturbing the current point, if it coincided with a demand point, was global convergence guaranteed. C.Y. Wang [22] proved that Weiszfeld's algorithm has linear rate of convergence under certain conditions and sublinear otherwise. More recently (1980s), P.H. Calamai and

A.R. Conn [2,3,4] and M.L. Overton [13] introduced second order methods which involved local quadratic convergence and global convergence under conditions. G.L. Xue [25,26], and Xue and J.B. Rosen [15] proved unconditional global convergence and conditional local quadratic convergence for a second order algorithm and computational comparisons were carried out between Weiszfeld's algorithm and Newton's algorithm on a parallel machine.

Most papers address only positive weights reflecting the inherent assumption that all points 'attract' the central facility. However, in real world there exists an abundance of example problems where certain points 'repel' the central facility. For example nuclear plants, sewage treatment plants, or polluting industrial units may be desired to be as close as possible to their customers so that transportation costs are minimized but at the same time environmental considerations require that these facilities be as far as possible from residential areas and fragile ecological systems. This need to locate a facility away from certain points can be quantified through the use of negative weights as shown in [16,19]. A negative weight means that the value of the objective function is increased as the facility approaches the corresponding point. Therefore, the global optimum location of a facility is now the one that balances the repulsion and the attraction acting on the central facility. It is interesting to note that the introduction of negative weights greatly increases the complexity of the problem.

Weber's problem with some negative weights was first considered by L.-N. Tellier [17], who studied the case of two attractive and one repulsive point. Later, Tellier and D. Pollanski [18] analyzed exhaustively all different cases involving three demand points and derived statistical conclusions regarding the types of possible solutions. Drezner and Wesolowsky [6] proved a number of theoretical results and proposed a heuristic algorithm for locating the global minimum solution. However, it was Chen and others [5] who first presented an exact outer approximation algorithm for Weber's problem with attraction and repulsion by exploiting the d.c. structure of the problem. In addition, they [5] extend their procedure to exponentially decaying repulsion and facility location within a set of disjoint convex polygons. Later, Maranas and Floudas [11] proposed a branch and bound type global optimization algorithm for solving Weber's problems with attraction

and repulsion. The approach was based on the iterative solution of a set of convex and concave lower bounding problems. Convergence to an  $\epsilon$ -global minimum was proven and examples were solved with as many as 10,000 points. By analyzing the computational results they observed that for any given number of points  $N$  the difficulty of the problem increases as we introduce more repulsive points. This trend continues until about equal numbers of attractive and repulsive points are reached. Then, a sharp decrease in computational requirements is observed as more repulsive points are added. In fact, it is easier to solve problems involving more repulsive points than attractive ones. The standard deviation of the total number of required iterations and function evaluations is fairly small for all ratios of attractive to repulsive points with the sole exception of the  $N^+ = N^- = N/2$  case where the standard deviation is substantially increased. For a given ratio of attractive to repulsive points the CPU requirements increase almost linearly with  $N$  reflecting the fact that most of CPU time is spent on function evaluations.

A generalization of Weber's problem is the maximization of the sum of decreasing convex functions of arbitrary metrics. H. Tuy and F.A. Al-Khayyal [20] proposed the first algorithm for finding global solutions to the problem by reducing it to a sequence of unconstrained nondifferentiable convex minimization problems. Later, they [21] extended this work to account for repulsion as well and proposed a d.c. reformulation of the problem which enabled them to develop a global optimization procedure.

### Abstract

A well-studied problem in the area of computational biology is the sequence alignment problem. Three mixed-integer linear optimization models have been developed to address the global pairwise sequence alignment problem in a mathematically rigorous fashion. These formulations, in addition to their rigor, allow for (a) the natural introduction of functionally important conservation constraints, (b) the creation of a rank-ordered list of the highest scoring alignments and (c) the refinement of alignments by using pairwise interaction scores from simplified force fields. The third model, a path selection approach, employs some of the algorithmic advantages of dynamic programming methods, to outperform other optimization models.

### Keywords and Phrases

Sequence alignment; Integer linear optimization; Global pairwise alignment; Rank-order list of alignments

### Introduction

Sequence alignment methods aim to both identify related protein sequences and determine the best alignment between them. This approach provides a rough measure of evolutionary distance and may indicate possible relationships between the protein structure and function of similar sequences. Multiple scoring matrices have been developed based on the techniques of the percent of accepted mutations (PAM) [3] and protein blocks (BLOSUM) [5] to quantify this evolutionary distance between aligned residues.

The pairwise sequence alignment problem is most commonly addressed through either (i) global alignment or (ii) local alignment techniques. The goal of global alignment algorithms is to determine the highest

scoring overall alignment spanning the length of both sequences. One widely used approach for this problem is a dynamic programming approach proposed by Needleman and Wunsch [10].

Proteins may share sequence similarity in some regions, but not in others. Local alignment algorithms are more suited to these problems and strive to align only the highest scoring subsequence match. Smith and Waterman extended the dynamic programming approach for global pairwise sequence alignment problems to address the local alignment problem [14]. Dynamic programming approaches are computationally inadequate for large scale database searches, so a number of heuristic algorithms for local pairwise sequence alignment have been proposed [1,2,11,12].

Several researchers have studied the effect of including information about near-optimal alignments. The investigation of the suboptimal paths and scores allows for an evaluation of the reliability of portions of a sequence alignment. A review of several approaches to this problem and their impact can be found elsewhere [17].

In some cases, an alignment between two sequences can be improved by constraining the problem to include biologically important information in the overall alignment. One example of this is the required conservation of certain residues that form a motif necessary for function. This problem has been addressed recently by dynamic programming algorithms [4,15].

## Models

Several integer linear optimization (ILP) models have been developed to rigorously and completely address the problem of global pairwise sequence alignment in a general fashion. A comparison of the three approaches, a template-based model, a template-free model, and a path selection model are presented in the following sections. The formulation of the problem as an integer linear optimization problem provides a deterministic guarantee of identifying the global maximum alignment [6], allows for the introduction of integer cut constraints, provides a framework for the introduction of functionally-specific constraints, and shows promise for the optimal identification of pairwise interactions.

## Template-Based Model

Consider two protein sequences  $S1, S2$  of lengths  $M$  and  $N$  respectively, where  $M > N$ . Let the index  $i$  represent each position in Sequence  $S1$  and the index  $j$  represent each position in  $S2$ , as shown in Eqs. 1–2.

$$i \in 1, 2 \dots M \quad (1)$$

$$j \in 1, 2 \dots N \quad (2)$$

The template-based optimization model assigns each amino acid of both sequences to a template to generate the optimal alignment. Equation 3 defines a template length  $K$  as the sum of the length of the larger sequence and the parameter  $N\_GAPS_m$ , representing the maximum number of allowed gaps. This model requires the introduction of an index  $k$ , representing the position in the template, as defined by Eq. 4.

$$K = M + N\_GAPS_m \quad (3)$$

$$k \in 1, 2 \dots K \quad (4)$$

The assignment of an amino acid to a template position requires the definition of the binary variables,  $y_{ik}$  and  $z_{jk}$ , as shown in Eqs. 5–6.

$$y_{ik} = \begin{cases} 1 & \text{if amino acid } i \text{ of } S1 \text{ is assigned to} \\ & \text{template position } k \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

$$z_{jk} = \begin{cases} 1 & \text{if amino acid } j \text{ of } S2 \text{ is assigned to} \\ & \text{template position } k \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

A position in the template may not have an amino acid assigned to it in the overall alignment. Therefore, Eqs. 7–8 introduce additional binary variables to represent these alignment gaps.

$$yg_k = \begin{cases} 1 & \text{if template position } k \text{ is a gap} \\ & \text{for Sequence } S1 \\ 0 & \text{otherwise} \end{cases} \quad (7)$$

$$zg_k = \begin{cases} 1 & \text{if template position } k \text{ is a gap} \\ & \text{for Sequence } S2 \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

The objective function of this optimization model maximizes the alignment score, which is the sum of a scoring matrix value for each matching amino acid pair minus any associated penalties for gaps inserted in the

sequence. The scoring matrix will assign a weight,  $w_{ij}$ , to any template position  $k$  that contains the amino acid in position  $i$  of Sequence S1 and also the amino acid in position  $j$  of S2.

For an affine gap penalty model with no penalties for gaps that begin or end a sequence, the objective function can then be posed as shown in Eq. 9. The contribution of the scoring matrix at positions  $i, j, w_{ij}$ , is considered only if position  $i$  of Sequence 1 is assigned to position  $k$  of the template,  $y_{ik}$ , and if position  $j$  of Sequence 2 is assigned to position  $k$  of the template,  $z_{jk}$ . The gap opening existence terms of Sequence 1,  $go_k^{S1}$ , and Sequence 2,  $go_k^{S2}$ , are weighted by the gap opening penalty value of  $wo$  to assess the penalty for the first residue of any gap in a sequence. The existence of a gap extension variable of either sequence,  $gl_k^{S1}$  and  $gl_k^{S2}$ , produces a penalty of  $wl$  for each occurrence. The active  $gl_k^{S1}$  and  $gl_k^{S2}$  variables that are contained within a beginning or an ending gap are counteracted by the product of  $gb_k^{S1}$ ,  $gb_k^{S2}$ ,  $ge_k^{S1}$ , or  $ge_k^{S2}$  with  $wl$ . Gap opening penalties at the beginning or end of a sequence are explicitly omitted through only summing over the reduced index, such that  $2 \leq k \leq K - 1$ .

$$\begin{aligned} \max \sum_i \sum_j \sum_k w_{ij} \cdot y_{ik} \cdot z_{jk} - \sum_{k=2}^{K-1} (go_k^{S1} + go_k^{S2}) \cdot wo \\ - \sum_{k=2}^{K-1} [(gl_k^{S1} - gb_k^{S1} - ge_k^{S1}) \\ + (gl_k^{S2} - gb_k^{S2} - ge_k^{S2})] \cdot wl \end{aligned} \quad (9)$$

The objective function of Eq. 9 requires the linearization of the product of two binary variables and is subject to numerous constraints. The details of the model are available elsewhere [8].

### Template-Free Model

Unlike the previously described mixed-integer linear programming formulation of the global pairwise sequence alignment problem in Sect. “**Template-Based Model**”, the optimization model presented here does not assign the amino acids of each sequence to a template. However, information about the maximum number of allowable gaps is still included in this model, through the variable  $K$  in Eq. 3.

In the template-free model, a binary variable,  $z_{ij}$ , is defined in Eq. 10 to represent the alignment of position  $i$  in S1 to position  $j$  in S2. A method to handle gaps in the sequence still must be introduced into the model to account for the evolutionary changes that lead to residue insertions and deletions. Aligning a gap residue to another gap residue is not allowed. This observation leads to two possibilities of gap occurrences. A gap can either be in Sequence 1, across from a residue  $j$  in Sequence 2 or in Sequence 2, across from a residue  $i$  in Sequence 1. These possibilities are modeled with the binary variables  $zg_i$  and  $yg_j$ , defined by Eq. 11–12.

$$z_{ij} = \begin{cases} 1 & \text{if position } j \text{ in S2 aligns with} \\ & \text{position } i \text{ in S1} \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

$$zg_i = \begin{cases} 1 & \text{if no position } j \text{ in S2 aligns} \\ & \text{to the residue in position } i \text{ of S1} \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

$$yg_j = \begin{cases} 1 & \text{if no position } i \text{ in S1 aligns} \\ & \text{to the residue in position } j \text{ of S2} \\ 0 & \text{otherwise} \end{cases} \quad (12)$$

The objective function in Eq. 13 maximizes the sum of the weights of the residue-residue alignments minus the sum of the gap penalties, plus the appropriate terms that remove the penalties from the gaps at the beginning and ends of the sequences. The scoring matrix values at any given pair of positions,  $w_{ij}$  are included when the binary variables indicating a sequence alignment that matches positions  $i$  and  $j$ ,  $z_{ij}$ , are activated. For an affine gap penalty model, the variables representing the existence of a gap opening,  $go_j^{S1}$  and  $go_j^{S2}$ , and the existence of a gap extension,  $gl_j^{S1}$  and  $gl_j^{S2}$ , are multiplied by their respective weights,  $wo$  and  $wl$ . If a gap residue is present at the beginning or ending of a sequence, it will be accounted for in an active value for one of  $gb_j^{S1}$ ,  $ge_j^{S1}$ ,  $gb_i^{S2}$ ,  $ge_i^{S2}$  to remove the penalty assigned by the previous terms.

$$\begin{aligned} \max \sum_{ij} w_{ij} z_{ij} \\ - \sum_j (wo \cdot go_j^{S1} + wl \cdot gl_j^{S1}) \end{aligned}$$

$$\begin{aligned}
& - \sum_i (w_o \cdot g o_i^{S2} + w_l \cdot g l_i^{S2}) \\
& + \sum_{j>1}^{N-1} w_l \cdot (g b_j^{S1} + g e_j^{S1}) \\
& + \sum_{i>1}^{M-1} w_l \cdot (g b_i^{S2} + g e_i^{S2}) \\
& + w_o \cdot (g e_1^{S1} + g e_1^{S2}) \\
& + w_o \cdot (g e_M^{S1} + g e_N^{S2})
\end{aligned} \tag{13}$$

The objective function of Eq. 13 is subject to numerous constraints. The details of these constraints are available elsewhere [9].

### Path Selection Model

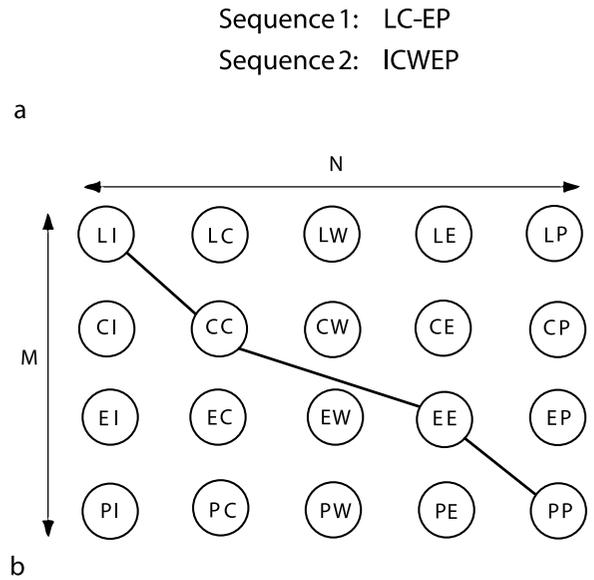

Let us introduce a binary variable  $N_{ij}$  that represents the alignment of the residue at position  $i$  in Sequence 1 to the residue at position  $j$  in Sequence 2. This binary variables performs a similar role as  $z_{ij}$  in Sect. “Template-Free Model”. The typical assignment of this match assesses a weight,  $w_{ij}$ , based on a scoring matrix developed through evolutionary analysis of protein sequences.

A successful sequence alignment will have many active  $N_{ij}$  variables, which we will designate as nodes. Let the binary variable  $y_{i'i'j'j'}$  represent the existence of a connecting path between node  $N_{ij}$  and a neighboring node  $N_{i'j'}$ . Associated with this connecting path, is a weight parameter,  $C_{i'i'j'j'}$ , which can be calculated in advance from the scoring matrix  $w$  and any position dependent gap penalty form that is specified a priori. An example of the representation of the node and path variables is illustrated in Fig. 1.

Once these variables have been defined, the objective function of the optimal sequence alignment is merely the sum of the product of the variable for the existence of the path,  $y_{i'i'j'j'}$ , and the path weight,  $C_{i'i'j'j'}$  as shown in Eq. 14.

$$\max \sum_i \sum_{i'>i} \sum_j \sum_{j'>j} y_{i'i'j'j'} \cdot C_{i'i'j'j'} \tag{14}$$

The variable  $y_{i'i'j'j'}$  is defined only as the existence of a contact between two neighboring nodes, where each node  $N_{i',j'}$  that has an incoming connecting path activated must also have an outgoing path. In effect, this constraint can be thought of as a “mass” balance around

**Global Pairwise Protein Sequence Alignment via Mixed-Integer Linear Optimization, Figure 1**

(a) Alignment of two hypothetical sequence fragments. (b) A node and path representation of the alignment problem as formulated by the mathematical model. Note the three active paths connecting the four selected node variables

the node. This constraint is specified for all nodes except those that are allowed to begin or end an alignment by Eq. 15.

$$\begin{aligned}
& \sum_{i<i'<j<j'} y_{i'i'j'j'} - \sum_{i''>i'>j''>j'} y_{i'i''j''j'} = 0 \\
& \forall 1 < i' < M, 1 < j' < N
\end{aligned} \tag{15}$$

Equation 16 requires an alignment that matches the first residue in one of the two sequences to a residue in the other sequence. This constraint invalidates any alignment that aligns the first residue in both sequences to a gap, a physically meaningless alignment and allows for the path weights,  $C_{i'i'j'j'}$ , to be precalculated.

$$\begin{aligned}
& \sum_{i'>1} \sum_j \sum_{j'>j} y_{i=1,i'j'j'} + \sum_{i'>i'>j'>j} y_{i'i',j=1,j'} \\
& - \sum_{i'>1} \sum_{j'>1} y_{i=1,i',j=1,j'} = 1
\end{aligned} \tag{16}$$

If one sequence ends in a gap, the terminal residues of the other sequence must be prevented from aligning to earlier residues in a physically unrealistic way. Equations

tion 17 allows exactly one active node  $N_{i,j}$  involving a terminal residue in either Sequence 1 or Sequence 2.

$$\begin{aligned} \sum_{i < M} \sum_j \sum_{j' > j} y_{i,i'=M,jj'} + \sum_i \sum_{i' > i} \sum_{j < N} y_{ii'j,j'=N} \\ - \sum_{i < M} \sum_{j < N} y_{i,i'=M,j,j'=N} = 1 \end{aligned} \quad (17)$$

It is more efficient and more meaningful to restrict the search to within a maximum alignment length,  $K$ . Equations 18–19 require the sum of the sequence length and the number of gaps created by the alignment to be less than the maximum alignment length for Sequences 1 and 2 respectively.

$$\begin{aligned} \sum_i \sum_{i' > i} \sum_j \sum_{j' > j+1} (j' - j) \cdot y_{ii'jj'} + \\ \sum_i \sum_{i' > i} \sum_{j' > 1} (j - 1) \cdot y_{ii',j=1,j'} + \\ \sum_i \sum_{i' > i} \sum_{j < N} (j' - N) \cdot y_{ii'jj'=N} + M \leq K \end{aligned} \quad (18)$$

$$\begin{aligned} \sum_i \sum_{i' > i+1} \sum_j \sum_{j' > j} (i' - i) \cdot y_{ii'jj'} + \\ \sum_{i' > 1} \sum_j \sum_{j' > j} (j - 1) \cdot y_{i=1,i'jj'} + \\ \sum_{i < M} \sum_j \sum_{j' > j} (j' - N) \cdot y_{i,i'=M,jj'} + N \leq K \end{aligned} \quad (19)$$

Equations 14–19 form the general mathematical model for the path selection approach to the global pairwise sequence alignment problem. Any of the three models presented can be expanded to include functionally-specific constraints, integer cut constraints, and pairwise interactions. Only the constraints necessary to include these features in the path selection model will be presented here.

### Functionally-Specific Constraints

For some sequence alignment problems, specific residues are related to the function of a protein and should be maintained in a meaningful sequence alignment. This idea can be enforced in a mathematically rigorous way. These constraints can only be defined if the node existence variables,  $N_{ij}$ , are connected to the

path existence variables,  $y_{ii'jj'}$ . One way to accomplish this is by summing over a pair of indices within the path variables, as shown in Eqs. 20–21.

$$\sum_{i < i', j < j'} y_{ii'jj'} = N_{i'j'} \quad \forall i' > 1, j' > 1 \quad (20)$$

$$\sum_{i' > i, j' > j} y_{ii'jj'} = N_{ij} \quad \forall i = 1 \text{ or } j = 1 \quad (21)$$

Constraints enforcing residue identity can then be written in terms of the  $N_{ij}$  variables. If position  $i^*$  in Sequence 1 must be conserved to maintain function, then Eq. 22 enforces this requirement.

$$\sum_{j:AA_{i^*}=AA_j} N_{i^*j} = 1 \quad (22)$$

### Integer Cut Constraints

This alignment model can be further extended by introducing integer cut constraints. After each solve of the above model, the previous solution is excluded from the feasible solution space by Eq. 23.  $A$  is the set of active variables in the solution to be excluded,  $I$  is the set of inactive variables and  $\text{card}(A)$  is the cardinality of set  $A$ , or the number of members of set  $A$ .

$$\sum_{(ii'jj') \in A} y_{ii'jj'} - \sum_{(ii'jj') \in I} y_{ii'jj'} \leq \text{card}(A) - 1 \quad (23)$$

### Pairwise Interaction Scores

A score can also be assigned for the alignment of a pair of amino acids  $i, i'$  in one sequence to a specific pair of amino acids  $j, j'$  in the second sequence. One promising application of these pairwise interactions scores is the ability to better evaluate the fitness of an alignment between a protein of known structure and an unknown protein with remote sequence homology. A number of recently developed  $C^\alpha$ -based distance dependent force fields [7,13,16] are a good source for these scores because they allow some flexibility between the backbones of these two structures.

A pairwise interaction score requires the definition of the variable  $z_{ii'jj'}$ , representing the successful alignment of both  $i, j$  ( $N_{ij}$ ) and  $i', j'$  ( $N_{i'j'}$ ). This variable is initially introduced in Eq. 24 as the product of two node existence binary variables.

$$z_{ii'jj'} = N_{ij} \cdot N_{i'j'} \quad \forall i, i', j, j' \quad (24)$$

Equation 24 is nonlinear and must be linearized using standard optimization techniques by Eqs. 25–27, which replace Eq. 24.

$$\sum_{ij} z_{ii'jj'} \leq N_{i'j'} \quad \forall i', j' \quad (25)$$

$$\sum_{i'j'} z_{ii'jj'} \leq N_{ij} \quad \forall i, j \quad (26)$$

$$N_{ij} + N_{i'j'} - 1 \leq z_{ii'jj'} \quad \forall i, i', j, j' \quad (27)$$

Let the score of a pairwise interaction be denoted as  $P_{ii'jj'}$ . The objective function of Eq. 14 is expanded to include an additional contribution as shown in Eq. 28.

$$\max \sum_i \sum_{i'>i} \sum_j \sum_{j'>j} y_{ii'jj'} \cdot C_{ii'jj'} + z_{ii'jj'} \cdot P_{ii'jj'} \quad (28)$$

The ability of the sequence alignment models to easily allow for pairwise interaction scores illustrates their true power and flexibility. The model is guaranteed to converge to the optimal solution even for problems of this type. This guarantee suggests the effectiveness that could be achieved by incorporating such a model into a fold recognition framework.

## Results and Discussion

The mixed-integer linear programming models of Sect. “Models” can address generic sequence alignment problems of a reasonable size. This method will be illustrated on an alignment of G-protein coupled receptors with the use of integer cut constraints and an alignment of pancreatic trypsin inhibitors demonstrating the use of functionally-relevant conservation constraints. All the alignments are calculated using the BLOSUM62 scoring matrix and an affine gap model with a gap opening penalty of 11 and a gap extension penalty of 1.

### G-protein Coupled Receptors

G-protein coupled receptors are a type of membrane protein that regulate material and ion transport across a cell membrane, a reason they are a popular target for drug development. The alignment of the seventh transmembrane helix of bovine rhodopsin (34 amino acids) to the seventh transmembrane helix of H1R (35

### Global Pairwise Protein Sequence Alignment via Mixed-Integer Linear Optimization, Figure 2

A rank-ordered list of the top four optimal alignments of the helix 7 region of the human histamine receptor (Sequence 1) to the helix 7 region of the bovine rhodopsin (Sequence 2) for a template length of 50 residues

amino acids), the first human histamine receptor, will be considered to illustrate alignment uncertainty [9]. Figure 2 shows the the regions of uncertainty in the sequence alignment using integer cut constraints. There is a strong conservation of alignment at the ends of the selected sequence, including the preservation of the highly conserved NPxxY motif. The central regions of the aligned sequences shows more variability. This observation could be a result of less structural conservation in the region, or less sequence similarity required for structural (and functional) conservation.

A comparison of the computational resources required for this problem is presented in Table 1. A larger template length results in a more complex optimization problem to be solved. The path selection model significantly outperforms the other formulations, especially for the larger template lengths.

**Global Pairwise Protein Sequence Alignment via Mixed-Integer Linear Optimization, Figure 3**  
Optimal alignment of bombyx mori kazal-type serine proteinase inhibitor 1 (Sequence 1) to bovine pancreatic trypsin inhibitor (Sequence 2), given the requirement of cysteine conservation and a template length of 100

#### Global Pairwise Protein Sequence Alignment via Mixed-Integer Linear Optimization, Table 1

Computational performance of the template-based (TB), template-free (TF) and path selection (PS) models for helix 7 of the G-protein coupled receptor proteins (run times in seconds on an Intel Pentium 3.2 GHz processor, using CPLEX 9.0)

K	TB	TF	PS	Objective
40	1000+	35.21	1.30	26,25,25,25
45	1000+	177.8	5.27	26,25,25,25
50	1000+	1000+	14.71	26,25,25,25

#### Serine Protease Inhibitors

Serine protease inhibitors are responsible for regulating serine proteases, proteins necessary for hydrolyzing peptides. One well-studied protein within this class is the bovine pancreatic trypsin inhibitor (BPTI). Its native three-dimensional structure is stabilized by 3 disulfide bonds that are conserved across the class of serine protease inhibitors. An alignment of BPTI (58 amino acids) to the bombyx mori (domestic silkworm) kazal-type serine protease inhibitor (76 amino acids) has previously been investigated in the context of introducing constraints for the functionally important conservation of the disulfide bonds [8]. The results of such an alignment are presented in Fig. 3. The six conserved cysteine residues necessary for the formation of the three disul-

#### Global Pairwise Protein Sequence Alignment via Mixed-Integer Linear Optimization, Table 2

K	TB	TF	PS	Objective
80	886.4	0.36	0.64	141
90	1000+	80.3	1.74	141
100	1000+	912.4	2.77	141

fide bridges that stabilize the functional protein are apparent from this alignment.

A comparison of the computational resources required for this problem is presented in Table 2. Even with the inclusion of the conservation constraints, the path selection model still solves this alignment example quite rapidly for large template lengths. Although the template-free approach slightly outperforms the path selection approach for short template length restrictions, it does not scale very well with increases in template length. Similar to the first example, the template-free approach solves the problem significantly faster than the template-based approach, but the path selection approach is superior to both of the mixed-integer linear programming techniques.

### Keywords

Stochastic dynamic programming; Multiperiod stochastic program

A *supply chain* (SC) may be defined as an integrated process where several business entities such as suppliers, manufacturers, distributors, and retailers work together to plan, coordinate and control the flow of materials, parts, and finished goods from suppliers to customers. This chain is concerned with two distinct flows: a forward flow of materials and a backward flow of information. Similarly, a *global supply chain* (GSC) may be defined as a SC where one or more of these business entities operate in different countries. For many years, researchers and practitioners have concentrated on the individual processes and entities within the SC. Within the past few years, however, there has been an increasing effort in optimizing the entire SC. This article intends to highlight some of the early results from the 1960s to 1995 that have led to today's SC research and most of the recent results that address the design and management of GSC networks (as of 2000).

Within manufacturing and logistics research, the current stream of SC research is largely built on prior work in the area of multi-echelon inventory models. The early works [4,5] and [14] form the basis for most of the research done in this area. See [13] and [3] for extensive reviews of multi-echelon inventory models. For detailed and more recent discussions of multi-echelon models, see [12,19,20].

As companies began to realize the benefits of optimizing the SC as a single entity, researchers began utilizing operations research (OR) techniques to better model supply chains. See [2] for an extensive review of the literature in SC modeling. Typically, a SC model tries to determine:

- the transportation modes to be used;
- the suppliers to be selected;
- the amount of inventory to be held at various locations in the chain;
- the number of warehouses and plants to be used; and
- the location and capacities of these warehouses and plants.

However, as a result of the globalization of the economy, the models have become more complex. GSC models now often try to include factors such as exchange rates, international interest rates, trade barriers, taxes and duties, market prices, and duty drawbacks. All of these factors are generally difficult to include in mathematical models because of the uncertainty and nonlinearity they introduce.

See [21] and [7] for extensive reviews on GSC models. [21] concentrates on strategic production-distribution models whereas [7] focus on the integration of SC network optimization with real options pricing methods. This article complements these reviews by giving a chronological listing of the models in both areas.

In [15] an international *facility location* model is presented. This is one of the first mathematical programs that includes financial aspects in GSC modeling. The authors develop a *large scale nonlinear mixed integer programming problem* (MIP). The objective function takes into account the expected profit and the variance of the profit, where the variance of the profit is multiplied by a risk aversion factor. Plant capacities, market demands and financial constraints are included in the model. The formulation considers production and transportation costs, exchange rate fluctuations, international interest rates, market prices, import tariffs, and export taxes.

In [9] a deterministic model is proposed for maximizing the after tax profit of a large scale international distribution network. Transportation costs, fixed setup costs, variable production and purchasing costs, and fixed vendor costs are included in the model. The model

enforces production capacity constraints, demand limits, material requirements at each plant, supplier capacity constraints, balance constraints at plants and distribution centers, feasible flow constraints, and offset trade requirements. The model is run sequentially over a fixed time horizon and computational results are presented for various problem sizes.

In [6] the differences are analyzed between an international SC model and a single-country model, and a dynamic, nonlinear MIP model is developed. The inclusion of features such as duties, tariffs, tax rates, and exchange rates produce models that are very difficult to solve optimally even for small size problems.

In [8] a normative model is presented for the operations of a global company. Plant location, capacity and product mix, and material and cash flow determination are the decisions included in the model. The model consists of a master problem and a set of subproblems. The master problem is a *multiperiod stochastic program* and the subproblems are single period stochastic programs. These problems are linked through a set of submodels such as a stochastic SC model, a financial flow model, a stochastic exchange rate model, and a price-demand model.

In [17] a *stochastic dynamic programming* (DP) model is developed that treats the SC as equivalent to owning a financial option instrument. The value of the option depends on the real exchange rate. The authors consider production switching between two manufacturing plants located in different countries depending on the real exchange rate. The model does not consider characteristics such as multiple products or different SC stages. The model becomes intractible for more than one exchange rate process.

In [1] a comprehensive, multiperiod, multicommodity MIP model is proposed which is used to optimize the SC of Digital Equipment Corporation (DEC). The objective of the model is to minimize a function of total production and distribution cost, savings from credit, and an additional term which contains production and transportation times. The total cost includes fixed and variable costs of production, transportation cost, material handling, inventory, and overhead costs. The savings from credit are due to reexporting products. The model enforces constraints on demand satisfaction, production and throughput capacities at each facility, and bounds on decision variables. In addition,

international constraints such as duty drawback, duty relief, and offset trade are included. The authors describe how DEC used this model to manage their GSC.

In [18] a multiperiod stochastic DP is introduced that allows the firm to switch among several production modes to maximize profit. The production modes they consider are exporting from the home country, a joint venture with local partners, and establishing a wholly owned subsidiary for a foreign firm. It concludes by identifying cases in which one of these modes would be preferred to the others.

In [16] a stochastic DP formulation is developed for the valuation of global manufacturing strategy options. A hierarchical approach is proposed. First, the exchange rates are modeled by multinomial approximations. Then, options for alternative product and SC network designs are determined based on the firm's global manufacturing strategy. Finally, an MIP model for each exchange rate within every period is solved and the value of several manufacturing options is determined. The expected profit for each policy option is found by solving a stochastic DP using the values of the manufacturing policies.

In [11] the problem of operating a network of plants that are partially-owned subsidiaries of a multinational corporation is analyzed. Using real data, a model of three subsidiaries and four countries is developed for one industry and the effects of coordination under various macroeconomic conditions are discussed.

In [10] optimal policies for operating a network of plants located in different countries is studied. It is assumed that production costs are stochastic and are influenced by factors such as exchange rates, inflation, taxes, and tariffs. There is a one-time charge for switching (production volume changes between countries) and variable production costs are either concave or piecewise linear convex at each plant. It is also assumed that demand is deterministic and stationary. Under these assumptions a two-country, single market stochastic DP model is developed. The authors show that the optimal policy is always a barrier policy when switching costs are linear or step functions. (*A barrier policy* is a policy in which each plant operates either at a minimum or a maximum output level.)

The literature on GSC management is quite recent and the models developed usually do not consider most of the uncertainties that international corpora-

tions face. Each model addresses a limited number of the aspects of managing a GSC. There is an ongoing effort to develop more comprehensive and practical GSC design models that will accommodate the needs of the rapidly changing global economy.

### Introduction

Global terrain methods [5,6,7] are a class of methods for solving nonlinear programming problems that are based on the simple concept of intelligently following valleys up and down on the terrain or landscape of three times continuously differentiable or  $C^3$  objective function surfaces. They belong to the class of integral path or path following methods [1,2,3,4,8] and can also be used to solve systems of nonlinear equations formulated as nonlinear least-squares problems. The overall approach is based on the reliable and efficient computation of minima, saddle points, and singular points and a terrain-following algorithm to efficiently move from one stationary point to another or to a boundary of the feasible region. What makes global terrain methods superior to other path following methods is the Newton-based *predictor-corrector* method used to move uphill on the objective function landscape.

### Formulation

The problem under consideration is that of finding a number of minima, saddle points, and singular points of a  $C^3$  objective function,  $\phi = \phi(z)$ , defined on  $R^n$  subject to bounds on variables,  $c(z)$ , where  $z$  are the optimization variables. Let  $F = F(z)$  denote the gradient of  $\phi$  and  $J(z)$  denote the  $n \times n$  symmetric Jacobian matrix of  $F$  (or Hessian matrix of  $\phi$ ).

### Problem Statement

The problem can be stated in the form

$$\text{Find } \{z_k^*\} : z_k^* \leq c(z^*) \text{ such that } \nabla(F^T F) = 0, \quad (1)$$

where  $\{z_k^*\}$  denotes a set of minima, saddle points, and/or singular points, and the constraints are given by

$$-z_i^* \leq z_i^L \text{ and } z_i^* \leq z_i^U, \quad (2)$$

where  $z_i^L$  and  $z_i^U$  are the lower and upper bounds on the variable  $z_i$ .

Note that  $\nabla(F^T F) = J^T F = 0$  implies that either

$$F(z_k^*) = 0, \quad (3)$$

$$\det J = 0 \text{ with null space vector } F \neq 0. \quad (4)$$

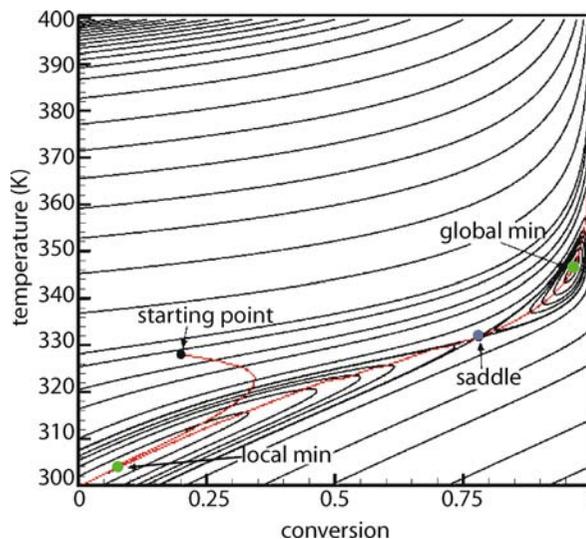

If  $z_k^*$  satisfies Eq. (3), it is either a minimum or a saddle point of  $\varphi$  whereas if  $z_k^*$  satisfies Eq. (4), it is a singular point of  $J$ . To distinguish between minima and saddle points, the Hessian matrix of  $F^T F$  is required, which is

$$H = J^T J + \Sigma F_i G_i, \quad (5)$$

where  $F_i$  is the  $i$ th element function of  $F$  and where  $G_i$  is the corresponding element Hessian matrix of  $F_i$ . If all eigenvalues of  $H$  are positive,  $z_k^*$  is a minimum of  $\varphi$ . If at least one eigenvalue of  $H$  is negative,  $z_k^*$  is a saddle point of  $\varphi$ .

### Geometrical Foundation

Figure 1 shows the contours of  $F^T F$  along with the terrain path for a simple two dimensional reactor example. To understand the underlying geometric foundation on which global terrain methods are built, consider two neighboring contours or level curves along the curved valley shown in Fig. 1. Note that the distance,  $\Delta$ , between any two neighboring level curves in the normalized gradient direction is largest exactly in the valley and that this distance decreases in magnitude as points move out of the valley along the same neighboring level curves (i. e., the contours become more tightly packed together). Therefore the norm of  $J^T F$  must be smaller at any point in the valley than at any neighboring point on any given level curve since the same change in the least-squares function results from the largest change in distance. Thus the valley connecting the stationary points shown in Fig. 1 can be characterized as the collection of local minima in the norm of  $J^T F$  over a set of level curves. This same constrained extremum in the gradient norm also characterizes ridges, ledges and other distinct features of the objective function landscape in any  $n$ -dimensional space.

Global Terrain Methods, Figure 1  
Contours of a least squares surface

Valleys, ridges, ledge, etc. can be defined mathematically by a set of solutions,  $V$ , to a sequence of general nonlinearly, constrained optimization problems

$$V = \{\min g^T g \text{ such that } F^T F = L, \text{ for all } L \in \Lambda\}, \quad (6)$$

where  $F$  and  $J$  are defined as before and where  $g = 2J^T F$ ,  $L$  is any given value (or level) of the least-squares objective function, and  $\Lambda$  is some collection of contours. That is, for any given level curve, we find the point on  $L$  that corresponds to a local minimum in  $g^T g$ . The collection of minima for all levels gives all (or part) of a valley, ridge, or ledge. Equation (6) forms the geometrical backbone for global terrain methods and plays an important role in the development of predictor-corrector algorithms used to implement those ideas. Moreover,  $\Lambda$  is actually a computational by-product of the terrain-following approach.

It is useful to simultaneously monitor behavior on the landscape of  $F^T F$  and the objective function landscape, noting that minima and saddle points on  $\varphi$  are minima on  $F^T F$  while singular points on  $\varphi$  are saddle points on  $F^T F$ . Valleys on both surfaces closely align.

### Methods

Terrain-following methods are comprised of a sequence of sub-problems that unfold dynamically dur-

ing the course of solving a nonlinear programming problem. Since global terrain methods move up and down the landscape of  $F^T F$ , these sub-problems include

- 1) Reliable downhill equation solving.
- 2) Reliable and efficient computation of singular points.
- 3) Efficient uphill movement comprised of predictor-corrector calculations.
- 4) Reliable and efficient eigenvalue-eigenvector computations.
- 5) Effective bookkeeping.
- 6) A termination criterion to decide when the computations have finished.
- 7) Advanced techniques to deal with bifurcations and non-differentiable points.

### 1) Moving Downhill

Downhill computations use a trust region method and are capable of finding minima, saddle points, and sometimes singular points on an objective function surface. In finding the first point, say  $z_1^*$ , initiation of downhill computations is arbitrary. On subsequent downhill sub-problems, calculations always begin in the direction of the smallest negative eigenvalue of  $H$ .

The basic downhill iteration is defined as follows

$$\Delta = -\beta \Delta_N + (\beta - 1)g, \quad (7)$$

where  $\Delta_N = J^{-1}F$  is the Newton direction and  $\beta \in [0, 1]$  is determined by the following simple rules. If  $\|\Delta_N\| \leq R$ , then  $\beta = 1$ , where  $R$  is the trust region radius. If  $\|\Delta_N\| > R$  and  $\|F\| \geq R$ , then  $\beta = 0$ . Otherwise,  $\beta$  is the unique value in Eq. (7) on  $[0, 1]$  that satisfies  $\|\Delta\| = R$ . The new iterate is accepted if it reduces  $\|F\|$ . Otherwise, the new iterate is rejected, the trust region radius is reduced and the calculations are repeated until a reduction in  $\|F\|$  occurs. Downhill movement is terminated when either  $\|F\| \leq \varepsilon$ , where  $\varepsilon$  is a convergence tolerance, or  $\|F\| / \|\Delta_N\| \leq \zeta$ , where  $\zeta$  is some small number (typically  $10^{-6}$ ). This latter condition implies that the Newton step is very large in comparison to the gradient and the computations are converging to a singular point. The algorithm then switches to quadratic acceleration.

### 2) Acceleration to Singular Points

During downhill movement, quadratic acceleration is used if  $\|F\| / \|\Delta_N\| \leq \zeta$ . Quadratic acceleration is also used during uphill calculations to converge to singular points and is defined by

$$\Delta = -H^{-1}J^T F. \quad (8)$$

During acceleration, norm reduction in  $F$  is not enforced because  $H$  can have eigenvalues of mixed sign.

### 3) Moving Uphill

Uphill movement is initiated in the eigen-direction associated with the smallest positive eigenvalue of the Hessian matrix  $H$  and consists of two basic parts – Newton predictor steps and successive quadratic programming (SQP) corrector steps.

**Uphill Predictor Steps** Predictor steps follow a valley uphill but will ‘drift’ from the valley – as shown in the slight zigzag in the terrain path in Fig. 1, which shows this ‘drift’ (followed by corrector steps). Uphill Newton steps are defined by

$$\Delta_p = \alpha \Delta_N, \quad (9)$$

where  $\Delta_N = J^{-1}F$  and the step size  $\alpha \in (0, 1]$ .

**Uphill Corrector Steps** Corrector steps (again see Fig. 1) are used intermittently to force iterates back to a valley and are invoked when the condition

$$\theta = 57.295 \arccos \left[ (\Delta_N^T c) / (\|\Delta_N\| \|v\|) \right] \geq \Theta, \quad (10)$$

is satisfied, where  $v$  is the current estimate of the eigenvector associated with the smallest positive eigenvalue of  $H$  and  $\Theta$  is 5 degrees. Corrector steps are formulated as

$$\min g^T g \text{ such that } F^T F = L, \quad (11)$$

where  $L$  is the current value of  $F^T F$ . Corrector steps are iterative and are considered converged when the necessary conditions

$$F^T F - L = 0, \quad (12)$$

$$Hg - \lambda g = 0, \quad (13)$$

are satisfied. Corrector steps are computed using a successive quadratic programming (SQP) method; however, other methods can be used for this purpose. The SQP formulation for the problem defined by Eq. (11) is given by

$$\begin{aligned} \min g^T H \Delta_c + \frac{1}{2} \Delta_c^T M \Delta_c \text{ such that} \\ g^T \Delta_c = -(F^T F - L), \end{aligned} \quad (14)$$

where  $M$  is the Hessian matrix of the Lagrangian function. The Lagrangian function is defined by  $L = g^T g - \lambda(F^T F - L)$ , where  $\lambda$  is a Lagrange multiplier and where  $M$  is approximated by the rule  $M = H^T H - \lambda H$ .

#### 4) Eigenvalue-Eigenvector Computations

It is not always necessary to find all eigenvalues and eigenvectors of  $H$  to decide whether to begin the next phase of the computations uphill or downhill – particularly for problems with large  $n$ . Often it is sufficient to compute a subset of eigenvalues and eigenvectors, which can be conveniently performed using the inverse power method. The inverse power method solves the inverse form of

$$Hv - \lambda v = 0, \quad (15)$$

by constructing the iteration

$$v_{k+1} = \lambda_k H^{-1} v_k, \quad (16)$$

$$\lambda_{k+1} = \frac{v_{k+1}^T v_{k+1}}{v_{k+1}^T H^{-1} v_{k+1}}, \quad (17)$$

where the calculations alternate between Eqs. (16) and (17) until  $\|v_{k+1} - \lambda_k H^{-1} v_k\| < \varepsilon$ , where  $\varepsilon$  is some pre-specified tolerance. Note that an estimate of  $v$  is necessary to begin the inverse power method. Once the first eigenvalue, say  $\lambda_1$ , and its corresponding eigenvector,  $v_1$ , have been determined, the Hessian matrix is deflated using symmetric orthonormal projection to give an  $(n-1) \times (n-1)$  symmetric matrix whose basis spans the space orthogonal to  $v_1$ . The inverse power method is used to find the next eigenvalue,  $\lambda_2$ , and its associated eigenvector,  $v_2$ , and then  $v_2$  is lifted to  $R^n$ . This procedure of deflation by orthonormal projection to form an  $(n-j) \times (n-j)$  symmetric matrix whose

basis spans the space orthogonal to  $\{v_1, v_2, \dots, v_j\}$  followed by the inverse power method and the lifting of  $v_{j+1}$  to  $R^n$  is continued until as many eigenvalues and eigenvectors as desired are determined.

#### 5) Effective Bookkeeping

Another important aspect of global terrain methods is that it is possible to avoid calculating the same  $z_k^*$  more than once by effective bookkeeping. This is accomplished by storing solution information that includes the set of solutions, the solution types (i. e., minimum, saddle point, or singular point), corresponding values of  $\varphi$  and  $F^T F$ , and the current set of eigenconnections (i. e., the smallest positive eigenvalue and associated eigenvector for minima and saddles, and the largest negative eigenvalue and associated eigenvector for singular points). Following the determination of the first stationary or singular point,  $z_1^*$ , uphill movement proceeds in the  $+/-$  eigen-direction associated with the smallest positive eigenvalue of  $H$ . Assume that two new stationary or singular points,  $z_2^*$  and  $z_3^*$ , have been determined by these uphill calculations. The next move will be downhill from  $z_2^*$  in the eigen-directions,  $v_2$ , associated with the largest negative eigenvalue,  $\lambda_2$ , of  $H$  at  $z_2^*$ . However since  $z_2^*$  and  $z_3^*$  are connected by path to  $z_1^*$ , care must be exercised so as not follow the path back to  $z_1^*$ . To do this, nearest neighbors are determined by finding  $k$  such that

$$\|z_2^* - z_k^*\| \text{ is minimum for all } k \neq 2. \quad (18)$$

Let  $j$  be the index for which Eq. (18) is satisfied. Following this, the direction  $d_2 = z_2^* - z_j^*$  is defined. Correct downhill movement away from  $z_2^*$  is defined by whichever inequality

$$v_2^T d_2 < 0 \quad \text{or} \quad -v_2^T d_2 < 0, \quad (19)$$

is satisfied. Note that the selection of the proper condition in Eq. (19) guarantees that initial movement from  $z_2^*$  will be in the direction away from the nearest solution  $z_j^*$ . Equations (18) and (19) can be easily generalized to give

$$\|z_i^* - z_k^*\| \text{ is minimum for all } k \neq K, \quad (20)$$

$$v_i^T d_i < 0 \quad \text{or} \quad -v_i^T d_i < 0, \quad (21)$$

where  $d_2 = z_2^* - z_j^*$ ,  $j$  is the index that satisfies Eq. (20), and  $K$  is the current number of solutions.

## 6) Termination

Termination occurs when either the desired number of points  $\{z_k^*\}$  have been calculated or a certain number of bounds are encountered. The first termination criterion is straightforward. In the normal case, termination occurs when two bounds have been encountered. When bifurcations have been detected, then the number of bounds that must be encountered for termination to occur is  $n_b + 2$ , where  $n_b$  is the number of distinct bifurcations.

## 7) Advanced Techniques

For any global terrain method to be effective it must also to address issues such as parametric disconnectedness, integral path bifurcations, and non-differentiable points or manifolds.

### Parametric Disconnectedness

Following solutions parametrically is the basis for many homotopy-continuation methods. However, when parametric solutions exist on disconnected branches of solution curves, continuation methods can have difficulties. Global terrain methods are completely unaffected by parametric disconnectedness since they operate in variable and not parameter space.

### Non-differentiable Points and Manifolds

There are many engineering applications that exhibit non-differentiable points and/or manifolds as a consequence of inherent switching contained in the objective function. At the ‘switch’ points, non-differentiability can occur and there can be families of ‘switch’ points that form manifolds. Non-differentiable points or manifolds are easily detected because they often exhibit retrograde curvature as well as other qualitative changes in model behavior that can be readily monitored.

Figure 2 illustrates a case in which there is a non-differentiable manifold. In this figure,  $z_1 = C_{10}$ ,  $z_2 = C_{18}$ ,  $z_3 = C_{21}$ ,  $z_1 + z_2 + z_3 = 1$ , which is why the feasible region is triangular shaped, and  $0 \leq z_i \leq 1$ ,  $i = 1, 2, 3$ . This curved manifold of non-differentiable points denotes the boundary between qualitatively different types of behavior for the case where  $\phi = \min[\phi_1, \phi_2]$

at each  $z$  and is usually not mentioned in discussions of optimization of physical models. However, it is important in computations. The global terrain methodology has no difficulties finding stationary and singular points on  $F^T F$  in this case because it monitors all aspects of the  $\varphi$  thereby allowing switching take place on the fly and the correct stationary and singular points to be easily found.

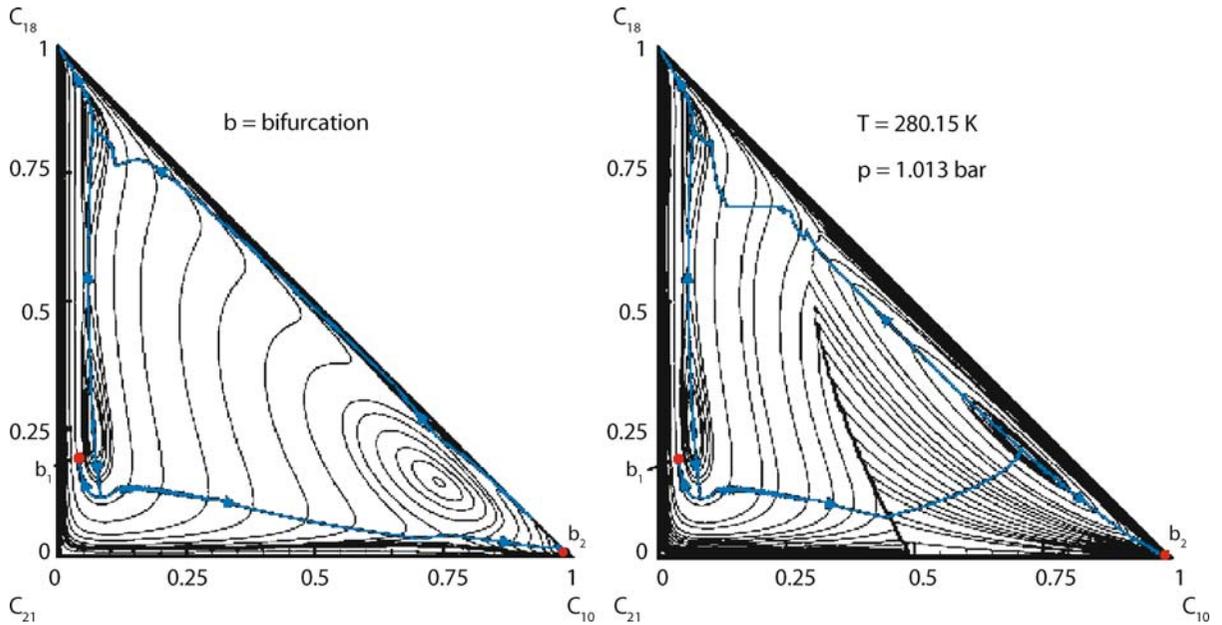

### Integral Path Bifurcations

There are many applications in which integral paths either split into two or become tangent to a contour. These occurrences are called integral path bifurcations and can significantly impact the reliability of global terrain methods. Fortunately, Gauss curvature can provide a deterministic measure of the presence of bifurcation points.

It is often easier to understand integral bifurcations from a geometrical perspective. Consider Fig. 3 where  $z_1 = C_{18}$ ,  $z_2 = C_{19}$ ,  $z_3 = C_{22}$ ,  $z_1 + z_2 + z_3 = 1$ , and  $0 \leq z_i \leq 1$ ,  $i = 1, 2, 3$ . Note that there is a pitchfork bifurcation at the point denoted by the point  $b$  on the integral path that runs from the two minima and the saddle point of  $F^T F$  in the center of the triangle toward the saddle point and minimum very close to the hypotenuse of the triangular region. If the integral path bifurcation at  $b$  goes undetected, then the saddle point and minimum closest to the hypotenuse will not be found because corrector iterations will force iterates to turn toward the left or right hand branches of the pitchfork that end at the corners of the hypotenuse. Note, however, that the level curves begin to flatten in the neighborhood of the bifurcation point as the path moves toward the hypotenuse. This flattening, together with an eigenvector exchange from  $J^T F$  to a vector in the tangent subspace of the level constraint, is a necessary condition for integral path *pitchfork* bifurcations, like the one that occurs at  $b$ . Moreover, flattening is relatively easy to measure by calculating (Gauss) curvature along a contour.

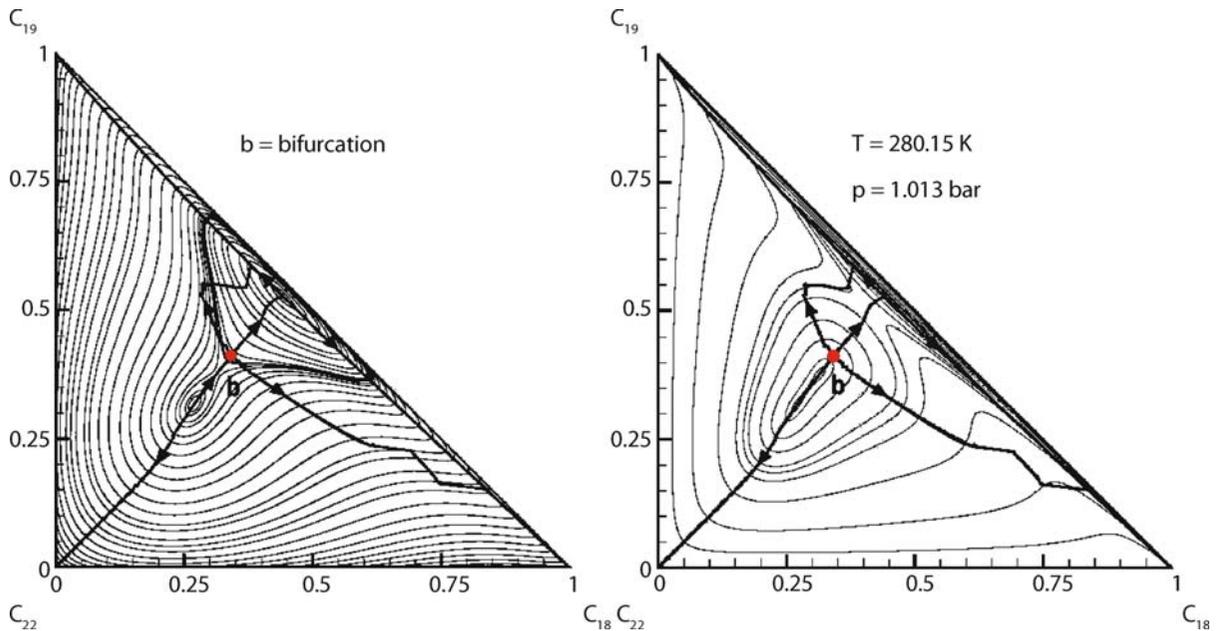

### Gauss Curvature

To measure Gauss or Gauss–Kronecker curvature, it is necessary to calculate eigenvalues of the Hessian matrix,  $H$ , projected onto the tangent subspace of the level constraint, which is orthogonal to the gradient at any

Global Terrain Methods, Figure 2

An Objective Function & Gradient Surface with a Non-Differentiable Manifold (left)  $b(F_1^T F_1)$ ; (right) a Composite  $F^T F$

Global Terrain Methods, Figure 3

Integral Path Bifurcation on Objective Function & Gradient Surfaces (left) Landscape of  $\varphi$ ; (right) Landscape of  $F^T F$

given point along the integral path. Gauss–Kronecker curvature corresponds to the determinant of this projected Hessian matrix. When the number of unknowns is two, this curvature is called Gauss curvature. De-

creasing Gauss or Gauss–Kronecker curvature in a particular part of the feasible region indicates that the level curves are flattening and provides a strong reason to check for an exchange in the ‘minimum’ eigenvector of

$H$  and, if warranted, to search for an integral path bifurcation.

Current implementation of these ideas measures flattening by calculating a few of the smallest eigenvalues (and eigenvectors) of the projection of  $H$  onto the tangent subspace *at each iteration* of the calculations. Without a theoretical basis that defines how often Gauss curvature should be measured, intermittent measurement seems ad hoc at best since very small regions of decreasing Gauss curvature could go undetected.

### Finding Integral Path Tangent Bifurcations

This type of bifurcation point can be detected by measuring Gauss curvature and by comparing vectors along the flow of an integral path and vectors in the tangent subspace of the level sets for points on the path. When Gauss curvature decreases and the flow of the integral path becomes collinear to the tangent subspace, a tangent bifurcation point has occurred. Generally, this shows up as a ‘jump’ in the path to a point a considerable distance away on a neighboring level curve. Between these two points the value of the constrained minimum defining the path is degenerate and  $H$  has repeated eigenvalues.

### Finding Integral Path Pitchfork Bifurcations

When flattening occurs but the flow of the integral path is not collinear to the tangent subspace of the level constraint, an eigenvalue exchange is sought. This exchange in the minimum eigenvalue of  $H$  from one associated with  $J^T F$  to one associated with the tangent subspace of a level curve is easily determined by monitoring the eigenvalue associated with the terrain path and the smallest eigenvalue of the matrix  $H$  projected onto the tangent subspace. Once an eigenvalue exchange is detected, the algorithm searches for a possible bifurcation point by locating a maximum in the norm of  $J^T F$  on the level curve, say  $L^*$ , where the eigenvalue exchange has been detected. This is because as contours flatten, the distance between these level curves becomes smaller and smaller, which is an indication that the nature of  $\|J^T F\|$  on  $L^*$  has changed from a constrained minimum to a constrained maximum. See the discussion in [7]. Therefore, an approximate bifurcation point

is calculated by solving the NLP problem

$$\max g^T g \text{ such that } F^T F = L^* . \quad (22)$$

Note that Eq. (22) is very similar to Eq. (11). Thus the numerical methodology needed to solve Eq. (22) already exists in the form of the corrector algorithm. However, it is important to note that predictor iterates rarely land exactly on the contour corresponding to a pitchfork bifurcation because finite step sizes are used in the predictor-corrector calculations. They generally land close and thus the solution to Eq. (22) is usually a very good approximation of the bifurcation point – since all that is really needed to follow all branches of a pitchfork bifurcation is knowledge at a point following the eigenvector exchange. Moreover, because contours in the neighborhood of a pitchfork bifurcation point can be very flat, solving Eq. (22) can be challenging in some cases. Extreme flatness creates numerical problems because it implies that the Kuhn–Tucker conditions for Eq. (22) have a near singular coefficient matrix. Therefore, good step size control should be used when solving Eq. (22).

### Finding All Branches Associated with a Bifurcation Point

Once a bifurcation point is located, all branches from the bifurcation must be followed in order to increase the probability of finding all relevant solution information. Locating these branches is reasonably straightforward. Tangent bifurcation points are characterized by collinearity and provide only a single branch for further exploration that, as noted, manifests itself by a ‘jump’ to a widely different point on a neighboring level curve. Pitchfork bifurcation points, on the other hand, provide three branches of further exploration defined by the gradient to the level curve  $L^*$ , and  $+/-$  the ‘minimum’ eigenvector of  $H$  projected onto the tangent subspace at the bifurcation on  $L^*$ . Each of these vectors is easily computed. The gradient vector at a bifurcation, which corresponds to the middle part of the pitchfork, is a readily available byproduct of the calculations. The ‘minimum’ eigenvector of  $H$  on the tangent subspace at  $L^*$  is also easily determined. What is difficult is locating the valleys that correspond to the pair of minima of  $g^T g$  on  $L^*$ . For this a careful initialization of our corrector algorithm is required to solve Eq. (11) with  $L = L^*$ .

## Cases

There are several problem cases that are encompassed by the global terrain-following formulations and methods presented in earlier sections. These cases include

- 1) Nonlinear objective functions with simple bounds on variables.
- 2) Systems of nonlinear algebraic equations.
- 3) Nonlinear objective functions with simple bounds and linear constraints.

### 1) Nonlinear Objective Functions with Simple Bounds

This is the case on which the developments in the formulation and methods sections are based and no further discussion is necessary.

### 2) Systems of Nonlinear Algebraic Equations

For a system of algebraic equations,  $F = 0$  is usually given and  $\varphi$  is irrelevant. The function of interest becomes the traditional nonlinear least squares function,  $F^T F$ , and the terrain methodology follows the strategies outlined in previous sections.

### 3) Nonlinear Objective Functions with Simple Bounds and Linear Constraints

Nonlinear programming problems that involve linear equality constraints are easily handled by global terrain methods by using the linear constraints to eliminate optimization variables. For  $m$  linear constraints,  $m$  optimization variables can be eliminated. However, it is important to understand that the gradient and Hessian matrix of  $\varphi$  must be adjusted to accommodate this variable elimination. This can be done by either using projection methods or by explicitly doing the elimination before formulating the optimization problem to be solved by the terrain methodology.

If projection is used then  $F$  is replaced by  $P^T F$ , where  $P$  is the  $n \times m$  orthonormal projection matrix whose columns are orthogonal to all rows of the Jacobian matrix of the linear constraints. That is, if  $J_{LEQ}$  is the  $m \times n$  Jacobian of the  $m$  linear equality constraints, then the projection matrix  $P$  satisfies  $J_{LEQ} P = 0$ . Additionally, the Hessian matrix of  $\phi$ ,  $J$ , must reflect implicit elimination and is easily computed to be  $P^T J P$ . These projections of  $F$  and  $J$  permit the use of the terrain

methodology in  $R^{n-m}$  while still allowing any bounds on all variables to be enforced.

Graph; Coloring; Optimization; Approximation; Algorithms

A graph  $G = (V, E)$  consists of a *vertex set*  $V$  and an *edge set*  $E \subseteq V \times V$ . If  $e = (i, j) (\in E)$  is an edge of  $G$ , then  $e$  is *incident* to  $i$  and  $j$ , and  $i$  and  $j$  are *adjacent*. Similarly, if two edges are incident to the same vertex, they are adjacent.

A vertex coloring of  $G = (V, E)$  is an assignment of  $k$  colors to members of  $V$  (a *coloring*) so that adjacent vertices have different colors ( $G$  is  $k$ -colorable). The *graph coloring problem* (GC) is to find the minimum number  $k$  such that  $G$  is  $k$ -colorable.

When a positive integer weight  $w_i$  is associated with every  $i \in V$  and a color assignment satisfies:

- every vertex  $i$  gets  $w_i$  different colors,
  - $\forall (i, j) \in E, i$  and  $j$  get  $w_i + w_j$  different colors,
- then this color assignment is a *weighted coloring*. The *weighted graph coloring problem* asks for the minimum number of colors needed for a weighted coloring of  $G$ .

An *edge coloring* and a *total coloring* of a given graph can be defined in a similar way:

- An edge coloring assigns colors to edges so that adjacent edges have different colors.
- A total coloring assigns colors to vertices and edges so that any pair of adjacent vertices, adjacent edges, and a vertex and any incident edge will have different colors.

The *edge coloring problem* or the *total coloring problem* asks for the minimum number of colors needed for an edge coloring or a total coloring, respectively [12,28,30]. Although the weighted graph coloring, edge coloring, and total coloring problems seem different from GC, they can be transformed into a GC [33,42]. Further generalizations of GC tend to change the structure of a coloring solution, and they move closer to other well-known combinatorial optimization problems [16,37].

GC is well-known in graph theory and combinatorial optimization. It starts with the famous four-coloring conjecture [24,38] which says four colors are enough to color any geographic map so that every country gets a color different from those used by its neighbors. Although the four-coloring conjecture is now considered a theorem [1,2], the process to prove or disprove it has inspired many interesting questions [32], and has helped the development of several branches of science, for example, the GC and the graph theory [27]. The interest in GC also comes from its vast number of applications in solving real world problems. For example, GC can be used to model problems in timetabling, scheduling, computer science, information systems, telecommunications, and other industrial applications [9,11,39]. Typically, a graph is constructed with its vertices representing items of interest

and edges representing some undesirable binary relationship.

GC has several mathematical programming formulations. For example, one can use an integer variable  $x_{ik} = 1$  to indicate when a vertex  $i$  is colored by  $k$ , and  $x_{ik} = 0$  otherwise. One can also use an integer variable  $y_k = 1$  to indicate color  $k$  is assigned to at least one vertex of  $G$ , and  $y_k = 0$  otherwise. Then, the solution to the following mathematical programming problem provides an optimal (minimum) coloring of  $G$ :

$$\left\{ \begin{array}{l} \min \quad \sum_{k=1}^{|V|} y_k \\ \text{s.t.} \quad \sum_{k=1}^{|V|} x_{ik} = 1, \quad \forall i \in V, \\ x_{ik} + x_{jk} \leq 1, \quad \forall (i, j) \in E, \\ y_k \geq x_{ik}, \quad y_k, x_{ik} \in \{0, 1\}, \\ \forall i \in V, k = 1, \dots, |V|, \end{array} \right.$$

where  $|V|$  is the cardinality of the set  $V$ . In this problem, the objective function equals the number of colors used. The constraints ensure that every vertex is colored, that no adjacent vertices get the same color, and that the counting of used colors is correct.

For a feasible coloring, one can group the vertices into subsets based on their colors. Thus, vertices of each subset will be mutually nonadjacent. Such a subset of vertices is called a *stable set*, a *color class*, or an *independent set* [5,8,35,41]. Using the concept of a stable set, one can formulate GC as a set partitioning problem.

Let  $S_1, \dots, S_t$  be all the stable sets of  $G$ . Let  $A_S$  be a  $0-1$  matrix whose rows are the characteristic vectors of the  $S_j$ s. One can use a variable  $s_j = 1$  to indicate that all members of  $S_j$  have the same color, and  $s_j = 0$  otherwise. Then the solution to the following problem also provides an optimal (minimum) coloring of  $G$ :

$$\left\{ \begin{array}{l} \min \quad \sum_{j=1}^t s_j \\ \text{s.t.} \quad s A_S = \vec{1}, \\ s_j \in \{0, 1\}, \quad j = 1, \dots, t, \end{array} \right.$$

where  $s = (s_1, \dots, s_t)$ , and  $\vec{1} = (1, \dots, 1)$  is of dimension  $|V|$ .

Other mathematical formulations of GC based on quadratic programming, semidefinite programming etc. are also available. Different formulations have their own distinctive advantages in understanding the problem structure and in designing solution methods to solve the problem [22,33,34].

Checking whether  $G$  is  $k$ -colorable for an arbitrary integer  $k$  is an  $NP$ -complete problem [14,23]. It remains  $NP$ -complete even for fixed  $k \geq 3$  [14,40]. Therefore, it is unlikely that the solution time of GC can be bounded by any polynomial function (*polynomial time*) [13]. However, GC can be solved in polynomial time for graphs of some special structures. For example, polynomial algorithms exist for perfect graphs, Meyniel graphs, and triangulated graphs [3,4,15,17,19,41].

Let us define the *performance guarantee* of an approximation method to be the worst ratio between the approximation solution value and the corresponding optimal solution value over all graphs of size  $|V|$ . Then,  $O(|V| \log |V|)$  seems to be the first performance guarantee provided by a polynomial time GC heuristic [20]. This performance guarantee has been improved over the years. Let  $k$  be the optimal (minimum) number of colors needed to color a graph, and let  $\Delta$  be the *maximum degree* (number of edges incident to a vertex) among all vertices. The two recent performance guarantees achieved by polynomial approximation algorithms for GC are  $O(|V|(\log \log |V|)^2 / (\log |V|)^3)$  and  $\min\{O(\Delta^{1-2/k}), O(|V|^{1-3/(k+1)})\}$  [18,22]. On the other hand, it is known that unless  $P = NP$ , it is  $NP$ -hard to approximate an optimal graph coloring within a performance guarantee of  $O(|V|^\epsilon)$ ,  $\epsilon > 0$  [14,15].

Available solution methods for GC can be divided into approximation algorithms and exact algorithms. These methods find a feasible graph coloring and an optimal graph coloring, respectively [29].

A popular way to find an approximation solution to GC is the *sequential greedy coloring heuristic* (SGCH). In a SGCH, the vertices are ordered in a sequence and are colored one at a time according to the sequence. Every vertex is colored by the smallest (first) feasible color. It is not hard to see that the initial vertex sequence decides the resulting graph coloring of a SGCH.

It is also known that there exists at least one sequence under which a SGCH will find an optimal coloring. However, finding an optimal vertex sequence is

$NP$ -hard. Extensive work aimed at finding ‘good’ vertex sequences can be found in the literature [10,32]. Once a feasible coloring is available, further improvement can be made using various methods, including: interchange, iterative improvement, and other searching techniques (such as simulated annealing and tabu search) [36].

To date, the most popular and efficient way to find an optimal solution to GC is through a *branch and bound* (BB), or *implicit enumeration*, algorithm. A BB algorithm typically consists of two parts: the *forward phases* and the *backtrack phases*. A forward phase starts from a partial coloring (e.g.  $\emptyset$ ) and colors the remaining vertices to find a feasible graph coloring. For example, a SGCH can be used in place of a forward phase. A backtrack phase will decide the starting point of the next forward phase so that an alternative feasible graph coloring can be found.

Now let us consider how a simple BB algorithm [7] finds an optimal coloring of  $G = (V, E)$ . Let  $UB$  be the value of a current best coloring (initially set  $UB = \infty$ ). Suppose the first forward phase applies a SGCH to vertex sequence  $(v_1, \dots, v_{|V|})$  and finds a feasible coloring of  $G$ . The number of colors used by the feasible coloring will be the new  $UB$ . Apparently,  $UB$  is an upper bound on the value of any feasible coloring that one needs to search for.

Since SGCH assigns the smallest feasible color to every vertex, a backtrack phase can be carried out by scanning the vertices in the reverse order of  $(v_1, \dots, v_{|V|})$ . That is, finding the first vertex  $v_j$  that can be recolored by an alternative feasible color  $< UB$ , not used for  $v_j$  before. The new forward phase will start from the partial coloring of  $\{v_1, \dots, v_{j-1}\}$  and applies a SGCH to  $(v_j, \dots, v_{|V|})$ , up to a  $v_i$  whose smallest feasible color is  $UB$ , or to  $v_{|V|}$  that has a feasible color  $< UB$ . In the latter case, a better coloring is found. Then the BB algorithm will backtrack and repeat the above until it backtracks to vertex  $v_1$  (the algorithm terminates).

Various improvement measurements are designed and tested for the above basic BB method. They include ‘look ahead’, ‘dynamic reordering’, choosing an appropriate feasible color (instead of the ‘smallest’) to color a vertex, using tighter lower and upper bounds, and a column generation approach [6,21,26,31,33]. These improvements have greatly reduced the search tree size and enhanced our ability to solve GC optimally. The

state-of-the-art method for solving GC on randomly generated graphs seems to be limited to graphs of 100 vertices [21,31,42,43].

Planarization; Graph; Planar graph; Heuristics; Exact algorithms

A graph is said to be *planar* if it can be drawn on the plane in such a way that no two of its edges cross. Given

a graph  $G = (V, E)$  with vertex set  $V$  and edge set  $E$ , the objective of *graph planarization* is to find a minimum cardinality subset of edges  $F \subseteq E$  such that the graph  $G' = (V, E \setminus F)$ , resulting from the removal of the edges in  $F$  from  $G$ , is planar. This problem is also known as the *maximum planar subgraph* problem. A related and simpler problem is that of finding a *maximal planar subgraph*, which is a planar subgraph  $G' = (V, E')$  of  $G$  such that the addition of any edge  $e \in E \setminus E'$  to  $G'$  destroys its planarity.

Graph planarization is known to be *NP*-hard [21]. The proof of *NP*-completeness of its decision version is based on a transformation from the Hamiltonian path problem restricted to bipartite graphs. Although exact methods for solving the maximum planar subgraph problem have been recently proposed, most algorithms to date attempt to find good approximate solutions.

In this article, we survey graph planarization and related problems. In the next section, we describe variants and applications of the basic problem formulated above. Next, we describe the branch and cut algorithm of M. Jünger and P. Mutzel [16]. We then review work on heuristics based on planarity testing and those based on two-phase procedures. Finally, computational results are considered.

## Variants and Applications

An application of graph planarization arises in the design of integrated circuits, in which a graph describing the circuit has to be decomposed into a minimum number of layers, each of which is a planar graph [19]. Other applications arise from variants of the basic graph planarization problem.

One such variant is the *maximum weighted planar graph* problem, in which positive weights are associated with the edges of the graph and one seeks a planar subgraph of maximum weight. Note that the basic graph planarization problem is a special case of the maximum weighted planar graph problem, in which all edge weights are equal to one. An application of this problem to *facility layout* is described in [13]. A graph is built in which the vertices represent the facilities and the edges define the relationships between them. The weight of each edge is the desirability that the two facilities that define the edge be adjacent in the design. A maximum weighted planar subgraph corresponds to

a feasible layout with maximum benefit. In this paper, the authors also propose simulated annealing and tabu search heuristics for the approximate solution of the maximum weighted planar graph problem. Constructive heuristics based on maintaining a triangulated subgraph while making node and edge insertions are given in [8,11], and [20].

Another related variant is that of drawing a given graph such that the number of *edge crossings* is minimized. The *crossing number* problem has practical applications in *circuit design* and graph drawing, such as in CASE tools [27] and automated graphical display systems. One particular case is that of minimizing straight-line crossings in layered graphs. A GRASP and path relinking approach for the two-layer case is given in [17], where one can also find a survey of the literature. Algorithms for graph drawing are reviewed in [6].

In the *planar augmentation* problem, one wants to determine the minimum number of edges that need to be added to a planar graph such that the resulting graph is still planar and at least  $k$ -connected, where  $k$  is usually fixed to two or three. This variant has applications in automatic *graph drawing*, as well as in the design of *survivable networks* [24].

## An Exact Algorithm

An exact branch and bound algorithm for the weighted graph planarization problem was introduced in [10], but was limited to small dense graphs. Only recently (1999) has there been a leap in the performance of exact methods for graph planarization with the *Jünger–Mutzel branch and cut algorithm* [16], which we describe next.

Given a graph  $G = (V, E)$ , their approach uses facet-defining inequalities for the planar subgraph polytope  $\mathcal{PLS}(G)$ . Let  $x_e$  be a 0–1 variable associated with each edge  $e \in E$ , such that  $x_e = 1$  if and only if edge  $e$  appears in the maximum planar subgraph of  $G$ . Furthermore, let  $x(F) = \sum_{e \in F} x_e$ , for  $F \subseteq E$ .

Trivial inequalities  $0 \leq x_e \leq 1$  are implicitly handled by the linear programming (LP) solver. The inequality  $x(E) \leq 3|V| - 6$  is added to the initial linear program. Let  $x$  be the optimal solution of the LP relaxation associated with some node of the enumeration tree. For  $0 \leq \epsilon \leq 1$ , let  $E_\epsilon = \{e \in E \mid x_e \geq 1 - \epsilon\}$  and consider the graph  $G_\epsilon = (V, E_\epsilon)$ , to which the

*Hopcroft–Tarjan planarity-testing algorithm* [14] is applied. The algorithm stops if it finds an edge set  $F$  which induces a nonplanar graph in  $G$ . If the inequality  $x(F) \leq |F| - 1$  is violated, it is added to the set of constraints of the current LP. The back edge of the path which proved the nonplanarity of the graph induced in  $G$  by  $F$  is removed and the planarity-testing algorithm proceeds, eventually identifying other forbidden subgraphs of the graph  $G_\epsilon$ . Although these forbidden subgraphs do not necessarily define facets of  $\mathcal{PLS}(G)$ , they must contain facet-defining subgraphs. Facet-defining inequalities are identified as follows. Once a forbidden set  $F$  is found, where the inequality  $x(F) \leq |F| - 1$  is violated, one successively deletes each edge  $f \in F$  and applies the planarity-testing algorithm. If the graph induced by  $F \setminus \{f\}$  is planar, then edge  $f$  is returned to  $F$ . In at most  $|F|$  steps,  $F$  is reduced to a smaller edge set which induces a minimal planar subgraph, leading to the facet-defining inequality  $x(F) \leq |F| - 1$  still violated by the current LP solution. Another simple heuristic searches for violated Euler facet-defining inequalities  $x(F) \leq 3|V'| - 6$  or  $x(F) \leq 2|V'| - 4$ , where  $(V', F)$  is, respectively, a clique or a complete bipartite subgraph of  $G$ .

After an LP has been solved, its solution is exploited by the planarity-testing algorithm, to produce a feasible solution for the graph planarization problem. Such feasible solutions are used as lower bounds that are used not only for fathoming nodes in the branch and cut tree, but also for fixing variables using their reduced costs during a cutting plane phase. Other heuristics are implemented to enhance the practical performance of the algorithm.

Branching is done if no cutting plane has been found for the current infeasible solution. The variable chosen for branching is one with fractional value closest to  $1/2$ , among those with maximum cost coefficient in the objective function.

### Heuristics Based on Planarity Testing

The first linear time algorithm for planarity testing was proposed by J. Hopcroft and R.E. Tarjan [14]. T. Chiba, I. Nishioka and I. Shirakawa [4] used the basic ideas of this approach to devise an algorithm for finding a maximal planar subgraph of  $G = (V, E)$  with time complexity  $O(|V||E|)$ . Later, J. Cai, X. Han and Tarjan [3]

proposed another version of the above planarity testing algorithm. This new algorithm is based on processing edges instead of paths. It leads to another algorithm to find a maximal planar subgraph, with improved  $O(|E| \log |V|)$  time complexity.

A. Lempel, S. Even and I. Cederbaum [18] have proposed another approach to planarity testing. Although its original complexity was  $O(|V|^2)$ , K. Booth and G. Lueker [2] have shown that it can be implemented in linear time using PQ-trees. A few algorithms for finding a maximal planar subgraph based on this planarity testing approach have been proposed in the literature. However, Jünger, S. Leipert and Mutzel [15] show that attempts following this strategy are forced to fail.

Another approach for finding a maximal planar subgraph of a given graph works as follows. Start with an empty subgraph and successively add the edges of the original graph, whenever such addition maintains the planarity of the subgraph under construction. Using any of the planarity testing algorithms above described, such approach can be implemented in  $O(|V||E|)$  time complexity. An incremental planarity testing algorithm, based on an  $O(\log |V|)$  time-per-operation strategy for the problem of maintaining a planar graph under edge additions, was proposed by G. Di Battista and R. Tamassia [7]. Hence, their algorithm leads to a more efficient implementation of the incremental approach for finding a maximal planar subgraph with  $O(|E| \log |V|)$  time complexity.

### Two-Phase Heuristics

The heuristics described in this section are based on the separation of the computation into two phases. The first phase consists in devising a linear permutation of the nodes of the input graph, followed by placing them along a line. The second phase determines two sets of edges that may be represented without crossings above and below that line, respectively. Y. Takefuji and K.C. Lee [25] were the first to propose a heuristic using this idea. They use an arbitrary sequence of nodes in the first phase and apply a parallel heuristic using a neural network for the second phase. Takefuji, Lee, and Y.B. Cho [26] claimed superior performance of the two-phase approach of Takefuji and Lee [25] with respect to the heuristics described in the previous section.

Their approach was later extended and improved by O. Goldschmidt and A. Takvorian [12]. In the first phase, these authors attempt to use a linear permutation of the nodes associated with an Hamiltonian cycle of  $G$ . Two strategies are used:

- i) a randomized algorithm [1] that almost certainly finds a Hamiltonian cycle if one exists; and
- ii) a greedy deterministic algorithm that seeks a Hamiltonian cycle.

In the latter, the first node in the linear permutation is a minimum degree node in  $G$ . After the first  $k$  nodes of the permutation have been determined, say  $v_1, \dots, v_k$ , the next node  $v_{k+1}$  is selected from the nodes adjacent to  $v_k$  in  $G$  having the least adjacencies in the subgraph  $G_k$  of  $G$  induced by  $V \setminus \{v_1, \dots, v_k\}$ . If there is no node of  $G_k$  adjacent to  $v_k$  in  $G$ , then  $v_{k+1}$  is selected as a minimum degree node in  $G_k$ .

Let  $H = (E, I)$  be a graph where each of its nodes corresponds to an edge of the input graph  $G$ . Nodes  $e_1$  and  $e_2$  of  $H$  are connected by an edge if the corresponding edges of  $G$  cross with respect to the linear permutation of the nodes established during the first phase. A graph is called an *overlap graph* if its nodes can be placed in one-to-one correspondence with a family of intervals on a line. Two intervals are said to *overlap* if they cross and none is contained in the other. Two nodes of the overlap graph are connected by an edge if and only if their corresponding intervals overlap. Hence, the graph  $H$  as constructed above is the overlap graph associated with the representation of  $G$  defined by the linear permutation of its nodes.

The second phase of the heuristic of Goldschmidt and Takvorian consists in two-coloring a maximum number of the nodes of the overlap graph  $H$ , such that each of the two color classes  $\mathcal{B}$  (blue) and  $\mathcal{R}$  (red) forms an independent set. Equivalently, the second phase seeks a *maximum bipartite subgraph* of the overlap graph  $H$ , i. e. a bipartite subgraph having the largest number of nodes. This problem is equivalent to drawing the edges of the input graph  $G$  above or below the line where its nodes have been placed, according to their linear permutation. A greedy algorithm is used to construct a maximal bipartite subgraph of the overlap graph. This algorithm finds a maximum independent set  $\mathcal{B} \subseteq E$  of the overlap graph  $H = (E, I)$ , reduces the overlap graph by removing from it the nodes in  $\mathcal{B}$  and all edges incident to nodes in  $\mathcal{B}$ , and then finds

a maximum independent set  $\mathcal{R} \subseteq E \setminus \mathcal{B}$  in the remaining overlap graph  $H' = (E \setminus \mathcal{B}, I')$ . The two independent sets so obtained induce a bipartite subgraph of the original overlap graph, not necessarily with a maximum number of nodes.

The linear permutation obtained in the first phase affects the size of the planar subgraph found in the second phase of the above heuristic. Moreover, it is not clear that the permutation produced by the greedy algorithm is the best. To produce possibly better permutations, *randomization* and *local search* have been introduced in the *greedy algorithm* by M.G.C. Resende and C.C. Ribeiro [22] in the form of a *greedy randomized adaptive search procedure* (GRASP).

A GRASP [9] is an iterative process, in which each iteration consists of two phases: construction and local search. The construction phase builds a feasible solution, whose neighborhood is explored by local search. The best solution over all GRASP iterations is returned as the result.

In the construction phase, a feasible solution is built, one element at a time. At each construction iteration, the next element to be added is determined by ordering all elements in a candidate list with respect to a greedy function that estimates the benefit of selecting each element. The adaptive component of the heuristic arises from the fact that the benefits associated with every element are updated at each iteration of the construction phase to reflect the changes brought on by the selection of the previous elements. The probabilistic component of a GRASP is characterized by randomly choosing one of the best candidates in the list, but usually not the top candidate. This way of making the choice allows for different solutions to be obtained at each iteration, but does not necessarily jeopardize the power of GRASP's adaptive greedy component.

The solutions generated by a GRASP construction are not guaranteed to be locally optimal, even with respect to simple neighborhood definitions. Hence, it is almost always beneficial to apply a local search to attempt to improve each constructed solution. A local search algorithm works in an iterative fashion by successively replacing the current solution by a better solution from its neighborhood.

Resende and Ribeiro [22] proposed an extension of the above described heuristic of Goldschmidt and Takvorian, in which a GRASP is used for finding

a linear permutation of the nodes. In the construction phase of this GRASP, the greedy algorithm used in the first phase by Goldschmidt and Takvorian is randomized: instead of selecting the node of minimum degree among those yet unselected, the selection is made from a set of low degree nodes. The local search phase of this GRASP explores the neighborhood of the current permutation by swapping the positions of two nodes at a time, attempting to reduce the number of possible edge crossings.

Incorporating the second phase of the Goldschmidt–Takvorian heuristic to the above GRASP for finding a linear permutation of the nodes results in a GRASP for graph planarization.

Each iteration of this GRASP produces three edge sets:  $\mathcal{B}$  (blue edges),  $\mathcal{R}$  (red edges), and  $\mathcal{P}$  (the remaining edges, which are referred to as the *pale edges*). By construction,  $\mathcal{B}$ ,  $\mathcal{R}$ , and  $\mathcal{P}$  are such that no red or pale edge can be colored blue. Likewise, pale edges cannot be colored red. However, if there exists a pale edge  $p \in \mathcal{P}$  such that all blue edges that cross with  $p$  (let  $\widehat{\mathcal{B}}_p \subseteq \mathcal{B}$  be the set of those blue edges) do not cross with any red edge  $r \in \mathcal{R}$ , then all blue edges  $b \in \widehat{\mathcal{B}}_p$  can be colored red and  $p$  can be colored blue. In case this reassignment of colors is possible, then the size of the planar subgraph is increased by one edge. This post-optimization procedure is incorporated at the end of each GRASP iteration.

### Computational Results

Detailed results on a set of 75 test problems described in the literature [5,12] are reported in [22]. The description of the code used can be found in [23]. Here, we summarize computational results illustrating the effectiveness of the two-phase heuristics described in the previous section, as well as that of the exact branch and cut algorithm. These results are based on a Fortran implementation of the GRASP heuristic of Resende and Ribeiro [22], on the original code of the branch and cut algorithm of Jünger and Mutzel [16], and on published results for the heuristics of Takefuji and Lee [25] and Goldschmidt and Takvorian [22] (using the greedy algorithm for building the linear permutation of the nodes).

We give, in the table below, results comparing the four approaches on a subset of the test problems de-

scribed in [12]. For each instance, the table lists the number of nodes, the number of edges, and the size of the planar subgraphs produced by each algorithm. A time limit of 1000 seconds (on a SUN SPARCstation 10/41) was imposed on the runs of the branch and cut algorithm and the best solution found was returned as a heuristic solution when optimality was not attained in that time limit. This time limit was reached on instances G12–G19.

The results in this table show that the Goldschmidt–Takvorian algorithm is a substantial improvement over the neural network approach of Takefuji and Lee. The GRASP consistently outperforms both other two-phase heuristics, not only for the problems reported in this table, but also for all of the remaining instances considered in [22].

Problem	Nodes	Edges	T-L	G-T	R-R	J-M
G1	10	22	20	20	20	20
G2	45	85	80	80	82	82
G3	10	24	21	21	24	24
G4	10	25	22	21	24	24
G5	10	26	22	21	24	24
G6	10	27	22	21	24	24
G7	10	34	23	22	24	24
G8	25	69	58	60	69	69
G9	25	70	59	60	69	69
G10	25	71	58	59	69	69
G11	25	72	60	59	69	69
G12	25	90	61	62	67	68
G13	50	367	70	131	135	125
G14	50	491	100	136	143	133
G15	50	582	101	142	144	138
G16	100	451	92	180	196	187
G17	100	742	116	219	236	213
G18	100	922	115	237	246	223
G19	150	1064	127	297	311	290

A comparison of GRASP with the branch and cut algorithm depends heavily on the instances. The results reported in [22] can be separated into two groups. On 49 of the 55 instances in the first group, the GRASP either matched or produced better solutions than the branch and cut algorithm. On 30 of those 55 instances, the GRASP solution was strictly better than the branch and cut solution. Note that, on these instances, the branch and cut algorithm was forced to stop because

of the 1000 second time limit. However, on all the remaining 20 instances, the branch and cut algorithm performs remarkably well and outperforms all other algorithms.

## Introduction

Due to its fundamental nature and versatile modelling power, the *Graph Realization Problem* is one of the most well-studied problems in distance geometry and has received attention in many communities. In that problem, one is given a graph  $G = (V, E)$  and a set of non-negative edge weights  $\{d_{ij} : (i, j) \in E\}$ , and the goal is to compute a *realization* of  $G$  in the Euclidean space  $\mathbb{R}^k$  for a given dimension  $k \geq 1$ , i. e. to place the vertices of  $G$  in  $\mathbb{R}^k$  such that the Euclidean distance between every pair of adjacent vertices  $v_i, v_j$  is equal to the prescribed weight  $d_{ij}$ . The Graph Realization Problem and its variants arise from applications in very diverse areas, the two most prominent of which being molecular conformation (see, e. g., [13,15,16,19,32]) and wireless sensor network localization (see, e. g., [2,8,14,22,24]). In molecular conformation, one is interested in determining the spatial structure of a molecule from a set of geometric constraints; in wireless sensor network localization, one is interested in inferring the locations of sensor nodes in a sensor network from connectivity-imposed proximity constraints. Thus, in these contexts, an algorithm that finds a realization of the vertices in the required dimension will have interesting biochemical and engineering consequences. Unfortunately, unless  $P = NP$ , there is no efficient algorithm for solving the Graph Realization Problem for any fixed  $k \geq 1$  ([23]; see also [3,4]). Nevertheless, many heuristics have been developed for the problem over the years, and various approaches have been taken to improve their efficiency (see, e. g., [1,2,13,14,15,18,20]). However, these approaches have their limitations. Specifically, either they solve the original problem only for a very restricted family of instances, or it is not clear when the algorithm would solve the original problem. Thus, an interesting question arises: given a relaxation of the Graph Realization Problem, can one derive reasonably general conditions under which the relaxation is *exact*?

We begin by examining a semidefinite programming (SDP) relaxation proposed by [10] in Section Formulation. We introduce the notion of unique  $k$ -realizability and show that the SDP relaxation is exact if and only if the input instance is uniquely  $k$ -realizable, where  $k$  is the given dimension. The notion of unique  $k$ -realizability is attractive, as it has a straightforward geometric interpretation and is also very suitable for the algorithmic treatment of the Graph Realization Problem.

Although we have formulated the Graph Realization Problem as a feasibility problem, it is clear that one can also formulate various optimization versions of it. One particularly useful objective is to maximize the sum of the distances between certain pairs of non-adjacent vertices. Such an objective essentially stretches apart pairs of non-adjacent vertices, and is more likely to flatten a high-dimensional realization into a lower dimensional one. Indeed, such a device has been proven to be very useful for finding low-dimensional realizations both in theory (see, e. g., [6,7]) and in practice (see, e. g., [9,29,30]). In Section Applications, we show how these ideas can be incorporated into the SDP model and demonstrate a connection between SDP theory and tensegrity theory in discrete geometry.

## Formulation

We begin by introducing the semidefinite programming (SDP) relaxation proposed by [10]. Let  $G = (V, E)$  be a graph, and let  $k \geq 1$  be an integer. Let  $V_1 = \{1, \dots, n\}$  and  $V_2 = \{n+1, \dots, n+m\}$  be a partition of  $V$ . The vertices in  $V_1$  (resp.  $V_2$ ) are said to be *unpinned* (resp. *pinned*). Specifically, let  $\mathbf{a} = (a_i)_{i \in V_2}$  be given, where  $a_i \in \mathbb{R}^k$  for all  $i \in V_2$ . Then, the vertex  $i \in V_2$  is constrained to be at  $a_i$ , while there are no such restrictions on the vertices in  $V_1$ . For our purposes, we may assume that  $V_2 \neq \emptyset$ , since we can always pin one vertex at the origin. We may also assume that  $E' = \{(i, j) : i, j \in V_2\} \subset E$ , since the distance between any two pinned vertices is trivially known. Now, let  $E_1 = \{(i, j) \in E : i, j \in V_1\}$  be the set of edges between two unpinned vertices, and let  $E_2 = \{(i, j) \in E : i \in V_2, j \in V_1\}$  be the set of edges between a pinned and an unpinned vertex. Let  $\mathbf{d} = (d_{ij}^2)_{(i,j) \in E_1}$  (resp.  $\bar{\mathbf{d}} = (\bar{d}_{ij}^2)_{(i,j) \in E_2}$ ) be a set of weights on the edges in  $E_1$  (resp.  $E_2$ ). We are then in-

interested in finding vectors  $x_1, \dots, x_n \in \mathbb{R}^k$  such that:

$$\begin{aligned} \|x_i - x_j\|^2 &= d_{ij}^2 && \text{for } (i, j) \in E_1 \\ \|a_i - x_j\|^2 &= \bar{d}_{ij}^2 && \text{for } (i, j) \in E_2 \end{aligned} \tag{1}$$

Here,  $\|\cdot\|$  is the Euclidean norm, i.e.  $\|x\| = (\sum_{i=1}^k x_i^2)^{1/2}$  for  $x \in \mathbb{R}^k$ . We say that  $\mathbf{p} = (p_1, \dots, p_n) \in \mathbb{R}^{kn}$  is a realization of  $(G, (\mathbf{d}, \bar{\mathbf{d}}), \mathbf{a})$  in  $\mathbb{R}^k$  if it satisfies (1). One may obtain a semidefinite relaxation of (1) as follows. Let  $X = [x_1 \ x_2 \ \dots \ x_n]$  be the  $k \times n$  matrix that needs to be determined. Then, for all  $(i, j) \in E_1$ , we have:

$$\begin{aligned} \|x_i - x_j\|^2 &= (e_i - e_j)^T X^T X (e_i - e_j) \\ &= (e_i - e_j)(e_i - e_j)^T \bullet (X^T X) \end{aligned}$$

and for all  $(i, j) \in E_2$ , we have:

$$\begin{aligned} \|a_i - x_j\|^2 &= \begin{pmatrix} a_i \\ -e_j \end{pmatrix}^T [I_k \ X]^T [I_k \ X] \begin{pmatrix} a_i \\ -e_j \end{pmatrix} = \\ &= \begin{pmatrix} a_i \\ -e_j \end{pmatrix} \begin{pmatrix} a_i \\ -e_j \end{pmatrix}^T \bullet \begin{bmatrix} I_k & X \\ X^T & X^T X \end{bmatrix} \end{aligned}$$

Here,  $e_i$  is the  $i$ th standard basis vector of  $\mathbb{R}^n$ ,  $I_k$  is the  $k$ -dimensional identity matrix, and  $\bullet$  is the Frobenius inner product on the space of symmetric matrices, i.e.  $A \bullet B = \text{tr}(A^T B) = \sum_{i,j=1}^n a_{ij} b_{ij}$  for symmetric  $n \times n$  matrices  $A$  and  $B$ . Thus, problem (1) becomes that of finding a symmetric matrix  $Y \in \mathbb{R}^{n \times n}$  and a matrix  $X \in \mathbb{R}^{k \times n}$  that satisfy the following system:

$$\begin{aligned} (e_i - e_j)(e_i - e_j)^T \bullet Y &= d_{ij}^2 \\ &\text{for } (i, j) \in E_1 \\ \begin{pmatrix} a_i \\ -e_j \end{pmatrix} \begin{pmatrix} a_i \\ -e_j \end{pmatrix}^T \bullet \begin{bmatrix} I_k & X \\ X^T & Y \end{bmatrix} &= \bar{d}_{ij}^2 \\ &\text{for } (i, j) \in E_2 \\ Y &= X^T X \end{aligned} \tag{2}$$

By relaxing  $Y = X^T X$  to  $Y \succeq X^T X$  and using Schur's complement (see, e.g., [11]), we obtain the following relaxed problem:

$$\begin{aligned} \sup & 0 \\ \text{subject to} & E_{ij} \bullet Z = d_{ij}^2 && \text{for } (i, j) \in E_1 \\ & \bar{E}_{ij} \bullet Z = \bar{d}_{ij}^2 && \text{for } (i, j) \in E_2 \\ & Z \succeq \mathbf{0}, Z_{1:k,1:k} = I_k \end{aligned} \tag{3}$$

where  $Z_{1:k,1:k}$  is the  $k \times k$  principal submatrix of  $Z$  indexed by the first  $k$  rows (columns),

$$\begin{aligned} E_{ij} &= \begin{pmatrix} \mathbf{0} \\ e_i - e_j \end{pmatrix} \begin{pmatrix} \mathbf{0} \\ e_i - e_j \end{pmatrix}^T \\ \text{and } \bar{E}_{ij} &= \begin{pmatrix} a_i \\ -e_j \end{pmatrix} \begin{pmatrix} a_i \\ -e_j \end{pmatrix}^T \end{aligned}$$

Note that this formulation forces any feasible solution matrix to have rank at least  $k$ . To derive the dual of (3), let  $(\theta_{ij})_{(i,j) \in E_1}$  and  $(w_{ij})_{(i,j) \in E_2}$  be the dual multipliers of the constraints on  $E_1$  and  $E_2$ , respectively. Then, the dual of (3) is given by:

$$\begin{aligned} \inf & I_k \bullet V + \sum_{(i,j) \in E_1} \theta_{ij} d_{ij}^2 \\ & + \sum_{(i,j) \in E_2} w_{ij} \bar{d}_{ij}^2 \\ \text{subject to} & U \equiv \begin{bmatrix} V & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} + \sum_{(i,j) \in E_1} \theta_{ij} E_{ij} \\ & + \sum_{(i,j) \in E_2} w_{ij} \bar{E}_{ij} \succeq \mathbf{0} \\ & \theta_{ij} \in \mathbb{R} \text{ for all } (i, j) \in E_1; \\ & w_{ij} \in \mathbb{R} \text{ for all } (i, j) \in E_2 \end{aligned} \tag{4}$$

Note that the dual is always feasible, as  $V = \mathbf{0}$ ,  $\theta_{ij} = 0$  for all  $(i, j) \in E_1$  and  $w_{ij} = 0$  for all  $(i, j) \in E_2$  is a feasible solution. Moreover, this solution has a dual objective value of 0. Thus, by the SDP strong duality theorem, if the primal is also feasible, then there is no duality gap between (3) and (4). Moreover, if  $Z$  is feasible for (3) and  $U$  is optimal for (4), then by complementarity, we have  $\text{rank}(Z) + \text{rank}(U) \leq k + n$ . In particular, since  $\text{rank}(Z) \geq k$ , we must have  $\text{rank}(U) \leq n$ .

We are interested in deriving the conditions under which the relaxation (3) is exact for (2). Towards that end, let us first introduce a definition:

**Definition 1** We say that an instance  $(G, (\mathbf{d}, \bar{\mathbf{d}}), \mathbf{a})$  is uniquely  $k$ -realizable if (i) there is a unique realization  $\mathbf{p} = (p_1, \dots, p_n)$  of  $(G, (\mathbf{d}, \bar{\mathbf{d}}), \mathbf{a})$  in  $\mathbb{R}^k$ , and (ii) there does not exist  $p'_1, \dots, p'_n \in \mathbb{R}^l$ , where  $l > k$ , such that:

$$\begin{aligned} \|p'_i - p'_j\|^2 &= d_{ij}^2 && \text{for } (i, j) \in E_1 \\ \left\| \begin{pmatrix} a_i \\ \mathbf{0} \end{pmatrix} - p'_j \right\|^2 &= \bar{d}_{ij}^2 && \text{for } (i, j) \in E_2 \\ p'_i &\neq \begin{pmatrix} p_i \\ \mathbf{0} \end{pmatrix} && \text{for some } 1 \leq i \leq n \end{aligned}$$

For the motivation of this definition, see [25]. We remark that Definition 1 can be viewed as a new notion of rigidity which takes into account both the combinatorial and the geometric aspects of the Graph Realization Problem.

At this point it is fair to ask whether Definition 1 is vacuous, i. e. whether uniquely  $k$ -realizable instances exist at all. It is not hard to see that they do exist for all  $k \geq 1$ . In fact, there exists a family of uniquely  $k$ -realizable instances in which the number of edges scales linearly with the number of vertices ([25]). This refutes a common belief in the literature (see, e. g., [2,5]) that the graph of any uniquely  $k$ -realizable instance must have  $\Omega(n^2)$  edges.

Having established the existence of uniquely  $k$ -realizable instances, we are now ready to state the main theorem of this section. For a proof, see [25,27].

**Theorem 1** *Let  $G = (V, E)$  be connected, and let  $\mathbf{d}, \bar{\mathbf{d}}$  and  $\mathbf{a}$  be given. Then, the following are equivalent:*

- (1) *The instance  $(G, (\mathbf{d}, \bar{\mathbf{d}}), \mathbf{a})$  is uniquely  $k$ -realizable.*
- (2) *The max-rank solution matrix of (3) has rank  $k$ .*
- (3) *The solution matrix of (3) satisfies  $Y = X^T X$ .*

Although unique  $k$ -realizability is a useful notion in determining the solvability of the Graph Realization Problem, it is not stable under perturbation. Indeed, there exist instances that are uniquely  $k$ -realizable, but may no longer be so after small perturbation of the unpinned vertices; see [27]. This motivates us to define another notion called strong  $k$ -realizability:

**Definition 2** We say that an instance  $(G, (\mathbf{d}, \bar{\mathbf{d}}), \mathbf{a})$  is strongly  $k$ -realizable if (4) has a rank- $n$  optimal dual slack matrix.

Note that if an instance is strongly  $k$ -realizable, then it is uniquely  $k$ -realizable by complementarity and Theorem 1, since the rank of any solution to (3) is equal to  $k$ .

Given an instance  $\mathcal{I} = (G, (\mathbf{d}, \bar{\mathbf{d}}), \mathbf{a})$ , we say that the instance  $(G', (\mathbf{d}', \bar{\mathbf{d}}'), \mathbf{a})$  is a *sub-instance* of  $\mathcal{I}$  if  $G'$  is a subgraph of  $G$  that includes all the pinned vertices, and  $(\mathbf{d}', \bar{\mathbf{d}}')$  is the restriction of  $(\mathbf{d}, \bar{\mathbf{d}})$  on  $G'$ . As indicated by the following theorem, the notion of strong  $k$ -realizability is very useful in identifying the uniquely  $k$ -realizable sub-instances of a given instance. Its proof can be found in [25,27].

**Theorem 2** *Suppose that a given instance  $\mathcal{I}$  contains a sub-instance  $\mathcal{I}'$  that is strongly  $k$ -realizable. Then, in*

*any solution to (3), the submatrix that corresponds to  $\mathcal{I}'$  has rank  $k$ .*

## Applications

It is often observed in practice that by “stretching apart” pairs of non-adjacent vertices, one is more likely to flatten a high-dimensional realization into a lower dimensional one. We now formalize this observation using elements of tensegrity theory (see, e. g., [12,21]). We begin with some definitions:

**Definition 3** A *tensegrity*  $G(\mathbf{p})$  is a graph  $G = (V, E)$  together with a configuration  $\mathbf{p} = (p_1, \dots, p_n) \in \mathbb{R}^{kn}$  such that each edge is labelled as a cable, strut, or bar; each vertex is labelled as pinned or unpinned; and vertex  $i \in V$  is assigned the coordinates  $p_i \in \mathbb{R}^k$  for  $1 \leq i \leq n$ .

The label on each edge is intended to indicate its functionality. Cables (resp. struts) are allowed to decrease (resp. increase) in length (or stay the same length), but not to increase (resp. decrease) in length. Bars are forced to remain the same length. As before, a pinned vertex is forced to remain where it is. Given a graph  $G = (V, E)$  and a set  $\mathbf{d}$  of weights on the edges, if  $(i, j)$  is a cable (resp. strut), then  $d_{ij}$  will be the upper (resp. lower) bound on its length. If  $(i, j)$  is a bar, then  $d_{ij}$  will simply be its length.

An important concept in the study of tensegrities is that of an *equilibrium stress*:

**Definition 4** An *equilibrium stress* for  $G(\mathbf{p})$  is an assignment of real numbers  $\omega_{ij} = \omega_{ji}$  to each edge  $(i, j) \in E$  such that for each unpinned vertex  $i$  of  $G$ , we have:

$$\sum_{j:(i,j) \in E} \omega_{ij}(p_i - p_j) = \mathbf{0} \quad (5)$$

Furthermore, we say that the equilibrium stress  $\omega = \{\omega_{ij}\}$  is *proper* if  $\omega_{ij} = \omega_{ji} \geq 0$  (resp.  $\leq 0$ ) if  $(i, j)$  is a cable (resp. strut).

Clearly, the zero stress  $\omega = \mathbf{0}$  is a proper equilibrium stress, but it is not too interesting. On the other hand, suppose that  $G(\mathbf{p})$  has a non-zero equilibrium stress, and that at least one of the incident edges of vertex  $i$  has a non-zero stress. Then, Eq. (5) implies that the set of vectors  $\{p_j - p_i : (i, j) \in E\}$  is linearly dependent, and

hence those vectors span a lower dimensional space. Thus, it would be nice to have conditions that guarantee the existence of a non-zero proper equilibrium stress. It turns out that the concept of an *unyielding tensegrity* is useful for that purpose.

**Definition 5** Let  $G = (V, E)$  be a graph, and let  $\mathbf{p}$  and  $\mathbf{q}$  be two configurations of  $G$ . We say that  $G(\mathbf{p})$  *dominates*  $G(\mathbf{q})$  (denoted by  $G(\mathbf{p}) \succeq G(\mathbf{q})$ ) if for every pinned vertex  $i$ , we have  $p_i = q_i$ , and for every edge  $(i, j) \in E$ , we have:

$$\|p_i - p_j\| \begin{cases} \geq \\ = \\ \leq \end{cases} \|q_i - q_j\| \quad \text{if } (i, j) \text{ is a } \begin{cases} \text{cable} \\ \text{bar} \\ \text{strut} \end{cases}$$

We call  $G(\mathbf{p})$  an *unyielding tensegrity* and  $\mathbf{p}$  an *unyielding configuration* if any other configuration  $\mathbf{q}$  with  $G(\mathbf{p}) \succeq G(\mathbf{q})$  satisfies  $\|p_i - p_j\| = \|q_i - q_j\|$  for all  $(i, j) \in E$ .

We are now ready to state the following theorem due to [6], which plays a crucial role in the characterization of the so-called 3-realizable graphs (informally, a graph  $G$  is 3-realizable if, given any set  $\mathbf{d}$  of edge weights, whenever  $(G, \mathbf{d})$  is realizable at all, then it can also be realized in  $\mathbb{R}^3$ ; for further details, see [7]):

**Theorem 3** *If  $G(\mathbf{p})$  is an unyielding tensegrity with exactly one strut or cable, then  $G(\mathbf{p})$  has an equilibrium stress that is non-zero on at least one edge.*

Belk’s proof of Theorem 3 uses the Inverse Function Theorem and hence is not constructive. It turns out that the problem of computing an unyielding configuration  $\mathbf{p}$  of a graph  $G$  can be formulated as an SDP. What is even more interesting is that the optimal dual multipliers of the SDP will give rise to a non-zero proper equilibrium stress for  $G(\mathbf{p})$ . Consequently, we obtain a constructive proof of Theorem 3. In fact, the SDP-based proof yields more information than that offered by Belk’s proof.

Specifically, let  $V_1, V_2, E_1, E_2$  be as before, and set  $E_1^c = \{(i, j) \notin E : i, j \in V_1\}$  and  $E_2^c = \{(i, j) \notin E : i \in V_2, j \in V_1\}$ . Let  $C_1, S_1$  be disjoint subsets of  $E_1^c$ , and let  $C_2, S_2$  be disjoint subsets of  $E_2^c$ . The pairs in  $C_i$  are intended to be *cables*, and those in  $S_i$  are intended to be *struts*. We remark that we do not assume the sets  $C_1, C_2, S_1, S_2$  to be non-empty.

Now, consider the following SDP, where we augment the formulation (3) with an objective function:

$$\begin{aligned} \sup \quad & \sum_{(i,j) \in S_1} E_{ij} \bullet Z + \sum_{(i,j) \in S_2} \tilde{E}_{ij} \bullet Z \\ & - \sum_{(i,j) \in C_1} E_{ij} \bullet Z - \sum_{(i,j) \in C_2} \tilde{E}_{ij} \bullet Z \\ \text{subject to} \quad & E_{ij} \bullet Z = d_{ij}^2 \quad \text{for } (i, j) \in E_1 \\ & \tilde{E}_{ij} \bullet Z = \tilde{d}_{ij}^2 \quad \text{for } (i, j) \in E_2 \\ & Z \succeq \mathbf{0}, Z_{1:k,1:k} = I_k \end{aligned} \tag{6}$$

The dual of (6) is given by:

$$\begin{aligned} \inf \quad & I_k \bullet V + \sum_{(i,j) \in E_1} \theta_{ij} d_{ij}^2 \\ & + \sum_{(i,j) \in E_2} w_{ij} \tilde{d}_{ij}^2 \\ \text{subject to} \quad & U \equiv - \sum_{(i,j) \in S_1} E_{ij} - \sum_{(i,j) \in S_2} \tilde{E}_{ij} \\ & + \sum_{(i,j) \in C_1} E_{ij} + \sum_{(i,j) \in C_2} \tilde{E}_{ij} \\ & + \begin{bmatrix} V & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} + \sum_{(i,j) \in E_1} \theta_{ij} E_{ij} \\ & + \sum_{(i,j) \in E_2} w_{ij} \tilde{E}_{ij} \succeq \mathbf{0} \end{aligned} \tag{7}$$

We then have the following theorem due to [26]:

**Theorem 4** *Let  $G = (V, E)$ ,  $\mathbf{d}, \tilde{\mathbf{d}}$  and  $\mathbf{a}$  be given such that:*

- (1) *there is at least one pinned vertex, and*
  - (2) *the graph  $G \setminus \{n + 2, \dots, n + m\}$  is connected.*
- Consider the SDP (6), where we assume that:*
- (3) *it is strictly feasible, and*
  - (4) *the objective function is not vacuous, i. e. at least one of the sets  $C_1, C_2, S_1, S_2$  is non-empty.*

*Let  $\bar{\mathbf{x}} = (\bar{x}_1, \dots, \bar{x}_n) \in \mathbb{R}^{1n}$  be the positions of the unpinned vertices in  $\mathbb{R}^l$  (for some  $l \geq k$ ), obtained from the optimal primal matrix  $\bar{Z}$ , and let  $\{\bar{\theta}_{ij}, \bar{w}_{ij}\}$  be the optimal dual multipliers. Suppose that we assign the stress  $\bar{\theta}_{ij}$  (resp.  $\bar{w}_{ij}$ ) to the bar  $(i, j) \in E_1$  (resp.  $(i, j) \in E_2$ ), a stress of 1 to all the cables in  $C_1 \cup C_2$ , and a stress of  $-1$  to all the struts in  $S_1 \cup S_2$ . Then, the resulting assignment yields a non-zero proper equilibrium stress for the*

tensegrity  $G'(\bar{\mathbf{x}}, \bar{\mathbf{a}})$ , where  $G' = (V, E \cup C_1 \cup C_2 \cup S_1 \cup S_2)$  and  $\bar{\mathbf{a}} = (\bar{a}_{n+1}, \dots, \bar{a}_{n+m})$ , where:

$$\bar{a}_i = \begin{pmatrix} a_i \\ \mathbf{0} \end{pmatrix} \in \mathbb{R}^l$$

The intuition behind the proof of Theorem 4 is simple. Suppose that (6) and (7) achieve the same optimal value, and that the common optimal value is attained by the primal matrix  $\bar{Z}$  and the dual matrix  $\bar{U}$ . Then, the desired result should follow from one of the conditions for strong duality, namely the identity  $\bar{Z}\bar{U} = \mathbf{0}$ . Of course, strong duality for SDP does not necessarily hold, and even when it does, there is no guarantee that the optimal value is attained by any matrix (see, e. g., [17] for some examples). Thus, some additional technical assumptions are needed, and items (2) and (3) in the statement of Theorem 4 turn out to be sufficient. In fact, the conclusion of Theorem 4 remains valid if we replace (3) by the following:

(3') the optimal value of (7) is attained by some dual feasible matrix

We remark that in most applications of Theorem 4, there will only be one pinned vertex, namely  $a_{n+1} = \mathbf{0}$ . Thus, primal strict feasibility can be ensured if the given weights  $\mathbf{d}$  admit a realization whose vertices are in general position, and the connectivity condition is simply the statement that  $G$  is connected. However, the strict feasibility assumption (or the dual attainment assumption) does weaken the applicability of Theorem 4. In particular, Theorem 4 is not as general as Theorem 3, although this can be fixed (see [25] for details).

Besides strict feasibility, it is also assumed that the given instance has at least one pinned vertex. Such an assumption is necessary in order to ensure that the entries of  $\bar{Z}$  are bounded, but one can no longer argue that the net stress exerted on a pinned vertex is zero. However, if there is only one pinned vertex in the given instance, then the net stress exerted on it will be zero. Thus, one may assume without loss of generality that the given instance has one pinned vertex.

Finally, observe that the assumptions in the statement of Theorem 4 buy us some additional information that is not offered by Theorem 3. Specifically, the equilibrium stress obtained in Theorem 4 is non-zero on all the cables and struts, and the magnitudes of the stress on all the cables and struts can be prescribed (by assign-

ing appropriate weights to each summand in the primal objective function).

### Relation to the Maximum Variance Unfolding Method

The idea of stretching apart pairs of non-adjacent vertices has also been used in the artificial intelligence community to detect and discover low-dimensional structure in high-dimensional data. For instance, in [29] (see also [30]), the authors proposed the so-called *Maximum Variance Unfolding* (MVU) method for the problem of manifold learning. The idea is to map a given set of high-dimensional vectors  $p_1, \dots, p_n \in \mathbb{R}^l$  to a set of low-dimensional vectors  $q_1, \dots, q_n \in \mathbb{R}^k$  (where  $1 \leq k \ll l$  are given) with maximum total variance, while at the same time preserves the local distances. More precisely, consider an  $n$ -vertex connected graph  $G = (V, E)$ , where the set  $E$  of edges represents the set of distances that need to be preserved. The desired set of low-dimensional vectors can then be obtained by solving the following quadratic program:

$$\begin{aligned} & \text{maximize} && \sum_{i=1}^n \|x_i\|^2 \\ & \text{subject to} && \sum_{i=1}^n x_i = \mathbf{0} \\ & && \|x_i - x_j\|^2 = \|p_i - p_j\|^2 \\ & && \text{for } (i, j) \in E \\ & && x_i \in \mathbb{R}^k \quad \text{for } 1 \leq i \leq n \end{aligned} \tag{8}$$

To explain the rationale behind the above formulation, we observe that the first constraint centers the solution vectors at the origin and eliminates the translational degree of freedom. Moreover, it implies that the objective function of (8) can be written as:

$$\sum_{i=1}^n \|x_i\|^2 = \frac{1}{2n} \sum_{i,j=1}^n \|x_i - x_j\|^2$$

Thus, we see that the MVU method attempts to “unfold” the manifold by pulling the data points as far apart as possible while preserving the local distances. We remark that such a technique has also been used for the problem of sensor network localization (see, e. g., [9,31]). Now, using the ideas in Section Formulation, we can formulate a semidefinite relaxation of (8)

as follows:

$$\begin{aligned}
 & \sup && I \bullet X \\
 \text{subject to} &&& ee^T \bullet X = 0 \\
 &&& E_{ij} \bullet X = \|v_i - v_j\|^2 \quad \text{for } (i, j) \in E \\
 &&& X \succeq \mathbf{0}
 \end{aligned} \tag{9}$$

Here,  $e = (1, 1, \dots, 1)$ ,  $E_{ij} = (e_i - e_j)(e_i - e_j)^T$ , and  $e_i$  is the  $i$ th standard basis vector of  $\mathbb{R}^n$ . It turns out that problem (9) and its dual are closely related to the problem of finding the fastest mixing Markov process on a graph, as well as to various spectral methods for dimensionality reduction. We shall not elaborate on these results here and refer the interested reader to [28,33] for further details. Instead, we will show that the MVU problem (9) can be viewed as a problem of finding an unyielding configuration of a certain tensegrity. To begin, suppose that we are given an  $n$ -vertex connected graph  $G = (\{1, \dots, n\}, E)$  and a configuration  $\mathbf{p} = (p_1, \dots, p_n) \in \mathbb{R}^{ln}$  of the vertices. Consider the tensegrity  $G'(\mathbf{p}')$ , where  $G'$  is obtained from  $G$  by adding a new vertex  $n + 1$  and connecting it to all the vertices of  $G$ , and  $\mathbf{p}' = (\mathbf{p}, \mathbf{0}) \in \mathbb{R}^{l(n+1)}$ , i. e. vertex  $n + 1$  is located at the origin. Furthermore, we label the edges in  $E$  as bars and the edges in  $S \equiv \{(n+1, i) : 1 \leq i \leq n\}$  as struts. Suppose that we pin vertex  $n + 1$  at the origin, i. e.  $a_{n+1} = \mathbf{0}$ . Now, consider the following SDP:

$$\begin{aligned}
 & \sup && \sum_{i:(n+1,i) \in S} \tilde{E}_{n+1,i} \bullet Z \\
 \text{subject to} &&& E_{ij} \bullet Z = \|p_i - p_j\|^2 \quad \text{for } (i, j) \in E \\
 &&& Z \succeq \mathbf{0}, Z_{1:k,1:k} = I_k
 \end{aligned} \tag{10}$$

where:

$$E_{ij} = \begin{pmatrix} \mathbf{0} \\ e_i - e_j \end{pmatrix} \begin{pmatrix} \mathbf{0} \\ e_i - e_j \end{pmatrix}^T$$

and  $\tilde{E}_{n+1,i} = \begin{pmatrix} \mathbf{0} \\ -e_i \end{pmatrix} \begin{pmatrix} \mathbf{0} \\ -e_i \end{pmatrix}^T$

It is clear that (10) is an instance of (6). Moreover, it can be shown ([25]) that the positions  $\tilde{\mathbf{x}} \in \mathbb{R}^{ln}$  of the unpinned vertices obtained from the optimal primal matrix  $\tilde{Z}$  are automatically centered at the origin,

even though such a constraint is not explicitly enforced. Thus, we see that problem (10) is equivalent to the MVU problem (9).

From the above discussion, we see that the formulation (6) is more general than the MVU formulation (9). Moreover, the flexibility in the formulation (6) often allows one to achieve the desired dimensionality reduction which the MVU formulation cannot achieve. For instance, consider the case where the input graph  $G$  is a tree. It is not hard to show that there is a placement of struts such that *all* the optimal solutions to (6) have rank 1 and hence they all give rise to one-dimensional realizations. On the other hand, the MVU formulation may yield a two-dimensional realization; see [25] for an example.

Optimization problems that involve a large finite number of alternatives often arise in industry, government and science. In these problems, one is given a finite solution set  $X$  and a real-valued function  $f: X \rightarrow \mathbf{R}$ , and one seeks a solution  $x^* \in X$  with  $f(x^*) \leq f(x)$ ,  $\forall x \in X$ . Common examples include designing efficient telecommunication networks and constructing cost effective airline crew schedules. To find the optimal solution in a combinatorial optimization problem it is theoretically possible to enumerate the solutions and evaluate each with respect to the stated objective. However, from a practical perspective, it is infeasible to follow such a strategy of complete enumeration because the number of combinations often grows exponentially with the size of problem.

Much work has been done over the last five decades to develop optimal seeking methods that do not explicitly require an examination of each alternative. This research has given rise to the field of *combinatorial optimization* (see [55]), and an increasing capability to solve ever larger real-world problems. Nevertheless, most problems found in industry and government are either computationally intractable by their nature, or sufficiently large so as to preclude the use of exact algorithms. In such cases, *heuristic methods* are usually employed to find good, but not necessarily guaranteed optimal solutions. The effectiveness of these methods depends upon their ability to adapt to a particular realization, avoid entrapment at local optima, and exploit the basic structure of the problem, such as a network or a natural ordering among its components. Furthermore, restart procedures, controlled randomization, efficient data structures, and preprocessing are also beneficial. Building on these notions, various heuristic search techniques have been developed that have demonstrably improved our ability to obtain

good solutions to difficult combinatorial optimization problems. The most promising of such techniques include simulated annealing [35], tabu search [27,28,29], genetic algorithms [30] and GRASP (greedy randomized adaptive search procedures) [21,22].

In this article, we review GRASP. The components of a basic GRASP heuristic are addressed and enhancements proposed to the basic heuristic are discussed. The paper concludes with a brief literature review of applications of GRASP.

## A Basic GRASP

A GRASP is a *multistart* or iterative process, in which each GRASP iteration consists of two phases, a *construction phase*, in which a feasible solution is produced, and a *local search phase*, in which a local optimum in the neighborhood of the constructed solution is sought. The best overall solution is kept as the result. The pseudocode below illustrates a GRASP procedure for minimization in which  $\text{maxitr}$  GRASP iterations are done.

```

 $x^* = \infty$ ;
FOR  $k = 1, \dots, \text{maxitr}$  DO
  construct  $(g(\cdot), \alpha, x)$ ;
  local  $(f(\cdot), x)$ ;
  IF  $f(x) < f(x^*)$  DO
     $x^* = x$ ;
  END IF;
END FOR

```

### Procedure $\text{grasp}(f(\cdot), g(\cdot), \text{maxitr}, x^*)$

In the construction phase, a feasible solution is iteratively constructed, one element at a time. The basic GRASP construction phase is similar to the *semigreedy heuristic* proposed independently by J.P. Hart and A.W. Shogan [31]. At each construction iteration, the choice of the next element to be added is determined by ordering all candidate elements (i.e. those that can be added to the solution) in a candidate list  $C$  with respect to a *greedy function*  $g: C \rightarrow \mathbf{R}$ . This function measures the (myopic) benefit of selecting each element. The heuristic is adaptive because the benefits associated with every element are updated at each iteration of the construction phase to reflect the changes brought on by the selection of the previous element. The probabilistic

component of a GRASP is characterized by randomly choosing one of the best candidates in the list, but not necessarily the top candidate. The list of best candidates is called the *restricted candidate list* (RCL). This choice technique allows for different solutions to be obtained at each GRASP iteration, but does not necessarily compromise the power of the adaptive greedy component of the method. Let  $\alpha \in [0, 1]$  be a given parameter. The pseudocode below describes a basic GRASP construction phase.

```

 $x = \emptyset;$ 
Initialize candidate set  $C$ ;
WHILE  $C \neq \emptyset$  DO
   $\underline{s} = \min\{g(t) : t \in C\};$ 
   $\bar{s} = \max\{g(t) : t \in C\};$ 
  RCL =  $\{s \in C : g(s) \leq \underline{s} + \alpha(\bar{s} - \underline{s})\};$ 
  Select  $s$ , at random, from the set RCL;
   $x = x \cup \{s\};$ 
  Update candidate set  $C$ ;
END WHILE

```

**Procedure**  $\text{construct}(g(\cdot), \alpha, x)$

The pseudocode shows that the parameter  $\alpha$  controls the amounts of greediness and randomness in the algorithm. A value  $\alpha = 0$  corresponds a *greedy construction* procedure, while  $\alpha = 1$  produces *random construction*.

As is the case for many deterministic methods, the solutions generated by a GRASP construction are not guaranteed to be locally optimal with respect to simple neighborhood definitions. Hence, it is almost always beneficial to apply a local search to attempt to improve each constructed solution. A local search algorithm works in an iterative fashion by successively replacing the current solution by a better solution in the neighborhood of the current solution. It terminates when no better solution is found in the neighborhood. The *neighborhood structure*  $N$  for a problem  $P$  relates a solution  $s$  of the problem to a subset of solutions  $N(s)$ . A solution  $s$  is said to be *locally optimal* if there is no better solution in  $N(s)$ . The key to success for a local search algorithm consists of the suitable choice of a neighborhood structure, efficient neighborhood search techniques, and the starting solution.

While such local optimization procedures can require exponential time from an arbitrary starting point, empirically their efficiency significantly improves as the initial solution improves. Through the use of customized data structures and careful implementation, an efficient construction phase can be created which produces good initial solutions for efficient local search. The result is that often many GRASP solutions are generated in the same amount of time required for the local optimization procedure to converge from a single random start. Furthermore, the best of these GRASP solutions is generally significantly better than the single solution obtained from a random starting point. The pseudocode below describes a basic local search procedure.

```

 $H = \{y \in N(x) : f(y) < f(x)\};$ 
WHILE  $|H| > 0$  DO
  Select  $x \in H$ ;
   $H = \{y \in N(x) : f(y) < f(x)\};$ 
END WHILE

```

**Procedure**  $\text{local}(f(\cdot), N(\cdot), x)$

It is difficult to formally analyze the quality of solution values found by using the GRASP methodology. However, there is an intuitive justification that views GRASP as a repetitive sampling technique. Each GRASP iteration produces a sample solution from an unknown distribution of all obtainable results. The mean and variance of the distribution are functions of the restrictive nature of the candidate list. For example, if the cardinality of the restricted candidate list is limited to one, then only one solution will be produced and the variance of the distribution will be zero. Given an effective greedy function, the mean solution value in this case should be good, but probably suboptimal. If a less restrictive cardinality limit is imposed, many different solutions will be produced implying a larger variance. Since the greedy function is more compromised in this case, the mean solution value should degrade. Intuitively, however, by order statistics and the fact that the samples are randomly produced, the best value found should outperform the mean value. Indeed, often the best solutions sampled are optimal.

An especially appealing characteristic of GRASP is the ease with which it can be implemented. Few parameters need to be set and tuned, and therefore development can focus on implementing efficient data structures to assure quick GRASP iterations. Finally, GRASP can be trivially implemented in parallel. Each processor can be initialized with its own copy of the procedure, the instance data, and an independent random number sequence. The GRASP iterations are then performed in parallel with only a single global variable required to store the best solution found over all processors.

### Enhancements to the Basic GRASP

A number of enhancements to the basic GRASP, presented in the previous section, have been proposed in the literature. In this section we review the use path relinking, long-term memory, the proximate optimality principle, and bias functions in a GRASP. We discuss a parallelization scheme and the use of GRASP in hybrid metaheuristics.

#### Path Relinking

M. Laguna and R. Martí [43] adapted the concept of *path relinking* for use within a GRASP. To test their concept, they implemented a GRASP with path relinking for the 2-layer straight line crossing minimization problem. A small set of high-quality, or elite, solutions is stored to serve as guiding solutions for path relinking. Each GRASP iteration produces a locally optimal solution  $x^*$ . A solution  $y^*$  is chosen at random from the elite set and a path of solutions linking  $x^*$  to  $y^*$  is constructed by applying a series of changes to the original solution. For example, let  $x^* = (1, 0, 0, 0)$  and  $y^* = (0, 1, 0, 1)$ . A path relinking of  $x^*$  and  $y^*$  is  $x^* = (1, 0, 0, 0) \rightarrow (0, 0, 0, 0) \rightarrow (0, 1, 0, 0) \rightarrow (0, 1, 0, 1) = y^*$ . Each of these path solutions is evaluated for solution quality. Laguna and Martí report that often improvements to the incumbent are found in this path relinking.

#### Long-Term Memory

Long-term memory is the basis for tabu search. Besides path relinking, which can be thought of as a form of long-term memory, other uses of long term memory have been proposed for use in a GRASP. C. Fleurent and F. Glover [26] observe the fact that the basic GRASP does

not make use of information gathered in previous iterations and propose a long term memory scheme to address this issue. M. Prais and C.C. Ribeiro [64] propose a scheme to learn an appropriate value for the RCL parameter  $\alpha$ .

Fleurent and Glover introduced a way to use long-term memory in multistart heuristics such as GRASP. Their scheme maintains a set  $S$  of elite solutions to be used in the construction phase. To become an elite solution a solution  $s$  must be either better than the best member of  $S$ , or better than the worst member of  $S$  and sufficiently different from the other elite solutions. For example, one can count identical solution vector components and set a threshold for rejection. A *strongly determined variable* is one that cannot be changed without eroding the objective or changing significantly other variables. A *consistent variable* is one that receives a particular value in a large portion of the elite solution set. Let  $I(e)$  be a measure of the strongly determined and consistent features of choice  $e$ , i. e.  $I(e)$  becomes larger as  $e$  resembles solutions in elite set  $S$ . The intensity function  $I(e)$  is used in the construction phase as follows. Recall that  $g(e)$  is the greedy function. Let  $E(e) = F(g(e), I(e))$  be a function of the greedy and the intensification functions. For example,  $E(e) = \lambda g(e) + I(e)$ . The intensification scheme biases selection from the RCL to those elements  $e$  with a high value of  $E(e)$  by setting the probability of selecting  $e$  to be  $p(e) = E(e) / \sum_{s \in \text{RCL}} E(s)$ . The function  $E(e)$  can vary with time by changing the value of  $\lambda$ , e. g. initially  $\lambda$  is set to a large value and when diversification is called for,  $\lambda$  is decreased. A procedure for changing the value of  $\lambda$  is given by Fleurent and Glover. See also [11] for an application of this long-term memory strategy.

#### Reactive GRASP

The term ‘reactive GRASP’ was introduced by Prais and Ribeiro [64] for a GRASP that reacts to solutions produced by different settings of the RCL parameter  $\alpha$  and seeks to adjust  $\alpha$  to give the GRASP an appropriate level of greediness and randomness. At each GRASP iteration, the value of  $\alpha$  is chosen from a discrete set of values  $\{\alpha_1, \dots, \alpha_m\}$ . The probability of selecting the value  $\alpha_k$  is  $p(\alpha_k)$ , for  $k = 1, \dots, m$ . Reactive GRASP adaptively changes the probabilities  $\{p(\alpha_1), \dots, p(\alpha_m)\}$  to favor

values that produce good solutions. Consider applying Reactive GRASP to a minimization problem. Initially the probabilities are set as  $p(\alpha_k) = 1/m$ , for  $i = 1, \dots, m$ , so that the values are selected uniformly. To adaptively redefine the probabilities, define  $F(S^*)$  to be the value of the best solution found so far and let  $A_i$  be the average value of the solutions obtained with  $\alpha_i$ . Prais and Ribeiro propose a period of warm-up iterations to initialize the  $A_i$  values. Periodically (say every  $N_\alpha$  iterations) the quantities  $q_i = (F(S^*)/A_i)^\delta$  are computed for  $i = 1, \dots, m$  and the probabilities are updated to  $p(\alpha_i) = q_i / \sum_{j=1}^m q_j$ , for  $i = 1, \dots, m$ . Observe that the more suitable a value  $\alpha_i$  is, the larger the value of  $q_i$  is and, consequently, the higher the value of  $p(\alpha_i)$ , making  $\alpha_i$  more likely to be selected. The parameter  $\delta$  can be used as an attenuation parameter. See also [16] for an application of reactive GRASP.

### Proximate Optimality Principle

The *proximate optimality principle* is based on the idea that ‘good solutions at one level are likely to be found close to good solutions at an adjacent level’ [29]. Fleurent and Glover [26] provide a GRASP interpretation of this principle. They suggest that imperfections introduced during steps of GRASP construction can be ‘ironed-out’ by applying local search during (and not only at the end of) GRASP construction. Because of efficiency considerations, a practical implementation of POP to GRASP is to apply local search during a few points in the construction phase and not during each construction iteration. See also [11] for an application of the proximate optimality principle.

### Global Convergence

In [52] it was pointed out that GRASP with a fixed nonzero RCL parameter  $\alpha$  is not asymptotically convergent to a global optimum. During construction, a fixed RCL parameter may rule out a candidate that is present in all optimal solutions. Several remedies have been proposed to get around this problem. The most straightforward is the use of a randomly selected  $\alpha$  [72]. In this approach, the parameter is selected at random from the continuous interval  $[0, 1]$  at the start of each GRASP iteration. That value is used during the entire iteration. Since a subset of the iterations are random, the

algorithm becomes asymptotically globally convergent. Reactive GRASP, as described above, can also be made asymptotically globally convergent by making  $\alpha_m = 1$ , i. e. allowing the choice of a value that produces a random GRASP iteration. J.L. Bresina [13] introduced the concept of a *bias function* to select a candidate element to be included in the solution. Bresina’s method, which is directly applicable to GRASP construction, also allows for purely random construction and is therefore asymptotically globally convergent. At each construction step, the elements in the candidate set  $C$  are ranked by their greedy function values. A bias value  $\text{bias}(r)$  is assigned to the  $r$ th ranked element. Bresina proposes several bias functions. In logarithmic bias,  $\text{bias}(r) = 1/\log(r + 1)$ . In linear bias,  $\text{bias}(r) = 1/r$ . In polynomial bias of order  $n$ ,  $\text{bias}(r) = 1/r^n$ . In exponential bias,  $\text{bias}(r) = 1/e^r$ . Finally, in random bias,  $\text{bias}(r) = 1$ . During construction, the probability of selecting the  $r$ th ranked candidate is  $\text{bias}(r) / \sum_{i=1}^{|C|} \text{bias}(i)$ . See also [11] for an application of this bias function strategy.

### Parallel GRASP

Parallel implementation of GRASP is straightforward. Two general strategies have been proposed. In search space decomposition, the search space is partitioned into several regions and GRASP is applied to each in parallel. An example of this is the GRASP for maximum independent set [23,69] where the search space is decomposed by fixing two vertices to be in the independent set. In iteration parallelization, the GRASP iterations are partitioned and each partition is assigned to a processor. See [54,56,57,58,67] for examples of parallel implementations of GRASP. Some care is needed so that different random number generator seeds are assigned to the different iterations. This can be done by running the random number generator through an entire cycle, recording all  $N_g$  seeds in a seed array. Iteration  $i$  is started with  $\text{seed}(i)$ . GRASP has been implemented on distributed architectures. In [58] a *PVM-based implementation* is described. Two *MPI-based implementations* are given in [4,50]. A.C.F. Alvim [4] proposes a general scheme for MPI implementations. A master process manages seeds for slave processors. It passes blocks of seeds to each slave processor and awaits

the slaves to indicate that they have finished processing the block and need another block. Slaves also pass back to the master the best solution found for each block of iterations.

### GRASP in Hybrid Metaheuristics

GRASP has been used in *hybrid metaheuristic* schemes. Laguna and J.L. González-Velarde [41] proposed a GRASP in which local search is done by tabu search. See also [16,46] for implementations of GRASP using tabu search as the local search procedure. Simulated annealing can also be used as a GRASP local search procedure if the initial temperature is low so that it remains near the neighborhood of the constructed solution. R.K. Ahuja, J.B. Orlin and A. Tiwari [3] use GRASP construction as a mechanism for generating the initial population in a genetic algorithm. GRASP is used in [45] in a genetic algorithm to implement a type of crossover called *perfect offspring*.

### Applications of GRASP

We now turn our attention to a number of GRASP implementations that have appeared in the literature, covering a wide range of applications. An early tutorial on GRASP appears in [22]. We group the work into two categories, applications to operations research problems and to industrial applications.

#### Operations Research Problems

Applications of GRASP to operations research problems can be classified into eight categories: scheduling problems, routing problems, logic, partitioning problems, location problems, graph theoretic problems, assignment problems, and nonconvex network flow problems.

GRASP has been applied to several scheduling problems, including operations sequencing in discrete parts manufacturing [7], flight scheduling [18], just-in-time scheduling in parallel machines [41], printed wire assembly scheduling [9,19], single machine scheduling with sequence dependent setup costs and delay penalties [24], field technician scheduling [79], flowshop with setup costs [76,77], and bus-driver scheduling [45].

Applications of GRASP to routing problems include vehicle routing with time windows [38], vehicle routing [32], aircraft routing [5], inventory routing problem with satellite facilities [10], and permanent virtual circuit (PVC) routing [66].

Problems in logic have been approached with GRASP. These include the satisfiability problem [68], maximum satisfiability [58,71,72], and inference of logical clauses from examples [15].

GRASP has been applied to partitioning problems, including graph two partition [40] and number partitioning [6].

Applications of GRASP to location problems include  $p$ -hub location [36], pure integer capacitated plant location [14], location with economies of scale [33], single source capacitated plant location [16], location of concentrators in network access design [74], and maximum covering [67].

GRASP has been used for finding approximate solutions to a number of graph theoretic problems, including set covering [21], maximum independent set [23,69], maximum clique with weighted edges [48], graph planarization [73,75], 2-layer straight line crossing minimization [43], sparse graph coloring [42], maximum weighted edge subgraph [47], the Steiner tree problem in graphs [49,50], feedback vertex set in directed graphs [60], maximum clique [1,61], and the capacitated minimum spanning tree problem [2].

Several assignment problems have been approached with GRASP. A GRASP was introduced for the quadratic assignment problem in [44]. A parallel version of this GRASP is described in [57]. Fortran subroutines for dense and sparse quadratic assignment problems can be found respectively in [70] and [59]. A modified local search for the GRASP for quadratic assignment problems is proposed in [65]. GRASP has been used to generate the initial population of a genetic algorithm for the quadratic assignment problem [3]. Long term memory schemes have been adapted to a GRASP for the quadratic assignment problem in [26]. A GRASP for the biquadratic assignment problem is described in [51]. GRASP has been applied to two multidimensional assignment problems [53,78] and to the radio link frequency assignment problem [62]. A GRASP for the generalized assignment problem was proposed in [46].

GRASP has been used for finding approximate solutions to a concave-cost network flow problem [34].

### Industrial Applications

Industrial applications of GRASP can be classified into seven categories: manufacturing, transportation, telecommunications, automatic drawing, electrical power systems, military, and biology.

GRASP has been applied to several manufacturing problems, including operations sequencing in discrete parts manufacturing [7], cutting path and tool selection in computer-aided process planning [17], manufacturing equipment selection [8], component grouping [37], and printed wire assembly scheduling [9,19].

Applications of GRASP in transportation include flight scheduling and maintenance base planning [18], intermodal trailer assignment [20], and aircraft routing in response to groundings and delay [5].

In telecommunications, GRASP has been applied to the design of SDH mesh-restorable networks [63], the Steiner tree problem in graphs [49,50], permanent virtual circuit (PVC) routing [66], location of concentrators in network access design [74], traffic scheduling in satellite switched time division multi-access (SS/TDMA) systems [64], location of points of presence (PoPs) [67], and to the multicriteria radio link frequency assignment problem [62].

GRASP has been applied to automatic drawing problems, including seam drawing in mosaicing of aerial photographic maps [25], graph planarization [73,75], and 2-layer straight line crossing minimization [43].

GRASP has been applied to other industrial problems. An application to *electrical power systems* is transmission expansion planning [12]. A military application of GRASP is in multitarget multisensor tracking [53]. GRASP has been applied in biology for protein structure prediction [39].

### Conclusion

We have surveyed the literature on greedy randomized adaptive search procedures (GRASP) in the 1990s. In these years many enhancements to the basic GRASP introduced in 1988 have been proposed. The number

and variety of applications has grown and continues to grow.

Polynomial equations; Zeros; Gröbner basis

Polynomial equations (in several variables) arise in many areas connected to management science. They could describe the feasible set of an optimization problem, the Karush–Kuhn–Tucker conditions for the same problem, or maybe constraints on the positions of the links of a robot arm in a flexible manufacturing system.

There are many analogies between polynomial equations and their special case, linear equations.

- One might want to solve the equations, i. e. find one or all solutions, determine whether a solution is unique or determine whether the system is inconsistent.
- One might want to answer more abstract questions, such as whether a given equation is a consequence of a given set of equations (cf. ► **Farkas lemma**; ► **Farkas lemma: Generalizations**).

For linear equations a fundamental concept is that of a (linear) basis and the fundamental tool is that of Gaussian elimination, by which one can construct a basis from a given set of vectors. Similarly, for polynomials there is the corresponding concepts of a *Gröbner basis* and the *Buchberger algorithm*, which for a given set of polynomials constructs a Gröbner basis. In particular one can convert a system of polynomial equations to triangular form, which allows for a solution by back substitution. In Gaussian elimination, the variables/columns have an ordering that influences the end result. Similarly, for Gröbner bases we need an order, not only for the variables, but for *monomials*, i. e. the simplest possible polynomials, such as  $x_1^3 x_4$ , that are products of variables. In this short note we will review Gröbner basis for polynomial equations.

Before defining a Gröbner base we will give an example.

*Example 1* Suppose we want to find the local optima of the following optimization problem ([4, Problem 337]; also used in [3]), by solving the KKT-conditions:

$$(P) \begin{cases} \min & f(x) = 9x_1^2 + x_2^2 + 9x_3^2 \\ \text{s.t.} & g_1(x) = 1 - x_1 x_2 \leq 0 \\ & g_2(x) = 1 - x_2 \leq 0 \\ & g_3(x) = x_3 - 1 \leq 0. \end{cases}$$

The KKT conditions for (P) are:

$$(KKT) \begin{cases} 18x_1 - \lambda_1 x_2 = 0 \\ 2x_2 - \lambda_1 x_1 - \lambda_2 = 0 \\ 18x_3 + \lambda_3 = 0 \\ \lambda_1(1 - x_1 x_2) = 0 \\ \lambda_2(1 - x_2) = 0 \\ \lambda_3(x_3 - 1) = 0. \end{cases}$$

Further suppose we use a *lexicographical order* of the monomials such that  $x_1 > x_2 > x_3 > \lambda_1 > \lambda_2 > \lambda_3$ . Then, computing the Gröbner basis for the set of polynomials in the above system and forming the corresponding

equation system, we get

$$\left\{ \begin{array}{l} 18x_1 - x_2\lambda_1 \\ x_2\lambda_1 - 36x_3 + 18\lambda_2 \\ x_2\lambda_2 - \lambda_2 \\ 2x_2 - \lambda_1 - \lambda_2 \\ 18x_3 - \lambda_3 \\ \lambda_1^3 - 36\lambda_1 - 18\lambda_2^2 + 36\lambda_2 \\ \lambda_1\lambda_2 + \lambda_2^2 - 2\lambda_2 \\ \lambda_2^3 + 14\lambda_2^2 - 32\lambda_2 \\ \lambda_3^2 + 18\lambda_3 \end{array} \right. = 0$$

This system has an obvious triangular structure, that we have tried to display graphically. The last equation contains only  $\lambda_3$ . Then comes equations in  $\lambda_2$  (and possibly  $\lambda_3$ ) and so on. In a similar way as in Gaussian elimination, the system can thus be solved by back substitution. In each step, one then has to solve a single variable polynomial equation, giving possibly several solutions, each of which is substituted into the preceding equations. Thus the solution process evolves in a tree-like structure. It might happen, that one has to solve for a variable that is already computed. Then of course the solutions have to agree, else they are discarded.

The above type of structure will always occur if there are finitely many solutions. It might happen, though, that the system allows a manifold of solutions. In this case it might e. g. happen that the last equation contains two variables or that you in the back substitution process comes to an equation with two (or more) undetermined variables. These equations then give a parametrization of the manifold.

### What is a Gröbner Basis

In Gaussian elimination the variables are ordered and the basic reduction rule is to replace the equations  $f = 0$ ,  $g = 0$  by  $f = 0$ ,  $g - cf = 0$  where the constant  $c$  is chosen so that the leading terms in  $g$  and  $cf$  coincide.

In systems of polynomial equations we do something quite similar. First we extend the ordering of the variables to a total ordering of all monomials in a way such that  $m' < m'' \Rightarrow mm' < mm''$  for all monomials  $m$ ,  $m'$  and  $m''$  and so that 1 is the least one.

The basic reduction rule is now to replace the equations  $f = 0$ ,  $g = 0$  by  $f = 0$ ,  $g - cmf = 0$  where the constant  $c$  and the monomial  $m$  are chosen so that the leading terms of  $g$  and  $cmf$  coincide. This implies that  $h = g - cmf$  is 'smaller' than  $g$  in the ordering. If such a reduction of  $g$  with  $f$  is possible and  $h = g - cmf$  we will write  $g \rightarrow_f h$ .

**Definition 2** A finite set  $G$  of polynomials is a *Gröbner basis* if for every polynomial  $q$  there exist a *unique*  $r$  and a finite reduction chain  $q \rightarrow_{g_1} q_1 \rightarrow_{g_2} \cdots \rightarrow_{g_k} q_k = r$  for some  $g_1, \dots, g_k$  in  $G$  and such that  $r$  cannot be reduced further. The unique polynomial  $r$  is called the *normal form* of  $q$  modulo  $G$ .

Given a finite set of vectors we can use Gaussian elimination to compute a basis of vectors spanning the same linear space. Given a finite set  $P$  of polynomials (and an admissible monomial ordering), one can use the Buchberger algorithm to compute a Gröbner basis  $G$ , spanning the same 'space' of polynomials as  $P$ . (By the space of polynomial spanned by  $P$  is meant the *ideal* generated by  $P$ , i. e. the set of finite linear combinations  $q_1p_1 + \cdots + q_s p_s$  where the  $p_i$ -s are in  $P$  and the  $q_i$ -s are arbitrary polynomials.) We say that  $G$  is a Gröbner basis for  $P$ . Moreover, the common zeros of  $P$  are the same as those of  $G$ .

### What are Gröbner Bases good for

Roughly speaking, all questions concerning a system of polynomial equations  $f_1 = \cdots = f_s = 0$  can be answered if we have a corresponding Gröbner basis. Here we list just a few of them.

- Is the system solvable?
- If the system is solvable, how many solutions are there, and which are they?
- How many real solutions are there? (in case the coefficients are real). Here we can also allow for inequalities.
- Is it possible to eliminate some of the variables?
- Given some polynomial  $f$ , does  $f$  vanish whenever  $f_1 \cdots f_s$  does? This can be used for automated proofs in geometry.
- Given some polynomial  $f$ , does there exist polynomials  $q_1, \dots, q_s$  such that  $f = q_1f_1 + \cdots + q_sf_s$ ?
- Is it possible to describe the algebraic relations between the  $f_i$ -s, i. e. the set of polynomials  $q$  in  $s$  variables such that  $q(f_1, \dots, f_s)$  is the zero polynomial.

- Can a given polynomial  $f$  be written as  $f = q(f_1, \dots, f_s)$  for some polynomial  $q$  in  $s$  variables, and in case it can, is it possible to compute  $q$ ?
- Can we compute a vector space basis for the vector space of polynomials modulo  $f_1 \cdots f_s$ ?

### Using Gröbner Bases and Learning more About them

Essentially all major mathematical computer packages with symbolic capabilities contain modules for Gröbner bases. The main examples are Maple and Mathematica. For a short but more detailed introduction to Gröbner bases, see [3]. The book [2] gives a rather short introduction to the field. One standard textbook is [1]

Dynamic programming; Continuous-time optimal control; Hamilton–Jacobi–Bellman equation

Even though *dynamic programming* [2] was originally developed for the solution of problems which exhibit discrete types of decisions, it has also been applied to continuous formulations. In this article, the application of dynamic programming to the solution of continuous-time optimal control problems is discussed. By discretizing the problem, applying the dynamic programming equations, then returning to the continuous domain, a partial differential equation results, the *Hamilton–Jacobi–Bellman equation* (HJB equation). This equation is often referred to as the *continuous-time equivalent of the dynamic programming*

*algorithm*. In this article, the HJB equation will first be derived. A simple application will be presented, in addition to its use in solving the linear quadratic control problem. Finally, a brief overview of some solution methods and applications presented in the literature will be given.

### Problem Formulation

The dynamic programming approach will be applied to a system of the following form:

$$\begin{cases} \dot{z}(t) = f(z(t), u(t)), \\ z(0) = z_0, \end{cases} \quad 0 \leq t \leq T, \quad (1)$$

where  $z(t) \in \mathbf{R}^n$  is the state vector at time  $t$  with time derivative given by  $\dot{z}(t)$ ,  $u(t) \in U \subset \mathbf{R}^m$  is the control vector at time  $t$ ,  $U$  is the set of control constraints, and  $T$  is the terminal time. The function  $f(z(t), u(t))$  is continuously differentiable with respect to  $z$  and continuous with respect to  $u$ . The set of admissible control trajectories are given by the piecewise constant functions,  $\{u(t): u(t) \in U, \forall t \in [0, T]\}$ . It is assumed that for any admissible control trajectory, that a state trajectory  $z^u(t)$  exists and is unique.

The objective is to determine a control trajectory and the corresponding state trajectory which minimizes a cost function of the form:

$$h(z^u(T)) + \int_0^T g(z^u(t), u(t)) dt, \quad (2)$$

where the functions  $g$ , and  $h$  are continuously differentiable with respect to both  $z$  and  $u$ .

### Derivation

The derivation of the Hamilton–Jacobi–Bellman equation is taken from [3]. The time horizon is first dis-

cretized into  $N$  equally spaced intervals with:

$$\delta = \frac{T}{N}.$$

Also, the state and control are represented by:

$$\begin{aligned} z_k &= z(k\delta), \quad k = 0, \dots, N, \\ u_k &= u(k\delta), \quad k = 0, \dots, N. \end{aligned}$$

The continuous-time system is approximated by:

$$z_{k+1} = z_k + f(z_k, u_k)\delta.$$

The cost function is rewritten as:

$$h(z_N) + \sum_{k=0}^{N-1} g(z_k, u_k)\delta.$$

The dynamic programming algorithm is now applied with the following definitions:

- $J^*(t, z)$  is the optimal cost-to-go for the continuous problem;
- $\widehat{J}^*(t, z)$  is the optimal cost-to-go for the discrete approximation.

The dynamic programming equations then take the form:

$$\widehat{J}^*(N\delta, z) = h(z), \tag{3}$$

$$\begin{aligned} \widehat{J}^*(k\delta, z) &= \min_{u \in U} \left[ g(z, u)\delta + \widehat{J}^*((k+1)\delta, z + f(z, u)\delta) \right], \\ & \quad k = 0, \dots, N-1. \end{aligned} \tag{4}$$

It is assumed that  $\widehat{J}^*(t, z)$  has the necessary differentiability requirements to write the following Taylor series expansion:

$$\begin{aligned} \widehat{J}^*((k+1)\delta, z + f(z, u)\delta) &= \widehat{J}^*(k\delta, z) + \nabla_t \widehat{J}^*(k\delta, z)\delta \\ & \quad + \nabla_z \widehat{J}^{*\top}(k\delta, z)f(z, u)\delta + o(\delta), \end{aligned} \tag{5}$$

where  $o(\delta)$  represents second order terms which satisfy  $o(\delta)/\delta \rightarrow 0$  as  $\delta \rightarrow 0$ . Substituting (5) into (4) results in:

$$\begin{aligned} \widehat{J}^*(k\delta, z) &= \min_{u \in U} \left[ g(z, u)\delta + \widehat{J}^*(k\delta, z) \right. \\ & \quad \left. + \nabla_t \widehat{J}^*(k\delta, z)\delta + \nabla_z \widehat{J}^{*\top}(k\delta, z)f(z, u)\delta + o(\delta) \right]. \end{aligned} \tag{6}$$

Dividing (6) by  $\delta$  and  $\widehat{J}^*(k\delta, z)$ , and taking the limit as  $\delta \rightarrow 0$  with the assumption that

$$\lim_{\substack{k \rightarrow \infty \\ \delta \rightarrow 0 \\ k\delta = t}} \widehat{J}^*(k\delta, z) = J^*(t, z)$$

results in

$$\begin{aligned} 0 &= \min_{u \in U} \left[ g(z, u) + \nabla_t J^*(t, z) \right. \\ & \quad \left. + \nabla_x J^{*\top}(t, z)f(z, u) \right], \quad \forall t, z, \end{aligned} \tag{7}$$

with the boundary condition

$$J^*(T, z) = h(z).$$

This partial differential equation is known as the Hamilton–Jacobi–Bellman equation (HJB equation).

### Sufficiency Theorem

This theorem is presented in [3]. Suppose  $V(t, z)$  is a solution to the HJB equation, that is,  $V$  is continuously differentiable with respect to  $z$  and  $t$  and satisfies:

$$\begin{aligned} 0 &= \min_{u \in U} \left[ g(z, u) + \nabla_t V(t, z) \right. \\ & \quad \left. + \nabla_x V^\top(t, z)f(z, u) \right], \quad \forall z, t, \end{aligned} \tag{8}$$

$$V(T, z) = h(z), \quad \forall z. \tag{9}$$

Suppose also that  $\mu^*(t, z)$  attains the minimum in (8) for all  $t$  and  $z$ . Let  $z^*(t)$  be the state trajectory obtained from the given initial condition  $z(0)$  when the control trajectory  $u^*(t) = \mu^*(t, z^*(t))$  is used. (That is,  $z^*(0) = z(0)$ ,  $\dot{z}^* = f(z^*(t), \mu^*(t, z^*(t)))$ ); one also assumes that this differential equation has a unique solution starting at any pair  $(t, z)$  and that the control trajectory is piecewise continuous in time.) Then  $V$  is the unique solution of the HJB equation and is equal to the optimal cost-to-go function

$$V(t, z) = J^*(t, z), \quad \forall z, t.$$

Furthermore, the control trajectory,  $u^*(t)$  is optimal for all  $t \in [0, T]$ .

### Example

Consider the simple dynamic system:

$$\dot{z}(t) = u(t)$$

with the control bounded by  $u(t) \in [-1, 1]$  and time over the range  $t \in [0, T]$ . The cost function is given as:

$$\frac{1}{2}z(T)^2.$$

Writing the HJB equation for this system gives

$$0 = \min_{u \in [-1, 1]} [\nabla_t V(t, z) + \nabla_z V(t, z)u], \quad \forall t, z,$$

with the boundary condition,

$$V(T, z) = \frac{1}{2}z^2.$$

The obvious choice of a control policy is to drive the state to zero as fast as possible and keep it there. This corresponds to the policy:

$$\mu^*(t, z) = -\operatorname{sgn}(z) = \begin{cases} 1 & \text{if } z < 0, \\ 0 & \text{if } z = 0, \\ -1 & \text{if } z > 0. \end{cases}$$

The cost associated with this policy for a given initial time and state is:

$$J^*(t, z) = \frac{1}{2}(\max\{0, |z| - (T - t)\})^2.$$

This function satisfies the terminal condition  $J^*(T, z) = z^2/2$ . Also,

$$\begin{aligned} \nabla_t J^*(t, z) &= \max\{0, |z| - (T - t)\}, \\ \nabla_z J^*(t, z) &= \operatorname{sgn}(z) \max\{0, |z| - (T - t)\}. \end{aligned}$$

Substituting these expressions into the HJB equation results in

$$0 = \min_{u \in [-1, 1]} [1 + \operatorname{sgn}(z)u] \max\{0, |z| - (T - t)\},$$

which can be shown to hold for all  $(t, z)$ . The minimum is attained for  $u = -\operatorname{sgn}(z)$ , and one therefore concludes from the sufficiency theorem presented above that  $J^*(t, z)$  is indeed the optimal cost-to-go function.

### Linear-Quadratic Problem

Consider a general  $n$ -dimensional time-invariant linear system

$$\dot{z}(t) = Az(t) + Bu(t)$$

with a cost function defined by

$$\begin{aligned} & z^\top(T)Q_T z(T) \\ & + \int_0^T z^\top(t)Qz(t) + u^\top(t)Ru(t) dt, \end{aligned}$$

where the matrices  $Q$  and  $Q_T$  are symmetric positive semidefinite, and the matrix  $R$  is symmetric positive definite. The HJB equation is written as

$$\begin{aligned} 0 = \min_{u \in \mathbb{R}^m} [ & z^\top Qz + u^\top Ru \\ & + \nabla_t V(t, z) + \nabla_z V^\top(t, z)(Az + Bu) ], \\ & V(T, z) = z^\top Q_T z. \end{aligned} \quad (10)$$

Try a solution of the form:

$$V(t, z) = z^\top K(t)z,$$

where  $K(t)$  is a symmetric  $n \times n$  matrix. One then has

$$\begin{aligned} \nabla_z V(t, z) &= 2K(t)z, \\ \nabla_t V(t, z) &= z^\top \dot{K}(t)z. \end{aligned}$$

Substituting the above expressions into (10) results in

$$\begin{aligned} 0 = \min_{u \in \mathbb{R}^m} [ & z^\top Qz + u^\top Ru + z^\top \dot{K}(t)z \\ & + 2z^\top K(t)Az + 2z^\top K(t)Bu ]. \end{aligned} \quad (11)$$

The minimum is obtained when the gradient with respect to  $u$  is zero. This results in

$$2B^\top K(T)z + 2Ru = 0$$

or

$$u = -R^{-1}B^\top K(t)z.$$

Substituting this expression into (11), the following results:

$$\begin{aligned} 0 = z^\top ( & \dot{K}(t) + K(t)A + A^\top K(t) \\ & - K(t)BR^{-1}B^\top K(t) + Q) z. \end{aligned}$$

Therefore,  $K(t)$  must satisfy the following matrix differential equation:

$$\begin{aligned} \dot{K}(t) = & -K(t)A - A^\top K(t) \\ & + K(t)BR^{-1}B^\top K(t) - Q, \end{aligned}$$

with the terminal condition

$$K(T) = Q_T.$$

This equation is known as the *continuous-time Riccati equation*.

### Solution Methods and Applications

In the general case of a nonlinear system, the solution can not be determined analytically and numerical methods need to be relied on. The numerical solution of the Hamilton–Jacobi–Bellman equation is not trivial due to its partial differential nature. Additionally the HJB equation and accompanying numerical methods have been used to solve a wide variety of problems.

See [4] for many applications in the area of optimal control, and for an advocate solution by the *method of characteristics*. This classical technique for the solution of partial differential equations can be found in many textbooks. See [6] for remarks about the application of the HJB equation to minimum time optimal control problems. See [1] for an approximate method for the solution of the time-invariant HJB equation. The method consists of a reduction to a set on linear partial differential equations and an approximation via the *Galerkin spectral method*. It also presents an extensive review of various approximation approaches and an application for the voltage regulation of a power generator. See [7] for an alternating direction algorithm for the solution of HJB equations. See [5] for an application for the optimal path timing of robot manipulators and for the approximate solution of the resulting HJB equation using *finite difference methods*.

The aforementioned references are a subset of the various solution methods for and applications of the Hamilton–Jacobi–Bellman equation.

subdifferential of F.H. Clarke

Variational expressions, also called for historical reasons *variational principles*, play a significant role in mechanics. They have their origin in the study of problems of analytical mechanics, which have extensively been studied in previous centuries, a time where scientists used to work multidisciplinary. Today, variational principles provide the basis for a correct and efficient modeling of a variety of physical phenomena, for instance, they provide the theoretical basis of the *finite element method* [19].

Variational equalities are the commonly met form of variational expressions. Having in mind problems which can be obtained from the minimization of a smooth (i. e., sufficiently differentiable) potential energy function, one may consider the variation of this function at a given point. A necessary condition for this function to attain a critical point is that every variation of the function in the neighborhood of this point is equal to zero. Thus, one formulates a variational equality problem. In mechanics, the differential of a potential energy function has the physical meaning of (stored or consumed) work. Let us consider a problem in *elastostatics*. In a formulation based on displacements, all variations of the system's variables around a sought point are called *virtual displacements*. For obvious reasons the variational equality is called in this case *principle of virtual work*: for small virtual displacements around the equilibrium the virtual work of the system is equal to zero. Analogously, one arrives at the principles of complementary virtual work, or at mixed variational principles (the latter being derived from saddle point theorems). At this point it should be mentioned that a variational formulation may also be written for certain classes of problems which does not possess a potential.

The introduction of inequality constraints in the studied problem, or the assumption of nondifferentiable (nonsmooth) potential energy functions, lead to variational inequalities or more complicated variational problems. Intuitively speaking, either not all virtual variations of the problem variables around a given point are permitted (the case of inequality constraints, for instance, unilateral contact constraints), or, a linear approximation of the potential energy function is no more sufficient (the case of nondifferentiable or nonsmooth energy). Convex problems have certain theoretical and numerical advantages. They are connected with monotone operators. This is the case, e. g., of small displacement and deformation elastostatics with monotone material laws or interface and boundary conditions. These problems lead to *variational inequalities* and, in some cases, to convex (possibly nonsmooth) energy minimization problems (convex superpotentials in the sense of J.-J. Moreau [10]). The techniques of *convex analysis* and minimization can be used for their effective solution. Unilateral contact problems [10,15,17] and problems of elasto-

plasticity [7,17] have been studied within this framework.

Hemivariational inequalities are connected with nonconvex and possibly nonsmooth energy functions. In elastostatics, convexity is usually lost if the effects of large displacements or deformations are considered. Moreover, falling branches in material, interface or boundary laws lead to nonconvex potentials. The latter laws may be of a phenomenological nature and may be used for modeling of delamination and strength degradation effects, fracture, etc. Several methods have been developed for the study of nonconvex problems. The notion of the generalized gradient in the sense of F.H. Clarke has been used by P.D. Panagiotopoulos for the construction of hemivariational inequalities [16,17,18]. Following the example of nonsmooth analysis, he called this new field *nonsmooth mechanics*. A short introduction to this theory and its applications in mechanics is outlined in this article. The interested reader may also consult ► **Nonconvex energy functions: Hemivariational inequalities** and the monographs [14,18].

One should mention that the study of hemivariational inequalities provides an interesting field for mathematicians and engineers alike. For engineers several types of hemivariational inequalities have been used for the study and the efficient numerical treatment of yet unsolved or partially solved problems, e.g., in nonmonotone semipermeability problems, in modeling of delamination of simple and multilayered plates, in the theory of composite structures and adhesive joints, etc. Several of these concrete practical applications can not be treated by more naive, without mathematical justification engineering methods. Furthermore, the potential of this research field can be estimated if one thinks that nonconvex energy functions are connected with instabilities, complex dynamics, fractals and chaos. Certainly, a lot of work remains to be done in this area.

### Abstract Hemivariational Inequality

The derivation of hemivariational inequalities is based on the mathematical notion of the generalized gradient of Clarke (denoted here by  $\bar{\partial}$ ). In contrast to the variational inequalities, the hemivariational inequalities are not equivalent to minimum problems, but they give rise to substationarity problems. A hemivariational inequality

problem reads: find  $u \in V$  such as to satisfy the inequality

$$a(u, v - u) + \int_{\Omega} j^0(u, v - u) d\Omega \geq (l, v - u), \quad \forall v \in V. \quad (1)$$

In the abstract form used here, let  $V$  be a real Hilbert space,  $V'$  be its dual space and such that  $V \subset L^2(\Omega) \subset V'$ , with continuous and dense injections. The problem is defined in  $\Omega$ , which is an open bounded subset of  $\mathbf{R}^n$ . Furthermore let  $(\cdot, \cdot)$  be the  $L^2(\Omega)$  product and the duality pairing,  $\|\cdot\|$  the norm of  $V$  and  $|\cdot|_2$  the  $L^2(\Omega)$ -norm. Note that  $(\cdot, \cdot)$  extends uniquely from  $V \times L^2(\Omega)$  to  $V \times V'$ . Further, let  $V \subset L^2(\Omega)$  be compact and  $V \cap L^\infty(\Omega)$  be dense in  $V$  for the  $V$ -norm, and have a Galerkin base. The bilinear form  $a(\cdot, \cdot): V \times V \rightarrow \mathbf{R}$  is symmetric continuous and coercive, i.e. there exists  $c > 0$  constant such that

$$a(v, v) \geq c \|v\|^2, \quad \forall v \in V. \quad (2)$$

Moreover  $j: \mathbf{R} \rightarrow \mathbf{R}$  denotes a locally Lipschitz function which is defined by the following procedure: let  $\beta \in L^\infty_{\text{loc}}(\mathbf{R})$  and consider

$$\bar{\beta}_\mu(\xi) = \text{esssup}_{|\xi_1 - \xi| \leq \mu} \beta(\xi_1) \quad (3)$$

and

$$\bar{\bar{\beta}}_\mu(\xi) = \text{essinf}_{|\xi_1 - \xi| \leq \mu} \beta(\xi_1). \quad (4)$$

They are increasing and decreasing functions of  $\mu$ , respectively and thus the limits for  $\mu \rightarrow 0_+$  exist. We denote them by  $\bar{\beta}(\xi)$  and  $\bar{\bar{\beta}}(\xi)$  respectively and we define the multivalued function

$$\widehat{\beta}(\xi) = [\bar{\beta}(\xi), \bar{\bar{\beta}}(\xi)]. \quad (5)$$

If  $\beta(\xi \pm 0)$  exists for every  $\xi \in \mathbf{R}$ , then a locally Lipschitz function  $j: \mathbf{R} \rightarrow \mathbf{R}$  can be determined (up to an additive constant) such that  $\widehat{\beta}(\xi) = \bar{\partial}j(\xi)$ . Finally, in relation (1)  $j^0(u, v - u)$  denotes the generalized gradient of the nonconvex and nonsmooth locally Lipschitz potential  $j$ . By definition one has the following connection with the generalized gradient, in the sense of Clarke:

$$j^0(u, v) = \{\max \langle w, v \rangle : w \in \partial_{\text{CL}} j(u)\}. \quad (6)$$

Speaking in terms of mechanics one identifies relation (1) to be a virtual work expression in inequality form.

The first term is the internal work, the second term is the energy contribution of the nonlinear elements modeled by the nonconvex superpotential  $j$  and the right-hand side term represents the loading contribution. Detailed formulations of variational problems, up to the hemivariational inequality (1) for concrete applications follow in the next section.

### Elastostatics with Nonlinear Boundary Conditions

A variational formulation is a statement that a solution of an operator equation subjected to certain boundary and/or initial conditions makes an expression involving variations of the quantities of the problems equal to zero or nonnegative. Thus one may distinguish between the bilateral or equality problems and the unilateral or inequality problems. Certain variational principles for a deformable body with nonlinear boundary interaction effects are derived in this section in order to demonstrate the hemivariational inequalities and their relation to classical equations and convex variational inequalities. Let  $\Omega \in \mathbb{R}^3$  be an open bounded subset occupied by a deformable body in its undeformed state. On the assumption of small deformations we can write the relation:

$$\int_{\Omega} \sigma_{ij}(u) \varepsilon_{ij}(v - u) \, d\Omega + \int_{\Omega} f_i(v_i - u_i) \, d\Omega + \int_{\Gamma} \sigma_{ij} n_j (v_i - u_i) \, d\Gamma, \quad \forall v \in V, \quad (7)$$

for  $u \in V$ . Here  $V$  denotes the function space of the displacements which will be defined further. Relation (7) is the expression of the principle of virtual work for the body when it is considered free, without constraints on its boundary  $\Gamma$ . For the derivation of (7) the following steps are followed. The elastostatic equilibrium equation is first considered:

$$\sigma_{ij,j} + f_i = 0, \quad (8)$$

where the  $f_i$  is the volume force vector. Relation (8) is multiplied by the virtual variation  $v_i - u_i$  and then an integration over  $\Omega$  is performed. On the assumption of appropriately smooth functions, the Green –

Gauss theorem is applied. One recalls here the strain-displacement relation (small deformation theory):

$$\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}). \quad (9)$$

Let a linearly elastic body be assumed, i. e., the constitutive material relation reads:

$$\sigma_{ij} = C_{ijhk} \varepsilon_{hk}, \quad (10)$$

where  $C = \{ C_{ijhk} \}$ ,  $i, j, h, k = 1, 2, 3$ , is the elasticity tensor which satisfies the well-known symmetry and ellipticity properties

$$C_{ijhk} = C_{jihk} = C_{khij}, \quad (11)$$

$$C_{ijhk} \varepsilon_{ij} \varepsilon_{hk} \geq c \varepsilon_{ij} \varepsilon_{hk}, \quad \forall \varepsilon = \{ \varepsilon_{ij} \}. \quad (12)$$

The bilinear form of linear elasticity  $\alpha(\cdot, \cdot)$  reads in this case:

$$\alpha(u, v) = \int_{\Omega} C_{ijhk} \varepsilon_{ij}(u) \varepsilon_{hk}(v) \, d\Omega. \quad (13)$$

For further reference one splits the last term in (7) into the work of the normal and of the tangential tractions to the boundary. Then (7) may also be written in the form:

$$\int_{\Omega} \sigma_{ij} \varepsilon_{ij}(v - u) \, d\Omega + \int_{\Omega} f_i(v_i - u_i) \, d\Omega + \int_{\Gamma} S_N(v_N - u_N) \, d\Gamma + \int_{\Gamma} S_{T_i}(v_{T_i} - u_{T_i}) \, d\Gamma, \quad \forall v \in V. \quad (14)$$

### Single-Valued Boundary Laws and Variational Equalities

Let us assume first that on  $\Gamma$  the classical boundary conditions  $S_N = 0$  and  $u_{T_i} = 0$ ,  $i = 1, 2, 3$ , hold. Then (14) with (13) leads to the following variational equality:

$$\left\{ \begin{array}{l} \text{Find } u \in V_0 = \{ v : v \in V, v_{T_i} = 0 \text{ on } \Gamma \} \\ \text{s.t. } \alpha(u, v) = \int_{\Omega} f_i v_i \, d\Omega, \quad \forall v \in V_0. \end{array} \right. \quad (15)$$

Analogously, one treats all linear or nonlinear boundary conditions which can be expressed in an equality form. Relation (15), under appropriate smoothness assumptions, imply that the governing equations of the mechanical problem (8) and the assumed boundary conditions hold in a weak (integral or energetic) form.

**Multivalued, Monotone Laws and Variational Inequalities**

Let us assume now that on  $\Gamma$  the general monotone multivalued boundary condition

$$-S \in \partial j(u) \tag{16}$$

holds. Here  $j(u)$  is assumed to be a convex superpotential and  $\partial$  denotes the subdifferential of convex analysis. Moreover, all (normal and tangential) contributions of boundary displacements  $u$  and tractions  $S$  are included in (16), which holds as a multidimensional boundary condition at each point of the boundary  $\Gamma$ . Relation (16) is, by definition of the subdifferential, equivalent to:

$$j(v) - j(u) \geq -S_i(v_i - u_i), \quad \forall v = \{v_i\} \in \mathbb{R}^3. \tag{17}$$

By using (17) and (7) one gets the variational inequality:

$$\left\{ \begin{array}{l} \text{Find } u \in V \text{ with } j(u) < \infty, \\ \text{s.t. } \alpha(u, v - u) + \int_{\Gamma} (j(v) - j(u)) \, d\Gamma \geq \int_{\Omega} f_i(v_i - u_i) \, d\Omega, \\ \forall v \in V \text{ with } j(v) < \infty. \end{array} \right. \tag{18}$$

It is trivial to formulate analogous variational inequalities for more simple one-dimensional laws. This is the case where independent contact laws and tangential (e. g., due to friction) mechanisms are assumed on the boundary  $\Gamma$ . One should mention in passing that unilateral contact relations are included in this formulation by means of the indicator function in the place of  $j(u)$ . The *indicator function* is defined by  $I_{U_{ad}}(u) = 0$  if  $u \in U_{ad}$  and  $+\infty$  otherwise, and includes the inequality constraints that describe the no-penetration requirements.

**Multivalued, Nonmonotone Laws and Hemivariational Inequalities**

In this case the basic building element is the definition of boundary conditions and material laws based on Clarke subdifferential (6). For instance, let on  $\Gamma$  the nonmonotone, possibly multivalued boundary condition

$$-S \in \partial_{CL} j(u) \tag{19}$$

hold, where  $j$  is a locally Lipschitz superpotential functional. Combining (7) with the inequality

$$j^0(u, v - u) \geq -S_i(v_i - u_i), \quad \forall v = \{v_i\} \in \mathbb{R}^3, \tag{20}$$

which defines on  $\Gamma$  the condition (19), one gets the following hemivariational inequality:

$$\left\{ \begin{array}{l} \text{Find } u \in V \\ \text{s.t. } \alpha(u, v - u) + \int_{\Gamma} j^0(u, v - u) \, d\Gamma \geq \int_{\Omega} f_i(v_i - u_i) \, d\Omega, \\ \forall v \in V. \end{array} \right. \tag{21}$$

If instead of (19) one assumes on  $\Gamma$  that:

$$-S_N \in \partial_{CL} j_N(u_N), -S_T \in \partial_{CL} j_T(u_T), \tag{22}$$

then one gets analogously the hemivariational inequality:

$$\left\{ \begin{array}{l} \text{Find } u \in V \\ \text{s.t. } \alpha(u, v - u) + \int_{\Gamma} j_N^0(u_N, v_N - u_N) \, d\Gamma + \int_{\Gamma} j_T^0(u_T, v_T - u_T) \, d\Gamma \geq \int_{\Omega} f_i(v_i - u_i) \, d\Omega, \\ \forall v \in V. \end{array} \right. \tag{23}$$

The last type of variational expressions involving  $j^0(\cdot, \cdot)$  or  $j_N^0(\cdot, \cdot)$  and  $j_T^0(\cdot, \cdot)$  have been called *hemivariational inequalities* by Panagiotopoulos, who introduced and studied them in mechanics [14,16,17,18]. Note that in the more general case in which  $j$  or  $j_N$  and  $j_T$  are not locally Lipschitz  $j^0(\cdot, \cdot)$  in (21) and  $j_N^0(\cdot, \cdot), j_T^0(\cdot, \cdot)$  in (23) are replaced by  $j^\uparrow(\cdot, \cdot)$  and  $j_N^\uparrow(\cdot, \cdot), j_T^\uparrow(\cdot, \cdot)$ . Moreover a combination of monotone subdifferential laws (cf. (6)) and nonmonotone laws (cf. (19)) for different (nonoverlapping) parts of the boundary  $\Gamma$  is possible. One then gets variational-hemivariational inequality problems.

The solution of variational problems, like the variational equalities, or the hemivariational inequalities derived previously, satisfies the operator equations of the problem, e. g. the equation of equilibrium, and the boundary conditions of the problem in a weak sense. This means, roughly speaking, that these relations are satisfied in an integral form, on the body or the boundary of the structure respectively. Analogous considerations are familiar within the weak formulations used in the finite element method.

**Inequality or Nonsmooth Mechanics**

A boundary value problem is called *bilateral* (resp. *unilateral*) if it leads to variational equality (resp. variational, or hemivariational inequality) formulations. The unilateral problems are called *inequality problems* too. Inequality problems in mechanics usually characterize structures with variable mechanical behavior, i. e. where the material or boundary law depends on the direction of the stress or boundary traction variation. Due to their connection with nonsmooth energy functions, all inequality problems belong to the area called by Panagiotopoulos *nonsmooth mechanics* [11,12].

**Discretized Hemivariational Inequalities for Nonlinear Material Laws**

In order to make the subject more accessible to engineers a discretized hemivariational inequality is formulated in this section. A finite element discretization is assumed. All relations are written in an elementary matrix analysis form. An elastic structure with both classical, linearly elastic and degrading elements is considered.

The *stress equilibrium equations* read:

$$\overline{G}\bar{s} = \begin{pmatrix} G & G_n \end{pmatrix} \begin{pmatrix} s \\ s_n \end{pmatrix} = p \tag{24}$$

where  $\overline{G}$  is the equilibrium matrix of the discretized structure which takes into account the stress contribution of the linear  $s$  and nonlinear  $s_n$  elements and  $p$  is the loading vector.

The *strain-displacement compatibility equations* take the form:

$$\bar{e} = \begin{pmatrix} e \\ e_n \end{pmatrix} = \overline{G}^\top u = \begin{pmatrix} G^\top \\ G_n^\top \end{pmatrix} u, \tag{25}$$

where  $e, u$  are the deformation and displacement vectors respectively.

The linear material constitutive law for the structure reads:

$$s = K_0(e - e_0), \tag{26}$$

where  $K_0$  is the natural and stiffness flexibility matrix and  $e_0$  is the initial deformation vector.

The nonlinear material law is considered in the form:

$$s_n \in \partial_{CL}\phi_n(e_n). \tag{27}$$

Here  $\phi_n(\cdot)$ , is a general nonconvex superpotential and summation over all nonlinear elements gives the total strain energy contribution of them as:

$$\Phi_n(e_n) = \sum_{i=1}^q \phi_n^{(i)}(e_n). \tag{28}$$

Finally classical support boundary conditions complete the description of the problem.

The discretized form of the virtual work equation reads:

$$s^\top(e^* - e) + s_n^\top(e_n^* - e_n) = p^\top(u^* - u), \quad \forall e^*, u^*, e_n^*. \tag{29}$$

Entering the elasticity law (26) into the virtual work equation (29), and using (25) we get:

$$u^\top GK_0^\top G^\top(u^* - u) - (p + GK_0e_0)^\top(u^* - u) + s_n^\top(e_n^* - e_n) = 0, \quad \forall u^* \in V_{ad}, \tag{30}$$

where  $K = G^T K_0^T G$  denotes the stiffness matrix of the structure,  $\bar{p} = p + GK_0 e_0$  denotes the nodal equivalent loading vector and  $V_{ad}$  includes all support boundary conditions of the structure.

Further one considers the nonlinear elements (27) in the inequality form:

$$s_n^T(e_n^* - e_n) \leq \Phi_n^o(e_n^* - e_n), \quad \forall e_n^*, \quad (31)$$

where  $\Phi_n^o(e_n^* - e_n)$  is the directional derivative of the potential  $\Phi_n$ . Thus the following discretized hemivariational inequality is obtained:

$$\left\{ \begin{array}{l} \text{Find kinematically admissible} \\ \text{displacements } u \in V_{ad} \\ \text{s.t. } u^T K(u^* - u) - \bar{p}^T(u^* - u) \\ \quad + \Phi_n^o(u_n^* - u_n) \geq 0, \\ \quad \forall u^* \in V_{ad}. \end{array} \right. \quad (32)$$

Equivalently a substationarity problem for the total potential energy can be written:

$$\left\{ \begin{array}{l} \text{Find } u \in V_{ad} \\ \text{s.t. } \Pi(u) = \text{stat}_{v \in V_{ad}} \{\Pi(v)\}. \end{array} \right. \quad (33)$$

Here the potential energy reads  $\Pi(v) = \frac{1}{2}v^T K v - \bar{p}^T v + \Phi_n(v)$ , where the first two terms (quadratic potential) are well-known in the structural analysis community.

### Other Applications in Mechanics

Hemivariational inequalities have been used for the modeling and solution of delamination effects in composite and multilayered plates, in composite structures, for nonmonotone friction and skin effects and for nonlinear mechanics applications (for instance, in the analysis of semi-rigid joints in steel structures). Details can be found in [9,11,12,17,18] and in the citations given there. Another area of applications are nonconvex problems arising in elastoplasticity (cf. [4,5,6]). Some nonconvex problems in elastoplasticity have been treated by hemivariational inequality techniques in [17,18]. Mathematical results which are useful for the study of hemivariational inequalities can also be found in [2,3,13,14].

### Numerical Algorithms

A number of algorithms based on nonsmooth and nonconvex optimization concepts, on engineering methods or heuristics and on combination of these two approaches have been tested till now for the numerical solution of hemivariational inequality problems. Both finite elements and boundary elements have been used, the latter for boundary only nonlinear problems; see

► **Nonconvex energy functions: Hemivariational inequalities** and [1,8,9,17].

Eigenvalue problem; Hemivariational inequalities; Critical point theory; Unilateral mechanics

The theory of *hemivariational inequalities* has been created by P.D. Panagiotopoulos et al. (see [3,5,6,7]) for studying nonconvex and nonsmooth energy functions under nonmonotone multivalued laws. In this setting many relevant models lead to *nonsmooth eigenvalue problems*. A typical example is provided by the analysis of hysteresis phenomena. To illustrate it we present here the loading and unloading problems with *hysteresis* modes.

Consider a plane linear elastic body  $\Omega$  with the boundary  $\Gamma$  whose mechanical behavior is described by the virtual displacement variable  $u$  and the scalar parameter  $\lambda$  which determines the magnitude of the external loading on the system. The variable  $u$  must satisfy certain boundary or support conditions. For the sake of simplicity we assume that  $u = 0$  on  $\Gamma$ , so the space of kinematically admissible displacements  $u$  is the *Sobolev*

space  $H_0^1(\Omega)$ , that is the closure of  $C_0^\infty(\Omega)$  with respect to the  $L^2$ -norm of the gradient. Let us suppose that there exist a fundamental (pre-bifurcation) solution  $\lambda \mapsto u_0(\lambda)$  and another solution  $\lambda \mapsto u(\lambda) = u_0(\lambda) + z(\lambda)$  that coincide for  $\lambda < \lambda_0$ . Then one has  $\lim_{\lambda \rightarrow \lambda_0} z(\lambda) = 0$  and the hysteresis bifurcation mode has the expression

$$u_1(\lambda_0) := \lim_{\lambda \rightarrow \lambda_0} \|z(\lambda)\|^{-1} z(\lambda). \tag{1}$$

Using the principle of virtual works together with physically realistic assumptions on the data  $\theta$  and  $S$  (see e. g. [7]), we obtain the relation

$$a(u_1(\lambda_0), v) + \langle S(u_1(\lambda_0)), v \rangle - \lambda_0 \int_{\Omega} u_1(\lambda_0) v dx = 0, \quad \forall v \in H_0^1(\Omega). \tag{2}$$

It is justified to accept that a generalized nonmonotone reaction-displacement  $(-S, u)$  holds in  $\Omega$  expressed by the next law

$$\int_{\Omega} j^0(u_1(\lambda_0); v) dx \geq \langle S(u_1(\lambda_0)), v \rangle, \quad \forall v \in H_0^1(\Omega), \tag{3}$$

where  $j: \mathbf{R} \rightarrow \mathbf{R}$  stands for a *locally Lipschitz function* with the *generalized gradient*  $\partial j$  and the *generalized directional derivative*

$$j^0(x; y) = \max \{ \langle z, y \rangle : z \in \partial j(x) \}$$

(see [2]). Relations (2) and (3) yield the following eigenvalue problem in hemivariational inequality form: Find  $(u = u(\lambda), \lambda) \in H_0^1(\Omega) \times \mathbf{R}$  such that

$$a(u, v) + \int_{\Omega} j^0(u; v) dx \geq \lambda \int_{\Omega} uv dx, \quad \forall v \in H_0^1(\Omega). \tag{4}$$

Additional information concerning problems of type (4) can be found in [3,5,6,7].

Relation (4), as well as other models, motivates the study of abstract eigenvalue problems for hemivariational inequalities. The specific case of Problem (4) can be reformulated as follows: given a Banach space  $V$  embedded in  $L^2(\Omega)$ , i. e. the space of square-integrable functions on  $\Omega \subset \mathbf{R}^N$ , a continuous symmetric bilinear form  $a: V \times V \rightarrow \mathbf{R}$  and a locally Lipschitz function

$j: \mathbf{R} \rightarrow \mathbf{R}$  with an appropriate growth condition for its generalized gradient, find  $u \in V$  and  $\lambda \in \mathbf{R}$  such that

$$a(u, v) + \int_{\Omega} j^0(u; v) dx \geq \lambda \int_{\Omega} uv dx, \quad \forall v \in V. \tag{5}$$

Note that this last mathematical model can also be used to formulate various other problems in Mechanics like unilateral bending problems in elasticity.

A general approach for studying the abstract eigenvalue problem (5) is the nonsmooth critical point theory as developed by K.-C. Chang [1]. In that paper the *minimax principles* in the critical point theory are extended from the smooth functionals (see [8]) to the case of locally Lipschitz functionals. In this respect we associate to Problem (5), for each  $\lambda$ , the locally Lipschitz functional  $I_\lambda: V \rightarrow \mathbf{R}$ ,

$$I_\lambda(u) = \frac{1}{2} a(u, u) + \int_{\Omega} j(u) dx - \frac{\lambda}{2} \int_{\Omega} u^2 dx, \quad \forall u \in V. \tag{6}$$

Note that a *critical point*  $u$  of  $I_\lambda$ , i. e.  $0 \in \partial I_\lambda(u)$ , is a solution of (5) because

$$\begin{aligned} \partial I_\lambda(u) &\subset a(u, \cdot) - \lambda(u, \cdot)_{L^2} \\ &+ \partial \int_{\Omega} j(u) dx \subset a(u, \cdot) - \lambda(u, \cdot)_{L^2} + \int_{\Omega} \partial j(u) dx \end{aligned}$$

(see [2]). Thus, to solve (5), it suffices to establish the existence of nontrivial critical points of the functional  $I_\lambda$  introduced in (6). To this end we proceed along the lines in [4] by arguing in an abstract framework.

Given a Banach space  $V$  and a bounded domain  $\Omega$  in  $\mathbf{R}^m$ ,  $m \geq 1$ , let  $T: V \rightarrow L^s(\Omega; \mathbf{R}^N)$  be a *compact linear operator*, where  $L^s(\Omega; \mathbf{R}^N)$  stands for the Banach space of all Lebesgue measurable functions  $f: \Omega \rightarrow \mathbf{R}^N$  for which  $|f|^s$  is integrable with  $1 < s < \infty$ . Let  $F: V \rightarrow \mathbf{R}$  be a locally Lipschitz function and let  $G: \Omega \times \mathbf{R}^N \rightarrow \mathbf{R}$  be a (Carathéodory) function such that  $G(x, y)$  is measurable in  $x \in \Omega$ , locally Lipschitz in  $y \in \mathbf{R}^N$  and  $G(x, 0) = F(0) = 0$ ,  $x \in \Omega$ . The hypotheses below are imposed

H1)  $|w| \leq c(1 + |y|^{s-1}), \forall w \in \partial_y G(x, y), x \in \Omega, y \in \mathbf{R}^N$ , with a constant  $c > 0$ ;

H2) i)  $F(v) - r \langle z, v \rangle \geq \alpha \|v\|_V^\sigma - \alpha_0, \forall v \in V, z \in \partial F(v)$ ;

ii)  $G(x, y) - r \langle w, y \rangle \geq -b |y|^{\sigma_0} - b_0$ , for a.e.  $x \in \Omega, y \in \mathbf{R}^N, w \in \partial_y G(x, y)$ , with positive constants  $r, \alpha, \alpha_0, b, b_0, \sigma, \sigma_0$ , where  $1 \leq \sigma_0 < \min \{ \sigma, r^{-1}, s \}$ ;

H3) any bounded sequence  $\{v_n\} \subset V$  for which there is  $z_n \in \partial F(v_n)$  converging in  $V^*$  contains a convergent subsequence in  $V$ ;

H4) i)  $\liminf_{v \rightarrow 0} F(v) \|v\|_V^{-p} > 0$ ;

ii)

$$\begin{aligned} & \liminf_{v \rightarrow 0} F(v) \|v\|_V^{-p} \\ & + |\Omega|^{(s-p)/p} \|T\|^p \liminf_{y \rightarrow 0} G(x, y) |y|^{-p} \\ & > 0 \end{aligned}$$

uniformly with respect to  $x, 1 \leq p < s$ ;

H5)

$$\begin{aligned} & \liminf_{t \rightarrow +\infty} F(tv_0) t^{-1/r} \\ & < -\liminf_{t \rightarrow +\infty} t^{-1/r} \int_{\Omega} G(x, tTv_0) dx \end{aligned}$$

for some  $v_0 \in V$ .

The following statement is our main result in studying the abstract eigenvalue problem (5).

**Theorem 1** Assume that the hypotheses H1)–H5) hold. Then there exists a nontrivial critical point  $u \in V$  of  $I: V \rightarrow \mathbf{R}$  defined by

$$I(v) = F(v) + \int_{\Omega} G(x, (Tv)(x)) dx, \quad v \in V.$$

Moreover, there exists  $z \in \partial F(u)$  and  $w \in L^{s(s-1)}(\Omega; \mathbf{R}^N)$  such that

$$\begin{aligned} & w(x) \in \partial_y G(x, (Tu)(x)) \quad \text{a.e. } x \in \Omega, \\ & \langle z, v \rangle_V + \int_{\Omega} \langle w(x), (Tv)(x) \rangle dx = 0, \quad v \in V. \end{aligned}$$

Conversely, if  $u \in V$  verifies the relations above, corresponding to some  $z$  and  $w$ , and the function  $G(x, \cdot)$  is regular at  $(Tu)(x)$  (in the sense of F.H. Clarke [2]) for each  $x \in \Omega$ , then  $u$  is a critical point of  $I$ .

The foregoing locally Lipschitz functional  $I$  satisfies the Palais–Smale condition in the sense of Chang [1]. Indeed, let  $(v_n)$  be a sequence in  $V$  with  $I(v_n) \leq M$  and for which there exists a sequence  $J_n \in \partial I(v_n)$  with  $J_n \rightarrow 0$  in  $V^*$ . Then from H2) and taking into account that

$$\begin{aligned} & J_n = z_n + T^* w_n, \\ & z_n \in \partial F(v_n), \\ & w_n(x) \in \partial_y G(x, (Tv_n)(x)) \quad \text{a.e. } x \in \Omega, \end{aligned}$$

we infer that

$$\begin{aligned} & M + r \|v_n\|_V \geq F(v_n) - r \langle z_n, v_n \rangle_V \\ & + \int_{\Omega} (G(x, (Tv_n)(x)) - r \langle w_n(x), (Tv_n)(x) \rangle) dx \\ & \geq \alpha \|v_n\|_V^\sigma + C_1 \|v_n\|_V^{\sigma_0} + C_2, \end{aligned}$$

with real constants  $C_1, C_2$ , provided that  $n$  is large enough. It is clear that the estimate above implies that the sequence  $(v_n)$  is bounded in  $V$ . Then a standard argument based on the assumption H3) allows to conclude that  $(v_n)$  possesses a strongly convergent subsequence. Namely, the boundedness of  $(v_n)$  implies that  $(Tv_n)$  is bounded in  $L^s(\Omega; \mathbf{R}^N)$ . Thus  $(w_n)$  is bounded in  $L^{s(s-1)}(\Omega; \mathbf{R}^N)$  due essentially to the assumption H1). Since  $T^*$  is a compact operator and  $J_n \rightarrow 0$  we derive that  $(z_n)$  has a convergent subsequence in  $V^*$ . This fact combined with the boundedness of  $(v_n)$  allows to use the hypothesis H3). The claim that the locally Lipschitz functional  $I$  verifies the Palais–Smale condition is proved.

Assumption H4) insures the existence of some constants  $\delta > 0, A > 0$  and  $B > 0$ , with

$$A - B |\Omega|^{(s-p)/p} \|T\|^p > 0,$$

such that

$$F(v) \geq A \|v\|_V^p, \quad \|v\|_V \leq \delta, \tag{7}$$

and

$$G(x, y) \geq -B |y|^p, \quad \forall x \in \Omega, \quad |y| \leq \delta.$$

Combining the inequality above with H1) one obtains that

$$\begin{aligned} & \int_{\Omega} G(x, (Tv)(x)) dx \geq -(A - \eta) \|v\|_V^p, \\ & \|v\|_V \leq \rho, \tag{8} \end{aligned}$$

for some  $\eta > 0$  and  $0 < \rho \leq \delta$ . Indeed, assumption H1) and Lebourg’s mean value theorem imply that  $G$  fulfills the following growth condition

$$|G(x, y)| \leq a_1 + a_2 |y|^s, \quad \forall x \in \Omega, \quad y \in \mathbf{R}^N,$$

with constants  $a_1, a_2 \geq 0$ . The two estimates above for  $G(x, y)$  show that

$$G(x, y) \geq -B |y|^p - (a_1 \delta^{-s} + a_2) |y|^s, \quad \forall x \in \Omega, \quad y \in \mathbf{R}^N.$$

Then one deduces from the continuity of  $T$  that one has

$$\begin{aligned} & \int_{\Omega} G(x, (Tv)(x)) dx \\ & \geq \left( -B |\Omega|^{(s-p)/p} \|T\|^p - (a_1 \delta^{-s} + a_2) \|T\|^s \|v\|_V^{s-p} \right) \|v\|_V^p, \end{aligned} \quad \forall v \in V.$$

Since  $s > p$  we see that the numbers  $\eta > 0$  and  $\rho > 0$  can be chosen so small that relation (8) be verified.

By (7) and (8) we arrive at the conclusion that there exist positive numbers  $\rho, \eta$  such that

$$I(v) \geq \eta, \quad \|v\|_V = \rho. \tag{9}$$

The formula

$$\begin{aligned} & \partial_t(t^{-1/r} G(x, ty)) \\ & = \frac{1}{r} t^{-1-1/r} [r \langle \partial_y G(x, ty), ty \rangle - G(x, ty)], \end{aligned}$$

the absolute continuity property and H2ii) show that

$$\begin{aligned} & t^{-1/r} G(x, ty) - G(x, y) \\ & = \int_1^t \partial_{\tau}(\tau^{-1/r} (G(x, \tau y))) d\tau \leq C |y|^{\sigma_0} + C_0 \end{aligned}$$

for a.e.  $x \in \Omega, y \in \mathbf{R}^N, t > 1$ , where  $C, C_0$  are positive constants. Then one obtains

$$\begin{aligned} & I(t\theta v_0) \leq (t\theta)^{1/r} \\ & \times \left[ F(t\theta v_0)(t\theta)^{-1/r} + \bar{C} \|v_0\|_V^{\sigma_0} \theta^{\sigma_0-1/r} + \bar{C}_0 \theta^{-1/r} + \theta^{-1/r} \int_{\Omega} G(x, \theta(Tv_0)(x)) dx \right] \end{aligned}$$

for all  $t > 1, \theta > 1$ , with new positive constants  $\bar{C}, \bar{C}_0$ . In view of H5) and since  $\sigma_0 < 1/r$ , we can find  $\theta$  sufficiently large such that

$$\begin{aligned} & \bar{C} \|v_0\|_V^{\sigma_0} \theta^{\sigma_0-1/r} + \bar{C}_0 \theta^{-1/r} \\ & + \theta^{-1/r} \int_{\Omega} G(x, \theta(Tv_0)(x)) dx < -\liminf_{\tau \rightarrow +\infty} F(\tau v_0) \tau^{-1/r}. \end{aligned}$$

With such fixed number  $\theta$ , we see that there exists arbitrarily large  $t$  satisfying

$$\begin{aligned} & F(t\theta v_0)(t\theta)^{-1/r} + \bar{C} \|v_0\|_V^{\sigma_0} \theta^{\sigma_0-1/r} + \bar{C}_0 \theta^{-1/r} \\ & + \theta^{-1/r} \int_{\Omega} G(x, \theta(Tv_0)(x)) dx < 0. \end{aligned}$$

We deduce that

$$I(t_n v_0) \leq 0 \tag{10}$$

for a subsequence  $t_n \rightarrow \infty$ . The properties (9) and (10) permit to apply the *mountain pass theorem* in the nonsmooth version of Chang [1]. This yields the desired critical point  $u$  of  $I$ . The other assertions of the first part of Theorem are direct consequences of the last statement.

The converse part of Theorem follows from the next formula

$$\partial \int_{\Omega} G(x, u(x)) dx = \int_{\Omega} \partial_y G(x, u(x)) dx, \quad \forall u \in L^s(\Omega; \mathbf{R}^N),$$

which is valid under the growth condition in H1) and the regularity assumption for  $G$  (see [2]). The proof of Theorem is thus complete.

In the case of problem (4) we choose  $V = H_0^1(\Omega)$ , the compact linear operator  $T: H_0^1(\Omega) \rightarrow L^s(\Omega)$  equal to the embedding  $H_0^1(\Omega) \subset L^s(\Omega)$  with  $2 < s < 2m(m-2)^{-1}$  if  $m \geq 3$ ,

$$F(v) = \frac{1}{2} \int_{\Omega} (|\nabla v|^2 - \lambda v^2) dx, \quad \forall v \in H_0^1(\Omega),$$

where for simplicity we take  $a(u, v) = \int_{\Omega} \nabla u \cdot \nabla v dx$ , and  $G(x, t) = j(t)$ . A significant possible choice for  $j$  is the following one

$$j(t) = -\frac{|t|^s}{s} + \int_0^t \beta(\tau) d\tau, \quad t \in \mathbf{R}, \tag{11}$$

where  $\beta \in L_{loc}^{\infty}(\mathbf{R})$  verifies  $t \beta(t) \geq 0$  for  $t$  near 0,  $|\beta(t)| \leq c(1 + |t|^{\gamma}), t \in \mathbf{R}$ , with constants  $c > 0, 0 \leq \gamma < 1$ .

**Corollary 2** Let  $j: \mathbf{R} \rightarrow \mathbf{R}$  be given by (11). If  $\lambda_1$  denotes the first eigenvalue of  $-\Delta$  on  $H_0^1(\Omega)$ , then for every  $\lambda < \lambda_1$  the problem (5) with  $a$  as above, has a nontrivial eigenfunction  $u \in H_0^1(\Omega)$  which solves in addition the nonsmooth Dirichlet problem containing both superlinear and sublinear terms

$$\Delta u + \lambda u + |u|^{s-2} u \in [\underline{\beta}(u(x)), \overline{\beta}(u(x))] \\ \text{a.e. } x \in \Omega, u = 0 \text{ on } \partial\Omega,$$

where the notations in [1] are used.

The argument consists in verifying the assumptions H1)–H5) for the functional  $I = I_\lambda$ , for  $\lambda < \lambda_1$ , with  $I_\lambda$  described in (6). To this end it is sufficient to take  $r \in (1/s, 1/2)$ ,  $p = \sigma = 2$ ,  $\sigma_0 = \gamma + 1$  and  $v_0 \in H_0^1(\Omega) \setminus \{0\}$ . Applying Theorem one finds the stated result.

Other related results and applications for eigenvalue problems in the form of hemivariational inequalities are given in [3,4,5,6,7] and the references therein.

Semicoercive hemivariational inequality; Unilateral growth condition; Pseudomonotone mapping; Recession functional

Let  $V = H^1(\Omega; \mathbf{R}^N)$ ,  $N \geq 1$ , be a vector valued Sobolev space of functions square integrable together with their first partial distributional derivatives in  $\Omega$ ,  $\Omega$  being a bounded domain in  $\mathbf{R}^m$ ,  $m > 2$ , with sufficiently smooth boundary  $\Gamma$ . Assume that  $V$  is compactly imbedded into  $L^p(\Omega; \mathbf{R}^N)$  ( $1 < p < 2m/m - 2$ ), [12]. We write  $\|\cdot\|_V$  and  $\|\cdot\|_{L^p(\Omega; \mathbf{R}^N)}$  for the norms in  $V$  and  $L^p(\Omega; \mathbf{R}^N)$ , respectively. For the pairing over  $V^* \times V$  the symbol  $\langle \cdot, \cdot \rangle_V$  will be used,  $V^*$  being the dual of  $V$ .

Let  $A: V \rightarrow V^*$  be a bounded, *pseudomonotone operator*. This means that  $A$  maps bounded sets into bounded sets and that the following conditions hold [3,5]:

- i) The effective domain of  $A$  coincides with the whole  $V$ ;
- ii) If  $u_n \rightarrow u$  weakly in  $V$  and  $\limsup_{n \rightarrow \infty} \langle Au_n, u_n - u \rangle_V \leq 0$ , then  $\liminf_{n \rightarrow \infty} \langle Au_n, u_n - v \rangle_V \geq \langle Au, u - v \rangle_V$  for any  $v \in V$ .  
Note that i) and ii) imply that  $A$  is demicontinuous, i. e.
- iii) If  $u_n \rightarrow u$  strongly in  $V$ , then  $Au_n \rightarrow Au$  weakly in  $V^*$ .

Moreover, we assume that  $V$  is endowed with a direct sum decomposition  $V = \widehat{V} + V_0$ , where  $V_0$  is a finite-dimensional linear subspace, with respect to which  $A$  is semicoercive, i. e.  $\forall u \in V$  there exist  $\widehat{u} \in \widehat{V}$  and  $\theta \in V_0$  such that  $u = \widehat{u} + \theta$  and

$$\langle Au, u \rangle_V \geq c(\|\widehat{u}\|_V) \|\widehat{u}\|_V, \quad (1)$$

where  $c: \mathbf{R}^+ \rightarrow \mathbf{R}$  stands for a coercivity function with  $c(r) \rightarrow \infty$  as  $r \rightarrow \infty$ . Further, let  $j: \mathbf{R}^N \rightarrow \mathbf{R}$  be a locally Lipschitz function fulfilling the *unilateral growth conditions* ([16,21]):

$$j^0(\xi; \eta - \xi) \leq \alpha(r)(1 + |\xi|^\sigma), \quad \forall \xi, \eta \in \mathbf{R}^N, |\eta| \leq r, r \geq 0, \quad (2)$$

and

$$j^0(\xi; -\xi) \leq k|\xi|, \quad \forall \xi \in \mathbf{R}^N, \quad (3)$$

where  $1 \leq \sigma < p$ ,  $k$  is a nonnegative constant and  $\alpha: \mathbf{R}^+ \rightarrow \mathbf{R}^+$  is assumed to be a nondecreasing function from  $\mathbf{R}^+$  into  $\mathbf{R}^+$ . Here,  $j^0(\cdot; \cdot)$  stands for the *directional Clarke derivative*

$$j^0(\xi; \eta) = \limsup_{\substack{h \rightarrow 0 \\ \lambda \rightarrow 0_+}} \frac{j(\xi + h + \lambda\eta) - j(\xi + h)}{\lambda}, \quad (4)$$

by means of which the *Clarke generalized gradient* of  $j$  is defined by [6]

$$\partial j(\xi) := \{ \mu \in \mathbf{R}^N : j^0(\xi; \eta) \geq \mu \cdot \eta, \forall \eta \in \mathbf{R}^N \}, \quad \xi, \eta \in \mathbf{R}^N.$$

*Remark 1* The unilateral growth condition (2) is the generalization of the well known sign condition used for the study of nonlinear partial differential equations in the case of scalar-valued function spaces (cf. [27,28]).

Consider the problem of finding  $u \in V$  such as to satisfy the hemivariational inequality

$$\langle Au - g, v - u \rangle_V + \int_{\Omega} j^0(u; v - u) d\Omega \geq 0, \quad \forall v \in V. \quad (5)$$

It will be assumed that  $g \in V^*$  fulfills the *compatibility condition*

$$\langle g, \theta \rangle_V < \int_{\Omega} j^\infty(\theta) d\Omega, \quad \forall \theta \in V_0 \setminus \{0\}, \quad (6)$$

where  $j^\infty: \mathbf{R}^N \rightarrow \mathbf{R} \cup \{+\infty\}$  stands for the recession functional given by (cf. [2,4,10])

$$j^\infty(\xi) = \liminf_{\substack{\eta \rightarrow \xi \\ t \rightarrow +\infty}} [-j^0(t\eta; -\eta)], \quad \xi \in \mathbf{R}^N. \quad (7)$$

Because of (1), the problem to be considered here will be referred to as a *semicoercive hemivariational inequality*.

The notion of hemivariational inequality has been first introduced by P.D. Panagiotopoulos in [22,23] for the description of important problems in physics and engineering, where nonmonotone, multivalued boundary or interface conditions occur, or where some nonmonotone, multivalued relations between stress and strain, or reaction and displacement have to be taken into account. The theory of hemivariational inequalities (as the generalization of variational inequalities, cf. [7]) has been proved to be very useful in understanding of many problems of mechanics involving nonconvex, nonsmooth energy functionals. For the general study of hemivariational inequalities and their applications, see [13,14,15,17,18,19,20,21,24,26] and the references quoted there. Some results in the area of static, semicoercive inequality problems can be found in [9,10,25].

To prove the existence of solutions to (5), the Galerkin method combined with the pseudomonotone regularization of the nonlinearities will be applied.

Let us start with the following preliminary results.

The regularization  $\widetilde{j}_R^0(\cdot; \cdot)$ ,  $R > 0$ , of the Clarke directional derivative  $j^0(\cdot; \cdot)$  will be defined as follows: for any  $\xi, \eta \in \mathbf{R}^N$ , set

$$\widetilde{j}_R^0(\xi, \eta) = \begin{cases} j^0(\xi; \eta) & \text{if } |\xi| \leq R, \\ j^0\left(R\frac{\xi}{|\xi|}; \eta\right) & \text{if } |\xi| > R. \end{cases} \quad (8)$$

**Lemma 2** *Suppose that (2) and (3) are fulfilled. Then for  $R > 0$ ,*

$$\widetilde{j}_R^0(\xi; \eta - \xi) \leq \widetilde{\alpha}(r)(1 + |\xi|^\sigma), \quad \forall \xi \in \mathbf{R}^N, \quad \forall \eta \in \mathbf{R}^N, |\eta| \leq r, r \geq 0. \quad (9)$$

$$\widetilde{j}_R^0(\xi; -\xi) \leq k|\xi|, \quad \forall \xi \in \mathbf{R}^N, \quad (10)$$

where  $\widetilde{\alpha}: \mathbf{R}^+ \rightarrow \mathbf{R}^+$  is a nondecreasing function independent of  $R$ .

*Proof* To establish (9) and (10) it suffices to consider the case  $|\xi| \geq R$  and to invoke the estimates

$$\begin{aligned} \widetilde{j}_R^0(\xi; \eta - \xi) &= j^0\left(R\frac{\xi}{|\xi|}; \eta - \xi\right) \\ &\leq j^0\left(R\frac{\xi}{|\xi|}; \eta - R\frac{\xi}{|\xi|}\right) \\ &\quad + \frac{|\xi| - R}{R} j^0\left(R\frac{\xi}{|\xi|}; -R\frac{\xi}{|\xi|}\right) \\ &\leq \alpha(|\eta|)(1 + R^\sigma) + \frac{|\xi| - R}{R} kR \\ &\leq \alpha(r)(1 + |\xi|^\sigma) + k|\xi|, \\ &\forall \xi, \eta \in \mathbf{R}^N, |\eta| \leq r, r \geq 0, \end{aligned}$$

and

$$\begin{aligned} \widetilde{j}_R^0(\xi; -\xi) &= j^0\left(R\frac{\xi}{|\xi|}; -\xi\right) \\ &\leq \frac{|\xi|}{R} j^0\left(R\frac{\xi}{|\xi|}; -R\frac{\xi}{|\xi|}\right) \leq \frac{|\xi|}{R} kR = k|\xi|, \end{aligned}$$

respectively. The proof is complete.

For any  $R > 0$ , the following regularization of the primal problem can be formulated:

$$(P_R)\text{Find } (u_R, \chi_R) \in V \times L^q(\Omega; \mathbf{R}^N),$$

$1/p + 1/q = 1$ , such that

$$\begin{aligned} \langle Au_R - g, v - u_R \rangle_V \\ + \int_{\Omega} \chi_R \cdot (v - u_R) \, d\Omega = 0, \quad \forall v \in V, \quad (11) \end{aligned}$$

$$\chi_R \in \Gamma_R(u_R), \quad (12)$$

where

$$\Gamma_R(u_R) := \left\{ \psi \in L^q(\Omega; \mathbf{R}^N) : \int_{\Omega} \psi \cdot v \, d\Omega \leq \int_{\Omega} \widetilde{j}_R^0(u_R; v) \, d\Omega, \quad \forall v \in L^p(\Omega; \mathbf{R}^N) \right\}.$$

In order to show that  $(P_R)$  has solutions, the following auxiliary result is to be applied.

**Lemma 3** Suppose that (1)-(3) and (6) hold. Then there exists  $R_0 > 0$  such that for any  $R > R_0$  the set of all  $u \in V$  with the property that

$$\langle Au - g, u \rangle_V - \int_{\Omega} \tilde{j}_R^0(u; -u) \, d\Omega \leq 0 \tag{13}$$

is bounded in  $V$ , i. e. there exists  $\mathcal{M} > 0$  (possibly depending on  $R > R_0$ ), such that (13) implies

$$\|u\|_V \leq \mathcal{M}. \tag{14}$$

*Proof* Suppose on the contrary that this claim is not true, i. e. there exists a sequence  $\{u_n\}_{n=1}^{\infty} \subset V$  with the property that

$$\langle Au_n - g, u_n \rangle_V - \int_{\Omega} \tilde{j}_R^0(u_n; -u_n) \, d\Omega \leq 0, \tag{15}$$

where  $\|u_n\|_V \rightarrow \infty$  as  $n \rightarrow \infty$ . By the hypothesis, each element  $u_n$  can be represented as

$$u_n = \widehat{u}_n + e_n \theta_n, \tag{16}$$

where  $\widehat{u}_n \in \widehat{V}$ ,  $e_n \geq 0$ ,  $\theta_n \in V_0$ ,  $\|\theta_n\|_V = 1$ , and  $\langle Au_n, u_n \rangle_V \geq c(\|\widehat{u}_n\|_V) \|\widehat{u}_n\|_V$ . Taking into account (3) it follows that

$$\begin{aligned} 0 &\geq \langle Au_n - g, u_n \rangle_V - \int_{\Omega} \tilde{j}_R^0(u_n; -u_n) \, d\Omega \\ &\geq c(\|\widehat{u}_n\|_V) \|\widehat{u}_n\|_V - \|g\|_{V^*} \|\widehat{u}_n\|_V \\ &\quad - e_n \langle g, \theta_n \rangle_V - k \int_{\Omega} |u_n| \, d\Omega \\ &\geq c(\|\widehat{u}_n\|_V) \|\widehat{u}_n\|_V - \|g\|_{V^*} (\|\widehat{u}_n\|_V + e_n) \\ &\quad - k_1 \|\widehat{u}_n\|_V - e_n k_1 \|\theta_n\|_V, \end{aligned} \tag{17}$$

where  $k_1 = \text{const}$ . The obtained estimates imply that  $\{e_n\}$  is unbounded. Indeed, if it would not be so, then due to the behavior of  $c(\cdot)$  at infinity,  $\{\widehat{u}_n\}$  had to be bounded. In such a case the contradiction with  $\|u_n\|_V \rightarrow \infty$  as  $n \rightarrow \infty$  results. Therefore one can suppose without loss of generality that  $e_n \rightarrow +\infty$  as  $n \rightarrow \infty$ . The next claim is that

$$\frac{1}{e_n} \widehat{u}_n \rightarrow 0 \text{ strongly in } V. \tag{18}$$

Indeed, if  $\{\|\widehat{u}_n\|_V\}$  is bounded, then (18) follows immediately. If  $\|\widehat{u}_n\|_V \rightarrow \infty$  then  $c(\|\widehat{u}_n\|_V) \rightarrow +\infty$ . From (17) one has

$$k_1 + \|g\|_{V^*} \geq (c(\|\widehat{u}_n\|_V) - \|g\|_{V^*} - k_1) \frac{\|\widehat{u}_n\|_V}{e_n}.$$

Thus, the boundedness of the sequence

$$\left\{ (c(\|\widehat{u}_n\|_V) - \|g\|_{V^*} - k_1) \frac{\|\widehat{u}_n\|_V}{e_n} \right\}_{n=1}^{\infty}$$

results, which in view of

$$c(\|\widehat{u}_n\|_V) - \|g\|_{V^*} - k_1 \rightarrow +\infty \text{ as } n \rightarrow \infty$$

implies the assertion (18). The obtained results give rise to the following representation of  $u_n$ :

$$u_n = e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right),$$

where  $\widehat{u}_n/e_n \rightarrow 0$  strongly in  $V$  and  $\theta_n \rightarrow \theta$  in  $V_0$  as  $n \rightarrow \infty$  for some  $\theta \in V_0$  with  $\|\theta\|_V = 1$  (recall that  $V_0$  has been assumed to be finite dimensional). Moreover, the compact imbedding  $V \subset L^p(\Omega; \mathbf{R}^N)$  permits one to suppose that  $\widehat{u}_n/e_n \rightarrow 0$  and  $\theta_n \rightarrow \theta$  a.e. in  $\Omega$ .

Further, (15), together with the fact that  $A$  is semi-coercive, leads to

$$\begin{aligned} 0 &\geq \langle Au_n - g, u_n \rangle_V - \int_{\Omega} \tilde{j}_R^0(u_n; -u_n) \, d\Omega \\ &\geq (c(\|\widehat{u}_n\|_V) - \|g\|_{V^*}) \|\widehat{u}_n\|_V - e_n \langle g, \theta_n \rangle_V \\ &\quad + e_n \\ &\quad \cdot \int_{\Omega} -\tilde{j}_R^0 \left( e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right) \, d\Omega. \end{aligned}$$

Hence

$$\begin{aligned} \langle g, \theta_n \rangle_V &\geq (c(\|\widehat{u}_n\|_V) - \|g\|_{V^*}) \frac{1}{e_n} \|\widehat{u}_n\|_V \\ &\quad + \int_{\Omega} -\tilde{j}_R^0 \left( e_n \left( \frac{\widehat{u}_n}{e_n} + \theta_n \right); -\frac{\widehat{u}_n}{e_n} - \theta_n \right) \, d\Omega. \end{aligned} \tag{19}$$

Now observe that either

$$(c(\|\widehat{u}_n\|_V) - \|g\|_{V^*}) \frac{1}{e_n} \|\widehat{u}_n\|_V \rightarrow 0 \text{ as } n \rightarrow \infty,$$

if  $\{\|\widehat{u}_n\|_V\}$  is bounded, or

$$(c(\|\widehat{u}_n\|_V) - \|g\|_{V^*}) \frac{1}{e_n} \|\widehat{u}_n\|_V \geq 0$$

for sufficiently large  $n$ , if  $\|\widehat{u}_n\|_V \rightarrow \infty$  as  $n \rightarrow \infty$ . Therefore, for any case

$$\liminf_{n \rightarrow \infty} (c(\|\widehat{u}_n\|_V) - \|g\|_{V^*}) \frac{1}{e_n} \|\widehat{u}_n\|_V \geq 0.$$

Moreover, by (10) the estimate follows:

$$- \widetilde{j}_R^0 \left( e_n \left( \frac{\widehat{u}_n}{e_n} + \theta_n \right); -\frac{\widehat{u}_n}{e_n} - \theta_n \right) \geq -k \left| \frac{\widehat{u}_n}{e_n} + \theta_n \right|. \quad (20)$$

This allows the application of Fatou's lemma in (19), from which one is led to

$$\begin{aligned} \langle g, \theta \rangle_V &\geq \liminf_{n \rightarrow \infty} \int_{\Omega} \left[ -\widetilde{j}_R^0 \left( e_n \left( \frac{\widehat{u}_n}{e_n} + \theta_n \right); -\frac{\widehat{u}_n}{e_n} - \theta_n \right) \right] d\Omega \\ &\geq \int_{\Omega} \liminf_{n \rightarrow \infty} \left[ -\widetilde{j}_R^0 \left( e_n \left( \frac{\widehat{u}_n}{e_n} + \theta_n \right); -\frac{\widehat{u}_n}{e_n} - \theta_n \right) \right] d\Omega. \end{aligned} \quad (21)$$

Taking into account (8) and upper semicontinuity of  $j^0(\cdot, \cdot)$ , one can easily verify that

$$\begin{aligned} \liminf_{n \rightarrow \infty} \left[ -\widetilde{j}_R^0 \left( e_n \left( \frac{\widehat{u}_n}{e_n} + \theta_n \right); -\frac{\widehat{u}_n}{e_n} - \theta_n \right) \right] \\ \geq -j^0 \left( R \frac{\theta}{|\theta|}; -\theta \right), \end{aligned}$$

which leads to

$$\langle g, \theta \rangle_V \geq \int_{\Omega} -j^0 \left( R \frac{\theta}{|\theta|}; -\theta \right) d\Omega. \quad (22)$$

Since  $j^\infty(\cdot)$  is lower semicontinuous and  $V_0$  is finite dimensional, from (6) it follows that a  $\delta > 0$  can be found such that for any  $\theta \in V_0$  with  $\|\theta_V\| = 1$ ,

$$\langle g, \theta \rangle_V + \delta < \int_{\Omega} j^\infty(\theta) d\Omega. \quad (23)$$

With the help of Fatou's lemma (permitted by (20)) we arrive at

$$\liminf_{R \rightarrow \infty} \int_{\Omega} -j^0 \left( \frac{R}{|\theta|} \theta; -\theta \right) d\Omega \geq \int_{\Omega} j^\infty(\theta) d\Omega.$$

The upper semicontinuity of  $j^0(\cdot; \cdot)$  allows us to conclude the existence of  $R_\theta > 0$  and  $\varepsilon_\theta > 0$  such that

$$\int_{\Omega} -j^0 \left( \frac{R}{|\theta'|} \theta'; -\theta' \right) d\Omega \geq \int_{\Omega} j^\infty(\theta) d\Omega - \frac{\delta}{2}$$

for each  $R > R_\theta$  and  $\theta' \in V_0$  with  $\|\theta - \theta'\|_V < \varepsilon_\theta$ . As the sphere  $\{v \in V_0: \|v\|_V = 1\}$  is compact in  $V_0$ , there exists  $R_0 > 0$  such that

$$\int_{\Omega} -j^0 \left( \frac{R}{|\theta|} \theta; -\theta \right) d\Omega \geq \int_{\Omega} j^\infty(\theta) d\Omega - \frac{\delta}{2},$$

for any  $\theta \in V_0$  with  $\|\theta\|_V = 1$ ,  $R > R_0$ . This combined with (23) contradicts (22). Accordingly, the existence of a constant  $\mathcal{M} > 0$  has been established such that (13) implies (14), whenever  $R > R_0$ . The proof of Lemma 3 is complete.

**Proposition 4** *Let us assume all the hypotheses stated above. Then for any  $R > R_0$  the problem  $(P_R)$  possesses at least one solution. Moreover, if  $(u_R, \chi_R)$  is a solution of  $(P_R)$ , then*

$$\|u_R\|_V \leq M \quad (24)$$

for some constant  $M$  not depending on  $R > R_0$ .

*Proof* Let  $\Lambda$  be the family of all finite-dimensional subspaces  $F$  of  $V$ , ordered by inclusion. Denote by  $i_F: F \rightarrow V$  the inclusion mapping of  $F$  into  $V$  and by  $i_F^*: V^* \rightarrow F^*$  the dual projection mapping of  $V^*$  into  $F^*$ ,  $F^*$  being the dual of  $F$ . The pairing over  $F^* \times F$  will be denoted by  $\langle \cdot, \cdot \rangle_F$ . Set  $A_F := i_F^* \circ A \circ i_F$  and  $g_F := i_F^* g$ .

Fix  $R > R_0$ . For any  $F \in \Lambda$  consider a finite-dimensional regularization of  $(P_R)$ :

$$(P_F) \quad \text{Find } (u_F, \chi_F) \in F \times L^q(\Omega; \mathbf{R}^N) \in F$$

such that

$$\langle Au_F - g, v \rangle_V + \int_{\Omega} \chi_F \cdot v d\Omega = 0, \forall v \in F, \quad (25)$$

$$\chi_F \in \Gamma_R(u_F). \quad (26)$$

The first task is to show that for each  $F \in \Lambda$ ,  $(P_F)$  has solutions. Notice that  $\Gamma_R(\cdot)$  has nonempty, convex and closed values and if  $\psi \in \Gamma_R(v)$ ,  $v \in L^p(\Omega; \mathbf{R}^N)$ , then

$$\|\psi\|_{L^q(\Omega; \mathbf{R}^N)} \leq K_R, \tag{27}$$

for some  $K_R > 0$  depending on the Lipschitz constant of  $j$  in the ball  $\{\eta \in \mathbf{R}^N: |\eta| \leq \mathbf{R}\}$ . Moreover, from the upper semicontinuity of  $j_R^0(\cdot; \cdot)$  and Fatou's lemma it follows immediately that  $\Gamma_R$  is upper semicontinuous from  $L^p(\Omega; \mathbf{R}^N)$  to  $L^q(\Omega; \mathbf{R}^N)$ ,  $L^q(\Omega; \mathbf{R}^N)$  being endowed with the weak topology.

Further, let  $\tau_F: L^q(\Omega; \mathbf{R}^N) \rightarrow F^*$  be the operator that to any  $\psi \in L^q(\Omega; \mathbf{R}^N)$  assigns  $\tau_F \psi \in F^*$  defined by

$$\langle \tau_F \psi, v \rangle_F := \int_{\Omega} \psi \cdot v \, d\Omega \quad \text{for any } v \in F. \tag{28}$$

Note that  $\tau_F$  is a linear and continuous operator from the weak topology of  $L^q(\Omega; \mathbf{R}^N)$  to the (unique) topology on  $F^*$ . Therefore  $G_F: F \rightarrow 2^{F^*}$ , given by the formula

$$G_F(v_F) := \tau_F \Gamma_R(v_F) \quad \text{for } v_F \in F, \tag{29}$$

is upper semicontinuous.

By the pseudomonotonicity of  $A$  it follows that  $A_F: F \rightarrow F^*$  is continuous. Thus,  $A_F + G_F - g_F: F \rightarrow 2^{F^*}$  is an upper semicontinuous multivalued mapping with nonempty, bounded, closed and convex values. Moreover, for any  $v_F \in F$  and  $\psi_F \in G_F(v_F)$  one has

$$\begin{aligned} &\langle A_F v_F + \psi_F - g_F, v_F \rangle_F \\ &\geq \langle A v_F - g, v_F \rangle_V - \int_{\Omega} \tilde{j}_R^0(v_F; -v_F) \, d\Omega. \end{aligned} \tag{30}$$

Hence, in view of Lemma 3, for  $R > R_0$  there exists  $\mathcal{M} > 0$  not depending on  $F \in \Lambda$  such that the condition  $\|v_F\|_V = \mathcal{M} + 1$  implies

$$\langle A_F v_F + \psi_F - g_F, v_F \rangle_F \geq 0. \tag{31}$$

Accordingly, one can invoke [1, Corol. 3, p. 337] to deduce the existence of  $u_F \in F$  with

$$\|u_F\|_V \leq \mathcal{M} + 1 \tag{32}$$

such that  $0 \in A_F u_F + G_F(u_F) - g_F$ . This implies that for some  $\chi_F \in \Gamma_R(u_F)$  it follows that  $\psi_F = \tau_F(\chi_F)$  and  $(u_F, \chi_F)$  is a solution of  $(P_F)$ .

In the next step it will be shown that  $(P_R)$ ,  $R > R_0$ , has solutions.

For  $F \in \Lambda$ , let

$$\mathcal{W}_F := \bigcup_{\substack{F' \in \Lambda, \\ F' \supset F}} \left\{ u_{F'} \in V: \begin{array}{l} (u_{F'}, \chi_{F'}) \\ \text{satisfies } (P_{F'}) \\ \text{for some} \\ \chi_{F'} \in L^q(\Omega; \mathbf{R}^N) \end{array} \right\}.$$

The symbol  $\text{weakcl}(\mathcal{W}_F)$  will be used to denote the closure of  $\mathcal{W}_F$  in the weak topology of  $V$ . From (32) one gets

$$\text{weakcl}(\mathcal{W}_F) \subset B_V(O, \mathcal{M} + 1), \quad \forall F \in \Lambda,$$

where  $B_V(O, \mathcal{M} + 1) := \{v \in V \mid \|v\|_V \leq \mathcal{M} + 1\}$ . Thus, the family  $\{\text{weakcl}(\mathcal{W}_F): F \in \Lambda\}$  is contained in the weakly compact set  $B_V(O, \mathcal{M} + 1)$  of  $V$ . Further, for any  $F_1, \dots, F_k \in \Lambda, k = 1, 2, \dots$ , the inclusion  $\mathcal{W}_{F_1} \cap \dots \cap \mathcal{W}_{F_k} \supset \mathcal{W}_F$  results, with  $F = F_1 + \dots + F_k$ . Therefore, the family  $\{\text{weakcl}(\mathcal{W}_F): F \in \Lambda\}$  has the finite intersection property. This implies that  $\bigcap_{F \in \Lambda} \text{weakcl}(\mathcal{W}_F)$  is not empty. From now on, let  $u_R \in B_V(O, \mathcal{M} + 1)$  belong to this intersection.

Fix  $v \in V$  arbitrarily and choose  $F \in \Lambda$  such that  $u_R, v \in F$ . Thus, there exists a sequence  $\{u_{F_n}\} \subset \mathcal{W}_F$  with  $u_{F_n} \rightarrow u_R$  weakly in  $V$ . Let  $\chi_{F_n} \in \Gamma_R(u_{F_n})$  denote the corresponding sequence for which  $(u_{F_n}, \chi_{F_n})$  is a solution of  $(P_{F_n})$  (for simplicity of notation, the symbols  $\{u_n\}$  and  $\{\chi_n\}$  will be used instead of  $u_{F_n}$  and  $\chi_{F_n}$ , respectively). Therefore

$$\begin{aligned} \langle Au_n - g, w - u_n \rangle_V + \int_{\Omega} \chi_n \cdot (w - u_n) \, d\Omega = 0, \\ \forall w \in F_n. \end{aligned} \tag{33}$$

Since  $\|\chi_n\|_{L^q(\Omega; \mathbf{R}^N)} \leq K_R$  and  $L^q(\Omega; \mathbf{R}^N)$  is reflexive, it can also be supposed that for some  $\chi_R \in L^q(\Omega; \mathbf{R}^N)$ ,  $\chi_n \rightarrow \chi_R$  weakly in  $L^q(\Omega; \mathbf{R}^N)$ . By the hypothesis, the imbedding  $V \subset L^p(\Omega; \mathbf{R}^N)$  is compact, so  $u_n \rightarrow u_R$  strongly in  $L^p(\Omega; \mathbf{R}^N)$ . Consequently, by the upper semicontinuity of  $\Gamma_R$  from  $L^p(\Omega; \mathbf{R}^N)$  to  $L^q(\Omega; \mathbf{R}^N)$  ( $L^q(\Omega; \mathbf{R}^N)$  being endowed with the weak topology) it follows immediately that  $\chi_R \in \Gamma_R(u_R)$ , i. e. (12) holds. Moreover,  $\int_{\Omega} \chi_n \cdot (u_R - u_n) \, d\Omega \rightarrow 0$  as  $n \rightarrow \infty$  and (33) with  $w = u_R$  lead to  $\lim \langle Au_n, u_n - u_R \rangle_V = 0$ . Accordingly, the pseudomonotonicity of  $A$  allows the conclusion that  $\langle Au_n, u_n \rangle_V \rightarrow \langle Au_R, u_R \rangle_V$  and  $Au_n \rightarrow Au_R$

weakly in  $V^*$ . Finally, substituting  $w = v$  in (33) and letting  $n \rightarrow \infty$  give in conclusion (11) with  $v \in V$  chosen arbitrarily. Thus the existence of solutions of  $(P_R)$  has been established.

Let us proceed to the boundedness of solutions  $\{u_R\}_{R>R_0}$  of  $(P_R)$ . Suppose on the contrary that this claim is not true. Then according to (11) and (12) there would exist a sequence  $R_n \rightarrow \infty$  such that  $\|u_{R_n}\|_V \rightarrow \infty$  as  $n \rightarrow \infty$ , and

$$\langle Au_{R_n} - g, u_{R_n} \rangle_V - \int_{\Omega} \widetilde{j}_{R_n}^0(u_{R_n}; -u_{R_n}) d\Omega \leq 0. \tag{34}$$

From now on, for simplicity of notations, instead of the subscript ‘ $R_n$ ’ we write ‘ $n$ ’. Eq. (34) allows us to follow the lines of the proof of Lemma 3. First, analogously one arrives at the representation

$$u_n = e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right),$$

with  $\widehat{u}_n/e_n \rightarrow 0$  strongly in  $V$  and  $\theta_n \rightarrow \theta_0$  in  $V_0$  as  $n \rightarrow \infty$  for some  $\theta_0 \in V_0$  with  $\|\theta_0\|_V = 1$ . Secondly, the counterpart of (21) can be obtained in the form

$$\langle g, \theta \rangle_V \geq \liminf_{n \rightarrow \infty} \int_{\Omega} \left[ -\widetilde{j}_{R_n}^0 \left( e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right) \right] d\Omega. \tag{35}$$

But

$$\begin{aligned} & \widetilde{j}_{R_n}^0 \left( e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right) \\ &= j^0 \left( e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right), \end{aligned}$$

if  $|\widehat{u}_n + e_n \theta_n| \leq R_n$  and

$$\begin{aligned} & \widetilde{j}_{R_n}^0 \left( e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right) \\ &= j^0 \left( \frac{R_n}{\left| \frac{1}{e_n} \widehat{u}_n + \theta_n \right|} \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right), \end{aligned}$$

if  $|\widehat{u}_n + e_n \theta_n| > R_n$ . Therefore we easily conclude, using (7), that

$$\begin{aligned} & \liminf_{n \rightarrow \infty} -\widetilde{j}_{R_n}^0 \left( e_n \left( \frac{1}{e_n} \widehat{u}_n + \theta_n \right); -\frac{1}{e_n} \widehat{u}_n - \theta_n \right) \\ & \geq j^\infty(\theta_0). \end{aligned}$$

Consequently, by Fatou’s lemma,

$$\langle g, \theta_0 \rangle_V \geq \int_{\Omega} j^\infty(\theta_0) d\Omega,$$

contrary to (6). Thus, the boundedness of  $\{u_R\}_{R>R_0}$  follows and the proof of Proposition 4 is complete.

The next result is related to the compactness property of  $\{\chi_R: R > R_0\}$  in  $L^1(\Omega; \mathbf{R}^N)$ .

**Proposition 5** *Let a pair  $(u_R, \chi_R) \in V \times L^q(\Omega; \mathbf{R}^N)$  be a solution of  $(P_R)$ . Then the set*

$$\left\{ \begin{array}{l} (u_R, \chi_R) \\ \text{is a solution of} \\ \chi_R \in L^q(\Omega; \mathbf{R}^N): \\ \text{for some } u_R \in V, \\ R > R_0 \end{array} \right\}$$

*is weakly precompact in  $L^1(\Omega; \mathbf{R}^N)$ .*

*Proof* According to the Dunford–Pettis theorem [8] it is sufficient to show that for each  $\varepsilon > 0$  a  $\delta > 0$  can be determined such that for any  $\omega \subset \Omega$  with  $\text{meas } \omega < \delta$ ,

$$\int_{\omega} |\chi_R| d\Omega < \varepsilon, \quad R > R_0. \tag{36}$$

Fix  $r > 0$  and let  $\eta \in \mathbf{R}^N$  be such that  $|\eta| \leq r$ . Then, by (9), from  $\chi_R \cdot (\eta - u_R) \leq \widetilde{j}_R^0(u_R; \eta - u_R)$  it results that

$$\chi_R \cdot \eta \leq \chi_R \cdot u_R + \widetilde{\alpha}(r)(1 + |u_R|^\sigma) \tag{37}$$

a.e. in  $\Omega$ . Let us set

$$\eta \equiv \frac{r}{\sqrt{N}} (\text{sgn } \chi_{R_1}, \dots, \text{sgn } \chi_{R_N}),$$

where  $\chi_{R_i}, i = 1, \dots, N$ , are the components of  $\chi_R$  and where  $\text{sgn } y = 1$  if  $y > 0$ ,  $\text{sgn } y = 0$  if  $y = 0$ , and  $\text{sgn } y = -1$  if  $y < 0$ . It is not difficult to verify that  $|\eta| \leq r$  for almost all  $x \in \Omega$  and that

$$\chi_R \cdot \eta \geq \frac{r}{\sqrt{N}} |\chi_R|.$$

Therefore, by (37) the estimate follows

$$\frac{r}{\sqrt{N}} |\chi_R| \leq \chi_R \cdot u_R + \widetilde{\alpha}(r)(1 + |u_R|^\sigma).$$

Integrating this inequality over  $\omega \subset \Omega$  yields

$$\int_{\omega} |\chi_R| \, d\Omega \leq \frac{\sqrt{N}}{r} \int_{\omega} \chi_R \cdot u_R \, d\Omega + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) \text{meas } \omega + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) (\text{meas } \omega)^{(p-\sigma)/p} \|u_R\|_{L^p(\Omega)}^{\sigma} \, d\Omega. \quad (38)$$

Thus, from (24) one obtains

$$\begin{aligned} & \int_{\omega} |\chi_R| \, d\Omega \\ & \leq \frac{\sqrt{N}}{r} \int_{\omega} \chi_R \cdot u_R \, d\Omega + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) \text{meas } \omega \\ & \quad + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) (\text{meas } \omega)^{(p-\sigma)/p} \gamma^{\sigma} \|u_R\|_V^{\sigma} \, d\Omega \\ & \leq \frac{\sqrt{N}}{r} \int_{\omega} \chi_R \cdot u_R \, d\Omega + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) \text{meas } \omega \\ & \quad + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) (\text{meas } \omega)^{(p-\sigma)/p} \gamma^{\sigma} M^{\sigma} \, d\Omega \end{aligned} \quad (39)$$

$$(\|\cdot\|_{L^p(\Omega; \mathbf{R}^N)} \leq \gamma \|\cdot\|_V).$$

Further, it will be shown that

$$\int_{\omega} \chi_R \cdot u_R \, d\Omega \leq C \quad (40)$$

for some positive constant  $C$  not depending on  $\omega \subset \Omega$  and  $R > R_0$ . Indeed, from (10) one can easily deduce that

$$\chi_R \cdot u_R + k |u_R| \geq 0 \quad \text{a.e. in } \Omega.$$

Thus it follows that

$$\begin{aligned} & \int_{\omega} (\chi_R \cdot u_R + k |u_R|) \, d\Omega \\ & \leq \int_{\Omega} (\chi_R \cdot u_R + k |u_R|) \, d\Omega, \end{aligned}$$

and consequently

$$\int_{\omega} \chi_R \cdot u_R \, d\Omega \leq \int_{\Omega} \chi_R \cdot u_R \, d\Omega + 2k_1 \|u_R\|_V.$$

But  $A$  maps bounded sets into bounded sets. Therefore, by means of (11) and (24),

$$\begin{aligned} \int_{\Omega} \chi_R \cdot u_R \, d\Omega & = -\langle Au_R - g, u_R \rangle_V \\ & \leq \|Au_R - g\|_{V^*} \|u_R\|_V \leq C_0, \quad C_0 = \text{const}, \end{aligned}$$

and consequently, (40) easily follows. Further, from (39) and (40), for  $r > 0$ ,

$$\begin{aligned} \int_{\omega} |\chi_R| \, d\Omega & \leq \frac{\sqrt{N}}{r} C + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) \text{meas } \omega \\ & \quad + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) (\text{meas } \omega)^{(p-\sigma)/p} \gamma^{\sigma} M^{\sigma} \, d\Omega. \end{aligned} \quad (41)$$

This estimate is crucial for obtaining (36). Namely, let  $\varepsilon > 0$ . Fix  $r > 0$  with

$$\frac{\sqrt{N}}{r} C < \frac{\varepsilon}{2} \quad (42)$$

and determine  $\delta > 0$  small enough to fulfill

$$\begin{aligned} & \frac{\sqrt{N}}{r} \tilde{\alpha}(r) \text{meas } \omega \\ & \quad + \frac{\sqrt{N}}{r} \tilde{\alpha}(r) (\text{meas } \omega)^{(p-\sigma)/p} \gamma^{\sigma} M^{\sigma} \leq \frac{\varepsilon}{2}, \end{aligned}$$

provided that  $\text{meas } \omega < \delta$ . Thus, from (41) it follows that for any  $\omega \subset \Omega$  with  $\text{meas } \omega < \delta$ ,

$$\int_{\omega} |\chi_R| \, d\Omega \leq \varepsilon, \quad R > R_0. \quad (43)$$

Finally,  $\{\chi_R\}_{R>R_0}$  is equi-integrable and its precompactness in  $L^1(\Omega; \mathbf{R}^N)$  has been proved [8].

Now the main result will be formulated.

**Theorem 6** *Let  $A: V \rightarrow V^*$  be a pseudomonotone, bounded operator,  $j: \mathbf{R}^N \rightarrow \mathbf{R}$  a locally Lipschitz function. Suppose that (1)-(3) and (6) hold. Then there exist  $u \in V$  and  $\chi \in L^1(\Omega; \mathbf{R}^N)$  such that*

$$\begin{aligned} \langle Au - g, v - u \rangle_V + \int_{\Omega} \chi \cdot (v - u) \, d\Omega & = 0, \\ \forall v \in V \cap L^{\infty}(\Omega; \mathbf{R}^N), \end{aligned} \quad (44)$$

$$\begin{cases} \chi \in \partial j(u) & \text{a.e. in } \Omega, \\ \chi \cdot u \in L^1(\Omega). \end{cases} \quad (45)$$

Moreover, the hemivariational inequality holds:

$$\langle Au - g, v - u \rangle_V + \int_{\Omega} j^0(u; v - u) \, d\Omega \geq 0, \quad \forall v \in V, \quad (46)$$

where the integral above is assumed to take  $+\infty$  as its value if  $j^0(u; v - u) \notin L^1(\Omega)$ .

*Proof* The proof is divided into a sequence of steps.

*Step 1.* From Propositions 4 and 5 it follows that from the set  $\{u_R, \chi_R\}_{R>R_0}$  of solutions of  $(P_R)$  a sequence  $\{u_{R_n}, \chi_{R_n}\}$  can be extracted with  $R_n \rightarrow \infty$  as  $n \rightarrow \infty$  (for simplicity of notations it will be denoted by  $(u_n, \chi_n)$ ), such that

$$\langle Au_n - g, v - u_n \rangle_V + \int_{\Omega} \chi_n \cdot (v - u_n) \, d\Omega = 0, \forall v \in V, \quad (47)$$

and

$$\begin{cases} \chi_n \in \Gamma_{R_n}(u_n), \\ u_n \rightarrow u & \text{weakly in } V, \\ \chi_n \rightarrow \chi & \text{weakly in } L^1(\Omega; \mathbf{R}^N) \end{cases} \quad (48)$$

for some  $u \in V$  and  $\chi \in L^1(\Omega; \mathbf{R}^N)$ .

The boundedness of  $\{Au_n\}$  in  $V^*$  (recall that  $A$  has been assumed to be bounded and that  $\|u_n\|_V \leq M$ ) allows the conclusion that for some  $B \in V^*$ ,

$$Au_n \rightarrow B \quad \text{weakly in } V^* \quad (49)$$

(by passing to a subsequence, if necessary). Thus, (47) implies that the equality

$$\langle B - g, v \rangle_V + \int_{\Omega} \chi \cdot v \, d\Omega = 0 \quad (50)$$

is valid for any  $v \in V \cap L^\infty(\Omega; \mathbf{R}^N)$ .

*Step 2.* Now it will be proved that  $\chi \in \partial j(u)$  a.e. in  $\Omega$ , i.e. the first condition in (45) is fulfilled. Since  $V$  is compactly imbedded into  $L^p(\Omega; \mathbf{R}^N)$ , due to (48) one may suppose that

$$u_n \rightarrow u \quad \text{strongly in } L^p(\Omega; \mathbf{R}^N). \quad (51)$$

This implies that for a subsequence of  $\{u_n\}$  (again denoted by the same symbol) one gets  $u_n \rightarrow u$  a.e. in  $\Omega$ . Thus, from Egoroff's theorem it follows that for any  $\varepsilon > 0$  a subset  $\omega \subset \Omega$  with  $\text{meas } \omega < \varepsilon$  can be determined such that  $u_n \rightarrow u$  uniformly in  $\Omega \setminus \omega$  with  $u \in L^\infty(\Omega \setminus \omega; \mathbf{R}^N)$ . Let  $v \in L^\infty(\Omega \setminus \omega; \mathbf{R}^N)$  be an arbitrary

function. From the estimate

$$\begin{aligned} \int_{\Omega \setminus \omega} \chi_n \cdot v \, d\Omega &\leq \int_{\Omega \setminus \omega} \widetilde{j_{R_n}^0}(u_n; v) \, d\Omega \\ &= \int_{\Omega \setminus \omega} j^0(u_n; v) \, d\Omega, \quad (\text{for large } n) \end{aligned}$$

( $u_n$  remains pointwise uniformly bounded in  $\Omega \setminus \omega$  and  $R_n \rightarrow \infty$  as  $n \rightarrow \infty$ ) combined with the weak convergence in  $L^1(\Omega; \mathbf{R}^N)$  of  $\chi_n$  to  $\chi$ , (51) and with the upper semicontinuity of

$$L^\infty(\Omega \setminus \omega; \mathbf{R}^N) \ni u_n \mapsto \int_{\Omega \setminus \omega} j^0(u_n; v) \, d\Omega,$$

it follows that

$$\int_{\Omega \setminus \omega} \chi \cdot v \, d\Omega \leq \int_{\Omega \setminus \omega} j^0(u; v) \, d\Omega, \quad \forall v \in L^\infty(\Omega \setminus \omega; \mathbf{R}^N).$$

But the last inequality allows us to state that  $\chi \in \partial j(u)$  a.e. in  $\Omega \setminus \omega$ . Since  $\text{meas } \omega < \varepsilon$  and  $\varepsilon$  was chosen arbitrarily,

$$\chi \in \partial j(u) \quad \text{a.e. in } \Omega, \quad (52)$$

as claimed.

*Step 3.* Now it will be shown that  $\chi \cdot u \in L^1(\Omega)$ , i.e. the second condition in (45) holds. For this purpose we shall need the following truncation result for vector-valued Sobolev spaces.

**Theorem 7** ([20]) *For each  $v \in H^1(\Omega; \mathbf{R}^N)$  there exists a sequence of functions  $\{\varepsilon_n\} \subset L^\infty(\Omega)$  with  $0 \leq \varepsilon_n \leq 1$  such that*

$$\begin{aligned} \{(1 - \varepsilon_n)v\} &\subset H^1(\Omega; \mathbf{R}^N) \cap L^\infty(\Omega; \mathbf{R}^N) \\ (1 - \varepsilon_n)v &\rightarrow v \quad \text{strongly in } H^1(\Omega; \mathbf{R}^N). \end{aligned} \quad (53)$$

*Remark 8* For the truncation procedure of the form (53) in the case of a scalar-valued Sobolev space  $W^{p,m}(\Omega)$  the reader is referred to [11].

According to the aforementioned theorem, for  $u \in V$  one can find a sequence  $\{\varepsilon_k\} \subset L^\infty(\Omega)$  with  $0 \leq \varepsilon_k \leq 1$  such that  $\widetilde{u}_k := (1 - \varepsilon_k)u \in V \cap L^\infty(\Omega; \mathbf{R}^N)$  and  $\widetilde{u}_k \rightarrow u$  in  $V$  as  $k \rightarrow \infty$ . Without loss of generality it can be assumed that  $\widetilde{u}_k \rightarrow u$  a.e. in  $\Omega$ . Since it is already

known that  $\chi \in \partial j(u)$ , one can apply (3) to obtain  $\chi \cdot (-u) \leq j^0(u; -u) \leq k|u|$ . Hence

$$\chi \cdot \tilde{u}_k = (1 - \varepsilon_k)\chi \cdot u \geq -k|u|. \tag{54}$$

This implies that the sequence  $\{\chi \cdot \tilde{u}_k\}$  is bounded from below and  $\chi \cdot \tilde{u}_k \rightarrow \chi \cdot u$  a.e. in  $\Omega$ . On the other hand, due to (50) one gets

$$C \geq \langle -B + g, \tilde{u}_k \rangle_V = \int_{\Omega} \chi \cdot \tilde{u}_k \, d\Omega$$

for a positive constant  $C$ . Thus, by Fatou's lemma  $\chi \cdot u \in L^1(\Omega)$ , as required.

Step 4. Now the inequality

$$\liminf_{n \rightarrow \infty} \int_{\Omega} \chi_n \cdot u_n \, d\Omega \geq \int_{\Omega} \chi \cdot u \, d\Omega \tag{55}$$

will be established. It can be supposed that  $u_n \rightarrow u$  a.e. in  $\Omega$ , because  $u_n \rightarrow u$  strongly in  $L^p(\Omega; \mathbf{R}^N)$ . Fix  $v \in L^\infty(\Omega; \mathbf{R}^N)$  arbitrarily. Since  $\chi_n \in \Gamma_{R_n}(u_n)$ , Eq. (9) implies

$$\chi_n \cdot (v - u_n) \leq j_{R_n}^0(u_n; v - u_n) \leq \tilde{\alpha}(\|v\|_{L^\infty(\Omega; \mathbf{R}^N)})(1 + |u_n|^\sigma). \tag{56}$$

From Egoroff's theorem it follows that for any  $\varepsilon > 0$  a subset  $\omega \subset \Omega$  with  $\text{meas } \omega < \varepsilon$  can be determined such that  $u_n \rightarrow u$  uniformly in  $\Omega \setminus \omega$ . One can also suppose that  $\omega$  is small enough to fulfill  $\int_{\omega} \tilde{\alpha}(\|v\|_{L^\infty(\Omega; \mathbf{R}^N)})(1 + |u_n|^\sigma) \, d\Omega \leq \varepsilon$ ,  $n = 1, 2, \dots$ , and  $\int_{\omega} \alpha(\|v\|_{L^\infty(\Omega; \mathbf{R}^N)})(1 + |u^\sigma|) \, d\Omega \leq \varepsilon$ . Hence

$$\begin{aligned} & \int_{\Omega} j_{R_n}^0(u_n; v - u_n) \, d\Omega \\ & \leq \int_{\Omega \setminus \omega} j_{R_n}^0(u_n; v - u_n) \, d\Omega + \varepsilon \\ & = \int_{\Omega \setminus \omega} j^0(u_n; v - u_n) \, d\Omega + \varepsilon \quad (\text{for large } n), \end{aligned}$$

which by Fatou's lemma and upper semicontinuity of  $j^0(\cdot; \cdot)$  yields

$$\begin{aligned} & \liminf_{n \rightarrow \infty} \int_{\Omega} -j_{R_n}^0(u_n; v - u_n) \, d\Omega \\ & \geq \int_{\Omega} -j^0(u; v - u) \, d\Omega - 2\varepsilon. \end{aligned}$$

By arbitrariness of  $\varepsilon > 0$  and (56) one obtains

$$\begin{aligned} & \liminf_{n \rightarrow \infty} \int_{\Omega} \chi_n \cdot u_n \, d\Omega \\ & \geq \int_{\Omega} \chi \cdot v \, d\Omega - \int_{\Omega} j^0(u; v - u) \, d\Omega, \\ & \quad \forall v \in V \cap L^\infty(\Omega; \mathbf{R}^N). \tag{57} \end{aligned}$$

By substituting  $v = \tilde{u}_k := (1 - \varepsilon_k)u$  (with  $\tilde{u}_k$  as described in the truncation argument of Theorem 7) into the right-hand side of (57) one gets

$$\begin{aligned} & \liminf_{n \rightarrow \infty} \int_{\Omega} \chi_n \cdot u_n \, d\Omega \\ & \geq \liminf_{k \rightarrow \infty} \int_{\Omega} \chi \cdot \tilde{u}_k \, d\Omega \\ & \quad - \limsup_{k \rightarrow \infty} \int_{\Omega} j^0(u; \tilde{u}_k - u) \, d\Omega. \tag{58} \end{aligned}$$

Taking into account that  $\tilde{u}_k \rightarrow u$  a.e. in  $\Omega$ ,

$$j^0(u; \tilde{u}_k - u) = \varepsilon_k j^0(u; -u) \leq \varepsilon_k k|u| \leq k|u|$$

and  $|\chi \cdot u| \geq \chi \cdot \tilde{u}_k = (1 - \varepsilon_k)\chi \cdot u \geq -k|u|$ , Fatou's lemma and the dominated convergence can be used to deduce

$$\limsup_{k \rightarrow \infty} \int_{\Omega} j^0(u; \tilde{u}_k - u) \, d\Omega \leq 0,$$

and

$$\lim_{k \rightarrow \infty} \int_{\Omega} \chi \cdot \tilde{u}_k \, d\Omega = \int_{\Omega} \chi \cdot u \, d\Omega.$$

Finally, combining the last two inequalities with (58) yields (55), as required.

Step 5. The next claim is that

$$\langle B - g, u \rangle_V + \int_{\Omega} \chi \cdot u \, d\Omega = 0. \tag{59}$$

Indeed, (50) implies

$$\langle B - g, \tilde{u}_k \rangle_V + \int_{\Omega} \chi \cdot \tilde{u}_k \, d\Omega = 0, \tag{60}$$

with  $\{\tilde{u}_k\}$  as in Step 3. Since  $\chi \cdot u \in L^1(\Omega)$  and  $-k|u| \leq \chi \cdot \tilde{u}_k = (1 - \varepsilon_k)\chi \cdot u \leq |\chi \cdot u|$ , by the dominated convergence,

$$\int_{\Omega} \chi \cdot \tilde{u}_k \, d\Omega \rightarrow \int_{\Omega} \chi \cdot u \, d\Omega.$$

It means that (59) has to hold by passing to the limit as  $k \rightarrow \infty$  in (60).

Step 6. In this step it will be shown that the pseudomonotonicity of  $A$  and (47) imply (44). Indeed, (47) with  $v \in V \cap L^\infty(\Omega; \mathbf{R}^N)$  and (49) allows to state that

$$\begin{aligned} \limsup_{n \rightarrow \infty} \langle Au_n, u_n - u \rangle_V &\leq \langle B - g, v - u \rangle_V \\ &+ \int_{\Omega} \chi \cdot v \, d\Omega - \liminf_{n \rightarrow \infty} \int_{\Omega} \chi_n \cdot u_n \, d\Omega. \end{aligned}$$

Substituting  $v = \tilde{u}_k$  with  $\tilde{u}_k$  as in Step 3 and taking into account (55) one arrives at  $\limsup_{n \rightarrow \infty} \langle Au_n, u_n - u \rangle_V \leq 0$  (by the application of the limit procedure as  $k \rightarrow \infty$ ). Therefore the use of pseudomonotonicity of  $A$  is allowed and yields  $\langle Au_n, u_n \rangle_V \rightarrow \langle Au, u \rangle_V$  and  $Au_n \rightarrow B = Au$  weakly in  $V^*$  as  $n \rightarrow \infty$ . Finally, (47) implies (44), as claimed.

Step 7. In the final step of the proof it will be shown that (44) and (45) imply (46). For this purpose, choose  $v \in V \cap L^\infty(\Omega; \mathbf{R}^N)$  arbitrarily. From (2) one has  $\chi \cdot (v - u) \leq j^0(u; v - u) \leq \alpha(\|v\|_{L^\infty(\Omega; \mathbf{R}^N)})(1 + |u|^\sigma)$  with  $\chi \cdot (v - u) \in L^1(\Omega)$  and  $\alpha(\|v\|_{L^\infty(\Omega; \mathbf{R}^N)})(1 + |u|^\sigma) \in L^1(\Omega)$ . Hence  $j^0(u; v - u)$  is finite integrable and consequently, (46) follows immediately from (44).

Now consider the case  $j^0(u; v - u) \in L^1(\Omega)$  with  $v \notin V \cap L^\infty(\Omega; \mathbf{R}^N)$ . According to Theorem 7 there exists a sequence  $\tilde{v}_k = (1 - \varepsilon_k)v$  such that  $\{\tilde{v}_k\} \subset V \cap L^\infty(\Omega; \mathbf{R}^N)$  and  $\tilde{v}_k \rightarrow v$  strongly in  $V$ . Since

$$\langle Au - g, \tilde{v}_k - u \rangle_V + \int_{\Omega} j^0(u; \tilde{v}_k - u) \, d\Omega \geq 0,$$

so in order to establish (46) it remains to show that

$$\limsup_{k \rightarrow \infty} \int_{\Omega} j^0(u; \tilde{v}_k - u) \, d\Omega \leq \int_{\Omega} j^0(u; v - u) \, d\Omega.$$

For this purpose let us observe that  $\tilde{v}_k - u = (1 - \varepsilon_k)(v - u) + \varepsilon_k(-u)$  which combined with the convexity of  $j^0(u; \cdot)$  yields the estimate

$$\begin{aligned} j^0(u; \tilde{v}_k - u) &\leq (1 - \varepsilon_k)j^0(u; v - u) + \varepsilon_k j^0(u; -u) \\ &\leq |j^0(u; v - u)| + k|u|. \end{aligned}$$

Thus the application of Fatou's lemma gives the assertion. Finally, the proof of Theorem 6 is complete.

*Remark 9* The analogous result to that of Theorem 6 can be formulated for the hemivariational inequality (46) in which  $\int_{\Omega}(\cdot) \, d\Omega$  is replaced by the boundary integral  $\int_{\Gamma}(\cdot) \, d\Gamma$ , provided the imbedding  $H^1(\Omega) \subset L^p(\Gamma)$  is compact ( $1 < p < (2m - 2)/(m - 2)$ , [12]).

*Example 10* Let us consider a linear elastic body which in its undeformed state occupies an open, bounded, connected subset  $\Omega$  of  $\mathbf{R}^3$ .  $\Omega$  is referred to a fixed Cartesian coordinate system  $0x_1x_2x_3$  and its boundary  $\Gamma$  is assumed to be Lipschitz regular;  $n = (n_i)$  denotes the outward unit normal vector to  $\Gamma$ . We decompose  $\Gamma$  into two disjointed parts  $\Gamma_F$  and  $\Gamma_S$  such that  $\Gamma = \overline{\Gamma}_F \cup \overline{\Gamma}_S$ . As usual, the symbols  $u: \Omega \rightarrow \mathbf{R}^3$  and  $\sigma: \Omega \rightarrow \mathbf{S}^3$  are used to denote the displacement field and the stress tensor field, respectively. Here  $\mathbf{S}^3$  stands for the space of all real-valued  $3 \times 3$  symmetric matrices.

Consider the boundary value problem:

i) The equilibrium equations:

$$\sigma_{ij,j} + b_i = 0 \quad \text{in } \Omega. \tag{61}$$

ii) The displacement—strain relation:

$$\varepsilon_{ij}(u) = \frac{1}{2}(u_{i,j} + u_{j,i}) \quad \text{in } \Omega. \tag{62}$$

iii) Hook's law:

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl}(u) \quad \text{in } \Omega. \tag{63}$$

iv) The surface traction conditions

$$\sigma_{ij}n_j = F_i \quad \text{on } \Gamma_F. \tag{64}$$

v) The nonmonotone subdifferential boundary conditions

$$-S \in \partial j(u) \quad \text{on } \Gamma_S. \tag{65}$$

Here,  $S = (S_i) = (\sigma_{ijn_j})$  is the stress vector, and  $\partial j(\cdot)$  is the generalized gradient of Clarke of a locally Lipschitz function  $j: \mathbf{R}^3 \rightarrow \mathbf{R}$ ; the summation convention over repeated indices holds and the elasticity tensor  $C = (C_{ijkl})$  is assumed to satisfy the classical conditions of ellipticity and symmetry [24].

Let  $V = H^1(\Omega; \mathbf{R}^3)$ . By making use of the standard technique (cf. [24]), Eqs. (61)-(65) lead to the problem

of finding  $u \in V$  such as to satisfy the hemivariational inequality

$$\int_{\Omega} C_{ijkl} \varepsilon_{ij}(u) \varepsilon_{kl}(v - u) d\Omega - \int_{\Omega} b_i (v_i - u_i) d\Omega - \int_{\Gamma_F} F_i (v_i - u_i) d\Gamma + \int_{\Gamma_S} j^0(u; v - u) d\Gamma \geq 0, \quad \forall v \in V. \quad (66)$$

Define  $A: V \rightarrow V^*$  by

$$\langle Au, v \rangle_V = \int_{\Omega} C_{ijkl} \varepsilon_{ij}(u) \varepsilon_{kl}(v) d\Omega, \quad u, v \in V,$$

and let  $V_0 := \mathcal{R} = \{ \rho \in V : \varepsilon_{ij}(\rho) = 0, i, j = 1, 2, 3 \}$  denote the space of all rigid-body displacements. Then (1) holds (for details see [24, p. 121]). Accordingly, if (2) (with  $\sigma < 4$ ) and (3) are fulfilled and, moreover, the compatibility condition

$$\int_{\Omega} b_i \rho_i d\Omega + \int_{\Gamma_F} F_i \rho_i d\Gamma < \int_{\Gamma_S} j^\infty(\rho) d\Gamma$$

is valid for any  $\rho \in \mathcal{R} \setminus \{0\}$ , then the hypotheses of the theorem mentioned in Remark 9 are satisfied. Consequently, the existence of solutions to the hemivariational inequality (66) is ensured.

## Introduction

The **Traveling Salesman Problem (TSP)** is one of the most representative problems in combinatorial optimization. If we consider a salesman who has to visit  $n$  cities [46], the Traveling Salesman Problem asks for the shortest tour through all the cities such that no city is visited twice and the salesman returns at the end of the tour back to the starting city. Mathematically, the problem may be stated as follows: Let  $G = (V, E)$  be a graph, where  $V$  is a set of  $n$  nodes and  $E$  is a set of arcs, let  $C = [c_{ij}]$  be a cost matrix associated with  $E$ , where  $c_{ij}$  represents the cost of going from city  $i$  to city  $j$ , ( $i, j = 1, \dots, n$ ), the problem is to find a permutation  $(i_1, i_2, i_3, \dots, i_n)$  of the integers from 1 through  $n$  that minimizes the quantity  $c_{i_1 i_2} + c_{i_2 i_3} + \dots + c_{i_n i_1}$ .

We speak of a *Symmetric TSP*, if for all pairs  $(i, j)$ , the distance  $c_{ij}$  is equal to the distance  $c_{ji}$ . Otherwise, we speak of the *Asymmetric TSP* [7]. If the triangle inequality holds ( $c_{ij} \leq c_{i i_1} + c_{i_1 j}, \forall i, j, i_1$ ), the problem is said to be metric. If the cities can be represented as points in the plain such that  $c_{ij}$  is the Euclidean distance between point  $i$  and point  $j$ , then the corresponding TSP is called the Euclidean TSP. Euclidean TSP obeys in particular the triangle inequality  $c_{ij} \leq c_{i i_1} + c_{i_1 j}$  for all  $i, j, i_1$ .

An integer programming formulation of the Traveling Salesman Problem is defined in a complete graph

$G = (V, E)$  of  $n$  nodes, with node set  $V = \{1, \dots, n\}$ , arc set  $E = \{(i, j) | i, j = 1, \dots, n\}$ , and nonnegative costs  $c_{ij}$  associated with the arcs [8]:

$$c^* = \min \sum_{i \in V} \sum_{j \in V} c_{ij} x_{ij} \tag{1}$$

s.t.

$$\sum_{j \in V} x_{ij} = 1, \quad i \in V \tag{2}$$

$$\sum_{i \in V} x_{ij} = 1, \quad j \in V \tag{3}$$

$$\sum_{i \in S} \sum_{j \in S} x_{ij} \leq |S| - 1, \quad \forall S \subset V, S \neq \emptyset \tag{4}$$

$$x_{ij} \in \{0, 1\}, \quad \text{for all } i, j \in V, \tag{5}$$

where  $x_{ij} = 1$  if arc  $(i, j)$  is in the solution and 0 otherwise. In this formulation, the objective function clearly describes the cost of the optimal tour. Constraints (2) and (3) are degree constraints: they specify that every node is entered exactly once and left exactly once. Constraints (4) are subtour elimination constraints. These constraints prohibit the formation of subtours, i.e. tours on subsets of less than  $V$  nodes. If there was such a subtour on a subset  $S$  of nodes, this subtour would contain  $|S|$  edges and as many nodes. Constraints (4) would then be violated for this subset since the left-hand side of (4) would be equal to  $|S|$  while the right-hand side would be equal to  $|S| - 1$ . Because of degree constraints, subtours over one node (and hence, over  $n - 1$  nodes) cannot occur. For more formulations of the problem see [34,60].

The Traveling Salesman Problem (TSP) is one of the most famous hard combinatorial optimization problems. It has been proven that TSP is a member of the set of NP-complete problems. This is a class of difficult problems whose time complexity is probably exponential. The members of the class are related so that if a polynomial time algorithm was found for one problem, polynomial time algorithms would exist for all of them [41]. However, it is commonly believed that no such polynomial algorithm exists. Therefore, any attempt to construct a general algorithm for finding optimal solutions for the TSP in polynomial time must (probably) fail. That is, for any such algorithm it is possible to construct problem instances for which the execution time grows at least exponentially with the size of the input. Note, however, that time complexity here

refers to the worst case behavior of the algorithm. It can not be excluded that there exist algorithms whose average running time is polynomial. The existence of such algorithms is still an open question. Since 1950s many algorithms have been proposed, developed and tested for the solution of the problem. Algorithms for solving the TSP may be divided into two categories, *exact algorithms* and *heuristic–metaheuristic algorithms*.

### Heuristics for the Traveling Salesman Problem

There is a great need for powerful heuristics that find good suboptimal solutions in reasonable amounts of computing time. These algorithms are usually very simple and have short running times. There is a huge number of papers dealing with finding near optimal solutions for the TSP. Our aim is to present the most interesting and efficient algorithms and the most important ones for facing practical problems. In the 1960s, 1970s and 1980s the attempts to solve the Traveling Salesman Problem focused on **tour construction methods** and **tour improvement methods**. In the last fifteen years, metaheuristics, such as **simulated annealing**, **tabu search**, **genetic algorithms** and **neural networks**, were introduced. These algorithms have the ability to find their way out of local optima. Heuristics and metaheuristics constitute an increasingly essential component of solution approaches intended to tackle difficult problems, in general, and global and combinatorial problems in particular.

When a heuristic is designed, the question which arises is about the quality of the produced solution. There are three different ways that one may try to answer this question.

1. **Empirical.** The heuristic is applied to a number of test problem instances and the solutions are compared to the optimal values, if there are known, or to lower bounds on these values [33,35].
2. **Worst Case Analysis.** The idea is to derive bounds on the worst possible deviation from the optimum that the heuristic could produce and to devise bad problem instances for which the heuristic actually achieves this deviation [42].
3. **Probabilistic Analysis.** In the probabilistic analysis it is assumed that problem instances are drawn from certain simple probability distributions, and it is, then, proven mathematically that particular solu-

tion methods are highly likely to yield near-optimal solutions when the number of cities is large [43].

**Tour Construction** methods build up a tour step by step. Such heuristics build a solution (tour) from scratch by a growth process (usually a greedy one) that terminates as soon as a feasible solution has been constructed. The problem with construction heuristics is that although they are usually fast, they do not, in general, produce very good solutions. One of the simplest tour construction methods is the **nearest neighborhood** in which, a salesman starts from an arbitrary city and goes to its nearest neighbor. Then, he proceeds from there in the same manner. He visits the nearest unvisited city, until all cities are visited, and then returns to the starting city [65,68].

An extension of the nearest neighborhood method is the **double-side nearest neighborhood method** where the current path can be extended from both of its endnodes. Some authors use the name **Greedy** for Nearest Neighborhood, but it is more appropriately reserved for the special case of the greedy algorithm of matroid theory [39]. Bentley [11] proposed two very fast and efficient algorithms, the **K-d Trees** and the **Lazily Update Priority Queues**. In his paper, it was the first time that somebody suggested the use of data structures for the solution of the TSP. A priority queue contains items with associated values (the priorities) and support operations that [40]:

- remove the highest priority item from the queue and deliver it to the user,
- insert an item,
- delete an item, and
- modify the priority of an item.

The **insertion procedures** [68] take a subtour of  $V$  nodes and attempt to determine which node (not already in the subtour) should join the subtour next (the *selection step*) and then determine where in the subtour it should be inserted (the *insertion step*). The most known of these algorithms is the **nearest insertion algorithm**. Similar to the nearest insertion procedure are the **cheapest insertion** [65], the **arbitrary insertion** [12], the **farthest insertion** [65], the **quick insertion** [12], and the **convex hull insertion** [12] algorithms.

There is a number of heuristic algorithms that are designed for speed rather for quality of the tour they construct [40]. The three most known heuristic algo-

gorithms of this category are the **Strip algorithm**, proposed by Beardwood et al. [10], the **Spacefilling Curve** proposed by Platzmann and Bartholdi [58] and the **Fast Recursive Partitioning** heuristic proposed by Bentley [11]. The **saving algorithms** are exchange procedures. The most known of them is the **Clarke-Wright algorithm** [17]. Christofides [12,65] suggested a procedure for solving the TSP based on **spanning trees**. He proposed a method of transforming spanning trees to Eulerian graphs.

The **improvement methods** or **local search methods** start with a tour and try to find all tours that are “neighboring” to it and are shorter than the initial tour and, then, to replace it. The tour improvements methods can be divided into three categories according to the type of the neighborhood that they use [64]. Initially, the **constructive neighborhood methods**, which successively add new components to create a new solution, while keeping some components of the current solution fixed. Some of these methods will be presented in the next section where the most known metaheuristics are presented. Secondly, the **transition neighborhood methods**, which are the classic local search algorithms (classic tour improvement methods) and which iteratively move from one solution to another based on the definition of a neighborhood structure. Finally, the **population based neighborhood methods**, which generalize the two previous categories by considering neighborhoods of more than one solution.

The most known of the local search algorithms is the **2-opt heuristic**, in which two edges are deleted and the open ends are connected in a different way in order to obtain a new tour [48]. Note that there is only one way to reconnect the paths. The **3-opt heuristic** is quite similar with the 2-opt but it introduces more flexibility in modifying the current tour, because it uses a larger neighborhood. The tour breaks into three parts instead of only two [48]. In the general case,  $\delta$  edges in a feasible tour are exchanged for  $\delta$  edges not in that solution as long as the result remains a tour and the length of that tour is less than the length of the previous tour. **Lin-Kernighan method (LK)** was developed by Lin and Kernighan [37,49,54] and for many years was considered to be the best heuristic for the TSP. The **Or-opt procedure**, well known as **node exchange heuristic**, was first introduced by Or [56]. It removes a sequence of up-to-three adjacent nodes and inserts it

at another location within the same route. Or-opt can be considered as a special case of 3-opt (three arcs exchanges) where three arcs are removed and substituted by three other arcs. The **GENI algorithm** was presented by Gendreau, Hertz and Laporte [22]. GENI is a hybrid of tour construction and local optimization.

### Metaheuristics for the Traveling Salesman Problem

The last fifteen years an incremental amount of metaheuristic algorithms have been proposed. Simulated annealing, genetic algorithms, neural networks, tabu search, ant algorithms, together with a number of hybrid techniques are the main categories of the metaheuristic procedures. These algorithms have the ability to find their way out of local optima. A number of metaheuristic algorithms have been proposed for the solution of the Traveling Salesman Problem. The most important algorithms published for each metaheuristic algorithm are given in the following:

- **Simulated Annealing (SA)** belongs [1,2,45,64] to a class of local search algorithms that are known as *threshold accepting algorithms*. These algorithms play a special role within local search for two reasons. First, they appear to be quite successful when applied to a broad range of practical problems. Second, some threshold accepting algorithms such as SA have a stochastic component, which facilitates a theoretical analysis of their asymptotic convergence. Simulated Annealing [3] is a stochastic algorithm that allows random uphill jumps in a controlled fashion in order to provide possible escapes from poor local optima. Gradually the probability allowing the objective function value to increase is lowered until no more transformations are possible. Simulated Annealing owes its name to an analogy with the annealing process in condensed matter physics, where a solid is heated to a maximum temperature at which all particles of the solid randomly arrange themselves in the liquid phase, followed by cooling through careful and slow reduction of the temperature until the liquid is frozen with the particles arranged in a highly structured lattice and minimal system energy. This ground state is reachable only if the maximum temperature is sufficiently high and the cooling sufficiently slow.

Otherwise a meta-stable state is reached. The meta-stable state is also reached with a process known as quenching, in which the temperature is instantaneously lowered. Its predecessor is the so-called Metropolis filter. Simulated Annealing algorithms for the TSP are presented in [15,55,65].

- **Tabu search (TS)** was introduced by Glover [24,25] as a general iterative metaheuristic for solving combinatorial optimization problems. Computational experience has shown that TS is a well established approximation technique, which can compete with almost all known techniques and which, by its flexibility, can beat many classic procedures. It is a form of local neighbor search. Each solution  $S$  has an associated set of neighbors  $N(S)$ . A solution  $S' \in N(S)$  can be reached from  $S$  by an operation called a *move*. TS can be viewed as an iterative technique which explores a set of problem solutions, by repeatedly making moves from one solution  $S$  to another solution  $S'$  located in the neighborhood  $N(S)$  of  $S$  [31]. TS moves from a solution to its best admissible neighbor, even if this causes the objective function to deteriorate. To avoid cycling, solutions that have been recently explored are declared *forbidden or tabu* for a number of iterations. The tabu status of a solution is overridden when certain criteria (*aspiration criteria*) are satisfied. Sometimes, *intensification* and *diversification* strategies are used to improve the search. In the first case, the search is accentuated in the promising regions of the feasible domain. In the second case, an attempt is made to consider solutions in a broad area of the search space. The first Tabu Search algorithm implemented for the TSP appears to be the one described by Glover [23,29]. Limited results for this implementation and variants on it were reported by Glover [26]. Other Tabu Search algorithms for the TSP are presented in [74].
- **Genetic Algorithms (GAs)** are search procedures based on the mechanics of natural selection and natural genetics. The first GA was developed by John H. Holland in the 1960s to allow computers to evolve solutions to difficult search and combinatorial problems, such as function optimization and machine learning [38]. Genetic algorithms offer a particularly attractive approach for problems like traveling salesman problem since they are generally quite effective for rapid global search of large, non-linear and poorly understood spaces. Moreover, genetic algorithms are very effective in solving large-scale problems. Genetic algorithms mimic the evolution process in nature. GAs are based on an imitation of the biological process in which new and better populations among different species are developed during evolution. Thus, unlike most standard heuristics, GAs use information about a population of solutions, called individuals, when they search for better solutions. A GA is a stochastic iterative procedure that maintains the population size constant in each iteration, called a generation. Their basic operation is the mating of two solutions in order to form a new solution. To form a new population, a binary operator called crossover, and a unary operator, called mutation, are applied [61,62]. Crossover takes two individuals, called parents, and produces two new individuals, called offsprings, by swapping parts of the parents. Genetic algorithms for the TSP are presented in [9,51,59,64,67].
- **Greedy Randomized Adaptive Search Procedure - GRASP** [66] is an iterative two phase search method which has gained considerable popularity in combinatorial optimization. Each iteration consists of two phases, a construction phase and a local search procedure. In the construction phase, a randomized greedy function is used to build up an initial solution. This randomized technique provides a feasible solution within each iteration. This solution is then exposed for improvement attempts in the local search phase. The final result is simply the best solution found over all iterations. Greedy Randomized Adaptive Search Procedure algorithms for the TSP are presented in [50,51].
- The use of **Artificial Neural Networks** to find good solutions to combinatorial optimization problems has recently caught some attention. A neural network consists of a network [57] of elementary nodes (neurons) that are linked through weighted connections. The nodes represent computational units, which are capable of performing a simple computation, consisting of a summation of the weighted inputs, followed by the addition of a constant called the threshold or bias, and the application of a non-linear response (activation) function. The result of the computation of a unit constitutes its output. This output is used as an input for the nodes to which

it is linked through an outgoing connection. The overall task of the network is to achieve a certain network configuration, for instance a required input–output relation, by means of the collective computation of the nodes. This process is often called *self-organization*. Neural Networks algorithms for the TSP are presented in [4,6,53,69].

- The **Ant Colony Optimization (ACO)** metaheuristic is a relatively new technique for solving combinatorial optimization problems (COPs). Based strongly on the Ant System (AS) metaheuristic developed by Dorigo, Maniezzo and Coloni [19], ant colony optimization is derived from the foraging behaviour of real ants in nature. The main idea of ACO is to model the problem as the search for a minimum cost path in a graph. Artificial ants walk through this graph, looking for good paths. Each ant has a rather simple behavior so that it will typically only find rather poor-quality paths on its own. Better paths are found as the emergent result of the global cooperation among ants in the colony. An ACO algorithm consists of a number of cycles (iterations) of solution construction. During each iteration a number of ants (which is a parameter) construct complete solutions using heuristic information and the collected experiences of previous groups of ants. These collected experiences are represented by a digital analogue of trail pheromone which is deposited on the constituent elements of a solution. Small quantities are deposited during the construction phase while larger amounts are deposited at the end of each iteration in proportion to solution quality. Pheromone can be deposited on the components and/or the connections used in a solution depending on the problem. Ant Colony Optimization algorithms for the TSP are presented in [16,18,19,70].
- One way to invest extra computation time is to exploit the fact that many local improvement heuristics have random components, even if in their initial tour construction phase. Thus, if one runs the heuristic multiple times he will get different results and can take the best. The **Iterated Lin Kernighan algorithm (ILK)** [54] has been proposed by Johnson [39] and it is considered to be one of the best algorithms for obtaining a first local minimum. To improve this local minimum, the algorithm examines other local minimum tours ‘near’ the current local minimum. To generate these tours, ILK first applies a random and unbiased nonsequential 4-opt exchange to the current local minimum and then optimizes this 4-opt neighbor using the LK algorithm. If the tour obtained by this process is better than the current local minimum then ILK makes this tour the current local minimum and continues from there using the same neighbor generation process. Otherwise, the current local minimum remains as it is and further random 4-opt moves are tried. The algorithm stops when a stopping criterion based either on the number of iterations or the computational time is satisfied. Two other approaches are the **Iterated 3-opt** and the **Chained Lin-Kernighan** [5], where random kicks are generated from the solution and from these new points the exploration for a better solution is continued [40].
- **Ejection Chain Method** provides a wide variety of reference structures, which have the ability to generate moves not available to neighborhood search approaches traditionally applied to TSP [63,64]. Ejection Chains are variable depth methods that generate a sequence of interrelated simple moves to create a more complex compound move. An ejection consists of a succession of operations performed on a given set of elements, where the  $m_t$  operation changes the state of one or more elements which are said to be ejected in the  $m_t + 1$  operations. Of course, there is a possibility to appear changes in the state of other elements, which will lead to other ejections, until no more operations can be made [27]. Other Ejection Chain Algorithms are presented in [20,21].
- **Scatter Search** is an evolutionary strategy originally proposed by Glover [28,30]. Scatter Search operates on a set of reference solutions to generate a new set of solutions by weighted linear combinations of structured subset of solutions. The reference set is required to be made up of high quality and diverse solutions and the goal is to produce weighted centers of selected subregions that project these centers into regions of the solution space that are to be explored by auxiliary heuristic procedures.
- **Path Relinking** [28,30], combines solutions by generating paths between them using local search neighborhoods, and selecting new solutions encountered along these paths.

- **Guided Local Search (GLS)**, originally proposed by Voudouris and Chang [71,72], is a general optimization technique suitable for a wide range of combinatorial optimization problems. The main focus is on the exploitation of problem and search-related information to effectively guide local search heuristics in the vast search spaces of NP-hard optimization problems. This is achieved by augmenting the objective function of the problem to be minimized with a set of penalty terms which are dynamically manipulated during the search process to steer the heuristic to be guided. GLS augments the cost function of the problem to include a set of penalty terms and passes this, instead of the original one, for minimization by the local search procedure. Local search is confined by the penalty terms and focuses attention on promising regions of the search space. Iterative calls are made to local search. Each time local search gets caught in a local minimum, the penalties are modified and local search is called again to minimize the modification cost function. Guided Local Search algorithms for the TSP are presented in [71,72].
- **Noising Method** was proposed by Charon and Hudry [13] and is a metaheuristic where if it is wanted to minimize the function  $f^1$ , this method does not take the true values of  $f^1$  into account but it considers that they are perturbed in some way by noises in order to get a noised function  $f^1_{\text{noised}}$ . During the run of the algorithm, the range of the perturbing noises decreases (typically to zero), so that, at the end, there is no significant noise and the optimization of  $f^1_{\text{noised}}$  leads to the same solution as the one provided by a descent algorithm applied to  $f^1$  with the same initial solution. This algorithm was applied to the Traveling Salesman Problem by Charon and Hudry [14].
- **Particle Swarm Optimization (PSO)** is a population-based swarm intelligence algorithm. It was originally proposed by Kennedy and Eberhart as a simulation of the social behavior of social organisms such as bird flocking and fish schooling [44]. PSO uses the physical movements of the individuals in the swarm and has a flexible and well-balanced mechanism to enhance and adapt to the global and local exploration abilities. PSO algorithms for the solution of the Traveling Salesman Problem are presented in [32,47,73].
- **Variable Neighborhood Search (VNS)** is a metaheuristic for solving combinatorial optimization problems whose basic idea is systematic change of neighborhood within a local search [36]. Variable Neighborhood Search algorithms for the TSP are presented in [52].

### Keywords and Phrases

Optimization; Heuristic search

### Introduction

Heuristic search [7,9] is a common technique for finding a solution in a decision tree or graph containing one

or more solutions. Many applications in operations research and artificial intelligence rely on heuristic search as their primary solution method.

Heuristic search techniques can be classified into two broad categories: depth-first search (DFS) and best-first search (BFS). As a consequence of its better information base, BFS usually examines fewer nodes but occupies more storage space for maintaining the already explored nodes.

### Depth-First Search

DFS expands an initial state by generating its immediate successors. At each subsequent step, one of the most recently generated successors is selected and expanded. At terminal states, or when it can be determined that the current state does not lead to a solution, the search backtracks, that is, the node expansion proceeds with the next most recently generated state. Practical implementations use a stack data structure for maintaining the states (nodes) on the path to the currently explored state. The space complexity of the stack,  $O(d)$ , increases only linearly with the search depth  $d$ .

Backtracking is the most rudimentary variant of DFS. It terminates as soon as any solution has been found; hence, there is no guarantee for finding an optimal (least-cost) solution. Moreover, backtracking might not terminate in graphs containing cycles or when the search depth is unbounded.

Depth-first branch and bound (DFBB) [6] employs a heuristic function to eliminate parts of the search space that cannot contain an optimal solution. It continues after finding a first solution until the search space is completely exhausted. Whenever a better solution is found, the current solution path and its value are updated. Inferior subtrees, i. e., subtrees that are known to be worse than the current solution, are eliminated.

The alpha-beta algorithm [2] used in game tree searching is a variant of DFBB that operates on trees with alternating levels of AND and OR nodes [5]. Because the strength of play correlates to the depth of the search, much effort has been spent on devising efficient parallel implementations (► [parallel heuristic search](#)).

### Best-First Search

BFS sorts the sequence of node expansions according to a heuristic function. The  $A^*$  search algorithm [7] uses

a heuristic evaluation function  $f(n) = g(n) + h(n)$  to decide which successor node  $n$  to expand next. Here,  $g(n)$  is the cost of the path from the initial state to the current node  $n$  and  $h(n)$  is the estimated completion cost to a nearest goal state. If  $h$  does not overestimate the remaining cost,  $A^*$  is guaranteed to find an optimal (least-cost) solution: it is said to be admissible. It does so with a minimal number of node expansions [9]—no other search algorithm (with the same heuristic  $h$ ) can do better. This is possible, because  $A^*$  keeps the search graph in memory, occupying  $O(w^d)$  memory cells for trees of width  $w$  and depth  $d$ .

Best-first frontier search [4] also finds an optimal solution, but with a much lower space complexity than  $A^*$ . It only keeps the frontier nodes in memory and discards the interior (closed) nodes. Care must be taken to ensure that the search frontier does not contain gaps that would allow the search to leak back into interior regions. The memory savings are most pronounced in directed acyclic graphs. In the worst case, that is, in trees of width  $w$ , it still saves a fraction of  $1/w$  of the nodes that BFS would need to store.

Iterative-deepening  $A^*$  (IDA\*) [3] simulates  $A^*$ 's best-first node expansion by a series of DFSs, each with the cost-bound  $f(n)$  increased by the minimal amount. The cost-bound is initially set to the heuristic estimate of the root node,  $h(\text{root})$ . Then, for each iteration, the bound is increased to the minimum value that exceeded the previous bound. Like  $A^*$ , IDA\* is guaranteed to find an optimal solution [3], provided the heuristic estimate function  $h$  is admissible and never overestimates the path to the goal. IDA\* obeys the same asymptotic branching factor as  $A^*$  [7], if the number of newly expanded nodes grows exponentially with the search depth [3]. This growth rate, the heuristic branching factor, depends on the average number of applicable operators per node and the discrimination power of the heuristic function  $h$ .

### Applications

Typical applications of heuristic search techniques may be found in many areas—not only in the fields of artificial intelligence and operations research, but also in other parts of computer science.

In the two-dimensional rectangular cutting-stock problem [1], we are given a set  $R_s = \{(l_i, w_i), i = 1, \dots, m\}$

of  $m$  rectangles of width  $w_i$  and length  $l_i$  that are to be cut out of a single rectangular stock sheet  $S$ . Assuming that  $S$  is of width  $W$  and that the theoretically unbounded length is  $L$ , the problem is to find an optimal cut with minimal length expansion. Since the elements  $R_i$  are cut after the cutting pattern has been determined, we can look at the problem as a bin-packing or vehicle-routing problem, which are also known to be nondeterministic polynomial-time (NP) complete [8].

Very large scale integration (VLSI) floorplan optimization is a stage in the design of VLSI chips, where the dimensions of the basic building blocks (cells) must be determined, subject to the minimization of the total chip layout area. This can be done with a BFS or a DFBB approach. Again, only small problem cases can be solved optimally, because VLSI floorplan optimization is also NP-complete.

In the satisfiability problem, it must be determined whether a Boolean formula containing binary variables in conjunctive normal form is satisfiable, that is, whether an assignment of truth values to the variables exists for which the formula is true.

The 15-puzzle benchmark in single-agent game-tree search consists of 15 square tiles located in a square tray of size  $4 \times 4$ . One square, the “blank square,” is kept empty so that an orthogonally adjacent tile can slide into its position, thus leaving an empty position at its origin. The problem is to re-arrange a given initial configuration with the fewest number of moves into a goal configuration without lifting one tile over another. While it would seem easy to obtain any solution, finding optimal (shortest) solutions is NP-complete. The 15-puzzle spawns a search space of  $16! \approx 2 \cdot 10^{13}$  states.

### Keywords

Heuristics; Algorithms; Clique; Independent set

Throughout this article,  $G = (V, E)$  is an arbitrary undirected and weighted graph unless otherwise specified, where  $V = \{1, \dots, n\}$  is the vertex set of  $G$  and  $E \subseteq V \times V$  is its edge set. For each vertex  $i \in V$ , a positive weight  $w_i$  is associated with  $i$ , collected in the *weight vector*  $w \in \mathbf{R}^n$ . For a subset  $S \subseteq V$ , the weight of  $S$  is defined as  $W(S) = \sum_{i \in S} w_i$ , and  $G(S) = (S, E \cap S \times S)$  is the *subgraph induced by  $S$* . The *cardinality* of  $S$ , i. e., the number of its vertices, will be denoted by  $|S|$ .

A graph  $G = (V, E)$  is *complete* if all its vertices are pairwise adjacent, i. e.  $\forall i, j \in V$  with  $i \neq j$ , we have  $(i, j) \in E$ . A *clique*  $C$  is a subset of  $V$  such that  $G(C)$  is complete. The *clique number* of  $G$ , denoted by  $\omega(G)$  is the cardinality of the maximum clique. The maximum clique problem asks for cliques of maximum cardinality. The maximum weight clique problem asks for cliques of maximum weight. Given the weight vector  $w \in \mathbf{R}^n$ , the *weighted clique number* is the total weight of the maximum weight clique, and will be denoted by  $\omega(G, w)$ .

We should distinguish a *maximum clique* from a *maximal clique*. A maximal clique is one that is not a proper subset of any other clique. A maximum (weight) clique is a maximal clique that has the maximum cardinality (weight).

An *independent set* (also called *stable set* or *vertex packing*) is a subset of  $V$  whose elements are pairwise nonadjacent. The maximum independent set problem asks for an independent set of maximum cardinality. The size of a maximum independent set is the *stability number* of  $G$ , (denoted by  $\alpha(G)$ ). The maximum weight independent set problem asks for an independent set of maximum weight. Given the weight vector  $w \in \mathbf{R}^n$ , the *weighted stability number*, denoted  $\alpha(G, w)$ , is the weight of the maximum weight independent set.

The *complement graph* of  $G = (V, E)$  is the graph  $\bar{G} = (V, \bar{E})$ , where  $\bar{E} = \{(i, j) : i, j \in V, i \neq j \text{ and } (i, j) \notin E\}$ . It is easy to see that  $S$  is a clique of  $G$  if and only if  $S$  is an independent set of  $\bar{G}$ . Any result or algorithm obtained for one of the two problems has its equivalent forms for the other one. Hence  $\alpha(G) = \omega(\bar{G})$ , more generally,  $\alpha(G, w) = \omega(\bar{G}, w)$ .

The maximum clique and independent set problems are well-known examples of intractable combinatorial optimization problems [18]. Apart from the theoretical interest around these problems, they also find practical applications in such diverse domains as

computer vision, experimental design, information retrieval, fault tolerance, etc. Moreover, many important problems turn out to be easily reducible to them, and these include, for example, the Boolean satisfiability problem, the subgraph isomorphism problem, and the vertex covering problem. The maximum clique problem has also a certain historical value, as it was one of the first problems shown to be *NP*-complete in the now classical paper of R.M. Karp on computational complexity [64].

Due to their inherent computational complexity, exact algorithms are guaranteed to return a solution only in a time which increases exponentially with the number of vertices in the graph, and this makes them inapplicable even to moderately large problem instances. Moreover, a series of recent theoretical results show that the problems are in fact difficult to solve even in terms of approximation. Strong evidence of this fact came in 1991, when it was proved in [32] that if there is a polynomial time algorithm that approximates the maximum clique within a factor of  $2^{log^{1-\epsilon} n}$ , then any *NP*-hard problem can be solved in ‘quasipolynomial’ time (i. e., in  $2^{log^{O(1)} n}$  time). The result was further refined in [6,7] one year later. Specifically, it was proved that there exists an  $\epsilon > 0$  such that no polynomial time algorithm can approximate the size of the maximum clique within a factor of  $n^\epsilon$ , unless  $P = NP$ . Developments along these lines can be found in [14,15,49].

In light of these negative results, much effort has recently been directed towards devising efficient heuristics for maximum clique and independent set, for which no formal guarantee of performance may be provided, but are anyway of interest in practical application. Lacking (almost by definition) a general theory of how these algorithms work, their evaluation is essentially based on massive experimentation. In order to facilitate comparisons among different heuristics, a set of benchmark graphs arising from different applications and problems has recently been constructed in conjunction with the 1993 DIMACS challenge on cliques, coloring and satisfiability [63].

In this article we provide an informal survey of recent heuristics for maximum clique and related problems, and up-to-date bibliographic pointers to the relevant literature. A more comprehensive review and bibliography can be found in [18].

### Sequential Greedy Heuristics

Many approximation algorithms in the literature for the maximum clique problem are called *sequential greedy heuristics*. These heuristics generate a maximal clique through the repeated addition of a vertex into a partial clique, or the repeated deletion of a vertex from a set that is not a clique. Decisions on which vertex to be added in or moved out next are based on certain indicators associated with candidate vertices as, for example, the vertex degree. There is also a distinction between heuristics that update the indicators every time a vertex is added in or moved out, and those that do not. Examples of such heuristics can be found in [62,89]. The differences among these heuristics are their choice of indicators and how indicators are updated. A heuristic of this type can run very fast.

### Local Search Heuristics

Let us define  $C_G$  to be the set of all the maximal cliques of  $G$ . Basically, a sequential greedy heuristic finds one set in  $C_G$ , hoping it is (close to) the optimal set, and stops. A possible way to improve our approximation solutions is to expand the search in  $C_G$ . For example, once we find a set  $S \in C_G$ , we can search its ‘neighbors’ to improve  $S$ . This leads to the class of the *local search heuristics* [2]. Depending on the neighborhood structure and how the search is performed, different local search heuristics result.

A well-known class of local search heuristics in the literature is the *k-interchange heuristics*. They are based on the *k-neighbor* of a feasible solution. In the case of the maximum clique problem, a set  $C \in C_G$  is a *k-neighbor* of  $S$  if  $|C \Delta S| \leq k$ , where  $k \leq |S|$ . A *k-interchange heuristic* first finds a maximal clique  $S \in C_G$ , then it searches all the *k-neighbors* of  $S$  and returns the best clique found. Clearly, the main factors for the complexity of this class of heuristics are the size of the neighborhood and the searches involved. For example, in the *k-interchange heuristic*, the complexity grows roughly with  $O(n^k)$ .

A class of heuristics designed to search various sets of  $C_G$  is called the *randomized heuristics*. The main ingredient of this class of heuristics is the part that finds a random set in  $C_G$ . A possible way to do that is to include some random factors in the generation of a set of  $C_G$ . A randomized heuristic runs a heuristic (with ran-

dom factors included) a number of times to find different sets over  $C_G$ . For example, we can randomize a sequential greedy heuristic and let it run  $N$  times. The complexity of a randomized heuristic depends on the complexity of the heuristic and the number  $N$ .

An elaborated implementation of the randomized heuristic for the maximum independent set problem can be found in [33], where local search is combined with randomized heuristic. The computational results in it indicated that the approach was effective in finding large cliques of randomly generated graphs. A different implementation of a randomized algorithm for the maximum independent set problem can be found in [5].

### Advanced Search Heuristics

Local search algorithms are only capable of finding *local solutions* of an optimization problem. Powerful variations of the basic local search procedure have been developed which try to avoid this problem, many of which are inspired from various phenomena occurring in nature.

### Simulated Annealing

In condensed-matter physics, the term ‘annealing’ refers to a physical process to obtain a pure lattice structure, where a solid is first heated up in a heat bath until it melts, and next cooled down slowly until it solidifies into a low-energy state. During the process, the free energy of the system is minimized. Simulated annealing, introduced in 1983 by S. Kirkpatrick, C.D. Gelatt and M.P. Vecchi [65], is a randomized neighborhood search algorithm based on the physical annealing process. Here, the solutions of a combinatorial optimization problem correspond to the states of the physical system, and the cost of a solution is equivalent to the energy of the state.

In its original formulation, simulated annealing works essentially as follows. Initially, a tentative solution in the state space is somehow generated. A new neighboring state is then produced from the previous one and, if the value of the cost function  $f$  improves, the new state is accepted, otherwise it is accepted with probability  $\exp\{\Delta f/\tau\}$ , where  $\Delta f$  is the difference of the cost function between the new and the current state, and  $\tau$  is a parameter usually called the *temperature* in

analogy with physical annealing, which is varied carefully during the optimization process. The algorithm proceeds iteratively this way until a stopping condition is met. One of the critical aspects of the algorithm relates to the choice of the proper ‘cooling schedule,’ i. e., how to decrease the temperature as the process evolves. While a logarithmic slow cooling schedule (yielding an exponential time algorithm) provably guarantees the exact solution, faster cooling schedules, producing acceptably good results, are in widespread use. Introductory textbooks describing both theoretical and practical issues of the algorithm are [1,66].

E. Aarts and J. Korst [1], without presenting any experimental result, suggested the use of simulated annealing for solving the independent set problem, using a *penalty function* approach. Here, the solution space is the set of all possible subsets of vertices of the graph  $G$ , and the problem is formulated as one of maximizing the cost function  $f(V') = |V'| - \lambda |E'|$ , where  $|E'|$  is the number of edges in  $G(V')$ , and  $\lambda$  is a weighting factor exceeding 1.

M. Jerrum [61] conducted a theoretical analysis of the performance of a clique-finding *Metropolis process*, i. e., simulated annealing at fixed temperature, on random graphs. He proved that the expected time for the algorithm to find a clique that is only slightly bigger than that produced by a naive greedy heuristic grows faster than any polynomial in the number of vertices. This suggests that ‘true’ simulated annealing would be ineffective for the maximum clique problem.

Jerrum’s conclusion seems to be contradicted by practical experience. In [56], S. Homer and M. Peinado compare the performance of three heuristics, namely the greedy heuristic developed in [62], a randomized version of the Boppana–Halldórsson subgraph-exclusion algorithm [24], and simulated annealing, over very large graphs. The simulated annealing algorithm was essentially that proposed by Aarts and Korst, with a simple cooling schedule. This penalty function approach was found to work better than the method in which only cliques are considered, as proposed in [61]. The algorithms were tested on various random graphs as well as on DIMACS benchmark graphs. The authors ran the algorithms over an SGI workstation for graphs with up to 10,000 vertices, and on a Connection Machine for graphs with up to 70,000 vertices. The overall conclusion was that simulated annealing outperforms

the other competing algorithms; it also ranked among the best heuristics for maximum clique presented at the 1993 DIMACS challenge [63].

### Neural Networks

Artificial neural networks (often simply referred to as ‘neural networks’) are massively parallel, distributed systems inspired by the anatomy and physiology of the cerebral cortex, which exhibit a number of useful properties such as learning and adaptation, universal approximation, and pattern recognition (see [50,52] for an introduction).

In the mid 1980s, J.J. Hopfield and D.W. Tank [57] showed that certain feedback continuous neural models are capable of finding approximate solutions to difficult optimization problems such as the traveling salesman problem [57]. This application was motivated by the property that the temporal evolution of these models is governed by a quadratic Liapunov function (typically called ‘energy function’ because of its analogy with physical systems) which is iteratively minimized as the process evolves. Since then, a variety of combinatorial optimization problems have been tackled within this framework. The customary approach is to formulate the original problem as one of energy minimization, and then to use a proper relaxation network to find minimizers of this function. Almost invariably, the algorithms developed so far incorporate techniques borrowed from statistical mechanics, in particular mean field theory, which allow one to escape from poor local solutions. We mention the articles [69,82] and the textbook [88] for surveys of this field. In [1], an excellent introduction to a particular class of neural networks (the Boltzmann machine) for combinatorial optimization is provided.

Early attempts at encoding the maximum clique and related problems in terms of a neural network were already done in the late 1980s in [1,12,44,83], and [84] (see also [85]). However, little or no experimental results were presented, thereby making it difficult to evaluate the merits of these algorithms. In [68], F. Lin and K. Lee used the quadratic zero-one formulation from [78] as the basis for their neural network heuristic. On random graphs with up to 300 vertices, they found their algorithm to be faster than the implicit enumerative algorithm in [26], while obtaining slightly worse results in terms of clique size.

T. Grossman [45] proposed a discrete, deterministic version of the Hopfield model for maximum clique, originally designed for an all-optical implementation. The model has a threshold parameter which determines the character of the stable states of the network. The author suggests an annealing strategy on this parameter, and an adaptive procedure to choose the network's initial state and threshold. On DIMACS graphs the algorithm performs satisfactorily but it does not compare well with more powerful heuristics such as simulated annealing.

A. Jagota [58] developed several variations of the Hopfield model, both discrete and continuous, to approximate maximum clique. He evaluated the performance of his algorithms over randomly generated graphs as well as on harder graphs obtained by generating cliques of varying size at random and taking their union. Experiments on graphs coming from the Solomonoff-Levin, or 'universal' distribution are also presented in [59]. The best results were obtained using a stochastic steepest descent dynamics and a mean-field annealing algorithm, an efficient deterministic approximation of simulated annealing. These algorithms, however, were also the slowest, and this motivated Jagota et al. [60] to improve their running time. The mean-field annealing heuristic was implemented on a 32-processor Connection Machine, and a two-temperature annealing strategy was used. Additionally, a 'reinforcement learning' strategy was developed for the stochastic steepest descent heuristic, to automatically adjust its internal parameters as the process evolves. On various benchmark graphs, all their algorithms obtained significantly larger cliques than other simpler heuristics but ran slightly slower. Compared to more sophisticated heuristics, they obtained significantly smaller cliques on average but were considerably faster.

M. Pelillo [80] takes a completely different approach to the problem, by exploiting a continuous formulation of maximum clique and the dynamical properties of the so-called relaxation labeling networks. His algorithm is described in the next section.

### Genetic Algorithms

Genetic algorithms are parallel search procedures inspired from the mechanisms of evolution in natural

systems [45,55]. In contrast to more traditional optimization techniques, they work on a population of points, which in the genetic algorithm terminology, are called chromosomes or individuals. In the simplest and most popular implementation, chromosomes are simply long strings of bits. Each individual has an associated 'fitness' value which determines its probability of survival in the next 'generation': the higher the fitness, the higher the probability of survival. The genetic algorithm starts out with an initial population of members generally chosen at random and, in its simplest version, makes use of three basic operators: reproduction, crossover and mutation. Reproduction usually consists of choosing the chromosomes to be copied in the next generation according to a probability proportional to their fitness. After reproduction, the crossover operator is applied between pairs of selected individuals to produce new offsprings. The operator consists of swapping two or more subsegments of the the strings corresponding to the two chosen individuals. Finally, the mutation operator is applied, which randomly reverses the value of every bit within a chromosome with a fixed probability. The procedure just described is sometimes referred to as the 'simple' genetic algorithm [45].

One of the earliest attempts to solve the maximum clique problem using genetic algorithms was done in 1993 by B. Carter and K. Park [27]. After showing the weakness of the simple genetic algorithm in finding large cliques, even on small random graphs, they introduced several modifications in an attempt to improve performance. However, despite their efforts they did not get satisfactory results, and their general conclusion was that genetic algorithms need to be heavily customized in order to be competitive with traditional approaches, and that they are computationally very expensive. In a later study [79], genetic algorithms were proven to be less effective than simulated annealing. At almost the same time, T. Bäck and S. Khuri [8], working on the maximum independent set problem, arrived at the opposite conclusion. By using a straightforward, general-purpose genetic algorithm called GENeSYs and a suitable fitness function which included a graded penalty term to penalize infeasible solutions, they got interesting results over random and regular graphs with up to 200 vertices. These results indicate that the choice of the fitness function is crucial for genetic algorithms to provide satisfactory results.

A.S. Murthy et al. [74] also experimented with a genetic algorithm using a novel ‘partial copy crossover’, and a modified mutation operator. However, they presented results over very small (i. e., up to 50 vertices) graphs, thereby making it difficult to properly evaluate the algorithm.

T.N. Bui and P.H. Eppley [25] obtained encouraging results by using a hybrid strategy which incorporates a local optimization step at each generation of the genetic algorithm, and a vertex-ordering preprocessing phase. They tested the algorithm over some DIMACS graphs getting results comparable to that in [39]

Instead of using the standard binary representation for chromosomes, J.A. Foster and T. Soule [36] employed an integer-based encoding scheme. Moreover, they used a time weighting fitness function similar in spirit to those in [27]. The results obtained are interesting, but still not comparable to those obtained using more traditional search heuristics.

C. Fleurent and J.A. Ferland [35] developed a general-purpose system for solving graph coloring, maximum clique, and satisfiability problems. As far as the maximum clique problem is concerned, they conducted several experiments using a hybrid genetic search scheme which incorporates tabu search and other local search techniques as alternative mutation operators. The results presented are encouraging, but running time is quite high.

In [53], M. Hifi modifies the basic genetic algorithm in several aspects:

- a) a particular crossover operator creates two new different children;
- b) the mutation operator is replaced by a specific heuristic feasibility transition adapted to the weighted maximum stable set problem.

This approach is also easily parallelizable. Experimental results on randomly generated graphs and also some (unweighted) instances from the DIMACS testbed [63] are reported to validate this approach.

Finally, E. Marchiori [71] has developed a simple heuristic-based genetic algorithm which consists of a combination of the simple genetic algorithm and a naive greedy heuristic procedure. Unlike previous approaches, here there is a neat division of labor, the search for a large subgraph and the search for a clique being incorporated into the fitness function and the heuristic procedure, respectively. The algorithm out-

performs previous genetic-based clique finding procedures over various DIMACS graphs, both in terms of quality of solutions and speed.

### Tabu Search

Tabu search, introduced independently by F. Glover [41,42] and P. Hansen and B. Jaumard [48], is a modified local search algorithm, in which a prohibition-based strategy is employed to avoid cycles in the search trajectories and to explore new regions in the search space. At each step of the algorithm, the next solution visited is always chosen to be the best *legal neighbor* of the current state, even if its cost is worse than the current solution. The set of legal neighbors is restricted by one or more *tabu lists* which prevent the algorithm to go back to recently visited solutions. These lists are used to store historical information on the path followed by the search procedure. Sometimes the tabu restriction is relaxed, and tabu solutions are accepted if they satisfy some *aspiration level* condition. The standard example of a tabu list is one which contains the last  $k$  solutions examined, where  $k$  may be fixed or variable. Additional lists containing the last modifications performed, i. e., changes occurred when moving from one solution to the next, are also common. These types of lists are referred to as *short-term memories*; other forms of memories are also used to intensify the search in a promising region or to diversify the search to unexplored areas. Details on the algorithm and its variants can be found in [43] and [51].

In 1989, C. Friden et al. [37] proposed a heuristic for the maximum independent set problem based on tabu search. The size of the independent set to search for is fixed, and the algorithm tries to minimize the number of edges in the current subset of vertices. They used three tabu lists: one for storing the last visited solutions and the other two to contain the last introduced/deleted vertices. They showed that by using hashing for implementing the first list and choosing a small value for the dimensions of the other two lists, a best neighbor may be found in almost constant time.

In [38,86], three variants of tabu search for maximum clique are presented. Here the search space consists of complete subgraphs whose size has to be maximized. The first two versions are deterministic algorithms in which no sampling of the neighborhood is

performed. The main difference between the two algorithms is that the first one uses just one tabu list (of the last solutions visited), while the second one uses an additional list (with an associated aspiration mechanism) containing the last vertices deleted. Also, two diversification strategies were implemented. The third algorithm is probabilistic in nature, and uses the same two tabu lists and aspiration mechanism as the second one. It differs from it because it performs a random sampling of the neighborhood, and also because it allows for multiple deletion of vertices in the current solution. Here no diversification strategy was used. In [38,86] results on randomly generated graphs were presented and the algorithms were shown to be very effective. P. Soriano and M. Gendreau [87] tested their algorithms over the DIMACS benchmark graphs and the results confirmed the early conclusions.

R. Battiti and M. Protasi [13] extended the tabu search framework by introducing a reactive local search method. They modified a previously introduced reactive scheme by exploiting the particular neighborhood structure of the maximum clique problem. In general reactive schemes aim at avoiding the manual selection of control parameters by means of an internal feedback loop. Battiti and Protasi's algorithm adopts such a strategy to automatically determine the so-called prohibition parameter  $k$ , i. e., the size of the tabu list. Also an explicit memory-influenced restart procedure is activated periodically to introduce diversification. The search space consists of all possible cliques, as in the approach by Friden et al., and the function to be maximized is the clique size. The worst-case computational complexity of this algorithm is  $O(\max\{n, m\})$ , where  $n$  and  $m$  are the number of vertices and edges of the graph respectively. They noticed, however, that in practice, the number of operations tends to be proportional to the average degree of the vertices of the complement graph. They tested their algorithm over many DIMACS benchmark graphs obtaining better results than those presented at the DIMACS workshop in competitive time.

### Continuous Based Heuristics

In 1965, T.S. Motzkin and E.G. Straus [73] established a remarkable connection between the maximum clique problem and a certain quadratic programming prob-

lem. Let  $G = (V, E)$  be an undirected (unweighted) graph and let  $\Delta$  denote the standard simplex in the  $n$ -dimensional Euclidean space  $\mathbf{R}^n$ :

$$\Delta = \{x \in \mathbf{R}^n : x_i \geq 0 \text{ for all } i \in V, e^\top x = 1\},$$

where the letter  $e$  is reserved for a vector of appropriate length, consisting of unit entries (hence  $e^\top x = \sum_{i \in V} x_i$ ).

Now, consider the following quadratic function, sometimes called the *Lagrangian* of  $G$ :

$$g(x) = x^\top A_G x, \quad (1)$$

where  $A_G = (a_{ij})$  is the adjacency matrix of  $G$ , i. e. the symmetric  $n \times n$  matrix where  $a_{ij} = 1$  if  $(i, j) \in E$  and  $a_{ij} = 0$  if  $(i, j) \notin E$ , and let  $x^*$  be a global maximizer of  $g$  on  $\Delta$ . In [73] it is proved that the clique number of  $G$  is related to  $g(x^*)$  by the following formula:

$$\omega(G) = \frac{1}{1 - g(x^*)}.$$

Additionally, it is shown that a subset of vertices  $S$  is a maximum clique of  $G$  if and only if its *characteristic vector*  $x^S$ , which is the vector of  $\Delta$  defined as  $x_i^S = 1/|S|$  if  $i \in S$  and  $x_i^S = 0$  otherwise, is a global maximizer of  $g$  on  $\Delta$ . In [40,81], the Motzkin–Straus theorem has been extended by providing a characterization of maximal cliques in terms of local maximizers of  $g$  on  $\Delta$ .

One drawback associated with the original Motzkin–Straus formulation relates to the existence of spurious solutions, i. e., maximizers of  $g$  which are not in the form of characteristic vectors [77,81]. In principle, spurious solutions represent a problem since, while providing information about the cardinality of the maximum clique, they do not allow us to easily extract its vertices.

During the 1990s, there has been much interest around the Motzkin–Straus and related continuous formulations of the maximum clique problem. They suggest in fact a fundamentally new way of solving the maximum clique problem, by allowing us to shift from the discrete to the continuous domain in an elegant manner. As pointed out in [76], continuous formulations of discrete optimization problems turn out to be particularly attractive. They not only allow us to exploit the full arsenal of continuous optimization techniques, thereby leading to the development of new algorithms, but may also reveal unexpected theoretical properties.

In [77], P.M. Pardalos and A.T. Phillips developed a global optimization approach based on the Motzkin–Straus formulation and implemented an iterative clique retrieval process to find the vertices of the maximum clique. However, due to its high computational cost they were not able to run the algorithm over graphs with more than 75 vertices.

Pelillo [80] used *relaxation labeling algorithms* to approximately determining the size of the maximum clique using the original Motzkin–Straus formulation. These are parallel, distributed algorithms developed and studied in computer vision and pattern recognition, which are also surprisingly related to *replicator equations*, a class of dynamical systems widely studied in evolutionary game theory and related fields [54], Heuristics for maximum clique and independent set. The model operates in the simplex  $\Delta$  and possesses a quadratic Liapunov function which drives its dynamical behavior. It is these properties that naturally suggest using them as a local optimization algorithm for the Motzkin–Straus program. The algorithm is especially suited for parallel implementation, and is attractive for its operational simplicity, since no parameters need to be determined. Extensive simulations over random graphs with up to 2000 vertices have demonstrated the effectiveness of the approach and showed that the algorithm outperforms previous neural network heuristics.

In order to avoid time-consuming iterative procedures to extract the vertices of the clique, L.E. Gibbons, D.W. Hearn and Pardalos [39] have proposed a heuristic which is based on a parameterized formulation of the Motzkin–Straus program. They consider the problem of minimizing the function:

$$h(x) = \frac{1}{2}x^T A_{\overline{G}}x + \left( \sum_{i=1}^n x_i - 1 \right)^2$$

on the domain:

$$S(k) = \left\{ x \in \mathbf{R}^n : \sum_{i=1}^n x_i^2 \leq \frac{1}{k}, x_i \geq 0, \forall i \right\},$$

where  $k$  is a fixed parameter. Let  $x^*$  be a global minimizer of  $h$  on  $S(k)$ , and let  $V(k) = h(x^*)$ . In [39] it is proved that  $V(k) = 0$  if and only if there exists an independent set  $S$  of  $\overline{G}$  with size  $|S| \geq k$ . Moreover, the vertices of  $\overline{G}$  associated with the indices of the posi-

tive components of  $x^*$  form an independent set of size greater than or equal  $k$ .

These properties motivated the following procedure to find a maximum independent set of  $\overline{G}$  or, equivalently, a maximum clique of  $G$ . Minimize the function  $h$  over  $S(k)$ , for different values of  $k$  between predetermined upper and lower bounds. If  $V(k) = 0$  and  $V(k+1) \neq 0$  for some  $k$ , then the maximum clique of  $G$  has size  $k$ , and its vertices are determined by the positive components of the solution. Since minimizing  $h$  on  $S(k)$  is a difficult problem, they developed a heuristic based on the observation that by removing the nonnegativity constraints, the problem is that of minimizing a quadratic form over a sphere, a problem which is solvable in polynomial time. However, in so doing a heuristic procedure is needed to round the approximate solutions of this new problem to approximate solutions of the original one. Moreover, since the problem is solved approximately, we have to find the value of the spherical constraint  $1/k$  which yields the largest independent set. A careful choice of  $k$  is therefore needed. The resulting algorithm was tested over various DIMACS benchmark graphs [63] and the results obtained confirmed the effectiveness of the approach.

The spurious solution problem has been solved in [16]. Consider the following regularized version of function  $g$ :

$$\widehat{g}(x) = x^T A_G x + \frac{1}{2}x^T x \tag{2}$$

which is obtained from (1) by substituting the adjacency matrix  $A_G$  of  $G$  with

$$\widehat{A}_G = A_G + \frac{1}{2}I,$$

where  $I$  is the identity matrix. Unlike the Motzkin–Straus formulation, it can be proved that all maximizers of  $\widehat{g}$  on  $\Delta$  are strict, and are characteristic vectors of maximal/maximum cliques in the graph. In an exact sense, therefore, a one-to-one correspondence exists between maximal cliques and local maximizers of  $\widehat{g}$  in  $\Delta$  on the one hand and maximum cliques and global maximizers on the other hand. In [16,20], replicator equations are used in conjunction to this spurious-free formulation to find maximal cliques of  $G$ . Note that here the vertices comprising the clique are directly given by the positive components of the converged vectors, and no iterative procedure is needed to determine

them, as in [77]. The results obtained over a set of random as well as DIMACS benchmark graphs were encouraging, especially considering that replicator equations do not incorporate any mechanism to escape from local optimal solutions. This suggests that the basins of attraction of the global solution with respect to the quadratic functions  $g$  and  $\widehat{g}$  are quite large; for a thorough empirical analysis see also [23]. One may wonder whether a subtle choice of initial conditions and/or a variant of the dynamics may significantly improve the results, but experiments in [22] indicate this is not the case.

In [19] the properties of the following function are studied:

$$\widehat{g}_\alpha(x) = x^\top A_G x + \alpha x^\top x.$$

It is shown that when  $\alpha$  is positive all the properties enjoyed by the standard regularization approach [16] hold true. Specifically, in this case a one-to-one correspondence between local/global maximizers in the continuous space and local/global solutions in the discrete space exists. For negative  $\alpha$ 's an interesting picture emerges: as the absolute value of  $\alpha$  grows larger, local maximizers corresponding to maximal cliques disappear. In [19], bounds on the parameter  $\alpha$  are derived which affect the stability of these solutions. These results have suggested an *annealed replication heuristic*, which consists of starting from a large negative  $\alpha$  and then properly reducing it during the optimization process. For each value of  $\alpha$  standard replicator equations are run in order to obtain local solutions of the corresponding objective function. The rationale behind this idea is that for values of  $\alpha$  with a proper large absolute value only local solutions corresponding to large maximal cliques will survive, together with various spurious maximizers. As the value of  $\alpha$  is reduced, spurious solutions disappear and smaller maximal cliques become stable. An annealing schedule is proposed which is based on the assumption that the graphs being considered are random. In this respect, the proposed procedure differs from usual simulated annealing approaches, which mostly use a 'black-box' cooling schedule. Experiments conducted over several DIMACS benchmark graphs confirm the effectiveness of the proposed approach and the robustness of the annealing strategy. The overall conclusion is that the annealing procedure does help to avoid inefficient lo-

cal solutions, by initially driving the dynamics towards promising regions in state space, and then refining the search as the annealing parameter is increased.

The Motzkin–Straus theorem has been generalized to the weighted case in [40]. Note that the Motzkin–Straus program can be reformulated as a minimization problem by considering the function

$$f(x) = x^\top (I + A_{\overline{G}}) x,$$

where  $A_{\overline{G}}$  is the adjacency matrix of the complement graph  $\overline{G}$ . It is straightforward to see that if  $x^*$  is a global minimizer of  $f$  in  $\Delta$ , then we have:  $\omega(G) = 1/f(x^*)$ . This is simply a different formulation of the Motzkin–Straus theorem. Given a weighted graph  $G = (V, E)$  with weight vector  $w$ , let  $\mathcal{M}(G, w)$  be the class of symmetric  $n \times n$  matrices  $B = (b_{ij})_{i,j \in V}$  defined as  $2b_{ij} \geq b_{ii} + b_{jj}$  if  $(i, j) \notin E$  and  $b_{ij} = 0$  otherwise, and  $b_{ii} = 1/w_i$  for all  $i \in V$ .

Given the following quadratic program, which is in general indefinite,

$$\begin{cases} \min & f(x) = x^\top B x \\ \text{s.t.} & x \in \Delta, \end{cases} \quad (3)$$

in [40] it is shown that for any  $B \in \mathcal{M}(G, w)$  we have:

$$\omega(G, w) = \frac{1}{f(x^*)},$$

where  $x^*$  is a global minimizer of program (3). Furthermore, denote by  $x^S$  the *weighted characteristic vector* of  $S$ , which is a vector with coordinates  $x_i^S = w_i/W(S)$  if  $i \in S$  and  $x_i^S = 0$  otherwise. It can be seen that a subset  $S$  of vertices of a weighted graph  $G$  is a maximum weight clique if and only if its characteristic vector  $x^S$  is a global minimizer of (3). Notice that the matrix  $I + A_{\overline{G}}$  belongs to  $\mathcal{M}(G, e)$ . In other words, the Motzkin–Straus theorem turns out to be a special case of the preceding result.

As in the unweighted case, the existence of spurious solutions entails the lack of one-to-one correspondence between the solutions of the continuous problem and those of the original, discrete one. In [21] these spurious solutions are characterized and a regularized version which avoids this kind of problems is introduced, exactly as in the unweighted case (see also [17]). Replicator equations are then used to find maximal weight

cliques in weighted graphs, using this formulation. Experiments with this approach on both random graphs and DIMACS graphs are reported. The results obtained are compared with those produced by a very efficient maximum weight clique algorithm of the branch and bound variety. The algorithm performed remarkably well especially on large and dense graphs, and it was typically an order of magnitude more efficient than its competitor.

Finally, we mention the work by Massaro and Pelillo [72], who transformed the Motzkin–Straus program into a linear complementarity problem [31], and then solved it using a variation of Lemke’s well-known algorithm [67]. The preliminary results obtained over many weighted and unweighted DIMACS graphs show that this approach substantially outperforms all other continuous based heuristics.

### Miscellaneous

Another type of heuristics that finds a maximal clique of  $G$  is called the *subgraph approach* (see [11]). It is based on the fact that a maximum clique  $C$  of a subgraph  $G' \subseteq G$  is also a clique of  $G$ . The subgraph approach first finds a subgraph  $G' \subseteq G$  such that the maximum clique of  $G'$  can be found in polynomial time. Then it finds a maximum clique of  $G'$  and use it as the approximation solution. The advantage of this approach is that in finding the maximum clique  $C \subseteq G'$ , one has (implicitly) searched many other cliques of  $G'$  ( $C_{G'} \subseteq C_G$ ). Because of the special structure of  $G'$ , this implicit search can be done efficiently. In [11],  $G'$  is a maximal induced triangulated subgraph of  $G$ . Since many classes of graphs have polynomial algorithms for the maximum clique problem, the same idea also applies there. For example, the class of edge-maximal triangulated subgraphs was chosen in [9,90], and [91]. Some of the greedy heuristics, randomized heuristics and subgraph approach heuristics are compared in [90] and [91] on randomly generated weighted and unweighted graphs.

Various new heuristics were presented at the 1993 DIMACS challenge devoted to clique, coloring and satisfiability [63]. In particular, in [10] an algorithm is proposed which is based on the observation that finding the maximum clique in the union of two cliques can be done using bipartite matching techniques. In [46] re-

stricted backtracking is used to provide a trade-off between the size of the clique and the completeness of the search. In [70] an edge projection technique is proposed to obtain a new upper bound heuristic for the maximum independent set problem. This procedure was used, in conjunction with the Balas–Yu branching rule [11], to develop an exact branch and bound algorithm which works well especially on sparse graphs.

See [3] for a new population-based optimization heuristic inspired by the natural behavior of human or animal scouts in exploring unknown regions, and applied it to maximum clique. The results obtained over a few DIMACS graphs are comparable with those obtained using continuous-based heuristics but are inferior to those obtained by reactive local search.

Recently, DNA computing [4] has also emerged as a potential technique for the maximum clique problem [75,92]. The major advantage of DNA computing is its high parallelism, but at present the size of graphs this algorithm can handle is limited to a few tens.

Additional heuristics for the maximum clique/independent set and related problems on arbitrary or special class of graphs can be found in [28,29,30,34].

### Conclusions

During the 1990s, research on the maximum clique and related problems has yielded many interesting heuristics. This article has provided an expository survey on these algorithms and an up-to-date bibliography (as of 2000). However, the activity in this field is so extensive that a survey of this nature is outdated before it is written.

### Keywords

Local maximum principle; High-order tangent sets; High-order necessary conditions for optimality; Abnormal processes

We formulate a generalized local maximum principle which gives necessary conditions for optimality of abnormal trajectories in optimal control problems. The results are based on a hierarchy of primal constructions of high-order approximating cones (consisting of tangent directions for equality constraints, feasible directions for inequality constraints, and directions of decrease for the objective) and dual characterizations of empty intersection properties of these cones (see ► [High-order necessary conditions for optimality for abnormal points](#)). Characteristic for the theorem is that the multiplier associated with the objective is nonzero.

We consider an optimal control problem in Bolza form with fixed terminal time:

(OC) Minimize the functional

$$I(x, u) = \int_0^T L(x(t), u(t), t) dt + \ell(x(T)) \quad (1)$$

subject to the constraints

$$\begin{aligned} \dot{x}(t) &= f(x(t), u(t), t), \\ x(0) &= 0, \quad q(x(T)) = 0, \\ u(\cdot) &\in \mathcal{U} = \{u \in L^\infty_r(0, T) : u(t) \in U\}. \end{aligned}$$

The terminal time  $T$  is fixed and we make the following *regularity assumptions* on the data:  $L: \mathbf{R}^n \times \mathbf{R}^m \times [0, T] \rightarrow \mathbf{R}$  and  $f: \mathbf{R}^n \times \mathbf{R}^m \times [0, T] \rightarrow \mathbf{R}^n$  are  $C_\infty$  in  $(x, u)$  for every  $t \in [0, T]$ ; both functions and their derivatives are measurable in  $t$  for every  $(x, u)$  and the functions and all partial derivatives are bounded on compact subsets of  $\mathbf{R}^n \times \mathbf{R}^m \times [0, T]$ ;  $\ell: \mathbf{R}^n \rightarrow \mathbf{R}$  and  $q: \mathbf{R}^n \rightarrow \mathbf{R}^k$  are  $C^\infty$  and the rows of the Jacobian matrix  $q_x$  (i.e. the gradients of the equations defining the terminal constraint) are linearly independent;  $U \subset \mathbf{R}^m$  is a closed and convex set with nonempty interior. Let

$$H(\lambda_0, \lambda, x, u, t) = \lambda_0 L(x, u, t) + \lambda f(x, u, t) \quad (2)$$

be the Hamiltonian for the control problem. If the input-trajectory pair  $(x_*, u_*)$  is optimal for problem (OC), then the *local maximum principle* [7] states that there exist a constant  $\lambda_0 \geq 0$ , an absolutely continuous function  $\lambda: [0, T] \rightarrow (\mathbf{R}^n)^*$  (which we write as a row vector), which is a solution to the adjoint equation

$$\dot{\lambda} = -H_x(\lambda_0, \lambda(t), x_*(t), u_*(t), t),$$

with terminal condition

$$\lambda(T) = \lambda_0 \ell_x(x_*(T)) + v q_x(x_*(T)), \quad (3)$$

(for some row vector  $v \in (\mathbf{R}^k)^*$ ) such that  $(\lambda_0, \lambda(t)) \neq 0$  for all  $t \in [0, T]$  and the following local minimum condition holds for all  $u \in U$ :

$$\langle H_u(\lambda_0, \lambda(t), x_*(t), u_*(t), t), u - u_*(t) \rangle \geq 0. \quad (4)$$

Input-trajectory pairs  $(x_*, u_*)$  for which multipliers  $\lambda_0$  and  $\lambda$  exist such that these conditions are satisfied are called (*weak*) *extremals*. If  $\lambda_0 > 0$ , then it is possible to normalize  $\lambda_0 = 1$  and the extremal is called *normal* while extremals with  $\lambda_0 = 0$  are called *abnormal*. Although the terminology abnormal, which has its origins in the calculus of variations [4], seems to suggest that these type of extremals are an aberration, for optimal control problems this is not the case. The phenomenon is quite general and abnormal extremals

cannot be excluded from optimality a priori. For instance, there exist optimal abnormal trajectories for the standard problem of stabilizing the harmonic oscillator time-optimally in minimum time, a simple time-invariant linear system.

In the abnormal case conventional necessary conditions for optimality provide conditions which only describe the structure of the constraints. For example, if there are no control constraints, then these conditions only involve the equality constraint defined by the dynamics and terminal conditions as zero set of an operator  $F: Z \rightarrow Y$  between Banach spaces. If  $F'(z_*)$  is not onto, but  $\text{Im}F'(z_*)$  is closed (and this is always the case for the optimal control problem) then the standard Lagrange multiplier type necessary conditions for optimality (which imply the local maximum principle [7]) can be satisfied trivially by choosing a multiplier which annihilates the image of  $F'(z_*)$  and setting all other multipliers to zero.) The corresponding necessary conditions are independent of the objective and describe only the structure of the constraint yielding little information about the optimality of the abnormal trajectory.

Much of the difficulty in analyzing abnormal points in extremum problems can be traced back to the fact that the equality constraint is typically no longer a manifold near abnormal points, but intersections of manifolds are common. Hence, in order to develop necessary and/or sufficient conditions for optimality of abnormal extremals, it is imperative to analyze different branches of the zero-set of  $F$ . Finding these branches is at the heart of the matter. Generalizing a result of E.R. Avakov [2,3] in [10] a high-order generalization of the *classical Lyusternik theorem* is given which for general  $p \in \mathbf{N}$  describes the structure of  $p$ -order tangent directions to an operator equality constraint in a Banach space for nonregular operators under a more general surjectivity assumption involving the first  $p$  derivatives of the operator. Based on these results  $p$ -order tangent cones to the equality constraint can explicitly be calculated along critical directions which comprise the low order terms. Combining these cones with standard constructions of high-order cones of decrease for the functional and high-order feasible cones to inequality constraints, all taken along critical directions, generalized necessary conditions for optimality for extremum problems in Banach spaces can be derived which allow to incorporate the objective with a nonzero mul-

tiplier. Characteristic of these results is that they are parametrized by critical directions as it is ‘natural’ near abnormal points.

In [12] (see ► **High-order necessary conditions for optimality for abnormal points**) an abstract formulation of these results is presented for minimization problems in Banach spaces. The main result gives a dual characterization for the empty intersection property of the various approximating cones along critical directions, but primal arguments using the cones themselves are often equally effective. In this article we formulate these abstract results for the optimal control problem, but we only consider the so-called weak or local version of the maximum principle. This result is weaker than the *Pontryagin maximum principle* [15] in the sense that the Pontryagin maximum principle asserts that the Hamiltonian of the control problem is indeed minimized over the control set at every time along the reference trajectory by the reference control. The local version only gives the necessary conditions for optimality for this property. However, it is well-known how to use an argument of A. Ya. Dubovitskii to derive the Pontryagin maximum principle from the local version [7, Lecture 13] and a preliminary strong version of the results of this article is given in [9].

Other theories of necessary conditions which are tailored to abnormal processes include a method known as ‘weakening equality constraints’ introduced in [14] and developed further in [5]. References [2,3] are along the lines of the results described here and give necessary conditions for optimality of abnormal extremals based on quadratic approximations. Similarly, both weak and strong versions of a second order generalized maximum principle are given by the authors in [8]. While mostly optimization related techniques are used in these papers, on a different level [1] uses differential geometric techniques to develop a theory of the second variation for abnormal extremals. They give both necessary and sufficient conditions for so-called corank-1 abnormal extremals (extremals for which there exists a unique multiplier) in terms of the Jacobi equation and related Morse indices and nullity theorems. Second order necessary conditions for optimality in the type of accessory problem results without normality assumptions have first been given in [6]. Also, the results in [16] are derived without making normality assumptions.

### Regularity in the Equality Constraint

We model the optimal control problem (OC) in the framework of optimization theory as a minimization problem in a Banach space under equality and inequality constraints. Let  $W_{11}^n(0, T)$  denote the Banach space of all absolutely continuous functions  $x: [0, T] \rightarrow \mathbf{R}^n$  with norm  $|x| = \|x(0)\| + \int_0^T \|\dot{x}(s)\| ds$  and let  $\overline{W}_{11}^n(0, T) = W_{11}^n(0, T) \cap \{x \in W_{11}^n(0, T): x(0) = 0\}$ . Then the problem is to minimize the functional  $I$  over a class  $\mathcal{A}$  of input-trajectory pairs  $(x, u) \in \overline{W}_{11}^n(0, T) \times L_\infty^m(0, T)$  which is defined by equality constraints and the convex inequality constraint  $u \in \mathcal{U}$ . The equality constraints can be modeled as  $\mathcal{F} = \{(x, u) \in \overline{W}_{11}^n(0, T) \times L_\infty^m(0, T): F(x, u) = 0\}$  where  $F$  is the operator

$$F: \overline{W}_{11}^n(0, T) \times L_\infty^m(0, T) \rightarrow \overline{W}_{11}^n(0, T) \times \mathbf{R}^k$$

with  $F(x, u)$  given by

$$\left( x(\cdot) - \int_0^{\cdot} f(x(s), u(s), s) ds, \quad q(x(T)) \right).$$

It is easy to see that the operator  $F$  has continuous Fréchet derivatives of arbitrary order. For instance,  $F'(x, u)$  acting on  $(\eta, \xi) \in \overline{W}_{11}^n(0, T) \times L_\infty^m(0, T)$  is given by

$$\left( \eta(t) - \int_0^t f_x \eta + f_u \xi ds, \quad q_x(x(T))\eta(T) \right).$$

All partial derivatives of  $f$  are evaluated along a reference input-trajectory pair  $(x, u) \in \mathcal{A}$ . The formulas for higher order derivatives are given by equally straightforward multilinear forms.

We first describe the image of the operator  $F'(x_*, u_*)$  for a reference input-trajectory pair  $(x_*, u_*)$ . Denote the fundamental matrix of the variational equation by  $\Phi(t, s)$ , i. e.

$$\begin{aligned} \frac{\partial}{\partial t} \Phi(t, s) &= f_x(x(t), u(t), t)\Phi(t, s), \\ \Phi(s, s) &= \text{Id}. \end{aligned}$$

Furthermore, let  $R \subset \mathbf{R}^n$  denote the reachable subspace of the linearized system

$$\dot{h}(t) = f_x h + f_u v, \quad h(0) = 0, \tag{5}$$

at time  $T$ . It is well-known that  $R$  is a linear subspace of  $\mathbf{R}^n$  and that  $R = \mathbf{R}^n$  if and only if equation (5) is completely controllable. In general we have that

**Lemma 1**  $ImF'(x_*, u_*)$  consists of all pairs  $(a, b) \in \overline{W}_{11}^n(0, T) \times \mathbf{R}^k$  such that

$$b \in q_x(x_*(T)) \left( \int_0^T \Phi(T, s) \dot{a}(s) ds + R \right). \quad (6)$$

In particular,  $ImF'(x_*, u_*)$  is closed and of finite codimension.

The following characterizations of the nonregularity of the operator  $F$  and its codimension are well-known.

**Proposition 2** The codimension of  $F'(x_*, u_*)$  is equal to the number of linearly independent solutions to  $\dot{\lambda}(t) = -\lambda(t)f_x(x_*(t), u_*(t), t)$  which satisfy  $\lambda(t)f_u(x_*(t), u_*(t), t) \equiv 0$  on  $[0, T]$  and for which  $\lambda(T)$  is orthogonal to  $ker q_x(x_*(T))$ .

**Proposition 3** The operator  $F$  is nonregular at  $\Gamma = (x_*, u_*)$  if and only if  $\Gamma$  is an abnormal weak extremal which satisfies  $H_u(0, \lambda(t), x_*(t), u_*(t), t) \equiv 0$  on  $[0, T]$ .

### Critical Directions

We describe the set of critical directions along which high-order tangent approximations to the equality constraint  $\mathcal{F}$  can be set up. Let  $Z = \overline{W}_{11}^n(0, T) \times L_\infty^m(0, T)$  and suppose an admissible process  $z_* = (x_*, u_*) \in \mathcal{A}$  and a finite sequence  $H_{p-1} = (h_1, \dots, h_{p-1}) \in Z^{p-1}$  are given. The following operators allow to formalize high-order approximations to an equality constraint at nonregular points (see, ► **High-order necessary conditions for optimality for abnormal points**). For  $k = 1, \dots, p - 1$ , the directional derivatives  $\nabla^k F(z_*)(H_k)$  of  $F$  at  $z_*$  along the sequence  $H_k = (h_1, \dots, h_k)$  are given by

$$\sum_{r=1}^k \frac{1}{r!} \left( \sum_{j_1 + \dots + j_r = k} F^{(r)}(z_*)(h_{j_1}, \dots, h_{j_r}) \right) \quad (7)$$

and we let  $G_k[F](z_*; H_{k-1})$  denote the Fréchet-derivatives of the  $(k - 1)$ th directional derivative of  $F$  at  $z_*$  along  $H_{k-1}$ . Thus formally  $G_1[F](z_*) = F'(z_*)$  and

in general for  $k \geq 2$ ,  $G_k = G_k[F](z_*; H_{k-1}): Z \rightarrow Y$ ,  $v \rightarrow G_k(v)$ , is given by

$$G_k(v) = \sum_{r=1}^{k-1} \frac{1}{r!} \times \left( \sum_{j_1 + \dots + j_r = k-1} F^{(r+1)}(z_*)(h_{j_1}, \dots, h_{j_r}, v) \right). \quad (8)$$

We also denote by  $R_q[F](z_*; H_\ell)$  those terms in the Taylor expansion of  $F(z_* + \sum_{i=1}^p \varepsilon^i h_i)$  which are homogeneous of degree  $q \geq 2$ , but only involve vectors from  $H_\ell$ . The general structure of these remainders is given by

$$\sum_{r=2}^q \frac{1}{r!} \left( \sum_{\substack{j_1 + \dots + j_r = q, \\ 1 \leq j_k \leq \ell, \\ 1 \leq k \leq r}} F^{(r)}(z_*)(h_{j_1}, \dots, h_{j_r}) \right). \quad (9)$$

Let

$$Y_i = \sum_{k=1}^i Im G_k[F](z_*; H_{k-1}), \quad i = 1, \dots, p. \quad (10)$$

The following conditions are necessary for the existence of a  $p$ -order tangent vector along  $H_{p-1}$  [10]:

i) the first  $p - 1$  directional derivatives of  $F$  along  $H_{p-1}$  vanish,

$$\nabla^i F(z_*)(H_i) = 0, \forall i = 1, \dots, p - 1;$$

ii) the compatibility conditions

$$R_{p-1+i}[F](z_*; H_{p-1}) \in Y_i, \quad i = 1, \dots, p - 1,$$

are satisfied.

In these equations all partial derivatives of  $f$  are evaluated along the reference trajectory. These conditions are also sufficient if the operator  $F$  is  $p$ -regular at  $z_*$  in direction of the sequence  $H_{p-1}$  in the sense of the following definition.

**Definition 4** Let  $F: Z \rightarrow Y$  be an operator between Banach spaces. We say the operator  $F$  is  $p$ -regular at  $z_*$  in direction of the sequence  $H_{p-1} \in Z^{p-1}$  if the following conditions are satisfied:

- A1)  $F: Z \rightarrow Y$  is  $(2p - 1)$ -times continuously Fréchet differentiable in a neighborhood of  $z_*$ .
- A2) The subspaces  $Y_i, i = 1, \dots, p$ , are closed.
- A3) The map  $G_p = G_p[F](z_*; H_{p-1})$ ,

$$G_p: Z \rightarrow Y_1 \times \frac{Y_2}{Y_1} \times \dots \times \frac{Y}{Y_{p-1}}$$

$$v \mapsto G_p(v) = (G_1(v), \pi_1 G_2(v), \dots, \pi_{p-1} G_p(v)),$$

where  $\pi_i: Y_{i+1} \rightarrow Y_{i+1}/Y_i$  denotes the canonical projection onto the quotient space, is onto.

In the sense of this definition 1-regularity corresponds to the classical Lyusternik condition while 2-regularity is similar to Avakov’s definition [3]. Under these assumptions vectors  $h_p$  exist which extend  $H_{p-1}$  to  $p$ -order tangent vectors to  $\mathcal{F}$  at  $z_*$  [10,12].

For the critical directions for the objective  $I$  we focus on the least degenerate critical case and therefore make the following assumption:

- iii)  $I'(z_*)$  is not identically zero and  $\nabla^i I(z_*)(H_i) = 0$  for  $i = 1, \dots, p - 1$ .

The assumption that the first  $p - 1$  directional derivatives vanish is directly tied in with optimality. If there exists a first nonzero directional derivative  $\nabla^j I(z_*)(H_j)$  with  $j < i$  which is positive, then  $z_*$  indeed is a local minimum for any curve  $z(\varepsilon) = z_* + \sum_{i=1}^p \varepsilon^i h_i + o(\varepsilon^p)$ ,  $\varepsilon > 0$ , and none of the directions  $H_{p-1}$  is of any use in improving the value. We restrict to  $\varepsilon \geq 0$  since we also want to include inequality constraints. On the other hand, if  $\nabla^j I(z_*)(H_j) < 0$ , then  $H_j$  is indeed a direction of decrease and arbitrary high-order extensions of this sequence will give better values. Thus the reference trajectory is not optimal.

We also need to define the critical directions for the inequality constraint  $\mathcal{U}$  in the optimal control problem. More generally, we define a  $p$ -order feasible set to an inequality constraint in a Banach space.

**Definition 5** Let  $S \subset Z$  be a subset with nonempty interior. We call  $v$  a  $p$ -order feasible vector for  $S$  at  $z_*$  in direction of  $H_{p-1} = (h_1, \dots, h_{p-1}) \in Z^{p-1}$  if there exist an  $\varepsilon_0 > 0$  and a neighborhood  $V$  of  $v$  so that for all  $0 < \varepsilon \leq \varepsilon_0$ ,

$$z_* + \sum_{i=1}^{p-1} \varepsilon^i h_i + \varepsilon^p V \subset S.$$

The collection of all  $p$ -order feasible vectors  $v$  for  $S$  at  $z_*$  in direction of the sequence  $H_{p-1}$  will be called the  $p$ -order feasible set to  $S$  at  $z_*$  in direction of the sequence  $H_{p-1}$  and will be denoted by  $FS^{(p)}(S; z_*, H_{p-1})$ .

It follows from this definition that  $FS^{(p)}(S; z_*, H_{p-1})$  is open. It is also clear that  $FS^{(p)}(S; z_*, H_{p-1})$  is convex, if  $S$  is. Furthermore, if  $h_j \in FS^{(j)}(S; z_*, H_{j-1})$  for some integer  $j < p$ , then any vector  $v$  is allowed as a  $p$ -order feasible direction and thus trivially  $FS^{(p)}(S; z_*, H_{p-1}) = X$ .

For the optimal control problem and  $H_{p-1} = ((\eta_1, \xi_1), \dots, (\eta_{p-1}, \xi_{p-1}))$  let  $V_{p-1} = (\xi_1, \dots, \xi_{p-1}) \in L_\infty^m(0, T)^p$  denote the sequence of controls. Then the critical feasible directions for the convex inequality constraint  $\mathcal{U}$  in  $L_\infty^m(0, T)$  consist of all  $H_{p-1}$  for which iv)  $FS^{(p)}(\mathcal{U}; u_*, V_{p-1})$  is nonempty.

**Definition 6** We call a direction  $H_{p-1}$  a  $p$ -regular critical direction for the extremum problem at  $z_*$  if the operator  $F$  is  $p$ -regular at  $z_*$  along  $H_{p-1}$  and if conditions (i-iv) are satisfied.

**p-Order Local Maximum Principle**

Theorem 7 below gives a generalized  $p$ -order version of the maximum principle obtained from a dual characterization of the fact that if  $(x_*, u_*)$  is optimal, then the  $p$ -order tangent cones to the set  $\{F = 0\}$ , the  $p$ -order feasible cone to  $\mathcal{U}$  and the  $p$ -order cone of decrease for the functional  $I$  cannot intersect. Notice that we write covectors like  $\psi$  as row vectors. This is consistent with a multiplier interpretation of the adjoint variable. Also we denote partial derivatives by subscripts. For instance, if  $\nabla^i f(H_i)$  denotes the  $i$ th directional derivative of  $f = f(x, u, t)$  with respect to the sequence  $H_i$ , then  $(\nabla^i f(H_i))_x$  denotes its partial derivative in  $x$ . For example, suppose  $H_1 = (\eta_1, \xi_1)$ . Then

$$\nabla^1 f(H_1) = f_x(x, u, t)\eta_1 + f_u(x, u, t)\xi_1$$

and thus

$$(\nabla^1 f(H_1))_x = f_{xx}(x, u, t)\eta_1 + f_{ux}(x, u, t)\xi_1$$

and

$$(\nabla^1 f(H_1))_u = f_{xu}(x, u, t)\eta_1 + f_{uu}(x, u, t)\xi_1.$$

**Theorem 7 (p-order local maximum principle)** Suppose the admissible process  $(x_*, u_*)$  is optimal for the optimal control problem (OC). Then for every p-regular critical direction  $H_{p-1}$  there exist a number  $v_0 = v_0(H_{p-1}) \geq 0$ , vectors  $a_i = a(H_{p-1}) \in (\mathbf{R}^k)^*$ ,  $i = 0, \dots, p - 1$ , and absolutely continuous functions  $\psi(\cdot) = \psi(H_{p-1})(\cdot)$  and  $\rho_i(\cdot) = \rho_i(H_{p-1})(\cdot)$ ,  $i = 1, \dots, p - 1$ , from  $[0, T]$  into  $(\mathbf{R}^n)^*$ , which satisfy the following conditions along the optimal trajectory  $(x_*(t), u_*(t), t)$ :

a) nontriviality condition:  $v_0$  and the functional  $\lambda: L_\infty^m(0, T) \rightarrow \mathbf{R}$ ,  $\xi \mapsto \lambda(\xi)$ , given by

$$\int_0^T \left\langle v_0 L_u + \psi f_u + \sum_{i=1}^{p-1} \rho_i (\nabla^i f(H_i))_u, \xi \right\rangle dt \quad (11)$$

do not both vanish identically.

b) extended adjoint equation

$$\dot{\psi}(t) = -v_0 L_x - \psi(t) f_x - \sum_{i=1}^{p-1} \rho_i(t) (\nabla^i f(H_i))_x \quad (12)$$

with terminal condition

$$\psi(T) = v_0 \ell_x(x_*(T)) + a_0 q_x(x_*(T)) + \sum_{i=1}^{p-1} a_i (\nabla^i q(x_*(T); H_i))_x. \quad (13)$$

c) orthogonality conditions on the additional multipliers: The functions  $\rho_i(\cdot)$ ,  $i = 1, \dots, p - 1$ , satisfy

$$\begin{aligned} \dot{\rho}_i(t) &= -\rho_i(t) f_x, \quad \rho_i(t) f_u \equiv 0, \\ \rho_i(T) &= a_i q_x(x_*(T)) \end{aligned} \quad (14)$$

and for  $j = 1, \dots, i - 1$ , the following conditions are satisfied for a.e.  $t \in [0, T]$ :

$$\rho_i(t) (\nabla^j f(H_j))_x = 0, \quad (15)$$

$$\rho_i(t) (\nabla^j f(H_j))_u = 0, \quad (16)$$

$$a_i (\nabla^j q(x_*(1); H_j))_x = 0; \quad (17)$$

d) separation condition: for all vectors  $\xi \in FS^{(p)}(U; u_*, V_{p-1})$  we have that

$$\begin{aligned} 0 &\leq v_0 R_p[\ell](H_{p-1}) + a_0 R_p[q](H_{p-1}) \\ &+ \sum_{i=1}^{p-1} a_i R_{p+i}[q](H_{p-1}) \\ &+ \int_0^T \left\langle v_0 L_u + \psi f_u + \sum_{i=1}^{p-1} \rho_i(t) (\nabla^i f(H_i))_u, \xi \right\rangle dt \\ &+ \int_0^T v_0 R_p[L](H_{p-1}) + \psi(t) R_p[f](H_{p-1}) \\ &+ \sum_{i=1}^{p-1} \rho_i(t) R_{p+i}[f](H_{p-1}) dt. \end{aligned} \quad (18)$$

**Corollary 8** The separation condition d) implies the following p-order local minimum condition: along  $(x_*(t), u_*(t), t)$  we have for every  $u \in U$  and a.e.  $t \in [0, T]$ :

$$0 \leq \left\langle v_0 L_u + \psi(t) f_u + \sum_{i=1}^{p-1} \rho_i(t) (\nabla^i f(H_i))_u, u - u_*(t) \right\rangle. \quad (19)$$

In the case of a Lagrangian minimization problem which has no control constraints, or more generally if the control takes values in the interior of the control set, the functional  $\lambda$  vanishes identically. In this case we can normalize  $v_0 = 1$  and we obtain the following Corollary:

**Corollary 9 (p-order local maximum principle for Lagrangian problems)** Consider the optimal control problem (OC) without control constraints ( $U = \mathbf{R}^m$ ) and suppose the admissible process  $(x_*, u_*)$  is optimal. Then for every p-regular critical direction  $H_{p-1}$  there exist vectors  $a_i = a(H_{p-1}) \in (\mathbf{R}^k)^*$ ,  $i = 0, \dots, p - 1$ , and absolutely continuous functions  $\psi(\cdot) = \psi(H_{p-1})(\cdot)$  and  $\rho_i(\cdot) = \rho_i(H_{p-1})(\cdot)$ ,  $i = 1, \dots, p - 1$ , from  $[0, T]$  into  $(\mathbf{R}^n)^*$ , which satisfy the conditions b)–d) of Theorem 7 along the optimal trajectory  $(x_*(t), u_*(t), t)$  for  $v_0 = 1$ . In particular, we thus have

$$L_u + \psi(t) f_u + \sum_{i=1}^{p-1} \rho_i(t) (\nabla^i f(H_i))_u \equiv 0.$$

*Example 10* We illustrate Theorem 7 with an example. Consider the problem to minimize the functional  $I(x, u)$  given by

$$\int_0^T [(x_1 - 1)^2 + x_2^p + (x_3 + 1)^2 - 2] dt \quad (20)$$

over all  $(x, u) \in \overline{W}_{11}^3(0, T) \times L_\infty^2(0, T)$  subject to the dynamics

$$\dot{x}(t) = \begin{pmatrix} 0 \\ x_1^p \\ \alpha x_2^{p-1} x_3 \end{pmatrix} + \begin{pmatrix} 0 & 1 \\ -1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}, \quad (21)$$

initial condition  $x(0) = 0$  and terminal constraints  $x_1(T) = 0$  and  $x_3(T) = 0$ . Here  $p$  is an integer,  $p \geq 2$ , and  $\alpha$  is an arbitrary real number. For simplicity we have not imposed any control constraints.

It can easily be seen that the reference trajectory  $\Gamma = (x_*, u_*) \equiv (0, 0)$  is an abnormal extremal for each problem. In fact, setting  $\lambda(t) = (\nu, 0, \nu)$  with  $\nu \neq 0$  and  $\lambda_0 = 0$  defines an adjoint vector for  $\Gamma$  such that  $H_u \equiv 0$ . Hence  $F'(0, 0)$  is nonregular.

Theorem 7 can be used to eliminate  $\Gamma$  from optimality for any  $p \geq 2$ . We choose  $H_{p-1}$  of the form

$$H_{p-1} = ((\eta_1, \xi_1); (0, 0); \dots; (0, 0)) \quad (22)$$

with  $(\eta_1, \xi_1) \in F'(0, 0)$ . With this choice of directions the compatibility conditions ii) simplify considerably and reduce to the first condition only which becomes

$$\int_0^T (\eta_1^{[2]})^{p-1} (\eta_1^{[3]}) ds = 0.$$

Here the superscripts denote the components of the vector  $\eta_1$ . We satisfy this by choosing  $\eta_1^{[3]} = -\eta_1^{[1]} \equiv 0$  (i.e.,  $\xi_1^{[2]} \equiv 0$ ). Then choosing a nonzero  $\eta_1^{[2]}$  with zero boundary conditions defines a nontrivial vector  $H_{p-1}$  of the form (22) for which conditions i) and ii) in the definition of  $p$ -regular critical directions are satisfied. Furthermore, it is easily seen that the operator  $F$  is  $p$ -regular in direction of  $H_{p-1}$  at  $\Gamma$ . Finally, these di-

rections are also critical for the objective: we have  $I'(0, 0)(\eta_1, \xi_1) = 0$  and furthermore

$$\begin{aligned} \nabla^2 I(0, 0)(H_2) &= \frac{1}{2} I''(0, 0)((\eta_1, \xi_1); (\eta_1, \xi_1)) \\ &= \int_0^T (\eta_1^{[1]})^2 + (\eta_1^{[3]})^2 ds = 0 \end{aligned}$$

provided  $p > 2$ . Since no other  $I$ -derivatives arise in the directional derivatives  $\nabla^i I(0, 0)(H_i)$  for  $i = 3, \dots, p - 1$ , the direction  $H_{p-1} = ((\eta_1, \xi_1); (0, 0); \dots; (0, 0))$  with  $\eta_1^{[1]} = \eta_1^{[3]} \equiv 0$  and a nonzero  $\eta_1^{[2]}$  is a nonzero  $p$ -regular critical direction for the problem to minimize  $I$  subject to  $F = 0$  for any  $p \geq 2$ .

We thus can apply Theorem 7. Since there are no control constraints we can normalize the multipliers so that  $\nu_0 = 1$ . The additional multipliers  $\rho_i, i = 1, \dots, p - 1$ , are associated with elements in the dual spaces of the quotients  $Y_{i+1}/Y_i$  (see **High-order necessary conditions for optimality for abnormal points**). But here  $Y_i = \text{Im } F'(0, 0)$  for  $i = 1, \dots, p - 1$ , and  $Y_p$  is the full space. Thus we have  $\rho_i \equiv 0$  for  $i = 2, \dots, p - 1$  and the only nonzero multipliers are  $\psi$  and  $\rho_{p-1}$  which for simplicity of notation we just call  $\rho$ . Now (14) states that  $\rho$  is an adjoint multiplier for which the conditions of the local Maximum Principle for an abnormal extremal are satisfied. This multiplier is unique and of the form  $\rho(t) = (\nu, 0, \nu)$ , but  $\nu \in \mathbf{R}$  could be zero. For the extended adjoint equation and minimum condition (19) we need to evaluate the directional derivatives  $\nabla^{p-1} f(x, u)(H_i)$ . Straightforward, but a bit tedious calculations show that

$$(\nabla^{p-1} f(0, 0)(H_i))_x = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & (\eta_1^{[2]})^{p-1} \end{pmatrix}$$

and

$$(\nabla^{p-1} f(0, 0)(H_i))_u \equiv 0.$$

Thus the extended minimum condition reduces to  $\psi B \equiv 0$ , the minimum condition of the weak maximum principle. Hence also  $\psi_2(t) \equiv 0$  and  $\psi_1(t) = \psi_3(t)$ . But now the extended adjoint equation is given by

$$\dot{\psi}(t) = (2, 0, -2) - \rho \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & (\eta_1^{[2]})^{p-1} \end{pmatrix}$$

and thus

$$4 = \dot{\psi}_1(t) - \dot{\psi}_3(t) - \nu \left( \eta_1^{[2]}(t) \right)^{p-1} = -\nu \left( \eta_1^{[2]}(t) \right)^{p-1}.$$

But we can certainly choose  $\eta_1^{[2]}$  nonconstant to violate this condition. This contradiction proves that  $\Gamma$  cannot be optimal for the problem to minimize  $I$  for any  $p \geq 2$ .

## Conclusion

Theorem 7 is based on  $p$ -order approximations. If these remain inconclusive, higher order approximations can easily be set up. If the operator  $F$  is  $p$ -regular in direction of  $H_{p-1}$ , then given a  $p$ -regular tangent direction, it is possible to set up higher order approximations of arbitrary order. In fact, only a system of  $p$  linear equations needs to be solved in every step. These results provide a complete hierarchy of primal constructions of higher-order approximating directions and dual characterizations of empty intersection properties of approximating cones which can be used to give necessary conditions for optimality for increasingly more degenerate structures. For these results see [13].

High-order necessary conditions for optimality;  
Abnormal processes

We consider the problem of minimizing a functional  $I: X \rightarrow \mathbf{R}$  in a Banach space  $X$  under both *equality* and *inequality constraints*. The inequality constraints are of two types, either described by smooth functionals  $f: X \rightarrow \mathbf{R}$  as  $P = \{x \in X: f(x) \leq 0\}$  or described by closed convex sets  $C$  with nonempty interior. The equality constraints are given in operator form as  $Q = \{x \in X: F(x) = 0\}$  where  $F: X \rightarrow Y$  is an operator between Banach spaces. Models of this type are common in optimal control problems.

The standard first order Lagrange multiplier type necessary conditions for optimality at the point  $x_*$  state that there exist multipliers  $\lambda_0, \dots, \lambda_m, y^*$  which do not all vanish identically such that the *Euler–Lagrange equation*

$$\lambda_0 I'(x_*) + \sum_{j=1}^m \lambda_j f'_j(x_*) + F'^*(x_*)y^* = 0, \quad (1)$$

is satisfied (see for instance [7,9]). This article addresses the case when the Fréchet-derivative  $F'(x_*)$  of the operator defining the equality constraint is not onto, i. e. the regular case. In this case the *classical Lyusternik theorem* [14] does not apply to describe the tangent space to  $Q$  and (1) can be satisfied trivially by choosing a nonzero multiplier  $y^*$  from the annihilator of  $\text{Im}$

$F'(x_*)$  while setting all other multipliers zero. This generates so-called *abnormal points* for which the standard necessary conditions for optimality only describe the degeneration of the equality constraint without any relation to optimality. Here we describe an approach to high-order necessary conditions for optimality in these cases which is based a *high-order generalization of the Lyusternik theorem* [12]. By using this theorem one can determine the precise structure of polynomial approximations to  $Q$  at  $x^*$  when the surjectivity condition on  $F'(x_*)$  is not satisfied, but when instead a certain operator  $G_p$  which takes into account all derivatives up to and including order  $p$  is onto. The order  $p$  is chosen as the minimum number for which the operator  $G_p$  becomes onto. If  $G_p$  is onto, then the precise structure of  $q$ -order polynomial approximations to  $Q$  at  $x_*$  for any  $q \geq p$  can be determined. This leads to the notion of high-order tangent cones to the equality constraint  $Q$  at points  $x_*$  in a nonregular case. Combining these with high-order feasible cones for the inequality constraints and high-order cones of decrease, a generalization of the *Dubovitskii–Milyutin theorem* is formulated. From this theorem generalized necessary conditions for optimality can be deduced which reduce to classical conditions for normal cases, but give new and nontrivial conditions for abnormal cases.

First results of this type have been obtained for quadratic approximations ( $p = 2$ ) in [3,4,5] and [11]. Some of these conditions have been analyzed further also in connection with sufficient conditions for optimality, [1,2]. In [10] also quadratic approximations for problems with inequality constraints are considered. For the regular case when  $F'(x_*)$  is onto second order approximating sets were introduced in [6] to derive second order necessary conditions for optimality, while higher order necessary conditions for optimality in this case are given, for instance, in [8] or [15]. These, however, are not the topic of this article.

## A High-Order Formulation of the Dubovitskii–Milyutin Theorem

Let  $X$  and  $Y$  be Banach spaces. Let  $I: X \rightarrow \mathbf{R}$  be a functional,  $F: X \rightarrow Y$  an operator,  $f_j: X \rightarrow \mathbf{R}$ ,  $j = 1, \dots, m$ , functionals and let  $C \subset X$  be a closed convex set with nonempty interior. We assume that  $I$ , the functionals  $f_j$

and the operator  $F$  are sufficiently often continuously Fréchet-differentiable and consider the problem

$$(P) \begin{cases} \min_x & I \\ \text{s.t.} & x \in A = \left(\bigcap_{j=1}^m P_j\right) \cap Q \cap C, \\ & P_j = \{x \in X: f_j(x) \leq 0\} \\ & Q = \{x \in X: F(x) = 0\}. \end{cases}$$

We define high-order polynomial approximations to the admissible domain  $A$ . We denote sequences  $(h_1, \dots, h_k) \in X^k$  by  $H_k$  with the subscript giving the length of the sequence.

**Definition 1** Let  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$  and set  $x(\varepsilon) \doteq x_* + \sum_{i=1}^{p-1} \varepsilon^i h_i$ . We call  $H_{p-1}$  a  $(p-1)$ -order approximating sequence to a set  $S \subseteq X$  at  $x_* \in \text{Clos } S$ , respectively we call  $x: \varepsilon \rightarrow x(\varepsilon)$ , a  $(p-1)$ -order approximating curve, if there exist an  $\varepsilon_0 > 0$  and a function  $r$  defined on  $[0, \varepsilon_0]$  with values in  $X$ ,  $r: [0, \varepsilon_0] \rightarrow X$ , with the property that

$$x(\varepsilon) + r(\varepsilon) = x_* + \sum_{i=1}^{p-1} \varepsilon^i h_i + r(\varepsilon) \in S \tag{2}$$

and

$$\lim_{\varepsilon \rightarrow 0} \frac{\|r(\varepsilon)\|}{\varepsilon^{p-1}} = 0. \tag{3}$$

We call a  $(p-1)$ -order approximating sequence/curve  $(p-1)$ -order feasible if  $S$  is an inequality constraint, respectively  $(p-1)$ -order tangent if  $S$  is an equality constraint.

Let  $x_* \in F$  and assume as given a  $(p-1)$ -order approximating sequence  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$  with corresponding  $(p-1)$ -order approximation  $x(\varepsilon) \doteq x_* + \sum_{i=1}^{p-1} \varepsilon^i h_i$ . It is implicitly assumed that  $x_*$  has not been ruled out for optimality. Then we extend the existing  $(p-1)$ -order approximations to  $p$ -order approximations and derive the corresponding necessary conditions for optimality. The following definitions are direct generalizations of standard existing definitions [7].

**Definition 2** We call  $v_0$  a  $p$ -order vector of decrease for a functional  $I: X \rightarrow \mathbf{R}$  at  $x_* \in X$  in direction of the sequence  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$  if there exist

a neighborhood  $V$  of  $v_0$  and a number  $\alpha < 0$  so that for all  $v \in V$  we have

$$I\left(x_* + \sum_{i=1}^{p-1} \varepsilon^i h_i + \varepsilon^p v\right) = I(x(\varepsilon) + \varepsilon^p v) \leq I(x_*) + \alpha \varepsilon^p. \tag{4}$$

The collection of all  $p$ -order vectors of decrease for  $I$  at  $x_*$  in direction of the sequence  $H_{p-1}$  will be called the  $p$ -order set of decrease to  $I$  at  $x_*$  in direction of the sequence  $H_{p-1}$  and will be denoted by  $DS^{(p)}(I; x_*, H_{p-1})$ .

**Definition 3** We call  $v_0$  a  $p$ -order feasible vector for an inequality constraint  $P$  at  $x_* \in X$  in direction of  $H_{p-1}$  if there exist an  $\varepsilon_0 > 0$  and a neighborhood  $V$  of  $v_0$  so that for all  $0 < \varepsilon \leq \varepsilon_0$

$$x_* + \sum_{i=1}^{p-1} \varepsilon^i h_i + \varepsilon^p V = x(\varepsilon) + \varepsilon^p V \subset P. \tag{5}$$

The collection of all  $p$ -order feasible vectors  $v_0$  for  $P$  at  $x_*$  in direction of the sequence  $H_{p-1}$  will be called the  $p$ -order feasible set to  $P$  at  $x_*$  in direction of the sequence  $H_{p-1}$  and will be denoted by  $FS^{(p)}(P; x_*, H_{p-1})$ .

Note that by definition the  $p$ -order set of decrease to  $I$  and the  $p$ -order feasible set to  $P$ , both at  $x_*$  in direction of the sequence  $H_{p-1}$ , are open.

**Definition 4** We call  $h_p$  a  $p$ -order tangent vector to an equality constraint  $Q$  at  $x_*$  in direction of the sequence  $H_{p-1}$  if  $H_p = (h_1, \dots, h_p) \in X^p$  is a  $p$ -order approximating sequence to the set  $Q$  at  $x_* \in Q$ . The collection of all  $p$ -order tangent vectors to  $Q$  at  $x_*$  in direction of the sequence  $H_{p-1}$  will be called the  $p$ -order tangent set to  $Q$  at  $x_*$  in direction of the sequence  $H_{p-1}$  and will be denoted by  $TS^{(p)}(Q; x_*, H_{p-1})$ .

These approximating sets can be embedded into cones in the extended state-space  $X \times \mathbf{R}$ . This has the advantage that many classical results like the Minkowski–Farkas lemma or the annihilator lemma can be directly applied in calculating dual cones (see also [11]). Let us generally refer to  $p$ -order sets of decrease, feasible sets and tangent sets as  $p$ -order approximating sets and denote them by  $AS^{(p)}(Z; x_*, H_{p-1})$ . Then we define the corresponding approximating cones as follows:

**Definition 5** Given a  $p$ -order approximating set  $AS^{(p)}(Z; x_*, H_{p-1})$  to a set  $Z \subset X$  at  $x_*$  in direction

of the sequence  $H_{p-1}$ , the  $p$ -order approximating cone to  $Z$  at  $x_*$  in direction of  $H_{p-1}$ ,  $AC^{(p)}(Z; x_*, H_{p-1})$ , is the cone in  $X \times \mathbf{R}$  generated by the vectors  $(v, 1) \in AS^{(p)}(Z; x_*, H_{p-1}) \times \mathbf{R}$ .

Thus we talk of the  $p$ -order cone of decrease for the functional  $I$ ,  $p$ -order feasible cones for inequality constraints and  $p$ -order tangent cones for equality constraints, all at  $x_*$  in direction of the sequence  $H_{p-1}$ .

**Definition 6** Let  $C \subseteq Z$  be a cone in a Banach space  $Z$  with apex at 0. The dual (or polar) cone to  $C$  consists of all continuous linear functionals  $\lambda \in Z^*$  which are nonnegative on  $C$ , i. e.

$$C^* = \{ \lambda \in Z^* : \langle \lambda, v \rangle \geq 0, \forall v \in C \}. \tag{6}$$

Then we have

**Theorem 7 [11,13]** ( $p$ -order Dubovitskii–Milyutin theorem). Suppose the functional  $I$  attains a local minimum for problem (P) at  $x_* \in A$ . Let  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$  be a  $(p-1)$ -order approximating sequence such that the  $p$ -order cone of decrease for the functional  $I$ , the  $p$ -order feasible cones for the inequality constraints  $P_j$ ,  $j = 1, \dots, m$ , and  $C$ , and the  $p$ -order tangent cone to the equality constraint  $Q$ , all at  $x_*$  in direction of the sequence  $H_{p-1}$ , are nonempty and convex. Then there exist continuous linear functionals

$$\begin{aligned} \Psi_0 &= (\lambda_0, \mu_0) \in \left( DC^{(p)}(I; x_*, H_{p-1}) \right)^*, \\ \Psi_j &= (\lambda_j, \mu_j) \in \left( FC^{(p)}(f_j; x_*, H_{p-1}) \right)^*, \end{aligned}$$

for  $j = 1, \dots, m$ ,

$$\Omega = (\lambda_{m+1}, \mu_{m+1}) \in \left( FC^{(p)}(C; x_*, H_{p-1}) \right)^*$$

and

$$\Phi = (\lambda_{m+2}, \mu_{m+2}) \in \left( TC^{(p)}(Q; x_*, H_{p-1}) \right)^*,$$

all depending on  $H_{p-1}$ , such that

$$\sum_{j=0}^{m+2} \lambda_j \equiv 0, \quad \sum_{j=0}^{m+2} \mu_j \equiv 0 \tag{7}$$

hold. Furthermore, not all the  $\lambda_j, j = 0, \dots, m+2$ , vanish identically.

### High-Order Directional Derivatives

We describe a formalism to calculate higher derivatives [12,13] which will be needed to describe high-order approximating cones. Let  $F: X \rightarrow Y$  be an operator between Banach spaces which is sufficiently often continuously Fréchet differentiable in a neighborhood of  $x_* \in X$  and consider the Taylor expansion of  $F$  along a curve

$$\gamma(\varepsilon) = x_* + \sum_{i=1}^m \varepsilon^i h_i.$$

We have

$$F(\gamma(\varepsilon)) = F(x_*) + \sum_{i=1}^m \varepsilon^i \nabla^i F(x_*)(h_1, \dots, h_i) + \tilde{r}(\varepsilon),$$

where  $\nabla^i F(x_*)(h_1, \dots, h_i)$  is given by

$$\sum_{r=1}^i \frac{1}{r!} \left( \sum_{j_1 + \dots + j_r = i} F^{(r)}(x_*)(h_{j_1}, \dots, h_{j_r}) \right) \tag{8}$$

and  $\tilde{r}(\varepsilon)$  is a function of order  $o(\varepsilon^m)$  as  $\varepsilon \rightarrow 0$ . Note that  $\nabla^i F(x_*)(h_1, \dots, h_i)$  simply collects the  $\varepsilon^i$ -terms in this expansion. These terms, which we call the  $i$ th-order directional derivatives of  $F$  along the sequence  $H_i = (h_1, \dots, h_i)$ ,  $1 \leq i \leq m$ , are easily calculated by straightforward Taylor expansions. For example,

$$\begin{aligned} \nabla^1 F(x_*)(H_1) &= F'(x_*)h_1, \\ \nabla^2 F(x_*)(H_2) &= F'(x_*)h_2 + \frac{1}{2}F''(x_*)(h_1, h_1). \end{aligned}$$

The higher-order directional derivative  $\nabla^i F(x_*)$  is homogeneous of degree  $i$  in the directions in the sense that

$$\nabla^i F(x_*)(\varepsilon h_1, \dots, \varepsilon^i h_i) = \varepsilon^i \nabla^i F(x_*)(h_1, \dots, h_i).$$

In particular, no indices  $j_1$  and  $j_2$  with  $j_1 + j_2 > i$  can occur together as arguments in any of the terms in  $\nabla^i F(x_*)$ . Thus all vectors  $h_j$  whose index satisfies  $2j > i$  appear linearly in  $\nabla^i F(x_*)$  and are multiplied by terms which are homogeneous of degree  $i - j$ . In fact, there exist linear operators  $G_k = G_k[F](x_*; H_{k-1})$ ,  $k \in \mathbf{N}$ , depending on the derivatives up to order  $k$  of  $F$  in the point  $x_*$  and on the vectors  $H_{k-1} = (h_1, \dots, h_{k-1})$ , which describe the contributions of these components. We have  $G_1[F](x_*) = F'(x_*)$  and in general

$G_k = G_k[F](x_*; H_{k-1}): Z \rightarrow Y, v \rightarrow G_k(v)$ , is given by

$$G_k(v) = \sum_{r=1}^{k-1} \frac{1}{r!} \times \left( \sum_{j_1+\dots+j_r=k-1} F^{(r+1)}(x_*)(h_{j_1}, \dots, h_{j_r}, v) \right). \tag{9}$$

These operators  $G_k[F](x_*; H_{k-1})$  are the Fréchet-derivatives of the  $(k - 1)$ th directional derivative of  $F$  at  $x_*$  along  $H_{k-1}$ . Note that these terms are homogeneous of degree  $k - 1$ . For simplicity of notation we often suppress the arguments. For example, we write

$$G_1(v) = F'(x_*)v, \quad G_2(v) = F''(x_*)(h_1, v),$$

$$G_3(v) = F''(x_*)(h_2, v) + \frac{1}{2}F'''(x_*)(h_1, h_1, v).$$

Given an order  $p \in \mathbf{N}$ , it follows that we can separate the linear contributions of the vectors  $h_p, \dots, h_{2p-1}$  in derivatives of orders  $p$  through  $2p - 1$  and for  $i = 1, \dots, p$ , we have an expression of the form

$$\nabla^{p-1+i} F(x_*)(H_{p-1+i}) = \sum_{k=1}^i G_k[F](x_*; H_{k-1})h_{p+i-k} + R_{p-1+i}[F](x_*; H_{p-1}).$$

Here among the terms which are homogeneous of degree  $p - 1 + i$  the sum gives the terms which contain one of the vectors  $h_p, \dots, h_{p-1+i}$ , and the remainder  $R$  combines all other terms which only include vectors of index  $\leq p - 1$ . The general structure of the remainder  $R_q[F](z_*; H_\ell)$  for arbitrary  $q \geq 2$  and  $\ell$  is given by

$$\sum_{r=2}^q \frac{1}{r!} \left( \sum_{\substack{j_1+\dots+j_r=q, \\ 1 \leq j_k \leq \ell, \\ 1 \leq k \leq r}} F^{(r)}(x_*)(h_{j_1}, \dots, h_{j_r}) \right). \tag{10}$$

Thus  $R_q(H_\ell)$  consists of the terms which are homogeneous of degree  $q$ , but only involve vectors from  $H_\ell$ . For example,  $R_3[F](z_*; H_2)$  is given by

$$F''(z_*)(h_1, h_2) + \frac{1}{6}F^{(3)}(z_*)(h_1, h_1, h_1).$$

Note that the remainders only have contributions from derivatives of at least order two. These operators allow to formalize high-order approximations to an equality constraint at nonregular points [13].

### High-Order Tangent Cones

We first describe the set of critical directions along which high-order tangent approximations to the equality constraint  $Q$  can be set up. For a given admissible process  $z_* \in A$  and a finite sequence  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$ , let

$$Y_i = \sum_{k=1}^i \text{Im } G_k[F](x_*; H_{k-1}), \quad i = 1, \dots, p.$$

It is clear that the first  $p - 1$  directional derivatives of  $F$  along  $H_{p-1}$  must vanish,

$$\nabla^i F(z_*)(H_i) = 0, \quad \forall i = 1, \dots, p - 1, \tag{11}$$

if  $H_{p-1}$  is a  $(p - 1)$ -order tangent direction. But additional compatibility conditions of the form

$$R_{p-1+i}[F](x_*; H_{p-1}) \in Y_i, \quad i = 1, \dots, p - 1, \tag{12}$$

are necessary as well if we want to extend  $H_{p-1}$  to a  $p$ -order tangent direction  $H_p = (H_{p-1}; h_p)$ . Conditions (11) and (12) are indeed sufficient for the existence of  $p$ -order approximations along  $H_{p-1}$  under the following regularity condition:

**Definition 8** Let  $F: X \rightarrow Y$  be an operator between Banach spaces. We say the operator  $F$  is  $p$ -regular at  $x_*$  in direction of the sequence  $H_{p-1} \in X^{p-1}$  if the following conditions are satisfied:

- A1)  $F: X \rightarrow Y$  is  $(2p - 1)$ -times continuously Fréchet differentiable in a neighborhood of  $x_*$ ;
- A2) the subspaces  $Y_i, i = 1, \dots, p$ , are closed;
- A3) the map  $\mathcal{G}_p = \mathcal{G}_p[F](x_*; H_{p-1})$

$$\mathcal{G}_p: X \rightarrow Y_1 \times \frac{Y_2}{Y_1} \times \dots \times \frac{Y}{Y_{p-1}},$$

$$v \mapsto \mathcal{G}_p(v) = (G_1(v), \dots, \pi_{p-1}G_p(v)),$$

where  $\pi_i: Y_{i+1} \rightarrow Y_{i+1}/Y_i$  denotes the canonical projection onto the quotient space, is onto.

In the sense of this Definition, 1-regularity corresponds to the classical Lyusternik condition while 2-regularity is similar to Avakov's definition [5].

**Theorem 9** [12] Let  $H_{p-1}$  be a sequence so that  $\nabla^i F(x_*)(H_i) = 0$  for  $i = 1, \dots, p - 1$ , and suppose the operator  $F$  is  $p$ -regular at  $x_*$  in direction of  $H_{p-1}$ . Then

$TS^{(p)}(Q; x_*, H_{p-1})$  is nonempty if and only if for  $i = 1, \dots, p - 1$ , the compatibility conditions

$$R_{p-1+i}[F](x_*; H_{p-1}) \in Y_i$$

are satisfied. In this case  $TS^{(p)}(Q; x_*, H_{p-1})$  is the closed affine subspace of  $X$  given by the solutions to the linear equation

$$G_p[F](x_*; H_{p-1})(v) + R_{p-1}[F](x_*, H_{p-1}) = 0, \quad (13)$$

where  $R_{p-1}[F](x_*, H_{p-1}) \in Z$  is the point with components

$$(R_p[F](x_*; H_{p-1}), \pi_1 R_{p+1}[F](x_*; H_{p-1}), \dots, \pi_{p-1} R_{2p-1}[F](x_*; H_{p-1})).$$

This formulation of the result clearly brings out the geometric structure of the  $p$ -order tangent sets as closed affine linear subspaces of  $X$  generated by the kernel of  $G_p, \ker G_p$ .

**Corollary 10 [12]** Let  $H_{p-1}$  be a sequence such that the operator  $F$  is  $p$ -regular at  $x_*$  in direction of  $H_{p-1}$ . Suppose the first  $(p - 1)$  directional derivatives  $\nabla^i F(x_*)(H_i)$  vanish for  $i = 1, \dots, p - 1$ , and the compatibility conditions  $R_{p-1+i}[F](x_*; H_{p-1}) \in Y_i$  are satisfied for  $i = 1, \dots, p$ . Then the  $p$ -order tangent cone to  $Q = \{x \in X: F(x) = F(x_*)\}$  at  $x_*$  in direction of  $H_{p-1}$ ,  $TC^{(p)}(Q; x_*, H_{p-1})$ , consists of all solutions  $(w, \gamma) \in X \times \mathbf{R}_+$  (i. e.  $\gamma > 0$ ) of the linear equation

$$G_p[F](w) + \gamma R_{p-1}[F](x_*, H_{p-1}) = 0.$$

For applications to optimization problems we need the subspace of continuous linear functionals which annihilate  $G_p$ . Since the operator  $G_p$  is onto, it follows by the annihilator lemma or the closed-range theorem [9] that

$$(\ker G_p)^\perp = \text{Im}(G_p^*),$$

where  $G_p^*$ :

$$Z^* = Y_1^* \times \left(\frac{Y_2}{Y_1}\right)^* \times \dots \times \left(\frac{Y}{Y_{p-1}}\right)^* \rightarrow X^*,$$

denotes the adjoint map. Let

$$\tau_i: \left(\frac{Y_{i+1}}{Y_i}\right)^* \rightarrow Y_i^{\perp i+1}$$

denote the canonical isomorphism. Here  $\perp_{i+1}$  denotes the annihilator in  $Y_{i+1}$ , i. e.

$$Y_i^{\perp i+1} = \{y^* \in Y_{i+1}^*: \langle y^*, v \rangle = 0, \forall v \in Y_i\}$$

and we formally set  $Y_0 = \{0\}$ , so that  $Y_0^{\perp 1} \cong Y_1^*$ . Then we have:

**Proposition 11 [11,13]** A functional  $\lambda \in X^*$  lies in  $(\ker G_p)^\perp$  if and only if it can be represented in the form

$$\lambda = \sum_{i=1}^p G_i^*[F](x_*; H_{i-1})y_i^* \quad (14)$$

for some functionals  $y_i^* \in Y_{i-1}^{\perp i}, i = 1, \dots, p$ .

**Proposition 12 [11,13]** The dual or polar  $p$ -order tangent cone consists of all linear functionals  $(\lambda, \mu) \in X^* \times \mathbf{R}$  which can be represented in the following form: There exist functionals  $y_i^* \in Y_{i-1}^{\perp i}, i = 1, \dots, p$ , and a number  $r \geq 0$  such that

$$\begin{aligned} \lambda &= \sum_{i=1}^p G_i^*[F](x_*; H_{i-1})y_i^*, \\ \mu &= \sum_{i=1}^p \langle y_i^*, R_{p-1+i}[F](x_*; H_{p-1}) \rangle + r. \end{aligned}$$

### High-Order Cones of Decrease

We now consider critical directions for the objective  $I$  and determine the  $p$ -order sets of decrease of a functional  $I: X \rightarrow \mathbf{R}$ . These results also apply to  $p$ -order feasible sets to inequality constraints defined by smooth functionals. We assume as given a  $(p - 1)$ -order sequence  $H_{p-1}$  and we calculate the  $p$ -order set of decrease of  $I$  at  $x_*$  along  $H_{p-1}$ . Trivial cases arise if there exists a first nonzero directional derivative  $\nabla^i I(x_*)(H_i)$  of  $I$  with  $i \leq p - 1$ . In this case we have either  $DS^{(p)}(I; x_*, H_{p-1}) = \emptyset$  if  $\nabla^i I(x_*)(H_i) > 0$  or  $DS^{(p)}(I; x_*, H_{p-1}) = X$  if  $\nabla^i I(x_*)(H_i) < 0$ . In the first case the sequence  $H_{p-1}$  cannot be used to exclude optimality of  $x_*$  since indeed  $x_*$  is a local minimum along the approximating curve generated by  $H_{p-1}$ . In the second case  $h_i$  is an  $i$ th-order direction of decrease along  $H_{i-1}$  and thus every vector  $v \in X$  is admissible as a  $p$ th order component. The only nontrivial case arises

if  $\nabla^i I(x_*)(H_i) = 0$  for all  $i$  with  $i \leq p - 1$  and if  $I'(x_*) \neq 0$ .

**Proposition 13 [13]** *Suppose  $I'(x_*) \neq 0$  and for all  $i$  with  $i \leq p - 1$  we have  $\nabla^i I(x_*)(H_i) = 0$ . Then the  $p$ -order cone of decrease for the functional  $I$  at  $x_*$  in direction of  $H_{p-1}$ ,  $DC^{(p)}(I; x_*, H_{p-1})$ , consists of all vectors  $(w, \gamma) \in X \times \mathbf{R}$  which satisfy*

$$I'(x_*)w + \gamma R_p[I](x_*; H_{p-1}) < 0.$$

Thus  $DC^{(p)}(I; x_*, H_{p-1})$  is nonempty, open and convex. The dual or polar cone to  $DC^{(p)}(I; x_*, H_{p-1})$  can easily be calculated using the Minkowski–Farkas lemma [7].

### High-Order Feasible Cones to Inequality Constraints Given by Smooth Functionals

In this section we give the form of the  $p$ -order feasible cones,  $FC^{(p)}(P; x_*, H_{p-1})$ , for inequality constraints  $P$  described by smooth functionals,

$$P = \{x \in X: f(x) \leq 0\}.$$

Similar like for sets of decrease, if there exists a first index  $i \leq p - 1$  such that  $\nabla^i f(x_*)(H_i) \neq 0$ , then the constraint will either be satisfied for any  $p$ -order vector  $v \in X$  if  $\nabla^i f(x_*)(H_i) < 0$  or it will be violated if  $\nabla^i f(x_*)(H_i) > 0$ . This leads to the definition of  $p$ -order active constraints.

**Definition 14** The inequality constraint  $P$  is said to be  $p$ -order active along the sequence  $H_{p-1}$  if for all  $i, i = 1, \dots, p - 1$ , we have  $\nabla^i f(x_*)(H_i) = 0$ .

Only  $p$ -order active constraints enter the necessary conditions for optimality derived via  $p$ -order approximations along an admissible sequence  $H_{p-1}$ ;  $p$ -order inactive constraints generate zero multipliers since  $DS^{(p)}(P; x_*, H_{p-1}) = X$  ( $p$ -order complementary slackness conditions) and can be ignored for high-order approximations.

**Proposition 15** *If the constraint  $P = \{x \in X: f(x) \leq 0\}$  is  $p$ -order active along the sequence  $H_{p-1}$ , then the  $p$ -order feasible cone,  $FC^{(p)}(P; x_*, H_{p-1})$ , consists of all vectors  $(w, \gamma) \in X \times \mathbf{R}_+$  which satisfy*

$$f'(x_*)w + \gamma R_p[f](x_*; H_{p-1}) < 0.$$

Hence, if  $f'(x_*) \neq 0$ , then  $FC^{(p)}(P; x_*, H_{p-1})$  is nonempty, open and convex.

### High-Order Feasible Cones to Closed Convex Inequality Constraints

Let  $C \subset X$  be a closed convex set with nonempty interior. Again we assume that  $H_{p-1}$  is a  $(p - 1)$ -order feasible sequence. Note that it follows from Definition 3 that  $FS^{(p)}(C; x_*, H_{p-1})$  is open (since any vector in the neighborhood  $V$  of  $v$  also lies in  $FS^{(p)}(C; x_*, H_{p-1})$ ). It is also clear that  $FS^{(p)}(C; x_*, H_{p-1})$  is convex, since  $C$  is. Thus  $FC^{(p)}(C; x_*, H_{p-1})$  is an open, convex cone. Furthermore, if there exists an integer  $j < p$  so that  $h_j \in FS^{(j)}(C; x_*, H_{j-1})$ , then any vector  $v$  is allowed as a  $p$ -order feasible direction and thus trivially  $FS^{(p)}(C; x_*, H_{p-1}) = X$ , i.e. the convex constraint  $x \in C$  is not  $p$ -order active. In this case the necessary conditions for optimality along  $H_{p-1}$  are exactly the same as without  $C$ .

The dual or polar cone  $FC^{(p)}(C; x_*, H_{p-1})^*$  can be identified with all supporting hyperplanes to  $FS^{(p)}(C; x_*, H_{p-1})$  at  $x_*$ . More precisely, it consists of all linear functionals  $(\lambda, \mu) \in X^* \times \mathbf{R}$  which satisfy

$$\langle \lambda, v \rangle + \mu \geq 0, \quad \forall v \in FS^{(p)}(C; x_*, H_{p-1}).$$

**Corollary 16 [13]** *Let  $C \subset X$  be a closed convex set with nonempty interior and suppose the  $p$ -order feasible set  $FS^{(p)}(C; x_*, H_{p-1})$  is nonempty. If  $(\lambda, \mu) \in FC^{(p)}(C; x_*, H_{p-1})^*$ , then  $\lambda$  is a supporting hyperplane to  $C$  at  $x_*$ .*

### Generalized Necessary Conditions for Optimality

We now give generalized necessary conditions for optimality for problem (P) based on general  $p$ -order approximations. We assume as given a sequence  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$  with the following properties:

P1) The first  $p - 1$  directional derivatives of  $F$  along  $H_{p-1}$  vanish,

$$\nabla^i F(x_*)(H_i) = 0, \quad \forall i = 1, \dots, p - 1,$$

the compatibility conditions

$$R_{p-1+i}[F](x_*; H_{p-1}) \in Y_i$$

are satisfied for  $i = 1, \dots, p - 1$ , and the operator  $F$  is  $p$ -regular at  $x_*$  in direction of the sequence  $H_{p-1}$ .

- P2) Either the first nonvanishing derivative  $\nabla^i I(x_*)(H_i)$  is negative or  $\nabla^i I(x_*)(H_i) = 0$  for  $i = 1, \dots, p-1$ .
- P3) If the  $j$ th constraint is not  $p$ -order active, then the first nonzero derivative  $\nabla^i f(x_*)(H_i)$  is negative.
- P4)  $FS^{(p)}(C; x_*, H_{p-1})$  is nonempty.

These conditions guarantee respectively that the corresponding  $p$ -order approximating cones to the constraints or the functional  $I$  are nonempty and convex. The next theorem generalizes the classical first order necessary conditions for optimality for a mathematical programming problem with convex inequality constraints [7, Thm. 11.4].

**Theorem 17** *If  $x_*$  is optimal for problem (P), then given any sequence  $H_{p-1} = (h_1, \dots, h_{p-1}) \in X^{p-1}$  for which conditions P1)–P4) are satisfied, there exist Lagrange multipliers  $v_i \geq 0$ ,  $i = 0, \dots, m$ , functionals  $y_i^* \in Y_{i-1}^{\perp}$ ,  $i = 1, \dots, p$ , and a supporting hyperplane  $\langle \lambda, v \rangle + \mu \geq 0$  for all  $v \in FS^{(p)}(C; x_*, H_{p-1})$ , all depending on the sequence  $H_{p-1}$ , such that the multipliers  $v_i$ ,  $i = 0, \dots, m$ , and  $\lambda$  do not all vanish, and*

$$\lambda \equiv v_0 I'(x_*) + \sum_{j=1}^m v_j f'_j(x_*) + \sum_{i=1}^p G_i^* y_i^*, \quad (15)$$

$$\mu \leq v_0 R_p[I](x_*; H_{p-1}) + \sum_{j=1}^m v_j R_p[f_j](x_*; H_{p-1}) + \sum_{i=1}^p \langle y_i^*, R_{p-1+i}[F](H_{p-1}) \rangle. \quad (16)$$

Furthermore, the following  $p$ -order complementary slackness conditions hold:

- $v_0 = 0$  if  $DS^{(p)}(I; x_*, H_{p-1}) = X$ ;
- $v_j = 0$  if  $FS^{(p)}(P_j; x_*, H_{p-1}) = X$ ;
- $\lambda = 0$  if  $FS^{(p)}(C; x_*, H_{p-1}) = X$ .

**Remark 18** This theorem gives the formulation for the case which is *nondegenerate* in the sense that the operator  $G_p$  is onto and it is this condition which implies the nontriviality of the multipliers  $v_j$ ,  $j = 0, \dots, m$ , and  $\lambda$ . If  $G_p$  is not onto, but  $\text{Im} G_p$  is closed, while all the other conditions remain in effect, then a degenerate version of this theorem can easily be obtained by choosing a nontrivial multiplier  $\tilde{y}^* \in (\text{Im} G_p)^\perp$ . This then gives rise to nontrivial multipliers  $y_i^* \in Y_{i-1}^{\perp}$  which have the property that  $\sum_{i=1}^p G_i^* y_i^* \equiv 0$ . Thus (15) still

holds if we set  $v_j = 0$ , for  $j = 0, \dots, m$ , and  $\lambda = 0$ . Thus the difference is that it can only be asserted that not all of the multipliers  $v_j$ ,  $j = 0, \dots, m$ ,  $y_i^* \in Y_{i-1}^{\perp}$ ,  $i = 1, \dots, p$ , and  $\lambda$  do vanish.

Superpositions of functions; Algebraic equations;  $E$ -entropy; Information

The formulation of Hilbert's thirteenth problem [8] reads: 'impossibility of solving the general equation of degree 7 by means of any continuous functions depending only on two variables' [21].

On this basis, D. Hilbert proposed that the complexity of functions is specified essentially by the number of variables. However, as turned out later, this proposal being valid for analytic functions is not true in the general case. In particular, complexity of  $r$  times continuously differentiable functions of  $n$  variables depends not on the number of variables  $n$  but on the ratio  $n/r$ .

It is known that the equation of third degree can be reduced by translation to

$$X^3 + pX + q = 0,$$

which has the solution (S. del Ferro, 16th century)

$$X = \left[ -\frac{q}{2} + \sqrt{\frac{4p^3 + 27q^2}{4(27)}} \right]^{1/3} + \left[ -\frac{q}{2} - \sqrt{\frac{4p^3 + 27q^2}{4(27)}} \right]^{1/3}.$$

The equation of fourth degree can be solved by superposition of addition, multiplication, square roots, cube roots and fourth roots.

To try to solve *algebraic equations* of higher degree (a vain hope according to N.H. Abel and E. Galois), the

idea of W. Tschirnhausen in 1683 [24] was to adjoin a new equation, i. e., to

$$P(X) = 0$$

one adjoins

$$Y = Q(X),$$

where  $Q$  is a polynomial of degree strictly less than that of  $P$ , chosen expediently. In this way one can show that the roots of an equation of degree 5 can be expressed via the usual arithmetic operations in terms of radicals and of the solution  $\phi(x)$  of the quintic equation

$$X^5 + xX + 1 = 0$$

depending on the parameter  $x$ . Similarly for the equation of degree 6, the roots are expressible in the same way if we include also a function  $\theta(x, y)$ , a solution of a 6th-degree equation depending on two parameters  $x$  and  $y$ .

For degree 7 we would have to include also a function  $\sigma(x, y, z)$ , solution of the equation

$$X^7 + xX^3 + yX^2 + zX + 1 = 0.$$

Hence the natural question: Can  $\sigma(x, y, z)$  be expressed by superposition of algebraic functions of two variables [10]?

A great number of papers are devoted to the representability of functions as *superpositions of functions* depending on a smaller number of variables and satisfying certain additional conditions such as algebraicity, analyticity and smoothness. Hilbert was aware of the fact that superpositions of discontinuous functions represent all functions of a larger number of variables. He also knew about the existence of analytic functions of three variables that cannot be represented by any finite superpositions of analytic functions of two variables [8].

In the statement of his 13th problem, Hilbert proceeded from a result of Tschirnhausen [24], according to which a root of an algebraic equation of degree  $n > 5$ , i. e., a function  $f(x_1, \dots, x_n)$  determined by an equation

$$f^n + x_1 f^{n-1} + \dots + x_n = 0, \quad (1)$$

can be expressed as a superposition of algebraic functions of  $n-4$  variables [21]. Hilbert assumed that the

number  $n - 4$  cannot be reduced for  $n = 6, 7, 8$  and also proved that in order to solve an equation of degree  $n = 9$  it suffices to have functions of  $n - 5$  variables [9]. A. Wiman [26] extended the latter result to  $n > 9$ , while N. Chebotarev [6] reduced the number of variables involved in the representation of functions to  $n - 6$  for  $n \geq 21$  and to  $n - 7$  for  $n \geq 121$ .

Chebotarev was the first to attempt to find topological obstructions to the representability of algebraic functions as superpositions of algebraic functions, but his proofs were not convincing [5,17]. Using topological notions related to the behavior of a many-valued algebraic function on and near a branching manifold, it is proved that algebraic functions cannot be represented by complete superpositions of integral algebraic functions. Completeness means that the represented function must involve all the branches of the many-valued functions and not only one of them as, for example, in the formulas expressing solutions to equations of the 3rd and the 4th degree [21].

Certain topological obstructions to the representation by a complete superpositions of algebraic functions were constructed in this way [2]. V. Lin [15] established the following, most complete, result: In any neighborhood of the origin for  $n \geq 3$  the root  $f(x_1, \dots, x_n)$  of equation (1) is not a complete superposition of entire algebraic functions of fewer than  $n - 1$  variables and single-valued holomorphic functions of an arbitrary number of variables. Thus, from the standpoint of complete superpositions of entire algebraic functions, even fourth-degree equations cannot be solved without using functions of three variables [21].

Hilbert had had another motivation for his thirteenth problem: *nomography*, the method of solving equations by drawing a one-parameter family of curves. This problem, arising in the methods of computation of Hilbert's time, inspired the development of Kolmogorov's notion of  $\varepsilon$ -entropy [20]. Applications of  $\varepsilon$ -entropy have its crucial role in theories of approximation now used in computer science [22].

In *Kolmogorov  $\varepsilon$ -entropy*, a natural characteristic of a function class  $F$  is

$$H_\varepsilon(F) = \log_2 N_\varepsilon(F),$$

where  $N_\varepsilon(F)$  is the minimum number of points in an  $\varepsilon$ -net in  $F$ . Broadly speaking, the  $\varepsilon$ -entropy of a function class  $F$  is the amount of *information* needed to specify

with accuracy  $\varepsilon$  a function of the class  $F$ . A main problem in  $\varepsilon$ -entropy is estimates for the rate of growth of  $H_\varepsilon(F)$  as  $\varepsilon \rightarrow 0$  for Lipschitz functions, classes of analytic functions and functions possessing a given number of derivatives. A.N. Kolmogorov showed that the  $\varepsilon$ -entropy of  $r$  times continuously differentiable functions of  $n$  variables grows as  $\varepsilon^{-n/r}$  [20].

Since a digital computer can store only a finite set of numbers, functions must be replaced by such finite sets. Therefore, studies in  $\varepsilon$ -entropy are important for the correct estimation of the possibilities of computational methods for approximately representing functions, their implementation on computers and their storage in the computer memory.

Also  $\varepsilon$ -entropy has many other applications [23]. An  $\varepsilon$ -net of Lipschitz functions of  $n$  variables is constructed to design global optimization algorithms. This  $\varepsilon$ -net is based on the Kolmogorov's minimal  $\varepsilon$ -net of one-dimensional Lipschitz functions and is encoded in terms of monotone functions of  $k$ -valued logic. This construction gives a representation of an  $n$ -dimensional global optimization problem by a minimal number of one-dimensional ones without loss of information [13].

Let us briefly recall the history of the solution of the Hilbert's thirteenth problem by Kolmogorov and V. Arnold. Hilbert's problem was first solved on the basis of ideas by using technique developed by A. Kronrod [14]. In this way Kolmogorov proved that any continuous function of  $n \geq 4$  variables can be represented as a superposition of continuous functions of three variables [11]. For an arbitrary function of four variables the representation has the form

$$\begin{aligned} f(x_1, x_2, x_3, x_4) \\ = \sum_{r=1}^4 h^r[x_4, g_1^r(x_1, x_2, x_3), g_2^r(x_1, x_2, x_3)]. \end{aligned}$$

The question whether an arbitrary continuous function of three variables can be represented as a superposition of continuous functions of two variables remained open. The method reduced the representability of functions of three variables as superpositions of functions of two variables to a representability problem for functions defined on universal trees of three-dimensional space [21].

Contrary to the expectations of Hilbert and of his contemporary mathematicians, in 1957 Arnol'd [1], who was a student of Kolmogorov, solved the latter problem and gave the final solution to Hilbert's thirteenth problem in the form of a theorem asserting that any continuous function of  $n \geq 3$  variables can be represented as a superposition of functions of two variables [21].

A few weeks later Kolmogorov showed that any continuous function  $f$  of  $n$  variables can be represented as a superposition

$$f(x_1, \dots, x_n) = \sum_{q=1}^{2n+1} \chi_q \left[ \sum_{p=1}^n \phi^{pq}(x_p) \right] \quad (2)$$

of continuous functions of one variable and the operation of addition [12]. In Kolmogorov's representation (2) the inner functions  $\phi^{pq}$  are fixed and only the outer functions  $\chi_q$  depend on the represented function  $f$ .

The results of [11] do not follow from the theorem presented in [12] in their exact statements, but their essence (in the sense of the possibility of representing functions of several variables by means of superpositions of functions of a smaller number of variables and their approximation by superpositions of a fixed form involving polynomials in one variable and addition) is obviously contained in it [12]. The method for proving the theorem is more elementary than that in [1,11] and reduces to direct constructions and calculations. In Kolmogorov's opinion, the proof of the theorem was his most technically difficult achievement [21].

Thorough proofs of Kolmogorov's theorem and the lemmas of his paper [12] were published in [16,18,20] and others. G. Lorenz [16] noted that the outer functions  $\chi_q$  can be replaced by a single function  $\chi$ . D. Sprecher [18] reduced all the inner functions to translations and extensions of a single function  $\psi$  with the property that there exists  $\varepsilon > 0$  and  $\lambda > 0$  such that any continuous function of  $n$  variables can be represented as

$$f(x_1, \dots, x_n) = \sum_{q=1}^{2n+1} \chi[\lambda^p \psi(x_p + \varepsilon q) + q]. \quad (3)$$

B. Fridman [7] proved that the inner functions  $\phi^{pq}$  in (2) can be chosen so that they satisfy a Lipschitz condition. Sprecher [19] extended this result to the repre-

sentation (3) (the function  $\psi$  can be chosen to satisfy a Lipschitz condition).

It follows from Kolmogorov's representation (2) and Bari's representation [3] of any continuous function of one variable as a sum of three superpositions of absolutely continuous functions  $\sum f_k \circ g_k$  that all continuous functions of any number of variables can be represented by means of superpositions of absolutely continuous functions of one variable and the operation of addition [21].

In the opposite direction are the results of A. Vitushkin [25] and L. Bassalygo [4]. When we deal with superpositions of formal series or analytic functions it can be shown that, for example, almost every entire function has at an arbitrary point of  $C^3$  a germ which is not expressible by superposition of series in two variables. So there are many more entire functions of three variables than of two [10]. The result of Vitushkin is that there exist  $r$  times continuously differentiable functions of  $n$  variables that cannot be expressed in terms of finite superpositions of  $s \geq 1$  times continuously differentiable functions of  $k < n$  variables if  $n/r > ks$  [25], representability depends on  $n/r$ . Bassalygo proved that for any three functions  $\psi_k$  continuous on a square there exists a continuous function  $f$  which cannot be represented as  $\sum \chi_k \circ \psi_k$  for any continuous  $\chi_k$  [4].

History; Optimization

Did you ever watch how a spider catches a fly or a mosquito? Usually, a spider hides at the edge of its net. When a fly or a mosquito hits the net, the spider will pick up each line in the net to choose the tense one and then goes rapidly along the line to its prey. Why does the spider chooses the tense line? Some biologists explain that the line gives the shortest path from the spider to its prey.

Did you heard the following story about a wise general? He had a duty to capture a town behind a mountain. When he and his soldiers reached the top of the mountain, he found that his enemy had already approached the town very closely from another way. His dilemma was how to get in the town before the enemy arrive. It was a challenging problem for the general. The general solved the problem by asking each soldier to roll down the mountain in a blanket. Why is this faster? Physicists tell us that a free ball rolling down a mountain always chooses the most rapid way.

Do you know the tale of a horse match of Tian Gi? It is a story set in BC time. Tian Gi was a general in one of several small counties of China, called Qi. The King of Qi knew that Tian Gi had several good horses and ordered Tian Gi to have a horse match with him. The match consisted of three rounds. In each round, each

side chose a horse to compete with the other side. Tian Gi knew that his best horse could not compete with the best one of the King, his second best horse could not compete with the second best one of King, and his third best horse could not compete with the third best one of the King. Therefore, he did not use his best horse against the best horse of the King. Instead, he put his third best horse in the first round against the best one of the King, his best horse in the second round against the second best one of the King, and his second best horse in the third round against the third best one of the King. The final result was that although he lost the first round of the match, he won the last two rounds. Tian Gi's strategy was the best to win this match. Today, economists tell us that many economic systems and social systems can be modeled into games. Each contestant in the game tries to maximize certain benefits.

Optimality is a fundamental principle, establishing natural laws, ruling biologic behaviors, and conducting social activities. Therefore, optimization started from the earliest stages of human civilization. Of course, before mathematics was well established, optimization could be done only by simulation. One may find many wise men's stories in the human history about it. For example, to find the best way to get out of a mountain, someone followed a stream, and to find the best way to get out from a desert, someone set an old horse free and followed the horse's trace.

In the 19th century or even today, simulation is still used for optimizing something. For example, to find a shortest path on a network, one may make a net with rope in a proportional size and pull the net tightly between two destinations. The tense rope shows the shortest path. To find an optimal location of a school for three villages, one may drill three holes on a table and put a piece of rope in each hole. Then tie three rope-ends above the table together and hang a one-kg-weight on each rope-end under the table. When this mechanical system is balanced, the knot of the three rope-pieces points out the location of the school.

The history of optimization in mathematics can be divided into three periods.

In the first period, one did not know any general method to find a maximum/minimum point of a function. Only special techniques were found to maximize/minimize some special functions. A typical func-

tion is the quadratic function of one variable

$$y = ax^2 + bx + c.$$

The study of quadratic functions was closely related to the study of constantly-accelerating movement. What is the highest point that a stone is thrown out with certain initial speed and certain angle? What is the farthest point where a stone thrown with certain initial speed can reach when throwing angle varies? These were questions considered by some physicists and generals. In fact, the stone-throwing machine was an important weapon in military.

Today (as of 2000), computing maximum/minimum points of a quadratic function is still an important technique of optimization, existing in elementary mathematics books. The technique had been also extended to other functions such as

$$y = \frac{x^2 + x + 1}{x^2 + 2x + 3}.$$

Actually, multiplying both sides by  $x^2 + 2x + 3$  and simplifying, we obtain

$$(y - 1)x^2 + (2y - 1)x + (3y - 1) = 0.$$

Since  $x$  is a real number, we must have

$$(2y - 1)^2 - 4(y - 1)(3y - 1) \geq 0.$$

Therefore,

$$-8y^2 + 12y - 3 \geq 0,$$

that is,

$$2(3 - \sqrt{3}) \leq y \leq 2(3 + \sqrt{3}).$$

It is interesting to note that with this technique we obtained the global maximum and minimum of  $y$ .

A new period started in 1646 by P. de Fermat. He proposed, in his paper [5], a general approach to compute local maxima/minima points of a differentiable function, that is, setting the derivative of the function to be zero. Today, this approach is still included in almost all textbooks of calculus as an application of differentiation. In this period, optimization existed scattered and disorderly in mathematics. Because optimization had not become an important branch of applied mathematics, some mathematicians did not pay so much attention to results on optimization and some contributions

were even not put in any publication. This left many mysteries in the history of optimization.

For example, who is the first person who proposed the Steiner tree? It was one such mystery. To obtain a clear view, let us explain it in a little detail.

In the same paper mentioned above, Fermat also studied a problem of finding a point to minimize the total distance from it to three given points in the Euclidean plane. Suppose three given points are  $(x_1, y_1)$ ,  $(x_2, y_2)$ , and  $(x_3, y_3)$ . Then the total distance from a point  $(x, y)$  to these three points is

$$f(x, y) = \sum_{i=1}^3 \sqrt{(x - x_i)^2 + (y - y_i)^2}.$$

By Fermat's general method, the minimum point of  $f(x, y)$  must satisfy the following equations

$$\frac{\partial f}{\partial x} = \sum_{i=1}^3 \frac{x - x_i}{\sqrt{(x - x_i)^2 + (y - y_i)^2}} = 0,$$

$$\frac{\partial f}{\partial y} = \sum_{i=1}^3 \frac{y - y_i}{\sqrt{(x - x_i)^2 + (y - y_i)^2}} = 0.$$

However, obtaining  $x$  and  $y$  from this system of equations seems hopeless. Therefore, Fermat mentioned this problem again in a letter to A. Mersenne that it would be nice if a clear solution could be obtained for this problem.

E. Torricelli, a student of G. Galilei, obtained a clever solution with a geometric method. He showed that if three given points form a triangle without an angle of at least  $120^\circ$ , then the solution is a point at which three segments from it to three given points produce three angles of  $120^\circ$ . Otherwise, the solution is the given point at which the triangle formed by the three given points has an angle of at least  $120^\circ$ . This result can also be proved by the mechanic system described at the beginning of this article. In the first case, the knot of the three rope-pieces stays not at any given point and hence the balance condition of the three forces of equal magnitude yields the condition on the angles. In the second case, the knot falls in one of the three holes, and the condition on the angle guarantees that the knot would not move away from the hole.

Fermat's problem was extensively studied later and was generalized to four points by J.Fr. Fagnano in 1775 and to  $n$  points by P. Tedenat and S. L'Huiller in 1810.

Fagnano pointed out that it is very easy to find the solution of Fermat's problem for four points. When four given points form a convex quadrilateral, the solution of Fermat's problem is the intersection of two diagonals, i. e., the intersection of two diagonals minimizes the total distance from one point to four given points. Otherwise, there must be one of the given points lying inside the triangle formed by the other three given points; this given point is the solution.

On March 19, 1836, H.C. Schumacher wrote a letter to C.F. Gauss. In his letter, he mentioned a paradox about Fermat's problem: Consider a convex quadrilateral  $ABCD$ . It has been known that the solution of Fermat's problem for four points  $A, B, C$ , and  $D$  is the intersection  $E$  of diagonals  $AC$  and  $BD$ . Suppose extending  $DA$  and  $CB$  can obtain an intersection  $F$ . Now, moving  $A$  and  $B$  to  $F$ . Then  $E$  will also be moved to  $F$ . However, when the angle at  $F$  is less than  $120^\circ$ , the point  $F$  cannot be the solution of Fermat's problem for three given points  $F, D$ , and  $C$ . What happens?

On March 21, 1836, Gauss wrote a letter to Schumacher in which he explained that the mistake of Schumacher's paradox occurs at the place where Fermat's problem for four points  $A, B, C$ , and  $D$  is changed to Fermat's problem for three points  $F, C$ , and  $D$ . When  $A$  and  $B$  are identical to  $F$ , the total distance from  $E$  to four points  $A, B, C$ , and  $D$  equals  $2EF + EC + ED$ , not  $EF + EC + ED$ . Thus, the point  $E$  may not be the solution of Fermat's problem for  $F, C$ , and  $D$ . More importantly, Gauss proposed a new problem. He said that it is more interesting to find a shortest network rather than a point. Gauss also presented several possible connections of the shortest network for four given points.

Unfortunately, Gauss' letter was discovered only in 1986. From 1941 to 1986, many publications have followed R. Courant and H. Robbins who in their popular book [2] called Gauss' problem as the Steiner tree problem. The Steiner tree has become a popular and important name. If you search 'Steiner tree' with 'yahoo.com' on the internet, then you will receive a list of 4675 webpages on Steiner trees. We have no way to change back the name from Steiner trees to Gauss trees. It may be worth mentioning that J. Steiner, a geometrician in 19th century whose name is used for the shortest networks, has not been found so far to have any significant contribution to Steiner trees.

G.B. Dantzig, who first proposed the simplex method to solve linear programming in 1947, stated in [4]: ‘What seems to characterize the pre- 1947 era was lack of any interests in trying to optimize’. Due to the lack of interests in optimization, many important works appeared before 1947 were ignored. This happened not only for Steiner trees, but also to other areas of optimization, including some important contributions in linear and nonlinear programming.

The discovery of linear programming started a new age of optimization. However, in [4], Dantzig made the following comment: ‘Linear programming was unknown prior to 1947’. This is not quite correct; there were some late exceptions. J.B.J. Fourier (of Fourier series fame) in 1823 and the well-known Belgian mathematician Ch. de la Vallée Poussin in 1911 each wrote a paper about it. Their work had as much influence on post- 1947 developments as would finding in an Egyptian tomb an electronic computer built in 3000 BC. L.V. Kantorovich’s remarkable 1939 monograph on the subject was also neglected for ideological reasons in the USSR. It was resurrected two decades later after the major developments had already taken place in the West. An excellent paper by F.L. Hitchcock in 1941 on the transportation problem was also overlooked until after others in the late 1940s and early 1950s have independently rediscovered its properties.

He also recalled how he made his discovery: ‘My own contribution grew out of my World War II experience in the Pentagon. During the war period (1941–1945), I had become an expert on programming-planning methods using desk calculators. In 1946 I was mathematical advisor to the US Air Force Comptroller in the Pentagon. I had just received my PhD (for research I had done mostly before the war) and was looking for an academic position that would pay better than a low offer I had received from Berkeley. In order to entice me to not take another job, my Pentagon colleagues, D. Hitchcock and M. Wood, challenged me to see what I could do to mechanize the planning process. I was asked to find a way to more rapidly compute a time-staged development, training and logistical supply program. In those days *mechanizing* planning meant using analog devices or punch-card equipment. There were no electronic computers’.

This challenge problem made Dantzig discover his great work in linear programming without electronic

computer. But, we have to point out that it is due to the rapid development of computer technology that applications of linear programming can be made so wide and so great, and areas of optimization can have so fast growing.

In 1951, A.W. Tucker and his student H.W. Kuhn published the Kuhn–Tucker conditions. This is considered as an initial point of nonlinear programming. However, A. Takayama has an interesting comment on these conditions: ‘Linear programming aroused interest in constraints in the form of inequalities and in the theory of linear inequalities and convex sets. The Kuhn–Tucker study appeared in the middle of this interest with a full recognition of such developments. However, the theory of nonlinear programming when constraints are all in the form of equalities has been known for a long time – in fact, since Euler and Lagrange. The inequality constraints were treated in a fairly satisfactory manner already in 1939 by Karush. Karush’s work is apparently under the influence of a similar work in the calculus of variations by Valentine. Unfortunately, Karush’s work has been largely ignored’. Yet, this is another work that appeared before 1947 and it was ignored. In the 1960s, G. Zoutendijk, J.B. Rosen, P. Wolfe, M.J.D. Powell, and others published a number of algorithms for solving nonlinear optimization problems. These algorithms form the basis of contemporary nonlinear programming.

In 1954, L.R. Ford and D.R. Fulkerson initiated the study on network flows. This is considered as a starting point on *combinatorial optimization* although Fermat is the first one who studied a major combinatorial optimization problem. In fact, it was because of the influence of the results of Ford and Fulkerson, that interests on combinatorial optimization were growing, and so many problems, including Steiner trees, were proposed or re-discovered in history. In 1958, R.E. Gomory published the cutting plane method. This is considered as an initiation of *integer programming*, an important direction of combinatorial optimization.

In 1955, Dantzig published his paper [3] and E.M.L. Beale proposed an algorithm to solve similar problems. They started the study on *stochastic programming*. R.J.B. Wets in the 1960s, and J.R. Birge and A. Prékopa in the 1980s made important contributions in this branch of optimization.

Now, optimization has merged into almost every corner of economics. New branches of optimization appeared in almost every decade, *global optimization*, *nondifferential optimization*, *geometric programming*, *large scale optimization*, etc. No one in his/her whole life is able to study all branches in optimization. Each researcher can only be an expert in a few branches of optimization.

Of course, the rapid development of optimization is accomplished with recognition of its achievements. One important fact is that several researchers in optimization have received the Nobel Prize in economics, including Kantorovich and T.C. Koopmans. They received the Nobel Prize on economics in 1975 for their contributions to the theory of optimum allocation of resources. H.M. Markowitz received the Nobel Prize on economics in 1990 for his contribution on the quadratic programming model of financial analysis.

Today, optimization has become a very large and important interdisciplinary area between mathematics, computer science, industrial engineering, and management science. The 'International Symposium on Mathematical Programming' is one of major conferences on optimization. From the growing number of papers presented in this conference we may see the projection of growing optimization area:

1949) Chicago, USA, 34 papers;  
 1951) Washington DC, USA, 19 papers;  
 1955) Washington DC, USA, 33 papers;  
 1959) Santa Monica, USA, 57 papers;  
 1962) Chicago, USA, 43 papers;  
 1964) London, UK, 83 papers;  
 1967) Princeton, USA, 91 papers;  
 1970) The Hague, The Netherlands, 137 papers;  
 1973) Stanford, USA, about 250 papers;  
 1976) Budapest, Hungary, 327 papers;  
 1979) Montreal, Canada, 458 papers;  
 1982) Bonn, FRG, 554 papers;  
 1985) Cambridge, USA, 589 papers;  
 1988) Tokyo, Japan, 624 papers.  
 (This data is quoted from [1].)

With the current fast growth of computer technology optimization it is expected to continue its great speed of developments. These developments may contain include a deep understanding of the successful heuristics for combinatorial optimization problems with nonlin-

ear programming approaches. It may also include digital simulations to some natural optimization process. As many mysteries and open problems still exist in optimization, it will still be an area receiving a great attention.

**Keywords**

Optimization; Linear programming; Interior point methods; Homogeneous; Selfdual

The linear program

$$\begin{cases} \min & c^\top x \\ \text{s.t.} & Ax = b, \\ & x \geq 0 \end{cases} \quad (1)$$

may have an optimal solution, be primal infeasible or be dual infeasible for a particular set of data  $c \in \mathbf{R}^n$ ,  $b \in \mathbf{R}^m$ , and  $A \in \mathbf{R}^{m \times n}$ . In fact the problem can be both primal and dual infeasible for some data where (1) is denoted dual infeasible if the dual problem

$$\begin{cases} \max & b^\top y \\ \text{s.t.} & A^\top y + s = c, \\ & s \geq 0 \end{cases} \quad (2)$$

corresponding to (1) is infeasible. The vector  $s$  is the so-called *dual slacks*.

However, most methods for solving (1) assume that the problem has an optimal solution. This is in particular true for interior point methods. To overcome this problem it has been suggested to solve the *homogeneous and selfdual model*

$$\begin{cases} \min & 0 \\ \text{s.t.} & Ax - b\tau = 0, \\ & -A^\top y + c\tau \geq 0, \\ & b^\top y - c^\top x \geq 0, \\ & x \geq 0, \quad \tau \geq 0, \end{cases} \quad (3)$$

instead of (1). Clearly, (3) is a homogeneous LP and is selfdual which essentially follows from the constraints form a skew-symmetric system. The interpretation of (3) is  $\tau$  is a homogenizing variable and the constraints represent primal feasibility, dual feasibility, and reversed weak duality.

The homogeneous model (3) was first studied by A.J. Goldman and A.W. Tucker [2] in 1956 and they proved that (3) always has a nontrivial solution  $(x^*, y^*$ ,

$\tau^*)$  satisfying

$$\begin{cases} x_j^* s_j^* = 0, & \forall j \\ x_j^* + s_j^* > 0, & \forall j, \\ \tau^* \kappa^* = 0, \\ \tau^* + \kappa^* > 0, \end{cases} \quad (4)$$

where  $s^* := c\tau^* - A^\top y^* \geq 0$  and  $\kappa^* := b^\top y^* - c^\top x^* \geq 0$ . A solution to (3) satisfying the condition (4) is said to be a *strictly complementary solution*. Moreover, Goldman and Tucker showed that if  $(x^*, \tau^*, y^*, s^*, \kappa^*)$  is any strictly complementary solution, then exactly one of the two following situations occurs:

- $\tau^* > 0$  if and only if (1) has an optimal solution. In this case  $(x^*, y^*, s^*)/\tau^*$  is an optimal primal-dual solution to (1).
- $\kappa^* > 0$  if and only if (1) is primal or dual infeasible. In the case  $b^\top y^* > 0$  ( $c^\top x^* < 0$ ) then (1) is primal (dual) infeasible.

The conclusion is that a strictly complementary solution to (3) provides all the information required, because in the case  $\tau^* > 0$  then an optimal primal-dual solution to (1) is trivially given by  $(x, y, s) = (x^*, y^*, s^*)/\tau^*$ . Otherwise, the problem is primal or dual infeasible. Therefore, the main algorithmic idea is to compute a strictly complementary solution to (3) instead of solving (1) directly.

Y. Ye, M.J. Todd, and S. Mizuno [6] suggested to solve (3) by solving the problem

$$\begin{cases} \min & n^0 z \\ \text{s.t.} & Ax - b\tau - \bar{b}z = 0, \\ & -A^\top y + c\tau + \bar{c}z \geq 0, \\ & b^\top y - c^\top x + \bar{d}z \geq 0, \\ & \bar{b}^\top y - \bar{c}^\top x - \bar{d}\tau = -n^0, \\ & x \geq 0, \quad \tau \geq 0, \end{cases} \quad (5)$$

where

$$\begin{aligned} \bar{b} &:= Ax^0 - b\tau^0, \\ \bar{c} &:= -c\tau^0 + A^\top y^0 + s^0, \\ \bar{d} &:= c^\top x^0 - b^\top y^0 + \kappa^0, \\ n^0 &:= (x^0)^\top s^0 + \tau^0 \kappa^0, \end{aligned}$$

and

$$(x^0, \tau^0, y^0, s^0, \kappa^0) = (e, 1, 0, 1)$$

( $e$  is an  $n$  vector of all ones). It can be proved that the problem (5) always has an optimal solution. Moreover, the optimal value is identical to zero and it is easy to verify that if  $(x, \tau, y, z)$  is an optimal strictly complementary solution to (5), then  $(x, \tau, y)$  is a strictly complementary solution to (3). Hence, the problem (5) can be solved using any method that generates an optimal strictly complementary solution because the problem always has a solution. Note by construction then  $(x, \tau, y, z) = (x^0, \tau^0, y^0, 1)$  is an interior feasible solution to (5). This implies that the problem (1) can be solved by most feasible-interior point algorithms.

X. Xu, P.-F. Hung, and Ye [4] suggest an alternative solution method which is also an interior point algorithm, but specially adapted to the problem (3). The so-called *homogeneous algorithm* can be stated as follows:

- 1) Choose  $(x^0, \tau^0, y^0, s^0, \kappa^0) > 0$ .
0. Choose  $\varepsilon_f, \varepsilon_g > 0$  and  $\gamma \in (0, 1)$  and let  $\eta := 1 - \gamma$ .
- 2)  $k := 0$ .
- 3) Compute:

$$\begin{aligned} r_p^k &:= b\tau^k - Ax^k, \\ r_d^k &:= c\tau^k - A^T y^k - s^k, \\ r_g^k &:= \kappa^k + c^T x^k - b^T y^k, \\ \mu^k &:= \frac{(x^k)^T s^k + \tau^k \kappa^k}{n + 1}. \end{aligned}$$

- 4) If  $\|(r_p^k; r_d^k; r_g^k)\| \leq \varepsilon_f$  and  $\mu^k \leq \varepsilon_g$ , then terminate.
- 5) Solve the linear equations

$$\begin{aligned} Ad_x - bd_\tau &= \eta r_p^k, \\ A^T d_y + d_s - cd_\tau &= \eta r_d^k, \\ -c^T d_x + b^T d_y - d_\kappa &= \eta r_g^k, \\ S^k d_x + X^k d_s &= -X^k s^k + \gamma \mu^k e, \\ \kappa^k d_\tau + \tau^k d_\kappa &= -\tau^k \kappa^k + \gamma \mu^k, \end{aligned}$$

for  $(d_x, d_\tau, d_y, d_s, d_\kappa)$  where  $X^k := \text{diag}(x^k)$  and  $S^k := \text{diag}(s^k)$ .

- 6) For some  $\theta \in (0, 1)$ , let  $\alpha^k$  be the optimal objective value to

$$\begin{cases} \max & \theta \alpha \\ \text{s.t.} & \begin{pmatrix} x^k \\ \tau^k \\ s^k \\ \kappa^k \end{pmatrix} + \alpha \begin{pmatrix} d_x \\ d_\tau \\ d_s \\ d_\kappa \end{pmatrix} \geq 0, \\ & \alpha \leq \theta^{-1}. \end{cases}$$

7)

$$\begin{pmatrix} x^{k+1} \\ \tau^{k+1} \\ y^{k+1} \\ s^{k+1} \\ \kappa^{k+1} \end{pmatrix} := \begin{pmatrix} x^k \\ \tau^k \\ y^k \\ s^k \\ \kappa^k \end{pmatrix} + \alpha^k \begin{pmatrix} d_x \\ d_\tau \\ d_y \\ d_s \\ d_\kappa \end{pmatrix}$$

8)  $k = k + 1$ .

9) goto 3)

The following facts can be proved about the algorithm

$$\begin{cases} r_p^{k+1} = (1 - (1 - \gamma)\alpha^k)r_p^k, \\ r_d^{k+1} = (1 - (1 - \gamma)\alpha^k)r_d^k, \\ r_g^{k+1} = (1 - (1 - \gamma)\alpha^k)r_g^k, \end{cases}$$

and

$$\begin{aligned} & ((x^{k+1})^T s^{k+1} + \tau^{k+1} \kappa^{k+1}) \\ &= (1 - (1 - \gamma)\alpha^k)((x^k)^T s^k + \tau^k \kappa^k), \end{aligned}$$

which shows that the primal residuals ( $r_p$ ), the dual residuals ( $r_d$ ), the gap residual ( $r_g$ ), and the complementary gap ( $x^T s + \tau \kappa$ ) all are reduced strictly if  $\alpha^k > 0$  and at the same rate. This shows that  $(x^k, \tau^k, y^k, s^k, \kappa^k)$  generated by the algorithm converges towards an optimal solution to (3) (and the termination criteria in step 4) is ultimately reached). In principle the initial point and the stepsize  $\alpha^k$  should be chosen such that

$$\min_j (x_j^k s_j^k, \tau^k \kappa^k) \geq \beta \mu^k, \quad \text{for } k = 0, 1, \dots,$$

is satisfied for some  $\beta \in (0, 1)$  because this guarantees  $(x^k, \tau^k, y^k, s^k, \kappa^k)$  converges towards a strictly complementary solution. Finally, it is possible to prove that the algorithm has the complexity  $O(n^{3.5}L)$  given an appropriate choice of the starting point and the algorithmic parameters.

Further details about the homogeneous algorithm can be seen in [3,5]. Issues related to implementing the homogeneous algorithm are discussed in [1,4].

## Keywords

Hyperplane arrangement; Geometric semilattice; Orlik–Solomon algebra; Divisor; Singularity; Complement; Homotopy type; Poincaré polynomial; Ball quotient; Logarithmic form; Hypergeometric integral

Let  $V$  be an  $\ell$ -dimensional affine space over the field  $\mathbf{K}$ . An *arrangement of hyperplanes*,  $\mathcal{A}$ , is a finite collection of codimension one affine subspaces in  $V$ , [5].

## Some Examples

- 1) A subset of the coordinate hyperplanes is called a *Boolean arrangement*.
- 2) An arrangement is in *general position* if at each point it is locally Boolean.
- 3) The *braid arrangement* consists of the hyperplanes  $\{x_i = x_j; 1 \leq i < j \leq \ell\}$ . It is the set of reflecting hyperplanes of the symmetric group on  $\ell$  letters.
- 4) The reflecting hyperplanes of a finite reflection group is a *reflection arrangement*.

## Combinatorics

An edge  $X$  of  $\mathcal{A}$  is a nonempty intersection of elements of  $\mathcal{A}$ . Let  $L(\mathcal{A})$  be the set of edges partially ordered by reverse inclusion. Then  $L$  is a *geometric semilattice* with minimal element  $V$ , rank given by codimension, and maximal elements of the same rank,  $r(\mathcal{A})$ . The *Möbius function* on  $L$  is defined by  $\mu(V) = 1$  and for  $X > V$ ,  $\sum_{V \leq Y \leq X} \mu(Y) = 0$ . The *characteristic polynomial* of  $\mathcal{A}$  is  $\chi(\mathcal{A}, t) = \sum_{X \in L} \mu(X) t^{\dim X}$ . The  $\beta$ -invariant of  $\mathcal{A}$  is  $\beta(\mathcal{A}) = (-1)^{r(\mathcal{A})} \chi(\mathcal{A}, 1)$ . For a generic arrangement of  $n$  hyperplanes  $\chi(\mathcal{A}, t) = \sum_{k=0}^{r(\mathcal{A})} (-1)^k \binom{n}{k} t^{\ell-k}$ . For the braid arrangement  $\chi(\mathcal{A}, t) = t(t-1)(t-2) \cdots (t-(\ell-1))$ . Similar factorizations hold for all reflection arrangements involving the (co)exponents of the reflection group. Given a  $p$ -tuple of hyperplanes,  $S = (H_1, \dots, H_p)$ , let  $\cap S = H_1 \cap \cdots \cap H_p$  and note that  $\cap S$  may be empty. We say that  $S$  is *dependent* if  $\cap S \neq \emptyset$  and  $\text{codim}(\cap S) < |S|$ . Let  $E(\mathcal{A})$  be the exterior algebra on symbols  $(H)$  for  $H \in \mathcal{A}$  where product is juxtaposition. Define  $\partial: E \rightarrow E$  by  $\partial 1 = 0$ ,  $\partial(H) = 1$  and for  $p \geq 2$ ,  $\partial(H_1 \cdots H_p) = \sum_{k=1}^p (-1)^{k-1} (H_1 \cdots \widehat{H}_k \cdots H_p)$ . Let  $I(\mathcal{A})$  be the ideal of  $E(\mathcal{A})$  generated by  $\{S: \cap S = \emptyset\} \cup \{\partial S: S \text{ is dependent}\}$ . The *Orlik–Solomon algebra* of  $\mathcal{A}$  is

$A(\mathcal{A}) = E(\mathcal{A})/I(\mathcal{A})$ . See also connections with *matroid theory* [3].

### Divisor

The *divisor* of  $\mathcal{A}$  is the union of the hyperplanes,  $N(\mathcal{A})$ . If  $\mathbf{K} = \mathbf{R}$  or  $\mathbf{K} = \mathbf{C}$ , then  $N$  has the *homotopy type* of a wedge of  $\beta(\mathcal{A})$  spheres of dimension  $r(\mathcal{A}) - 1$ , [4]. The *singularities* of  $N$  are not isolated. The divisor of a general position arrangement has normal crossings, but this is not true for arbitrary  $\mathcal{A}$ . Blowing up  $N$  along all edges where it is not locally a product of arrangements yields a normal crossing divisor.

### Complement

The *complement* of  $\mathcal{A}$  is  $M(\mathcal{A}) = V - N(\mathcal{A})$ .

- 1) If  $\mathbf{K} = \mathbf{F}_q$ , then  $M$  is a finite set of cardinality  $|M| = \chi(\mathcal{A}, q)$ .
- 2) If  $\mathbf{K} = \mathbf{R}$ , then  $M$  is a disjoint union of open convex sets (*chambers*) of cardinality  $(-1)^\ell \chi(\mathcal{A}, -1)$ . If  $r(\mathcal{A}) = \ell$ ,  $M$  contains  $\beta(\mathcal{A})$  chambers with compact closure, [7].
- 3) If  $\mathbf{K} = \mathbf{C}$ , then  $M$  is an open complex (Stein) *manifold* of the homotopy type of a finite CW complex.

Its *cohomology* is torsion-free and its *Poincaré polynomial* is  $\text{Poin}(M, t) = (-t)^\ell \chi(\mathcal{A}, -t^{-1})$ . The product structure is determined by the isomorphism of graded algebras  $H^*(M) \simeq A(\mathcal{A})$ . The *fundamental group* of  $M$  has an effective presentation but the *higher homotopy groups* of  $M$  are not known in general. The complement of a Boolean arrangement is a complex torus. In a general position arrangement of  $n > \ell$  hyperplanes  $M$  has nontrivial higher homotopy groups. For the braid arrangement,  $M$  is called the pure braid space and its higher homotopy groups are trivial. The symmetric group acts freely on  $M$  with orbit space the braid space whose fundamental group is the *braid group*. The quotient of the divisor by the symmetric group is called the *discriminant*, which has connections with singularity theory.

### Ball Quotients

Examples of algebraic surfaces whose *universal cover* is the complex ball were constructed as ‘Kummer’ covers of the projective plane branched along certain arrangements of projective lines, [2].

### Logarithmic Forms

For  $H \in \mathcal{A}$  choose a linear polynomial  $\alpha_H$  with  $H = \ker \alpha_H$  and let  $Q(\mathcal{A}) = \prod_{H \in \mathcal{A}} \alpha_H$ . Let  $\Omega^p[V]$  denote all global regular (i. e., polynomial)  $p$ -forms on  $V$ . Let  $\Omega^p(V)$  denote the space of all global rational  $p$ -forms on  $V$ . The space  $\Omega^p(\mathcal{A})$  of logarithmic  $p$ -forms with poles along  $\mathcal{A}$  is

$$\Omega^p(\mathcal{A}) = \{\omega \in \Omega^p(V) : Q\omega \in \Omega^p[V], \\ Q(d\omega) \in \Omega^{p+1}[V]\}.$$

The arrangement is free if  $\Omega^1(\mathcal{A})$  is a free module over the polynomial ring. A *free arrangement*  $\mathcal{A}$  has integer exponents  $\{b_1, \dots, b_\ell\}$  so that  $\chi(\mathcal{A}, t) = \prod_{k=1}^\ell (t - b_k)$ . Reflection arrangements are free. This explains the factorization of their characteristic polynomials.

### Hypergeometric Integrals

Certain rank one *local system cohomology* groups of  $M$  may be identified with spaces of *hypergeometric integrals*, [1]. If the local system is suitably generic, these cohomology groups may be computed using the algebra  $A(\mathcal{A})$ . Only the top cohomology group is nonzero and it has dimension  $\beta(\mathcal{A})$ . See [6] for connections with the representation theory of *Lie algebras* and *quantum groups*, and with the *Knizhnik–Zamolodchikov differential equations* of physics.

### Keywords

Hyperplane arrangement; Polynomial time algorithm

A finite set  $S$  of hyperplanes in  $\mathbf{R}^d$  defines a dissection of  $\mathbf{R}^d$  into connected sets of various dimensions. We call this dissection the *arrangement*  $A(S)$  of  $S$ .

Given a vector  $\eta = (\eta_1, \dots, \eta_d) \in \mathbf{R}^d - \{0\}$  and a number  $\eta_0 \in \mathbf{R}$ , we may define a hyperplane  $H$  and associated halfspaces  $H^-, H^+$  by

$$\begin{aligned} H &= \{x \in \mathbf{R}^d : \eta \cdot x = \eta_0\}, \\ H^- &= \{x \in \mathbf{R}^d : \eta \cdot x < \eta_0\}, \\ H^+ &= \{x \in \mathbf{R}^d : \eta \cdot x > \eta_0\}. \end{aligned}$$

Clearly,  $H, H^-, H^+$  are disjoint and  $H \cup H^- \cup H^+ = \mathbf{R}^d$ .

We may now specify the location of a point relative to the set of hyperplanes  $S = \{H_1, \dots, H_n\}$ . For a point  $p$  and  $1 \leq j \leq n$ , define

$$s_j(p) = \begin{cases} -1 & \text{if } p \in H_j^-, \\ 0 & \text{if } p \in H_j, \\ +1 & \text{if } p \in H_j^+. \end{cases}$$

The vector  $s(p) = (s_1(p), \dots, s_n(p))$  is called the *position vector* of  $p$ .

Clearly there are at most  $3^n$  possible position vectors, however, in general most of these will not occur. We say that points  $p$  and  $q$  lie on the same face if  $s(p) = s(q)$ . The nonempty set of points with position vector  $r$  is called the *face*  $f(r)$ :

$$f(r) = \{p \in \mathbf{R}^d : s(p) = r\}$$

The nonempty sets of this form are called the *faces of the arrangement*  $A(S)$ . The position vector of a face  $f(r) = g$  is defined to be  $r$ ,

$$s(f(r)) = r.$$

A face  $f$  is called a  $k$ -face if its dimension is  $k$ . Special names are used to denote  $k$ -faces for special values of  $k$ : a 0-face is called a *vertex*, a 1-face is called an *edge*, a  $(d-1)$ -face is called a *facet*, and a  $d$ -face is called a *cell*. A face is said to be a *subface* of another face  $g$  if the dimension of  $f$  is one less than the dimension of  $g$  and  $f$  is contained in the boundary of  $g$ ; it follows that  $s_i(f) = 0$  unless  $s_i(f) = s_i(g)$  for  $1 \leq i \leq n$ . If  $f$  is a subface of  $g$ , then we also say that  $f$  and  $g$  are *incident* (upon each other) or that they define an *incidence*.

An arrangement  $A(S)$  of  $n \geq d$  hyperplanes is called *simple* if any  $d$  hyperplanes of  $S$  have a unique point in common and if any  $d + 1$  hyperplanes have no point in common. If  $n < d$ , we say that  $A(S)$  is simple if the common intersection of the  $n$  hyperplanes is a  $(d-n)$ -flat. For more details see [3,4] and [5].

As an application of hyperplane arrangements in algorithm design for optimization problems, see [1]. In it the problem of minimizing the Euclidean distance function on  $\mathbf{R}^n$  subject to  $m$  equality constraints and upper and lower bounds (box constraints) is considered. A parametric characterization in  $\mathbf{R}^m$  of the family of solutions to this problem is provided, thereby showing equivalence with a problem of search in an arrangement of hyperplanes in  $\mathbf{R}^m$ . This characterization and the technique for constructing arrangements due to H. Edelsbrunner, J. O'Rourke and R. Seidel are used to develop an exact algorithm for the problem. The algo-

rithm is strongly polynomial running in time  $\Theta(n^m)$  for each fixed  $m$ .

### Introduction

Kinetic phenomena drive the macroscopic behavior of biological, chemical, and physical systems. The lack of mechanistic understanding of these kinetic phenomena is still the major bottleneck for a more widespread application of model-based techniques in process design, optimization, and control. In recent years, kinetic phenomena have become of increasing importance given the rapidly developing capabilities for the numerical treatment of more complex models on the one hand and the need for predictive models on the other.

Despite this demand, kinetic modeling of process systems is still a challenge. This contribution presents systematic work processes to derive and validate models that capture the underlying physicochemical mechanisms of an observed behavior. The work process of *model-based experimental analysis* (or MEXA for short)

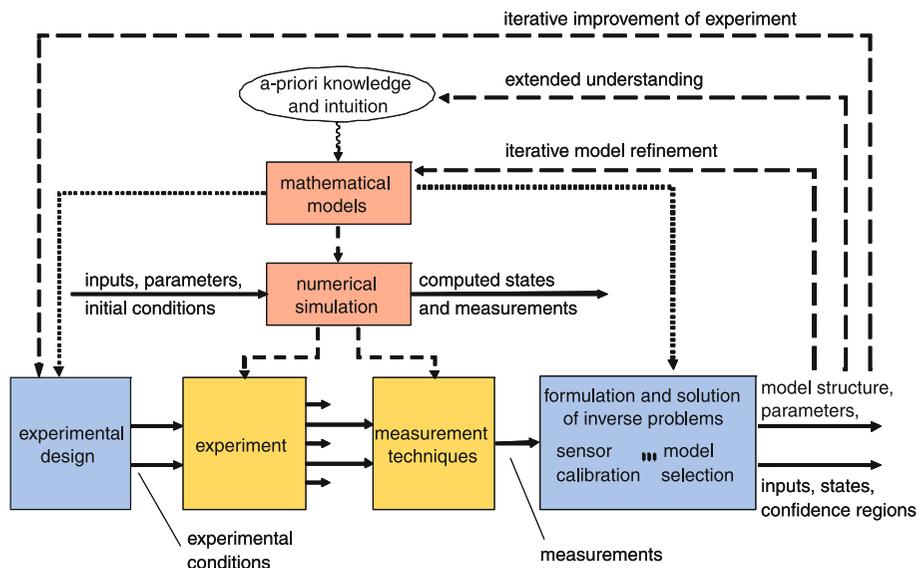

is introduced in the next section. The key factor in the procedure is an *incremental strategy for model structure refinement* tailored for the identification of reaction kinetics and transport phenomena [30]. While identification of kinetic models from experimental data can, in principle, be performed by application of standard statistical tools of nonlinear regression [2] and model discrimination [39], this direct approach in general leads to a large number of NLP or even MINLP problems being solved [16,21,34,37] that may be computationally prohibitive and in particular does not reflect the underlying physics. In contrast, the incremental identification approach discussed here presents a physically motivated and adapted divide-and-conquer strategy to the complex optimization problem of kinetic model identification. Applications of this approach in the areas of (bio)chemical reactions [6,12,13,15,32], multi-component diffusion [3,5], and heat transfer in fluid flow [22,25] are discussed.

### Methods and Applications

#### Model-Based Experimental Analysis

The typical work flow of the MEXA procedure is as follows (Fig. 1):

1. An initial *experiment* with a suitable measurement system is designed on the basis of a priori knowledge and intuition.
2. A first *mathematical model* of experiment and measurement system is proposed.
3. *Numerical simulation* studies are performed to explore the expected behavior of the experiment.
4. The model is then employed for rigorous *experimental design* [41] to gain maximum information with respect to the goal of the investigation.

Identification Methods for Reaction Kinetics and Transport, Figure 1  
Model-based experimental analysis [30]

5. The designed *experiment* is performed and at least some of the variables of interest are observed using appropriate *measurement techniques*.
6. *Formulation and solution of inverse problems* refers to combinations of state, parameter, and unknown input estimation as well as model structure identification and selection.
7. Typically, the first model does not reflect the studied phenomena with sufficient detail and accuracy. Therefore, *iterative model refinement*, intertwined with iterative improvement of the experimental and measurement techniques, must be carried out to improve the predictive capabilities of the model based on the extended understanding gained.

Work processes consisting of the steps design of experiments, data analysis, and modeling date back to at least the 1970s [26]. However, the development and benchmarking of such work processes has only recently been formulated as an important research objective, e. g., by the Collaborative Research Center CRC 540 “Model-based Experimental Analysis in Fluid Multi-Phase Reactive Systems” (<http://www.sfb540.rwth-aachen.de/>) at RWTH Aachen University as well as by Asprey and Macchietto [1]. The power of these work processes depends on the specific strategies employed for systematically improving both the model structure and the experimental setup in every refinement step during model

identification. While experimental design is the focus of the work of Asprey and Macchietto [1], the research in CRC 540 is complementary and emphasizes the strategy for model structure refinement as discussed in what follows.

#### Incremental vs. Simultaneous Model Identification

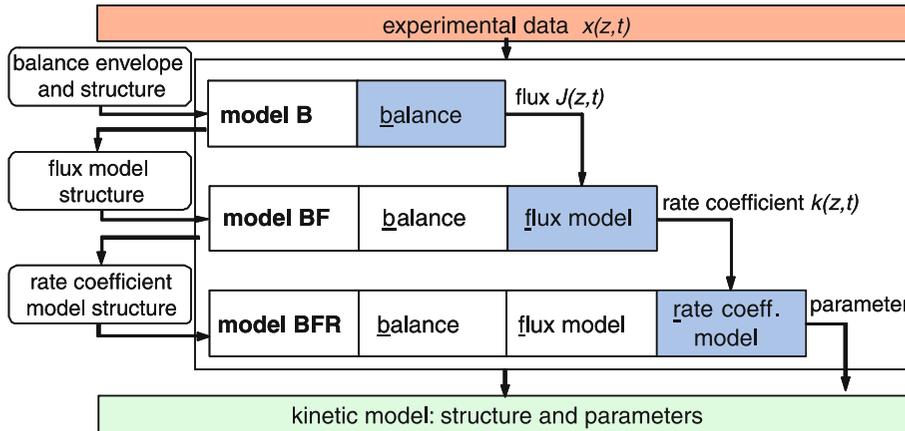

**Incremental Modeling and Identification** The key idea of the incremental approach for model structure refinement is to follow the incremental steps of systematic *model development* [29] also in *model identification* (Fig. 2).

Therefore, the main steps of model development and their connection to incremental identification are outlined next.

**Model B** In model development, balance envelopes and their interactions are determined first, the spatiotemporal resolution of the model is decided, and the extensive quantities  $x$  to be balanced are selected. The balance equation is formulated as a sum of generalized fluxes, e. g.,

$$\frac{\partial x}{\partial t} = -\nabla \cdot J_f + J_s, \quad (1)$$

$$\frac{dx}{dt} = A(x) + B(x)w. \quad (2)$$

Identification Methods for Reaction Kinetics and Transport, Figure 2  
Incremental modeling and identification [30]

Equation (1) exemplifies a balance for a distributed quantity  $x$  flowing with the flux  $J_f$  and being generated/consumed according to the source/sink term  $J_s$ . Note that further generalized fluxes may arise through initial or boundary conditions. A lumped quantity is balanced in Eq. (2), where  $A, B$  are matrix functions of appropriate dimensions describing, e. g., inter- and intraphase transport and source/sink terms. Note that no constitutive equations are considered yet to specify the generalized fluxes  $J(\cdot)^1$  (here:  $J_f, J_s, w$ ) as a function of the intensive thermodynamic state variables.

In incremental model identification, the unknown generalized fluxes  $J(\cdot)$  are estimated directly from the balance equation. For this purpose, measurements of the states  $x(\cdot)$  with sufficient resolution in time  $t$  and/or space  $z$  are assumed. The unknown flux  $J(\cdot)$  in the balance equation is then determined as a function of time and space coordinates – without the need for specifying a constitutive equation.

**Model BF** In model development, constitutive equations are specified for each flux term in the balances on the next decision level:

$$J(\cdot) = J(x(\cdot), \nabla x(\cdot), \dots, k(\cdot)). \quad (3)$$

This could be, e. g., correlations for interfacial fluxes or reaction rates.

<sup>1</sup>The  $(\cdot)$ -argument summarizes the spatial and/or respective temporal dependency of the quantity.

Similarly, in incremental model identification on level BF, flux model candidates (3) are selected or generated to relate the flux to rate coefficients, to measured states, and to their derivatives. The flux estimates obtained on level B are now interpreted as inferential measurements. These can then be used, together with the real measurements, to determine a rate coefficient  $k(\cdot)$  as a function of time and space. Often, the flux model can directly be solved for the rate coefficient function  $k(\cdot)$ .

**Model BFR** In model development, the rate coefficients introduced in the correlations on the level BF – such as a reaction rate or heat and mass transfer coefficients – often themselves depend on the states. Consequently, a model relating rate coefficients and states has to be chosen on yet another level BFR

$$k(\cdot) = k(x(\cdot), \nabla x(\cdot), \dots, \theta). \quad (4)$$

This cascaded decision process can continue as long as the submodels considered involve not only constant parameters  $\theta$  but also functions of the states. Mirroring this step in incremental model identification, a model for the rate coefficients is identified. This model (4) is assumed to only depend on the measured states and constant parameters. These parameters  $\theta$  can be computed from the estimated rate coefficients  $k(\cdot)$  and the measured states  $x(\cdot)$  by solving an algebraic regression problem.

Such a structured approach during model identification renders the individual decisions in the modeling and identification process completely transparent: the modeler is in full control of the model refinement process.

**Simultaneous Model Identification** In the previous section, it was shown that there exists a natural hierarchy in models of kinetic phenomena. Classic approaches to model identification, however, neglect this inherent structure. These *simultaneous* approaches assume that the model structure is correct and consider only the fully specified model (Fig. 2). Models for the flux expression (*Model BF*) and the phenomenological coefficients (*Model BFR*) have to be specified a priori.

In practical situations, these models are initially uncertain. Now, all assumptions on the process will *simultaneously* influence the results of the model identification procedure. The estimates may be biased if the parameter estimation is based on a model containing structural errors [42]. The theoretically optimal properties of a maximum likelihood approach [2] are therefore lost in the presence of structural model mismatch. Initialization and convergence may be difficult since the whole problem is solved in one step [18]. More importantly, it may be difficult in a simultaneous approach to identify which part of the model introduced the error.

Furthermore, several candidate model structures may exist for each kinetic phenomenon. The aggregation of such submodels with the balance equations will inevitably lead to a multitude of candidate models. Alternatively, general approximation schemes like neural nets can be used, often leading to several hundred unknown parameters. Both approaches may be prohibitive due to computational cost, especially when more complex or even distributed parameter systems are considered.

**Discussion of Identification Approaches** The incremental approach splits the identification procedure into a sequence of inverse problems, thereby reducing uncertainty and computational complexity. It thus has the potential to overcome a number of the disadvantages of the simultaneous approach:

- *Avoid combinatorial complexity:* Rather than postulating large numbers of nested model structures,

a structured, fully transparent process is used in the incremental model refinement strategy. An uncontrolled combinatorial growth of the number of model candidates is avoided.

- *Reduce uncertainty:* In the incremental approach, any decision on the model structure relates to a single physicochemical phenomenon. Submodel selection is guided by the previous estimation step, which provides input–output data inferred from the measurements. Identifiability can also be assessed more easily on the level of the submodel.
- *Computational advantages:* The decomposition inherent in incremental model refinement avoids the solution of many difficult output least-squares problems with (partial-)differential-algebraic constraints and potentially large data sets. Rather, an often *linear* inverse problem must be solved first. All the following problems are nonlinear regression problems with algebraic constraints – regardless of the complexity of the overall model. This decomposition not only facilitates initialization and convergence, but it also allows for incremental testing of model validity at every decision level for the submodels. Largely intractable estimation problems may become computationally feasible.

Still, it should be kept in mind that the incremental and the simultaneous methods were derived for different purposes: the incremental approach is aimed at gross elimination of candidate models and/or systematic derivation of suitable candidate *model structures*, whereas the simultaneous approach gives the best *parameter estimates* once the correct model structure is known [6].

Multistep approaches to model identification have been applied rather intuitively in the past. The sequence of flux estimation and parameter regression is, e. g., commonly employed in reaction kinetics as the so-called differential method [19]. More recently, a two-step approach has been applied for the hybrid modeling of fermentation processes [36,38]. First reaction fluxes are estimated from measured data, then neural networks and fuzzy models are employed to correlate the fluxes with the measurements. Mahoney et al. [28] estimate the crystal growth rate directly from the population balance equations using a method of characteristics approach and indicate the possibility of correlating it with solute concentration next.

Though the incremental refinement approach is rather intuitive, a successful implementation requires tailored ingredients such as

- high-resolution field measurement techniques for state variables,
- algorithms for model-free flux estimation by inversion of the balance equations,
- methodologies for the generation, assessment, and selection of the most suitable model structures, and
- model-based experimental design methods.

A detailed discussion of these areas in relation to incremental model identification can be found in [30]. Various aspects are highlighted in the following case studies. Here, the progress in the development of the incremental model identification approach is reported for challenging kinetic modeling problems of gradually increasing complexity from (bio)chemical reactions to diffusion in liquids and to heat transfer at falling liquid films. In addition, the incremental approach has been successful in the identification of hybrid process models [24].

## Case Studies

**(Bio)chemical Reaction Kinetics** The identification of the mechanism and kinetics of chemical reactions is one of the most relevant and still not yet fully satisfactorily solved tasks in process systems modeling [8]. In biological systems, the situation is often even more severe due to the complexity of living systems. The incremental identification approach has been applied for a variety of reaction systems [6,12,13,15,32]. Here, selected features are discussed to elucidate the general properties of this problem class.

### Model B: Reaction flux estimation in lumped systems

For illustration, we assume a well-mixed and isothermal homogenous reaction system. The balance equation for the mole number  $n_i$  of species  $i$  is then

$$\frac{dn_i}{dt} = f_i^{\text{in}} - f_i^{\text{out}} + f_i^{\text{r}}, \quad i = 1, \dots, n_c, \quad (5)$$

where  $f_i^{\text{in}}$ ,  $f_i^{\text{out}}$  are, respectively, the molar flow rates into and out of the reactor and  $f_i^{\text{r}}$  is the unknown reaction flux of species  $i$ . It is worth noting that the fluxes enter the balance equations linearly and the equations are decoupled for each species.

All reaction fluxes  $f_i^{\text{r}}$  can thus be estimated individually by numerical differentiation of concentration data for each measured species on *level B* from material balances only. Tikhonov-Arsenin filtering [31] or smoothing splines [6] with regularization parameter choice based on the L-curve or generalized cross-validation have been shown to give reliable estimates.

**Model BF: Estimation of reaction rates and stoichiometry** If the reaction stoichiometry is unknown, target factor analysis (TFA) [11] is used to test possible stoichiometries and to determine the number of relevant reactions. The reaction rates  $r(t)$  can then be calculated from the typically nonsquare linear equation system relating reaction fluxes  $f_i^{\text{r}}(t)$  and rates by the stoichiometric matrix  $N$ :

$$f^{\text{r}} = v(t)N^{\text{T}}r(t), \quad (6)$$

with  $v(t)$  denoting the reactor volume.

**Model BFR: Estimation of kinetic coefficients** On the next level, concentrations are determined either from smoothed measurements using nonparametric methods [40] or unmeasured concentrations are reconstructed from stoichiometry and mass balances [13]. Since a complete set of concentration and rate data is now available, candidate reaction rate laws of the general form

$$r(t) = m(c(t), \theta) \quad (7)$$

can now be discriminated by nonlinear algebraic regression [42].

Model identification may not immediately result in reliable model structures and parameters because of a lack of information content in the data. Iterative improvement with optimally chosen experimental conditions as suggested in the MEXA work process can then be employed [13].

The incremental identification method has been worked out for arbitrary reaction schemes with reversible or irreversible as well as dependent or independent reactions. The minimum type of concentration measurements required to guarantee identifiability has been assessed theoretically.

The incremental identification strategy has been used in a benchmark study considering a homogeneous reaction system [13]. Computational effort for model

identification could be reduced by almost two orders of magnitude using the structured search in the incremental method. The inclusion of data-driven model substructures in hybrid models is straightforward, as already exemplified for neural networks [15] and sparse grids [14]. The basic framework can easily be extended to nonisothermal systems, and even multiphase transport has been considered [12,23]. An application study to a biochemical reaction system is presented in [32].

**Multicomponent Diffusion** While phase equilibrium models are available even for complex multicomponent mixtures [17], there is a lack of experimentally validated diffusion models in particular for multicomponent liquid mixtures [9]. The incremental identification of diffusive mass transport models is therefore outlined in this section. The application is based on the recently introduced Raman diffusion experiment [4,7]. Here, one-dimensional interdiffusion of two initially layered liquid mixtures is observed by 1D-Raman spectroscopy. Concentration profiles  $c_i$  of all species are obtained with high resolution in time and space [20].

**Model B:** *Estimation of 1D-diffusion fluxes* For the 1D-diffusion process, the mass balance equation for each species  $i$  can be given as

$$\frac{\partial c_i}{\partial t} = -\frac{\partial J_i}{\partial z}, \quad i = 1, \dots, n_c - 1. \quad (8)$$

The determination of the diffusive flux  $J_i$  falls into the class of interior flux estimation in distributed parameter systems [30]. While interior fluxes cannot be determined in 2D or 3D situations without specification of a constitutive model, the model-free flux estimation is possible in the one-dimensional situation considered here. Only one nonzero mass flux component has to be determined from differentiated concentrations measured along a line in the direction of the diffusive flux. Such a strategy has been followed in [3,5].

The Raman concentration measurements were first differentiated with respect to time by means of spline smoothing [33] and subsequently integrated over the spatial coordinate to render a diffusive flux estimate without specifying a diffusion model:

$$J_i(z, t) = -\int_0^z \frac{\partial c_i(\xi, t)}{\partial t} d\xi. \quad (9)$$

This technique directly carries over to multicomponent diffusion [5] provided concentration measurements are available for every species. In particular, there is only a linear increase in complexity due to the natural decoupling of the multicomponent material balances (8).

**Model BF:** *Estimation of diffusion flux models* A flux model has to be introduced on the next level. For example, generalized Fick or Maxwell–Stefan models could be selected as candidates. In case of binary mixtures, the Fick diffusion coefficient can, e. g., be determined at any point in time and space:

$$D(z, t) = -\frac{J(z, t)}{\partial c(z, t)/\partial z}. \quad (10)$$

Positivity requirements may now be used, e. g., to assess model assumptions on this level.

**Model BFR:** *Estimation of model parameters* The estimated diffusion coefficient data can now be correlated with the measured concentrations to obtain a diffusion model:

$$D(z, t) = m(c(z, t), \theta). \quad (11)$$

Error-in-variables methods [10] and statistical model discrimination techniques [35] are employed to decide on the most appropriate model for the concentration dependence of the diffusion coefficient. This concentration dependency has been shown to be even identifiable from a single Raman diffusion experiment [3]. An application in food science has recently been presented in [27].

In case of multicomponent diffusion, the last two levels have to be merged because all species concentration gradients are determined by the diffusive flux of any species due to the cross effects of multicomponent diffusion [3,5]. The merged steps BF and BFR then allow for efficient initialization of these complex estimation problems.

**Heat Transfer at Falling Films** Liquid falling films are a challenging benchmark problem for general fluid multiphase reaction systems as they show all the relevant features of this problem class. Here, the first steps in the application of the incremental approach to heat transfer in falling films are considered [22,25].

**Model B:** *Boundary flux estimation in distributed systems* In order to study its heat transfer character-

istics, a laminar-wavy falling film is heated by resistance heating using a supporting wall as heater. Infrared thermography is employed to measure a transient 2D temperature field on the backside of the wall. An inverse heat conduction problem for the three-dimensional wall has to be solved to determine the boundary heat flux between the wall and the falling film as the first step of the incremental approach:

$$\frac{\partial T}{\partial t} = a\Delta T, \quad (12)$$

$$-\lambda\nabla T|_{\Gamma} = w(z_{\Gamma}, t), \quad (13)$$

$$-\lambda\nabla T|_{\Lambda} = q(z_{\Lambda}, t), \quad (14)$$

with  $\Gamma$  and  $\Lambda$  being the parts of the surface with unknown and with known boundary heat fluxes  $w(z_{\Gamma}, t)$  and  $q(z_{\Lambda}, t)$ , respectively. The boundary flux estimation problem is solved by means of a multigrid finite-element discretization of the heat conduction Eq. (12) in conjunction with the conjugate gradient method. Gradient computation is performed using the adjoint method. This framework allows for the solution of the discretized problem involving about three million variables on a desktop computer [22].

These results show that the identification of kinetic phenomena may become feasible even in complex flow problems using the structured search strategy of the incremental approach. A generalization of the presented problem to work out the full incremental identification concept for heat transfer problems in falling films is currently in progress [25].

Ill-posed variational problem; Well-posedness; Tikhonov regularization; Proximal point methods

It is generally accepted that the notion ‘ill-posed problem’ originates from a considered concept of *well-posedness*: A problem is called ill-posed if it is not well-posed. There are a lot of different notions of well-posedness (cf. [15,23,27,35,38] and [40]), which correspond to certain classes of variational problems and numerical methods and take into account the ‘quality’ of the input data, in particular their exactness. For a comparison of different concepts of well-posedness see [12,15] and [35].

For instance, Tikhonov well-posedness [35,38] is convenient if we deal with methods generating feasible minimizing sequences, and it is not appropriate to analyse stability of exterior penalty methods.

We shall proceed from two concepts of well-posedness which are suitable for wide classes of problems and methods.

The first concept is destined to the problem

$$\min \{J(u) : u \in K\}, \tag{1}$$

where  $K$  is a nonempty closed subset of a Banach space  $V$  with the norm  $\|\cdot\|$  and  $J : V \rightarrow \mathbf{R} \cup \{+\infty\}$  is a proper lower-semicontinuous functional.

**Definition 1** (cf. [27]) The sequence  $\{u^n\} \subset V$  is said to be a *generalized minimizing sequence* (*Levitin–Polyak minimizing sequence*) for (1) if

$$\lim_{n \rightarrow \infty} d(u^n, K) = 0$$

and

$$\lim_{n \rightarrow \infty} J(u^n) = \inf_{u \in K} J(u),$$

with

$$d(u, K) = \inf_{v \in K} \|u - v\|$$

distance function.

**Definition 2** (1) is called *well-posed* (*Levitin–Polyak well-posed*) if

- i) it is uniquely solvable, and
- ii) any generalized minimizing sequence converges to  $u^* = \arg \min\{J(u) : u \in K\}$ .

The second concept (cf. [20,23]) concerns (1) with

$$K = \{u \in U_0 : B(u) \leq 0\}, \tag{2}$$

$U_0 \subset V$  a convex closed set,  $B : U_0 \rightarrow Y$  a convex continuous mapping into a Banach space  $Y$ , and  $J : U_0 \rightarrow \mathbf{R}$  a convex continuous functional. The relation ‘ $\leq$ ’ in (2) and the convexity of  $B$  are defined according to a positive cone in  $Y$ .

In this case, the study of the dependence of a solution on data perturbations is often more natural and simpler than the analysis of the convergence of a generalized minimizing sequence.

We suppose that  $U_0$  is exactly given and a violation of the condition  $u \in U_0$  does not arise. For a fixed  $\delta > 0$ , the set of variations is defined by

$$\Phi_\delta = \left\{ \varphi_\delta \equiv (J_\delta, B_\delta) : \|J - J_\delta\|_{C(U_0)} \leq \delta, \sup_{u \in U_0} \|B(u) - B_\delta(u)\|_Y \leq \delta \right\}, \tag{3}$$

where  $J_\delta : U_0 \rightarrow \mathbf{R}$ ,  $B_\delta : U_0 \rightarrow Y$  are assumed to be continuous. Then, the problem

$$\min \{J_\delta(u) : u \in U_0, B_\delta(u) \leq 0\} \tag{4}$$

corresponds to an arbitrary but fixed variation  $\varphi_\delta \in \Phi_\delta$ . The set of optimal solutions of (4) will be denoted by  $U^*(\varphi_\delta)$ .

**Definition 3** Problem (1), (2) is called *well-posed* if

- i) it is uniquely solvable,
- ii) there exists a constant  $\delta_0 > 0$  such that for any  $\delta \in (0, \delta_0)$  and any  $\varphi_\delta \in \Phi_\delta$  the set  $U^*(\varphi_\delta)$  is nonempty,
- iii)  $\lim_{\delta \rightarrow 0} d(u^*, U^*(\varphi_\delta)) = 0$  for arbitrary  $\varphi_\delta \in \Phi_\delta$ .

Depending on the peculiarities of the problem considered, the ‘quality’ of data as well as the requirements to an approximation, other norms in (3) and additional assumptions w.r.t.  $J_\delta, B_\delta$  can be considered (for instance, convexity of  $J_\delta, B_\delta$ ). For a relaxation of the inequalities in (3) see [39,40].

Of course, the Definitions 2 and 3 are not equivalent, and in the framework of the chosen concept of well-posedness the problem is called *ill-posed* if any condition is violated in the corresponding definition used.

*Example 4* Problem (1), (2) with

$$\begin{aligned} V &= \mathbf{R}^3, \quad Y = \mathbf{R}^3, \\ J(u) &= u_2, \\ U_0 &= \{u \in \mathbf{R}^3 : 0 \leq u_k \leq 2\}, \\ B(u) &= \left( u_1 + u_2 - \frac{1}{2}, u_3 - \frac{1}{2}, -u_1 - u_2 - u_3 + 1 \right)^\top \end{aligned}$$

is well-posed according to Definition 2, but it is ill-posed according to Definition 3. This example reflects, in particular, the situation that an arbitrary small data perturbation may lead to an unsolvable problem.

*Example 5* The unconstrained problem

$$\text{minimize } J(u) = \sum_{k=1}^{\infty} k^{-1} u_k^2 \quad \text{over } V = l_2$$

is ill-posed according to both Definitions 2 and 3. To verify that take

$$u^n = (-1, 0, \dots, 0, \overset{n}{1}, 0 \dots), \quad \delta_n = \frac{1}{n},$$

$$J_{\delta_n} = \sum_{\substack{k=1, \\ k \neq n}}^{\infty} k^{-1} u_k^2 + \max\{n^{-1} u_n^2, n^{-1}\}.$$

If it is supposed that  $V$  is a reflexive Banach space,  $Y = C(T)$  (with  $T$  a compact set), that Problem (1), (2) is uniquely solvable and that Slater’s condition is valid, then the condition

$$\lim_{\delta \rightarrow +0} \sup_{u \in W_\delta} \|u - u^*\| = 0,$$

with

$$W_\delta = \{u \in U_0 : J(u) \leq J(u^*) + \delta, \\ \max_{t \in T} B(u)(t) \leq \delta\}$$

is necessary and sufficient for this problem to be well-posed according to Definition 3 (with convex  $J_\delta, B_\delta$ ) (cf. [20]).

Let us mention also concepts of well-posedness using different notions of hyper- or epiconvergence. As an example, identifying the functions with their epigraphs, in [9] for the class of Problem (1) the closeness of data is measured in the Attouch–Wets metric defined on the data space. Here, Problem (1) is said to be well-posed if it is uniquely solvable and its solution depends continuously (in  $V$ ) on the data perturbation (for details see [35]). These concepts are closely related to the classical idea of Hadamard of the continuous dependence of the solution on the data.

Some notions of well-posedness do not suppose uniqueness of a solution of the problem considered (cf. [35,40]). A corresponding generalization of Definition 2 leads to the following conditions:

- i) the optimal set  $U^*$  is nonempty,
- ii) each generalized minimizing sequence has a subsequence converging to an element of  $U^*$ , or (the weaker condition)
- ii’)  $d(u^n, U^*) \rightarrow 0$  for each generalized minimizing sequence  $\{u^n\}$ .

If the problem is ill-posed, the following difficulties occur:

- 1) using approximate data one cannot be sure that a solution of the ‘perturbed’ problem is close to the solution (or to the solution set) of the original problem;
- 2) in the majority of the numerical methods it is possible that the calculated minimizing sequence does not converge (in a suitable sense) to a solution of the problem.

It may also happen that standard solution methods break down for such problems.

*Example 6* Problem (1), (2) with

$$V = \mathbf{R}^2, \quad Y = C[0, 1], \quad J(u) = -u_1, \\ U_0 = \{u \in \mathbf{R}^2 : u_2 \geq 0\},$$

and

$$Bu(t) = u_1 - \left(t - \frac{1}{\sqrt{2}}\right)^2 u_2.$$

Obviously, solutions of this linear semi-infinite problem are points  $u^* \in U^* \equiv \{(0, a) : a \geq 0\}$ . Choosing a finite grid  $T'$  on  $[0, 1]$  with

$$t_0 = \arg \min \left\{ \left| t - \frac{1}{\sqrt{2}} \right| : t \in T' \right\}$$

and  $t_0 \neq 1/\sqrt{2}$ , then for the approximate problem (with  $T'$  instead of  $[0, 1]$ ), the ray

$$\left\{ u \in \mathbf{R}^2 : u_1 = \left(t_0 - \frac{1}{\sqrt{2}}\right)^2 u_2, \quad u_2 \geq 0 \right\}$$

is feasible and  $J(u) \rightarrow -\infty$  on this ray if  $\|u\| \rightarrow \infty$ .

This example shows the typical behavior of ill-posed semi-infinite problems: Although the original problem is solvable, the discretized ones may be not solvable, even if dense grids are used. Due to unsolvability of the discretized problems, the direct application of discretization and exchange methods for solving semi-infinite programs is impossible. Moreover, the assumptions required for the application of reduction methods are violated in this example, too. (For the conceptual description of the methods mentioned see [16]).

Nevertheless, it is well-known that some classical methods, applied to ill-posed problems, possess stabilizing qualities: They generate minimizing sequences with better convergence properties than those properties which are guaranteed for an arbitrary minimizing sequence.

For instance, for the ill-posed problem (1), where  $J$  is a convex functional of the class  $C^{1,1}$  and  $K$  is a convex closed subset of a Hilbert space  $V$ , the gradient projection method (with a constant steplength parameter and an inexact calculation of the gradient  $p^k \approx \nabla J(u^k)$  at each step  $k$ ) converges weakly to some element of  $U^*$  if  $U^* \neq \emptyset$  and  $\|p^k - \nabla J(u^k)\| \leq \epsilon_k, \sum_{k=1}^{\infty} \epsilon_k < \infty$  (cf. [33]).

In [20] it is shown that penalty methods applied to a finite-dimensional convex programming problem, for which the conditions ii), iii) in Definition 3 may be violated, converge to the unique solution of this problem if the exactness of the data is improved within the solution process by a special rule, depending on the change of the penalty parameter.

Stable methods for solving convex ill-posed variational problems are mainly based on *Tikhonov's regularization approach* (cf. [29,39,40]) and the *proximal point approach* (cf. [30,37]). Nowadays the direct application of these approaches (when multiple regularization of the original problem is performed and the regularized problems are solved with high accuracy) loses its importance in comparison with techniques using regularization inwards of the basic numerical algorithm which is suitably chosen for solving well-posed problems of the corresponding class of problems.

Let us briefly describe these techniques under the assumption that  $V$  is a Hilbert space. Suppose a certain basic method (for instance, discretization or penalization method) generates the sequence of auxiliary problems

$$J_i(u) \rightarrow \min, \quad u \in K_i \subset V,$$

then in the Tikhonov approach successively the auxiliary problems

$$J_i(u) + \alpha_i \|u - \bar{u}\|^2 \rightarrow \min, \quad u \in K_i, \tag{5}$$

$(\alpha_i > 0, \quad \lim \alpha_i = 0, \quad \bar{u} \in V \text{ a fixed element})$

are solved, whereas the proximal point approach leads to the following sequence of auxiliary problems

$$J_i(u) + \chi_i \|u - u^{i-1}\|^2 \rightarrow \min, \quad u \in K_i, \tag{6}$$

with  $0 < \chi_i < \bar{\chi}, u^{i-1}$  an approximate solution of (6) at the stage  $i := i-1$  and  $u^0 \in V$  an arbitrary starting point.

We refer to (5) and (6) as *Tikhonov's iterative regularization method* and *proximal-like method*, respectively.

Usually, dealing with a convex variational problem, the functions  $J_i$  are convex and the sets  $K_i$  are convex and closed. Therefore, the objective functions in the Problems (5) and (6) are strongly convex, and hence, these problems are uniquely solvable (if  $K_i \neq \emptyset$ ). It should be emphasized that, inasmuch  $\chi_i \rightarrow 0$  is not necessary for the convergence of the proximal-like methods (in particular,  $\chi_i \equiv \chi > 0$  can be chosen), they possess a better stability and provide a better efficiency of fast convergent methods solving the regularized auxiliary problems.

Theoretical foundations for the construction and the convergence analysis of Tikhonov's iterative regularization methods have been developed in [32,40]. We refer to some methods coupling Tikhonov's regularization with gradient projection methods [8], Newton methods [7], augmented Lagrangian [2] and penalty methods [40]. In the latter paper the stability of regularized penalty methods for Problem (1), (2) with  $Y = \mathbf{R}^n$  is proved without assuming convexity of  $J$  and  $B$ . For applications of Tikhonov's regularization in the framework of successive discretization of ill-posed variational problems see [28,40].

Proximal-like methods have been intensively developed during the last two decades. Starting with the papers [3] and [36], where the proximal method of multipliers has been investigated, regularized variants of different penalty methods (cf. [1,5,6,19]), steepest descent method [18], Newton methods [34,41] and quasi-Newton methods [10] have been suggested. In [21] proximal regularization is coupled with penalization and successive discretization for solving ill-posed convex semi-infinite problems, and in [22] a proximal method with successive discretization has been studied for solving elliptic variational inequalities. There is a couple of papers in which proximal regularization is used to obtain new decomposition (splitting) algorithms ([11,14,17]) and new bundle algorithms for non-differentiable optimization problems ([4,10,24,25,31]). In some papers mentioned a nonquadratic proximal regularization is carried out by means of the Bregman function [13].

General schemes for the investigation of proximal-like methods have been developed in [20,26] and [37].

The scheme in [20] includes a generalization of (6), where the proximal iterations are repeated for fixed  $J_i$ ,  $K_i$  until they provide an 'appropriate' decrease of the functional  $J_i$ .

### Keywords

Image space; Separation; Separation functions; Necessary conditions; Sufficient condition; Lagrange multipliers; Lagrange function; Euler equation

The study of the properties of the image of a real-valued function is an old one; recently, it has been extended to multifunctions and to vector-valued functions. However, in most cases the properties of the image have not been the purpose of study and their investigation has occurred as an auxiliary step toward other achievements (see, e. g., [4,16,17]).

Traces of the idea of studying the images of functions involved in a constrained extremum problem go back to the work of C. Carathéodory (in 1935, [3, Chap.5]). In the 1950s R. Bellman [1], with his celebrated maximum principle, proposed – for the first time in the field of optimization – to replace the given

unknown by a new one which runs in the image; however, also here the image is not the main purpose. Only in the late 1960s and 1970s some Authors, independently from each other, have brought explicitly such a study into the field of optimization [2,6,7,10,11].

The approach consists in introducing the space, call it image space (IS), where the images of the functions of the given optimization problem run. Then, a new problem is defined in the IS, which is equivalent to the given one. In a certain sense, such an approach has some analogies with what happens in the measure theory when one goes from Mengoli–Cauchy–Riemann measure to the Lebesgue one.

The approach will now briefly be described. Assume we are given the integers  $m$  and  $p$  with  $m \geq 0$  and  $0 \leq p \leq m$ , the subset  $X$  of a Hilbert space  $H$  whose scalar product is denoted by  $\langle \cdot, \cdot \rangle$ , and the functions  $f: X \rightarrow \mathbf{R}$ ,  $g_i: X \rightarrow \mathbf{R}$ ,  $i = 1, \dots, m$ . Consider the minimization problem:

$$(P) \begin{cases} \min & f(x), \\ \text{s.t.} & g_i(x) = 0, \quad i \in I^0, \\ & g_i(x) \geq 0, \quad i \in I^+, \quad x \in X, \end{cases}$$

where  $I^0 := \{1, \dots, p\}$ ,  $I^+ := \{p+1, \dots, m\}$ , and  $p = 0 \Rightarrow I^0 = \emptyset$ ,  $p = m \Rightarrow I^+ = \emptyset$ ;  $m = 0 \Rightarrow I := I^0 \cup I^+ = \emptyset$ . Here and in the sequel, all the considered extrema and integrals are supposed to exist; the discussion of their existence goes beyond the scope of this paper. Let us set  $g(x) := (g_1(x), \dots, g_m(x))$ ,  $O_p := (0, \dots, 0) \in \mathbf{R}^p$ ,  $C := O_p \times \mathbf{R}_+^{m-p}$  and  $R := \{x \in X: g(x) \in C\}$ , with the stipulation that  $C = \mathbf{R}_+^m$  when  $p = 0$  and  $C = O_m := (0, \dots, 0) \in \mathbf{R}^m$  when  $p = m$ ;  $m = 0$  does not require to define  $C$ .

A particular case of (P), call it  $(P)_{\text{iso}}$ , is a classic isoperimetric type problem defined in the following way. Let  $\mathcal{A}C_n(T)$  denote the class of absolutely continuous  $n$ -vector functions  $x(t) := (x_1(t), \dots, x_n(t))$  on  $T := [a, b] \subset \mathbf{R}$  with square integrable derivatives. By suitably defining the scalar product – and, consequently, the norm – such a class is a Hilbert space; set  $H = \mathcal{A}C_n(T)$  and

$$f(x) = \int_T \psi_0(t, x(t), \dot{x}(t)) dt,$$

$$g_i(x) = \int_T \psi_i(t, x(t), \dot{x}(t)) dt, \quad i \in I,$$

where  $\psi_i \mathbf{R}^{1+2n} \rightarrow \mathbf{R}$ ,  $i \in \{0\} \cup I$ , are given integrands. Fixed endpoints conditions can be included in the definition of  $X$ . We point out that the problems which can be reduced to the format of (P) share the characteristic of having a finite-dimensional image. Hence, certain problems, for instance of geodesic type, are not covered by (P); the image analysis of them is outside the scope of the present writing.

The IS approach arises naturally in as much as an optimality condition for (P) is achieved through the impossibility of a system. More precisely, by paraphrasing the very definition of global minimum we can say that a feasible  $\bar{x} \in X$  is a *global minimum point* for (P) if and only if the system (in the unknown  $x$ ):

$$(S) \begin{cases} \varphi(\bar{x}; x) := f(\bar{x}) - f(x) > 0, \\ g(x) \in C, \end{cases} \quad x \in X,$$

is impossible, or

$$(S') \quad \mathcal{H} \cap \mathcal{K}(\bar{x}) = \emptyset,$$

where  $\mathcal{H} := \{(u, v) \in \mathbf{R} \times \mathbf{R}^m : u > 0, v \in C\}$  and  $\mathcal{K}(\bar{x}) := \{(u, v) \in \mathbf{R} \times \mathbf{R}^m : u = \varphi(\bar{x}; x), v = g(x), x \in X\} = F(X)$ , where  $F := (\varphi, g)$ . It is easy to see that (S') holds if and only if

$$(S'') \quad \mathcal{H} \cap [\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}] = \emptyset,$$

where the difference is in vector sense and  $\text{clos}$  denotes closure.  $\mathcal{K}(\bar{x})$  is called the *image* of (P) and  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}$  its *conic extension*. The replacement of the image with its conic extension – which corresponds to modifying  $f$  and  $g$  – does not affect the optimality conditions and has several advantages. For instance, if  $f$  and  $-g$  are convex (or, more generally,  $(f, -g)$  is convex like [6,20]), then  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}$  is convex even if  $\mathcal{K}(\bar{x})$  is not. Note that a change of  $\bar{x}$  produces merely a translation of  $\mathcal{K}(\bar{x})$  with respect to the  $u$ -axis. Hence, the properties of the image can be studied independently of the choice of  $\bar{x}$ .

The analysis in the IS must be viewed as a preliminary and auxiliary step – and not as a concurrent analysis – for studying (P). If this aspect is understood, then the IS analysis may be highly fruitful. In fact, in the IS we may have a sort of ‘regularization’: The conic extension of the image of (P) may be convex or continuous or smooth when (P) (and its image) do not enjoy the same

property, so that convex or continuous or smooth analysis can be developed in the IS but not in  $H$ . (P) at  $H = \mathbf{R}^n$  and (P)<sub>iso</sub> have their unknowns in a finite and in an infinite-dimensional spaces, respectively; while the images of both problems run in a finite-dimensional space; hence, in the given spaces, namely  $\mathbf{R}^n$  and  $\mathcal{AC}_n(T)$ , they require substantially different mathematical tools, while in the IS they can be treated in the same way.

It is easy to show that (P) is equivalent to the following *image problem*:

$$IP \begin{cases} \max & u \\ \text{s.t.} & (u, v) \in \mathcal{K}(\bar{x}), \quad v \in C. \end{cases}$$

A maximum point, say  $(\hat{u}, \hat{v})$ , of IP is the image – through the pair  $(\varphi, g)$  – of a minimum point, say  $\hat{x}$ , of (P), and we have  $f(\bar{x}) - \hat{u} = f(\hat{x})$ , whatever  $\bar{x} \in X$  may be. If IP is replaced by the other one:

$$IP(\xi) \begin{cases} \max & u \\ \text{s.t.} & (u, v) \in \mathcal{K}(\bar{x}), \\ & v_i = \xi_i, \quad i \in I^0, \\ & v_i \geq \xi_i, \quad i \in I^+, \end{cases}$$

then the maximum, which is now a function of  $\xi := (\xi_1, \dots, \xi_m)$ , gives the so-called *perturbation function* (called also *optimal value function*) of (P), and, with obvious notation, we have  $f(\bar{x}) - \hat{u}(\xi) = f(\hat{x}(\xi))$ .

If in (P) minimization is replaced by maximization, then the entire image space analysis remains unchanged provided  $\varphi$  receives the new definition as  $\varphi(\bar{x}; x) := f(x) - f(\bar{x})$ .

To prove directly whether or not (S') (or (S'') and hence (S)) holds is generally impracticable. An indirect way of showing it consists in proving that  $\mathcal{H}$  and  $\mathcal{K}(\bar{x})$  lie in two disjoint level sets, respectively. This separation approach is exactly equivalent to finding a theorem of the alternative (cf. ► **Theorems of the alternative and optimization** and [6]) related to (S); only the mathematical languages are different. The separation scheme enjoys mainly a geometrical appeal, while in studying alternative the algebraic characters are dominant. In general terms, a separation scheme begins by introducing a family  $W$  of functionals such that the intersection of the positive level sets equals  $\mathcal{H}$ . If a  $w \in W$  is found whose nonpositive level set contains  $\mathcal{K}(\bar{x})$ , then (S) holds and  $\bar{x}$  is a solution of (P).

Let us consider the column vector  $v = (v_1, \dots, v_m)^\top$  and the row vectors  $\lambda = (\lambda_1, \dots, \lambda_m)$ ,  $\mu = (\mu_1, \dots, \mu_m)$ . A particular, but wide, family of type  $W$  is offered by the class of *parabolic-exponential functions*  $w: \mathbf{R}^{1+m} \rightarrow \mathbf{R}$ , defined by

$$W_{pe}: \quad w = w(u, v; \lambda, \mu) := u + \gamma(v; \lambda, \mu),$$

where  $\lambda \in C^* = \mathbf{R}^p \times \mathbf{R}_+^{m-p}$ ,  $\mu \in \mathbf{R}_+^m$ , and

$$\begin{aligned} \gamma(v; \lambda, \mu) \\ := - \sum_{i \in I^0} (\mu_i v_i^2 - \lambda_i v_i) + \sum_{i \in I^+} \lambda_i v_i \exp(-\mu_i v_i), \end{aligned}$$

where  $*$  marks positive polar, and  $\lambda, \mu$  are parameters which describe the family. At  $\mu = 0$ , this family collapses to that of linear functions:

$$W_\ell: \quad \ell = \ell(u, v; \lambda) := u + \langle \lambda, v \rangle, \quad \lambda \in C^*,$$

where  $\langle \cdot, \cdot \rangle$  marks the usual scalar product. It is easy to check that the family  $W_{pe}$  (and hence  $W_\ell$ ) fulfills the above mentioned intersection property (with respect to  $\lambda, \mu$ ). Starting from such a separation scheme, it is possible to develop most of the theory of constrained extrema as will be briefly shown.

The intersection of the positive level sets of the elements of  $W_{pe}$  is not open, since  $\mathcal{H}$  is not open. Therefore, an element of  $\mathcal{H}$  may be a limit point of elements of  $\mathcal{K}(\bar{x})$  or the Bouligand tangent cone to  $\mathcal{K}(\bar{x})$  at  $0_{1+m}$  may intersect  $\mathcal{H}$  even when (S') holds, so that no element of  $W_{pe}$  may exist which shows separation between  $\mathcal{H}$  and  $\mathcal{K}(\bar{x})$ . This drawback can be overcome by enlarging the family  $W_{pe}$ . For instance, in the linear case,  $W_\ell$  is replaced by the family  $\ell(u, v; \theta, \lambda) := \theta u + \lambda v$ ,  $\theta \geq 0$ ,  $\lambda \in C^*$ ,  $(\theta, \lambda) \neq 0$ ; at  $p = 0$ , this is the family considered in **► Theorems of the alternative and optimization**. Of course, such a relaxation does not guarantee any longer (S'), even if  $\mathcal{K}(\bar{x})$  is included in the nonpositive level set of  $\ell$ , since at  $\theta = 0$  the nonpositive level set of  $\ell$  intersects  $\mathcal{H}$ , the intersection containing the positive  $u$  axis. As a consequence, the separation scheme would be useless. A way of remedying this consists in cutting off the set of problems whose images can be included in the nonpositive level set of  $\ell$  at  $\theta = 0$  only. Such an exclusion, which is extended to the (linear) approximations of (P), is done by imposing suitable conditions on  $f$  and  $g$ , which are called *constraint qualifications* if they implicate only  $g$  and are called *regular-*

*ity conditions* if they implicate both  $f$  and  $g$  (cf. **► Theorems of the alternative and optimization**; [12]).

Now, let us show some consequences of the separation scheme. A first result is a sufficient condition. From the very definition of  $w$ , we see that the existence of vectors  $\lambda \in C^*$  and  $\mu \in \mathbf{R}_+^m$ , such that  $\mathcal{K}(\bar{x}) \subseteq \text{lev}_{\leq 0} w(u, v; \lambda, \mu)$  (where  $\text{lev}_{\leq 0}$  denotes nonpositive level set) is sufficient for  $\bar{x}$  to be a solution of (P). Hence, to achieve a sufficient condition in terms of  $X, f$  and  $g$  it is enough to replace, in the above inclusion,  $u$  and  $v$  with their expressions:

**Theorem 1** *Let  $\bar{x} \in \mathbf{R}$ . If there exist  $\bar{\lambda} \in C^*$  and  $\bar{\mu} \in \mathbf{R}_+^m$ , such that*

$$f(\bar{x}) - f(x) + \gamma(g(x); \bar{\lambda}, \bar{\mu}) \leq 0, \quad \forall x \in X, \quad (1)$$

*then  $\bar{x}$  is a global minimum point of (P).*

Let us introduce the function  $\mathcal{L}(x; \lambda, \mu) := f(x) - \gamma(g(x); \lambda, \mu)$ . It is a generalization of the classic *Lagrangian function*, which is found at  $\mu = 0$ . At  $p = m$ ,  $\mathcal{L}$  becomes the so-called *augmented Lagrangian function*. At  $p = m$  and  $\lambda = 0$ ,  $\mathcal{L}$  becomes the classic *Courant penalty function*. (See [5, p.12], where such a function has been introduced under the name 'sensitized'; see also [15].) Obviously, (1) holds if and only if  $f(\bar{x}) \leq \mathcal{L}(x; \bar{\lambda}, \bar{\mu})$ ,  $\forall x \in X$ . Under the equality

$$\gamma(g(\bar{x}); \bar{\lambda}, \bar{\mu}) = 0, \quad (2)$$

we have  $f(\bar{x}) = \mathcal{L}(\bar{x}; \bar{\lambda}, \bar{\mu})$ ; then (1), which is the algebraic form of a separation condition, can be rewritten in a different (but equivalent) form, which corresponds to a saddle-point condition. At  $\mu = 0$ , (2) collapses to the *orthogonal condition*

$$\langle \bar{\lambda}, g(\bar{x}) \rangle = 0, \quad (3)$$

which is classically known as *complementarity condition* [6,12], due to the role it has played in some algorithms. The fundamental condition (2), which subtends the entire theory of constrained extrema, will be proved within the next theorem.

**Theorem 2** *Let  $\bar{x} \in X$ . If there exist  $\bar{\lambda} \in C^*$  and  $\bar{\mu} \in \mathbf{R}_+^m$ , such that*

$$\begin{aligned} \mathcal{L}(\bar{x}; \lambda, \mu) \leq \mathcal{L}(\bar{x}; \bar{\lambda}, \bar{\mu}) \leq \mathcal{L}(x; \bar{\lambda}, \bar{\mu}), \\ \forall x \in X, \quad \forall \lambda \in C^*, \quad \forall \mu \in \mathbf{R}_+^m, \end{aligned} \quad (4)$$

*then  $\bar{x}$  is a global minimum point of (P).*

*Proof* It is enough to prove that (1)  $\Leftrightarrow$  (4).

( $\Rightarrow$ )  $\bar{x} \in \mathbf{R}, \bar{\lambda} \in C^* \Rightarrow \gamma(g(\bar{x}); \bar{\lambda}, \bar{\mu}) \geq 0$ ; the reverse of this inequality is implied by (1) at  $x = \bar{x}$ . Thus (2) follows. Because of (2), (1) is equivalent to the second of inequalities (4). It is easy to show that

$$g(\bar{x}) \in C \Leftrightarrow \gamma(g(\bar{x}); \lambda, \mu) \geq 0, \quad (5)$$

$$\forall \lambda \in C^*, \quad \forall \mu \in \mathbf{R}_+^m.$$

In fact, the implication  $\Rightarrow$  is trivial; the reverse implication follows quickly by reasoning ab absurdo. (2) and (5) imply the inequality

$$\gamma(g(\bar{x}); \bar{\lambda}, \bar{\mu}) \leq \gamma(g(\bar{x}); \lambda, \mu), \quad (6)$$

$$\forall \lambda \in C^*, \quad \forall \mu \in \mathbf{R}_+^m,$$

which is equivalent to the first of (4).

( $\Leftarrow$ ) The first of (4) is equivalent to (6) which implies  $\bar{x} \in \mathbf{R}$ , so that  $\gamma(g(\bar{x}); \bar{\lambda}, \bar{\mu}) \geq 0$ . The strict inequality contradicts (6) since,  $\forall i \in I^+$ ,  $\lambda_i g_i(\bar{x}) \exp(-\mu_i g_i(\bar{x}))$  can be made arbitrarily small so that the same happens to  $\gamma(g(\bar{x}); \lambda, \mu)$ . Hence (2) holds here too. Taking into account (2), it is easy to see that the second of inequalities (4) implies (1).

At  $\mu = 0$ , (4) is the classic saddle-point sufficient condition and (2) becomes (3). Note that Theorem 2 does not contain any assumption on  $X, f$  and  $g$ .

*Example 3* Let us set  $H = \mathbf{R}, X = ]-1, +\infty[, p = 0, m = 1, f(x) = \log(x + 1), g(x) = x$ . At  $\mu = 0$ , (4) is equivalent to the system of  $(\lambda - \bar{\lambda})\bar{x} \geq 0$  and

$$\log\left(\frac{x + 1}{\bar{x} + 1}\right) \geq \bar{\lambda}(x - \bar{x}),$$

$$\forall x \in ]-1, +\infty[, \quad \forall \lambda \geq 0,$$

which is impossible. Hence, the classic saddle-point condition is not satisfied. At  $\bar{\mu} > 0$ , (4) can be satisfied. In fact, at  $\bar{x} = 0$ , (4) is equivalent to  $\log(x + 1) \geq \bar{\lambda}x \exp(-\bar{\mu}x), \forall x \in ]-1, +\infty[$ , which is true if  $\bar{\lambda} = 1$  and  $\bar{\mu}$  is large enough. Hence, Theorem 2 can now be applied to state that  $\bar{x} = 0$  is a global minimum point of (P).

*Example 4* Let us set  $X \subset H = AC_2(T)$ , where  $T := [0, \tau]$  is the domain of the elements  $x = (x_1, x_2) \in H; x_1 = x_1(t)$  and  $x_2 = x_2(t), t \in T$ , are the parametric equations of a curve  $\gamma$  in  $\mathbf{R}^2$ ; given a positive real  $\ell, \tau$  must be such that the length of  $\gamma$  be  $\ell$ .  $X$  is now the set of pairs  $x =$

$(x_1, x_2) \in H$ , such that  $x_1(0) = x_2(0) = 0, x_2(t) \geq 0, \forall t \in T$ , each  $x_i$  is regular in the sense of Jordan and closed. Moreover, we set  $p = m = 1, T = [0, 2\pi]$ , and

$$f(x) = \int x_1 dx_2, \quad g(x) = \int \sqrt{dx_1^2 + dx_2^2} - \ell.$$

Consider the problem

$$P(\ell) \begin{cases} \max & f(x), \\ \text{s.t.} & g(x) = 0, \quad x \in X. \end{cases}$$

The solution of this classic isoperimetric problem is well known:

$$\bar{x}_1(t; \ell) = \frac{\ell}{2\pi} \cos\left(t - \frac{\pi}{2}\right),$$

$$\bar{x}_2(t; \ell) = \frac{\ell}{2\pi} \left[1 + \sin\left(t - \frac{\pi}{2}\right)\right],$$

$$t \in T = [0, 2\pi],$$

or, in nonparametric form,  $x_1^2 + x_2^2 - x_2 \ell/\pi = 0$ , and the maximum is  $\ell^2/4\pi$ . If in  $P(\ell)$  we replace  $g(x) = 0$  with  $g(x) = \xi$ , so that we consider  $P(\ell + \xi)$ , then  $\forall \bar{x} \in X$  we have

$$\max_{\substack{(u,v) \in \mathcal{K}(\bar{x}) \\ v = \xi}} (u) = f(\bar{x}) - \frac{(\ell + \xi)^2}{4\pi}.$$

It follows that  $\mathcal{K}(\bar{x})$  is included in a convex (with respect to  $u$ -axis) parabola; hence  $\mathcal{H}$  and  $\mathcal{K}(\bar{x})$  can be separated by a line, so that (1) and (4) can be verified at  $\mu = 0$ . Any  $\bar{x} \in X$  (and not necessarily an optimal one) allows to carry on the analysis in the image space. Of course, in general, it is impossible to have an explicit form of  $\mathcal{K}(\bar{x})$ . In the present example, to show explicitly a part of  $\mathcal{K}(\bar{x})$ , namely the perturbation function, we have exploited the knowledge of the maximum point.

Let us stress that the sufficient condition (1), as well as (4), is an important result; however, in general, it is not necessary and it is difficult to be verified since the inequality must be fulfilled  $\forall x \in X$ . Therefore, it is useful to weaken the analysis, by replacing  $\mathcal{K}(\bar{x})$  withan ‘approximation’ which be ‘easier’ to handle. A natural way of doing this consists in approximating  $\mathcal{K}(\bar{x})$  at  $F(\bar{x}) := (\varphi(\bar{x}; \bar{x}), g(\bar{x}))$  by means of its tangent cone (e.g., in the sense of Bouligand [4,6]); in general a cone is obviously easier than any set. For the sake of simplicity, now we will consider a particular case of (P)

and adopt a separation scheme less general than above, which however embeds the classic theory [12]; for more general results see [6,7,9,10,11,13,14,18,19,20].

Consider the particular case where  $p = 0$  (so that  $C = \mathbf{R}_+^m$ ; the presence of bilateral constraints makes the analysis extremely difficult, unless  $f$  and  $g$  are assumed to fulfill conditions which make applicable Dini or Lyusternik implicit function theorems) and  $X$  is open. Denote by  $C$  the set of *sublinear real-valued functions* (i. e., positively homogeneous of degree one and convex) defined on  $H$ ;  $f$  is *superlinear* if and only if  $-f$  is sublinear.  $f$  is said to be *C-differentiable* at  $\bar{x}$  if and only if  $\exists \mathcal{D}_C f: X \times X \rightarrow \mathbf{R}$ , such that  $\mathcal{D}_C(\bar{x}; \cdot) \in C$ , and

$$\lim_{z \rightarrow 0} \frac{1}{\|z\|} [\epsilon(\bar{x}; z) := f(\bar{x} + z) - f(\bar{x}) - \mathcal{D}_C f(\bar{x}; z)] = 0, \quad (7)$$

where  $\|\cdot\|$  is the norm in  $H$  generated by the scalar product and  $z$  belongs to a neighborhood, say  $Z$ , of  $\bar{x}$ .  $\mathcal{D}_C f$  is said to be the *C-derivative* of  $f$  at  $\bar{x}$ . If  $\mathcal{D}_C f$  is linear (the linear functions are obviously elements of  $C$ ), then  $f$  is *differentiable* [7]. It is easy to see that a *C-differentiable* function is *directionally differentiable* in any direction  $z$  (in the sense that there exists the limit of  $[f(\bar{x} + \alpha z) - f(\bar{x})]/\alpha$  as  $\alpha \downarrow 0$ ); the vice versa is not true, as shown by the following example(which generalizes the so-called *Peano function* showed by G. Peano to detect a famous mistake by Lagrange):

*Example 5*  $H = X = R = \mathbf{R}^2, x = (x_1, x_2), \bar{x} = 0, \|z\| = \|z\|_2, f(x) = (x_1^2 + x_2^2)^{1/2}$  if  $x \not\prec 0$  and  $f(x) = \alpha(x_2/x_1^2)(x_2^2 + x_1^2)^{1/2}$  if  $x \succ 0$ , where  $\alpha: \mathbf{R}_+ \setminus \{0\} \rightarrow \mathbf{R}$  is defined by  $\alpha(t) = 1$  if  $0 < t \leq 1$  or  $t \geq 3, \alpha(t) = 3 - 2t$  if  $1 < t \leq 2$  and  $\alpha(t) = 2t - 5$  if  $2 < t < 3$ . In this Example, at  $x = \bar{x}$  the directional derivative exists and is  $f'(\bar{x}; z) = (z_1^2 + z_2^2)^{1/2}$ , while it is not possible to verify (7). Note that  $f$  is continuous, but not locally Lipschitz, and  $f'(0; z) > 0, \forall z \in \mathbf{R}^2$ .

*Example 6*  $H = X = R = \mathbf{R}, f: \mathbf{R} \rightarrow \mathbf{R}_+$  with  $f(x) = |x| + x^2$  if  $x \in \mathbf{Q}$  and  $f(x) = |x| + 2x^2$  if  $x \notin \mathbf{Q}, \mathbf{Q}$  being the set of rational numbers.  $f$  is *C-differentiable* at  $\bar{x} = 0$  with *C-derivative*  $\mathcal{D}_C f(0; z) = |z|$ . Note that  $f$  is continuous at  $\bar{x} = 0$  only.

The *C-subdifferential* of a *C-differentiable* function  $f$  at  $\bar{x} \in X$  is defined by

$$\partial_C f(\bar{x}) := \left\{ z^* \in H': \begin{array}{l} \mathcal{D}_C f(\bar{x}; z) \geq \langle z^*, z \rangle, \\ \forall z \in Z \end{array} \right\},$$

where  $H'$  is the continuous dual of  $H$ ;  $z^*$  is called the *C-subgradient* of  $f$  at  $\bar{x}$ . When  $f$  is convex, then  $\partial_C f(\bar{x})$  collapses to the classic subdifferential which is denoted simply by  $\partial f(\bar{x})$ ; hence,  $\partial_C f(\bar{x})$  is nothing more than the subdifferential of  $\mathcal{D}_C f(\bar{x}; z)$  or  $\partial_C f(\bar{x}; z) = \partial \mathcal{D}_C f(\bar{x}; z)$ . When  $\mathcal{D}_C f(\bar{x}; z)$  is linear, then  $\partial_C f(\bar{x})$  is a singleton and collapses to the classic differential. In the latest example  $\partial_C f(0) = [-1, 1]$ . Consider the further example:  $H = X = R = \mathbf{R}, f(x) = x^2 \sin 1/x$  if  $x \neq 0$  and  $f(0) = 0$ . We find  $\mathcal{D}_C f(0; z) = 0, \forall z \in \mathbf{Z}$  (indeed  $f$  is differentiable), so that  $\partial_C f(0) = \{0\}$ , while the Clarke subdifferential [4] is  $[-1, 1]$ . Now consider the following regularity condition:

$$(RC) \quad T(\mathcal{K}(\bar{x})) \cap \{(u, v) \in \mathcal{H}: v = 0\} = \emptyset,$$

where  $T(\mathcal{K}(\bar{x}))$  is the Bouligand tangent cone of  $\mathcal{K}(\bar{x})$  at  $\bar{x}$ . Several conditions on  $f$  and  $g$  are well known (mainly when  $H = \mathbf{R}^n$ ) which guarantee (RC). Consider for instance the case where  $H = \mathbf{R}^n$  and  $f, g$  are derivable. (RC) holds if the gradients  $\nabla g_i(\bar{x}), i \in \{i \in I: g_i(\bar{x}) = 0\}$  are linearly independent. (RC) holds if  $g$  is affine. (RC) holds if  $g$  is concave and  $\exists \hat{x} \in X$  such that  $g(\hat{x}) > 0$ . For additional conditions see **► Theorems of the alternative and optimization; [6,12]**.

The approximation of (P), we want to discuss in the present particular case  $p = 0$ , consists in replacing  $f$  and  $-g_i, i \in I$ , with their *C-derivatives*. More precisely, instead of the map  $F = (\varphi, g)$ , we consider now the superlinear map

$$F_C(\bar{x}; z) := (-\mathcal{D}_C f(\bar{x}; z), g_i(\bar{x}) + \mathcal{D}_C g_i(\bar{x}; z) \quad i \in I),$$

which is the first order expansion of the  $(-C)$ -differentiable map  $F$ .  $\mathcal{K}(\bar{x})$  is now replaced by the cone  $\mathcal{K}_C(\bar{x}) := F_C(\bar{x}; X - \bar{x})$ . (S') is now replaced by

$$(S''') \quad \mathcal{H} \cap \mathcal{K}_C(\bar{x}) = \emptyset,$$

which holds if  $\bar{x}$  is a minimum point of (P) (but not necessarily vice versa due to the above approximation of  $\mathcal{K}(\bar{x})$ ; hence, from the necessity and sufficiency of

(S') we jump to the sole necessity of (S''), since  $\mathcal{H}$  and  $\mathcal{K}_C(\bar{x})$  are linearly separable; hence (S'') can be proved by means of the subclass of  $W_{pe}$  at  $\mu = 0$ . As a consequence the Lagrangian function  $\mathcal{L}$  (which, as we have seen above, is, up to a formal transformation, the separation function  $w$ ) will be used at  $\mu = 0$ ; thus we set  $L(x;\lambda) := \mathcal{L}(x;\lambda, 0)$ . This leads to the following necessary condition, whose proof can be found in [7].

**Theorem 7** *Let the functions  $f, -g_i, i \in I$ , be C-differentiable, and assume that (RC) be fulfilled. If  $\bar{x}$  is a minimum point of (P), then  $\exists \bar{\lambda} \in \mathbf{R}^m$ , such that*

$$\inf_{z \in B} \mathcal{D}_C L(\bar{x}; z; \bar{\lambda}) \geq 0, \tag{8}$$

$$g(\bar{x}) \geq 0, \quad \bar{\lambda} \geq 0, \tag{9}$$

$$\langle \bar{\lambda}, g(\bar{x}) \rangle = 0, \tag{10}$$

where  $\mathcal{D}_C L(\bar{x}; z; \bar{\lambda})$  is the C-derivative of  $L$  at  $x = \bar{x}, \lambda = \bar{\lambda}$ , and  $B := \{z: \|z\| = 1\}$ .

(8) is equivalent to

$$0 \in \partial_C f(\bar{x}) + \sum_{i \in I} \bar{\lambda}_i \partial_C (-g_i(\bar{x})), \tag{11}$$

which becomes

$$0 \in \partial f(\bar{x}) + \sum_{i \in I} \bar{\lambda}_i \partial (-g_i(\bar{x})), \tag{12}$$

if, in particular,  $X, f$  and  $-g$  are convex. When  $f$  and  $g$  are differentiable on  $X$ , then (8) collapses to  $\mathcal{V}_L = 0$  along  $x = \bar{x}$ , where  $\mathcal{V}_L$  is the first variation of  $L$ , and in case (P)<sub>iso</sub> becomes

$$\Psi'_x(t, \bar{x}, \bar{x}'; \bar{\lambda}) - \frac{d}{dt} \Psi'_{x'}(t, \bar{x}, \bar{x}'; \bar{\lambda}) = 0, \tag{13}$$

where  $\Psi := \psi_0 - \sum_{i \in I} \lambda_i \psi_i$  is the integrand of  $L$ . If  $X = H = \mathbf{R}^n$ , then (8) collapses to

$$L'_x(\bar{x}; \bar{\lambda}) = 0, \tag{14}$$

where  $L'_x$  is the gradient of  $L$  with respect to  $x$ .

Note that (13) is the classic Euler equation and (14) is the classic Lagrange equation;  $\bar{\lambda}$  is the vector of Lagrange multipliers which turns out to be the gradient of the hyperplane ( $w = 0$  at  $\mu = 0$ ) which separates the two sets of (S'').

Now, let us go back to the separation scheme which led to the sufficient condition (1). The choice of proving (S') indirectly through separation has a lot of interesting consequences which go beyond the initial purpose. One of them is the introduction of a (nonlinear) dual space: that of functionals  $w$ . When we restrict ourselves to  $W_{pe}$ , then the dual space is isomorphic to  $\mathbf{R}^{2m}$  (to  $\mathbf{R}^m$  at  $\mu = 0$ ; this is the classic duality scheme in finite-dimensional optimization). Such an isomorphism is the characteristic of constrained extremum problems having finite-dimensional image (independently of the dimension of the space where the unknown runs).

Having recognized that we have introduced a dual space, to define a dual problem is immediate. Indeed, looking at (1), since the inequality must be fulfilled  $\forall x \in X$ , it is straightforward, for each  $\lambda$  and  $\mu$ , to search for  $\max_{x \in X} w(\varphi(\bar{x}; x), g(x); \lambda, \mu)$  and then to find  $\lambda, \mu$  which make such a maximum as small as possible and, hopefully, not greater than zero. Hence, we are led to study the problem:

$$(P^*) \quad \max_{\lambda \in C^*, \mu \in \mathbf{R}_+^m} \min_{x \in X} \mathcal{L}(x; \lambda, \mu),$$

which we call *generalized dual problem* of (P); any pair  $(\lambda^*, \mu^*)$  which solves (P\*) is a *dual variable* [6,19]. At  $\mu = 0$ , (P\*) is the classic *dual problem* of (P) [12]; indeed, the classic duality theory starts by defining (P\*) as a dual problem, independently of the separation scheme and hence of the other theories like the saddle-point one. It is easy to show that the maximum in (P\*) is  $\leq$  of the minimum in (P); the difference between the latter and the former is called *duality gap*; it is now clear that a positive duality gap corresponds to a lack of separation between  $\mathcal{H}$  and  $\mathcal{K}(\bar{x})$  at the minimum point  $\bar{x}$ .

Another important topic which can be derived by the separation scheme is the penalization theory. Seemingly independent of the other topics of Optimization, it is indeed strictly related to them, since it can be drawn from the separation scheme, as will be now briefly outlined (recall the remark after Theorem 1). Consider again the family  $W_{pe}$  within which select a sequence, say  $\{w_r := w(u, v; \lambda^r, \mu^r)\}_{r=1}^\infty$ , of separation functions, such that the positive level set (with respect to  $(u, v)$ ) of  $w_{r+1}$  be strictly included in that of  $w_r$ . Then, we can try to 'fulfill (1) asymptotically' or to set up the sequence of problems:

$$(P_r) \quad \min_{x \in X} \mathcal{L}(x; \lambda^r, \mu^r); \quad r = 1, 2, \dots$$

Under suitable conditions, a limit point of  $\{x^r\}_1^\infty$  ( $x^r$  being a solution of (Pr)) is a solution of (P). See [6,15] for details.

Let us stress the fact that the separation scheme and its consequences come down from (S), and do not ‘see’ (P); they are unacquainted with the fact that the impossibility of (S) expresses optimality for (P). Therefore, it is obvious that the separation approach can be applied to every kind of problem which leads to the impossibility of a system like (S). In fact, such an approach can be applied to vector optimization and to variational inequalities [8], and to generalized systems [14,19].

### Keywords

Complementarity problem; Merit function; Optimization

The *nonlinear complementarity problem* (see [3,15]) is to find a point  $x \in \mathbf{R}^n$  such that

$$x \geq 0, \quad F(x) \geq 0, \quad \langle x, F(x) \rangle = 0, \quad (1)$$

where  $F : \mathbf{R}^n \rightarrow \mathbf{R}^n$  and  $\langle \cdot, \cdot \rangle$  denotes the usual inner product in  $\mathbf{R}^n$ . A popular approach for solving the nonlinear complementarity problem (NCP) is to construct a *merit function*  $f$  such that solutions of NCP are related in a certain way to the optimal set of the problem

$$\begin{cases} \min & f(x) \\ \text{s.t.} & x \in C. \end{cases}$$

Of practical interest is the case when the set  $C$  has simple structure and smoothness properties of  $F$  and dimensionality  $n$  of the variables space are preserved. There is a number of ways to reformulate the NCP as an equivalent optimization problem (for a survey, see [7]).

### Unconstrained Implicit Lagrangian

The first smooth unconstrained merit function was proposed by O.L. Mangasarian and M.V. Solodov [12]. This function is commonly referred to as the implicit Lagrangian; it has the following form:

$$\begin{aligned} M_\alpha(x) &= \langle x, F(x) \rangle \\ &+ \frac{1}{2\alpha} (\|(x - \alpha F(x))_+\|^2 - \|x\|^2) \\ &+ \frac{1}{2\alpha} (\|(F(x) - \alpha x)_+\|^2 - \|F(x)\|^2) \end{aligned}$$

where  $\alpha > 1$  is a parameter and  $(\cdot)_+$  denotes the orthogonal projection map onto the nonnegative orthant  $\mathbf{R}_+^n$ , i. e. the  $i$ th component of the vector  $(z)_+$  is  $\max\{0, z_i\}$ . It turns out that  $M_\alpha(x)$  is nonnegative on  $\mathbf{R}^n$  provided  $\alpha > 1$ , and is zero if and only if  $x$  is a solution of the NCP. If  $F$  is differentiable on  $\mathbf{R}^n$ , then so is  $M_\alpha(\cdot)$  and its gradient vanishes at all solutions of NCP for  $\alpha > 1$ . Hence, one can attempt to solve the NCP by means of solving the smooth unconstrained optimization problem

$$\begin{cases} \min & M_\alpha(x) \\ \text{s.t.} & x \in \mathbf{R}^n. \end{cases} \tag{2}$$

The implicit Lagrangian owes its name to the way the function was first derived in [12]. Consider the constrained minimization problem (MP)

$$\begin{cases} \min & \langle x, F(x) \rangle \\ \text{s.t.} & x \geq 0, F(x) \geq 0 \end{cases}$$

which is related to the NCP (1) in the sense that its global minima of zero coincide with the solutions of

NCP. Because of the special structure of the MP (the objective function is the inner product of the functions defining constraints), for every feasible  $\bar{x}$  such that  $\langle \bar{x}, F(\bar{x}) \rangle = 0$  it can be observed that  $\bar{x}$  plays the role of the *Lagrange multiplier* [2] for the constraint  $F(x) \geq 0$ , while  $F(\bar{x})$  plays a similar role for the constraint  $x \geq 0$ . Keeping in mind this observation, consider the *augmented Lagrangian* [1] for the above MP:

$$\begin{aligned} L_\alpha(x, u, v) &= \langle x, F(x) \rangle \\ &+ \frac{1}{2\alpha} (\|(-\alpha F(x) + u)_+\|^2 - \|u\|^2) \\ &+ \frac{1}{2\alpha} (\|(-\alpha x + v)_+\|^2 - \|v\|^2), \end{aligned}$$

where  $u \in \mathbf{R}^n$  and  $v \in \mathbf{R}^n$  are Lagrange multipliers corresponding to the constraints  $F(x) \geq 0$  and  $x \geq 0$  respectively. Since it is known a priori that at any solution  $\bar{x}$  of MP (and NCP) one could take  $\bar{u} = \bar{x}$  and  $\bar{v} = F(\bar{x})$ , it is intuitively reasonable to ‘solve’ for multipliers  $u$  and  $v$  in terms of the original variables. Replacing  $u$  by  $x$  and  $v$  by  $F(x)$  in the augmented Lagrangian, one obtains the implicit Lagrangian function  $M_\alpha(x)$ .

The parameter  $\alpha$  must be strictly bigger than one, because it can be checked that  $M_1(x) = 0$  for all  $x \in \mathbf{R}^n$ . Another interesting property is that the partial derivative of the implicit Lagrangian with respect to  $\alpha$  is also nonnegative for all  $x$ , and is zero if and only if  $x$  is a solution of the NCP [11]. However, a merit function based on this derivative is nonsmooth.

### Restricted Implicit Lagrangian

When the implicit Lagrangian is restricted to the nonnegative orthant  $\mathbf{R}_+^n$ , where nonnegativity of  $x$  is explicitly enforced, the last two terms in the expression for  $M_\alpha(x)$  can be dropped. Thus the restricted implicit Lagrangian is obtained:

$$N_\alpha(x) = \langle x, F(x) \rangle + \frac{1}{2\alpha} (\|(x - \alpha F(x))_+\|^2 - \|x\|^2),$$

where  $\alpha > 0$ . In this form, the function was introduced in [12]. It is also equivalent to the *regularized gap function* proposed by M. Fukushima [6] in the more general context of variational inequality problems (cf. also **Variational inequalities**).

The restricted implicit Lagrangian is nonnegative for all  $x \in \mathbf{R}_+^n$  provided the parameter  $\alpha$  is positive, and its zeroes coincide with solutions of the NCP. It also

inherits the differentiability of  $F$ . Thus the NCP can be solved via the bound constrained optimization problem

$$\begin{cases} \min & N_\alpha(x) \\ \text{s.t.} & x \geq 0. \end{cases} \quad (3)$$

Note that since it is known a priori that every solution of the NCP is nonnegative, one may also consider a bound constrained problem with the function  $M_\alpha(x)$ . However, for the constrained reformulations the function  $N_\alpha(x)$  is probably preferable because it is somewhat simpler.

### Regularity Conditions

It should be emphasized that only global solutions of optimization problems (2) and (3) are solutions of the underlying NCP (1). On the other hand, standard iterative methods are guaranteed to find stationary points rather than global minima of optimization problems. It is therefore important to derive conditions which ensure that these stationary points are also solutions of NCP. One such condition is *convexity*. However, the implicit Lagrangian is known to be convex only in the case of strongly monotone affine  $F$ , and provided parameter  $\alpha$  is large enough [17]. Clearly, this is very restrictive. Thus other regularity conditions were investigated.

For the unconstrained problem (2), the first sufficient condition was given by N. Yamashita and Fukushima [24]. They established that if the Jacobian  $\nabla F(\bar{x})$  is positive definite at a stationary point  $\bar{x}$  of (2), then  $\bar{x}$  solves the NCP. This result was later extended in [8] to the case when  $\nabla F(\bar{x})$  is a  $P$ -matrix. Finally, F. Facchinei and C. Kanzow [5] obtained a certain regularity condition which is both necessary and sufficient for a stationary point of the unconstrained implicit Lagrangian to be a solution of NCP (it is similar to the condition stated below for the restricted case).

For constrained problem (3), Fukushima [6] first showed the equivalence of stationary points to NCP solutions under the positive definiteness assumption on the Jacobian of  $F$ . A regularity condition which is both necessary and sufficient, was given by Solodov [20]: a point  $x \in \mathbf{R}_+^n$  is said to be regular if  $\nabla F(x)^\top$  reverses the sign of no nonzero vector  $z \in \mathbf{R}^n$  satisfying

$$z_P > 0, \quad z_C = 0, \quad z_N < 0, \quad (4)$$

where

$$\begin{aligned} C &:= \{i: x_i \geq 0, F_i(x) \geq 0, x_i F_i(x) = 0\}, \\ P &:= \{i: x_i > 0, F_i(x) > 0\}, \\ N &:= \{i: x_i \geq 0, F_i(x) < 0\}. \end{aligned}$$

Recall [4] that the matrix  $\nabla F(x)^\top$  is said to reverse the sign of a vector  $z \in \mathbf{R}^n$  if

$$z_i [\nabla F(x)^\top z]_i \leq 0, \quad \forall i \in \{1, \dots, n\}. \quad (5)$$

Therefore a point  $x \in \mathbf{R}_+^n$  is regular if the only vector  $z \in \mathbf{R}^n$  satisfying both (4) and (5) is the zero vector.

A stationary point of (3) solves the NCP if and only if it is regular in the sense of the given definition.

### Derivative-Free Descent Methods

When  $F$  is differentiable, so are the functions  $M_\alpha(x)$  and  $N_\alpha(x)$ . Therefore, any standard optimization algorithm which makes use of first order derivatives can be applied to problems (2) and (3). However, taking advantage of the underlying structure one can also devise special descent algorithms which do not use derivatives of  $F$ . This can be especially useful in cases when derivatives are not readily available or are expensive to compute.

In [24], it was shown that when  $F$  is *strongly monotone* and continuously differentiable, then the direction

$$\begin{aligned} d(x) &= (\beta - \alpha)(x - (x - \alpha F(x))_+) \\ &\quad + (1 - \alpha\beta)(F(x) - (F(x) - \alpha x)_+) \end{aligned}$$

is a descent direction for  $M_\alpha(\cdot)$  at  $x \in \mathbf{R}^n$ , provided  $\beta > 0$  is chosen appropriately. A descent method based on this direction with appropriate *line search*, converges globally to the unique solution of the NCP [24]. In [13], it was established that the *rate of convergence* is actually at least linear.

For the restricted implicit Lagrangian, a descent method with the direction

$$d(x) = (x - \alpha F(x))_+ - x$$

was proposed in [6]. The algorithm was proven to be convergent for the strongly monotone NCP (no rate of convergence has been established however). In [26], by using adaptive parameter  $\alpha$ , this method was further extended to monotone (not necessarily strongly monotone) and Lipschitz continuous (not necessarily differentiable) functions.

## Error Bounds

The implicit Lagrangian also appears useful for providing bounds on the distance from a given point to the solution set of the NCP. In particular, if  $F$  is affine then there exists a constant  $c > 0$  such that (see [11])

$$\text{dist}(x, S) \leq cM_\alpha(x)^{1/2}$$

for all  $x$  close to  $S$ , where  $S$  denotes the solution set. This inequality is called a local *error bound*. X.-D. Luo and P. Tseng [10] proved that, in the affine case, this bound is global (i. e. it holds for all  $x \in \mathbf{R}^n$ ) if and only if the associated matrix is of the class  $R_0$ .

For the nonlinear case, Kanzow and Fukushima [9] showed that  $M_\alpha(x)^{1/2}$  provides a global error bound if  $F$  is a *uniform  $P$ -function* which is Lipschitz continuous.

In the context of error bounds, the following relation established in [11] is useful: for all  $x \in \mathbf{R}^n$ ,

$$\alpha^{-1}(\alpha - 1) \|r(x)\|^2 \leq M_\alpha(x) \leq (\alpha - 1) \|r(x)\|^2$$

where

$$r(x) = x - (x - F(x))_+$$

is the *natural residual* [14]. Therefore the implicit Lagrangian  $M_\alpha(x)$  provides a local/global error bound if and only if so does the natural residual  $r(x)$ .

For the restricted implicit Lagrangian, one only has the following relation:

$$2\alpha N_\alpha(x) \geq \|r(x)\|^2.$$

Thus, in principle,  $N_\alpha(x)$  may provide a bound in cases when the natural residual does not.

For a general discussion of error bounds see [16].

## Extensions

The implicit Lagrangian can be extended to the context of generalized complementarity problems and variational inequality problems via its relation with the regularized gap function. As observed by J.-M. Peng and Y.X. Yuan [19], the function  $M_\alpha(x)$  can be represented as a difference of two regularized gap functions with parameters  $1/\alpha$  and  $\alpha$ . Since the regularized gap function can also be defined for variational inequalities, one might consider a similar expression in this more general context. Peng [18] established the equivalence of the variational inequality problem to unconstrained

minimization of a difference of regularized gap functions. This result was further extended by Yamashita, K. Taji and Fukushima [25] who obtained similar results for differences of regularized gap functions whose parameters are not necessarily the inverse of each other. For algorithms based on this approach, see [22].

For a unified treatment of extensions of the implicit Lagrangian and the regularized gap function for the generalized complementarity problems see [23].

Yet another context where the implicit Lagrangian can be used is optimization reformulation of the extended linear complementarity problem [21].

### Introduction

The role of convex analysis in optimization is well known. One of the major properties of a convex function is its representation as the upper envelope of a family of affine functions. More specifically, every lower semicontinuous proper convex function can be expressed as the supremum of the family of affine functions, majorized by it [4]. The subject of abstract convexity arose precisely by generalizing this idea (see [5,6]). A function is said to be abstract convex if and only if it can be represented as the upper envelope of a class of functions, usually called *elementary functions*. One of the first studies in abstract convexity concerned the analysis of *increasing and positively homogeneous* (IPH) functions. It was initially carried out for functions defined over  $\mathbb{R}_{++}^n$  and  $\mathbb{R}_+^n$ , where  $\mathbb{R}_{++}^n := \text{int } \mathbb{R}_+^n$ , and later on extended to an arbitrary closed convex cone in [1] and an arbitrary topological vector space in [3]. This study was further extended to include increasing and convex-along-rays (ICAR) functions over  $\mathbb{R}_+^n$ . The study of IPH and ICAR functions has given rise to the subject of *monotonic analysis*, the study of increasing functions enjoying some additional properties, which has important applications in global optimization (see [5] for more details). The systematic study of this subject was started in [1] and [2] by J. Dutta, J. E. Martinez-Legaz, and A. M. Rubinov, where they analyzed IPH and ICAR functions defined on a cone. In the present article, we extend this analysis to the study of ICAR functions defined over an arbitrary topological vector space. We want to emphasize that the role of IPH functions in monotonic analysis is the same as the role of sublinear functions in

convex analysis, whereas ICAR functions play the role of convex functions. We define elementary functions, which can be considered as generalizations of min-type functions, and demonstrate that ICAR functions are abstract convex with respect to the class of such elementary functions. This leads us to develop suitable notions of subdifferential for ICAR functions. Finally, we study the class of decreasing and convex-along-rays (DCAR) functions.

Let  $H$  be a set of functions  $h: X \rightarrow \mathbb{R}_{+\infty}$  defined on a set  $X$ . Recall (see [6]) that a function  $f: X \rightarrow \mathbb{R}_{+\infty}$  is called abstract convex with respect to  $H$  ( $H$ -convex) if there exists a set  $U \subseteq H$  such that  $f(x) = \sup\{h(x): h \in U\}$ . Let  $\text{supp}(f, H) := \{h \in H: h \leq f\}$  be the support set of a function  $f: X \rightarrow \mathbb{R}_{+\infty}$  with respect to  $H$ . The function  $\text{co}_H f: X \rightarrow \mathbb{R}_{+\infty}$  defined by  $\text{co}_H f(x) := \sup\{h(x): h \in \text{supp}(f, H)\}$  is called the  $H$ -convex hull of  $f$ . Clearly,  $f$  is  $H$ -convex if and only if  $f = \text{co}_H f$ . Let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be a proper function and  $x_0 \in \text{dom} f = \{x \in X: f(x) < +\infty\}$ . The set

$$\partial_H f(x_0) := \{h \in H: f(x) \geq f(x_0) + h(x) - h(x_0) \text{ for all } x \in X\}$$

is called the  $H$ -subdifferential of  $f$  at the point  $x_0$ . Obviously,  $\partial_H f(x_0)$  is nonempty if  $f(x_0) = \max\{h(x_0): h \in \text{supp}(f, H)\}$ .

Let  $(X, Y)$  be a pair of sets with a coupling function  $\varphi: X \times Y \rightarrow \mathbb{R}_{+\infty}$ . Denote by  $F_X$  the union of the set of all functions  $f: X \rightarrow \mathbb{R}_{+\infty}$  and the function  $-\infty$ , where  $-\infty(x) = -\infty$  for all  $x \in X$ . The Fenchel–Moreau conjugation corresponding to  $\varphi$  is the mapping  $f \rightarrow f^\varphi$  defined on  $F_X$  by

$$f^\varphi(y) = \sup_{x \in X} \{\varphi(x, y) - f(x)\}, \quad y \in Y.$$

Let  $\varphi'$  be the function defined on  $Y \times X$  by  $\varphi'(y, x) = \varphi(x, y)$ . Then the Fenchel–Moreau conjugation corresponding to  $\varphi'$  is the mapping  $g \rightarrow g^{\varphi'}$  defined on  $F_Y$  by

$$\begin{aligned} g^{\varphi'}(x) &:= \sup_{y \in Y} \{\varphi'(y, x) - g(y)\} \\ &= \sup_{y \in Y} \{\varphi(x, y) - g(y)\}. \end{aligned}$$

In the case where  $Y$  is a set of functions defined on set  $X$ , for each  $y \in Y$  and  $\gamma \in \mathbb{R}$ , consider the function  $h_{y,\gamma}(x) := y(x) - \gamma$ ,  $x \in X$ . Denote by  $H_Y$  the

set  $\{h_{y,\gamma}: y \in Y, \gamma \in \mathbb{R}\}$ . Let  $\varphi: X \times Y \rightarrow \mathbb{R}_{+\infty}$  defined by  $\varphi(x, y) = y(x)$ . The following result is well known (see, e. g., [5], Theorem 8.8):

**Theorem 1** *Let  $f \in F_X$ . Then  $f^{\varphi\varphi'} = \text{co}_{H_Y} f$ . In particular,  $f^{\varphi\varphi'} = f$  if and only if  $f$  is  $H_Y$ -convex.*

### ICAR Functions

Let  $X$  be a topological vector space. A set  $K \subseteq X$  is called conic if  $\lambda K \subseteq K$  for all  $\lambda > 0$ . We assume that  $X$  is equipped with a closed convex pointed cone  $K$  (the latter means that  $K \cap (-K) = \{0\}$ ). The increasing property of our functions will be understood to be with respect to the ordering  $\leq$  induced on  $X$  by  $K$ :

$$x \leq y \iff y - x \in K.$$

A function  $f: X \rightarrow \mathbb{R}_{+\infty}$  is called convex along rays (shortly CAR) if the function  $f_x(\alpha) = f(\alpha x)$  is convex on the ray  $[0, +\infty)$  for each  $x \in X$ . Similarly,  $f$  is called increasing along rays (shortly IAR) if the function  $f_x(\alpha) = f(\alpha x)$  is increasing on the ray  $[0, +\infty)$  for each  $x \in X$ . Also the function  $f: X \rightarrow \mathbb{R}_{+\infty}$  is called increasing if  $x \geq y \implies f(x) \geq f(y)$  and it is called decreasing if  $x \geq y \implies f(x) \leq f(y)$ . In the sequel, we shall study the increasing convex-along-rays (ICAR) and decreasing convex-along-rays (DCAR) functions. Consider the coupling function  $l: X \times X \rightarrow \mathbb{R}_+$  defined by

$$l(x, y) = \max\{\lambda \geq 0: \lambda y \leq x\},$$

with the conventions  $\max \emptyset := 0$  and  $\max \mathbb{R} := +\infty$ . This function is introduced and examined in [3]. We shall include some properties of  $l$  for the sake of completeness.

**Proposition 1** *For every  $x, x', y \in X$  and  $\gamma > 0$ , one has*

$$l(\gamma x, y) = \gamma l(x, y), \tag{1}$$

$$l(x, \gamma y) = \frac{1}{\gamma} l(x, y), \tag{2}$$

$$l(x, x) = 1 \iff x \notin -K, \tag{3}$$

$$x \leq x' \implies l(x, y) \leq l(x', y), \tag{4}$$

$$x \in K, y \in -K \implies l(x, y) = +\infty. \tag{5}$$

*Proof 1* We only prove (3). Note that, since  $0 \in K$ , we have  $l(x, x) \geq 1$  for all  $x \in X$ . If  $x \notin -K$ , then  $\lambda x \leq x$  for some  $\lambda > 0$ . This implies that  $\lambda \leq 1$ . Thus,  $l(x, x) = 1$ . Conversely, let  $l(x, x) = 1$ . Assume, toward a contradiction, that  $x \in -K$ . Then,  $\lambda x \leq x$  for all  $\lambda > 1$ , and so  $l(x, x) = +\infty > 1$ , which contradicts the assumption that  $l(x, x) = 1$ . Hence,  $x \notin -K$ .  $\square$

In view of the above proposition, for example, when  $x = y \in K$ , the maximum in the definition of  $l(x, y)$  is actually attained. The following proposition gives us a necessary condition for which  $l(x, y)$  is finite.

**Proposition 2** *If  $y \notin -K$ , then  $l(x, y) < +\infty$  for all  $x \in X$ .*

*Proof 2* If  $l(x, y) = +\infty$ , then there exists a sequence  $\lambda_n \rightarrow +\infty$  such that  $y \leq (1/\lambda_n)x$ . Hence  $y \leq 0$ .  $\square$

By ([3], Remark 2.1),  $l_y: X \rightarrow \bar{\mathbb{R}}_+$  is an IPH function for each  $y \in X$ . We also have the following proposition:

**Proposition 3** *Let  $y \notin -K$ . The function  $l_y: X \rightarrow \bar{\mathbb{R}}_+$  is upper semicontinuous.*

*Proof 3* Fix  $x \in X$ . Let  $\{x_n\} \subset X$  be such that  $x_n \rightarrow x$ . Set  $\lambda = \lim l_y(x_n)$ . If  $\lambda = 0$ , then, by the nonnegativity of  $l_y$ , we have  $l_y(x) \geq \lambda$ . Let  $\lambda > 0$ . It follows from  $y \notin -K$  that  $\lambda < +\infty$ . Consider the subsequence  $\{n_s\}_{s \geq 1}$  such that  $l_y(x_{n_s}) > 0$  and  $l_y(x_{n_s}) \rightarrow \lambda$ . We have  $x_{n_s} - l_y(x_{n_s})y \in K$  for all  $s \geq 1$ . Since  $K$  is closed, we get  $x - \lambda y \in K$  and so, by the definition of  $l$ ,  $l(x, y) \geq \lambda$ . Hence  $l_y$  is upper semicontinuous.  $\square$

Set  $X' = X \setminus (-K)$  and  $L' = \{l_y: y \notin -K\}$ . Fix  $y \in X'$ . Let  $l: X \rightarrow \bar{\mathbb{R}}_+$  defined by

$$l(x) := l_y(x).$$

We have  $\lambda l(x) = l(\lambda x)$  for all  $\lambda \in [0, +\infty)$ . (Note that  $l_y(x) < +\infty$  for all  $x \in X$ ). For each  $x \in X$ , consider the function  $l^x: \mathbb{R}_+ \rightarrow \mathbb{R}_+$  defined by

$$l^x(t) := l(tx) = l_y(tx).$$

It is not difficult to check that  $l^x$  is increasing and continuous. Hence the function  $l$  is ICAR, IAR, and continuous along rays.

**Proposition 4** *Let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be increasing and IAR. Then  $f(x) = f(0)$  for all  $x \leq 0$ .*

*Proof 4* Fix  $x \in X$  such that  $x \leq 0$ . It follows from  $x \leq 0$  and the monotonicity of  $f$  that  $f(x) \leq f(0)$ . On the other hand, since  $f$  is IAR, we have

$$f(x) = f_x(1) \geq f_x(0) = f(0).$$

Hence  $f(x) = f(0)$ .  $\square$

We give an example of an increasing function that is not IAR.

*Example 1* Consider the function  $f: \mathbb{R}^3 \rightarrow \mathbb{R}$  defined by

$$f(x) = \min_{1 \leq i \leq 3} x_i, \quad \forall x \in \mathbb{R}^3.$$

Recall that  $x \leq y$  if and only if  $x_i \leq y_i$  for all  $1 \leq i \leq 3$ . It is easy to see that  $f$  is increasing but, if we set  $x = (-2, 3, 4)$ , then  $f_x: [0, +\infty) \rightarrow \mathbb{R}$  is not increasing. Therefore,  $f$  is not IAR.

The following functions are samples of ICAR and IAR functions.

*Example 2* Consider the functions  $f: \mathbb{R}^n \rightarrow \mathbb{R}$  and  $g: \mathbb{R}^n \rightarrow \mathbb{R}$  defined by

$$f(x) = \begin{cases} \max_{1 \leq i \leq n} x_i & x \notin \mathbb{R}_-^n, \\ 0 & \text{otherwise.} \end{cases}$$

and

$$g(x) = \exp(f).$$

It is easy to check that  $f$  and  $g$  are ICAR and IAR with respect to coordinatewise ordering on  $\mathbb{R}^n$ .

Let  $W = L' \cup \{0\}$ , where  $0(x) = 0$  for all  $x \in X$ . Consider the set  $H = \{l - \gamma: l \in W, \gamma \in \mathbb{R}\}$ . We have the following result:

**Theorem 2** *Let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be a function. Then  $f$  is ICAR, IAR, and lscAR if and only if it is H-convex.*

*Proof 5* It is clear that each function  $h \in H$  is ICAR, IAR, and continuous along rays. Therefore each H-convex function is ICAR, IAR, and lscAR. Conversely, let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be an ICAR, IAR, and lscAR function. Consider  $y \in X$ . Since  $f_y$  is increasing, convex, and lsc, it follows from ([5], Lemma 3.1) that there exists a set  $V_y \subseteq \mathbb{R}_+ \times \mathbb{R}$  such that  $f_y(t) = \sup_{v \in V_y} \{v_1 t - v_2\}$ , for each  $t \geq 0$ , where

$v = (v_1, v_2) \in V_y$ . First, we suppose that  $y \notin -K$ . For  $v = (v_1, v_2) \in V_y$ , we set

$$h^v(x) = v_1 l_y(x) - v_2, \quad x \in X.$$

Clearly  $h^v \in H$ . Let  $v_1 = 0$  or  $l_y(x) = 0$ . Since  $f$  is IAR, we have

$$\begin{aligned} f(x) = f_x(1) &\geq f_x(0) = f(0) = f_y(0) \\ &\geq -v_2 = h^v(x), \quad \text{for all } x \in X. \end{aligned}$$

Suppose now that  $v_1 > 0$  and  $l_y(x) > 0$ . (Note that  $l_y(x) < +\infty$ ). Since  $x - l_y(x)y \in K$  and  $f$  is increasing, it follows that

$$h^v(x) \leq f_y(l_y(x)) = f(l_y(x)y) \leq f(x).$$

Thus,  $h^v(x) \leq f(x)$  for all  $x \in X$ , that is,  $h^v \in \text{supp}(f, H)$ , where

$$\text{supp}(f, H) = \{h \in H: h(x) \leq f(x), \quad \forall x \in X\}.$$

Therefore

$$\begin{aligned} \sup\{h^v(y), v \in V_y\} &\leq \sup\{h(y): h \in \text{supp}(f, H)\} \\ &\leq f(y). \end{aligned} \tag{6}$$

On the other hand, in view of (3), we have

$$\begin{aligned} f(y) = f_y(1) &= \sup_{v \in V_y} (v_1 - v_2) = \sup_{v \in V_y} (v_1 l_y(y) - v_2) \\ &= \sup_{v \in V_y} h^v(y). \end{aligned}$$

Thus,  $f(y) = \sup\{h(y): h \in \text{supp}(f, H)\}$ . We now assume that  $y \in -K$ . By Proposition 4, we have  $f(y) = f(0)$ . It follows from the proof of ([5], Lemma 3.1) that  $v_1 = 0$  for all  $v \in V_y$ . Consider  $v \in V_y$ . We set

$$h^v(x) = -v_2, \quad x \in X.$$

Then

$$\begin{aligned} f(x) = f_x(1) &\geq f(0) = \sup_{v \in V_y} -v_2 \geq h^v(x), \\ &\text{for all } x \in X \end{aligned}$$

and

$$f(y) = f(0) = \sup_{v \in V_y} -v_2 = \sup_{v \in V_y} h^v(y). \tag{7}$$

Hence  $\{h^v: v \in V_y\} \subseteq \text{supp}(f, H)$ , and in view of (6) and (7), we get  $f(y) = \sup\{h(y): h \in \text{supp}(f, H)\}$ . This completes the proof.  $\square$

It follows from ([3], Proposition 3.3) that there exists a bijection  $\psi$  from  $X' \cup \{0\}$  onto  $W$ . Therefore we can identify  $W$  with  $Y = X' \cup \{0\}$  by means of the mapping  $\psi$ .

We define the coupling function  $\varphi: X \times Y \rightarrow \mathbb{R}_{+\infty}$  by

$$\varphi(x, y) = \begin{cases} l_y(x) & y \in X', \\ \mathbf{0} & y = 0. \end{cases} \tag{8}$$

Combining Theorem 1 with Theorem 2, one gets:

**Theorem 3** A function  $f: X \rightarrow \mathbb{R}_{+\infty}$  is ICAR, IAR, and lscAR if and only if  $f = f^{\varphi\varphi'}$ .

### Subdifferentiability of ICAR Functions

Consider the subdifferential  $\partial_W$  of  $f: X \rightarrow \mathbb{R}_{+\infty}$  at point  $x_0 \in \text{dom}f$ :

$$\begin{aligned} \partial_W f(x_0) &= \{h \in W: f(x) \geq f(x_0) + h(x) - h(x_0) \\ &\quad \forall x \in X\}. \end{aligned}$$

We have the following result:

**Proposition 5** Let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be an ICAR and IAR function and  $x_0 \in X'$ . If  $\lambda x_0 \in \text{dom}f$  for some  $\lambda > 1$ , then  $\partial_W f(x_0)$  is nonempty and we have

$$\{\tau l_{x_0}: \tau \in \partial f_{x_0}(1)\} \subseteq \partial_W f(x_0), \tag{9}$$

where  $f_{x_0}(\alpha) = f(\alpha x_0)$ . Moreover, if  $f$  is strictly increasing at point  $x_0$  (i. e.,  $x \in X$ ,  $x \leq x_0$  and  $x \neq x_0$  imply  $f(x) < f_{x_0}$ ) and  $f_{x_0}$  is strictly increasing at point  $\alpha = 1$ , by replacing  $\partial_W$  with  $\partial_{L'}$ , then equality holds in (9).

*Proof 6* Since the increasing convex function  $f_{x_0}$  is continuous at 1, it has a subgradient  $\tau \geq 0$  at this point. Thus

$$\tau t - \tau 1 \leq f_{x_0}(t) - f_{x_0}(1) \quad \text{for all } t \geq 0. \tag{10}$$

Let  $x \in X$  be arbitrary. If  $l_{x_0}(x) = 0$ , then by setting  $t = l_{x_0}(x) = 0$  in (10), we have

$$\tau l_{x_0}(x) - \tau 1 \leq f_{x_0}(0) - f_{x_0}(1).$$

Since  $l_{x_0}(x_0) = 1$  and  $f$  is IAR, we get

$$\tau l_{x_0}(x) - \tau l_{x_0}(x_0) \leq f(x) - f(x_0).$$

Assume now that  $l_{x_0}(x) > 0$ . We have  $l_{x_0}(x)x_0 \leq x$ . In view of the monotonicity of  $f$ , one has

$$\begin{aligned} f(x) &\geq f(l_{x_0}(x)x_0) = f_{x_0}(l_{x_0}(x)) \\ &\geq f_{x_0}(1) + \tau l_{x_0}(x) - \tau. \end{aligned}$$

Thus

$$f(x) - f(x_0) \geq \tau l_{x_0}(x) - \tau l_{x_0}(x_0),$$

which shows that  $\tau l_{x_0} \in \partial_W f(x_0)$ . This implies that  $\partial_W f(x_0) \neq \emptyset$  and we have (9). Now, let  $f_{x_0}$  be strictly increasing at  $\alpha = 1$  and  $f$  be strictly increasing at  $x_0$ . In this case  $\tau$  is different from zero in the left-hand side of (9). Consider  $l \in \partial_{L'} f(x_0)$ . Then there exists  $y \in X'$  such that  $l = l_y$ . We have

$$f(x) - f(x_0) \geq l_y(x) - l_y(x_0), \quad \text{for all } x \in X. \quad (11)$$

We will show that  $l_y(x_0) > 0$ . Reasoning by contradiction, let us assume that  $l_y(x_0) = 0$ . It follows from (11) that  $f_{x_0}(t) - f_{x_0}(1) \geq 0$  for all  $t \geq 0$ . Since  $f_{x_0}$  is strictly increasing at point 1, we get a contradiction. Thus  $l_y(x_0) > 0$ . Since  $l_y(x_0)y \leq x_0$ , one has

$$\begin{aligned} f(x_0) &\geq f(l_y(x_0)y) \geq f(x_0) + l_y(l_y(x_0)y) - l_y(x_0) \\ &= f(x_0) + l_y(x_0)l_y(y) - l_y(x_0), \\ &= f(x_0). \end{aligned}$$

Hence  $f(x_0) = f(l_y(x_0)y)$ . Since  $f$  is strictly increasing at  $x_0$ , we get  $l_y(x_0)y = x_0$  or  $y = x_0/l_y(x_0)$ . Moreover, for all  $t \geq 0$ , by (11), we have

$$\begin{aligned} f_{x_0}(t) = f(tx_0) &\geq f(x_0) + l_y(tx_0) - l_y(x_0), \\ &= f_{x_0}(1) + l_y(x_0)(t - 1), \end{aligned}$$

which shows that  $l_y(x_0) \in \partial f_{x_0}(1)$ . We set  $\tau = l_y(x_0)$ . Then  $l = l_{x_0/\tau} = \tau l_{x_0}$ . This completes the proof.  $\square$

**Proposition 6** *Let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be an ICAR and IAR function. If  $x \in X'$  is a point such that the one-sided derivative  $f'(x, x) = 0$ , then  $x$  is a global minimizer of  $f$  over  $X$ .*

*Proof 7* Since the function  $f_x$  is convex and  $f'_x(1) = f'(x, x) = 0$ , we have  $f_x(1) = \min_{t \in [0, +\infty)} f_x(t)$ . Thus

$f_x(1) \leq f_x(0)$ . On the other hand, since  $f$  is IAR,  $f(x) = f_x(1) \geq f_x(0) = f(0)$ . Hence  $f(x) = f(0) = \min_{x \in X} f(x)$ .  $\square$

Recall that, by ([3], Proposition 3.3), we can identify  $L'$  with  $X'$  by means of the mapping  $\psi'$ . Let us denote by  $\partial_{X'} f(x_0)$  the set  $(\psi')^{-1}(\partial_{L'} f(x_0))$ . Then

$$\begin{aligned} \partial_{X'} f(x_0) &= \{y \in X': l_y(x) - l_y(x_0) \leq f(x) - f(x_0), \forall x \in X\}. \end{aligned}$$

**Proposition 7** *Let  $f: X \rightarrow \mathbb{R}$  be an ICAR and IAR function. Then*

$$\partial_{X'} f(0) = \{y \in X': l_y(x) \leq (f_x)'_+(0), \quad \forall x \in X'\},$$

where  $(f_x)'_+$  is the right derivative of the function  $f_x$  given by  $f_x(\alpha) = f(\alpha x)$ .

*Proof 8* For each  $y \in X'$ , one has

$$\begin{aligned} y \in \partial_{X'} f(0) &\iff l_y(x) - l_y(0) \leq f(x) - f(0), \\ &\quad \forall x \in X \\ &\iff l_y(\alpha x) \leq f_x(\alpha) - f_x(0), \\ &\quad \forall x \in X', \forall \alpha > 0 \\ &\iff l_y(x) \leq \frac{f_x(\alpha) - f_x(0)}{\alpha}, \\ &\quad \forall x \in X', \forall \alpha > 0 \\ &\iff l_y(x) \leq (f_x)'_+(0), \quad \forall x \in X'. \end{aligned}$$

The second of equivalence is a consequence of Proposition 1 and ([3], Remark 2.1).  $\square$

### DCAR Functions

In this section, we shall study decreasing convex-along-rays (DCAR) functions defined on  $X$ . To this end, we introduce the coupling function  $u: X \times X \rightarrow \mathbb{R}$  defined by

$$u(x, y) = \max\{\lambda \in \mathbb{R}: x \leq \lambda y\}.$$

Let  $x, x', y \in X$  be arbitrary and  $\gamma > 0$ . It is easy to check that the function  $u$  has the following properties:

- (1)  $x \leq x' \implies u(x', y) \leq u(x, y)$ ,
- (2)  $u(\gamma x, y) = \gamma u(x, y)$ ,
- (3)  $u(x, y) = +\infty \implies y \in K$ .

We have also  $u(-x, -y) = l(x, y)$ . For each  $y \in X$ , consider the cone

$$Q_y = \{x \in X: 0 \leq u(x, y) \leq +\infty\}.$$

**Lemma 1** Let  $y \in X$  and  $x, x' \in Q_y$ . The following inequality holds:

$$u(x + x', y) \geq u(x, y) + u(x', y). \tag{12}$$

*Proof 9* Let  $A = \{\alpha \in \mathbb{R} : \alpha x \leq y\}$ ,  $B = \{\beta \in \mathbb{R} : \beta x' \leq y\}$  and  $C = \{\gamma \in \mathbb{R} : \gamma(x + x') \leq y\}$ . In view of the transitive property of the relation  $\leq$ , we get  $A + B \subseteq C$  and this yields (12).  $\square$

It follows from the properties of  $u$  and Lemma 1 that  $Q_y$  is a downward convex cone. Fix  $y \in X$ . We define the function  $r_y: X \rightarrow \mathbb{R}_+$  by

$$r_y(x) = \begin{cases} u(x, y) & x \in Q_y, \\ 0 & \text{otherwise.} \end{cases} \tag{13}$$

By the properties of  $u$ , we get  $r_y$  is a decreasing and positively homogenous function of degree one. Let  $y \notin K$  and set  $r = r_y$ . It is not difficult to see that the function  $r^x: \mathbb{R}_+ \rightarrow \mathbb{R}_+$  defined by  $r^x(t) = r(tx)$  is increasing, convex, and continuous. Thus, for each  $y \notin K$ , the function  $r_y$  is DCAR, IAR, and continuous along rays.

*Example 3* Let  $X = \mathbb{R}^n$  and  $K$  be the cone  $\mathbb{R}_+^n$  of all vectors in  $\mathbb{R}^n$  with nonnegative coordinates. Let  $I = \{1, 2, \dots, n\}$ . Each vector  $x \in \mathbb{R}^n$  generates the following sets of indices:

$$\begin{aligned} I_+(x) &= \{i \in I : x_i > 0\}, \\ I_0(x) &= \{i \in I : x_i = 0\}, \\ I_-(x) &= \{i \in I : x_i < 0\}. \end{aligned}$$

Let  $x \in \mathbb{R}^n$  and  $c \in \mathbb{R}$ . Denote by  $\frac{c}{x}$  the vector with coordinates

$$\left(\frac{c}{x}\right)_i = \begin{cases} \frac{c}{x_i}, & i \notin I_0(x), \\ 0, & i \in I_0(x). \end{cases}$$

Then, for each  $x, y \in \mathbb{R}_+^n$ , we have

$$r_y(x) = \begin{cases} \min_{i \in I_-(y)} \frac{x_i}{y_i}, & x \in Q_y, \\ 0, & x \notin Q_y, \end{cases}$$

where

$$Q_y = \left\{ x \in \mathbb{R}^n : I_0(y) \cup I_-(y) \subseteq I_0(x) \cup I_-(x); \max_{i \in I_+(y)} \frac{x_i}{y_i} \leq \min_{i \in I_-(y)} \frac{x_i}{y_i} \right\}.$$

*Example 4* Consider the function  $g: \mathbb{R}^n \rightarrow \mathbb{R}$  defined by

$$g(x) = \begin{cases} -\min_{1 \leq i \leq n} x_i & x \notin \mathbb{R}_+^n, \\ 0 & \text{otherwise.} \end{cases}$$

It is easy to check that  $g$  is DCAR and IAR.

Now, let

$$U = \{r_y : y \in (X \setminus K)\} \cup \{0\}$$

and

$$H_U = \{h - \gamma : h \in U, \gamma \in \mathbb{R}\}.$$

It is clear that each  $H_U$ -convex function is DCAR, IAR, and *lscAR*. The proof of the following theorem is similar to that of Theorem 2, and therefore we omit its proof.

**Theorem 4** Let  $f: X \rightarrow \mathbb{R}_{+\infty}$  be a DCAR, IAR, and *lscAR* function. Then  $f$  is  $H_U$ -convex.

**Corollary 1** The function  $f: X \rightarrow \mathbb{R}_{+\infty}$  is  $H_U$ -convex if and only if it is DCAR, IAR, and *lscAR*.

**Introduction**

We study IPH (increasing and positively homogeneous of degree one) functions defined on a topological vector space  $X$  that is equipped with a closed convex pointed cone  $K$  (see [7]). The theory of IPH functions defined on a closed convex cone  $K$  in a topological vector space  $X$  is well developed [2]. There are two main results of this theory, which have a central role. First, each IPH function  $p$  defined on  $K$  can be represented as the Minkowski gauge of a normal closed along rays (Definitions 1 and 2) subset  $U$  of  $K$ , namely,  $U = \{x \in K : p(x) \leq 1\}$ . Conversely, the Minkowski gauge of a normal closed along rays set is an IPH function. The second result is based on ideas of abstract convexity: each IPH function defined on  $K$  can be represented as the upper envelope of a set of so-called min-type functions. This result can be considered as a certain form of a dual representation of IPH functions. IPH functions can be useful for the description of radiant and coradiant downward sets and, through them, can have applications to the study of some NTU games arising in mathematical economics [1,13] and to the analysis of topical functions, which are used in the analysis of discrete event systems [3,4,5]. Some of the results related to monotonic analysis on the space  $\mathbb{R}^n$  with respect to the coordinatewise order relation can be found in [5,6,10,11]. IPH functions defined on  $\mathbb{R}^n$  are examined in [5]. Nevertheless, as it turned out, the main results from [5] can be extended for arbitrary topological vector spaces. Such extension is one of the main topics of this article. The study of some problems in a more general framework clarifies and simplifies the main ideas and approaches. The results obtained can

be used, for example, in the study of vector optimization problems.

Let  $X$  be a topological vector space. We assume that  $X$  is equipped with a closed convex pointed cone  $K$  (the latter means that  $K \cap (-K) = \{0\}$ ). The increasing property of our functions will be understood to be with respect to the ordering  $\leq$  induced on  $X$  by  $K$ :

$$x \leq y \iff y - x \in K.$$

We use the following notations:

$$\mathbb{R} = (-\infty, +\infty),$$

$$\bar{\mathbb{R}} = \mathbb{R} \cup \{-\infty\} \cup \{+\infty\},$$

$$\mathbb{R}_{+\infty} = (-\infty, +\infty],$$

$$\mathbb{R}_+ = [0, +\infty),$$

$$\bar{\mathbb{R}}_+ = [0, +\infty],$$

$$\mathbb{R}_- = (-\infty, 0],$$

$$\bar{\mathbb{R}}_- = [-\infty, 0].$$

We accept the following conventions:

$$\frac{1}{0} = \infty, \quad \frac{1}{\infty} = 0. \tag{1}$$

A function  $p: X \rightarrow \bar{\mathbb{R}}$  is called positively homogeneous if  $p(\lambda x) = \lambda p(x)$  for all  $x \in X$  and  $\lambda \geq 0$ . Function  $p$  is called increasing if  $x \geq y \implies p(x) \geq p(y)$ . We shall study IPH (increasing and positively homogeneous of degree one) functions  $p$  such that  $0 \in \text{dom } p := \{x \in X : -\infty < p(x) < +\infty\}$ , and hence we have  $p(0) = 0$ .

The following definitions can be found in [9].

**Definition 1** A nonempty subset  $W$  of  $X$  is called closed along rays if  $(x \in W, \lambda_n > 0, \lambda_n x \in W, n = 1, 2, \dots, \lambda_n \rightarrow \lambda, \lambda > 0) \implies \lambda x \in W$ .

**Definition 2** A nonempty subset  $A$  of  $K$  is called normal if  $x \in A, x' \in K$  and  $x' \leq x$  imply  $x' \in A$ .

**Definition 3** A nonempty subset  $B$  of  $K$  is called conormal if  $x \in B, x' \in K$  and  $x \leq x'$  imply  $x' \in B$ .

A normal subset  $A$  of  $K$  is radiant, that is,  $x \in A$  and  $0 < \lambda < 1$  imply  $\lambda x \in A$ . A conormal subset  $B$  of  $K$  is coradiant, that is,  $x \in B$  and  $\lambda > 1$  imply  $\lambda x \in B$ . A set  $W \subseteq X$  is called downward if  $(x \in W, x' \leq x) \implies x' \in W$ . (In particular, the empty set is downward). Similarly, a set  $V \subseteq X$  is called

upward if  $(x' \in V, x' \leq x) \implies x \in V$ . Let  $W \subseteq X$  be a radiant set. The Minkowski gauge  $\mu_W: X \rightarrow \mathbb{R}_+$  of this set is defined by

$$\mu_W(x) = \inf\{\lambda > 0: \frac{x}{\lambda} \in W\}. \tag{2}$$

The Minkowski cogauge  $\nu_V: X \rightarrow \mathbb{R}_+$  of a coradiant set  $V \subseteq X$  is defined by

$$\nu_V(x) = \sup\{\lambda > 0: \frac{x}{\lambda} \in V\}. \tag{3}$$

It is easy to check that the Minkowski gauge of a downward set and the Minkowski cogauge of an upward set are IPH.

Consider the function  $l: K \times K \rightarrow \mathbb{R}_+$  defined by

$$l(x, y) = \max\{\lambda \in \mathbb{R}_+: \lambda y \leq x\}.$$

This function is introduced and examined in [2]. To motivate our study, we characterize the IPH functions defined on  $K$ .

**Theorem 1 ([2], Theorem 16)** *Let  $p: K \rightarrow \mathbb{R}_+$  be a function. Then  $p$  is IPH if and only if  $p(x) \geq l(x, y)p(y)$  for all  $x, y \in K$ , with the convention  $(+\infty) \times 0 = 0$ .*

**Characterizations of Nonnegative IPH Functions**

Carrying forward the motivation from Theorem 1, we shall now proceed to develop a similar type of property for IPH functions  $p: X \rightarrow \mathbb{R}_+$ . To achieve this, we need to introduce the coupling function  $l: X \times X \rightarrow \mathbb{R}_+$  defined by

$$l(x, y) := \max\{\lambda \geq 0: \lambda y \leq x\} \tag{4}$$

(we use the conventions  $\max \emptyset := 0$  and  $\max \mathbb{R}_+ := +\infty$ ). The next proposition gives some properties of the coupling function  $l$ .

**Proposition 1** *For every  $x, x', y \in X$  and  $\gamma > 0$ , one has*

$$l(\gamma x, y) = \gamma l(x, y), \tag{5}$$

$$l(x, \gamma y) = \frac{1}{\gamma} l(x, y), \tag{6}$$

$$l(x, y) = +\infty \implies y \in -K, \tag{7}$$

$$l(x, x) = 1 \iff x \notin -K, \tag{8}$$

$$x \in K, y \in -K \implies l(x, y) = +\infty, \tag{9}$$

$$x \leq x' \implies l(x, y) \leq l(x', y), \tag{10}$$

$$y \leq y' \implies l(x, y) \geq l(x, y'). \tag{11}$$

*Proof* We only prove parts (7) and (10). Let  $l(x, y) = +\infty$  for some  $x, y \in X$ . By (4) there exists a sequence  $\{\lambda_n\}_{n \geq 1}$  such that  $\lambda_n \rightarrow +\infty$  and  $y \leq 1/\lambda_n x$  for all  $n \geq 1$ . Since  $K$  is a closed cone, we get  $y \leq 0$ . This proves (7). To prove (10), let  $x \leq x', \Lambda_{x,y} = \{\lambda \geq 0: \lambda y \leq x\}$  and  $\Lambda_{x',y} = \{\gamma \geq 0: \gamma y \leq x'\}$ . It is clear that  $\Lambda_{x,y} \subseteq \Lambda_{x',y}$  (notice that if  $\Lambda_{x',y} = \emptyset$ , then  $\Lambda_{x,y} = \emptyset$ ). Hence  $l(x, y) \leq l(x', y)$ .  $\square$

*Example 1* Let  $X = \mathbb{R}^n$  and  $K$  be the cone  $\mathbb{R}_+^n$  of all vectors in  $\mathbb{R}^n$  with nonnegative coordinates. Let  $I = \{1, 2, \dots, n\}$ . Each vector  $x \in \mathbb{R}^n$  generates the following sets of indices:

$$I_+(x) = \{i \in I: x_i > 0\},$$

$$I_0(x) = \{i \in I: x_i = 0\}, \quad I_-(x) = \{i \in I: x_i < 0\}.$$

Let  $x \in \mathbb{R}^n$  and  $c \in \mathbb{R}$ . Denote by  $c/x$  the vector with coordinates

$$\left(\frac{c}{x}\right)_i = \begin{cases} \frac{c}{x_i}, & i \notin I_0(x), \\ 0, & i \in I_0(x). \end{cases}$$

Then, for each  $x, y \in \mathbb{R}^n$ , we have

$$l(x, y) = \begin{cases} \min_{i \in I_+(y)} \frac{x_i}{y_i}, & x \in K_y^+, \\ 0, & x \notin K_y^+, \end{cases}$$

where

$$K_y^+ = \{x \in \mathbb{R}^n: \forall i \in I_+(y) \cup I_0(y), x_i \geq 0; \max_{i \in I_+(y)} \frac{x_i}{y_i} \leq \min_{i \in I_-(y)} \frac{x_i}{y_i}\}.$$

We also need to introduce the coupling function  $u: X \times X \rightarrow \mathbb{R}_+$  defined by

$$u(x, y) := \min\{\mu \geq 0: x \leq \mu y\} \tag{12}$$

(with the convention  $\min \emptyset := +\infty$ ).

The following proposition gives some properties of the coupling function  $u$ .

**Proposition 2** For every  $x, x', y \in X$  and  $\gamma > 0$ , one has

$$u(\gamma x, y) = \gamma u(x, y), \tag{13}$$

$$u(x, \gamma y) = \frac{1}{\gamma} u(x, y), \tag{14}$$

$$u(x, y) = 0 \iff x \in -K, \tag{15}$$

$$u(x, x) = 1 \iff x \notin -K, \tag{16}$$

$$x \leq x' \implies u(x, y) \leq u(x', y), \tag{17}$$

$$y \leq y' \implies u(x, y) \geq u(x, y'). \tag{18}$$

*Example 2* Let  $X = \mathbb{R}^n$  and  $K$  be the cone  $\mathbb{R}_+^n$  of all vectors in  $\mathbb{R}^n$  with nonnegative coordinates. Then, for each  $x, y \in \mathbb{R}^n$ , we have

$$u(x, y) = \begin{cases} \max_{i \in I_+(y)} \frac{x_i}{y_i}, & x \in c_y^+, \\ 0, & x \notin c_y^+, \end{cases}$$

where

$$c_y^+ = \{x \in \mathbb{R}^n : \exists i \in I_+(y) \text{ s.t. } x_i \geq 0 \text{ and } \forall i \in I_-(y) \cup I_0(y), x_i \leq 0\}.$$

**Theorem 2** Let  $p: X \rightarrow \bar{\mathbb{R}}_+$  be a function. Then the following assertions are equivalent:

- (i)  $p$  is IPH.
- (ii)  $p(x) \geq \lambda p(y)$  for all  $x, y \in X$ , and  $\lambda > 0$  such that  $\lambda y \leq x$ .
- (iii)  $p(x) \geq l(x, y)p(y)$  for all  $x, y \in X$ , with the convention  $(+\infty) \times 0 = 0$ .
- (iv)  $p(x) \leq u(x, y)p(y)$  for all  $x, y \in X$ , with the convention  $(+\infty) \times 0 = +\infty$ .

*Proof* It is clear that (i) implies (ii). To prove the implication (ii)  $\rightarrow$  (iii), notice first that, due to (7),  $l(x, y) = +\infty$  implies that  $y \in -K$  and so  $p(y) = 0$ . Then, by the convention  $(+\infty) \times 0 = 0$ , we have  $p(x) \geq l(x, y)p(y)$ . If  $l(x, y) = 0$ , then, by the nonnegativity of  $p$ , we get  $p(x) \geq l(x, y)p(y)$ . Finally, let  $0 < l(x, y) < +\infty$ . Then in view of (4) and the closedness of  $K$ , we have  $x \geq l(x, y)y$ , and so (ii) implies

(iii). We shall now prove the implication (iii)  $\rightarrow$  (i). Consider  $x, y \in X$  such that  $y \leq x$ . By (4) we get  $l(x, y) \geq 1$ . Then (iii) yields that  $p(x) \geq p(y)$ . Hence  $p$  is increasing. Let  $x \in X, \lambda > 0$  and  $l(x, \lambda x) = +\infty$ . It follows from (6) and (7) that  $x, \lambda x \in -K$ . Since  $p$  is increasing, we get  $\lambda p(x) = p(\lambda x) = 0$ . Let  $x \notin -K$  and set  $y = \lambda x$ . Then, by (6) and (8), we have  $l(x, \lambda x) = 1/\lambda$ . Thus  $p(x) \geq 1/\lambda p(\lambda x)$ , and so  $\lambda p(x) \geq p(\lambda x)$ . By replacing  $\lambda$  with  $1/\lambda$  and  $x$  with  $\lambda x$ , we obtain  $p(\lambda x) \geq \lambda p(x)$ . This proves that  $p$  is positively homogeneous. We next prove the implication (i)  $\rightarrow$  (iv). Let  $u(x, y) = 0$ . By (15) we get  $x \leq 0$ . Then  $p(x) = 0$ , and so  $p(x) \leq u(x, y)p(y)$ . If  $u(x, y) = +\infty$ , then, in view of the convention  $(+\infty) \times 0 = +\infty$ , we have  $p(x) \leq u(x, y)p(y)$ . We now assume that  $0 < u(x, y) < +\infty$ . Then, in view of (12) and the closedness of  $K$ , we get  $x \leq u(x, y)y$ . Hence  $p(x) \leq u(x, y)p(y)$ . Finally, the proof of the implication (iv)  $\rightarrow$  (i) can be done in a manner analogous to that of the implication (iii)  $\rightarrow$  (i).  $\square$

We shall now describe a class of elementary functions with respect to which the IPH functions are supremally generated. Given  $y \in X$ , let us set  $l_y(x) := l(x, y)$  for all  $x \in X$ . Thus, by (4),

$$l_y(x) = \max\{\lambda \geq 0 : \lambda y \leq x\}, \quad \forall x \in X. \tag{19}$$

*Remark 1* The function  $l_y: X \rightarrow \bar{\mathbb{R}}_+$  is an IPH function for each  $y \in X$ . It obviously follows from (5) and (10).

Let  $L$  be the set of all supremally generating elementary functions, defined by (19), that is,

$$L := \{l_y : y \in X\}. \tag{20}$$

Consider the mapping  $\psi: X \rightarrow L$  defined by

$$\psi(y) = l_y, \quad y \in X.$$

We have the following proposition:

**Proposition 3** The mapping  $\psi: X \rightarrow L$  is onto. Moreover, it is antitone:

$$y_1 \leq y_2 \implies l_{y_2} \leq l_{y_1} \tag{21}$$

and antihomogeneous (positively homogeneous of degree  $-1$ ):

$$l_{\lambda y} = \lambda^{-1} l_y \quad \forall y \in X, \quad \forall \lambda > 0. \tag{22}$$

*Proof* By the definition of  $L$ ,  $\psi$  is obviously onto. Implications (21) and (22) follow from (11) and (6), respectively.  $\square$

The following example shows that the mapping  $\psi$  is not one-to-one.

*Example 3* Let  $X = \mathbb{R}^2$  and  $K = \mathbb{R}_+^2$ . Consider the distinct points  $y_1 = (a, b)$  and  $y_2 = (c, d)$ , where  $a, b, c$  and  $d$  are negative numbers. By the results obtained in Example 1, we have  $K_{y_1}^+ = K_{y_2}^+ = X$ . Since  $I_+(y_1) = I_+(y_2) = \emptyset$ , it follows that  $l_{y_1}(x) = l_{y_2}(x) = +\infty$  for every  $x \in X$ . Thus,  $l_{y_1} = l_{y_2}$ .

Let  $X' = X \setminus (-K)$  and  $L' = \{l_y : y \in X'\}$ . We can get:

**Proposition 4** *The mapping  $\psi' = \psi|_{X'}$  is a bijection from  $X'$  onto  $L'$ , where  $\psi|_{X'}$  is the restriction of  $\psi$  to  $X'$ .*

*Proof* Since, by the definition of  $L'$ ,  $\psi'$  is obviously onto, we only have to prove that  $\psi'$  is one-to-one. To this aim, assume that  $y_1, y_2 \in X'$  are such that  $l_{y_1} = l_{y_2}$ . By (8), we have  $1 = l(y_1, y_1) = l(y_1, y_2)$ . Hence, by (4), we get  $y_2 \leq y_1$ . By symmetry it follows that  $y_1 \leq y_2$ . Since  $K$  is pointed, we conclude that  $y_1 = y_2$ .  $\square$

Recall (see [8]) that a function  $p : X \rightarrow \mathbb{R}_+$  is called abstract convex with respect to the set  $L$  or  $L$ -convex if and only if there exists a set  $W \subseteq L$  such that  $p(x) = \sup_{l \in W} l(x)$ . If  $W \subseteq L'$ , then using  $\psi'$  we can identify  $W$  with some subset of  $X$ . In terms of  $X$ ,  $p$  is  $L'$ -convex if there exists a subset  $Y \subseteq X'$  such that  $p(x) = \sup_{y \in Y} l_y(x)$ . It follows from Remark 1 that  $L$  consists of nonnegative IPH functions, hence each  $L$ -convex function is IPH.

**Theorem 3** *Let  $p : X \rightarrow \mathbb{R}_+$  be a function and  $L$  be the set described by Eq. (20). Then  $p$  is IPH if and only if there exists a set  $Y \subseteq X$  such that*

$$p(x) = \max_{y \in Y} l_y(x) \quad \forall x \in X$$

(with the convention  $\max \emptyset := 0$ ). In this case, one can take  $Y = \{y \in X : p(y) \geq 1\}$ . Hence,  $p : X \rightarrow \mathbb{R}_+$  is IPH if and only if it is  $L$ -convex.

*Proof* We shall only show that every IPH function  $p : X \rightarrow \mathbb{R}_+$  satisfies  $p(x) = \max_{y \in Y} l_y(x)$ , for all  $x \in X$ , with

$$Y = \{y \in X : p(y) \geq 1\}.$$

It is clear that  $Y \cap (-K) = \emptyset$ . For any  $x, y \in X$  with  $p(y) \geq 1$ , it follows from Theorem 2 that  $p(x) \geq l_y(x)$ . This means that  $p \geq l_y$  for all  $y \in Y$ , and so  $p \geq \max_{y \in Y} l_y$ . If  $p(x) = 0$ , then, by nonnegativity of the function  $l_y$ , we have  $\max_{y \in Y} l_y(x) = 0 = p(x)$ . Assume now that  $0 < p(x) < +\infty$ . Since  $p(x/p(x)) = 1$ , we get  $x/p(x) \in Y$ . Moreover, it follows from (6) that  $p(x) = l(x, x/p(x))$ . Therefore,  $p(x) = \max_{y \in Y} l_y(x)$ . Finally, suppose that  $p(x) = +\infty$ . It follows from the positive homogeneity of  $p$  that  $(1/\lambda)x \in Y$  for all  $\lambda > 0$ . Then,  $\max_{y \in Y} l_y(x) \geq l_{(1/\lambda)x}(x) = \lambda$  for all  $\lambda > 0$ . This means that  $\max_{y \in Y} l_y(x) = +\infty = p(x)$ . This completes the proof.  $\square$

The IPH functions are also infimally generated by the elementary functions  $u_y : X \rightarrow \mathbb{R}_+$ ,  $y \in X$ , defined by

$$u_y(x) := u(x, y) = \min\{\mu \geq 0 : x \leq \mu y\}, \quad \forall x \in X.$$

In view of (13) and (17), it is clear that the function  $u_y$  is IPH. Set

$$U := \{u_y : y \in X\}. \tag{23}$$

We define the mapping  $\varphi : X \rightarrow \mathbb{R}_+$  by

$$\varphi(y) := u_y, \quad y \in X.$$

We omit the proof of the following results, which are similar to those of Propositions 3 and 4.

**Proposition 5** *The mapping  $\varphi : X \rightarrow U$  is onto. Moreover, it is antitone and antihomogeneous (positively homogeneous of degree -1).*

Let  $U' = \{u_y : y \in X'\}$ . We can get:

**Proposition 6** *The mapping  $\varphi' = \varphi|_{X'}$  is a bijection from  $X'$  onto  $U'$ , where  $\varphi|_{X'}$  is the restriction of  $\varphi$  to  $X'$ .*

A function  $p : X \rightarrow \mathbb{R}_+$  is called abstract concave with respect to the set  $U$ , or  $U$ -concave, if there exists a set  $W \subseteq U$  such that  $p(x) = \inf_{u \in W} u(x)$ . Since  $U$  consists of nonnegative IPH functions, we get each  $U$ -concave function is IPH.

The proof of the following theorem can be done in a manner analogous to the one of Theorem 3.

**Theorem 4** *Let  $p : X \rightarrow \mathbb{R}_+$  be a function and  $U$  be the set described by (23). Then  $p$  is IPH if and only if*

there exists a set  $W \subseteq U$  such that

$$p(x) = \min_{u_y \in W} u_y(x) \quad \forall x \in X.$$

In this case, one can take  $W = \{u_y : y \in X, p(y) \leq 1\}$ . Hence  $p : X \rightarrow \mathbb{R}_+$  is IPH if and only if it is  $U$ -concave.

**Abstract Convexity of Nonnegative IPH Functions**

We are now going to develop an abstract convexity (resp. abstract concavity) approach to IPH functions. The set  $L$  (resp.  $U$ ) will play the role of the conjugate space in the usual linear model, while IPH functions will be regarded as analogous to sublinear functions. The well-known dual object related to a sublinear function is the so-called polar function (see, for example, [12,14]). We now give an analog of this concept for IPH functions and define also a related notion of polar set of a set  $W \subset X$ .

**Definition 4** The lower polar function of  $p : X \rightarrow \mathbb{R}_+$  is the function  $p^0 : L \rightarrow \mathbb{R}_+$  defined by

$$p^0(l_y) = \sup_{x \in X} \frac{l_y(x)}{p(x)}, \quad l_y \in L \tag{24}$$

(with the conventions  $0/0 = 0$  and  $\infty/\infty = 0$ ).

**Theorem 5** Let  $p : X \rightarrow \mathbb{R}_+$  be a function. Then

$$p^0(l_y) \geq \frac{1}{p(y)} \quad \forall l_y \in L, \tag{25}$$

and  $p$  is IPH if and only if

$$p^0(l_y) = \frac{1}{p(y)} \quad \forall l_y \in L. \tag{26}$$

*Proof* By (8), (9), and (24) we have  $p^0(l_y) \geq l_y(y)/p(y) \geq 1/p(y)$  for every  $y \in X$ . Let  $p$  be an IPH function and  $x, y \in X$  be arbitrary. Suppose that  $0 < p(x) < +\infty$  and  $0 < p(y) < +\infty$ . It follows from Theorem 2 that

$$\frac{l_y(x)}{p(x)} \leq \frac{1}{p(y)}. \tag{27}$$

If  $p(x) = 0$ , then, by part (iii) of Theorem 2, we have  $l_y(x) = 0$  or  $p(y) = 0$ , which in both cases (27) holds. In view of (1), (27) holds in the other cases.

Therefore,  $p^0(l_y) = \sup_{x \in X} l_y(x)/p(x) \leq 1/p(y)$ . This, together with (25), yields that  $p^0(l_y) = 1/p(y)$ . To prove the converse, let  $x, y \in X$  be arbitrary. It follows from (26) that  $l_y(x)/p(x) \leq 1/p(y)$ . Thus,  $l_y(x)p(y) \leq p(x)$ . Since  $x$  and  $y$  are arbitrary, by Theorem 2 (the implication (iii)  $\implies$  (i)), we conclude that  $p$  is IPH.  $\square$

The set  $\text{supp}(p, L) = \{l_y \in L : l_y(x) \leq p(x) \quad \forall x \in X\}$  is called the support set of the function  $p : X \rightarrow \mathbb{R}_+$  with respect to set  $L$ . If  $p$  is finite-valued or IPH, then, in view of (9), we get  $\text{supp}(p, L) \subseteq L'$ , and using  $\psi'$  we can identify  $\text{supp}(p, L)$  with some subset of  $X$ . Let us denote by  $\text{supp}(p, X)$  the set  $(\psi')^{-1}(\text{supp}(p, L))$ . Then

$$\text{supp}(p, X) = \{y \in X : l_y \leq p\}.$$

We shall call  $\text{supp}(p, X)$  the  $X$ -support of  $p$ .

**Proposition 7** Let  $p : X \rightarrow \mathbb{R}_+$  be a function. Then,  $p$  is IPH if and only if

$$\text{supp}(p, X) = \{y \in X : p(y) \geq 1\}. \tag{28}$$

*Proof* Let  $p$  be an IPH function. We have

$$\begin{aligned} \text{supp}(p, X) &= \{y \in X : l_y(x) \leq p(x) \quad \forall x \in X\} \\ &= \{y \in X : p^0(l_y) \leq 1\}. \end{aligned}$$

Then (26) immediately yields (28). To prove the converse, let  $x, y \in X$  be arbitrary. If  $p(y) = 0$ , then it is clear that  $p(y)l_y(x) \leq p(x)$ . Let  $0 < p(y) < +\infty$ . Then, by hypothesis, we have  $r = y/p(y) \in \text{supp}(p, X)$ . Thus  $l_r(x) \leq p(x)$ , and by (6) we get  $l_y(x)p(y) \leq p(x)$ . Finally, let  $p(y) = +\infty$ . By (28),  $y \in \text{supp}(p, X)$ . Thus,  $l_y(x) \leq p(x)$ . If  $p(x) = 0$ , then the nonnegativity of  $l_y$  yields that  $l_y(x) = 0$ , and so  $l_y(x)p(y) \leq p(x)$ . Clearly the latter inequality holds for  $p(x) = +\infty$ . Let  $0 < p(x) < +\infty$ . Then  $r = x/p(x) \in \text{supp}(p, X)$ . Therefore,  $l_r(y) \leq p(y)$  and by (6),  $p(x)l_x(y) \leq p(y)$ . Hence, by Theorem 2,  $p$  is IPH, which completes the proof.  $\square$

**Proposition 8** For any set  $W \subseteq X$ , the following assertions are equivalent:

- (i)  $W$  is upward, coradial and closed along rays.
- (ii) There exists an IPH function  $p : X \rightarrow \mathbb{R}_+$  such that  $\text{supp}(p, X) = W$ . Furthermore, function  $p$  of (ii) is unique, namely,  $p$  is the Minkowski cogauge  $v_W$  of  $W$ .

*Proof* (i)  $\implies$  (ii). Let  $p = v_W$ . It is clear that  $p$  is positively homogeneous. Moreover, since  $W$  is upward,  $p$  is increasing. By [9, Proposition 5.6], since  $W$  is closed along rays and coradiant, one has

$$W = \{y \in X : p(y) \geq 1\}. \tag{29}$$

Whence in view of (28),  $W = \text{supp}(p, X)$ .

(ii)  $\implies$  (i). Let  $W = \text{supp}(p, X)$  for an IPH function  $p : X \longrightarrow \mathbb{R}_+$ . By (28)  $W$  is coradiant, upward, and closed along rays. Finally, the uniqueness of  $p$  in (ii) follows from the following equalities, the last one of which uses the convention  $\sup \emptyset = 0$  and is a consequence of (29):

$$\begin{aligned} p(y) &= \sup\{\lambda > 0 : \lambda \leq p(y)\} \\ &= \sup\left\{\lambda > 0 : 1 \leq p\left(\frac{y}{\lambda}\right)\right\} \\ &= \sup\left\{\lambda > 0 : \frac{y}{\lambda} \in W\right\} \\ &= v_W(y). \end{aligned}$$

This completes the proof. □

For a function  $p : X \longrightarrow \mathbb{R}_+$ , the  $L$ -subdifferential at a point  $x_0 \in X$  is defined as follows:

$$\partial_L p(x_0) = \{l_y \in L : p(x) - p(x_0) \geq l_y(x) - l_y(x_0)\}.$$

If  $\partial_L p(x_0) \subseteq L'$ , then the set  $\partial_X p(x_0) = (\psi')^{-1}(\partial_L p(x_0))$  will be called  $X$ -subdifferential of  $p$  at  $x_0$  (note that  $\partial_X p(x_0) \subseteq X'$ ). Thus

$$\partial_X p(x_0) = \{y \in X : p(x) - p(x_0) \geq l_y(x) - l_y(x_0)\}. \tag{30}$$

The following simple statement will be useful in the sequel.

**Proposition 9** *Let  $p : X \longrightarrow \mathbb{R}$  be an IPH function and  $x \in \text{dom } p$  be a point such that  $p(x) \neq 0$ . Then,  $r = x/p(x) \notin -K$ .*

*Proof* Let  $p(x) > 0$ . Then  $p(r) = 1 > 0$ . Since  $p$  is an IPH function, we get  $r \notin -K$ . If  $p(x) < 0$ , then  $p(-r) = -1$ . Then, in view of the monotonicity of  $p$ , we get  $-r \notin K$  or  $r \notin -K$ . This completes the proof. □

**Theorem 6** *Let  $p : X \longrightarrow \mathbb{R}_+$  be an IPH function and  $x \in \text{dom } p$  be a point such that  $p(x) \neq 0$ . Let  $r = x/p(x)$ . Then  $l_r \in \partial_L p(x)$ , and hence  $\partial_L p(x)$  is nonempty.*

*Proof* It follows from Proposition 9 and (7) that  $r \notin -K$  and  $l(y, r) < +\infty$  for all  $y \in X$ . Clearly  $p(x) \in \{\lambda \geq 0 : \lambda r \leq x\}$ . Then, by the definition of  $l$ , we have  $l(x, r) \geq p(x) > 0$ . We shall now show that  $l_r(y) \leq p(y)$  for any  $y \in X$ . To this end, let  $y \in X$  be arbitrary. If  $l(y, r) = 0$ , then  $l_r(y) \leq p(y)$ . Let  $0 < l(y, r) < +\infty$ . We have  $l(y, r)r \leq y$ . Since  $p$  is IPH, we get  $l(y, r)p(r) \leq p(y)$ . Because of  $p(r) = 1$ , we get  $l_r(y) \leq p(y)$ . Since  $y \in X$  was arbitrary, we conclude that  $l_r(x) = p(x)$  and  $l_r(y) \leq p(y)$  for all  $y \in X$ . This yields that  $l_r \in \partial_L p(x)$ . □

*Remark 2* Let  $\text{int } K \neq \emptyset$ . Consider nonzero IPH function  $p : X \longrightarrow \mathbb{R}_+$  and  $x \in X$  such that  $p(x) = 0$ . We can show  $\partial_L p(x) \neq \emptyset$ . Indeed, since  $p \neq 0$ , there exists  $r \in \text{int } K$  such that  $p(r) > 0$  (see [2], Proposition 6). Set  $r' = r/p(r)$ . It is clear that  $p(r') = 1$ , and so, by (28),  $r' \in \text{supp}(p, X)$ , that is,  $l_{r'}(t) \leq p(t)$  for all  $t \in X$ . It follows from the nonnegativity of  $l_{r'}$  that  $l_{r'}(x) = p(x) = 0$ . Hence,  $l_{r'} \in \partial_L p(x)$ .

We next define the upper polar function  $p_0 : U \longrightarrow \mathbb{R}_+$  of the function  $p : X \longrightarrow \mathbb{R}_+$  by

$$p_0(u_y) = \inf_{x \in X} \frac{u_y(x)}{p(x)}, \quad u_y \in U \tag{31}$$

(with the conventions  $0/0 = +\infty$  and  $+\infty/+\infty = +\infty$ ).

The proof of the following result can be done in a manner analogous to that of Theorem 5.

**Theorem 7** *Let  $p : X \longrightarrow \mathbb{R}_+$  be a function. Then*

$$p_0(u_y) \leq \frac{1}{p(y)}, \quad \forall u_y \in U, \tag{32}$$

and  $p$  is IPH if and only if

$$p_0(u_y) = \frac{1}{p(y)}, \quad \forall u_y \in U. \tag{33}$$

We shall now study the structure of support sets from above, which are characterized by the elementary functions  $u_y$  rather than by the functions  $l_y$  (which characterize support sets from below). We shall denote the support set from above, or upper support set, of the function  $p : X \longrightarrow \mathbb{R}_+$  with respect to set  $U$  as

$$\text{Supp}^+(p, U) = \{u_y \in U : u_y \geq p\}.$$

In what follows, we state the counterpart of Proposition 7 for the support set from above.

**Proposition 10** *Let  $p : X \rightarrow \mathbb{R}_+$  be a function. Then*

$$\text{Supp}^+(p, U) = \{u_y \in U : p_0(u_y) \geq 1\}. \tag{34}$$

Furthermore,  $p$  is IPH if and only if

$$\text{Supp}^+(p, U) = \{u_y \in U : p(y) \leq 1\}. \tag{35}$$

*Proof* Equality (34) follows easily from the definitions of  $\text{Supp}^+(p, U)$  and  $p_0$ . Furthermore, if  $p$  is IPH, then (35) follows from (33) and (34). To prove the converse, let  $x, y \in X$  be arbitrary. If  $0 < p(y) < +\infty$ , then  $u_{y/p(y)} \in \text{Supp}^+(p, U)$ . Thus,  $u_{y/p(y)}(x) \geq p(x)$ . By (14) we get  $p(y)u(x, y) \geq p(x)$ . If  $p(y) = +\infty$ , we have  $p(x) \leq u(x, y)p(y)$  (here we use the convention  $(+\infty) \times 0 = +\infty$ ). Finally, let  $p(y) = 0$ . It is clear that  $u_y \in \text{Supp}^+(p, U)$ . Thus,  $u_y(x) \geq p(x)$ . If  $u_y(x) = 0$ , then, in view of the nonnegativity of  $p$ , we get  $p(x) = 0$ , and so  $p(x) \leq u(x, y)p(y)$ . Now, suppose that  $0 < u_y(x) < +\infty$ . It follows from  $p(\lambda y) = 0$  for all  $\lambda > 0$  that  $u_{\lambda y} \in \text{Supp}^+(p, U)$  for all  $\lambda > 0$ , and in view of (14), we get  $(1/\lambda)u_y(x) = u_{\lambda y}(x) \geq p(x)$  for all  $\lambda > 0$ . This means that  $p(x) = 0$ . Therefore,  $p(x) \leq u(x, y)p(y)$ . Hence, by Theorem 2 (implication (iv)  $\implies$  (i)),  $p$  is IPH.  $\square$

For the function  $p : X \rightarrow \mathbb{R}_+$ , in a manner analogous to the case of  $L$ -subdifferential, we now define the  $U$ -superdifferential of  $p$  at  $x_0$  as follows:

$$\partial_U^+ p(x_0) := \{u_y \in U : u_y(x) - u_y(x_0) \geq p(x) - p(x_0)\}.$$

One can prove the following result for  $U$ -superdifferential in a manner analogous to the proof of Theorem 6, and therefore we omit its proof.

**Theorem 8** *Let  $p : X \rightarrow \mathbb{R}_+$  be an IPH function and  $x \in \text{dom } p$  be a point such that  $p(x) \neq 0$ . Let  $r = x/p(x)$ . Then  $u_r \in \partial_U^+ p(x)$ .*

**Definition 5** Let  $U \subseteq X$ . Then the left polar set of  $W$  is defined by

$$W^{ol} = \{x \in X : l(x, y) \leq 1 \quad \forall y \in W\}.$$

Analogously, we define the right polar set of  $V \subseteq X$ .

**Definition 6** Let  $V \subseteq X$ . Then the right polar set of  $V$  is defined by

$$V^{or} = \{y \in X : l(x, y) \leq 1 \quad \forall x \in V\}.$$

In the following theorem, we assume that  $\text{int } K \neq \emptyset$ .

**Theorem 9** *Let  $W, V \subseteq X$  and  $V \cap \text{int } K \neq \emptyset$ . Then the following assertions are true:*

- (i) *One has  $W = W^{olor}$  if and only if  $W$  is upward, coradiant and closed along rays.*
- (ii) *One has  $V = V^{orol}$  if and only if  $V$  is downward, radiant, and closed along rays.*

*Proof* Since  $X^{ol} = X^{or} = \emptyset$ ,  $\emptyset^{ol} = \emptyset^{or} = X$ , and  $X$  is upward, downward, radiant, coradiant and closed in itself, both statements are true when  $W = V = X$ . For the rest of the proof we shall assume that  $W \neq X$  and  $V \neq X$ .

- (i) Let  $W \subseteq X$  and  $W^{or} \neq \emptyset$ . By the definition of  $W^{or}$ , Remark 1, and Proposition 3,  $W^{or}$  is coradiant, upward, and closed along rays. Therefore,  $W = W^{olor}$  implies that  $W$  is coradiant, upward, and closed along rays. To prove the converse, we shall first show that  $W \subseteq W^{olor}$ . Let  $y \in W$ . Since for any  $x \in W^{ol}$  we have  $l_y(x) \leq 1$ , it is clear that  $y \in W^{olor}$ . We shall now show that  $W^{olor} \subseteq W$ . Let  $y \in W^{olor}$ . By Proposition 8 we have  $W = \text{supp}(p, X)$  for some IPH function  $p : X \rightarrow \mathbb{R}_+$ . Let  $x \in X$  and  $\lambda \in (p(x), +\infty)$  be arbitrary. For every  $y' \in W = \text{supp}(p, X)$ , since  $l_{y'}(x) \leq p(x) < \lambda$ , using (5), one gets  $l_{y'}(x/\lambda) = \lambda^{-1}l_{y'}(x) < 1$ , whence  $x/\lambda \in W^{ol}$ . Therefore,  $l_y(x) = \lambda l_{y'}(x/\lambda) < \lambda$ . Hence,  $l_y(x) \leq p(x)$ . This proves that  $l_y \leq p$ , that is,  $y \in \text{supp}(p, X) = W$ .
- (ii) Suppose that  $V^{ol}$  is a nonempty set. Then, by the definition of  $V^{ol}$ , Proposition 3, and Remark 1,  $V^{ol}$  is downward, radiant, and closed along rays. Therefore,  $V = V^{orol}$  implies that  $V$  is downward, radiant, and closed along rays. To prove the converse, we shall first show that  $V \subseteq V^{orol}$ . Let  $x \in V$ . Since for any  $y \in V^{or}$  we have  $l_y(x) \leq 1$ , it follows that  $x \in V^{orol}$ . We shall now show that  $V^{orol} \subseteq V$ . Let  $x \in V^{orol}$ . Consider the Minkowski gauge  $\mu_V : X \rightarrow \mathbb{R}_+$ . It follows from [9], Proposition 5.1 that

$$V = \{t \in X : \mu_V(t) \leq 1\}. \tag{36}$$

Thus, if  $\mu_V(x) = 0$ , then  $x \in V$ . Assume that  $\mu_V(x) > 0$ . Since  $V \cap \text{int } K \neq \emptyset$ , we get  $\mu_V(x) < +\infty$ . Set  $r = x/\mu_V(x)$ . By (28),  $r \in \text{supp}(\mu_V, X)$ . Then  $l_r(t) \leq \mu_V(t)$  for each  $t \in X$ . In view of (36), we obtain  $l_r(t) \leq 1$  for all  $t \in V$ , that is,  $r \in V^{or}$ . Thus,  $l_r(x) \leq 1$ , and so by (6) and (8),  $\mu_V(x) \leq 1$  (note that  $\mu_V(x) > 0$  implies that  $x \notin -K$ ). This proves that  $x \in V$ , which completes the proof.  $\square$

**Abstract Concavity of DPH Functions**

Recall that a function  $q : X \rightarrow \bar{\mathbb{R}}$  is called decreasing if  $x \geq y \implies q(x) \leq q(y)$ . If  $p$  is an IPH function, then the functions  $q(x) = p(-x)$  and  $q_*(x) = -p(x)$  are DPH (decreasing and positively homogeneous of degree one). Hence, DPH functions can be investigated by using the properties of IPH functions. In this section, we shall study DPH functions separately. To this end, we need to introduce the function  $g : X \times X \rightarrow \bar{\mathbb{R}}$  defined by

$$g(x, y) := \min\{\lambda \in \mathbb{R} : \lambda y \leq x\} \tag{37}$$

(with the conventions  $\min \emptyset := +\infty$  and  $\min \mathbb{R} := -\infty$ ).

The following proposition can be easily proved:

**Proposition 11** For every  $x, x', y \in X$  and  $\lambda > 0$ , one has

$$g(\lambda x, y) = \lambda g(x, y), \tag{38}$$

$$g(x, \lambda y) = \frac{1}{\lambda} g(x, y), \tag{39}$$

$$x \leq x' \implies g(x, y) \geq g(x', y), \tag{40}$$

$$g(x, y) = -\infty \implies y \in K, \tag{41}$$

$$g(x, x) = 1 \iff x \notin K. \tag{42}$$

It is worth noting that in (37) we cannot restrict the definition of  $g$  to  $\lambda \leq 0$  because we shall lose property (42).

For each  $y \in X$ , we consider the cones  $C_y, C_y^+$  and  $C_y^-$  defined by

$$C_y = \{x \in X : g(x, y) \in \mathbb{R}_{-\infty}\}, \tag{43}$$

$$C_y^+ = \{x \in C_y : g(x, y) > 0\}, \tag{44}$$

$$C_y^- = \{x \in C_y : g(x, y) \in \bar{\mathbb{R}}_-\}. \tag{45}$$

It is easy to check that  $C_y^-$  is an upward convex cone and  $C_y^+$  is a downward cone. Each element  $y \in X$  generates the following functions:

$$f_y^+(x) = \begin{cases} g(x, y), & x \in C_y^+ \\ +\infty, & \text{otherwise,} \end{cases} \tag{46}$$

and

$$f_y^-(x) = \begin{cases} g(x, y), & x \in C_y^- \\ +\infty, & \text{otherwise.} \end{cases} \tag{47}$$

Let  $F$  be the set of all functions defined by (46) and (47).

*Remark 3* The function  $f_y^-$  is DPH for each  $y \in X$ .

The proof of the following proposition is similar to that of Proposition 9, and therefore we omit its proof.

**Proposition 12** Let  $q : X \rightarrow \bar{\mathbb{R}}$  be a DPH function and  $x \in \text{dom } q$  be a point such that  $q(x) \neq 0$ . Then  $r = x/q(x) \notin K$ .

**Proposition 13** Let  $q : X \rightarrow \bar{\mathbb{R}}$  be a DPH function and  $x \in \text{dom } q$  be a point such that  $q(x) \neq 0$ . Let  $r = x/q(x)$ . Then the superdifferential  $\partial_F^+ q(x)$  is nonempty and the following assertions are true:

1. If  $q(x) > 0$ , then  $f_r^+ \in \partial_F^+ q(x)$ .
2. If  $q(x) < 0$ , then  $f_r^- \in \partial_F^+ q(x)$ .

*Proof* We only prove part (i). Since  $q(x) \in \{\lambda \in \mathbb{R} : \lambda r \leq x\}$ , by (37), we get  $g(x, r) \leq q(x)$ . In view of (39) and (42), we have

$$g(x, r) = q(x)g(x, x) = q(x) > 0$$

(note that since  $q(x) \neq 0$ , it follows from Proposition 12 that  $x \notin K$ ). By (44) and (46) we have  $x \in C_r^+$  and  $f_r^+(x) = g(x, r) \leq q(x)$ . We shall now show that  $f_r^+(y) \geq q(y)$  for every  $y \in X$ . Let  $y \in X$  be arbitrary. If  $y \notin C_r^+$ , then  $f_r^+(y) = +\infty \geq q(y)$ . Assume that  $y \in C_r^+$ . Then  $g(y, r)r \leq y$ . Since  $q$  is DPH, we get  $g(y, r)q(r) \geq q(y)$ . It follows from  $q(r) = 1$  and (46) that  $f_r^+(y) \geq q(y)$ . This yields that  $f_r^+(x) = q(x)$  and  $f_r^+(y) \geq q(y)$  for each  $y \in X$ . Hence  $f_r^+ \in \partial_F^+ q(x)$ .  $\square$

It follows from the preceding proposition that we do not need functions of the form (47) in the study of non-positive DPH functions. For each  $r \in X$ , we can consider the function  $s_r : X \rightarrow \bar{\mathbb{R}}_-$  defined by

$$s_r(x) = \begin{cases} g(x, r), & x \in C_r^- \\ 0, & x \notin C_r^-, \end{cases} \tag{48}$$

instead of the function  $f_r^-$  defined by (47). Let  $S$  be the set of all functions defined by (48). Since  $C_r^-$  is an upward set, we get that set  $S$  consists of nonpositive DPH functions; hence each  $S$ -concave function is DPH. We shall now give an infimal representation of DPH functions.

**Proposition 14** *Let  $q : X \rightarrow \mathbb{R}_-$  be a nonzero function. Then  $q$  is DPH if and only if it is  $S$ -concave.*

*Proof* We only prove the part if. Let  $W' = \text{supp}^+(q, S)$ . We shall show that  $W' \neq \emptyset$ . Consider  $x \in X$  such that  $q(x) < 0$ . Set  $r = x/q(x)$ . It follows from Proposition 12 and (41) that  $r \notin K$  and  $g(y, r) > -\infty$  for all  $y \in X$ . Since  $q(x) \in \{\lambda \in \mathbb{R} : \lambda r \leq x\}$ , by (37) we get  $g(x, r) \leq q(x) < 0$ . Then  $x \in C_r^-$ , and by (48) we obtain  $s_r(x) \leq q(x)$ . We shall now show that  $s_r(y) \geq q(y)$  for each  $y \in X$ . Let  $y \in X$  be arbitrary. If  $y \notin C_r^-$ , then  $s_r(y) = 0 \geq q(y)$ . Assume that  $y \in C_r^-$ . Then  $(-g(y, r))(-r) = g(y, r)r \leq y$ . Since  $q$  is DPH, we get  $-g(y, r)q(-r) \geq q(y)$ . It follows from  $q(-r) = -1$  and  $y \in C_r^-$  that  $s_r(y) \geq q(y)$ . Thus  $s_r \in W' = \text{supp}^+(q, S)$  and  $s_r(x) = q(x)$ . Finally, if  $q(x) = 0$ , then  $s(x) = 0$  for each  $s \in W'$ . Hence  $q(x) = \min_{s \in W'} s(x)$ , that is,  $q$  is  $S$ -concave.  $\square$

In the sequel, we introduce the function  $h : X \times X \rightarrow \mathbb{R}$  defined by

$$h(x, y) := \max\{\lambda \in \mathbb{R} : \lambda y \leq x\} \tag{49}$$

(we use the conventions  $\max \emptyset := -\infty$  and  $\max \mathbb{R} := +\infty$ ). The next proposition gives some properties of the coupling function  $h$ . We omit its easy proof.

**Proposition 15** *For every  $x, x', y \in X$  and  $\gamma > 0$ , one has*

$$h(\gamma x, y) = \gamma h(x, y), \tag{50}$$

$$h(x, \gamma y) = \frac{1}{\gamma} h(x, y), \tag{51}$$

$$h(x, y) = +\infty \implies y \in -K, \tag{52}$$

$$h(x, x) = 1 \iff x \notin -K, \tag{53}$$

$$x \leq x' \implies h(x, y) \leq h(x', y), \tag{54}$$

$$x \in K, y \in -K \implies h(x, y) = +\infty. \tag{55}$$

For each  $y \in X$ , consider the cones

$$K_y = \{x \in X : h(x, y) \in \mathbb{R}_{+\infty}\} \tag{56}$$

and

$$K_y^- = \{x \in K_y : h(x, y) < 0\}. \tag{57}$$

Clearly,  $K_y^-$  is a downward cone. Each element  $y \in X$  generates the function  $g_y^- : X \rightarrow \mathbb{R}_-$  defined by

$$g_y^-(x) = \begin{cases} h(x, y), & x \in K_y^- \\ -\infty, & x \notin K_y^-. \end{cases} \tag{58}$$

Let  $G_-$  be the set of all functions defined by (52). We conclude this section by a result on negative IPH functions.

**Theorem 10** *Let  $p : X \rightarrow \mathbb{R}_-$  be an IPH function and  $x \in \text{dom } p$  be a point such that  $p(x) \neq 0$ . Let  $r = x/p(x)$ . Then  $g_r^- \in \partial_{G_-} p(x)$ , and hence  $\partial_{G_-} p(x)$  is nonempty.*

*Proof* It is clear that  $p(x) < 0$ . Since  $p(x) \in \{\lambda \in \mathbb{R} : \lambda r \leq x\}$ , by (49) we get  $h(x, r) \geq p(x)$ . In view of Proposition 15, we have

$$h(x, r) = p(x)h(x, x) = p(x) < 0$$

(note that since  $p(x) \neq 0$ , it follows from Proposition 9 that  $x \notin -K$ ). By (51) and (52) we have  $x \in K_r^-$  and  $g_r^-(x) = h(x, r) \geq p(x)$ . We shall now show that  $g_r^-(y) \leq p(y)$  for every  $y \in X$ . Let  $y \in X$  be arbitrary. If  $y \notin K_r^-$ , then  $g_r^-(y) = -\infty \leq p(y)$ . Assume that  $y \in K_r^-$ . Then  $(-h(y, r))(-r) = h(y, r)r \leq y$ . Since  $p$  is IPH, we have  $-h(y, r)p(-r) \leq p(y)$ . It follows from  $p(-r) = -1$  and (52) that  $g_r^-(y) \leq p(y)$ . This yields that  $g_r^-(x) = p(x)$  and  $g_r^-(y) \leq p(y)$  for each  $y \in X$ . Hence  $g_r^- \in \partial_{G_-} p(x)$ .  $\square$

## The Problem

An inequality-constrained nonlinear programming problem may be posed in the form

$$\begin{cases} \min_{x \in \mathbb{R}^n} & f(x) \\ \text{s.t.} & c(x) \geq 0, \end{cases} \quad (1)$$

where  $f(x)$  is a nonlinear function and  $c(x)$  is an  $m$ -vector of nonlinear functions with  $i$ th component  $c_i(x)$ ,  $i = 1, \dots, m$ . We shall assume that  $f$  and  $c$  are sufficiently smooth. Let  $x^*$  denote a solution to (1). We are mainly concerned about smoothness in the neighborhood of  $x^*$ . In such a neighborhood we assume that both the gradient of  $f(x)$  denoted by  $g(x)$  and the  $m \times n$  Jacobian of  $c(x)$  denoted by  $J(x)$  exist and are Lipschitz continuous. As is the case with the unconstrained problem a solution to this problem may not exist. Typically additional assumptions are made to ensure a solution does exist. A common assumption is to assume that the objective  $f(x)$  is bounded below on the feasible set. However, even this is not sufficient to assure a minimizer exists but it is obviously a necessary condition for an algorithm to be assured of converging. If the feasible region is compact then a solution does exist. We shall only be concerned with local solutions.

## First Order Optimality Conditions

The problem is closely related to the equality-constrained problem. If it was known which constraints were active (exactly satisfied) at a solution and which were slack (strictly positive) then the optimality conditions for (1) could be replaced by the optimality conditions for the equality case. Note that this does not imply the inequality problem could be replaced by an equality problem when it comes to determining a solution by an algorithm. The inequality problem may have solutions corresponding to different sets of constraints being active. Also an equality problem may have solutions that are not solutions of the inequality problem. Nonetheless this equivalence in a local neighborhood enables us to determine the optimality conditions for this problem from those of an equality-constrained problem. In order to study the optimality conditions it is necessary to introduce some notation.

Let  $\widehat{c}(x)$  and  $\bar{c}(x)$  denote the constraints active and slack at  $x$  respectively. Likewise, let  $\widehat{J}(x)$  and  $\bar{J}$  denote

their respective Jacobians. Assume that  $\widehat{J}(x^*)$  is full rank. Points at which the Jacobian of the active constraints is full rank are said to be *regular*. It follows from the necessary conditions for the equality case that

$$\begin{aligned} g(x^*) - \widehat{J}(x^*)^\top \widehat{\lambda} &= 0, \\ \widehat{c}(x^*) &= 0, \\ \overline{c}(x^*) &> 0, \end{aligned}$$

where  $\widehat{\lambda}$  is vector of Lagrange multipliers. These equations may be written in the form:

$$\begin{aligned} g(x^*) - J(x^*)^\top \lambda^* &= 0, \\ c(x^*) &\geq 0, \\ \lambda^{*T} c(x^*) &= 0, \end{aligned}$$

where  $\lambda^*$  is the *extended set of Lagrange multipliers*. The set is extended by defining a multiplier to be zero for the slack constraints at  $x^*$   $\overline{c}(x^*)$ .

The above first order optimality conditions are not the only necessary conditions. Unlike the equality case there may be a feasible arc that moves off one or more of the active constraints along which the objective is reduced. In other words we need some characterization that is necessary for the active set to be binding. The key to identifying the binding set is to examine the sign of  $\widehat{\lambda}$ .

It follows from the definition of  $\widehat{\lambda}$  that

$$\widehat{\lambda} = (\widehat{J}\widehat{J}^\top)^{-1} \widehat{J}g, \tag{2}$$

where the argument  $x^*$  has been dropped for simplicity. Note that (2) implies that  $\|\widehat{\lambda}\|$  is bounded.

Define  $p$  as

$$\widehat{J}p = \delta e + e_j,$$

where  $\delta > 0$ ,  $e$  denotes the vector of ones and  $e_j$  is the unit column with one in the  $j$ th position. It follows from the assumption on the continuity of the Jacobian that  $x^* + \alpha p$  is feasible for  $0 \leq \alpha \leq \overline{\alpha}$  is sufficiently small. From the mean value theorem we have

$$f(x^* + \alpha p) = f(x^*) + \alpha p^\top g(x^* + \xi \alpha p),$$

where  $0 \leq \xi \leq 1$ . The Lipschitz continuity of  $g$  implies  $M$  exists such that

$$p^\top g(x^* + \xi \alpha p) \leq p^\top g(x^*) + \alpha M.$$

It follows that

$$f(x^* + \alpha p) \leq f(x^*) + \alpha(p^\top g(x^*) + \alpha M).$$

From the necessary conditions on  $x^*$  we get

$$p^\top g(x^*) = p^\top \widehat{J}^\top \widehat{\lambda},$$

which implies

$$f(x^* + \alpha p) \leq f(x^*) + \alpha(p^\top \widehat{J}^\top \widehat{\lambda} + \alpha M).$$

Using the definition of  $p$  gives

$$f(x^* + \alpha p) \leq f(x^*) + \alpha(\delta e^\top \widehat{\lambda} + \widehat{\lambda}_j + \alpha M).$$

It follows from the boundedness of  $\widehat{\lambda}$  that if  $\widehat{\lambda}_j < 0$  then for  $\delta$  sufficiently small there exists  $\overline{\alpha}$  such that for  $0 < \alpha \leq \overline{\alpha}$ ,

$$f(x^* + \alpha p) < f(x^*).$$

Consequently, a necessary condition for  $x^*$  to be a minimizer under the assumptions made is that  $\widehat{\lambda} \geq 0$ . Equivalently,  $\lambda^* \geq 0$ .

For different assumptions such as  $\widehat{J}$  not being full rank the condition need not hold as the following simple case illustrates. Suppose we have an equality-constrained problem with  $c(x) = 0$  then an equivalent inequality-constrained problem is

$$\begin{cases} \min_{x \in \mathbb{R}^n} & f(x) \\ \text{s.t.} & c(x) \geq 0, \\ & -c(x) \geq 0. \end{cases}$$

It follows that all constraints are active at a solution. We know in this case there are no necessary conditions on the Lagrange multipliers. Clearly the Jacobian of the active constraints is not full rank. Geometrically what breaks down is that there is no perturbation from  $x^*$  that moves feasible with respect to one constraint without violating at least one other constraint.

The condition  $c(x^*)^\top \lambda^* = 0$  is a *complementarity condition*. At least one of  $(c_i(x^*), \lambda_i^*)$  must be zero. It is possible for both to be zero. If there is no index for which both are zero then  $c(x^*)$  and  $\lambda^*$  are said to satisfy *strict complementarity*.

If  $\widehat{J}(x^*)$  is full rank then it follows from (2) that  $\lambda^*$  is an isolated point.

The function  $L(x, \lambda)$ ,

$$L(x, \lambda) = F(x) - \lambda^\top c(x),$$

is known as the *Lagrangian*. The optimality condition

$$g(x^*) - J(x^*)^\top \lambda^* = 0$$

is equivalent to  $\nabla_x L(x^*, \lambda^*) = 0$ . It is also equivalent to  $Z(x^*)^\top g(x^*) = 0$ , where the columns of  $Z(x)$  are a basis for the null space of the rows of  $\widehat{J}(x)$ . The vector  $Z(x)^\top g(x)$  is called the *reduced gradient*.

Clearly Lagrange multipliers play a significant role in defining the solution of an inequality-constrained problem. There is a significant difference in that role between linear and nonlinear constraints. In the case of linear constraints the numerical value of the multiplier plays no role in defining  $x^*$  only the sign of the multiplier is significant. For nonlinear constraints the numerical value as well as the sign is of significance. To appreciate why it first necessary to appreciate that for problems that are nonlinear in either the constraints or the objective, curvature of the functions are relevant in defining  $x^*$ . More precisely the curvature of the Lagrangian. It easily seen that curvature of the objective is relevant since for unconstrained problems no solution would exist otherwise. To appreciate that curvature in  $c(x)$  is relevant note that any problem can be transformed into a problem with just a linear objective by adding an extra variable. For example, add the constraint  $x_{n+1} - f(x) \geq 0$  and minimize  $x_{n+1}$  instead of  $f(x)$ . Since we have established the curvature of  $f(x)$  is relevant that relevance must still be there even though  $f(x)$  now appears only within a constraint. It is harder to appreciate that it is the relative curvature of the various constraints and objective that is of significance.

### Second Order Optimality Conditions

We shall now assume that the problem functions are twice continuous differentiable. From the unconstrained case it is known that a necessary condition is that  $\nabla^2 f(x^*)$  is positive semidefinite. Obviously a generalization of this condition needs to hold for (1). Again the Lagrangian will be shown to play a key role. We start by examining the behavior of  $f(x)$  along a feasible arc emanating from  $x^*$ . Although the first order optimality conditions make the first order change in the objective

along a feasible arc nonnegative, it could be zero. Consequently, the second order change needs to be nonnegative for arcs where this is true.

We restrict our interest to feasible arcs that remain on the set of constraints active at  $x^*$ . If  $x(\alpha)$  represents a twice differentiable arc, with  $x(0) = x^*$ , that lies on the active set then  $\widehat{c}(x(\alpha)) = 0$ . Define  $p \equiv d(x(0))/d\alpha$  and  $h \equiv d^2(x(0))/d\alpha^2$ . We have

$$\begin{aligned} \frac{d}{d\alpha} \widehat{c}_i(x(\alpha)) &= \nabla(\widehat{c}_i(x(\alpha)))^\top \frac{d}{d\alpha} x(\alpha), \\ \frac{d^2}{d\alpha^2} \widehat{c}_i(x(\alpha)) &= \frac{d}{d\alpha} x(\alpha)^\top \nabla^2 \widehat{c}_i(x(\alpha)) \frac{d}{d\alpha} x(\alpha) \\ &\quad + \nabla \widehat{c}_i(x(\alpha))^\top \frac{d^2}{d\alpha^2} x(\alpha). \end{aligned}$$

Since  $\widehat{c}(x(\alpha)) = 0$  it follows that

$$\frac{d^2}{d\alpha^2} \widehat{c}_i(x(0)) = \nabla \widehat{c}_i(x^*)^\top h + p^\top \nabla^2 \widehat{c}_i(x^*) p = 0. \quad (3)$$

Similarly we get

$$\frac{d^2}{d\alpha^2} f(x(0)) = g(x^*)^\top h + p^\top \nabla^2 f(x^*) p.$$

Since

$$\frac{d}{d\alpha} f(x(0)) = g(x^*)^\top p = 0$$

(otherwise there would be a descent direction from  $x^*$ ) we require that

$$g(x^*)^\top h + p^\top \nabla^2 f(x^*) p \geq 0.$$

Substituting for  $g(x^*)$  using the first order optimality conditions gives

$$h^\top J(x^*)^\top \lambda^* + p^\top \nabla^2 f(x^*) p \geq 0.$$

It follows from (3) and the definition of the extended multipliers that we require

$$-\sum_{i=1}^m \lambda_i^* p^\top \nabla^2 c_i(x^*) p + p^\top \nabla^2 f(x^*) p \geq 0.$$

From the definition of  $L(x^*, \lambda^*)$  and  $\widehat{J}(x^*) p = 0$  this condition is equivalent to requiring that  $Z(x^*)^\top \nabla^2 L(x^*, \lambda^*) Z(x^*)$  be positive semidefinite. This matrix is called the *reduced Hessian of the Lagrangian*. Since the

condition is on the second derivatives it is termed a *second order optimality condition*. It can now be appreciated that the numerical value of the Lagrange multipliers play a role in defining the solution of a nonlinearly-constrained problem. Note that when there are  $n$  active constraints then there is no feasible arc that remains on the active set and the second order optimality condition is empty. When  $\widehat{J}$  has  $n$  rows then the reduced Hessian has zero dimension. For convenience we can define symmetric matrices of zero dimension to be positive definite.

Necessary and sufficient conditions for  $x^*$  to be a minimizer are complex. However, sufficient conditions are easy to appreciate. We have established no feasible descent direction exists that moves off any of the active constraints. Consequently, if  $\widehat{\lambda} > 0$  then  $f(x)$  increases along any feasible arc emanating from  $x^*$  that moves off a constraint. We now only need to be sure the same is true for all arcs emanating from  $x^*$  that remaining on the active set. This is assured if

$$\frac{d^2}{d\alpha^2}f(x(0)) = g(x^*)^\top h + p^\top \nabla^2 f(x^*) p > 0,$$

which implies  $Z(x^*)^\top \nabla^2 L(x^*, \lambda^*) Z(x^*)$  is positive definite. Assuming that  $x^*$  is a regular point, strict complementarity hold, the first order necessary conditions hold, and the reduced Hessian at  $x^*$  is positive definite then  $x^*$  is a minimizer and an isolated point.

## Algorithms

Algorithms for inequality problems have a combinatorial element not present in algorithms for equality-constrained problems. The simplest case of linear programming (LP) illustrates the point. Under mild assumptions the solution of an LP is given by the solution of a set of linear equations, i. e. a vertex of the feasible region. The difficult issue is determining which of the constraints define those equations. If there are  $m$  inequality constraints and  $n$  variables there are  $m!/n!$  ( $n - m$ )! choices of active constraints. Even for modest values of  $m$  and  $n$  the possible choices are astronomical. This clearly rules out methods based on exhaustive search.

One class of methods to solve inequality problems are so-called *active set methods*, an example being the simplex method for LP. First a guess is made of the

active set (called the working set) and then an estimate to the solution of the resulting equality-constrained problem is computed (in the case of LP or quadratic programming (QP) this would be precise) and at the new point a new guess is made of the active set. The estimate of the solution of the equality-constrained problem is usually made by finding a point that satisfies an approximation to the first order necessary conditions. Unless an intelligent guess is made of the active set such algorithms are doomed to fail. Typically after the initial active set such algorithms generate subsequent working sets automatically. For linearly-constrained problems this is usually a very simple procedure. Assuming the current iterate is feasible an attempt is made to move to the new estimate of the solution. If this is infeasible the best (or a point better than the current iterate) is found along the direction to the new estimate. The constraints active at the new feasible point are then used to define the working set. Usually the active set will be the working set but occasionally we need to move off a constraint that is currently active. How to identify such a constraint is usually straightforward and can be done by examining an estimate to the Lagrange multipliers (obtained from the solution to the approximation of the first order necessary conditions). More complex strategies are possible that move off several constraints simultaneously.

An initial feasible point is found by solving an LP. One consequence of this strategy is that it is only necessary to consider working sets for which the objective function has a lower value than at the current iterate. Once we are in a neighborhood of the solution the working set does not change if strict complementarity holds at the solution and  $x^*$  is a regular point. Typically the change in the working set at each iteration of active set methods for linearly-constrained problems is small (usually one), which results in efficiencies when computing the estimate to the new equality-constrained problem. In practice active set methods work well and usually identify the active set at the solution with very little difficulty. For an LP the number of iterations required to identify the active set usually grows linearly with the size of the problem. However, pathological cases exist in which the number of iterations is astronomical and real LP problems do arise where the number of iterates required is much greater than the typical case. Nonetheless algorithms for linearly-constrained

problems based on active set methods are highly successful.

For nonlinear problem the issue of identifying the active set at the solution is usually less significant since even when the active set is known the number of iterations required to solve a problem may be large. A more relevant issue is that not knowing the active set causes some problems such as making the linear algebra routines much more complicated. For small problems this is of little consequence but in the large scale case it complicates the data structures required.

Nonlinearly-constrained problems are usually an order of magnitude more complicated to solve than linearly-constrained problems. One reason is that algorithms for problems with nonlinear constraints usually do not maintain feasible iterates. If a problem has just one nonlinear equality constraint then generating each member of a sequence that lies on that constraint is itself an infinite process. Methods that generate infeasible iterates need to have some means of assessing whether a point is better than another point. For feasible-point algorithms this is a simple issue since the objective provides a measure of merit. A typical approach is to define a merit function, which balances a change in the objective against the change in the degree of infeasibility. A commonly used *merit function* is

$$M(x, \rho) = f(x) + \rho \sum_{i=1}^m \max\{0, -c_i(x)\},$$

where  $\rho$  is a parameter that needs to be sufficiently large. Usually it will not be known what ‘sufficiently’ large is so this parameter is adjusted as the sequence of iterates is generated. Note that  $M(x, \rho)$  is not a smooth function and has a discontinuity in its derivative when any element of  $c(x)$  is zero. In particular it is not continuous at  $x^*$  when a constraint is active at  $x^*$ . Were this not the case then constrained problems could be transformed to unconstrained problems and solved as such. While transforming a constrained problem into a simple single smooth unconstrained problem is not possible the transformation approach is the basis of a variety of methods. A popular alternative to direct methods is to transform the problem into that of solving a sequence of smooth linearly-constrained problems. This is the method at the heart of *MINOS* (see [8,9]) one of the most widely used methods for solving

problems with nonlinear constraints. Other transformation methods transform the problem to that of solving a sequence of unconstrained or bounds-constrained problem. Transformation methods have an advantage of over direct methods when developing software. For example, if you have a method for solving large scale linearly-constrained problems then it can be used as a kernel in an algorithm to solve large scale nonlinearly-constrained problems.

The goal in a classification problem is to uncover a system that places examples into two or more mutually exclusive groups. Identifying a classification system is beneficial in several ways. First of all, examples can be organized in a meaningful way, which will make

the exploration and retrieval of examples belonging to specific group(s) more efficient. The tree-like directory structure, used by personal computers in organizing files, is an example of a classification system which enables users to locate files quickly by traversing the directory paths. A classification system can make the relations between the examples easy to understand and interpret. A poor classification strategy, on the other hand, may propose arbitrary, confusing or meaningless relations. An extracted classification system can be used to classify new examples. For an incomplete or stochastic system, its structure may pose questions whose answers may generalize the system or make it more accurate.

A special type of *classification problem*, called the *Boolean function inference problem*, is when all the examples are represented by binary (0 or 1) attributes and each example belongs to one of two categories. Many other types of classification problems may be converted into a Boolean function inference problem. For example, a multicategory classification problem may be converted into several two-category problems. In a similar fashion, example attributes can be converted into a set of binary variables.

In solving the Boolean function inference problem many properties of Boolean logic are directly applicable. A *Boolean function* will assign a binary value to each Boolean vector (example). See [22] for an overview of Boolean functions. Usually, a Boolean function is expressed as a conjunction of disjunctions, called the *conjunctive normal form* (CNF), or a disjunction of conjunctions, called the *disjunctive normal form* (DNF). CNF can be written as:

$$\bigwedge_{j=1}^k \left( \bigvee_{i \in \rho_j} x_i \right),$$

where  $x_i$  is either the attribute or its negation,  $k$  is the number of attribute disjunctions and  $\rho_j$  is the  $j$ th index set for the  $j$ th attribute disjunction. Similarly, DNF can be written as:

$$\bigvee_{j=1}^k \left( \bigwedge_{i \in \rho_j} x_i \right).$$

It is well known that any Boolean function can be written in CNF or DNF form. See [20] for an algorithm con-

verting any Boolean expression into CNF. Two functions in different forms are regarded as equivalent as long as they assign the same function values to all the Boolean vectors. However, placing every example into the correct category is only one part of the task. The other part is to make the classification criteria meaningful and understandable. That is, an inferred Boolean function should be as simple as possible. One part of the Boolean function inference problem that has received substantial research efforts is that of simplifying the representation of Boolean functions, while maintaining a general representation power.

### Inference of Monotone Boolean Functions

When the target function can be any Boolean function with  $n$  attributes, all of the  $2^n$  examples have to be examined to reconstruct the entire function. When we have a priori knowledge about the subclass of Boolean functions the target function belongs to, on the other hand, it may be possible to reconstruct it using a subset of the examples. Often one can obtain the function values on examples one by one. That is, at each inference step, an example is posed as a question to an oracle, which, in return, provides the correct function value. A function,  $f$ , can be defined by its oracle  $A_f$  which, when fed with a vector  $x = \langle x_1, \dots, x_n \rangle$ , returns its value  $f(x)$ . The inference of a Boolean function from questions and answers is known as *interactive learning of Boolean functions*. In many cases, especially when it is either difficult or costly to query the oracle, it is desirable to pose as few questions as possible. Therefore, the choice of examples should be based on the previously classified examples.

The *monotone Boolean functions* form a subset of the Boolean functions that have been extensively studied not only because of their wide range of applications (see [2,7,8] and [24]) but also their intuitive interpretation. Each attribute's contribution to a monotone function is either nonnegative or nonpositive (not both). Furthermore, if all of the attributes have nonnegative (or nonpositive) effects on the function value then the underlying monotone Boolean function is referred to as *isotone* (respectively *antitone*). Any isotone function can be expressed in DNF without using negated attributes. In combinatorial mathematics, the set of isotone Boolean functions is often represented by the *free distributive lattice* (FDL). To formally define monotone

Boolean function, consider ordering the binary vectors as follows [21]:

**Definition 1** Let  $E^n$  denote the set of all binary vectors of length  $n$ ; let  $x$  and  $y$  be two such vectors. Then, the vector  $x = \langle x_1, \dots, x_n \rangle$  *precedes* vector  $y = \langle y_1, \dots, y_n \rangle$  (denoted as  $x \preceq y$ ) if and only if  $x_i \leq y_i$  for  $1 \leq i \leq n$ . If, at the same time  $x \neq y$ , then  $x$  *strictly precedes*  $y$  (denoted as  $x \prec y$ ).

According to this definition, the order of vectors in  $E^2$  can be listed as follows:

$$\langle 11 \rangle \prec \langle 01 \rangle \prec \langle 00 \rangle$$

and

$$\langle 11 \rangle \prec \langle 10 \rangle \prec \langle 00 \rangle.$$

Note that the vectors  $\langle 01 \rangle$  and  $\langle 10 \rangle$  are in a sense incomparable.

Based on the order of the Boolean vectors, a nondecreasing monotone (isotone) Boolean function can be defined as follows [21]:

**Definition 2** A Boolean function  $f$  is said to be a *nondecreasing monotone Boolean function* if and only if for any vectors  $x, y \in E^n$ , such that  $x \prec y$ , then  $f(x) \prec f(y)$ .

A *nonincreasing monotone* (antitone) Boolean function can be defined in a similar fashion. As the method used to infer an antitone Boolean function is the same as that of a isotone Boolean function, we will restrict our attention to the isotone Boolean functions.

When analyzing a subclass of Boolean functions, it is always informative to determine its size. This may give some indications of how general the functions are and how hard it is to infer them. The number of isotone Boolean functions,  $\Psi(n)$ , defined on  $E^n$  is sometimes referred to as the  *$n$ th Dedekind number* after R. Dedekind, [6] who computed it for  $n = 4$ . Since then it has been computed for up to  $E^8$ .

- $\Psi(1) = 3$ ;
- $\Psi(2) = 6$ ;
- $\Psi(3) = 20$ ;
- $\Psi(4) = 168$  [6];
- $\Psi(5) = 7,581$  [4];
- $\Psi(6) = 7,828,354$  [28];
- $\Psi(7) = 2,414,682,040,998$  [5];
- $\Psi(8) = 56,130,437,228,687,557,907,788$  [29].

Wiedeman’s algorithm [29] employed a Cray-2 processor for 200 hours to compute the value for  $n = 8$ . This gives a flavor of the complexity of computing the exact number of isotone Boolean functions. The computational infeasibility for larger values of  $n$  provides the motivation for approximations and bounds. The best known bound on  $\Psi(n)$  is due to D. Kleitman, [12] and Kleitman and G. Markowsky, [13]:

$$\Psi(n) \leq 2^{\binom{n}{\lfloor n/2 \rfloor} (1+c \frac{\log n}{n})},$$

where  $c$  is a constant and  $\lfloor n/2 \rfloor$  is the integer part of  $n/2$ .

This bound, which is an improvement over the first bound obtained by G. Hansel, [11], are also based on the Hansel chains described below. Even though these bounds can lead to good approximations for  $\Psi(n)$ , when  $n$  is large, the best known asymptotic is due to A.D. Korshunov, [15]:

$$\Psi(n) \sim \begin{cases} 2^{\binom{n}{n/2}} e^{f(n)} & \text{for even } n, \\ 2^{\binom{n}{n/2-1/2}+1} e^{g(n)} & \text{for odd } n, \end{cases}$$

where

$$\begin{aligned} f(n) &= \binom{n}{n/2-1} \left( \frac{1}{2^{n/2}} + \frac{n^2}{2^{n+5}} - \frac{n}{2^{n+4}} \right), \\ g(n) &= \binom{n}{n/2-3/2} \left( \frac{1}{2^{(n+3)/2}} - \frac{n^2}{2^{n+6}} - \frac{n}{2^{n+3}} \right) \\ &\quad + \binom{n}{n/2-1/2} \left( \frac{1}{2^{(n+1)/2}} + \frac{n^2}{2^{n+4}} \right). \end{aligned}$$

I. Shmulevich [24] achieved a similar but slightly inferior asymptotic for even  $n$  in a simpler and more elegant manner, which led to some interesting distributional conjectures regarding isotone Boolean functions.

Even though the number of isotone Boolean functions is large, it is a small fraction of the number of general Boolean functions,  $2^{2^n}$ . This is the first hint towards the feasibility of efficiently inferring monotone Boolean functions. Intuitively, one would conjecture that the generality of this class was sacrificed. That is true, however, a general Boolean function consists of a set of areas where it is monotone. In fact, any Boolean function  $q(x_1, \dots, x_n)$  can be represented by several nondecreasing  $g_i(x)$  and nonincreasing  $h_j(x)$  monotone Boolean

functions in the following manner [17]:

$$q(x) = \bigvee_i \left( g_i(x) \bigwedge_j h_j(x) \right).$$

As a result, one may be able to solve the general Boolean function inference problem by considering several *monotone Boolean function inference* problems. Intuitively, the closer the target function is to a monotone Boolean function, the fewer monotone Boolean functions are needed to represent it and more successful this approach might be. In [17] the problem of joint restoration of two nested monotone Boolean functions  $f_1$  and  $f_2$  is stated. The approach in [17] allows one to further decrease the dialogue with an expert (*oracle*) and restore a complex function of the form  $f_1 \& \neg f_2$ , which is not necessarily monotone.

### The Shannon Function and the Hansel Theorem

The complexity of inferring isotone Boolean functions was mentioned in the previous section, when realizing that the number of isotone Boolean functions is a small fraction of the total number of general Boolean functions. In defining the most common complexity measure for the Boolean function inference problem, consider the following notation. Let  $M_n$  denote the set of all monotone Boolean functions, and  $A = \{F\}$  be the set of all algorithms which infer  $f \in M_n$ , and  $\varphi(F, f)$  be the number of questions to the oracle  $A_f$  required to infer  $f$ . The *Shannon function*  $\varphi(n)$  can be introduced as follows [14]:

$$\varphi(n) = \min_{F \in A} \left( \max_{f \in M_n} \varphi(F, f) \right).$$

An upper bound on the number of questions needed to restore a monotone Boolean function is given by the following equation (known as the *Hansel theorem*) [11]:

$$\varphi(n) = \binom{n}{\lfloor n/2 \rfloor} + \binom{n}{\lfloor n/2 \rfloor + 1}.$$

That is, if a proper *question-asking strategy* is applied, the total number of questions needed to infer any monotone Boolean function should not exceed  $\varphi(n)$ . The Hansel theorem can be viewed as the worst-case scenario analysis. Recall, from the previous section, that

all of the  $2^n$  questions are necessary to restore a general Boolean function. D.N. Gainanov [9] proposed three other criteria for evaluating the efficiency of algorithms used to infer isotone Boolean functions. One of them is the average case scenario and the two others consider two different ways of normalizing the Shannon function by the size of the target function.

### Hansel Chains

The vectors in  $E^n$  can be placed in chains (sequences of vectors) according to *monotonicity*. The Hansel chains is a particular set of chains that can be formed using a dimensionally recursive algorithm [11]. It starts with the single Hansel chain in  $E^1$ :

$$H^1 = \{\langle 0 \rangle, \langle 1 \rangle\}.$$

To form the Hansel chains in  $E^2$ , three steps are required, as follows:

- 1 Attach the element '0' to the front of each vector in  $H^1$  and get chain  $C^{2, \min} = \{\langle 00 \rangle, \langle 01 \rangle\}$ .
- 2 Attach the element '1' to the front of each vector in  $H^1$  and get chain  $C^{2, \max} = \{\langle 10 \rangle, \langle 11 \rangle\}$ .
- 3 Move the last vector in  $C^{2, \max}$ , i.e. vector  $\langle 11 \rangle$ , to the end of  $C^{2, \min}$ :  $H^{2,1} = \{\langle 00 \rangle, \langle 01 \rangle, \langle 11 \rangle\}$ ;  $H^{2,2} = \{\langle 10 \rangle\}$ .

To form the Hansel chains in  $E^3$ , these steps are repeated:

- 1  $C^{3,1, \min} = \{\langle 000 \rangle, \langle 001 \rangle, \langle 011 \rangle\}$ ;  
 $C^{3,2, \min} = \{\langle 010 \rangle\}$ .
- 2  $C^{3,1, \max} = \{\langle 100 \rangle, \langle 101 \rangle, \langle 111 \rangle\}$ ;  
 $C^{3,2, \max} = \{\langle 110 \rangle\}$ .
- 3  $H^{3,1} = \{\langle 000 \rangle, \langle 001 \rangle, \langle 011 \rangle, \langle 111 \rangle\}$ ;  
 $H^{3,2} = \{\langle 100 \rangle, \langle 101 \rangle\}$ ;  
 $H^{3,3} = \{\langle 010 \rangle, \langle 110 \rangle\}$ .

Note that since there is only one vector in the  $C^{3,2, \max}$  chain, it can be deleted after the vector  $\langle 110 \rangle$  is moved to  $C^{3,2, \min}$ . This leaves the three chains listed in Table 1. In general, the Hansel chains in  $E^n$  can be generated recursively from the Hansel chains in  $E^{n-1}$  by following the three steps described above.

A nice property of the Hansel chains is that all the vectors in a particular chain are arranged in increasing

**Inference of Monotone Boolean Functions, Table 1**  
Hansel chains for  $E^3$

chain #	vector in-chain index	vector
1	1	000
	2	001

	2	101
3	1	010
	2	110

order. That is, if the vectors  $V_j$  and  $V_k$  are in the same chain then  $V_j < V_k$  (i. e.,  $V_j$  strictly precedes  $V_k$  when  $j < k$ ). Therefore, if the underlying Boolean function is isotone, then one can classify vectors within a chain easily. For example, if a vector  $V_j$  is negative (i. e.,  $f(V_j) = 0$ ), then all the vectors preceding  $V_j$  in the same chain are also negative (i. e.,  $f(V_k) = 0$  for any  $k < j$ ). Similarly, if a vector  $V_j$  is positive, then all the vectors succeeding  $V_j$  in the same chain are also positive. The monotone ordering of the vectors in Hansel chains motivates the composition of an efficient question-asking strategy discussed in the next section.

### Devising a Smart Question-Asking Strategy

The most straightforward question-asking strategy, which uses Hansel chains, sequentially moves from chain to chain. Within each chain one may also sequentially select vectors to pose as questions. After an answer is given, the vectors (in other chains also) that are classified as a result of monotonicity are eliminated from further questioning. Once all the vectors have been eliminated, the underlying function is revealed. The maximum number of questions for this method, called the *sequential Hansel chains question-asking strategy*, will not exceed the upper limit  $\varphi(n)$ , given in the Hansel theorem, as long as the chains are searched in increasing size.

Although the sequential question-asking strategy is easy to implement and effective in reducing the total number of questions, there is still room for improvements. N.A. Sokolov [25] introduced an algorithm that sequentially moves between the Hansel chains in de-

Inference of Monotone Boolean Functions, Table 2  
Iteration 1

chain #	index of vectors in the chain	vector	vector classified	middle vector in the chain	reward $P$ if the vector is positive	reward $N$ if the vector is negative	selected middle vector with the largest $\min(P, N)$	answer	other vectors determined
1	1	000							
	2	001		←	4	2	←	1	
	3	011							1
	4	111							1
2	1	100		←	4	2			
	2	101							1
3	1	010		←	4	2			
	2	110							

creasing size and performs a middle vector search of each chain. His algorithm does not require storing all the Hansel chains since at each iteration it only requires a single chain. This advantage is obtained at the cost of asking more questions than needed.

In an entirely different approach, Gainanov [9] presented a heuristic that has been used in numerous algorithms for inferring a monotone Boolean function, such as in [3] and in [18]. This heuristic takes as input an unclassified vector and finds a border vector (maximal false or minimal true) by sequentially questioning neighboring vectors. The problem with most of the inference algorithms based on this heuristic is that they do not keep track of the vectors classified, only the resulting border vectors. Note that for an execution of this heuristic, all of the vectors questioned are not necessarily covered by the resulting border vector, implying that valuable information may be lost. In fact, several border vectors may be unveiled during a single execution of this heuristic, but only one is stored. Many of these methods are designed to solve large problems where it might be inefficient or even infeasible to store all of the information gained within the execution of the heuristic. However, these methods are not efficient (not even for small size problems), in terms of the number of queries they require.

One may look at each vector as carrying a ‘reward’ value in terms of the number of other vectors that will be classified concurrently. This reward value is a random variable that takes on one of two (one if the two values are the same) values depending on whether the

vector is a positive or a negative example of the target function. The expected reward is somewhere between these two possible values. If one wishes to maximize the expected number of classified vectors at each step, the probabilities associated with each of these two values need to be computed in addition to the actual values. Finding the exact probabilities is hard, while finding the reward values is relatively simple for a small set of examples.

This is one of the underlying ideas for the new inference algorithm termed the *binary search-Hansel chains question-asking strategy*. This method draws its motivation, for calculating and comparing the ‘reward’ values for the middle vectors in each Hansel chain, from the widely used *binary search algorithm* (see, for instance, [19]). Within a given chain, a binary search will dramatically reduce the number of questions (to the order of  $\log_2$  while the sequential search is linear). Once the ‘reward’ values of all the middle vectors have been found, the most promising one will be posed as a question to the oracle. Because each vector has two values, selecting the most promising vector is subjective and several different evaluative criteria can be used.

The binary search-Hansel chains question-asking strategy can be divided into the following steps:

- 1) Select the middle vector of the unclassified vectors in each Hansel chain.
- 2) Calculate the reward values for each middle vector. That is, calculate the number of vectors that can be classified as positive (denoted as  $P$ ) if it is positive and negative (denoted as  $N$ ) if it is negative.

**Inference of Monotone Boolean Functions, Table 3**

Iteration 2. The vector (100) is chosen and based on the answer, the class membership of the vectors (100) and (000) is determined

chain #	index of vectors in the chain	vector	vector classified	middle vector in the chain	reward $P$ if the vector is positive	reward $N$ if the vector is negative	selected middle vector with the largest $\min(P, N)$	answer	other vectors determined
1	1	000		←	4	1			0
	2	001	1						
	3	011	1						
	4	111	1						
2	1	100		←	2	2	←	0	
	2	101	1						
3	1	010		←	2	2			
	2	110							

- 3) Select the most promising middle vector, based on the  $(P, N)$  pairs of the middle vectors, and ask the oracle for its membership value.
- 4) Based on the answer in Step 3, eliminate all the vectors that can be classified as a result of the previous answer and the property of monotonicity.
- 5) Redefine the middle vectors in each chain as necessary.
- 6) Unless all the vectors have been classified, go back to Step 2.

The inference of a monotone Boolean function on  $E^3$  by using the binary search-Hansel chains question-asking strategy is illustrated below. The specifics of Iteration 1, described below, are also shown in Table 2. At the beginning of first iteration, the middle vectors in each Hansel chain (as described in Step 1) are selected and marked with the ‘←’ symbol in Table 2. Then, according to Step 2, the reward value for each one of these middle vectors is calculated. For instance, if (001) (the second vector in chain 1) has a function value of 1, then the three vectors (000), (001) and (010) are also classified as positive. That is, the value of  $P$  for vector (001) equals 4. Similarly, (000) will be classified as 0 if (001) is classified as 0 and thus its reward value  $N$  equals 2.

Once the ‘reward’ values of all the middle vectors have been evaluated, the most promising middle vector will be selected based on their  $(P, N)$  pairs. Here we choose the vector whose  $\min(P, N)$  value is the largest among the middle vectors. If there is a tie, it will be broken randomly. Based on this evaluative criterion, vector

2 is chosen in chain 1 and is marked with ‘←’ in the column ‘selected middle vector with the largest  $\min(P, N)$ ’. After receiving the function value of 1 for vector (001), its value is placed in the ‘answer’ column. This answer is used to eliminate all of the vectors succeeding (001). The middle vector in the remaining chains are updated as needed. At least one more iteration is required, as there still are unclassified vectors.

After the second iteration, no unclassified vectors are left in chains 1 and 2, and the middle of these chains need not be considered anymore. Therefore, an ‘X’ is placed in the column called ‘middle vector in the chain’ in Table 4. At the beginning of the third iteration, the vector (010) is chosen and the function value of the remaining two vectors (010) and (110) are determined. At this point all the vectors have been classified and the question-asking process stops.

The algorithm posed a total of three questions in order to classify all the examples. The final classifications listed in Table 5. corresponds to the monotone Boolean function  $x_2 \vee x_3$ .

**Conclusions**

This paper described some approaches and some of the latest developments in the problem of inferring monotone Boolean functions. As it has been described here, by using Hansel chains in the sequential question-asking strategy, the number of questions will not exceed the upper bound stated in the Hansel theorem. How-

ever, by combining the binary search of Hansel chains with the notion of an evaluative criterion, the number of questions asked can be further reduced. At present, the binary search-Hansel chains question-asking strategy is only applied to Hansel chains with a dimension of less than 10. However, it is expected that this method can be applied to infer monotone Boolean functions of larger dimensions with slight modifications.

In economics or biology there is no natural end time for a process. Nations as well as species have a very long future to consider. A mathematical abstraction for this phenomenon is the concept of *infinite time horizon* simply defined as an unbounded time interval of the form  $[0, +\infty)$ . The study of competing agents in a dynamic deterministic setting over a long time period can be cast in the framework of an infinite horizon dynamic game. This game is defined by the following 'objects':

- A system evolving over an infinite horizon is characterized by a *state*  $x \in X \subseteq \mathbf{R}^{m_0}$ . Some agents also called the *players*  $i = 1, \dots, p$  can influence the state's evolution through the choice of an appropriate *control* in an admissible class. The control value at a given time  $n$  for player  $i$  is denoted  $u_i(n) \in U_i \subseteq \mathbf{R}_{mi}$ .
- The state evolution of such a dynamical system may be described either as a difference equation, if discrete time is used, or a differential equation in a continuous time framework. For definiteness we fix our attention here on a stationary difference equation

and merely remark that similar comments apply for the case when other types of dynamical systems are considered.

$$x(n + 1) = f(x(n), u_1(n), \dots, u_p(n))$$

for  $n = 0, 1, \dots$ , where  $f: \mathbf{R}^{m_0} \times \dots \times \mathbf{R}^{m_p} \rightarrow \mathbf{R}^{m_0}$  is a given state transition function.

- We assume that the agents can observe the state of the system and remember the *history* of the system evolution up to the current time  $n$ , that is, the sequence

$$h_n = \{x(0), \mathbf{u}(0), \dots, \mathbf{u}(n - 1), x(n)\},$$

where  $\mathbf{u}(n)$  denotes the controls chosen by all players at period  $n$  (i. e.,  $\mathbf{u}(n) = (u_1(n), \dots, u_p(n))$ ). A *policy* or a *strategy* is a way for each agent, to adapt his/her current control choice to the history of the system, that is a mapping  $\gamma_i: (n, h_n) \rightarrow U_i$  which tells player  $i$  which control  $u_i(n) \in U_i$  to select given that the time period is  $n$  and the state history is  $h_n$ .

- Once such a model is formulated the question arises as to what strategy or policy should each agent adopt so that his/her decision provides him/her with the most benefit. The decision to adopt a good strategy is based on a performance criterion defined over the life of the agent (in this case  $[0, +\infty)$ ), that is, for each time horizon  $N$  the payoff to player  $i$  is determined by

$$J_N^i(x, \mathbf{u}) = \sum_{n=1}^N \beta_i^n g_i(x(n), \mathbf{u}(n)),$$

where  $x$  and  $\mathbf{u}$  denote the state and control evolutions over time,  $g_i: \mathbf{R}^{m_0} \times \dots \times \mathbf{R}^{m_p} \rightarrow \mathbf{R}$  is a given reward function and  $\beta_i \in [0, 1]$  is a discount factor for each player  $i = 1, \dots, p$ .

Two categories of difficulties have to be dealt with when one studies infinite horizon dynamic games:

- the consideration of an unbounded time horizon gives rise to the possibility of having diverging values for the performance criterion (i. e., tending to  $+\infty$  on all possible evolutions). This happens typically when there is no discounting ( $\beta_i = 1$ ). A related issue is the stability vs. instability of the optimally controlled system.

- A second category of difficulties are associated with the consideration of all possible actions and reactions of the different agents over time, since an infinite time horizon will always give any agent enough time to correct his/her strategy choice, if necessary.

The first difficulty is already present in a single agent system where the problem reduces to a dynamic optimization problem and is typically cast in the framework of the calculus of variations or optimal control in either discrete or continuous time. The second type of difficulty arises typically in nonzero-sum games.

### Unbounded Cost

To introduce the difficulties involved in studying infinite horizon problems we first consider the single player case. The single player case is the most studied of these problems with a relatively rich history beginning with the seminal paper of F. Ramsey [8]. Therefore we shall introduce the subject with the *Ramsey model*, using simpler notations than the one introduced above. In Ramsey's work a continuous time model for the economic growth of a nation is developed and analyzed. In discrete time, the dynamics for Ramsey's model is described by the difference equation

$$x_{n+1} = x_n + f(x_n) - c_n$$

with a fixed initial condition  $x_0$ . Here,  $x_n \geq 0$  denotes the amount of capital stock at the end of the time period  $n$ ;  $f(x_n)$  is a nonnegative valued function, known as the production function, which is defined for all positive  $x_n$  and represents the rate at which capital stock is produced given a stock level  $x_n$ ; and  $c_n > 0$  represents the rate at which the nation consumes the capital stock. Since a nation usually does not consume at a rate faster than it produces we also have the inequality constraint

$$0 \leq c_n \leq f(x_n) \quad \text{for all } n = 1, 2, \dots$$

The performance of the system is measured as an accumulation of social welfare over the time scale. Thus, up to a fixed time  $N$ , this is represented by the sum

$$J_N(\{c_n\}) = \sum_{n=1}^N U(c_n),$$

in which  $U(c_n)$  is called a *social utility function* and represents the 'rate of enjoyment' of society at a consump-

tion rate  $c_n$ . The goal of a decision maker in this model is to determine  $c_n$ ,  $n = 1, 2, \dots$ , so that

$$\lim_{N \rightarrow +\infty} J_N(\{c_n\}) = \lim_{N \rightarrow +\infty} \sum_{n=1}^N U(c_n)$$

is maximized. An immediate concern in attempting to solve such a problem is that the performance criterion is well defined. That is, for a given feasible element  $\{x_n, c_n\}$ ,  $n = 1, 2, \dots$ , is the above infinite series convergent? Additionally, if there exists feasible elements for which the convergence is assured how does one know if the supremum is finite. Ramsey was aware of these two difficulties and these issues were addressed in his work. In dealing with this lack of precision two ideas have arisen. The first of these is to introduce the notion of discounting to 'level the playing field' by scaling units to present value terms. This manifests itself through a positive weighting scheme. Specifically the performance criterion is modified through the introduction of a constant 'discount rate',  $\beta$ , between 0 and 1. That is, the above infinite series is replaced by

$$\lim_{N \rightarrow +\infty} J_N(\{c_n\}) = \lim_{N \rightarrow +\infty} \sum_{n=1}^N \beta^n U(c_n).$$

It is now an easy matter to see that if the sequence  $\{U(c_n)\}$  is bounded then the infinite series converges. Moreover, if all feasible sequences  $\{c_n\}$  are bounded and  $U(\cdot)$  is a continuous function it is easy to see that the supremum (as well as the infimum) over all such sequences is bounded above and the optimization problem is well defined. A criticism of discounting voiced by Ramsey is that it weights a decision maker's preference toward the present at the expense of the past. Consequently Ramsey seeks another approach. This alternate idea was that the rate at which a nation consumes is bounded and that ideally the best system would be one in which the rate is as large as possible. Thus Ramsey introduced the notion of a 'maximal sustainable rate of enjoyment' which he referred to as *bliss*. The notion of bliss, denoted by  $B$ , is defined now as an *optimal steady state* problem. That is,

$$\begin{aligned} B &= \max \{U(c) : c = f(x), x \geq 0\} \\ &= \max \{U(c) : c \geq 0\}. \end{aligned}$$

With this idea, the performance index is replaced by a new performance given as

$$\lim_{N \rightarrow +\infty} J_N(\{c_n\}) = \lim_{N \rightarrow +\infty} \sum_{n=1}^N B - U(c_n),$$

and the goal is to choose  $\{c_n\}$  as a minimizer instead of a maximizer. Observe that  $B - U(c_n) \geq 0$  for all  $n$  so that the above limit is bounded below by zero. Thus, if bliss is attained by some feasible sequence (that is,  $c_n = \bar{c}$  for all  $n$  sufficiently large with  $B = U(\bar{c})$ ), then the performance criterion is finite for at least one feasible element  $\{x_n, c_n\}$  and the minimization problem is well defined. Using the notion of bliss, Ramsey solved this problem using classical variational analysis (i. e., the Euler-Lagrange equation from the calculus of variations) to arrive at what is now referred to as *Ramsey's rule of economic growth*. Finally we remark that the solution, say  $\{x_n^*, c_n^*\}$ , obtained by Ramsey asymptotically approaches  $\{\bar{x}, \bar{c}\}$ , where  $\bar{x}$  the unique solution to the equation  $\bar{c} = f(x)$ .

The approach adopted by Ramsey in his model has become a prototype for studying more complex problems. In particular, the notion of bliss and the optimal steady state problem combined with the idea that bliss is obtained in finite time is now referred to as a *reduction to finite costs*. Finally the asymptotic convergence to the optimal steady state is referred to as an asymptotic turnpike property.

Since Ramsey 'solved' his problem through an application of necessary conditions he did not directly address the question of existence of an optimal solution. He assumed that the solution to the necessary condition was in fact a solution. However, in 1962, S. Chakravarty [4] gave a simple example in which the solution of Ramsey's rule was not a minimizer but a maximizer! This led to the quest for the existence of optimal solutions for these problems. As the performance objective is unbounded, the traditional notion of a minimizer is no longer valid. Thus, new types of optimality were introduced in the 1960s by C.C. von Weizäcker [10] to deal with this problem. These notions are now known as *overtaking optimality*, *weakly overtaking optimality*, and *finite optimality*. The most useful and strongest of these three types of optimality is *overtaking optimality*. In words, a sequence  $\{x_n^*, c_n^*\}$  is *overtaking optimal* if when compared with any other fea-

sible sequence  $\{x_n, c_n\}$  the finite horizon performance criterion,  $J_N(\{c_n^*\})$  is larger than  $J_N(\{c_n\})$  to within an arbitrarily small margin of error for all  $N$  sufficiently large.

The introduction of new types of optimality led to new important results concerning these problems. The first necessary conditions for these types optimality were given in 1974 by H. Halkin [5] in which the classical Pontryagin maximum principle was extended. Of particular notice in this result was the fact that the classical transversality condition found in corresponding finite horizon problems does not necessarily hold. This fact led to many results which insure some sort of boundary condition holds at infinity. The first general existence theorem for these optimization problems was given by W.A. Brock and H. Haurie [1] in 1976. During the 1980s these major results were extended in a variety of directions and many of these results are discussed in [3].

### Nonzero-Sum Infinite Horizon Games

We now turn our attention to  $p$ -player games. We use from now on the general notations introduced in the introduction. To simplify a little the exposition we shall use a simplified paradigm where each player is controlling his/her own dynamical system. Hence each player enjoys his/her own state and control, say  $\{x_i(n), u_i(n)\}$  for  $i = 1, \dots, p$  and  $n = 1, 2, \dots$ , and has a performance criterion, say  $J_N^i(\mathbf{x}, \mathbf{u})$ , which is described in discrete time up to the end of period  $N$  as

$$J_N^i(\mathbf{x}, \mathbf{u}) = \sum_{n=1}^N g_i(\mathbf{x}(n), \mathbf{u}(n)).$$

Here we use the notation

$$\mathbf{x}(n) = \{(x_1(n), \dots, x_p(n))\}$$

and

$$\mathbf{u}(n) = \{(u_1(n), \dots, u_p(n))\}.$$

From the notation we see that each players performance measure depends not only on their own decision but also those of the other players. This coupling may also occur in the dynamical system as well. In discrete time these systems may be represented by a system of  $p$  dif-

ference equations

$$x_i(n + 1) = f_i(\mathbf{x}(n), \mathbf{u}(n))$$

for  $n = 0, 1, \dots$  and  $i = 1, \dots, p$ .

The goal of each of the players is to ‘play’ the game so that their decisions provide them with the best performance possible. This action is in conflict with the other players and therefore generally it is not possible for the players to minimize or maximize their performance. The way one defines *optimality* in a game depends on the *mood of play*, i. e. if the players behave in a *cooperative* or in a *noncooperative* fashion.

### Cooperative Solution

If players cooperate they will want to reach an undominated solution, also called a *Pareto solution* after its originator, V. Pareto [7], who introduced the concept in 1896. A pair  $\{\mathbf{x}, \mathbf{u}\}$  is called a cooperative solution if there does not exist a feasible point  $\{\mathbf{y}, \mathbf{v}\}$  satisfying  $J^i(\mathbf{x}, \mathbf{u}) \geq J^i(\mathbf{y}, \mathbf{v})$  for all players  $i = 1, \dots, p$  with at least one strict inequality for one of the players. It is well known that such an equilibrium can be obtained by solving an appropriate single player game in which the payoff is a weighted sum of the payoffs of all of the players

$$J_r(\mathbf{x}, \mathbf{u}) = \sum_{j=1, \dots, p} r_j J^j(\mathbf{x}, \mathbf{u}),$$

$$r_j \geq 0, \quad j = 1, \dots, p.$$

In this way the problem is reduced to the case of infinite horizon optimization and the remarks made earlier apply.

### Noncooperative Solutions

If players do not cooperate one may consider that they will be satisfied of the outcome if, for each player, his/her strategy is the best response he/she can make to the strategies adopted by the other players. This is the concept of *equilibrium*, introduced in 1951 by J.F. Nash [6] in the context of matrix games. In general, the search for a *Nash equilibrium* can not be reduced to an optimization problem. Since each players decision is his/her best decision under the assumption that the decisions of the other players are fixed, the search for an equilibrium is equivalent to the search for a fixed-point

of a reaction mapping that associates with each strategy choice by the  $p$  players the set of optimal responses by each of them. To better understand this concept it is preferable to consider first a game defined in its *normal form*. Let  $\gamma_j \in \Gamma_j$  design the strategies of player  $j$ . Let  $V_j(\gamma_1, \dots, \gamma_p) \in \mathbf{R}$  be the payoff to player  $j$  associated with the strategy choices  $\underline{\gamma} = (\gamma_1, \dots, \gamma_p)$  of the  $p$  players.  $\underline{\gamma}^*$  is a Nash equilibrium if

$$V_j(\gamma_1^*, \dots, \gamma_j, \dots, \gamma_p^*) \leq V_j(\underline{\gamma}^*), \\ \forall \gamma_j \in \Gamma_j, \quad j = 1, \dots, p.$$

Now we introduce the product strategy set  $\underline{\Gamma} = \prod_{j=1}^p \Gamma_j$  and the mapping

$$\sigma: \underline{\Gamma} \times \underline{\Gamma} \rightarrow \mathbf{R}, \\ \sigma(\underline{\gamma}^1, \underline{\gamma}^2) = \sum_{j=1}^p V_j(\gamma_1^1, \dots, \gamma_j^2, \dots, \gamma_p^1).$$

Finally let us define the point to set mapping  $\Psi: \underline{\Gamma} \rightarrow 2^{\underline{\Gamma}}$  defined by

$$\Psi(\underline{\gamma}) = \left\{ \underline{\gamma}^+ : \sigma(\underline{\gamma}, \underline{\gamma}^+) = \sup_{\underline{\gamma}^0 \in \underline{\Gamma}} \sigma(\underline{\gamma}, \underline{\gamma}^0) \right\}.$$

$\Psi$  is the *best response mapping* for the game. A fixed-point of  $\Psi$  is a strategy vector  $\underline{\gamma}^*$  such that

$$\underline{\gamma}^* \in \Psi(\underline{\gamma}^*).$$

$\underline{\gamma}^*$  is a fixed-point of  $\Psi$  if and only if it is a Nash equilibrium.

In a dynamic setting the concept of strategy is closely related to the *information structure* of the game. We have assumed, in the beginning that the players can remember the whole (state and control) history of the dynamical system they contribute to control. This is the most precise information that can be available to the players at each instant of time. On the other end we can assume that the only information available to a player is the initial state of the system  $x^0 = x(0)$  and the current time  $t$ . A strategy  $\gamma_j$  for player  $j$  will thus be an *open-loop control*  $\{u_j(n)\}_{n=0, \dots, \infty}$ . An equilibrium in this class of strategies is called an *open-loop Nash equilibrium*. An intermediate case is the one where each player can observe the state of the system at each time

period but does not recall the previous history of the system, neither the state nor the control values. A (stationary) strategy  $\gamma_j$  for player  $j$  will thus be a *closed-loop control* or a feedback control  $\gamma_j: \mathbf{x} \mapsto u_j = \gamma_j(\mathbf{x})$ . An equilibrium in this class of strategies is called a *feedback Nash equilibrium*. In the economics literature, feedback strategies are also called *Markov strategies* to emphasize the lack of memory in the information structure.

For a single agent deterministic system, i. e. an optimal control problem, the information structure does not really matter. The agent will not be able to do better than the optimal open-loop control, even if he/she has a perfect memory. In a two-player zero-sum dynamic game this will also be the case. In a nonzero-sum game the different information structures lead to different types of equilibria.

A criticism of the open-loop Nash equilibrium is that it is not necessarily *subgame perfect* in the sense of R. Selten [9]. This means that if a player deviates from the equilibrium control for a while and then decides to play again ‘correctly’, then the previously defined equilibrium is not an equilibrium any more. A *feedback Nash equilibrium* can be made subgame perfect if one uses *dynamic programming* to characterize it. A *memory strategy Nash equilibrium* can also be made subgame perfect. Furthermore, the possibility to remember past actions or state values permit the player to define a so-called *communication equilibrium* where, before the play the agents communicate with each other and decide to use a specific *memory strategy equilibrium*. The memory permits the inclusion of threats that would support a cooperative outcome. The cooperative outcome becomes also a Nash equilibrium outcome. This type of results have been known as the ‘*folks theorem*’ in economics. The infinite horizon is essential to obtain this type of result.

Nevertheless, the open-loop concept still has wide interest for a variety of reasons. In infinite horizon games the notion of overtaking Nash equilibrium is defined analogously to the concept in the single-player. These ideas have just recently begun to be studied extensively with the first existence theory for open-loop Nash equilibria and a corresponding turnpike theory being given in 1996 in [2]. Finally, from a practical setting, the numerical computation of a feedback Nash equilibrium is much less understood than the computation of an open-loop Nash equilibrium. The analo-

gous theory for feedback (or closed-loop) equilibria is still waiting to be developed.

In closing, the theory of infinite horizon dynamic games is for the most part still in its infancy and much remains to be studied and researched. One important open question concerns the existence of overtaking feedback Nash equilibria and another is that once such an equilibrium is known to exist can a robust numerical procedure for computation of equilibrium be developed.

Information-based complexity; Information-based optimization; Real number model; Linear programming; Nonlinear optimization; High-dimensional integration; Mathematical finance; Curse of dimensionality

This article concerns optimization in two senses. The first is that *information-based complexity* (IBC) is the

study of the minimal computational resources to solve continuous mathematical problems. (Other types of mathematical problems are also studied; the problems studied by IBC will be characterized later.) J.F. Traub and A.G. Werschulz [14] provide an expository introduction to the theory and applications of IBC, with over 400 recent papers and books. A general formulation with proofs can be found in [13].

The second is that the *computational complexity of optimization problems* is one of the areas studied in IBC. S.A. Vavasis [16 pag. 135] calls this *information-based optimization*. We will discuss information-based complexity and information-based optimization in turn.

### Information-Based Complexity

To introduce computational complexity, we first define the *model of computation*. The model of computation states which operations are permitted and how much they cost. The model of computation is based on two assumptions:

- 1) We can perform arithmetic operations and comparisons on real numbers at unit cost.
- 2) We can perform an information operation at cost  $c$ . Usually,  $\gg 1$ .

We comment on these assumptions. The *real number model* (Assumption 1) is used as an abstraction of the floating-point model typically used in scientific computation. Except for the possible effect of roundoff errors and numerical stability, complexity results will be the same in these two models.

The real number model should be contrasted with the *Turing machine model*, typically used for discrete problems. The cost of an operation in a Turing machine model depends on the size of the operands, which is not a good assumption for floating point numbers. For a full discussion of the pros and cons of the Turing machine and real number models see [14 Chapt. 8]. Whether the real number or Turing machine model is used can make an enormous difference. For example, L.G. Khachiyan [3] shows that *linear programming* is polynomial in the Turing machine model. In 1982, Traub and H. Woźniakowski [15] showed that Khachiyan's algorithm is not polynomial in the real number model and conjectured that linear programming is not polynomial in this model. This conjecture is still open.

The purpose of information operations (Assumption 2) is to replace the input by a finite set of numbers. For integration, the information operations are typically function evaluations.

### Computational Complexity of High-Dimensional Integration

We illustrate some of the important ideas of IBC with the example of high-dimensional integration.

We wish to compute the integral of a real-valued function  $f$  of  $d$  variables over the unit cube in  $d$  dimensions. Typically, we have to settle for computing a numerical approximation with an error  $\varepsilon$ . To guarantee an  $\varepsilon$ -approximation we have to know some global information about the integrand. We assume that the class  $F$  of integrands has smoothness  $r$ . One such class is  $F_r$ , which consists of those functions having continuous derivatives of order through  $r$ , these derivatives satisfying a uniform bound.

A real function of a real variable cannot be entered into a digital computer. We evaluate  $f$  at a finite number of points and we call the set of values of  $f$  the local information, for brevity *information*, about  $f$ . An algorithm combines the function values into a number that approximates the integral.

In the worst-case setting we want to guarantee an error at most  $\varepsilon$  for every  $f \in F$ . The computational complexity, for brevity complexity, is the least cost of computing the integral to within  $\varepsilon$  for every  $f$ . We want to stress that the complexity depends on the problem and on  $\varepsilon$ , but not on the algorithm. Every possible algorithm, whether or not it is known, and all possible points at which the integrand is evaluated are permitted to compete when we consider least possible cost.

It can be shown that if  $F = F_r$ , then the complexity of our integration problem is of order  $\varepsilon^{-dr}$ . If  $r = 0$ , e. g., if our set of integrands consists of uniformly bounded continuous functions, the complexity is infinite. That is, it is impossible to solve the problem to within  $\varepsilon$ . Let  $r$  be positive and in particular let  $r = 1$ . Then the complexity is of order  $\varepsilon^{-d}$ . Because of the exponential dependence on  $d$ , we say the problem is computationally intractable. This is sometimes called the *curse of dimensionality*.

We will compare this  $d$ -dimensional integration problem with the well-known traveling salesman prob-

lem (TSP), an example of a discrete combinatorial problem. The input is the location of the  $n$  cities and the desired output is the minimal route; the city locations are usually represented by a finite number of bits. Therefore the input can be exactly entered into a digital computer. The complexity of this problem is unknown but conjectured to be exponential in the number of cities. That is, the problem is conjectured to be computationally intractable and many other combinatorial problems are conjectured to be intractable.

Most problems in scientific computation which involve multivariate functions belonging to  $F_r$  have been proven computationally intractable in the number of variables in the worst-case setting. These include nonlinear equations [10], partial differential equations [19], function approximation [7], integral equations [19], and optimization [6]. Material on the computational complexity of optimization will be presented in the second half of this article.

Very high-dimensional integrals occur in many disciplines. For example, problems with dimension ranging from the hundreds to the thousands occur in mathematical finance. Path integrals, which are of great importance in physics, are infinite-dimensional, and therefore invite high-dimensional approximations. This motivates our interest in breaking the curse of dimensionality. Since this is a complexity result, we cannot get around it by a clever algorithm. We can try to break the curse by settling for a stochastic assurance rather than a worst-case deterministic assurance. Examples of stochastic assurance are provided by the randomized and average case settings which we will consider below. We can also try to break the curse by changing the class of inputs. A good example of this occurs in mathematical finance.

### Mathematical Finance

The valuation of financial instruments often requires the calculation of very high-dimensional integrals. Dimensions of 360 and higher are not unusual. Furthermore, since the integrals can be very complicated requiring between  $10^5$  and  $10^6$  floating point operations per integrand evaluation, it is important to minimize the number of evaluations. Extensive numerical testing shows that these problems do not suffer from the curse

of dimensionality. A possible explanation is given by I. Sloan and Woźniakowski [11], who show that the curse can be broken by changing the class of integrands to capture the essence of the mathematical finance problem. See [14 Chapt. 4] for a survey of high-dimensional integration and mathematical finance.

### General Theory

In general, IBC is defined by the assumptions that the *information* concerning the mathematical model is

- partial,
- contaminated, and
- priced.

Referring to the integration example, the mathematical input is the integrand and the information is a finite set of function values. It is *partial* because the integral cannot be recovered from function values. For a partial differential equation the mathematical input consists of the functions specifying the initial value and/or boundary conditions. Generally, the mathematical input is replaced using a finite number of information operations. These operations may be functionals on the mathematical input or physical measurements that are fed into a mathematical model.

In addition to being partial the information is often *contaminated* by, for example, round-off or measurement error ([8]). If the information is partial or contaminated it is impossible to solve the problem exactly. Finally, the information is *priced*. As examples, functions can be costly to evaluate or information needed for oil exploration models can be obtained by setting off shocks. With the exception of certain finite-dimensional problems, such as roots of systems of polynomial equations and problems in numerical linear algebra, the problems typically encountered in scientific computation have information that is partial and/or contaminated and priced.

As part of our study of complexity we investigate *optimal algorithms*, that is, algorithms whose cost is equal or close to the complexity of the problem. This has sometimes led to new solution methods. The reason that we can often obtain the complexity and an optimal algorithm for IBC problems is that partial and/or contaminated information permits arguments at the information level. This level does not exist for combinatorial problems where we usually have to settle for trying

to establish a complexity hierarchy and trying to prove conjectures such as  $P \neq NP$ .

A powerful tool at the information level is the notion of the *radius of information*,  $R$ . The radius of information measures the intrinsic uncertainty of solving a problem using given information. We can compute an  $\varepsilon$ -approximation if and only if  $R \leq \varepsilon$ . The radius depends only on the problem being solved and the available information; it is independent of the algorithm. The radius of information is defined in all IBC settings.

### Information-Based Optimization

We turn to the application of IBC concepts to information-based optimization.

In their seminal book, A.S. Nemirovsky and D.B. Yudin [6] study a *constrained optimization* problem. They wish to minimize a nonlinear function subject to nonlinear constraints. Let  $f = [f_0, \dots, f_m]$ , where  $f_0$  denotes the objective function and  $f_1, \dots, f_m$  denote constraints. Let  $F$  be the product of  $m+1$  copies of  $F_r$ . Then

$$\text{comp}(\varepsilon) = \Theta \left( \left( \frac{1}{\varepsilon} \right)^{d/r} \right).$$

Thus this problem suffers from the curse of dimensionality.

Vavasis [16 Chapt. 6] reports on the worst-case complexity of minimizing an objective function with box constraints. He assumes objective functions defined on the unit cube in  $d$  dimensions and takes  $F$  as the class of continuous functions with uniform Lipschitz constant  $L$ . For *global minimization*,

$$\text{comp}(\varepsilon) = \Theta \left( \left( \frac{L}{2\varepsilon} \right)^d \right).$$

Thus global minimization is intractable.

In contrast to global minimization, the problem of computing a *local minimum* is tractable with suitable conditions on  $F$ . Let  $F$  consist of continuously differentiable real functions on  $[0, 1]^d$  whose gradients satisfy a uniform Lipschitz condition with constant  $M$ . Then  $4d(M/\varepsilon)^2$  function and gradient evaluations are sufficient.

As discussed above, there are two ways one can attempt to break the curse of dimensionality: by settling

for a stochastic assurance, or by changing the class of inputs. For the constrained optimization problem, we first describe changing the class of functions, and then turn to weakening the assurance.

Nemirovsky and Yudin [6] take  $F = F_{\text{conv}}$  to be the class of convex functions that satisfy a Lipschitz condition with a uniform constant on a bounded convex set  $D$ . Then

$$\text{comp}(\varepsilon) = \Theta \left( \log \frac{1}{\varepsilon} \right),$$

where the constant in the  $\Theta$ -notation depends polynomially on the dimension  $d$  of  $D$  and  $m$ , the number of constraints. Thus, convexity breaks the curse of dimensionality.

The worst-case deterministic assurance may be weakened to a stochastic assurance; we report on the randomized and average case settings.

Nemirovsky and Yudin [6] show that *randomization* does not break the curse of dimensionality for computing the minimum value of the nonlinear constrained problem. G.W. Wasilkowski [17] establishes an even more negative result if an  $\varepsilon$ -approximation to the value of  $x$  that minimizes  $f_0$  is sought. He permits randomization and shows that for all  $\varepsilon < 1/2$ , this problem is unsolvable even if  $d = 1$ .

The results considered so far use a sequential model of computation. One could also ask about the complexity under a *parallel model of computation*. If we have  $k$  processors running in parallel, how much can the computation of the minimum be sped up? Clearly, the best possible speedup is  $k$ . Nemirovsky [5] considers this problem for the case  $F = F_{\text{conv}}$ , showing that

$$\text{comp}^{\text{par}}(\varepsilon, k) = \Omega \left( \left( \frac{d}{\ln(2kd)} \right)^{1/3} \ln \left( \frac{1}{\varepsilon} \right) \right),$$

where the  $\Omega$ -constant is independent of  $k$  and  $\varepsilon$ . Hence we find that

$$\frac{\text{comp}(\varepsilon)}{\text{comp}^{\text{par}}(\varepsilon, k)} = O \left( \left( \frac{\ln(2kd)}{d} \right)^{1/3} \right),$$

which is much less than  $k$ . Thus parallel computation is not very attractive for this problem.

The average case setting looks more promising than the randomized setting, but since it is technically very

difficult, the results to date are quite limited. In the average case setting we want to guarantee that the expected error is at most  $\varepsilon$  and we minimize the expected cost.

In the *average case setting*, an a priori measure must be placed on  $F$ . Typically, this measure is *Gaussian*; in particular, *Wiener measures* are used. Since the distribution of the random variable  $\min_x f(x)$  is difficult to obtain, the average case analysis of the global optimization problem is very difficult. Only partial results have been obtained.

Let  $d = 1$  and  $F \subset C^r[0, 1]$ . Assume that  $F$  is endowed with the  $r$ -fold Wiener measure. Wasilkowski [18] shows that approximately  $(\varepsilon^{-1} \sqrt{\ln \varepsilon^{-1}})^{1/(r+1/2)}$  function evaluations suffice. This is better than the worst case, where some  $\varepsilon^{-1/r}$  function values are needed.

Stronger results have been obtained for the case of  $d = 1$  and  $r = 0$ , i. e., optimization for continuous scalar functions, equipped with the Wiener measure. K. Ritter [9] considers the case of *nonadaptive methods*, showing that

$$\text{comp}^{\text{non}}(\varepsilon) = \Theta \left( \left( \frac{1}{\varepsilon} \right)^2 \right).$$

Moreover, the optimal evaluation points are equidistant knots. More recently (1997), J.M. Calvin [1] investigates *adaptive methods* for this problem, showing that for any  $\delta \in (0, 1)$ ,

$$\text{comp}^{\text{ad}}(\varepsilon) = O \left( \left( \frac{1}{\varepsilon} \right)^{1/(1-\delta)} \right).$$

The study of optimization in the average case setting is a very promising area for future research. Important open problems include:

- obtaining multivariate results,
- obtaining lower bounds,
- obtaining better upper bounds.

We now restrict our attention to the special optimization problem of linear programming (LP), which we discuss in the worst-case setting.

In 1979, Khachiyan [3] studied an *ellipsoid algorithm* and proved that LP is polynomial in the Turing machine model. In 1982, Traub and Woźniakowski [15] showed that the cost of this ellipsoid algorithm is not polynomial in the real-number model, and con-

cluded that the LP problem is not polynomial in the real-number model. This nicely illustrates the difference between the cost of an algorithm and the complexity of a problem, since the result concerning the cost of the ellipsoid algorithm leaves open the question of problem complexity. The Traub–Woźniakowski conjecture remains open.

A related open question is whether LP can be solved in *strongly polynomial time*. (Note that the underlying models of computation are different: the real-number model versus the Turing machine model.) This question is also still open, with results known only for special cases. In 1984, N. Megiddo [4] showed that LP can be solved in linear time if the number of variables is fixed, while in 1986, É. Tardos [12] showed that many LP problems that arise from combinatorial applications can be solved in strongly polynomial time.

We now discuss the computation of *fixed points*, which we include here because the result involves ellipsoid methods. The problem is to compute the fixed point of  $f(x)$ ; that is, to solve the nonlinear equation  $x = f(x)$  for any  $f \in F$ , where  $F$  is the class of functions on  $[0, 1]^d$  having a Lipschitz constant of  $q$ , with  $q \in (0, 1)$ .

The simple iteration algorithm  $x_{i+1} = f(x_i)$ , with  $x_0 = 0$ , can compute an  $\varepsilon$ -approximation with at most

$$n_{\text{si}}(\varepsilon, q) = \left\lceil \frac{\ln 1/\varepsilon}{\ln 1/q} \right\rceil$$

evaluations of  $f$ . Thus the simple iteration algorithm behaves poorly if  $q$  is close to one.

Z. Huang, Khachiyan, and K. Sikorski [2] show that an inscribed ellipsoid algorithm computes an  $\varepsilon$ -approximation with

$$n_{\text{e}}(\varepsilon, q) = O \left( d \left( \ln \frac{1}{\varepsilon} + \ln \frac{1}{1-q} \right) \right)$$

function evaluations. Thus their algorithm is excellent for computing fixed points of functions with  $q$  close to unity; that is, almost noncontracting functions.

### Keywords

LCP; Zero-one integer programming

Let  $M$  be a given  $n \times n$  matrix, and let  $q$  be a given  $n$  vector. The *linear complementary problem* (LCP; cf. also ▶ [Linear complementarity problem](#)) is to find a vector  $x$  which satisfies the following system:

$$\begin{cases} x \geq 0, \\ Mx + q \geq 0, \\ x^T(Mx + q) = 0. \end{cases} \quad (1)$$

When some or all the variables are required to be integers, the problem is called *integer linear complementary problem* (ILCP).

Suppose that for each  $i$  ( $i = 1, \dots, k$ ), the variable  $x_i$  is required to be integer among

$$x_i \in \{0, \dots, n_i\},$$

while for each  $i$  ( $i = k+1, \dots, n$ ), the variable  $x_i$  is continuous and

$$0 \leq x_i \leq \beta_i.$$

The problem can be formulated as the feasibility problem which finds a solution  $x$  and  $z$  such that

$$\begin{cases} 0 \leq M_i x + q_i \leq B_i(1 - z_i), \\ 0 \leq n_i z_i - x_i, & i = 1, \dots, k, \\ x_i \in \{0, \dots, n_i\}, & i = 1, \dots, k, \\ 0 \leq \beta_i z_i - x_i, & i = k + 1, \dots, n, \\ 0 \leq x_i \leq \beta_i, & i = k + 1, \dots, n, \\ z \in \{0, 1\}^n, \end{cases}$$

(2)

where  $M_i$  is the  $i$ th row of  $M$ ,  $q_i$  is the  $i$ th component of  $q$  and  $B_i$  is the optimal value of the following problem:

$$\begin{cases} \max & M_i x + q_i \\ \text{s.t.} & x_i \in \{0, \dots, n_i\}, \quad i = 1, \dots, k, \\ & 0 \leq x_i \leq \beta_i, \quad i = k + 1, \dots, n, \end{cases}$$

which can be solved analytically.

It has been shown [2] that if the region (2) is empty, the associated (ILCP) has no solution. Otherwise, if  $(\bar{x}, \bar{z})$  satisfies (2), then  $\bar{x}$  solves the (ILCP).

Obviously, when all the variables of LCP are zero-one integers, the (ILCP) is formulated as a *zero-one integer feasibility problem* of the form:

$$\begin{cases} \text{Find} & x, z \\ \text{s.t.} & 0 \leq M_i x + q_i \leq B_i(1 - z_i), \\ & 0 \leq z_i - x_i, \quad i = 1, \dots, n, \\ & x, z \in \{0, 1\}^n, \end{cases} \quad (3)$$

where

$$B_i = \max \{M_i x + q_i : x \in \{0, 1\}^n\}.$$

It is worth noting that the *minimum norm solution* of the zero-one (ILCP) can be obtained by solving the following *linear zero-one integer problem*:

$$\begin{cases} \min & \sum_{i=1}^n x_i \\ \text{s.t.} & (x, z) \text{ satisfies (3)}. \end{cases} \quad (4)$$

We note that there are many algorithms for solving the problem with practical size.

Integer variables without known upper bounds make the problem much harder. Let us consider the (ILCP) defined below:

$$\begin{cases} \text{Find} & x \\ \text{s.t.} & x \geq 0, \\ & Mx + q \geq 0, \\ & x^T(Mx + q) = 0, \\ & x_i \text{ is integer for } i = 1, \dots, k. \end{cases}$$

This problem can be rewritten in the form:

$$\begin{cases} \text{Find} & \alpha, y, z \\ \text{s.t.} & 0 \leq My + \alpha q \leq e - z, \\ & 0 \leq \alpha, \\ & 0 \leq y \leq z, \\ & z \in \{0, 1\}^n, \\ & y_i/\alpha \text{ is integer for } i = 1, \dots, k, \end{cases} \quad (5)$$

where  $e$  is a vector of all ones. If  $(\bar{\alpha}, \bar{y}, \bar{z})$  solves (5), i. e., for each  $i = 1, \dots, k$ ,  $\bar{y}_i/\bar{\alpha}$  is integer,  $x = \bar{y}/\bar{\alpha}$  solves its associated (ILCP). See [3] and [2] for a proof of the equivalence.

The (ILCP) arises in several contexts such as polymatrix games in pure strategies, economic equilibrium with discrete activity levels and spatial price equilibrium in discrete commodities. See [2], for details.

Let us consider the *polymatrix game*. Suppose that each player  $i$  ( $i = 1, \dots, n$ ) has a finite number  $m_i$  of strategies, and the partial payoffs to player  $i$ , resulting from choices by him/her and player  $j$ , are given by  $m_i \times m_j$  matrices  $A^{ij}$  ( $i, j = 1, \dots, n$ ). The elements of  $A^{ij}$  are assumed to be positive without loss of generalities.

Let

$$X^{i\top} = (X_1^i, \dots, X_{m_i}^i), \quad i = 1, \dots, n,$$

be a vector where each component  $X_s^i$  expresses the probability of  $i$  playing his  $s$ th strategy. It has been shown [1] that finding equilibria of polymatrix games is equivalent to find solutions of the linear complementarity problem defined below.

Let

$$v^i = (X^i)^\top \sum_{j \neq i} A^{ij} X^j, \quad i = 1, \dots, n.$$

Also, let us define

$$x^T = (X^{1T}, \dots, X^{nT}, v^1, \dots, v^n),$$

$$q^T = (\underbrace{0, \dots, 0}_{\sum_{i=1}^n m_i}, \underbrace{-1, \dots, -1}_n),$$

and

$$M = \begin{pmatrix} 0 & A^{12} & \dots & A^{1n} & -e & 0 & \dots & 0 \\ A^{21} & 0 & \dots & A^{2n} & 0 & -e & \dots & 0 \\ \vdots & \vdots & & \vdots & \vdots & \vdots & & \vdots \\ A^{n1} & A^{n2} & \dots & 0 & 0 & 0 & \dots & -e \\ e^T & 0 & \dots & 0 & 0 & 0 & \dots & 0 \\ 0 & e^T & \dots & 0 & 0 & 0 & \dots & 0 \\ \vdots & \vdots & & \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & \dots & e^T & 0 & 0 & \dots & 0 \end{pmatrix},$$

where  $e$  is a vector of all ones whose dimension is given by context. Then, the above polymatrix game can be equivalently written as (1). Moreover, suppose that some players,  $i$  ( $i = 1, \dots, k$ ), can select only one pure strategies, while the other players,  $i$  ( $i = k+1, \dots, n$ ), can select mixed strategies. For each player  $i$  ( $i = 1, \dots, k$ ), the vector  $X^i$  is required to be zero-one integer, which results (ILCP).

## Introduction

Owing to the exponential growth of traffic demand, there is an emerging challenge as well as an opportunity for service providers to employ Internet Protocol (IP) backbone networks carried on top of optical transport networks, forming IP over optical infrastructure. This technology is poised to take over most of broadband operational services as an integrated transport platform for the following reasons. Optical networks offer the capability to carry numerous wavelength signals or channels simultaneously without interaction between each wavelength, known as wavelength division multiplexing (WDM) [14,16,18].

Also WDM optical switches are known to be reliable, support high speed, and are economical, which makes them an attractive selection for the default modern transport network. Moreover, new emerging services that require high bandwidth and reliability (such as Internet Protocol TV – IPTV [2]) are considering optical networks as the underlying network to directly carry the traffic. However, to best efficiently utilize WDM networks, network operators face a number of management and operation challenges, which often require complex mathematical models and advanced optimization techniques. This article focuses on these challenges and briefly review how integer linear programming (ILP) formulation and algorithms have been

developed and applied to the domain of optical networks.

## Motivations and Challenges in Optimization Models

The management and operation of WDM networks involve a number of challenges, which should address the physical topology formation, logical topology formation, survivability and fault management. Designing a new transport network is very complex, as it requires one to make decisions on where to place optical nodes so as to provide survivability, connectivity, and cost-effectiveness. Once the physical topology has been fixed, the logical topology of the backbone is decided by setting up lightpaths from one optical node to another. In transport networks, providing survivability and fault management is the most important task. Especially, routing should rapidly recover from any failure in the logical topology, because even a short outage reflects a massive amount of traffic loss in high-speed transport networks. The management and operation of these complex challenges benefit greatly from using mathematical modeling and optimization techniques.

Today's backbone mostly takes a form of a layered IP over optical network. For survivability, it is extremely important to address the practical issue of *how IP routing and protection schemes can effectively exploit the lower layer path diversity*. IP layer failures are known to occur most frequently, while fiber span failures are catastrophic in that they lead to multiple simultaneous upper layer failures. Moreover, some of the IP layer failures can be only addressed in the IP layer, as lower layer (optical) survivability mechanisms cannot detect failures occurring at higher (IP or applications) layers. In order to rapidly recover from network-wide failures and provide persistent end-to-end path quality, service providers may set up two diverse paths: the service (primary) path and the restoration (backup) path. Any failure in the service path can be hidden, as traffic can be instantly rerouted to the restoration path. Obviously, the efficacy of the restoration path depends heavily on how disjoint these two paths are (under the most frequent single failures). Therefore, it is important to understand how the layering employed in the network affects the correlation of failures among paths.

This demonstrates the importance of protection against failures in layered networks arising out of shared risk resource groups (SRRG). An example of SRRG is multiple IP links sharing a common optical component, including ducts or conduits through which multiple optical links are routed under the ground. To effectively deliver high-quality services to customers, network providers are required to incorporate this SRRG information into their routing and protection schemes, which has become one of the most challenging problems in networking practice. Note that the SRRG-diverse constraint involves multiple link failure models, in the form of shared risk link groups (SRLGs) and shared risk node groups (SRNGs). Most of previous studies in IP-over-WDM networks considered only two possible alternatives of routing and protection schemes: protection at the optical layer or restoration at the IP layer [7,11,15,16,17].

### Path-Protection (Diverse) Routing Problem

Finding a backup path that is disjoint for each working or “primary” path, in general, has been recognized as *path-protection* schemes and has been widely studied in optical networks. Medard et al. [12] focused on the problem of identifying two redundant trees from a single source to a set of destinations that can survive any single link failure (i. e., the elimination of any vertex in the graph leaves each destination vertex connected to the source via at least one of the directed trees). Ellinas et al. [5] focused on the problem of identifying two diverse paths that are SRRG failure resilient. They were the first to theoretically prove that if an arbitrary set of links can belong to a common SRLG, then the problem of finding SRLG-diverse paths between a given source and destination is NP-complete for unicast traffic. Subsequently, Zang et al. [22] proposed heuristic algorithms for the combined problem of finding SRLG-diverse paths and wavelength assignment for one-to-one (unicast) traffic. Most recently, Cha et al. [2] studied the SRLG-diverse routing for one-to-many (multicast) traffic, where they focused on the combined problem of minimizing the network cost of multicasting traffic from dual sources to multiple destinations while providing path protection against a single SRLG failure.

### Minimum Color Problem

Coudert et al. [4] proposed new techniques for the minimum color path problem for multiple failure tolerance from a SRRG failure. The consequence minimum color *st*-cut problem was also shown to be NP-complete and hard to approximate. Each SRRG is associated with a so-called color in a colored graph  $G_c = (V, E, C)$ , where  $C$  is a family of subsets of  $E$ . The minimum color path problem is to find a path from a node  $s$  to a node  $t$  that minimizes the number of different colors of its links. This problem was proven to be NP-complete in [21] and polynomial in the special case where all the edges of each color have a common extremity. Many insightful theoretical results of this problem were reported in [4].

**Definition 1** [4] Let  $G = (V, E, C)$  be a colored graph, where  $C$  is a partition of  $E$ . The minimum color cut consists in finding a minimal set of colors disconnecting  $G$ . Let  $s, t \in V$  be two distinct vertices in  $G$ . The minimum color *st*-cut problem is to find a minimal set of colors disconnecting  $s$  from  $t$ .

**Theorem 1** [4] *The minimum color st-cut is NP-hard.*

Coudert et al. [4] proved this theorem by proposing the reduction of each set of the set cover instance to a color of the minimum *st*-cut instance.

**Theorem 2** [4] *The minimum color st-cut problem is not approximable within a factor  $o(\log n)$  unless  $NP \subseteq TIME(n^{O(\log \log n)})$ .*

**Theorem 3** [4] *When the edges of each color induce a connected subgraph the minimum color st-cut and the minimum color cut problems are polynomial.*

**Theorem 4** [4] *The minimum color st-cut is  $k$ -approximable when the number of connected components of the subgraph induced by edges of each color is bounded by  $k$ .*

Define a nonnegative variable for each node, where some edge  $e$  between nodes  $i$  and  $j$  institutes a cut if  $x_i \neq x_j$ . If any edge of color  $c$  institutes a cut, then  $c$  is a color cut. Let a binary variable  $y_c$  be associated with each color  $c$ , where  $y_c = 1$  when the color  $c$  is selected to be in a set of color cut, and  $y_c = 0$  otherwise. The minimum color *st*-cut problem can be formulated as a mixed integer linear program as follows:

$$\min \sum_{c \in C} y_c \quad (1)$$

$$\text{subject to } y_c \geq |x_i - x_j| \forall c \in C, \forall i, j \in c, \quad (2)$$

$$x_i \geq 0 \quad \forall i \in V, \quad (3)$$

$$x_s = 0, x_t = 1. \quad (4)$$

### Finding the Dual Link Problem

The problems related to finding a pair of link or node disjoint paths in single cost networks have been studied since the mid 1980s [19]. The min-sum problem of dual link is to minimize the sum of the costs of the two disjoint paths and can be solved using a polynomial time algorithm called the shortest pair of paths [19]. In a recent study, the min-sum problem was shown to be a special case of the min-cost flow problem [2]. In contrast to the min-sum problem, the min-max problem, whose objective is to minimize the length of the longer one of the two paths was proven to be NP-complete [10]. The min-min problem, whose objective is to minimize the length of the shorter one of the two paths, can also be proven to be NP-complete [20] by using the reduction of a the well-known 3-satisfiability (3SAT) problem. The proof can be described as follows [20]. An instance of 3SAT is a boolean formula that is the AND of  $m$  clauses  $C_j (j = 1, \dots, m)$ . A clause is the OR of three literals, each of which is an occurrence of variable  $x_i (i = 1, \dots, n)$  or its negation. A truth assignment is a function  $\tau : \{x_i\} \rightarrow \{\text{true}, \text{false}\}$ .  $C_j$  is satisfied by  $\tau$  if it contains a literal with truth value. The question of 3SAT is to determine whether there is a truth assignment that satisfies all  $m$  clauses simultaneously. With the 3SAT approach, Xu et al. [20] proposed the following theorem.

**Theorem 5 [20]** *The problem of finding two node/link-disjoint paths between a pair of source and destination nodes in a directed/undirected network with minimum cost for the shorter one is NP-complete.*

### SRRG-Diverse Routing Problem

The SRRG-diverse routing problem can be considered to be a generalization of the link-diverse/disjoint routing problem. In a multicast context, the link-disjoint path-protection problem can be viewed as a diverse routing problem of identifying two redundant trees from a single source to a set of destinations

that can survive any single link failure [6,12]. The diverse routing problem has been previously shown to be NP-complete [1,7,8]. During the past few years, there has been increasing interest in the diverse routing problem with SRRG-diverse constraints as SRRG-diversity requirements play a very crucial role in real life network provisioning problems. An example of real life problems is finding a pair of diverse paths at the optical layer, which involves the search of two SRLG-diverse paths as each link at the OXC (optical cross connect) layer may be related to several SRLGs. Many recent studies have shown that the generalized SRLG (or SRRG) diverse routing is a special case of the diverse routing problem, which is also NP-complete [5,8,11,13,22]. Among those studies, the diverse routing problem of unicast (one-to-one) traffic with SRLG-diverse constraints has been proven to be NP-complete [5]. In later studies, the diverse routing problem was extended to many special cases (e.g., diverse routing under both wavelength capacity and path length constraints [22], multicast routing under SRLG-diverse constraint [3]).

Cha et al. [3] proposed a generalized case of the SRRG-diverse routing problem where there are two source nodes. The problem can be formally defined as follows. Let  $G = (V, E)$  be an undirected graph representing the backbone network. We denote the set of network nodes by  $V$ , while  $E$  is the set of duplex communications links (edges). Let the number of nodes and edges be  $n$  and  $m$ , respectively. There is a set of two source nodes, denoted by  $S \subset V$ , and there is a set of destination nodes, denoted by  $D \subset V$ . Denote  $B$  as a set of SRLGs. Each link  $(i, j) \in E$  in the graph has a cost function  $(c_{ij})$  associated with it and belongs to a subset of SRLGs in  $B$ . Note that the cost  $c_{ij}$  is the sum of the port cost at nodes  $i$  and  $j$  and the transport cost relative to the distance of link  $(i, j)$ . This problem was proven to be NP-hard in [3] by using a reduction from the SRLG-diverse path problem [5].

**Theorem 6** *The two-source SRRG-diverse routing problem is strongly NP-hard.*

This theorem was proven in [3] where this problem was claimed to be a generalization of the problem of finding SRLG-diverse paths between a source and a destination in a given graph (SRG (shared risk group)-diverse routing) proposed in the paper by Ellinas et al. [5]. We add

two nodes ( $|S|$ ) in the graph and two links connecting each of the two new nodes with the source with the costs of 0. Assume that the two new links do not share any SRLGs. We then add  $|D|$  nodes and  $2 * |D|$  edges. Each of these nodes is connected to the destination node by two edges that do not share any SRLGs. Then the transformation is complete and clearly polynomial.

The ILP of the two-source SRRG-diverse routing problem can be formulated as follows. Define the following decision variables.  $Y_{i,j}^s = 1$  if link  $(i, j)$  is used by the multicast tree rooted at source node  $s$ ; 0 otherwise.  $X_{i,j,d}^s = 1$  if link  $(i, j)$  is used by the multicast tree rooted at source node  $s$  to destination  $d$ ; 0 otherwise.  $Z_{b,d}^s = 1$  if the path from source  $s$  to destination  $d$  uses an SRLG  $b$ ; 0 otherwise. The ILP formulation is given by

$$\min \sum_{s \in S} \sum_{(i,j) \in E} Y_{i,j}^s c_{i,j} \quad (5)$$

$$\text{subject to } Y_{i,j}^s \geq X_{i,j,d}^s \quad \forall (i, j) \in E, \quad (6)$$

$$\forall s \in S, \forall d \in D,$$

$$\sum_{\{j|(i,j) \in E\}} X_{i,j,d}^s - \sum_{\{j|(j,i) \in E\}} X_{j,i,d}^s = \sigma_{i,d}^s \quad \forall i \in V, \forall s \in S, \forall d \in D, \quad (7)$$

$$Z_{b,d}^s \geq X_{i,j,d}^s \quad \forall (i, j) \in b, \forall s \in S, \forall d \in D, \quad (8)$$

$$\forall b \in B,$$

$$\sum_{s \in S} Z_{b,d}^s \leq 1 \quad \forall d \in D, \forall b \in B, \quad (9)$$

$$X_{i,j,d}^s, Y_{i,j}^s, Z_{b,d}^s \in \{0, 1\} \quad \forall s \in S, \forall d \in D, \quad (10)$$

$$\forall (i, j) \in E, \forall b \in B,$$

$$\text{where } \sigma_{i,d}^s = \begin{cases} 1 & \text{if } i = s, \\ -1 & \text{if } i = d, \\ 0 & \text{otherwise.} \end{cases} \quad (11)$$

The constraints in (6) ensure that an edge must be selected by the multicast tree when it is used by the multicast tree to carry any traffic. The flow constraints in (7) ensure the flow conservation at each node, allowing each destination to have a flow path from the source. More precisely,  $\sigma_{i,d}^s$  is the net flow capacity generated, carried, or destined at node  $i$  for destination  $d$  by the multicast tree rooted at node  $s$ , which should have the

value of 1 if node  $i$  is the source,  $-1$  if node  $i$  is the destination (acting as a sink), and 0 otherwise (whether node  $i$  belongs to the multicast tree or not). The constraints in (8) ensure that a SRLG must be selected by the path from a source to a destination when a link that belongs to the SRLG is used by the path. The constraints in (9) state that  $W_d^b$  is greater than or equal to the number of number of distinct sources that uses bundle  $b$  to reach  $d$ ; that is, if  $b$  is used in only one or none of the sources to reach  $b$ , the value is greater than or equal to zero.

### Shared Path-Protection Problem

Sahasrabuddhe et al. [17] proposed fault management in IP over WDM networks using techniques which are protection at the WDM layer and restoration at the IP layer. ‘‘Protection’’ refers to preprovisioned failure recovery (i. e., set up a backup lightpath for every primary lightpath), whereas ‘‘restoration’’ refers to more dynamic recovery (i. e., overprovision the network so that after a fiber failure, the network should still be able to carry all the traffic it was carrying before the fiber failure). Typically, their protection scheme focuses on shared path protection against single fiber span failures, where multiple independent primary paths share the backup path capacity to minimize the total capacity required in the network.

Given  $E$  as a set of unidirectional fiber links in the network,  $F$  as a set of bidirectional fibers in the network,  $R_{ij}$  as a set of alternate routes for node pair  $ij$ , and  $W$  as the maximum number of wavelengths on a link, the ILP of the shared path-protection routing problem can be formulated as follows. Define the following decision variables.  $w_k$  is the number of wavelengths used by primary lightpaths on link  $k$ ,  $s_k$  is the number of spare wavelengths used on link  $k$ , and  $V_{ij}$  is the number of primary lightpaths between node pair  $ij$ .  $m_k^w = 1$  if one or more backup lightpaths are using wavelength  $w$  on link  $k$ ; 0 otherwise.  $\gamma_{ij,r}^w = 1$  if the  $r$ th route between node pair  $ij$  utilizes wavelength  $w$  before any fiber failures; 0 otherwise.  $\delta_{ij,p}^{b,w} = 1$  if a primary on route between node pair  $ij$  is protected by route between the node pair by employing wavelength; 0 otherwise. The ILP of the shared path-protection routing problem is rather complicated as it considers end-to-end lightpath assignment on the physical links, physical diversity of the primary and backup paths, and sharing backup path

capacity for failure-independent primary paths. Therefore, the key ILP is formulated as follows (please refer to [17] for the complete set of equations):

$$\min \sum_{k=1}^E (w_k + s_k) \quad (12)$$

$$\text{subject to } \sum_{ij} \sum_{p \in R_{ij}: f \in p} \sum_{b \in R_{ij}: k \in b} \delta_{ij,p}^{b,w} \leq 1 \quad (13)$$

$$1 \leq f \leq F, 1 \leq k \leq E, 1 \leq w \leq W,$$

$$w_k + s_k \leq W \quad 1 \leq k \leq E, \quad (14)$$

$$\sum_{r \in R_{ij}} \sum_{w=1}^W \gamma_{ij,r}^w = V_{ij} \quad \forall ij, \quad (15)$$

$$\sum_{ij} \sum_{r \in R_{ij}, k \in r} \sum_{w=1}^W \gamma_{ij,r}^w = w_k \quad 1 \leq k \leq E, \quad (16)$$

$$\sum_{w=1}^W m_k^w = s_k \quad 1 \leq k \leq E, \quad (17)$$

$$\left( \sum_{ij} \sum_{r \in R_{ij}, k \in r} \gamma_{ij,r}^w \right) + m_k^w \leq 1 \quad 1 \leq k \leq E, \\ 1 \leq w \leq W, \quad (18)$$

$$\sum_{w=1}^W \gamma_{ij,r}^w = \sum_{b \in R_{ij}, b \neq p} \sum_{w=1}^W \delta_{ij,p}^{b,w} \quad \forall ij, \forall p \in R_{ij}, \\ 1 \leq w \leq W. \quad (19)$$

The objective of ILP is to minimize the total capacity used given in (12). The crux of the formulation is at the set of constraints in (13), which ensure that two backup lightpaths share wavelength  $w$  on link  $k$  *only if* the corresponding primary paths are fiber-disjoint. The above ILP formulation includes constraints for setting up lightpaths with shared path protection, where the number of channels on each link is bounded by (14), the number of primary lightpaths between a node pair is defined by (15), the number of primary lightpaths traversing a link is defined by (16), the spare capacity of each link is defined by (17), the usage of primary or backup lightpaths on a wavelength is defined by (18), and every primary lightpath is ensured to be protected by a backup lightpath by (19). In addition, multicommodity flow constraints (omitted here) are added to ensure the amount of traffic sourced from node to destination node is covered by the capacity of the wavelength.

Note that additional constraints on the number of receivers and transmitters used can be incorporated in the model [17].

### Path-Restoration Problem

Path-restoration techniques have been frequently employed to provide highly capacity efficient (close to) real-time restoration of a network failure. In contrast to the path-protection routing, the operation mode of the path restoration only uses the full bandwidth from the primary while finding an alternative path. The path-restoration routing problem can involve different network layers: physical (optical) and IP. The optical path restoration directly replaces the prefailure capacity at the transmission carrier signal level, which has no performance effects in the upper layers. On the other hand, the IP path restoration dynamically reroutes the signals around failures using routing table updates or dynamic call-routing. An interior gateway protocol (IGP) is widely used to dynamically find an alternative path and perform load sharing in traffic distribution.

### Optical Path Restoration Problem

Iraschko and Grover [9] studied the path-restoration routing problem, where the task is to deploy a set of replacement signal paths between two end nodes of the failed span, capable of yielding the maximum total amount of replacement capacity, while respecting the finite number of spare links on each span. They assume that, given failure scenarios, a predefined set of distinct eligible routes are precomputed for end node pairs (i. e., primary paths). Then, the goal of the path-restoration routing problem is to maximize the total of all restoration flow assignments for those primary paths, using only the commodities selected by the failure scenario and only the surviving spans in the reserve network. It also requires that all flow assignments made over all routes, for all simultaneously restored node pairs, should not exceed the spare capacity of any span in the reserve network. The outcome of such optimized design will require minimal capacity for the reserve network.

The ILP of the path-restoration routing problem can be formulated as follows. Define the following decision variables and parameters. Let  $i$  represent a failure scenario, such as a single span cut or a node loss.  $D_i$

is the number of end node pairs that have lost one or more units of demand owing to the failure  $i$  and  $r$  is the index to indicate these node pairs,  $r \in (1 \cdots D_i)$ .  $X_i^r$  is the number of demand units lost by an end pair  $r$  under failure  $i$ . Finally, the network is  $G(N, E, s)$ , where  $N$  is the set of nodes,  $E$  is the set of spans, and  $s$  is the vector of spare capacities on each span  $s_j$ . The ILP formulation is given by

$$\max \sum_{r=1}^{D_j} \sum_{p=1}^{P_i^r} f_i^{r,p} \quad (20)$$

$$\text{subject to } \sum_{p=1}^{P_i^r} f_i^{r,p} = X_i^r \quad \forall r \in (1 \cdots D_i), \quad (21)$$

$$\sum_{r=1}^{D_j} \sum_{p=1}^{P_i^r} \delta_{i,j}^{r,p} f_i^{r,p} \leq s_j \quad \forall j \in E, \quad (22)$$

$$f_i^{r,p} \geq 0, \text{ integer } \quad \forall (r, p), \quad (23)$$

where  $f_i^{r,p}$  is a whole number assignment of flow to the  $p$ th route available for restoration of node pair  $r$  under failure scenario  $i$ .  $P_i^r$  is the total number of eligible restoration routes available to node pair  $r$  for the restoration of failure  $i$ .  $\delta_{i,j}^{r,p} = 1$  if span  $j$  is in the  $p$ th eligible route for restoration of node pair  $r$  in the event of failure scenario  $i$ ; 0 otherwise.

### IP Path-Restoration Problem

In the IP-layer communication, as apposed to the abovementioned optical path restoration problem, the path-restoration problem is defined differently on the basis of the WDM protection model from Sect. “**Shared Path-Protection Problem**” (for the complete model, see [17]). The key ILP model for this IP path restoration problem is given by

$$\max \sum_{sd} \sum_{ij} \lambda_{sd}^{ij} \quad (24)$$

$$\text{subject to } \sum_j \sum_{r \in R_{ij}} \gamma_{i,j,r}^w \leq Trans_i^w \quad \forall i, 1 \leq w \leq W, \quad (25)$$

$$\sum_i \sum_{r \in R_{ij}} \gamma_{i,j,r}^w \leq Rec_j^w \quad \forall j, 1 \leq w \leq W, \quad (26)$$

$$\sum_{ij} \sum_{r \in R_{ij}, k \in r} \gamma_{ij,r}^w \leq 1 \quad 1 \leq k \leq E, 1 \leq w \leq W, \quad (27)$$

where the objective function in (24) is to minimize the average hop distance before a fault, the constraints in (25) and (26) ensure that node  $i$  uses at most  $Trans_i^w$  transmitters and node  $j$  uses at most  $Rec_j^w$  receivers on wavelength  $w$ , and the constraints in (27) ensure that the wavelength  $w$  on link  $j$  is used either by a primary lightpath or by backup lightpaths.

### Concluding Remarks

In this article, we reviewed how ILP formulations are used in WDM optical networking. In optical networks, preprovisioning the networks to support fast restoration of failures is critical, which means to set up physically disjoint backup paths (links) for the primary paths (links). Here, ILP formulations are valuable in finding the global optimal backup paths among all the possible alternative paths for traffic demands of interest. A set of constraints in ILP can be set up to represent the restoration flow balance constraint, the link capacity flow constraint, and physical diversity of the primary and backup paths.

### Keywords

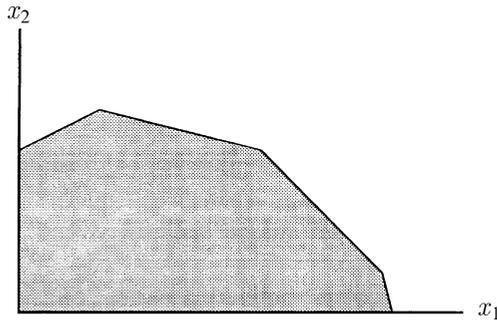

Integer programming; Combinatorial optimization; Enumeration; Polyhedral methods; Disjunctive programming; Lift-and-project

One of the byproducts of World War II was the discovery that the routing of ship convoys, and other human activities like transportation, production, allocation, etc. could be modeled mathematically, i. e. the often intricate choices that they involve could be captured into a system of equations and inequalities and could be optimized according to some agreed upon criterion. The simplest such model, involving only linear functions, became known as linear programming. Parallel developments have led to the discovery of the computer, which made it practical to solve linear programs of a realistic size. A few years later the theory was extended to systems involving nonlinear convex functions. Convexity was needed to ensure that any local optimum is a global optimum.

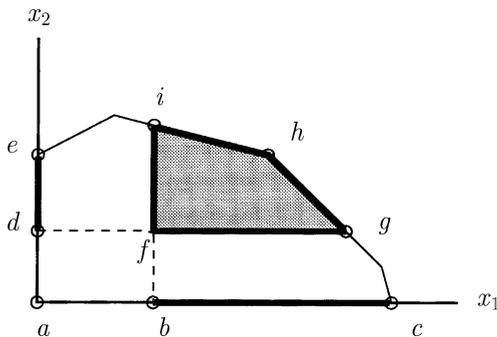

An amazing variety of activities and situations can be adequately modeled as linear programs (LPs) or convex nonlinear programs (NLPs). Adequately means that the degree of approximation to reality that such a representation involves is acceptable. However, as the world that we inhabit is neither linear nor convex, the most common obstacle to the acceptability of these models is their inability to represent nonconvexities or discontinuities of different sorts. This is where integer programming comes into play: it is a universal tool for modeling nonconvexities of various kinds.

To illustrate, imagine a factory that produces two items and whose capacity is determined by the four linear constraints represented in Fig. 1. These inequalities, along with  $x_1 \geq 0$ ,  $x_2 \geq 0$  (only nonnegative amounts can be produced), define the feasible set, shown as the shaded area. Since the latter is a convex polyhedron, if profit is a linear function of the amounts produced, then an optimal (i. e. profit-maximizing) production plan will correspond to one of the vertices of the polyhedron.

Imagine now that the following reasonable condition is imposed: for each item there is a threshold quantity below which it is not worth producing it. The threshold is  $b$  units for item 1 and  $d$  units for item 2. Furthermore, at least one of the two items must be produced. As shown in Fig. 2., the feasible set now consists

Integer Programming, Figure 1  
Feasible set without thresholds

Integer Programming, Figure 2  
Feasible set with thresholds

of three separate pieces: the two lines  $[b, c]$  and  $[d, e]$ , and the shaded area (polyhedron) whose vertices are  $f, g, h, i$ . Depending on the slope of the objective function, the optimum may now occur at any of the points  $b, c, d, e, g, h, i$ . The problem has become qualitatively different. The ‘threshold’ conditions, of the form ‘either  $x_1 = 0$  or else  $x_1 \geq b$ ’, and ‘either  $x_2 = 0$  or  $x_2 \geq d$ ’, as well as the condition ‘at most one of  $x_1 = 0$  and  $x_2 = 0$  can hold’, cannot be modeled by linear or convex programming techniques. The same is true of a host of other ‘logical’ conditions: disjunctions (‘either this or that’; ‘at least one of several constraints must hold’, ‘at most one of several variables can be positive’), implications (‘if this action is taken, then that action must be taken’), precedence relations (‘this event must precede that’, ‘this action cannot start until some others are completed’), etc. Yet, it is quite obvious that conditions of this type are in no way exceptional; on the contrary, their presence is pervasive in many real world situations.

A linear (nonlinear) programming problem whose variables are restricted to integer values is called a linear

(nonlinear) integer programming problem, or simply an *integer program* (IP, linear unless otherwise stated). If only some of the variables are restricted to integer values, we have a *mixed integer program* (MIP). Such a problem can be stated as

$$\left\{ \begin{array}{l} \min \quad cx \\ \text{s.t.} \quad Ax \geq b \\ \quad \quad x \geq 0 \\ \quad \quad x_j \text{ integer} \\ \quad \quad j \in N_1 \subseteq N, \end{array} \right.$$

where  $A$  is a given  $m \times n$  matrix,  $c$  and  $b$  are given vectors of conformable dimensions,  $N := \{1, \dots, n\}$  and  $x$  is a variable  $n$ -vector. The ‘pure’ integer program (IP) is the special case of MIP when  $N_1 = N$ . If, in addition, all entries of  $A, b, c$  are integer, then the slack or surplus variables can also be restricted to integers.

Integer programming as a field started in the mid-1950s. A number of excellent textbooks are available for its study [15,16,17,20].

### Scope and Applicability

Applications of integer programming abound in all spheres of decision making. Some typical real-world problem areas where integer programming is particularly useful as a modeling tool, include facility (plant, warehouse, hospital, fire station) location; scheduling (of personnel, production, other activities); routing (of trucks, tankers, aircraft); design of communication (road, pipeline, telephone, computer) networks; capital budgeting; project selection; analysis of capital development alternatives. Various problems in science (physics: the Ising spin glass problem; genetics: the sequencing of DNA segments) and medicine (optimizing tumor radiation patterns) have been successfully modeled as integer programs. In engineering (electrical, chemical, civil and mechanical) the sphere of applications is growing steadily.

By far the most important special case of integer programming is the (pure or mixed) 0–1 *programming problem*, in which the integer-constrained variables are restricted to 0 or 1. This is so because a host of frequently occurring nonconvexities, such as the ones listed above, can be formulated via 0–1 variables. If the constraint set of the production planning problem

shown in Fig. 1 is

$$a_{i1}x_1 + a_{i2}x_2 \leq b_i, \quad i = 1, \dots, 4,$$

$$x_1 \geq 0, \quad x_2 \geq 0,$$

then the conditions

$$x_1 \leq 0 \quad \text{or} \quad x_1 \geq b,$$

$$x_2 \leq 0 \quad \text{or} \quad x_2 \geq d,$$

$$x_1 > 0 \quad \text{or} \quad x_2 > 0,$$

imposed in the variant shown in Fig. 2., can be formulated by introducing two 0–1 variables,  $\delta_1$  and  $\delta_2$ , and the constraints

$$b\delta_1 \leq x_1 \leq c\delta_1,$$

$$d\delta_2 \leq x_2 \leq e\delta_2,$$

$$\delta_1 + \delta_2 \geq 1, \quad \delta_1, \delta_2 \in \{0, 1\}.$$

Next we present a few well-known pure and mixed integer models.

The *fixed charge problem* asks for the minimization, subject to linear constraints, of a function of the form  $\sum_i c_i(x_i)$ , with

$$c_i(x_i) := \begin{cases} f_i + c_i x_i & \text{if } x_i > 0, \\ 0 & \text{if } x_i = 0. \end{cases}$$

Whenever  $x_i$  is bounded by  $U_i$  and  $f_i > 0$  for all  $i$ , such a problem can be restated as a (linear) MIP by setting

$$c_i(x_i) = c_i x_i + f_i y_i,$$

$$x_i \leq U_i y_i,$$

$$y_i \in \{0, 1\} \text{ for all } i.$$

Clearly, when  $x_i > 0$  then  $y_i$  is forced to 1, and when  $x_i = 0$  the minimization of the objective function drives  $y_i$  to 0.

The *facility location problem* consists of choosing among  $m$  potential sites (and associated capacities) of facilities to serve  $n$  clients at a minimum total cost:

$$\left\{ \begin{array}{l} \min \quad \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} + \sum_{i=1}^m f_i y_i \\ \sum_{i=1}^m x_{ij} = d_j, \quad j = 1, \dots, n, \\ \sum_{j=1}^n x_{ij} \leq a_i y_i, \quad i = 1, \dots, m, \\ x_{ij} \geq 0, \quad i = 1, \dots, m; j = 1, \dots, n, \\ y_i \in \{0, 1\}, \quad i = 1, \dots, m \end{array} \right.$$

Here  $d_j$  is the demand of client  $j$ ,  $a_i$  is the capacity of a potential facility to be located at site  $i$ ,  $c_{ij}$  is the per-unit cost of shipments from facility  $i$  to client  $j$ , and  $f_i$  is the fixed cost of opening a facility of capacity  $a_i$  at location  $i$ . In any feasible solution, the indices  $i$  such that  $y_i = 1$  designate the chosen locations for the facilities to be opened.

Variants of this problem include the *uncapacitated facility location problem* (where  $d_j = 1$  for all  $j$  and the constraints involving the capacities can be replaced by  $x_{ij} \leq y_i$ ,  $i = 1, \dots, m$ ,  $j = 1, \dots, n$ ), the *warehouse location problem* (which considers cheap bulk shipments from plants to warehouses and expensive packaged shipments to retailers), and various *emergency facility location problems* (where one chooses locations to minimize the maximum distance traveled by any user of a facility, rather than the sum of travel costs).

The *knapsack problem* is an integer program with a single constraint:

$$\max \{cx : ax \leq b, x \geq 0 \text{ integer}\},$$

where  $c$  and  $a$  are positive  $n$ -vectors, while  $b$  is a positive scalar. When the variables are restricted to 0 or 1, we have the *0–1 knapsack problem*.

A variety of situations can be fruitfully modeled as *set covering problems*: Given a set  $M$  and a family of weighted subsets  $S_1, \dots, S_n$  of  $M$ , find a minimum-weight collection  $C$  of subsets whose union is  $M$ . If  $A$  is a 0–1 matrix whose rows correspond to the elements of  $M$  and whose columns are the incidence vectors of the subsets  $S_1, \dots, S_n$ , and  $c$  is the  $n$ -vector of subset-weights, the problem can be stated as

$$\left\{ \begin{array}{l} \min \quad cx \\ Ax \geq 1 \\ x \in \{0, 1\}^n, \end{array} \right.$$

where the right-hand side of the inequality is the  $m$ -vector of 1s. This model and its close relative, the *set partitioning problem* (in which  $\geq$  is replaced by  $=$ ) has been (and is being) widely used in airline, bus, and train crew scheduling (each row represents a leg of a trip that has to be covered; each column stands for a potential duty period of a crew). Another application is in medical diagnostics (each column represents a diagnostic test, each row stands for a pair of diseases, with a 1 in column  $j$  if the pair's reactions to the tests are different, and a 0 if they are the same; the goal being to select

a minimum-cost battery of tests guaranteed not to yield identical outcomes for any two diseases).

**Combinatorial Optimization**

A host of interesting combinatorial problems can be formulated as 0–1 programming problems defined on graphs, undirected or directed, vertex-weighted or edge-weighted. The joint study of these problems by mathematical programmers and computer scientists, starting from around 1960, has led to the development of the burgeoning field called *combinatorial optimization* [7]. Some typical problems of this field are: edge matching (finding a maximum-weight collection of pairwise non-adjacent edges) and edge covering (finding a minimum-weight collection of edges that together cover every vertex); vertex packing (finding a maximum-weight independent set, i. e. collection of pairwise non-adjacent vertices) and vertex covering (finding a minimum-weight collection of vertices that together cover every edge); maximum clique (finding a maximum cardinality complete subgraph) and minimum vertex coloring (partitioning the vertices into a minimum number of independent sets, i. e. coloring the vertices with a minimum number of colors such that all adjacent pairs differ in color); the traveling salesman problem (finding a cycle of minimum total edge-weight that meets every vertex).

We will briefly discuss two of the above problems, which in a sense span the universe of combinatorial optimization. At one end of the spectrum, the *matching problem* on a graph  $G = (V, E)$  can be stated as

$$\begin{cases} \max & x(E) \\ \text{s.t.} & x(\delta(v)) \leq 1, \quad v \in V, \\ & x \geq 0, \quad x_e \text{ integer}, \quad e \in E, \end{cases}$$

where for  $F \subset E$ ,  $x(F) = \sum_{e \in F} x_e$ , and  $\delta(v)$  is the set of edges incident with  $v$ . Its weighted version asks for maximizing  $\sum_{e \in E} w_e x_e$ , where  $w_e$  is the weight of edge  $e$ . This problem has the nice property that the integrality condition can be omitted if the above nonnegativity and degree constraints are supplemented with the inequalities

$$x(\gamma(S)) \leq \frac{|S| - 1}{2} \quad \text{for all } S \subseteq V, \quad |S| \text{ odd,}$$

where  $\gamma(S)$  is the set of edges with both ends in  $S$ .

In other words, the ‘odd set inequalities’, along with the nonnegativity and degree constraints, fully describe the convex hull of incidence vectors of matchings. The discovery of this remarkable phenomenon in the mid-1960s ([8]) has started a massive pursuit of facets of the convex hull of other combinatorial polyhedra, and can be viewed as the inaugural step in the development of the field called *polyhedral combinatorics*. Close relatives of the matching problem are the *perfect matching problem* (in which a maximum or minimum-weight matching is sought, when it exists, that leaves no vertex unmatched), the *2-matching problem* (in which the degree constraints have right-hand side 2) and more generally, the *b-matching*, or *degree-constrained subgraph problem* (in which the degree constraint for vertex  $v$  has the positive integer  $b_v$  as right-hand side). In each of these cases, a complete description of the convex hull of feasible integer points is available in the form of a class of inequalities similar to the above ones, which makes these problems polynomially solvable.

At the other end of the spectrum, one of the hardest and most thoroughly investigated combinatorial optimization problems is the *traveling salesman problem* (TSP) already mentioned, in which a salesman is looking for a cheapest tour of  $n$  cities, given the cost of travel between all pairs of cities. This is the prototype model for situations dealing with the optimal sequencing of objects (e. g., items to be processed on a machine in the presence of sequence-dependent setup costs). The standard formulation on a complete directed graph with node set  $N$  and arc costs  $c_{ij}$  is

$$\begin{cases} \min & \sum_{i \in N} \sum_{j \in N \setminus \{i\}} c_{ij} x_{ij} \\ \text{s.t.} & \sum_{j \in N \setminus \{i\}} x_{ij} = 1, \quad i \in N, \\ & \sum_{i \in N \setminus \{j\}} x_{ij} = 1, \quad j \in N, \\ & \sum_{i \in S} \sum_{j \in S \setminus \{i\}} x_{ij} \leq |S| - 1 \\ \text{for} & S \subset N, \quad 2 \leq |S| \leq n - 1, \\ & x_{ij} \in \{0, 1\}, \quad i, j \in N, \quad i \neq j. \end{cases}$$

The first two sets of equations define an assignment problem whose solutions are spanning unions of directed cycles. The third set, consisting of inequalities called subtour elimination constraints, exclude all cy-

cles with fewer than  $n = |N|$  arcs. The number of solutions – tours – is factorial in the number of nodes. Problems with random costs can be solved even for thousands of nodes, but some cost structures that occur in practice tend to give rise to very hard problems even at small sizes: a class of machine scheduling problems at chemical plants turn out to be hard to solve as TSPs on 30–50 node directed graphs. The TSP has become a test bed for the development of, and experimentation with, various approaches to combinatorial optimization. A summary of results until the mid- 1980s is to be found in [12].

A generalization of the TSP, in which the salesman does not have to visit all the cities, but gets a prize for every city that he does visit, is called the *prize collecting traveling salesman problem* (PCTSP). It asks for a cheapest tour of just enough cities to collect a required amount of prize money. This is the model used for scheduling the daily ‘rounds’ of a steel rolling mill, an operation that combines the tasks of selecting the items for the next round with that of putting them in the proper sequence. On a directed graph with loops, it can be formulated as the problem of finding a directed cycle of minimum arc cost subject to an upper bound on the sum of loop penalties on nodes not included in the cycle:

$$\left\{ \begin{array}{l} \min \quad \sum_{i \in N} \sum_{j \in N \setminus \{i\}} c_{ij} x_{ij} \\ \text{s.t.} \quad \sum_{j \in N \setminus \{i\}} x_{ij} + y_i = 1, \quad i \in N \\ \quad \quad \sum_{i \in N \setminus \{j\}} x_{ij} + y_j = 1, \quad j \in N \\ \quad \quad \sum_{i \in S} \sum_{j \in S \setminus \{i\}} x_{ij} + \sum_{i \in S \setminus \{k\}} y_i - y_\ell \leq |S| - 1 \\ \text{for} \quad S \subset N, \quad 2 \leq |S| \leq n - 1, \\ \quad \quad k \in S, \quad \ell \in N \setminus S, \\ \quad \quad \sum_{i \in N} w_i y_i \leq U, \\ \quad \quad x_{ij} \in \{0, 1\}, \quad y_i \in \{0, 1\}, \quad \forall i, j. \end{array} \right.$$

The first two sets of equations are satisfied by any spanning union of cycles and loops, while the third set of constraints excludes multiple cycles. Finally, the last inequality bounds at  $U$  the weighted sum of loop variables.

## Solution Methods

Unlike linear programs, which are polynomially solvable, integer programming problems, including 0–1 programming and most combinatorial optimization problems, are notoriously difficult: in the language of computational complexity theory, they are *NP*-complete. Polynomial time integer programming algorithms do not exist. However, sometimes an integer program can be solved as a linear program, in the sense that solving the linear programming relaxation (L) of the integer program (i. e. the problem obtained by removing the integrality conditions), one obtains an integer solution. In particular, this is the case when all the basic solutions of (L) are integer. For an arbitrary integer vector  $b$ , the constraint set  $Ax \geq b, x \geq 0$ , if feasible, is known [10] to have only integer basic solutions if and only if the matrix  $A$  is totally unimodular (i. e. all square submatrices of  $A$  have a determinant equal to 0, 1 or  $-1$ ).

The best-known instances of total unimodularity are the vertex-edge incidence matrices of directed graphs, and of undirected bipartite graphs. As a consequence, shortest path and network flow problems on arbitrary directed graphs, as well as edge matching (or covering) and vertex packing (or covering) problems on undirected bipartite graphs, are in fact linear programs, as are all those integer programs whose LP relaxation has as its coefficient matrix the incidence matrix of a directed graph, or that of an undirected bipartite graph, with arbitrary integer right-hand sides.

Apart from this important but very special class of problems, the difficulty in solving integer programs, as already mentioned, lies in the nonconvexity of the feasible set, which makes it impossible to establish global optimality from local conditions. The two principal approaches to solving integer programs try to circumvent this difficulty in two different ways.

The first approach, which until the late 1980s was the standard way of solving integer programs, is *enumerative* (branch and bound, implicit enumeration). It partitions the feasible set into successively smaller subsets tied together as nodes of a branch and bound tree, calculates bounds on the objective function value over each subset, and uses these bounds to discard certain subsets (nodes) from further consideration. The lower bounds (in a minimization problem) typically come

from solving the linear programming relaxation corresponding to the given node, the upper bounds come from integer solutions found at some of the nodes. The procedure ends when each subset has either produced a feasible solution, or was shown to contain no better solution than the one in hand. The efficiency of the procedure depends crucially on the strength of the bounds. Two early prototypes of this approach are due to A.H. Land and A.G. Doig [11] and E. Balas [1].

The second approach, known as the *cutting plane method*, is a convexification procedure: it approximates the convex hull of the set of feasible integer points by a sequence of inequalities that cut off (hence the term ‘cutting planes’) part of the linear programming polyhedron, without removing any feasible integer point. The first finitely convergent procedure of this type, which uses modular arithmetic to derive valid cutting planes for pure integer programs, is due to R.E. Gomory [9]. V. Chvátal [6] has shown that the procedure can be viewed as one of *integer rounding*, in which positive multiples of  $Ax \geq b$ ,  $x \geq 0$  are added up and the coefficients of the resulting inequality are rounded down to the nearest integer. The resulting inequalities form the elementary closure of  $Ax \geq b$ ,  $x \geq 0$ . The procedure can then be applied to the elementary closure, and so on. The number of times the procedure needs to be iterated in order to obtain the convex hull of feasible integer points is called the Chvátal rank of the given polyhedron. No bound is known on the Chvátal rank of an arbitrary integer polyhedron (convex hull of feasible integer points). By contrast, the matching polyhedron has Chvátal rank one, since the odd set inequalities can be obtained from the degree inequalities by integer rounding.

The Gomory–Chvátal procedure has been extended to mixed integer programming and has been enhanced by the use of subadditive functions and group theory.

A different approach comes from *disjunctive programming* [2,3], or linear programming with logical conditions (conjunctions, disjunctions and implications involving inequalities). In this approach, which uses the tools of convex analysis, like polarity and projection, 0–1 programming (pure or mixed) is viewed as optimization over the (nonconvex) union of (convex) polyhedra, i. e. a set of the form  $\cup_{i \in Q} P_i$ , where  $P_i = \{x: A^i x \geq b^i\}$ ,  $i \in Q$ . There is a compact characterization of the convex hull  $P_D := \text{conv } \cup_{i \in Q} P_i$  in a higher-

dimensional space, whose projection onto the original space yields all the valid cutting planes. Thus  $\alpha x \geq \beta$  is a valid inequality for  $\cup_{i \in Q} P_i$  if and only if  $\alpha \geq u^i A^i$  and  $\beta \leq u^i b^i$  for some  $u^i \geq 0$ ,  $i \in Q$ . A central result of this approach is that an important class of disjunctive programs, called *facial*, which includes pure and mixed 0–1 programs, are *sequentially convexifiable*. For a 0–1 program (pure or mixed) with  $n$  0–1 variables and a linear programming relaxation  $P_0$ , this means that one can impose the 0–1 condition on  $x_1$  and generate the convex hull  $P_1$  of  $P_{00} \cup P_{01}$ , where  $P_{00} := \{x \in P_0: x_1 = 0\}$ ,  $P_{01} := \{x \in P_0: x_1 = 1\}$ ; then impose the 0–1 condition on  $x_2$  and generate the convex hull  $P_2$  of  $P_{10} \cup P_{11}$ , where  $P_{10} := \{x \in P_1: x_2 = 0\}$ ,  $P_{11} := \{x \in P_1: x_2 = 1\}$ ; etc., and at the end of  $n$  steps, the convex hull  $P_n$  of  $P_{n-1,0} \cup P_{n-1,1}$  turns out to be the convex hull of  $\{x \in P_0: x_j \in \{0, 1\}, j = 1, \dots, n\}$ . This property does not hold for arbitrary integer programs, and is thus a main distinguishing feature of 0–1 programs. If one defines the disjunctive rank of a polyhedron as the number of times the above procedure has to be iterated in order to generate all of its facets, it follows that an arbitrary 0–1 programming polyhedron has disjunctive rank  $n$ .

Although these results date back to 1974, it was not until the early 1990s that they were implemented into an efficient computational tool called *lift-and-project* ([4]). The name conveys the idea of a higher-dimensional representation of the convex hull (lifting), which is then projected back to generate cutting planes. In the meantime, L. Lovász and A. Schrijver [13] (see also [18]) developed a closely related procedure which derives higher-dimensional representations of a 0–1 programming polyhedron by multiplying the constraint set of  $P_0$  with the inequalities  $x_j \geq 0$  and  $1 - x_j \geq 0$ ,  $j \in N$ , then linearizing the resulting quadratic forms, and projecting them back into the original space. As in the disjunctive programming approach,  $n$  iterations of this procedure yield the convex hull of the 0–1 programming polyhedron. However, the quadratic forms obtained during the procedure can also be used to derive *positive semidefiniteness constraints* that are stronger than the inequalities obtained by linearization.

Semidefiniteness constraints aside, a streamlined version of the Lovász–Schrijver procedure, in which  $P_0$  is multiplied at every iteration by just one pair of inequalities  $x_j \geq 0$ ,  $1 - x_j \geq 0$ , rather than by all pairs, was shown in [4] to be equivalent to the disjunctive

programming procedure for 0–1 polyhedra, in that the linearized version of the quadratic constraints obtained by multiplication is exactly the same as the higher-dimensional representation of the convex hull used in disjunctive programming. The paper [4] also showed how to use a cut generating linear program (CGLP) to obtain lift-and-project (or disjunctive) cuts that are deepest in a well defined sense. Most importantly, these cuts can be generated in a subspace, i. e. using only a subset of the variables, and then lifted to the full space. It was this aspect which has led to a computational breakthrough. Earlier attempts to implement cutting plane procedures of whatever type for general integer or 0–1 programs foundered on the phenomenon known as ‘stalling’: in the process of generating a sequence of cutting planes and reoptimizing the linear program, after a while the new cuts tended to become shallower and the process tended to run into numerical difficulties. Now the possibility of lifting cuts generated in a subspace has opened the door to combining the enumerative and convexifying approaches into a *branch and cut procedure*, which generates cutting planes as long as they ‘work’, but branches whenever the cut generating ‘stalls’. This was made possible by the fact that cuts generated at a node of the search tree can be lifted to be valid at any node. The outcome was a robust procedure, considerably more efficient than either a branch and bound or a cutting plane algorithm by itself [5].

Besides these two basic approaches (enumerative and convexifying), two further procedures need to be mentioned that do not belong to either category, but can be combined with either of them. Both procedures essentially *decompose* the problem, one of them by partitioning the variables, the other by partitioning the constraints. The first one, known as *column generation*, starts with a subset of the columns and generates the missing columns as needed, by pricing them out. It is an extension to integer programming of well-known linear programming decomposition techniques. The second one, known as *Lagrangian relaxation*, works with a subset of the constraints, while assigning Lagrange multipliers to the remaining constraints and taking them into the objective function.

Each of the approaches outlined above aims at solving the integer program exactly. However, due to the NP-completeness of the problem, approximation methods and *heuristics* play an increasingly important role

in this field. Some highly efficient heuristics are known for several special structures. As to the general problem, heuristics have so far been less uniformly successful.

### The State of the Art

Until about 1985, most of the integer programming problems encountered in practice were too large to be solved in useful time by existing algorithms and codes. This situation has drastically changed during the decade of the 1990s. MIPLIB is a collection of integer programming problems that various people have tried to solve over the last two decades or so, often unsuccessfully. It contains scores of instances varying in structure, size and computational toughness. A few years ago even those instances that could be solved took a very long time. Today a large majority of these problems have been solved and can be solved in useful time. A number of tools are available for this purpose. Among academic codes, we mention MIPO [5], MINTO [14] and ABACUS [19]. The best-known commercial codes are CPLEX, XPRESS and OSL.

### Keywords

Toric ideal; Gröbner basis; Integer programming; Computer algebra; Test sets; universal Gröbner basis; Sensitivity analysis; Group relaxation; Lattice program; Scarf formulation

This article highlights some of the recent results in theoretical integer programming that have been obtained by studying integer programs using tools from commutative algebra and algebraic geometry. The main computational tool involved in the discussion here is the Gröbner basis of a special polynomial ideal called a ‘toric ideal’ [29]. For connections between Gröbner

bases of toric ideals and polytopes see [29] and for Gröbner basis theory for general polynomial ideals see [1] and [11]. Toric ideals and more generally, ‘lattice ideals’ [32], have been the subject of much research in the past decade. The discussion in this article follows a specific route through the work done in this area. All effort will be made to include references needed for details and further reading.

### Toric Ideals and Integer Programming

We will be concerned with integer programs of the form  $IP_{A,c}(b) := \min\{c \cdot x : Ax = b, x \in \mathbf{N}^n\}$  where  $A$  is a fixed  $d \times n$  integer matrix of rank  $d$ . Here  $\mathbf{N}$  denotes the nonnegative integers. The right-hand side vector  $b$  will be assumed to lie in the monoid  $\text{pos}_Z(A) := \{Ax : x \in \mathbf{N}^n\}$  which guarantees that  $IP_{A,c}(b)$  is always feasible. Let  $\ker_Z(A)$  denote the  $(n - d)$ -dimensional saturated lattice  $\{u \in \mathbf{Z}^n : Au = 0\}$ . For simplicity we assume that  $\ker_Z(A) \cap \mathbf{N}^n = \{0\}$  which implies that  $P_b := \text{conv}\{x \in \mathbf{N}^n : Ax = b\}$  is a polytope for all  $b \in \text{pos}_Z(A)$ . For  $b \in \text{pos}_Z(A)$  and a  $v \in P_b \cap \mathbf{N}^n$  the set of lattice points in  $P_b$  is precisely the congruence class in  $\mathbf{N}^n$  of  $v$  modulo  $\ker_Z(A)$ .

The *toric ideal* of  $A$  is the  $d$ -dimensional binomial prime ideal

$$I_A := \left\langle x^{u^+} - x^{u^-} : u := u^+ - u^- \in \ker_Z(A), u^+, u^- \in \mathbf{N}^n \right\rangle$$

in  $k[\mathbf{x}] := k[x_1, \dots, x_n]$  where  $k$  is a field. The cost vector  $c$  lies in  $\mathbf{R}^n$  and for each polynomial  $f = \sum_{i=1}^l k_i x^{\alpha_i} \in I_A$  the *initial term* of  $f$  with respect to  $c$ , denoted as  $\text{in}_c(f)$ , is the sum of those terms in  $f$  for which  $c \cdot \alpha_i$  is maximal. The *initial ideal* of  $I_A$  with respect to  $c$  is then the ideal  $\text{in}_c(I_A) := \langle \text{in}_c(f) : f \in I_A \rangle \subset k[\mathbf{x}]$ . We will assume unless stated otherwise that the cost vector  $c$  is such that  $\text{in}_c(I_A)$  is a *monomial ideal*, i.e.,  $\text{in}_c(I_A)$  can be generated by monomials. Such a  $c$  is said to be *generic* with respect to  $IP_{A,c}$ , the family of all integer programs  $IP_{A,c}(b)$  as  $b$  and  $c$  vary. Equivalently,  $c$  is generic with respect to  $IP_A$  if and only if each integer program in the family  $IP_A, c := \{IP_{A,c}(b) : b \in \text{pos}_Z(A)\}$  has a unique optimal solution. Note that each lattice point  $\alpha \in \mathbf{N}^n$  is a solution to a unique integer program in  $IP_{A,c}$  since  $\alpha$  lies in  $P_{A\alpha}$  and in no other polytope of the form  $P_b$ . The following theorem relates  $\text{in}_c(I_A)$  to  $IP_{A,c}$ .

**Lemma 1** *The lattice point  $\alpha \in \mathbf{N}^n$  is a nonoptimal solution to  $IP_{A,c}(A\alpha)$  if and only if the monomial  $x^\alpha$  lies in the initial ideal  $\text{in}_c(I_A)$ .*

*Proof* The lattice point  $\alpha \in \mathbf{N}^n$  is a nonoptimal solution to  $IP_{A,c}(A\alpha)$  if and only if there exists  $\beta$  in  $P_{A\alpha} \cap \mathbf{N}^n$  such that  $c \cdot \alpha > c \cdot \beta$ . This is equivalent to the statement that  $x^\alpha - x^\beta$  is a nonzero element of  $I_A$  with  $\text{in}_c(x^\alpha - x^\beta) = x^\alpha$ .

The *standard monomials* of  $\text{in}_c(I_A)$  are precisely all the monomials in  $k[\mathbf{x}]$  that do not lie in  $\text{in}_c(I_A)$ .

**Corollary 2** *A monomial  $x^\gamma \in k[\mathbf{x}]$  is a standard monomial of  $\text{in}_c(I_A)$  if and only if  $\gamma$  is the unique optimal solution to the integer program  $IP_{A,c}(A\gamma)$ .*

By Corollary 2, there is a bijection between the standard monomials of  $\text{in}_c(I_A)$  and the elements of the monoid  $\text{pos}_Z(A)$ .

### The Conti-Traverso Algorithm

In [9], P. Conti and C. Traverso gave an algorithm to solve integer programs using Gröbner bases of toric ideals. A *Gröbner basis* with respect to  $c$ , of the toric ideal  $I_A$ , is any finite subset  $\mathcal{H}$  of  $I_A$  such that  $\text{in}_c(I_A) = \langle \text{in}_c(f) : f \in \mathcal{H} \rangle$ . A Gröbner basis  $\mathcal{H}$  is *reduced* if it has the additional property that for each  $f \in \mathcal{H}$ , the coefficient of  $\text{in}_c(f)$  is the identity in  $k$  and  $\text{in}_c(f)$  does not divide any term in another element  $g$  of  $\mathcal{H}$ . Reduced Gröbner bases are unique.

Let  $\mathcal{G}_c$  denote the reduced Gröbner basis of  $I_A$  with respect to  $c$ . Then  $\mathcal{G}_c$  has the form  $\{x^{\alpha_i} - x^{\beta_i} : i = 1, \dots, t\}$  where  $\alpha_i - \beta_i \in \ker_Z(A)$ ,  $\alpha_i, \beta_i \in \mathbf{N}^n$  and  $\text{supp}(\alpha_i) \cap \text{supp}(\beta_i) = \emptyset$  for all  $i = 1, \dots, t$ . For  $p \in \mathbf{Z}^n$ ,  $\text{supp}(p) := \{i \in [n] := \{1, \dots, n\} : p_i \neq 0\}$  denotes the *support* of  $p$ . If  $x^{\alpha_i} - x^{\beta_i} \in \mathcal{G}_c$  then we always assume that  $c \cdot \alpha_i > c \cdot \beta_i$ .

**Lemma 3** *If  $\mathcal{G}_c = \{x^{\alpha_i} - x^{\beta_i} : i = 1, \dots, t\}$  is the reduced Gröbner basis of  $I_A$  with respect to  $c$  then*

- i)  $\{x^{\alpha_i} : i = 1, \dots, t\}$  is the minimal generating set of the initial ideal  $\text{in}_c(I_A)$ ; and
- ii) for each binomial  $x^{\alpha_i} - x^{\beta_i} \in \mathcal{G}_c$ ,  $\beta_i$  is the unique optimal solution to the integer program  $IP_{A,c}(A\alpha_i)$ .

*Proof* Part i) follows from the definition of reduced Gröbner bases. For each binomial  $x^{\alpha_i} - x^{\beta_i} \in \mathcal{G}_c$  we have  $A\alpha_i = A\beta_i$ ,  $\alpha_i, \beta_i \in \mathbf{N}^n$  and  $c \cdot \alpha_i > c \cdot \beta_i$ . If  $\beta_i$  is a nonoptimal solution to  $IP_{A,c}(A\alpha_i)$  then  $x^{\beta_i}$  lies in  $\text{in}_c(I_A)$  by Lemma 1 and hence some  $x^{\alpha_j}$  for  $j = 1, \dots, t$

will divide  $x^{\beta_i}$  contradicting the definition of a reduced Gröbner basis.

The conditions in Lemma 3 are in fact also sufficient for a finite subset of binomials in  $I_A$  to be the reduced Gröbner basis of  $I_A$  with respect to  $c$ . Given  $f \in I_A$ , the normal form of  $f$  with respect to  $\mathcal{G}_c$  is the unique remainder obtained upon dividing  $f$  by  $\mathcal{G}_c$ . See [11] for details on the *division algorithm* in  $k[\mathbf{x}]$ . The structure of  $\mathcal{G}_c$  implies that the normal form of a monomial  $x^\nu$  with respect to  $\mathcal{G}_c$  is a monomial  $x^{\nu'}$  such that both  $\nu$  and  $\nu'$  are solutions to  $\text{IP}_{A,c}(A\nu)$ . The Conti-Traverso algorithm for  $\text{IP}_{A,c}$  can be summarized as follows.

	Input: The matrix $A$ and cost vector $c$ .
	Pre-processing:
1	Find a generating set for the toric ideal $I_A$ .
2	Compute the reduced Gröbner basis, $\mathcal{G}_c$ , of $I_A$ with respect to the cost vector $c$ .
	To solve $\text{IP}_{A,c}(b)$ :
3	Find a solution $\nu$ to $\text{IP}_{A,c}(b)$ .
4	Compute the normal form $x^{\nu^*}$ of the monomial $x^\nu$ with respect to the reduced Gröbner basis $\mathcal{G}_c$ . Then $\nu^*$ is the optimal solution to $\text{IP}_{A,c}(b)$ .

**Conti-Traverso algorithm: How to solve programs in  $\text{IP}_{A,c}$**

*Proof* In order to prove the correctness of this algorithm, it suffices to show that for each solution  $\nu$  of  $\text{IP}_{A,c}(b)$ , the normal form of  $x^\nu$  modulo  $\mathcal{G}_c$  is the monomial  $x^{\nu^*}$  where  $\nu^*$  is the unique optimal solution to  $\text{IP}_{A,c}(b)$ . Suppose  $x^w$  is the normal form of the monomial  $x^\nu$ . Then  $w$  is also a solution to  $\text{IP}_{A,c}(b)$  since the exponent vectors of all monomials  $x^{w'}$  obtained during division of  $x^\nu$  by  $\mathcal{G}_c$  satisfy  $b = A\nu = Aw'$ ,  $w' \in \mathbb{N}^n$ . If  $w \neq \nu^*$ , then  $x^w - x^{\nu^*} \in I_A$  and  $\text{in}_c(x^w - x^{\nu^*}) = x^w$  since  $c \cdot w > c \cdot \nu^*$ . This implies that  $x^w \in \text{in}_c(I_A)$  and hence can be further reduced by  $\mathcal{G}_c$  contradicting the definition of the normal form.

**Computational Issues**

The Conti-Traverso algorithm above raises several computational issues. In Step 1, we require a generating set of the toric ideal  $I_A$  which can be a computationally challenging task as the size of  $A$  increases. The original Conti-Traverso algorithm starts with the ideal  $J_A :=$

$\langle x_j t^{a_j^-} - t^{a_j^+} : j = 1, \dots, n, t_0 t_1 \cdots t_d - 1 \rangle$  in the larger polynomial ring  $k[t_0, \dots, t_d, x_1, \dots, x_n]$  where  $a_j = a_j^+ - a_j^-$  is the  $j$ th column of the matrix  $A$ . The toric ideal  $I_A = J_A \cap k[\mathbf{x}]$  and hence the reduced Gröbner basis of  $I_A$  with respect to  $c$  can be obtained by *elimination* (see [11 Chapt. 3]). Although conceptually simple, this method has its limitations as the size of  $A$  increases since it requires  $d + 1$  extra variables over those present in  $I_A$  and the *Buchberger algorithm* for computing Gröbner bases [8] is sensitive to the number of variables involved. Two different algorithms for computing a generating set for  $I_A$  without introducing extra variables can be found in [5] and [18] respectively.

Once the generating set of  $I_A$  has been found, one needs to compute the reduced Gröbner basis  $\mathcal{G}_c$  of  $I_A$ . This can be done by any *computer algebra package* that does Gröbner basis computations like Macaulay2, Maple, Reduce, Singular or Cocoa to name a few. Cocoa has a dedicated implementation for toric ideals [6]. As the size of the problem increases, a straightforward computation of reduced Gröbner bases of  $I_A$  can become expensive and even impossible. Several tricks can be applied to help the computation, many of which are problem specific.

In Step 3 of the Conti-Traverso algorithm above one requires an initial solution to  $\text{IP}_{A,c}(b)$ . The original Conti-Traverso algorithm achieves this indirectly during the elimination procedure. Theoretically this task can be as hard as solving  $\text{IP}_{A,c}(b)$ , although in practice this depends on the specific problem at hand. The last step – to compute the normal form of a monomial with respect to the current reduced Gröbner basis – is (relatively speaking) a computationally easy task.

In practice, one is often only interested in solving  $\text{IP}_{A,c}(b)$  for a fixed  $b$ . In this situation, the Buchberger algorithm can be *truncated* to produce a sufficient set of binomials that will solve this integer program [35]. This idea was originally introduced in [36] in the context of 0 – 1 integer programs in which all the data is nonnegative. See also [10]. A ‘nontoric algorithm’ for solving integer programs with fixed right-hand sides was recently proposed in [4].

**Test Sets in Integer Programming**

A geometric interpretation of the Conti-Traverso algorithm above and more generally of the Buchberger al-

gorithm for toric ideals can be found in [34]. A *test set* for  $IP_{A,c}$  is a finite subset of vectors in  $\ker_{\mathbb{Z}}(A)$  such that for an integer program  $IP_{A,c}(b)$  and a nonoptimal solution  $v$  to this program, there is some  $u$  in the test set such that  $c \cdot v > c \cdot (v - u)$ . By interpreting a binomial  $x^{\alpha_i} - x^{\beta_i} \in \mathcal{G}_c$  as the vector  $\alpha_i - \beta_i \in \ker_{\mathbb{Z}}(A)$ , it can be seen that  $\mathcal{G}_c$  is the unique minimal test set for the family  $IP_{A,c}$ . A closely related test set for integer programming is the set of *neighbors of the origin* introduced by H.E. Scarf [26].

The binomial  $x^{\alpha_i} - x^{\beta_i} \in \mathcal{G}_c$  can also be viewed as the directed line segment  $[\alpha_i, \beta_i]$  directed from  $\alpha_i$  to  $\beta_i$ . For each  $b \in \text{pos}_{\mathbb{Z}}(A)$  we now construct a directed graph  $\mathcal{F}_{b,c}$  as follows: the vertices of this graph are the solutions to  $IP_{A,c}(b)$  and the edges of this graph are all possible directed line segments from  $\mathcal{G}_c$  that connect two vertices of this graph. Then  $\mathcal{G}_c$  is a necessary and sufficient set of directed line segments such that  $\mathcal{F}_{b,c}$  is a connected graph with a unique sink (at the optimal solution) for each  $b \in \text{pos}_{\mathbb{Z}}(A)$ . This geometric interpretation of  $\mathcal{G}_c$  can be used to solve several problems. By reversing the directions on all edges in  $\mathcal{F}_{b,c}$ , one obtains a directed graph with a unique root. One can enumerate all lattice points in  $P_b$  by searching this graph starting at its root. This idea was used in [33] to solve a class of manufacturing problems. The graphs  $\mathcal{F}_{b,c}$  provide a way to connect all the feasible solutions to an integer program by lattice moves. This idea was applied to statistical sampling in [13].

## Universal Gröbner Bases

A subset  $\mathcal{U}_A$  of  $I_A$  is a *universal Gröbner basis* for  $I_A$  if  $\mathcal{U}_A$  contains a Gröbner basis of  $I_A$  with respect to all (generic) cost vectors  $c \in \mathbb{R}^n$ . The *Graver basis* of  $A$  [16] is a finite universal Gröbner basis of  $I_A$  that can be described as follows. For each  $\sigma \in \{+, -\}^n$ , let  $\mathcal{H}_{\sigma}$  be the unique minimal generating set (over  $\mathbb{N}$ ) of the semigroup  $\ker_{\mathbb{Z}}(A) \cap \mathbb{R}_{\sigma}^n$ . Then the Graver basis,  $\text{Gr}_A := \cup_{\sigma} \mathcal{H}_{\sigma} \setminus \{0\}$ . An algorithm to compute  $\text{Gr}_A$  can be found in [30]. It was shown in [34] that all reduced Gröbner bases of  $I_A$  are contained in  $\text{Gr}_A$  which implies that there are only finitely many distinct reduced Gröbner bases for  $I_A$  as  $c$  varies over generic cost vectors. Let  $\text{UGB}_A$  denote the union of all the distinct reduced Gröbner bases of  $I_A$ . Then  $\text{UGB}_A$  is a universal Gröbner basis of  $I_A$  that is contained in the Graver basis  $\text{Gr}_A$ . The

following theorem from [30] characterizes the elements of  $\text{UGB}_A$  and thus allows one to test whether a binomial  $x^{\alpha_i} - x^{\beta_i} \in \text{Gr}_A$  belongs  $\text{UGB}_A$ . A second test can also be found in [30]. A vector  $u \in \mathbb{Z}^n$  is said to be *primitive* if the g.c.d. of its components is one.

**Theorem 4** *For a primitive vector  $u \in \ker_{\mathbb{Z}}(A)$ , the binomial  $x^{u^+} - x^{u^-}$  belongs to  $\text{UGB}_A$  if and only if the line segment  $[u^+, u^-]$  is a primitive edge in the polytope  $P_{Au^+}$ .*

The *degree* of a binomial  $x^{\alpha_i} - x^{\beta_i} \in I_A$ , is defined to be  $\sum \alpha_{ij^+} + \sum \beta_{ij}$ . The degree of the universal Gröbner basis  $\text{UGB}_A$  is then simply the maximum degree of any binomial in  $\text{UGB}_A$ . This number is an important complexity measure for the family of integer programs that have  $A$  as coefficient matrix. The current best bound for the degree of  $\text{UGB}_A$  is as follows. See [29, Chapt. 4] for a full discussion.

**Theorem 5** *The degree of a binomial  $x^{\alpha_i} - x^{\beta_i} \in \text{UGB}_A$ , is at most  $(n - d)(d + 1)D(A)$  where  $D(A)$  is the maximum absolute value of the determinant of a  $d \times d$  submatrix of  $A$ .*

It has been conjectured that this bound can be improved to  $(d + 1)D(A)$  and some partial results in this direction can be found in [17].

The universal Gröbner bases of several special instances of  $A$  have been investigated in the literature, a few of which we mention here. For the family of  $1 \times n$  matrices  $A(n) := [1, \dots, n]$  it was shown in [12] that the Graver basis of  $A(n)$  is in bijection with the *primitive partition identities* with largest part  $n$ . A matrix  $A \in \mathbb{Z}^{d \times n}$  is *unimodular* if the absolute values of the determinants of all its nonsingular maximal minors are the same positive constant. For  $u \in \ker_{\mathbb{Z}}(A)$ , the binomial  $x^{u^+} - x^{u^-} \in I_A$  is a *circuit* of  $A$  if  $u$  is primitive and has minimal support with respect to inclusion. Let  $C_A$  denote the set of circuits of  $A$ . Then in general,  $C_A \subseteq \text{UGB}_A \subseteq \text{Gr}_A$ . If  $A$  is unimodular, then all of the above containments hold at equality although the converse is false: there are nonunimodular matrices for which  $C_A = \text{Gr}_A$ . If  $A_n$  is the node-edge incidence matrix of the complete graph  $K_n$  then the elements in  $\text{UGB}_{A_n}$  can be identified with certain subgraphs of  $K_n$ . Gröbner bases of these matrices were investigated in [23]. The integer programs associated with  $A_n$  are the *b-matching prob-*

lems in the literature [24]. See [29, Chapt. 14] for some other specific examples of Gröbner bases.

**Variation of Cost Functions in Integer Programming**

We now consider all cost vectors in  $\mathbf{R}^n$  (not just the generic ones) and study the effect of varying them. As seen earlier  $I_A$  has only finitely many distinct reduced Gröbner bases as  $c$  is varied over the generic cost vectors. We say that two cost vectors  $c_1$  and  $c_2$  are *equivalent* with respect to  $IP_A$  if for each  $b \in \text{pos}_Z(A)$ , the integer programs  $IP_{A,c_1}(b)$  and  $IP_{A,c_2}(b)$  have the same set of optimal solutions. The Gröbner basis approach to integer programming allows a complete characterization of the structure of these equivalence classes of cost vectors.

**Theorem 6 [30]**

- i) *There exists only finitely many equivalence classes of cost vectors with respect to  $IP_A$ .*
- ii) *Each equivalence class is the relative interior of a convex polyhedral cone in  $\mathbf{R}^n$ .*
- iii) *The collection of all these cones defines a complete polyhedral fan in  $\mathbf{R}^n$  called the Gröbner fan of  $A$ .*
- iv) *Let  $db$  denote any probability measure with support  $\text{pos}_Z(A)$  such that  $\int_b b \, db < \infty$ .*

*Then the Minkowski integral  $St(A) = \int_b P_b \, db$  is an  $(n - d)$ -dimensional convex polytope, called the state polytope of  $A$ . The normal fan of  $St(A)$  equals the Gröbner fan of  $A$ .*

Gröbner fans and state polytopes of graded polynomial ideals were introduced in [25] and [2] respectively. For a toric ideal both these entities have self contained construction methods that are rooted in the combinatorics of these ideals [30]. For a software system for computing Gröbner fans of toric ideals see [21].

We call  $P_b$  for  $b \in \text{pos}_Z(A)$  a *Gröbner fiber* of  $A$  if there is some  $x^{u^+} - x^{u^-} \in \text{UGB}_A$  such that  $b = Au^+ = Au^-$ . Since there are only finitely many elements in  $\text{UGB}_A$  the matrix  $A$  has only finitely many Gröbner fibers. Then the *Minkowski sum* of all Gröbner fibers of  $A$  is a state polytope of  $A$ . For a survey of algorithms to construct state polytopes and Gröbner fans of graded polynomial ideals see [29, Chapt. 2; 3]. The Gröbner fan of  $A$  provides a model for *global sensitivity analysis* for the family of integer programs  $IP_{A,c}$ .

We now briefly discuss a theory analogous to the above for linear programming based on results in [7] and [14]. For a comparison of integer and linear programming from this point of view see [30]. Let  $LP_{A,c}(b) := \min\{c \cdot x : Ax = b, x \geq 0\}$  where  $A$  and  $c$  are as before and  $b$  is any vector in the rational polyhedral cone  $\text{pos}(A) := \{Ax : x \geq 0\}$ . We define two cost vectors  $c_1$  and  $c_2$  to be *equivalent* with respect to  $LP_A$  if the linear programs  $LP_{A,c_1}(b)$  and  $LP_{A,c_2}(b)$  have the same set of optimal solutions for all  $b \in \text{pos}(A)$ . Let  $\mathcal{A} := \{a_1, \dots, a_n\}$  be the vector configuration in  $\mathbf{Z}^d$  consisting of the columns of  $A$ . For a subset  $\sigma \subseteq \mathcal{A}$ , we let  $\text{pos}(\sigma)$  denote the cone generated by  $\sigma$ . A *polyhedral subdivision*  $\Delta$  of  $\mathcal{A}$  is a collection of subsets of  $\mathcal{A}$  such that  $\{\text{pos}(\sigma) : \sigma \in \Delta\}$  is a set of cones in a polyhedral fan whose support is  $\text{pos}(A)$ . The elements of  $\Delta$  are called the *faces* or *cells* of  $\Delta$ . For convenience we identify  $\mathcal{A}$  with the set of indices  $[n]$  and any subset of  $\mathcal{A}$  by the corresponding subset  $\sigma \subseteq [n]$ . A cost vector  $c \in \mathbf{R}^n$  induces the *regular subdivision*  $\Delta_c$  of  $\mathcal{A}$  [7,14] as follows:  $\sigma$  is a face of  $\Delta_c$  if there exists a vector  $y \in \mathbf{R}^d$  such that  $a_j \cdot y = c_j$  whenever  $j \in \sigma$  and  $a_j \cdot y < c_j$  otherwise. A cost vector  $c \in \mathbf{R}^n$  is said to be *generic* with respect to  $LP_A$  if every linear program in the family  $LP_{A,c}$  has a unique optimal solution. When  $c$  is generic for  $LP_A$ , the regular subdivision  $\Delta_c$  is in fact a *triangulation* called the *regular triangulation* of  $\mathcal{A}$  with respect to  $c$ .

Two cost vectors  $c_1$  and  $c_2$  are equivalent with respect to  $LP_A$  if and only if  $\Delta_{c_1} = \Delta_{c_2}$ . The equivalence class of  $c$  with respect to  $LP_A$  is hence  $\{c' \in \mathbf{R}^n : \Delta_{c'} = \Delta_c\}$  which is the relative interior of a polyhedral cone in  $\mathbf{R}^n$  called the *secondary cone* of  $c$ , denoted as  $S_c$ . The cone  $S_c$  is  $n$ -dimensional if and only if  $c$  is generic with respect to  $LP_A$ . The set of all equivalence classes of cost vectors fit together to form a complete polyhedral fan in  $\mathbf{R}^n$  called the *secondary fan* of  $A$ . This fan is the normal fan of a polytope called the *secondary polytope* of  $A$ . See [7] for construction methods for both the secondary fan and polytope of  $A$ .

We conclude this section by showing that the Gröbner and secondary fans of  $A$  are related. The *Stanley-Reisner ideal* of  $\Delta_c$  is the square-free monomial ideal  $\langle x_{i_1} \cdots x_{i_r} : \{i_1, \dots, i_r\} \text{ is a nonface of } \Delta_c \rangle \subset k[\mathbf{x}]$ .

**Theorem 7 [28]** *The radical of the initial ideal  $\text{in}_c(I_A)$  is the Stanley-Reisner ideal of the regular triangulation  $\Delta_c$ .*

**Corollary 8 [28]**

- i) The Gröbner fan of  $A$  is a refinement of the secondary fan of  $A$ .
- ii) A secondary polytope of  $A$  is a summand of a state polytope of  $A$ .

Corollary 8 reaffirms the view that integer programming is an arithmetic refinement of linear programming.

**Group Relaxations in Integer Programming**

We now investigate group relaxations of integer programs in the family  $IP_{A,c}$  from an algebraic point of view. The results in this section are taken from [19,20] and [32], sometimes after an appropriate translation into polyhedral language. See these papers for the algebraic motivations that led to these results.

The group relaxation of  $IP_{A,c}(b)$  [15] is the program  $Group^\sigma(b) := \min \{ \tilde{c}_\sigma \cdot x_\sigma : A_\sigma x_\sigma + A_{\bar{\sigma}} x_{\bar{\sigma}} = b, x_{\bar{\sigma}} \geq 0, x = (x_\sigma, x_{\bar{\sigma}}) \in \mathbf{Z}^n \}$ , where  $A_\sigma$ , the submatrix of  $A$  whose columns are indexed by  $\sigma \subseteq [n]$ , is the optimal basis of the linear program  $LP_{A,c}(b)$  and  $\tilde{c}_\sigma = c_\sigma - c_\sigma A_\sigma^{-1} A_{\bar{\sigma}}$ . Here the cost vector  $c$  has also been partitioned as  $c = (c_\sigma, c_{\bar{\sigma}})$  using the set  $\sigma \subseteq [n]$ .

**Definition 9** Suppose  $\mathcal{L}$  is any sublattice of  $\mathbf{Z}^n$ ,  $w \in \mathbf{R}^n$  and  $v \in \mathbf{N}^n$ . The lattice program  $Lat_{\mathcal{L},w}(v)$  defined by this data is

$$\begin{cases} \min & w \cdot u \\ \text{s.t.} & u \equiv v \pmod{\mathcal{L}}, \\ & u \in \mathbf{N}^n. \end{cases}$$

Lattice programs are a generalization of integer programs:  $IP_{A,c}(b) = Lat_{\mathcal{L},c}(v)$  where  $\mathcal{L} = \ker_{\mathbf{Z}}(A)$  and  $v$  is any feasible solution to  $IP_{A,c}(b)$ . Gröbner basis methods for integer programs can be extended to solve lattice programs (see [20,32]). Given the lattice  $\mathcal{L}$  and a cost vector  $w$ , we first construct the lattice ideal  $I_{\mathcal{L}} = \langle \mathbf{x}^\alpha - \mathbf{x}^\beta : \alpha - \beta \in \mathcal{L}, \alpha, \beta \in \mathbf{N}^n \rangle \subset k[\mathbf{x}]$ . We then compute the reduced Gröbner basis of  $I_{\mathcal{L}}$  with respect to  $w$  denoted as  $\mathcal{G}_w(I_{\mathcal{L}})$ . (If  $w$  does not induce a total order on  $\mathbf{N}^n$  via the inner product  $w \cdot x, x \in \mathbf{N}^n$ , then we use a tie breaking term order to refine the order induced by  $w$ .) For a particular lattice program  $Lat_{\mathcal{L},w}(v)$ , the optimal solution is the exponent vector of the normal form of  $x^v$  with respect to  $\mathcal{G}_w(I_{\mathcal{L}})$ .

Let  $\tau \subseteq [n]$  and  $\pi_\tau: \mathbf{Z}^n \rightarrow \mathbf{Z}^{|\tau|}$  be the coordinate projection map where the coordinates indexed by  $\tau$  are eliminated. Consider the lattice  $\mathcal{L}_\tau := \pi_\tau(\mathcal{L})$  where  $\mathcal{L} = \ker_{\mathbf{Z}}(A)$ . Given a basis  $\{b_1, \dots, b_{n-d}\}$  of  $\mathcal{L}$ , the set  $\{\pi_\tau(b_1), \dots, \pi_\tau(b_{n-d})\}$  forms a basis for  $\mathcal{L}_\tau$ . Further,  $\pi_\tau: \mathcal{L} \rightarrow \mathcal{L}_\tau$  is an isomorphism whenever  $\text{rank}(A_\tau) = |\tau|$ .

**Proposition 10 [32]** Let  $v$  be a feasible solution to  $IP_{A,c}(b)$  and  $A_\sigma$  be the optimal basis of  $LP_{A,c}(b)$ . Then the group relaxation  $Group^\sigma(b)$  of  $IP_{A,c}(b)$  is the lattice program  $Lat_{\mathcal{L}_\sigma, \tilde{c}_\sigma}(\pi_\sigma(v))$  where  $\tilde{c}_\sigma = \pi_\sigma(c - c_\sigma(A_\sigma)^{-1}A) = c_{\bar{\sigma}} - c_\sigma A_\sigma^{-1} A_{\bar{\sigma}}$ .

The program  $Group^\sigma(b)$  can be solved by Gröbner basis methods as explained earlier or by dynamic programming [15]. The optimal solution  $x_\sigma^*$  to  $Group^\sigma(b)$  is then lifted to the unique vector  $x^* = (x_\sigma^*, x_{\bar{\sigma}}^*) \in \mathbf{Z}^n$  by solving the equation  $A_\sigma x_\sigma + A_{\bar{\sigma}} x_{\bar{\sigma}}^* = b$ . If all components of  $x_\sigma^*$  are nonnegative then  $x^*$  is the optimal solution to  $IP_{A,c}(b)$ . Otherwise  $c \cdot x^*$  is a lower bound to the optimal value of  $IP_{A,c}(b)$ .

When  $Group^\sigma(b)$  fails to solve  $IP_{A,c}(b)$ , L. Wolsey [37] suggested using extended group relaxations of  $IP_{A,c}(b)$ . We introduce a more general set of extended group relaxations of  $IP_{A,c}(b)$  inspired by the following close relationship between the linear programs in  $LP_{A,c}$  and the regular triangulation  $\Delta_c$ .

**Proposition 11 [30]** The optimal solutions  $x$  to  $LP_{A,c}(b)$  are the solutions to the problem: Find  $x \in \mathbf{R}^n$  such that  $Ax = b, x \geq 0$ , and  $\text{supp}(x)$  is a subset of a face of  $\Delta_c$ .

Proposition 11 says that the set  $\sigma$  in  $Group^\sigma(b)$  is a maximal face of  $\Delta_c$ .

**Definition 12** Consider the integer program  $IP_{A,c}(b)$  and a feasible solution  $v$  to this program. Let  $\tau$  be a face of  $\Delta_c$  and  $\sigma$  be any maximal face of  $\Delta_c$  containing  $\tau$ . Then the group relaxation of  $IP_{A,c}(b)$  with respect to  $\tau$  denoted as  $Group^\tau(b)$  is the lattice program  $Lat_{\mathcal{L}_\tau, \tilde{c}_\tau}(\pi_\tau(v))$  where  $\tilde{c}_\tau := \pi_\tau(c - c_\sigma A_\sigma^{-1}A)$ .

The extended group relaxations in [37] are precisely those  $Group^\tau(b)$ s where  $\tau$  is a subset of the maximal face  $\sigma$  of  $\Delta_c$  that gives the optimal basis of  $LP_{A,c}(b)$ . Clearly, one such relaxation will solve  $IP_{A,c}(b)$ . However, we consider all relaxations of  $IP_{A,c}(b)$  of the form  $Group^\tau(b)$  as  $\tau$  varies over all faces of  $\Delta_c$  in order to

avoid keeping track of which  $b$  is being considered and what the optimal basis of  $\text{LP}_{A,c}(b)$  is.

It was shown in [32] that the lattice program  $\text{Group}^\tau(b)$  is related to the *localization* of the initial ideal  $\text{in}_c(I_A)$  at the prime ideal  $p_\tau := \langle x_j : j \notin \tau \rangle$  in  $k[\mathbf{x}]$ . Since group relaxations are always defined with respect to a face  $\tau$  of  $\Delta_c$ , we are guaranteed that  $\text{rank}(A_\tau) = |\tau|$  which allows a unique lifting of the optimal solution of  $\text{Group}^\tau(b)$  to a vector in the same congruence class modulo  $\mathcal{L}$  as the solutions to  $\text{IP}_{A,c}(b)$ .

**Theorem 13** [20] *Suppose  $u' \in \mathbb{N}^{|\bar{\tau}|}$  is the optimal solution to the group relaxation  $\text{Group}^\tau(b)$ . Then there exists a unique  $u \in \mathbb{Z}^n$  such that  $A(u - v) = 0$  for any feasible solution  $v$  to  $\text{IP}_{A,c}(b)$  and  $\pi_\tau(u) = u'$ . If  $u \geq 0$  then it is the optimal solution to  $\text{IP}_{A,c}(b)$ .*

A group relaxation  $\text{Group}^\tau(b)$  is easiest to solve when  $\tau$  is a maximal face of  $\Delta_c$ . In this situation, the lattice ideal  $I_{\mathcal{L}_\tau}$  is zero dimensional and hence their Gröbner bases are easier to compute than otherwise. We call such group relaxations the *Gomory relaxations* of  $\text{IP}_{A,c}(b)$ . In general one is most interested in those group relaxations  $\text{Group}^\tau(b)$  that solve  $\text{IP}_{A,c}(b)$  with  $|\tau|$  as large as possible. In the rest of this section we study several structural properties of these ‘least tight’ extended group relaxations that solve programs in  $\text{IP}_{A,c}$ . We first need a diversion into combinatorics.

For  $m \in \mathbb{N}^n$ , we define *support* of  $x^m \in k[\mathbf{x}]$  to be  $\text{supp}(m)$ .

**Definition 14** For a monomial  $x^m \in k[\mathbf{x}]$  and  $\sigma \subseteq [n]$ , we say that  $(x^m, \sigma)$  is an *admissible pair* of a monomial ideal  $M$  if

- i)  $\text{supp}(m) \cap \sigma = \emptyset$ ; and
- ii) every monomial in  $x^m \cdot k[x_j : j \in \sigma]$  is a standard monomial of  $M$ .

There is a natural partial order on the set of all admissible pairs of  $M$  given by  $(x^m, \sigma) \leq (x^{m'}, \sigma')$  if and only if  $x^m$  divides  $x^{m'}$  and  $\text{supp}(x^{m'}/x^m) \cup \sigma' \subseteq \sigma$ .

**Definition 15** An admissible pair  $(x^m, \sigma)$  of  $M$  is called a *standard pair* of  $M$  if it is a minimal element in the poset of all admissible pairs with respect to the above partial order.

The standard pairs of  $M$  induce a unique covering of the set of standard monomials of  $M$  which we refer to as the *standard pair decomposition* of  $M$ . This decomposition was introduced in [31] to study the associated

primes of  $M$  and their multiplicities and thus the arithmetic degree [3] of  $M$ . When  $M$  is the initial ideal of a toric ideal stronger conclusions can be drawn. In our exposition below we bypass much of the algebraic results associated with the standard pair decomposition of  $M$ , but instead use these results to motivate appropriate definitions to continue our discussion of group relaxations.

**Definition 16**

- i) For  $\tau \subseteq [n]$ , we define the *multiplicity* of  $\tau$ , denoted as  $\text{mult}(\tau)$ , to be the number of standard pairs of the form  $(x^m, \tau)$  in the standard pair decomposition of  $M$ .
- ii) The sum of the multiplicities of  $\tau$  as  $\tau$  varies over the subsets of  $[n]$  is called the *arithmetic degree* of  $M$ , denoted as  $\text{arithdeg}(M)$ .

In the rest of this section we let  $M = \text{in}_c(I_A)$ .

**Proposition 17** [29, Sect. 12.D]

- i) If  $(x^m, \tau)$  is a standard pair of  $\text{in}_c(I_A)$  then  $\tau$  is a face of  $\Delta_c$ .
- ii) The standard pair  $(1, \sigma)$  occurs in the standard pair decomposition of  $\text{in}_c(I_A)$  if and only if  $\sigma$  is a maximal face of  $\Delta_c$ . In this case,  $\text{mult}(\sigma)$  is the normalized volume of  $\sigma$  in  $\Delta_c$ .

The *normalized volume* of a maximal face  $\sigma \in \Delta_c$  is the quotient  $|\det(A_\sigma)|/T$  where  $T$  is the g.c.d. of all  $|\det(A_{\sigma'})|$  as  $\sigma'$  varies over the maximal faces of  $\Delta_c$ . We note that the converse to Proposition 17i) is false. If  $\tau$  is a nonmaximal face of  $\Delta_c$  then there may not be a standard pair of the form  $(x^m, \tau)$  in the standard pair decomposition of  $\text{in}_c(I_A)$ .

The standard pair decomposition of  $\text{in}_c(I_A)$  reduces the problem of solving integer programs in  $\text{IP}_{A,c}$  to solving systems of linear equations: if  $\beta$  is the optimal solution to the program  $\text{IP}_{A,c}(b)$ , then the monomial  $x^\beta$  is covered by some standard pair  $(x^u, \tau)$ . Thinking of  $u$  as a vector in  $\mathbb{N}^{|\bar{\tau}|}$  (by adding zero components if necessary), we get  $\beta_{\bar{\tau}} = u$  and  $\beta_\tau$  is the unique solution to the linear system  $A_\tau x_\tau = b - A_{\bar{\tau}} u$ . Therefore, if the standard pairs of  $\text{in}_c(I_A)$  are known a priori, then one can set up  $\text{arithdeg}(\text{in}_c(I_A))$ -many systems of linear equations – one for each standard pair. For each  $b \in \text{pos}_Z(A)$ , one then solves for  $\beta_\tau$  as above. Whenever the  $\beta_\tau$  obtained this way is both integral and nonnegative, we have found the optimal solution to  $\text{IP}_{A,c}(b)$ . Hence

$\text{arithdeg}(\text{in}_c(I_A))$  can be seen as a complexity measure of  $\text{IP}_{A,c}$ . See [22] for another preprocessing of  $\text{IP}_{A,c}$  that reduces solving  $\text{IP}_{A,c}(b)$  to solving a sequence of sub-problems involving super additive functions.

**Theorem 18** [20]

i) *The integer program  $\text{IP}_{A,c}(b)$  is solved by the group relaxation  $\text{Group}^\tau(b)$  if and only if the monomial  $x^\beta$ , where  $\beta$  is the optimal solution to  $\text{IP}_{A,c}(b)$ , is covered by a standard pair  $(x^\alpha, \tau')$  of  $\text{in}_c(I_A)$  for some  $\tau' \supseteq \tau$ .*

In order to state the main results, we need yet another interpretation of group relaxations of programs in  $\text{IP}_{A,c}$ .

Let  $\phi_A: \mathbb{N}^n \rightarrow \mathbb{Z}^d$  be the linear map  $x \mapsto Ax$ . Then  $P_b$  is the convex hull of  $\phi_A^{-1}(b)$  for each  $b \in \text{pos}_{\mathbb{Z}}(A)$ . Consider a matrix  $B \in \mathbb{Z}^{n \times (n-d)}$  such that the columns of  $B$  form a basis for  $\ker_{\mathbb{Z}}(A)$  (as an Abelian group). For  $v \in \phi_A^{-1}(b)$  we can identify  $\phi_A^{-1}(b)$  with the lattice points in the polytope

$$Q_v := \left\{ u \in \mathbb{R}^{n-d} : Bu \leq v \right\}, \tag{1}$$

via the bijection  $Q_v \cap \mathbb{Z}^{n-d} \rightarrow \phi_A^{-1}(b)$  such that  $u \rightarrow v - Bu$ . Under this bijection,  $v \in \phi_A^{-1}(b)$  corresponds to  $0 \in Q_v$ . We refer to  $Q_v$  as a *Scarf formulation* of  $P_b = \text{conv}(\phi_A^{-1}(b))$ . If  $v, v' \in \phi_A^{-1}(b)$ , then  $Q_v$  and  $Q_{v'}$  are simply lattice translates of each other.

**Proposition 19** *If  $v$  is a feasible solution to  $\text{IP}_{A,c}(b)$ , then  $\text{IP}_{A,c}(b)$  is equivalent to*

$$\min \left\{ -(cB) \cdot u : u \in Q_v \cap \mathbb{Z}^{n-d} \right\} \tag{2}$$

*Proof* A lattice point  $v^*$  is the optimal solution to  $\text{IP}_{A,c}(b)$ :

$\Leftrightarrow$  there exists  $u^* \in \mathbb{Z}^{n-d}$  such that  $v^* = v - Bu^* \geq 0$  and  $c(v - Bu^*) < c(v - Bu)$  for all  $u \neq u^* \in \mathbb{Z}^{n-d}$  with  $v - Bu \geq 0$

$\Leftrightarrow$  there exist  $u^* \in Q_v \cap \mathbb{Z}^{n-d}$  such that  $-(cB) \cdot u^* < -(cB) \cdot u$  for all  $u \in Q_v \cap \mathbb{Z}^{n-d}$

$\Leftrightarrow u^*$  is the optimal solution of the integer program (2).

We will refer to the integer program (2) as a *Scarf formulation* of  $\text{IP}_{A,c}(b)$ . Using the optimal solution  $u^*$  of the Scarf formulation (2), we define the following sub-polytope of  $Q_v$ :

$$Q_v(u^*) := \left\{ u \in \mathbb{R}^{n-d} : Bu \leq v, -(cB) \cdot u \leq -(cB) \cdot u^* \right\}. \tag{3}$$

**Theorem 20** *Let  $v \in \mathbb{N}^n$  be a feasible solution to  $\text{IP}_{A,c}(b)$ . Then  $u^*$  is the optimal solution to (2) if and only if  $u^*$  is the unique lattice point in  $Q_v(u^*)$ . In particular,  $v$  is the optimal solution to  $\text{IP}_{A,c}(b)$  if and only if  $0$  is the unique lattice point in  $Q_v(0) = \{u \in \mathbb{R}^{n-d} : Bu \leq v, -(cB) \cdot u \leq 0\}$ .*

*Proof* A vector  $u^* \in \mathbb{Z}^{n-d}$  is the optimal solution to (2) if and only if  $u^*$  is in  $Q_v$  and there is no  $u \in Q_v \cap \mathbb{Z}^{n-d}$  such that  $-(cB) \cdot u < -(cB) \cdot u^*$ . Since  $c$  is a generic cost vector, this is equivalent to  $u^*$  being the unique lattice point in  $Q_v(u^*)$ . The second statement follows immediately.

**Corollary 21** *A monomial  $x^v$  is a standard monomial of  $\text{in}_c(I_A)$  if and only if  $0$  is the unique lattice point in  $Q_v(0)$ .*

Let  $B^\tau$  denote the submatrix of  $B$  whose rows are indexed by the set  $\tau \subseteq [n]$ .

**Lemma 22** *Suppose  $\sigma$  is a maximal face of  $\Delta_c$  and  $\tau$  a subface of  $\sigma$ . Then  $\tilde{c}_\tau B^\tau = cB$  where  $\tilde{c}_\tau = \pi_\tau(c - c_\sigma(A_\sigma)^{-1}A)$ .*

*Proof* Since the support of  $c - c_\sigma(A_\sigma)^{-1}A$  is contained in  $\bar{\tau}$ ,  $\tilde{c}_\tau B^\tau = (c - c_\sigma(A_\sigma)^{-1}A)B = cB$ .

**Theorem 23** *Let  $v$  be a feasible solution to  $\text{IP}_{A,c}(b)$ , and suppose that  $\sigma$  is a maximal face of  $\Delta_c$  and  $\tau$  a subface of  $\sigma$ . Then the group relaxation  $\text{Group}^\tau(b)$  is the integer program  $\min \{-(cB) \cdot u : B^\tau u \leq \pi_\tau(v), u \in \mathbb{Z}^{n-d}\}$ .*

*Proof* Since  $\mathcal{L}_\tau = \{B^\tau u : u \in \mathbb{Z}^{n-d}\}$ , we have:

$$\begin{aligned} & \text{Lat}_{\mathcal{L}_\tau, \tilde{c}_\tau}(\pi_\tau(v)) \\ & := \min \left\{ \tilde{c}_\tau \cdot w : \begin{array}{l} w \equiv \pi_\tau(v) \pmod{\mathcal{L}_\tau}, \\ w \in \mathbb{N}^{|\bar{\tau}|} \end{array} \right\} \\ & = \min \left\{ \tilde{c}_\tau \cdot w : \begin{array}{l} w \in \mathbb{N}^{|\bar{\tau}|}, \\ w = \pi_\tau(v) - B^\tau u, \\ u \in \mathbb{Z}^{n-d} \end{array} \right\} \\ & = \min \left\{ \tilde{c}_\tau \cdot w : \begin{array}{l} \pi_\tau(v) - B^\tau u \geq 0, \\ u \in \mathbb{Z}^{n-d} \end{array} \right\} \\ & = \min \left\{ \tilde{c}_\tau \cdot (\pi_\tau(v) - B^\tau u) : \begin{array}{l} B^\tau u \leq \pi_\tau(v), \\ u \in \mathbb{Z}^{n-d} \end{array} \right\} \\ & = \min \left\{ (-\tilde{c}_\tau B^\tau) \cdot u : \begin{array}{l} B^\tau u \leq \pi_\tau(v), \\ u \in \mathbb{Z}^{n-d} \end{array} \right\} \end{aligned}$$

$$= \min \left\{ -(cB) \cdot u : \begin{array}{l} B^{\bar{v}}u \leq \pi_{\tau}(v), \\ u \in \mathbf{Z}^{n-d} \end{array} \right\}$$

by Lemma 22.

We will denote the polyhedron obtained from  $Q_v$  by removing the inequalities corresponding to  $\tau$  by  $Q_v^{\bar{\tau}}$ . By the above theorem, solving the group relaxation of  $IP_{A,c}(b)$  with respect to  $\tau \in \Delta_c$  is equivalent to minimizing the linear functional  $-(cB) \cdot u$  over the lattice points in  $Q_v^{\bar{\tau}}$ . Now we can characterize which group relaxations will solve  $IP_{A,c}(b)$ .

**Corollary 24**

- i) Let  $v$  be a feasible solution to  $IP_{A,c}(b)$ . Then  $Group^{\tau}(b)$  solves  $IP_{A,c}(b)$  if and only if the programs  $\min\{-(cB) \cdot u : u \in Q_v \cap \mathbf{Z}^{n-d}\}$  and  $\min\{-(cB) \cdot u : u \in Q_v^{\bar{\tau}} \cap \mathbf{Z}^{n-d}\}$  have the same optimal solutions.
- ii) If  $v$  is optimal for  $IP_{A,c}(b)$ , then  $Group^{\tau}(b)$  solves  $IP_{A,c}(b)$  if and only if  $0$  is the unique lattice point in  $Q_v^{\bar{\tau}}(0) := \{u \in \mathbf{R}^{n-d} : B^{\bar{v}}u \leq \pi_{\tau}(v), -(cB) \cdot u \leq 0\}$ .

For a polyhedron  $P = \{x \in \mathbf{R}^p : Tx \leq t\}$  we say that an inequality  $T_i x \leq t_i$  is essential if the relaxation of the polyhedron obtained by removing  $T_i x \leq t_i$  contains a new lattice point.

**Theorem 25 [19]** An admissible pair  $(x^v, \tau)$  is a standard pair of  $in_c(I_A)$  if and only if  $0$  is the unique lattice point in  $Q_v^{\bar{\tau}}(0)$  and all of the inequalities in the system  $B^{\bar{v}}u \leq \pi_{\tau}(v)$  are essential.

Using the above characterization of the standard pairs of  $in_c(I_A)$  we obtain a combinatorial interpretation  $formult(\tau)$  and  $arithdeg(in_c(I_A))$ .

**Corollary 26**

- i) The multiplicity of  $\tau$  is the number of polytopes of the form  $Q_v^{\bar{\tau}}(0) := \{u \in \mathbf{R}^{n-d} : B^{\bar{v}}u \leq v, -(cB) \cdot u \leq 0\}$  where  $v \in \mathbf{N}^{|\bar{\tau}|}$ ,  $0$  is the unique lattice point in  $Q_v^{\bar{\tau}}(0)$  and all inequalities in  $B^{\bar{v}}u \leq v$  are essential.
- ii) The arithmetic degree of  $in_c(I_A)$  is the total number of such polytopes  $Q_v^{\bar{\tau}}(0)$  as  $\tau$  ranges over the subsets of  $[n]$ .

The result that  $mult(\sigma)$  is the normalized volume of  $\sigma$  when  $\sigma$  is a maximal face of  $\Delta_c$  is a special case of the above more general interpretation of multiplicity. See [19].

**Corollary 27** For the initial ideal  $in_c(I_A)$ , the following are equivalent:

- i) The initial ideal  $in_c(I_A)$  has no standard pairs of the form  $(x^m, \tau)$  where  $\tau$  is a nonmaximal face of  $\Delta_c$ .
- ii) For a face  $\tau \in \Delta_c$ , if there exists a  $v \in \mathbf{N}^{|\bar{\tau}|}$  such that  $Q_v^{\bar{\tau}}(0)$  contains the origin as its unique lattice point and all inequalities are essential then  $\tau$  is a maximal face of  $\Delta_c$  and  $Q_v^{\bar{\tau}}(0)$  is a simplex.
- iii) All programs in  $IP_{A,c}$  can be solved by group relaxations with respect to maximal faces of  $\Delta_c$ .
- iv) The arithmetic degree of  $in_c(I_A)$  is  $vol(conv(A))$ .

Proposition 17 shows that the set of all  $\tau$  in  $\Delta_c$  that index standard pairs of  $in_c(I_A)$  is a sub poset (with respect to inclusion) of the face lattice of  $\Delta_c$ . We denote this subposet by  $Std(\Delta_c)$ . Note that both (face lattice of)  $\Delta_c$  and  $Std(\Delta_c)$  have the same maximal elements. We now show that the elements of  $Std(\Delta_c)$  come in chains.

**Theorem 28 [19]** Let  $\tau, |\tau| < d$  be a nonmaximal face of  $\Delta_c$  such that  $\tau \in Std(\Delta_c)$ . Then there exists some  $\tau' \in \Delta_c$  such that  $\tau' \in Std(\Delta_c)$  with the property that

- i)  $\tau' \supset \tau$  and
- ii)  $|\tau'| = |\tau| + 1$ .

See [19] for a proof of this theorem. The tools needed in the proof are polyhedral and depend heavily on the polyhedral interpretation of a standard pair as given in Theorem 25. In terms of group relaxations, Theorem 28 is saying that whenever there is a  $b \in pos_Z(A)$  that is solved by a ‘least tight’  $Group^{\tau}(b)$ , then there exists a  $b' \in pos_Z(A)$  that is solved by a ‘least tight’  $Group^{\tau'}(b)$  where

- i)  $\tau' \supset \tau$  and
- ii)  $|\tau'| = |\tau| + 1$ .

Hence the ‘least tight’ extended group relaxations that solve the programs in  $IP_{A,c}$  form saturated chains in the poset  $Std(\Delta_c)$ .

Since a maximal face of  $\Delta_c$  has dimension  $d$ , the length of a maximal chain in  $Std(\Delta_c)$ , which we denote as  $length(Std(\Delta_c))$ , is at most  $d$ . However, when  $n - d$  which is the the corank of  $A$  is small compared to  $d$ ,  $length(Std(\Delta_c))$  has a stronger upper bound as shown below. We need the following result [27, Corol. 16.5a]:

**Theorem 29** Let  $Ax \leq b$  be a system of linear inequalities in  $n$  variables, and let  $c \in \mathbf{R}^n$ . If  $\max\{c \cdot x : Ax \leq b, x \in \mathbf{Z}^n\}$  is finite, then  $\max\{c \cdot x : Ax \leq b, x \in \mathbf{Z}^n\} = \max\{c \cdot x : A'x \leq b', x \in \mathbf{Z}^n\}$  for some subsystem  $A'x \leq b'$  of  $Ax \leq b$  with at most  $2^n - 1$  inequalities.

**Theorem 30** *The length of a maximal chain in  $\text{Std}(\Delta_c)$  is at most  $\min(d, 2^{n-d} - (n - d + 1))$ .*

*Proof* Suppose  $v$  is the optimal solution to  $\text{IP}_{A,c}(b)$  which is equivalent to  $\min\{- (cB) \cdot u : Bu \leq v, u \in \mathbb{Z}^{n-d}\}$ . By Theorem 29, we need at most  $2^{n-d} - 1$  inequalities to describe the same integer program. This means we can remove at least  $n - (2^{n-d} - 1)$  inequalities from  $Bu \leq v$  without changing the optimal solution. Therefore by Theorem 23,  $\text{IP}_{A,c}(b)$  can be solved by a group relaxation with respect to a  $\tau \in \Delta_c$  of size at least  $n - (2^{n-d} - 1)$ . This implies that the maximal length of a chain in  $\text{Std}(\Delta_c)$  is at most  $d - (n - (2^{n-d} - 1)) = 2^{n-d} - (n - d + 1)$ .

**Corollary 31** *If  $A \in \mathbb{Z}^{d \times n}$  has corank two, then  $\text{length}(\text{Std}(\Delta_c)) \leq 1$ .*

*Proof* In this situation,  $2^{n-d} - (n - d + 1) = 4 - (4 - 2 + 1) = 4 - 3 = 1$ .

**Corollary 32** *All programs in the family  $\text{IP}_{A,c}$  can be solved by group relaxations with respect to a  $\tau \in \Delta_c$  of size at least  $\max(0, n - (2^{n-d} - 1))$ .*

We conclude by remarking that the bound in Theorem 30 is sharp. See [19] for details.

### Overview

An *integer programming problem* (IP) is an optimization problem in which some or all of the variables are restricted to take on only integer values. The exposition presented here will focus on the case in which the objective and constraints of the optimization problem are defined via linear functions. In addition, for simplicity, it will be assumed that all of the variables are restricted to be nonnegative integer valued. Thus, the mathematical formulation of the problem under consideration can be stated as:

$$(IP) \begin{cases} \max & c^T x \\ \text{s.t.} & Ax \leq b \\ & x \in \mathbf{Z}_+^n, \end{cases}$$

where  $A \in \mathbf{R}^{m \times n}$ ,  $b \in \mathbf{R}^m$  and  $c \in \mathbf{R}^n$ . For notational convenience, let  $S$  denote the *constraint set* of problem (IP); i. e.,

$$S := \{x \in \mathbf{Z}_+^n : Ax \leq b\}.$$

The classical approach to solving integer programs is branch and bound [39]. The branch and bound method is based on the idea of iteratively partitioning the set  $S$  (branching) to form subproblems of the original integer program. Each subproblem is solved – either exactly or approximately – to obtain an upper bound on the subproblem objective value. The driving force behind the branch and bound approach lies in the fact that if an upper bound for the objective value of a given subproblem is less than the objective value of a known integer feasible solution (e. g., obtained by solving some other subproblem) then the optimal solution of the original integer program cannot lie in the subset of  $S$  associated with the given subproblem. Hence, the upper bounds on subproblem objective values are, in essence, used to construct a proof of optimality without exhaustive search.

One concept that is fundamental to obtaining upper bounds on subproblem objective values is that of problem relaxation. A *relaxation* of the optimization problem

$$\max \{c^\top x : x \in S\}$$

is an optimization problem

$$\max \{c_R^\top x : x \in S_R\},$$

where  $S \subseteq S_R$  and  $c^\top x \leq c_R^\top x$  for all  $x \in S$ . Clearly, solving a problem relaxation provides an upper bound on the objective value of the underlying problem. Perhaps the most common relaxation of problem (IP) is the *linear programming relaxation* formed by relaxing the integer restrictions and enforcing appropriate bound conditions on the variables; i. e.,  $c_R = c$  and  $S_R = \{x \in \mathbf{R}^n : Ax \leq b, l \leq x \leq u\}$ .

A formal statement of a general branch and bound algorithm [48] is presented in Table 1. The notation  $L$  is used to denote the list of active subproblems  $\{\text{IP}^i\}$ , where  $\text{IP}^0 = (\text{IP})$  denotes the original integer program. The notation  $\bar{z}_i$  denotes an upper bound on the optimal objective value of  $\text{IP}^i$ , and  $\underline{z}_{ip}$  denotes the *incumbent*

**Integer Programming: Branch and Bound Methods, Table 1**  
General branch and bound algorithm

- 1 (*Initialization*): Set  $L = \{\text{IP}^0\}$ ,  $\bar{z}_0 = +\infty$ , and  $\underline{z}_{ip} = \infty$ .
- 2 (*Termination*): If  $L = \emptyset$ , then the solution  $x^*$  which yielded the incumbent objective value  $\underline{z}_{ip}$  is optimal. If no such  $x^*$  exists (i. e.,  $\underline{z}_{ip} = -\infty$ ), then (IP) is infeasible.
- 3 (*Problem selection and relaxation*): Select and delete a problem  $\text{IP}^i$  from  $L$ . Solve a relaxation of  $\text{IP}^i$ . Let  $z_i^R$  denote the optimal objective value of the relaxation, and let  $x^{iR}$  be an optimal solution if one exists. (Thus,  $z_i^R = c^\top x^{iR}$ , or  $z_i^R = -\infty$ .)
- 4 (*Fathoming and Pruning*):
  - i) If  $z_i^R \leq \underline{z}_{ip}$  go to Step 2.
  - ii) If  $z_i^R > \underline{z}_{ip}$  and  $x^{iR}$  is integral feasible, update  $\underline{z}_{ip} = z_i^R$ . Delete from  $L$  all problems with  $\bar{z}_i \leq \underline{z}_{ip}$ . Go to Step 2.
- 5 (*Partitioning*): Let  $\{S^{ij}\}_{j=1}^{j=k}$  be a partition of the constraint set  $S^i$  of the problem  $\text{IP}^i$ . Add problems  $\{\text{IP}^{ij}\}_{j=1}^{j=k}$  to  $L$ , where  $\text{IP}^{ij}$  is  $\text{IP}^i$  with feasible region restricted to  $S^{ij}$  and  $\bar{z}_{ij} = z_i^R$  for  $j = 1, \dots, k$ .  
Go to Step 2.

*objective value* (i. e., the objective value corresponding to the current best integral feasible solution to (IP)).

The actual implementation of a branch and bound algorithm is typically viewed as a *tree search*, where the problem at the root node of the tree is the original (IP). The tree is constructed in an iterative fashion with new nodes formed by *branching* on an existing node for which the optimal solution of the relaxation is fractional (i. e., some of the integer restricted variables have fractional values). Typically, two child nodes are formed by selecting a fractional valued variable and adding appropriate constraints in each child subproblem to ensure that the associated constraint sets do not include solutions for which this chosen branching variable assumes the same fractional value.

The phrase *fathoming a node* is used in reference to criteria that imply that a node need not be explored further. As indicated in Step 4, these criteria include:

- a) the objective value of the subproblem relaxation at the node is less than or equal to the incumbent objective value; and

b) the solution for the subproblem relaxation is integer valued.

Note that a) includes the case when the relaxation is infeasible, since in that case its objective value is  $-\infty$ . Condition b) provides an opportunity to *prune* the tree; effectively fathoming nodes for which the objective value of the relaxation is less than or equal to the updated incumbent objective value. The tree search ends when all nodes are fathomed.

A variety of strategies have been proposed for intelligently selecting branching variables, for problem partitioning, and for selecting nodes to process. However, no single collection of strategies stands out as being best in all cases. In the remainder of this article, some of the strategies that have been implemented or proposed are summarized. An illustrative example is presented. Some of the related computational strategies – *preprocessing and reformulation*, *heuristic procedures*, and the concept of *reduced cost fixing* – which have proved to be highly effective in branch and bound implementations are considered. Finally, there is a discussion of recent linear programming based branch and bound algorithms that have employed *interior point methods* for the subproblem relaxation solver, which is in contrast to using the more traditional simplex-based solvers.

Though branch and bound is a classic approach for solving integer programs, there are practical limitations to its success in applications. Often integer feasible solutions are not readily available, and node pruning becomes impossible. In this case, branch and bound fails to find an optimal solution due to memory explosion as a result of excessive accumulation of active nodes. In fact, general integer programs are *NP-hard*; and consequently, as of this writing (1998), there exists no known *polynomial time algorithm* for solving general integer programs [30].

In 1983, a breakthrough in the computational possibilities of branch and bound came as a result of the research by H. Crowder, E.L. Johnson, and M.W. Padberg. In their paper [22], cutting planes were added at the root node to strengthen the LP formulation before branch and bound was called. In addition, features such as reduced cost fixing, heuristics and preprocessing were added within the tree search algorithm to facilitate the solution process. See ► **Integer programming: Cutting plane algorithms** for de-

tails on cutting plane applications to integer programming.

Since branch and bound itself is an inherently parallel technique, there has been active research activity among the computer science and operations research communities in developing parallel algorithms to improve its solution capability.

Most commercial integer programming solvers use a branch and bound algorithm with linear programming relaxations. Unless otherwise mentioned, the descriptions of the strategies discussed herein are based on using the linear programming relaxation.

See [48] for references not listed here; [51] also includes useful material about branch and bound.

## Partitioning Strategies

When linear programming relaxation is employed, partitioning is done via addition of linear constraints. Typically, two new nodes are formed on each division. Suppose  $x^R$  is an optimal solution to the relaxation of a branch and bound node. Common partitioning strategies include:

- *Variable dichotomy* [23]. If  $x_j^R$  is fractional, then two new nodes are created, one with the simple bound  $x_j \leq \lfloor x_j^R \rfloor$  and the other with  $x_j \geq \lceil x_j^R \rceil$ ; where  $\lfloor \cdot \rfloor$  and  $\lceil \cdot \rceil$  denote the floor and the ceiling of a real number. In particular, if  $x_j$  is restricted to be binary, then the branching reduces to fixing  $x_j = 0$  and  $x_j = 1$ , respectively. One advantage of simple bounds is that they maintain the size of the basis among branch and bound nodes, since the simplex method can be implemented to handle both upper and lower bounds on variables without explicitly increasing the dimensions of the basis.
- *Generalized-upper-bound dichotomy (GUB dichotomy)* [8]. If the constraint  $\sum_{j \in Q} x_j = 1$  is present in the original integer program, and  $x_i^R$ ,  $i \in Q$ , are fractional, one can partition  $Q = Q_1 \cup Q_2$  such that  $\sum_{j \in Q_1} x_j^R$  and  $\sum_{j \in Q_2} x_j^R$  are approximately of equal value. Then two branches can be formed by setting  $\sum_{j \in Q_1} x_j = 0$  and  $\sum_{j \in Q_2} x_j = 0$ , respectively.
- *Multiple branches for bounded integer variable*. If  $x_j^R$  is fractional, and  $x_j \in \{0, \dots, l\}$ , then one can create  $l + 1$  new nodes, with  $x_j = k$  for node  $k$ ,  $k = 0, \dots, l$ . This idea was proposed in the first branch and

bound algorithm by A.H. Land and A.G. Doig [39], but currently (1998) is not commonly used.

### Branching Variable Selection

During the partitioning process, branching variables must be selected to help create the children nodes. Clearly the choice of a branching variable affects the running time of the algorithm. Many different approaches have been developed and tested on different types of integer programs. Some common approaches are listed below:

- *Most/least infeasible integer variable.* In this approach, the integer variable whose fractional value is farthest from (closest to) an integral value is chosen as the branching variable.
- *Driebeck–Tomlin penalties* [25,57]. Penalties give a lower bound on the degradation of the objective value for branching each direction from a given variable. The penalties are the cost of the dual pivot needed to remove the fractional variable from the basis. If many pivots are required to restore primal feasibility, these penalties are not very informative. The *up penalty*, when forcing the value of the  $k$ th basic variable up, is

$$u_k = \min_{j:a_{kj}<0} \frac{(1-f_k)\bar{c}_j}{-a_{kj}},$$

where  $f_k$  is the fractional part of  $x_k$ ,  $\bar{c}_j$  is the reduced cost of variable  $x_j$ , and the  $a_{kj}$  are the transformed matrix coefficients from the  $k$ th row of the optimal dictionary for the LP relaxation. The *down penalty*  $d_k$  is calculated as

$$d_k = \min_{j:a_{kj}>0} \frac{f_k\bar{c}_j}{a_{kj}}.$$

Once the penalties have been computed, a variety of rules can be used to select the branching variable (e.g.,  $\max_k \max(u_k, d_k)$ , or  $\max_k \min(u_k, d_k)$ ). A penalty can be used to eliminate a branch if the LP objective value for the parent node minus the penalty is worse than the incumbent integer solution. Penalties are out of favor because their cost is considered too high for their benefit.

- *Pseudocost estimate.* Pseudocosts provide a way to estimate the degradation to the objective value by forcing a fractional variable to an integral value. The technique was introduced in 1970 by M. Benichou et

al. [10]. Pseudocosts attempt to reflect the total cost, not just the cost of the first pivot, as with penalties. Once a variable  $x_k$  is labeled as a candidate branching variable, the pseudocosts are computed as:

$$U_k = \frac{\bar{z}_k - z_k^u}{1 - f_k} \quad \text{and} \quad D_k = \frac{\bar{z}_k - z_k^d}{f_k},$$

where  $\bar{z}_k$  is the objective value of the parent,  $z_k^u$  is the objective value resulting from forcing up, and  $z_k^d$  is the objective value from forcing down. (If the subproblem is infeasible, the associated pseudocost is not calculated.) If a variable has been branched upon repeatedly, an average may be used.

The branching variable is chosen as that with the maximum degradation, where the degradation is computed as:  $D_k f_k + U_k (1 - f_k)$ . Pseudocosts are not considered to be beneficial on problems where there is a large percentage of integer variables.

- *Pseudoshadow prices.* Similar to pseudocosts, pseudoshadow prices estimate the total cost to force a variable to an integral value. Up and down pseudoshadow prices for each constraint and pseudoshadow prices for each integer variable are specified by the user or given an initial value. The degradation in the objective function for forcing an integer variable  $x_k$  up or down to an integral value can be estimated. The branching variable is chosen using criteria similar to penalties and pseudocosts. See [27,40] for precise mathematical formulations on this approach.
- *Strong branching.* This branching strategy arose in connection with research on solving difficult instances of the traveling salesman problem and general mixed zero-one integer programming problems [2,12,13]. Applied to zero-one integer programs within a simplex-based branch and cut setting, strong branching works as follows. Let  $N$  and  $K$  be positive integers. Given the solution of some linear programming relaxation, make a list of  $N$  binary variables that are fractional and closest to 0.5 (if there are fewer than  $N$  fractional variables, take all fractional variables). Suppose that  $I$  is the index set of this list. Then, for each  $i \in I$ , fix  $x_i$  first to 0 and then to 1 and perform  $K$  iterations (starting with the *optimal basis* for the LP relaxation of the current node) of the dual simplex method with steepest edge pricing. Let  $L_i, U_i, i \in I$ , be the objective values

that result from these simplex runs, where  $L_i$  corresponds to fixing  $x_i$  to 0 and  $U_i$  to fixing it to 1. A branching variable can be selected based on the best weighted-sum of these two values.

- *Priorities selection.* Variables are selected based on their priorities. Priorities can be user-assigned, or based on objective function coefficients, or on pseudocosts.

**Node Selection**

Given a list of active problems, one has to decide which subproblem should be selected to be examined next. This in turn will affect the possibilities of improving the incumbent, the chance of node fathoming, and the total number of problems needed to be solved before optimality is achieved. Below, various strategies given in [7,10,11,20,27,29,31,47] are presented.

- *Depth-first search with backtracking.* Choose a child of the previous node as the next node; if it is pruned, choose the other child. If this node is also pruned, choose the most recently created unexplored node, which will be the other child node of the last successful node.
- *Best bound.* Among all unexplored nodes, choose the one which has the best LP objective value. In the case of maximization, the node with the largest LP objective value will be chosen. The rationale is that since nodes can only be pruned when the relaxation objective value is less than the current incumbent objective value, the node with largest LP objective value cannot be pruned, since the best objective value corresponding to an integer feasible solution cannot exceed this largest value.
- *Sum of integer infeasibilities.* The sum of infeasibilities at a node is calculated as

$$s = \sum_j \min(f_j, 1 - f_j).$$

Choose the node with either maximum or minimum sum of integer infeasibilities.

- *Best estimate using pseudocosts.* This technique was introduced [10] along with the idea of using pseudocosts to select a branching variable. The individual pseudocosts can be used to estimate the resulting integer objective value attainable from node  $k$ :

$$\epsilon_k = \bar{z}_k - \sum_i \min(D_i f_i, U_i(1 - f_i)),$$

where  $\bar{z}_k$  is the value of the LP relaxation at node  $k$ . The node with the best estimate is chosen.

- *Best estimate using pseudoshadow prices.* Pseudoshadow prices can also be used to provide an estimate of the resulting integer objective value attainable from the node, and the node with the best estimate can then be chosen.
- *Best projection [29,47].* Choose the node among all unexplored nodes which has the best projection. The projection is an estimate of the objective function value associated with an integer solution obtained by following the subtree starting at this node. It takes into account both the current objective function value and a measure of the integer infeasibility. In particular, the projection  $p_k$  associated with node  $k$  is defined as

$$p_k = \bar{z}_k - \frac{s_k(\bar{z}_0 - z_{ip})}{s_0},$$

where  $\bar{z}_0$  denotes the objective value of the LP at the root node,  $z_{ip}$  denotes an estimate of the optimal integer solution, and  $s_k$  denotes the sum of the integer infeasibilities at node  $k$ .

The projection is a weighting between the objective function and the sum of infeasibilities. The weight  $(\bar{z}_0 - z_{ip})/s_0$  corresponds to the slope of the line between node 0 and the node producing the optimal integer solution. It can be thought of as the cost to remove one unit of infeasibility. Let  $n_k$  be the number of integer infeasibilities at node  $k$ . A more general projection formula is to let  $w_k = \mu n_k + (1 - \mu) s_k$ , where  $\mu \in [0, 1]$ , and define

$$p_k = \bar{z}_k - \frac{w_k(\bar{z}_0 - z_{ip})}{w_0}.$$

*Example 1* Here, a two-variable integer program is solved using branch and bound. The most infeasible integer variable is used as the branching variable, and best bound is used for node selection. Consider the problem

$$\text{IP}^0 \begin{cases} \max & 13x_1 + 8x_2 \\ \text{s.t.} & x_1 + 2x_2 \leq 10 \\ & 5x_1 + 2x_2 \leq 20 \\ & x_1 \geq 0, \quad x_2 \geq 0, \\ & x_1, x_2 \text{ integer.} \end{cases}$$

Initially,  $L$  consists of just this problem  $IP^0$ . The solution to the LP relaxation is  $x_1^0 = 2.5, x_2^0 = 3.75$ , with value  $z_0^R = 59.5$ . The most infeasible integer variable is  $x_1$ , so two new subproblems are created,  $IP^1$  where  $x_1 \geq 3$  and  $IP^2$  where  $x_1 \leq 2$ , and  $L = \{IP^1, IP^2\}$ .

Both problems in  $L$  have the same bound 59.5, so assume the algorithm arbitrarily selects  $IP^1$ . The optimal solution to the LP relaxation of  $IP^1$  is  $x_1^1 = 3, x_2^1 = 2.5$ , with value  $z_1^R = 59$ . The most infeasible integer variable is  $x_2$ , so two new subproblems of  $IP^1$  are created,  $IP^3$  where  $x_2 \geq 3$  and  $IP^4$  where  $x_2 \leq 2$ , and now  $L = \{IP^2, IP^3, IP^4\}$ .

The algorithm next examines  $IP^2$ , since this is the problem with the best bound. The optimal solution to the LP relaxation is  $x_1^2 = 2, x_2^2 = 4$ , with value  $z_2^R = 58$ . Since  $x^2$  is integral feasible,  $z_{ip}$  can be updated to 58 and  $IP^2$  is fathomed.

Both of the two problems remaining in  $L$  have best bound greater than 58, so neither can yet be fathomed. Since these two subproblems have the same bound 59, assume the algorithm arbitrarily selects  $IP^3$  to examine next. The LP relaxation to this problem is infeasible, since it requires that  $x$  satisfy  $x_1 \geq 3, x_2 \geq 3$  and  $5x_1 + 2x_2 \leq 20$  simultaneously. Therefore,  $z_3^R = -\infty$ , and this node can be fathomed by bounds since  $z_3^R \leq z_{ip}$ .

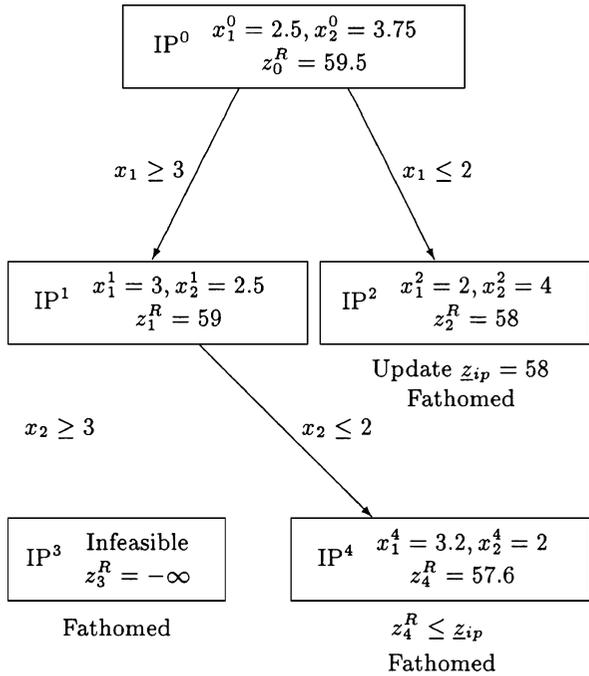

That leaves the single problem  $IP^4$  in  $L$ . The solution to the LP relaxation of this problem is  $x_1^4 = 3.2, x_2^4 = 2$ , with value  $z_4^R = 57.6$ . Since  $z_4^R \leq z_{ip}$ , this subproblem can also be fathomed by bounds. The set  $L$  is now empty, so  $x^2$  is optimal for the integer programming problem  $IP^0$ .

The progress of the algorithm is indicated in Fig. 1. Each box contains the name of the subproblem, the solution to the LP relaxation, and the value of the solution.

**Preprocessing and Reformulation**

Problem preprocessing and reformulation has been shown to be a very effective way of improving integer programming formulations prior to and during branch and bound [14,15,18,19,22,24,33,34,35,54]. Below, some commonly employed preprocessing techniques are listed. For more details on these procedures, see the references.

- 1) Removal of empty (all zeros) rows and columns. Detection of implicit bounds and implicit slack variables.

**Integer Programming: Branch and Bound Methods, Figure 1**  
Branch and bound example

- 2) Removal of rows dominated by multiples of other rows, including pairs of rows for which the support of one is a subset of the support of the other.
- 3) Strengthen the bounds within rows by comparing individual variables and coefficients to the right-hand side. Additional strengthening may be possible for integral variables using rounding.
- 4) Use variable bounds to determine upper and lower bounds for the left-hand side of a constraint, and compare these bounds to the right-hand side. Where possible, conclude that a constraint is inconsistent, redundant, or forces the fixing of some or all variables in its support. Several of these row-driven operations can be dualized to columns.
- 5) *Aggregation*: Given an equality constraint where the bound on some variable is implied by the satisfaction of the bounds on the other variables, this variable can be substituted out, and the constraint deleted. Note that free variables always satisfy this condition. Note also that in order to control fill-in (and coefficient growth), not all such substitutions may be desirable. For integral variables, there is the added restriction that they can be eliminated only if their integrality is implied by the integrality of

the remaining variables. For integer programming problems, an added advantage of aggregation relative to LP's, is that the reduction in the number of equality constraints increases the relative dimension of the underlying polytope.

- 6) *Coefficient reduction*: Consider a constraint  $\sum_{j \in K} a_j x_j \geq b$  in which all  $a_j \geq 0$  and all  $x_j \geq 0$ . If  $x_j$  is a 0–1 variable and  $a_j > b$ , for some  $j \in K$ , replace  $a_j$  by  $b$ . A stronger version of this procedure is possible when the problem formulation involves other constraints of appropriate structure.
- 7) *Logical implications and probing*:
  - a) *Logical implications*: Choose a binary variable  $x_k$  and fix it to 0 or 1. Perform 4. This analysis may yield logical implications such as  $x_k = 1$  implies  $x_j = 0$ , or  $x_k = 1$  implies  $x_j = 1$ , for some other variable  $x_j$ . The implied equality is then added as an explicit constraint.
  - b) *Probing*: Perform logical implications recursively. An efficient implementation of probing appears to be very difficult. Details of computational issues regarding probing are discussed in [33], and [54].

## Heuristics

Heuristic procedures provide a means for obtaining integer feasible solutions quickly, and can be used repeatedly within the branch and bound search tree. A good heuristic – one that produces good integer feasible solutions – is a crucial component in the branch and bound algorithm since it provides an upper bound for reduced cost fixing (discussed later) at the root, and thus allows reduction in the size of the linear program that must be solved. This in turn may reduce the time required to solve subsequent linear programs at nodes within the search tree. In addition, a good upper bound increases the likelihood of being able to fathom active nodes, which is extremely important when solving large scale integer programs as they tend to create many active nodes leading to memory explosion.

Broadly speaking, five ideas are commonly used in developing heuristics. The first idea is that of greediness. Greedy algorithms work by successively choosing variables based on best improvement in the objective value. Kruskal's algorithm [37], which is an exact algorithm for finding the minimum-weight spanning tree in a graph, is one of the most well-known greedy

algorithms. Greedy algorithms have been applied to a variety of problems, including 0–1 knapsack problems [36,41,53], uncapacitated facility location problems [38,56], set covering problems [3,4], and the traveling salesman problem [52].

A second idea is that of local search, which involves searching in a local neighborhood of a given integer feasible solution for a feasible solution with a better objective value. The  $k$ -interchange heuristic is a classic example of a local search heuristic [38,44,46]. Simulated annealing is another example, but with a bit of a twist. It allows, with a certain probability, updated solutions with less favorable objective values in order to increase the likelihood of escaping from a local optimum [16].

*Randomized enumeration* is a third idea that is used to obtain integer feasible solutions. One such method is that of genetic algorithms (cf. ► **Genetic algorithms**), where the randomness is modeled on the biological mechanisms of evolution and natural selection [32]. Recent work on applying a genetic algorithm to the set covering problem can be found in [9].

The term *primal heuristics* refers to certain LP-based procedures for constructing integral feasible solutions from points that are in some sense good, but fail to satisfy integrality. Typically, these nonintegral points are obtained as optimal solutions of LP relaxations. Primal heuristic procedures involve successive variable fixing and rounding (according to rules usually governed by problem structure) and subsequent re-solves of the modified primal LP [6,12,14,34,35].

The fifth general principle is that of *exploiting the interplay between primal and dual solutions*. For example, an optimal or heuristic solution to the dual of an LP relaxation may be used to construct a heuristic solution for the primal (IP). Problem dependent criteria based on the generated primal-dual pair may suggest seeking an alternative heuristic solution to the dual, which would then be used to construct a new heuristic solution to the primal. Iterating back-and-forth between primal and dual heuristic solutions would continue until an appropriate termination condition is satisfied [21,26,28].

It is not uncommon that a heuristic involves more than one of these ideas. For example, pivot-and-complement is a simplex-based heuristic in which binary variables in the basis are pivoted out and replaced by slack variables. When a feasible integer solution is

obtained, the algorithm performs a local search in an attempt to obtain a better integer feasible solution [5]. Obviously, within a branch and bound implementation, the structure of the problems that the implementation is targeted at influences the design of an effective heuristic [2,12,13,14,22,26,34,35,43].

### Continuous Reduced Cost Implications

*Reduced cost fixing* is a well-known and important idea in the literature of integer programming [22]. Given an optimal solution to an LP relaxation, the reduced costs  $\bar{c}_j$  are nonpositive for all nonbasic variables  $x_j$  at lower bound, and nonnegative for all nonbasic variables at their upper bounds. Let  $x_j$  be a nonbasic variable in a continuous optimal solution having objective value  $z_{LP}$ , and let  $z_{ip}$  be the objective value associated with an integer feasible solution to (IP). The following are true:

- a) If  $x_j$  is at its lower bound in the continuous solution and  $z_{LP} - z_{ip} \leq -\bar{c}_j$ , then there exists an optimal solution to the integer program with  $x_j$  at its lower bound.
- b) If  $x_j$  is at its upper bound in the continuous solution and  $z_{LP} - z_{ip} \leq \bar{c}_j$ , then there exists an optimal solution to the integer program with  $x_j$  at its upper bound.

When reduced cost fixing is applied to the root node of a branch and bound tree, variables which are fixed can be removed from the problem, resulting in a reduction in the size of the integer program. A variety of studies have examined the effectiveness of reduced cost fixing within the branch and bound tree search [12,14,22,34,35,49,50].

### Subproblem Solver

When linear programs are employed as the relaxations within a branch and bound algorithm, it is common to use a simplex-based algorithm to solve each subproblem, using *dual simplex* to reoptimize from the optimal basis of the parent node. This technique of *advanced basis* has been shown to reduce the number of simplex iterations to solve the child node to optimality, and thus speedup the overall computational effort. Recently with the advancement in computational technology, the increase in the size of integer programs, and the success of interior point methods (cf. also ► [Linear programming: Interior point methods](#)) to solve large scale linear programs [1,45] there are some branch and bound

algorithms employing interior point algorithms as the linear programming solver [17,42,43,55]. In this case, advanced basis is no longer available and care has to be taken to take advantage of warmstart vectors for the interior point solver so as to facilitate effective computational results. In [42,43], a description of the ideas of ‘*advanced warmstart*’ and computational results are presented.

#### Keywords

Cutting planes; Branch and bound; Integer program; Exact algorithms

Branch and cut methods are exact algorithms for *integer programming problems*. They consist of a combination of a cutting plane method (cf. ► [Integer programming: Cutting plane algorithms](#)) with a branch and bound algorithm (cf. ► [Integer programming: Branch and bound methods](#)). These methods work by solving a sequence of linear programming relaxations of the integer programming problem. Cutting plane methods improve the relaxation of the problem to more closely approximate the integer programming problem, and branch and bound algorithms proceed by a sophisticated divide-and-conquer approach to solve problems. The material in this entry builds on the material contained in the entries on cutting plane and branch and bound methods.

Perhaps the best known branch and cut algorithms are those that have been used to solve *traveling salesman problems*. This approach is able to solve and prove optimality of far larger instances than other methods. Two papers that describe some of this research and also serve as good introductions to the area of branch and cut algorithms are [21,32]. A more recent work on the branch and cut approach to the traveling salesman problem is [1]. Branch and cut methods have also been used to solve other combinatorial optimization problems; recent references include [8,10,13,23,24,26]. For these problems, the cutting planes are typically derived

from studies of the polyhedral combinatorics of the corresponding integer program. This enables the addition of strong cutting planes (usually facet defining inequalities), which make it possible to considerably reduce the size of the branch and bound tree. Far more detail about these strong cutting planes can be found in ► **Integer programming: Cutting plane algorithms.**

Branch and cut methods for general integer programming problems are also of great interest (see, for example, the papers [4,7,11,16,17,22,28,30]). It is usually not possible to efficiently solve a general integer programming problem using just a cutting plane approach, and it is therefore necessary to also to branch, resulting in a branch and cut approach. A pure branch and bound approach can be sped up considerably by the employment of a cutting plane scheme, either just at the top of the tree, or at every node of the tree.

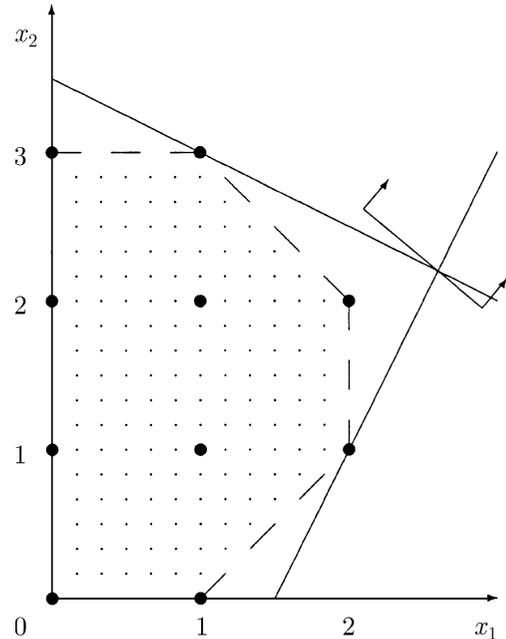

For general problems, the specialized facets used when solving a specific combinatorial optimization problem are not available. Some useful families of general inequalities have been developed; these include cuts based on knapsack problems [17,22,23], Gomory cutting planes [5,12,19,20], lift and project cutting planes [3,4,29,33], and Fenchel cutting planes [9]. All of these families of cutting planes are discussed in more detail later in this entry.

The software packages MINTO [30] and ABACUS [28] implement branch and cut algorithms to solve integer programming problems. The packages use standard linear programming solvers to solve the relaxations and they have a default implementation available. They also offer the user many options, including how to add cutting planes and how to branch.

*Example 1* Consider the integer programming problem

$$\begin{cases} \min & -5x_1 - 6x_2 \\ \text{s.t.} & x_1 + 2x_2 \leq 7 \\ & 2x_1 - x_2 \leq 3 \\ & x_1, x_2 \geq 0 \text{ and integer.} \end{cases}$$

This problem is illustrated in Fig. 1. The feasible integer points are indicated. The *linear programming relaxation* (or *LP relaxation*) is obtained by ignoring the integrality restrictions; this is given by the polyhedron contained in the solid lines.

**Integer Programming: Branch and Cut Algorithms, Figure 1**  
A branch-and-cut example

The first step in a branch and cut approach is to solve the linear programming relaxation, which gives the point (2.6, 2.2), with value  $-26.2$ . There is now a choice: should the LP relaxation be improved by adding a cutting plane, for example,  $x_1 + x_2 \leq 4$ , or should the problem be divided into two by splitting on a variable?

Assume the algorithm makes the second choice, and further assume that the decision is to split on  $x_2$ , giving two new problems:

$$\begin{cases} \min & -5x_1 - 6x_2 \\ \text{s.t.} & x_1 + 2x_2 \leq 7 \\ & 2x_1 - x_2 \leq 3 \\ & x_2 \geq 3 \\ & x_1, x_2 \geq 0 \text{ and integer,} \end{cases}$$

and

$$\begin{cases} \min & -5x_1 - 6x_2 \\ \text{s.t.} & x_1 + 2x_2 \leq 7 \\ & 2x_1 - x_2 \leq 3 \\ & x_2 \leq 2 \\ & x_1, x_2 \geq 0 \text{ and integer.} \end{cases}$$

The optimal solution to the original problem will be the better of the solutions to these two subproblems. The solution to the linear programming relaxation of the first subproblem is (1, 3), with value  $-23$ . Since this solution is integral, it solves the first subproblem. This solution becomes the incumbent best known feasible solution. The optimal solution for the linear programming relaxation of the second subproblem is (2.5, 2), with value  $-24.5$ . Since this point is nonintegral, it does not solve the subproblem. Therefore, the second subproblem must be attacked further.

It is possible to branch using  $x_1$  in the second subproblem; instead, assume the algorithm uses a cutting plane approach and adds the inequality  $x_1 + 2x_2 \leq 6$ . This is a valid inequality, in that it is satisfied by every integral point that is feasible in the second subproblem. Further, this inequality is a cutting plane: it is violated by (2.5, 2). Adding this inequality to the relaxation and resolving gives the optimal solution (2.4, 1.8), with value  $-22.6$ . The subproblem still does not have an integral solution. However, notice that the optimal value for this modified relaxation is larger than the value of the incumbent solution. The value of the optimal integral solution to the second subproblem must be at least as large. Therefore, the incumbent solution is better than any feasible integral solution for the second subproblem, so it actually solves the original problem.

Of course, there are several issues to be resolved with this algorithm, including the major questions of deciding whether to branch or to cut and deciding how to branch and how to generate cutting planes. Notice that the cutting plane introduced in the second subproblem is not valid for the first subproblem. This inequality can be modified to make it valid for the first subproblem by using a *lifting* technique, which is discussed later in this entry.

### A Standard Form

To fix notation, the following problem is regarded as the standard form mixed integer linear programming problem in this entry:

$$\begin{cases} \min & c^\top x \\ \text{s.t.} & Ax \leq b \\ & x \geq 0 \\ & x_i \text{ integer, } i = 1, \dots, p. \end{cases}$$

Here,  $x$  and  $c$  are  $n$ -vectors,  $b$  is an  $m$ -vector, and  $A$  is an  $m \times n$  matrix. The first  $p$  variables are restricted to be integer, and the remainder may be fractional. If  $p = n$  then this is an integer programming problem. If a variable is restricted to take the values 0 or 1 then it is a binary variable. If all variables are binary then the problem is a binary program.

### Primal Heuristics

In the example problem, it was possible to prune the second subproblem by bounds, once an appropriate cutting plane had been found. The existence of a good incumbent solution made it possible to prune in this way. In this case, the solution to the linear programming relaxation of the first subproblem was integral, providing the good incumbent solution. In many cases, it takes many stages until the solution to a relaxation is integral. Therefore, it is often useful to have good heuristics for converting the fractional solution to a relaxation into a good integral solution that can be used to prune other subproblems. Primal heuristics are discussed further in ► [Integer programming: Branch and bound methods](#).

### Preprocessing

A very important component of a practical branch and cut algorithm is preprocessing to eliminate unnecessary constraints, determine any fixed variables, and simplify the problem in other ways. Preprocessing techniques are discussed in ► [Integer programming: Branch and bound methods](#).

### Families of Cutting Planes

Perhaps the first family of cutting planes for general mixed integer programming problems were *Chvátal-Gomory cutting planes* [15,19,20]. These inequalities can be derived from the final tableau of the linear programming relaxation, and they are discussed in more detail in ► [Integer programming: Cutting plane algorithms](#). These cuts can be useful if they are applied in a computationally efficient manner [5,12]. Gomory cuts can contain a large number of nonzeros, so care is required to ensure that the LP relaxation does not become very hard with large memory requirements. The cuts are generated directly from the basis inverse, so

care must also be taken to avoid numerical difficulties.

One of the breakthroughs in the development of branch and cut algorithms was the paper by H.P. Crowder, E.L. Johnson, and M.W. Padberg [17]. This paper showed that it was possible to solve far larger general problems than had previously been thought possible. The algorithm used extensive preprocessing, good primal heuristics, and cutting planes derived from *knapsack problems* with binary variables. Any inequality in binary variables can be represented as a knapsack inequality  $\sum_{i \in N} a_i x_i \leq b$  with all  $a_i > 0$  for some subset  $N$  of the variables, eliminating variables or replacing a variable  $x_j$  by  $1 - x_j$  as necessary. The facial structure of the knapsack polytope can then be used to derive valid inequalities for the problem. For example, if  $R \subseteq N$  with  $\sum_{i \in R} a_i > b$  then  $\sum_{i \in R} x_i \leq |R| - 1$  is a valid inequality. Further, if  $R$  is a minimal such set, so deleting any member of  $R$  leaves the sum of coefficients smaller than  $b$ , then the inequality defines a facet of the corresponding knapsack polytope. Other inequalities can be derived from the knapsack polytope. These inequalities have been extended to knapsacks with general integer variables and one continuous variable [11] and to binary problems with generalized upper bounds [34].

Another family of useful inequalities are *lift-and-project* or *disjunctive inequalities*. These were originally introduced by E. Balas [2], and it is only in the last few years that the value of these cuts has become apparent for general integer programming problems [3,4]. Given the feasible region for a binary programming problem  $S := \{x: Ax \leq b, x_i = 0, 1, \forall i\}$ , each variable can be used to generate a set of disjunctive inequalities. Let  $S_j^0 := \{x: Ax \leq b, 0 \leq x_i \leq 1, \forall i, x_j = 0\}$  and  $S_j^1 := \{x: Ax \leq b, 0 \leq x_i \leq 1, \forall i, x_j = 1\}$ . Then  $S \subseteq S_j^0 \cup S_j^1$ , so valid inequalities for  $S$  can be generated by finding valid inequalities for the convex hull of  $S_j^0 \cup S_j^1$ . These inequalities are generated by solving linear programming problems. Because of the expense, the cuts are usually only generated at the root node. Nonetheless, they can be very effective computationally.

Other general cutting planes have been developed. The paper [16] describes several families and discusses routines for identifying violated inequalities. Fenchel cutting planes, which are generated using ideas from Lagrangian duality and convex duality, are introduced in [9].

## When to Add Cutting Planes

The computational overhead of searching for cutting planes can be prohibitive. Therefore, it is common to not search at every node of the tree. Alternatives include searching at every eighth node, say, or at every node at a depth of a multiple of eight in the tree.

Generally, at each node of the branch and bound tree, the linear programming relaxation is solved, cutting planes are found, these are added to the relaxation, and the process is repeated. Usually, there comes a point at which the process tails off, that is, the solution to one relaxation is not much better than the solutions to the recent relaxations. It is then advisable to stop work on this node and branch. Tailing off is a function of lack of knowledge about the polyhedral structure of the relaxation, rather than a fundamental weakness of the cutting plane approach [32]. In some implementations, a fixed number of rounds of cutting plane searching are performed at a node, with perhaps several rounds performed at the root node, and fewer rounds performed lower in the tree.

The *cut-and-branch* variant adds cutting planes only at the root node of the tree. Usually, an implementation of such a method will expend a great deal of effort on generating cutting planes, requiring time far greater than just solving the relaxation at the root. The benefits of cut-and-branch include

- all generated cuts are valid throughout the tree, since they are valid at the root.
- bookkeeping is reduced, since the relaxations are identical at each node.
- no time is spent generating cutting planes at other nodes.

Cut-and-branch is an excellent technique for many general integer programs, but it lacks the power of branch and cut for some hard problems. See [16] for more discussion of the relative computational performance of cut-and-branch and branch and cut.

## Lifting Cuts

A cut added at one node of the branch and cut tree may well not be valid for another subproblem. Of course, it is not necessary to add the cut at any other node, in which case the cut is called a *local cut*. This cut will then only affect the current subproblem and its descendants. The drawback to such an approach is in the potential mem-

ory requirement of needing to store a different version of the problem for each node of the tree. In order to make a cut valid throughout the tree (or *global*), it is necessary to *lift* it.

Lifting can be regarded as a method of rotating a constraint. Returning to the example problem once again, the constraint  $x_1 + 2x_2 \leq 6$  is valid if  $x_2 \leq 2$ . To extend this constraint to be valid when  $x_2 \geq 3$ , consider the inequality

$$x_1 + 2x_2 + \alpha(x_2 - 2) \leq 6.$$

It is desired to take  $\alpha$  as large as possible while ensuring that this is a valid inequality. If  $x_2 = 3$  then  $x_1 \leq 1$ , so the inequality is valid for  $x_2 = 3$  provided  $\alpha \leq -1$ . If  $x_2 = 1$ , the inequality is valid provided  $\alpha \geq -2$ . Finally, the inequality is valid when  $x_2 = 0$  provided  $\alpha \geq -2.5$ . Combining these conditions gives that the valid range is  $-2 \leq \alpha \leq -1$ . The two extreme choices  $\alpha = -1$  and  $\alpha = -2$  give the valid inequalities  $x_1 + x_2 \leq 4$  and  $x_1 \leq 2$ , respectively. Other valid choices for  $\alpha$  give inequalities that are convex combinations of these two. In this way, valid inequalities for one node of the tree can be extended to valid inequalities at any node.

See [11] for more discussion of lifting in the case of general mixed integer linear programming problems. It is often not possible to lift inequalities for such problems because the upper and lower bounds on the coefficients conflict. Of course, if an inequality is valid at the root node then it is valid throughout the tree so there is no need to lift. This is one of the reasons why general inequalities such as Chvátal-Gomory cuts or lift-and-project cuts are often more successfully employed in a cut-and-branch approach.

The method of calculating coefficients in the case of binary problems is now outlined – see [31] for more details. The inequality generated at a node in the tree will generally only use the variables that are not fixed at that node. Lifting can be used to make the inequality valid at any node of the tree. It is necessary to apply the lifting process for each variable that has been fixed at the node, examining the opposite value for that variable. For example, if the inequality

$$\sum_{j \in J} a_j x_j \leq h \quad \text{for some subset } J \subseteq \{1, \dots, n\}$$

is valid at a node where  $x_i$  has been fixed to zero, the lifted inequality takes the form

$$\sum_{j \in J} a_j x_j + \alpha_i x_i \leq h$$

for some scalar  $\alpha_i$ . This scalar should be maximized in order to make the inequality as strong as possible. Now, maximizing  $\alpha_i$  requires solving another integer program, so it may be necessary to make an approximation. This process has to be applied successively to each variable that has been fixed at the node. The order in which the variables are examined may well affect the final inequality, and other valid inequalities can be obtained by lifting more than one variable at a time.

### Implementation Details

Many details of tree management can be found in ► **Integer programming: Branch and bound methods**. This includes node selection, branching variable selection, and storage requirements, among other issues. Typically, a branch and bound algorithm stores the solution to a node as a list of the indices of the basic variables. Branch and cut algorithms may require more storage if cuts are added locally, because it is then necessary to be able to recreate the current relaxation at any active node with just the appropriate constraints. If cuts are added globally, then it suffices to store a single representation of the problem.

It is possible to fix variables using information about reduced costs and the value of the best known feasible integral solution, as described in ► **Integer programming: Cutting plane algorithms**. Once variables have been fixed in this way, it is often possible to fix additional variables using logical implications. In order to fully exploit the fixing of variables, *parent node reconstruction* [32] is performed as follows. Once a parent node has been selected, it is not immediately divided into two children, but is solved again using the cutting plane algorithm. When the cutting plane procedure terminates, the optimal reduced cost vector has been reconstructed and this is used to perform variable fixing.

Many branch and cut implementations use a *pool of cuts* [32]. This is typically a set of constraints that have been generated earlier and either not included in the relaxation or subsequently dropped because they no longer appeared to be active. It is easy to check these

cuts for violation and this is usually done before more involved separation routines are invoked. The pool of cuts also makes it possible to reconstruct the parent node more efficiently, partly because difficulties with tailing off are reduced.

### Solving Large Problems

The difficulty of a particular integer programming problem is not purely a function of the size of the problem. There are problems in the MIPLIB test set [6] with just a few hundred variables that prove resistant to standard solution approaches. The difficulty is caused by an explosion in the size of the tree.

For some problems, difficulties are caused by the size of the LP relaxation, and *interior point methods* may be useful in such cases. Interior point methods are superior to simplex methods for many linear programming problems with thousands of variables. However, restarting is harder with an interior point method than with a simplex method when the relaxation is only slightly changed. Therefore, for very large problems, the first relaxation at the top node of the tree can be solved using an interior point method, and subsequent relaxations can be solved using the (dual) simplex method. For some problems, the relaxations are just too large to be handled with a simplex method. For example, the relaxations of the *quadratic assignment problem* given in [25] were solved using interior point methods. Interior point methods also handle degeneracy better than the simplex method. Therefore, the branch and cut solver described in [1] occasionally uses an interior point method to handle some subproblems.

One way to enable the solution of far larger problems is to use a *parallel computer*. The nature of branch and cut and branch and bound algorithms makes it possible for them to exploit coarse grain parallel computers efficiently: typically, a linear programming relaxation is solved on a node of the computer. It is possible to use one node to manage the distribution of linear programs to nodes. Alternatively, methods have been developed where a common data structure is maintained and all nodes access this data structure to obtain a relaxation that requires solution, for example [18]. For a discussion of parallel branch and cut algorithms, see [7,27]. It is also possible to generate cutting planes in parallel; see, for example, [14].

### Conclusions

Branch and cut methods have been successfully used to solve both specialized integer programming problems such as the traveling salesman problem and vehicle scheduling, and also general integer programming problems. In both cases, these methods are the most promising techniques available for proving optimality. For specialized problems, cutting planes are derived using the polyhedral theory of the underlying problem. For general mixed integer linear programming problems, important components of an efficient implementation include preprocessing, primal heuristics, routines for generating cutting planes such as lift-and-project or Gomory's rounding procedure or cuts derived from knapsack problems, and also routines for lifting constraints to strengthen them. This is an active research area, with refinements and developments being continuously discovered.

Cutting planes; Integer program; Exact algorithms

Cutting plane methods are exact algorithms for *integer programming problems*. They have proven to be very useful computationally in the last few years, especially when combined with a branch and bound algorithm (cf. ► [Integer programming: Branch and bound methods](#)) in a branch and cut framework (cf. ► [Integer programming: Branch and cut algorithms](#)). These methods work by solving a sequence of linear programming relaxations of the integer programming problem. The relaxations are gradually improved to give better approximations to the integer programming problem, at least in the neighborhood of the optimal solution. For hard instances that cannot be solved to optimality, cutting plane algorithms can produce approximations to the optimal solution in moderate computation times, with guarantees on the distance to optimality.

Cutting plane algorithms have been used to solve many different integer programming problems, including the *traveling salesman problem* [1,15,33], the *lin-*

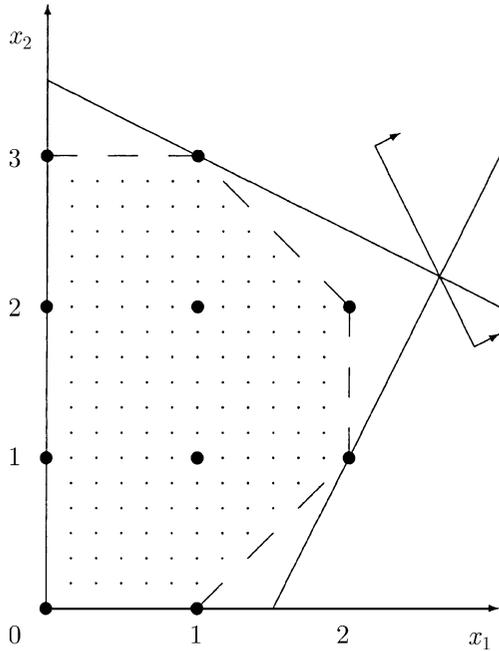

*ear ordering problem* [16,29,30], *maximum cut problems* [4,28,36], and *packing problems* [18,31]. See [22] for a survey of applications of cutting plane methods, as well as a guide to the successful implementation of a cutting plane algorithm. G.L. Nemhauser and L. Wolsey [32] provide an excellent and detailed description of cutting plane algorithms and the other material in this entry, as well as other aspects of integer programming. The book [34] and also the more recent article [35] are excellent sources of additional material.

Cutting plane algorithms for general integer programming problems were first proposed by R.E. Gomory in [12,13]. Unfortunately, the cutting planes proposed by Gomory did not appear to be very strong, leading to slow convergence of these algorithms, so the algorithms were neglected for many years. The development of polyhedral theory and the consequent introduction of strong, problem specific cutting planes led to a resurgence of cutting plane methods in the 1980s, and cutting plane methods are now the method of choice for a variety of problems, including the traveling salesman problem. Recently, there has also been some research showing that the original cutting planes proposed by Gomory can actually be useful. There has also been research on other types of cutting planes for general integer programming problems. Current research is focused on developing cutting plane algorithms for a variety of hard combinatorial optimization problems, and on solving large instances of integer programming problems using these methods. All of these issues are discussed below.

*Example 1* Consider, for example, the integer programming problem

$$\left\{ \begin{array}{l} \min \quad -2x_1 - x_2 \\ \text{s.t.} \quad x_1 + 2x_2 \leq 7 \\ \quad \quad 2x_1 - x_2 \leq 3 \\ \quad \quad x_1, x_2 \geq 0 \quad \text{and integer.} \end{array} \right.$$

This problem is illustrated in Fig. 1. The feasible integer points are indicated. The *linear programming relaxation* (or *LP relaxation*) is obtained by ignoring the integrality restrictions; this is given by the polyhedron contained in the solid lines. The boundary of the *convex hull* of the feasible integer points is indicated by dashed lines.

Integer Programming: Cutting Plane Algorithms, Figure 1  
A cutting plane example

If a cutting plane algorithm were used to solve this problem, the linear programming relaxation would first be solved, giving the point  $x_1 = 2.6$ ,  $x_2 = 2.2$ , which has value  $-7.4$ . The inequalities  $x_1 + x_2 \leq 4$  and  $x_1 \leq 2$  are satisfied by all the feasible integer points but they are violated by the point  $(2.6, 2.2)$ . Thus, these two inequalities are valid *cutting planes*. These two constraints can then be added to the relaxation, and when the relaxation is solved again, the point  $x_1 = 2$ ,  $x_2 = 2$  results, with value  $-6$ . Notice that this point is feasible in the original integer program, so it must actually be optimal for that problem, since it is optimal for a relaxation of the integer program.

If, instead of adding both inequalities, just the inequality  $x_1 \leq 2$  had been added, the optimal solution to the new relaxation would have been  $x_1 = 2$ ,  $x_2 = 2.5$ , with value  $-6.5$ . The relaxation could then have been modified by adding a cutting plane that *separates* this point from the convex hull, for example  $x_1 + x_2 \leq 4$ . Solving this new relaxation will again result in the optimal solution to the integer program. This illustrates the basic structure of a cutting plane algorithm:

- Solve the linear programming relaxation.
- If the solution to the relaxation is feasible in the integer programming problem, STOP with optimality.

- Otherwise, find one or more cutting planes that separate the optimal solution to the relaxation from the convex hull of feasible integral points, and add a subset of these constraints to the relaxation.
- Return to the first step.

Typically, the first relaxation is solved using the primal simplex algorithm. After the addition of cutting planes, the current primal iterate is no longer feasible. However, the dual problem is only modified by the addition of some variables. If these extra dual variables are given the value 0 then the current dual solution is still dual feasible. Therefore, subsequent relaxations are solved using the dual simplex method.

Notice that the values of the relaxations provide lower bounds on the optimal value of the integer program. These lower bounds can be used to measure progress towards optimality, and to give performance guarantees on integral solutions.

### Totally Unimodular Matrices

Consider the integer program

$$\min \{c^T x : Ax = b, 0 \leq x \leq u, x \text{ integer}\},$$

where  $A$  is an  $m \times n$  matrix,  $c$ ,  $x$ , and  $u$  are  $n$ -vectors, and  $b$  is an  $m$ -vector. A cutting plane method attempts to refine a linear programming relaxation until it gives a good approximation of the convex hull of feasible integer points, at least in the region of the optimal solution. In some settings, the solution to the initial linear programming relaxation  $\min \{c^T x : Ax = b, 0 \leq x \leq u\}$  may give the optimal solution to the integer program. This is guaranteed to happen if the constraint matrix  $A$  is *totally unimodular*, that is, the determinant of every square submatrix of  $A$  is either 0 or  $\pm 1$ . Examples of totally unimodular matrices include the node-arc incidence matrix of a directed graph, the node-edge incidence matrix of a bipartite undirected graph, and interval matrices (where each row of  $A$  consists of a possibly empty set of zeroes followed by a set of ones followed by another possibly empty set of zeros). It therefore suffices to solve the linear programming relaxation of *maximum flow problems* and *shortest path problems* on directed graphs, the *assignment problem*, and some problems that involve assigning workers to shifts, among others.

### Chvátal–Gomory Cutting Planes

One method of generating cutting planes involves combining together inequalities from the current description of the linear programming relaxation. This process is known as *integer rounding*, and the cutting planes generated are known as *Chvátal–Gomory cutting planes*. Integer rounding was implicitly described by Gomory in [12,13], and described explicitly by V. Chvátal in [7].

Consider again the example problem given earlier. The first step is to take a weighted combination of the inequalities. For example,

$$0.2(x_1 + 2x_2 \leq 7) + 0.4(2x_1 - x_2 \leq 3)$$

gives the valid inequality for the relaxation:

$$x_1 \leq 2.6.$$

In any feasible solution to the integer programming problem, the left hand side of this inequality must take an integer value. Therefore, the right hand side can be rounded down to give the following valid inequality for the integer programming problem:

$$x_1 \leq 2.$$

This process can be modified to generate additional inequalities. For example, taking the combination  $0.5(x_1 + 2x_2 \leq 7) + 0(2x_1 - x_2 \leq 3)$  gives  $0.5x_1 + x_2 \leq 3.5$ , which is valid for the relaxation. Since all the variables are constrained to be nonnegative, rounding down the left hand side of this inequality will only weaken it, giving  $x_2 \leq 3.5$ , also valid for the LP relaxation. Now rounding down the right hand side gives  $x_2 \leq 3$ , which is valid for the integer programming problem, even though it is not valid for the LP relaxation.

Gomory originally derived constraints using the optimal simplex tableau. The LP relaxation of the simple example above can be expressed in equality form as:

$$\begin{cases} \min & -2x_1 - x_2 \\ \text{s.t.} & x_1 + 2x_2 + x_3 = 7 \\ & 2x_1 - x_2 + x_4 = 3 \\ & x_i \geq 0, \quad i = 1, \dots, 4. \end{cases}$$

Notice that if  $x_1$  and  $x_2$  take integral values, then so must  $x_3$  and  $x_4$ . Solving this LP using the simplex algorithm gives the optimal tableau

7.4	0	0	0.8	0.6
2.2	0	1	0.4	-0.2
2.6	1	0	0.2	0.6

The rows of the tableau are linear combinations of the original objective function and constraints, and cutting planes can be generated using them. The objective function row implies that  $0.8x_3 + 0.6x_4 \geq 0.4$  in any integral feasible solution. It can be seen that this is equivalent to requiring that  $2x_1 + x_2 \leq 7$ , by substituting for  $x_3$  and  $x_4$  from the equality form given above. It is also possible to generate constraints from the other rows of the tableau. For example, the first constraint row of the tableau is equivalent to the equality  $2.2 = x_2 + 0.4x_3 - 0.2x_4$ . The fractional part of the right-hand side of this equation is  $0.4x_3 + 0.8x_4$ . This must be at least as large as the fractional part of the left hand side in any feasible integral solution, giving the valid cutting plane  $0.4x_3 + 0.8x_4 \geq 0.2$ , which is equivalent to  $x_1 \leq 2.5$ . Similarly, the final row of the tableau can be used to generate the constraint  $0.2x_3 + 0.6x_4 \geq 0.6$ , or equivalently  $7x_1 - x_2 \leq 13$ . In practice, the cut added to the tableau should be expressed in the nonbasic variables, here  $x_3$  and  $x_4$ , since the tableau will then be in standard form for the dual simplex algorithm.

*Gomory's cutting plane algorithm* solves an integer program by solving the LP relaxation to optimality, generating a cutting plane from a row of the tableau if necessary, adding this additional constraint to the relaxation, solving the new relaxation, and repeating until the solution to the relaxation is integral. It was shown in [13] that if a cutting plane is always generated from the first possible row, then Gomory's cutting plane algorithm will solve an integer program in a finite number of iterations.

Unfortunately, this finite convergence appears to be slow. However, it was shown in [3,6] that Gomory's cutting plane algorithm can be made competitive with other methods if certain techniques are used, such as adding many Chvátal–Gomory cuts at once.

It follows from the finite convergence of Gomory's cutting plane algorithm that every valid inequality for the convex hull of feasible integral points is either generated by repeated application of integer rounding or is dominated by an inequality generated in such a way. There are many different ways to generate a given in-

equality using integer rounding. The *Chvátal rank* of a valid inequality is the minimum number of successive applications of the integer rounding procedure that are needed in order to generate the inequality; it should be noted that a rank 2 inequality can be generated by applying the integer rounding procedure to a large number of rank 1 and rank 0 inequalities, for example.

It was shown in [26] that Gomory cutting planes can be generated even when an interior point method is used to solve the LP relaxations, because much of the information in the simplex tableau can still be obtained easily.

### Strong Cutting Planes From Polyhedral Theory

The resurgence of interest in cutting plane algorithms in the 1980s was due to the development of *polyhedral combinatorics* and the consequent implementation of cutting plane algorithms that used *facets* of the convex hull of integral feasible points as cuts. A facet is a face of a polytope that has dimension one less than the dimension of the polytope. Equivalently, to have a complete linear inequality description of the polytope, it is necessary to have an inequality that represents each facet.

In the example above, the convex hull of the set of feasible integer points has dimension 2, and all of the dashed lines represent facets. The valid inequality  $x_1 + 2x_2 \leq 7$  represents a face of the convex hull of dimension 0, namely the point (1, 3).

If a complete description of the convex hull of the set of integer feasible points is known, then the integer problem can be solved as a linear programming problem by minimizing the objective function over this convex hull. Unfortunately, it is not easy to get such a description. In fact, for an *NP*-complete problem [11] (cf. also ► **NP-complete problems and proof methodology**), such a description must contain an exponential number of facets, unless  $P = NP$ .

The paper [22] contains a survey of problems that have been solved using *strong cutting plane* algorithms. Typically in these algorithms, first a partial polyhedral description of the convex hull of the set of integer feasible points is determined. This description will usually contain families of facets of certain types. *Separation routines* for these families can often be developed; such a routine will take as input a point (for example, the optimal solution to the LP relaxation), and return

as output violated constraints from the family, if any exist.

The prototypical combinatorial optimization problem that has been successfully attacked using cutting plane methods is the *traveling salesman problem*. In this problem, a set of cities is provided along with distances between the cities. A route that visits each city exactly once and returns to the original city is called a *tour*. It is desired to choose the shortest tour. This problem has many applications, including printed circuit board (PCB) production: a PCB needs holes drilled in certain places to hold electronic components such as resistors, diodes, and integrated circuits. These holes can be regarded as the cities, and the objective is to minimize the total distance traveled by the drill.

The traveling salesman problem can be represented on a graph,  $G = (V, E)$ , where  $V$  is the set of vertices (or cities) and  $E$  is the set of edges (or links between the cities). Each edge  $e \in E$  has an associated cost (or length)  $c_e$ . If the incidence vector  $x$  is defined by

$$x_e = \begin{cases} 1 & \text{if edge } e \text{ is used,} \\ 0 & \text{otherwise,} \end{cases}$$

then the traveling salesman problem can be formulated as

$$\min \left\{ \sum c_e x_e : x \text{ the incidence vector of a tour} \right\}.$$

Notice that for a tour, at each vertex the sum of the edge variables must be two; this is called a degree constraint. This leads to the relaxation of the traveling salesman problem:

$$\begin{cases} \min & \sum c_e x_e \\ \text{s.t.} & \sum_{e \in \delta(v)} x_e = 2 \quad \text{for all vertices } v \\ & x_e = 0 \text{ or } 1 \quad \text{for all edges } e. \end{cases}$$

Here,  $\delta(v)$  denotes the set of all edges incident to vertex  $v$ . All tours are feasible in this formulation, but it also allows infeasible solutions corresponding to *subtours*, consisting of several distinct unconnected loops. To force the solution to be a tour, it is necessary to include *subtour elimination constraints* of the form

$$\sum_{e \in \delta(U)} x_e \geq 2$$

for every subset  $U \subseteq V$  with cardinality  $2 \leq |U| \leq |V|/2$ , where  $\delta(U)$  denotes the set of edges with exactly one endpoint in  $U$ . Any feasible solution to the relaxation given above which also satisfies the subtour elimination constraints must be the incidence vector of a tour. Unfortunately, the number of subtour elimination constraints is exponential in the number of cities. This led G.B. Dantzig et al. to propose a cutting plane algorithm in [9], where the subtour elimination constraints are added as cutting planes as necessary.

The degree constraints and the subtour elimination constraints, together with the simple bounds  $0 \leq x_e \leq 1$ , are still not sufficient to describe the convex hull of the incidence vectors of tours. This approach of [9] has been extended in recent years by the incorporation of additional families of cutting planes – see, for example, [1,15,33].

Thus, cutting plane algorithms can be used even when the integer programming formulation of the problem has an exponential number of constraints. Similar ideas are used in papers on the matching problem [10,14], maximum cut problems [4,28,36], and the linear ordering problem [16,30], among others. The pioneering work of J. Edmonds on the matching problem gave a complete description of the matching polytope, and this work was used in subsequent algorithms; it was also an inspiration to future work on many other problems and even to the formulation of complexity theory and the concept of a ‘good’ algorithm.

### Alternative General Cutting Planes

A knapsack problem is an integer programming problem with just one linear inequality constraint. A general integer programming problem can be regarded as the intersection of several knapsack problems, one for each constraint. This observation was used in [8,19,20] to solve general integer programming problems. The approach consists of finding facets and strong cutting planes for the knapsack problem and adding these constraints to the LP relaxation of the integer program as cutting planes.

There has been interest recently in other families of cutting planes for general integer programming problems. Two such families of cuts are *lift-and-project cuts* [2] and *Fenchel cuts* [5]. To find a cut of this type, it is generally necessary to solve a linear programming problem.

These alternative general cutting planes are not usually strong enough on their own to solve an integer programming problem, and they are most successfully employed in branch and cut algorithms for integer programming; they are discussed in more detail in ► [Integer programming: Branch and cut algorithms](#).

### Fixing Variables

If the *reduced cost* of a nonbasic variable is sufficiently large at the optimal solution to an LP relaxation, then that variable must take its current value in any optimal solution to the integer programming problem. To make this more precise, suppose the binary variable  $x_j$  takes value zero in the optimal solution to an LP relaxation and that the reduced cost of this variable is  $r_j$ . The optimal value of the relaxation gives a lower bound  $\underline{z}$  on the optimal value of the integer programming problem. The value  $z_{UB}$  of the best known feasible integral solution provides an upper bound on the optimal value. Any feasible point in the relaxation with  $x_j = 1$  must have value at least  $\underline{z} + r_j$ , so such a point cannot be optimal if  $r_j > z_{UB} - \underline{z}$ . Similar tests can be derived for nonbasic variables at their upper bounds. It is also possible to fix variables when an interior point method is used to solve the relaxations [26].

Once some variables have been fixed in this manner, it is often possible to fix further variables using logical implications. For example, in a traveling salesman problem, if  $x_e$  has been set equal to one for two edges incident to a particular vertex, then all other edges incident to that vertex can have their values fixed to zero.

### Solving Large Problems

It is generally accepted that interior point methods are superior to the simplex algorithm for solving sufficiently large linear programming problems. The situation for cutting plane algorithms for large integer programming problems is not so clear, because the dual simplex method is very good at reoptimizing if only a handful of cutting planes are added. Nonetheless, it does appear that interior point cutting plane algorithms may well have a role to play, especially for problems with very large relaxations (thousands of variables and constraints) and where a large number of cutting planes are added simultaneously (hundreds or thousands). LP relaxations of integer programming problems can experience severe degeneracy, which can cause the simplex

method to stall. Interior point methods suffer far less from the effects of degeneracy.

In [27], an interior point cutting plane algorithm is used for a maximum cut problem on a sparse graph, and the use of the interior point solver enables the solution of far larger instances than with a simplex solver, because of both the size of the problems and their degeneracy.

A combined interior point and simplex cutting plane algorithm for the linear ordering problem is described in [30]. In the early stages, an interior point method is used, because the linear programs are large and many constraints are added at once. In the later stages, the dual simplex algorithm is used, because just a few constraints are added at a time and the dual simplex method can then reoptimize very quickly. The combined algorithm is up to ten times faster than either a pure interior point cutting plane algorithm or a pure simplex cutting plane algorithm on the larger instances considered.

The polyhedral combinatorics of the quadratic assignment problem are investigated in [21]. It was found necessary to use an interior point method to solve the relaxations, because of the size of the relaxations.

### Provably Good Solutions

Even if a cutting plane algorithm is unable to solve a problem to optimality, it can still be used to generate good feasible solutions with a *guaranteed bound to optimality*. This approach for the traveling salesman problem is described in [23]. The value of the current LP relaxation provides a lower bound on the optimal value of the integer programming problem. The optimal solution to the current LP relaxation (or a good feasible solution) can often be used to generate a good integral feasible solution using a heuristic procedure. The value of an integral solution obtained in this manner provides an upper bound on the optimal value of the integer programming problem.

For example, for the traveling salesman problem, edges that have  $x_e$  close to one can be set equal to one, edges with  $x_e$  close to zero can be set to zero, and the remaining edges can be set so that the solution is the incidence vector of a tour. Further refinements are possible, such as using 2-change or 3-change procedures to improve the tour, as described in [25].

This has great practical importance. In many situations, it is not necessary to obtain an optimal solution, and a good solution will suffice. If it is only necessary to have a solution within 0.5% of optimality, say, then the cutting plane algorithm can be terminated when the gap between the lower bound and upper bound is smaller than this tolerance. If the objective function value must be integral, then the algorithm can be stopped with an optimal solution once this gap is less than one.

### Equivalence of Separation and Optimization

The *separation problem* for an integer programming problem can be stated as follows:

Given an instance of an integer programming problem and a point  $x$ , determine whether  $x$  is in the convex hull of feasible integral points. Further, if it is not in the convex hull, find a separating hyperplane that cuts off  $x$  from the convex hull.

An algorithm for solving a separation problem is called a separation routine, and it can be used to solve an integer programming problem.

The *ellipsoid algorithm* [17,24] is a method for solving linear programming problems in polynomial time. It can be used to solve an integer programming problem with a cutting plane method, and it will work in a polynomial number of stages, or calls to the separation routine. If the separation routine requires only polynomial time then the ellipsoid algorithm can be used to solve the problem in polynomial time. It can also be shown that if an optimization problem can be solved in polynomial time then the corresponding separation problem can also be solved in polynomial time.

There are instances of any *NP*-hard problem that cannot be solved in polynomial time unless  $P = NP$ . Therefore, a cutting plane algorithm cannot always generate good cutting planes quickly for *NP*-hard problems. In practice, fast heuristics are used, and these heuristics may occasionally be unable to find a cutting plane even when one exists.

### Conclusions

Cutting plane methods have been known for almost as long as the simplex algorithm. They have come back into favor since the early 1980s because of the development of strong cutting planes from polyhedral theory.

In practice, cutting plane methods have proven very successful for a wide variety of problems, giving provably optimal solutions. Because they solve relaxations of the problem of interest, they make it possible to obtain bounds on the optimal value, even for large instances that cannot currently be solved to optimality.

### Keywords

Integer programming; Duality

One of the more elegant and satisfying ideas in the theory of optimization is linear programming duality. The dual of a linear programming problem is not only interesting theoretically but has great practical value, because it provides *sensitivity analysis*, bounds on the optimal value, and marginal values for resources.

It is natural to want to extend duality to integer programming in order to obtain these same benefits. The matter is not so simple, however. Linear programming duality actually represents several concepts of duality that happen to coincide in the case of linear programming but diverge as one moves to other types of optimization problems. The benefits also decouple, because each duality concept provides some of them but not others.

Five types of integer programming duality are surveyed here. None is clearly superior to the others, and their strengths and weaknesses are summarized in at the end of the article.

### Linear Programming Duality

A brief summary of *linear programming duality* will provide a foundation for the rest of the discussion. Consider the linear programming (primal) problem,

$$\begin{cases} \max & cx \\ \text{s.t.} & Ax \leq b \\ & x \geq 0, \end{cases} \quad (1)$$

where  $A$  is an  $m \times n$  matrix. The dual problem may be stated

$$\begin{cases} \min & ub \\ \text{s.t.} & uA \geq c \\ & u \geq 0, \end{cases} \quad (2)$$

where  $u$  is a vector of *dual variables*. This is a *strong dual* because its optimal value is the same as that of the primal problem, unless both primal and dual are infeasible. (An unbounded or infeasible maximization problem is regarded as having optimal value  $\infty$  or  $-\infty$ , respectively, and analogously for minimization problems.)

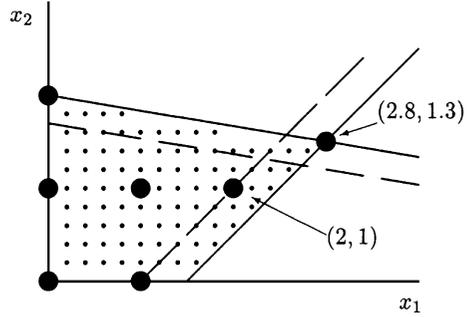

The linear programming dual brings at least three important benefits.

- a) (Bounds) The value of any feasible dual solution provides an upper bound on the optimal value of the primal problem. For any  $x$  and  $y$  that are primal and dual feasible, respectively,  $ub \geq uAx \geq cx$ . The first inequality is due to the fact that  $Ax \leq b$  and  $u \geq 0$ , and the second is due to the fact that  $uA \geq c$  and  $x \geq 0$ . By finding a dual feasible solution, one can estimate how much a primal feasible solution falls short of optimality. Although this property is less important for linear programming, where robust solution algorithms are available, it is essential for integer programming.
- b) (Sensitivity analysis) Due to a), the dual solution provides a partial sensitivity analysis. Let  $\bar{u}$  be an optimal solution of the dual problem (2), so that  $\bar{u}b$  is the optimal value of both primal and dual. If the right-hand side of the constraint in (1) is perturbed by  $\Delta b$ , so that it becomes  $Ax \leq b + \Delta b$ , then the dual (2) becomes

$$\begin{cases} \min & u(b + \Delta b) \\ \text{s.t.} & uA \geq c \\ & u \geq 0. \end{cases} \quad (3)$$

Because only the objective function changes,  $\bar{u}$  is feasible in (3) as well as (2). So  $\bar{u}(b + \Delta b)$  is an upper bound on the optimal value of the perturbed primal problem. The (possibly negative) change in the optimal value  $\bar{u}b$  of the original problem is bounded above by  $\bar{u}\Delta b$ . The change is in fact equal to  $\bar{u}\Delta b$  if the perturbation  $\Delta b$  lies within easily computable ranges.

- c) (Complementary slackness) Due to b), the marginal values of resources are readily available. If the right-hand side  $b_i$  of a particular constraint of (1) represents a resource constraint, then a change  $\Delta b_i$  in the amount of resource available raises the optimal profit by at most  $\bar{u}_i \Delta b_i$ . In particular there is a *com-*

**Integer Programming Duality, Figure 1**

The shaded polyhedron is the feasible set of a linear programming problem with optimal solution  $(x_1, x_2) = (2.8, 1.3)$  and optimal value 69. The dashed lines represent a perturbation of the right-hand sides. The black dots represent feasible solutions of the corresponding integer programming problem, which has optimal solution  $(x_1, x_2) = (2, 1)$  and optimal value 50

*plementary slackness* property, which says that a surplus resource has no marginal value. If  $\bar{x}$  is optimal in (1), then  $\bar{u}(b - A\bar{x}) = 0$ .

Consider for example the linear programming problem

$$\begin{cases} \max & 20x_1 + 10x_2 \\ \text{s.t.} & x_1 + 4x_2 \leq 8 \\ & 2x_1 - 2x_2 \leq 3 \\ & x_1, x_2 \geq 0, \end{cases} \quad (4)$$

which is graphed in Fig. 1. The optimal dual solution is  $(u_1, u_2) = (6, 7)$ . If the two constraints represent two resource limitations, then the resources have marginal values of at most 6 and 7, respectively. If one less unit of each resource is available (represented by dashed lines in Fig. 1.), then the change in the objective function value is bounded above by  $-6 - 7 = -13$ . In fact, the profit decreases by exactly 13.

### Integer Programming

Integer programming modifies the linear programming problem (1) by requiring the variables to take integral values:

$$\begin{cases} \max & cx \\ \text{s.t.} & Ax \leq b \\ & x \geq 0 \text{ and integer.} \end{cases} \quad (5)$$

In *mixed integer/linear programming* (MILP) some variables are continuous and some are integral. For ease of exposition, the discussion here is restricted to pure (unmixed) integer programming.

The example problem (4) may be modified to obtain the integer programming problem,

$$\begin{cases} \max & 20x_1 + 10x_2 \\ \text{s.t.} & x_1 + 4x_2 \leq 8 \\ & 2x_1 - 2x_2 \leq 3 \\ & x_1, x_2 \geq 0 \text{ and integers.} \end{cases} \quad (6)$$

Figure 1 illustrates this problem as well.

In linear programming, a constraint with slack at the optimal solution is redundant. It may be omitted without changing the optimal solution. The example shows that this is untrue for integer programming. Both constraints in (6) contain slack at the solution  $(x_1, x_2) = (2, 1)$ . Yet removing either would result in a different solution.

The concept of a marginal value is problematic in integer programming. Let the *value function*  $v^*(b)$  indicate the optimal value of (1) or (5) for a given right-

hand side  $b$ . In linear programming the marginal value of resource  $i$  is essentially the partial derivative of  $v^*(b)$  with respect to  $b_i$ . Yet in integer programming  $v^*(b)$  is a step function with respect to any  $b_i$ , as illustrated by the dotted line in Fig. 2. So it is unclear what would be meant by a marginal value. However, there may be a complementary slackness property of some kind, depending on the duality in question.

### Surrogate Duality

One general scheme for formulating integer programming duals is to define a family of relaxations of the original problem that are parameterized by dual variables. The dual problem is then the problem of finding the tightest relaxation. It will be seen that the linear programming dual does exactly this.

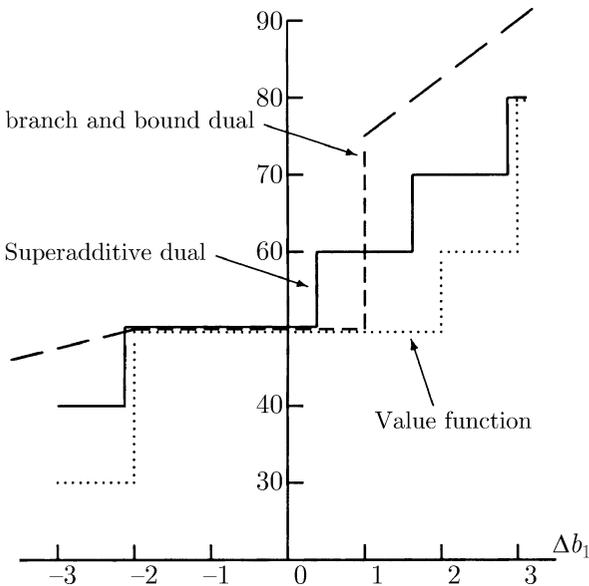

One instance of this scheme is *surrogate duality* [9,10,11]. The integer programming problem (5) can be relaxed by replacing the constraints  $Ax \leq b$  with a *surrogate constraint*, i. e., a nonnegative linear combination of the inequalities in  $Ax \leq b$ . This yields a *surrogate relaxation* of (1):

$$\begin{cases} \max & cx \\ \text{s.t.} & uAx \leq ub \\ & x \geq 0 \text{ and integer.} \end{cases} \quad (7)$$

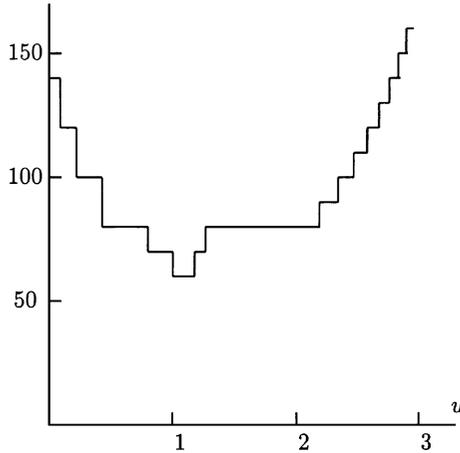

This is a relaxation in the sense that its feasible set contains that of (5). Its optimal value  $\sigma(u)$  is therefore an upper bound on that of (5) for any  $u \geq 0$ . The surrogate relaxation may be much easier to solve than the original problem because it has only one constraint (other than nonnegativity). The surrogate dual problem is to find a  $u$  that gives the best bound:

$$\begin{cases} \min & \sigma(u) \\ \text{s.t.} & u \geq 0. \end{cases} \quad (8)$$

The surrogate relaxation of a linear programming problem (1) is (7) without the integrality constraint. From strong linear programming duality, its optimal value is  $\sigma(u) = \min_{\alpha} \{\alpha ub : \alpha uA \geq \alpha c, \alpha \geq 0\}$ . So the surrogate dual (8) becomes precisely the linear programming dual (2).

**Integer Programming Duality, Figure 2**  
Upper bounds on the optimal value of an integer programming problem provided by the superadditive and branch and bound duals, as a function of the right-hand side perturbation  $\Delta b_1$ . The value function indicates the exact optimal value for each  $\Delta b_1$

**Integer Programming Duality, Figure 3**  
Plot of  $\sigma(1, u)$  for a surrogate dual problem

Surrogate duality can be illustrated with the integer programming problem (6). The surrogate relaxation is

$$\begin{cases} \min & 20x_1 + 10x_2 \\ \text{s.t.} & (1 + 2u)x_1 + (4 - 2u)x_2 \leq 8 + 3u \\ & x_1, x_2 \geq 0 \text{ and integers.} \end{cases}$$

Because there are only two constraints and only the ratio  $u_2/u_1$  matters,  $u_1$  is set to 1 and  $u_2$  replaced with  $u$ . A plot of  $\sigma(1, u)$  appears in Fig. 3.

The primary utility of the surrogate dual is to provide an upper bound on the optimal value of the original problem. In the example, the dual attains its optimal value of 60 when  $1 < u \leq 20/17$ . This is better than the bound of 69 provided by the linear programming relaxation. But there is a duality gap of  $60 - 50 = 10$ .

One might speculate that the surrogate multipliers indicate the relative importance of the two constraints, but it is unclear what this means. One can say, however, that omitting a constraint with a vanishing multiplier does not raise the optimal value above that of the surrogate dual. Vanishing multipliers therefore identify redundant constraints when there is no duality gap.

The surrogate dual (8) must be solved by a search method that does not require gradient or subgradient information. Possible algorithms are discussed in [16]. The dual problem need not be solved to optimality, because only an upper bound is sought in any case.

## Lagrangian Duality

Another form of relaxation duality, *Lagrangian duality* [5,6,7], removes some of the more troublesome constraints from (5) but inserts into the objective function a penalty for violating them. Thus the constraints are partitioned into ‘hard’ constraints  $A^1x \leq b^1$  and ‘easy’ constraints  $A^2x \leq b^2$ :

$$\begin{cases} \max & cx \\ \text{s.t.} & A^1x \leq b^1 \\ & A^2x \leq b^2 \\ & x \geq 0 \text{ and integer.} \end{cases} \quad (9)$$

The hard constraints are *dualized* to obtain the *Lagrangian relaxation*:

$$\begin{cases} \max & cx + u(b^1 - A^1x) \\ \text{s.t.} & A^2x \leq b^2 \\ & x \geq 0 \text{ and integer.} \end{cases} \quad (10)$$

This is a relaxation in the sense that its optimal value  $\theta(u)$  is an upper bound on the optimal value of (5). For any  $x$  that is feasible in (9),  $cx \leq cx + u(b^1 - A^1x)$  because  $u \geq 0$  and  $b^1 - A^1x \geq 0$ . The *Lagrangian dual problem* is

$$\begin{cases} \min & \theta(u) \\ \text{s.t.} & u \geq 0. \end{cases} \quad (11)$$

If all the constraints of (9) are dualized, then the Lagrangian dual is no improvement over the linear programming dual. In this case  $\theta(u) = \max \{(c - uA)x + ub : x \geq 0, \text{ integer}\}$ . So  $\theta(u) = ub$  when  $c - uA \leq 0$  and is  $\infty$  otherwise. The Lagrangian dual problem (2) is now the problem of minimizing  $ub$  subject to  $c - uA \leq 0$  and  $u \geq 0$ , which is precisely the linear programming dual (2). (It follows that linear programming duality is a special case of Lagrangian duality.)

The Lagrangian dual is therefore useful only when some constraints are not dualized. These constraints must be carefully chosen so that the integer programming problem (5) is easy to solve. It may, for example, decouple into smaller problems or have other special structure.

As an example of Lagrangian duality, suppose that the first constraint of (6) is dualized. The Lagrangian

relaxation is

$$\begin{cases} \max & 20x_1 + 10x_2 + u(8 - x_1 - 4x_2) \\ \text{s.t.} & 2x_1 - 2x_2 \leq 3 \\ & x_1, x_2 \geq 0 \text{ and integers.} \end{cases}$$

The optimal solution of the Lagrangian dual is  $u = 6$ , with value  $\theta(u) = 62$ , slightly worse than the surrogate bound of 60 but still better than the linear programming bound of 69.

The Lagrangian and surrogate duals can be compared in general if the surrogate relaxation dualizes the same constraints as the Lagrangian relaxation. In this case it can be shown that the surrogate duality gap is never larger than the Lagrangian duality gap [7], and it tends to be smaller. The Lagrangian relaxation has the advantage, however, that it is often easier to solve than the surrogate relaxation that dualizes the same constraints. Moreover,  $\theta(u)$  is convex and piecewise linear. A subgradient optimization method can be used to find a global minimum of  $\theta(u)$  by finding a local minimum. In fact, if  $\theta(u) = cx_u + u(b - Ax_u)$ , then  $b - Ax_u$  is a subgradient of  $\theta(u)$  at  $u$ .

When there is no duality gap, the Lagrangian multipliers  $u_i$  can be viewed as sensitivities to right-hand side perturbations, with respect to at least one optimal solution. It can be shown that there is no duality gap if and only there exists a feasible solution  $\bar{x}$  of (5) and  $\bar{u} \geq 0$  that satisfy  $\theta(\bar{u}) = c\bar{x} + \bar{u}(b^1 - A^1\bar{x})$  and complementary slackness:  $\bar{u}(b^1 - A^1\bar{x}) = 0$ . However, solution of the Lagrangian dual does not necessarily yield a solution  $\bar{x}$  with these properties. Further search may be required.

### Superadditive Duality

So far the linear programming dual has been viewed as a relaxation dual, of either the surrogate or Lagrangian type. It can also be viewed as representing the classical duality of vectors and linear functionals. For this purpose the dual of (1) is written:

$$\begin{cases} \min & f(b) \\ \text{s.t.} & f(A) \geq c \\ & f \in F. \end{cases} \tag{12}$$

Here  $f$  is a linear functional defined by a nonnegative row vector  $u$ , so that  $f(b) = ub$  and  $f(A) = uA$ . The minimization is over the set  $F$  of all such functionals.

A similar dual of the integer programming problem (5) can be written as (12), but with minimization over a broader class  $F$  of functions. It can be shown that if  $F$  is the class of superadditive nondecreasing functions  $f$  with  $f(0) = 0$ , then (12) is a strong integer programming dual. This *superadditive dual* [2,15,20,24] provides sensitivities to right-hand side perturbations. It is also possible, at least in principle, to construct a function  $f$  that solves the dual, by means of a cutting plane algorithm.

A *superadditive function*  $f$  is one that satisfies  $f(a + b) \geq f(a) + f(b)$  for all vectors  $a, b$ . The superadditive dual satisfies weak duality because if  $x$  is feasible in (5) and  $f$  is feasible in (12), then

$$cx \leq \sum_j f(a^j)x_j \leq \sum_j f(a^jx_j) \leq f(Ax) \leq f(b),$$

where  $a^j$  is row  $j$  of  $A$ . The first inequality follows from  $f(A) \geq c$ . The second is due to superadditivity of  $f$  and the fact that multiplication by a nonnegative integer  $x_j$  creates a sum of zero or more terms (also  $f(0) = 0$ ). The third is due to superadditivity. The fourth follows from the fact that  $f$  is nondecreasing and  $Ax \leq b$ .

Strong duality can be established by exhibiting a dual feasible solution  $f$  for which there is no duality gap. Let a *rounding function* be a function of the form

$$R(d) = \lfloor M_k \lfloor M_{k-1} \cdots \lfloor M_1 d \rfloor \cdots \rfloor \rfloor, \tag{13}$$

where each  $M_i$  is a nonnegative matrix and  $\lfloor \alpha \rfloor$  is  $\alpha$  rounded down. A *Chvátal function* has the form  $uR$ , where  $u \geq 0$  and  $R$  is a rounding function. Because Chvátal functions clearly belong to  $F$ , it suffices to exhibit a Chvátal function  $uR$  for which  $uR(b)$  is the optimal value of (5).

This is done by generating Chvátal-Gomory cuts. A rank 1 *Chvátal-Gomory cut* for  $Ax \leq b, x \geq 0$  is an inequality of the form  $\lfloor mA \rfloor x \leq \lfloor mb \rfloor$ , where  $m \geq 0$  defines a linear combination of the rows of  $Ax \leq b$ . Rank 2 cuts are obtained by applying the same operation to rank 1 cuts, and so forth. Chvátal showed that the integer hull of any polyhedron (i. e., the convex hull of its integral points) is described by finitely many cuts of finite rank.

This implies that for some rounding function  $\bar{R}$ ,  $\bar{R}(A)x \leq \bar{R}(b)$  and  $x \geq 0$  describe the integer hull of  $P = \{x \geq 0: Ax \leq b\}$ . So the optimal value of the integer

programming problem (5) is the optimal value of

$$\begin{cases} \max & cx \\ \text{s.t.} & \bar{R}(A)x \leq \bar{R}(b) \\ & x \geq 0. \end{cases} \quad (14)$$

The linear programming dual of (14) is

$$\begin{cases} \min & u\bar{R}b \\ \text{s.t.} & u\bar{R}(A) \geq c \\ & u \geq 0. \end{cases} \quad (15)$$

If  $\bar{u}$  solves problem (15), then its optimal value  $\bar{u}\bar{R}(b)$  is the optimal value of (14) and therefore of the original integer programming problem (5). Thus  $f = \bar{u}\bar{R}$  is a Chvátal function that solves the dual problem (12).

The dual solution provides sensitivity analysis with respect to right-hand sides. Due to weak duality,  $\bar{u}\bar{R}(b + \Delta b)$  is an upper bound on the optimal value when the right-hand side in (5) is perturbed to  $b + \Delta b$ . There is a form of complementary slackness, because for any optimal solution  $\bar{x}$  of (5),  $(\bar{u}\bar{R}(A) - c)\bar{x} = 0$ .

Consider again the example problem (6). It will be seen below that  $\bar{R}$  is

$$\bar{R}(d) = \left[ \begin{pmatrix} \frac{2}{3} & \frac{1}{3} & 0 \\ 0 & 0 & 1 \end{pmatrix} \left[ \begin{pmatrix} \frac{4}{5} & \frac{1}{10} \\ \frac{1}{5} & \frac{1}{2} \end{pmatrix} d \right] \right]. \quad (16)$$

Problem (14) is

$$\begin{cases} \max & 20x_1 + 10x_2 \\ \text{s.t.} & x_1 + 2x_2 \leq 4 \\ & x_1 - x_2 \leq 1 \\ & x_1, x_2 \geq 0. \end{cases}$$

The solution of (15) is  $\bar{u} = (10 \ 10)$ . So if the right-hand side of (6) is perturbed by  $\Delta b = (\Delta b_1, \Delta b_2)$ , the new optimal value of (6) is bounded above by

$$(10 \ 10) \left[ \begin{pmatrix} \frac{2}{3} & \frac{1}{3} & 0 \\ 0 & 0 & 1 \end{pmatrix} \left[ \begin{pmatrix} \frac{4}{5} & \frac{1}{10} \\ \frac{1}{5} & \frac{1}{2} \end{pmatrix} \begin{pmatrix} 8 + \Delta b_1 \\ 3 + \Delta b_2 \end{pmatrix} \right] \right].$$

For instance, if each resource is reduced by one ( $\Delta b = (-1, -1)$ ), then the new optimal value is at most 50. In fact it is exactly 50. Figure 2 plots  $\bar{u}\bar{R}(b + \Delta b)$  against  $\Delta b_1$  for comparison with the value function  $v^*(b + \Delta b)$ . Note that there is complementary slackness, because  $(\bar{u}\bar{R}(A) - c)\bar{x} = [(20 \ 10) - (20 \ 10)](2, 1) = 0$ .

### Solving the Superadditive Dual

A solution of the dual problem (12) can be constructed in stages that correspond to Chvátal ranks [3,14,23]. It is assumed without practical loss of generality that the components of  $A$ ,  $b$  and  $c$  are rational numbers.

The first stage proceeds as follows. Let  $x^1, \dots, x^p$  be the vertices of  $P_0 = P$ . For each  $x^k$  consider the cone  $C_k$  of directions  $d$  for which  $x^k$  maximizes  $dx$  subject to  $x \in P_0$ . To describe  $C_k$ , let  $\bar{A}x \leq \bar{b}$  be the constraints of  $Ax \leq b$  that are active at  $x^k$  (i. e., the constraints  $a^i x \leq b_i$  for which  $a^i x^k = b_i$ ), and let  $-\bar{I}x \leq 0$  be the active constraints of  $-x \leq 0$  (the constraints  $-x_j \leq 0$  for which  $x_j^k = 0$ ). Then  $C_k$  is the cone spanned by the rows of  $\bar{A}$  and  $-\bar{I}$ .

It suffices to identify a Hilbert basis [8] for  $C_k$ ; i. e., a set of directions  $d^1, \dots, d^q$  such that every integer vector in  $C_k$  is a nonnegative integer combination of  $d^1, \dots, d^q$ . Assume without loss of generality that the components of  $\bar{A}$  are integers (the inequalities  $\bar{A}x \leq \bar{b}$  can be multiplied by appropriate integers to achieve this). Then the integer vectors  $d^1, \dots, d^q$  in the set

$$\{\lambda\bar{A} - \mu\bar{I} : 0 \leq \lambda \leq e, 0 \leq \mu \leq e\}$$

form a Hilbert basis for  $C_k$ , where  $e$  is a row vector of ones.

The next step is to generate rank 1 Chvátal-Gomory cuts associated with  $x^k$ . First note that each inequality of the form  $d^j x \leq d^j x^k$  supports  $P_0$  at  $x^k$  and is therefore a nonnegative linear combination of the rows of  $\bar{A}x \leq \bar{b}$ ,  $-\bar{I}x \leq 0$ . Thus one can write

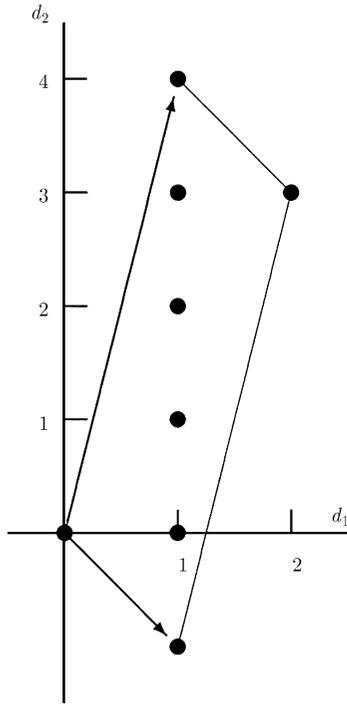

$$d^j = m^j \bar{A} - p^j \bar{I}. \quad (17)$$

The multipliers  $m^j$  and  $p^j$  can be obtained by solving (17). The valid inequalities  $d^j x \leq \lfloor d^j x^k \rfloor$  are clearly rank 1 cuts for  $Ax \leq b$ ,  $-x \leq 0$ . Rank 1 cuts are generated in this fashion for all the vertices  $x^k$ .

Now let  $P_1$  be defined by all of the rank 1 cuts generated, plus  $x \geq 0$ . Let the rows of  $M_1$  be the vectors  $m^j$  corresponding to rank 1 cuts that define facets of  $P_1$ . Then  $P_1 = \{x \geq 0 : \lfloor M_1 A \rfloor x \leq \lfloor M_1 b \rfloor\}$ .

This same procedure is now applied to the vertices of  $P_1$  to obtain  $M_2$  and  $P_2$ , and so forth until all the vertices of  $P_k$  are integral. At this point (13) is the desired rounding function  $\bar{R}$ , and  $f = \bar{u}\bar{R}$  solves the dual (12).

The Hilbert bases and inequalities  $d^j x \leq \lfloor d^j x^k \rfloor$  for problem (6) appear in Table 1. (The origin need not be

**Integer Programming Duality, Figure 4**  
The black dots indicate a Hilbert basis for the cone spanned by  $(1, 4)$  and  $(1, -1)$

considered as a vertex.) At vertex  $x^1 = (2.8, 1.3)$ , for example, the two constraints  $x_1 + 4x_2 \leq 8$  and  $2x_1 - 2x_2 \leq 3$  are active, and so the cone  $C_1$  is spanned by  $(1, 4)$  and  $(1, -1)$ . The Hilbert basis consists of the integer vectors of the region depicted in Fig. 4.

The polyhedra  $P_1$  and  $P_2$  are shown by dashed and dotted lines, respectively, in Fig. 5. Their facets (other than  $x \geq 0$ ) and the corresponding vectors  $m^j$  appear in Table 2. The vectors  $M_1$  and  $M_2$  that appear in the rounding function (16) can be read from Table 2.

**Another Functional Dual**

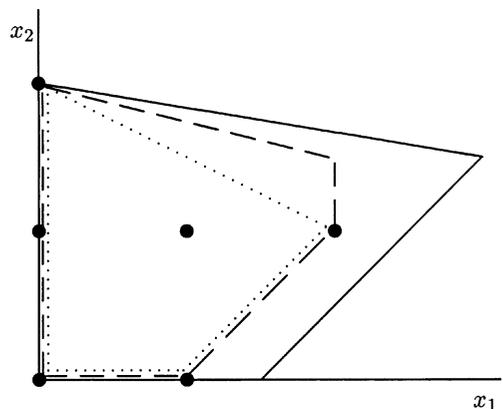

It is practical to solve the superadditive dual only when the problem is small or has special structure. An alternative is to derive a dual solution for (12) from the branch and bound tree that solves the primal problem, as proposed in [18] on the basis of work in [24]. This maneuver sacrifices an independently computed upper bound on the optimal value, but it provides useful sensitivity analysis in a more practical fashion than the superadditive dual. It might be called a ‘branch and bound dual’.

**Integer Programming Duality, Table 1**  
Hilbert basis vectors  $d^j$  and rank 1 cuts  $d^j x \leq \lfloor d^j x^k \rfloor$  corresponding to vertices  $x^k$  of an integer programming problem

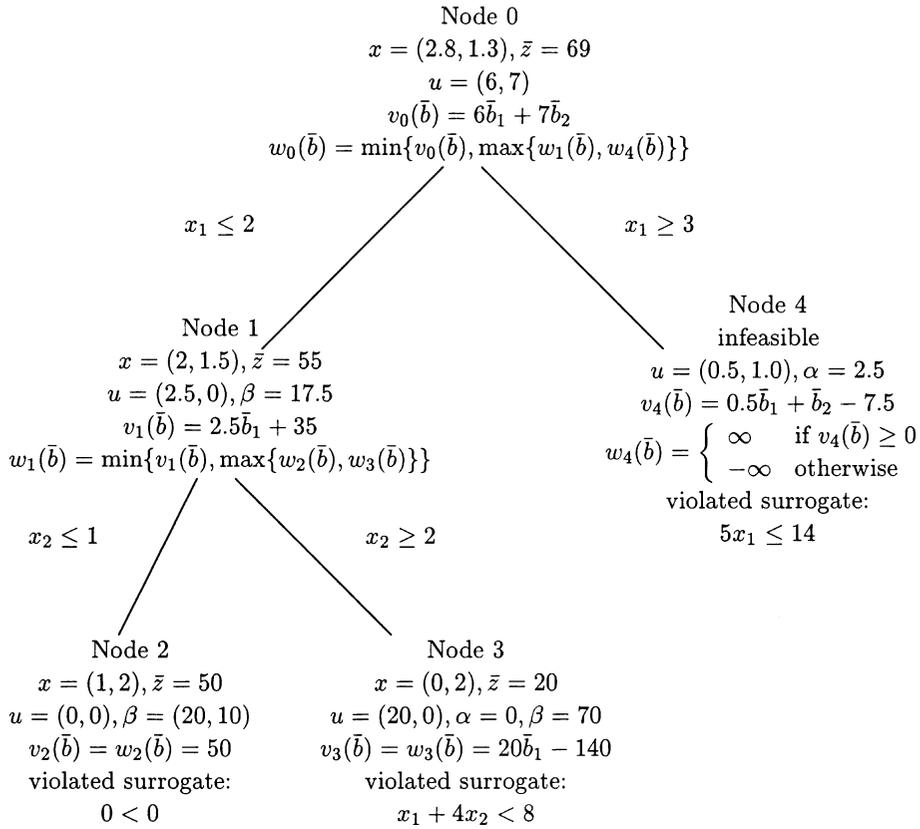

$x^k$	$d^j$	$d^j x \leq \lfloor d^j x^k \rfloor$
(2.8, 1.3)	(1, -1)	$x_1 - x_2 \leq 1$
	(1, 0)	$x_1 \leq 2$
	(1, 1)	$x_1 + x_2 \leq 4$
	(1, 2)	$x_1 + 2x_2 \leq 5$
	(1, 3)	$x_1 + 3x_2 \leq 6$
	(1, 4)	$x_1 + 4x_2 \leq 8$
	(2, 3)	$2x_1 + 3x_2 \leq 9$
(1.5, 0)	(0, -1)	$-x_2 \leq 0$
	(1, -1)	$x_1 - x_2 \leq 1$
	(1, -2)	$x_1 - 2x_2 \leq 1$
(0, 2)	(-1, 0)	$-x_1 \leq 0$
	(0, 1)	$x_2 \leq 2$
	(0, 2)	$2x_2 \leq 4$
	(0, 3)	$3x_2 \leq 6$
	(1, 3)	$x_1 + 3x_2 \leq 6$

Polyhedra  $P_1, P_2$  and vectors  $m^j$  corresponding to their facets

$P_i$	Facet	$m^j$
$P_1$	$x_1 + 3x_2 \leq 6$	$(\frac{4}{5} \ \frac{1}{10})$
	$x_1 \leq 2$	$(\frac{1}{5} \ \frac{2}{5})$
	$x_1 - x_2 \leq 1$	$(0 \ \frac{1}{2})$
$P_2$	$x_1 + 2x_2 \leq 4$	$(\frac{2}{3} \ \frac{1}{3} \ 0)$
	$x_1 - x_2 \leq 1$	$(0 \ 0 \ 1)$

**Integer Programming Duality, Figure 5**  
The polyhedra  $P_0$  (solid line),  $P_1$  (dashed line), and  $P_2$  (dotted line) for an integer programming problem

**Integer Programming Duality, Figure 6**  
 A branch and bound tree with information relevant to the branch and bound dual and the inference dual

Rather than superadditive functions, the feasible set  $F$  in (12) will contain functions of the form

$$f(d) = \min\{yd + y_0, \max\{f_1(d), f_2(d)\}\}, \quad (18)$$

where  $y \geq 0$  and  $f_1$  and  $f_2$  are either identically zero or of the form (18). Weak duality is easily shown. Strong duality is shown by constructing a solution as follows.

At each node  $t$  of the branch and bound tree for (5), one solves the linear relaxation

$$\begin{cases} \max & cx \\ \text{s.t.} & Ax \leq b & (u) \\ & -x \leq -L^t & (\alpha) \\ & x \leq U^t & (\beta), \end{cases} \quad (19)$$

where the lower and upper bounds  $L^t, U^t$  are defined by branching, and associated dual variables are shown on the right. By weak linear programming duality,  $v_t(\bar{b}) = u\bar{b} - \alpha L^t + \beta U^t$  is an upper bound on the optimal value of (19) with perturbed right-hand side  $d = b + \Delta b$ . If

(19) is infeasible, let  $u, \alpha, \beta$  be the dual solution of the phase I problem in which the objective function is the sum of negative constraint violations. In this case  $v_t(\bar{b})$  is  $-\infty$  if  $u\bar{b} - \alpha + \beta < 0$  and is  $\infty$  otherwise.

Now if  $t_1, t_2$  are the successor nodes of node  $t$  in the search tree,

$$w_t(\bar{b}) = \min\{v_t(\bar{b}), \max\{w_{t_1}(\bar{b}), w_{t_2}(\bar{b})\}\}$$

is an upper bound on the optimal value of (19) with right-hand side  $\bar{b} = b + \Delta b$  and integral  $x$ . (At leaf nodes, the max expression is omitted.) The recursively computed function  $w_0$  associated with the root node solves the dual problem (12) because  $w_0(b)$  is the optimal value of (5).

The dual solution  $w_0$  for the example problem (6) is indicated in the branch and bound tree for this problem depicted in Fig. 6. A plot of  $w_0(b + \Delta b)$  as a function of  $\Delta b_1$  appears in Fig. 2.

### Inference Duality

Still another interpretation of the linear programming dual views it as an inference problem. It wishes to find the smallest upper bound  $z^*$  on the objective function that can be inferred from the constraints. This dual of (1) can be written

$$\begin{cases} \min & z \\ \text{s.t.} & \begin{pmatrix} Ax \leq b \\ x \geq 0 \end{pmatrix} \text{ imply } cx \leq z. \end{cases} \quad (20)$$

A corollary of the classical Farkas lemma states that the constraints  $Ax \leq b, x \geq 0$  imply  $cx \leq z$  if and only if they are infeasible or some surrogate  $uAx \leq ub$  dominates  $cx \leq z$ ; i. e.,  $uA \geq c$  and  $ub \leq z$ . So the inference dual (20) seeks the smallest  $ub$  for which  $uA \geq c$  and  $u \geq 0$  (assuming the constraints are feasible), which is precisely the linear programming dual.

The inference dual can be generalized to integer programming if the implication in (20) is interpreted differently [4,13]. Constraints  $Ax \leq b, x \geq 0$  imply  $cx \leq z$  if and only if all *integer* (rather than all real) vectors  $x$  that satisfy the former also satisfy the latter. There is obviously no duality gap, because the maximum value  $z^*$  of  $cx$  is the smallest upper bound on  $cx$  implied by the constraints. As will be seen, inference duality allows calculation of sensitivity ranges for all problem data (not just right-hand sides) by solving linear programming problems.

To solve the dual (20) is in effect to exhibit a proof that the value of  $cx$  is at most  $z^*$ . In linear programming, a proof is a nonnegative linear combination of constraints, and the optimal dual multipliers  $u$  encode the desired proof. A method of proof suitable for integer programming is developed in [12], but for present purposes it suffices to reconstruct a proof from the branch and bound tree that solves the primal problem. Actually it will be proved that  $cx$  is at most  $z^* + \Delta z$  (for any  $\Delta z \geq 0$ ), to provide a more flexible analysis.

The proof is by contradiction. Assume, contrary to the claim, that the optimal value of (5) is strictly more than  $z^* + \Delta z$ . Then each branch of the tree can be seen as leading to a contradiction. At any given leaf node  $t$  let  $z_{LB}$  be the value of the best integral solution found so far ( $z_{LB} = -\infty$  if none has been found). One of the following cases obtains.

a) The linear relaxation (19) is infeasible. Then the dual solution  $(u, \alpha, \beta)$  proves infeasibility; i. e.,  $u^t A$

$-\alpha + \beta \geq 0$  and  $u^t b - \alpha^t L^t + \beta^t U^t < 0$ . So the constraints  $u^t Ax \leq u^t b, L^t \leq x \leq U^t, x \geq 0$  are also infeasible. In other words, the bounds  $L^t \leq x \leq U^t$  are inconsistent with the surrogate  $u^t Ax \leq u^t b$ .

b) The solution of (19) is integral with value  $\bar{z}_t$ , where  $\bar{z}_t > z^{LB}$ . So the constraints

$$\begin{cases} -cx < -\bar{z}_t - \Delta z \\ Ax \leq b \\ -x \leq -L^t \\ x \leq U^t \end{cases} \quad (21)$$

are infeasible. If  $(u^t, \alpha^t, \beta^t)$  is the dual solution of (19), the multipliers  $(1, u^t, \alpha^t, \beta^t)$  prove infeasibility of (21). This means that the bounds  $L^t \leq x \leq U^t$  are inconsistent with the surrogate  $(u^t A - c)x < u^t b - \bar{z}_t - \Delta z$ .

c) The optimal value  $\bar{z}$  of (19) satisfies  $\bar{z} \leq z_t^{LB}$ , where  $z_t^{LB}$  is the current lower bound (the tree is pruned at this node). Here the bounds  $L^t \leq x \leq U^t$  are inconsistent with the surrogate  $(u^t A - c)x < u^t b - z_t^{LB} - \Delta z$ .

Thus there is a contradiction at every leaf node, because the bounds  $L^t \leq x \leq U^t$  are inconsistent with some surrogate at every leaf node.

The key to sensitivity analysis is that a contradiction remains at every leaf node, and the proof remains valid, so long as the bounds remain inconsistent with the surrogates after perturbation of the data. To analyze how much perturbation is possible, the following observation is helpful. The bounds  $L \leq x \leq U$  are inconsistent with inequality  $dx \leq \delta$  if and only if there exists a vector  $\bar{d} \geq 0$  such that

$$\begin{cases} dL - \bar{d}(U - L) > \delta \\ \bar{d} \geq d, \quad \bar{d} \geq 0. \end{cases} \quad (22)$$

Now let (5) be perturbed as follows:

$$\begin{cases} \max & (c + \Delta c)x \\ \text{s.t.} & (A + \Delta A)x \leq b + \Delta b \\ & x \geq 0 \text{ and integer.} \end{cases} \quad (23)$$

Thus the violated surrogate in case a) becomes  $u^t(A + \Delta A)x \leq u^t(b + \Delta b)$ , and similarly in cases b) and c). Using (22), the optimal value of (23) rises no more than  $\Delta z$  ( $\Delta z \geq 0$ ) if the perturbation satisfies the following

**Integer Programming Duality, Table 3**  
**Properties of five integer programming duals**

Type of dual	Strong duality?	Computational bounds?	Sensitivity analysis?	Complementary slackness?
Surrogate	No	Yes	Very limited, even if no duality gap	No
Lagrangian	No	Yes	For RHS, if no duality gap	Yes, if no duality gap
Superadditive	Yes	Not practical	For RHS only	Yes
Branch and bound	Yes	No	For RHS only	No
Interface	Yes	No	Bounds for all problem data	No

for some  $\bar{q}^t \geq 0$  at every leaf node  $t$ ,

$$\begin{cases} (q^t + \Delta q^t)L^t - \bar{q}^t(U^t - L^t) \\ \geq u^t(A + \Delta A) + z_t \\ \bar{q}^t \geq q^t + \Delta q^t, \quad \bar{q}^t \geq 0. \end{cases} \quad (24)$$

Here

$$\begin{aligned} q^t &= u^t A - u_0^t c, \\ \Delta q^t &= u^t \Delta A - u_0^t \Delta c, \\ (u_0^t, z_t) &= \begin{cases} (0, \epsilon) & \text{in case a),} \\ (1, \bar{z}_t + \Delta z) & \text{in case b),} \\ (1, z_t^{LB} + \Delta z) & \text{in case c).} \end{cases} \end{aligned}$$

This can be checked by linear programming. Note that the perturbations  $\Delta A, \Delta b, \Delta c$  are not restricted to be nonnegative. Ranges for any perturbation can be computed by minimizing and maximizing it subject to (24) with all other perturbations set to zero.

The dual solutions in Fig. 6 suffice to generate the inequalities (24) for the example problem (6). Leaf nodes 2, 3 and 4 respectively illustrate cases b), c) and a). For instance, the inequalities for leaf node  $t = 2$  are

$$\begin{aligned} -2\Delta c_1 - \Delta c_2 - 2\bar{q}_1^2 - \bar{q}_2^2 &\geq 0, \\ \bar{q}_1^2 &\geq -20 - \Delta c_1, \quad \bar{q}_1^2 \geq 0, \\ \bar{q}_2^2 &\geq -10 - \Delta c_2, \quad \bar{q}_2^2 \geq 0. \end{aligned}$$

At leaf nodes 3 and 4 one must assume some large but finite upper bound on variables  $x_j$  for which  $U_j$  is otherwise infinite. The resulting sensitivity range for  $b_1$  is given below, along with the ranges yielded by the superadditive dual, the branch and bound dual, and the true value function (the last three from Fig. 2).

- inference dual:  $-\infty < \Delta b_1 < 1$ ;
- superadditive dual:  $-\infty < \Delta b_1 < 0.375$ ;
- branch and bound dual:  $-\infty < \Delta b_1 < 1$ ;
- maximum range:  $-\infty < \Delta b_1 < 2$ .

No perturbation within the maximum range causes the optimal value to rise above 50. The various forms of sensitivity analysis generally provide more conservative ranges (the same is true of classical linear programming). This example shows that the superadditive dual, although the hardest to compute, does not necessarily provide the sharpest analysis. The inference dual, unlike the others, provides ranges for all problem data:

$$\begin{aligned} \begin{pmatrix} -\infty \\ -\infty \end{pmatrix} &< \Delta b < \begin{pmatrix} 1 \\ \frac{1}{2} \end{pmatrix}, \\ \begin{pmatrix} -\frac{1}{3} + \epsilon & -\frac{1}{3} + \epsilon \\ 0 & 0 \end{pmatrix} &\leq \Delta A < \begin{pmatrix} \infty & \infty \\ \infty & \infty \end{pmatrix}, \\ (0 \quad 0) &\leq \Delta c < (\infty \quad \infty). \end{aligned}$$

By setting  $\Delta z$  to 10 rather than zero in (24), one obtains ranges within which perturbations do not increase the optimal value more than 10, and so forth.

Like branch and bound duality, inference duality is computationally impractical if the branch and bound tree is too large, although it requires fewer data from the tree. It does not provide an explicit approximation of the value function as superadditive and branch and bound duality do. However, only inference duality provides easily computable sensitivity ranges, not only for right-hand sides but for all problem data.

**Conclusions**

Table 3 summarizes the properties of the various duals. The surrogate and Lagrangian duals are used primarily

for computational purposes, because they provide independent bounds on the optimal value. The remaining duals are useful for sensitivity analysis. The super-additive and branch and bound duals provide a more complete analysis of right-hand side sensitivity. The latter requires a branch and bound solution of the problem but considerably less computation. Inference duality requires a branch and bound solution and provides only sensitivity ranges, but ranges can be obtained for all problem data by solving linear programming problems.

One can also formulate a dual based on congruence relations [21] that is not discussed here. H.P. Williams provides an interesting discussion of this and some other duals (surrogate, Lagrangian, superadditive) in [22]. General treatments of Lagrangian and superadditive duality may be found in [17,19], with a brief discussion of surrogate duality in the former. Excellent presentations of Lagrangian duality appear in [6] and [1, Chap. 6].

Lagrangian relaxation; Integer programming; Lagrangian dual; Lagrange multipliers; Branch and bound

Relaxation is important in optimization because it provides bounds on the optimal value of a problem. One of the more popular forms of relaxation is Lagrangian relaxation, which is used in integer programming and elsewhere.

A problem is relaxed by making its constraints weaker, so that the feasible set is larger, or by approximating the objective function. In the case of a minimization problem, the optimal value of the relaxation is a lower bound on the optimal value of the original problem. For a maximization problem it is an upper bound. The art of relaxation is to design a relaxed problem that is easy to solve and yet provides a good bound.

## Purpose of Relaxation

Relaxation bounds are useful for two reasons. First, they can indicate whether a suboptimal solution is close to the optimum. If a minimization problem, for example, is hard to solve, one might settle for a suboptimal solution whose value is close to a known lower bound. An optimal solution would not be much better.

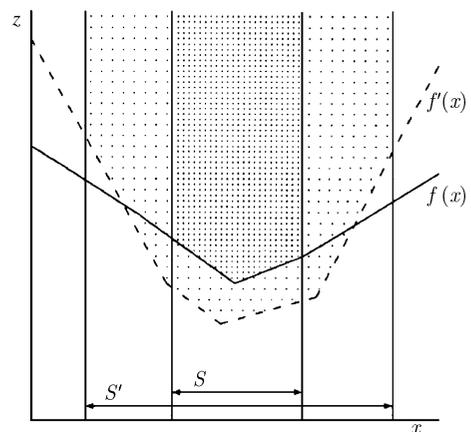

Second, relaxation bounds are useful in accelerating a search for an optimal solution. In a solution of an integer programming problem, for example, one normally solves a relaxation of the problem at each node of the *branch and bound* tree. Suppose again that the objective is to minimize. If the value of the relaxation at some node is greater than or equal to the value of a feasible solution found earlier in the search, then there is no point in branching further at that node. Any optimal solution

found by branching further will have a value no better than that of the relaxation and therefore no better than that of the solution already found. Lagrangian relaxation is often used in this context, because it may provide better bounds than the standard linear programming (LP) relaxation.

## Lagrangian Relaxation

Lagrangian relaxation is named for the French mathematician J.L. Lagrange, presumably due to the occurrence of what we now call Lagrange multipliers in his calculus of variations [2]. Because this form of relaxation changes the objective function as well as enlarging the feasible set, it is necessary to broaden the concept of relaxation somewhat.

Consider the problem of minimizing a function  $f(x)$  subject to  $x \in S$ , where  $x$  is a vector of variables and  $S$  the set of feasible solutions. The *epigraph* of the problem is the set of all points  $(z, x)$  for which  $x \in S$  and  $z \geq f(x)$ . This is illustrated in Fig. 1. The problem of minimizing  $f'(x)$  subject to  $x \in S'$  is a *relaxation* of the original problem if its epigraph contains the epigraph of the original problem. That is, a)  $S \subset S'$  and b)  $f(x) \leq f'(x)$  for all  $x \in S$ . Relaxation is therefore conceived as enlarging the epigraph; enlarging the feasible set is a special case. It is clear that the optimal value of a relaxation still provides a lower bound on the optimal value of the original problem.

**Integer Programming: Lagrangian Relaxation, Figure 1**  
Epigraph of an optimization problem  $\min \{f(x); x \in S\}$  (darker shaded area) and of a relaxation  $\min \{f'(x); x \in S'\}$  (darker and lighter shaded areas)

Lagrangian relaxation is available for problems in which some of the constraints are inequalities or equations. Such problems may be written as

$$\text{minimize } f(x) \quad (1)$$

$$\text{subject to } g(x) \leq 0 \quad (2)$$

$$x \in S. \quad (3)$$

Here,  $g(x)$  is a vector of functions  $(g_1(x), \dots, g_m(x))$ , and (2) is a family of  $m$  constraints  $g_i(x) \leq 0$ . There is no loss of generality in omitting equality constraints  $h_i(x) = 0$  from this formulation, because they can be written as two inequality constraints,  $h_i(x) \leq 0$  and  $-h_i(x) \leq 0$ . The constraints (3) may take any form, inequality or otherwise.

The *Lagrangian relaxation* is formed by ‘dualizing’ the constraints (2):

$$\left\{ \begin{array}{l} \min \quad f(x) + \lambda g(x) \\ x \in S. \end{array} \right. \quad (4)$$

Here,  $\lambda = (\lambda_1, \dots, \lambda_m)$  is a vector of nonnegative *Lagrange multipliers* that correspond to the inequality constraints. The aim of dualization is to remove the hardest constraints from the constraint set, so that the relaxed problem is relatively easy to solve.

The Lagrangian relaxation is in fact a relaxation because its epigraph contains the epigraph of the original problem (1)-(3). This can be verified by checking conditions a) and b):

- The feasible set of the original problem is a subset of the feasible set of the relaxation, because the relaxation omits some of the original constraints.
- If  $x$  is feasible in the original problem, then  $f(x) \geq f(x) + \lambda g(x)$ . This is because  $\lambda \geq 0$  and, due to the feasibility of  $x$ ,  $g(x) \leq 0$ .

### The Lagrangian Dual

A relaxation can be constructed simply by eliminating the constraints (2) rather than dualizing them. One might ask what is the advantage of dualization. One rationale is that when the Lagrange multipliers are properly chosen, the penalties  $\lambda_i g_i(x)$  in the objective function hedge against infeasibility. To the extent that constraints  $g_i(x) \leq 0$  are violated and the bound

thereby weakened, the objective function will be penalized, restoring the quality of the bound.

Fortunately one can search for a proper choice of multipliers. The Lagrangian relaxation is actually a ‘family’ of relaxations, parameterized by the vector  $\lambda$  of multipliers. This provides the possibility of searching over values of  $\lambda$  to find a relaxation that gives a good lower bound on the optimal value.

The problem of finding the best possible relaxation bound is the *Lagrangian dual* problem. If  $\theta(\lambda)$  is the optimal value of the relaxation (4), the Lagrangian dual of (1)-(3) is the problem of maximizing  $\theta(\lambda)$  subject to  $\lambda \geq 0$ .

Under certain conditions the best relaxation bound is equal to the optimal value of the original problem (1)-(3) [1]. Generally, however, it falls short. The amount by which it falls short is the *duality gap*.

The Lagrangian dual problem has three attractive features:

- It need not be solved to optimality. Any feasible solution provides a valid lower bound.
- Its objective function  $\theta(\lambda)$  is always a concave function of  $\lambda$ . One need only find a local maximum, which is necessarily a global maximum as well.
- Its solutions have a *complementary slackness* property. If certain  $\lambda_i$ 's are positive in an optimal solution of the dual problem, then the corresponding constraints  $g_i(x) \leq 0$  are satisfied as equations in some optimal solution of the primal problem (1)-(3).

A serious drawback of the Lagrangian dual is that simply evaluating the objective function  $\theta(\lambda)$  for a given  $\lambda$  normally requires solution of an optimization problem. The relaxation must be carefully chosen so that this is practical. Moreover the function  $\theta$  is typically nondifferentiable.

Why is the Lagrangian dual a ‘dual’? Perhaps because it generalizes the LP dual, which is the Lagrangian dual of an LP problem. To see this, consider the LP problem  $\min \{cx : Ax \geq a, x \geq 0\}$ . Its Lagrangian dual is to maximize

$$\begin{aligned} \theta(\lambda) &= \min_{x \geq 0} \{cx + \lambda(a - Ax)\} \\ &= \min_{x \geq 0} \{(c - \lambda A)x + \lambda a\} \end{aligned}$$

over  $\lambda \geq 0$ . So  $\theta(\lambda)$  is  $-\infty$  if some component of  $c - \lambda A$  is negative and is  $\lambda a$  otherwise. This means that

maximizing  $\theta(\lambda)$  over  $\lambda \geq 0$  is equivalent to maximizing  $\lambda a$  subject to  $\lambda A \leq c$  and  $\lambda \geq 0$ , which is precisely the LP dual.

The duality relationship holds more convincingly, however, between two problem-solving strategies: solution of strengthenings and solution of relaxations [12]. Methods that solve strengthenings include branching methods, local search heuristics, and other techniques that enumerate solutions or partial solutions by fixing some or all of the variables. Solution of each strengthening provides an upper bound on the optimal value, and the goal is to find the smallest upper bound. If the search is exhaustive, the smallest upper bound is equal to the optimal value.

The dual strategy is to solve relaxations of the problem in order to find the largest possible lower bound on the optimal value. There is no obvious way to enumerate relaxations, however, unless they are somehow parametrized, in which case one can enumerate values of the parameters. The Lagrangian dual is one way of doing this but by no means the only. Another is the *surrogate dual* [7,8,9], in which the relaxed constraint set is a nonnegative linear combination of inequality constraints, and relaxations are parametrized by the vector of multipliers in the linear combination. The dual approach also differs from the primal in that an exhaustive enumeration normally does not guarantee that the best bound obtained is equal to the optimal value. There is usually a duality gap.

## Integer Programming

The application of Lagrangian ideas to integer programming dates back at least to H. Everett [4]. In this arena the optimization problem (1)-(3) becomes,

$$\begin{cases} \min & cx \\ \text{s.t.} & Ax \leq a \\ & Bx \leq b \\ & x_j \text{ integer for all } j. \end{cases} \quad (5)$$

The 'hard' constraints  $Ax \leq a$  are dualized in the Lagrangian relaxation,

$$\begin{cases} \min & cx + \lambda(Ax - a) \\ \text{s.t.} & Bx \leq b \\ & x_j \text{ integer for all } j, \end{cases} \quad (6)$$

and  $\theta(\lambda)$  is the minimum value of this problem for a given  $\lambda$ . The optimal value  $z_{LD}$  of the Lagrangian dual is a lower bound on the optimal value  $z_{IP}$  of (5). It will be seen shortly that the bound  $z_{LD}$  is at least as good as the bound  $z_{LP}$  obtained by solving the LP relaxation of (5). (The LP relaxation is the result of dropping the integrality constraints.)

In the context of integer programming, the Lagrangian function  $\theta(\lambda)$  is not only concave but piecewise linear. This is because  $\theta(\lambda)$  is the maximum of a set of linear functions  $cx + \lambda(Ax - a)$  over all integral values of  $x$  that satisfy  $Bx \leq b$ .

A fundamental property of the Lagrangian dual is that  $z_{LD}$  is equal to the optimal value  $z_C$  of

$$\begin{cases} \min & cx \\ \text{s.t.} & Ax \leq a \\ & x \in \text{conv}(S), \end{cases} \quad (7)$$

where  $S$  is the set of integer points satisfying  $Bx \leq b$ , and  $\text{conv}(S)$  is the convex hull of  $S$  [6]. The Lagrangian dual can therefore be written as an LP problem, if a linear description of  $\text{conv}(S)$  is available.

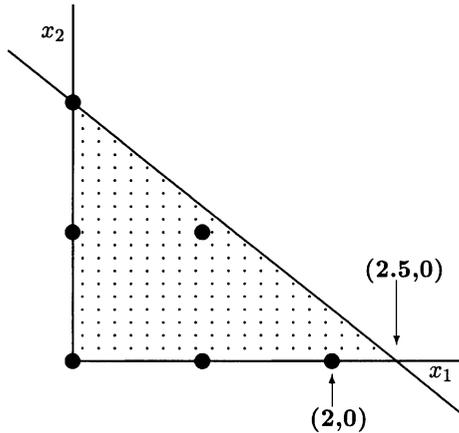

The reasoning behind this fact goes as follows. Because the feasible set of (7) is that of an LP problem, the optimal value of its Lagrangian dual is equal to  $z_C$ . To see that it is also equal to  $z_{LD}$ , thereby proving  $z_C = z_{LD}$ , it suffices to show that the Lagrangian relaxation of (7) always has the same optimal value as the Lagrangian relaxation of (5). But this is true because the former is the same problem as the latter, except that the constraints in former are  $x \in \text{conv}(S)$  and in the latter are  $x \in S$ . This substitution has no effect on the optimal value because the objective function is linear.

It can now be seen that the bound  $z_{LD}$  is always at least as good as  $z_{LP}$ . Let  $C_{IP}$  be the problem (7) corresponding to (5), and let  $C_{LP}$  be the problem (7) corresponding to the LP relaxation of (5).  $C_{LP}$ 's feasible set contains that of  $C_{IP}$ , and its optimal value is therefore less than or equal to  $z_{LD}$ . But because  $C_{LP}$  is identical to (5)'s LP relaxation,  $z_{LP} \leq z_{LD}$ .

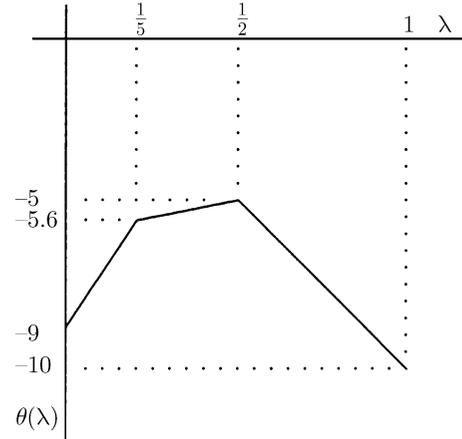

When  $Bx \leq b$  happens to describe a polyhedron whose vertices have integral coordinates,  $C_{IP}$  and  $C_{LP}$  are the same problem. In this case  $z_{LD} = z_{LP}$ .

To sum up,

$$z_{LP} \leq z_{LD} = z_C \leq z_{IP},$$

**Integer Programming: Lagrangian Relaxation, Figure 2**  
 Feasible set of an integer programming problem (large dots) and its linear programming relaxation (area shaded by small dots). The point (2, 0) is the optimal solution, and (2.5, 0) is the solution of the LP relaxation

**Integer Programming: Lagrangian Relaxation, Figure 3**  
 The Lagrangian function  $\theta(\lambda)$  for an integer programming problem. The optimal value of the Lagrangian dual problem is  $\theta(1/2) = -5$

where the first inequality is an equation when  $Bx \leq b$  describes an integral polyhedron.

As an example consider the integer programming problem (Fig. 2):

$$\begin{cases} \min & -2x_1 - x_2 \\ \text{s.t.} & 4x_1 + 5x_2 \leq 10 \\ & 0 \leq x_j \leq 3 \\ & x_j \text{ integer, } j = 1, 2. \end{cases} \quad (8)$$

The optimal solution is  $x = (2, 0)$ , with value  $z_{IP} = -4$ . Dualizing the first constraint decouples the variables:

$$\begin{aligned} \theta(\lambda) &= \min_{\substack{0 \leq x_j \leq 3 \\ x_j \text{ integer}}} \{-2x_1 - x_2 + \lambda(4x_1 + 5x_2 - 10)\} \\ &= \min_{\substack{0 \leq x_j \leq 3 \\ x_j \text{ integer}}} \{(4\lambda - 1)x_1 + (5\lambda + 1)x_2 - 10\lambda\}. \end{aligned}$$

Because of the decoupling,  $\theta(\lambda)$  is easily computed:

$$\theta(\lambda) = \begin{cases} 17\lambda - 9 & \text{if } 0 \leq \lambda \leq \frac{1}{5}, \\ 2\lambda - 6 & \text{if } \frac{1}{5} \leq \lambda \leq \frac{1}{2}, \\ -10\lambda & \text{if } \lambda \geq \frac{1}{2}. \end{cases}$$

It is evident in Fig. 3 that  $\theta$  is a concave, piecewise linear function. The optimal value of the Lagrangian dual is  $z_{LD} = \theta(1/2) = -5$ , resulting in a duality gap of  $z_{IP} -$

$z_{LD} = 1$ . The optimal value of the LP relaxation is likewise  $-5$ , so that in the present case  $z_{LP} = z_{LD}$ . This is predictable because  $Bx \leq b$  consists of the bounds  $0 \leq x_j \leq 3$ , which define an integral polyhedron.

In practical applications, the Lagrangian relaxation is generally constructed so that it can be solved in polynomial time. It might be a problem in which the variables can be decoupled, as in the above example, or whose feasible set is an integral polyhedron. Popular relaxations include assignment or transportation problems, which can be solved quickly.

A notable example is the *traveling salesman problem* on  $n$  cities:

$$\text{minimize } \sum_{ij} c_{ij}x_{ij} \quad (9)$$

subject to

$$\sum_j x_{ij} = 1, \quad \text{all } i, \quad (10)$$

$$\sum_i x_{ij} = 1, \quad \text{all } j, \quad (11)$$

$$\sum_{i \notin V} \sum_{j \in V} x_{ij} \geq 1, \quad \text{all nonempty } V \subset \{2, \dots, n\}, \quad (12)$$

$$x_{ij} \geq 0, \quad x_{ij} \text{ integral, all } i, j. \quad (13)$$

If the assignment constraints (10) are dualized, the Lagrangian relaxation minimizes

$$\begin{aligned} \sum_{ij} c_{ij}x_{ij} + \sum_i \lambda_i \left( \sum_j x_{ij} - 1 \right) \\ = \sum_{ij} (c_{ij} + \lambda_i)x_{ij} - \sum_i \lambda_i \end{aligned}$$

subject to (11)-(13). This is equivalent to finding a minimum-cost spanning arborescence that is rooted at node 1, which can be done in polynomial time [3]. Alternatively, the Lagrangian relaxation can be solved as an LP problem without the integrality constraints, because the same optimal value results [3]. See [10,14] for a survey of efforts along this line.

### Solving the Dual

Subgradient optimization is a popular method for solving the Lagrangian dual, because subgradients of  $\theta$  (and gradients when they exist) can be readily calculated.

Let  $X(\bar{\lambda})$  be the set of optimal solutions of the Lagrangian relaxation (4) when  $\lambda = \bar{\lambda}$ . If  $X(\bar{\lambda})$  is a singleton  $\{\bar{x}\}$ , then the gradient of  $\theta$  at  $\bar{\lambda}$  is simply the vector  $g(\bar{x})$ . This is because for values of  $\lambda$  in a neighborhood of  $\bar{\lambda}$ ,  $\theta(\lambda)$  is the linear function  $f(\bar{x}) + \lambda g(\bar{x})$ .

More generally, for any  $\bar{x} \in X(\bar{\lambda})$ ,  $g(\bar{x})$  is a subgradient of  $\theta$  at  $\bar{\lambda}$ . In fact, every subgradient of  $\theta$  at  $\bar{\lambda}$  is a convex combination of subgradients that correspond to the solutions in  $X(\bar{\lambda})$ .

In the integer programming case, the subgradients of  $\theta$  at  $\bar{\lambda}$  are  $A\bar{x} - a$  for each  $\bar{x} \in X(\bar{\lambda})$ , and convex combinations thereof. Consider the example (8), where

$$X(\lambda) = \begin{cases} \{(3, 3)\} & \text{if } 0 \leq \lambda < 1/5, \\ \{(3, 3), (3, 0)\} & \text{if } \lambda = 1/5, \\ \{(3, 0)\} & \text{if } 1/4 < \lambda < 1/2, \\ \{(3, 0), (0, 0)\} & \text{if } \lambda = 1/2, \\ \{(0, 0)\} & \text{if } \lambda > 1/2. \end{cases}$$

Thus at  $\lambda = 0$ ,  $\theta$  has the gradient (slope) of  $4(3) + 5(3) - 10 = 17$ . At  $\lambda = 1/5$ , the subgradients of  $\theta$  are 17, 2, and their convex combinations; i. e., all slopes in the interval [2, 17]. This can be seen in Fig. 3.

### Further Reading and Extensions

A lucid geometrical exposition of Lagrangian duality may be found in [1, Chap. 6]. A widely read treatment

of its application to integer programming is [5]. A recent tutorial is [11], which also surveys methods for solving the dual. [13, Sect. III.2.6] describes some methods for strengthening the Lagrangian relaxation. There is a vast literature on applications and enhancements.

The idea of the Lagrangian dual need not be limited to the use of Lagrange multipliers. A dual problem can be solved over any parametrized family of relaxations. The dual problem might be solved by a local search heuristic over the parameter space.

**Integrated Planning and Scheduling, Figure 1**  
Time relation between planning and scheduling

tors that affect the efficient operation of these systems. The main objective of integrated planning and scheduling is the allocation of resources that change dynamically over the time domain, and the coordination of the activities that are required to satisfy customer demand. One difference between planning and scheduling is the time scale over which the actions for these factors are triggered. During the planning phase, allocation of available resources and satisfaction of the given demand are made for a medium-term horizon that is usually expressed in months. During the scheduling phase, however, short-term allocation of available resources and the timing of the production of specific orders are the main decisions and these involve time scales of days to weeks.

During both planning and scheduling phases, the time horizon to be planned is divided into time slots. The main difference between planning and scheduling problems in terms of execution times is the length of time scales. Whereas the time scale for the planning phase is longer, the time scales for the scheduling phase are shorter as shown in Fig. 1.

For a realistic case, the time period for the planning phase is measured in weeks or months, therefore, total production and the inventory of each product at the end of each time period are the only performance issues for the system. For scheduling, however, the length of the time slots is measured in hours. Therefore in addition to the production quantity, the production sequence of each product becomes important during scheduling.

Traditionally planning and scheduling have been performed separately on the shop floor, but this decomposition of two activities leads to decreased efficiency of the operations performed in the production centers. Moreover, medium-term plans may result in infeasible projections if they are made without consideration of

### Introduction

Integrated planning and scheduling of events in production systems are among the most important fac-

short-term performance requirements, and conversely, short-term plans may cause myopic decisions without consideration of long-term performance issues.

Ideally, an integrated model is required in which planning and scheduling can be considered simultaneously. This model should include both medium-term capacity utilization and production level values and short-term production sequence and machine assignment decisions. Due to simultaneous consideration of medium- and short-term decisions, the representation of time slots is one of the primary concerns in integrated planning and scheduling problems.

### Representation of Time Slots

The first decision that should be taken during the modeling of the planning and scheduling of a system is the representation of time. Time can be represented in integrated planning and scheduling problems using discrete or continuous formulations [2]. The choice of time representation is related to whether an event in the system can take place only at predefined times or at any instant. If the events can take place only at predefined times, then a discrete time representation is required.

*Discrete Time Model:* In a discrete time model, the whole planning horizon is divided into predefined time intervals. This representation assumes that an event can occur only at the boundaries of each time interval [4]. Therefore, during the solution of the model, no planning horizons, other than the boundaries of a finite number of time slots, are considered, and this simplification makes the model more tractable. To express the exact behavior of the system during the planning horizon, however, the length of the time slots should be kept as short as possible, which may cause an explosive increase in the number of variables. On the other hand, increasing the length of time slots may give infeasible results.

*Continuous Time Model:* In the continuous time model an event can occur at any instant within the whole planning horizon. This makes the model more dependable and flexible and the total number of variables decreases. The representation of some constraints becomes more complex, however, and this decreases the tractability of the model [2].

*Mixed Time Representation:* A mixed time representation that includes both discrete and continuous time

has also been studied [3]. In this situation, the time slots are fixed and the durations of the processes are kept constant in discrete time. The durations of the process task are expressed as variables in the mixed time representation. This is accomplished by setting the durations of the process tasks to be multiples of a fixed time grid.

### Problem Definition

In this section, the model given by Dogan and Grossmann [1] is examined in detail. Given that several products are to be produced in a single production unit, the planning horizon is divided into planning periods of one week and each week-long planning period is divided into  $N$  time slots, where there are  $N$  products to be produced. At the end of each week, the demand is determined for each product. The production level in the system is constant and it is also a cost issue for the model. Transition time of production with respect to production sequence is given within this system.

The problem is the determination of products that should be produced each week and the sequencing of the production of these items. During sequencing, the production time, the amount and production duration are determined for each product. In addition, the inventory levels should be determined for each time period.

#### The MILP Model:

The objective of the model is the maximization of profit.

$$\begin{aligned} & \sum_i \sum_t p_{it} S_{it} - c_{inv} \sum_i \sum_t Area_{it} \\ & - \sum_i \sum_t c_{it}^{oper} X_{it} - \sum_i \sum_k \sum_l \sum_t c_{ik}^{trans} Z_{iklt} \\ & - \sum_t \sum_i \sum_k c_{ik}^{trans} TRT_{ikt} \quad (1) \end{aligned}$$

In the objective function,  $p_{it}$  is the price of product  $i$  in time period  $t$ ,  $S_{it}$  is the amount of sales of product  $i$  in time period  $t$ ,  $c_{inv}$  is the inventory cost,  $Area_{it}$  is the area below the inventory versus time graph for product  $i$  at time period  $t$ ,  $c_{it}^{oper}$  is the operating cost for product  $i$  in time period  $t$ ,  $X_{it}$  is the amount of the product  $i$  produced in time period  $t$ ,  $c_{ik}^{trans}$  is the transition cost from product  $i$  to product  $k$ ,  $Z_{iklt}$  is a binary variable that indicates that production of product  $i$  is followed by product  $k$  in time slot  $l$  of the time period  $t$ , and  $TRT_{ikt}$  is

a binary variable that denotes production of product  $i$  is followed by product  $k$  at the end of time period  $t$ .

The first term of the objective function gives the revenue generated, the second term is the inventory cost, the third term is the total operation cost, the fourth term is the transition cost within each week, and the last term is the transition cost between each week.

The assignment of production orders and corresponding processing times for each order are given by the following:

$$\sum_i W_{ilt} = 1 \quad \forall l, t \quad (2)$$

$$0 \leq \tilde{\theta}_{ilt} \leq H_t W_{ilt} \quad \forall i, l, t \quad (3)$$

$$\theta_{it} = \sum_l \tilde{\theta}_{ilt} \quad \forall i, t \quad (4)$$

$$\tilde{X}_{ilt} = r_i \tilde{\theta}_{ilt} \quad \forall i, l, t \quad (5)$$

$$X_{it} = \sum_l \tilde{X}_{ilt} \quad \forall i, t \quad (6)$$

In Eqs. (2)–(6),  $W_{ilt}$  is a binary variable that denotes the production of product  $i$  in the time slot  $l$  of the time period  $t$ ,  $\tilde{\theta}_{ilt}$  is the production time of product  $i$ , in time slot  $l$  of the time period  $t$ ,  $H_t$  is the length of time period  $t$ ,  $X_{it}$  is the total production time of the product  $i$  in the time period  $t$ , and  $\tilde{X}_{ilt}$  is the production amount of product  $i$  in time slot  $l$  of the time period  $t$ .

Equation (2) states that only one product can be produced in the each time slot. According to Eq. (3), the production time of product  $i$ , at time slot  $l$  of the time period  $t$  will be zero, if this product is not assigned to time slot  $l$  of time period  $t$ . Equation (4) states that the total production time of the product  $i$ , at time period  $t$  is equal to the sum of the production time of this product during time slots of the corresponding time period. Equation (5) represents the total production amount of product  $i$ , during time slot  $l$  of the time period  $t$ , and Eq. (6) calculates the total production of product  $i$ , during the time period  $t$ .

The transition from one product to another product is expressed by the following constraint:

$$Z_{iklt} \geq W_{ilt} + W_{k,l+1;t} - 1 \quad \forall i, k, l, t \quad (7)$$

Equation (7) ensures that if product  $k$  is produced after product  $i$ , in the time period  $l$ , then  $Z_{iklt}$  will be equal to 1, otherwise it will be 0.

An important consideration is the starting and ending times for each task in the production schedule. The following constraints are used to calculate them:

$$Te_{lt} = Ts_{lt} + \sum_i \tilde{\theta}_{ilt} + \sum_i \sum_k \tau_{ik} Z_{iklt} \quad \forall l, t \quad (8)$$

$$TRT_{ikt} \geq W_{ilt} + W_{k,ll,t+1} - 1 \quad \forall i, k, t, l = N, ll = 1 \quad (9)$$

$$Te_{lt} + \sum_i \sum_k \tau_{ik} TRT_{ikt} = Ts_{ll,t+1} \quad \forall t, l = N, ll = 1 \quad (10)$$

$$Te_{lt} = Ts_{l+1t} \quad \forall l \neq N, t \quad (11)$$

$$Te_{Nt} \leq HT_t \quad \forall t \quad (12)$$

In Eq. (8),  $Te_{lt}$  is the end of the time slot  $l$  of the time period  $t$ ,  $Ts_{lt}$  is the start time of the time slot  $l$  of the time period  $t$  and  $\tau_{ik}$  is the transition time between product  $i$  and product  $k$ . Equation (8) states that the end of time slot  $l$  of time period  $l$  is equal to the start time plus the total processing time for the products produced in that slot and the total transition time. In Eq. (9),  $TRT_{ikt}$  is equal to 1, if at the end of period  $t$  production of product  $i$  takes place, and at the beginning of the time period  $t+1$  production of product  $k$  takes place.

Equations (10) and (11) ensure the connectivity between consecutive time periods. In Eq. (12),  $HT_t$  is the length of the time period  $t$  and Eq. (12) also ensures that the end time of the last time slots in each time period cannot be greater than the length of the corresponding time period.

The inventory levels for each product are updated with the following constraints:

$$INV_{it} = INV_{i0} + \sum_l r_i \tilde{\theta}_{ilt} \quad \forall i, t = 1 \quad (13)$$

$$INV_{it} = INVO_{it-1} + \sum_l r_i \tilde{\theta}_{ilt} \quad \forall i, t \neq 1 \quad (14)$$

$$INVO_{it} = INV_{it} - S_{it} \quad \forall i, t \quad (15)$$

$$Area_{it} \geq INVO_{it-1} H_t + r_i \theta_{it} H_t \quad \forall i, t \quad (16)$$

In Eq. (13),  $INV_{it}$  is the inventory level of the product  $i$  at time period  $t$  and  $INV_{i0}$  is the initial in-

ventory of product  $i$ . Equation (13) updates the inventory of each product in the first time period. In Eq. (14),  $INVO_{it-1}$  is the inventory of product  $i$  at time period  $t-1$  after demand of that product is satisfied. Equation (14) establishes the inventory and production quantity relationship for all periods other than initial time period. According to Eq. (15), the amount of inventory of product  $i$  after demand of it is satisfied is equal to total inventory of product  $i$  minus sales of this product for each time period. In Eq. (16)  $Area_{it}$  is the area below the inventory versus time plot for product  $i$  at time period  $t$ . As the exact area is nonlinear the equation overestimates this area.

The demand for products is incorporated into the integrated planning and scheduling model with the following constraints:

$$S_{it} \geq d_{it} \quad \forall i, t \tag{17}$$

$$NY_{it} = \sum_l W_{ilt} \quad \forall i, l, t \tag{18}$$

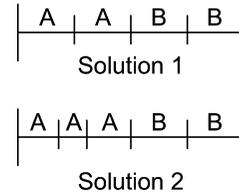

$$YOP_{it} \geq W_{ilt} \quad \forall i, l, t \tag{19}$$

$$YOP_{it} \leq NY_{it} \leq NYOP_{it} \quad \forall i, t \tag{20}$$

$$NY_{it} \geq N - \left[ \left( \sum_i YOP_{it} \right) - 1 \right] - M(1 - W_{ilt}) \quad \forall i, t \tag{21}$$

$$NY_{it} \leq N - \left[ \left( \sum_i YOP_{it} \right) - 1 \right] - M(1 - W_{ilt}) \quad \forall i, t \tag{22}$$

In Eqs. (17)–(22), the  $d_{it}$  is the demand for the product  $i$  at time period  $t$ ,  $NY_{it}$  is the number of time slots during which product  $i$  is produced in the time period  $t$ ,  $YOP_{it}$  is a binary variable that shows whether product  $i$  is produced during time period  $t$  and  $M$  is a sufficiently large number. In Eq. (17), the lower bound of demand satisfied is ensured. In Eq. (18), the number of time slots during which product  $i$  is produced within the time period  $t$  is found. Equation (19) ensures that if production of product  $i$  at time slot  $l$  of time period  $t$  takes place, then  $YOP_{it}$  will be equal to

**Integrated Planning and Scheduling, Figure 2**  
An example of degenerate solution

1. In Eqs. (21) and (22) the occurrence of a degenerate solution is prevented. According to the model formulation, if production of a product takes place in more than one time slot in the given time period, these time slots should be consecutive. If the production takes place in non-consecutive time slots, then the solution obtained will be suboptimal because of the existence of transition costs. The reason for degeneracy in this consecutive production is illustrated in Fig. 2.

As seen in Fig. 2 both solutions give the same objective value since the total production time of all products is the same and therefore, without Eqs. (21) and (22) the model formulation will be highly degenerate.

**Solution Strategy**

The integrated planning and scheduling model presented in Eqs. (1)–(22) gives rise to a complex mixed-integer programming problem. In the model, inventory and demand satisfaction trends are observed weekly because these two performance issues are planned in the medium-term time horizon. Timing and assignment constraints, however, are applied for each time slot within a week. An important assumption in this model is the production center. It is assumed that there is only one production center that carries out all of the planning and scheduling activities but the model is intractable even for this specific case of the problem. This intractability is not specific to this formulation as most planning and scheduling models that include realistic details are intractable. Two approaches are considered for addressing the intractability of the problem. In the first approach, an integrative model is first formulated and then, with respect to some defined criterion, a decomposition scheme is applied to the model. In the second approach, a simple modeling technique such as single-item capacitated or incapacitated lot sizing is formulated and then a superposition of all the en-

tire simple models is derived to apply to the planning and scheduling scheme.

In the first approach, both planning and scheduling problems are considered in an integrative manner and the quality of the result depends on the decomposition scheme. The aim of the decomposition is to decrease of the intractability of the model by removing from the formulation those details that make the model computationally complex. These details are the scheduling constraints that ensure feasibility on the shop floor. In this approach, an iterative solution is applied to make the problem computationally tractable while generating feasible schedules.

According to this method, an integrative planning and scheduling model is first constructed and then the details that make the model difficult to solve are removed or aggregated on the time domain or with respect to common parts. This high-level model is solved to obtain a temporary solution that is then applied with respect to the scheduling criteria. If the obtained solution is feasible on the shop floor, it is accepted. Otherwise, the system returns to the high-level model and changes it to make it to produce a feasible plan. The success of the results of the high-level plan depends on the accuracy of this model. If the model is not accurate enough to produce a feasible solution, much iteration can be done, although this is undesirable for the dependability and tractability of the model.

To avoid the direct solution of the integrated MILP planning and scheduling model, a bilevel decomposition algorithm that applies a hierarchical decomposition scheme has been proposed by Dogan and Grossmann [1]. In this scheme, the original model is decomposed into two separate models. The first model is the upper-level planning model that determines the products to be produced and the level of production and inventory in each time period. The second model is the lower-level planning and scheduling model that is modeled initially. In the lower-level problem, the original model formulation is solved by only applying it to the products that the upper-level planning model has decided to produce.

The upper-level planning problem is an MILP model and it is used to predict an upper bound for the original model formulation. This is obtained by ignoring the detailed sequencing constraint that is important for scheduling model. The result of the lower-

level model, which is obtained by using the result of the upper-level model, creates a lower bound for the global optimum. As the lower-level model which is solved with respect to the result of high-level planning problem is a sub-problem of the original model, the result produced is feasible.

The proposed algorithm is applied in an iterative manner. The upper bound found by the upper-level planning problem and the lower-bound found by the detailed planning and scheduling model are compared. If the difference between these bounds is less than some predefined tolerance value, the algorithm terminates. Otherwise, some integer and logic cuts are added to the upper-level planning model to obtain a more refined solution for the original model.

Zhu and Majozi [6] proposed another decomposition algorithm to address the intractability of a planning and scheduling model for multipurpose batch plants. They classified the economic concerns of the model as part of the planning problem and sequencing concerns of the model as a part of the scheduling problem. The proposed decomposition scheme of the detailed planning and scheduling problem is based on the assumption of a block angular structure for the model. With respect to the block angular structure of the model, there should be two types of blocks in the model. The first type is the constraints that are common for all plants in the system. In the multi-plant model, the first blocks are concerned with the allocation of resources, such as raw materials and labor. The second type of blocks concern the set of constraints that are specific to each plant. These second-type blocks intersect with the sequence of resources allocated by the constraints of the first block. In the context of the planning and scheduling problem, the first type of blocks represent the planning problem and the second type of blocks represent the scheduling problem for each plant, separately. The proposed solution lies in the extraction of the block angular structure of the integrated model. After this step, the model is decomposed into two separate parts: The first part consists of only planning blocks. Within these constraints, the allocations of common resources are planned so that they can be classified as part of the model for the planning problem. The second part consists of only scheduling blocks, which include separate sets of constraints for each plant. In this second part the aim is to obtain the

optimal schedule for each plant and therefore it is classified as a scheduling problem.

To apply this decomposition scheme successfully, the integrated model must satisfy two main conditions. The first condition is the convexity of the constraints. If that is the case, the feasible region of the integrated model will form a convex set. Therefore, the schedules obtained from the separate scheduling block problems for a given optimal resource allocation will provide the global optimal solution of the integrated model. The second condition to be satisfied is the block angular decomposability of the integrated model formulation. It is necessary to show that all scheduling constraints can be separated into a non-intersecting set of constraints in order to satisfy this condition. This makes the scheduling part of the decomposition scheme, plant specific. On the shop floor this structure can be achieved if manufacturing of the products begin and end in the same plant.

After the model has been decomposed, an iterative solution approach is applied to get the feasible and near optimal schedule. First the planning problem that includes *A* blocks is solved and the allocation of the common resources to the each plant is obtained. Then this result is incorporated into separate scheduling models to produce detailed schedules for each plant. If the results of the scheduling problems do not match the targets of the planning problem, the planning problem is resolved with the results obtained from scheduling problem. This procedure continues until the differences between the results of the planning problem and scheduling problems converge to a small threshold value.

In the second approach, superposition of the simple and frequently studied models such as lot-sizing models is used. Pocket and Wolsey [5] proposed a single item decomposition method to deal with the intractability problem. In this method, a capacitated lot-sizing problem is solved for each finished product individually. This model is solved to satisfy the demand for the end product and the inventory and production quantity of the end product are also monitored during the solution process. The proposed model is solved only for single product and multi-product cases, however, and as some products may share common resources, there may be infeasibilities when the schedules are combined. The superpositioning of individual models is re-

quired in order to address this problem. The bill of materials (BOM) should be used during the superposition since each end product is produced by using many intermediate products. The single-item decomposition technique begins by solving a capacitated lot-sizing model for each product, which is the master production scheduling (MPS) model [5]. After the solution of the MPS, the batch size of each product during the planning horizon is obtained. The batch sizes are decomposed into batches of intermediate products by using the BOM. A rough cut capacity planning (RCCP) is executed in parallel to roughly check the feasibility of the MPS model with respect to the capacity available. In cases of infeasibility, the MPS model is revisited or the capacity of the rare resource is increased.

## Conclusions

The execution of planning and scheduling tasks separately on the shop floor causes infeasible and sub-optimal decisions. To prevent these problems, it is necessary to optimize the planning and scheduling tasks simultaneously but models in which planning and scheduling are integrated can become computationally intractable because of the highly complex structure of the model. To deal with this problem, two approaches can be used. In the first approach the detailed planning and scheduling model is decomposed into simpler ones, and these models are solved iteratively with the detailed original model until a feasible solution that has satisfactory objective value is obtained. In contrast, in the second approach, a single model is solved for each product individually and then superposition of these models is used to determine the feasibility of the results with respect to some shared resources.

Interior-point methods; Positive semidefinite matrices; Barrier function; Potential function; Central path; Path-following; Newton's method

The problem of optimizing a linear function of an unknown symmetric positive semidefinite matrix, subject to finitely many linear equations and inequalities, is called the *semidefinite programming* (SDP) problem. As is clear from the above definition, the SDP problem is a generalization of the very well known linear programming (LP) problem.

Parallel to the great success of LP in applications, at the time of this writing, there is a tremendous amount of activity and excitement regarding the applications of SDP. Even at these early stages of the development, the applications are far-reaching.

The SDP problem brings together many fields of engineering, computer science and mathematics. The theory and practice of SDP both draw from and contribute

to a very large number of fields. For applications in combinatorial optimization see [4], for eigenvalue optimization see [8], and for applications in engineering, system and control theory see [22]. Also see the special issue of *Mathematical Programming* dedicated to SDP [14], as well as the *Handbook on Semidefinite Programming* [18] and the proceedings of a Fields Institute workshop [15].

### Preliminaries

Let a symmetric  $n \times n$  matrix  $X$  with real entries be given. Then  $X$  is *positive semidefinite*, denoted  $X \succeq 0$ , if  $u^T X u \geq 0$  for all  $u \in \mathbb{R}^n$ .  $X$  is *positive definite*, denoted  $X \succ 0$ , if  $u^T X u > 0$  for all  $u \in \mathbb{R}^n \setminus \{0\}$ . To define linear functions of this variable  $X$ , one equips the space of  $n \times n$  matrices with an inner-product:  $\langle C, X \rangle$  denotes the trace of  $(C^T X)$ . Using this notation, one can define a specific form of the SDP problem. Let a symmetric  $n \times n$  matrix  $C$ , a column vector  $b$ , and  $m$  symmetric  $n \times n$  matrices  $A_1, A_2, \dots, A_m$  be given. Then the following is the primal form of SDP:

$$(P) \min \langle C, X \rangle, \\ \langle A_i, X \rangle = b_i, \quad i \in \{1, \dots, m\}, \\ X \succeq 0.$$

Any SDP problem can be put into the above form. The dual of (P) can be defined (similarly to the LP dual) as follows:

$$(D) \max b^T y, \\ \sum_{i=1}^m y_i A_i + S = C, \\ S \succeq 0.$$

Without loss of generality, it can be assumed that the matrices  $A_1, A_2, \dots, A_m$  are linearly independent. If they are linearly dependent, then either the system  $\langle A_i, X \rangle = b_i, i \in \{1, \dots, m\}$  has no solution, or there are some redundant equations which can be eliminated. In the first case, (P) is infeasible. In the second case, all redundant equations and corresponding  $A_i, b_i$  can be eliminated, to arrive at an equivalent problem satisfying the assumption. Under this assumption, for any solution,  $(y, S)$ , of the equation  $\sum_{i=1}^m y_i A_i + S = C$ , the  $S$  part of the solution uniquely identifies  $y$ . Sometimes, in interior-point algorithms, it is convenient to refer only to  $S$  when one mentions a feasible solution of (D).

Even though one writes “min” and “max” in the definitions of  $(P)$  and  $(D)$ , the optimum values of these problems may not be attained, and even if they are attained, primal and the dual objective values may not equal each other. Thus, the duality theory for SDP is quite a bit more complicated than that for LP. (See [16] and the references therein, for a discussion of various duals and duality theorems.)

However, if we assume that there exists

$$X^{(0)} \succ 0$$

such that

$$\langle A_i, X^{(0)} \rangle = b_i, \quad i \in \{1, \dots, m\}$$

and that there exists  $(y^{(0)}, S^{(0)})$  such that

$$\sum_{i=1}^m y_i^{(0)} A_i + S^{(0)} = C, \quad S^{(0)} \succ 0,$$

then the duality theory guarantees that the optimum values of both problems  $(P)$  and  $(D)$  are attained and that they are equal.

Now, we introduce the very general notion of *interior-point methods*. These are the methods of solving convex optimization problems by generating a sequence which lies in the relative interior of a convex set defined by the “difficult” constraints. In this definition, one envisions an abstract formulation of convex optimization problems in which one has a maximal set of linear equality constraints and some convex set constraint. The convex set constraint is the “difficult” constraint.

The basic idea of interior-point methods goes back at least to Frisch [3] (1950s) and to Fiacco and McCormick [2] (1960s). However, the current modern interior-point algorithms have their origins in Karmarkar’s groundbreaking work [6].

The general definition above does not refer to the fact that much of the interest is in the algorithms that can be proven to generate approximately optimal solutions in polynomially many iterations in the dimension of the problem and a desired accuracy, prescribed as a part of the input. The amount and the type of work required per iteration will be described shortly. Certain practical variants of such interior-point algorithms turn out to be very fast and robust for a wide range of applications. Indeed, as in just like any other optimization problem, the algorithms which perform very well

in extensive computational tests spark great interest for theoretical investigations in the area to further our comprehension of the efficiency of the interior-point methods as well as our understanding of the degree of difficulty of certain SDP problems for interior-point approaches.

At the time of this writing, the most popular algorithms are the primal–dual ones. These algorithms work almost equally hard in improving both the primal and the dual solutions. However, for certain applications, primal-only (or dual-only) algorithms, which work almost exclusively on the primal problem and use the dual to only generate bounds on the optimum value, are indispensable. This is usually due to the special structure of the problem at hand. The main ingredients of interior-point methods for SDP will be illustrated for primal-dual algorithms.

Interior-point algorithms can be classified with respect to many criteria. A rather obvious criterion is the initial iterate  $(X^{(0)}, y^{(0)}, S^{(0)})$ . All interior-point algorithms start with  $X^{(0)} \succ 0$ ,  $S^{(0)} \succ 0$ , and keep all iterates positive definite. If the algorithm allows  $X^{(0)}$  or  $(y^{(0)}, S^{(0)})$  not to satisfy the corresponding equality constraints, then the algorithm is called an *infeasible-start interior-point algorithm*. In this article, the illustration of the details of the methods will be done mostly for feasible starting points.

If  $X$  is feasible in  $(P)$  and  $(y, S)$  is feasible in  $(D)$ , then

$$\langle C, X \rangle - b^T y = \langle X, S \rangle \geq 0.$$

In the above,  $\langle X, S \rangle = 0$  if and only if both  $X$  and  $(y, S)$  are optimal in their respective problems. For the above reasons,  $\langle X, S \rangle$  is called the *duality gap*.

Next, some important concepts used in the making of an interior-point algorithm are mentioned. Once the initial iterate,  $(X^{(0)}, y^{(0)}, S^{(0)})$ , such that  $X^{(0)} \succ 0$ ,  $S^{(0)} \succ 0$ , is given, one needs to generate a *search direction*  $(d_x, d_y, d_s)$  along which to move. Then a *step size*  $\alpha > 0$  describing how much to move in the given search direction must be determined. Practical methods allow two different step sizes: one for the primal iterate  $X^{(k)}$ , and the other for the dual iterate  $(y^{(k)}, S^{(k)})$ . Below, the main steps of a very basic interior-point algorithm for SDP are given. For this description and the rest of the article a common step size  $\alpha$ , for both iterates, is used.

The way in which the search directions and the step sizes are determined has a very significant impact on

```

InputInstance( $C, A_1, \dots, A_m, b, X^{(0)}, y^{(0)}, S^{(0)}, \epsilon$ );
iteration counter  $k := 0$ ;
WHILE  $\langle X^{(k)}, S^{(k)} \rangle > \epsilon$  DO
    find a search direction  $(d_x, d_y, d_s)$ ;
    find a step size  $\alpha > 0$  such that
         $X^{(k)} + \alpha d_x > 0, S^{(k)} + \alpha d_s > 0$ ;
    set  $(X^{(k+1)}, y^{(k+1)}, S^{(k+1)}) :=$ 
         $(X^{(k)}, y^{(k)}, S^{(k)}) + \alpha(d_x, d_y, d_s)$ ;
    set  $k := k + 1$ ;
END{WHILE};
OUTPUT( $X^{(k)}, y^{(k)}, S^{(k)}$ )

```

### Interior Point Methods for Semidefinite Programming, Algorithm 1

#### Main steps of an interior-point algorithm

the performance of interior-point methods. Two of the main theoretical foundations for choosing the search direction are mentioned below.

#### Path-Following Algorithms

Many practical algorithms are influenced by this foundation. One first picks a *barrier function*,  $F(X)$ . This is a function which is defined on the set of symmetric, positive-definite matrices such that for every sequence of matrices from this set, converging to a point on the boundary of the set, the value of  $F$  tends to infinity. For improved theoretical and/or practical performance, one must enforce further conditions on the barrier function. For the purposes of this article, the barrier function (which does possess many of the such desired properties) is

$$F(X) := -\ln \det X,$$

the negation of the logarithm of the determinant of  $X$ . Consider the family of optimization problems parameterized by  $\mu > 0$ :

$$\begin{aligned}
 (P_\mu) \quad & \min \langle C, X \rangle + \mu F(X), \\
 & \langle A_i, X \rangle = b_i, \forall i, \\
 & X \geq 0.
 \end{aligned}$$

The unique minimizer of this optimization problem defines a point  $(X(\mu), y(\mu), S(\mu))$  on the *primal-dual central path*. Here,  $y(\mu)$  and  $S(\mu)$  represent the dual variables for the equality and the semidefiniteness constraints of  $(P_\mu)$ , respectively. As  $\mu \rightarrow 0$ ,

$(X(\mu), y(\mu), S(\mu))$  converges to the optimal solutions of  $(P)$  and  $(D)$ .

The primal-dual central path can be expressed more explicitly.  $(X(\mu), y(\mu), S(\mu))$  is the unique solution of the following system

$$\begin{aligned}
 \langle A_i, X \rangle &= b_i, \quad \forall i, X \succ 0, \\
 \sum_{i=1}^m y_i A_i + S &= C, \\
 S &= \mu X^{-1}.
 \end{aligned}$$

Path-following algorithms choose the search direction to approximately follow this path. They are usually based on *Newton's method* or are related to it. For a review of such search directions, see [7] and [19].

#### Potential Reduction Algorithms

For these algorithms, one defines a *potential function*, based on a barrier function, to measure how good a given point is with respect to the duality gap and the proximity to the central path:

$$\phi(X, S) := (n + q) \ln \langle X, S \rangle + F(X) + F(S).$$

One chooses  $q := \Theta(\sqrt{n})$  for (current) the best theoretical complexity results and  $q := \Theta(n)$  or larger for better practical performance. In this setting, the search directions are usually obtained by computing a *steepest-descent direction* for the potential function  $\phi(X, S)$  and projecting it onto the appropriate linear subspace to satisfy the equality constraints in  $(P)$  and  $(D)$ .

#### Step Size

Once the search direction  $(d_x, d_y, d_s)$  is computed, then a practical interior-point algorithm usually calculates  $\alpha$  as a constant fraction of the maximum step size that keeps the next iterate positive definite. In a path-following algorithm for robustness of the performance, or good theoretical results, one might want to confine all (or some) of the iterates into a neighborhood of the central path. In a potential reduction algorithm, one usually chooses the value of  $\alpha$  as the minimizer of  $\phi$  along the given search direction. There are many other possibilities, see the potential reduction survey [20] and the references therein (such as [11] and [12]).

Currently, interior-point methods provide the fastest algorithms in theory with respect to the worst-case complexity bounds proven so far. In the current

practice, interior-point methods also provide the fastest and most robust solution techniques for general SDP problems. One such theoretical result can be summarized as follows.

**Theorem:** Let  $X^{(0)}, y^{(0)}, S^{(0)}$ , a feasible solution of (P) and (D), and  $\epsilon > 0$  such that

$$n \ln \left( \frac{\langle X^{(0)}, S^{(0)} \rangle}{n} \right) + F(X^{(0)}) + F(S^{(0)}) \leq \sqrt{n} \ln(1/\epsilon)$$

be given. Then (certain variants of) the potential-reduction interior-point algorithm described above will generate in  $O(\sqrt{n} \ln(1/\epsilon))$  iterations feasible interior points  $X, S$  such that

$$\langle X, S \rangle \leq \epsilon \langle X^{(0)}, S^{(0)} \rangle.$$

In the above theorem, the function

$$n \ln \left( \frac{\langle X, S \rangle}{n} \right) + F(X) + F(S)$$

is a proximity measure. It is nonnegative for every pair of interior points  $(X, S)$ . It is equal to zero if and only if  $(X, S)$  lies on the central path (for  $\mu := \langle X, S \rangle/n$ ).

Alizadeh [1], and Nesterov and Nemirovskii [10] independently generalized interior-point methods to SDP problems. The above theorem is a specialization of a more general result for *convex programming* problems from [10]. A similar result was independently obtained for SDP [1].

### Search Directions

In obtaining search directions, both path-following and potential reduction approaches end up with some linear system of equations, defined by the input of the problem, the current iterate  $(X^{(k)}, S^{(k)})$  and some other parameters of the algorithm. The resulting system has the following structure:

$$\begin{aligned} \langle A_i, d_x \rangle &= r_i^{(P)}, \quad \forall i, \\ \sum_{i=1}^m (d_y)_i A_i + d_s &= r^{(D)}, \quad \mathcal{E}d_x + \mathcal{F}d_s = r^{(XS)}, \end{aligned}$$

where  $r^{(P)}$  is an  $m$ -vector representing the primal residual (infeasibility of  $X^{(k)}$ ),  $r^{(D)}$  is an  $n \times n$  symmetric matrix representing the dual residual (infeasibility of

$(y^{(k)}, S^{(k)})$ ), and  $\mathcal{E}$  and  $\mathcal{F}$  are linear operators on  $n \times n$  symmetric matrices. The operators  $\mathcal{E}$  and  $\mathcal{F}$  vary from one algorithm to the next and depend on the current iterate, as well as some other parameters of the underlying algorithm. The choice of  $\mathcal{E}$  and  $\mathcal{F}$  can have profound theoretical and/or practical effects on the performance of the algorithm. Finally,  $r^{(XS)}$  denotes an  $n \times n$  symmetric matrix, a residual related to the desired value of  $\langle X, S \rangle$  for the next iterate as well as the desired value of the proximity measure for the next iterate.

In solving such systems to determine the search directions, many tools from numerical analysis become relevant. Moreover, one must exploit the existing structure of the problem at hand to be able to efficiently solve the large-scale instances.

As shown in [10], many of the fundamental ideas of interior-point methods can be applied to general convex programming problems. For primal-dual interior-point algorithms for general convex programming problems, see also [9] and [21]. The most general theoretical results in this direction rely on the existence of very special barrier functions for every convex set (see [10], also see [5] for connections of interior-point methods to many other branches of mathematics via the barrier functions for SDP and more general convex optimization problems).

Another important issue is that of the initial point and the detection of infeasibility in interior-point methods. For such problems, the quality of the initial point and the value of the *condition measures* (measuring in the input space how far a given instance is from the boundary separating feasible and infeasible instances, etc. [17]) for the given instance are good attributes for evaluating the performance of the methods.

Interval analysis; Process design; Process simulation; Process synthesis; Process optimization

Interval analysis can provide valuable tools in several aspects of chemical process design, including steady-state process simulation and optimization, and the initial synthesis and screening of process alternatives. The discussion below highlights the use of interval analysis in these areas. For a general description of problems and issues in chemical engineering design, see [8] and [7].

## Process Simulation

Process simulators are used to compute the performance of a chemical process given its design (the *process simulation* problem), or to compute a design that meets given performance specifications (the *process design* problem). In either case, the central problem in steady-state process simulation is the solution of an  $n \times n$  system of nonlinear algebraic equations  $\mathbf{f}(\mathbf{x}) = \mathbf{0}$ , where  $n$  may be very large (hundreds of thousands or more) and the equation system represents a mathematical model of the process, including material and energy balances, thermodynamic equilibrium relationships, and other equations needed to describe the process.

For solving the process model, Newton and quasi-Newton methods are widely used, but may not reliably converge, especially since a good initial guess is often hard to obtain. To improve convergence in these circumstances, various approaches have been used. These include trust region techniques, such the *dogleg method* [4], and *homotopy continuation* methods (e. g., [10]).

---

## Interval Analysis: Application to Chemical Engineering Design Problems

MARK A. STADTHERR

Department Chemical Engineering,

University Notre Dame, Notre Dame, USA

An additional difficulty is that in process simulation there are invariably upper and lower bounds on the variables,  $\mathbf{x}^L \leq \mathbf{x} \leq \mathbf{x}^U$ , violation of which may cause some functions to become undefined. Bounds are often dealt with in an ad hoc manner involving truncation or reflection of the correction step. A more natural way of dealing with bounds is to use a mathematical programming approach (e. g., [1]), in which the bounds become an integral part of the problem. While a number of the techniques noted above demonstrate excellent global convergence properties in practice, none offer a rigorous mathematical guarantee of convergence.

A further difficulty in solving the nonlinear equation systems arising in process simulation is that they may have multiple solutions. With the exception of homotopy based methods, none of the techniques mentioned above are designed for finding multiple solutions when they exist. While in practice homotopy based methods are frequently able to locate all solutions to a problem, they offer no guarantee that all solutions have been found, except in special cases.

All of the difficulties noted above, namely the lack of good initial guesses, the presence of variable bounds, and the possibility of multiple solutions, can be dealt with using interval analysis. For example, R.E. Swaney and C.E. Wilhelm [11] use a technique, based on repeated solution of linear programs, which, through the use of bounds generated using interval analysis within a branch and bound framework, provides rigorous global convergence to a solution of the process model.

C.A. Schnepper and M.A. Stadtherr [5] use an *interval Newton* approach. This can rigorously enclose any and all solutions to the process model, and is essentially initialization independent, since it requires only initial intervals for the variables, and some of these bounds may be specified as part of the problem. Both serial and parallel implementations are described in [5], and provision is made for efficient handling of sparse matrices. Several example problems were successfully solved, ranging in size from 3 to 177 variables, including problems with multiple solutions. Performance on the larger problems was unpredictable, with two problems of over one hundred variables being solved very efficiently, even with very large initial bounds on the variables, but one problem of 50 variables being unsolvable due to excessive computation time. However, for this

50-variable problem, once smaller, more intelligently chosen (using knowledge of boiling points and critical temperatures) initial intervals were used, the problem was easily and efficiently solved.

### Process Optimization

Perhaps the most natural formulation for a process design problem is as an optimization problem. The process simulation problem is then viewed as an optimization problem with zero degrees of freedom. A typical process optimization problem features a nonlinear objective function, nonlinear equality constraints (the process model), nonlinear inequality constraints, and upper and lower bounds on variables. Frequently these nonlinear programming problems are nonconvex as well, prompting interest in global optimization techniques to deal with the potential for multiple extrema.

Several approaches to global optimization in process engineering have been proposed, including both deterministic and nondeterministic methods. Among the deterministic techniques used are branch and bound, cutting plane, primal-dual decomposition, and interval analysis. The work of R. Vaidyanathan and M.M. El-Halwagi [9] provides a good example of the use of interval analysis in this context. This is an interval branch and bound approach that is guaranteed to yield the global solution. The procedure is accelerated by using a 'distrust region' method for eliminating infeasible portions of the search space and by use of local methods for some purposes.

R.P. Byrne and I.D.L. Bogle [3] and Byrne [2] also use an interval branch and bound approach, but treat the interval lower bounding process as a convex programming problem. In [2] it is also shown how this interval-based approach can be applied in the context of modular process optimization software. Since modular software predominates commercially, this work is of particular interest.

### Process Synthesis

Before the process simulation and optimization problems discussed above can be formulated, it is necessary to synthesize and screen process alternatives. These provide the base case problems for later process simulation and optimization studies. When there is uncertainty in design specifications, or when the design spec-

ification covers a range of values, then interval analysis can be a particularly useful tool in *process synthesis*.

For example, see [6] for a problem involving the processing of high level nuclear waste. In this problem, the waste to be processed is characterized by intervals of composition, as are the requirements for a stable glass product. In [6], an interval propagation scheme that exploits the structure of the problem and a simple process model is developed, and it is demonstrated how to use this to screen process alternatives and to infer other knowledge about the process design.

## Conclusion

Interval analysis provides tools that can be used to solve process simulation problems with complete reliability, providing a method that can guarantee with mathematical and computational certainty that the correct result is found, and thus eliminating computational problems that are encountered with conventional techniques. The method is essentially initialization independent, deals with variable bounds naturally, and also guarantees the enclosure of multiple solutions if present. In process optimization, similar guarantees can also be provided that the global extremum has been found. There are many other problems in chemical process design, for instance in many aspects of process synthesis, that likewise are amenable to solution using this powerful approach.

Interval analysis; Differential equation

Optimization can involve *differential equations*, for instance in the formulation of constraints. Interval analysis provides methods for computing interval-valued functions, for example polynomials with interval coefficients, guaranteed to contain solutions to differential equations. Methods have been developed for initial and boundary value problems for both ordinary (ODE) and partial (PDE) differential equations [1]–[32].

For the initial value problem in ODEs, the Cauchy–Peano approach of classical analysis can be made into a constructive method using interval analysis. With interval arithmetic and interval extensions to standard functions, we can computationally verify sufficient conditions for existence of solutions, as well as construct upper and lower bounds on solutions. The techniques of automatic differentiation provide for efficient use of and (using interval arithmetic) bounding of remainder terms in Taylor series expansions, making interval *Taylor series* an effective method for initial value problems in ODEs [5,13,21]. See especially [33].

Many problems in differential equations, both initial and boundary value problems for ODEs and PDEs, can be reformulated as integral equations. Interval analysis provides means for using fixed-point theory and Picard–Lindelöf-type iteration constructively on such reformulations [3,4,9,15], [17]–[29].

For initial value problems, it was noticed early on [12] that local coordinate transformations are often needed to prevent excessive growth (‘the wrapping effect’) of the widths of interval enclosures. It has been

a continuing project to improve on such transformations [6,8,12,13,14,16,17,21,28,30,32,33].

Variable-precision interval computation provides a means of controlling computational error in ill-posed problems [1,2,7,8]. Using interval methods, we can, in principle (with enough computing), find solutions to prescribed accuracy for differential equations [28].

Some examples will illustrate the kinds of results obtainable by interval methods.

*Example 1* A problem that occurs in chemical reactor theory involves the differential equation

$$y'' + \frac{1}{x}y' + be^{(-\frac{1}{|x|})} = 0, \quad 0 \leq x \leq 1, \quad b > 0,$$

with boundary values  $y'(0) = 0$  and  $y(1) = t > 0$ .

It turns out there may be one or more solutions depending on the values of  $t$  and  $b$ . Using interval methods, it can be proved easily [20] that, for every  $t, b > 0$ , we have

$$y(t) \in t + b \left[ e^{-\frac{1}{t}} \frac{(1-x^2)}{4}, \frac{(1-x^2)}{4} \right]$$

for all solutions  $y$  and all  $0 \leq x \leq 1$ .

*Example 2* Consider the nonlinear hyperbolic PDE

$$u_{xy} = 1 + (u_x + u_y)u$$

with initial conditions  $u(x, 0) = 0$  and  $u(0, y) = 0$ .

Using interval methods, we can prove [23] that for all  $0 \leq x \leq 0.5$  and all  $0 \leq y \leq 0.5$ , the solution  $u(x, y)$  is contained in the interval-valued function

$$xy + [0.1666, 0.2144](x^2y^3 + x^3y^2).$$

This means that we have guaranteed lower and upper bounds on the solution, namely

$$xy + 0.1666(x^2y^3 + x^3y^2) \leq u(x, y) \leq xy + 0.2144(x^2y^3 + x^3y^2)$$

for all  $x$  and  $y$  in  $[0, 0.5]$ .

*Example 3* Consider the initial value problem [21]

$$x' = ct^2 + x^b \quad \text{with} \quad x(0) = a.$$

Suppose there is uncertainty about the values of  $a, b$  and  $c$ , and all we know is that  $0 \leq a \leq 0.1, 0.2 \leq b \leq 0.38, 3.3 \leq c \leq 3.6$ .

In a single iteration of the integral equation representation of the problem, we find that every solution satisfies

$$1.1t^3 \leq x(t) \leq 0.1 + t + 1.2t^3$$

for all  $t \in [0, 0.6]$  and all  $a, b, c$  in the given ranges.

*Moving coordinate systems* for initial value problems help reduce the growth of interval bounds from one expansion step to the next. The *wrapping effect* arises from a rotation of the vector field associated with the differential equations. Such a rotation cannot be followed by interval vector bounds, which are boxes with faces parallel to the coordinate planes. This wrapping effect can be partially controlled in a number of ways with varying degrees of success. R.E. Moore [16] suggested the use of the ‘connection matrix’. F. Krückeberg [12] devised an algorithm he called the *3PM process*. R.J. Lohner [13] suggests the use of parallepipeds and also QR-decomposition for matrix transformations of enclosing hyper-rectangles.

Among the sample programs given in [10 Appendix D] there is ‘AWA’, (AnfangsWert Aufgabe) for initial value problems ([10, pp. 248–251]). AWA implements the ideas of Lohner concerning control of the wrapping effect. Five options are provided:

- 0) interval vector;
- 1) parallelepiped;
- 2) QR-decomposition;
- 3) intersections of 0) and 1);
- 4) intersections of 0) and 2).

For an example using AWA, we considered a *Volterra model of conflicting populations*

$$\begin{aligned}x_1' &= 2x_1(1 - x_2), \\x_2' &= -x_2(1 - x_1),\end{aligned}$$

with initial conditions  $x_1(0) = 1$  and  $x_2(0) = 3$ .

*Automatic differentiation* software is incorporated in AWA which automatically introduces auxiliary variables  $T_1, T_2, \dots$  as needed, and derives recursion relations for generating Taylor coefficients  $(x_1)_k$  and  $(x_2)_k$ ,  $k \geq 1$ , line-by-line from a compiler code list, see [31]. For the example above, the automatically derived recursion relations for derivatives of any order would look

like the following:

$$\left\{ \begin{array}{ll} T_1 = 1 - x_2, & \text{so } (T_1)_k = -(x_2)_k, \\ T_2 = x_1 T_1, & \text{so } (T_2)_k = \sum_{j=0}^k (x_1)_j (T_1)_{k-j}, \\ (x_1)_1 = 2T_2, & \text{so } (x_1)_{k+1} = \frac{2}{k+1} (T_2)_k, \\ T_3 = 1 - x_1, & \text{so } (T_3)_k = -(x_1)_k, \\ T_4 = x_2 T_3, & \text{so } (T_4)_k = \sum_{j=0}^k (x_2)_j (T_3)_{k-j}, \\ (x_2)_1 = -T_4, & \text{so } (x_2)_{k+1} = -\frac{1}{k+1} (T_4)_k. \end{array} \right.$$

The interval Taylor expansion about some  $t_0$  is then, for  $i = 1, 2$ :

$$(x_i)(t_0 + h) = \left\{ \sum_{j=0}^{K-1} (x_i)_j(t_0) h^j \right\} + R_i h^K,$$

where the remainder coefficients  $R_i$ ,  $i = 1, 2$ , are computed from the above recursion relations with *interval inputs* (also found automatically) for  $x_1 = (x_1)_0$  and  $x_2 = (x_2)_0$ .

Using the program AWA given on the diskette for C-XSC, we obtained the following results using the options described.

Using nine terms in the Taylor expansions,  $K = 9$ , and continuing the solution to  $t = 10$ , using a relatively large stepsize  $h = 0.1$ , we obtained different results for two options, both containing the exact solution.

Option 0) produced

$$x_2(10) \in [0.347636 \dots, 0.350002 \dots],$$

whereas option 1) produced the narrower enclosure

$$x_2(10) \in [0.34875 \dots, 0.34888 \dots].$$

The optimal choices of all the various program parameters and the method of coordinate transformation and how they depend on a particular initial value problem are matters that are still being studied. See [5,13,14,33].

J.S. Ely [7] developed a *variable precision interval package* (VPI), using the programming language C++, and applied it to the study of the following ill-posed partial differential equation from the theory of vortex

dynamics ([8]):

$$\frac{\partial z^*(p, t)}{\partial t} = \frac{1}{4\pi i} \text{P.V.} \int B(q) \cot \left[ \frac{z(p, t) - z(q, t)}{2} \right] dq$$

with initial condition  $z(p, 0) = p$ , and the integral taken over  $[0, 2\pi]$ .

Here,  $z(p, t)$  is a  $2\pi$  periodic, complex function of two real variables  $p$  and  $t$ ,  $z^*$  denotes complex conjugation,  $B(q) = 1 + A \cos(q)$ , and P.V. stands for the Cauchy principal value of the singular integral.

In order to obtain satisfactory results on this difficult problem, in particular to determine the time of onset of turbulence, and to rule out rounding errors as the cause of the observed behavior of the computer simulation, as many as 896 bits were used in the interval arithmetic. To improve efficiency, trigonometric transformations were used for a reformulation of the differential equation. Further speed-ups were obtained using *parallel programming* for a distributed network of computers, and in another version a Cray supercomputer. The results [7,8] settled a long-standing controversy concerning the reliability of the mathematical model in the face of previously unknown effects of rounding error. It is certainly not obvious in advance how many bits are needed for such a difficult problem. The point is that with interval computation we can see, from the widths of interval results, how accurately the answers have been determined. If we have not yet obtained desired accuracy, we can repeat the computations carrying more bits. This can be automated so that, in the words of O. Aberth [1]: ‘We expect the computer to do whatever is necessary to obtain such answers’.

See [3] for further discussion of interval methods for differential equations, and some nontrivial applications (e.g.: existence proofs for bifurcations, computer assisted proofs in dynamics, globally convergent domain decomposition methods).

### Keywords

Complex interval matrix; Real interval matrix; Vertex matrix of an interval matrix; Real symmetric interval matrix; Hermitian interval matrix; Interval of variation of an eigenvalue of an interval matrix; Extreme eigenvalue of an interval matrix

Most of the square matrices appearing in practice undergo quantization that can be coarse and are represented by finite precision numbers. Hence, the underlying unquantized matrices belong to real (complex) interval matrices whose entries are closed intervals (rectangles). Interval matrices can also be used to model unstructured matrix perturbations. This self contained article focuses on eigenvalue bounds of interval matrices and provides proofs to all theorems and lemmas.

The organization of this article is as follows. In Section 1 we study the eigenvalues of  $(n \times n)$ -dimensional real symmetric interval matrices and show that the exact real interval of variation of their first and last eigenvalues can be found by considering two sets of vertex matrices each of cardinality  $2^{n-1}$ . In addition, we give a counterexample that falsify the conjecture that for  $n \geq 3$  the interval(s) of variation of the other eigenvalues is attained at vertex matrices. We also remark that this result can be applied to real skew-symmetric interval matrices, as well as to finding the interval of variation of the real part of the eigenvalues of a class of interval matrices whose endpoints are real symmetric matrices. In Section 2 we study the eigenvalues of  $(n \times n)$ -dimensional Hermitian interval matrices and show that the exact real interval of variation of their first and last eigenvalues can be found by considering two sets of vertex matrices each of cardinality  $2^{(n^2+n-2)/2}$ . The above mentioned counterexample also falsifies the conjecture that for  $n \geq 3$  the interval(s) of variation of the other eigenvalues is attained at vertex matrices. We also remark that this result can be applied to skew-Hermitian interval matrices, as well as to finding the interval of variation of of the real part of the eigenvalues of a class of interval matrices whose endpoints are Hermitian matrices with their imaginary part fixed. Finally, in Section 3 we present rectangular bounds for the eigenvalues of complex interval matrices.

In signal processing, control, and statistics real symmetric and Hermitian interval matrices represent, e. g., the quantized sampled covariance matrices of vector stochastic processes and their eigenvalues represent the variances of their decorrelated elements.

In a recent global optimization algorithm, see [1], real symmetric interval matrices were used to tightly bound the sets of Hessian matrices resulting from the objective function's nonconvex addends and then their minimal eigenvalues were used to tightly convexify them.

Eigenvalues of general interval matrices are useful to study robust stability margins of analog and discrete systems, and convergence rates in numerical analysis. The reader interested in additional work in this area is referred to [7] and the references therein, [5]; and, [4,6,10], where Toeplitz and Hankel interval matrices were studied. Genetic algorithms are promising for solving the above problems for large  $n$ .

### Real Symmetric Interval Matrices

A real  $(n \times n)$ -dimensional symmetric interval matrix  $\mathbf{S} = \mathbf{S}[\underline{S}, \bar{S}]$ , where  $\underline{S}$  and  $\bar{S}$  are both real symmetric matrices is defined by

$$\mathbf{S} \equiv \left\{ S = [s_{k\ell}]: \begin{array}{l} S = S^\top, \\ \underline{s}_{k\ell} \leq s_{k\ell} \leq \bar{s}_{k\ell}, \\ k, \ell = 1, \dots, n \end{array} \right\}, \quad (1)$$

where the superscript  $\top$  denotes transposition. Further, let  $\mathcal{S} \subset \mathbf{S}$  denote the set of all vertex matrices such that if  $S = [s_{k\ell}] \in \mathcal{S}$ , then  $s_{k\ell} = \underline{s}_{k\ell}$  or  $s_{k\ell} = \bar{s}_{k\ell}$ . Note that  $|\mathcal{S}| = 2^{(n^2+n)/2}$ , where  $|\mathcal{S}|$  denotes the cardinality of  $\mathcal{S}$ .

It is well known that all the eigenvalues of a real symmetric matrix  $S$  are real, see e. g. [11]. So let  $\lambda_1(S) \leq \dots \leq \lambda_n(S)$  be the ordered eigenvalues of  $S$  and  $\lambda(S) \equiv \{\lambda_k(S): k = 1, \dots, n\}$ . Further, let  $\lambda_k(\mathbf{S}) \equiv \{\lambda: \lambda = \lambda_k(S), S \in \mathbf{S}\}$ ,  $\lambda(\mathbf{S}) \equiv \{\lambda: \lambda \in \lambda(S), S \in \mathbf{S}\}$ ,

$$\begin{cases} \underline{\lambda}_k(\mathbf{S}) \equiv \min(\lambda_k(\mathbf{S})), \\ \bar{\lambda}_k(\mathbf{S}) \equiv \max(\lambda_k(\mathbf{S})). \end{cases} \quad (2)$$

Because  $\mathbf{S}$  is a compact set (i. e., closed and bounded in  $\mathbf{R}^m$ , where  $m = (n^2 + n)/2$  is the number of free parameters of  $\mathbf{S}$ ) and the eigenvalues of a matrix depend continuously upon its entries [9 Appendix D], it follows from [14 Thm. 4.16] that  $\underline{\lambda}_k(\mathbf{S})$  and  $\bar{\lambda}_k(\mathbf{S})$  are attained. That is, there exist matrices  $\underline{S}_k, \bar{S}_k \in \mathbf{S}$  that satisfy  $\underline{\lambda}_k(\mathbf{S}) = \lambda_k(\underline{S}_k)$ ,  $\bar{\lambda}_k(\mathbf{S}) = \lambda_k(\bar{S}_k)$ , where  $k = 1, \dots, n$ .

The purpose of this Section is to study the problem of computing the possibly overlapping eigenvalue intervals  $\Lambda_k(\mathbf{S}) = [\underline{\lambda}_k(\mathbf{S}), \bar{\lambda}_k(\mathbf{S})]$ , where  $k = 1, \dots, n$ .

We have shown in [3] and [7] that the four endpoints of  $\Lambda_1(\mathbf{S})$  and  $\Lambda_n(\mathbf{S})$  are attained by considering two subsets of  $\mathcal{S}$  each of size at most  $2^{n-1}$ , see Theorem below.

Regarding  $\Lambda_k(\mathbf{S})$  for  $k = 2, \dots, n - 1$  and  $n > 2$  we present below a  $(3 \times 3)$ -dimensional real symmetric interval matrix  $\mathbf{S}$  and a matrix  $S_o \in \mathbf{S}$  for which  $\bar{\lambda}_2(\mathbf{S}) \geq \bar{\lambda}_2(S_o) > \bar{\lambda}_2(S)$ . That is, for  $k \neq 1, n$  the endpoints of  $\Lambda_k(\mathbf{S})$  are not necessarily attained at vertex matrices of  $\mathcal{S}$ .

It is well known that if  $S \in \mathbf{S}$ ,  $\lambda_1(S)$  and  $\lambda_n(S)$  are attained at the minimal and maximal values, respectively, of the set  $\{\mathbf{x}^\top \mathbf{S} \mathbf{x}: \|\mathbf{x}\| = 1, \mathbf{x} \in \mathbf{R}^n\}$  [11 Thm. 5.2], where  $\|\mathbf{x}\|$  denotes the Euclidean norm of the vector  $\mathbf{x}$ . Note

that because  $\mathbf{x}^T \mathbf{S} \mathbf{x} = (-\mathbf{x})^T \mathbf{S} (-\mathbf{x})$  we can let  $x_1 \geq 0$ . Hence, the endpoints of  $\Lambda_1(\mathbf{S})$  are given by

$$\underline{\lambda}_1(\mathbf{S}) = \min_{\mathbf{S} \in \mathbf{S}} \min_{\substack{\mathbf{x} \in \mathbb{R}^n, \\ \|\mathbf{x}\|=1, \\ x_1 \geq 0}} \mathbf{x}^T \mathbf{S} \mathbf{x} \tag{3}$$

and

$$\bar{\lambda}_1(\mathbf{S}) = \max_{\mathbf{S} \in \mathbf{S}} \min_{\substack{\mathbf{x} \in \mathbb{R}^n, \\ \|\mathbf{x}\|=1, \\ x_1 \geq 0}} \mathbf{x}^T \mathbf{S} \mathbf{x} \tag{4}$$

Similarly, one can give expressions for the endpoints of  $\Lambda_n(\mathbf{S})$ , or, alternatively use the relation  $\Lambda_n(\mathbf{S}) = -\Lambda_1(-\mathbf{S})$ .

Expanding  $\mathbf{x}^T \mathbf{S} \mathbf{x}$ , where  $\mathbf{x} \in \mathbb{R}^n$  and  $S \in \mathbf{S}$  we obtain

$$\mathbf{x}^T \mathbf{S} \mathbf{x} = \sum_{k=1}^n s_{kk} x_k^2 + 2 \sum_{k=1}^n \sum_{\ell=k+1}^n s_{k\ell} x_k x_\ell. \tag{5}$$

Since  $x_1 \geq 0$ ,  $\mathbf{x}$  may vary in  $2^{n-1}$  closed orthants wherein the sign pattern of its elements is preserved. Let  $\mathbf{O}_p \subset \mathbb{R}^n$ ,  $p = 1, \dots, 2^{n-1}$ , denote the set of unit-length real vectors  $\mathbf{x}$  with  $x_1 \geq 0$  that belong to the  $p$ th orthant, where the orthants are ordered according to the binary order of the signs of the last  $n-1$  elements of  $\mathbf{x}$  and a negative (nonnegative) element corresponds to ‘0’ (‘1’).

Hence we obtain the following subset of  $\mathbf{S}$ :

$$\underline{\mathbf{S}} \equiv \left\{ \begin{array}{l} S = \arg \min_{\mathbf{S} \in \mathbf{S}} \mathbf{x}^T \mathbf{S} \mathbf{x}, \\ \text{some } \mathbf{x} \in \mathbf{O}_p^o, \\ p = 1, \dots, 2^{n-1} \end{array} \right\} \\ = \{ \underline{\mathbf{S}}^p : p = 1, \dots, 2^{n-1} \}, \tag{6}$$

where  $\underline{\mathbf{S}}^p = [s_{k\ell}^p]$ ,  $\mathbf{O}_p^o$  denotes the interior of  $\mathbf{O}_p$ , and

$$s_{k\ell}^p = \begin{cases} \underline{s}_{kk} & \text{if } k = \ell, \\ \underline{s}_{k\ell} & \text{if } (x_k x_\ell > 0) \wedge (k \neq \ell), \\ \bar{s}_{k\ell} & \text{if } (x_k x_\ell < 0) \wedge (k \neq \ell). \end{cases} \tag{7}$$

Similarly as above, by maximizing  $\mathbf{x}^T \mathbf{S} \mathbf{x}$  over  $S \in \mathbf{S}$  and some  $\mathbf{x} \in \mathbf{O}_p^o$  one arrives at  $\bar{\mathbf{S}}^p$  and  $\bar{\mathbf{S}}$ , where  $\bar{\mathbf{S}}^p \in \bar{\mathbf{S}} \subset \mathbf{S}$  and  $|\bar{\mathbf{S}}| = |\underline{\mathbf{S}}|$ .

**Theorem 1**

$$\underline{\lambda}_1(\mathbf{S}) = \lambda_1(\underline{\mathbf{S}}), \quad \bar{\lambda}_1(\mathbf{S}) = \lambda_1(\bar{\mathbf{S}}),$$

and

$$\underline{\lambda}_n(\mathbf{S}) = \lambda_n(\underline{\mathbf{S}}), \quad \bar{\lambda}_n(\mathbf{S}) = \lambda_n(\bar{\mathbf{S}}).$$

*Proof* We will prove that  $\underline{\lambda}_1(\mathbf{S}) = \lambda_1(\underline{\mathbf{S}})$ . The rest of the proof is similar and will therefore be omitted. Because the minimization in (3) is over a compact set (i. e.,  $\{\mathbf{x}, S : \mathbf{x} \in \mathbb{R}^n, \|\mathbf{x}\| = 1, S \in \mathbf{S}\}$ ) and  $\mathbf{x}^T \mathbf{S} \mathbf{x}$  is a real continuous function of  $\mathbf{x}$  and  $S$ , it follows that  $\mathbf{x}^T \mathbf{S} \mathbf{x}$  attains its minimal value for some  $\mathbf{x}^o \in \mathbf{O}^p$  and  $S^o \in \mathbf{S}$ . By expanding the quadratic form  $\mathbf{x}^{oT} S^o \mathbf{x}^o$  as in (5) it can be seen that  $\mathbf{x}^{oT} S^o \mathbf{x}^o \geq \mathbf{x}^{oT} \underline{\mathbf{S}}^p \mathbf{x}^o \geq \mathbf{x}^{pT} \underline{\mathbf{S}}^p \mathbf{x}^p$ , where  $\mathbf{x}^p$  denotes the unit length eigenvector of  $\underline{\mathbf{S}}^p \in \underline{\mathbf{S}}$  corresponding to  $\lambda_1(\underline{\mathbf{S}}^p)$ . Moreover, because  $\mathbf{x}^o$  and  $S^o$  solve the optimization problem (3) it follows that  $\mathbf{x}^{oT} S^o \mathbf{x}^o \leq \mathbf{x}^{pT} \underline{\mathbf{S}}^p \mathbf{x}^p$ . Hence  $\mathbf{x}^{oT} S^o \mathbf{x}^o = \mathbf{x}^{pT} \underline{\mathbf{S}}^p \mathbf{x}^p$  and therefore  $\underline{\lambda}_1(\mathbf{S}) = \lambda_1(\underline{\mathbf{S}})$ .

Note that similar results as in Theorem 1 hold for real skew-symmetric interval matrices, see [13].

*Remark 2* Let  $\mathbf{S}[\underline{\mathbf{S}}, \bar{\mathbf{S}}]$  be defined as before with  $\underline{\mathbf{S}} = \underline{\mathbf{S}}^T$  and  $\bar{\mathbf{S}} = \bar{\mathbf{S}}^T$ . Define the real interval matrix  $\mathbf{B}[\underline{\mathbf{S}}, \bar{\mathbf{S}}] \supset \mathbf{S}[\underline{\mathbf{S}}, \bar{\mathbf{S}}]$  by  $\mathbf{B} \equiv \{B = [b_{k\ell}] : [s_{k\ell} \leq b_{k\ell} \leq \bar{s}_{k\ell}], k, \ell = 1, \dots, n\}$ . Using Bendixon’s theorem [11 Thm. 5.3] (i. e., for  $B \in \mathbf{B}$ ,  $\min \Re \lambda(B) \geq \underline{\lambda}(B')$  and  $\max \Im \lambda(B) \leq \bar{\lambda}(B')$ , where  $B' \equiv \frac{(B+B^T)}{2}$ , and  $\Re, \Im$  denote the real and imaginary parts, respectively), it follows that  $\min \Re \lambda(\mathbf{B}[\underline{\mathbf{S}}, \bar{\mathbf{S}}]) = \underline{\lambda}(\mathbf{S})$  and  $\max \Im \lambda(\mathbf{B}[\underline{\mathbf{S}}, \bar{\mathbf{S}}]) = \bar{\lambda}(\mathbf{S})$ . Hence, using Theorem 1 we obtain that  $\min \Re \lambda(\mathbf{B}) = \underline{\lambda}(\underline{\mathbf{S}})$  and  $\max \Re \lambda(\mathbf{B}) = \bar{\lambda}(\bar{\mathbf{S}})$ , see also [12].

*Example 3* Let the 3-dimensional real symmetric matrix  $\mathbf{S} = [\underline{\mathbf{S}}, \bar{\mathbf{S}}]$  be given by

$$\underline{\mathbf{S}} = \begin{pmatrix} 2 & 1 & -7 \\ 1 & 3 & -1 \\ -7 & -1 & -1 \end{pmatrix}, \\ \bar{\mathbf{S}} = \begin{pmatrix} 6 & 2 & -2 \\ 2 & 11 & 7 \\ -2 & 7 & 5 \end{pmatrix}.$$

Here  $\mathbf{S}$  contains  $2^6 = 64$  vertex matrices, i. e.,  $|\mathbf{S}| = 64$ . Using MatLab we obtain that  $\bar{\lambda}(\mathbf{S}) = \bar{\lambda}(S_v) = 10.1549$ , where

$$S_v = \begin{pmatrix} 6 & 1 & -7 \\ 1 & 11 & -1 \\ -7 & -1 & 5 \end{pmatrix}.$$

Next, results of  $10^5$  computer runs produced the following matrix  $S_o \in \mathbf{S}$ ,

$$S_o = \begin{pmatrix} 5.2054 & 1.6556 & -6.8321 \\ 1.6556 & 10.9244 & 1.9721 \\ -6.8321 & 1.9721 & 4.6703 \end{pmatrix}$$

with  $\bar{\lambda}_2(S_o) = 11.3514$ . Hence  $\bar{\lambda}_2(\mathbf{S}) \geq \bar{\lambda}_2(S_o) > \bar{\lambda}_2(\mathbf{S})$ .

Next, considering  $-\mathbf{S} = \{S: -S \in \mathbf{S}\}$  we obtain that  $S_1 \equiv -S_o \in -\mathbf{S}$  satisfies  $\underline{\lambda}_2(S_1) = -\bar{\lambda}_2(-S_o)$  and consequently  $\underline{\lambda}_2(-\mathbf{S}) \leq \underline{\lambda}_2(S_1) < \underline{\lambda}_2(-S)$ , where  $-S$  has a similar meaning as  $-\mathbf{S}$ .

Hence, the endpoints of  $\Lambda_2(\mathbf{S})$  need not be attained at vertex matrices of  $\mathbf{S}$ .

### Hermitian Interval Matrices

An  $(n \times n)$ -dimensional Hermitian interval matrix  $\mathbf{H} = \mathbf{H}[\underline{H}, \bar{H}]$ , where  $\underline{H}$  and  $\bar{H}$  are both Hermitian matrices is defined by

$$\begin{aligned} \mathbf{H} &\equiv \{H : H = H^*, \\ &\Re \underline{h}_{k\ell} \leq \Re h_{k\ell} \leq \Re \bar{h}_{k\ell}, \quad \Im \underline{h}_{k\ell} \leq \Im h_{k\ell} \leq \Im \bar{h}_{k\ell}, \\ &k, \ell = 1, \dots, n, \quad k \geq \ell\}, \end{aligned} \tag{8}$$

where  $\Im h_{kk} = 0, k = 1, \dots, n$ ,  $*$  denotes the Hermitian operator (i.e. conjugation followed by transposition). Further, let  $\mathcal{H} \subset \mathbf{H}$  denote the set of all vertex matrices such that if  $H = [h_{k\ell}] \in \mathcal{H}$ , then  $h_{k\ell} = \underline{h}_{k\ell}$  or  $h_{k\ell} = \bar{h}_{k\ell}$ . Note that the cardinality of  $\mathcal{H}$  is  $|\mathcal{H}| = 2^{n^2}$ . It is well known that the eigenvalues of an Hermitian matrix  $H$  are real, see e.g. [11]. So let  $\lambda_1(H) \leq \lambda_2(H) \leq \dots \leq \lambda_n(H)$  be the ordered eigenvalues of  $H$  and  $\lambda(H) = \{\lambda_k(H) : k = 1, \dots, n\}$ . Further, let as before  $\lambda_k(\mathbf{H}) \equiv \{\lambda : \lambda = \lambda_k(H), H \in \mathbf{H}\}, \lambda(\mathbf{H}) \equiv \{\lambda : \lambda \in \lambda(H), H \in \mathbf{H}\}, \underline{\lambda}_k(\mathbf{H}) \equiv \min(\lambda_k(\mathbf{H}))$ , and  $\bar{\lambda}_k(\mathbf{H}) \equiv \max(\lambda_k(\mathbf{H}))$ .

Because  $\mathbf{H}$  is a compact set (i.e., closed and bounded in  $\mathbb{R}^{n^2}$ , where  $n^2$  is the number of free real parameters of  $\mathbf{H}$ ) and the eigenvalues of a matrix depend continuously upon its entries [9, Appendix D], it follows from [14, Thm. 4.16] that  $\underline{\lambda}_k(\mathbf{H})$  and  $\bar{\lambda}_k(\mathbf{H})$  are

attained. That is, there exist matrices  $\underline{H}_k, \bar{H}_k \in \mathbf{H}$  that satisfy  $\underline{\lambda}_k(\mathbf{H}) = \lambda_k(\underline{H}_k), \bar{\lambda}_k(\mathbf{H}) = \lambda_k(\bar{H}_k)$ , where  $k = 1, \dots, n$ .

The purpose of this Section is to study the problem of computing the possibly overlapping eigenvalue intervals  $\Lambda_k(\mathbf{H}) = [\underline{\lambda}_k(\mathbf{H}), \bar{\lambda}_k(\mathbf{H})]$ , where  $k = 1, \dots, n$ . We have shown in [2] and [7] that the four endpoints of  $\Lambda_1(\mathbf{H})$  and  $\Lambda_n(\mathbf{H})$  are attained by considering two subsets of  $\mathcal{H}$  each of size at most  $2^{(n^2+n-2)/2}$ , see Theorem 4 below.

Regarding  $\Lambda_k(\mathbf{H})$  for  $k = 2, \dots, n - 1$  and  $n \geq 3$ , since real-symmetric interval matrices are a special case of Hermitian interval matrices, it follows from Example 3 that for  $k \neq 1, n$  the endpoints of  $\Lambda_k(\mathbf{H})$  are not necessarily attained at vertex matrices of  $\mathcal{H}$ .

It is well known that if  $H \in \mathbf{H}$ ,  $\lambda_1(H)$  and  $\lambda_n(H)$  are attained at the minimal and maximal values, respectively, of the set  $\{x^* Hx : \|x\| = 1, x \in \mathbb{C}^n\}$ , see [11 Thm. 5.2]. Note that because  $x^* Hx = (e^{i\phi} x)^* H(e^{i\phi} x)$  for all  $\phi$  we can choose  $x_1 \in \mathbb{R}^+$ , where  $\mathbb{R}^+ = \{x \in \mathbb{R} : x \geq 0\}$ . Hence, the endpoints of  $\Lambda_1(\mathbf{H})$  are given by

$$\underline{\lambda}_1(\mathbf{H}) = \min_{H \in \mathbf{H}} \min_{\substack{x \in \mathbb{C}^n, \\ \|x\|=1, \\ x_1 \in \mathbb{R}^+}} x^* Hx \tag{9}$$

and

$$\bar{\lambda}_1(\mathbf{H}) = \max_{H \in \mathbf{H}} \min_{\substack{x \in \mathbb{C}^n, \\ \|x\|=1, \\ x_1 \in \mathbb{R}^+}} x^* Hx. \tag{10}$$

Similarly, one can give expressions for the endpoints of  $\Lambda_n(\mathbf{H})$ , or, alternatively use the relation  $\Lambda_n(\mathbf{H}) = -\Lambda_1(-\mathbf{H})$ . Since  $x_1 \in \mathbb{R}^+, x \in \mathbb{C}^n$  may vary in  $2^{2n-2}$  closed orthants contained in  $\mathbb{R}^{2n-1}$  wherein the sign pattern of its elements is preserved. Let  $\mathbf{O}_p, p = 1, \dots, 2^{2n-2}$ , denote the set of unit-length real vectors  $x$  with  $x_1 \in \mathbb{R}^+$  that belong to the  $p$ th orthant, where the orthants are ordered according to the binary order of the signs of the vector  $(\Re x_2, \Im x_2, \dots, \Re x_n, \Im x_n) \in \mathbb{R}^{2n-2}$  and a negative (nonnegative) element corresponds to ‘0’ (‘1’).

Expanding  $x^* Hx$ , where  $x = u + iv, u, v \in \mathbb{R}^n$  and  $H = B + jC \in \mathbf{H}, B = B^T \in \mathbb{R}^{n \times n}, C = -C^T \in \mathbb{R}^{n \times n}$ , and

noting that  $\text{diag}(C) = 0$  we obtain

$$\begin{aligned} \mathbf{x}^* H \mathbf{x} &= b_{11} u_1^2 \\ &+ \sum_{k=2}^n b_{kk} (u_k^2 + v_k^2) \\ &+ 2 \sum_{\ell=2}^n [b_{1\ell} u_1 u_\ell + c_{1\ell} (-u_1 v_\ell)] \\ &+ 2 \sum_{k=2}^n \sum_{\ell=k+1}^n [b_{k\ell} (u_k u_\ell \\ &+ v_k v_\ell) + c_{k\ell} (-u_k v_\ell + v_k u_\ell)]. \end{aligned} \tag{11}$$

Hence, minimizing  $\mathbf{x}^* H \mathbf{x}$  over  $H = [h_{k\ell}] = [b_{k\ell} + ic_{k\ell}] \in \mathbf{H}$  and some  $\mathbf{x} \in \mathbf{O}_p^o$  we obtain that only part of the entries  $b_{k\ell}$  and  $c_{k\ell}$  can be chosen at vertex points, i. e.,

$$\underline{b}_{k\ell}^p = \begin{cases} \underline{h}_{kk} & \text{if } k = \ell, \\ \Re \underline{h}_{1\ell} & \text{if } (u_\ell > 0) \wedge (\ell > k = 1), \\ \Re \bar{h}_{1\ell} & \text{if } (u_\ell < 0) \wedge (\ell > k = 1), \\ \Re \underline{h}_{k\ell} & \text{if } (u_k u_\ell > 0, v_k v_\ell > 0) \\ & \wedge (\ell > k > 1), \\ \Re \bar{h}_{k\ell} & \text{if } (u_k u_\ell < 0, v_k v_\ell < 0) \\ & \wedge (\ell > k > 1). \end{cases} \tag{12}$$

and

$$\underline{c}_{k\ell}^p = \begin{cases} 0 & \text{if } k = \ell, \\ \Im \underline{h}_{1\ell} & \text{if } (v_\ell < 0) \wedge (\ell > k = 1), \\ \Im \bar{h}_{1\ell} & \text{if } (v_\ell > 0) \wedge (\ell > k = 1), \\ \Im \underline{h}_{k\ell} & \text{if } (u_k v_\ell < 0, v_k u_\ell > 0) \\ & \wedge (\ell > k > 1), \\ \Im \bar{h}_{k\ell} & \text{if } (u_k v_\ell > 0, v_k u_\ell < 0) \\ & \wedge (\ell > k > 1). \end{cases} \tag{13}$$

Let  $\mathcal{H}^p \subset \mathcal{H}$  denote the set of all vertex matrices that satisfy (12) and (13). Using (12) and (13) one can set in  $B$  and  $C$  their diagonal, first column, first row, and if  $\ell > k > 1$  either an entry of  $B$  or of  $C$ , see [2] for more details. Hence, since the number of free parameters in  $\mathbf{H}$  is  $n^2$ , it follows that  $|\mathcal{H}^p| = 2^{\frac{(n^2-3n+2)}{2}}$ . Further, let  $\underline{\mathcal{H}}^p = \left\{ \underline{H}^{p\ell} : \ell = 1, \dots, 2^{\frac{(n^2-3n+2)}{2}} \right\}$  and  $\underline{\mathcal{H}} = \left\{ \underline{\mathcal{H}}^p : p = 1, \dots, 2^{2n-2} \right\}$  hence  $|\underline{\mathcal{H}}| = 2^{\frac{(n^2+n-2)}{2}}$ . Similarly as above, by maximizing  $\mathbf{x}^* H \mathbf{x}$  over  $H \in \mathbf{H}$  and

some  $\mathbf{x} \in \mathbf{O}_p^o$  we arrive at  $\overline{\mathcal{H}}^p$  and  $\overline{\mathcal{H}}$ , where  $\overline{\mathcal{H}}^p \subset \overline{\mathcal{H}} \subset \mathcal{H}$ ,  $|\overline{\mathcal{H}}^p| = |\underline{\mathcal{H}}^p|$ , and  $|\overline{\mathcal{H}}| = |\underline{\mathcal{H}}|$ .

**Theorem 4**

$$\underline{\lambda}_1(\mathbf{H}) = \lambda_1(\underline{\mathcal{H}}), \quad \bar{\lambda}_1(\mathbf{H}) = \lambda_1(\overline{\mathcal{H}})$$

and

$$\underline{\lambda}_n(\mathbf{H}) = \lambda_n(\underline{\mathcal{H}}), \quad \bar{\lambda}_n(\mathbf{H}) = \lambda_n(\overline{\mathcal{H}}).$$

*Proof* We will prove that  $\underline{\lambda}_1(\mathbf{H}) = \lambda_1(\underline{\mathcal{H}})$ . The rest of the proof is similar and will therefore be omitted. Because the minimization in (3) is over a compact set (i. e.,  $\{\mathbf{x}, H: \mathbf{x} \in \mathbf{C}^n, \|\mathbf{x}\| = 1, H \in \mathbf{H}\}$ ) and  $\mathbf{x}^* H \mathbf{x}$  is a real continuous function of  $\mathbf{x}$  and  $H$ , it follows that  $\mathbf{x}^* H \mathbf{x}$  attains its minimal value for some  $\mathbf{x}^o \in \mathbf{O}^p$  and  $H^o \in \mathbf{H}$ . By expanding  $\mathbf{x}^{o*} H \mathbf{x}^o$  as in (11) and noting that  $\mathbf{x}^o$  is constant, it can be seen that there is an  $\underline{H}^{p\ell} \in \underline{\mathcal{H}}^p$  for which  $\mathbf{x}^{o*} H^o \mathbf{x}^o \geq \mathbf{x}^{o*} \underline{H}^{p\ell} \mathbf{x}^o \geq \mathbf{x}^{p\ell*} \underline{H}^{p\ell} \mathbf{x}^{p\ell}$ , where  $\mathbf{x}^{p\ell}$  denotes the unit-length eigenvector of  $\underline{H}^{p\ell}$  corresponding to  $\lambda_1(\underline{H}^{p\ell})$ . Moreover, because  $\mathbf{x}^o$  and  $H^o$  solve the optimization problem (9), it follows that  $\mathbf{x}^{o*} H^o \mathbf{x}^o \leq \mathbf{x}^{p\ell*} \underline{H}^{p\ell} \mathbf{x}^{p\ell}$ . Hence  $\mathbf{x}^{o*} H^o \mathbf{x}^o = \mathbf{x}^{p\ell*} \underline{H}^{p\ell} \mathbf{x}^{p\ell}$  and therefore  $\underline{\lambda}_1(\mathbf{H}) = \lambda_1(\underline{\mathcal{H}})$ .

Note that similar results as in Theorem 4 hold for skew-Hermitian interval matrices.

*Remark 5* This remark is similar to Remark 2. Let  $\mathbf{H}[\underline{H}, \overline{H}]$  be defined as before with  $\underline{H} = \underline{H}^*$ ,  $\overline{H} = \overline{H}^*$ , and  $\Im \underline{H} = \Im \overline{H}$ . Define the complex interval matrix  $\mathbf{A}[\underline{H}, \overline{H}] \supset \mathbf{H}[\underline{H}, \overline{H}]$  by

$$\mathbf{A} \equiv \left\{ A = [a_{k\ell}] : \begin{array}{l} \Re \underline{h}_{k\ell} \leq \Re a_{k\ell} \leq \Re \bar{h}_{k\ell}, \\ \Im a_{k\ell} = \Im \underline{h}_{k\ell}, \\ k, \ell = 1, \dots, n \end{array} \right\}.$$

Using Bendixon’s theorem and Theorem 4, it follows that  $\min \Re \lambda(\mathbf{A}[\underline{H}, \overline{H}]) = \underline{\lambda}(\mathbf{H}) = \lambda(\underline{\mathcal{H}})$  and  $\max \Re \lambda(\mathbf{A}[\underline{H}, \overline{H}]) = \bar{\lambda}(\mathbf{H}) = \lambda(\overline{\mathcal{H}})$ .

**Complex Interval Matrices**

In this Section we present rectangular bounds on the eigenvalues of a complex interval matrix by extending similar results for a real interval matrix [13]. A complex interval matrix, denoted by  $\mathbf{A}$ , is defined by  $\mathbf{A} \equiv \mathbf{B} + i\mathbf{C}$ , where  $\mathbf{B} \equiv \{B: \underline{B} \leq B \leq \overline{B}, B \in \mathbb{R}^{n \times n}\}$ ,  $\mathbf{C} \equiv \{C: \underline{C} \leq C \leq \overline{C}, C \in \mathbb{R}^{n \times n}\}$ ,  $i^2 = -1$ , and

$\underline{B}, \overline{B}, \underline{C}, \overline{C} \in \mathbb{R}^{n \times n}$  are fixed matrices. Further, let  $\underline{A} = \underline{B} + i\underline{C}$ ,  $\overline{A} = \overline{B} + i\overline{C}$ , and  $A_c = \frac{(\underline{A} + \overline{A})}{2}$ .

Let  $\lambda = \lambda_r + i\lambda_i$  ( $\lambda_r, \lambda_i \in \mathbb{R}^1$ ) and  $\mathbf{x} = \mathbf{u} + i\mathbf{v}$  ( $\mathbf{u}, \mathbf{v} \in \mathbb{R}^{n \times 1}$ ,  $\|\mathbf{x}\| = 1$ ) be an eigenvalue and the corresponding unit length eigenvector of some matrix  $A \in \mathbf{A}$ . First, note that  $\|\mathbf{x}\| = 1$  implies

$$\|\mathbf{x}\|^2 = \mathbf{x}^* \mathbf{x} = \mathbf{u}^T \mathbf{u} + \mathbf{v}^T \mathbf{v} = 1. \tag{14}$$

Let  $A = B + iC$ ,  $B \in \mathbf{B}$ ,  $C \in \mathbf{C}$ . Since  $A\mathbf{x} = \lambda\mathbf{x}$  we obtain

$$\begin{aligned} (\lambda_r + i\lambda_i)\mathbf{x} &= (B + iC)(\mathbf{u} + i\mathbf{v}) \\ &= B\mathbf{u} - C\mathbf{v} + i(B\mathbf{v} + C\mathbf{u}). \end{aligned}$$

Premultiplying the above equation by  $\mathbf{x}^* = \mathbf{u}^T - i\mathbf{v}^T$ , equating the real and imaginary parts, and noting that  $\mathbf{x}^* \mathbf{x} = 1$  we obtain

$$\lambda_r = \mathbf{u}^T B \mathbf{u} - \mathbf{u}^T C \mathbf{v} + \mathbf{v}^T B \mathbf{v} + \mathbf{v}^T C \mathbf{u}$$

and

$$\lambda_i = -\mathbf{v}^T B \mathbf{u} + \mathbf{v}^T C \mathbf{v} + \mathbf{u}^T B \mathbf{v} + \mathbf{u}^T C \mathbf{u}.$$

We have that  $\mathbf{u}^T B \mathbf{u} = \mathbf{u}^T B' \mathbf{u} \leq \overline{\lambda}(B') \mathbf{u}^T \mathbf{u}$  and  $\mathbf{v}^T B \mathbf{v} = \mathbf{v}^T B' \mathbf{v} \leq \overline{\lambda}(B') \mathbf{v}^T \mathbf{v}$ , see [11], where

$$B' \equiv \frac{B + B^T}{2}. \tag{15}$$

Note that similar results pertain to the real matrix  $C$ .

Hence, using (14) we obtain

$$\lambda_r \leq \overline{\lambda}(B') - \mathbf{u}^T C \mathbf{v} + \mathbf{v}^T C \mathbf{u}. \tag{16}$$

Choose  $B_c = \frac{(\underline{B} + \overline{B})}{2}$  and  $C_c = \frac{(\underline{C} + \overline{C})}{2}$ , then

$$\begin{aligned} \overline{\lambda}(B') &= \max_{\|\mathbf{x}\|=1, \mathbf{x} \in \mathbb{R}^n} \mathbf{x}^T B \mathbf{x} \\ &= \max_{\|\mathbf{x}\|=1, \mathbf{x} \in \mathbb{R}^n} (\mathbf{x}^T B_c \mathbf{x} + \mathbf{x}^T (B - B_c) \mathbf{x}) \\ &\leq \overline{\lambda}(B'_c) + \max_{\|\mathbf{x}\|=1, \mathbf{x} \in \mathbb{R}^n} |\mathbf{x}|^T \Delta_B |\mathbf{x}| \\ &= \overline{\lambda}(B'_c) + \overline{\lambda}(\Delta'_B), \end{aligned} \tag{17}$$

where  $|\mathbf{x}| \equiv \text{abs}(\mathbf{x})$  taken elementwise,

$$\Delta_B \equiv \overline{B} - B_c, \tag{18}$$

and both  $\Delta'_B$  and  $B'_c$  have similar meaning as  $B'$  defined in (15).

To obtain the final form of the upper bound on  $\lambda_r$ ,  $\overline{\lambda}_r$ , it remains to carry out the following derivation:

$$\begin{aligned} & -\mathbf{u}^T C \mathbf{v} + \mathbf{v}^T C \mathbf{u} \\ &= -\mathbf{u}^T C_c \mathbf{v} + \mathbf{v}^T C_c \mathbf{u} - \mathbf{u}^T (C - C_c) \mathbf{v} + \mathbf{v}^T (C - C_c) \mathbf{u} \\ &\leq \max_{\|(\mathbf{u}^T, \mathbf{v}^T)\|=1} (-\mathbf{u}^T C_c \mathbf{v} + \mathbf{v}^T C_c \mathbf{u}) \\ &\quad + \max_{\|(\mathbf{u}^T, \mathbf{v}^T)\|=1} (|\mathbf{u}|^T \Delta_C |\mathbf{v}| + |\mathbf{v}|^T \Delta_C |\mathbf{u}|) \\ &\leq \max_{\|(\mathbf{u}^T, \mathbf{v}^T)\|=1} \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix}^T \begin{pmatrix} 0 & -C_c \\ C_c & 0 \end{pmatrix} \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix} \\ &\quad + \max_{\|(\mathbf{u}^T, \mathbf{v}^T)\|=1} \begin{pmatrix} |\mathbf{u}| \\ |\mathbf{v}| \end{pmatrix}^T \begin{pmatrix} 0 & \Delta_C \\ \Delta_C & 0 \end{pmatrix} \begin{pmatrix} |\mathbf{u}| \\ |\mathbf{v}| \end{pmatrix} \\ &\leq \overline{\lambda}(C'_c) + \overline{\lambda}(\Delta'_C), \end{aligned} \tag{19}$$

where  $\Delta_C$  has similar meaning as  $\Delta_B$  defined in (18),

$$\begin{aligned} C'_c &\equiv \begin{pmatrix} 0 & \frac{-C_c + C_c^T}{2} \\ \frac{C_c - C_c^T}{2} & 0 \end{pmatrix}, \\ \Delta'_C &\equiv \begin{pmatrix} 0 & \Delta'_C \\ \Delta'_C & 0 \end{pmatrix}, \end{aligned} \tag{20}$$

and  $\Delta'_C$  has similar meaning as  $B'$  defined in (15). Hence, using (16), (17), and (19) we finally obtain

$$\lambda_r \leq \overline{\lambda}_r = \overline{\lambda}(B'_c) + \overline{\lambda}(\Delta'_B) + \overline{\lambda}(C'_c) + \overline{\lambda}(\Delta'_C). \tag{21}$$

The lower bound on  $\lambda_r$ ,  $\underline{\lambda}_r$ , can be obtained by noting that  $-\lambda = -\lambda_r - i\lambda_i$  is an eigenvalue of  $-A \in -\mathbf{A} = -\mathbf{B} + i(-\mathbf{C})$ , where  $-\mathbf{B} = \{B: -\overline{B} \leq B \leq -\underline{B}, B \in \mathbb{R}^{n \times n}\}$  and,  $-\mathbf{C} = \{C: -\overline{C} \leq C \leq -\underline{C}, C \in \mathbb{R}^{n \times n}\}$  using (21) and then replacing the roles of  $\mathbf{B}$  and  $\mathbf{C}$  by  $-\mathbf{B}$  and  $-\mathbf{C}$  we obtain

$$\lambda_r \geq \underline{\lambda}_r = \underline{\lambda}(B'_c) - \overline{\lambda}(\Delta'_B) + \underline{\lambda}(C'_c) - \overline{\lambda}(\Delta'_C). \tag{22}$$

The upper and lower bounds on  $\lambda_i$  can be similarly obtained by noting that  $-i\lambda = \lambda_i - i\lambda_r$  is an eigenvalue of  $-iA \in -i\mathbf{A} = \mathbf{C} + i(-\mathbf{B})$ , using (21) and (22), respectively, and then replacing the roles of  $\mathbf{B}$  and  $\mathbf{C}$  by  $\mathbf{C}$  and  $-\mathbf{B}$ . We thus obtain

**Theorem 6** Let  $A = B + iC$  be as defined above,  $A_c = \frac{(\underline{A} + \overline{A})}{2} = B_c + iC_c$  be the central matrix of  $A$ , and  $\lambda = \lambda_r + i\lambda_i$  be any eigenvalue of the matrix  $A \in \mathbf{A}$ , then

$$\underline{\lambda}_r \leq \lambda_r \leq \overline{\lambda}_r \quad \text{and} \quad \underline{\lambda}_i \leq \lambda_i \leq \overline{\lambda}_i,$$

where

$$\begin{aligned}\underline{\lambda}_r &= \underline{\lambda}(B'_c) - \bar{\lambda}(\Delta'_B) + \underline{\lambda}(C''_c) - \bar{\lambda}(\Delta''_C), \\ \bar{\lambda}_r &= \bar{\lambda}(B'_c) + \bar{\lambda}(\Delta'_B) + \bar{\lambda}(C''_c) + \bar{\lambda}(\Delta''_C), \\ \underline{\lambda}_i &= \underline{\lambda}(C'_c) - \bar{\lambda}(\Delta'_C) - \bar{\lambda}(B''_c) - \bar{\lambda}(\Delta''_B), \\ \bar{\lambda}_i &= \bar{\lambda}(C'_c) + \bar{\lambda}(\Delta'_C) - \underline{\lambda}(B''_c) + \bar{\lambda}(\Delta''_B);\end{aligned}$$

all the primed matrices (i. e.,  $B'_c$ ,  $C'_c$ ,  $\Delta'_B$ , and  $\Delta'_C$ ) have similar meaning as  $B'$  defined in (15);  $\Delta_B$  is as in (18) and  $\Delta_C$  has similar meaning; and,  $C'_c$  and  $\Delta''_C$  are as in (20) with  $B'_c$  and  $\Delta''_B$  having similar meaning, respectively.

**Corollary 7** Note the following consequences:

- i) if  $\bar{\lambda}_r < 0$ , then the interval matrix  $A$  is Hurwitz stable.
- ii) if the rectangle

$$\{(x, y): \underline{\lambda}_r \leq x \leq \bar{\lambda}_r, \underline{\lambda}_i \leq y \leq \bar{\lambda}_i\}$$

is contained in the open unit disk, then  $A$  is Schur stable.

Some computational simplifications for Theorem 6 can be obtained by using the following lemmas.

**Lemma 8** Let  $C''_c$  be as defined in (20), then  $\bar{\lambda}(C''_c) = -\underline{\lambda}(C'_c) = \rho(\frac{C_c - C_c^T}{2})$ , where  $\rho(A) = \{|\lambda|: \lambda \in \lambda(A)\}$  denotes the spectral radius of the matrix  $A$ .

*Proof* Let  $G = (C_c - C_c^T)/2$  and  $Gv = \lambda v$  (note that since  $G$  is skew symmetric,  $\lambda$  is purely imaginary, see [11]); the eigenvalues of  $C'_c$  are  $\pm i\lambda$  with corresponding eigenvectors  $(v^T, \mp iv^T)^T$ , which gives the desired result.

Note that this Lemma can also be applied to  $B''_c$ .

**Lemma 9** Let

$$D \equiv \begin{pmatrix} 0 & S \\ S & 0 \end{pmatrix},$$

where  $S \in \mathbf{R}^{n \times n}$  and  $S = S^T$ , then  $\bar{\lambda}(D) = -\underline{\lambda}(D) = \rho(S)$ .

*Proof* The eigenvectors of  $D$  are  $(w^T, \pm w^T)^T$ , where  $w$  is an eigenvector of  $S$ . Hence the eigenvalues of  $D$  are  $\pm \lambda$ , with  $\lambda$  an eigenvalue of  $S$ , which gives the desired result.

Note that this Lemma can also be applied to  $\Delta''_B$  and  $\Delta''_C$ .

21	6	3	5
20	7	6	4

In global optimization algorithms, the computer must repeatedly evaluate an objective function, as well as, possibly, inequality and equality constraints. Such functions are given as algebraic expressions or as subroutines or sections of computer code. When such computer code is executed, operations are applied to the *independent variables*, producing *intermediate terms*. These intermediate terms are, in turn, combined to produce other intermediate terms, or, eventually, the objective function value. For example, consider the problem

$$\begin{cases} \min & \phi(x) = x_1^2 - x_1^2 x_2^2 + x_2^2 \\ \text{over the box} & \mathbf{x} = ([-1, 1], [-1, 1])^\top. \end{cases} \quad (1)$$

To evaluate  $\phi$ , the computer may start with the independent variable values  $v_1 = x_1$  and  $v_2 = x_2$  internally produce quantities  $v_3, v_4, v_5$ , and  $v_6$ , to finally produce the dependent variable value  $\phi(x) = v_7$ . Table 1 indicates how this may be done.

A list such as in Table 1 may be represented as a table of addresses of variables and operations. For example, if the operation  $x_p \leftarrow x_q^2$  corresponds to operation code 5,  $x_p \leftarrow x_q x_r$  corresponds to operation code 4,  $x_p \leftarrow x_q + x_r$  corresponds to operation code 20, and  $x_p \leftarrow x_q - x_r$  corresponds to operation code 21, then the set of relations in Table 1 is represented by Table 2.

Such a sequence of operations is called a *code list*, but is sometimes called other things, such as a *tape*. As-

suming the axioms of real arithmetic hold for evaluation, code lists for a given algebraic expression or portion of a computer program are not unique.

The concept of a code list is familiar to computer science students who have worked with compilers, since a compiler produces such lists while translating algebraic expressions into machine language. However, code lists and access to the intermediate expressions are of particular importance in interval global optimization, for the following reasons.

- Code lists provide a convenient internal representation for the objective and constraints, to be used for *automatic differentiation*, for both point and interval evaluation of objectives, gradients, and *Hessian matrices*.
- The values of the intermediate quantities can be used within the optimization algorithm in processes that reduce the size of the search region.
- Symbolic manipulation can reduce the overestimation, or *interval dependency* that would otherwise occur with interval evaluations.

Details are given below.

### Use In Automatic Differentiation

A code list can be used either as a pattern to specify the computations in the *forward mode* of automatic differ-

entiation or as a symbolic representation of the system of equations to be solved in the *backward mode*. See [7] for an in-depth look at the forward mode of automatic differentiation, and see [3] for somewhat more recent research on the subject. See [6, pp. 37–39] for some examples and additional references. Also see ► [Automatic differentiation: Introduction, history and rounding error estimation](#).

### Use In Constraint Satisfaction Techniques.

Since each intermediate variable in the code list is connected to one or two others via an elementary, invertible operation, narrow bounds on one such intermediate variable can be used to obtain narrow bounds on others. For example, suppose that the code list in Table 1 has been symbolically differentiated, to get the code list in Table 3. Then, if the subbox  $\mathbf{x} = ([0.5, 1], [-1, -0.5])^T$  is to be considered for possible inclusion of optima, the derivative code list in Table 3 can be evaluated by *forward substitution* to obtain the interval set of intermediate values in Table 4. Furthermore, since (1) is an unconstrained problem, an optimum must occur where  $\partial\phi/\partial x_1 = 0$  and  $\partial\phi/\partial x_2 = 0$ . In particular, any global optimizer  $x^*$  must have

$$v_{10}(x^*) = 0. \quad (2)$$

Using (2) in line (viii) of the derivative code list in Table 5,

$$v_9 = v_8 - v_{10},$$

whence

$$\tilde{v}_9 \leftarrow [1, 2] - 0,$$

$$\mathbf{v}_9 \leftarrow \tilde{v}_9 \cap \mathbf{v}_9 = [1, 2].$$

Now, using (vii) of Table 5,

$$\tilde{v}_4 \leftarrow \frac{\mathbf{v}_9}{\mathbf{v}_8} = \frac{[1, 2]}{[1, 2]} = [0.5, 2],$$

$$\mathbf{v}_4 \leftarrow \tilde{v}_4 \cap \mathbf{v}_4 = [0.5, 1].$$

Now using (ii) of Table 5 gives

$$\tilde{v}_2 \leftarrow \sqrt{\mathbf{v}_4} \cup -\sqrt{\mathbf{v}_4} \quad (3)$$

$$\subseteq [0.70, 1] \cup [-1, -0.70],$$

$$\mathbf{v}_2 \leftarrow \tilde{v}_2 \cap \mathbf{v}_2 = [-1, -0.70]. \quad (4)$$

The last computation represents a narrowing of the range of one of the independent variables.

Interval Analysis: Intermediate Terms, Table 4

$v_1 = [.5, 1],$
$v_2 = [-1, -.5],$
$v_3 = [.25, 1],$
$v_4 = [.25, 1],$
$v_5 = [.0625, 1],$
$v_6 = [-.75, .9375],$
$v_7 = [-.5, 1.9375],$
$v_8 = [1, 2],$
$v_9 = [.25, 2],$
$v_{10} = [-1, 1.75],$
$v_{11} = [-2, -1],$
$v_{12} = [-2, -.25],$
$v_{13} = [.25, 2],$
$v_{14} = [-1.75, 1],$
$\phi \in [-.5, 1.9375],$
$\frac{\partial \phi}{\partial x_1} \in [-1, 1.75],$
$\frac{\partial \phi}{\partial x_2} \in [-1.75, 1].$

Interval Analysis: Intermediate Terms, Table 5

	$v_1 = x_1,$
	$v_2 = x_2,$
(i)	$v_3 = v_1^2,$
(ii)	$v_4 = v_2^2,$
(iii)	$v_5 = v_3 v_2,$
(iv)	$v_6 = v_1^3,$
(v)	$v_7 = v_6 + v_4,$
(vi)	$v_8 = v_7 + 1,$
(vii)	$v_8 + v_5 = 0,$
(viii)	$v_8 - 3v_5 = 0$

(A similar computation could also have been carried out to obtain narrower bounds on  $v_1$ .)

If, in addition, an upper bound  $\bar{\phi} = 0$  for the global optimum of  $\phi$  is known, then

$$v_7 \in [-\infty, 0] \cap [-0.5, 1.9375] = [-0.5, 0].$$

This can now be used in Table 3, (v), along with new intermediate variable bounds, wherever possible, to obtain

$$\begin{aligned} \tilde{v}_4 &\leftarrow v_7 - v_6 = [-0.5, 0] - [-0.75, 0.9375] \\ &= [-1.4375, 0.75], \\ v_4 &\leftarrow v_4 \cap \tilde{v}_4 = [0.5, 0.75]. \end{aligned}$$

Now using Table 3, (vii),

$$\begin{aligned} \tilde{v}_9 &\leftarrow [1, 2][0.5, 0.75] = [0.5, 1.5], \\ v_9 &\leftarrow \tilde{v}_9 \cap v_9 = [1, 1.5], \end{aligned}$$

then using (viii) and  $v_{10} = 0$  gives  $v_8 = [1, 1.5]$ . Finally, using Table 3, (vi), gives

$$v_1 \leftarrow [0.5, 0.75] \cap [0.5, 1] = [0.5, 0.75]. \tag{5}$$

Now, evaluating  $\phi$  in (1) (or redoing the forward substitution represented in Table 4) at  $(x_1, x_2) = ([0.5, 0.75], [-1, -0.70])$  gives

$$\begin{aligned} \phi &\in [.5, .75]^2 - [.5, .75]^2[-1, -.7]^2 + [-1, -.7]^2 \\ &= [.25, .5625] - [.25, .5625][.49, 1] + [.49, 1] \\ &= [.25, .5625] + [-.5625, -.1225] + [.49, 1] \\ &= [.1775, 1.44], \end{aligned}$$

contradicting the known upper bound  $\bar{\phi} = 0$ . This proves that there can be no global optimizer of (1) within  $([0.5, 1], [-1, -0.5])^T$ . (Note that, in fact, there are no global optimizers in  $([-1, 1], [-1, 1])^T$  if the problem is considered to be unconstrained.)

The above procedure is easily automated, as is done in, say, *GlobSol* [2,6], *UniCalc* [1], or other interval constraint propagation software.

This example illustrates a more general technique, associated with *constraint propagation* and *logic programming*. See [4] for an introduction to this view of the subject, and see [5] for alternate techniques of interval constraint satisfaction.

**Use In Symbolic Preprocessing.**

To understand how symbolic analysis based on the code list may help, consider the following example:

$$\left\{ \begin{array}{ll} \text{Find} & \text{all solutions to} \\ & f(x) = 0, f = (f_1, f_2)^T \\ \text{within} & \text{the box } \mathbf{x} = ([-2, 0], [-1, 1])^T \\ \text{where} & f_1(x_1, x_2) = x_1^3 + x_1^2 x_2 + x_2^2 + 1 \\ & f_2(x_1, x_2) = x_1^3 - 3x_1^2 x_2 + x_2^2 + 1. \end{array} \right. \tag{6}$$

A possible code list is  
There is much interval dependency in this system, both in the individual equations (since each variable occurs in various terms), and between the equations (since the

equations share common terms). However, examination of the code list in Table 5 reveals that a change of variables can make the system more amenable to interval computation. Seeing that (vii) and (viii) are linear in  $v_5$  and  $v_8 = v_4 + v_6 + 1$ , define

$$\begin{cases} y_1 = v_5 = x_1^2 x_2, \\ y_2 = v_4 + v_6 = x_1^3 + x_2^2. \end{cases} \quad (7)$$

Then the system becomes

$$\begin{cases} y_2 + y_1 + 1 = 0, \\ y_2 - 3y_1 + 1 = 0. \end{cases} \quad (8)$$

Thus, the linear system (8) may be solved easily for  $y_1$  and  $y_2$ . The interval bounds may then be plugged into (7) to obtain  $x_1$  and  $x_2$ . There is no overestimation in any of the expressions for function components or partial derivatives in either (8) or (7).

Additional research should reveal how to automate this change of variables process.

Nondifferentiability; Interval slopes; Verification;

Interval computations; Global optimization

Nondifferentiable problems arise in various places in global optimization. One example is in  $l_1$  and  $l_\infty$  optimization. That is,

$$\min_x \phi(x) = \min \|F\|_1 = \min_x \sum_{i=1}^m |f_i(x)| \quad (1)$$

and

$$\min_x \phi(x) = \min \|F\|_\infty = \min_x \left\{ \max_{1 \leq i \leq m} |f_i(x)| \right\}, \quad (2)$$

where  $x$  is an  $n$ -vector, arise in data fitting, etc., and  $\phi$  has a discontinuous gradient. In other problems, piecewise linear or piecewise quadratic approximations are used, and the gradient or the Hessian matrix are discontinuous. In fact, in some problems, even the objective function can be discontinuous.

Much thought has been given to nondifferentiability in algorithms to find local optima, and various techniques have been developed for local optimization. Some of these techniques can be used directly in interval global optimization algorithms. However, the power of interval arithmetic to bound the range of a point-valued function, even if that function is discontinuous, can be used to design effective algorithms for nondifferentiable or discontinuous problems whose structure is virtually identical to that of algorithms for differentiable or continuous problems.

### Posing As Continuous Problems

Several techniques are available for re-posing problems as differentiable problems, in particular for Problem (1) and Problem (2). One such technique, suggested in [2, p. 74] and elsewhere, involves rewriting the forms  $|e|$ ,  $\max\{e_1, e_2\}$ , and  $\min\{e_1, e_2\}$  occurring in variable expressions in the objective and constraints in terms of additional constraints, as follows:

- Replace an expression  $|e|$  by a new variable  $x_{n+1}$  and the two constraints  $x_{n+1} \geq 0$  and  $x_{n+1}^2 = e^2$ .

- Replace  $\max\{e_1, e_2\}$  by

$$\frac{e_1 + e_2 + |e_1 - e_2|}{2}.$$

- Replace  $\min\{e_1, e_2\}$  by

$$\frac{e_1 + e_2 - |e_1 - e_2|}{2}.$$

Alternately, as explained in [1] and elsewhere, the entire Problems (1) and (2) can be replaced by constrained problems. In particular, (1) can be replaced by

$$\begin{cases} \min & \sum_{i=1}^m v_i \\ \text{s.t.} & v_i \geq f_i(x), \quad i = 1, \dots, m, \\ & v_i \geq -f_i(x), \quad i = 1, \dots, m, \end{cases} \quad (3)$$

where the  $v_i$  are new variables.

Likewise, (2) can be replaced by

$$\begin{cases} \min & v \\ \text{s.t.} & v \geq f_i(x), \quad i = 1, \dots, m, \\ & v \geq -f_i(x), \quad i = 1, \dots, m, \end{cases} \quad (4)$$

where  $v$  is a new variable.

### A Special Method for Minimax Problems

In [4], a special interval algorithm for (2) is presented.

#### Treating As Continuous Problems

Due to inclusion properties of interval arithmetic, interval algorithms based on a particular degree of smoothness can be effective, essentially unchanged when less smoothness is present. In particular,

- If the objective function is discontinuous, algorithms designed for continuous objective functions can be used effectively.
- If the function is nonsmooth (that is, if the gradient has discontinuities), then algorithms based on second order information can often be used effectively.

For a brief discussion and further references for these general algorithms, see ► **Interval analysis: Unconstrained and constrained optimization**. For a more in-depth discussion of how continuous algorithms can be used for discontinuous problems, see [3, Chap. 6]. The main ideas are highlighted below.

Minima of  $\phi: \mathbf{R}^n \rightarrow \mathbf{R}^1$  can still be located when the objective  $\phi$  is discontinuous because bounds on the range of  $\phi$  are all that is necessary to do a branch and bound search. For a simple example, suppose

$$\phi(x) = \begin{cases} x^2 & \text{if } x \leq 1, \\ 1 + x & \text{if } x > 1, \end{cases} \quad (5)$$

and suppose the interval  $[-2, 2]$  is to be searched for global minima. For illustration purposes, suppose  $\phi(0.25) = 0.125$  has been evaluated, so that 0.125 is an upper bound on the global optimum, and suppose the subinterval  $\mathbf{x} = [0.5, 1.5]$  is to be analyzed. To obtain an interval enclosure for the range of  $\phi$  over  $\mathbf{x}$ , we take

$$\begin{aligned} \phi(x) &\in [0.5, 1.0]^2 \cup (1 + [1.0, 1.5]) \\ &= [0.25, 1.0] \cup [2.0, 2.5] = [0.25, 2.5], \end{aligned}$$

where  $\mathbf{a} \sqcup \mathbf{b}$  is the smallest interval that contains both  $\mathbf{a}$  and  $\mathbf{b}$ . Thus, since  $0.125 < [0.25, 2.5]$ , a minimum of  $\phi$  cannot possibly occur within the interval  $[0.5, 1.5]$ .

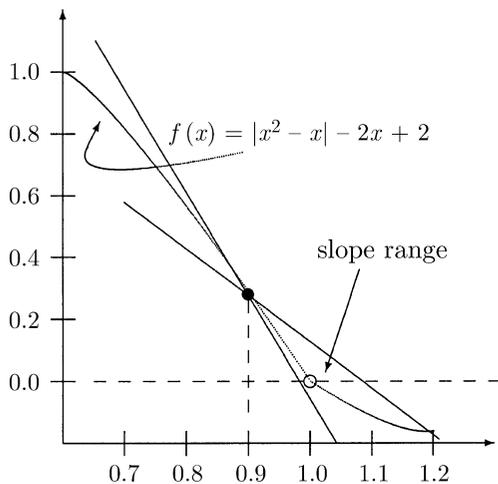

Similar considerations apply if the gradient  $\nabla\phi$  is discontinuous. In such cases, the gradient test (see **► Interval analysis: Unconstrained and constrained optimization**) will keep boxes that either contain zeros of the gradient or critical points corresponding to gradient discontinuities where the gradient changes sign.

When the gradient is discontinuous, interval Newton methods can still be used for iteration, as well as to verify existence. (See [3, (6.4) and (6.5), p. 217] for a formula; see **► Interval Newton methods** for an introduction to interval Newton methods; see **► Interval fixed point theory** for an explanation of interval fixed point theory.) Application to problems with discontinuous gradients is based on extended interval arithmetic (with infinities) and astute computation of slope bounds; see [3, pp. 214–215] for details.

*Example 1* Consider

$$f(x) = |x^2 - x| - 2x + 2 = 0. \quad (6)$$

This function has both a root and a cusp at  $x = 1$ , with a left derivative of  $-3$  and a right derivative of  $-1$  at  $x = 1$ . If  $1 \in \mathbf{x}$ , then a slope enclosure is given by  $\mathbf{S}(f, \mathbf{x}, x) = [-3, -1](\mathbf{x} + x - 1) - 2$ .

**Interval Analysis: Nondifferentiable Problems, Figure 1**  
The concept of a slope range for a nondifferentiable function

Consider using the interval Newton method

$$\begin{aligned} \tilde{\mathbf{x}} &\leftarrow \check{x}^{(k)} - \frac{f(\check{x}^{(k)})}{\mathbf{S}(f, \mathbf{x}^{(k)}, \check{x}^{(k)})}, \\ \mathbf{x}^{(k+1)} &\leftarrow \mathbf{x}^{(k)} \cap \tilde{\mathbf{x}}, \end{aligned}$$

with  $\check{x}^{(k)}$  equal to the midpoint  $\check{x} = 0.9$  of  $\mathbf{x}^{(k)}$ , and  $\mathbf{x}^{(0)} = [0.7, 1.1]$ , where  $\mathbf{S}(f, \mathbf{x}^{(k)}, \check{x}^{(k)})$  is a bound on the slope enclosure of  $f$  at  $\check{x}$ . (See Fig. 1 for the concept of slope range.)

An initial slope enclosure is then  $\mathbf{S}(f, [0.7, 1.1], 0.9) = [-3, -1]$ ,

$$\tilde{\mathbf{x}} = .9 - \frac{.29}{[-3, -1]} = [.99\bar{6}, 1.19],$$

and  $\mathbf{S}(f, [0.7, 1.1], 0.9) = [-3, -1]$ . If this interval Newton method is iterated, then on iteration 3, existence of a root within  $\mathbf{x}^{(3)}$  was proven, since  $\mathbf{x}^{(3)} \subset \text{int}\mathbf{x}^{(2)}$ , where  $\text{int}\mathbf{x}^{(2)}$  is the interior of  $\mathbf{x}^{(2)}$ . For details, see [3, pp. 224–225].

### Introduction

There are many applications of optimization for dynamical systems, including parameter estimation from time series data, determination of optimal operating profiles for batch and semibatch processes, optimal start-up, shutdown, and switching of continuous system, etc. To address such problems, one approach is to discretize any control profiles that appear as decision variables. There are then basically two types of methods available: (1) the complete discretization or simultaneous approach [20,28], in which both state variables and control profiles are discretized, and (2) the control parameterization or sequential approach [3,26], in which only the control profiles are discretized. In this article, only the sequential approach is considered. Since these

problems are often nonconvex and thus may exhibit multiple local solutions, the classical techniques based on solving the necessary conditions for a local minimum may fail to determine the global optimum. This is true even for a rather simple temperature-control problem with a batch reactor [12]. Therefore, there is an interest in *global* optimization algorithms which can rigorously *guarantee* optimal performance.

There has been significant recent work on this problem. For example, Esposito and Floudas [6,7] used the  $\alpha$ BB approach [1,2] to address the global optimization of dynamic systems. In this method, convex underestimating functions are used in connection with a branch-and-bound framework. A theoretical guarantee of attaining an  $\epsilon$ -global solution is offered as long as rigorous underestimators are used, and this requires that sufficiently large values of  $\alpha$  be used. However, this is difficult in this context because determining proper values of  $\alpha$  depends on the Hessian of the function being underestimated, and this matrix is not available in explicit functional form when the sequential approach is used. Thus, as discussed in more detail by Papamichail and Adjiman [21], this approach does not provide a theoretical guarantee of global optimality. Alternative approaches have been given by Chachuat and Latifi [4] and by Papamichail and Adjiman [21,22] that do provide a theoretical guarantee of  $\epsilon$ -global optimality; however, this is achieved at a high computational cost. Singer and Barton [25] have described a branch-and-bound approach for determining a theoretically guaranteed  $\epsilon$ -global optimum with significantly less computational effort. In this method, convex underestimators and concave overestimators are used to construct two bounding initial value problems (IVPs), which are then solved to obtain lower and upper bounds on the trajectories of the state variables [24]. However, the bounding IVPs are solved using standard numerical methods that do not provide guaranteed error estimates, and so this approach does not provide fully guaranteed results from a computational standpoint.

In this article we discuss an approach [8,9] for the deterministic global optimization of dynamical systems based on interval analysis. A key feature of the method is the use of a verifying solver [10] for parametric ordinary differential equations (ODEs), which is used to produce guaranteed bounds on the solutions of dynamic systems with interval-valued parameters. This is

combined with a technique for domain reduction based on using Taylor models [19] in an efficient constraint propagation scheme. The result is that problems can be solved to global optimality with both mathematical and computational certainty.

## Formulation

In this section we give the mathematical formulation of the nonlinear dynamic optimization problem to be addressed. Assume the system is described by the nonlinear ODE model  $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \boldsymbol{\theta})$ . Here  $\mathbf{x}$  is the vector of state variables (length  $n$ ) and  $\boldsymbol{\theta}$  is a vector of adjustable parameters (length  $p$ ), which may be a parameterization of a control profile  $\theta(t)$ . The model is given as an autonomous system; a nonautonomous system can easily be converted into autonomous form by treating the independent variable ( $t$ ) as an additional state variable with derivative equal to 1. The objective function  $\varphi$  is expressed in terms of the adjustable parameters and the values of the states at discrete points  $t_\mu, \mu = 0, 1, \dots, r$ . That is,  $\phi = \phi[\mathbf{x}_\mu(\boldsymbol{\theta}), \boldsymbol{\theta}; \mu = 0, 1, \dots, r]$ , where  $\mathbf{x}_\mu(\boldsymbol{\theta}) = \mathbf{x}(t_\mu, \boldsymbol{\theta})$ . If an integral appears in the objective function, it can be eliminated by introducing an appropriate quadrature variable.

The optimization problem is then stated as

$$\begin{aligned} \min_{\boldsymbol{\theta}, \mathbf{x}_\mu} \phi[\mathbf{x}_\mu(\boldsymbol{\theta}), \boldsymbol{\theta}; \mu = 0, 1, \dots, r] \quad (1) \\ \text{subject to } \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \boldsymbol{\theta}), \\ \mathbf{x}_0 = \mathbf{x}_0(\boldsymbol{\theta}), \\ t \in [t_0, t_r], \\ \boldsymbol{\theta} \in \Theta. \end{aligned}$$

Here  $\Theta$  is an interval vector that provides upper and lower parameter bounds (uppercase will be used to denote interval-valued quantities, unless noted otherwise). We assume that  $\mathbf{f}$  is  $(k-1)$  times continuously differentiable with respect to the state variables  $\mathbf{x}$ , and  $(q+1)$  times continuously differentiable with respect to the parameters  $\boldsymbol{\theta}$ . We also assume that  $\varphi$  is  $(q+1)$  times continuously differentiable with respect to the parameters  $\boldsymbol{\theta}$ . Here  $k$  is the order of the truncation error in the interval Taylor series (ITS) method to be used in the integration procedure, and  $q$  is the order of the Taylor model to be used to represent parameter dependence. When a typical sequential approach is used, an ODE solver is applied to the constraints

with a given set of parameter values, as determined by the optimization routine. This effectively eliminates  $\mathbf{x}_\mu, \mu = 0, 1, \dots, r$ , and leaves a bound-constrained minimization in the adjustable parameters  $\boldsymbol{\theta}$  only. The method discussed here can also be extended to optimization problems with general state path constraints, and more general equality or inequality constraints on parameters. This is done by adapting the constraint propagation procedure (CPP) discussed below to handle the additional constraints.

## Methods

### Taylor Models

Makino and Berz [13] have described a remainder differential algebra (RDA) approach that uses Taylor models for bounding function ranges. This represents an approach for controlling the “dependency problem” of interval arithmetic, which leads to overestimation of function ranges. In the RDA approach, a function is represented using a model consisting of a Taylor polynomial and an interval remainder bound.

One way of forming a Taylor model of a function is by using a truncated Taylor series. Consider a function  $f: \mathbf{x} \in \mathbf{X} \subset \mathbb{R}^m \rightarrow \mathbb{R}$  that is  $(q+1)$  times partially differentiable on  $\mathbf{X}$  and let  $\mathbf{x}_0 \in \mathbf{X}$ . The Taylor theorem states that for each  $\mathbf{x} \in \mathbf{X}$ , there exists a  $\zeta \in \mathbb{R}$  with  $0 < \zeta < 1$  such that

$$\begin{aligned} f(\mathbf{x}) = \sum_{i=0}^q \frac{1}{i!} [(\mathbf{x} - \mathbf{x}_0) \cdot \nabla]^i f(\mathbf{x}_0) \\ + \frac{1}{(q+1)!} [(\mathbf{x} - \mathbf{x}_0) \cdot \nabla]^{q+1} f[\mathbf{x}_0 + (\mathbf{x} - \mathbf{x}_0)\zeta], \end{aligned} \quad (2)$$

where the partial differential operator  $[\mathbf{g} \cdot \nabla]^k$  is

$$\begin{aligned} [\mathbf{g} \cdot \nabla]^k \\ = \sum_{\substack{j_1 + \dots + j_m = k \\ 0 \leq j_1, \dots, j_m \leq k}} \frac{k!}{j_1! \dots j_m!} g_1^{j_1} \dots g_m^{j_m} \frac{\partial^k}{\partial x_1^{j_1} \dots \partial x_m^{j_m}}. \end{aligned} \quad (3)$$

The last (remainder) term in (2) can be quantitatively bounded over  $0 < \zeta < 1$  and  $\mathbf{x} \in \mathbf{X}$  using interval arithmetic or other methods to obtain an interval remainder bound  $R_f$ . The summation in (2) is a  $q$ th

order polynomial (truncated Taylor series) in  $(\mathbf{x} - \mathbf{x}_0)$  which we denote by  $p_f(\mathbf{x} - \mathbf{x}_0)$ . A  $q$ th order Taylor model  $T_f$  for  $f(\mathbf{x})$  then consists of the polynomial  $p_f$  and the interval remainder bound  $R_f$  and is denoted by  $T_f = (p_f, R_f)$ . Note that  $f \in T_f$  for  $\mathbf{x} \in \mathbf{X}$  and thus  $T_f$  encloses the range of  $f$  over  $\mathbf{X}$ .

In practice, it is more useful to compute Taylor models of functions by performing Taylor model operations. Arithmetic operations with Taylor models can be done using the RDA operations described by Makino and Berz [13,14], which include addition, multiplication, reciprocal, and intrinsic functions. Therefore, it is possible to compute a Taylor model for any function representable in a computer environment by simple operator overloading through RDA operations. When RDA operations are performed, only the coefficients of  $p_f$  are stored and operated on; however, rounding errors are bounded and added to  $R_f$ . It has been shown that, compared with other rigorous bounding methods, the Taylor model can be used to obtain sharper bounds for modest to complicated functional dependencies [13,19].

An interval bound on a Taylor model  $T = (p, R)$  over  $\mathbf{X}$  is denoted by  $B(T)$ , and is found by determining an interval bound  $B(p)$  on the polynomial part  $p$  and then adding the remainder bound; that is,  $B(T) = B(p) + R$ . The range bounding of the polynomials  $B(p) = P(\mathbf{X} - \mathbf{x}_0)$  is an important issue, which directly affects the performance of Taylor model methods. Unfortunately, the exact range bounding of an interval polynomial is nondeterministic polynomial-time hard, and direct evaluation using interval arithmetic is very inefficient, often yielding only loose bounds. Thus, various bounding schemes [15,19] have been used, mostly focused on exact bounding of the dominant parts of  $P$ , i.e., the first- and second-order terms. However, exact bounding of a general interval quadratic is also computationally expensive (in the worst case, exponential in the number of variables  $m$ ). Lin and Stadtherr [8] have adopted a very simple compromise approach, in which only the first-order and the *diagonal* second-order terms are considered for exact bounding, and other terms are evaluated directly. That is,

$$B(p) = \sum_{i=1}^m \left[ a_i (X_i - x_{i0})^2 + b_i (X_i - x_{i0}) \right] + Q, \quad (4)$$

where  $Q$  is the interval bound of all other terms, and is obtained by direct evaluation with interval arithmetic. In (4), since  $X_i$  occurs twice, there exists a dependency problem. For  $|a_i| \geq \omega$ , where  $\omega$  is a small positive number, (4) can be rearranged so that each  $X_i$  occurs only once; that is,

$$B(p) = \sum_{i=1}^m \left[ a_i \left( X_i - x_{i0} + \frac{b_i}{2a_i} \right)^2 - \frac{b_i^2}{4a_i} \right] + Q. \quad (5)$$

In this way, the dependence problem in bounding the interval polynomial is alleviated so that a sharper bound can be obtained. If  $|a_i| < \omega$ , direct evaluation can be used instead.

### Verifying Solver for Parametric ODEs

When a traditional sequential approach is applied to the optimization of nonlinear dynamical systems, the objective function  $\varphi$  is evaluated, for a given value of  $\theta$ , by applying an ODE solver to the constraints to eliminate the state variables  $\mathbf{x}$ . In the global optimization approach discussed here, a sequential approach based on interval analysis is used. This approach requires the evaluation of bounds on  $\varphi$ , given some parameter interval  $\Theta$ . Thus, an ODE solver is needed that can compute bounds on  $\mathbf{x}_\mu$ ,  $\mu = 0, 1, \dots, r$ , for the case in which the parameters are interval-valued. Interval methods (also called validated methods or verified methods) for ODEs [16] provide a natural approach for computing the desired enclosure of the state variables at  $t_\mu$ ,  $\mu = 0, 1, \dots, r$ . An excellent review of interval methods for IVPs has been given by Nedialkov et al. [17]. Much work has been done for the case in which the initial values are given by intervals, and there are several software packages available that deal with this case. However, less work has been done on the case in which parameters are also given by intervals. In the global optimization method discussed here, a verifying solver for parametric ODEs [10], called VSPODE, is used to produce guaranteed bounds on the solutions of dynamic systems with interval-valued initial states and parameters. In this section, we review the key ideas behind the method used in VSPODE, and outline the procedures used. Additional details are given by Lin and Stadtherr [10].

Consider the parametric ODE system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \theta), \quad \mathbf{x}_0 \in \mathbf{X}_0, \quad \theta \in \Theta, \quad (6)$$

where  $t \in [t_0, t_r]$  for some  $t_r > t_0$ . The interval vectors  $X_0$  and  $\Theta$  represent enclosures of initial values and parameters, respectively. It is desired to determine a verified enclosure of all possible solutions to this initial value problem. We denote by  $\mathbf{x}(t; t_j, X_j, \Theta)$  the set of solutions  $\mathbf{x}(t; t_j, X_j, \Theta) = \{\mathbf{x}(t; t_j, \mathbf{x}_j, \theta) \mid \mathbf{x}_j \in X_j, \theta \in \Theta\}$ , where  $\mathbf{x}(t; t_j, \mathbf{x}_j, \theta)$  denotes a solution of  $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \theta)$  for the initial condition  $\mathbf{x} = \mathbf{x}_j$  at  $t = t_j$ . We will outline a method for determining enclosures  $X_j$  of the state variables at each time step  $j = 1, \dots, r$ , such that  $\mathbf{x}(t_j; t_0, X_0, \Theta) \subseteq X_j$ .

Assume that at  $t_j$  we have an enclosure  $X_j$  of  $\mathbf{x}(t_j; t_0, X_0, \Theta)$ , and that we want to carry out an integration step to compute the next enclosure  $X_{j+1}$ . Then, in the first phase of the method, the goal is to find a step size  $h_j = t_{j+1} - t_j > 0$  and an a priori enclosure (coarse enclosure)  $\tilde{X}_j$  of the solution such that a unique solution  $\mathbf{x}(t; t_j, \mathbf{x}_j, \theta) \in \tilde{X}_j$  is guaranteed to exist for all  $t \in [t_j, t_{j+1}]$ , all  $\mathbf{x}_j \in X_j$ , and all  $\theta \in \Theta$ . One can apply a traditional interval method, with high-order enclosure, to the parametric ODEs by using an ITS with respect to time. That is,  $h_j$  and  $X_j$  are determined such that for  $X_j \subseteq \tilde{X}_j^0$ ,

$$\begin{aligned} \tilde{X}_j &= \sum_{i=0}^{k-1} [0, h_j]^i F^{[i]}(X_j, \Theta) + [0, h_j]^k F^{[k]}(\tilde{X}_j^0, \Theta) \\ &\subseteq \tilde{X}_j^0. \end{aligned} \quad (7)$$

Here  $\tilde{X}_j^0$  is an initial estimate of  $\tilde{X}_j$ ,  $k$  denotes the order of the Taylor expansion, and the coefficients  $F^{[i]}$  are interval extensions of the Taylor coefficients  $f^{[i]}$  of  $\mathbf{x}(t)$  with respect to time. Satisfaction of (7) demonstrates [5] that there exists a unique solution  $\mathbf{x}(t; t_j, \mathbf{x}_j, \theta) \in \tilde{X}_j$  for all  $t \in [t_j, t_{j+1}]$ , all  $\mathbf{x}_j \in X_j$ , and all  $\theta \in \Theta$ .

In the second phase of the method, a tighter enclosure  $X_{j+1} \subseteq \tilde{X}_j$  is computed such that  $\mathbf{x}(t_{j+1}; t_0, X_0, \Theta) \subseteq X_{j+1}$ . This is done by using an ITS approach to compute a Taylor model  $T_{x_{j+1}}$  of  $x_{j+1}$  in terms of the parameter vector  $\theta$  and initial state vector  $\mathbf{x}_0$ , and then obtaining the enclosure  $X_{j+1} = B(T_{x_{j+1}})$  by bounding  $T_{x_{j+1}}$  over  $\theta \in \Theta$  and  $\mathbf{x}_0 \in X_0$ . To determine enclosures of the ITS coefficients  $f^{[i]}(\mathbf{x}_j, \theta)$  an approach combining RDA operations with the mean value theorem is used to obtain the Taylor models

$T_{f^{[i]}}$ . Now using an ITS for  $x_{j+1}$  with coefficients given by  $T_{f^{[i]}}$ , one can obtain a result for  $T_{x_{j+1}}$  in terms of the parameters and initial states. In order to address the wrapping effect [16], results are propagated from one time step to the next using a type of Taylor model in which the remainder bound is not an interval but a parallelepiped. That is, the remainder bound is a set of the form  $\mathcal{P} = \{A\mathbf{v} \mid \mathbf{v} \in V\}$ , where  $A \in \mathbb{R}^{n \times n}$  is a real and regular matrix. If  $A$  is orthogonal, as from a QR-factorization, then  $\mathcal{P}$  can be interpreted as a rotated  $n$ -dimensional rectangle. Complete details of the computation of  $T_{x_{j+1}}$  were given by Lin and Stadtherr [10].

The approach outlined above, as implemented in VSPODE, has been tested by Lin and Stadtherr [10], who compared its performance with results obtained using the popular VNODE package [18]. For the test problems used, VSPODE provided tighter enclosures on the state variables than VNODE, and required significantly less computation time.

### Deterministic Global Optimization Method

In this section, we summarize a method for the deterministic global optimization of dynamical systems, based on the use of the tools described above. As noted previously, when a sequential approach is used, the state variables are effectively eliminated using the ODE constraints, in this case by employing VSPODE, leaving a bound-constrained minimization of  $\phi(\theta)$  with respect to the adjustable parameters (decision variables)  $\theta$ . The optimization method discussed here can be thought of as a type of branch-and-bound method, with a CPP used for domain reduction. Therefore, it can also be viewed as a branch-and-reduce algorithm. The basic idea is that only those parts of the decision variable space  $\Theta$  that satisfy the constraint  $c(\theta) = \phi(\theta) - \hat{\phi} \leq 0$ , where  $\hat{\phi}$  is a known upper bound on the global minimum found using local minimization, need to be retained. To perform this domain reduction, a CPP can be used.

Partial information expressed by a constraint can be used to eliminate incompatible values from the domain of its variables. This domain reduction can then be propagated to all constraints on that variable, where it may be used to further reduce the domains of other variables. This process is known as constraint propaga-

tion. It is applied to a sequence of subintervals of  $\Theta$ , which arises in a bisection process. For a subinterval  $\Theta^{(k)}$ , the Taylor model  $T_{\phi_k}$  of the objective function  $\phi$  over  $\Theta^{(k)}$  is computed. To do this, Taylor models of  $x_\mu$ , the state variables at times  $t_\mu$ ,  $\mu = 1, \dots, r$ , in terms of  $\theta$  are determined using VSPODE. Note that  $T_{\phi_k}$  then consists of a  $q$ th order polynomial in the decision variables  $\theta$ , plus a remainder bound. The part of  $\Theta^{(k)}$  that can contain the global minimum must satisfy the constraint  $c(\theta) = \phi(\theta) - \hat{\phi} \leq 0$ . In the CPP outlined here,  $B(T_c)$  is determined and then there are three possible outcomes (in the following, an underline is used to indicate the lower bound of an interval, and an overline is used to indicate the upper bound):

1. If  $\underline{B(T_c)} > 0$ , then no  $\theta \in \Theta^{(k)}$  will ever satisfy the constraint; thus, the CPP can be stopped and  $\Theta^{(k)}$  discarded. Testing for this outcome amounts to checking if the lower bound of  $T_{\phi_k}$ ,  $\underline{B(T_{\phi_k})}$ , is greater than  $\hat{\phi}$ . If so, then  $\Theta^{(k)}$  can be discarded because it cannot contain the global minimum and need not be tested further.
2. If  $\overline{B(T_c)} \leq 0$ , then every  $\theta \in \Theta^{(k)}$  will always satisfy the constraint; thus,  $\Theta^{(k)}$  cannot be reduced and the CPP can be stopped. This amounts to checking if the upper bound of  $T_{\phi_k}$ ,  $\overline{B(T_{\phi_k})}$ , is less than  $\hat{\phi}$ . This also indicates, with certainty, that there is a point in  $\Theta^{(k)}$  that can be used to update  $\hat{\phi}$ , which can then be done using a local optimization routine.
3. If neither of the previous two cases occur, then part of the interval  $\Theta^{(k)}$  may be eliminated. To do this, an approach [8,9] based on the range bounding strategy for Taylor models is used, as given by (5). If insufficient reduction of  $\Theta^{(k)}$  occurs, then it is bisected and the resulting subintervals are added to the sequence of subintervals to be processed.

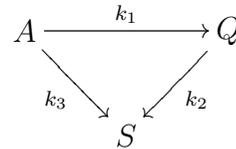

Complete details of the optimization method based on these ideas were given by Lin and Stadtherr [8,9]. It can be implemented either as an  $\epsilon$ -global algorithm, or, by incorporating interval-Newton steps in the method, as an exact ( $\epsilon = 0$ ) algorithm. The latter requires the application of VSPODE to the first- and second-order sensitivity equations. An exact algorithm using interval-Newton steps was implemented by Lin and Stadtherr [8] for the special case of parameter estimation problems. However, this has not been fully implemented for more general cases.

## Cases

Lin and Stadtherr [8,9] have tested the performance of the algorithm discussed above on a variety of test problems. In this section we summarize the results for two of these problems. Both example problems were solved using an Intel Pentium 4 3.2 GHz machine running Red Hat Linux. The VSPODE package [9], with a  $k = 17$  order ITS,  $q = 3$  order Taylor model, and QR approach for wrapping, was used to integrate the dynamical systems in each problem. Using a smaller value of  $k$  will result in the need for smaller step sizes in the integration and so will tend to increase computation time. Using a larger value of  $q$  will result in somewhat tighter bounds on the states, though at the expense of additional complexity in the Taylor model computations.

## Catalytic Cracking of Gas Oil

This problem involves parameter estimation in a model representing the catalytic cracking of gas oil (A) to gasoline (Q) and other side products (S), as described by Tjoa and Biegler [27] and also studied by several others [4,7,22,25]. The reaction is

Only the concentrations of A and Q were measured. This reaction scheme involves nonlinear reaction kinetics. A least-squares objective was used for parameter estimation, resulting in the optimization problem

$$\min_{\theta} \phi = \sum_{\mu=1}^{20} \sum_{i=1}^2 (\hat{x}_{\mu,i} - x_{\mu,i})^2$$

$$\text{subject to } \dot{x}_1 = -(\theta_1 + \theta_3)x_1^2,$$

$$\dot{x}_2 = \theta_1 x_1^2 - \theta_2 x_2,$$

$$t \in [0, 0.95],$$

$$x_\mu = \mathbf{x}(t_\mu),$$

$$x_0 = (1, 0)^T,$$

$$\theta \in [0, 20] \times [0, 20] \times [0, 20],$$

where  $\hat{x}_\mu$  is given experimental data. Here the state vector,  $\mathbf{x}$ , is defined as the concentration vector  $(A, Q)^T$  and the parameter vector,  $\theta$ , is defined as  $(k_1, k_2, k_3)^T$ .

For the  $\epsilon$ -global algorithm, with a relative convergence tolerance of  $\epsilon^{\text{rel}} = 10^{-3}$ , 14.3 s was required to solve this problem. For the exact ( $\epsilon = 0$ ) global algorithm using interval-Newton, 11.5 s was required. For this problem, the exact algorithm required less computation than the  $\epsilon$ -global algorithm. However, this may or may not be the case for other problems [8]. Papamichail and Adjiman [22] solved this problem to  $\epsilon$ -global optimality in 35,478 s (Sun UltraSPARC-II 360 MHz; Matlab), and Chachuat and Latifi [4] obtained an  $\epsilon$ -global solution in 10,400 s (unspecified machine; prototype implementation). Singer and Barton [25] solved this problem to  $\epsilon$ -global optimality for a series of absolute tolerances, so their results are not directly comparable. However, the computational cost of their method on this problem appears to be quite low. These other methods all provide for  $\epsilon$ -convergence only.

### Singular Control Problem

This example is a nonlinear singular optimal control problem originally formulated by Luus [11] and also considered by Esposito and Floudas [7], Chachuat and Latifi [4], and Singer and Barton [25]. This problem is known to have multiple local solutions. In autonomous form and using a quadrature variable, this problem is given by

$$\begin{aligned} \min_{\theta(t)} \phi &= x_5(t_f) \\ \text{subject to } \dot{x}_1 &= x_2, \\ \dot{x}_2 &= -x_3\theta + 16x_4 - 8, \\ \dot{x}_3 &= \theta, \\ \dot{x}_4 &= 1, \\ \dot{x}_5 &= x_1^2 + x_2^2 \\ &\quad + 0.0005(x_2 + 16x_4 - 8 - 0.1x_3\theta^2)^2, \\ \mathbf{x}_0 &= (0, -1, -\sqrt{5}, 0, 0)^T, \\ t &\in [t_0, t_f] = [0, 1], \\ \theta &\in [-4, 10]. \end{aligned} \tag{8}$$

The control  $\theta(t)$  is parameterized as a piecewise constant profile with a specified number of equal time intervals. Five problems are considered, corresponding to one, two, three, four, and five time intervals in the parameterization. Each problem was solved to an absolute tolerance of  $\epsilon^{\text{abs}} = 10^{-3}$ . Computational results [9]

are presented in Table 1. This shows, for each problem, the globally optimal objective value  $\phi^*$  and the corresponding optimal controls  $\theta^*$ , as well as the CPU time (in seconds) and number of iterations required. Chachuat and Latifi [4] solved the two-interval problem to  $\epsilon$ -global optimality using four different strategies, with the most efficient requiring 502 CPU seconds, using an unspecified machine and a “prototype” implementation. Singer and Barton [25] solved the one-, two-, and three-interval cases with  $\epsilon^{\text{abs}} = 10^{-3}$  using two different problem formulations (with and without a quadrature variable) and two different implementations (with and without branch-and-bound heuristics). The best results in terms of efficiency were achieved with heuristics and without a quadrature variable, with CPU times of 1.8, 22.5, and 540.3 s (1.667 GHz AMD Athlon XP2000+) for the one-, two-, and three-interval problems, respectively. This compares with CPU times of 0.02, 0.32, and 10.88 s (3.2 GHz Intel Pentium 4) for the method discussed here. Even accounting for the roughly factor of 2 difference in the speeds of the machines used, the method described here appears to be well over an order of magnitude faster. The four- and five-interval problems were solved [9] in 369 and 8,580.6 CPU seconds, respectively, and apparently had not been solved previously using a method rigorously guaranteed to find an  $\epsilon$ -global minimum. It should be noted that the solution to the three-interval problem, as given in Table 1, differs from the result reported by Singer and Barton [25], which is known to be a misprint [23].

### Conclusions

In this article, we have described an approach for the deterministic global optimization of dynamical systems, including parameter estimation and optimal control problems. This method [8,9] is based on interval analysis and Taylor models and employs a type of sequential approach. A key feature of the method is the use of a new verifying solver [10] for parametric ODEs, which is used to produce guaranteed bounds on the solutions of dynamic systems with interval-valued parameters. This is combined with techniques for domain reduction based on using Taylor models in an efficient constraint propagation scheme. The result is that problems can be solved to global op-

**Interval Analysis for Optimization of Dynamical Systems, Table 1**  
**Results [9] for the singular control problem**

Time intervals	$\varphi^*$	$\theta^*$	CPU time (s)	No. of iterations
1	0.4965	(4.071)	0.02	9
2	0.2771	(5.575, -4.000)	0.32	71
3	0.1475	(8.001, -1.944, 6.042)	10.88	1, 414
4	0.1237	(9.789, -1.200, 1.257, 6.256)	369.0	31, 073
5	0.1236	(10.00, 1.494, -0.814, 3.354, 6.151)	8, 580.6	493, 912

tinality with both mathematical and computational certainty. On parameter estimation problems, an exact ( $\epsilon = 0$ ) algorithm, using interval-Newton steps, can be applied at a cost comparable to, and perhaps less than, that of the  $\epsilon$ -global algorithm. The new approach can provide significant improvements in computational efficiency, potentially well over an order of magnitude, relative to other recently described methods.

### Introduction

The ability of interval arithmetic (IA) [21,22,23,24] to automatically compute reliable solution bounds in nu-

merical computations makes it an ideal mechanism for solving continuous nonlinear global optimization problems. To date, most efforts at developing parallel IA methods for global optimization have used the branch and bound (B&B) global search strategy [1,4,8]. The sequential B&B-based IA global optimization algorithm [10,17] executes a tree-like search process which is naturally parallelized and amenable to massive coarse-grained data parallelism (i. e. workload scalable [14]).

Several noteworthy advances in parallel algorithms for global optimization using interval arithmetic have occurred over the past few years [7,15,26]. In addition, new software packages have been developed as a result of recent implementations of new or existing parallel IA global optimization algorithms [13,29]. A parallel programming language expressing a *message-driven* model is utilized in one implementation, resulting in a significantly different computational flow than is typical with the more classic and popular message-passing (e. g. MPI, PVM) and shared-memory (e. g. pthreads) parallel implementations [20]. Recently, the ubiquity of *multi-core* processor architectures has opened up new possibilities for exploiting thread-level parallelism.

In the sections that follow, a sequential (B&B) IA global optimization algorithm is presented along with relevant IA and parallel computing definitions. Next, a general formulation of a parallel IA global optimization algorithm (PIAGO) based on the B&B global search strategy is presented. In the methods section, a survey of recent algorithmic advances, novel implementations, and pertinent language and programming environments is discussed. Finally, some concluding remarks are made along with thoughts on fertile future research avenues.

### Definitions

#### Interval Arithmetic

A “box” is an  $n$ -dimensional interval:

$$\begin{aligned} X &= \{\vec{x} : \underline{x}_i \leq x_i \leq \overline{x}_i, i = 0, 1, \dots, n-1\} \\ &= ([\underline{x}_0, \overline{x}_0], [\underline{x}_1, \overline{x}_1], \dots, [\underline{x}_{n-1}, \overline{x}_{n-1}])^T \\ &= (\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_{n-1})^T. \end{aligned}$$

Boldface letters and capital letters are used to denote interval quantities and vectors, respectively (as

proposed in [17]). The midpoint of  $X$  is denoted,  $m(X)$ . The width of  $X$  is denoted,  $w(X)$ . The greatest lower bound and the least upper bound for the interval  $x$  is denoted  $\underline{x}$  and  $\bar{x}$ , respectively.

### Sequential IA Branch and Bound

A canonical sequential (B&B) IA global optimization algorithm, SIAGO, iterates over a prioritized list of boxes, representing current candidate subregions (of the initial search space) for containing global minimizer(s). The prioritized list,  $Q$ , is typically implemented as a heap data structure (see Algorithm 1). In each iteration, a box,  $X$ , is removed from  $Q$ . If  $w(X)$  and  $w(f(X))$  are less than the prescribed tolerances,  $\epsilon_x$  and  $\epsilon_f$ , respectively, then  $X$  is placed on the solution list,  $S$ ; Otherwise,  $X$  is subdivided into smaller boxes,  $X_0, X_1, \dots, X_{k-1}$ . Each of the  $k$  boxes,  $X_i$ , is subjected to a set of deletion/reduction tests. Surviving  $X_i$  boxes are placed onto  $Q$ .

The boolean operator, *Delete()*, takes as input a box,  $X$ , and a floating point number,  $U^*$  (the upper bound on the smallest function value known thus far), and returns TRUE if and only if one of the following tests returns TRUE:

- $f(X) > U^*$
- if  $\bar{X}$  is strictly feasible (i. e. does not lie on the boundary of the feasible space) and  $0 \notin \nabla_i f(X)$  (the gradient) for some  $i = 0, \dots, n - 1$ ,
- if  $X$  is strictly feasible and the Hessian,  $\nabla^2 f(X)$ , is not positive semi-definite anywhere in  $X$
- interval Newton's method can eliminate all of  $X$ .

These tests are known as the *midpoint test*, *monotonicity test*, *Hessian test*, and *Newton test*, respectively. More elaborate versions of SIAGO exist today (e. g. Newton's method box reduction, unique critical point existence tests) [10,16] but have little effect on the survey in Sect. "Methods" of parallel IA global optimization algorithms<sup>1</sup>.

### Formulation

The following two facts about SIAGO (see Algorithm 1) reveal a potential for scalable parallelism.

First, *Delete()* can be performed independently on different feasible subregions and therefore can be done

<sup>1</sup>SIAGO efficiency can affect experimental parallel speedup measurements as noted in Sect. "Superlinear Speedup"

```

U* = ∞, Q.insert(X); // initial box
while true do
  repeat
    if Q.empty then S.print, Halt Q.remove(X)
  until f(X) ≤ U*; // cut-off test
  if WithinTol(X, εx, εf, U*) then
    S.insert(X)
  else
    Subdivide(X, X0, X1, ..., Xk-1) for i=0 to k-1
    do
      if not Delete(Xi, U*) then
        U* = min(f(m(Xi)), U*) Q.insert(Xi)
      end
    end
  end
end
end

```

Interval Analysis: Parallel Methods for Global Optimization, Algorithm 1  
SIAGO

in parallel. This allows for "massive" data parallelism as sub-boxes can be distributed across all processors.

Actually, some dependence exists for the midpoint test (see  $U^*$  in Algorithm 1). However, this dependence only affects the "sharpness" of this test and not the correctness. In practice, newly discovered lower  $U^*$  values are shared among all participating processors via broadcasts or shared memory (see Sect. "Parallel Computer Models").

Second, if a feasible region is not deleted (and not reduced via interval Newton's method), the procedure, *Subdivide()*, will divide it into  $k$  subregions which together entirely cover the whole feasible region. The workload has just grown by  $k$ .

Such workload growth makes possible workload scalability [14]. This means that the workload can scale to match the parallel computing power (i. e. CPU utilization is optimized). In fact, the workload growth of SIAGO is potentially exponential and for high dimensional problems can overtake the parallel computing power and memory resources.

The exponential workload growth of SIAGO is no surprise in that the global optimization problem in general is NP-hard (i. e. no algorithm has yet been found which is better than simply performing a complete space search for the solution, requiring exponen-

tial time in the worst case). IA allows one to remove (or reduce using interval Newton's method) potentially large "chunks" of the search space with the hope of pruning/squeezing one's way to a solution.

### Parallel Computer Models

A parallel version of SIAGO is implementable on two basic categories of parallel computers: shared memory multiprocessors (including multi-core processors common today) and distributed memory multicomputers. Although multiprocessors are easier to program than multicomputers (one doesn't have to worry about communication primitives), multicomputers have been the most popular choice for PIAGO for several reasons. First, multicomputers are more scalable. Second, there are freely-available, robust, easy-to-use parallel programming language extensions such as Parallel Virtual Machine (PVM) and the Message Passing Interface (MPI). Third, multicomputers are more cost effective (e. g. a simple cluster of workstations (COW) with inexpensive gigabit Ethernet). Fourth, the massive workload generated by PIAGO implementations on hard global optimization problems (for which PIAGO algorithms were designed to solve) keeps each processor busy working on a local subregion of the search space. If an effective workload management scheme is adopted (see Sect. "Workload Management"), CPU utilization will be maximized and communication will not be a limiting factor.

### PIAGO

A generalized distributed memory parallel IA global optimization algorithm (PIAGO) has the following form:

```
Initialize/Startup all processors
Perform SIAGO in parallel
    manage workload
    broadcast improved  $U^*$  values
Detect global termination state
Terminate all processors
```

Interval Analysis: Parallel Methods for Global Optimization,  
Algorithm 2  
PIAGO

### Workload Management

Workload in PIAGO algorithms is characterized at any given time by the set of boxes remaining to be processed or searched. PIAGO methods distinguish themselves primarily in the manner they manage workload (see Algorithm 2). In SIAGO, workload resides on a single priority queue of boxes,  $Q$ . In PIAGO, workload can be centrally managed on a single "master" node (processor), or it can be distributed among all nodes with each processor managing its own local  $Q$ . Hybrid schemes can also be employed consisting of a centrally managed global priority search queue on the master node working in concert with local search queues on each slave node.

**Distributed Management** In this scheme, workload is distributed either statically to all processors at the beginning of the computation (*static load balancing*) or dynamically during computation (*dynamic load balancing*). With dynamic load balancing, processors coordinate and redistribute workload during computation in order to maximize CPU utilization and minimize total execution time. Workload state information (e. g. local search queue size) is continually (but not necessarily frequently) broadcast among all processors.

Dynamic load balancing is generally scalable. However, each processor must communicate (by request, event, or at programmed time intervals) workload state information in order to make effective workload balancing decisions. Too much state information being broadcast frequently detracts from box processing and may saturate the machine's bandwidth. Stale information concerning a processor's state risks poor load balancing decisions being made on an inaccurate depiction of the current global state.

**Centralized Management** In this scheme (sometimes called master/slave), one master node is responsible for managing (scheduling) the workload. Slave (worker) nodes request work (or are "pushed" work) from the master. The master node is responsible for scheduling the workload in a way that maximizes CPU utilization and (hopefully) minimizes total execution time.

One advantage of centralized control is that workload can be prioritized globally (e. g. boxes,  $X$ , ordered on a priority queue based on minimum  $f(X)$ ). Global

termination detection is easy: The computation is done when the master node has no more workload and all slave processors are idle. Load balancing is achieved through effective scheduling.

Centralized workload management is not scalable, in the theoretical sense. In practice, a centralized scheme is successful provided the master node does not become a “bottleneck”. Communication between one master node and a large set of worker nodes can become intensive and exhaust the communication bandwidth of the parallel machine. Moreover, memory and CPU resources on one processor are limited (relative to the total CPU power and memory of the parallel machine) and can easily become saturated if stressed with too much workload or communication.

**Hybrid Workload Management** Hybrid schemes allow each worker processor to manage its own local  $Q$  while still maintaining a master process responsible for handling work requests from idle processors. The benefits of the hybrid approach over the pure centralized approach are two-fold:

- fewer requests for work (to the master) are required since each worker must first complete its local workload (including self-generated workload resulting from box splitting) before it becomes idle
- the potential memory bottleneck at the master is mitigated since the local memory resources on each worker are utilized.

The main disadvantage of the hybrid approach versus the centralized approach is the sacrifice of total (global) workload ordering. The master node “running out of boxes” or a worker process generating too much work to be held in local memory are two other issues that need to be addressed.

The main advantages of the hybrid approach compared to the distributed approach are two-fold:

- a better approximation to a total workload ordering
- fewer possible retransmissions for work as the master node is (usually) guaranteed to have boxes.

Because the hybrid approach still uses a master node for scheduling workload, this method inherits the scalability weakness of its centralized parent.

### Load Balancing

One necessary condition for load balancing is ensuring no worker processor sits idle. A second goal of load

balancing in PIAGO algorithms is the distribution of “quality” boxes among the worker processors. A quality box is defined as a box more likely to contain a minimizer (or near minimizer). It is natural to expect that global minima will be discovered more quickly if participating processors focus their efforts on subregions of the workspace that more likely to contain minimizers. Early improvements to the SIAGO algorithm recognized this fact and (efficiently) sorted boxes,  $X$ , on increasing  $f(X)$  using a priority search queue,  $Q$ .

### Superlinear Speedup

Speedup is defined as  $S_m = T_1/T_m$ , where  $T_1$  is the sequential execution time (e.g. SIAGO on one processor) and  $T_m$  is the parallel execution time (e.g. PIAGO on  $m$  processors). Theoretically, superlinear speedup (i.e.  $S_m > p$ ) of an efficient algorithm is not possible [6]. In practice, however, superlinear speedup has been reported often for B&B algorithms in general and PIAGO algorithms in particular [2,5,7,13,15,18,20,25,26].

One reason why superlinear speedup may be achieved in practice is that the sequential algorithm may be inefficient. Some of the earliest PIAGO implementations reported large superlinear speedups. For example, a superlinear speedup of 170 is reported on 32 nodes in [25]. Using a priority search queue ordered on lowest  $f(X)$  [9], Leclerc [18] reports only sublinear speedup of approximately 1/2 for the same problem.

In [2] a theorem is presented that “clearly indicates that no substantial superlinear speedup is possible, assuming that the *best-first* strategy is used”. Here, *best-first* strategy refers to the same lowest  $f(X)$  ordering of boxes on the search queue used by Leclerc. Note, the theorem does not claim that the *best-first* strategy is best strategy to use. It only claims that if the *best-first* strategy is used for both the the sequential version and the parallel version, then superlinear speedup is not expected.

In fact, most of the superlinear speedups that have been reported recently are just slightly above linear. This can be explained by the combination of one or more of the following factors:

- high memory utilization in the sequential case may result in poor caching and possible paging thus extending execution time

- non-deterministic timing anomalies (race conditions) that occur in parallel executions may not have been “smoothed out” by averaging the results of many execution runs
- the partial breadth-first search that parallelization introduces into the computation may indeed accelerate finding global solutions for some problems.

## Methods

Following is a survey of PIAGO methods that have evolved over the past 15 years. Performance comparisons of the various methods based on execution times are difficult to make. For example, differences in implementation hardware, the problems being solved, and IA software used, will affect execution times.

Instead, most articles report speedup as a measure of the efficiency of the parallel algorithm. However, speedup is also dependent on the several factors including box ordering on the search queue, memory utilization, non-deterministic parallel “race condition” effects, implementation hardware, and the specific problem being solved (see Sect. “[Superlinear Speedup](#)”). For these reasons, no effort is made to compare the various algorithms with regard to reported efficiency.

Various acceleration techniques or general improvements to SIAGO are not considered. It is assumed that such improvements would benefit most if not all of the methods surveyed.

Finally, no discussion of global termination detection is made. Although this is an interesting topic [28], the methods (both centralized and distributed) are few, well analyzed, and not affected by the particular nature of B&B IA global optimization algorithms. Moreover, the contribution of global termination detection to the total execution time for hard problems is negligible.

The key component differentiating the various PIAGO algorithms is workload management (see Sect. “[Workload Management](#)”). Each considered PIAGO algorithm is categorized into one of distributed, centralized, or hybrid categories. A discussion of the workload management scheme is given along with relevant comments concerning scalability, code complexity, and communication costs.

## Distributed Approaches

As mentioned in “[Distributed Management](#)”, distributed workload approaches are generally scalable. Asynchronous non-blocking communication is more efficient, but also more difficult to program. By either interleaving messaging probing (e.g. MPI\_Iprobe) within the main computation loop (see Algorithm 1) or dedicating a separate thread to the task of receiving messages, one can use efficient non-blocking communication in the approaches that follow. No further discussion of synchronous versus asynchronous communication is made.

Let  $P_0, P_1, \dots, P_{m-1}$  represent  $m$  processors on a parallel machine. Let  $\widetilde{W}_0, \widetilde{W}_1, \dots, \widetilde{W}_{m-1}$  represent recorded workload state information for each processor. A given processor can query the (approximate) current workload queue size or minimum  $f(\mathbf{X})$  on processor  $j$  using  $\widetilde{W}_j.Qsize$  or  $\widetilde{W}_j.Qlbf$  (the lower bound on the function over all boxes in the queue), respectively.

**The Leclerc Approach** This approach [18,19] is fully distributed and utilizes the best-first queuing strategy. It uses the load balancing procedure listed in Procedure *loadbalance* with the function *WorkloadBalanced* returning TRUE when the processor’s  $Q$  is empty (i.e. no work). This is a simple demand-driven load balancing scheme. The lowest  $f(\mathbf{X})$  value for boxes on each processor’s local  $Q$  are broadcast at regular intervals to all processors and recorded in  $\widetilde{W}$ .

```
// Load balance on processor,  $P_i$ 
 $E = \{i\}$  if not WorkloadBalanced( $Q, \widetilde{W}$ ) then
  repeat
     $P_b = \min(\widetilde{W}_i.Qlbf), i \notin E$  Request fraction
    of boxes from  $P_b$  if no boxes received then
       $E = E \cup \{b\}$ 
  end
  until boxes received
end
```

Interval Analysis: Parallel Methods for Global Optimization, Procedure

```
loadbalance( $i$ )
```

**The Hu, Kearfott, Xu, and Yang Approach** This approach [13] is similar to the one used by Leclerc, but

with an initial static assignment of one box to each processor on startup. One box is requested, instead of a fraction of boxes, when a processor becomes idle. From the paper it is unclear to which processor(s) a request for workload is made. It is also unclear whether workload state information,  $\widetilde{W}$ , is maintained.

**The Caprani and Madsen Approach** This simple, yet promising approach [3] uses static load balancing rather than dynamic load balancing. First, a “good”  $U^*$  is computed on one processor. Next, a “sufficient number” (e.g.  $10m$ ) of sub-boxes are generated using SIAGO and placed into  $m$  sets of “approximately equal difficulty”. The  $m$  sets along with  $U^*$  are statically distributed onto  $m$  processors. SIAGO is performed on each processor with no communication.

**The Eriksson and Lindström Approach** Here [5], load balancing is considered on a specialized parallel computer—an Intel iPSC/2 hypercube. No workload state information,  $\widetilde{W}$ , is maintained. In order to load balance qualitatively as well as quantitatively, a hybrid of two load balancing strategies is used: *receiver-initiated* and *sender-initiated*.

The receiver-initiated load balancer is conceptually similar to Procedure *loadbalance*. But, rather than a selection based on  $\min(\widetilde{W}_i.Qlbf)$ , an un-prioritized linear search (for a non-idle node) along a ring is performed. This ensures no processor stays idle for very long.

The sender-initiated load balancer seeks to balance qualitatively. Here, the “best” box on the  $Q$  (i. e. the one with the lowest  $f(X)$ ) is “pushed” to a random processor each time  $G$  boxes have been split. The frequency of a push operation,  $G$ , on a particular processor is decremented by one when the pushed box gets placed at the front of the  $Q$  of the randomly selected processor; otherwise,  $G$  is incremented by one. The net effect is that if truly “good” boxes are being pushed, then they will continue to be pushed at a high frequency; otherwise, pushes will occur less often.

**The Gau and Stadther Approach** Here [7] two fundamental algorithms are proposed. First is the synchronous work stealing (SWS) approach. This approach is very similar to the approaches by Hu, Kearfott, Xu, and Yang, and Leclerc. The difference is that largest  $Q$  length is used instead of lowest  $f(X)$ .

Next, an asynchronous diffusive load balancing (ADLB) scheme is proposed. A group of “nearest neighbors” is defined. Neighbors exchange workload information. Then, boxes are either “pushed” or “pulled” to/from neighbors depending on workload distribution inequities as determined by each processor. The mechanism is analogous to heat or mass diffusion.

In theory this approach should be able to handle qualitative issues regarding workload. However, this is not considered in the paper.

**The Martínez, Casado, Alvarez, and García Approach** This recent approach [20] is most novel for its implementation language—Charm++. The execution model of Charm++ is message-driven (i. e. the arrival of messages “triggers” associated computations). This model is similar to a data flow machine.

Essentially a process (chare) runs on each processor. This process responds to (is triggered by) messages to either process a box, *Process-Box*, or update  $U^*$ , *update- $U^*$* . A *Process-Box* message can either:

- reject the box with no messages generated
- subdivide the box generating two *Process-Box* messages sent to two random processors
- send a message to the main chare to enqueue a new solution.

Messages can be prioritized so that *update- $U^*$*  messages take precedence over *Process-Box* messages. This should help improve the efficiency of the parallel algorithm. Also, *Process-Box* messages can be prioritized on lowest  $f(X)$  in order to load balance qualitatively.

Data flow solutions are truly elegant. Load balancing quantitatively and qualitatively is achieved via randomness and built-in message prioritization.

## Centralized Approaches

**The Henriksen and Madsen Approach** An early implementation of a PIAGO algorithm using a centralized workload manager is that of Henriksen and Madsen [11]. A master node maintains the priority workload queue,  $Q$ , and schedules work to each slave processor. When a slave node splits a box, it keeps only one box and sends the remainder back to the master, to be inserted into  $Q$ .  $U^*$  is also maintained at the master.

The algorithm is load balanced (both quantitatively and qualitatively) and has the advantage of total order-

ing of boxes. However, its weakness is poor scalability. The master quickly becomes a memory bottleneck and communication “hotspot” on parallel machines with 32 or more nodes [2].

To be fair, however, such an algorithm is better suited to shared memory multiprocessors, and in particular, multi-core processors (e. g. AMD Opteron, Intel Core 2 Duo). Though multi-core processors don’t offer as great an opportunity for massive parallelism (usually 16 cores or less on a processor), they are ubiquitous today and inexpensive. Therefore, one can envision Henriksen and Madsen’s approach being used on a distributed memory multicomputer in which the individual processors are multi-core. A more scalable algorithm would be used on the multicomputer architecture as a whole, but the centralized approach could be used as a multithreaded PIAGO application running on each multi-core processor.

The advantage of this hierarchical workload management approach is a better approximation to the best-first strategy. In addition, more efficiency would be obtained with the centralized implementation on each multi-core processor, since shared memory is faster than message passing. The main disadvantage would be code complexity.

### Hybrid Approaches

As was mentioned in Sect. “Centralized Approaches”, pure centralized approaches, though offering total ordering of the workload  $Q$ , are not scalable. Hybrid approaches are theoretically not scalable either. However, some of the scalability issues are mitigated by leveraging local memory on worker processors. Three hybrid approaches are considered.

**The Berner Approach** Here [2], a master node handles requests from idle processors. A dynamically adjusted variable,  $max$ , is used to “throttle” the workload on the worker processors as well as help ensure the master does not run out of work. Processors with more than  $max$  boxes on the local  $Q$  will send “some of them” to the master.

**The Ibraev Approach** This approach [15] is a variation on the Berner approach, with the master (leader) node continually “floating” to the processor that discovers a better  $f(X)$ . Workers discovering a possibly

lower  $f(X)$  “challenge” the current leader. The current leader makes a determination as to the next leader and broadcasts the index of the new leader along with the improved  $f(X)$  to all processors.

In this approach, no effort is made to approximate a totally ordered global  $Q$ . Rather, the approach seeks only to ensure that work requests are made to the processor with the best quality boxes.

**The Tapamo and Frommer Approach** Tapamo and Frommer [26] propose a variation of the Berner approach which allows non-idle processors to serve requests. The master node keeps track of the lengths of each processor’s local  $Q$ . When one or more processors become idle, the master then instructs non-idle processors (in decreasing order of  $Q$  length) to concurrently satisfy requests from idle processors.

Workload state information (i. e. local  $Q$  sizes) must be sent to the master at some frequency. The same issues regarding this frequency are present in the various distributed approaches (See Sect. “Distributed Management”). Delay is introduced due to the indirection of requests having to “pass” through the master node.

### Conclusions

The pure centralized workload management scheme is clearly impractical to implement on large distributed memory multicomputers due to issues of scalability. Fully distributed algorithms are scalable but some would question their efficiency based on concerns that the following phenomena may significantly impact performance:

- frequent broadcasting of workload state
- repeated retransmissions for workload due to idle  $P_b$  in Procedure *loadbalance*
- a global best-fit exploration of boxes is not being performed (i. e. perhaps the best quality boxes are not being evenly distributed).

Hybrid methods were apparently developed to resolve one or more of the perceived deficiencies of distributed methods and the scalability problem of the pure centralized method. Though hybrid methods have reduced bottleneck potential, they still suffer from poor scalability.

A closer examination of the apparent deficiencies of the distributed methods is worth making. Efficient (up

to practically constant-time) broadcast primitives have been implemented [27,12]. Thus, it would seem, that frequent broadcasting of workload state may not significantly effect performance. Moreover, the frequency of broadcast can easily be throttled if required.

A good estimate of the workload state on each processor for large problems is reasonable to expect. Thus, a high probability exists that the first or possibly second request will fall on a non-idle processor with “good” work. Retransmissions may in fact be few.

Finally, a global best-fit exploration of boxes is not being performed using distributed schemes. However, such a totally ordered exploration is not being done using any of the hybrid methods either. An argument claiming hybrid methods yield better approximations to a global ordering is difficult to make.

A complete and fair assessment of the various PIAGO algorithms (in particular distributed methods versus hybrid methods) should cover a wide range of difficult global optimization test problems. The same efficient SIAGO algorithm (e. g. using best-first ordering) should be used in each and a common hardware platform should be utilized. Furthermore, multiple runs of each test case should be run and averaged in order to “smooth out” non-deterministic parallel computation effects. To date no such comprehensive analysis has been performed.

### Keywords and Phrases

Branch-and-bound; Interval arithmetic; Optimization; Subdivision direction

The selection of subdivision direction is one of the points where the efficiency of the basic **branch-and-bound algorithm** for unconstrained global optimization can be improved (see **Interval analysis: un-**

**constrained and constrained optimization**). The traditional approach is to choose that direction for subdivision in which the actual box has the largest width. If the inclusion function  $\phi(x)$  is the only available information about the problem

$$\min_{x \in x_0} \phi(x),$$

then it is usually the best possible choice. If, however, other information like the inclusion of the gradient ( $\nabla\phi$ ), or even the inclusion of the Hessian ( $H$ ) is calculated, then a better decision can be made.

### Subdivision Directions

All the rules select a direction with a merit function:

$$k := \arg \max_{i=1}^n D(i), \quad (1)$$

where  $D(i)$  is determined by the given rule. If many such optimal  $k$  indices exist then the algorithm can choose the smallest one, or it can select an optimal direction randomly.

**Rule A.** *The first rule was the interval-width oriented rule. This rule chooses the coordinate direction with*

$$D(i) := w(x_i). \quad (2)$$

*This rule is justified by the idea that, if the original interval is subdivided in a uniform way, then the width of the actual subintervals goes to zero most rapidly.*

*The algorithm with Rule A is convergent both with and without the monotonicity test [8]. This rule allows a relatively simple analysis of the convergence speed (as in [8], Chapter 3, Theorem 6).*

**Rule B.** *E. Hansen described another rule (initiated by G. W. Walster [5]). The direct aim of this heuristic direction selection rule is to find the component for which  $W_i = \max_{t \in x_i} \phi(m_1, \dots, m_{i-1}, t, m_{i+1}, \dots, m_n) - \min_{t \in x_i} \phi(m_1, \dots, m_{i-1}, t, m_{i+1}, \dots, m_n)$  is the largest (where  $m_i = (\underline{x}_i + \bar{x}_i)/2$  is the midpoint of the interval  $x_i$ ). The factor  $W_i$ , that should reflect how much  $\phi$  varies as  $x_i$  varies over  $x_i$ , is then approximated by  $w(\nabla\phi_i(x))w(x_i)$  (where  $\nabla\phi_i(x)$  denotes the  $i$ th component of  $\nabla\phi(x)$ ). The latter is not an upper bound for*

$W_i$  (cf. [5] page 131 and Example 2 in Section 3 of [4]), yet it can be useful as a merit function.

Rule B selects the coordinate direction, for which (1) holds with

$$D(i) := w(\nabla\phi_i(\mathbf{x}))w(\mathbf{x}_i). \tag{3}$$

It should be noted that the basic bisection algorithm represents only one way in which Rule B was applied in [5]. There the subdivision was, e. g., also carried out for many directions in a single iteration step.

**Rule C.** The next rule was defined by Ratz [9]. The underlying idea was to minimize the width of the inclusion:  $w(\phi(\mathbf{x})) = w(\phi(\mathbf{x}) - \phi(m(\mathbf{x}))) \approx w(\nabla\phi(\mathbf{x})(\mathbf{x} - m(\mathbf{x}))) = \sum_{i=1}^n w(\nabla\phi_i(\mathbf{x})(\mathbf{x}_i - m(\mathbf{x}_i)))$ . Obviously, that component is to be chosen for which the term  $w(\nabla\phi_i(\mathbf{x})(\mathbf{x}_i - m(\mathbf{x}_i)))$  is the largest. Thus, Rule C can also be formulated with (1) and

$$D(i) := w(\nabla\phi_i(\mathbf{x})(\mathbf{x}_i - m(\mathbf{x}_i))). \tag{4}$$

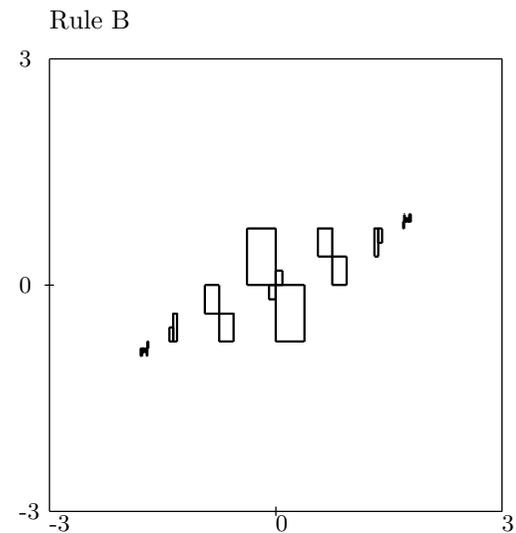

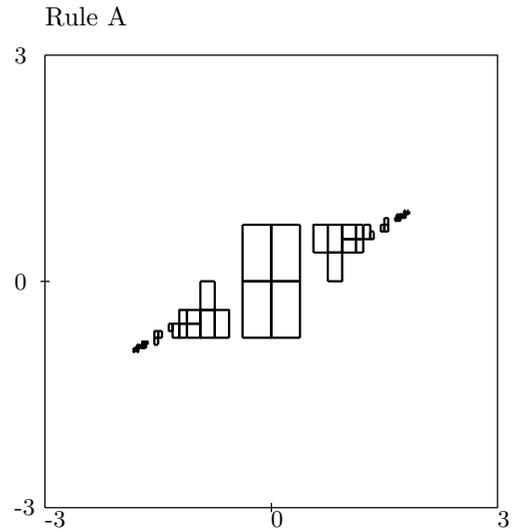

The important difference between (3) and (4) is that in Rule C the width of the multiplied intervals is maximized, not the multiplied widths of the respective intervals (and these are in general not equal). After a short calculation, the right-hand side of (4) can be written as  $\max\{|\min \nabla\phi_i(\mathbf{x})|, |\max \nabla\phi_i(\mathbf{x})|\}w(\mathbf{x}_i)$ . This corresponds to the maximum smear defined by R.B. Kearfott (used as a direction selection merit function solving systems of nonlinear equations [6,7]) for the case  $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$ . It is easy to see that the Rules B and C give the same merit function value if and only if either  $\underline{\nabla\phi}_i(\mathbf{x}) = 0$  or  $\overline{\nabla\phi}_i(\mathbf{x}) = 0$ .

**Rule D.** The fourth rule, Rule D is derivative-free like Rule A, and reflects the machine representation of the inclusion function  $\phi(\mathbf{x})$  (see [5]). It is again defined by (1) and by

$$D(i) := \begin{cases} w(\mathbf{x}_i) & \text{if } 0 \in \mathbf{x}_i, \\ w(\mathbf{x}_i) / \langle \mathbf{x}_i \rangle & \text{otherwise,} \end{cases} \tag{5}$$

where  $\langle \mathbf{x} \rangle$  is the mignitude of the interval  $\mathbf{x}$ :  $\langle \mathbf{x} \rangle := \min_{x \in \mathbf{x}} |x|$ .

This rule may decrease the excess width  $w(\phi(\mathbf{x})) - w(\phi^u(\mathbf{x}))$  of the inclusion function (where  $\phi^u(\mathbf{x})$  is the

**Interval Analysis: Subdivision Directions in Interval Branch and Bound Methods, Figure 1**  
Remaining subintervals after 250 iteration steps of the model algorithm with the direction selection Rules A, and B for the Three-Hump-Camel-Back problem [3]

range of  $\phi$  on  $\mathbf{x}$ ) that is caused in part by the floating point computer representation of real numbers. Consider the case when the component widths are of similar order, and the absolute value of one component is dominant. The subdivision of the latter component may result in a worse inclusion, since the representable numbers are sparser in this direction.

**Rule E.** Similar to Rule C, the underlying idea of Rule E is to minimize the width of the inclusion, but this time based on second order information (suggested by Ratz [10]):

$$D(i) := w((\mathbf{x}_i - m(\mathbf{x}_i))(\nabla\phi_i(m(\mathbf{x}))) + \frac{1}{2} \sum_{j=1}^n (\mathbf{H}_{ij}(\mathbf{x})(\mathbf{x}_i - m(\mathbf{x}_i))). \quad (6)$$

Many interval optimization codes use **automatic differentiation** to produce the gradient and Hessian values. For such an implementation the subdivision selection Rule E requires not much overhead.

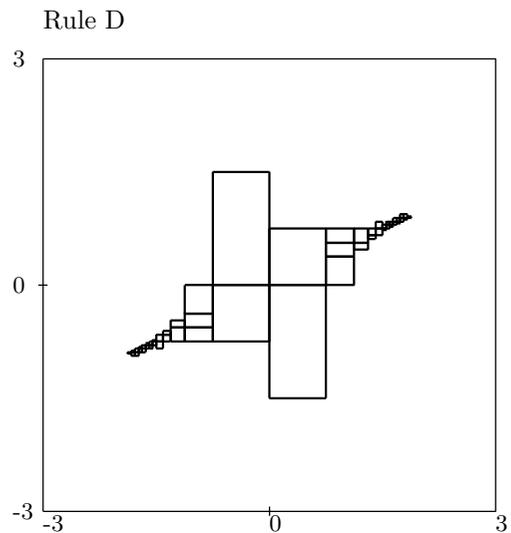

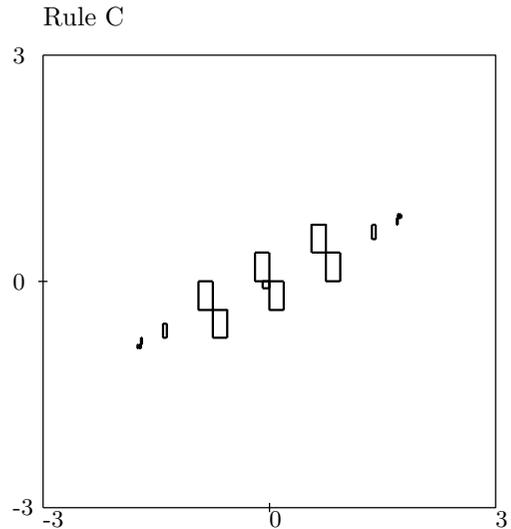

### Properties of Direction Selection Rules

Both the theoretical and numerical properties of subdivision direction selection rules have been studied extensively [1,3,4,10,11]. The exact definitions, theorems and details of numerical comparison tests can be found in these papers. Denote the global minimum value by  $\phi^*$ .

### Theoretical Properties

In [4] the property of balanced direction selection has been defined. A subdivision direction selection rule is balanced basically if the B&B algorithm with this direction selection rule will not be unfair with any coordinate direction: each direction will be selected an infinite number of times in each infinite subdivision sequence of the leading boxes generated by the optimization algorithm. A global minimizer point  $\mathbf{x}' \in \mathbf{x}^0$  is called hidden global minimizer point, if there exists a subbox  $\mathbf{x}' \subseteq \mathbf{x}^0$  with positive volume for which  $\mathbf{x}' \in \mathbf{x}'$  and  $\phi(\mathbf{x}') = \phi^*$  while there exists an other global minimizer point  $\mathbf{x}''$  of the same problem such that  $\phi(\mathbf{x}'') < \phi^*$  holds for each subbox  $\mathbf{x}'' \subseteq \mathbf{x}^0$  with positive volume that contains  $\mathbf{x}''$  [11]. Now the following statements can be made:

1. The basic branch-and-bound algorithm converges in the sense that  $\lim_{s \rightarrow \infty} w(\mathbf{x}^s) = 0$  if and only if the interval subdivision selection rule is balanced [4] (where  $\mathbf{x}^s$  is the leading box of the algorithm in the iteration step number  $s$ ).
2. Assume that the subdivision direction selection rule is balanced. Then the basic B&B algorithm converges to global minimizer points in the sense that

Interval Analysis: Subdivision Directions in Interval Branch and Bound Methods, Figure 2

Remaining subintervals after 250 iteration steps of the model algorithm with the direction selection Rules C, and D for the Three-Hump-Camel-Back problem [3]

$\lim_{s \rightarrow \infty} \phi(\mathbf{x}^s) = \phi^*$ , the set of accumulation points  $A$  of the leading box sequence is not empty, and  $A$  contains only global minimizer points.

3. Assume that the optimization algorithm converges for a given problem in the sense that  $\lim_{s \rightarrow \infty} \phi(\mathbf{x}^s) = \phi^*$ . Then either the algorithm proceeds on the problem as one with a balanced

direction-selection rule, or there exists a box  $y$  such that  $\phi(x) = \phi^*$  for all  $x \in y$ , and  $w(y_i) > 0$  ( $i = 1, 2, \dots, n$ ) for all coordinate directions that are selected only a finite number of times.

4. The subdivision selection Rules A and D are balanced, and thus the related algorithms converge to global minimizer points.
5. Either the subdivision selection Rules B and C choose each direction an infinite number of times (they behave as balanced), or the related algorithms converge to a positive width subinterval of the search region  $x_0$  that contains only global minimizer points.
6. Sonja Berner proved that the basic algorithm is convergent with Rule E in the sense of  $\lim_{s \rightarrow \infty} \phi(x^s) = \phi^*$ , if an additional condition holds for the inclusion function [1].
7. If the branch-and-bound algorithm with any of the direction selection Rules A–E converges to a global minimizer point, then it converges to all non-hidden global minimizer points [11].

### Numerical Properties

The numerical comparison tests were carried out on a wide set of test problems and in several computational environments. The set of numerical test problems contained the standard global optimization test problems [3,4], the set of problems studied in [5], and also some additional ones [10,11]. The computing environments include IBM RISC 6000-580 and HP 9000/730 workstations and Pentium PC-s. The programs were coded in FORTRAN-90, PASCAL-XSC, and also in C++. The tests were carried out both with simple natural interval extension and with more sophisticated inclusion functions involving centered forms. The derivatives were handcoded in some test [4], while they were generated by automatic differentiation in the others [3,10,11]. The range of the investigated algorithms included simple B&B procedures and also optimization codes with many acceleration devices (like the ► **interval Newton method**).

The conclusions were essentially the same: the Rules B, C, and E had similar, substantial efficiency improvements against Rules A and D, and these improvements were the greater the more difficult the solved problem was. The average performance of Rule D was the worst.

Rule C was usually the best, closely followed by Rule B and E. It seems that the use of Rule E is justified only if the second derivatives are calculated also for other purposes. The numerical results were diverse, thus if the user has a characteristic problem set, then it is worth to test all the subdivision direction selection rules to find the most fitting one.

A computationally intensive numerical study [2] has proven that the most efficient subdivision direction selection rules are not those that minimize the width of the objective function inclusions for the result subintervals (which was the common belief), but those that maximize the lower bound of the worse subinterval obtained or minimize the width of the intersection of the result subintervals. The decisions of these a posteriori rules coincide the most with the a priori Rules B, C, and E. These findings confirm the earlier mentioned numerical efficiency results.

### Keywords

Interval Newton operator; Nonlinear equations

A system of *nonlinear equations* can be represented in vector form as  $f(x) = 0$ , where the components are  $f_i(x) = f_i(x_1, \dots, x_n) = 0, i = 1, \dots, n$ .

Sometimes we seek one solution; sometimes we are interested in locating all solutions.

A naive interval approach can be used to search a *box* (an interval vector)  $V$  for solutions. Using repeated bisections in various coordinate directions, we can chisel off parts of  $V$  that cannot contain a solution. That is, if  $f(W)$  does not contain the zero vector for some  $W$  in  $V$ , then we can delete  $W$  as containing no solutions to  $f(x) = 0$ . The remaining parts of  $V$  contain all the solutions, if any, that were in the initial  $V$ .

For differentiable systems, there are much more efficient methods for finding a solution or the set of all solutions. Even so, the naive approach does have its uses. In practice it often pays to combine a number of techniques.

One approach to solving  $f(x) = 0$  is to formulate an equivalent fixed-point problem, and use iterative methods to solve it. We can define

$$g(x) = x + Yf(x)$$

for any linear mapping  $Y$ . If  $Y$  is nonsingular, then  $f(x) = 0$  is equivalent to  $g(x) = x$ .

If  $g$  is continuous and  $S$  is a compact, convex subset of  $\mathbf{R}^n$ , and  $g$  maps  $S$  into itself, then  $g$  has a fixed point in  $S$  and so  $f(x) = 0$  has a solution in  $S$ .

An interval vector  $V$  is a compact, convex set, so  $g(V) \subset V$  implies  $f(x) = 0$  for at least one point  $x$  in  $V$ .

Classical iterative methods consider sequences of points generated by

$$x^{(k+1)} = g(x^{(k)})$$

starting from some initial point  $x^{(0)}$ .

If we denote the Jacobian matrix for the system by  $f'(x)$ , then choosing  $Y = -f'(x)^{-1}$ , we will have Newton's method. If we take  $Y$  as an approximation to  $-f'(x)^{-1}$ , then we obtain a Newton-like method.

Interval versions of Newton's method, however, also involve *intersections*, as we will see.

An *interval Newton method* for finite systems of nonlinear equations was introduced by R.E. Moore [11,12]. Subsequently, many improvements have been made, e. g., [4,6,7,8,10,13,16,17,18].

In order to explain as clearly as possible, consider the one-dimensional case. We have the mean value theorem for continuously differentiable  $f$ :

$$f(x) = f(x^{(0)}) + f'(\xi)(x - x^{(0)})$$

for some  $\xi$  between  $x^{(0)}$  and  $x$ .

We have  $f(x) = 0$  if  $x$  satisfies

$$x = x^{(0)} - [f'(\xi)]^{-1}f(x^{(0)}).$$

Now the ordinary Newton method replaces the unknown  $\xi$  by  $x^{(0)}$ .

The initial idea was to use an interval for  $\xi$  and use interval computation throughout the iterations. If we start with an interval, say  $X^{(0)}$ , that contains  $x^{(0)}$  and happens to also contain a solution, say  $x$ , of  $f(x) = 0$ , then  $X^{(0)}$  also contains  $\xi$  and therefore  $x$  is contained in

$$N(X^{(0)}) = x^{(0)} - [f'(X^{(0)})]^{-1}f(x^{(0)})$$

( $N$  for Newton), where  $f'(X^{(0)}) \subset \{f'(x):x \in X^{(0)}\}$ . The first idea was to iterate  $X^{(k+1)} = N(X^{(k)})$ , but this turns out not to converge in all cases.

Then the following idea was proposed, [12]. Since a solution  $x$  in  $X^{(0)}$  is also in  $N(X^{(0)})$ , it follows that  $x$  is also contained in the intersection:  $X^{(0)} \cap N(X^{(0)})$ .

Therefore, we iterate

$$X^{(k+1)} = X^{(k)} \cap N(X^{(k)})$$

with

$$N(x^{(k)}) = y^{(k)} - [f'(X^{(k)})]^{-1} f(y^{(k)}),$$

choosing  $y^{(k)}$  in  $X^{(k)}$ , say the midpoint of  $X^{(k)}$ .

With this modification, the interval Newton method does what we want, as will be explained. From the above arguments we have proved that for an interval  $X$ ,

1) if  $N(X) \cap X$  is empty, then there is no solution in  $X$ .

If we divide by an interval containing zero, we may obtain one, or the union of two, semi-infinite intervals for  $N(X)$ . The intersection with the finite interval  $X$  in the interval Newton method, reduces the result to a finite interval, or the union of two finite intervals, or the empty set.

During the iterations, if  $X^{(k)}$  turns out to be the union of two intervals, we put one on a list and proceed to further iterate with the other one. This idea was first presented in E.R. Hansen [6].

We can also prove that [5,6]:

2) if  $N(X) \subset X$ , then there exists a unique solution in  $N(X)$ .

The existence follows for the compact, convex interval  $X$ , and from the continuity of  $f'$ . The uniqueness follows from the boundedness of  $N(X) \subset X$ . If there were two solutions in  $N(X)$ , then  $f'(y)$  would be zero for some  $y$  in  $X$  and  $N(X)$  would be unbounded.

If  $f$  is twice continuously differentiable, then we can also prove the following [16]:

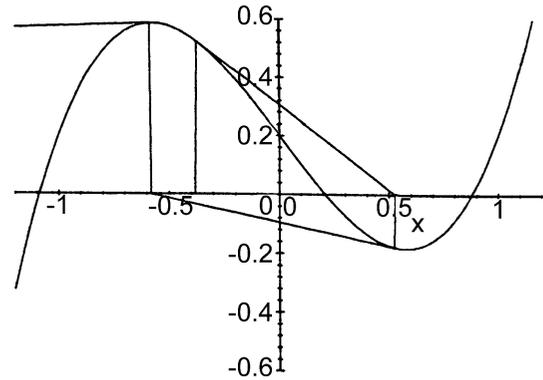

3) if  $N(X) \subset X$ , then the interval Newton method converges quadratically to the unique solution in  $X$ , as does the *ordinary* Newton method from any starting point in  $X$ .

'Quadratically' here means there is a constant  $C$  such that  $w(X^{(k+1)}) < Cw(X^{(k)})^2$ ,  $k = 1, 2, \dots$ , where  $w(X)$  denotes the width of an interval  $X$ ; thus,  $w([a, b]) = b - a$ .

We illustrate the different behaviors of the ordinary Newton method and the interval Newton method in the following figures. Fig 1 shows that the ordinary Newton method cannot find the middle solution unless we start very close to it.

The first three iterations of the ordinary Newton method

$$x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)}$$

Interval Analysis: Systems of Nonlinear Equations, Figure 1  
The ordinary Newton method

for  $f(x) = x^3 - x + 0.2$ , starting with  $x^{(0)} = -0.375$ , are shown in Fig 1. The algorithm produces  $x^{(1)} = 0.528 \dots$ ,  $x^{(2)} = -0.584 \dots$ ,  $x^{(3)} = -22.569 \dots$ . In order to converge to the middle root, we need an initial guess  $x^{(0)}$  very close to that root.

The *interval Newton method* finds all three solutions on the starting interval  $X^{(0)} = [-1.2, 1.2]$  without difficulty. We choose that starting interval because the roots of a polynomial

$$p(z) = a_n z^n + \dots + a_1 z + a_0$$

with  $a_n \neq 0$  are well-known to lie in the complex disk

$$|z| \leq \max \left\{ 1, |a_n|^{-1} \sum_{k < n} |a_k| \right\};$$

so, for the example  $p(x) = x^3 - x + 0.2$ , the real roots are known to satisfy

$$-1.2 \leq x \leq 1.2.$$

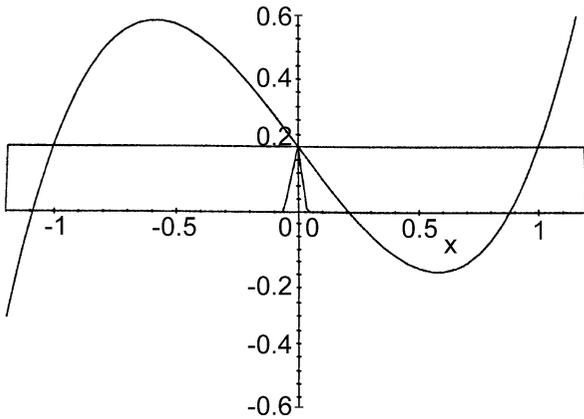

If the intersection  $N(X^{(k)}) \cap X^{(k)}$  splits into two intervals, we list one and analyze the other. See Fig 2 and Fig 3

We used the usual recursive algorithm for evaluating the polynomial and its derivative, namely

```

p ← a_n
p' ← 0
FOR i = n - 1 TO 0 STEP -1 DO
    p' ← x p' + p
    p ← a_i + x p
END DO

```

**Interval Analysis: Systems of Nonlinear Equations, Figure 2**  
The interval  $N([-1.2, 1.2]) \cap [-1.2, 1.2]$  splits into  $[-1.2, -0.0602 \dots] \cup [0.0375 \dots, 1.2]$ . We list the first and analyze the second. See Fig 3

Of course, for the interval Newton method, the evaluations are carried out in interval arithmetic with outward rounding. The real coefficients are entered as degenerate intervals, for example

$$0 \equiv [0, 0], \quad 1 \equiv [1, 1], \quad 0.2 \equiv [0.2, 0.2].$$

Recalling that we began with the initial interval  $X^{(0)} = [-1.2, 1.2]$ , we find that the midpoint of  $X^{(0)}$  is  $y^{(0)} = [0, 0]$  and so:

$$\begin{aligned} N(X^{(0)}) &= y^{(0)} - [p'(X^{(0)})]^{-1} p(y^{(0)}) \\ &= [0, 0] - \frac{1}{[-5.32, 3.32]} [0.2, 0.2] \\ &= (-\infty, -0.06024 \dots] \cup [0.03759 \dots, \infty). \end{aligned}$$

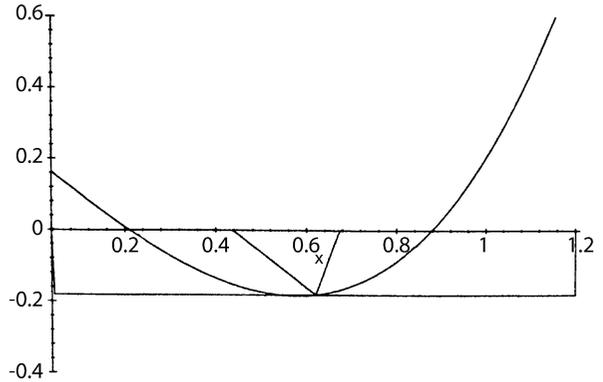

When we intersect this union with  $X^{(0)}$ , we obtain

$$[-1.2, -0.06024 \dots] \cup [0.030759 \dots, 1.2].$$

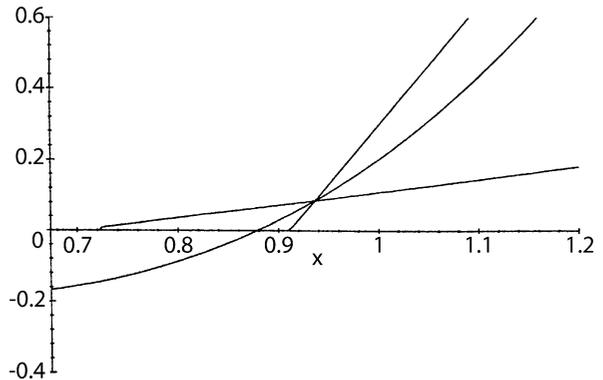

The calculation of  $p'([-1.2, 1.2])$  was as follows:

$$\begin{aligned} p'([-1.2, 1.2]) &= [3, 3][[-1.2, 1.2][[-1.2, 1.2]] - [1, 1] \\ &= [3, 3][[-1.44, 1.44]] - [1, 1] \\ &= [-4.32, 4.32] - [1, 1] \\ &= [-5.32, 3.32]. \end{aligned}$$

Referring to Fig 2 and Fig 3, we see that the interval Newton method first splits the starting interval  $X^{(0)}$  into

**Interval Analysis: Systems of Nonlinear Equations, Figure 3**  
The interval being analyzed,  $X = [0.0375 \dots, 1.2]$ , is shown enlarged for clarity. Again  $N(X) \cap X$  splits into two intervals  $[0.0375 \dots, 0.436 \dots] \cup [0.6738 \dots, 1.2]$ . We list the first and analyze the second. See Fig 4

**Interval Analysis: Systems of Nonlinear Equations, Figure 4**  
We analyze the interval  $X = [0.6738 \dots, 1.2]$ . This time we have  $N(X) \subset X$ , because  $N(X) = [0.724 \dots, 0.911 \dots]$ , so we will have convergence to the unique solution in  $X$

two subintervals  $[-1.2, -0.0602 \dots]$  and  $[0.0375 \dots, 1.2]$ , then it splits the second one again into two subintervals  $[0.0375 \dots, 0.436 \dots]$  and  $[0.6738 \dots, 1.2]$ .

The intervals

$$[-1.2, 0.0602 \dots] \quad \text{and} \quad [0.0375 \dots, 0.0436 \dots]$$

were listed for later analysis, and the interval  $[0.6738 \dots, 1.2]$  was analyzed. With  $X^{(0)} = [0.6738 \dots, 1.2]$ , the method produced

$$N(X^{(0)}) = [0.724 \dots, 0.911 \dots] \subset X^{(0)},$$

so there is a unique solution in that  $X^{(0)}$ .

We can prove the following:

- 4) If  $N(X) \subset X$  and we carry out the interval computations with outward rounding after a fixed number of digits (or bits), the iterations

$$X^{(k+1)} = N(X^{(k)}) \cap X^{(k)}, \quad k = 0, 1, \dots,$$

with  $X^{(0)} = X$  form a nested sequence of intervals containing the solution until, after a finite number of iterations we can stop with  $X^{(k+1)} = X^{(k)}$ .

This follows from the fact that there are only finitely many different machine numbers of a given 'precision', that is with a given finite number of digits (bits). In the example at hand, the final results were as follows. For  $X^{(0)} = [0.6738 \dots, 1.2]$ , after four iterations:

THERE IS A ROOT IN

$$[0.8788850662, 0.8788850663].$$

The program then removed a new  $X^{(0)} = [0.037 \dots, 0.436]$  from the list. It turned out that  $N(X^{(0)}) = [0.2007 \dots, 0.213 \dots] \subset X^{(0)}$ , so there is a unique solution in the new  $X^{(0)}$ . After three iterations, we obtained:

THERE IS A ROOT IN

$$[0.2091488484, 0.2091488485].$$

Finally, the program removed the last remaining interval on the list, namely  $[-1.2, -0.06 \dots]$ , which is then taken as a new  $X^{(0)}$ . This time the intersection came into play because

$$N(X^{(0)}) = (-\infty, -0.809 \dots] \cup [-0.04 \dots, \infty).$$

The intersection of this union with  $X^{(0)} = [-1.2, -0.06 \dots]$  gave the single interval

$$X^{(1)} = N(X^{(0)}) \cap X^{(0)} = [-1.2, -0.809 \dots].$$

After four iterations, we obtained the result:

THERE IS A ROOT IN

$$[-1.0880339147, -1.0880339146].$$

A final message was printed out (which happens when the list becomes empty after the last one taken out is analyzed):

THERE ARE NO MORE ROOTS IN

$$[-1.2, 1.2].$$

The following additional examples were carried out, using a program implementing the interval Newton method just described, in C-XSC [9], and run on an Intel 486 processor.

- 1) Find the real roots in  $[-3, 3]$  of

$$p(x) = x^3 - 1.5201x^2 + 0.770201x - 0.1300755.$$

This polynomial is the expanded form of

$$p(x) = (x - 0.5)(x - 0.51)(x - 0.5101),$$

thus the roots are fairly closely packed.

When we entered  $p(x)$  as

$$x*x*x - 1.5201*x*x + 0.770201*x - 0.1300755,$$

the program SES (Single Equation Solver, in C-XSC [9]) produced three roots in the intervals (shown outwardly rounded to six places):

$$[0.510099, 0.510101],$$

$$[0.509999, 0.510001],$$

$$[0.499999, 0.500001].$$

Sadly, when we entered  $p(x)$  as

$$x^3 - 1.5201*x^2 + 0.770201*x - 0.1300755,$$

the program SES produced a false result, a 'root' in the interval  $[0.168885, 0.168886]$ .

Unfortunately, one must be cautious when using a *programmed implementation* ('software') even for a method that is guaranteed. It can be very difficult to prove the correctness of a computer program, particularly when it still has bugs, such as the implementation of  $x^3$  in an early version of SES. Hopefully, it has been fixed in later versions. Usually extensive testing of a program before its release will uncover most such bugs. The subject of proving correctness of computer programs is a difficult and active area of research in computer science.

Here are some additional examples run in C-XSC. They were all independently checked with another program written from scratch and run on another computer. This is another way to test a computer implementation of a computational method.

2) Find all the roots in  $[.01, 1.0]$  of

$$f(x) = x^2 + \sin\left(\frac{1}{x}\right).$$

The program found 30 roots from right to left, becoming more and more closely packed. The first four digits of the last three roots found were .0109, .0106, .0102.

The last root lies in the interval (shown to 11 digits)  $[.01026804972, .01026804973]$ .

The CPU time was 0.16 seconds using C-XSC on a 486 processor.

3) An example suggested by E.A. Galperin, see [14], is

$$f(x) = x^2 + \sin\left(\frac{1}{x^p}\right), \quad p = 1, 2, 3.$$

We ran the program to find all roots in  $[0.1, 1.0]$  for the cases  $p = 1, 2, 3$ .

Three roots were found right to left for  $p = 1$ ; thirty-one roots for  $p = 2$ ; and 318 roots for  $p = 3$ . The last root found for  $p = 3$  lies in the interval

$$[0.10003280626, 0.10003280628].$$

To find all the 318 closely packed roots in the case  $p = 3$ , the CPU time was 1.5 seconds using C-XSC on a 486 processor.

The method generalizes to  $n$  dimensions. Interval Newton methods for  $n$ -dimensional nonlinear systems have some remarkable properties; among them are the following:

- 1) If  $N(X) \cap X$  is empty, then there is no solution in  $X$ ;
- 2) If  $N(X) \subset X$ , then there is a unique solution in  $N(X)$ ;
- 3) If  $N(X) \subset X$ , then the interval Newton method, with  $X^{(0)} = X$ , converges quadratically to the unique solution in  $X$ , as does the ordinary Newton method from any starting point in  $X$ .
- 4) If  $N(X) \subset X$ , with outward rounding in the interval computation of  $N(X)$ , then the interval Newton method converges in a finite number of iterations, because of the intersection, to an interval vector containing the unique solution in  $X$ , using the stopping criterion: STOP when  $X^{(k+1)} = X^{(k)}$ .

The general form of such algorithms is

$$X^{(k+1)} = N(X^{(k)}) \cap X^{(k)},$$

where the *interval Newton operator*  $N$  is defined in various ways.

The original way, [12], was

$$N(X^{(k)}) = m(X^{(k)}) - f'(X^{(k)})^{-1} f(m(X^{(k)})),$$

where  $m(X^{(k)})$  is the midpoint of  $X^{(k)}$ . Newer versions (see e. g. [4,7,10,18]) avoid having to find the inverse of the Jacobian matrix  $f'(X)$  for an interval vector  $X$ .

*Krawczyk's variation* [10] was to define  $N(X)$  as

$$N(X) = y - Yf(y) + \{I - YF'(X)\}Z,$$

where  $y$  is the midpoint of the interval vector  $X$ ,  $I$  is the identity matrix,  $Y$  is a nonsingular real matrix, such as an approximation to the inverse of  $f'(m(X))$ , and  $Z = X - y$ .

In cases 2) and 3) above, the subsequent iterations converge to the solution (quadratically, if  $Y$  converges to  $[f'(m(X))]^{-1}$  as the width of  $X$  goes to zero); and with outward rounding in a computer implementation, the iterations will stop at a finite value of  $k$  with the stopping criterion: STOP if  $X^{(k+1)} = X^{(k)}$ .

For a technique for searching for a *safe starting region*  $X^{(0)}$  satisfying 2) from which convergence to a solution is guaranteed, see [13,16]. The technique involves starting with a large initial box and using bisections in a depth-first search in suitable directions to find a sub-box that satisfies property 2) above.

To find enclosures of all solutions in a given initial box, we form a list of 'sub-boxes' (interval vectors) in a way analogous to that explained in the one-dimensional example. When the intersection  $N(X) \cap X$  produces two sub-boxes, we can list one and analyze (continue iterations with) the other, or we can list them both and choose some other box on the list to analyze next. Such an interval method lends itself to *parallelization*. We can distribute sub-boxes remaining on the list to processors in a network, and gain a speed-up factor. This is particularly important for applications to *global optimization*; see e. g. [8,15].

### Numerical Example

A solution was sought for the following nine-dimensional system obtained from P. Rabinowitz (private communication). The system concerns finding weights and argument spacings for a certain type of multidimensional

mensional integration formula

$$\begin{aligned}
 x_1 + x_3 + x_5 + 2x_7 &= 1, \\
 x_1x_2 + x_3x_4 + 2x_5x_6 + 2x_7x_8 + 2x_7x_9 &= \frac{2}{3}, \\
 x_1(x_2)^2 + x_3(x_4)^2 + 2x_5(x_6)^2 \\
 + 2x_7(x_8)^2 + 2x_7(x_9)^2 &= \frac{2}{5}, \\
 x_1(x_2)^3 + x_3(x_4)^3 + 2x_5(x_6)^3 \\
 + 2x_7(x_8)^3 + 2x_7(x_9)^3 &= \frac{2}{7}, \\
 x_1(x_2)^4 + x_3(x_4)^4 + 2x_5(x_6)^4 \\
 + 2x_7(x_8)^4 + 2x_7(x_9)^4 &= \frac{2}{9}, \\
 x_5(x_6)^2 + 2x_7x_8x_9 &= \frac{1}{9}, \\
 x_5(x_6)^4 + 2x_7(x_8)^2(x_9)^2 &= \frac{1}{25}, \\
 x_5(x_6)^3 + x_7x_8(x_9)^2 + x_7(x_8)^2x_9 &= \frac{1}{15}, \\
 x_5(x_6)^4 + x_7x_8(x_9)^3 + x_7(x_8)^3x_9 &= \frac{1}{21}.
 \end{aligned}$$

A solution was sought in the unit 9-cube. We started with an initial box slightly larger than the unit 9-cube in case there was a solution on the boundary. A depth-first search for a safe starting region was carried out and was successful after 168 bisections in a certain sequence of coordinate directions determined by the program as the process proceeded, see [16]. Finally, a solution was quickly bounded in a small box (9-dimensional interval vector here). The reader is invited to try a favorite non-interval nonlinear systems solver to find a solution of this system. Better still, find all the solutions and prove there are no more, as the interval method did.

An alternative approach using interval analysis to solve nonlinear systems is computing the *topological degree* of the mapping  $f$  over a box ( $n$ -dimensional interval vector). See [1,2].

For access to voluminous literature, available software, current research efforts, conferences, etc. in the area of interval computation, see [21].

Constrained optimization; Automatic result verification; Interval computations; Global optimization

Interval algorithms for constrained and unconstrained optimization are based on adaptive, exhaustive search of the domain. Their overall structure is virtually identical to *Lipschitz optimization* as in [4], since interval evaluations of an objective function  $\phi$  over an interval vector  $\mathbf{x}$  correspond to estimation of the range of  $\phi$  over  $\mathbf{x}$  with Lipschitz constants. However, there are additional opportunities for acceleration of the process with interval algorithms, and use of outwardly rounded interval arithmetic gives the computations the rigor of a mathematical proof.

The interval algorithms are both complicated and accelerated by the presence of constraints, as is explained below.

See [5,2] or [3] for further details of concepts in this article.

The basic problem is

$$\begin{cases} \min & \phi(x) \\ \text{s.t.} & c(x) = 0 \\ & g(x) \leq 0, \end{cases} \quad (1)$$

where  $\phi: \mathbf{x} \subset \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $c: \mathbf{x} \rightarrow \mathbf{R}^{m_1}$ , and  $g: \mathbf{x} \rightarrow \mathbf{R}^{m_2}$ , where  $\mathbf{x}$  is an interval vector

$$\mathbf{x} = ([\underline{x}_1, \bar{x}_1], \dots, [\underline{x}_n, \bar{x}_n])^\top.$$

The values  $m_1 = 0$  and  $m_2 = 0$  will be allowed, in which case the problem is considered to be unconstrained. It is emphasized here that, in problem (1), a *global optimum*, that is, the lowest possible value of  $\phi$  over the feasible set, is sought.

### The Basic Branch and Bound Algorithm for Unconstrained Optimization

The overall outline of an interval branch and bound algorithm for unconstrained global optimization is given in Table 1.

One way that a box is rejected in step 2b) of this algorithm is by using a bound on the range of the function  $\phi$  over the interval vector (box)  $\mathbf{x}$ . In particular, suppose the value  $\phi(x)$  at a point  $x$  is known. Then  $\phi(x)$

## Interval Analysis: Unconstrained and Constrained Optimization, Table 1

INPUT: an initial box  $\mathbf{x}_0$ .

OUTPUT: a list  $C$  of boxes that have been proven to contain critical points and a list  $U$  of boxes with small objective function values, but which could not otherwise be resolved.

1. Initialize a list of boxes  $L$  by placing the initial search region  $\mathbf{x}_0$  in  $L$ .
2. DO WHILE  $L \neq \emptyset$ .
  - a) Remove the first box  $\mathbf{x}$  from  $L$ . (The boxes in  $L$  are in general in a particular order, depending on the actual algorithm.)
  - b) (Process  $\mathbf{x}$ ) Do one of the following:
    - reject  $\mathbf{x}$ ;
    - reduce the size of  $\mathbf{x}$ ;
    - determine that  $\mathbf{x}$  contains a unique critical point, then find the critical point to high accuracy;
    - subdivide  $\mathbf{x}$  to make it more likely to succeed at rejecting, reducing, or verifying uniqueness.
  - c) Do the following to the box(es) resulting from Step 2b):
    - If  $\mathbf{x}$  was rejected, do nothing.
    - If more than one box was derived from  $\mathbf{x}$ , insert all but one of them into  $L$ . Call the remaining box derived from  $\mathbf{x}$   $\tilde{\mathbf{x}}$ .
    - If there is a  $\tilde{\mathbf{x}}$  that has been proven to contain critical point, insert it into  $C$ .
    - If there is a  $\tilde{\mathbf{x}}$  that is small, but has not been proven to contain feasible point, insert it into  $U$ .

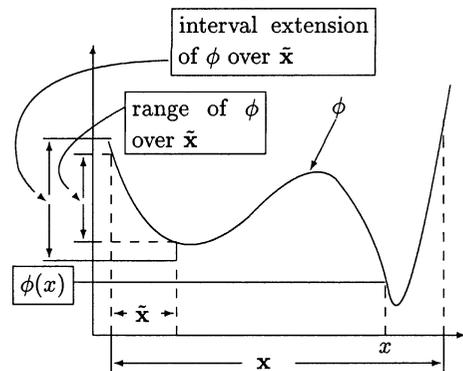

END DO

is an upper bound for the global optimum. (In fact, if  $\phi$  has been evaluated at various points, then the minimum of the resulting values is a usable upper bound on the global optimum.) Now suppose a lower bound  $\phi$  on the range of  $\phi$  over a box (or more generally, a region)  $\mathbf{x} \subset \mathbf{R}^n$  can be computed, and that  $\phi > \phi(x)$ . Then there cannot be any global optimizers of  $\phi$  within  $\mathbf{x}$ . The value  $\phi$  can be obtained through an interval function value. This process is illustrated in the following figure.

The lower bound  $\phi$  for the objective over the box  $\mathbf{x}$  need not be obtained via interval computations. Indeed, if a Lipschitz constant  $L_x$  for  $\phi$  is known over  $\mathbf{x}$ , and  $\phi(\tilde{x})$  is known for  $\tilde{x}$ , the center of  $\mathbf{x}$ , then, for any  $\tilde{x} \in \mathbf{x}$ ,

$$\phi(\tilde{x}) \geq \phi(\tilde{x}) - \frac{1}{2}L_x \|w(\mathbf{x})\|,$$

where  $w(\mathbf{x})$  is the vector of widths of the components of the interval vector  $\mathbf{x}$ . However, getting rigorous bounds on Lipschitz constants can require more human effort than the interval computation, and often results in bounds that are not as sharp as those from interval computation. (However, heuristically obtained ap-

Interval Analysis: Unconstrained and Constrained Optimization, Figure 1

The midpoint test: Rejecting  $\tilde{\mathbf{x}}$  because of a high objective value

proximate Lipschitz constants, as employed in the calculations in [4], have been highly successful at solving practical problems, albeit not rigorously.) Similarly, automated computations for Lipschitz constants as presently formulated result in bounds that are prov-

ably not as sharp as interval computations. Furthermore, use of properly rounded interval arithmetic, if used both in computing  $\phi$  and  $\phi(x)$ , allows one to conclude *with mathematical rigor* that there are no global optima of  $\phi$  within  $\mathbf{x}$ .

Use of this lower bound for  $\phi$  is sometimes called the *midpoint test*, since the points  $x$  at which  $\phi(x)$  is evaluated are often taken to be the vectors of midpoints of the boxes  $\mathbf{x}$  produced during the subdivision process. (Actually, some implementations use the output of an approximate or local optimizer as  $x$ , to get an upper bound on the global optimum that is as low as possible.)

The simplest possible branch and bound algorithms need to contain both a box rejection mechanism and a subdivision mechanism. A common subdivision mechanism is to form two sub-boxes by bisecting the widest coordinate interval of  $\mathbf{x}$  (with possible scaling factors). Heuristics and scaling factors, as well as several references to the literature, appear in [3, §4.3.2, p. 157 ff]. Alternatives to bisection, such as trisection, forming two boxes by cutting other than at a midpoint, etc. have also been discussed at conferences and studied empirically [1].

### Acceleration Tools

Early and simple algorithms contain *only* the midpoint test mechanism and bisection mechanism described above. Such algorithms produce as output a large list  $U$  of small boxes (with diameters smaller than a stopping tolerance) and no list  $C$  of boxes that contain verified critical points. The list  $U$  in such algorithms contains clusters of boxes around actual global optimizers. Some Lipschitz constant-based algorithms are of this form. Note, however, that such algorithms are of limited use in high dimensions, since the number of boxes produced increases exponentially in the dimension  $n$ .

Interval computations provide more powerful tools for accelerating the algorithm. For a start, if an interval extension of the gradient  $\nabla\phi(\mathbf{x})$  is computable then  $0 \notin \nabla\phi(\mathbf{x})$  implies that  $\mathbf{x}$  cannot contain a critical point, and  $\mathbf{x}$  can be rejected. This tool for rejecting a box  $\mathbf{x}$  is sometimes called the *monotonicity test*, since  $0 \notin (\nabla\phi(\mathbf{x}))_i$  implies  $\phi$  is monotonic over  $\mathbf{x}$  in the  $i$ th component  $x_i$ , where  $(\nabla\phi(\mathbf{x}))_i$  represents the  $i$ th component of the interval evaluation of the gradient  $\nabla\phi$ .

Perhaps the most powerful interval acceleration tool is *interval Newton methods*, applied to the system  $\nabla\phi = 0$ . Interval Newton methods can result in quadratic convergence to a critical point in the sense that the widths of the coordinates of the image of  $\mathbf{x}$  are proportional to the square of the widths of the coordinates of  $\mathbf{x}$ . Interval Newton methods also can prove existence and uniqueness of a critical point or nonexistence of a critical point in  $\mathbf{x}$ . Thus, the need to subdivide a relatively large  $\mathbf{x}$  is often eliminated, making a previously impractical algorithm practical. See ► [Interval Newton methods](#) and ► [Interval fixed point theory](#).

For a more detailed algorithm, and for a discussion of parallelization of the branch and bound process, see ► [Interval analysis: Parallel methods for global optimization](#).

### Differences Between Unconstrained and Constrained Optimization

If  $m_1 > 0$  or  $m_2 > 0$  in problem (1), then the problem is one of *constrained optimization*. The midpoint test cannot be applied directly to constrained problems, since  $\phi(x)$  is guaranteed to be an upper bound on the global optimum only if the constraints  $c(x) = 0$  and  $g(x) \leq 0$  are also satisfied at  $x$ . If there are only inequality constraints and none of the inequality constraints are active at  $x$ , then an interval evaluation of  $g(x)$  will rigorously verify  $g(x) < 0$ , and  $x$  can be used in the midpoint test. However, if there are equality constraints (or if one or more of the inequality constraints is active), then an interval evaluation will yield  $0 \in \mathbf{c}(x)$  (or  $0 \in \mathbf{g}_i(x)$  for some  $i$ ), and it cannot be concluded that  $x$  is feasible. In such cases, a small box  $\check{\mathbf{x}}$  can be constructed about  $x$ , and it can be verified with interval Newton methods that  $\check{\mathbf{x}}$  contains a feasible point. The upper bound of the interval evaluation  $\phi(\check{\mathbf{x}})$  then serves as an upper bound on the global optimum, for use in the midpoint test. For details and references, see ► [Interval analysis: Verifying feasibility](#).

On the other hand, constraints can be beneficial in eliminating infeasible boxes  $\mathbf{x}$ . In particular,  $0 \notin \mathbf{c}(\mathbf{x})$  or  $g(\mathbf{x}) > 0$  implies that  $\mathbf{x}$  can be rejected.

It is sometimes useful to consider *bound constraints* of the form  $x_i \geq x_i$  and  $x_j \leq x_j$  separately from the general inequality constraints  $g(x) \leq 0$ . Such bound constraints can generally coincide with the limits on

the search region  $\mathbf{x}_0$ , but are distinguished from simple search bounds. (It is possible for an unconstrained problem to have no optima within a search region, but it is not possible if all of the search region limits represent bound constraints.) See [3, §5.2.3, p. 180 ff] for details.

*Example 1* Consider

$$\begin{cases} \min & \phi(x) = -(x_1 + x_2)^2 \\ \text{s.t.} & c(x) = x_2 - 2x_1 = 0. \end{cases} \quad (2)$$

Example (2) represents a constrained optimization problem with a single equality constraint and no bound constraints or inequality constraints. To apply the midpoint test in a rigorously verified algorithm, a box must first be found in which a feasible point is verified to exist. Suppose that a point algorithm, such as a generalized Newton method, has been used to find an approximate feasible point, say  $\tilde{x} = (\frac{1}{4}, \frac{1}{2})^\top$ . Now observe that  $\nabla c \equiv (-2, 1)^\top$ . Therefore, as suggested in [Interval analysis: Verifying feasibility](#),  $x_2$  can be held fixed at  $x_2 = 1/2$ . Thus, to prove existence of a feasible point in a neighborhood of  $\tilde{x}$ , an interval Newton method can be applied to  $f(x_1) = c(x_1, 0.5) = 0.5 - 2x_1$ . We may choose initial interval  $\mathbf{x}_1 = [0.25 - \epsilon, 0.25 + \epsilon]$  with  $\epsilon = 0.1$ , to obtain

$$\mathbf{x}_1 = [-.15, -.35],$$

$$\tilde{\mathbf{x}}_1 = 0.25 - \frac{0}{-2} = [0.25, 0.25] \subset \mathbf{x}_1,$$

This computation proves that, for  $x_2 = 0.5$ , there is a feasible point for  $x_1 \in [0.25, 0.25]$ . (See [Interval Newton methods](#) and [Interval fixed point theory](#).) We may now evaluate  $\phi$  over the box  $([-0.25, -0.25], [0.5, 0.5])^\top$  (that is degenerate in the second coordinate, and also happens to be degenerate in the first coordinate for this example). We thus obtain

$$\phi([0.25, 0.25], [0.5, 0.5]) = \left[ -\frac{9}{16}, -\frac{9}{16} \right],$$

and  $-9/16$  has been proven to be an upper bound on the global optimum for example problem (2).

## Introduction

Constrained optimization problems are of the form

$$\begin{cases} \min & \phi(x) \\ \text{s.t.} & c_i(x) = 0, \quad i = 1, \dots, m, \\ & g_j(x) \leq 0, \quad j = 1, \dots, q_1, \\ & \underline{x}_{i_k} \leq x_{i_k}, \quad k = 1, \dots, q_2 - \mu, \\ & x_{i_k} \leq \bar{x}_{i_k}, \quad k = \mu + 1, \dots, q_2, \end{cases} \quad (1)$$

where  $\phi: \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $c_i: \mathbf{R}^n \rightarrow \mathbf{R}$ , and  $g_j: \mathbf{R}^n \rightarrow \mathbf{R}$ .

In interval branch and bound algorithms for finding global optima for problem (1), a search box of the form

$$\mathbf{x} = \left\{ (x_1, \dots, x_n)^\top \in \mathbb{R}^n : \begin{array}{l} \underline{x}_i \leq x_i \leq \bar{x}_i, \\ 1 \leq i \leq n \end{array} \right\} \quad (2)$$

is generally given, where some of the sides in (2) correspond to bound constraints of problem (1), and the other sides merely define the extent of the search region. If there are no constraints  $c_i$  and  $g_j$ , then the box  $\mathbf{x}$  is systematically tessellated into sub-boxes. The branch and bound algorithm, in its most basic form, proceeds as follows: Over each sub-box  $\tilde{\mathbf{x}}$ ,  $\phi(\tilde{\mathbf{x}})$  is computed for some  $\tilde{x} \in \tilde{\mathbf{x}}$ , and the range of  $\phi$  over  $\tilde{\mathbf{x}}$  is bounded (e.g. with a straightforward interval evaluation). If there are no constraints  $c_i$  and  $g_j$ , then the value  $\phi(\tilde{x})$  represents an upper bound on the minimum of  $\phi$ . The minimum such value  $\phi$  is kept as the tessellation and search proceed; if any box  $\tilde{\mathbf{x}}$  has a lower range bound greater than  $\underline{\phi}$ , it is rejected as not containing a global optimum. See [1,2], or [3] for details of such algorithms.

The situation is more complicated in the constrained case. In particular, the values  $\phi(\tilde{x})$  cannot be taken as upper bounds on the global optimum unless it is known that  $\tilde{x}$  is feasible. More generally, an upper bound on the range of  $\phi$  over a small box  $\tilde{\mathbf{x}}$  can be taken as an upper bound for the global optimum provided it is proven that there exists a feasible point of problem (1) within  $\tilde{\mathbf{x}}$ . This article outlines how this can be done.

## General Feasibility: the Fritz John Conditions

An interval Newton method (see ► [Interval Newton methods](#)) can sometimes be used to prove existence of a feasible point of problem (1) that is a critical point of  $\phi$ . In particular, the interval Newton method can sometimes prove existence of a solution to the Lagrange multiplier or *Fritz John system* within  $\tilde{\mathbf{x}}$ . For the Fritz John system, it is convenient to consider the  $q_2$  bound constraints in the same form as the  $q_1$  general inequality constraints, so that there are  $q = q_1 + q_2$  general inequality constraints of the form  $g_j(x) \leq 0$ . With that, the Fritz John system can be written as

$$F(x, u, v) = \begin{pmatrix} u_0 \nabla \phi(x) + \sum_{j=1}^q u_j \nabla g_j + \sum_{i=1}^m v_i \nabla c_i(x) \\ u_1 g_1 \\ \vdots \\ u_q g_q \\ c_1(x) \\ \vdots \\ c_m(x) \\ (u_0 + \sum_{j=1}^q u_j + \sum_{i=1}^m v_i^2) - 1 \end{pmatrix} = 0, \quad (3)$$

where  $u_j \geq 0$ ,  $j = 1, \dots, q$ , the  $v_i$  are unconstrained, and the last equation is one of several possible normalization conditions. For details, see [1, §10.5] or [2, §5.2.5].

However, computational problems occur in practice with the system (3). It is more difficult to find a good approximate critical point (for an appropriate small box  $\tilde{\mathbf{x}}$ ) of the entire system (3) than it is to find a point where the inequality and equality constraints are satisfied. Furthermore, if an interval Newton method is applied to (3) over a large box, the corresponding interval Jacobi matrix or slope matrix typically contains singular matrices and hence is useless for

existence verification. This is especially true if it is difficult to get good estimates for the *Lagrange multipliers*  $u_j$  and  $v_i$ . For this reason, the techniques outlined below are useful.

### Feasibility of Inequality Constraints

Proving feasibility of the inequality constraints is sometimes possible by evaluating the  $g_j$  with interval arithmetic: If  $\mathbf{g}_j(\tilde{\mathbf{x}}) \leq 0$ , then every point in  $\tilde{\mathbf{x}}$  is feasible with respect to the constraint  $g_j(x) \leq 0$ ; see [3]. However, if  $\tilde{\mathbf{x}}$  corresponds to a point at which  $g_j$  is active, then  $0 \in \mathbf{g}_j(\tilde{\mathbf{x}})$ , and no conclusion can be reached from an interval evaluation. In such cases, feasibility can sometimes be proven by treating  $g_j(x) = 0$  as one of the equality constraints, then using the techniques below.

### Infeasibility

An inequality constraint  $g_j$  is proven infeasible over  $\tilde{\mathbf{x}}$  if  $\mathbf{g}_j(\tilde{\mathbf{x}}) > 0$ , and an equality constraint  $c_i$  is infeasible over  $\tilde{\mathbf{x}}$  if either  $c_i(\tilde{\mathbf{x}}) > 0$  or  $c_i(\tilde{\mathbf{x}}) < 0$ . See [3].

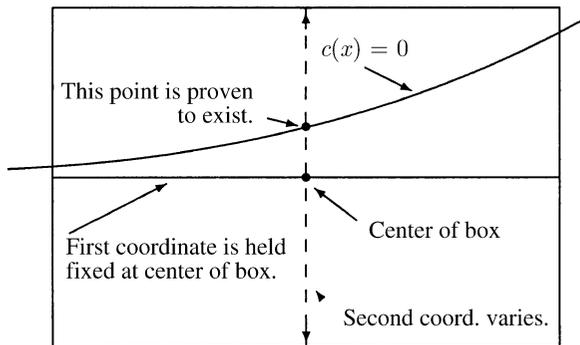

### Feasibility of Equality Constraints

The equality constraints

$$c(x) = (c_1(x), \dots, c_m(x))^T = 0,$$

$c: \mathbb{R}^n \rightarrow \mathbb{R}^m$ ,  $n \geq m$ , can be considered an underdetermined system of equations, whereas interval Newton methods generally prove existence and/or uniqueness for square systems. However, fixing  $n - m$  coordinates  $\check{x}_i \in \tilde{x}_i$  allows interval Newton methods to work with  $\tilde{c}: \mathbb{R}^m \rightarrow \mathbb{R}^m$ , to prove existence of a feasible point within  $\tilde{\mathbf{x}}$ . In principle, indices of the coordinates to be held fixed are chosen to correspond to coordinates in which  $c$  is varying least rapidly. For a set of test problems, the most successful way appears to be choosing those coordinates corresponding to the rightmost columns after Gaussian elimination with complete pivoting has been applied to the rectangular matrix  $c'(\check{x})$  for some  $\check{x} \in \tilde{\mathbf{x}}$ . Figure 1 illustrates the process in two dimensions.

Certain complications arise. For example, if bound constraints or inequality constraints are active, then either the point  $\check{x}$  must be perturbed or else the bound or inequality constraints must be treated as equality constraints. Handling this case by perturbation is discussed in [2, p. 191ff].

**Interval Analysis: Verifying Feasibility, Figure 1**  
Proving that there exists a feasible point of an underdetermined constraint system

For the original explanation of the Gaussian elimination-based process, see [1, §12.4]. In [2, §5.2.4], additional background, discussion, and references appear.

Constraint programming; Continuous constraint satisfaction problems; Local consistency; Propagation

Interval constraint processing is an alternative technology designed to process sets of (generally nonlinear) continuous or mixed *constraints* over the real numbers. It associates propagation and *search* techniques developed in *artificial intelligence* and methods from interval analysis.

Interval constraints are used in the design of the constraint solving and optimization engines of most modern *constraint programming* languages and have been used to solve industrial applications in areas like mechanical design, chemistry, aeronautics, medical diagnosis or image synthesis.

The term interval constraint is a generic term denoting a constraint (that is a first order atomic formula such as an equation, inequation or more generally a relation) in which variables are associated with intervals. These intervals denote domains of possible values for these variables. In general, intervals are defined over the real numbers but the concept is general enough to address other constraint domains (e. g. non

negative integers, Booleans, lists, sets, etc.). When defined over the real numbers, interval constraint sets are often called *continuous* or *numerical constraint satisfaction problems*.

The main idea underlying interval constraint processing—also called *interval propagation*—is, given a set of constraints  $S$  involving variables  $\{v_1, \dots, v_n\}$  and a set of *floating point intervals*  $\{I_1, \dots, I_n\}$  representing the domains of possible values of variables, to isolate a set of  $\{n\}$ -ary *canonical boxes* (Cartesian products of  $I_i$ s subintervals whose bounds are either equal or consecutive floating point numbers) approximating the constraint system solution space. To compute such a set, a search procedure navigates through the Cartesian product  $I_1 \times \dots \times I_n$  alternating pruning and branching steps.

The pruning step uses a relational form of *interval arithmetic* [1,11]. Given a set of constraints over the reals, interval arithmetic is used to compute local approximations of the solution space for a given constraint. This approximation results in the elimination of values from the domains of the variables and these domain modifications are propagated through the whole constraint set until reaching a stable state. This stable state is closely related to the notion of *arc consistency* [9,10], a well-known concept in artificial intelligence. The branching step consists in a bisection-based divide-and-conquer procedure on which a number of strategies and heuristics can be applied.

Interval constraints were first introduced by J.G. Cleary in [5]. The initial goal was to address the incorrectness of floating point numerical computations in the *Prolog* language while introducing a relational form of arithmetic more adapted to the language formal model. These ideas, clearly connected to the concepts developed in *constraint logic programming* [6,7], were then implemented in *BNR-Prolog* [12]. Since then, many other constraint languages and systems have used interval constraints as their basic constraint solving engine, for example *CLP(BNR)* [4], *Prolog IV* [13] or *Numerica* [16].

In the interval framework, the basic data structure is a set of ordered pairs of numbers taken in a finite set of particular rational numbers augmented with the two infinities (this set generally coincides with a set of IEEE floating point numbers). Such a pair, called a floating point interval or, more concisely, an interval, denotes,

as expected, the set of real numbers in between the lower and upper bounds. Operations and relations over the reals can be lifted to intervals (using floating point operations and outward rounding) so as to keep numerical errors under control. In particular, correctness of computations is guaranteed by a fundamental theorem due to R.E. Moore [11].

Assuming a finite set of intervals closed under intersection, every relation  $\rho$  over  $\mathbf{R}$  can be approximated with its *interval enclosure* (i. e. the intersection of all intervals containing it). The approximation of any  $\{n\}$ -ary relation is then defined as the Cartesian product of its projection approximations. These Cartesian products of intervals are called *boxes*. The set of boxes, partially ordered by inclusion, is the complete lattice made of the fixed points of the closure operator that maps  $\{n\}$ -ary relations over  $\mathbf{R}$  to their approximations. The intersection of all boxes containing an  $n$ -ary relation defines an outer approximation notion. A dual notion of inner approximation can be defined as the union of all boxes contained in the relation.

Given a finite set of constraints  $S$  and an initial  $n$ -ary box  $X$  representing the domains (intervals) for all variables occurring in  $S$ , every constraint in  $S$  represents an  $n$ -ary relation  $\rho$  (modulo an appropriate cylindricalification). The main idea is then to compute a box approximating the solution set defined by  $S$  and  $X$ . In the interval constraint framework, this approximation is generally computed by applying the following algorithm, called here *NC3* to reflect its similarity to the arc consistency algorithm *AC3* [10].

The call to the function *narrow* in *NC3* is an algorithmic narrowing process. Every constraint  $c$  in  $S$  and its corresponding relation  $\rho$  is associated with an operator  $N_c$ , called *constraint narrowing operator*, mapping boxes to boxes and verifying the properties of correctness, contractance, monotonicity and idempotence, that is for every boxes  $X, X'$

- 1)  $X \cap \rho \subseteq N_c(X)$ ;
- 2)  $N_c(X) \subseteq X$ ;
- 3)  $X \subseteq X'$  implies  $N_c(X) \subseteq N_c(X')$
- 4)  $N_c(N_c(X)) = N_c(X)$ .

When such operators are associated with the constraints of a set  $S$ , the function *narrow*( $X, c$ ) simply returns  $N_c(X)$ . The algorithm stops when a stable state is reached, i. e. no (strict) narrowing is possible with respect to any constraint. The result of the main step

```
function NC3()
```

```
  input:  $S$ , a (nonempty) constrain system,  
          $X$ , a (nonempty) box
```

```

```

```
     $X' \leftarrow \text{narrow}(X, c)$ 
```

```
    % if  $X'$  is empty,  $S$  is inconsistent
```

```
    IF  $X' = \emptyset$  THEN return  $\emptyset$ 
```

```
    % Queue the constraints whose variables'
```

```
    % domains have changed. Delete  $c$  from  $Q$ 
```

```
    Let  $S' = \{c \in S : \exists v \in \text{var}(c), X'_v \subset X_v\}$ 
```

```
     $Q \leftarrow Q \cup S' \setminus \{c\}$ 
```

```
     $X \leftarrow X'$ 
```

```
  UNTIL  $Q$  is empty
```

```
  return  $X$ 
```

```
END % NC3
```

#### NC3: A generic narrowing algorithm

is to remove (some) incompatible values from the domains of the variables occurring in  $c$ . Furthermore, it can be shown that *NC3* terminates, is correct (the final box contains all solutions of the initial system included in  $\{X\}$ , confluent (selection of constraints in the main loop is strategy independent) and computes the greatest common fixed point of the constraint narrowing operators that is included in the initial box [2].

Over the real numbers, different constraint narrowing operators can be defined, resulting in different local consistency notions. A system is said to be *locally consistent* (with respect to a family of constraint narrowing operators), if the Cartesian product of the domains of its variables is a common fixed point of the constraint narrowing operators associated with its constraints. The main local consistency notions used in continuous constraint satisfaction problems are: first order local consistencies deriving from arc consistency (*hull* (or *2B*) consistency [4,8], *box consistency* [3], and higher order local consistencies deriving from  $k$ -consistency (*3B*, *kB-consistency* [8], *box(2)-consistency* [14]).

More precisely, let *apx*( $c$ ) denote the smallest box enclosing the relation associated with a constraint  $c$ . The family of constraint narrowing operators  $N$  defined as: For all box  $X$  and all constraint  $c$ ,  $N_c(X) = \text{apx}(X \cap c)$  is the support of hull consistency. These opera-

tors can be computed for very simple constraints, often named primitive constraints (e. g.  $x + y = z$ ,  $\sin(x) = y$ , ...) and complex constraints are decomposed into primitive constraints, eventually adding fresh variables.

The definition of *box consistency* involves the introduction of *projection constraints*. Given a multivariate constraint  $c$  over the reals, the projection constraint of  $c$  with respect to a variable  $v$  is obtained by computing an interval extension of the constraint and by replacing every variable but  $v$  with the interval corresponding to its domain. The constraint narrowing operator associated with this projection constraint computes the greatest interval  $[a, b]$  such that  $[a, a^+$  and  $(b^-, b]$ , where  $a^+$  (resp.  $b^-$ ) denotes the successor (resp. the predecessor) of  $a$  (resp.  $b$ ), verify the projection constraint. Besides the fact that this technique does not require the addition of any additional variable, these operators can be computed with an algorithm mixing interval Newton methods (cf. ► [Interval Newton methods](#)), propagation and bisection-based search.

Higher-order local consistencies are based on their first order counterparts. Operationally, the idea is to improve the enclosures accuracy by eliminating subintervals of the locally consistent domains that can be detected locally inconsistent. The general procedure is as follows: Consider a hull consistent interval constraint system  $(S, X)$ . An equivalent 3B-consistent system is a system  $(S, X')$  such that, for every variable  $v$ , if  $X'_v = [a, b]$ , the system  $(S, X'_{v \leftarrow [a, a^+]})$  (resp.  $(S, X'_{v \leftarrow [b^-, b]})$ ) is hull consistent, where  $X'_{v \leftarrow I}$  denotes the Cartesian product  $X'$  where  $X'_v$  is replaced with  $I$ . Box(2)-consistency is defined in the same manner with respect to box consistency. The computational cost of higher-order local consistencies is generally high, but the local gain in accuracy was shown to outperform most existing techniques in several challenging problems (see, for example the circuit design problem in [\[14\]](#)).

Finally, the above mentioned interval constraint techniques are also used for unconstrained and constrained optimization problems (see for example [\[15,16\]](#)).

Interval computations; Global optimization

Interval methods (interval Newton methods and the Krawczyk method) can be used to prove existence and uniqueness of solutions to linear and nonlinear finite-dimensional and infinite-dimensional systems, given floating-point approximations to such solutions. (See ► [Interval Newton methods](#); and [6,8].) In turn, these

existence-proving interval operators have a close relationship with the classical theory of fixed-point iteration. This relationship is sketched here.

### Classical Fixed Point Theory and Interval Arithmetic

Various fixed point theorems, applicable in finite- or infinite-dimensional spaces, state roughly that, if a mapping maps a set into itself, then that mapping has a fixed point within that set. For example, the *Brouwer fixed point theorem* states that, if  $D$  is homeomorphic to the closed unit ball in  $\mathbf{R}^n$  and  $P$  is a continuous mapping such that  $P$  maps  $D$  into  $D$ , then  $P$  has a fixed point in  $D$ , that is, there is an  $x \in D$  with  $x = P(x)$ .

Interval arithmetic can be naturally used to test the hypotheses of the Brouwer fixed point theorem. An interval extension  $\mathbf{P}$  of  $P$  has the property that, if  $\mathbf{x}$  is an interval vector with  $\mathbf{x} \subseteq D$ , then  $\mathbf{P}(\mathbf{x})$  contains the range  $\{P(x) : x \in \mathbf{x}\}$ , and an interval extension  $\mathbf{P}$  can be obtained simply by evaluating  $P$  with interval arithmetic. Furthermore, with *outward roundings*, this evaluation can be carried out so that the floating point intervals (whose end points are machine numbers) *rigorously* contain the actual range of  $P$ . Thus, if  $\mathbf{P}(\mathbf{x}) \subset \mathbf{x}$ , one can conclude that  $P$  has a fixed point within  $\mathbf{x}$ .

Another fixed point theorem, *Miranda's theorem*, follows from the Brouwer fixed point theorem, and is directly useful in theoretical studies of several interval methods. Miranda's theorem is most easily stated with the notation of interval computations: Suppose  $\mathbf{x} \subset \mathbf{R}^n$  is an interval vector, and for each  $i$ , look at the lower  $i$ th face  $\mathbf{x}_i$  of  $\mathbf{x}$ , defined to be the interval vector all of whose components except the  $i$ th component are those of  $\mathbf{x}$ , and whose  $i$ th component is the lower bound  $x_i$  of the  $i$ th component  $\mathbf{x}_i$  of  $\mathbf{x}$ . Define the upper  $i$ th face  $\mathbf{x}_{\bar{i}}$  of  $\mathbf{x}$  similarly. Let  $P: \mathbf{x} \rightarrow \mathbf{R}^n$ ,  $P(x) = (P_1(x), \dots, P_n(x))$  be continuous, and let  $\mathbf{P} = (\mathbf{P}_1, \dots, \mathbf{P}_n)$  be any interval extension of  $P$ . Miranda's theorem states that, if

$$\mathbf{P}_i(\mathbf{x}_i)\mathbf{P}_i(\mathbf{x}_{\bar{i}}) \leq 0, \quad (1)$$

then  $P$  has a fixed point within  $\mathbf{x}$ .

### The Krawczyk Method and Fixed Point Theory

R.E. Moore provided one of the earlier careful analyses of interval Newton methods in [5]. There, the *Krawczyk*

method was analyzed as follows: The chord method is defined as

$$P(x) = x - Yf(x), \quad (2)$$

where the iteration matrix is normally taken to be  $Y = (f'(\tilde{x}))^{-1}$  for some Jacobi matrix  $f'(\tilde{x})$  with  $\tilde{x} \in \mathbf{x}$ , where solutions of  $f(x) = 0, f: D \subseteq \mathbf{R}^n \rightarrow \mathbf{R}^n$  are sought. A mean value extension is then used:

$$P(x) \in P(\check{x}) + \mathbf{P}'(\mathbf{x})(x - \check{x}),$$

whence

$$\begin{aligned} \mathbf{K}(\mathbf{x}, \check{x}) &= \mathbf{P}(\mathbf{x}) \\ &= P(\check{x}) + \mathbf{P}'(\mathbf{x})(\mathbf{x} - \check{x}) \\ &= \check{x} - Yf(\check{x}) + (I - Yf'(\mathbf{x}))(\mathbf{x} - \check{x}) \end{aligned} \quad (3)$$

is an interval extension of  $P$ . Thus, the fact that the range of  $P$  obeys

$$\{P(x): x \in \mathbf{x}\} \subseteq \mathbf{P}(\mathbf{x}) = K(\mathbf{x}, \check{x})$$

coupled with the Brouwer fixed point theorem implies that, if

$$K(\mathbf{x}, \check{x}) \subseteq \mathbf{x},$$

then there exists a fixed point of  $P$ , and hence solution  $x^* \in K(\mathbf{x}, \check{x}), f(x^*) = 0$ .

By analyzing the norm  $\|I - Yf'(\mathbf{x})\|$ , Moore further concludes, basically, that if

$$\|I - Yf'(\mathbf{x})\| < 1,$$

then any solution  $x^* \in \mathbf{x}$  must be unique; for an exact statement and details, see [5].

### Interval Newton Methods and Fixed Point Theory

Traditional interval Newton methods are of the form

$$\mathbf{N}(f, \mathbf{x}, \check{x}) = \check{x} + \mathbf{v}, \quad (4)$$

where  $\mathbf{v}$  is an interval vector that contains all solutions  $v$  to point systems  $Av = -f(\check{x})$ , for  $A \in \mathbf{f}'(\mathbf{x})$ , where  $\mathbf{f}'(\mathbf{x})$  is either an interval extension to the Jacobi matrix of  $f$  over  $\mathbf{x}$  or an interval slope matrix; see ► **Interval Newton methods**. [7, Thm. 5.1.7] asserts that, if  $\mathbf{N}(f, \mathbf{x}, \check{x}) \subset \text{int } \mathbf{x}$ , where  $\mathbf{f}'(\mathbf{x})$  is a 'Lipschitz set' for  $\mathbf{f}$ ,  $\text{int } \mathbf{x}$  denotes the interior of  $\mathbf{x}$ , and  $\check{x} \in \text{int}(\mathbf{x})$ , then there

is a solution of  $f(x) = 0$  within  $\mathbf{N}(f, \mathbf{x}, \check{x})$ , and this solution is unique within  $\mathbf{x}$ . Classical fixed point theory is used in the succinct proof of this general theorem.

When the interval Gauss–Seidel method is used to find the solution set bounds  $\mathbf{v}$ , a very clear correspondence to Miranda's theorem can be set up. This is done in [3].

### Uniqueness

In classical fixed point theory, the contractive mapping theorem (a nongeneric property) is often used to prove uniqueness. For example, suppose  $P$  is Lipschitz with Lipschitz constant  $L < 1$ , that is,

$$\|P(x) - P(y)\| \leq L \|x - y\| \quad \text{for some } L < 1. \quad (5)$$

Then  $x = P(x)$  and  $y = P(y)$  implies  $\|x - y\| = \|P(x) - P(y)\| \leq L \|x - y\|$ , which can only happen if  $x = y$ . (This argument appears in many elementary numerical analysis texts, such as [4].)

An alternate proof of uniqueness involves nonsingularity (i. e., *regularity*) of the mapping  $f$  for which we seek  $x$  with  $f(x) = 0$ . In particular, if  $f(x) = Ax$  is linear, corresponding to a nonsingular matrix  $A$ , then  $f(x) = 0$  and  $f(y) = 0$  implies

$$0 = f(x) - f(y) = Ax - Ay = A(x - y), \quad (6)$$

whence nonsingularity of  $A$  implies  $x - y = 0$ , i. e.  $x = y$ .

Without interval arithmetic, the argument in (6) cannot be generalized easily to nonlinear systems. Basically, invertibility implies uniqueness, and one must somehow prove invertibility. However, with interval arithmetic, uniqueness follows directly from an equation similar to (6), and regularity can be proven directly with an interval Newton method. In particular, if the image under the interval Newton method (4) is bounded, then every point matrix  $A \in \mathbf{f}'(\mathbf{x})$  must be nonsingular. (This is because the bounds on the solution set to the linear system  $\mathbf{f}'(\mathbf{x})\mathbf{v} = -f(\check{x})$  must contain the set of solutions to all systems of the form  $Av = -f(\check{x}), A \in \mathbf{f}'(\mathbf{x})$ .) Then, the mean value theorem implies that, for every  $x \in \mathbf{x}, y \in \mathbf{x}$ ,

$$f(x) - f(y) = A(x - y) \quad \text{for some } A \in \mathbf{f}'(\mathbf{x}). \quad (7)$$

This is in spite of the fact that, in (7),  $A$  is in general not equal to any  $f'(x)$  for some  $x \in \mathbf{x}$ . In fact, (7) follows

from considering  $f$  componentwise:

$$f_i(y) = f_i(x) + (\nabla f_i(c_i))^T (y - x),$$

for some  $c_i$ , different for each  $i$ , on the line connecting  $x$  and  $y$ ; the matrix  $A \in \mathbf{f}'(\mathbf{x})$  can be taken to have its  $i$ th row equal to  $(\nabla f_i(c_i))^T$ . Thus, because of the nonsingularity of  $A$  in (7),  $f(x) = 0, f(y) = 0$  implies  $0 = A(x - y)$  and  $x = y$ .

Summarizing the actual results,

$$\mathbf{N}(f, \mathbf{x}, \check{x}) \subset \text{int } \mathbf{x}, \quad (8)$$

where  $\mathbf{N}(f, \mathbf{x}, \check{x})$  is as in (4), then classical fixed-point theory combined with properties of interval arithmetic implies that there is a unique solution to  $f(x) = 0$  in  $\mathbf{N}(f, \mathbf{x}, \check{x})$ , and hence in  $\mathbf{x}$ .

If slope matrices are used in place of an interval Jacobi matrix  $\mathbf{f}'(\mathbf{x})$ , then (7) no longer holds, and (8) no longer implies uniqueness. However, a two-stage process, involving evaluation of an interval derivative over a small box containing the solution and evaluation of a slope matrix over a large box containing the small box, leads to an even more powerful existence and uniqueness test than using interval Jacobi matrices alone. This technique perhaps originally appeared in [9]. A statement and proof of the main theorem can also be found in [3, Thm. 1.23, p. 64].

### Infinite-Dimensional Problems

Many problems in infinite-dimensional spaces (e.g. certain variational optimization problems) can be written in the form of a compact operator fixed point equation,  $x = P(x)$ , where  $P: S \rightarrow S$  is some compact operator operating on some normed linear space  $S$ . In many such cases,  $P$  is approximated numerically from a finite-dimensional space of basis functions  $\{\phi_i: i = 1, \dots, n\}$  (e.g. splines or finite element basis functions  $\phi_i$ ), and the approximation error can be computed. That is,  $P(x) = P_n(y) + R_n(y)$ , where  $y \in \mathbf{R}^n$  is an approximation to  $x \in S$ , and  $R_n(y)$  is the error that is computable as a function of  $y$ . Thus, a fixed point iteration can be set up of the form

$$y \leftarrow \tilde{P}_n(y) \equiv P_n(y) + R_n(y), \quad (9)$$

where  $y \in \mathbf{R}^n$ . (The dimension  $n$  can be increased as iteration proceeds.)

For (9), the *Schauder fixed point theorem* is an analogue of the Brouwer fixed point theorem; see [1, p. 154]. Furthermore, interval extensions can be provided to both  $P_n$  and  $R_n$ , so that an analogue to finite-dimensional computational fixed point theory exists. In particular, if

$$\tilde{P}_n(\mathbf{y}) \subset \text{int } \mathbf{y}, \quad (10)$$

then there exists a fixed point of  $P$  within the ball in  $S$  centered at the midpoint of  $\mathbf{y}$  and with radius equal to the radius of  $\mathbf{y}$ . (For these purposes,

$$\mathbf{y} = \sum_{i=1}^n \mathbf{a}_i \phi_i$$

can be identified with the interval vector  $(\mathbf{a}_1, \dots, \mathbf{a}_n)^T$  corresponding to the coefficients in the expansion.) For details, see [6, Chap. 15]. Also see [2] for a theoretical development and various examples worked out in detail.

### Keywords

Global optimization; Nonsmooth optimization;  
Unbounded optimization; Interval methods

We give an overview of the general ideas involved in solving constrained and unconstrained global optimization problems using interval arithmetic. We include a discussion of a few prototype optimization algorithms and enumerate some applications in engineering, chemistry, manufacturing, economics and physics.

### Introduction

Let  $I$  be the set of real compact intervals,  $\mathbf{R}$  the set of reals,  $m$  a positive integer,  $X \in I^m$ , and  $f: X \rightarrow \mathbf{R}$  the objective function. We assume that a *global minimum*  $f^*$  of  $f$  exists over  $X$ . Let  $X^*$  be the set of *global minimizers* of  $f$  over  $X$ . Then the *global unconstrained optimization problem* is written down concisely as

$$\min_{x \in X} f(x) \quad (1)$$

which means that  $f^*$  or  $X^*$  is to be determined. The *global constrained optimization problem* arises if a more general set  $M \subseteq \mathbf{R}^m$ , the so-called *feasible domain*, is considered. Solution methods for global constrained problems use the tools for global unconstrained problems, but additionally, further concepts are needed such

as numerical proofs of the guaranteed existence of feasible points in subareas of the working domain. Therefore we separate the treatment of the constrained case from the treatment of the unconstrained case.

The first interval techniques for treating global optimization problems were established by [13,20,30,31,46,64,65,66,67,71,72,74,81,98,103,104,105], etc. Although some of these references were focusing on special problems like convex or signomial programming, they provided concepts which would give insight into more general problems where they were later applied.

The overview that we provide in this article, can only cast a quick glance at the various topics that will be considered. Their thorough investigation may be found in [33,39,47,48,49,56,70,90,95,100].

Solving an optimization problem such as (1) requires, in general, the repetitive comparison of continua of values and the choosing of an optimum value. Since interval computation is a tool for handling continua, it provides competitive methods for solving global optimization problems. Simple prototype algorithms for unconstrained problems are discussed in order not to get too sophisticated. We choose three variants, on the one hand in order to keep track of the historical origins, on the other hand in order to show how small changes in the prototypes influence their convergence behavior. These prototypes are based on ideas of S. Skelboe [103], R.E. Moore [74], N.S. Asaithambi, Z. Shen and Moore [2], E.R. Hansen [30,31], and K. Ichida and Y. Fujii [46]. We do not have the space to provide prototype algorithms for constrained problems as well in this article. Thus we only discuss parts which we have to add to the unconstrained prototypes in order to get a procedure for constrained problems.

In general, interval algorithms for solving global optimization problems consist of

- i) the main algorithm,
- ii) accelerating devices.

The main algorithm is a *sequential deterministic algorithm* where *branch and bound techniques* are used. (An algorithm is called sequential if the  $n$ th step of the computation depends on the former steps. A method is deterministic if stochastic methods are avoided. By branch and bound principles is meant that the whole area  $X$  or  $M$  is not searched uniformly for the global minimizers; instead some parts (branches) are preferred. The branching depends on the bounding. It is

required that for any box  $Y$  of the working area a lower bound for  $f$  over  $Y$  is known or computable.)

Interval arithmetic is used for point i) to achieve the bounds needed for the branch and bound techniques ( $f$  need not be Lipschitz, convex, etc.) and for point ii) to remove superfluous parts of the domains  $X$  or  $M$ .

The contents of this article is as follows: In the next two sections we introduce the interval tools which are required in the article. In section 4, three algorithms for solving (1) are presented. They are seemingly very similar, but their convergence properties, which are discussed in section 5, are different. The three algorithms are also of interest for historical reasons. A survey of acceleration devices, which aim to speed up the computation, is given in section 6. It is shown in section 7 that interval analysis is an excellent means for dealing with problems which have an unbounded domain or a nonsmooth objective function. In section 8, the constrained case is touched upon. Applications of these methods are collected in the final section 9.

## Interval Arithmetic

The interval tools which are needed for the explanation of the basic features of interval methods in global optimization are described in this section. A thorough introduction to the whole area of interval arithmetic can be found, for example, in [1,4,52,74,102], etc. More advanced readers will enjoy [79]. The development of interval tools appropriate for dealing with optimization problems is presented in [88,90]; cf. also the Appendix of [86].

The *interval arithmetic operations* are defined by

$$A * B = \{a * b : a \in A, b \in B\} \quad \text{for } A, B \in I, \quad (2)$$

where the symbol  $*$  may denote  $+$ ,  $-$ ,  $\cdot$ , or  $/$ . In general,  $A/B$  is not defined if  $0 \in B$ . (But see the sections on ‘interval Newton methods’ and ‘global optimization over unbounded domains’ below.) The meaning of (2) is the following: If some unknown reals  $\alpha, \beta$  are included in known intervals, say  $\alpha \in A, \beta \in B$ , then it is guaranteed that the desired result  $\alpha * \beta$ , which is in general unknown, is contained in the known interval  $A * B$ . Definition (2) is equivalent to the following rules,

$$[a, b] + [c, d] = [a + c, b + d],$$

$$[a, b] - [c, d] = [a - d, b - c],$$

$$\begin{aligned}
& [a, b] \cdot [c, d] \\
& = [\min(ac, ad, bc, bd), \max(ac, ad, bc, bd)], \\
\frac{[a, b]}{[c, d]} & = [a, b] \cdot \left[ \frac{1}{d}, \frac{1}{c} \right] \quad \text{if } 0 \notin [c, d].
\end{aligned}$$

Therefore, the interval arithmetic operations can easily be realized on a computer. The algebraic properties of (2) are different from those of real arithmetic operations. The distributive law, for instance, does not hold for (2). A summary of the algebraic behavior of interval arithmetic is given in [85].

The main interval arithmetic tool applied to optimization problems is the concept of an inclusion function. Let again  $X \in I^m$  and  $f: X \rightarrow \mathbf{R}$ . The set of compact intervals contained in  $X$  is denoted by  $I(X)$ . Let  $\bar{f}(Y) = \{f(x): x \in Y\}$  for  $Y \in I(X)$  be the range of  $f$  over  $Y$ . A function  $F$  is called an *inclusion function* for  $f$  if

$$\bar{f}(Y) \subseteq F(Y) \quad \text{for any } Y \in I(X).$$

The left and the right endpoint of  $F(Y)$  will be denoted by  $\min F(Y)$  and  $\max F(Y)$ , respectively.

Inclusion functions can be constructed in any programming language in which interval arithmetic is simulated or implemented via natural interval extensions: Firstly, let  $g$  be any function pre-declared in some programming language (like  $\sin$ ,  $\cos$ ,  $\exp$ , etc.). Then the corresponding *pre-declared interval function* IG is defined by

$$\text{IG}(Y) = \bar{g}(Y)$$

for any  $Y \in I$  contained in the domain of  $g$ .

Since the monotonicity intervals of pre-declared functions  $g$  are well known it is easy to realize the interval functions IG on a computer. Nevertheless, the influence of rounding errors may be considered, see [30], for instance.

Secondly, let  $f(x)$  be any function expression in the variable  $x \in \mathbf{R}^m$ . So,  $f(x)$  may be an explicit formula or described by an algorithm not containing logical connectives at the moment. For simplicity, we assume that  $f(x)$  is representable in a programming language. Let  $Y \in I^m$  or let  $Y$  be an interval variable over  $I^m$ . Then the expression which arises if each occurrence of  $x$  in  $f(x)$  is replaced by  $Y$ , if each occurrence of a pre-declared function  $g$  in  $f(x)$  is replaced by IG, and if the arithmetic

operations in  $f(x)$  are replaced by the corresponding interval arithmetic operations, is called the *natural interval extension* of  $f(x)$  to  $Y$ , and it is denoted by  $f(Y)$ , see [71]. Due to (2) and the definition of the IG's we get the *inclusion principle* for (programmable) functions

$$a \in Y \quad \text{implies} \quad f(a) \in f(Y). \quad (3)$$

Therefore,  $f(Y)$ , seen as a function in  $Y$ , is an inclusion function for the function  $f(x)$ .

For example, if  $f(x) = x_1 \sin x_2 - x_3$  for  $x \in \mathbf{R}^3$ , then  $f(Y) = Y_1 \in Y_2 - Y_3$  is the natural interval extension of  $f(x)$  to  $Y \in I^3$ .

If logical connectives occur in an expression, the extensions are similar, cf. [55,87].

Due to the algebraic properties of interval arithmetic, different expressions for a real function  $f$  can lead to interval expressions which are different as functions. For example, if  $f_1(x) = x - x^2$  and  $f_2(x) = x(1 - x)$  for  $x \in \mathbf{R}$ , then  $f_1(Y) = Y - Y^2 = [-1, 1]$  and  $f_2(Y) = Y(1 - Y) = [0, 1]$  for  $Y = [0, 1]$ . For comparison,  $\bar{f}(Y) = [0, \frac{1}{4}]$ . In general, the problem arises as to how to find expressions of a given function that lead to natural interval extensions that are as good as possible. A partial solution to this problem can be found in [88].

A measure of the quality of an inclusion function  $F$  for  $f: X \rightarrow \mathbf{R}$  is the so-called *excess width* ([71]), defined as  $w(F(Y)) - w(\bar{f}(Y))$  for all  $Y \in I(X)$ , where  $w([a, b]) = b - a$  is the width of an interval.  $F$  is called of *order*  $\alpha > 0$  if

$$w(F(Y)) - w(\bar{f}(Y)) = O(w(Y^\alpha)) \quad \text{for } Y \in I(X),$$

where the width of a box  $Y = Y_1 \times \dots \times Y_m$  is defined by  $w(Y) = \max_{i=1, \dots, m} w(Y_i)$ . In order to obtain good computational results it is necessary to choose inclusion functions having as high an order  $\alpha$  as possible, when  $w(Y)$  is small, see for example [88].

The endpoints of the intervals must be machine numbers, if interval arithmetic is implemented on a machine. This leads to a special topic called *machine interval arithmetic*. It can be considered as an approximation to interval arithmetic on computer systems.

Machine interval arithmetic is based on the inclusion isotonicity of the interval operations in the following manner: Let us again assume that  $\alpha, \beta$  are the unknown exact values at any stage of the calculation, and that only including intervals are known,  $\alpha \in A, \beta \in B$ .

Then  $A, B$  might not be representable on the machine. Therefore  $A$  and  $B$  are replaced by the *smallest machine intervals* that contain  $A$  and  $B$ ,

$$A \subseteq A_M, \quad B \subseteq B_M.$$

A machine interval is an interval which has left and right endpoints that are machine numbers. From (2) it follows that

$$A * B \subseteq A_M * B_M.$$

The interval  $A_M * B_M$  need not be a machine interval and it is therefore approximated by  $(A_M * B_M)_M$  which is the smallest interval representable on the machine and which contains  $A_M * B_M$ . This leads to the *inclusion principle of machine interval arithmetic*:

$$\alpha \in A, \beta \in B \quad \text{implies} \quad \alpha * \beta \in (A_M * B_M)_M. \quad (4)$$

Thus, the basic principle of interval arithmetic is retained in machine interval arithmetic, that is, the exact unknown result is contained in the corresponding known interval, and *rounding errors are under control*.

We sum up: When a concrete problem has to be solved then our procedure is as follows: Firstly, the theory is done in interval arithmetic, secondly, the calculation is done in machine interval arithmetic, and finally, the inclusion principle provides the transition from interval arithmetic to machine interval arithmetic.

Many software packages for interval arithmetic are meanwhile available, which work under Fortran 77, Fortran 90, Pascal, C, C++, Prolog, etc. A good survey can be found, for instance, in [57].

### Interval Newton Methods

Interval Newton methods are excellent methods for determining *all zeros* of a continuously differentiable vector-valued function  $\phi: X \rightarrow \mathbf{R}^m$  where  $X \in I^m$ . These methods are important tools for nonlinear optimization problems since they can be used for computing all critical points of the objective function,  $f$ , by applying the methods to  $J_\phi(x)$ , where  $\phi$  is the gradient function of  $f$  and  $J_\phi$  the Jacobian of  $\phi$ , or for solving the Karush–Kuhn–Tucker or John conditions in constrained optimization.

The interval Newton method was introduced by Moore [71] and it has been further extensively developed by many researchers. The latest state of art for interval Newton methods may be found in [79]. See also

► **Interval Newton methods.** The extensive treatment of the interval Newton method is not part of this introductory article so that we sketch it in an extremely simplified manner just in order to make the aim of the method understandable. For a detailed treatment see, for instance, [1,33,79,90,93], etc.

Interval Newton methods are closely connected to solving systems of linear interval equations. An unfortunate notation is widely used to describe this situation since it uses the notation of interval arithmetic in a doubtful manner which can lead to misunderstandings. I.e., let  $A \in I^{m \times m}$ ,  $B \in I^m$  then the solution of the *linear interval equation* (with respect to  $x$  or  $X$ )

$$Ax = B \quad \text{or} \quad AX = B$$

is not an interval vector  $X_0$  that satisfies the equation,  $AX_0 = B$ , as one would expect. The solution is defined as the set

$$X = \{x \in \mathbb{R}^m : ax = b \text{ for some } a \in A, b \in B\}.$$

Thus, for example, the solution of the linear interval equation

$$[1, 2]x = [1, 2]$$

is  $X = [1/2, 2]$ . In general, the solution set is not a box if  $m \geq 2$ .

It is therefore the aim of interval arithmetic solution methods to find at least a box which contains the solution set.

Accordingly, if  $c \in \mathbf{R}^m$ , then the solution of the linear interval equation

$$A(x - c) = B \quad \text{or} \quad A(X - c) = B$$

with respect to  $x$  or  $X$  is defined to be the set

$$X := c + Y := \{c + y : y \in Y\}$$

where  $Y$  is the solution of the interval equation  $Ay = B$ .

The following prototype algorithm aims to determine the zeros of  $\phi: X \rightarrow \mathbf{R}^m$  in  $X \in I^m$ . Let  $J(Y)$  be an inclusion function for the Jacobian matrix  $J_\phi(x)$  for  $Y \in I(X)$ .

1. Set  $X_0 := X$ .
2. For  $n = 0, 1, \dots$ 
  - a) choose  $x_n \in X_n$ ,
  - b) determine a superbox  $Z_{n+1}$  of the solution  $Y_{n+1}$  of the linear interval equation with respect to  $Y$ ,  $J(X_n)(x_n - Y) = \phi(x_n)$ ,
  - c) set  $X_{n+1} := Z_{n+1} \cap X_n$ .

### The interval Newton algorithm

Since we use it later we emphasize that *one iteration of the interval Newton algorithm* is just the execution of a), b) and c) for a particular value of  $n$ .

Interval Newton methods are distinguished by the particular choice of the superbox  $Z_{n+1}$ . For example, if  $Z_{n+1}$  is the box hull of  $Y_{n+1}$ , that is, the smallest box containing  $Y_{n+1}$ , then the method is called the interval Newton method (in the proper sense). If  $Z_{n+1}$  is obtained by using interval Gauss–Seidel steps combined with preconditioning as will be explained in the sequel, the method is named after Hansen and S. Sengupta [35]. Krawczyk’s method [60] and Hansen–Greenberg’s methods [34] are also widely used. Convergence properties exist under certain assumptions. The following general properties are useful for understanding the principle of application of the algorithm, see [1,71,73,79]:

- 1) If a zero,  $\xi$ , of  $\phi$  exists in  $X$  then  $\xi \in X_n$  for all  $n$ . This means that no zero is ever lost! This implies that:
- 2) If  $X_n$  is empty for some  $n$  then  $\phi$  has no zeros in  $X$ .
- 3) If  $Z_{n+1}$  is obtained by Gauss–Seidel or Gauss elimination, possibly combined with preconditioning as mentioned below then
  - i) if  $Z_{n+1} \subseteq X_n$  for some  $n$  then  $\phi$  has a zero in  $X$ ,
  - ii)  $Z_{n+1} \subseteq \text{int } X_n$  for some  $n$  then  $\phi$  has a unique zero in  $X$  (where  $\text{int}$  means topological interior).
- 4) Under certain conditions one obtains

$$w(X_{n+1}) \leq \alpha(w(X_n))^2$$

for some constant  $\alpha \geq 0$ .

A very promising realization of the interval Newton algorithm is the Hansen–Sengupta version [35] where the linear system occurring in the Newton iteration step is solved by a *preconditioning step* and by *relaxation steps* (Gauss–Seidel).

Now we discuss just one iteration of the Hansen–Sengupta variant and suppress the index  $n$  when writ-

ing down the formulas that occur in the  $n$ th iteration. That is, we write

$$J(X)(x - Y) = \phi(x) \quad (5)$$

instead of

$$J(X_n)(x_n - Y) = \phi(x_n)$$

and, accordingly, we search for a superset  $Z$  of the solution set of (5), where  $X$ ,  $J(X)$ ,  $x$  and  $\phi(x)$  are given. The solution set of (5) is also denoted by  $Y$ .

### The Preconditioning Step

It was already argued by Hansen and R.R. Smith [37] that (5) was best solved by pre-multiplying by an approximate inverse of the midpoint of  $J(X)$ . If the approximate inverse is  $B$ , we obtain

$$BJ(X)(x - Y) = B\phi(x)$$

or

$$M(x - Y) = b \quad (6)$$

where  $M = BJ(X)$  and  $b = B\phi(x)$ . In this manner the system has been modified to a system that is almost diagonally dominant provided the widths of the Jacobian entries are not too large and it is then amenable to Gauss–Seidel type iterations. It is obvious that the solution set of (6) contains the solution set of (5) such that no solution is lost in the above transformation. During the last years much research has been focusing on the preconditioning step, cf. for example, [59].

### The Relaxation Steps (Gauss–Seidel)

The relaxation procedure for linear interval equations was developed in [36]. It consists mainly in the interpretation of the well-known noninterval Gauss–Seidel iteration procedure in an interval context. But much care is taken in the interval realization if division through intervals that contain zero occurs. We do not have the space for a complete discussion and refer, for example, to [33,90,93].

Instead of a relaxation iteration, interval Gauss elimination can be used. This is nothing more than the well-known Gauss elimination performed in an interval setting. Interval Gauss elimination is not as robust

as the interval Gauss–Seidel steps. It is, however, more effective under certain conditions (for instance, if the Jacobian or the preconditioned Jacobian matrix is diagonally dominant, see [79]). Practical experiences show that it is best to combine Gauss–Seidel steps with Gaussian elimination, cf. [33,79,90].

There is no urgent need for discussing convergence properties of the interval Newton algorithm since only single iterations are incorporated into the optimization algorithms, cf. the sections on ‘accelerating and related devices’ and ‘applications’ below, and hence the convergence theory of the latter is applicable, cf. the sections on ‘convergence properties of the prototype algorithms’ and ‘applications’ below. Only if it is already certain or very likely that the computation is approaching a global minimizer does it make sense to switch to the complete interval Newton algorithm and enjoy finally the quadratic convergence property (cf. property 4). Such a situation occurs, for example, if the objective function, in the unconstrained case, or the Lagrangian in the constrained case, is convex.

### Three Prototype Algorithms for the Unconstrained Problem

The algorithms are designed to determine  $f^*$  or  $X^*$  or both as will be described later. They have the box  $X$ , the inclusion function  $F$  for  $f: X \rightarrow \mathbf{R}$  and some accuracy parameters which may occur in the termination criteria, as input parameters. The termination criteria will depend on the actual case and will not be specified here, but see, for example, item c) in the section on ‘convergence properties of the prototype algorithms’. For historical reasons, we go back to the roots of interval arithmetic optimization theory. We start with Moore’s algorithm [71], which used uniform subdivision, but we already incorporate the first branch and bound steps as proposed by Skelboe [103], and finally we land at Hansen’s algorithm [30,31], which was the first algorithm which featured convergence to both, to  $f^*$  and to  $X^*$ .

Algorithm 1 initializes a list  $\mathcal{L} = \mathcal{L}_1$  consisting of one pair  $(X, y)$ , see Step 3. Then the list is modified and enlarged at each iteration, see Steps 8 and 9. At the  $n$ th iteration a list  $\mathcal{L} = \mathcal{L}_n$  consisting of  $n$  pairs is present,

$$\mathcal{L}_n = ((Z_{ni}, z_{ni}))_{i=1}^n \quad \text{where } z_{ni} = \min F(Z_{ni}).$$

1. Calculate  $F(X)$ .
2. Set  $y := \min F(X)$ .
3. Initialize list  $\mathcal{L} = ((X, y))$ .
4. Choose a coordinate direction  $k$  parallel to an edge of maximum length of  $X = X_1 \times \dots \times X_m$ , i.e.  $k \in \{i : w(X) = w(X_i)\}$ .
5. Bisect  $X$  normal to direction  $k$  obtaining boxes  $V_1, V_2$  such that  $X = V_1 \cup V_2$ .
6. Calculate  $F(V_1), F(V_2)$ .
7. Set  $v_i := \min F(V_i)$  for  $i = 1, 2$ .
8. Remove  $(X, y)$  from the list  $\mathcal{L}$ .
9. Enter the pairs  $(V_1, v_1)$  and  $(V_2, v_2)$  into the list such that the second members of all pairs of the list do not decrease.
10. Denote the first pair of the list by  $(X, y)$ .
11. If the termination criteria hold, go to 13.
12. Go to 4.
13. End.

#### Algorithm 1: Moore–Skelboe

The leading pair of the list  $\mathcal{L}_n$  will be denoted by

$$(X_n, y_n) = (Z_{n1}, z_{n1}).$$

The boxes  $X_n$  are called the *leading boxes* of the algorithm. It is assumed that the termination criteria of Step 11 are not satisfied during the whole computation such that the algorithm will not stop. In this case an infinite sequence of lists is produced.

Algorithm 1 was mainly established to determine  $f^*$ . Now, Ichida and Fujii [46] and Hansen [30,31] focused on the boxes  $Z_{ni}$  in order to get reasonable inclusions for  $X^*$ . While midpoint tests (cf. [2,30,31,46]) have no impact on the convergence properties of Algorithm 1, they are now important when getting inclusions of  $X^*$ . *Midpoint tests* are incorporated as follows: Let  $f_n$  be the lowest function value which has been calculated up to the completion of the list  $\mathcal{L}_n$ . (If no function values are available then  $\min_{i=1, \dots, n} \max F(X_i)$  can be taken as  $f_n$ .) Then all pairs  $(Z_{ni}, z_{ni})$  of  $\mathcal{L}$  are discarded that satisfy

$$f_n < z_{ni}.$$

This gives a reduced list  $\bar{\mathcal{L}}_n$ . Let  $U_n = \cup Z_{ni}$  for all  $Z_{ni}$  of the reduced list. Then two different procedures are known:

- Algorithm 2 [46] emerges from Algorithm 1 by keeping track of  $\bar{\mathcal{L}}_n$  instead of  $\mathcal{L}_n$  (and thus having  $U_n$  available at each iteration).
- Algorithm 3 [30,31] is like Algorithm 2, but the reduced lists  $\bar{\mathcal{L}}_n$  are ordered with respect to the age or the widths of the boxes.

Variants of the three prototypes occur if the ordering of the lists and the bisection directions are changed, cf. the next two sections.

### Convergence Properties of the Prototype Algorithms

The results presented in this section are proven in [77,86,89].

Let us first consider Algorithm 1. As in the previous section, we denote the leading pairs of Algorithm 1 by  $(X_n, y_n)$ . One can show that

$$\text{a) } w(X_n) \rightarrow 0 \text{ as } n \rightarrow \infty.$$

This fact seems to be self-evident but it is not. For example, small modifications of the basic algorithm do not satisfy a) as is the case with the cyclic bisection method [74]. From the assumption

$$w(F(Y)) - w(\bar{f}(Y)) \rightarrow 0 \quad \text{as } w(Y) \rightarrow 0 \\ (Y \in I(X)) \quad (7)$$

it follows that

b)

$$y_n \leq f^* \quad \text{for any } n, \\ y_n \rightarrow f^* \quad \text{as } n \rightarrow \infty, \\ f^* - y_n \leq w(F(X_n)) \text{ (error estimate).}$$

Assumption (7) is not very restrictive. It is almost always satisfied if natural interval extensions are used. However, (7) does not imply continuity, Lipschitz condition on  $f$ , etc. Let  $F$  now satisfy

$$w(F(Y)) \rightarrow 0 \quad \text{as } w(Y) \rightarrow 0. \quad (8)$$

Clearly, (8) implies (7) and the continuity of  $f$ . Then

$$\text{c) } w(F(X_n)) \rightarrow 0 \text{ as } n \rightarrow \infty$$

(that is, the error estimate tends to 0 and can thus be used for termination criteria),

d) each accumulation point of the sequence  $(X_n)$  is a global minimizer.

The convergence order of the approach  $y_n \rightarrow f^*$  is described by the following two results:

- e) Let any  $\alpha > 0$  and any converging sequence of reals be given. Then, to any  $f$ , there exists an inclusion function of order  $\alpha$  for which  $(y_n)$  converges slower than the given sequence.

This result indicates that the convergence can be arbitrarily slow and that no worst case exists, which is usually taken in order to establish formulas for the convergence speed or convergence order. If, however, only isotone inclusion functions ( $F$  is called *isotone* if  $Y \subseteq Z$  implies  $F(Y) \subseteq F(Z)$ ) are considered then the following estimate of the convergence speed is valid. Practically this estimate characterizes the complete convergence theory since it is always possible to find isotone inclusion functions with small effort.

- f) If  $F$  is isotone and of order  $\alpha$ , then

$$f^* - y_n = O(n^{-\frac{\alpha}{m}}).$$

In [16] some variants of this assertion are proven.

Algorithms 2 and 3 have nearly the same behavior as Algorithm 1 if the convergence to  $f^*$  is considered. Their properties with respect to a determination of  $X^*$  are as follows:

Let  $(U_n)$  be the sequence of unions produced by Algorithm 2. If (8) is assumed, then

- g) the sequence  $(U_n)$  is nested and converges (with respect to the Hausdorff metrics for compact sets) to a superset  $D \supseteq X^*$ . The probability, that  $D$  is not equal to  $X^*$  is zero, however.

Let now  $(U_n)$  be the sequence of unions produced by Algorithm 3. If (8) is assumed, then

- h) the sequence  $(U_n)$  is nested and converges to  $X^*$ .

Therefore, Hansen's Algorithm 3 is the only one of the three which features a satisfactory and guaranteed convergence to  $f^*$  and  $X^*$ . This algorithm will therefore play the main role in our further considerations.

### Accelerating and Related Devices

Algorithm 3 and its predecessors which we have treated so far are based on the *exhaustion principle*, that is, the principle of removing areas (subboxes of  $X$ ) which cannot contain a global minimizer. In the same manner we realize that the *branch and bound principle* forms the

overlying structure, that is, areas are processed which have the largest chance to contain a global minimizer. This is a time-consuming process and it is therefore important to combine the principle mentioned with techniques for speeding up the computations. In this section we deal with only a few of these techniques in order to demonstrate how they may be combined with the basic algorithm. Much research is done in order to find an optimal combination of the basic algorithms and the acceleration devices, cf. for instance, [26,31,33,48,49,93,95,96].

In the following we give an overview of several acceleration devices and other tools that are used to improve the computational efficiency of unconstrained interval based global optimization. Most of them are also developed for constrained optimization.

### The Monotonicity Test

It can be applied if  $f$  is differentiable and if an inclusion function for  $\nabla f$  is available ([30,31,72]). It allows one to automatically recognize that  $f$  is strictly monotone in one of the variables in the subbox  $Y \subseteq X$  on which the algorithm is focusing. Then  $Y$  can be discarded from the list if  $Y$  lies in the interior of  $X$  or otherwise  $Y$  can be replaced by an edge piece of  $Y$ . This can be done since the parts removed do not contain a global minimizer. I. e., let  $G_i$  be an inclusion function of  $\partial f/\partial x_i$  for  $i = 1, \dots, m$ . If now  $0 \notin G_i(Y)$  just for one index  $i$ , then  $f$  is strictly monotone in the variable  $x_i$  over  $Y$  such that  $Y$  can be discarded or replaced by an edge piece as mentioned before. (For the application of the test it is already sufficient that  $f$  is *locally Lipschitz*, cf. the next section).

### The Interval Newton Method

If  $f$  is twice continuously differentiable and if an inclusion function for the Hessian matrix function,  $f$ , exists then the interval Newton algorithm can be applied to  $f'$  in order to get boxes that contain all zeros of  $f'$ . Together with the monotonicity test, the interval Newton algorithm counts as one of the most effective tools for solving optimization problems. The main advantage is not only the localization of the zeros of  $f'$ , but also a computationally very successful performance. This is based on the properties mentioned in the section on 'interval Newton methods' which result

in reducing or splitting the search area. Finally, the contraction shows quadratic convergence under reasonable conditions.

Interval Newton methods can be applied in two different manners:

- i) The method is applied to  $f'$  in  $X$  (necessarily combined with some splittings of the search area) until all critical points of  $f$  are included in sufficiently small boxes  $Z$ , for example where  $w(Z) < \epsilon$ . Then the search for the global minimizers is restricted to these remaining boxes  $Z$  and to the facet of  $X$ . This approach is, however, not too effective since these zeros can be saddle points, local maximizers, or even local but not global minimizers. Hence the following procedure is used generally:
- ii) Each iteration of the optimization algorithm is combined with the monotonicity test and one or two interval Newton iterations. I. e., after having  $X$  bisected into the subboxes  $V_1$  and  $V_2$ , cf. Step 5 of Algorithm 3, the midpoint test, the monotonicity test and one interval Newton iteration is applied to  $V_1$  and  $V_2$  in order to diminish the size of  $V_1, V_2$  or to discard them. This procedure avoids superfluous and costly interval Newton iterations in boxes in which  $f$  is strictly monotone or which have too large function values.

The interval Newton can be improved by using slopes whenever possible, cf. [79]. See also 'use of good inclusion functions' below.

### Finding a Function Value as Small as Possible

The smaller the smallest known or computed function value is at the  $n$ th iteration the more effective is the midpoint test, that is, boxes are removed earlier than without these values.

There are many possible techniques for getting lower function values such as statistical and line search methods, bundle methods (line search in the nonsmooth case), descent methods, Newton-like methods, where the application of the methods depends on the differentiability of the objective function. Many of these variations lead to so-called globally convergent methods. This does not mean that a global solution is found, however, it does mean that a local solution is always found. Good results in finding small function values have been attained with generating a not very dense set

of points and to use them as starting points for the globally convergent methods mentioned above.

### Bisections

The computations can be accelerated by a good choice of

- A) the next box of the list to be bisected; and
- B) the bisection direction of that box.

These two topics did not draw too much attention in the first years of interval optimization. They were considered as a tiresome task for completing the algorithms rather than topics important for the success of the algorithms. Meanwhile it has been recognized how important the right choice of box and bisection direction is for keeping computation time and costs low. The right choice of bisection direction is equally important for the global zero search of systems of functions.

Strategies for *choosing the next box* include uniform subdivision [71], bisecting a box which has a minimal lower bound, cf. Algorithms 1 and 2, bisecting that box which has been longest on the list [31], bisecting a box which has maximum width [31], last in-first out [79], that is, the youngest boxes are always processed first which keeps the list length short under certain circumstances.

When a box has been selected for getting bisected one has to *choose the bisection direction*. Historically, the first three criteria were uniform subdivision [71] (that is, bisections were done in all  $m$  directions), cyclic bisection [74] (that is, the bisection directions change cyclically, i. e., the first box gets bisected normal to the first coordinate direction, the second normal to the second coordinate direction, etc.), and bisection normal to one of the longest box edges [31].

It turned out that using the box width as the only criterion for deciding the bisection direction could be very ineffective. For a typical example, see [91]. The conclusion from such examples is that the choice of the bisection direction should consider the behavior of the function  $f$  over the box as well. Hence, formulas for deciding a bisection direction are built up using bounds for the box width of the objective function and bounds for the first and second partial derivatives. Natural interval extensions of noninterval scaling formulas are also used. Our own tests and experiments show that an optimum bisection strategy does not exist and that

it is reasonable to use several bisection strategies each pursuing another heuristic aim. This led to systematic investigations of bisections and also trisections by several authors, mainly [15,18,53,54,96,97,106]. For further strategies see [93], where also a survey of convergence properties of some of the strategies can be found, and [92].

### Use of Good Inclusion Functions, Slope Arithmetic

The better the inclusion functions are, the more effective are the tests like midpoint test, monotonicity test, etc., cf. for instance, [88]. The derivatives can frequently be replaced by slopes which leads to inclusions with smaller width. There is also an automatic slope arithmetic available which is comparable to automatic differentiation, cf. 'automatic differentiation' below. The interested reader is referred to [1,40,61,62,79,88,101].

### The Nonconvexity Test

The aim of this test is to verify that the objective function is nowhere convex in some subbox  $Y \in I(X)$  by computationally checking whether the Hessian of the objective function does not satisfy some standard conditions of convexity. Then the interior of  $Y$  cannot contain a minimizer.  $f \in C^2$  is assumed. The first such test seems to date back to [64].

### Thin Evaluation of the Hessian Matrix

If interval Newton steps are incorporated they will be applied to  $\phi = f'$  where the matrix  $J_\phi(Y) = H_f(Y)$  is required and  $H_f(Y)$  is the natural interval extension of the Hessian matrix. By certain rearrangements of  $H_f(Y)$  and a special method of getting an interval extension, where not all real entries are replaced by intervals, it is possible to obtain an interval matrix which is thinner, hence better (cf. 'use of good inclusion functions' above) than  $H_f(Y)$ . A detailed discussion and formulas can be found in [33,90].

### Constraint Logic Programming

(also known as *constraint solving*) involves techniques where, among others, equations (for example, the Karush–Kuhn–Tucker or F. John conditions) are primarily not evaluated numerically but seen as constraints for or as relations between the variables (a con-

cept overtaken from artificial intelligence). The relation is then used to shrink the search domain. For example, the equation (constraint)  $y - x^2 = 0$  immediately enables the halfspace defined by  $y < 0$  to be removed from the working area. There are several methods based on that idea which are best embedded in appropriate languages, where symbolic manipulation such as PROLOG is available. For example, a method called *relational interval algebra* is embedded in the computer language CLP having PROLOG as metalanguage (cf. [7] or [83]). In this connection it is also opportune to automatically add redundant constraints in order to accelerate the computations (see, for example, [5] or [82]).

Another approach is called *branch and prune* ([41]). The *pruning* concept aims to shrink the search area by several tests. The crucial property which is searched for is the so-called *box consistency* which has been introduced in [6] and is also known in connection with discrete combinatorial search problems. The box consistency is primarily used to indicate the existence of solutions in the considered subarea and is some kind of a substitution of interval Newton techniques. An interesting means for proving box consistency is the *bound consistency* which requires the checking of the facets of the box instead of the box itself. The branch and prune algorithm is embedded in NUMERICA, which is designed as a modeling language for global optimization and related problems, cf. [41].

There are several other approaches that are based on constrained logical programming such as the use of relational manipulations or of set-valued operations, see for example, [3] or [45] and the references listed there.

### Automatic Differentiation

This technique seems to go back to [108]. It helps to reduce costs when computing derivatives or their inclusion functions, or expressions like  $(x - c)^T f'(c)$ ,  $(Y - c)f'(Y)$ ,  $(x - c)f'(Y)$ ,  $(Y - c)^T f'(Y)(Y - c)$ , etc., where  $x, c \in X$ ,  $Y \in I(X)$ . There are two modes of automatic differentiation, a forward and a reverse. Both modes use recursive techniques for evaluating function values and chain rules of differentiation. In the forward mode all intermediate values of the function are simultaneously determined with the corresponding intermediate values of derivative, Hessian, etc, and all these intermediate values are computed from values calculated in former

steps. The reverse mode requires some structural planning of the formulas similar to the construction of Kantorovich graphs of functional expressions, where a new variable is assigned to each node. The differentiation finally starts backwards from the function in dependency of the variables introduced. Both modes have advantages.

Our own experiences, however, show that in case of interval expressions like  $(Y - c)f'(Y)$  or in case of computing generalized gradients, it is not always wise to use automatic differentiation. The reason is that in such cases information about dependencies between intervals can be lost so that the widths of the resulting interval values increase unnecessarily.

For a detailed description of automatic differentiation cf. for instance, [23,24,29,84].

### Parallel Computations

for global optimization were investigated and implemented primarily by [8,12,21,22].

## Global Optimization Over Unbounded Domains and Nonsmooth Optimization

### Global Optimization over Unbounded Domains

Almost all methods for solving global optimization problems need the assumption that a bounded domain which contains the solution points is known. The boundedness is necessary for the numerical computation as well as for guaranteeing the convergence properties. If an a-priori box  $X$  as search area for the global solutions is not known, it is possible to extend the previous algorithms, especially Algorithm 3 in such a manner, that they can operate over unbounded boxes as well cf. [90,94]. It is not even necessary, to change the algorithms formally, one only has to define midpoint and width of infinite intervals (both values have to be finite) and an arithmetic for infinite intervals. This arithmetic should provide intervals with minimal widths in order to get reasonable inclusion functions. It would go too far to present this arithmetic here, but a short example could be illustrative: This arithmetic assigns to the quotient  $[0, \infty]/[0, \infty]$  the value  $[0, \infty]$ , whereas by an arithmetic which is called Kahan–Novea–Ratz arithmetic in [55] the value  $[-\infty, \infty]$  results. Most of the convergence properties of the section on ‘convergence

properties of the prototype algorithms' remain valid under slight modifications of the assumptions since one can interpret the algorithms as algorithms in  $(\overline{\mathbb{R}})^m$  where  $\overline{\mathbb{R}}$  is the two-point compactification of the real axis,  $\mathbf{R}$ . Thus compact intervals are generated by the algorithms and that is all one needs for convergence proofs. For details see [90,94] or the survey in [93].

### Nonsmooth Optimization

A broad spectrum of mathematical programming problems can be reduced to nondifferentiable problems without constraints or with simple constraints. The use of exact nonsmooth penalty functions in problems of nonlinear programming, maximum functions to estimate discrepancies in constraints, piecewise smooth approximation of technical-economic characteristics in practical problems of optimal planning and design, minimax compromise function in problems of multicriterion optimization, all generate problems of nonsmooth optimization. Thus, the objective function,  $f$ , of the optimization problem may look like  $f(x) = \max\{f_1(x), \dots, f_n(x)\}$  where  $f_i \in C^1$ , or like  $f(x) = \mu f_0(x) + \sum_{i=1}^k \max(0, f_i(x))$  which is a typical objective function arising from penalty methods where  $f_0, f_i \in C^1$  and  $\mu > 0$  is a (reciprocal) penalty factor.

Interval methods have no difficulties at all to handle nonsmooth problems, a fact which was discovered in [87] and rediscovered in [55] with great emphasis. The construction of inclusion functions does not depend at all on the smoothness of a function. The application of monotonicity tests and other devices where gradients are used (for instance, local noninterval methods, cf. 'finding a function value as small as possible' in the section on 'accelerating and related devices') is still possible as long as the function is *locally Lipschitz*, which means that, at any argument,  $x$  of the function,  $f$ , an open neighborhood of  $x$ , say  $U_x$ , exists in which  $f$  satisfies a Lipschitz condition. It follows by a theorem of H. Rademacher that  $f$  is differentiable almost everywhere in  $U_x$ . Let  $\Omega$  be the set of points in  $U_x$  at which  $f$  is not differentiable, and let  $S$  be any other set of Lebesgue measure 0. Then the *generalized gradient* (also called *subdifferential*) of  $f$  at  $x$  is defined as

$$\begin{aligned} \partial f(x) \\ = \text{conv} \left\{ \lim_{n \rightarrow \infty} \nabla f(x_n) : x_n \rightarrow x, x_n \notin S \cup \Omega \right\} \end{aligned}$$

where  $\text{conv}$  denotes the convex hull, cf. [14]. Let  $(x, y) \subseteq \mathbf{R}^m$  denote the open line segment between  $x$  and  $y$ . A theorem of G. Lebourg says that, if  $y \in U_x$  with  $(x, y) \subseteq U_x$  is given then some  $u \in (x, y)$  exists such that

$$f(y) - f(x) \in (y - x)^\top \partial f(u). \quad (9)$$

Locally, (9) can be approximated by means of the Lipschitz constant. Globally, (9) can be used to find inclusion functions of  $f$  of a mean value type explicitly: If  $G(Y)$  is a (not necessarily bounded) box that contains  $\partial f(u)$  for any  $u \in Y$ , then

$$F(Y) = f(c) + (Y - c)^\top G(Y) \quad \text{for } Y \in I(X),$$

where  $c$  denotes the midpoint of  $Y$  (any other point of  $Y$  may also be chosen), is an inclusion function of  $f$  and appropriate for its use in the Algorithms 1 to 3. Furthermore,  $G(Y)$  can be used for the *monotonicity test*: If only one component of  $G(Y)$  does not contain zero, then  $f$  is strictly monotone with respect to the corresponding direction.

Algorithms 1 to 3 as well as the monotonicity test therefore can be applied to problem (1) without modifications, if the objective function of  $f$  is locally Lipschitz. It is, however, only possible to apply the interval Newton algorithm for a very restricted class of functions since second 'derivatives' of locally Lipschitz functions are not yet explored satisfactory. With the aid of the infinite interval arithmetic mentioned in the subsection above one can admit also unbounded subdifferentials and handle them. For the construction of inclusion functions of the objective function and the subdifferential and for numerical tests (with bounded and unbounded search areas) see, for instance, [27,28,55,87,90,94]. For further results in connection with estimates of the penalty factor see [111].

### Constrained Optimization

The principles which were developed in the previous sections are also useful for constrained problems, that is,

$$\min_{x \in M} f(x) \quad (10)$$

where  $M \subseteq \mathbf{R}^m$  means the feasible set defined by constraints

$$\begin{aligned} g_i(x) &\leq 0, & i = 1, \dots, k, \\ h_j(x) &= 0, & j = 1, \dots, s. \end{aligned}$$

For simplicity, we assume that  $M \subseteq X$  for some  $X \in I^m$  and that the functions  $f$ ,  $g_i$  and  $h_j$  are defined on  $X$ . For a successful treatment of problem (10) we need inclusion functions  $F$ ,  $G_i$  and  $H_j$  of  $f$ ,  $g_i$  and  $h_j$ , respectively which satisfy (8) and which have the property that

$$\begin{cases} w(G_i(Y)) \rightarrow 0 & \text{as } w(Y) \rightarrow 0, \\ w(H_j(Y)) \rightarrow 0 & \text{as } w(Y) \rightarrow 0 \end{cases} \quad (11)$$

for  $i = 1, \dots, k$ ,  $j = 1, \dots, s$ , and  $Y \in I(X)$ .

Then a very effective means of interval arithmetic is the *infeasibility test* which is applicable to any  $Y \in I(X)$ : If either

$$G_i(Y) > 0 \quad \text{for some } i \in \{1, \dots, k\}$$

or if

$$0 \notin H_j(Y) \quad \text{for some } j \in \{1, \dots, s\}$$

then all points of  $Y$  are infeasible. (The notation  $[a, b] > 0$  or  $[a, b] \leq 0$  is used to indicate that  $a > 0$  or  $b \leq 0$  holds, respectively.) Hence the box  $Y$  can never contain a solution of (10) such that  $Y$  can be discarded from any procedure for solving (10). Conversely, if

$$G_i(Y) \leq 0 \quad \text{for } i = 1, \dots, k,$$

and

$$H_j(Y) = 0 \quad \text{for } j = 1, \dots, s,$$

then all points of  $Y$  are feasible (*feasibility test*). This is due to the inclusion principle, (3), by which  $a \in Y$  implies  $g_i(a) \in G_i(Y)$  as well as  $h_j(a) \in H_j(Y)$  for all indices  $i$  and  $j$ , that is,  $g_i(a) \leq 0$  and  $h_j(a) = 0$  for all  $i$  and  $j$ . This gives, in fact, the guarantee that every point  $a \in Y$  is feasible. However, if equality constraints are present in (10) it is extremely unlikely that conditions like  $H_j(Y) = 0$  are satisfied such that the feasibility test is rather an academic tool if  $s > 0$ .

There are principally two main possibilities for solving the constrained problem. The first possibility is to transform the problem to an unconstrained problem within a penalty setup and apply the methods of the former sections together with the feasibility, respectively infeasibility, test in order to have the guarantee to be in  $M$  or to discard infeasible areas. The second possibility is a direct approach where Algorithm 3 is enriched by feasibility and infeasibility test and adapted to handle the constrained case. We will now give a brief discussion of these possibilities.

## The Penalty Approach

There are two kinds of penalty functions which are usually preferred. The first one is the so-called  $L_1$ -exact penalty function,  $\phi(x) = \mu f(x) + \sum_{i=1}^k \max(0, g_i(x)) + \sum_{j=1}^s |h_j(x)|$ , cf. also the subsection ‘nonsmooth optimization’ in the previous section. The second one, already introduced by R. Courant, is defined as  $\psi(x) = \mu f(x) + \sum_{i=1}^k \max(0, g_i(x))^2 + \sum_{j=1}^s (h_j(x))^2$ . In both cases,  $\mu$  is a penalty factor. For details, and how penalty methods are applied to solve constrained optimization problems, cf. [25]. (Augmented Lagrangian functions could also be taken for the penalty approach.) When locally solving (10) with standard noninterval methods,  $\phi$  has the advantage that there exists a  $\mu$  so that the local minimizers of  $\phi$  are also local minimizers of (10), but has the disadvantage of being nonsmooth. The use of  $\psi$  has the advantage of dealing with a smooth function (provided  $f$  and the constraints are smooth), but the disadvantage, that the minimizers of  $\psi$  might attain the solutions of (10) only asymptotically as  $\mu$  tends to zero. If  $f$  and the constraint functions are smooth there exists a value  $\mu$  in both cases of penalty functions so that the global minimizers of  $\phi$  and  $\psi$  are also global solutions of (10) when solving (10) with interval methods. The explicit determination of this number  $\mu$  is still under investigation, cf. [111]. On the other hand, the knowledge of the value is not necessary if only convergence is expected because infeasible areas are removed by the infeasibility test which has to be incorporated in the prototype algorithm such as Algorithm 3. The knowledge of the value of  $\mu$  accelerates the computation. A further discussion would be too extensive for this article.

## The Direct Approach

Algorithm 3 is also appropriate as a base algorithm for dealing with the constrained case. In order to consider the constraints, one just has to add the feasibility and infeasibility test and to apply the latter test as a box deleting device to the boxes  $V_1$  and  $V_2$  after Step 5 of the algorithm. If it turns out that the box is feasible, it should be marked as *feasible* by a flag or a Boolean value. The remaining boxes of the list are *indeterminate*, that is, the tests executed up to the current state of the computation have not yet been able to decide whether the box is feasible or not. It can happen that boxes  $V_i$  which are feasible (respectively, infeasible) are not rec-

ognized as feasible (respectively, infeasible) by the feasibility (respectively, infeasibility) test. This is due to the excess width (see the section ‘interval arithmetic’ above) which, for instance, can cause that  $0 \in G_i(V)$  for some box  $V$  occurs even if  $0 < \overline{g}_i(V)$  holds. The continued processing of the indeterminate boxes of the list by the steps of Algorithm 3, however, reduces the box widths to zero so that their excess widths also tend to zero as long as (11) is assumed. This implies also that the *union of the boxes of  $\mathcal{L}$  tends, as the computation proceeds, to  $M$  with respect to the Hausdorff metrics* (cf. [90]) if one dropped the midpoint test.

The *midpoint test* itself helps to discard feasible as well as indeterminate boxes which contain no global minimizer. The execution is as in the unconstrained case: Let  $f_n$  be the lowest function value which has been calculated up to the completion of the list  $\mathcal{L}_n$ . Then all pairs  $(Z_{ni}, z_{ni})$  of  $\mathcal{L}$  are discarded that satisfy

$$f_n < z_{ni}.$$

It is important for the correctness of the algorithm that only function values of points  $x \in M$  are admitted. Hence, if  $x$  is taken from a feasible box of the list,  $x$  is certainly feasible. If the list contains only indeterminate boxes no direct access to feasible points of  $M$  is at hand. This is regularly the case if equality constraints are present. But without the knowledge of points  $x \in M$  the midpoint test cannot be executed. Two possibilities are known for overcoming this hurdle. The first possibility is the so-called  $\epsilon$ -inflation. It accepts that the constraints are satisfied within a tolerance of  $\epsilon$ . If  $\epsilon$ -inflation, which is widely used in noninterval computations, is applied then the reliability of the computation is lost. Thus this possibility is avoided as far as possible in interval computations.

The second possibility to overcome the difficulties arising by equality constraints is based on the application of Moore’s *test for the existence of solutions of equations* [73]. Hansen and G.W. Walster [38] were the first who suggested to apply this test to constrained optimization. It is used in the following manner: If  $Y$  is an indetermined box under processing and one looks for a feasible point in  $Y$ , the equality constraints and the inequality constraints which are active with respect to  $Y$  are combined to a system of equations. Then interval Newton iterations are applied to this system in  $Y$ , not to solve the system but only to prove the existence of

a solution within  $Y$  by a contraction of the Newton operator. Then all boxes  $(Z_{ni}, z_{ni})$  of the list (feasible or indetermined) can be discarded that satisfy  $\max f(Y) < z_{ni}$  since  $\max f(Y)$  is an upper bound for a function value of a feasible point. If the system of equations shows more variables than equations, some variables are replaced by constants.

The existence test in  $Y$  is best done in the following manner: Apply a local simple noninterval optimization algorithm to the objective function  $\psi(x) = \sum_{i=1}^k \max(0, g_i(x))^2 + \sum_{j=1}^s (h_j(x))^2$  (this is the Courant penalty function for  $f(x) = 0$ , cf. the first subsection in this section) in order to come near a feasible point, say  $c$ . Put a small box which has to lie in  $Y$  around  $c$  and apply the existence test to the system in the box (eventually cleaned up by meanwhile inactive inequality constraints). If the test is positive, the existence of a feasible point in the box and hence in  $Y$  is guaranteed. However, it is not at all a proof that  $Y$  is infeasible if the test fails.

An improvement is due to [58] where techniques to search for points  $c \in Y$  are designed so that the chances of finding a nearby feasible point is optimal. Also the number of variables can be larger than the number of equations in the underlying system.

The convergence of the union of the list boxes to the set of global minimizers can be shown if the test for the existence of feasible points is applied systematically and successfully to the boxes of the list (as far as they are indeterminate). Other convergence proofs can be found in [8,90].

In order to not only get a convergent but also a fast convergent algorithm, *acceleration devices and related techniques* are again extremely important for practical computations. Well-known techniques are the following:

- i) *Interval Newton iterations.* They are applied to the F. John conditions to enclose the stationary points, similar as to the unconstrained case. Since the number of equations exceeds the number of variables by 1 in the F. John conditions, an additional equation is added which does not influence obtaining the stationary points, cf. [39]. As in the unconstrained case, the interval Newton iterations are not executed until termination, but they merge with the steps of the optimization algorithm. Again, if an iteration shows the existence of a F. John point, it is

a feasible point and can be used for the midpoint test.

In contrast to several authors we do not count the interval Newton iterations as basic steps of an optimization algorithm, since they do not influence the convergence, only the convergence speed of the algorithm.

- ii) *Monotonicity and nonconvexity test*, cf. the section on ‘accelerating and related devices’. These tests are best applied to feasible boxes, but there are also exemptions of this suggestion, cf. [70,93]. Also *linearization of the constraints* supplementing the infeasibility test is used [33].
- iii) *Good inclusion functions, slope arithmetic, automatic differentiation, bisections, parallel algorithms, constrained logic programming*, are already mentioned in the section on ‘accelerating and related devices’.
- iv) *Local search devices*. In order to get soon function values of feasible points, local noninterval optimization procedures are applied to the function  $\psi$ , as defined above, related to the current box until one reaches a feasible point or until one is near a feasible point. In the latter case the existence test has to be applied at this approximation w. r. to a small surrounding box in order to guarantee the existence. In case of full-dimensional feasible domains, the local search can be continued with  $\phi$  instead  $\psi$ , but one has to take care not to leave the domain  $M$ .

It turned out that the performance of the algorithm was greatly influenced by how the steps of the optimization algorithm and the acceleration devices were combined. Several investigations dealing with this matter have been done, cf. for example, [8,18,19,26,38,39,49,56,95,100,109,110].

## Applications

Global optimization using interval arithmetic has been applied to optimization problems in a variety of science, engineering and social science areas. Below we briefly describe representative examples from several areas.

### Chemistry and Chemical Engineering

Many optimization problems in the fields of chemistry and chemical engineering can be investigated ef-

fectively using the tools described in the previous sections.

As a first example we consider the diagram of a chemical process showing the processing units and the connections between them. This depicts the flow of chemical components through the system and it is often referred to as process flowsheeting and the associated optimization problems are called process flowsheeting problems. They require the solution of large sparse differential-algebraic systems. In [99] a parallel interval Newton algorithm combined with bisection techniques is applied to solve a number of simple problems of this type where the parallelization is required in order to complete the computations within a reasonable timeframe.

The reliable prediction of phase stability in a chemical process simulation has been considered by [42,43]. It is pointed out that conventional methods that are initialization dependent may converge to trivial or non-physical solutions or to a nonglobal local minimum. It is furthermore shown that these difficulties can be avoided using a cubic equation of the state model combined with interval tools. Their technique is initialization independent and it solves the phase stability problem with complete reliability. In [44] the approach is further developed with respect to computational efficiency. An enhanced method is presented based on sharpening the range of the interval functions that occur in the algorithm. It is shown that the computation time can be reduced by nearly an order of magnitude in some cases.

The paper [69] addresses the problem of minimizing the Gibbs free energy in the  $m$ -component multiphase chemical and phase equilibrium problem involving different thermodynamic models. The solution method is based on the tangent-plane criterion of Gibbs and it is reduced to a finite sequence of local optimization steps in  $K(m - 1)$ -dimensional space where  $K \leq m$  is the number of phases, and global optimization steps in  $(m - 1)$ -dimensional space. The algorithm developed in the lower-dimensional space uses techniques from interval analysis. Some promising results are reported for the algorithm. A parallel interval algorithm for the problem was developed in [9]. Chemists performing photoelectron spectroscopy collide photons with atoms or molecules. These collisions result in the ejections of photoelectrons. The chemist is

left with a photoelectron spectrum which is a plot of the number of photoelectrons ejected as a function of the kinetic energy of the photoelectron. A typical spectrum consists of a number of peaks. The chemist would like to resolve the individual peaks in the spectrum. In the paper [76] a test problem is constructed as a sum of two Gaussian functions involving a number of parameters. These parameters are found using interval techniques of global optimization.

### Physics, Electronics and Mechanical Engineering

A wide variety of problems in physics, electronics and mechanical engineering can be formulated as optimization problems amenable to the techniques described in the previous sections. We provide some representative examples below.

An early application is found in [68] who applies interval global optimization to electronic switching systems for efficiency reasons.

In [10] interval global optimization is used to determine rigorous bounds on Taylor maps of general optical systems. It is also pointed out that stability for storage rings and other weakly nonlinear systems can be guaranteed using their developments.

In [78] Hansen's method is applied to a demagnifying system for electron beam lithography device for finding all real minimizers of a real valued objective function of several variables.

Computer-aided simulation tools for liquid crystal displays have been developed in recent years. These tools calculate the molecule orientation of the liquid crystal material by minimizing an energy function. The results of such simulations are used to optimize notebook computer displays. In the paper [80] interval global optimization is used to calculate all minimizing molecule configurations.

Interval global optimization is applied to the optimal design of a flat composite plate and a composite stiffened panel structure in [63]. The methodology is to generate a feasible suboptimal interval which is used to examine the manufacturing tolerance in the design optimization.

### Economics

Global optimization using interval analysis has also found applications in economics. Two examples are presented below.

A model of copyable products such as software is considered by [107] who based their model on the model developed by I.E. Besanko and W.L. Winston [11]. In the paper [107] this model is solved for a globally optimal result using an interval branch and bound method.

In [50] another problem in economics is considered. The problem is to minimize an econometric function

$$\sum (y_t - \hat{\beta}_1 - \hat{\beta}_2 X_{t2} - \hat{\beta}_2^2 X_{t3})^2$$

where the data are artificially generated for the variables. Several tests are performed and it is shown that interval methods are competitive with other methods such as simulated annealing.

### Keywords

Interval arithmetic; Optimization; Linear systems of equations

In many applications the coefficients of real linear systems are, due to measurement or approximation errors, not known exactly. Therefore, the family of real linear systems

$$A \cdot x = b, \quad (1)$$

where  $A, b$  satisfy the inequalities

$$|A^c - A| \leq \Delta, \quad |b - b^c| \leq \delta \quad (2)$$

is considered. The absolute value and comparisons are used entrywise. The matrices  $A^c, A, \Delta \in \mathbf{R}^{n \times n}$  are real  $n \times n$  matrices,  $b^c, b, \delta \in \mathbf{R}^n$ , and  $\Delta, \delta$ , which describe the perturbation bounds, are assumed to be nonnegative. This family of real linear systems is called an *interval linear system*, because each matrix  $A$ , right-hand side  $b$  is contained in the interval matrix  $\mathbf{A} := [A^c - \Delta, A^c + \Delta]$ , interval vector  $\mathbf{b} := [b^c - \delta, b^c + \delta]$ , respectively.

$A^c$  and  $b^c$  are called the *centers* of the interval linear system.

The corresponding *solution set*  $X$  is defined as the union of all solutions of this family, that is

$$X := \{x \in \mathbf{R}^n : x, A, b \text{ satisfy (1), (2)}\}. \quad (3)$$

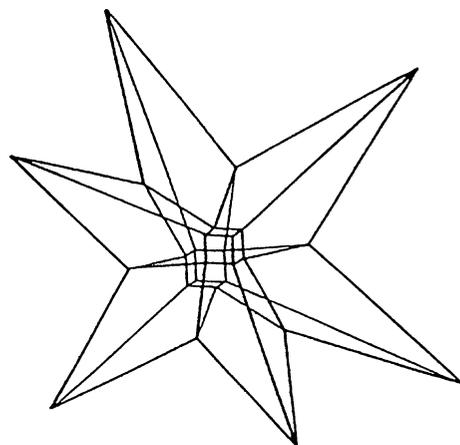

Naturally, the main interest is to determine the exact range of each component of the solution set, that is to calculate the exact or *optimal componentwise bounds*

$$\min \{x_i : x \in X\}, \quad \max \{x_i : x \in X\} \quad (4)$$

for  $i = 1, \dots, n$ . The minima and maxima exist provided  $\mathbf{A}$  is *regular*, that is all matrices  $A \in \mathbf{A}$  are nonsingular. Otherwise,  $\mathbf{A}$  is called *singular*, and  $X$  is unbounded or empty.

In general, the solution set  $X$  is not convex and has a complicated shape: see Fig. 1 which is taken from a book of A. Neumaier [18, p. 97]. Hence, calculating bounds for the solution set  $X$  is a global optimization problem. Moreover,  $X$  needs not to be connected or bounded. This is shown by the simple one-dimensional equation  $A \cdot x = 1$ ,  $A \in [-1, 1]$  with solution set  $X = (-\infty, -1] \cup [1, \infty)$ .

From the point of view of complexity theory, J. Rohn [25] has proved that the problem of calculating bounds for the solution set is *NP-hard*. Roughly speaking, he has shown that there is no polynomial time algorithm which calculates bounds of the solution set with overestimation less than any given positive constant.

**Interval Linear Systems, Figure 1**  
A projection of a three-dimensional solution set

This is true, even if the interval matrix  $\mathbf{A}$  is *strongly regular*, i. e. if the spectral radius  $\rho(|(A^c)^{-1}| \cdot \Delta)$  is less than one. If  $\mathbf{A}$  is strongly regular, then the regularity of  $\mathbf{A}$  follows immediately by observing that for  $A \in \mathbf{A}$  there holds

$$A = A^c - \tilde{\Delta} = A^c \cdot (I - (A^c)^{-1} \cdot \tilde{\Delta}), \tag{5}$$

where  $|\tilde{\Delta}| \leq \Delta$ . Hence, singularity of  $A$  is equivalent to the fact that  $(A^c)^{-1} \cdot \tilde{\Delta}$  has the eigenvalue 1. Since  $\rho(|(A^c)^{-1}| \cdot \Delta) < 1$  it follows that  $A$  is regular. By Perron–Frobenius theory, strong regularity implies that the radius matrix  $\Delta$  is not too large. For further NP-hardness results related to other interval problems see [27].

During the last three decades the problem of calculating componentwise bounds for  $X$ , not necessarily optimal bounds, has received much attention, and many methods were developed. No attempt can be made in this short survey to review all different approaches. But the literature given in this section shall serve as a guide for further reading.

The first algorithm for calculating optimal componentwise bounds was given by W. Oettli and W. Prager [19,20]. There the solution set  $X$  is described as the set of feasible solutions of a special system of nonlinear inequalities:

$$X = \{x \in \mathbb{R}^n : |A^c x - b^c| \leq \Delta \cdot |x| + \delta\} \tag{6}$$

But in each orthant this system is a convex polyhedron. Hence, in each orthant optimal bounds can be calculated by using linear programming techniques. Unfortunately, there are  $2^n$  orthants, and therefore this method needs for each instance a priori exponential time, and can work only for problems of very small size.

Recently, based on the result of Oettli and Prager, in [9] a more efficient method for calculating optimal bounds is presented. This method uses linear programming techniques in only those orthants which are intersected by the solution set  $X$ .

Starting with the pioneering book of R.E. Moore [15], a large number of methods were proposed using the tools of interval arithmetic. Many algorithms can be found for example in the monographs [2,16], and [18]. These methods are polynomial time algorithms, calculate only componentwise (not optimal) bounds, and work under special assumptions: in almost all cases strong regularity of  $\mathbf{A}$  is required.

In interval arithmetic the elementary operations for intervals  $\mathbf{x} = [\underline{x}, \bar{x}], \mathbf{y} = [\underline{y}, \bar{y}] \in \mathbb{IR}$  are defined by

$$\mathbf{x} * \mathbf{y} = \{x * y : x \in \mathbf{x}, y \in \mathbf{y}\} \tag{7}$$

where  $*$   $\in$   $\{+, -, \cdot, / \}$ , and in case of division  $0 \notin \mathbf{y}$  is assumed. By a simple monotonicity argument it follows that

$$\mathbf{x} * \mathbf{y} = [\min S, \max S], \tag{8}$$

where the set  $S$  is defined by

$$S := \{\underline{x} * \underline{y}, \underline{x} * \bar{y}, \bar{x} * \underline{y}, \bar{x} * \bar{y}\}.$$

Interval operations between real matrices, interval matrices, real vectors and interval vectors are defined as in the real case, only the real operations are replaced by the corresponding interval operations (7).

For example, if  $R = (r_{ij}) \in \mathbf{R}^{n \times n}$  is a real  $n \times n$  matrix, and  $\mathbf{b} \in \mathbf{IR}^n$ , then  $R \cdot \mathbf{b}$  is defined as follows: the real coefficients  $r_{ij}$  are replaced by the point intervals  $\mathbf{r}_{ij} = r_{ij} = [r_{ij}, r_{ij}]$  and

$$(R \cdot \mathbf{b})_i := \sum_{j=1}^n \mathbf{r}_{ij} \cdot \mathbf{b}_j.$$

By definition (7), for all  $i$  the equation

$$(R \cdot \mathbf{b})_i = \left\{ \sum_{j=1}^n r_{ij} \cdot b_j : b \in \mathbf{b} \right\}$$

holds. Therefore  $R \cdot \mathbf{b}$  is the smallest interval vector containing the set  $\{R \cdot b : b \in \mathbf{b}\}$ . But in general,  $R \cdot \mathbf{b}$  overestimates the latter set.

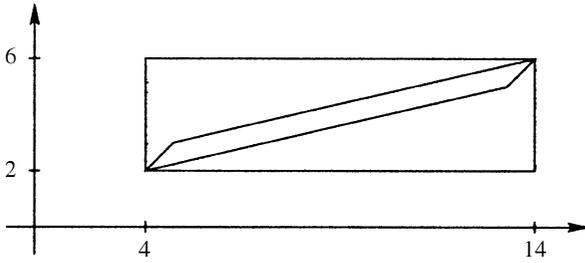

*Example 1* Let

$$R = \begin{pmatrix} 1 & 3 \\ 1 & 1 \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} [1, 2] \\ [1, 4] \end{pmatrix},$$

then  $R \cdot \mathbf{b} = ([4, 14], [2, 6])^T$ , but  $\{R \cdot b : b \in \mathbf{b}\}$  is the convex hull of the set  $\{(4, 2)^T, (13, 5)^T, (5, 3)^T, (14, 6)^T\}$ , see Fig. 2.

In many interval methods for calculating bounds of  $X$  the interval linear system is first preconditioned by an appropriate matrix  $R$ , which in most cases is an approximate inverse of the center  $A^c$ . This yields the preconditioned interval linear system

$$(R \cdot \mathbf{A}) \cdot x = R \cdot \mathbf{b}. \tag{9}$$

Interval Linear Systems, Figure 2

with interval matrix  $R \cdot A$  and interval right hand side  $R \cdot b$ .

From the discussion above it follows that  $R \cdot A$ ,  $R \cdot b$  overestimate the sets  $\{R \cdot A: A \in \mathbf{A}\}$ ,  $\{R \cdot b: b \in \mathbf{b}\}$ , respectively. Therefore, the solution set  $X'$  of the preconditioned interval linear system (9) contains but overestimates the solution set  $X$ . However, for small  $\Delta$  the interval matrix  $R \cdot A$  is close to the identity matrix and diagonal dominant. Hence, only small overestimations will occur.

Bounds for the solution set  $X'$  of the preconditioned interval linear system (9) are then calculated by using interval Gaussian elimination (cf. for example [1,7]), interval Gauss–Seidel iteration (cf. for example [6,17,22]), or fixed point iteration (cf. for example [14,28]). In general, these bounds are not optimal for  $X'$ , and the overestimation depends on the method.

But recently E.R. Hansen [5], and Rohn [26] have presented a polynomial time algorithm for calculating optimal bounds for the solution set  $X'$  of the preconditioned interval system (9). Only two matrix inversions are required.

Preconditioning of interval linear systems was first suggested by Hansen and R. Smith [7]. Later, R.B. Kearfott [11,12] introduced the so-called width optimal preconditioners by using linear programming techniques.

Preconditioning requires the computation of an approximate inverse. For sparse linear systems the inverse in general is full. Therefore, the approaches described above are not applicable for large dimensions. But recently, S.M. Rump [29,30] generalized his iteration method (cf. [28]) to sparse nonlinear systems without preconditioning with a full inverse. His idea, roughly spoken, was to replace the inverse by a lower bound of the smallest singular value of the center matrix.

Last, an interval method not using preconditioning should be mentioned. This method is a branch and bound scheme proposed by S.P. Shary [31].

In the following, two methods are described in more detail. First, in the next section 2 Rump's method [28] is presented. This method is implemented in several programming packages like ACRITH [8], ARITHMOS [3], PASCAL-XSC [4], and PROFIL [13]. Moreover, as mentioned above, the method can be modified for solving sparse interval linear systems and nonlinear systems. Then, in the last section the method presented in [9] for calculating optimal bounds of  $X$  is described.

### An Iterative Interval Method

It is assumed that  $A$ ,  $b$  satisfy the inequalities (2),  $R$  is an approximate inverse of  $A^c$ , and  $\check{x}$  is an approximate solution of  $A^c x = b^c$ . No assumptions about the quality of these approximations are made. It is well known from numerical linear algebra that defect iteration with the iteration function

$$\begin{aligned} f(x) &:= x + R \cdot (b - A(\check{x} + x)) \\ &= R \cdot (b - A\check{x}) + (I - RA)x \end{aligned} \quad (10)$$

can be used to improve the quality of the approximation  $\check{x}$ . This function is continuous, and if for a given interval vector  $\mathbf{x}$  the condition  $f(\mathbf{x}) \subseteq \mathbf{x}$  holds, then by Brouwer's fixed point theorem there exists  $\hat{x} \in \mathbf{x}$  with  $f(\hat{x}) = \hat{x}$ . Using (10) yields  $R \cdot (b - A(\check{x} + \hat{x})) = 0$ . If  $R$  is nonsingular, then  $A(\check{x} + \hat{x}) = b$  implying that  $\check{x} + \hat{x} \in \check{x} + \mathbf{x}$  is the exact solution of  $Ax = b$ . Moreover, by using a contradiction argument, it can be shown that the solution  $\check{x} + \hat{x}$  is unique and  $R$ ,  $A$  are nonsingular provided that  $f(\mathbf{x})$  is contained in  $\text{int}(\mathbf{x})$ , the interior of  $\mathbf{x}$ .

An immediate consequence is that if the condition

$$R \cdot (\mathbf{b} - \mathbf{A} \cdot \check{x}) + (I - R \cdot \mathbf{A}) \cdot \mathbf{x} \subseteq \text{int}(\mathbf{x}) \quad (11)$$

is satisfied, then  $f(\mathbf{x}) \subseteq \text{int}(\mathbf{x})$  holds for all  $A \in \mathbf{A}$ ,  $b \in \mathbf{b}$ . Hence  $X \subseteq \check{x} + \mathbf{x}$ . Notice that (11) can be easily checked by using interval arithmetic.

The remaining problem is to find an appropriate box  $\mathbf{x}$  satisfying (11). The following iteration starting with  $\mathbf{x}^0 := R \cdot (\mathbf{b} - \mathbf{A} \cdot \check{x})$  can be used:

$$\begin{aligned} \mathbf{y}^k &:= \mathbf{x}^k \cdot [1 - \epsilon, 1 + \epsilon] + [-\mu, \mu] \cdot e, \\ \mathbf{x}^{k+1} &:= \mathbf{x}^0 + (I - R \cdot \mathbf{A}) \cdot \mathbf{y}^k. \end{aligned} \quad (12)$$

The values  $\epsilon, \mu > 0$  are called inflation parameters, and  $e$  is the vector with 1 in each component. The main property of this iteration is that (cf. [30]) for every starting box  $\mathbf{x}^0$  holds

$$\begin{aligned} \exists k \in \mathbb{N} : \mathbf{x}^{k+1} &\subseteq \text{int}(\mathbf{y}^k) \\ \Updownarrow \\ \rho(|I - R \cdot \mathbf{A}|) &< 1, \end{aligned}$$

where  $\rho$  denotes the spectral radius of the absolute value of  $I - R \cdot \mathbf{A}$ . This means that after a finite number of steps bounds  $\check{\mathbf{x}} + \mathbf{x}^{k+1}$  of  $X$  are calculated, provided the spectral radius  $\rho(|I - \mathbf{R}\mathbf{A}|) < 1$ ; this means that  $\mathbf{A}$  is strongly regular. For practical applications it is recommended to execute at most  $k = 10$  iteration steps, and  $\mu$  should be greater than the smallest positive floating point number. Obviously, by using this parameters we get an  $O(n^3)$  polynomial time algorithm.

*Example 2* To demonstrate how this algorithm works, the following interval linear system with centers

$$A^c = \begin{pmatrix} 1.2 & 1.2 \\ -1.2 & 1.2 \end{pmatrix}, \quad b^c = \begin{pmatrix} 1.5 \\ 3.5 \end{pmatrix},$$

and perturbation bounds

$$\Delta = \begin{pmatrix} 0.2 & 0.2 \\ 0.2 & 0.2 \end{pmatrix}, \quad \delta = \begin{pmatrix} 0.5 \\ 0.5 \end{pmatrix}$$

is considered.

This system is a slight modification of an example of Rohn [23]. We have chosen  $\epsilon = 0.05$  and  $\mu$  equal to the smallest positive machine number. In the following, five (appropriately rounded) decimal digits are displayed. The two-dimensional interval vector with components equal to  $[-1, 1]$  is denoted by  $[-\mathbf{1}, \mathbf{1}]$ .

The spectral radius  $\rho(|I - R \cdot \mathbf{A}|) \approx 0.3333 < 1$  where  $R \approx (A^c)^{-1}$ , and therefore the iteration (12) will compute a box containing the solution set  $X$  in finitely steps.

The approximate solution of the center system is  $\check{\mathbf{x}} = (-0.83333, 2.0833)^T$  yielding the starting box  $\mathbf{x}^0 := R \cdot (\mathbf{b} - \mathbf{A} \cdot \check{\mathbf{x}}) = 0.9028 \cdot [-\mathbf{1}, \mathbf{1}]$ .

Iteration (12) yields

$$\begin{aligned} \mathbf{y}^0 &= 0.9480 \cdot [-\mathbf{1}, \mathbf{1}], & \mathbf{x}^1 &= 1.2188 \cdot [-\mathbf{1}, \mathbf{1}], \\ \mathbf{y}^1 &= 1.2797 \cdot [-\mathbf{1}, \mathbf{1}], & \mathbf{x}^2 &= 1.3294 \cdot [-\mathbf{1}, \mathbf{1}], \\ \mathbf{y}^2 &= 1.3959 \cdot [-\mathbf{1}, \mathbf{1}], & \mathbf{x}^3 &= 1.3681 \cdot [-\mathbf{1}, \mathbf{1}]. \end{aligned}$$

Hence, for  $k = 2$  it follows  $\mathbf{x}^3 \subseteq \text{int}(\mathbf{y}^2)$ , and the solution set  $X$  is contained in

$$\check{\mathbf{x}} + \mathbf{y}^2 = \begin{pmatrix} [-2.2014, 0.5348] \\ [0.7152, 3.4514] \end{pmatrix} \tag{13}$$

For numerical results of this method and its generalization to sparse systems, see [29,30]. There, examples up to 1000000 variables including the ‘Harwell test cases’ are presented.

### Optimal Bounds

As pointed out in the introduction, a polynomial time algorithm may overestimate the solution set  $X$  drastically or may fail. Therefore, in this section a method (cf. [9]) which produces optimal bounds of  $X$  if and only if  $\mathbf{A}$  is regular is described.

An immediate consequence of (6) is that the solution set  $X$  is the finite union of convex polyhedrons. To see this, let  $\{-1, 1\}^n$  denote the set of all sign vectors with components equal to 1 or  $-1$ . For a sign vector  $s \in \{-1, 1\}^n$  let  $D(s)$  denote the diagonal matrix with diagonal  $s$  and  $\mathbf{R}^n(s) := \{x \in \mathbf{R}^n : D(s) \cdot x \geq 0\}$ . Then the intersection  $X(s) := X \cap \mathbf{R}^n(s)$  of the solution set with the orthant corresponding to  $s$  is given by the following system of linear inequalities

$$\begin{aligned} (A^c - \Delta \cdot D(s)) \cdot x &\leq b^c + \delta \\ (A^c + \Delta \cdot D(s)) \cdot x &\geq b^c - \delta \\ D(s) \cdot x &\geq 0. \end{aligned} \tag{14}$$

Therefore, for a fixed orthant  $\mathbf{R}^n(s)$  optimal bounds of  $X(s)$  can be calculated by minimizing and maximizing each coordinate  $x_i$  subject to the constraints (14). These are linear programming problems which can be solved in polynomial time, implying that optimal bounds of  $X(s)$  can also be calculated in polynomial time.

Now, one can get optimal bounds of  $X$  by calculating optimal bounds of  $X(s)$  for each orthant  $\mathbf{R}^n(s)$ . Unfortunately, there are  $2^n$  orthants, and this approach can work only for very small dimension  $n$ .

For interval linear systems with  $\Delta = 0, \delta = 0$  the solution set  $X$  is by definition equal to the exact solution of the corresponding real linear system, and therefore  $X$  will be in one orthant (with exception of degenerated

cases). With growing radii  $\Delta, \delta$  the solution set may intersect more orthants. But in many cases only few orthants will intersect the solution set.

Then most of the computing time of the above approach will be spent for checking that  $X \cap \mathbf{R}^n(s)$  is empty for almost all orthants. Therefore, the question arises if it is possible to construct an algorithm which picks up exactly those orthants where  $X \cap \mathbf{R}^n(s)$  is nonempty. In the following such an algorithm is presented. This approach heavily relies on the following topological alternative statement, which says that for nonempty  $X$  exactly one of the following two statements is true:

- i)  $X$  is compact and connected, and  $\mathbf{A}$  is regular;
- ii)  $X$  is unbounded, each topologically connected component of  $X$  is unbounded, and  $\mathbf{A}$  is singular.

An immediate consequence is that the solution set  $X$  cannot be the union of bounded and unbounded topologically connected components. Therefore, each method which only calculates optimal bounds of a topologically connected component of  $X$  suffices to solve the problem. To do this, the representation graph  $G = (V, E)$  of the solution set  $X$  with the set of nodes

$$V = \{s \in \{-1, 1\}^n : X(s) \neq \emptyset\}, \quad (15)$$

and the set of edges

$$E = \left\{ \{s, t\} : \begin{array}{l} s, t \in V, \text{ } s \text{ and } t \text{ differ in} \\ \text{exactly one component} \end{array} \right\} \quad (16)$$

is defined.

Now the following basic relationship between the solution set and its representation graph can be proved:

- a) Each nonempty topologically connected component  $\widehat{X}$  of  $X$  can be represented in the form

$$\widehat{X} = \cup \{X(s) : s \in U\}, \quad (17)$$

where  $U$  is the node set of a connected component of  $G$ .

- b) If  $X$  is nonempty and bounded, then  $G = (V, E)$  is a connected graph, and

$$X = \cup \{X(s) : s \in V\}. \quad (18)$$

This property gives the possibility to apply to the implicitly defined representation graph  $G$  the well-known graph search method (see for example [21]) for calculating a connected component:

- 1) Compute a starting node  $s \in V$  by solving the midpoint system  $A^c x = b^c$ . The vector  $s$  is defined as the sign vector of this solution, and stored in a list  $L$ .
- 2) Put a sign vector  $s \in L$ , and solve the linear programming problems

$$\begin{cases} \min \{x_i : x \in X(s)\}, \\ \max \{x_i : x \in X(s)\} \end{cases} \quad (19)$$

for  $i = 1, \dots, n$ .

If a problem is unbounded, then an unbounded topologically connected component of  $X$  is found. Hence, each other topologically connected component of  $X$  is unbounded,  $\mathbf{A}$  is singular and the method is stopped. Otherwise, the linear programming problems calculate optimal bounds of  $X(s)$ , which are also stored. By definition of the edge set  $E$ , it follows immediately that

$$t := (s_1, \dots, s_{i-1}, -s_i, s_{i+1}, \dots, s_n) \quad (20)$$

is adjacent to  $s$ , if and only if one of the lp's in (19) has the exact bound equal to zero. All neighbored nodes  $t$  of  $s$  are stored in list  $L$ , except those which have been already treated. Then we proceed by going to 2), and repeat this process until  $L$  is empty.

It follows that this algorithm terminates in a finite number of steps, and either calculates optimal bounds of the solution set and proves regularity of  $\mathbf{A}$ , or shows that  $X$  is unbounded and  $\mathbf{A}$  is singular. The algorithm searches only in those orthants which have a nonempty intersection with the solution set, and avoids all other ones. Therefore,  $|V|$  calls of a polynomial time algorithm are needed, where  $|V|$  is the number of nonempty intersections of the solution set with the orthants.

In many cases in practice, due to physical or economical requirements, only few variables will change the sign implying that only few orthants will be intersected by the solution set. In those cases the method works efficiently. Nevertheless, due to the mentioned NP-hardness results of Rohn, there are also cases where an exponential computing time occurs.

*Example 3* In order to see how this algorithm behaves in detail, the example of the previous section is discussed. The solution  $\check{x} = (-0.8333, 2.0833)^\top$  gives the sign vector  $s = (-1, 1)$  which is stored in  $L$ .

Now we take this sign vector from list  $L$  (then  $L$  is empty) and solve the lp's (19) which gives the optimal

bounds of  $X(s)$

$$\begin{pmatrix} [-1.9167, -0.0595] \\ [1.3095, 3.1667] \end{pmatrix}. \quad (21)$$

No optimal bound has a value equal to zero, which implies that  $s = (-1, 1)$  has no neighbor with respect to the edge set  $E$ . It follows that  $X(s)$  is a topologically connected component and  $X = X(s)$ . Therefore, (21) gives the optimal bounds of  $X$ .

Following, the original example of Rohn [24] is discussed, which differs from the previous one by changing

$$A_c := \begin{pmatrix} 500.5 & 500.5 \\ -500.5 & 500.5 \end{pmatrix},$$

$$\Delta := \begin{pmatrix} 499.5 & 499.5 \\ 499.5 & 499.5 \end{pmatrix}.$$

Thus very large perturbations  $\Delta$  are allowed, and the spectral radius  $\rho(|(A^c)^{-1}| \cdot \Delta) = 1.9960$ . Hence the iteration method of the previous section cannot work, because  $A$  is not strongly regular. The solution  $\tilde{x} = (-0.001998, 0.004995)^T$  gives  $s = (-1, 1)^T$  and  $L = \{s\}$ .

Now  $s$  is removed from list  $L$  (then  $L$  is empty) and the lp's (19) yield the following optimal bounds of  $X(s)$ :

$$\begin{pmatrix} [-3.9950, 0] \\ [0.001002, 3.9980] \end{pmatrix}. \quad (22)$$

One optimal bound of the first component has a value equal to zero. Therefore, by (20)  $t = (-s_1, s_2)^T = (1, 1)^T$  is adjacent to  $s$  and list  $L := \{t\}$ .

Now we take  $t$  from list  $L$  (then  $L$  is empty), and the lp's (19) yield the optimal bounds of  $X(t)$ :

$$\begin{pmatrix} [0, 1.9950] \\ [0.0030, 2.0000] \end{pmatrix}. \quad (23)$$

Only the lower optimal bound of the first component is equal to zero. This gives the adjacent sign vector  $s = (-t_1, t_2) = (-1, 1)^T$ . But this is the sign vector already treated, and therefore not stored in list  $L$ . Since list  $L$  is empty, the algorithm is finished, and the optimal bounds (22) and (23) together deliver the optimal bounds

$$\begin{pmatrix} [-3.9950, 1.99950] \\ [0.001002, 3.9980] \end{pmatrix} \quad (24)$$

for the solution set  $X$ .

By comparing the bounds (21) and (13), we see that the optimal bounds (21) clearly improve the bounds (13) calculated by the iteration method of the previous section. This overestimation is mainly due to the preconditioning with the midpoint inverse. However, the bounds (13) give additionally the information that the solution set  $X$  intersects at most 2 orthants. Thus, an a priori estimation on the computing time for the exact method in this section is given: the above method has only to search in two orthants. Hence, first using in the strongly regular case a polynomial time method, provides rough bounds for  $X$  as well as a bound for the computing time which is needed for calculating exact bounds.

Several other examples up to dimension  $n = 50$  can be found in [9] and [10].

## Introduction

*Interval Newton methods* combine the classical Newton method, the *mean value theorem*, and *interval analysis*. The result is an iterative method that can be used both to refine enclosures to solutions of *nonlinear systems of equations*, to prove *existence* and *uniqueness* of such solutions, and to provide *rigorous bounds* on such solutions, including tight and rigorous bounds on critical points of constrained optimization problems. Interval Newton methods can also prove nonexistence of solutions within regions. Such capabilities can be used in isolation, for example, to provide rigorous *error bounds* for an approximate solution obtained with floating point computations, or as an integral part of global *branch and bound algorithms*.

## Univariate Interval Newton Methods

Suppose  $f: \mathbf{x} = [\underline{x}, \bar{x}] \rightarrow \mathbb{R}$  has a continuous first derivative on  $\mathbf{x}$ , suppose that there exists  $x^* \in \mathbf{x}$  such that  $f(x^*) = 0$ , and suppose that  $\check{x} \in \mathbf{x}$ . Then, since the mean value theorem implies

$$0 = f(x^*) = f(\check{x}) + f'(\xi)(x^* - \check{x}),$$

we have  $x^* = \check{x} - \frac{f(\check{x})}{f'(\xi)}$  for some  $\xi \in \mathbf{x}$ . If  $\mathbf{f}'(\mathbf{x})$  is any interval extension of the derivative of  $f$  over  $\mathbf{x}$ , then

$$x^* \in \check{x} - \frac{f(\check{x})}{\mathbf{f}'(\mathbf{x})} \quad \text{for any } \check{x} \in \mathbf{x}. \quad (1)$$

(Note that, in certain contexts, a *slope set* for  $f$  centered at  $\check{x}$  may be substituted for  $\mathbf{f}'(\mathbf{x})$ ; see [1] for further references.) Equation (1) forms the basis of the *univariate*

*interval Newton operator*:

$$\mathbf{N}(\mathbf{f}, \mathbf{x}, \check{x}) = \check{x} - \frac{f(\check{x})}{\mathbf{f}'(\mathbf{x})}. \quad (2)$$

Because of (1), any solutions of  $f(x) = 0$  that are in  $\mathbf{x}$  must also be in  $\mathbf{N}(\mathbf{f}, \mathbf{x}, \check{x})$ . Furthermore, local convergence of iteration of the interval Newton method (2) is quadratic in the sense that the width of  $\mathbf{N}(\mathbf{f}, \mathbf{x}, \check{x})$  is roughly proportional to the square of the width of  $\mathbf{x}$ . Furthermore, if an interval derivative extension (in contrast to an interval slope) is used for  $\mathbf{f}'(\mathbf{x})$ , then

$$\mathbf{N}(\mathbf{f}, \mathbf{x}, \check{x}) \subset \text{int}(\mathbf{x}),$$

where  $\text{int}(\mathbf{x})$  represents the interior of  $\mathbf{x}$ , implies that there is a unique solution of  $f(x) = 0$  within  $\mathbf{N}(\mathbf{f}, \mathbf{x}, \check{x})$ , and hence within  $\mathbf{x}$ .

## Multivariate Interval Newton Methods

Multivariate interval Newton methods are analogous to univariate ones in the sense that they obey an iteration equation similar to equation (2), and in the sense that they have quadratic convergence properties and can be used to prove existence and uniqueness. However, multivariate interval Newton methods are complicated by the necessity to bound the solution set of a linear system of equations with interval coefficients.

Suppose now that  $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ , suppose  $\mathbf{x}$  is an interval vector (i. e. a *box*), and suppose that  $\check{x} \in \mathbb{R}^n$ . (If interval derivatives, rather than slope sets, are to be used, then further suppose that  $\check{x} \in \mathbf{x}$ .) Then a general form for multivariate interval Newton methods is

$$\mathbf{N}(f, \mathbf{x}, \check{x}) = \check{x} + \mathbf{v}, \quad (3)$$

where  $\mathbf{v}$  is an interval vector that contains all solutions  $\mathbf{v}$  to point systems  $A\mathbf{v} = -f(\check{x})$ , for  $A \in \mathbf{f}'(\mathbf{x})$ , where  $\mathbf{f}'(\mathbf{x})$  is an interval extension to the Jacobi matrix of  $f$  over  $\mathbf{x}$ . (Under certain conditions,  $\mathbf{f}'$  may be replaced by an interval slope matrix.) As with the univariate interval Newton method, under certain natural smoothness conditions,

- $\mathbf{N}(f, \mathbf{x}, \check{x})$  must contain all solutions  $x^* \in \mathbf{x}$  with  $f(x^*) = 0$ . (Consequently, if  $\mathbf{N}(f, \mathbf{x}, \check{x}) \cap \mathbf{x} = \emptyset$ , then there are no solutions of  $f(x) = 0$  in  $\mathbf{x}$ .)
- For  $\mathbf{x}$  containing a solution of  $f(x) = 0$  and the widths of the components of  $\mathbf{x}$  sufficiently small, the width of  $\mathbf{N}(f, \mathbf{x}, \check{x})$  is roughly proportional to the square of the widths of the components of  $\mathbf{x}$ .

- If  $\mathbf{N}(f, \mathbf{x}, \check{x}) \subset \text{int}(\mathbf{x})$ , where  $\text{int}(\mathbf{x})$  represents the interior of  $\mathbf{x}$ , then there is a unique solution of  $f(x) = 0$  within  $\mathbf{N}(f, \mathbf{x}, \check{x})$ , and hence within  $\mathbf{x}$ .

For details and further references, see [1, §1.5].

Finding the interval vector  $\mathbf{v}$  in the iteration formula (3), that is, bounding the solution set to the interval linear system

$$\mathbf{f}'(\mathbf{x})\mathbf{v} = -f(\check{x}),$$

is a major aspect of the multivariate interval Newton method. Finding the narrowest possible intervals for the components of  $\mathbf{v}$  is, in general, an NP-hard problem. (See ► **Complexity classes in optimization.**) However, procedures that are asymptotically good in the sense that the overestimation in  $\mathbf{v}$  decreases as the square of the widths of the elements of  $\mathbf{f}'$  can be based on first *preconditioning* the interval matrix  $\mathbf{f}'(\mathbf{x})$  by the inverse of its matrix of midpoints or by other special preconditioners (see [1, Chapt. 3]), then applying the interval Gauss–Seidel method or interval Gaussian elimination.

### Existence-Proving Properties

The existence-proving properties of interval Newton methods can be analyzed in the framework of classical fixed-point theory. See ► **Interval fixed point theory**, or [1, §1.5.2]. Of particular interest in this context is a variant interval Newton method, not fitting directly into the framework of formula (3), that is derived directly by considering the classical chord method (Newton method with fixed iteration matrix) as a fixed point iteration. Called the *Krawczyk method*, this method has various nice theoretical properties, but its image is usually not as narrow as other interval Newton methods. See [1, p. 56].

Uniqueness-proving properties of interval Newton methods are based on proving that each point matrix formed elementwise from the interval matrix  $\mathbf{f}'(\mathbf{x})$  is nonsingular.

*Example 1* For an example of a multivariate interval Newton method, take

$$\begin{aligned} f_1(x) &= x_1^2 - x_2^2 - 1, \\ f_2(x) &= 2x_1x_2, \end{aligned}$$

with

$$\mathbf{x} = \begin{pmatrix} [0.9, 1.2] \\ [-0.1, 0.1] \end{pmatrix}, \quad \check{x} = \begin{pmatrix} 1.05 \\ 0 \end{pmatrix}.$$

An interval extension of the Jacobi matrix for  $f$  is

$$\mathbf{f}'(\mathbf{x}) = \begin{pmatrix} 2x_1 & -2x_2 \\ 2x_2 & 2x_1 \end{pmatrix},$$

and its value at  $\mathbf{x}$  is

$$\begin{pmatrix} [1.8, 2.4] & [-0.2, 0.2] \\ [-0.2, 0.2] & [1.8, 2.4] \end{pmatrix}.$$

The usual procedure (although not required in this special case) is to precondition the system

$$\mathbf{f}'(\mathbf{x})\mathbf{v} = -f(\check{x}),$$

say, by the inverse of the midpoint matrix

$$Y = \begin{pmatrix} 2.1 & 0 \\ 0 & 2.1 \end{pmatrix}^{-1} = \begin{pmatrix} 0.476 & 0 \\ 0 & 0.476 \end{pmatrix}$$

to obtain

$$Y\mathbf{f}'(\mathbf{x})\mathbf{v} = -Yf(\check{x}),$$

i. e., rounded out,

$$\begin{aligned} &\begin{pmatrix} [0.85, 1.15] & [-.096, .096] \\ [-.096, .096] & [0.85, 1.15] \end{pmatrix} \mathbf{v} \\ &= \begin{pmatrix} [-.0488, 0.487] \\ 0 \end{pmatrix}. \end{aligned}$$

(Rigor is not lost by taking floating point approximations for the preconditioner, but the interval arithmetic should be outwardly rounded.) The interval Gauss–Seidel method can then be used to compute sharper bounds on  $\mathbf{v} = \mathbf{x} - \check{x}$ , beginning with  $\mathbf{v} = \begin{pmatrix} [-0.15, 0.15] \\ [-0.1, 0.1] \end{pmatrix}$ . That is,

$$\begin{aligned} \tilde{\mathbf{v}}_1 &\subset \frac{[-0.0488, -0.0488] - [-0.096, 0.096]\mathbf{v}_2}{[0.85, 1.15]} \\ &\subset [-0.0688, -0.034]. \end{aligned}$$

Thus, the first component of  $\mathbf{N}(f, \mathbf{x}, \check{x})$  is

$$\check{x} + \mathbf{v} \subset [0.9833, 1.016].$$

In the second step of the interval Gauss–Seidel method,

$$\begin{aligned} \tilde{\mathbf{v}}_2 &= \frac{0 - [-0.096, 0.096]\tilde{\mathbf{v}}_1}{[0.85, 1.15]} \\ &\subset [-0.00778, 0.00778], \end{aligned}$$

so, rounded out,  $\mathbf{N}(f, \mathbf{x}, \check{\mathbf{x}})$  is computed to be

$$\begin{pmatrix} [0.981, 1.016] \\ [-0.00778, 0.00778] \end{pmatrix} \subset \begin{pmatrix} [0.9, 1.2] \\ [-0.1, 0.1] \end{pmatrix}.$$

This last inclusion proves that there exists a unique solution to  $f(x) = 0$  within  $\mathbf{x}$ , and hence, within  $\mathbf{N}(f, \mathbf{x}, \check{\mathbf{x}})$ . Furthermore, iteration of the procedure will result in bounds on the exact solution that become narrow quadratically.

Inventory management; Multistage inventory management; Supply chain; EOQ; Newsboy problem; (s, S) policy; Periodic review model; Continuous review model; Metric

A supply chain (SC) can be defined as an integrated system, where various firms work together, including suppliers of raw materials, manufacturers, distributors and retailers. Their efforts are concentrated on transforming the raw materials into final products that satisfy customer requirements, and delivering these products to the right place, at the right time. A SC contains two basic, integrated processes:

- a) production planning and inventory management (IM); and
- b) distribution and logistics processes [6].

This article gives a brief review of literature on *single-stage IM* and *multistage IM* models. The objective is to provide an overview of this research and emphasize current achievements in this field. Inventories exist

throughout the SC in the form of raw materials, work-in-process, and finished goods. Typical relevant inventory costs are: inventory carrying costs, order costs, and shortage costs. These costs often tend to conflict, in other words, decreasing one generally requires increasing another. The main motivation for keeping inventories is to cope with the uncertainty of external demand, supply and lead-time [18]. Keeping inventories is important to increase customer service level and reduce distribution costs, but it is estimated [5] that inventories cost approximately 20% to 40% of their value per year. Thus, managing inventories in a scientific manner to maintain minimal levels required for meeting service objectives makes economic sense. K. Arrow [2] presents an interesting discussion of the motives of a firm for holding inventories. There are several opportunities for streamlining SC inventories. It is important to understand that for a given service level the lowest inventory investment results when the entire SC is considered as a single system. Such coordinated decisions at Xerox and Hewlett Packard reduced their inventory levels by over 25% [9].

### Single Stage Inventory Management Models

The simplest inventory model is the deterministic economic order quantity (EOQ) model presented by F. Harris [12]. He recognized this problem in 1913 in his work at Westinghouse. The model determines the constant order quantity that minimizes the average annual cost of purchasing and carrying inventory, assuming deterministic and constant demand rate, no shortages, and zero order lead-times. A number of important scholars turned their attention to mathematical inventory models during the 1950s. A collection of mathematical models by Arrow, S. Karlin and H.E. Scarf [3] influenced later work in this area. At about the same time, H.M. Wagner and T.M. Whitin [24] developed a solution algorithm to the dynamic lot-sizing problem subject to time varying demand. Their model assumes periodic, deterministic demand over a finite planning horizon, no capacity restrictions on production, and zero inventory at the beginning and the end of the planning horizon. This problem is formulated as a mixed integer linear program (MILP) and can be represented as a fixed-charge network flow problem. The Wagner–Whitin algorithm is best illus-

trated using a shortest-path graph representation. Although the Wagner–Whitin model gives an optimal solution, in practice other heuristic lot-sizing algorithms are adopted. See [18] for a survey on the EOQ lot-sizing, silver-meal, least unit cost heuristics, etc. These models trade-off productivity losses from making small batches and the opportunity costs of tying up capital in inventory due to large batches. U.S. Karmarkar [14] extends the lot-sizing model to include lead-time related costs. Inventory control models subject to uncertain demand are basically of two types: *periodic review models* and *continuous review models*. Periodic review models exist for one planning period or for multiple planning periods. The single-period, stochastic inventory model is known as the *newsboy model*. The case of single period models with fixed order cost and initial inventories, leads to the optimality of  $(s, S)$  *optimal policies*. These policies state that if inventory position is less than  $s$ , then order up to  $S$ , otherwise do not order. The periodic review models with an infinite horizon are formulated in a dynamic programming framework [23]. Continuous review systems under uncertain demand track demands as they occur and the inventory position is always known. These models lead to the  $(Q, R)$  *policy*, under which a fixed amount of  $Q$  units is ordered each time the inventory position reaches a certain level  $R$ . The model typically assumes either backordering or lost sales when shortages occur.

### Multistage Inventory Management Models

Coordinating decisions at different levels of an organization comes as a need to reduce operating costs. This coordination can be seen in terms of integrating different decision types e. g., facility location, inventory planning, distribution, etc., or linking decisions within the same function at different stages in the SC. Multistage inventory management models (MSIM models) concentrate on integrating IM policies in different stages of the SC. The typical MSIM problem analyzed in the literature is a two-level system composed of a number of retailers being served by a central warehouse. The demand at each retailer is satisfied using on-hand inventory. When insufficient inventory is available, a back-order typically occurs, and demand must be satisfied later using inventory from the warehouse. The model decides on the inventory level at each retailer and the

warehouse, such that a set of prespecified criteria is satisfied at minimum inventory-related costs. The first MSIM model was developed by A. Clark and Scarf [7]. They consider a system with a single product and  $N$  facilities, where facility  $i$  supplies facility  $i + 1$ , for  $i = 1, \dots, N - 1$ . The model considers a periodic review of the inventory level and assumes fixed lead-times, a finite planning horizon, backordering of demand shortages and variable order cost. The aim is to find IM policies to be applied in each of the echelons, such that system cost is minimized. They show that under the above assumptions an optimal policy for the system can be found by decomposing the problem into  $N$  separate single-location problems and solving the problem recursively. The above model was extended to incorporate an infinite horizon and lead time uncertainty. A generalization of the system described above is the *multi-echelon arborescence system*, where each location has a unique supplier. A.F. Veinott [23] provides an excellent summary of these early modeling efforts. One of the earliest continuous review MSIM models was presented by C.C. Sherbrooke [21]. He considers a two-stage system with several retailers and a single warehouse that supplies to these retailers. He introduces the well-known METRIC approximation to determine the optimal level of inventory in the system. The METRIC approximation assumes a Poisson distribution of demand and constant replenishment lead-times. S.C. Graves [11] extends the METRIC approximation by estimating the mean and the variance of the outstanding retailer orders. He fits the negative binomial distribution to these parameters to determine the optimal inventory policy. S. Axsäter [4] provides an exact solution to the problem and shows that the METRIC approximation provides an underestimate, whereas Graves' two-parameter approximation [11] overestimates the retailer backorders. The above studies use the *one-for-one ordering policy* ( $S - 1, S$ ), i.e., an order is placed as soon as a demand occurs. This policy is appropriate for items with high value and a low demand rate. Axsäter [4] shows that the models used for the one-for-one ordering policy can be extended in the case of batch ordering with only one retailer. Analysis of batch ordering policies in arborescent systems (when the number of retailers is greater than one) is similar to Sherbrooke's model. B.L. Deuermeyer and L.B. Schwarz [8] were the first to analyze such a system. They estimate the mean and the vari-

ance of lead-time demand to obtain average inventory levels and backorders at the warehouse, assuming that lead-time demand is normally distributed. The retailer lead-time demand is also approximated using a normal distribution. In addition to reviewing the literature in the area, [15,17] and [22] also provide several extensions to the Deuermeyer and Schwarz model. In [10] the concept of stability in a capacitated, multi-echelon production-inventory system under a base-stock policy is introduced. W.L. Maxwell and others [16] extend the analysis to multiproduct, continuous review and deterministic demand, MSIM problems. Their model tends to schedule the orders for each of the products over an infinite horizon so as to minimize the long-run average cost. The authors define a new class of policies in which each product uses a stationary interval of time between successive orders. Their model finds a lot-sizing rule that is within 6% of the average cost of the optimal policy. R. Roundy [19] develops a similar multistage, multiproduct lot-sizing model. Under the assumption that the ratio of the order intervals of any two products is an integer power of two, it is shown that the solution is within 2% of optimality.

D. Sculli and others [20] extend the analysis of MSIM systems for the case when two suppliers are used to replenish stock of a single item. They calculate the mean and the standard deviation of the effective lead time demand and interarrival time when replenishment orders are placed at the same time with the two suppliers, in a continuous review system. The lead-time distribution of each supplier is assumed to be normal. R. Ganeshan [9] presents a near-optimal ( $s, Q$ ) inventory policy for a production/distribution network with multiple suppliers replenishing a central warehouse, which distributes to a large number of retailers. The model concentrates on inventory analysis at the retailers and the warehouse, and demand process at the warehouse. The model finds a near-optimal order quantity and a reorder point at both the retailer and the distribution center (DC) under stochastic demand and lead-time, subject to customer service constraints. The main contribution of this model is the integration of the above components for analyzing simple supply chains. P. Afentakis and others [1] develop a procedure for optimally solving medium size lot-scheduling problems in multistage structures with periodic review of the inventory and dynamic deterministic demand. They formu-

late the problem in terms of *echelon stock*, which simplifies its decomposition by Lagrangian relaxation. An efficient *branch and bound* algorithm is used to solve the problem.

M.C. van der Heijden and others [13] consider the periodic review, order-up-to ( $R, S$ ) inventory system under stochastic demand. They propose a new approach to calculate the mean physical stock. The standard approximation appears to yield inaccurate results in the case of low service levels. Low service levels usually occur at intermediate nodes in optimal solutions for multi-echelon systems.

## Conclusions

With the trend toward just-in-time deliveries and reduction of inventories, many firms are reexamining their inventory and logistics policies. Some firms are altering their inventory, production and shipping policies, and others are working on coordinating inventory decisions throughout their SC, with the goal of reducing costs and improving service. Single stage IM models give some insights on how to manage inventories under certain demand and lead-time considerations, while MSIM models take the analysis further, coordinating inventory decisions throughout the SC. This article reviews the literature on single-stage and multi-stage inventory management models, with an emphasis on achievements in this field.

*Lagrangian conditions* are often necessary, but not sufficient, for a minimum of an optimization problem in continuous variables. Sufficiency holds under convex assumptions, which are however often not satisfied in applications. Invexity is a less restrictive assumption than convexity, under which Lagrangian conditions are sufficient for a minimum, and also related duality results hold. It also provides a structure, showing relations with various other kinds of generalized convexity.

Consider a *constrained minimization problem*

$$(P1) \begin{cases} \min & f(x), \\ \text{s.t.} & g_j(x) \leq 0, \\ & j = 1, \dots, m, \end{cases}$$

where the functions  $f$  and  $g_j$  are differentiable. Define the Lagrangian  $L(\cdot; \lambda) := f(\cdot) + \sum \lambda_j g_j(\cdot)$ , where  $\lambda = (\lambda_1, \dots, \lambda_m)$  is a vector of nonnegative Lagrange multipliers. When  $p$  is a feasible point, define also a reduced Lagrangian  $L_{(p)}(\cdot; \lambda)$  obtained by omitting constraints

inactive at  $p$  (thus, when  $g_j(p) < 0$ .) A minimum point  $p$  for (P1), assuming some regularity for the constraints, is then a *Karush–Kuhn–Tucker* (KKT) point, namely one where the gradient of the Lagrangian with respect to  $x$  satisfies  $L_{(p)}'(p; \lambda) = 0$  for some  $\lambda \geq 0$ . However, a KKT point is not generally a minimum point. It is, in particular, if the functions  $f$  and each  $g_k$  are convex. However, convexity often does not hold in applications, and less restrictive conditions are sought when a KKT point is a minimum.

A differentiable vector function  $F := (f, g_1, \dots, g_m)$ , with gradient  $F'$ , is called *invex* if, for some *scale function*  $\eta$ , and all  $x$  and  $p$ ,

$$(INV) \quad F(x) - F(p) \geq F'(p)\eta(x, p).$$

This property was first called  $\eta$ -convex by M.A. Hanson [11].

Usually, at a given  $p$ ,  $\eta(x, p) = (x - p) + o(\|x - p\|)$ . In particular,  $F$  is convex if  $\eta(x, p) = x - p$ . If  $F$  is invex and  $\lambda \geq 0$ , then it follows that  $L_{(p)}(\cdot; \lambda)$  is invex, so if  $x$  is a feasible point, then

$$\begin{aligned} f(x) - f(p) &\geq L_{(p)}(x, \lambda) - L_{(p)}(p, \lambda) \\ &\geq L'_{(p)}(p; \lambda)\eta(x, p) = 0, \end{aligned}$$

from KKT, so that  $p$  is a minimum point of (P1). This minimum is global if (INV) holds globally, otherwise local. (But how can (INV) be verified, as a global property?)

By a similar argument, since  $L(\cdot; v)$  is invex when  $v \geq 0$ , duality holds for (P1) and the *Wolfe dual* problem:

$$(D1) \begin{cases} \max & f(u) + \sum v_j g_j(u) \\ \text{s.t.} & f'(u) + \sum v_j g'_j(u) = 0, \\ & v_1 \geq 0, \dots, v_m \geq 0, \end{cases}$$

if KKT holds for (P1) and the invex property holds (see [17]). Duality means that  $f(x) \geq f(u) + \sum v_j g_j(u)$  whenever  $x$  and  $u, v$  are feasible for their respective problems, and also that the optimum objectives are equal. Consider also the *Mond–Weir dual* [18]:

$$(D2) \begin{cases} \max & f(u) \\ \text{s.t.} & f'(u) + \sum v_j g'_j(u) = 0, \\ & v_1 \geq 0, \dots, v_m \geq 0, \\ & \sum v_j g_j(u) \geq 0. \end{cases}$$

Assume that  $F$  is invex. If  $x$  is feasible for (P1) and  $(x, u)$  for (D2), then

$$\begin{aligned} f(x) - f(u) &\geq f'(u)\eta(x, u) \\ &= -\sum \lambda_j g'_j(u)\eta(x, u) \\ &\geq \sum (-v_j g_j(x) + v_j g_j(u)) \geq 0, \end{aligned}$$

and this, with KKT, proves duality.

If the vector function  $F$  is locally Lipschitz, rather than differentiable, then (INV) is replaced by *generalized invex* (see [6]):

$$(INV2) \quad F(x) - F(p) \geq F^\circ(p, \eta(x, p)).$$

where  $F^\circ(p, d)$  denotes Clarke's generalized directional derivative (see [2]) of  $F$  at  $p$  in direction  $d$ . Most properties of (INV) extend to (INV2). In particular, if  $F_1, F_2, \dots$  are (generalized) invex functions with the same scale function  $\eta$ , then so also are  $\max_j F_j(\cdot)$ , any element of the convex hull  $\text{co } F_j(\cdot)$ , and (if it exists)  $\lim_j F_j(\cdot)$ . But the assumption of the same  $\eta$  is necessary here.

Suppose now that the following *V-invex* property (see [14]) holds for  $g_0(\cdot) := f(\cdot) - f(p)$  and for the active constraints  $g_j(\cdot)$  (those for which  $g_j(p) = 0$ ):

$$\forall x: \quad g_j(x) - g_j(p) \geq \beta_j(x, p)g'_j(p)\eta(x, p).$$

Note that  $\eta(\cdot, \cdot)$  is a vector function, the same for each  $j$ , and the weight  $\beta_j(\cdot, \cdot)$  is a positive scalar function. If KKT holds, and if  $x$  is feasible for (P1), then setting  $\mu_j := \lambda_j / \beta_j$ , the minimum follows from

$$\begin{aligned} f(x) - f(p) &\geq L_{(p)}(x; \mu) - L_{(p)}(p; \mu) \\ &\geq \sum \beta_j \mu_j g'_j(p)\eta(x, p) = 0. \end{aligned}$$

In the problem (P1), set  $G_j(x) := r_j(x) g_j(x)$ , where  $r_j(\cdot) > 0$ ; then  $g_j(x) \leq 0$  if and only if  $G_j(x) \leq 0$  ( $j = 1, \dots, m$ ), and  $f(x) \geq f(p)$  if and only if  $G_0(x) \geq 0$ . So (P1) is equivalently formulated in terms of the weighted constraint functions  $G_j$ . For each active constraint  $g_j(x) \leq 0$  with  $g_j$  invex,

$$G_j(x) - G_j(p) = G_j(x) \geq \beta_j(x, p)G'_j(p)\eta(x, p),$$

where the weight  $\beta_j(x, p) = r_j(x)/r_j(p)$ . Thus the  $G_j$  have the V-invex property. Note also that if  $n$  and  $d$  are real functions with  $n(\cdot) \geq 0$  and  $d(\cdot) > 0$ , and  $n$  and  $-d$  are invex with the same scale function, then [14] the

ratio  $n(\cdot)/d(\cdot)$  is V-invex with the same scale function, and weight  $\beta(x, p) = d(p)/d(x)$ .

Invexity for (P1) can also be relaxed to the requirement, called *Type I* in [12]:

$$\begin{aligned} f(x) - f(p) &\geq f'(p)\eta(x, p); \\ -g_j(p) &\geq g'_j(p)\eta(x, p), \quad \forall j \in J, \end{aligned}$$

where  $J$  is the set of indices of constraints active at  $p$ . If this property holds at a KKT point  $p$ , and  $g_j(x) \leq 0$  ( $\forall j$ ), then

$$f(x) - f(p) \geq -\sum_{j \in J} \lambda_j g'_j(p)\eta(x, p) \geq 0,$$

thus  $p$  is a minimum for (P1).

Invexity is related as follows to some other properties. The vector function  $F: \mathbf{R}^n \rightarrow \mathbf{R}^r$  is *convexifiable* if  $H := F \circ \phi^{-1}$  is convex, for some invertible transformation  $\phi: \mathbf{R}^n \rightarrow \mathbf{R}^n$ . For  $0 < \alpha < 1$ ,

$$\begin{aligned} (CL) \quad (1 - \alpha)F(p) + \alpha F(x) & \\ &= (1 - \alpha)H(\phi(p)) + \alpha H(\phi(x)) \\ &\geq H((1 - \alpha)\phi(p) + \alpha\phi(x)) \\ &= F(\xi(\alpha, x, p)) \end{aligned}$$

if  $H$  is convex, where

$$(K) \quad \xi(\alpha, x, p) := \phi^{-1}((1 - \alpha)\phi(p) + \alpha\phi(x)).$$

This reduces, for a convex function  $F$ , to  $\xi(\alpha, x, p) = (1 - \alpha)p + \alpha x$ . If  $\phi$  is differentiable, then also

$$\begin{aligned} (K2) \quad \frac{\partial}{\partial \alpha} \xi(\alpha, x, p)|_{\alpha=0} & \\ &= \phi^{-1'}(\phi(p))[\phi(x) - \phi(p)] \equiv \eta(x, p). \end{aligned}$$

Hence, letting  $\alpha \downarrow 0$ , invexity follows. Thus,

$$\text{Convexifiable} \Rightarrow (CL) + (K) \Rightarrow \text{Invex},$$

with the second implication assuming differentiable functions. The name 'invex' was given [4], from *invariant convex*, since invex preserves that part of the convex property that is invariant to the transformation  $\phi$ . (See also [1].) The property (CL), together with the existence of  $(\partial / \partial \alpha) \xi(\alpha, x, p)|_{\alpha=0}$ , was called *protoconvex* in [10]. It holds, in particular, if  $\xi(\alpha, x, p) = p + \alpha \phi(x - p)$  holds in (CL). If  $F$  is locally Lipschitz, then (CL) and

(K2) for all  $x$  and  $p$  in a domain imply generalized invex. Note that invex does not imply convexifiable. A counterexample (see [8]) is  $F(x) := (-x_1x_2 + 1, -x_1x_2 + 1)$ .

Suppose that  $f$  is invex, with scale function  $\eta$ , and that  $\phi$  is a differentiable invertible transformation of the domain space. An application of the chain rule shows that  $f \circ \phi$  is also invex, with a new scale function

$$\hat{\eta}(\alpha, \beta) = \phi'(\phi(\alpha))^{-1}\eta(\phi(\beta), \phi(\alpha)).$$

This invariance of invexity to domain transformations extends to two relaxed properties (see [15,18]), defined by:

- *quasi-invex*:

$$f(x) \leq f(p) \Rightarrow f'(p)\eta(x, p) \leq 0;$$

- *pseudo-invex*

$$f(x) < f(p) \Rightarrow f'(p)\eta(x, p) < 0.$$

These reduce to *quasiconvex* (respectively *pseudoconvex*; see [16,19]) when  $\eta(x, p) = x - p$ . If  $f$  is quasi-invex (respectively, pseudo-invex) with scale function  $\eta$ , then  $f \circ \phi$  is quasi-invex (respectively pseudo-invex) with scale function  $\hat{\eta}$ . Note that each pseudoconvex real function is invex, but not conversely.

In (P1), if  $f$  is pseudo-invex, and each  $g_j$  is quasi-invex, all with the same scale function  $\eta$ , then KKT is sufficient for a minimum. For each active constraint,

$$g_j(x) \leq 0 = g_j(p) \Rightarrow g'_j(p)\eta(x, p) \leq 0.$$

Then  $\sum \lambda_j g'_j(p) \eta(x, p) \leq 0$ , hence KKT gives  $f'(p) \eta(x, p) \geq 0$ . From pseudoconvexity,  $f(x) \geq f(p)$ , proving the minimum. There are various results (see [18,21]) showing sufficiency of KKT for a minimum, when various combinations of the functions  $f$  and  $g_j$  have specified pseudo-invex and quasi-invex properties, all with the same scale function  $\eta$ . Some further examples of pseudo-invex functions are given in [15] (they called *η-pseudoconvex*.)

The property (CL) is called *convex-like* (see [13]). If  $\Gamma \subset \mathbf{R}^n$  is a convex set,  $F$  is (CL), and  $Q$  is the orthant  $\mathbf{R}_+^{m+1}$ , then  $F(\Gamma) + Q$  is a convex set. For, taking  $x, p \in \Gamma$  and  $q, r \in Q$ , with  $0 < \alpha < 1$ ,

$$(1 - \alpha)[F(p) + q] + \alpha[F(x) + r] - [F(\xi(\alpha, x, p) + (1 - \alpha)q + \alpha r)] \in Q.$$

From this follows (see [3,8,13]) the *basic alternative theorem* that

$$(BAT) \quad \begin{aligned} & \neg(\exists x \in \Gamma): F(x) < 0 \\ \Leftrightarrow & (\exists 0 \neq \rho \geq 0): \rho F(\cdot) \geq 0. \end{aligned}$$

Consider (P1) with inactive constraints omitted. If (CL) holds, then (from (BAT)) (P1) reaches a minimum at  $p$  if and only if there are nonnegative multipliers  $\tau$  and  $\lambda$ , not both zero, for which

$$\tau[f(x) - f(p)] + \lambda g(x) \geq 0, \quad \forall x.$$

If Slater's constraint qualification holds, that  $g(c) < 0$  for some  $c$ , then  $\tau = 1$  can be assumed. If  $f$  and  $g$  are directionally differentiable, then the directional derivatives satisfy

$$f'(p; d) + \lambda g'(p; d) \geq 0$$

for each direction  $d$ . If  $f$  and  $g$  are Lipschitz functions and (CL) holds, then

$$0 \in \partial(f + \lambda g)(p), \quad \lambda g(p) = 0,$$

is necessary and sufficient for a minimum, where  $\partial$  denotes here Clarke's subdifferential [2].

When is a vector function invex at a point  $p$ ? Assume now twice differentiable functions, and expand

$$\begin{aligned} F(x) &= F(p) + F'(p)v + \frac{1}{2}v^T F''(p).v + \dots, \\ \eta(x, p) &= v + \frac{1}{2}v^T Q.v + \dots, \end{aligned}$$

where  $v = x - p$ , and  $v^T F''(p).v$  means that component  $j$  of  $F$  has second order term  $v^T F''_j(p) v$ , and similarly for  $v^T Q.v$ ; denote the matrix component  $k$  of  $Q$ . by  $Q_k$ . Then ([5]), by substituting in (INV), local invexity implies that

$$F''(p)_s - \sum_k F'(p)_{sk} Q_k$$

is positive semidefinite, for each  $s$ . Conversely, if each of these matrices is positive definite, then  $F$  is locally invex at  $p$ .

Some further classes of invex functions are described as follows (see [9]). Let  $X_0$  be an open domain in  $\mathbf{R}^n$ , let  $A: X_0 \rightarrow \mathbf{R}^m$  be convex, and let  $B: X_0 \rightarrow \mathbf{R}$  be differentiable and satisfy  $B(X_0) \subset (0, \infty)$ . Then  $A(\cdot)/B(\cdot)$

is invex if also  $B$  is convex with  $A(X) \subset -\mathbf{R}_+^m$ , or if  $B$  is concave with  $A(X_0) \subset \mathbf{R}_+^m$ . If  $g: X_0 \rightarrow \mathbf{R}^m$  is differentiable, and  $g'(a) d < 0$  for some direction  $d$ , then  $g$  is invex at the point  $a$ .

Let  $\phi: \mathbf{R}^n \rightarrow \mathbf{R}^n$  be an invertible  $C^2$  mapping; let  $r: \mathbf{R}_+ \rightarrow \mathbf{R}_+$  be strictly increasing, with  $r(0) = 0, r'(0) = 0$ , and  $r''(0) < 0$  on some interval. Then  $r$  and  $h(\cdot) := r \circ \|\cdot\|$  are pseudoconvex, and  $h \circ \phi$  is pseudo-invex (hence also quasi-invex).

The invex property, and also pseudo-invex, quasi-invex and V-invex, are also applicable when the spaces  $\mathbf{R}^n$  and  $\mathbf{R}^m$  are replaced by infinite-dimensional normed spaces of functions, such as occur in *optimal control* (see [3,8]) and *continuous programming* (see [7,20]). The definitions, and proofs of basic properties (see [3,7,8]), are unchanged, interpreting  $a \geq b$  as  $a - b \in Q$ , where the *order cone*  $Q$  is a closed convex cone. Examples of spaces of control functions are the spaces  $C(\mathbf{R}^r)$  (respectively,  $PC(I, \mathbf{R}^r)$ ) of continuous (respectively, piecewise continuous) functions from an interval  $I$  into  $\mathbf{R}^r$ , with the uniform norm, and the space  $L^2(I, \mathbf{R}^r)$  of square-integrable functions from  $I$  into  $\mathbf{R}^r$ . Consider, for example, an integral objective function  $f(x) := \int_0^T \phi(x(t), \dot{x}(t), t) dt$ , where  $f \in C^1(0, T)$ ,  $\phi$  is differentiable, and  $\dot{x}(t) = (\frac{d}{dt})x(t)$ . Assume boundary conditions  $x(0) = x_0, x(T) = x_T$ . Denote  $\phi_x(x(t), \dot{x}(t), t) := (\frac{\partial}{\partial x})\phi(x(t), t)$ , and similarly  $\phi_{\dot{x}}$ . Then the gradient  $f'(p)$  of  $f$  at  $p \in C^1[0, T]$  is given by

$$\begin{aligned} f'(p)z &= \int_0^T \phi_x(p(t), \dot{p}(t), t)z(t) dt \\ &= \int_0^T \left[ \phi_x(p(t), \dot{p}(t), t) - \frac{d}{dt}\phi_{\dot{x}}(p(t), \dot{p}(t), t) \right] \\ &\quad \times z(t) dt \end{aligned}$$

after integrating by parts. Then  $f$  is *invex* if, for some scale function  $\eta$ ,

$$\begin{aligned} f(x) - f(p) &\geq \int_0^T \left[ \phi_x(p(t), \dot{p}(t), t) - \frac{d}{dt}\phi_{\dot{x}}(p(t), \dot{p}(t), t) \right] \\ &\quad \times \eta(x(t), p(t), t) dt. \end{aligned}$$

For a constraint  $\psi(x(t), t) \leq 0 (\forall t \in [0, T])$ , the analog of the term  $\sum \lambda_j g_j(x)$  in the Lagrangian is

$$\int_0^T \lambda(t)\psi(x(t), t) dt,$$

and invexity requires that

$$\begin{aligned} &\int_0^T \lambda(t) [\psi(x(t), t) - \psi(p(t), t)] dt \\ &\geq \int_0^T \lambda(t)\psi_x(p(t), t)\eta(x(t), p(t), t) dt. \end{aligned}$$

There are converse KKT and duality properties for such infinite-dimensional problems (see e.g. [8,20]), using invexity quite similarly to finite-dimensional problems.

### Problem Statement

Given a finite set  $X$  with an ordering  $\preceq$ , a real function  $g$  on  $X$  and a positive weight function  $w$  on  $X$ , the *isotonic regression problem* is to find a function  $g^*$  which

minimizes

$$\sum_{x \in X} [g(x) - f(x)]^2 w(x),$$

among the class  $F$  of isotonic functions  $f$  defined on  $X$ , i. e.

$$F = \{f: \forall x, y \in X \text{ and } x \preceq y \Rightarrow f(x) \leq f(y)\}.$$

The function  $g^*$  is called *isotonic regression*, and it exists and is unique [5].

Isotonic regression can be viewed as a *least squares problem* under order restrictions; here, order restrictions on parameters can be regarded as requiring that the parameter, as a function of an index, will be isotonic (the adjective ‘isotonic’ is used as a synonym for ‘order preserving’) with respect to an order on the index set.

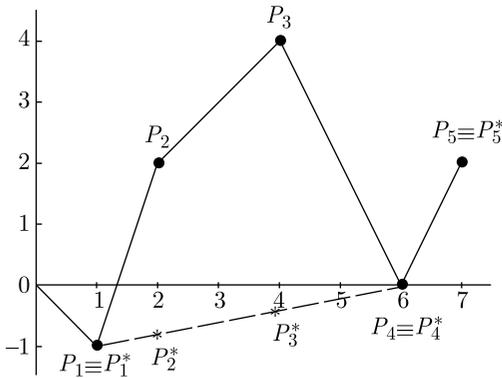

If  $\preceq$  is reflexive, transitive, antisymmetric and every pair of elements are comparable, the problem is called *simple order isotonic regression*.

A very important result in the theory of isotonic regression, is that the increasing function  $f$  closest to a given function  $g$  on  $X$  in the (weighted) least squares sense, can be constructed graphically. A geometrical interpretation of isotonic regression over a simple order finite set  $X = \{x_1, \dots, x_n\}$  is the following. Let  $W_j = \sum_{i=1}^j w(x_i)$  and  $G_j = \sum_{i=1}^j g(x_i) w(x_i)$ ; the points  $P_j = (W_j, G_j)$  obtained plotting the cumulative sums  $G_j$  against the cumulative sums  $W_j$ ,  $j = 0, \dots, n$  ( $W_0 = 0$ ,  $G_0 = 0$ ), constitute the *cumulative sum diagram* (CSD) of a given function  $g$  with weights  $w$ . The isotonic regression of  $g$  is given by the *slope* of the *greatest convex minorant* (GCM) (i. e., the graph of the supremum of all convex functions whose graphs lie below the CSD) of the CSD; the slope of the segment joining  $P_{j-1}$  to  $P_j$  is just  $g(x_j)$ ,  $j = 1, \dots, n$ , while the slope of the segment joining  $P_{i-1}$  to  $P_j$ ,  $i \leq j$  is the weighted average

$$Av\{x_i, \dots, x_j\} = \frac{\sum_{r=i}^j g(x_r) w(x_r)}{\sum_{r=i}^j w(x_r)}.$$

Therefore, the value of the isotonic regression  $g^*$  at the point  $x_j$  is just the slope of the GCM at the point  $P_j^* = (W_j, G_j^*)$ , where  $G_j^* = \sum_{i=1}^j g^*(x_i) w(x_i)$ . Note that, if  $P_j^*$  is a ‘corner’ of the graph,  $g^*$  is the slope of the segment extending to the left. An illustrative example is shown in Fig. 1.

$j$	$w(x_j)$	$W_j$	$g(x_j)$	$G_j$	$g^*(x_j)$	$G_j^*$
1	1	1	-1	-1	-1	-1
2	1	2	3	2	1/5	-4/5
3	2	4	1	4	1/5	-2/5
4	2	6	-2	0	1/5	0
5	1	7	2	2	2	2

Isotonic Regression Problems, Figure 1  
Example of CSD and GCM

Other isotonic regression problems are based on a less restrictive kind of order: *partial order* and *quasi-order*. In the partial order isotonic regression problem the binary relation  $\leq$  on  $X$  is reflexive, transitive and antisymmetric, but there may be noncomparable elements. In the quasi-order isotonic regression problem, the ordering relation satisfies only the first two conditions.

The isotonic regression problem arises in both statistics and operations research. Applications in statistics are discussed in [2,10] and [14]. Applications in operations research can be found in [11] and [15].

The problem under consideration is also of theoretical interest being one of the very few quadratic problems known for which *strongly polynomial solution* algorithms exist (an algorithm is said to be *strongly polynomial* if the number of elementary arithmetic operations it requires is a polynomial in the problem parameter and not just the size of the input data). That is why many researcher in the area of order restricted statistical inference have paid a great deal of attention to the problem of developing algorithms for isotonic regression. Most of the algorithms proposed involve averaging  $g$  over suitably selected subsets  $S$  of  $X$  on each of which  $g^*(x)$  is constant.

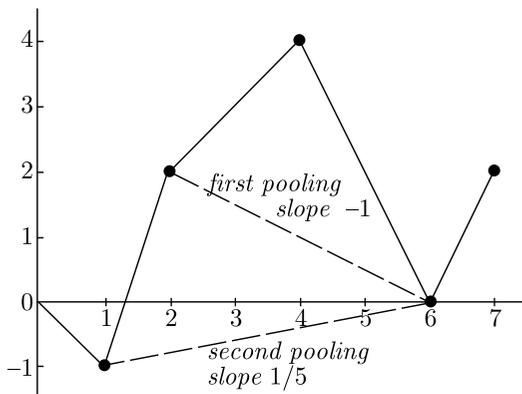

### The Pool Adjacent Violators Algorithm

The first and the most widely used algorithm for the simply ordered isotonic regression is the pool adjacent violators algorithm (PAV) proposed by M. Ayer et al. [1] in 1955.

This algorithm follows directly from the geometrical interpretation of isotonic regression. As it is said before, the solution of the problem under consideration is given by the left derivative of the greatest convex function lying below the CSD. If, for some index  $i$ ,  $g(x_{i-1}) > g(x_i)$ , then the graph of the part of the GCM between the points  $P_{i-2}^*$  and  $P_i^*$  is a straight line segment. Thus the CSD could be altered by connecting  $P_{i-2}$  with  $P_i$  by a straight line segment, without changing the GCM. The PAV algorithm is based on this idea of successive approximation to the GCM. (See Fig. 2 for a geometrical interpretation of ‘pooling’ adjacent violators.)

In describing the algorithm, an arbitrary set of consecutive elements of  $X$  will be referred to as a *block*. The

$j$	1	2	3	4	5
$w(x_j)$	1	1	2	2	1
$g(x_j)$	-1	3	1	-2	2
First pool					
$w(x_j)$	1	2	4	4	1
$g(x_j)$	-1	3	-1	-1	2
Second pool					
$w(x_j)$	1	5	5	5	1
$g(x_j) \equiv g^*(x_j)$	-1	1/5	1/5	1/5	2

Isotonic Regression Problems, Figure 2  
Geometrical interpretation of pooling adjacent violators

aim is to find the *solution blocks*, that is a partitioning of  $X$  into sets on each of which the isotonic regression function  $g^*$  is constant.

The PAV algorithm starts from the initial block class  $\Delta$  consisting of the singleton sets  $\{x_i\}$ ,  $1 \leq i \leq n$ . At each stage of the algorithm, a new block class is obtained from the previous block class by joining the blocks together until the final partition is reached. If  $g(x_1) \leq \dots \leq g(x_n)$ , then the initial partition is also the final partition, and  $g^*(x_i) = g(x_i)$ ,  $i = 1, \dots, n$ .

Otherwise, select any of the pairs of violators of the ordering; that is, select an index  $i$  such that  $g(x_i) > g(x_{i+1})$ . 'Pool' these two values of  $g$ : i. e., join the two points  $x_i$  and  $x_{i+1}$  in a block  $\{x_i, x_{i+1}\}$  ordered between  $\{x_{i-1}\}$  and  $\{x_{i+2}\}$ , and associate to this block the average value  $Av\{x_i, x_{i+1}\}$  and the weight  $w(x_i) + w(x_{i+1})$ . After each step in the algorithm, the average values associated with the blocks are examined to see whether or not they are in the required order. If so, the final partition has been reached, and the value of  $g^*$  at each point of a block is the 'pooled' value associated with the block. If not, a pair of adjacent violating blocks is selected, and pooled to form a single block, with associated weight the sum of their weights and associated average value the weighted average of their average values, completing another step of the algorithm.

A pseudocode for PAV algorithm is presented below, where  $B$  is the first block in  $\Delta$  and  $B_+$  is the block that follows  $B$  in the blocks partition.

```

 $\Delta = \{\{x_1\}, \dots, \{x_n\}\}$ 
REPEAT
  set  $B$  and  $B_+$ 
  WHILE  $B_+ \neq 0$ 
    IF  $AvB \geq AvB_+$  THEN
       $\Delta = \Delta \setminus \{B, B_+\} \cup \{B \cup B_+\}$ 
       $B = B \cup B_+$ 
       $g^*(x) = AvB, \forall x \in B$ 
    ELSE
       $B = B_+$ 
    ENDIF
     $B_+ = succ(B)$ 
  ENDWHILE
UNTIL there are no violating blocks

```

A pseudocode for PAV algorithm

S.J. Grotzinger and C. Witzgall [9] have shown that the computational complexity of the PAV algorithm is  $O(n)$ .

### Minimum Lower Set Algorithm

The first algorithm proposed for partially order isotonic regression is the *minimum lower sets* (MLS) due to H.D. Brunk [4].

For describing this algorithm, as for most of the algorithms for general partial order, it is convenient to introduce the concept of 'level set' that generalizes the concept of 'block'. In order to define this set, important concepts are lower and upper set. A set  $L \subseteq X$  is called *lower set* if  $\forall x \in X$  and  $\forall y \in L$  with  $x \preceq y \Rightarrow x \in L$ . A set  $U \subseteq X$  is called *upper set* if  $\forall x \in X$  and  $\forall y \in U$  with  $x \preceq y \Rightarrow x \in U$ . Finally,  $S \subseteq X$  is called *level set* if there are a lower set  $L \subseteq X$  and an upper set  $U \subseteq X$  such that  $S = L \cap U$ .

The isotonic regression with respect to any partial order is constant on level sets. The MLS algorithm computes the isotonic regression function by partitioning  $X$  into  $l$  level sets  $S_1, \dots, S_l$  such that  $AvS_1 < \dots < AvS_l$ . In doing that, the algorithm performs  $l$  steps in each of which searches for the largest level set of minimum average  $S_i$  among the level sets  $L_{i+1} \cap L_i^C$ , where  $L_i^C$  is the complement of  $L_i$ . The isotonic regression values are given by the weighted average of the observations in each of the level set that belong to the solution partition.

In the following a pseudocode for MLS algorithm is given, where  $\mathbf{L}$  is the lower set family of  $X$ .

M.J. Best and N. Chakravarti [3] have proved that the MLS algorithm is of computational complexity  $O(n^2)$ .

```

select  $L_1 \subseteq X : AvB_1 = AvL_1$ 
      =  $\min\{AvL : L \in \mathbf{L}\}$ 
 $i = 1$ 
REPEAT
   $i = i + 1$ 
  select  $L_2 \subseteq X : AvB_i = Av(L_2 \cap L_1^C)$ 
        =  $\min\{Av(L \cap L_1^C) : L \in \mathbf{L}\}$ 
   $L_1 = L_2$ 
UNTIL  $X$  is exhausted
 $g^*(x) = AvB_j, \forall x \in B_j, j = 1, \dots, i$ 

```

A pseudocode for MLS algorithm

## Other Algorithms

Several other algorithms are available for solving the isotonic regression problem as well as its various special cases. Their description are provided in [2,3,6,7,8,10,11,12,13,15], among others.

Best and Chakravarti, in their paper [3], have pointed out that several of the proposed algorithms are *active set quadratic programming methods* and that this methodology provides a unifying framework for studying algorithms for isotonic regression.

Entropy; Uncertainty; Optimization; Jaynes; Shannon

C.E. Shannon's seminal discovery [7] (1948) of his entropy measure in connection with communication theory has found useful applications in several other probabilistic systems. E.T. Jaynes has further extended its scope by discovering the *maximum entropy principle* (MaxEnt) [1] (1957) which is inherent in the process of optimization of the entropy measure when some incomplete information is given about a system in the form of moment constraints. MaxEnt has, over the past four decades, given rise to an interdisciplinary methodology for the formulation and solution of a large class of probabilistic systems. Furthermore, MaxEnt's natural kinship with the Bayesian methods of analyses has

further bolstered its importance as a viable tool for statistical inference.

#### Entropy and Uncertainty

The word *entropy* first originated in the discipline of thermodynamics, but Shannon entropy has a much broader meaning since it deals with the more pervasive concept of *information*. The word entropy itself has now crept into common usage to mean transformation of a quantity, or phenomenon, from order to disorder. This implies an irreversible rise in *uncertainty*. In fact, the word uncertainty would have been more unambiguous as to its intended meaning in the context of information theory, but for historic reasons, the usage of the word entropy has come to stay in the literature.

Uncertainty arises both in probabilistic phenomena such as in the tossing of a coin and, equally well, in deterministic phenomena where we know that the outcome is not a chance event, but we are merely *fuzzy* about the possibility of the specific outcome. What is germane to our study of MaxEnt is only *probabilistic uncertainty*. The concept of probability that is used in this context is what is generally known as the *subjective interpretation* as distinct from the *objective interpretation* based on frequency of outcome of an event. The subjective notion of probability considers a probability distribution as representing a *state of knowledge* and hence it is observer dependant.

The underlying basis for an initial probability assignment is given by the *Laplace's principle of insufficient reason*. According to this, if in an experiment with  $n$  possible outcomes, we have no information except that each probability  $p_i \geq 0$  and  $\sum_{i=1}^n p_i = 1$ , then the most unbiased choice is the uniform distribution:  $(1/n, \dots, 1/n)$ . Laplace's principle underscores the

choice of maximum uncertainty based on logical reasoning only.

### Why Choose Maximum Uncertainty?

We shall now consider the example of a die in order to highlight the importance of maximum uncertainty as a preamble to our later discussion of MaxEnt. When the only information available is that the die has six faces, the uniform probability distribution  $(1/6, \dots, 1/6)$ , satisfying the natural constraint

$$\sum_{i=1}^n p_i = 1, \quad p_1 \geq 0, \dots, p_6 \geq 0, \quad (1)$$

represents the maximum uncertainty. If, in addition, we are also given the mean number of points on the die, that is, if we are given that

$$p_1 + 2p_2 + 3p_3 + 4p_4 + 5p_5 + 6p_6 = 4.5, \quad (2)$$

the choice of distributions is restricted to the incomplete information given by both (1) and (2), and, consequently, the maximum uncertainty encountered at the first stage is reduced. Since there are only two independent equations in six variables, there is an infinity of probability distributions satisfying the constraints. Out of all such distributions, one can anticipate the existence of a distribution giving rise to the maximum uncertainty  $S_{\max}$ . The importance of  $S_{\max}$  can be deduced from a careful consideration of the process by which uncertainty is reduced (or never increased) by providing more and more information in terms of moment constraints. If we use any distribution from amongst the infinity of distributions satisfying the constraints that is different from the one corresponding to  $S_{\max}$ , it would imply that we would be using some information in addition to those given by (1) and (2). But scientific objectivity would behoove that we should use only the information that is given to us, and scrupulously avoid using any extraneous information. The principle of maximum uncertainty can, accordingly, be stated as:

Out of all probability distributions consistent with a given set of constraints, the distribution with maximum uncertainty should be chosen.

At first glance, it may seem paradoxical that while the goal is reduction of uncertainty, we are actually trying

to maximize it. However, what we are ensuring by the principle of maximum uncertainty is that we are *maximally uncertain about what we do not know*.

### Shannon Entropy

The conclusion from the example of the die is that in making inferences based on incomplete information, the probability distribution that has the maximum uncertainty permitted by the available information should be used. It is therefore necessary to have a quantitative measure of uncertainty in a probability distribution. A unique function was defined by Shannon [7] to measure uncertainty. Let  $\mathbf{p} = (p_1, \dots, p_n)$  be a probability distribution satisfying the natural constraint

$$\sum_{i=1}^n p_i = 1. \quad (3)$$

Shannon's measure of entropy (uncertainty) for this distribution is given by

$$S = - \sum_{i=1}^n p_i \ln p_i \quad (4)$$

Shannon arrived at this unique measure by first stating the desirable properties that such a measure should have. Since not all this long list of properties are independent, he considered a smaller independent set of properties and deduced the uniqueness of (4). Similarly, A.I. Kinchin [5] assumed a different independent set and arrived at the same measure.

The Shannon entropy measure is the basis for Jaynes' maximum entropy principle. Of particular importance is the *property of concavity* of the measure which guarantees the existence of a maximum entropy distribution with all  $p_i \geq 0$ . Shannon's work in information theory did not involve optimization and as such he did not make use of the concavity property whereas here, it is central to the development.

### Jaynes' Maximum Entropy Formalism

We will now present Jaynes' maximum entropy formalism based on discrete multivariate distributions of the random variable  $X$  and state some important results arising from it.

The ensemble,

$$(X, \mathbf{p}) = ((x_1, p_1), \dots, (x_n, p_n)),$$

where  $n$  is finite, represents all the possible realizations of  $X$  and their probabilities of occurrence.  $\mathbf{p}$  is estimated by maximizing the Shannon measure (4) subject to the natural constraint (3) and the moment constraints

$$\sum_{i=1}^n p_i g_{ri} = a_r, \quad r = 1, \dots, m; \quad p_i \geq 0. \quad (5)$$

The Lagrangian is given by

$$L = - \sum_{i=1}^n p_i \ln p_i - (\lambda_0 - 1) \left( \sum_{i=1}^n p_i - 1 \right) - \sum_{r=1}^m \lambda_r \left( \sum_{i=1}^n p_i g_{ri} - a_r \right) \quad (6)$$

where  $\lambda_0, \dots, \lambda_m$  are the  $(m + 1)$  Lagrange multipliers corresponding to the  $(m + 1)$  constraints of (3) and (5).

$$\frac{\partial L}{\partial p_i} = 0 \Rightarrow -\ln p_i - \lambda_0 - \sum_{r=1}^m \lambda_r g_{ri} = 0 \quad (7)$$

or,

$$p_i = \exp(-\lambda_0 - \lambda_1 g_{1i} - \dots - \lambda_m g_{mi}), \quad (8)$$

for  $i = 1, \dots, n$ . The  $m$  multipliers are determined by substituting for  $p_i$  from (8), in (3) and (5) so that

$$\sum_{i=1}^n \exp \left( -\lambda_0 - \sum_{j=1}^m \lambda_j g_{ji} \right) = 1 \quad (9)$$

and

$$\sum_{i=1}^n g_{ri} \exp \left( -\lambda_0 - \sum_{j=1}^m \lambda_j g_{ji} \right) = a_r, \quad (10)$$

for  $r = 1, \dots, m$ , or

$$\exp(\lambda_0) = \sum_{i=1}^n \exp \left( - \sum_{j=1}^m \lambda_j g_{ji} \right) \quad (11)$$

and

$$a_r \exp(\lambda_0) = \sum_{i=1}^n g_{ri} \exp \left( - \sum_{j=1}^m \lambda_j g_{ji} \right), \quad (12)$$

for  $r = 1, \dots, m$  so that

$$a_r = \frac{\sum_{i=1}^n g_{ri} \exp \left( - \sum_{j=1}^m \lambda_j g_{ji} \right)}{\sum_{i=1}^n \exp \left( - \sum_{j=1}^m \lambda_j g_{ji} \right)}, \quad (13)$$

$r = 1, \dots, m$ . Equation (11) gives  $\lambda_0$  as a function of  $\lambda_1, \dots, \lambda_m$ . Equations (13) give  $a_1, \dots, a_m$  as functions of  $\lambda_1, \dots, \lambda_m$ .

Based on the above formalism, we can derive the following results which are useful in applications.

- The Lagrange multiplier  $\lambda_0$  is a convex function of  $\lambda_1, \dots, \lambda_m$ .
- The value of the maximum entropy  $S_{\max} = \lambda_0 + \lambda_1 a_1 + \dots + \lambda_m a_m$ .
- $S_{\max}$  is a concave function of  $a_1, \dots, a_m$ .
- The Lagrange multipliers  $\lambda_1, \dots, \lambda_m$  are the partial derivatives of  $S_{\max}$  with respect to  $a_1, \dots, a_m$ , respectively.
- An alternative proof that MaxEnt gives globally maximum values of entropy, that is,  $S_{\max} - S \geq 0$ , can be given on the basis of Shannon's inequality

$$\sum_{i=1}^n q_i \ln \frac{q_i}{p_i} \geq 0 \quad (14)$$

where  $\mathbf{q}$  is the probability distribution with entropy  $S$ .

- Jaynes' formalism also leads to *Jaynes' entropy concentration theorem* that asserts that the constrained maximum probability distribution is the one that best represents our state of knowledge about the behavior of the system and that MaxEnt is the preferred method of inferring that distribution. The conclusion is based on (14) and the chi-square test.
- Jaynes' formalism is applicable to continuous-variate probability distributions also.
- In our earlier discussion, we had stated that the statement of the *Laplace's principle of insufficient reason* was based purely on logic. We can now show that uniform distribution results from MaxEnt when only the natural constraint (3) is specified.

### Applications of MaxEnt and Conclusions

As the very first application, Jaynes demonstrated the power of MaxEnt by deriving all the principal distributions of statistical mechanics without reference to the classical methods of derivation [1]. An important application that closely followed the application of MaxEnt to statistical mechanics, was the correspondence that M. Tribus [9,10] established with the laws of thermodynamics. This application, incidentally, clarified the connection between the Shannon entropy and ther-

modynamic entropy. He also demonstrated that most of the statistical distributions that are commonly encountered can be derived from MaxEnt by making use of appropriate moment constraints, which, later, came to be known as *characterizing moments*. Thus, he established the integral link between information theory and statistics. For example, the normal distribution is a maximum-entropy distribution resulting from maximizing the Shannon entropy with respect to the characterizing moments of mean and variance.

These remarkable successes set in motion the applications of MaxEnt in several other disciplines. To name only a few, MaxEnt has been applied to problems in urban and regional planning, transportation, business, economics, finance, statistical inference, operations research, queueing theory, nonlinear spectral analysis, pattern recognition and image processing, computerized tomography, risk analysis, population growth models, chemical reactions and many other areas. These are all problems that are inherently probabilistic in nature or, alternatively, where the MaxEnt model is made to fit by artificially interpreting probabilities as proportions. References to these problems can be found in [2,3,4].

For the past ten years, the direction of research into MaxEnt has gone in the direction of using the principle in conjunction with Bayes theorem. There has been a series of workshops conducted under this heading which appears in the series [6].

Also of great interest is the concept of minimum entropy which is found useful in recognizing patterns contained in an information structure. However, research in this direction has been hampered by the computational complexity in determining the quantity because it results from the global minimization of a concave function which is a *NP*-hard problem.

Closely associated with MaxEnt are the methods of optimization based on Kullback–Leibler measure [8] to measure distance between two probability distributions. However, the school dedicated to the use of MaxEnt steers clear of this approach since it does not involve the concept of entropy.

## Keywords

Job-shop; Scheduling; Complexity; Heuristics

The *job-shop problem* may be formulated as follows. Given are  $n$  jobs  $j = 1, \dots, n$  and  $m$  machines  $M_1, \dots, M_m$ . Job  $j$  consists of a sequence

$$O_{1j}, \dots, O_{n_j, j}$$

of  $n_j$  operations which must be processed in the given order, i. e.  $O_{i+1, j}$  cannot start before  $O_{ij}$  is completed for  $i = 1, \dots, n_j - 1$ . Associated with each operation  $O_{ij}$  there is a processing time  $p_{ij}$  and a machine  $\mu_{ij} \in \{M_1, \dots, M_m\}$ .  $O_{ij}$  must be processed for  $p_{ij}$  time units on machine  $\mu_{ij}$ . Each job can be processed by at most one machine at a time and each machine can process only one operation at a time. If not stated differently preemptions of operations are not allowed. One has to find a feasible schedule which minimizes the makespan.

It is assumed that all processing times are nonnegative integers and that all jobs and machines are available at starting time zero. Furthermore, if not stated differently, *machine repetition* is allowed, i. e.  $\mu_{i+1, j} = \mu_{ij}$  is possible.

For a precise formulation of the job-shop problem, let  $\mathcal{O}$  be the set of all operations, let  $p(k)$  be the processing time of operation  $k \in \mathcal{O}$ , and define  $(k, l) \in C$  if and only if  $k = O_{ij}$  and  $l = O_{i+1, j}$  for some job  $j$  and some  $i = 1, \dots, n_j - 1$ . Finally, let  $M(k)$  be the machine on which operation  $k$  must be processed.

Then the job-shop problem may be formulated as disjunctive linear program (cf. ► **Linear programming**):

$$\min \max_{k \in \mathcal{O}} \{s(k) + p(k)\} \quad (1)$$

such that

$$\begin{aligned} s(k) + p(k) &\leq s(l) \\ \text{for all } k, l \in \mathcal{O}; (k, l) \in C, \end{aligned} \quad (2)$$

$$\begin{aligned} s(k) + p(k) &\leq s(l) \quad \text{or} \quad s(l) + p(l) \leq s(k) \\ \text{for all } k, l \in \mathcal{O}; k \neq l; M(k) = M(l), \end{aligned} \quad (3)$$

$$s(k) \geq 0 \quad \text{for all } k \in \mathcal{O}. \quad (4)$$

$s(k)$  represents the starting time of operation  $k$ . Due to (2) all operations of the same job are processed in the

right order. The constraints (3) make sure that a machine cannot process two operations at the same time.

The job-shop problem may be represented by a *mixed graph*  $G = (\mathcal{O}, C, D)$  with vertex set  $\mathcal{O}$ , the set  $C$  of (directed) arcs, and a set  $D = \{\{k, l\}: k, l \in \mathcal{O}; k \neq l; M(k) = M(l)\}$  of (undirected) edges. Furthermore, the processing time  $p(k)$  is associated with each vertex  $k \in \mathcal{O}$ . The arcs are called *conjunctions* and the edges are called *disjunctions*.

The basic scheduling decision is to define a processing order of the operations on each machine, i. e. to fix precedence relations between these operations.

In the mixed graph model this is done by orienting edges, i. e. by turning disjunctions into conjunctions. A set  $S$  of these oriented edges is called an *orientation*. An orientation  $S$  is called a *complete orientation* if

- every edge becomes oriented; and
- the resulting directed graph  $G(S) = (\mathcal{O}, C \cup S)$  has no cycles.

A complete orientation  $S$  defines a feasible schedule which is calculated in the following way. For each operation  $k$  let  $l(k)$  be the length of a longest path to vertex  $k$  in  $G(S)$ . A path to  $k$  is a sequence of vertices  $v_1, \dots, v_r = k$  with  $(v_i, v_{i+1})$  is an arc for  $i = 1, \dots, r - 1$ . The length of a path  $P$  to  $k$  is the sum of all processing times of operations in  $P$  excluding operation  $k$ . Choose  $l(k)$  as the starting time of operation  $k$ . It is not difficult to see that this schedule is feasible. Furthermore, the length of the longest path in  $G(S)$  defines the makespan of this schedule. A corresponding path is called *critical path*.

On the other hand a feasible schedule  $s = (s(k))_{k \in \mathcal{O}}$  defines a complete orientation  $S$  and the critical path length in  $G(S)$  is not greater than the makespan of the schedule  $s$ . Thus, one may restrict attention to schedules defined by complete orientations.

There are only a few special cases of the job-shop problem which are polynomially solvable (cf. ► **Complexity classes in optimization**). They will be discussed next.

## Complexity Results

The two-machine job-shop problem in which each job has at most two operations can be solved by a simple extension of Johnson's algorithm for the two machine flow-shop problem [16]. Let  $I_i$  be the set of jobs with operations on  $M_i$  only ( $i = 1, 2$ ), and let  $I_{1,2}$  ( $I_{2,1}$ ) be the

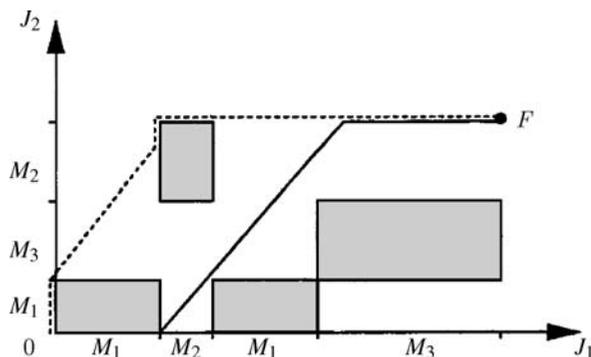

set of jobs which are processed first on  $M_1$  ( $M_2$ ) and then on  $M_2$  ( $M_1$ ). Order the latter two sets by means of Johnson's algorithm and the former two sets arbitrarily. Then one obtains an optimal schedule by executing the jobs on  $M_1$  in order  $(I_{12}, I_1, I_{21})$  and on  $M_2$  in order  $(I_{21}, I_2, I_{12})$ .

In [15] the two-machine job-shop problem with unit-time operations ( $p_{ij} = 1$ ) and no machine repetition is solved in time linear in the total number of operations, through a rule that gives priority to the longest remaining job. Despite the fact that this algorithm is fast it is not polynomial if we represent each job  $j$  by the machine which processes the first operation  $O_{1j}$  and the number  $n_j$  of operation of  $j$ . However, there exists a clever implementation of this algorithm which is polynomial ([17,26]). Surprisingly, the problem is *NP*-hard if we allow repetition of machines [12].

This, however, is probably as far as one can get if the number of jobs is not fixed but part of the input. Two-machine job-shop problems with  $n_j \leq 3$  or  $p_{ij} \in \{1, 2\}$  are *NP*-hard as well as three machine problems with  $n_j \leq 2$  or  $p_{ij} = 1$  ([18,19]).

The job-shop problem with two jobs may be formulated as a shortest path problem in the plane with regular objects as obstacles [2]. Figure 1 shows a shortest path problem with obstacles which corresponds to a job-shop problem with two jobs with  $n_1 = 4$  and  $n_2 = 3$ . The processing times of the operations of job 1 (job 2) are represented by intervals on the  $x$ -axis ( $y$ -axis) which are arranged in the order in which the corresponding operations are to be processed. Furthermore, the intervals are labeled by the machines on which the corresponding operations must be processed.

A feasible schedule corresponds to a path from 0 to  $F$  consisting of segments which are either parallel to one of the axes or diagonal, and avoids the interior of any rectangular obstacle. If one defines the length of the diagonal parts of the path to be equal to the projections of these parts on one of the axes then the length of the path corresponds to the length of the schedule. It can be shown that this geometric problem can be formulated as a shortest path problem in an acyclic network with  $O(r^2)$  arcs where  $r = \max\{n_1, n_2\}$  and that this network can be calculated in time  $O(r^2 \log r)$  which is also the complexity for solving the problem [7]. The corresponding preemptive problem can be solved in  $O(r^3)$  time by allowing

Job-shop Scheduling Problem, Figure 1  
Path problem with obstacles

the paths to go horizontally or vertically through the obstacles [24].

The two-machine job-shop problem with a fixed number  $k$  of jobs has been solved with time complexity  $O(n^{2k})$  [9]. However, the three machine job-shop problem with  $k = 3$  is *NP*-hard [25] (cf. also ► **Complexity theory**). If one allows preemption even the two-machine problem with  $k = 3$  is *NP*-hard [12]. This is very surprising because the corresponding problem without preemption is polynomially solvable.

### Branch and Bound Algorithms

Effective branch and bound algorithms (cf. ► **Integer programming: Branch and bound methods**) have been developed for the job-shop scheduling problem from the 1990s onwards ([3,11,13,20]). Rather than a description of each of these algorithms in detail some of the main concepts, like lower and upper bounds, branching rules, and immediate selection are presented.

Most of the branch and bound algorithms use the mixed graph model. The nodes of the enumeration tree correspond to orientations of edges representing sets of feasible schedules. Branching is done by adding further orientations in different ways. The leaves of the enumeration tree correspond to complete orientations while the root is defined by the empty orientation. Given an orientation  $S$  one may define heads and tails. A *head*  $r(k)$  of operation  $k$  is a lower bound for an earliest possible starting time of  $k$ . A *tail*  $q(k)$  of operation  $k$  is a lower bound for the time period between the finishing time of operation  $k$  and the optimal makespan. A simple way to derive a head  $r(k)$  would be to calcu-

late the length of a longest path to  $k$  in  $G(S)$ . Similarly, a tail  $q(k)$  could be calculated as the length of a longest path starting in  $k$  excluding  $p(k)$ .

Let  $P$  be a critical path in  $G(S)$  and  $L(S)$  be the length of  $P$ . A maximal sequence  $u_1, \dots, u_l$  of successive operations in  $P$  to be processed on the same machine is called a *block* if it contains at least two operations.

The following block theorem is used in connection with branch and bound algorithms. It also plays an important role when defining neighborhoods for local search methods.

**Theorem 1 (block theorem)** *Let  $S$  be a complete orientation. If there exists another complete orientation  $S'$  such that  $L(S') < L(S)$ , then in  $S'$  at least one operation of some block  $B$  of  $G(S)$  has to be processed before the first or after the last operation of  $B$ .*

## Upper Bounds

Each feasible solution provides an *upper bound*. At the root of the enumeration tree some time is invested for calculating a good upper bound to start with. This is accomplished by applying tabu search using an appropriate neighborhood. Some branch and bound algorithms also calculate heuristically a feasible solution satisfying the given orientation in each vertex of the enumeration tree. If this solution provides a better upper bound than the current one then the current bound is updated. Furthermore, informations provided by the heuristic solution are used for the branching process.

## Lower Bounds

*Lower bounds* are calculated for each node of the enumeration tree, i. e. for the set of solutions feasible with respect to the current orientation  $S$ . Lower bounds may be calculated constructively or destructively. *Constructive lower bounds* are calculated by solving relaxations of the problem. The *destructive methods* work as follows. For a given integer  $U$  one tries to prove that there exists no feasible solution with value  $C_{\max} \leq U$ . In this case  $U + 1$  is a valid lower bound. In case of a failure one repeats the test for a smaller  $U$ -value. Binary search can be applied to find a large lower bound.

The length of a critical path in  $G(S)$  provides a constructive lower bound which can be calculated fast. Good bounds are provided by certain one-machine relaxations denoted as *head-body-tail problem*: Given

a set of jobs  $j = 1, \dots, n$  with release times (heads)  $r(j)$ , processing times  $p(j)$ , and tails  $q(j)$  to be processed on a single machine. Find a schedule with starting times  $s(j)$  satisfying the release times such that  $\max_{j=1}^n \{s(j) + p(j) + q(j)\}$  is minimized.

Unfortunately the one-machine head-body-tail problem is *NP-hard*. However, the preemptive version of this problem can be solved in time  $O(n \log n)$  by applying the following scheduling rules:

- Take the release times and completion times as decision points.
- Schedule jobs in increasing order of decision points preferring an available job with longest tail.

By applying this algorithm to all operations to be processed on  $M_k$  one gets a lower bound  $L_k$  ( $k = 1, \dots, m$ ). The best of all these  $L_k$ -values is chosen.

Other constructive lower bounds are based on two job relaxations [10] and cutting plane approaches (cf. also ► [Integer programming: Cutting plane algorithms](#)) [3].

For destructive methods one assumes that  $U$  is a fictive upper bound and wants to prove that no feasible schedule satisfying  $C_{\max} \leq U$  exists. From  $U$  one derives the time window  $[r(k), d(k)]$  with  $d(k) = U - q(k)$  in which each operation  $k$  must be processed if  $U$  is valid. For each job  $j = 1, \dots, n$  let  $\mathcal{S}_j$  the set of schedules for  $j$  which are feasible with respect to its time window. The feasibility problem can be reduced to a zero-one linear program as follows. For each schedule  $\sigma \in \mathcal{S}_j$  ( $j = 1, \dots, n$ ) one defines  $a(\sigma, i, t) = 1$  if  $\sigma$  requires machine  $M_i$  in time-period  $[t-1, t]$  and  $a(\sigma, i, t) = 0$  otherwise. Let  $x_{j\sigma}$  a 0-1 decision variable that indicates whether job  $j$  is scheduled according to schedule  $\sigma$ . Then there exists no feasible schedule if and only if the following linear program has an optimal solution value  $\lambda^* > 1$  (see [20]).

$$\min \lambda \quad (5)$$

such that

$$\sum_{\sigma \in \mathcal{S}_j} x_{j\sigma} = 1, \quad j = 1, \dots, n, \quad (6)$$

$$\sum_{j=1}^n \sum_{\sigma \in \mathcal{S}_j} a(\sigma, i, t) x_{j\sigma} \leq \lambda, \quad i = 1, \dots, m; \quad t = 1, \dots, U, \quad (7)$$

$$x_{j\sigma} \in \{0, 1\}, \quad j = 1, \dots, n; \quad \sigma \in \mathcal{S}_j. \quad (8)$$

Due to (6) exactly one schedule is chosen from each set  $S_j$ . The left-hand side of (7) counts the number of jobs to be processed on machine  $M_i$  in time-period  $[t-1, t]$ . Thus, one has a feasible schedule if and only if  $\lambda^* = 1$ . To check infeasibility one uses the continuous version of (5) to (8) where (8) is replaced by

$$x_{j\sigma} \geq 0, \quad j = 1, \dots, n; \quad \sigma \in S_j.$$

A second destructive lower bound based on immediate selection will be discussed later.

### Branching

The simplest branching scheme is to choose a not yet oriented edge and orient it in the two possible ways. Another more sophisticated branching scheme is based on the block theorem. There is a branch to several children of the same father node in the enumeration tree. The idea behind such a branching is to orient many edges when branching (see [11]). In [20] a time oriented branching schemes has been used.

### Immediate Selection

By branching disjunctions are oriented. There is another method to orient disjunctions which is due to [13]. This method is called *immediate selection*. It uses an upper bound  $UB$  for the optimal makespan and simple lower bounds based on heads  $r(k)$  and tails  $q(k)$  of operations  $k$ .

Let  $I$  be a set of  $n$  operations to be processed on the same machine and consider a strict subset  $J \subset I$  and an operation  $c \in I \setminus J$ . If condition

$$\min_{j \in J \cup \{c\}} r(j) + \sum_{j \in J \cup \{c\}} p(j) + \min_{j \in J} q(j) \geq UB \quad (9)$$

holds, then all operations  $j \in J$  must be processed before operation  $c$  if we want to improve the current upper bound  $UB$ . This follows from the fact that the left-hand side of (9) is a lower bound for all schedules in which  $c$  does not succeed all jobs in  $J$ . Due to integrality, (9) is equivalent to

$$\min_{j \in J \cup \{c\}} r(j) + \sum_{j \in J \cup \{c\}} p(j) + \min_{j \in J} q(j) > UB - 1$$

or

$$\min_{j \in J \cup \{c\}} r(j) + \sum_{j \in J \cup \{c\}} p(j) > \max_{j \in J} d(j), \quad (10)$$

where  $d(j) := UB - q(j) - 1$ .

$(J, c)$  is called a *primal pair* if (9) or, equivalently, (10) holds. The corresponding arcs  $j \rightarrow c$  with  $j \in J$  are called *primal arcs*. Similarly,  $(c, J)$  is called a *dual pair* and arcs  $c \rightarrow j$  are called *dual arcs* if

$$\min_{j \in J} r(j) + \sum_{j \in J \cup \{c\}} p(j) > \max_{j \in J \cup \{c\}} d(j) \quad (11)$$

holds. In this case all operations  $j \in J$  must be processed after operation  $c$  if we want to improve the current solution value  $UB$ .

It can be shown [9] that all primal and dual arcs for the set  $I$  can be calculated in  $O(n^2)$  time.

Immediate selection is applied to speed up a branch and bound algorithm. For each machine the set  $I$  of all operations to be processed on this machine is considered and all corresponding primal and dual arcs are calculated. Then heads and tails are recalculated and the whole process is repeated until there are no new primal or dual arcs to be added.

By this method the orientation  $S$  is increased step by step. A possible outcome of this process is that one deduces a graph  $G(S)$  which contains cycles. This implies that there exists no feasible solution with makespan  $\leq UB$ .

Immediate selection and a corresponding cycle check is applied to each node of the enumeration tree. If the cycle check is positive, one can backtrack.

Immediate selection is also used to calculate a lower bound by the destructive method.

### Heuristic Procedures

Using a branch and bound algorithm and immediate selection J. Carlier and E. Pinson [13] were able to solve the notorious  $10 \times 10$  benchmark problem in [21] for the first time. Recently (2000),  $15 \times 15$  benchmark problems have been solved [6]. Problems of dimension  $n \times n$  for  $n > 15$  are still out of the reach if one is interested in optimal solutions. Thus, the only way to find solutions for larger job-shop problems is to apply heuristics, which provide solutions which are not too far away from the optimum. Some of these heuristics will be discussed next.

### Priority Rule Based Heuristics

These are probably most frequently applied due to their ease of implementation and low computation times.

The idea of a priority heuristic is to schedule operations step by step each as early as possible. In each step among all unscheduled operations with the property that their conjunctive predecessors are scheduled a candidate with the highest priority is chosen to be scheduled next. For extended summaries and discussions of priority rules see [5,14,23].

### Shifting Bottleneck Heuristic

(See [1,4].) This is one of the most powerful heuristics for the job-shop scheduling problem. In each iteration a machine  $M_i$  is chosen and all disjunctions between operations to be processed on  $M_i$  are oriented. This is done according to the exact solution of the head-body-tail problem for  $M_i$ . Thus, after  $k$  steps the disjunctions for  $k$  machines are oriented. Let  $\mathcal{M}_k$  the set of these  $k$  machines. Before choosing a new machine  $M_i \notin \mathcal{M}_k$  in the next step the orientations for the machines in  $\mathcal{M}_k$  are updated by applying the head-body-tail algorithm to each of the machines in  $\mathcal{M}_k$  in a given machine order. As a machine  $M_i \notin \mathcal{M}_k$  added to  $\mathcal{M}_k$  in the next step a *bottleneck machine* is chosen. A bottleneck machine is a machine  $M_i \notin \mathcal{M}_k$  with a largest head-body-tail problem solution value. It is important to note that before each application of the solution procedure for a head-body-tail problem heads and tails are updated according to the current orientation.

### Local Search

An important class of heuristics are *local search* methods like iterative improvement, simulated annealing (cf. ► [Simulated annealing](#)), tabu search and genetic algorithms (cf. ► [Genetic algorithms](#)). All these methods have been applied to the job-shop problem (see [27] for an excellent survey).

The local search techniques are based on the concept of local improvement. Given an existing solution or representation of such a solution, a modification is made in order to obtain a different (usually better) solution.

For the job-shop problem solutions are represented by complete orientations. To modify a solution one usually restricts to critical paths (which must be destroyed for improving the current makespan). One possibility for modifications is to choose an arc  $(v, w)$  on

a critical path such that  $v$  and  $w$  are processed on the same machine and replace  $(v, w)$  by the reverse arc  $(w, v)$ . It can be shown that the corresponding new orientation is complete again, i. e. no cycles are created by such a reversal. Other modifications are based on the block theorem. One modifies an orientation by shifting an operation of some block at the beginning or the end of the block. Such modifications are not defined if the resulting selections are not complete, i. e. contain cycles.

One of the best local search methods in terms of solution quality and computation time is a tabu search procedure described in [22].

Kantorovich; Linear programming; Economics; Functional analysis

L.V. Kantorovich was born in St. Petersburg, Russia, on January 6, 1912 and died on April 7, 1986. Kantorovich shared the 1975 *Nobel Prize* for Economics with T. Koopmans for their work on the optimal allocation of scarce resources [4,5].

Kantorovich was educated at Leningrad State Univ., receiving his doctorate in mathematics (1930) there at the age of 18. He became a professor at Leningrad in 1934, a position he held until 1960. He headed the department of mathematics and economics in the Siberian branch of the U.S.S.R. Academy of Sciences from 1961 to 1971 and then served as head of the research laboratory at Moscow's Institute of National Economic Planning (1971–1976). Kantorovich was elected to the prestigious Academy of Sciences of the Soviet Union (1964) and was awarded the Lenin

Prize in 1965. For detailed interesting information on the life and scientific views of Kantorovich, see his paper [2]

Kantorovich was one of the first to use *linear programming* as a tool in economics. His most famous work is [1]. The characteristic of Kantorovich's work is a combination of theoretical and applied research. His first works concerned delicate problems of set theory. Later he became one of the first Soviet specialists on *functional analysis*. In the 1930s he laid down the foundations of the theory of *semi-ordered spaces* which constitutes now a vast chapter of functional analysis bordering algebra and measure theory. At the same time he anticipated the ideas of the future *theory of generalized functions* which became current only in the 1950s. Kantorovich obtained beautiful results on approximation theory. The approach to Sobolev's embedding theorem suggested by Kantorovich (based on his estimations of integral operators) is well known.

Complexity; Computation; Information; Randomness; Algorithmic complexity; Algorithmic information; Algorithmic entropy; Solomonoff–Kolmogorov–Chaitin complexity; Descriptive complexity; Shortest program length; Algorithmic randomness

In the mid 1960s R. Solomonoff [16], A.N. Kolmogorov [11] and G. Chaitin [4] independently invented the field now generally known as Kolmogorov complexity. It is also known variously as *algorithmic complexity*, *algorithmic information*, *algorithmic entropy*, *Solomonoff–Kolmogorov–Chaitin complexity*, *descriptive complexity*, *shortest program length*, *algorithmic randomness* and others. An extensive history of the field can be found in [14].

The Kolmogorov complexity formalizes the notion of amount of information necessary to uniquely describe a digital object. A digital object means one that can be represented as a finite binary string, for example, a genome, an Ising microstate, or an appropriately coarse-grained representation of a point in some continuum state space. In particular, the Kolmogorov complexity of a string of bits is the length of the shortest computer program that prints that string and stops running. The Kolmogorov complexity of an object is a form of absolute information of the individual object. This is not possible to do by Shannon's information theory. Unlike Kolmogorov complexity, information theory is only concerned with the average information of a random source [14].

Solomonoff was addressing the problem: How do we assign a priori probabilities to hypotheses when we

begin an experiment? He represented a scientist's observations as a series of binary digits and weighted together all the programs for a given result into a probability measure. The scientist seeks to explain these observations through a theory, which can be regarded as an algorithm capable of generating the series and extending it, that is, predicting future observations. For any given series of observations there are always several competing theories and the scientist must choose among them. The model demands that the smallest algorithm, the one consisting of the fewest bits, be selected. Stated another way, this rule is the familiar formulation of *Occam's razor*: Given differing theories of apparently equal merit, the simplest is to be preferred [6].

Thus in the Solomonoff model a theory that enables one to understand a series of observations is seen as a small computer program that reproduces the observations and makes predictions about possible future observations. The smaller the program, the more comprehensive the theory and the greater the degree of understanding. Observations that are random cannot be reproduced by a small program and therefore cannot be explained by a theory. In addition the future behavior of a random system cannot be predicted. For random data the most compact way for the scientist to communicate his or her observations is to publish them in their entirety [6].

Kolmogorov and Chaitin independently suggested that computers be applied to the problem of defining what is meant by a random finite binary string of 0s and 1s [5]. In the traditional foundations of the mathematical theory of probability, as expounded by Kolmogorov in his classic [10], there is no place for the concept of an individual random string of 0s and 1s. Yet it is not altogether meaningless to say that the string

```
001110100001110011010000111110
```

is more random than the string

```
000000000000000000000000000000
```

for we may describe the second string as thirty 0s, but there is no shorter way to specify the first string than by just writing it all out [5].

We believe that the random strings of a given length are those that require the longest programs. Those

strings of length  $n$  that can be obtained by putting into a computer program much shorter than  $n$  are the non-random strings. The more possible it is to compress a binary string into a short program calculation, the less random is the string.

Solomonoff, Kolmogorov and Chaitin saw that the notion of ‘computable’ lay at the heart of their questions. They arrived at equivalent notions, showing that these two questions are fundamentally related.

The Kolmogorov complexity of a string is low if it can easily be obtained by a computation, whereas it will be high if it is difficult to obtain it [1]. The difficulty is measured by the length of the shortest program that computes the string on a universal Turing machine. The use of Turing machines to determine the length of the shortest program that computes a particular bit-string is intuitive: since a universal Turing machine can simulate any other Turing machine, the length of the program computing string  $s$  on Turing machine  $T$ , can only differ from the program computing the same string on Turing machine  $T'$  by a finite length  $l(T, T')$ , the length of the prefix code necessary to simulate  $T$  on  $T'$ . As this difference is constant (for each string  $s$ ), the length of the shortest program to compute string  $s$  on a universal Turing machine is constant in the limit of infinitely long strings  $s$  and the *Kolmogorov complexity* of string  $s$  is defined as

$$K(s) = \min \{|p| : s = A_T(p)\},$$

where  $|p|$  stands for the length of program  $p$  and  $A_T(p)$  represents the result of running program  $p$  on Turing machine  $T$ .

This measure can be illustrated by a few examples. A blank tape (the string with all zeros) is clearly a highly regular string and correspondingly its Kolmogorov complexity will be low. Indeed, the program needed to produce this string can be very short: print zero, advance, repeat. The same is true, of course, for every string with a repetitive pattern.

Another way of viewing algorithmic regularity is by saying that an algorithmically regular string can be compressed to a much smaller size: the size of the smallest program that computes it. More interesting is the regularity of a string that can be obtained by the application of a finite but nontrivial algorithm, such as the calculation of the transcendental number  $\pi$ . The string representing the binary equivalent of  $\pi$  certainly

appears completely random, yet the minimal program necessary to compute it is finite. Thus, such a string is also classified as algorithmically regular (though not quite as regular as the blank tape) [1].

Kolmogorov complexity also provides a means to define randomness in this context. According to the Kolmogorov measure, a string  $r$  is declared random if the size of the smallest program to compute  $r$  is as long as  $r$  itself, i. e.,

$$K(r) \approx |r|.$$

Why should this definition of randomness be preferable to any other we might come up with? The answer to that was provided by P. Martin-Loef, who was a postdoc of Kolmogorov. Roughly, he demonstrated that the definition ‘an  $n$ -bit string  $s$  is random if and only if  $K(s) \geq n$ ’ ensures that every such individual random string possesses with certainty all effectively testable properties of randomness that hold for strings produced by random sources on the average [9].

The algorithmic definition of randomness provides a new foundation for the theory of probability. By no means does it supersede classical probability theory, which is based on an ensemble of possibilities, each of which is assigned a probability. Rather, the algorithmic approach complements the ensemble method by giving precise meaning to concepts that had been intuitively appealing but that could not be formally adopted [6].

The Kolmogorov complexity of a string  $s$  is also defined as the negative base-2 logarithm of the string’s algorithmic probability  $P(s)$  [2,18]. This in turn is defined as the probability that a standard universal computer  $T$ , randomly programmed, would embark on a computation yielding  $s$  as its sole output, afterward halting. The algorithmic probability  $P(s)$  may be thought of a weighted sum of contributions from all programs that produce  $s$ , each weighted according to the negative exponential of its binary length.

Turning to the sum of  $P(s)$  over outputs, the sum  $\sum_s P(s)$  is not equal to unity, because, as is well known, an undecidable subset of all universal computations fail to halt and so produce no output. Therefore  $\sum_s P(s)$  is an uncomputable irrational number less than 1. This number, called *Chaitin’s Omega* [7], has many remarkable properties [8], such as the fact that its uncomputable digit string is a maximally compressed form of the information required to solve the halting problem [2].

Though very differently defined, Kolmogorov complexity is typically very close to ordinary statistical entropy  $-\sum p \log p$  in value. To take a simple example, it is known that almost all  $N$ -bit strings drawn from a uniform distribution (of statistical entropy  $N$  bits) have Kolmogorov complexity nearly  $N$  bits. More generally, in any concisely describable ensemble of digital objects, i. e., a canonical ensemble of Ising microstates at a given temperature, the ensemble average of the objects' Kolmogorov complexity closely approximates the whole ensemble's statistical entropy [2,18]. In the case of continuous ensembles, the relation between Kolmogorov complexity and statistical entropy is less direct because it depends on the choice of coarse-graining. Some of the conceptual issues involved are discussed in [17].

The basic flaw in the Kolmogorov construction (as far as physical complexity is concerned) is the absence of a context [1]. This is easily rectified by providing the Turing machine with a tape  $u$ , which represents the physical 'universe', while the Turing machine with  $u$  as input computes various strings from  $u$ .

The *conditional Kolmogorov complexity* of a string  $s$  is defined as the length of the shortest program that computes  $s$  given string  $u$  [12]

$$K(s|u) = \min \{ |p| : s = A_T(p, u) \},$$

where the notation  $A_T(p, u)$  is introduced as the result of the computation running  $p$  on Turing machine  $T$  with  $u$  as input tape. The conditional complexity measures the remaining randomness in string  $s$ , i. e., it counts those bits that are not correlated with bits in  $u$ . In other words, the program  $p$  is the maximally compressed string containing those bits that cannot be computed from  $u$ , as well as the instructions necessary to compute those bits of  $s$  that can be obtained from  $u$ .

The latter part of the program is of vanishing length in the limit of infinitely long strings, which implies that the program  $p$  mainly contains the remaining randomness of  $s$ . The mutual complexity is defined by

$$K(s : u) = K(s) - K(s|u),$$

which clearly just measures the number of bits that mean something in the universe  $u$ .

Let us consider  $K(s : u)$  in more detail. Its meaning becomes clearer if instead of considering a string  $s$  obtained by Turing machine  $T$  with universe  $u$ , the ensemble of strings  $S$  that can be obtained from a universe

$u$  with  $T$  is considered. This ensemble can be thought of as a probabilistic mixture subject to random bit-flips.

In other words, the output tapes to be connected to a heat bath can be imagined. In that case, an entropy  $H(S)$  can be associated with the ensemble of strings  $S$ . Consider a Turing machine operating on  $u$ , a specific universe. Obtaining  $s$  from  $u$  then constitutes a measurement on the universe  $U$  and consequently not only reduces the conditional entropy of  $S$  given  $u$ , but also the conditional entropy of  $U$  given  $s$ .

Note that the universe is assumed here to be fully known, i. e., there is only one tape  $u$  in the ensemble  $U$ . While this must not strictly be so, sometimes it is convenient to assume that there is no randomness in the universe. Also, the length of the smallest program that computes  $s$  from  $u$ , averaged over the possible realizations of  $s$ , then just equals the conditional entropy of  $S$  given  $u$  [1].

It is known that the average Kolmogorov complexity over an ensemble of strings just equals the entropy of the ensemble. Then

$$H(S|u) = \langle K(s|u) \rangle_S = - \sum_s p(s|u) \log p(s|u) \quad (1)$$

and

$$\langle K(s) - K(s|u) \rangle_S = H(S) - H(S|u).$$

Note that (1) is not strictly a conditional entropy, as no average over different realizations of the universe takes place. Indeed, it looks just like a conventional Shannon entropy only with all probabilities being probabilities conditional on  $u$ .

Determining the Kolmogorov complexity of a string is a difficult problem. For this reason, Kolmogorov complexity remained more of a curiosity than a practical mathematical tool. In the last few years, mainly due to P. Vitanyi and M. Li, a significant progress in using Kolmogorov complexity has been made [14].

In particular, several successful applications of Kolmogorov complexity in the theory of computation are made and the general pattern of the incompressibility method emerged [14]. The incompressibility method and Kolmogorov complexity is truly a versatile mathematical tool. The incompressibility method is a basic general technique such as the 'pigeon hole argument', the 'counting method' or the 'probabilistic method'. It is

a sharper relative of classical information theory (absolute information of individual object rather than average information over a random ensemble) and yet satisfies many of the laws of classical information theory, although with a slight error term. Applications of Kolmogorov complexity have been given in a number of areas, including [14]:

- randomness of individual finite objects or infinite strings, Martin–Loef tests for randomness, Gödel’s incompleteness result, information theory of individual objects;
- universal probability, general inductive reasoning, inductive inference, prediction, mistake bounds, computational learning theory, inference in statistics;
- the incompressibility method, combinatorics, graph theory, Kolmogorov 0–1 laws, probability theory;
- theory of parallel and distributed computation, time and space complexity of computations, average case analysis of algorithms, language recognition, string matching, routing in computer networks, circuit theory, formal language and automata theory, parallel computation, Turing machine complexity, complexity of tapes, stacks, queues, average complexity, lower bound proof techniques;
- structural complexity theory, oracles;
- logical depth, universal optimal search, physics and computation, dissipationless reversible computing, information distance and picture similarity, thermodynamics of computing, statistical thermodynamics and Boltzmann entropy.

Based on the Turing model of computation, the field of Kolmogorov complexity probably will need to be modified to account for the new quantum modes of computation. From recent studies there appear more facts that this modification is likely to be based on notions that go beyond the framework of space-time (for example [15]) and sought within the world view, which considers natural systems not as separate entities but as integrated parts of a undivided whole [3].

An attempt to contribute to such a modification is made in [13]. The results are based on a mathematical structure, called a web of relations, that is a collection of hierarchical formations of integer relationships. The web of relations allows to introduce a concept of structural complexity to measure the complexity of a binary string in terms of corresponding hierarchical forma-

tions of integer relationships. Importantly, the concept of structural complexity is based on the integers only and does not rely on notions that derive from space-time.

## Krein–Milman Theorem

GABRIELE E. DANNINGER-UCHIDA  
University Vienna, Vienna, Austria

MSC2000: 90C05

### Article Outline

[Keywords](#)

[See also](#)

[References](#)

### Keywords

Convex; Convex hull; Extreme point

A theorem stating that a compact closed set can be represented as the convex hull of its extreme points. First shown by H. Minkowski [4] and studied by some others ([1,2,5]), it was named after the paper by M. Krein and D. Milman [3]. See also, for example, [6,7,8].

**Theorem 1** *Let  $C \subset \mathbb{R}^n$  be convex and compact, let  $S = \text{ext}(C)$  be the set of extreme points of  $C$ .*

*Then  $\text{conv}(S) = C$ , i. e. the convex hull of the extreme points of  $C$  coincides with the set  $C$ .*

*Proof* Since  $S \subset C$ ,  $\text{conv}(S) \subset \text{conv}(C) = C$ . So we are left to show that  $C \subset \text{conv}(S)$ . We prove this by induction.

Let  $d = \dim C$ . For  $d = -1$  ( $C = \emptyset$ ),  $d = 0$  and  $d = 1$  the proof is trivial.

Let us assume that the theorem is true for all convex compact sets of dimension  $d - 1 \geq 0$ . If  $x \in C$ , but not in  $\text{conv}(S)$ , there exists a line segment in  $C$  such that  $x$  is in the interior of it (since  $x$  is not an extreme point). This line segment intersects the (relative) boundary of  $C$  in two points  $u$  and  $v$ . At least one of them is not extremal, else  $x \in \text{conv}(S)$ . Assume  $u \notin S$ . Since  $u$  is on

the (relative) boundary of  $C$  there exists a supporting hyperplane  $H$  of  $C$ , that contains  $u$ . So  $u \in C \cap H = \text{conv}(\text{ext}(C \cap H))$  (by induction, since  $\dim(C \cap H) \leq d-1$ ). But  $\text{ext}(C \cap H) = \text{ext}(C) \cap H$  and so  $u \in \text{ext}(C) \cap H \subset \text{ext}(C)$ .

An analogous result holds for  $v$ . Since  $x \in [u, v]$ ,  $x = \lambda u + (1 - \lambda)v$  with  $\lambda \in ]0, 1[$  and so  $x \in \text{conv}(\text{ext}(C))$ .

**Keywords**

Optimality conditions; KT point; Constraint qualification; Complexity

In this article we discuss necessary conditions for local optimality for an optimization problem in terms of a system of equations and inequalities which form the well-known Kuhn–Tucker KT conditions. Under suitable convexity assumptions about the objective function and the feasible domain, the Kuhn–Tucker conditions are sufficient even for global optimality. However, in the nonconvex case sufficiency is no longer guaranteed. The material of this article has been adapted from [2] and [4].

First, we consider the nonlinear optimization problem with inequality constraints,

$$\min_{x \in S} f(x), \tag{1}$$

where  $S = \{x: g_i(x) \leq 0, i = 1, \dots, p\} \subseteq \mathbf{R}^n$ . We may assume that all the functions in the optimization problem are continuously differentiable on an open set containing  $S$ .

A vector  $d \in \mathbf{R}^n$  is called a *feasible direction* at  $x^*$  if there exists  $\lambda^* > 0$  such that  $x^* + \lambda d \in S$  for every  $0 < \lambda \leq \lambda^*$ . Let  $Z(x^*)$  denote the set of all feasible directions at  $x^*$ . A local minimum point  $x^* \in S$  satisfies  $d^T \nabla f(x^*) \geq 0$  for every feasible direction  $d \in Z(x^*)$ .

Let

$$I(x^*) := \{i \in \{1, \dots, p\}: g_i(x^*) = 0\}$$

be the index set of the *active constraints* at  $x^*$ . Recall that  $d^T \nabla g_i(x^*) < 0$  implies  $g_i(x^* + \lambda d) < g_i(x^*)$  for  $0 < \lambda \leq \bar{\lambda}_i$ , for some  $\bar{\lambda}_i > 0$ , and  $d^T \nabla g_i(x^*) > 0$  implies  $g_i(x^* + \lambda d) > g_i(x^*)$ ,  $0 < \lambda \leq \tilde{\lambda}_i$ , for some  $\tilde{\lambda}_i > 0$ . Moreover, each constraint which is not active in  $x^*$ , i. e., for which we have  $g_i(x^*) < 0$ , does not influence  $Z(x^*)$ , because  $g_i(x) \leq 0$  holds in a neighborhood of  $x^*$ . It follows that  $\{d: d^T \nabla g_i(x^*) < 0, i \in I(x^*)\} \subseteq Z(x^*) \subseteq \{d: d^T \nabla g_i(x^*) \leq 0, i \in I(x^*)\} =: L(x^*)$ .

It is easy to see that for linearly constrained problems, where  $g_i(x) = a_i^T x - b_i$ ,  $a_i \in \mathbf{R}^n \setminus \{0\}$ ,  $b_i \in \mathbf{R}$ , we have  $Z(x^*) = L(x^*)$ . On the other hand, one can readily construct examples of nonlinear constraints such that

$$Z(x^*) = \{d: d^T \nabla g_i(x^*) < 0, i \in I(x^*)\}.$$

Now  $\{d: d^T \nabla g_i(x^*) < 0\}$  is an open set whereas  $L(x^*)$  is closed. Recall that the closure  $\text{cl } M$  of a set  $M \subseteq \mathbf{R}^n$  is the smallest closed set containing  $M$ . Because of the continuity of the inner product  $d^T \nabla g_i(x^*)$ , we see that  $d^T \nabla f(x^*) \leq 0$  for every  $d \in Z(x^*)$  implies that  $d^T \nabla f(x^*) \leq 0$  for every  $d \in \text{cl } Z(x^*)$ . Hence, the condition  $d^T \nabla f(x^*) \leq 0$  for every  $d \in \text{cl } Z(x^*)$  is as well necessary for  $x^*$  to be a local minimum point. Clearly, by the discussion so far, we have  $\text{cl } Z(x^*) \subseteq L(x^*)$ . One would expect that also  $\text{cl } \{d: d^T \nabla g_i(x^*) < 0, i \in I(x^*)\} = L(x^*)$ , and hence  $\text{cl } Z(x^*) = L(x^*)$ . Indeed, this is true, apart from a few rather pathological cases. An example of such a pathological case is  $S = \{x \in \mathbf{R}: g_1(x) := x^2 \leq 0\}$  and  $x^* = 0$ . Here we have  $S = Z(x^*) = \text{cl } Z(x^*) = \{0\}$ , but  $L(x^*) = \{d \in \mathbf{R}: d \cdot 2 \cdot 0 \leq 0\} = \mathbf{R}$ .

The constraints of the optimization problem  $\min_{x \in S} f(x)$  are said to be *regular* in  $x^* \in S$  when  $L(x^*) = \text{cl } Z(x^*)$ . Every condition which ensures regularity in this sense is called a *constraint qualification*. Three of the most well-known constraint qualifications are given in the next theorem.

**Theorem 1** *Each of the following conditions is a constraint qualification:*

- $g_i(x) = a_i^T x - b_i$ ,  $a_i \in \mathbf{R}^n \setminus \{0\}$ ,  $b_i \in \mathbf{R}$  ( $i = 1, \dots, p$ ; linear constraints).
- $g_i(x)$  is convex ( $i = 1, \dots, p$ ), and there exists  $\bar{x}$  satisfying  $g_i(\bar{x}) < 0, \dots, p$ ; Slater condition).
- The vectors  $\nabla g_i(x^*)$ ,  $i \in I(x^*)$  are linearly independent.

The first two conditions ensure regularity in every  $x^* \in S$  whereas the third requires knowledge of  $x^*$ .

Finally, one applies the well-known *Farkas lemma* (cf. ► **Farkas lemma**). This states that, whenever  $d^T \nabla f(x^*) \geq 0$  for every  $d$  satisfying  $d^T \nabla g_i(x^*) \leq 0, i \in I(x^*)$ , there exists  $\lambda_i \geq 0, i \in I(x^*)$  such that

$$\nabla f(x^*) + \sum_{i \in I(x^*)} \lambda_i \nabla g_i(x^*) = 0.$$

Since  $I(x^*)$  is not known in advance, one formulates this equation in the following equivalent form:

**Theorem 2** *Let  $f, g_i$  be continuously differentiable on an open set containing  $S$ , and let  $x^*$  be a local minimum point such that the constraints are regular in  $x^*$ . Then the following KT conditions hold:*

- $g_i(x^*) \leq 0, i = 1, \dots, p;$
- there exist  $\lambda_i \geq 0$  such that  $\lambda_i g_i(x^*) = 0, i = 1, \dots, p;$
- $\nabla f(x^*) + \sum_{i=1}^p \lambda_i \nabla g_i(x^*) = 0.$

**Theorem 3** The KT conditions are sufficient for a constrained global minimum at  $x^*$  provided that the functions  $f(x)$  and  $g_i(x), i = 1, \dots, p,$  are convex.

*Proof* By convexity of  $f(x)$  and  $g_i(x)$  we have

$$f(x) \geq f(x^*) + (x - x^*)^T \nabla f(x^*),$$

$$g(x) \geq g(x^*) + (x - x^*)^T \nabla g(x^*).$$

Multiplying the last inequalities by  $\lambda_i$  and adding to the first one we obtain:

$$f(x) + \sum_{i=1}^p \lambda_i g_i(x)$$

$$\geq f(x^*) + \sum_{i=1}^p \lambda_i g_i(x^*)$$

$$+ (x - x^*)^T \left[ \nabla f(x^*) + \sum_{i=1}^p \lambda_i \nabla g_i(x^*) \right].$$

Since the last two terms vanish because of the KT conditions, this implies  $f(x) \geq f(x^*) - \sum_{i=1}^p \lambda_i g_i(x) \geq f(x^*)$  for all  $x \in S,$  that is  $x^*$  is a global minimum.

Note that no constraint qualification is required in the above Theorem.

Consider now problems with inequality and equality constraints

$$\min_{x \in S} f(x),$$

where

$$S = \left\{ x: \begin{array}{l} g_i(x) \leq 0 \ (i = 1, \dots, p), \\ h_i(x) = 0 \ (i = 1, \dots, t) \end{array} \right\}.$$

**Theorem 4** Let  $f, g_i (i = 1, \dots, p), h_i (i = 1, \dots, t)$  be continuously differentiable in an open set containing  $S,$  and let  $x^*$  be a local minimum point. Further, assume that the vectors  $\nabla g_i(x^*) (i \in I(x^*)), \nabla h_i(x^*) (i = 1, \dots, t)$  are linearly independent. Then the following KT conditions hold:

- $g_i(x^*) \leq 0 (i = 1, \dots, p), h_i(x^*) = 0 (i = 1, \dots, t).$
- There exist  $\lambda_i \geq 0 (i = 1, \dots, p)$  and  $\mu_i \in \mathbf{R} (i = 1, \dots, t)$  such that

$$\nabla f(x^*) + \sum_{i=1}^p \lambda_i \nabla g_i(x^*) + \sum_{i=1}^t \mu_i \nabla h_i(x^*) = 0,$$

$$\lambda_i g_i(x^*) = 0 \ (i = 1, \dots, p).$$

When the functions  $f, g_i (i = 1, \dots, p)$  are convex, and the functions  $h_i(x)$  are affine then the above two conditions are again sufficient for  $x^*$  to be a global minimum.

Next, we consider the situation when Kuhn–Tucker theory is applied to nonconvex programming. We illustrate some difficulties arisen from nonconvexity by the following simple examples of concave minimization problems.

*Example 5* Consider the problem

$$\left\{ \begin{array}{l} \min \quad -(x_1^2 + x_2^2) \\ \text{s.t.} \quad x_1 \leq 1. \end{array} \right.$$

The KT conditions for this problem are

$$x_1^* - 1 \leq 0, \quad \lambda_1(x_1^* - 1) = 0, \quad \lambda_1 \geq 0,$$

$$\lambda_1 - 2x_1^* = 0, \quad -2x_2^* = 0.$$

It is easy to see that the KT conditions are satisfied at  $x^* = (0, 0)$  with  $\lambda_1 = 0$  and at  $x^* = (1, 0)$  with  $\lambda_1 = 2.$  The first is a global maximum. The second is neither a local minimum nor a local maximum. The problem has no local minima. Moreover,  $\inf\{f(x): x \in S\} = -\infty$  since  $f$  is unbounded from below over  $S.$

*Example 6*

$$\left\{ \begin{array}{l} \min \quad 2x - x^2 \\ \text{s.t.} \quad 0 \leq x \leq 3. \end{array} \right.$$

The KT conditions for this problem are

$$\lambda_1(x^* - 3) = 0, \quad \lambda_2 x^* = 0,$$

$$2(1 - x^*) + \lambda_1 - \lambda_2 = 0,$$

$$\lambda_1 \geq 0, \lambda_2 \geq 0.$$

Since the objective function is strictly concave local minima occur at the endpoints of the interval  $[0, 3].$  The point  $x^* = 3$  is the global minimizer. The endpoints satisfy the KT conditions ( $x^* = 0$  with  $\lambda_1 = 0, \lambda_2 = 2$  and  $x^* = 3$  with  $\lambda_1 = 4, \lambda_2 = 0).$  However, we can easily see that the KT conditions are also satisfied at  $x^* = 1$  (with  $\lambda_1 = \lambda_2 = 0)$  and that this is a global maximum point.

These examples show that for minimization problems with nonconvex functions KT points may not be local minima.

Next, we consider the complexity of the problem of deciding existence of a Kuhn–Tucker point for

quadratic programming problems. When the feasible domain is unbounded, we prove that the decision problem is *NP*-hard.

Most classical optimization algorithms compute points that satisfy the Kuhn–Tucker *KT* conditions. When the feasible domain is not bounded it is not easy to check existence of a *KT* point. More precisely, consider the following quadratic problem

$$\begin{cases} \min & f(x) = c^\top x + \frac{1}{2}x^\top Qx \\ \text{s.t.} & x \geq 0 \end{cases} \quad (2)$$

where  $Q$  is an  $n \times n$  symmetric matrix, and  $c \in \mathbf{R}^n$ . The Kuhn–Tucker optimality conditions for this problem become the following so-called *linear complementarity problem* (denoted by  $LCP(Q, c)$ ): Find  $x \in \mathbf{R}^n$  (or prove that no such an  $x$  exists) such that

$$Qx + c \geq 0, \quad x \geq 0, \quad x^\top(Qx + c) = 0.$$

Hence, the complexity of finding (or proving existence) of Kuhn–Tucker points for the above quadratic problem is reduced to the complexity of solving the corresponding *LCP*.

**Theorem 7** *The problem  $LCP(Q, c)$ , where  $Q$  is symmetric, is *NP*-hard.*

*Proof* Consider the  $LCP(Q, c)$  problem in  $\mathbf{R}^{n+3}$  defined by

$$Q_{(n+3) \times (n+3)} = \begin{pmatrix} -I_n & e_n & -e_n & 0_n \\ e_n^\top & -1 & -1 & -1 \\ -e_n^\top & -1 & -1 & -1 \\ 0_n^\top & -1 & -1 & -1 \end{pmatrix}$$

and  $c_{n+3}^\top = (a_1, \dots, a_n, -b, b, 0)$ , where  $a_i, i = 1, \dots, n$ , and  $b$  are positive integers,  $I_n$  is the  $(n \times n)$ -unit matrix and the vectors  $e_n \in \mathbf{R}^n, 0_n \in \mathbf{R}^n$  are defined by

$$e_n^\top = (1, \dots, 1), \quad 0_n^\top = (0, \dots, 0).$$

Define now the following *knapsack problem*: Find a feasible solution to the system

$$\sum_{i=1}^n a_i x_i = b, \quad x_i \in \{0, 1\} \quad (i = 1, \dots, n).$$

This problem is known to be *NP*-complete [1]. Next we will show that  $LCP(Q, c)$  is solvable if and only if the associated knapsack problem is solvable.

Obviously, if  $x$  solves the knapsack problem, then  $y = (a_1 x_1, \dots, a_n x_n, 0, 0, 0)^\top$  solves  $LCP(Q, c)$ .

Conversely, assume the point  $y$  solves  $LCP(Q, c)$  given above. Since  $Qy + c \geq 0, y \geq 0$  we obtain  $y_{n+1} = y_{n+2} = y_{n+3} = 0$ . This in turn implies that  $\sum_{i=1}^n y_i = b$  and  $0 \leq y_i \leq a_i$ . Finally, if  $y_i < a_i$ , then  $y^\top (Qy + c) = 0$  enforces  $y_i = 0$ . Hence,  $x = (y_1/a_1, \dots, y_n/a_n)$  solves the knapsack problem.

Therefore, even in quadratic programming, the problem of ‘deciding whether a Kuhn–Tucker point exists’ is *NP*-hard.

Calculus of variations; Lagrange multipliers

J.L. Lagrange (1736–1813) made significant contributions to many branches of mathematics and physics, among them the theory of numbers, the theory of equations, ordinary and partial differential equations, the calculus of variations, analytic geometry and mechanics. By his outstanding discoveries he threw the first seeds of thought that later nourished C.F. Gauss and N.H. Abel.

During the first thirty years of his life he lived in Turin (France, now Italy) and, as a boy, his tastes were more classical than scientific. His interest in mathematics began while he was still in school when he read a paper by E. Halley on the uses of algebra in optics. He then began a course of independent study, and excelled so rapidly in the field of mathematical analysis that by the age of nineteen he was appointed professor at the Royal Artillery School and helped to found the Royal Academy of Science in 1757. His ideas had greatly impressed L. Euler, one of the giants of Euro-

pean mathematics. Euler and Lagrange, together, would join the first rank of the eighteenth century mathematicians, and their careers and research were often related [5].

In 1759 Lagrange focused his research in analysis and mechanics and wrote ‘Sur la Propagation du son dans les fluides’, a very difficult issue for that time [4]. From 1759 to 1761 he had his first publications in the ‘Miscellanea of the Turin Academy’. His reputation was established.

Lagrange developed a new calculus which would enrich the sciences, called *calculus of variations*. In its simplest form the subject seeks to determine a functional relationship  $y = f(x)$  such that an  $\int_a^b g(x, y) dx$  could produce a maximum or a minimum. It was viewed as a mathematical study of economy or the ‘best income’ [4]. That was Lagrange’s earliest contribution to the optimization area.

In 1766, Lagrange was appointed the Head of the Berlin Academy of Science, succeeding Euler. In offering this appointment, Frederick the Great wanted to turn his Academy into one of the best institutes of its day, proclaiming that the ‘greatest mathematician in Europe’ should live near the ‘greatest king in Europe’ [1]. During this period, he had a prosperous time, developing important works in the field of calculus, introducing the strictness in the calculus differential and integral. Later (1767) he published a memoir on the approximation of roots of polynomial equations by means of continued fractions; in 1770 he wrote a paper considering the *solvability of equations* in terms of permutations on their roots.

After Frederick’s death, Lagrange left Berlin and became a member of the Paris Academy of Science by the invitation of Louis XVI (1787). He remained in Paris for the rest of his career, making a lengthy treatise on

the numerical solution of equations, representing a significant portion of his mathematical research. His papers on solution of third - and fourth-degree polynomial equations by radicals received considerable attention. His methods, laid in the early development of group theory to solving polynomials, were later taken by E. Galois. Lagrange's name was attached to one of the most important theorems of group theory [3]:

**Theorem 1** *If  $o$  is the order of a subgroup  $g$  of a group  $G$  of order  $O$ , then  $o$  is a factor of  $O$ .*

In 1788 he published his masterpiece, the treatise 'Mécanique Analytique', which summarized and unified all the work done in the field of general mechanics since the time of I. Newton. This work, notable for its use of theory of differential equations, transformed mechanics into a branch of mathematical analysis. As W. Hamilton later said, 'he made a kind of scientific poem' [6].

In 1793, Lagrange headed a commission, which included P.S. Laplace and A. Lavoisier, to devise a new system of weights and measures. Out of this came the metric system.

Lagrange developed the method of variation of parameters in the solution of nonhomogeneous linear differential equations. In the determination of maxima and minima of a function, say  $f(x, y, z, w)$ , subject to constraints such as  $g(x, y, z, w) = 0$  and  $h(x, y, z, w) = 0$ , he suggested the use of *Lagrange multipliers* to provide an elegant algorithm. By this method two undetermined constants  $\lambda$  and  $\mu$  are introduced, forming the function  $F \equiv f + \lambda g + \mu h$ , from the related equations  $F_x = 0, F_y = 0, F_z = 0, F_w = 0, g = 0$ , and  $h = 0$ , the multipliers  $\lambda$  and  $\mu$  are then eliminated, and the problem is solved. This procedure and its variations have emerged as a very important class of optimization method [1,2].

One can characterize Lagrange's contribution to optimization as his formalist foundation. Most of his results were retained and developed further by the following generations, who gave to his theory a different and practical course.

By the end of his life, Lagrange could not think futuristically for the mathematics. He felt that other sciences such as chemistry, physics and biology would attract the ablest minds of the future. His pessimism was unfounded. Much more was to be forthcoming with

Gauss and his successors, making the nineteenth century the richest in the history of mathematics.

Lagrange-type function; IPH functions; Multiplicative inf-convolution; Zero duality gap; Exact penalty function

Lagrange and penalty function methods provide a powerful approach, both as a theoretical tool and a computational vehicle, for the study of constrained optimization problems. However, for a nonconvex constrained optimization problem, the classical Lagrange primal-dual method may fail to find a minimum as a zero duality gap is not always guaranteed. A large penalty parameter is, in general, required for classical quadratic penalty functions in order that minima of penalty problems are a good approximation to those of the original constrained optimization problems. It is well-known that penalty functions with too large parameters cause an obstacle for numerical implementation. Thus the question arises how to generalize classical Lagrange and penalty functions, in order to obtain an appropriate scheme for reducing constrained optimization problems to unconstrained ones that will be suitable for sufficiently broad classes of optimization problems from both the theoretical and computational viewpoints.

One of the approaches for such a scheme is as follows: an unconstrained problem is constructed, where the objective function is a convolution of the objective and constraint functions of the original problem. While a linear convolution leads to a classical Lagrange function, different kinds of nonlinear convolutions lead to interesting generalizations. We shall call functions that appear as a convolution of the objective function and the constraint functions, *Lagrange-type functions*. It can be shown that these functions naturally arise as a result of a nonlinear separation of the image set of the problem and a cone in the image-space of the problem under consideration (see [4]). The class of Lagrange-type functions includes also augmented Lagrangians, corresponding to the so-called canonical dualizing parameterization. However, augmented Lagrangians constructed by means of some general dualizing parameterizations cannot be included in this scheme.

Consider the following problem  $P(f,g)$ :

$$\min f(x) \quad \text{subject to} \quad x \in X, g(x) \leq 0,$$

where  $X$  is a metric space,  $f$  is a real-valued function defined on  $X$ , and  $g$  maps  $X$  into  $\mathbb{R}^m$ , that is,  $g(x) = (g_1(x), \dots, g_m(x))$ , where  $g_i$  are real-valued functions defined on  $X$ . We assume that the set of feasible solutions  $X_0 = \{x \in X: g(x) \leq 0\}$  is nonempty and that the objective function  $f$  is bounded from below on  $X$ .

Let  $\Omega$  be a set of parameters and  $h: \mathbb{R}^{1+m} \times \Omega \rightarrow \mathbb{R}$  be a function. Let  $\eta \in \mathbb{R}$ . Then the function

$$L(x, \omega) = h(f(x) - \eta, g(x); \omega) + \eta, \quad x \in X, \omega \in \Omega, \quad (1)$$

is called a Lagrange-type function for problem  $P(f,g)$  corresponding to  $h$  and  $\eta$ , and  $h$  is called a convolution function.

If  $h$  is linear with respect to the first variable, more specifically:

$$h(u, v; \omega) = u + \chi(v; \omega),$$

where  $\chi: \mathbb{R}^m \times \Omega \rightarrow \mathbb{R}$  is a real-valued function, then the parameter  $\eta$  can be omitted. Indeed, for each  $\eta \in \mathbb{R}$ , we have

$$L(x, \omega) = f(x) + \chi(g(x); \omega).$$

However in general nonlinear situation the presence of  $\eta$  is important and different  $\eta$  lead to Lagrange-type functions with different properties.

One of the possible choices of the number  $\eta$  is  $\eta = f(x_*)$  where  $x_*$  is a reference point, in particular  $x_*$  is a solution of  $P(f,g)$  (see [4]). Then the Lagrange-type function has the form

$$L(x, \omega) = h(f(x) - f(x_*), g(x); \omega) + f(x_*), \quad x \in X, \omega \in \Omega.$$

The Lagrange-type function (1) is a very general scheme and includes linear Lagrange functions, classical penalty functions, and augmented Lagrange functions as special cases.

Let  $\Omega = \mathbb{R}_+^m$  and  $p$  be a real-valued function defined on  $\mathbb{R}^{1+m}$ . Define

$$h(u, v; \omega) = p(u, \omega_1 v_1, \dots, \omega_m v_m). \quad (2)$$

The Lagrange-type function has the form

$$L_p(x, \omega) = p(f(x) - \eta, \omega_1 g_1(x), \dots, \omega_m g_m(x)) + \eta.$$

We can obtain fairly good results if the function  $p$  enjoys some properties. In particular, we assume that

- (i)  $p$  is increasing;
- (ii)  $p(u, 0_m) \leq u$ , for all  $u \in \mathbb{R}$ . (Here  $0_m$  is the origin of  $\mathbb{R}^m$ .) One more assumption is useful for applications.

(iii)  $p$  is positively homogeneous ( $p(\lambda x) = \lambda p(x)$  for  $\lambda > 0$ ).

If both (i) and (iii) hold, then  $p$  is called an IPH function. Let  $p$  be a real-valued function defined on  $\mathbb{R}^{1+m}$  and  $h$  be a convolution function defined by (2). Then

(a) If  $p$  enjoys properties (i) and (ii), then

$$\sup_{w \in \Omega} h(u, v; w) \leq u, \quad \forall u \in \mathbb{R}, v \in \mathbb{R}_-^m.$$

(b) If  $p$  is an IPH function and  $p(u, e_i) > 0$ , where  $e_i$  is the  $i$ -th unit vector,  $i = 1, \dots, m$ , then

$$\sup_{w \in \Omega} h(u, v; w) = +\infty, \quad \forall v \notin \mathbb{R}_-^m.$$

We now give some examples of Lagrange-type functions. First two examples correspond to functions of the form (2).

1) Let  $p(u, v) = u + \sum_{i=1}^m v_i$ . Then  $L_p(x, \omega) = f(x) + \sum_{i=1}^m \omega_i g_i(x)$  coincides with the classical Lagrange function.

2) Let  $p(u, v) = u + \sum_{i=1}^m v_i^+$  where  $v^+ = \max(v, 0)$ . Then  $L_p(x, \omega) = f(x) + \sum_{i=1}^m \omega_i g_i(x)^+$  coincides with the classical (linear) penalty function. If  $p(u, v) = u + \sum_{i=1}^m (v_i^+)^2$ , then  $L_p(x, \omega) = f(x) + \sum_{i=1}^m \omega_i (g_i(x)^+)^2$  is a quadratic penalty function.

We now give the definition of a penalty-type function. Let  $\Omega$  be a set of parameters and  $h: \mathbb{R}^{1+m} \times \Omega \rightarrow \mathbb{R}$  be a convolution function with the property:

$$h(u, v; \omega) = u, \quad u \in \mathbb{R}, v \in \mathbb{R}_-^m, \omega \in \Omega.$$

Then the Lagrange-type function  $L(x, \omega)$ , corresponding to  $h$ , is called a penalty-type function.

Next two examples cannot be presented in the form (2).

3) Augmented Lagrangians

Let  $\sigma: \mathbb{R}^m \rightarrow \mathbb{R}$  be an augmenting function, i. e.,  $\sigma(0) = 0$  and  $\sigma(z) > 0$ , for  $z \neq 0$ , and  $\Omega \subset \{(y, r): y \in \mathbb{R}^m, r \geq 0\}$  be a set of parameters satisfying  $(0, 0) \in \Omega$  and  $(y, r) \in \Omega$  implying  $(y, r') \in \Omega$ , for all  $r' \geq r$ . Let  $h: \mathbb{R}^m \times \Omega \rightarrow \mathbb{R}$  be the convolution function defined by

$$\begin{aligned} h(u, v; (y, r)) &= \inf_{z+v \leq 0} (u - [y, z] + r\sigma(z)) \\ &= u + \inf_{z+v \leq 0} (-[y, z] + r\sigma(z)). \end{aligned}$$

Then the Lagrange-type function, corresponding to  $\eta = 0$ , coincides with the augmented Lagrangian [5], that is,

$$\begin{aligned} L(x, (y, r)) &= h(f(x), g(x); (y, r)) \\ &= \inf_{z+g(x) \leq 0} (f(x) - [y, z] + r\sigma(z)). \end{aligned}$$

4) Morrison-type functions. Let  $\Omega = \mathbb{R}_+$  and

$$h(u, v, \omega) = ((u - \omega)^+)^2 + \sigma(v_1^+, \dots, v_m^+),$$

where  $\sigma$  is an augmenting function. Then the Lagrange-type function corresponding to  $\eta = 0$  has the form

$$L(x, \omega) = ((f(x) - \omega)^+)^2 + \sigma(g_1(x)^+, \dots, g_m(x)^+).$$

Functions of this kind have been introduced by Morrison [6].

Consider problem  $P(f, g)$ , a convolution function  $h: \mathbb{R}^{1+m} \times \Omega \rightarrow \mathbb{R}$  and the corresponding Lagrange-type function

$$L(x, \omega) = h(f(x) - \eta, g(x); \omega) + \eta.$$

The dual function  $q: \Omega \rightarrow \bar{\mathbb{R}} = \mathbb{R} \cup \{-\infty, +\infty\}$  of  $P(f, g)$  with respect to  $h$  and  $\eta$  is defined by

$$q(\omega) = \inf_{x \in X} h(f(x) - \eta, g(x); \omega) + \eta, \quad \omega \in \Omega.$$

Consider the dual problem to  $P(f, g)$  with respect to  $h$  and  $\eta$ :

$$\max q(\omega), \quad \text{subject to } \omega \in \Omega.$$

We are interested in the following questions: Find conditions under which

1) the weak duality holds, i. e.,

$$M(f, g) := \inf_{x \in X_0} f(x) \geq \sup_{\omega \in \Omega} q(\omega) := M^*(f, g);$$

2) the zero duality gap property holds, i. e.,

$$\inf_{x \in X_0} f(x) = \sup_{\omega \in \Omega} q(\omega);$$

3) an exact Lagrange parameter exists, i. e., the weak duality holds and there exists  $\bar{\omega} \in \Omega$  such that

$$\inf_{x \in X_0} f(x) = \inf_{x \in X} L(x, \bar{\omega});$$

4) a strong exact parameter exists: there exists an exact parameter  $\bar{\omega} \in \Omega$  such that

$$\begin{aligned} \operatorname{argmin} P(f, g) &:= \operatorname{argmin}_{x \in X_0} f(x) \\ &= \operatorname{argmin}_{x \in X} L(x, \bar{\omega}); \end{aligned}$$

5) a saddle point exists and generates a solution of  $P(f, g)$ . The first part of this question means that there exists  $(x_*, \omega_*) \in X \times \Omega$  such that

$$L(x, \omega_*) \leq L(x_*, \omega_*) \leq L(x_*, \omega), \quad (3)$$

$$x \in X, \omega \in \Omega.$$

The second part means that (3) implies  $x_* \in \operatorname{argmin} P(f, g)$ .

The weak duality allows one to estimate from below the optimal value  $M(f, g)$  by solving the unconstrained problem  $\inf_{x \in X} L(x, \omega)$ . The zero duality gap property allows one to find  $M(f, g)$  by solving a sequence of unconstrained problems  $\inf_{x \in X} L(x, \omega_t)$  where  $\{\omega_t\} \subset \Omega$ . The existence of an exact Lagrange parameter  $\bar{\omega}$  means that  $M(f, g)$  can be found by solving one unconstrained problem  $\inf_{x \in X} L(x, \bar{\omega})$ . The existence of a strong exact parameter  $\bar{\omega}$  means that the solution set of  $P(f, g)$  is the same as that of  $\min_{x \in X} L(x, \bar{\omega})$ .

Let  $h : \mathbb{R}^{1+m} \times \Omega \rightarrow \mathbb{R}$  be a convolution function such that

$$\sup_{\omega \in \Omega} h(u, v; \omega) \leq u, \quad \text{for all } (u, v) \in \mathbb{R} \times \mathbb{R}_+^m. \quad (4)$$

Then the weak duality holds.

Condition (4) can be guaranteed if

$$\begin{aligned} h(u, v; w) &= p(u, w_1 v_1, \dots, w_m v_m), \\ (u, v) &\in \mathbb{R}^{1+m}, w \in \mathbb{R}_+^m, \end{aligned}$$

and  $p : \mathbb{R}^{1+m} \rightarrow \mathbb{R}$  is an IPH function satisfying

$$p(1, 0_m) \leq 1, \quad p(-1, 0_m) \leq -1.$$

Assume that  $\eta$  is a lower estimate of the function  $f$  over the set  $X$ , i. e.,  $f(x) - \eta \geq b > 0$ , for all  $x \in X$ . Then, in order to establish the weak duality, we need only to consider convolution functions defined on  $[b, +\infty) \times \mathbb{R}^m \times \Omega$  such that

$$\sup_{\omega \in \Omega} h(u, v; \omega) \leq u, \quad \forall (u, v) \in [b, +\infty) \times \mathbb{R}_+^m. \quad (5)$$

To investigate the zero duality gap property, we further assume that, for any  $\epsilon \in (0, b)$ , there exists  $\delta > 0$  such that

$$\inf_{\omega \in \Omega} h(u, v; \omega) \geq u - \epsilon, \quad \forall u \geq b, v \in \mathbb{R}_+^m; \quad (6)$$

and that, for each  $c > 0$ , there exists  $\bar{\omega} \in \Omega$  such that

$$h(u, v; \bar{\omega}) \geq cr(v), \quad \forall u \geq b, v \in \mathbb{R}_+^m, \quad (7)$$

where  $r : \mathbb{R}^m \rightarrow \mathbb{R}$  is such that  $r(v) \leq 0 \iff v \in \mathbb{R}_+^m$ .

Assume further that

(f<sub>1</sub>) The function  $f$  is uniformly positive on  $X_0$ , i. e.,

$$\inf_{x \in X_0} f(x) = M(f, g) > 0;$$

(f<sub>2</sub>) The function  $f$  is uniformly continuous on an open set containing the set  $X_0$ ;

(g) The mapping  $g$  is continuous and the set-valued mapping

$$D(\delta) = \{x \in X : r(g(x)) \leq \delta\}$$

is upper semi-continuous at the point  $\delta = 0$ .

**Theorem 1** Under the assumptions (5)–(7) and (f<sub>1</sub>), (f<sub>2</sub>) and (g), the zero duality gap property holds for  $P(f, g)$  with respect to the Lagrange-type function  $L(x, \omega)$ , corresponding to  $h$  and  $\eta = 0$ .

Let  $b \geq 0$ . Define a convolution function  $h : [b, +\infty) \times \mathbb{R}^m \rightarrow \mathbb{R}$  by

$$h(u, v; \omega) = p(u, \omega_1 v_1, \dots, \omega_m v_m),$$

where  $p : \mathbb{R}_+ \times \mathbb{R}^m \rightarrow \mathbb{R}$  is an increasing function satisfying

$$p(u, 0_m) \leq u, \quad \text{for all } u \geq 0. \quad (8)$$

Consider the  $P(f, g)$  with uniformly positive objective function  $f$  on  $X$ . Let  $L$  be the Lagrange-type function defined by

$$L(x, \omega) = p(f(x), \omega_1 g_1(x), \dots, \omega_m g_m(x)),$$

where  $p$  is defined on  $\mathbb{R}_+ \times \mathbb{R}^m$ . Define the perturbation function  $\beta(y)$  of  $P(f, g)$  by

$$\beta(y) = \inf\{f(x) : x \in X, g(x) \leq y\}, \quad y \in \mathbb{R}^m.$$

**Theorem 2** Let  $p$  be a continuous increasing function satisfying (7). Let the zero duality gap property with respect to  $p$  holds. Then the perturbation function  $\beta$  is lower semi-continuous at the origin.

Further assume that  $p$  satisfies the following property: there exist positive numbers  $a_1, \dots, a_m$  such that, for all  $u > 0, (v_1, \dots, v_m) \in \mathbb{R}^m$ , we have

$$p(u, v_1, \dots, v_m) \geq \max(u, a_1 v_1, \dots, a_m v_m). \quad (9)$$

**Theorem 3** Assume that  $p$  is an increasing convolution function that possesses properties (8) and (9). Let perturbation function  $\beta$  of problem  $P(f, g)$  be lower semi-continuous at the origin. Then the zero duality gap property with respect to  $p$  holds.

*Remark 1* The perturbation function  $\beta$  depends on  $P(f, g)$  and doesn't depend on the exogenous function  $p$ . It is worth noting that Theorems 2 and 3 establish equivalence relations between the zero duality gap property with respect to different  $p$  from a broad class of convolution functions.

*Remark 2* If  $p$  is a linear function, then the lower semicontinuity does not imply the zero duality gap property, so we need to impose a condition that does not hold for linear functions. This is the role of (9). The results similar to Theorem 2 and Theorem 3 hold also for penalty type functions, where  $p(u, v)$  is a function defined on  $\mathbb{R}_+ \times \mathbb{R}_+^m$  and  $L(x, \omega) = p(f(x), \omega_1 g_1(x)^+, \dots, g_m(x)^+)$ . In such a case (9) should be valid only for  $u > 0, v \in \mathbb{R}_+^m$ . This requirement is very weak and is valid for many increasing functions including the function  $p(u, v) = u + \sum_{i=1}^m v_i$ .

Let the Lagrange-type function be of the following form

$$L(x, \omega) = f(x) + \chi(g(x); \omega), \quad x \in X, \omega \in \Omega.$$

Consider set  $K$  of functions  $\chi: \mathbb{R}^m \times \Omega \rightarrow \mathbb{R}$  with the following two properties

- (i)  $\chi(\cdot, \omega)$  is lower semi-continuous for all  $\omega \in \Omega$ ;
- (ii)  $\sup_{\omega \in \Omega} \chi(v; \omega) = 0$ , for all  $v \in \mathbb{R}_+^m$ .

Consider a point  $(x_*, \omega_*) \in X \times \Omega$  such that

$$L(x_*, \omega_*) = \min_{x \in X} L(x, \omega_*), \quad (10)$$

$$\chi(g(x_*); \omega_*) = 0. \quad (11)$$

**Theorem 4** Let  $\chi \in K$ . If (10) and (11) hold for  $x_* \in X_0$  and  $\omega_* \in \Omega$ , then  $\omega_*$  is an exact Lagrange parameter.

The most advanced theory has been developed for two special classes of Lagrange-type functions. One of them is augmented Lagrangians (see article in encyclopedia). The other class consists of penalty-type functions for problems with a positive objective and a single constraint. This penalty-type functions are composed by convolutions functions of the form (2) with IPH functions  $p$ .

*Remark 3* Consider problem  $P(f, g)$  with  $m$  constraints  $g_1, \dots, g_m$ . We can convert these constraints to a single one by many different ways. In particular, the system  $g_1(x) \leq 0, \dots, g_m(x) \leq 0$  is equivalent to the single inequality  $f_1(x) := \sum_{i=1}^m g_i^+(x) \leq 0$ . The function  $f_1$  is non-smooth. If all functions  $g_i(x)$  are smooth then a smoothing procedure can be applied to  $f_1$  (see [13] for details). Problems with a single constraint are convenient to be dealt with from many points of view.

Let  $P(f, f_1)$  be a problem with a positive objective  $f$  and a single constraint  $f_1$ . We consider here only IPH functions  $s_k$  defined on  $\mathbb{R}_+^2$  by:

$$s_k(u, v) = (u^k + v^k)^{1/k}, \quad u, v \geq 0. \quad (12)$$

(Many results that are valid for  $s_k$  can be extended also for IPH functions  $p: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+$  with properties  $p(1, 0) = 1, \lim_{u \rightarrow +\infty} p(1, u) = +\infty$ .)

A penalty-type function  $L_k^+$  corresponding to  $s_k$  has the form  $L_k^+(x, d) = (f(x)^k + d^k f_1^+(x)^k)^{1/k}$ . Here  $d^k$  is a penalty parameter. It can be shown that the exact parameter does not exist if  $k > 1$  for the 'regular' problems in a certain sense, so we will here consider only the classical penalty function with  $k=1$  and lower order penalty functions with  $k < 1$ . It can be shown that the existence of an exact parameter for  $k \leq 1$  implies the existence of exact parameters for  $k'$  with  $0 < k' < k$ . One of the main questions that can be studied in the framework of this class of penalty-type functions is the size of exact penalty parameters. Generally speaking, we can diminish the size of exact parameter using the choice of  $k$  and some simple reformulations of the problem  $P(f, f_1)$  in hand.

For the function  $L_k^+$  an explicit value of the least exact penalty parameter can be expressed through the

perturbation function. Let  $\beta(y)$  be the perturbation function of the problem  $P(f, f_1)$ . Note that  $\beta(0) = M(f, f_1)$  and  $\beta$  is a decreasing function, so  $\beta(y) \leq M(f, f_1)$ . For the sake of simplicity, we assume that  $\beta(y) < M(f, f_1)$  for all  $y > 0$ . Let

$$\bar{d}_k = \sup_{y > 0} \frac{(M(f, f_1)^k - \beta^k(y))^{1/k}}{y}. \quad (13)$$

Then the least exact parameter exists if and only if the supremum in (13) is finite and the least exact parameter is equal to  $\bar{d}_k$ . For  $k = 1$  the existence easily follows from the calmness results of Burke [1].

Let  $f^c(x) = f(x) + c$  with  $c > 0$  and  $d_{c,k}$  be the least exact parameter for problem  $P(f^c, f_1)$ . Then it can be proved that  $d_{c,k} \rightarrow 0$  as  $c \rightarrow +\infty$ .

Assume that functions  $f$  and  $f_1$  are Lipschitz. Since  $k < 1$  the function  $L_k^+$  is not locally Lipschitz at points  $x$  where  $f_1(x) = 0$ , so we need to have a special smoothing procedure in order to apply numerical method for the unconstrained minimization of this function. Such a procedure is described in [14]. This procedure can be applied for different types of lower order penalty functions.

Another approach for constructing a Lipschitz penalty function with a small exact parameter is also of interest (see [11] and references therein).

Let  $\sigma$  be a strictly increasing continuous concave function defined on  $[a, +\infty)$  where  $a > 0$ . Assume that  $\sigma(a) \geq 0$  and  $\lim_{y \rightarrow +\infty} \sigma(y) = 0$  where  $\sigma'_+$  is the right derivative of the concave function  $\sigma$ . Consider the function  $f^{\sigma,c}(x) = \sigma(f(x) + c)$  and the classical penalty function for  $L_{1,\sigma,c}^+(x, d) = \sigma(f(x) + c) + df_1(x)$  for the problem  $P(f^{\sigma,c}, f_1)$ . Let  $d_{\sigma,c}$  be the least exact parameter of  $L_{1,\sigma,c}^+$  (assuming that this parameter exists). Then we can assert that  $d_{\sigma,c} \rightarrow 0$  as  $c \rightarrow 0$  under very mild assumptions.

**The Primal Problem  
and the Lagrangian Dual Problem**

For a given *primal optimization problem* (P) it is possible to construct a related *dual* problem which depends on the same data and often facilitates the analysis and solution of (P). This section focuses on the *Lagrangian dual*, a particular form of dual problem which has proven to be very useful in many optimization applications.

A general form of *primal problem* is

$$(P) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & g(x) \leq 0, \\ & h(x) = 0, \\ & x \in S, \end{cases}$$

where  $f$  is a scalar function of the  $n$ -dimensional vector  $x$ , and  $g$  and  $h$  are vector functions of  $x$ .  $S$  is a nonempty subset of  $\mathbf{R}^n$ . It is convenient to associate *dual variables* with the constraints as follows: components of the *dual vector*  $u$  correspond to components of the vector constraint  $g(x) \leq 0$ , and similarly the components of  $v$  are associated with components of the constraint  $h(x) = 0$ .

There is a great deal of flexibility in defining problem (P). For example, any or all of the explicit constraints  $g(x) \leq 0$  and  $h(x) = 0$  could be incorporated in the definition of the set  $S$ . This, of course, governs the number and type of dual variables. As will be seen in the examples, defining  $S$  is the first step in defining a Lagrangian dual of (P). To illustrate the basic duality results, certain assumptions regarding the functions  $f$ ,  $g$  and  $h$  and the set  $S$  will be made to simplify the pre-

sentation below. For more thorough treatments, see the references.

Given (P), define the *Lagrangian function*  $L(x, u, v) = f(x) + u^T g(x) + v^T h(x)$ . The *Lagrangian dual problem* is then

$$(D) \quad \begin{cases} \max & \theta(u, v) \\ \text{s.t.} & u \geq 0, \end{cases}$$

where, for fixed  $(u, v)$ , the dual function  $\theta$  is defined in terms of the *infimum of the Lagrangian function* with respect to  $x \in S$ :

$$\theta(u, v) = \inf_{x \in S} L(x, u, v).$$

Below are five examples of primal problems and their duals. The first is a geometrical example, three are classes of optimization problems: linear programs, convex programs, and quadratic programs, and the final example is an integer program.

*Example 1 (geometrical problem)* In this two-variable example, a linear function is to be minimized over the intersection of the unit disk and the nonnegative orthant. The optimal solution is at the origin with objective value zero.

$$(P1) \quad \begin{cases} \min & x_1 + x_2 \\ \text{s.t.} & x_1^2 + x_2^2 \leq 1, \\ & -x_1 \leq 0, \\ & -x_2 \leq 0, \end{cases}$$

Letting  $S = \{(x_1, x_2) : x_1^2 + x_2^2 \leq 1\}$ , the dual problem is

$$(D1) \quad \begin{cases} \max & \theta(u) \\ \text{s.t.} & u \geq 0, \end{cases}$$

where

$$\theta(u) = \min_{x_1^2 + x_2^2 \leq 1} (1 - u_1)x_1 + (1 - u_2)x_2.$$

Note that  $\min$  replaces  $\inf$  in the definition of  $\theta$  since it is clear that the infimum exists and is finite for this example.

*Example 2 (linear programming)* Duality is an important topic in any treatment of linear programming. This example shows that the Lagrangian dual of a primal linear program is equivalent to the *dual linear program* as

it is usually formulated in textbooks. Letting the primal be

$$(P2) \quad \begin{cases} \min & c^\top x \\ \text{s.t.} & b - Ax \leq 0, \\ & x \geq 0, \end{cases}$$

and choosing  $S = \{x: x \geq 0\}$ , the Lagrangian dual is

$$(D2) \quad \begin{cases} \max & \theta(u) \\ \text{s.t.} & u \geq 0 \end{cases}$$

where

$$\theta(u) = \inf_{x \geq 0} c^\top x + u^\top (b - Ax).$$

This reduces to

$$\theta(u) = b^\top u + \begin{cases} 0 & \text{if } (c - A^\top u) \geq 0, \\ -\infty & \text{otherwise.} \end{cases}$$

Assuming there are nonnegative values of  $u$  such that  $c \geq A^\top u$ , these would be the only viable choices for the maximization of  $\theta(u)$  and therefore (D2) takes the form familiar from linear programming duality:

$$\begin{cases} \max & b^\top u \\ \text{s.t.} & A^\top u \leq c, \\ & u \geq 0. \end{cases}$$

*Example 3 (differentiable convex programming)* One of the first nonlinear duals was developed by P. Wolfe [27] for the primal problem

$$(P3) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & g(x) \leq 0, \\ & x \in S, \end{cases}$$

where  $S$  is an open convex set, and  $f$  and  $g$  are differentiable convex functions defined on  $S$ . The Lagrangian function is  $L(x, u) = f(x) + u^\top g(x)$ , and it is further assumed that  $\theta(u) \neq -\infty$  for all  $u \geq 0$ . With these assumptions the Lagrangian function is convex in  $x$  and has a minimum where its gradient is zero. That is, the requirement  $\theta(u) = \min_{x \in S} L(x, u)$  is the same as requiring  $\nabla_x L(x, u) = 0$ . Thus the dual problem may be written

$$(D3) \quad \begin{cases} \max & L(x, u) \\ \text{s.t.} & \nabla_x L(x, u) = 0, \\ & u \geq 0. \end{cases}$$

*Example 4 (convex quadratic programming)* An important special case of the preceding example is the problem

$$(P4) \quad \begin{cases} \min & \frac{1}{2}x^\top Hx + d^\top x \\ \text{s.t.} & Ax \leq b, \\ & x \in \mathbb{R}^n, \end{cases}$$

where  $H$  is a given symmetric positive definite  $n \times n$  matrix and  $d$  is a given vector in  $\mathbf{R}^n$ . Applying the results for (P3) above and using the equality constraints of (D3) to eliminate  $x$ , the dual of can be written

$$(D4) \quad \begin{cases} \max & \theta(u) = -\frac{1}{2}u^\top (AH^{-1}A^\top)u \\ & -u^\top (b + AH^{-1}d) - \frac{1}{2}d^\top H^{-1}d \\ \text{s.t.} & u \geq 0. \end{cases}$$

Thus, the dual of (P4) is also a quadratic program in the dual variables  $u$ .

*Example 5 (integer program)* The following numerical example of a linear problem with binary variables will be used to illustrate various dual properties in the following sections.

$$(P5) \quad \begin{cases} \min & 20 - x_1 - 5x_2 - 7x_3 \\ \text{s.t.} & x_1 + 3x_2 + 4x_3 \leq 5, \\ & x_j \in \{0, 1\}, \quad j = 1, 2, 3. \end{cases}$$

For this problem, let  $S$  be defined by the binary restrictions on the components of  $x$ . Then  $L(x, u) = 20 - x_1 - 5x_2 - 7x_3 + u(x_1 + 3x_2 + 4x_3 - 5)$  and the dual problem is

$$(D5) \quad \begin{cases} \max & \theta(u) \\ \text{s.t.} & u \geq 0, \end{cases}$$

where

$$\begin{cases} \theta(u) = \min & (u - 1)x_1 + (3u - 5)x_2 \\ & + (4u - 7)x_3 - 5u + 20 \\ \text{s.t.} & x_j \in \{0, 1\}, \quad j = 1, 2, 3. \end{cases}$$

## Weak and Strong Duality

For a given primal problem (P) and associated dual problem (D), a fundamental relationship showing that

the two objective function values bound each other is given by the following *weak duality* result:

**Theorem 6** *If  $\bar{x}$  is feasible to (P) and  $(\bar{u}, \bar{v})$  is feasible to (D), then*

$$f(\bar{x}) \geq \theta(\bar{u}, \bar{v}).$$

*Proof*

$$\begin{aligned} \theta(u, v) &= \inf_{x \in S} L(x, u, v) \\ &\leq f(\bar{x}) + \bar{u}^\top g(\bar{x}) + \bar{v}^\top h(\bar{x}) \leq f(\bar{x}). \end{aligned}$$

The first inequality follows since  $\bar{x} \in S$  and the second from  $\bar{u}^\top g(\bar{x}) \leq 0$  and  $h(\bar{x}) = 0$ .  $\square$

If the optimal primal and dual objective values are equal, *strong duality* is said to hold for the primal and dual pair. The following theorem illustrates such a result for the the pair (P3) and (D3).

**Theorem 7** *Let  $x^*$  be an optimal solution for (P3) and assume the function  $g$  satisfies some constraint qualification. Then there exists a vector  $u^*$  such that  $(x^*, u^*)$  solves (D3) and*

$$f(x^*) = L(x^*, u^*).$$

*Proof* Under the assumptions there exists a  $u^* \geq 0$  such that  $(x^*, u^*)$  satisfies the *Karush–Kuhn–Tucker conditions*:

$$\begin{aligned} \nabla_x L(x^*, u^*) &= 0, \\ u^{*T} g(x^*) &= 0, \end{aligned}$$

from which it follows that

$$f(x^*) = L(x^*, u^*)$$

and that  $(x^*, u^*)$  is feasible to (D3). Using this and the weak duality theorem gives

$$L(x^*, u^*) \geq L(x, u)$$

for any  $(x, u)$  satisfying the constraints of (D3). The results of the theorem follow.  $\square$

The references contain additional strong duality results, including cases where differentiability is not required. However, as will be seen in examples below, it often happens that there is a difference, known as the *duality gap*, between the optimal values of the primal and dual objective functions.

## Properties of the Lagrangian Dual Function

The Lagrangian dual function enjoys two useful properties: it is concave and, although it is not necessarily differentiable, it is relatively straightforward to compute a *subgradient* at any dual feasible point.

**Theorem 8**  *$\theta(u, v)$  is concave.*

*Proof* For fixed  $x$ ,  $L(x, u, v)$  is linear in  $(u, v)$  and thus  $\theta(u, v)$  is the infimum of a (possibly infinite) collection of functions linear in  $(u, v)$ .  $\square$

It is important to note that the above result is true under very general conditions. In particular, it is true when the set  $S$  is discrete.

Since  $\theta(u, v)$  is concave, it is known that at least one *linear supporting function* exists at each  $(u, v)$ . Collectively, the gradients of all linear supports at  $(u, v)$  is called the set of *subgradients* of  $\theta$  at  $(u, v)$ .

For any  $(u, v)$  for which  $\theta(u, v)$  is finite, denote  $S(u, v)$  as the solution set of the minimization defining  $\theta(u, v)$ .

**Theorem 9** *For fixed  $(\bar{u}, \bar{v})$ , let  $\bar{x} \in S(\bar{u}, \bar{v})$ . Then  $(g(\bar{x}), h(\bar{x}))$  is a subgradient of  $\theta$  at  $(\bar{u}, \bar{v})$ .*

*Proof* For any  $(u, v)$

$$\begin{aligned} \theta(u, v) &= \inf_{x \in S} f(x) + u^\top g(x) + v^\top h(x) \\ &\leq f(\bar{x}) + u^\top g(\bar{x}) + v^\top h(\bar{x}) \\ &= f(\bar{x}) + (u - \bar{u})^\top g(\bar{x}) + \bar{u}^\top g(\bar{x}) \\ &\quad + (v - \bar{v})^\top h(\bar{x}) + \bar{v}^\top h(\bar{x}). \end{aligned}$$

Hence

$$\theta(u, v) \leq \theta(\bar{u}, \bar{v}) + g(\bar{x})^\top (u - \bar{u}) + h(\bar{x})^\top (v - \bar{v}).$$

$\square$

If  $S(\bar{u}, \bar{v})$  is a single point  $\bar{x}$ , then there is only one subgradient of  $\theta$  at  $(\bar{u}, \bar{v})$  in which case  $\theta$  is differential at  $(\bar{u}, \bar{v})$ , i. e.,  $\nabla \theta(\bar{u}, \bar{v}) = (g(\bar{x}), h(\bar{x}))$ .

From the above,  $\theta$  is always concave and it is relatively easy to calculate a slope at any point. Much use of this is made in algorithms for large scale integer programs. Also, the fact that the maximum value of the dual provides a lower bound to the optimal objective function value in methods (such as *branch and bound*) for solving the primal problem. While strong duality

generally holds for convex programs, this is rarely true for integer programs.

Revisiting the examples of the first section, for Example 1 the Karush–Kuhn–Tucker conditions can be employed to derive

$$\theta(u) = -\sqrt{(1 - u_1)^2 + (1 - u_2)^2}.$$

There is no duality gap for this problem, the dual maximum occurs at  $(u_1, u_2) = (1, 1)$  where  $\theta$  is zero, in agreement with the primal minimum. The dual function is differentiable except at its maximizing point. The dual function of Example 2, a linear program, is linear and thus it is concave and differentiable everywhere. Similarly, in Example 4, since  $H$  is positive definite,  $H^{-1}$  is also positive definite and the dual function is again concave and differentiable everywhere. For Example 5, the integer program, values of  $u$  feasible to the dual problem,  $S(u)$  and  $\theta(u)$  are given in Table 1.  $S(u)$  is the triple  $(x_1(u), x_2(u), x_3(u))$ .

Figure 1 is a graph of the function  $\theta(u)$ . Again,  $\theta(u)$  is a concave function and it is differentiable except at

$$u = 1, \frac{5}{3}, \frac{7}{4}.$$

The maximum dual value is

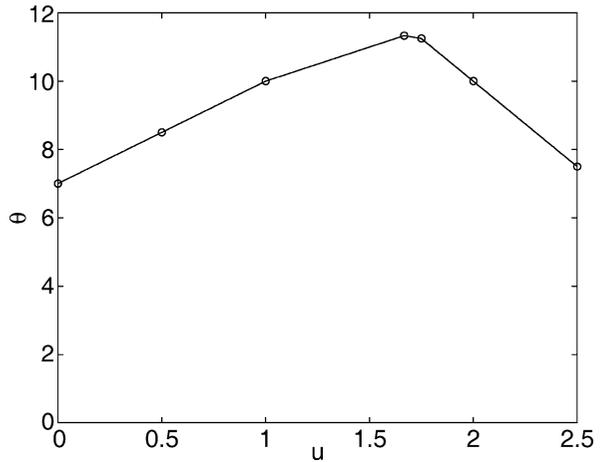

$$\theta\left(\frac{5}{3}\right) = 11\frac{1}{3},$$

which indicates a duality gap of size  $2/3$  since the optimal value of (P5) is  $f(1, 0, 1) = 12$ .

By contrast, Theorem 8 does not apply in Example 3 because the objective of (D3), a Lagrangian function, depends on both  $x$  and  $u$ , rather than the dual variables alone. Lagrangian functions are generally not concave.

**Lagrangian Duality: BASICS, Table 1**  
Values of the dual function for Example 5

$u$	$S(u)$	$\theta(u)$
$0 < u < 1$	$(1, 1, 1)$	$7 + 3u$
$1$	$\{(1, 1, 1) \cup (0, 1, 1)\}$	$8 + 2u$
$1 < u < 5/3$	$(0, 1, 1)$	$8 + 2u$
$5/3$	$\{(0, 1, 1) \cup (0, 0, 1)\}$	$13 - u$
$5/3 < u < 7/4$	$(0, 0, 1)$	$13 - u$
$7/4$	$\{(0, 0, 1) \cup (0, 0, 0)\}$	$20 - 5u$
$7/4 < u$	$(0, 0, 0)$	$20 - 5u$

### Geometrical Interpretations of Lagrangian Duality

#### The Resource-Payoff Space

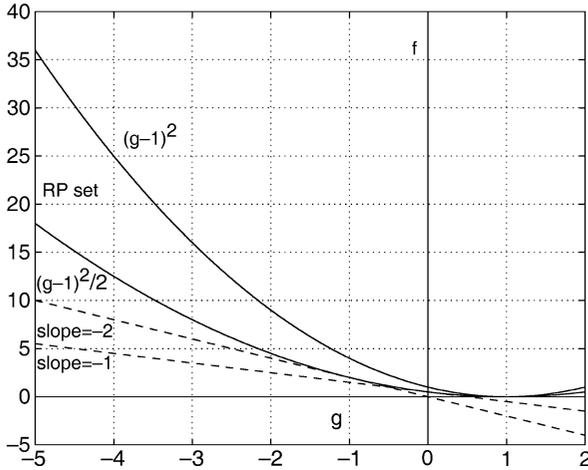

One interpretation of the dual problem is provided via the resource-payoff set RP for problem (P). To illustrate geometrically, assume that (P) has just one inequality constraint  $g(x) \leq 0$  and there are no explicit equality constraints. Then the resource-payoff set for the problem is the set of points defined by

$$RP = \{(g(x), f(x)) : x \in S\}.$$

That is, RP is a mapping of all  $x \in S$  into the  $(g, f)$ -plane. In this plane, the Lagrangian equated to a constant  $\theta$  has the form  $f + ug = \theta$ , which defines a line of slope  $-u$  and intercept  $\theta$ . For any  $u \geq 0$ , the dual function  $\theta(u)$  is defined by minimizing  $f(x) + ug(x)$  over  $x \in S$ . Thus  $\theta(u)$  is the intercept of a linear support to the resource-payoff set at  $\{(g(x), f(x)) : x \in S(u)\}$ . To illustrate, consider the problem

$$(P6) \begin{cases} \min & x_1^2 + x_2^2 \\ \text{s.t.} & 1 - x_1 - x_2 \leq 0, \\ & -x_1 \leq 0, \\ & -x_2 \leq 0. \end{cases}$$

The optimal solution is  $x_1^* = x_2^* = 1/2$  and  $f(x_1^*, x_2^*) = 1/2$ . Letting  $S = \{(x_1, x_2) : x_1 \geq 0, x_2 \geq 0\}$ , and  $g(x_1, x_2) = 1 - x_1 - x_2$ , the resource-payoff set is a subset of  $\mathbb{R}^2$  defined by  $RP = \{(g(x_1, x_2), f(x_1, x_2)) : x_1 \geq 0, x_2 \geq 0\}$ .

**Lagrangian Duality: BASICS, Figure 2**  
RP set for (P6)

0}. It can be verified that RP consists of all points in  $\mathbf{R}^2$  between the curves  $(g - 1)^2$  and  $(g - 1)^2/2$  for  $g \leq 1$  as shown in Fig. 2.

The two linear supports of RP shown have slopes of  $-2$  and  $-1$ , corresponding to  $u$  values of  $2$  and  $1$ . With  $u = 2$ ,  $(x_1(u), x_2(u))$  is the singleton  $(1, 1)$  and  $(g(x(u)), f(x(u))) = (-1, 2)$ . The line with slope  $-2$  passing through the point  $(g, f) = (-1, 2)$  intersects the  $f$ -axis at the origin. Thus  $\theta(2) = 0 < f(x^*)$ , illustrating the weak duality theorem.

For  $u = 1$ ,  $(x_1(u), x_2(u)) = (1/2, 1/2)$  and  $(g(x(u)), f(x(u))) = (0, 1/2)$ . Since this point lies on the  $f$ -axis it follows that  $\theta(1) = 1/2 = f(x^*)$ . This illustrates the strong duality theorem.

As an alternative consider Example 5, the *binary linear programming* problem. Since  $S$  is discrete, RP consists of the eight points in  $\mathbf{R}^2$  listed in the last two columns of Table 2. The optimal solution to the problem is  $x^* = (1, 0, 1)$ ,  $f(x^*) = 12$ . The resource-payoff set for this example is shown in Fig. 3. The lines in the figure trace out the lower envelope of the resource-payoff set and are found by minimizing the Lagrangian function over  $S$  using  $u^1 = 7/4$ ,  $u^2 = 5/3$  and  $u^3 = 1$ . The lines with slope  $-7/4$ ,  $-5/3$ , and  $-1$  intersect the  $f$ -axis at

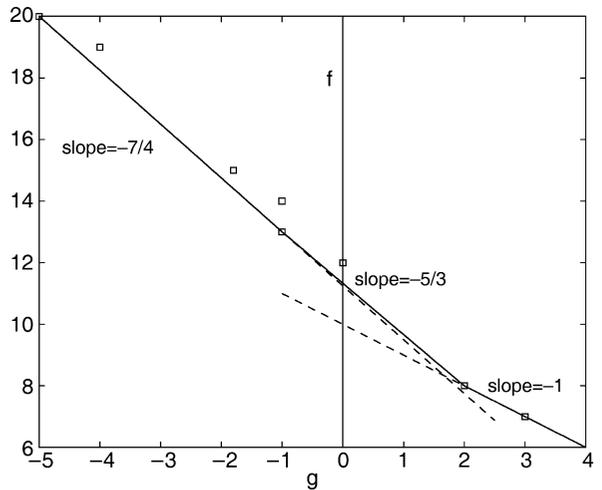

$$11\frac{1}{4}, 11\frac{1}{3}, 10,$$

respectively. Thus

$$\theta\left(\frac{7}{4}\right) = 11\frac{1}{4}, \theta(1) = 10, \theta\left(\frac{5}{3}\right) = 11\frac{1}{3}.$$

**Lagrangian Duality: BASICS, Table 2**  
Values of  $g$  and  $f$  for Example 5

$x_1$	$x_2$	$x_3$	$g(x_1, x_2, x_3)$ $x_1 + 3x_2 + 4x_3 - 5$	$f(x_1, x_2, x_3)$ $20 - x_1 - 5x_2 - 7x_3$
0	0	0	-5	20
0	0	1	-1	13
0	1	0	-2	15
0	1	1	2	8
1	0	0	-4	19
1	0	1	0	12
1	1	0	-1	14
1	1	1	3	7

**Lagrangian Duality: BASICS, Figure 3**  
The set RP for Example 5

The duality gap for this problem, as noted earlier, is

$$f(x^*) - \theta(u^*) = 12 - 11\frac{1}{3} = \frac{2}{3}.$$

These two examples illustrate a sufficient condition for there to be no duality gap. There is no gap if the point  $(g(x^*), f(x^*))$  lies on the *lower envelope* of the resource-payoff set, and there is a *linear support* of slope  $-u \leq 0$  at that point with intercept  $f(x^*)$ .

This condition is satisfied for (P6), but not for (P5). However, if the constraint in (P5) is replaced by  $g(x) = x_1 + 2x_2 + 4x_3 - 4 \leq 0$ , the condition is satisfied. The effect of this constraint change can be seen in Table 2 and Fig. 3. In the table, the  $g$  column entries would be

increased by 1, and thus  $f(x^*) = 13$ , with  $x^* = (x_1^*, x_2^*, x_3^*) = (0, 0, 1)$ . In Fig. 3, the  $f$ -axis would be shifted one unit to be left. In this case, note that  $(g(x^*), f(x^*))$  now lies on the lower envelope of the set RP. Furthermore, an optimal dual variable is any value  $u^* \in [5/3, 7/4]$ .

### Gap Function

Another geometrical interpretation can be given for the primal problem

$$(P7) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & Ax = b, \\ & x \geq 0, \end{cases}$$

where  $f$  is assumed convex and differentiable. In what follows, let  $S = \{x \in \mathbf{R}^n: Ax = b, x \geq 0\}$  which is assumed to be a compact subset of  $\mathbf{R}^n$ .

For any feasible  $x$ , define the *gap function* by

$$\begin{aligned} G(x) &= \max_{y \in S} \nabla f(x)^\top (x - y) \\ &= -\min_{y \in S} \nabla f(x)^\top (y - x). \end{aligned}$$

The gap function has several interesting properties. Letting  $y(x)$  be the solution of the linear program defining  $G(x)$ , note first that the gap function at  $x$  is the negative of the *directional derivative* of  $f$  at  $x$  in the direction  $(y(x) - x)$ . Second, it can be used to construct a lower bound on the optimal solution  $f(x^*)$  of (P7). To see this, consider the convexity inequality

$$f(y) \geq f(x) + \nabla f(x)^\top (y - x), \quad \forall y \in S.$$

Minimizing both sides over  $y \in S$  implies

$$f(x^*) \geq f(x) - G(x), \quad \forall x \in S.$$

By the weak duality result, a lower bound for  $f(x^*)$  can also be obtained by evaluating the dual objective at any dual feasible solution. The next theorem employs the Wolfe dual of (P7) to show that the bound given above is equivalent to obtaining the maximum dual objective value for a given  $x$ .

Let  $v$  and  $u$  be the dual variables associated with  $Ax = b$  and  $x \geq 0$ , respectively. The *Lagrangian function* of (P7) is  $L(x, v, u) = f(x) + v^\top (b - Ax) - u^\top x$ . Then, for the given  $x$ , the maximum dual objective value is

$$d(x) = \max_{(v, u) \in D(x)} L(x, v, u),$$

where  $D(x)$  is the set of all multipliers such that  $(x, v, u)$  is feasible to the Wolfe dual:

$$D(x) = \{(v, u): \nabla_x L(x, v, u) = 0 \text{ and } u \geq 0\}.$$

**Theorem 10** For any  $x \in S$ ,  $G(x) = f(x) - d(x)$ .

*Proof* First it is verified that  $D(x)$  is nonempty so that  $d(x)$  is well defined. This will be true if there exists a  $v$  such that  $A^\top v \leq \nabla f(x)$ . By adaptation of Farkas' lemma (cf. also ► [Farkas lemma](#); ► [Farkas lemma: Generalizations](#)) such a  $v$  exists if and only if the alternative system

$$\nabla f(x)^\top z < 0, \quad Az = 0, \quad z \geq 0$$

has no solution. However  $Az = 0, z \geq 0$  imply that  $x + \lambda z \in S$  for all  $\lambda \geq 0$ . Since  $S$  is assumed to be compact, the only possibility is  $z = 0$  and the alternative system has no solution. Thus  $D(x)$  is nonempty.

The dual constraints imply that  $u^\top x = \nabla f(x)^\top x - v^\top Ax$ , so

$$d(x) = \begin{cases} \max_v & f(x) - \nabla f(x)^\top x + v^\top b \\ \text{s.t.} & A^\top v \leq \nabla f(x). \end{cases}$$

By linear programming duality

$$\begin{cases} \max & b^\top v \\ \text{s.t.} & A^\top v \leq \nabla f(x) \end{cases} = \begin{cases} \min & \nabla f(x)^\top y \\ \text{s.t.} & Ay = b \\ & y \geq 0, \end{cases}$$

and it follows that

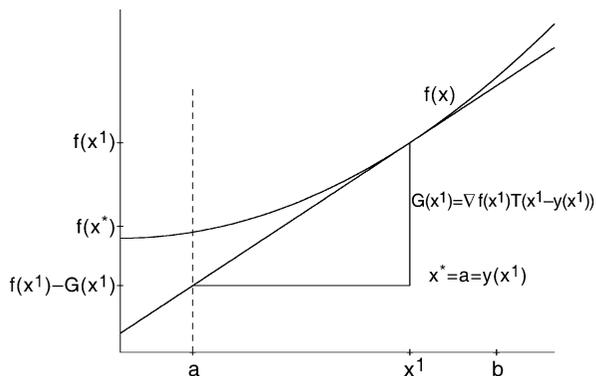

$$\begin{aligned} d(x) &= f(x) + \min_{y \in S} \nabla f(x)^\top (y - x) \\ &= f(x) - G(x). \end{aligned}$$

□

Expressing the duality gap in terms of  $x$  allows a simple interpretation of weak and strong duality in the convex case. Figure 4 illustrates the gap function in one variable with  $S$  being the interval  $[a, b]$ . Let  $x = x^1$ . The linear function

$$f(x^1) + \nabla f(x^1)^\top (y - x^1)$$

is the tangent line shown. It has a minimum in  $S$  at  $y(x^1) = a$  which, by convexity, must lie below  $f(x^*)$ . Hence the weak duality result holds:  $f(x^*) \geq f(x^1) - G(x^1) =$

**Lagrangian Duality: BASICS, Figure 4**

**A one variable interpretation of weak and strong duality**

$d(x^1)$ . Strong duality occurs when  $x^1 = x^*$  and the minimum of the linear function (i. e., the tangent at  $x^*$ ) has the value  $f(x^*)$ . In this case  $G(x^*) = 0$ . If  $x^*$  were at an interior point of  $S$ , and/or if  $x^1$  is infeasible to  $S$ , this same interpretation holds provided only that  $f(x^1)$  and  $\nabla f(x^1)$  are defined.

## Summary

This section has illustrated basic results and geometrical interpretations of Lagrangian duality. The reference list below is a selection of texts and journal articles on this topic for further reading.

Proximal algorithms

Optimization problems concern the minimization or maximization of functions over some set of conditions called constraints. The original treatment of constrained optimization problems was to deal only with equality constraints via the introduction of *Lagrange multipliers* which found their origin in basic mechanics. Modeling real world situations often requires using inequality constraints leading to more challenging optimization problems. Lagrange multipliers are used in optimality conditions and play a key role to devise algorithms for constrained problems. What will be summarized here are the basic elements of various algorithms

based on Lagrangian multipliers to solve constrained optimization problems, and particularly convex optimization problems. A standard formulation of an optimization problem is:

$$(O) \quad \min \{f(x) : x \in X \cap C\},$$

where  $X$  is a certain subset of  $\mathbf{R}^n$  and  $C$  is the set of constraints described by equality and inequality constraints

$$C = \left\{ x \in \mathbf{R}^n : \begin{array}{l} g_i(x) \leq 0, \quad i = 1, \dots, m, \\ h_i(x) = 0, \quad i = 1, \dots, p \end{array} \right\}.$$

All the functions in problem (O) are real valued functions on  $\mathbf{R}^n$ , and the set  $X$  can be described by more abstract constraints of the problem. A point  $x \in X \cap C$  is called a *feasible solution* of the problem, and an *optimal solution* is any feasible point where the local or global minimum of  $f$  relative to  $X \cap C$  is actually attained. By a *convex problem* we mean the case where  $X$  is a convex set, the functions  $f, g_1, \dots, g_m$  are convex and  $h_1, \dots, h_p$  are affine. Recall that a set  $S \subset \mathbf{R}^n$  is *convex* if the line segment joining any two different points of  $S$  is contained in it.

Let  $S$  be a convex subset of  $\mathbf{R}^n$ . A real valued function  $f: S \rightarrow \mathbf{R}$  is convex if for any  $x, y \in S$  and any  $\lambda \in [0, 1]$ ,

$$f(\lambda x + (1 - \lambda)y) \leq \lambda f(x) + (1 - \lambda)f(y).$$

Convexity plays a fundamental role in optimization (even in nonconvex problems). One of the key facts is that when a convex function is minimized over a convex set, every local optimal solution is global. Another, fundamental point is that a powerful duality theory can be developed for convex problems, which as we shall see, is also at the root of the development and analysis of Lagrangian multiplier methods.

### Augmented Lagrangians

The basic idea of augmented Lagrangian methods for solving constrained optimization problems, also called *multiplier methods*, is to transform a constrained problem into a sequence of unconstrained problems. The approach differs from the penalty-barrier methods, [13] from the fact that in the functional defining the unconstrained problem to be solved, in addition to a penalty parameter, there are also multipliers associated with the

constraints. Multiplier methods can be seen as a combination of penalty and dual methods. The motivation for these methods came from the desire of avoiding ill-conditioning associated with the usual penalty-barrier methods. Indeed, in contrast to penalty methods, the penalty parameter need not to go to infinity to achieve convergence of the multiplier methods. As a consequence, the augmented Lagrangian has a ‘good’ conditioning, and the methods are robust for solving nonlinear programs. Augmented Lagrangian methods were proposed independently by M.R. Hestenes [16] and M.J.D. Powell [26] for the case of equality constraints, and extended for the case of inequality constraints by R.T. Rockafellar [27]. Many other researchers have contributed to the development of augmented Lagrangian methods, and for an excellent treatment and comprehensive study of multiplier methods, see [7] and references therein.

### Quadratic Lagrangian

We start by briefly describing the basic steps involved in generating a multiplier method for the equality constrained problem

$$(E) \quad \min \{f(x) : h_i(x) = 0, i = 1, \dots, p\}.$$

Here  $f$  and  $h_i$  are real valued functions on  $\mathbf{R}^n$  and no convexity is assumed (which will not help anyway because of the nonlinear equality constraints). Also for simplicity we let  $X = \mathbf{R}^n$ . The ordinary Lagrangian associated with (E) is

$$l(x, y) = f(x) + \sum_{i=1}^p y_i h_i(x).$$

One of the oldest and simplest way to solve (E) is by sequential minimization of the Lagrangian ([2]). Namely, we start with an initial multiplier  $y_k$  and minimize  $l(x, y^k)$  over  $x \in \mathbf{R}^n$  to produce  $x^k$ . We then update the multiplier sequence via the formula:

$$y_i^{k+1} = y_i^k + s^k h_i(x^k), \quad i = 1, \dots, p,$$

where  $s_k$  is a stepsize parameter. The rational behind the above method is that it can be simply interpreted as a gradient-type algorithm to solve an associated dual problem. Unfortunately, such a method while simple requires too many assumptions on the problem’s data

to generate points converging rapidly toward an optimal solution. Thus this *primal-dual framework* is not in general particularly attractive. However, combining the primal-dual idea to the one of penalty leads to another class of algorithms called *multiplier methods*. In these methods one uses instead of the classical Lagrangian  $l(x, y)$  a ‘penalized’ Lagrangian of the form:

$$P_c(x, y) = f(x) + \sum_{i=1}^p y_i h_i(x) + \frac{c}{2} \sum_{i=1}^p h_i^2(x),$$

where  $c > 0$  is a penalty parameter. Then, starting with an initial multiplier  $y^k$  and penalty parameter  $c^k$ , the augmented Lagrangian  $P_c$  is minimized with respect to  $x$  and at the end of each minimization, the multipliers (and sometimes also the penalty parameter) are updated according to some scheme and we continue the process until convergence. More precisely, the method of multipliers generates the sequences  $\{y^k\} \subset \mathbf{R}^m$ ,  $\{x^k\} \subset \mathbf{R}^n$  as follows. Given a sequence of nondecreasing scalars  $c_k > 0$ , compute

$$\begin{aligned} x^{k+1} &\in \arg \min \{L_{c_k}(x, y^k) : x \in \mathbf{R}^n\}, \\ y_i^{k+1} &= y_i^k + c_k h_i(x^{k+1}), \quad i = 1, \dots, p. \end{aligned}$$

The rational behind the updating of the multipliers  $y^k$  is that if the generated sequence  $x^k$  converges to a local minimum then the sequence  $y^k$  will converge to the corresponding Lagrange multiplier  $y^*$ . Under reasonable assumptions, this happens without increasing the parameter  $c^k$  to infinity and thus avoids the difficulty with ill-conditioning. The above scheme provides with the key steps in devising a multiplier method for equality constrained optimization problems. We now turn to the case of problems with inequality constraints:

$$(I) \quad \min \{f(x) : g_i(x) \leq 0, i = 1, \dots, m\}.$$

One simple way to treat this case is to transform the inequality constraints to equality using squared variables and then apply the multiplier framework previously outlined. Thus, we convert problem (I) to the equality constrained problem in the variables  $(x, z)$ :

$$\begin{cases} \min & f(x) \\ \text{s.t.} & g_i(x) + z_i^2 = 0, \quad i = 1, \dots, m, \end{cases}$$

where  $z \in \mathbf{R}^m$  are additional variables. The quadratic augmented Lagrangian to be minimized with respect to

$(x, z)$  thus takes the form:

$$Q_c(x, z, y) = f(x) + \sum_{i=1}^m y_i(g_i(x) + z_i^2) + \frac{c}{2} \sum_{i=1}^m (g_i(x) + z_i^2)^2.$$

The key observation here is that the minimization with respect to  $z$  can be carried out analytically. One can verify via simple calculus that for fixed  $(x, y)$ ,  $\min_{z \in \mathbb{R}^m} Q_c(x, z, y) = L_c(x, y)$ , with

$$L_c(x, y) = f(x) + \frac{1}{2c} \sum_{i=1}^m [\max^2\{0, y_i + c g_i(x)\} - y_i^2].$$

Summarizing, the multiplier method for the inequality constrained problem (I) consists of the following two steps:

$$x^{k+1} \in \arg \min \{L_{c_k}(x, y^k) : x \in \mathbb{R}^n\},$$

$$y^{k+1} = \max\{0, y^k + c_k g(x^{k+1})\}.$$

For the general optimization problem (O), namely the case of mixed equality and inequality constraints, Lagrangian multiplier methods can be developed in a similar fashion. Convergence results to a local minimum for the above schemes can be established under second order sufficiency assumptions, ([7,28]). In the case of convex programs, namely when in problem (I) the functions  $f, g_1, \dots, g_m$  are assumed convex functions, (or more generally in problem (O), if we also assume  $h_i$  affine and  $X$  convex), much stronger convergence results can be established under mild assumptions ([29]). A typical result is as follows.

*Assumption 1* The set of optimal solutions of the convex problem (I) is nonempty and compact and the set of multiplier is nonempty and compact.

The assumption on the optimal set of multipliers is guaranteed under the standard *Slater constraint qualification*:

$$\exists \hat{x} : g_i(\hat{x}) \leq 0, \quad i = 1, \dots, m.$$

Under assumption 1, one can prove that the sequence  $y^k$  converges to some Lagrange multiplier  $y^*$

and any limit point of the sequence  $x^k$  is an optimal solution of the convex program. Note that we do not require that  $c_k$  is sufficiently large and convergence is obtained from any starting point  $y^0 \in \mathbb{R}^m$ .

The multiplier method for inequality constrained problems was derived by using slack variables in the inequality constraints and then by applying the multiplier method which was originally devised for problems having only equality constraints. An alternative way of constructing an augmented Lagrangian method is via the *proximal framework*.

### Proximal Minimization

Consider the convex optimization problem

$$(C) \quad \min \{F(x) : x \in \mathbb{R}^n\},$$

where  $F: \mathbb{R}^n \rightarrow (-\infty, +\infty]$  is a proper, lower semicontinuous convex function. One method to solve (C) is to ‘regularize’ the objective function using the *proximal map* of J.-J. Moreau [22]. Given a real positive number  $c$ , a *proximal approximation* of  $f$  is defined by:

$$F_c(x) = \inf_u \{F(u) + (2c)^{-1} \|x - u\|^2\}. \tag{1}$$

The resulting function  $F_c$  enjoys several important properties: it is convex and differentiable with gradient which is Lipschitz with constant  $(c^{-1})$  and when minimized possesses the same set of minimizers and the same optimal value than problem (C). The quadratic regularization process of the function  $f$  leads to an iterative procedure for solving problem (C), called the *proximal point algorithm* [21,30]. The method is as follows: given an initial point  $x_0 \in \mathbb{R}^n$  a sequence  $\{x_k\}$  is generated by solving:

$$x^{k+1} = \arg \min \left\{ F(x) + \frac{1}{2c_k} \|x - x^k\|^2 \right\}, \tag{2}$$

where  $\{c_k\}_{k=1}^\infty$  is a sequence of positive numbers.

One of the most powerful application of the proximal algorithm is when applied to the dual of an optimization problem. Indeed, as shown by Rockafellar [27,29], a direct calculation shows that  $L_c$  can be written as

$$L_c(x, y) = \max_{\lambda \in \mathbb{R}_+^m} \left\{ l(x, \lambda) - \frac{1}{2c} \|\lambda - y\|^2 \right\}, \tag{3}$$

where the maximum is attained uniquely at  $\lambda_i = \max\{0, y_i + c g_i(x)\}$ ,  $i = 1, \dots, m$ . Here  $l: \mathbf{R}^n \times \mathbf{R}_+^m \rightarrow \mathbf{R}$  denotes the usual Lagrangian associated with the inequality constrained problem (I) and  $\mathbf{R}_+^m$  stands for the nonnegative orthant. This shows that the quadratic augmented Lagrangian is nothing else but the Moreau proximal regularization of the ordinary Lagrangian, and the quadratic multiplier method can be interpreted as applying the proximal minimization algorithm on the dual problem associated with (I):

$$(D) \quad \sup \{d(y): y \geq 0\},$$

where  $d(y) := \inf_x l(x, y)$  is the dual functional. This interplay between the proximal algorithm and multiplier methods is particularly interesting since it offers the possibility of designing and analyzing the convergence properties of the later from the former, and also leads to consider useful potential extensions of multiplier methods which are discussed next.

### Modified Lagrangians

One of the main disadvantages of the quadratic multiplier methods for inequality constrained problems is that even when the original problem is given twice continuously differentiable, the corresponding functional  $L_c$  is not. Indeed, note that with twice continuously differentiable data  $\{f, g_i\}$ , the augmented Lagrangian  $L_c$  is continuously differentiable in  $x$ . However, the Hessian matrix of  $L_c$  is discontinuous for all  $x$  such that  $g_i(x) = -c^{-1} y_i$ . This may cause difficulties in designing an efficient unconstrained minimization algorithm for  $L_c$  and motivates the search for alternative augmented Lagrangian to handle inequality constrained problems, which we call here *modified Lagrangians*. These Lagrangians possess better differentiability properties to allow the use of efficient Newton-like methods in the minimization step. Modified Lagrangians can be found in several works, [1,15,19,20]. An approach originally developed in [19] proposed a class of methods which uses instead of  $L_c$  a modified Lagrangian of the form:

$$B_c(x, y) := f(x) + c^{-1} \sum_{i=1}^m y_i \psi(c g_i(x)),$$

where  $\psi$  is a scalar penalty function which is at least  $C^2$  and satisfies some other technical conditions. For each

choice of  $\psi$  we then have a multiplier method which consists of the sequence of unconstrained minimization problems

$$x^{k+1} \in \arg \min_{x \in \mathbf{R}^n} B_{c^k}(x, y^k),$$

followed by the multiplier updates

$$y_i^{k+1} = y_i^k \psi'(c_k g_i(x^{k+1})), \quad i = 1, \dots, m.$$

The multiplier updating formula can be simply explained as follows. Suppose the functions in problem (I) are given differentiable, then  $x^{k+1}$  minimizes  $B_{c_k}(x, y^k)$  means that  $\nabla_x B_{c_k}(x^{k+1}, y^k) = 0$ , i. e.,

$$\nabla f(x^{k+1}) + \sum_{i=1}^m y_i^k \psi'(c_k g_i(x^{k+1})) \nabla g_i(x^{k+1}) = 0,$$

and using the multiplier updates defined above the equation reduces to:

$$\nabla f(x^{k+1}) + \sum_{i=1}^m y_i^{k+1} \nabla g_i(x^{k+1}) = 0,$$

showing that  $(x^{k+1}, y^{k+1})$  also satisfies the optimality conditions for minimizing the classical Lagrangian, namely  $\nabla_x l(x^{k+1}, y^{k+1}) = 0$ . Interesting special cases of the generic method described above includes the exponential method ([23,35]) with the choice  $\psi(t) = e^t - 1$  and the modified barrier method [24] which is based on the choice  $\psi(t) = -\ln(1-t)$ . More examples and further analysis of these methods can be found in [25].

Another way of constructing modified Lagrangians is in view of the results from the previous section, to try alternative proximal regularization terms which could lead to better differentiability properties of the corresponding augmented Lagrangian functional. This approach was considered in [32], who suggested new classes of proximal approximation of a function given by

$$F_\lambda(x) := \inf_u \{f(u) + \lambda^{-1} D(u, x)\}. \tag{4}$$

Here,  $D(\cdot, \cdot)$ , which replaces the quadratic proximal term in (1), is a measure of ‘closeness’ between  $x, y$  satisfying  $D(x, y) \geq 0$  with equality if and only if  $x = y$ . One generic form for  $D$  is the use of a ‘proximal-like’

term defined by

$$D(x, y) := d_\varphi(x, y) := \sum_{i=1}^n y_i \varphi(y_i^{-1} x_i),$$

where  $\varphi$  is a given convex function defined on the non-negative real line and which satisfies some technical conditions ([33]). The motivation of using such functional emerges from the desire of eliminating nonnegativity constraints such as the ones present in the dual problem. Thus, by mimicking (2) and (3) with the proximal term  $d_\varphi$ , one can design a wide variety of modified Lagrangians methods with an appropriate choice of  $\varphi$ . The basic steps of the modified multipliers method then emerging can be described as follows: Given a sequence of positive numbers  $\{c_k\}$ , and initial points  $x^k \in \mathbf{R}^n$ ,  $y^k \in \mathbf{R}_+^m$  (the positive orthant) generate iteratively the next points by solving

$$x^{k+1} \in \arg \min \left\{ M_{c_k}(x, y^k) : x \in \mathbf{R}^n \right\}, \quad (5)$$

followed by the multiplier updates

$$y^{k+1} \in \arg \max_{y \geq 0} \{ y' g(x^{k+1}) - c_k^{-1} d_\varphi(y, y^k) \}, \quad (6)$$

where  $M_c$  is the modified Lagrangian defined by

$$M_c(x, y) = \sup_{\mu \in \mathbf{R}_+^m} \{ l(x, \mu) - c^{-1} d_\varphi(\mu, y) \} \quad (7)$$

i. e., the proximal-like regularization of the usual Lagrangian  $l(x, \mu)$  associated with problem (I). In the equation (6),  $g(x)$  denotes the column vector  $(g_1(x), \dots, g_m(x))' \in \mathbf{R}^m$  and the prime denotes transposition. The method is viable since both (6) and (7) can be solved analytically, and the computational analysis and effort should concentrate on (5). This method of multipliers is nothing else but a proximal-like algorithm applied to the dual problem (D) ([17]) i. e., starting with  $y^0 \in \mathbf{R}_+^m$ , generate a sequence  $\{y^k\}$  by solving

$$y^{k+1} = \arg \max_{y \geq 0} \{ d(y) - c_k^{-1} d_\varphi(y, y^k) \}.$$

The above scheme gives rise to a rich family of numerical methods, which includes (with an appropriate choice of  $\varphi$ ) several classes of nonquadratic multiplier methods ([7,24,35]). One of the main advantage of using these modified multiplier methods is that in contrast with the usual quadratic augmented Lagrangian

function, the modified Lagrangian for various choices of  $d_\varphi$  is twice continuously differentiable if the problem's data  $f, g$  are. Thus, this opens the possibility of using Newton methods for solving efficiently (5).

Under assumption 1 and appropriate condition on the kernel  $\varphi$  one can prove convergence results for these modified multiplier methods similar to the one obtains in the quadratic case ([17]). There has been considerable recent research on modified Lagrangian methods and for further results see [3,4,5,11,18,25].

The Lagrangian functional plays a central role in the analysis and algorithmic development of constrained optimization problems. Lagrangian based methods and the related proximal framework have been used in other optimization contexts, such as convexification of nonconvex optimization problems [6,28], decomposition algorithms [9,12,31,34], semidefinite programming [10] and in many other applications, see e. g., [8,14] where more references can be found.

### Abstract

The Laplace method has found many applications in the theoretical and applied study of optimization problems. It has been used to study: the asymptotic behavior of stochastic algorithms, ‘phase transitions’ in combinatorial optimization, and as a smoothing technique

for non-differentiable minimax problems. This article describes the theoretical foundation and practical applications of this useful technique.

**Background**

Laplace’s method is based on an ingenious trick used by Laplace in one his papers [19]. The technique is most frequently used to perform asymptotic evaluations to integrals that depend on a scalar parameter  $t$ , as  $t$  tends to infinity. Its use can be theoretically justified for integrals in the following form:

$$I(t) = \int_{\mathcal{A}} \exp \left\{ \frac{-f(x)}{T(t)} \right\} d\Lambda(x).$$

Where  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ ,  $T : \mathbb{R} \rightarrow \mathbb{R}$ , are assumed to be smooth, and  $T(t) \rightarrow 0$  as  $t$  tends to  $\infty$ .  $\mathcal{A}$  is some compact set, and  $\Lambda$  is some measure on  $\mathcal{B}$  (the  $\sigma$ -field generated by  $\mathcal{A}$ ). We know that since  $\mathcal{A}$  is compact, the continuous function  $f$  will have a global minimum in  $\mathcal{A}$ . For simplicity, assume that the global minimum  $x^*$  is unique, and that it occurs in the interior  $\mathcal{A}$ . Under these conditions, and as  $t$  tends to infinity, only points that are in the immediate neighborhood of  $x^*$  contribute to the asymptotic expansion of  $I(t)$  for large  $t$ . The heuristic argument presented above can be made precise. The complete argument can be found in [2], and in [4]. Instead we give a heuristic but didactic argument that is usually used when introducing the method.

**Heuristic Foundations of the Method**

For the purpose of this subsection only, assume that  $f$  is a function of one variable, and that  $\mathcal{A}$  is given by some interval  $[a, b]$ . It will be instructive to give a justification of the method based on the one dimensional integral:

$$K(t) = \int_a^b \exp \left\{ -\frac{f(x)}{t} \right\} dx.$$

Suppose that  $f$  has a unique global minimum, say  $c$ , such that  $c \in (a, b)$ . As  $t$  is assumed to be large, we only need to take into account points near  $c$  when evaluating  $K(t)$ . We therefore approximate  $K(t)$  by  $K(t; \epsilon)$ . The latter quantity is given by:

$$K(t; \epsilon) = \int_{c-\epsilon}^{c+\epsilon} \exp \left\{ -\frac{f(x)}{t} \right\} dx.$$

Expanding  $f$  to second order, and by noting that  $f'(c) = 0$ , we obtain the following approximation:

$$\begin{aligned} K(t; \epsilon) &\approx \int_{c-\epsilon}^{c+\epsilon} \exp \left\{ -\frac{f(c) + \frac{1}{2}f''(c)(x-c)^2}{t} \right\} dx \\ &= \exp \left\{ -\frac{f(c)}{t} \right\} \int_{c-\epsilon}^{c+\epsilon} \exp \left\{ -\frac{f''(c)(x-c)^2}{2t} \right\} dx. \end{aligned}$$

The limits of the integral above can be extended to infinity. This extension can be justified by the fact only points around  $c$  contribute to the asymptotic evaluation of the integral.

$$\begin{aligned} K(t; \epsilon) &\approx \exp \left\{ -\frac{f(c)}{t} \right\} \int_{-\infty}^{+\infty} \exp \left\{ -\frac{f''(c)(x-c)^2}{2t} \right\} dx \\ &= \exp \left\{ -\frac{f(c)}{t} \right\} \sqrt{\frac{2\pi t}{f''(c)}}. \end{aligned}$$

In conclusion we have that:

$$\lim_{t \rightarrow \infty} K(t) = \exp \left\{ -\frac{f(c)}{t} \right\} \sqrt{\frac{2\pi t}{f''(c)}}.$$

Rigorous justifications of the above arguments can be found in [4]. These types of results are standard in the field of asymptotic analysis. The same ideas can be applied to optimization problems.

**Applications**

Consider the following problem:

$$\begin{aligned} F^* &= \min f(x) \\ \text{s.t } g_i(x) &\leq 0 \quad i = 1, \dots, l. \end{aligned} \tag{1}$$

Let  $S$  denote the feasible region of the problem above, and assume that it is nonempty, and compact, then:

$$\lim_{t \downarrow 0} -\epsilon \ln c(t) = F^*. \tag{2}$$

Where,

$$\begin{aligned} c(t) &\triangleq \int_S \exp \left\{ \frac{-f(x)}{t} \right\} d\Lambda \\ &= \int_{\mathbb{R}^n} \exp \left\{ \frac{-f(x)}{t} \right\} I_x(S) d\Lambda. \end{aligned} \tag{3}$$

$\Lambda$  is any measure on  $(\mathbb{R}^n, \mathcal{B})$ . A proof of Eq. (2) can be found in [16].

The relationship in Eq. (3) can be evaluated using the Laplace method. The link between the Laplace method and optimization has been explored in:

- Stochastic methods for global optimization.
- Phase transitions in combinatorial optimization.
- Algorithms for worst case analysis.

These application areas will be explored next.

### Stochastic Methods for Global Optimization

Global optimization is concerned with the computation of global solutions of Eq. (1). In other words, one seeks to compute  $F^*$ , and if possible obtaining points from the following set:

$$S^* = \{x \in S \mid f(x) = F^*\}.$$

Often the only way to solve such problems is by using a stochastic method. Deterministic methods are also available but are usually applicable to low dimensional problems. When designing stochastic methods for global optimization, it is often the case that the algorithm can be analyzed as a stochastic process. Then in order to analyze the behavior of the algorithm we can examine the asymptotic behavior of the stochastic process. In order to perform this analysis we need to define a probability measure that has its support in  $S^*$ . This strategy has been implemented in [3,6,7,8,9,10,16].

A well known method for obtaining a solution to an unconstrained optimization problem is to consider the following Ordinary Differential Equation (ODE):

$$dX(t) = -\nabla f(X(t))dt. \quad (4)$$

By studying the behavior of  $X(t)$  for large  $t$ , it can be shown that  $X(t)$  will eventually converge to a stationary point of the unconstrained problem. A review of, so called, continuous-path methods can be found in [22]. More recently, application of this method to large scale problems was considered by Li-Zhi et al. [13]. A deficiency of using Eq. (4) to solve optimization problems is that it will get trapped in local minima. In order to allow the trajectory to escape from local minima, it has been proposed by various authors (e. g. [1,3,7,8,12,16]) to add a stochastic term that would allow the trajectory to “climb” hills. One possible augmentation to Eq. (4)

that would enable us to escape from local minima is to add noise. One then considers the *diffusion process*:

$$dX(t) = -\nabla f(X(t))dt + \sqrt{2T(t)}dB(t). \quad (5)$$

Where  $B(t)$  is the standard Brownian motion in  $\mathbb{R}^n$ . It has been shown in [3,7,8], under appropriate conditions on  $f$ , that if the *annealing schedule* is chosen as follows:

$$T(t) \triangleq \frac{c}{\log(2+t)}, \quad \text{for some } c \geq c_0, \quad (6)$$

where  $c_0$  is a constant positive scalar (the exact value of  $c_0$  is problem dependent). Under these conditions, as  $t \rightarrow \infty$ , the transition probability of  $X(t)$  converges (weakly) to a probability measure  $\Pi$ . The latter, has its support on the set of global minimizers. A characterization of  $\Pi$  was given by Hwang in [11]. It was shown that  $\Pi$  is the weak limit of the following, so called, *Boltzmann density*:

$$p(t, x) = \left[ \exp \left\{ -\frac{f(x)}{T(t)} \right\} \right] \left[ \int_{\mathbb{R}^n} \exp \left\{ -\frac{f(x)}{T(t)} \right\} dx \right]^{-1}. \quad (7)$$

Discussion of the conditions for the existence of  $\Pi$ , can be found in [11]. A description of  $\Pi$  in terms of the Hessian of  $f$  can also be found in [11]. Extensions of these results to constrained optimization problems appear in [16].

### Phase Transitions in Combinatorial Optimization

The aim in combinatorial optimization is to select from a finite set of configurations of the system, the one that minimizes an objective function. The most famous combinatorial problem is the Travelling Salesman Problem (TSP). A large part of theoretical computer science is concerned with estimating the complexity of combinatorial problems. Loosely speaking, the aim of computational complexity theory is to classify problems in terms of their degree of difficulty. One measure of complexity is time complexity, and worst case time complexity has been the aspect that received most attention. We refer the interested reader to [15] for results in this direction. We will briefly summarize results that have to do with average time complexity, the Laplace method, and phase transitions.

Most of complexity theory is concerned with worst case complexity. However, many useful methods (e. g. the simplex method) will require an exponential amount of time to converge only in pathological cases. It is therefore of great interest to estimate average case complexity. The physics community has recently proposed the use of tools from statistical mechanics as one way of estimating average case complexity. A review in the form of a tutorial can be found in [14]. Here we just briefly adumbrate the main ideas.

The first step in the statistical mechanics approach is to define a probability measure on the configuration of the system. This definition is done with the Boltzmann density:

$$p_t(C) = \frac{\exp\{-\frac{1}{t}f(C)\}}{\sum_C \exp\{-\frac{1}{t}f(C)\}}.$$

The preceding equation is of course the discrete version of Eq. (7). Using the above definition, the average value of the objective function is given by:

$$\langle f_t \rangle = \sum_C p_t(C) f(C).$$

Tools and techniques of statistical mechanics can be used to calculate ‘computational phase transitions’. A computational phase transition is an abrupt change in the computational effort required to solve a combinatorial optimization problem. It is beyond the scope of this article to elaborate on this interesting area of optimization. We refer the interested reader to the review in [14]. The book of Talagrand [20] presents some rigorous results on this subject.

### Worst Case Optimization

In many areas where optimization methods can be fruitfully applied, worst case analysis can provide considerable insight into the decision process. The fundamental tool for worst case analysis is the continuous minimax problem:

$$\min_{x \in X} \Phi(x),$$

where  $\Phi(x) = \max_{y \in Y} f(x, y)$ . The continuous minimax problem arises in numerous disciplines, including  $n$ -person games, finance, economics and policy optimization (see [18] for a review). In general, they are used by the decision maker to assess the worst-case

strategy of the opponent and compute the optimal response. The opponent can also be interpreted as nature choosing the worst-case value of the uncertainty, and the solution would be the strategy which ensures the optimal response to the worst-case. Neither the robust decision maker nor the opponent would benefit by deviating unilaterally from this strategy. The solution can be characterized as a saddle point when  $f(x, \cdot)$  is convex in  $x$  and  $f(\cdot, y)$  is concave in  $y$ . A survey of algorithms for computing saddle points can be found in [5,18].

Evaluating  $\Phi(x)$  is extremely difficult due to the fact that global optimization is required over  $Y$ . Moreover, this function will in general be non-differentiable. For this reason, it has been suggested by many researchers (e. g. [17,21]) to approximate  $\Phi(x)$  with  $\Phi(x; t)$  given by:

$$\Phi(x; t) = \int_Y \exp\left\{-\frac{f(x, y)}{t}\right\} dy.$$

This is of course another application of the Laplace method, and it can easily be seen that:

$$\lim_{t \downarrow 0} -t \ln \Phi(x; t) = \Phi(x).$$

This idea has been implemented in [17,21] with considerable success.

Large scale trust region problem; Exact penalty function; D.C. programming; Eigenvalue problem; Semidefinite programming

The *trust region* (TR) problem consists in minimizing a general quadratic function  $q: \mathbf{R}^n \rightarrow \mathbf{R}$  of the type

$$q(x) = \frac{1}{2}x^\top Qx + c^\top x$$

subject to an ellipsoidal constraint  $x^\top Hx \leq r^2$  with the symmetric matrix  $H$  positive definite and  $r$  a positive scalar. By rescaling and without loss of generality, it can be assumed for sake of simplicity  $H = I$ , hence the TR problem is

$$\begin{cases} \min & q(x) \\ \text{s.t.} & \|x\|^2 \leq r^2, \end{cases} \quad (1)$$

where  $\|\cdot\|$  denotes the  $\ell_2$  norm.

The interest in this problem initially arose in the context of unconstrained optimization when  $q(x)$  is a local quadratic model of the objective function which is 'trusted' to be valid over a restricted ellipsoidal region centered around the current iterate. However, it has been shown later that problems with the same structure of (1) are at the basis of algorithms for solving general constrained nonlinear programming problems (e.g. [2,14,19,21,27,28] and references therein), and for obtaining bounds for integer programming problems

(e. g. [10,11,12,17,18,26]; cf. also ► **Integer programming**).

Many papers have been devoted to study the specific features of Problem (1). It is well known [7,22] that a feasible point  $x^*$  is a global solution for (1) if and only if there exists a scalar  $\lambda^* \geq 0$  such that the following KKT conditions are satisfied:

$$\begin{aligned}(Q + \lambda^* I)x^* &= -c, \\ \lambda^*(\|x^*\|^2 - r^2) &= 0,\end{aligned}$$

and furthermore  $Q + \lambda^* I \succcurlyeq 0$ , where  $\succcurlyeq$  denotes positive semidefiniteness of the matrix.

Note that a complete characterization of global minimizers is given without requiring any convexity assumption on the matrix  $Q$ . Moreover, it has been proved that an approximation to the global solution can be computed in polynomial time (see, for example, [1,24,25]). Hence Problem (1) can be considered an ‘easy’ problem from a theoretical point of view. These peculiarities led to the development of ‘ad hoc’ algorithms for finding a global solution of Problem (1). The first ones proposed in [7,16,22] were essentially based on the solution of a sequence of linear system of the type  $(Q + \lambda_k I)x = -c$  for a sequence  $\{\lambda_k\}$ . These algorithms produce an approximate global minimizer of Problem (1), but rely on the ability to compute a Cholesky factorization of the matrix  $(Q + \lambda_k I)$  at each iteration  $k$ , and hence these methods are appropriate when forming a factorization for different values of  $\lambda_k$  is realistic in terms of both memory and time requirements. Indeed, they are appropriate for large scale problems with special structure, but in the general case, when no sparsity pattern is known, one cannot rely on factorizations of the matrices involved.

Thus one concentrates on iterative methods of conjugate gradient type (cf. ► **Conjugate-gradient methods**) that require only matrix-vector products. Among the methods that have been proposed to solve *large scale trust region* problems, the following two main categories can be identified:

- methods that produce a sequence of KKT points of (1) with progressive improvement of the objective function;
- methods that solve (1) via a sequence of parametric eigenvalue problems.

### Algorithms Based on Successive Improvement of KKT Points

Methods in this class are based on special properties of KKT points of Problem (1). Indeed one can prove the following properties:

- 1) given a KKT point that is not a global minimizer, it is possible to find a new feasible point with a lower value of the objective function [5,13];
- 2) the number of distinct values of the objective function  $q(x)$  at KKT points is bounded from above by  $2m + 2$  where  $m$  is the number of negative eigenvalues of  $Q$  [13].

Exploiting these properties, a global minimizer of Problem (1) can be found, by applying a finite number of times an algorithm that, starting from a feasible point, locates a KKT point with a lower value of the objective function.

An algorithmic scheme of methods in this framework is summarized in the pseudocode of Table 1. The procedure described above is well-posed in the sense that it enters the ‘DO cycle’ a finite number of steps, since by Property 2, the function can assume at most a finite number of values at a KKT point.

To complete the scheme of Table 1 and obtain an efficient algorithm for the solution of Problem (1), it remains to specify how to move from a non global KKT

procedure TR-IMPROVE-KKT()
  input instance (Q, c, r, x0);
  Set k = 0; x = xk; (starting point)
  find a KKT point  $\hat{x}^k$  s.t.  $q(\hat{x}^k) \leq q(x^k)$ ;
  DO (until a global minimizer is found)
    (escape from a nonglobal KKT point)
    find x s.t.  $\|x\| \leq r$ ,  $q(x) < q(\hat{x}^k)$ ;
    (update starting point)
    set k = k + 1, xk = x;
    (find a ‘better’ KKT point)
    find a KKT point  $\hat{x}^k$  s.t.
       $q(\hat{x}^k) \leq q(x^k)$ ;
  OD;
  RETURN (solution)
END TR-IMPROVE-KKT;

```

point to a feasible point while improving the objective function, and how to define a globally and 'fast' convergent algorithm to locate a KKT point.

To check global optimality of a KKT point (i. e. to check if  $Q + \lambda I \geq 0$ ), one needs an estimate of the KKT multiplier  $\lambda$  corresponding to the point  $x$ , and has to verify whether  $\lambda \geq -\lambda_{\min}(Q)$ . To obtain  $\lambda$  the following multiplier function can be used

$$\lambda(x) = -\frac{1}{2r^2}x^\top(Qx + c), \quad (2)$$

which is consistent, namely at a KKT point  $\lambda(x) = \lambda$ . If  $\lambda < -\lambda_{\min}(Q)$ , then  $(x, \lambda)$  is a nonglobal KKT point and a negative curvature direction for the matrix  $Q + \lambda I$  exists, namely a vector  $z$  such that  $z^\top(Q + \lambda I)z < 0$ . To perform the step 'escape from a non global KKT point', one can use such a direction. Roughly speaking and without discussing the details (see [5,13]), a new feasible point can be obtained by moving from  $x$  along  $z$  itself or along a direction easily obtainable from  $z$  of a computable quantity  $\alpha$ . The efficiency of this step depends on the ability of finding efficiently such a vector  $z$ . Hence a procedure that finds an approximation of the minimum eigenvalue of  $(Q + \lambda I)$  and of the corresponding eigenvector is needed. In the large scale setting, this can be done efficiently by using a Lanczos method [3,23] which meets the requirement of limited storage and needs only matrix-vector products.

In the algorithmic scheme of Table 1, it remains to define how to find efficiently a KKT point for Problem (1). Two different approaches have been recently (1998) proposed to perform this step; one is based on a continuously differentiable exact penalty function approach, the other is based on a difference of convex function approach. In both cases, the basic idea is to reformulate the constrained Problem (1) in a different form that allows one to use ideas typical of other fields of mathematical programming. Both approaches, which are described briefly in the sequel, treat indifferently the so called 'easy and hard' cases of Problem (1) and require only matrix vector products.

### Exact Penalty Function Based Algorithm (EPA)

The main idea at the basis of a *continuously differentiable exact penalty function approach* is the reformulation of the constrained Problem (1) as an unconstrained

one. In particular, a continuously differentiable function  $P(x)$  can be defined [13] such that Problem (1) is 'equivalent' to the unconstrained problem

$$\min_{x \in \mathbb{R}^n} P(x).$$

The merit function takes full advantage of the structure of Problem (1) and it is a piecewise quartic function, whose definition relies on the particular multiplier function (2). The analytic expression of  $P$  is

$$P(x) = q(x) - \frac{\varepsilon}{4}\lambda(x)^2 + \frac{\varepsilon}{4} \max\left(0, \frac{2}{\varepsilon}(\|x\|^2 - r^2) + \lambda(x)\right)^2,$$

where  $0 < \varepsilon < 2r^4/[r^2(\|Q\| + 1) + \|c\|^2]$ . The function  $P(x)$  has the following features:

- it has compact level sets;
- stationary (global minimum) points of  $P(x)$  are KKT (global minimum) points of Problem (1) and vice versa; moreover  $P(x) = q(x)$  at these points;
- the penalty parameter  $\varepsilon$  need not be updated;
- for points such that  $\|x\|^2 \leq r^2$  it results  $P(x) \leq q(x)$ ;
- $P(x)$  is twice continuously differentiable in a neighborhood of a KKT point that satisfies strict complementarity.

The unconstrained reformulation of Problem (1) can be exploited to define an algorithm for finding a KKT point while improving the value of objective function with respect to the initial one. Indeed any unconstrained method for the minimization of  $P(x)$  can be used. Starting from a point  $x_0$ , any of these algorithms produce a sequence of the type

$$x^{k+1} = x^k + \alpha^k d^k, \quad (3)$$

where  $d^k$  is a suitable direction,  $\alpha^k$  is a stepsize along  $d^k$ . The sequence  $\{x^k\}$  need not to be feasible for Problem (1). The boundedness of the level sets of  $P(x)$  guarantees the boundedness of the iterates and that any convergent unconstrained method obtains a stationary point  $\bar{x}$  for  $P$  such that  $P(\bar{x}) < P(x_0)$ . Furthermore a stationary point of  $P(x)$  is a KKT point of Problem (1) and  $P(\bar{x}) = q(\bar{x})$ . If, in addition,  $x_0$  is a feasible point, the following relation holds:

$$q(\bar{x}) = P(\bar{x}) < P(x_0) \leq q(x_0),$$

which means that  $\bar{x}$  is a KKT point of Problem (1) with a value of the objective function lower than the value at the starting point.

As regard the efficiency of the algorithms, in terms of rate of convergence and computational requirement, a ‘good’ direction  $d^k$  can be defined, by further exploiting the features of the unconstrained reformulation. Indeed, in a neighborhood of points satisfying the strict complementarity assumption,  $P(x) \in C^2$  and therefore any unconstrained truncated Newton algorithm [4] can be easily adapted in order to define globally convergent methods which show a superlinear rate of convergence. Methods in this class include conjugate gradient based iterative method that requires only matrix-vector products and hence are suitable for large scale instances.

The resulting algorithmic scheme is reported in Table 2.

In the nonconvex case ( $Q \not\prec 0$ ) strict complementarity holds in a neighborhood of every global minimizer of Problem (1) [13]. However, this may not be true in a neighborhood of a KKT point and the function  $P(x)$  may be not twice differentiable there. Nevertheless algorithms which exhibit superlinear rate of convergence can be defined. In fact, drawing inspiration from the results in [6], the direction  $d^k$  is defined as the approximate solution of one of the following linear systems:

$$\begin{cases} \text{if } \|x^k\|^2 - r^2 < -\varepsilon \frac{\lambda^k}{2}, \text{ then} \\ \quad (Q + \lambda^k I)d^k = -(Qx^k + c), \\ \text{if } \|x^k\|^2 - r^2 \geq -\varepsilon \frac{\lambda^k}{2}, \text{ then} \end{cases} \quad (4)$$

$$\begin{pmatrix} Q + \lambda^k I & x^k \\ (x^k)^\top & 0 \end{pmatrix} \begin{pmatrix} d^k \\ z^k \end{pmatrix} = \begin{pmatrix} -Qx^k - c \\ r^2 - \|x^k\|^2 \end{pmatrix}.$$

The solution of the linear systems (4), can be determined approximately by using the truncated Newton method proposed in [8]. The direction  $d^k$  satisfies suitable descent conditions with respect to the penalty function  $P$ , which can be used to measure the progressive improvement of the iterate. The stepsize  $\alpha^k$  can be determined by any Armijo-type line search [9] that uses  $P$  as merit function.

It is possible to prove that the sequence  $\{x^k\}$  produced by (3) with  $d^k$  obtained by (4) and  $\{\lambda(x^k)\}$  by (2) converges to a KKT point  $(\hat{x}, \hat{\lambda})$ . Moreover if the KKT point  $(\hat{x}, \hat{\lambda})$  satisfies  $z^\top(Q + \hat{\lambda}I)z > 0$  for all  $z: z^\top \hat{x} = 0$  whenever  $\|\hat{x}\|^2 = r^2$  and  $\hat{\lambda} > 0$ , then there

  RETURN(KKT point);
END KKT point by EPA;
    
```

exists a neighborhood of  $\hat{x}$  where the rate of convergence of the algorithm is superlinear.

**D.C. Decomposition Based Algorithm (DCA)**

This algorithm is based on an appropriate reformulation of Problem (1) as the minimization of the difference of convex functions [5]. DCA has been proposed for solving large scale d.c. programming problems. The key aspect in d.c. optimization (cf. ► **D.C. programming**) relies on the particular structure of the objective function to be minimized on  $\mathbf{R}^n$  that is expressed as  $f(x) = g(x) - h(x)$ , with  $g$  and  $h$  being convex. One uses the tools of convex analysis applied to the two components  $g$  and  $h$  of the d.c. function. In particular d.c. duality plays a fundamental role to understand how DCA works. Indeed for a generic d.c. problem, DCA constructs two sequences  $\{x^k\}$  and  $\{y^k\}$  and it can be viewed as a sort of decomposition approach of the primal and dual d.c. problems. It must be pointed out that a d.c. function has infinitely many d.c. decompositions that give rise to different primal dual pairs of d.c. problems and so to different DCA relative to these d.c. decompositions. Thus, choosing a d.c. decomposition may have an important influence on the qualities (such as robustness, stability, rate of convergence) of the DCA. This aspect is related to regularization techniques in d.c. programming.

In the special case of Problem (1), a quite appropriate d.c. decomposition has been proposed, so that DCA becomes very simple and it requires only matrix-vector products. To apply DCA to Problem (1), a *d.c. decomposition* of the objective function  $f(x) = q(x) + \chi_F(x)$

must be defined, where  $\chi_F(x)$  is the indicator function for the feasible set, namely

$$\chi_F(x) = \begin{cases} 0 & \text{if } \|x\|^2 \leq r^2, \\ \infty & \text{otherwise.} \end{cases}$$

From the computational point of view, the most efficient decomposition that has been proposed is

$$g(x) = \frac{1}{2}\rho \|x\|^2 + c^\top x + \chi_F(x),$$

$$h(x) = \frac{1}{2}x^\top(\rho I - Q)x,$$

with  $\rho > 0$  and such that  $(\rho I - Q) \succeq 0$ . In this case the sequence  $\{y^k\}$  is obtained by the following rule  $y^k = (\rho I - Q)x^k$  and  $x^{k+1}$  is obtained as the solution of the problem

$$\min_{x \in \mathbb{R}^n} \frac{1}{2}\rho \|x\|^2 + x^\top(c - y^k) + \chi_F(x).$$

Thus  $x^{k+1}$  is the projection of  $(y^k - c)/\rho$  onto the feasible region  $\|x\|^2 \leq r^2$ . The scheme for obtaining KKT points by DCA is reported in Table 3.

It has been proved [5] that algorithm DCA generates a sequence of feasible points  $\{x^k\}$  with strictly decreasing value of the objective function and such that  $\{x^k\}$  converges to a KKT point.

In practice the convergence rate depends on the choice of the parameter  $\rho$ . A possible choice (the best one according to some numerical experimentations

performed in [5]) consists in taking  $\rho$  as close as possible to the largest eigenvalue of the matrix  $Q$ , namely  $\rho = \max\{\lambda_{\max}(Q) + \varepsilon, 10^{-3}\}$  with  $\varepsilon > 0$  and sufficiently small. Actually only a low accuracy estimate of  $\lambda_{\max}(Q)$ , which can be found by using a Lanczos method, is needed.

### Parametric Eigenvalue Reformulation Based Algorithms

The algorithms in this framework are based on the reformulation of the TR problem into a parametric eigenvalue problem of a bordered matrix. It must be noted that, if the linear term is not present in the function  $q(x)$ , i. e.  $c = 0$ , Problem (1) is a pure quadratic problem that corresponds to finding the smallest eigenvalue of the matrix  $Q$ . Indeed the intuitive observation behind this idea is that given a real number  $t$ , one can write

$$\frac{1}{2}t + q(x) = \frac{1}{2} \begin{pmatrix} 1 \\ x \end{pmatrix}^\top \begin{pmatrix} t & c^\top \\ c & Q \end{pmatrix} \begin{pmatrix} 1 \\ x \end{pmatrix}$$

and for a fixed  $t$  the goal is to minimize the function  $q(x)$  over the set  $\{x: \|x\|^2 + 1 = r^2 + 1\}$ , that is to minimize a pure quadratic form  $z^\top D(t) z/2$  over a spherical region where

$$D(t) = \begin{pmatrix} t & c^\top \\ c & Q \end{pmatrix}.$$

This suggests that a solution of (1) may be found using eigenpairs of the matrix  $D(t)$  where  $t$  is a parameter to be adjusted. Indeed, in both the algorithms proposed in this framework a key role is played by eigenpairs of the matrix  $D(t)$ . At each iteration the main computational step is the calculation of the smallest eigenvalue and a corresponding normalized eigenvector of the parametric matrix  $D(t)$ . The evaluation of the eigenvalue-eigenvector pair can be done by using Lanczos method as a black box. Therefore methods can exploit sparsity in the matrices and requires only matrix-vector multiplications. Moreover, only one element of the matrix  $D(t)$  is changed at each iteration of both the algorithms and so consecutive steps of Lanczos algorithm become cheaper.

Both algorithms have to distinguish between the easy and hard case of Problem (1). The hard case is said to occur when the vector  $c$  is orthogonal to the eigenspace associated to the smallest eigenvalue of  $Q$ ,

i. e.  $c^T y = 0$ , for all  $y \in S_{\min}$  with

$$S_{\min} = \{x \in \mathbb{R}^n : Qx = \lambda_{\min}(Q)x\}.$$

Depending on whether the easy or the hard case occurs, eigenpairs of the perturbed matrix  $D(t)$  satisfies different properties. In the easy case, the smallest eigenvalue  $\mu_{\min}(D(t))$  is simple and such that  $\mu_{\min}(D(t)) < \lambda_{\min}(Q)$  for all values  $t$ . Moreover in this case the corresponding eigenvector has the first component not equal to zero and this plays a fundamental role in defining the iteration of both the algorithms. In the hard case caution should be used, due to the fact that the first component of the eigenvector corresponding to the smallest eigenvalue of  $D(t)$  may be zero. Actually, any vector of the form  $(0, y^T)^T$  with  $y \in S_{\min}$  is an eigenvector of the matrix  $D(t)$  if and only if  $c \perp S_{\min}$ .

The two algorithms in this framework are briefly described below. Although the basic idea behind both the algorithms is the same, namely inverse interpolation for a parametric eigenvalue problem, the second one is embedded in a semidefinite programming framework. So the first one is referred to as ‘inverse interpolation parametric eigenvalue’ (IPE) approach and the second one as ‘semidefinite programming approach’ (SDP).

**Inverse Interpolation Parametric Eigenvalue Formulation (IPE)**

In [23] it is observed that if an eigenvector  $z$  of  $D(t)$  corresponding to a given eigenvalue  $\mu$  can be normalized so that its first component is one, that is  $z = (1, x^T)^T$ , then a solution of the TR problem can be found in terms of eigenpairs of  $D(t)$ . This corresponds to the easy case and indeed the pair  $(x, \mu)$  satisfies

$$\begin{pmatrix} t & c^T \\ c & Q \end{pmatrix} \begin{pmatrix} 1 \\ x \end{pmatrix} = \mu \begin{pmatrix} 1 \\ x \end{pmatrix},$$

from which we get:

$$\begin{pmatrix} t - \mu = -c^T x, \\ (Q - \mu I)x = -c. \end{pmatrix}$$

For  $\mu < \lambda_{\min}(Q)$ , that holds in the easy case with  $\mu = \mu_{\min}(D(t))$ , the matrix  $(Q - \mu I)$  is positive definite and hence one can define the function

$$\phi(\mu) = -c^T x = c^T (Q - \mu I)^{-1} c,$$

whose derivative is

$$\phi'(\mu) = c^T (Q - \mu I)^{-2} c = \|x\|^2.$$

For a given value of  $t$ , finding the smallest eigenvalue  $\mu(t) := \mu_{\min}(D(t)) < \lambda_{\min}(Q)$  and the corresponding eigenvector of  $D(t)$  and then normalizing the eigenvector to have its first component equal to one  $(1, x_{\mu(t)}^T)^T$  will provide a mean to evaluate the function  $\phi(\mu)$  and its derivative. If  $t$  can be adjusted so that the corresponding  $x_{\mu(t)}$  satisfies  $\phi'(\mu(t)) = \|x_{\mu(t)}\|^2 = r^2$  with  $t - \mu(t) = -c^T x_{\mu(t)}$ , and  $\mu(t) \leq 0$  then  $(x, -\mu(t))$  satisfies the optimality conditions for Problem (1). Whereas if, during the course of adjusting  $t$ , it happens that  $\mu(t) > 0$  with  $\|x_{\mu(t)}\|^2 < r^2$  then the optimal solution of Problem (1) is actually unconstrained and can be found by solving the system  $Qx = -c$  with any iterative method.

Hence using the parametric eigenvalue formulation, the optimal value of  $(x^*, \lambda^*)$  of Problem (1) can be found by solving a sequence of eigenvalue problems adjusting iteratively the parameter  $t$ . In order to make this observation useful, a modified Lanczos methods, the *implicit restarted Lanczos method* [23], is used for computing the smallest eigenvalue and the corresponding eigenvector of  $D(t)$ . Moreover a rapidly convergent iteration to adjust  $t$  has been developed, based on a two-point interpolant method. Recalling that the goal is to adjust  $t$  so that  $\phi(\mu) = t - \mu$  and  $\phi'(\mu) = r^2$ , an interpolation based iteration that exploits the structure of the problem is proposed. The method is based upon an interpolant  $\hat{\phi}(\mu)$  of  $\phi(\mu)$  of the form

$$\hat{\phi}(\mu) = \frac{\gamma^2}{\alpha - \mu} + \beta(\alpha - \mu) + \delta.$$

The values of the parameters  $\alpha, \beta, \gamma, \delta$  appearing in the interpolant function  $\hat{\phi}(\mu)$  are determined using the values of two iterations  $(x^k, \mu^k), (x^{k-1}, \mu^{k-1})$  according to the following rules. The value  $\delta$  is chosen so as to provide the current estimate  $\delta_{\min}$  of  $\lambda_{\min}(Q)$ . In particular, if  $\|x^k\| < r$  or  $\|x^{k-1}\| < r$

$$\delta = \min \left( \delta_{\min}, \frac{(x^k)^T Q x^k}{\|x^k\|^2} \right);$$

if  $\|x^k\| > r$  and  $\|x^{k-1}\| > r$  then

$$\delta = \min \left( \frac{(x^k)^T Q x^k}{\|x^k\|^2}, \frac{(x^{k-1})^T Q x^{k-1}}{\|x^{k-1}\|^2} \right)$$

**Large Scale Trust Region Problems, Table 4**  
**A pseudocode for TR based on (IPE)**

```

procedure TR INTERPOL-PARAM-EIG()
  input instace (Q, c, r, x0);
  (initialization)
  Find λmin(Q) and its eigenvector x;
  set k = 0, tk = 0, xk = x, μk = λmin(Q).
  DO (until |  $\frac{\|x^k\|^2 - r^2}{r^2}$  | ≤ tol)
    construct the interpolator  $\hat{\phi}(\mu)$ ;
    find  $\hat{\mu} : \hat{\mu}'(\hat{\mu}) = r^2$ , that is:
       $\hat{\mu} = \alpha - \left(\frac{\gamma^2}{r^2 + \beta}\right)^{1/2}$  ;
    set tk+1 =  $\hat{\mu} + \hat{\phi}(\hat{\mu})$ , that is:
       $t^{k+1} = \hat{\lambda} + \delta + \beta(\alpha - \hat{\mu}) + \frac{\gamma^2}{\alpha - \hat{\mu}}$ ;
    compute μk+1 = μmin(D(tk+1))
      and the corresponding normalized eigenvector
       $\left(1, (x^{k+1})^\top\right)^\top$  ;
    set k = k + 1;
  OD;
  RETURN(solution)
END TR INTERPOLATION-PARAM-EIG;

```

and  $\delta_{\min} = \min(\delta_{\min}, \delta) \geq \lambda_{\min}(Q)$ . The other coefficient are chosen to satisfy  $\hat{\phi}(\mu^k) = -c^\top x^k, \hat{\phi}'(\mu^k) = \|x^k\|^2, \hat{\phi}'(\mu^{k-1}) = \|x^{k-1}\|^2$ .

An algorithmic scheme for finding the global minimizer of Problem (1) in the easy case, is reported in Table 4.

It has been proved in [23] that there exists a neighborhood of  $-\lambda^*$  such that if  $\mu^0, \mu^1$  are in this neighborhood, all the sequence  $\{\mu^k\}$  is well defined, remains in the neighborhood and converge superlinearly to  $-\lambda^*$  with the corresponding iterates  $x^k$  converging superlinearly to  $x^*$ .

Unfortunately, the iteration described above can break down in the hard case. Indeed the iteration is based on the ability to normalize the eigenvector of the bordered matrix  $D(t)$ . This is not possible when the first component is equal to zero, that is in the hard case. From the computational point of view, also a near-hard case can be difficult and it is important to detect these cases and to define alternative rules so as to obtain a convergent iteration. This can be done, by using

again eigenpairs of the bordered matrix and additional information such as the value of an upper bound  $\lambda_U$  on the optimal value  $\lambda^*$ . When the hard case is detected the new iteration should be used. The convergence of this new iteration can be established but unfortunately the rate of convergence is no longer superlinear.

**Semidefinite Programming Approach (SDP)**

In [20] a primal-dual simplex type method for Problem (1) has been proposed, which is essentially based on a primal dual pair of semidefinite programming problems. Primal-dual pairs of SDP provide a general framework for TR problem. The idea arises from the fact that Problem (1) enjoys strict duality, that is there is no duality gap and

$$q(x^*) = \min_x \max_\lambda L(x, \lambda) = \max_\lambda \min_x L(x, \lambda),$$

where  $L(x, \lambda) = q(x) + \lambda(\|x\|^2 - r^2)$  denotes the Lagrangian function. By exploiting this feature it is possible to define a primal-dual pair of linear SDP problems that are strictly connected with the TR problem. In particular, a dual for Problem (1) is

$$\begin{cases} \max & (r^2 + 1)\mu_{\min}(D(t)) - t, \\ \text{s.t.} & \mu_{\min}(D(t)) \leq 0. \end{cases} \tag{5}$$

The objective function in (5) is a real valued concave function. When the constraint in Problem (1) is an equality one, its dual problem (5) is an unconstrained problem, and as an immediate consequence, the non convex constrained TR problem is transformed into a convex problem and hence it can be solved in polynomial time by the results for general convex programs.

Problem (5) can be easily reformulated as a SDP problem, by introducing an additional variable  $\mu \in \mathbf{R}$ :

$$\begin{cases} \max & (r^2 + 1)\mu - t, \\ \text{s.t.} & D(t) - \mu I \geq 0, \\ & \mu \leq 0. \end{cases} \tag{6}$$

Slater’s condition holds for Problem (6), and it is possible to write its Lagrangian dual that is:

$$\begin{cases} \min & \text{trace}(D(0)X), \\ \text{s.t.} & \text{trace}(X) \leq r^2 + 1, \\ & X_{11} = 1 \\ & X \geq 0. \end{cases} \tag{7}$$

The algorithm parallels the dual simplex method for linear programming. At each iteration it maintains dual feasibility for Problem (6) and complementary slackness, while iterating to get primal feasibility of Problem (7) ( $X_{11} = 1$ ) and reduce the duality gap.

Essentially these steps can be summarized as follows:

- 1) find a basic solution  $(t, \mu_{\min}(D(t)))$  of Problem (6);
- 2) find an approximate solution of Problem (7), by using the complementary slackness relation

$$\text{trace}((D(t) - \mu I)X) = 0;$$

an eigenvector  $z(t) = (z_0(t), v(t)^T)^T$  corresponding to  $\mu_{\min}(D(t))$  is used and  $X = (r^2 + 1)zz^T$  so that the constraint on the trace of  $X$  in Problem (7) is satisfied;

- 3) use inverse interpolation to predict a value of the parameter  $t$  such that  $X_{11} = 1$  and/or the duality gap

$$\text{trace}(D(0)X) - ((r^2 + 1)\mu - t)$$

is decreasing.

Some differences occur depending on whether the easy or the hard case happens. Let us denote by  $z(t) = (z_0(t), v(t)^T)^T$  the eigenvector of  $D(t)$  corresponding to  $\mu_{\min}(D(t))$ .

In the easy case, the first component  $z_0(t) \neq 0$  and the vector  $v(t)/z_0(t)$  is the unique optimal solution of

$$\begin{cases} \min & q(x) \\ \text{s.t.} & \|x\|^2 = \frac{1-z_0(t)^2}{z_0(t)^2}. \end{cases}$$

Hence, a value  $t^*$  such that  $(1-z_0(t^*)^2)/z_0(t^*)^2 = r^2$  must be found and then the point  $x^* = v(t^*)/z_0(t^*)$  with multiplier  $\lambda^* = -\mu_{\min}(D(t^*))$  is the unique solution of Problem (1). The correct value of  $t$  can be found by standard search procedures and the algorithm produces an interval containing  $t^*$  that is iteratively updated.

In the hard case,  $z_0(t)$  may be zero. However there is still a value  $t_0$  such that  $\mu_{\min}(D(t_0)) = \lambda_{\min}(Q)$  and a corresponding eigenvector  $z(t_0)$  exists with first component not equal to zero. In order to obtain the value  $t_0$ , consider, without loss of generality, a diagonal  $Q$  with elements  $\lambda_i$  in increasing order, so that  $\lambda_1 = \lambda_{\min}(Q)$ . Assume that  $p$  is the multiplicity of  $\lambda_{\min}(Q)$ , and define

$$t_0 = \lambda_{\min}(Q) + \sum_{k=p+1}^n \frac{c_k}{\lambda_k - \lambda_{\min}(Q)}.$$

Then the smallest eigenvalue  $\mu_{\min}(D(t_0)) = \lambda_{\min}(Q)$  with multiplicity  $p + 1$ .

Two cases can occur. If  $(1-z_0(t_0)^2)/z_0(t_0)^2 > r^2$  then the value  $t^* < t_0$ . This case can be treated as the preceding easy case since there exists  $t < t_0$  such that the eigenvalue  $\mu_{\min}(D(t))$  is simple, it results  $\mu_{\min}(D(t)) < \lambda_{\min}(Q)$ , and the corresponding eigenvector satisfies  $(1-z_0(t)^2)/z_0(t)^2 = r^2$ . On the other hand, if  $z_0^2(t_0) \geq 1/(r^2 + 1)$ , then a primal step to the boundary of the feasible region of Problem (7) is taken while improving the objective function. In particular, let  $w \in S_{\min}$  with  $\|w\| = 1$ , then the vector

$$x^* = \frac{v}{z_0(t_0)} + \left[ \left( r^2 - \frac{1-z_0^2(t_0)}{z_0^2(t_0)} \right) w \right]^{\frac{1}{2}}$$

together with  $\lambda^* = -\lambda_{\min}(Q)$  satisfy the optimality conditions for Problem (1) and  $t^* = t_0$ . Hence in the hard case, a vector is found that allows to move to the correct radius while improving the objective function.

Inverse interpolation on the value of the first component  $z_0$  of the eigenvector corresponding to  $\mu_{\min}(D(t^k))$  is used to predict a new value for  $t^{k+1}$ .

A brief scheme of the algorithm is in Table 5.

  RETURN(solution)
END TR PRIMAL-DUAL-SDP;
    
```

## Conclusion

All the algorithms described above appear to be potentially equivalent from the computational point of view. They have been implemented in MATLAB [15] codes and the results of the numerical testing are reported in the corresponding papers.

### Keywords

Large scale problem; Unconstrained optimization

A large scale unconstrained optimization problem can be formulated as the problem of finding a local minimizer of a real valued function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  over the space  $\mathbf{R}^n$ , namely to solve the problem

$$\min_{x \in \mathbf{R}^n} f(x), \quad (1)$$

where the dimension  $n$  is large. The notion of 'large scale' is machine dependent and hence it could be difficult to state a priori when a problem is of large size. However, today an unconstrained problem with more than one thousand variables is usually considered a *large scale problem*.

Besides its own theoretical importance, the growing interest in the last years in solving problems of large size derives from the fact that problems with a larger and larger number of variables are arising very frequently

from real world as a result of modeling systems with a very complex structure.

The main difficulty in dealing with large scale problems is the fact that effective algorithms for small scale problems do not necessarily translate into efficient algorithms when applied to solve large problems. Therefore in most cases it is improper to tackle a problem with a large number of variables by using one of the many existing algorithms for the small scale case relying on the growing powerful of the modern computers (see, e. g., [11,13,34] for a review on the existing methods for small scale unconstrained optimization).

A basic feature of an algorithm for large scale problems is a low storage overhead needed to make practicable its implementation. Moreover, whenever a large scale problem has some structure it should be exploited to define reliable algorithms; in fact, often the structure of a problem reflects in the sparsity of the Hessian matrix of the function  $f$  which can be efficiently exploited.

Methods for unconstrained optimization differ according to how much information on the function  $f$  is available. In the framework of large scale unconstrained optimization it is usually required that the user provides at least subroutines which evaluate the objective function and its gradient for any point  $x$ . More effective methods can be obtained if second order derivatives are known. When the derivatives are not available they can be obtained by finite difference or by using automatic differentiation. Throughout we assume that the function  $f$  is twice continuously differentiable, i. e. that the gradient  $g(x) = \nabla f(x)$  and the Hessian matrix  $H(x) = \nabla^2 f(x)$  of the function  $f$  exist and are continuous. Moreover, we denote by  $\|v\|$  the Euclidean norm of a vector  $v \in \mathbf{R}^n$ .

As in the small scale case, most of the large scale unconstrained algorithms are iterative methods which generate a sequence of points according to the scheme

$$x_{k+1} = x_k + \alpha_k d_k \quad (2)$$

where  $d_k \in \mathbf{R}^n$  is a search direction and  $\alpha_k \in \mathbf{R}$  is a steplength obtained by means of a one-dimensional search. Obviously, also in large scale optimization it is important that an algorithm presents both the *global convergence* (i. e. convergence of the sequence  $\{x_k\}$  towards a stationary point from any starting point) and a good *convergence rate*.

A basic method for solving large scale unconstrained optimization problems can be considered the *steepest descent method* obtained by setting  $d_k = -g(x_k)$  in (2). This method is based on the linear approximation of the objective function  $f$  and hence only first order information are need. Due to its very limited storage required by a standard implementation, steepest descent method could be considered very attractive in the large scale setting; moreover the global convergence can also be ensured. However, its convergence rate is only linear and therefore it is too slow to be used. A particular rule for computing the stepsize  $\alpha_k$  has been proposed [39] and this led to a significant improvement of the efficiency of the steepest descent method.

One of the most effective methods for solving unconstrained problems is the Newton method (cf. ► **Unconstrained nonlinear optimization: Newton–Cauchy framework**). It is based on the quadratic approximation of  $f(x_k + w)$  given by

$$\phi_k(w) = f(x_k) + g(x_k)^\top w + \frac{1}{2} w^\top H(x_k) w \quad (3)$$

and it is defined by iterations of the form

$$x_{k+1} = x_k + s_k \quad (4)$$

where the search direction  $s_k$  is obtained by minimizing the quadratic model of the objective function (3) over  $\mathbf{R}^n$ . On the one hand, Newton method presents quadratic convergence rate and it is scale invariant, but, on the other hand, in its pure form it is not globally convergent. Globally convergent modifications of the Newton method has been defined following the line search approach and the trust region approach (see, e. g. [11,12,27]; cf. also ► **Large scale trust region problems**), but the main difficulty, in dealing with large scale problems, is represented by the possibility to efficiently solve, at each iteration, linear systems which arise in computing the search direction  $s_k$ . In fact, the problem dimension could be too large for any explicit use of the Hessian matrix and iterative methods must be used to solve systems of linear equations instead of factorizations of the matrices involved. Indeed, whereas in the small scale setting the Newton direction  $s_k$  is usually determined by using direct methods for solving the linear system

$$H(x_k)s = -g(x_k), \quad (5)$$

when  $n$  is large, it is impossible to store or factor the full  $n \times n$  Hessian matrix unless it is a sparse matrix. Moreover the exact solution, at each iteration, of the system (5) could be too burdensome and not justified when  $x_k$  is far from a solution. In fact, since the benefits of using the Newton direction are mainly local (i. e. in the neighborhood of a solution), it should not be necessary a great computational effort to get an accurate solution of system (5) when  $g(x_k)$  is large.

On the basis of these remarks, in [8] the *inexact Newton methods* were proposed. They represent the basic approach underlying most of the Newton-type large scale unconstrained algorithms. The main idea is to approximately solve the system (5) still ensuring a good convergence rate of the method by using a particular trade-off rule between the computational burden required to solve the system (5) and the accuracy with which it is solved. The measure of this accuracy is the relative residual

$$\frac{\|r_k\|}{\|g(x_k)\|}, \quad \text{where } r_k = H(x_k)s_k + g(x_k) \quad (6)$$

and  $s_k$  is an approximate solution of (5). The analysis given in [8] shows that if the sequence  $\{x_k\}$  generated by (4) converges to a point  $x_*$  and if

$$\lim_{k \rightarrow \infty} \frac{\|r_k\|}{\|g(x_k)\|} = 0, \quad (7)$$

then  $\{x_k\}$  converges superlinearly to  $x_*$ . This result is at the basis of the *truncated Newton methods* which represent one of the most effective approach for solving large scale problems. This class of methods was introduced in [9] within the line search based Newton-type methods. They are based on the fact that whenever the Hessian matrix  $H(x_k)$  is positive definite, to solve the Newton equation (5) is equivalent to determine the minimizer of the quadratic model (3). Therefore, in these methods, a Newton-type direction, i. e. an approximate solution of (5), is computed by applying the (linear) conjugate gradient (CG) method (cf. ► **Conjugate-gradient methods**) [23] to approximately minimize the quadratic function (3). A scheme of a line search based truncated Newton algorithm is the following:

**Line search based truncated Newton algorithm**

OUTER iterations

For  $k = 0, 1, \dots$

  Compute  $g(x_k)$

  Test for convergence

INNER iterations

  (Computation of the direction  $s_k$ )

  Iterate CG algorithm until

  a termination criterion is satisfied

  Compute a stepsize  $\alpha_k$  by a line search procedure

  Set  $x_{k+1} = x_k + \alpha_k s_k$

**A scheme for a truncated Newton algorithm**

Given a starting point  $x_0$ , at each iteration  $k$ , a Newton-type direction  $s_k$  is computed by truncating the CG iterates – the inner iterations – whenever a required accuracy is obtained. The definition of an effective truncation criterion represents a key aspect of any truncated Newton method and a natural choice is represented by monitoring when the relative residual (6) is sufficiently small. Moreover, by requiring that  $\|r_k\| / \|g(x_k)\| \leq \eta_k$  with  $\lim_{k \rightarrow \infty} \eta_k \rightarrow 0$ , the condition given by (7) is satisfied and hence the superlinear convergence is guaranteed [9]. In particular  $\eta_k$  can be chosen to ensure that, as a critical point is approached, more accuracy is required. Other truncation criteria based on the reduction of the quadratic model can be defined [31]. Numerical experiences showed that a relatively small number of CG iterations is needed, in most cases, for obtaining a good approximation of the Newton direction and this is one the main advantage of the truncated Newton methods since a considerable computational savings can be obtained still ensuring a good convergence rate. The performance of the CG algorithm used in the inner iterations can be improved by using a preconditioning strategy based either on the information gained during the outer iterations or on some scaling of the variables. Several different preconditioning schemes have been proposed and tested [29,40]. Truncated Newton methods can be modified to enable their use whenever the Hessian matrix is not available; in fact, the CG method only needs the product of the Hessian matrix with a displacement vector, and this product can be approximated by finite difference [35]. The resulting method is called *discrete truncated Newton method*. In [41] a Fortran package (TNPACK) imple-

menting a line search based (discrete) truncated Newton algorithm which uses a preconditioned conjugate gradient is proposed. However, additional safeguard is needed within truncated Newton algorithms since the Hessian matrix could be not positive definite. In fact, the CG inner iterations may break down before satisfying the termination criterion when the Hessian matrix is indefinite. To handle this case, whenever a *direction of negative curvature* (i. e. a direction  $d_k$  such that  $d_k^T H(x_k) d_k < 0$ ) is encountered, the inner iterations are usually terminated and a *descent direction* (i. e. a direction  $d_k$  such that  $g(x_k)^T d_k < 0$ ) is computed [9]. More sophisticated strategies can be applied for iteratively solving the system (5) when it is indefinite [6,15, 36,43]. In particular, the equivalent characterization of the linear conjugate gradient algorithm via the Lanczos method can be exploited to define a truncated Newton algorithm which can be used to solve problems with indefinite Hessian matrices [28]. In fact, the Lanczos algorithm does not requires the Hessian matrix to be positive definite and hence it enables to obtain an effective Newton-type direction.

A truncated Newton method which uses a *non-monotone line search* (i. e. which does not enforce the monotone decrease of the objective function values) was proposed in [20] and the effectiveness of this approach was shown especially in the solution of ill-conditioned problems. Moreover in the CG-truncated scheme proposed in [20] an efficient strategy to handle the indefinite case is also proposed.

A new class of truncated Newton algorithms for solving large scale unconstrained problems has been defined in [25]. In particular, a nonmonotone stabilization framework is proposed based on a *curvilinear line search*, i. e. a line search along the curvilinear path

$$x(\alpha) = x_k + \alpha^2 s_k + \alpha d_k,$$

where  $s_k$  is a Newton-type direction and  $d_k$  is a particular negative curvature direction which has some resemblance to an eigenvector of the Hessian matrix corresponding to the minimum eigenvalue. The use of the combination of these two directions enables, also in the large scale case, to define a class of line search based algorithms which are globally convergent towards points which satisfy second order necessary optimality conditions, i. e. stationary points where the Hessian matrix is

positive semidefinite. Besides satisfying this important theoretical property, this class of algorithms was also shown to be very efficient in solving large scale unconstrained problems [25,26]. This is also due to the fact that a Lanczos based iterative scheme is used to compute both the directions without terminating the inner iterations when indefiniteness is detected and, as result, more information about the curvature of the objective function are conveyed.

Truncated Newton methods have been also defined within the trust region based methods. These methods are characterized by iterations of the form (4) where, at each iteration  $k$ , the search direction  $s_k$  is determined by minimizing the quadratic model of the objective function (3) in a neighborhood of the current iterate, namely by solving the problem

$$\min_{\|s\| \leq \Delta} \phi_k(s), \quad (8)$$

where  $\Delta$  is the trust region radius. Also in this framework most of the existing algorithms require the solution of systems of linear equations. Some approaches are the *dogleg methods* [10,38] which aim to solve problem (8) over a one-dimensional arc and the method proposed in [5] which solves problem (8) over a two-dimensional subspace. However, whenever the problem dimension is large, it is impossible to rely on matrix factorizations, and iterative methods must be used. If the quadratic model (3) is positive definite and the trust region radius is sufficiently large that the trust region constraint is inactive at the unconstrained minimizer of the model, problem (8) can be solved by using the preconditioned conjugate gradient method [42,44]. Of course, a suitable strategy is needed whenever the unconstrained minimizer of the quadratic model is no longer lying within the trust region and the desired solution belongs to the trust region boundary. A simple strategy to handle this case was proposed in [42] and [44] and it considers the piecewise linear path connecting the CG iterates, stopping at the point where this path leaves the trust region. If the quadratic model (3) is indefinite, the solution must also lie on the trust region boundary and the piecewise linear path can be again followed until either it leaves the trust region, or a negative curvature direction is found. In this latter case, two possibilities have been considered: in [42] the path is continued along this direction until the bound-

ary is reached; in [44] the minimizer of the quadratic model within the trust region along the steepest descent direction (the *Cauchy point*) is considered. This class of algorithms represents a trust region version of truncated Newton methods and an efficient implementation is carried out within the LANCELOT package [7]. These methods have become very important in large scale optimization, due to both their strong theoretical convergence properties and good efficiency in practice, but they are known to possess some drawbacks. Indeed, they are essentially unconcerned with the trust region until they blunder into its boundary and stop. Moreover, numerical experiences showed that very frequently this untimely stop happens during the first inner iterations when a negative curvature is present and this could deteriorate the efficiency of the method. In order to overcome this drawback an alternative strategy is proposed in [16] where ways of continuing the process once the boundary of the trust region is reached are investigated. The key point of this approach is the use of the Lanczos method and the fact that preconditioned conjugate gradient and Lanczos methods generate different bases for the same Krylov space. Several other large scale trust region methods (cf. ► **Large scale trust region problems**) have been proposed.

Another class of methods which can be successfully applied to solve large scale unconstrained optimization problems is the wide class of the nonlinear conjugate gradient methods [14,23]. They are extensions to the general (nonquadratic) case of the already mentioned linear conjugate gradient method. They represent a compromise between steepest descent method and Newton method and they are particularly suited for large scale problems since there is never a need to store a full Hessian matrix. They are defined by the iteration scheme (2) where the search direction is of the form

$$d_k = -g(x_k) + \beta_k d_{k-1} \quad (9)$$

with  $d_0 = -g(x_0)$  and where  $\beta_k$  is a scalar such that the algorithm reduces to the linear conjugate gradient method if the objective function  $f$  is a strictly convex quadratic function and  $\alpha_k$  in (2) is obtained by means of an exact line search (i. e.,  $\alpha_k$  is the one-dimensional minimizer of  $f(x_k + \alpha d_k)$  with respect to  $\alpha$ ). The most widely used formulas for  $\beta_k$  are *Fletcher-Reeves* (FR)

and *Polak–Ribière* (PR) formulas given by

$$\beta_k^{\text{FR}} = \frac{\|g(x_k)\|^2}{\|g(x_{k-1})\|^2},$$

$$\beta_k^{\text{PR}} = \frac{g(x_k)^\top [g(x_k) - g(x_{k-1})]}{\|g(x_{k-1})\|^2}.$$

Many efforts have been devoted to investigate the global convergence for nonlinear conjugate gradient methods. A widespread technique to enforce the global convergence is the use of a regular *restart* along the steepest descent direction every  $n$  iterations obtained by setting  $\beta_k = 0$ . However, computational experiences showed that this restart can have a negative effect on the efficiency of the method; on the other hand, in the large scale setting, restarting does not play a significant role since  $n$  is large and very few restarts can be performed. Global convergence results have been obtained for the *Fletcher–Reeves method* without restart both in the case of exact line search [46] and when  $\alpha_k$  is computed by means of an inexact line search [1]; then, the global convergence was extended to methods with  $|\beta_k| \leq \beta_k^{\text{FR}}$  [14]. As regards the global convergence of the *Polak–Ribière method*, for many years it was proved with exact line search only under strong convexity assumptions [37]. Global convergence both for exact and inexact line search can also be enforced by modifying the *Polak–Ribière method* by setting  $\beta_k = \max\{\beta_k^{\text{PR}}, 0\}$  [14]; this strategy correspond to restart the iterations along the steepest descent direction whenever a negative value of  $\beta_k$  occurs. However, an inexact line search which ensures global convergence of the *Polak–Ribière method* for nonconvex function has been obtained in [21]. As regards the numerical performance of these two methods, extensive numerical experiences showed that, in general, *Polak–Ribière method* is usually more efficient than the *Fletcher–Reeves method*. An efficient implementation of the *Polak–Ribière method* (with restarts) is available as routine VA14 within the Harwell subroutine library [22]. See, e. g., [34] for a detailed survey on the nonlinear conjugate gradient methods.

Another effective approach to large scale unconstrained optimization is represented by the *limited-memory BFGS method* (L-BFGS) proposed in [32] and then studied in [24,30]. This method resembles

the BFGS quasi-Newton method, but it is particularly suited for large scale (unstructured) problems because the storage of matrices is avoided. It is defined by the iterative scheme (2) with the search direction given by

$$d_k = -H_k g(x_k)$$

and where  $H_k$  is the approximation to the inverse Hessian matrix of the function  $f$  at the  $k$ th iteration. In the BFGS method the approximation  $H_k$  is updated by means of the BFGS correction given by

$$H_{k+1} = V_k^\top H_k V_k + \rho_k s_k s_k^\top$$

where  $V_k = I - \rho_k y_k s_k^\top$ ,  $s_k = x_{k+1} - x_k$ ,  $y_k = g(x_{k+1}) - g(x_k)$ , and  $\rho_k = 1/y_k^\top s_k$ . In the L-BFGS method, instead of storing the matrices  $H_k$ , a prefixed number (say  $m$ ) of vectors pairs  $\{s_k, y_k\}$  that define them implicitly are stored. Therefore, during the first  $m$  iterations the L-BFGS and the BFGS methods are identical, but when  $k > m$  only information from the  $m$  previous iterations are used to obtain  $H_k$ . The number  $m$  of BFGS corrections that must be kept can be specified by the user. Moreover, in the L-BFGS the product  $H_k g(x_k)$  which represents the search direction is obtained by means of a recursive formula involving  $g(x_k)$  and the most recent vectors pairs  $\{s_k, y_k\}$ . An implementation of L-BFGS method is available as VA15 routine within the Harwell subroutine library [22]. An interesting numerical study of L-BFGS method and a comparison of its numerical performance with the discrete truncated Newton method and the *Polak–Ribière conjugate gradient method* are reported in [30]. The results of a numerical experience with limited-memory quasi-Newton and truncated Newton methods on standard library test problems and on two real life large scale unconstrained optimization applications can be found in [45]. A method which combines the discrete Newton method and the L-BFGS method is proposed in [4] to produce an efficient algorithm able to handle also ill-conditioned problems.

Limited memory quasi-Newton methods represent an adaptation of the quasi-Newton methods to large scale *unstructured optimization*. However, the quasi-Newton approach can be successfully applied to large scale problems with a particular structure. In fact, fre-

quently, an optimization problem has some structure which may be reflected in the sparsity of the Hessian matrix. In this framework, the most effective method is the *partitioned quasi-Newton method* proposed in [18,19]. It is based on the fact that a function  $f$  with a sparse Hessian is a *partially separable function*, i. e. it can be written in the form

$$f(x) = \sum_{i=1}^{n_e} f_i(x)$$

where the element functions  $f_i$  depends only on a few variables. Many practical problems can be formulated (or recasted) in this form showing a wide range of applicability of this approach. The basic idea of the partitioned quasi-Newton method is to decompose the Hessian matrix into a sum of Hessians of the element functions  $f_i$ . Each approximation to the Hessian of  $f_i$  is then updated by using dense updating techniques. These small matrices are assembled to define an approximation to the Hessian matrix of  $f$  used to compute the search direction. However, the element Hessian matrices may not be positive definite and hence BFGS formula cannot be used, and in this case a symmetric rank one formula is used. Global convergence results have been obtained under convexity assumption of the function  $f_i$  [17]. An implementation of the partitioned quasi-Newton method is available as VE08 routine of the Harwell subroutine library [22]. A comparison of the performance of partitioned quasi-Newton, LBFGS, CG Polak–Ribière and truncated discrete Newton methods is reported in [33].

Another class of methods which has been extended to large sparse unconstrained optimization are *tensor methods* [3]. Tensor methods are based on fourth order model of the objective function and are particularly suited for problems where the Hessian matrix has a small rank deficiency.

To conclude, it is worthy to outline that in dealing with large scale unconstrained problems with a very large number of variables (more than  $10^4$ ) high performance computer architectures must be considered. See e. g. [2] for the solution of large scale optimization problems on vector and parallel architectures.

The reader can find the details of the methods mentioned in this brief survey in the specific cited references.

L-convexity; M-convexity; Discrete convex analysis; Submodular function; Matroid

In the field of nonlinear programming (in continuous variables), convex analysis [20,21] plays a pivotal role both in theory and in practice. An analogous theory for discrete optimization (nonlinear integer programming), called ‘discrete convex analysis’ [15,16], is developed for L-convex and M-convex functions by adapting the ideas in convex analysis and generalizing the results in matroid theory. The L- and M-convex functions are introduced in [15] and [12,18], respectively.

### Definitions of L- and M-Convexity

Let  $V$  be a nonempty finite set and  $\mathbf{Z}$  be the set of integers. For any function  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  define  $\text{dom } g$

$= \{p \in \mathbf{Z}^V : g(p) < +\infty\}$ , called the *effective domain* of  $g$ .

A function  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  with  $\text{dom } g \neq \emptyset$  is called *L-convex* if

$$g(p) + g(q) \geq g(p \vee q) + g(p \wedge q) \quad (p, q \in \mathbf{Z}^V),$$

$$\exists r \in \mathbf{Z} : g(p + \mathbf{1}) = g(p) + r \quad (p \in \mathbf{Z}^V),$$

where  $p \vee q = (\max(p(v), q(v)) | v \in V) \in \mathbf{Z}^V$ ,  $p \wedge q = (\min(p(v), q(v)) | v \in V) \in \mathbf{Z}^V$ , and  $\mathbf{1}$  is the vector in  $\mathbf{Z}^V$  with all components being equal to 1.

A set  $D \subseteq \mathbf{Z}^V$  is said to be an *L-convex set* if its indicator function  $\delta_D$  (defined by  $\delta_D(p) = 0$  if  $p \in D$ , and  $= +\infty$  otherwise) is an L-convex function, i. e., if

- i)  $D \neq \emptyset$ ;
- ii)  $p, q \in D \Rightarrow p \vee q, p \wedge q \in D$ ; and
- iii)  $p \in D \Rightarrow p \pm \mathbf{1} \in D$ .

A function  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  with  $\text{dom } f \neq \emptyset$  is called *M-convex* if it satisfies

- M-EXC) For  $x, y \in \text{dom } f$  and  $u \in \text{supp}^+(x - y)$ , there exists  $v \in \text{supp}^-(x - y)$  such that

$$f(x) + f(y) \geq f(x - \chi_u + \chi_v)$$

$$+ f(y + \chi_u - \chi_v),$$

where, for any  $u \in V$ ,  $\chi_u$  is the *characteristic vector* of  $u$  (defined by  $\chi_u(v) = 1$  if  $v = u$ , and  $= 0$  otherwise), and

$$\text{supp}^+(z) = \{v \in V : z(v) > 0\} \quad (z \in \mathbf{Z}^V),$$

$$\text{supp}^-(z) = \{v \in V : z(v) < 0\} \quad (z \in \mathbf{Z}^V).$$

A set  $B \subseteq \mathbf{Z}^V$  is said to be an *M-convex set* if its indicator function is an M-convex function, i. e., if  $B$  satisfies

- B-EXC) For  $x, y \in B$  and for  $u \in \text{supp}^+(x - y)$ , there exists  $v \in \text{supp}^-(x - y)$  such that  $x - \chi_u + \chi_v \in B$  and  $y + \chi_u - \chi_v \in B$ .

This means that an M-convex set is the same as the set of integer points of the base polyhedron of an integral submodular system (see [8] for submodular systems).

L-convexity and M-convexity are conjugate to each other under the *integral Fenchel–Legendre transformation*  $f \mapsto f^\bullet$  defined by

$$f^\bullet(p) = \sup \{ \langle p, x \rangle - f(x) : x \in \mathbf{Z}^V \}, \quad p \in \mathbf{Z}^V,$$

where  $\langle p, x \rangle = \sum_{v \in V} p(v) x(v)$ . That is, for L-convex function  $g$  and M-convex function  $f$ , it holds [15] that  $g^\bullet$  is M-convex,  $f^\bullet$  is L-convex,  $g^{\bullet\bullet} = g$ , and  $f^{\bullet\bullet} = f$ .

*Example 1 (Minimum cost flow problem)* L-convexity and M-convexity are inherent in the integer minimum-cost flow problem, as pointed out in [12,15]. Let  $G = (V, A)$  be a graph with vertex set  $V$  and arc set  $A$ , and let  $T \subseteq V$  be given. For  $\xi: A \rightarrow \mathbb{Z}$  its *boundary*  $\partial\xi: V \rightarrow \mathbb{Z}$  is defined by

$$\begin{aligned} \partial\xi(v) &= \sum \{\xi(a): a \in \delta^+v\} - \sum \{\xi(a): a \in \delta^-v\} \\ & \quad (v \in V), \end{aligned}$$

where  $\delta^+v$  and  $\delta^-v$  denote the sets of out-going and incoming arcs incident to  $v$ , respectively. For  $\tilde{p}: V \rightarrow \mathbb{Z}$  its *coboundary*  $\delta\tilde{p}: A \rightarrow \mathbb{Z}$  is defined by

$$\delta\tilde{p}(a) = \tilde{p}(\partial^+a) - \tilde{p}(\partial^-a) \quad (a \in A),$$

where  $\partial^+a$  and  $\partial^-a$  mean the initial and terminal vertices of  $a$ , respectively. Denote the class of one-dimensional discrete convex functions by

$$\begin{aligned} \mathcal{C}_1 &= \{\varphi: \mathbb{Z} \rightarrow \mathbb{Z} \cup \{+\infty\} \mid \text{dom } \varphi \neq \emptyset, \\ & \quad \varphi(t-1) + \varphi(t+1) \geq 2\varphi(t) \quad (t \in \mathbb{Z})\}. \end{aligned}$$

For  $\varphi_a \in \mathcal{C}_1$  ( $a \in A$ ), representing the arc-cost in terms of flow, the *total cost function*  $f: \mathbb{Z}^T \rightarrow \mathbb{Z} \cup \{+\infty\}$  defined by

$$f(x) = \inf_{\xi} \left\{ \begin{array}{l} \sum_{a \in A} \varphi_a(\xi(a)): \\ \partial\xi(v) = -x(v) \quad (v \in T), \\ \partial\xi(v) = 0 \quad (v \in V \setminus T) \end{array} \right\} \quad (x \in \mathbb{Z}^T)$$

is M-convex, provided that  $f > -\infty$  (i.e.,  $f$  does not take the value of  $-\infty$ ). For  $\psi_a \in \mathcal{C}_1$  ( $a \in A$ ), representing the arc-cost in terms of tension, the total cost function  $g: \mathbb{Z}^T \rightarrow \mathbb{Z} \cup \{+\infty\}$  defined by

$$g(p) = \inf_p \left\{ \begin{array}{l} \sum_{a \in A} \psi_a(\eta(a)): \\ \eta = -\delta\tilde{p}, \\ \tilde{p}(v) = p(v) \quad (v \in T) \end{array} \right\} \quad (p \in \mathbb{Z}^T)$$

is L-convex, provided that  $g > -\infty$ . The two cost functions  $f(x)$  and  $g(p)$  are conjugate to each other in the sense that, if  $\psi_a = \varphi_a^\bullet$  ( $a \in A$ ), then  $g = f^\bullet$ .

*Example 2 (Polynomial matrix)* Let  $A(s)$  be an  $m \times n$  matrix of rank  $m$  with each entry being a polynomial in a variable  $s$ , and let  $\mathcal{B} \subseteq 2^V$  be the family of bases of  $A(s)$  with respect to linear independence of the column vectors; namely,  $J \subseteq V$  belongs to  $\mathcal{B}$  if and only if  $|J| = m$  and the column vectors with indices in  $J$  are linearly independent. Then  $f: \mathbb{Z}^V \rightarrow \mathbb{Z} \cup \{+\infty\}$  defined by

$$f(x) = \begin{cases} -\deg_s \det A[J] & (x = \chi_J, J \in \mathcal{B}) \\ +\infty & (\text{otherwise}) \end{cases}$$

is M-convex, where  $\chi_J \in \{0, 1\}^V$  is the characteristic vector of  $J$  (defined by  $\chi_J(v) = 1$  if  $v \in J$ , and  $= 0$  otherwise),  $A[J]$  denotes the  $m \times m$  submatrix with column indices in  $J \in \mathcal{B}$ , and  $\deg_s(\cdot)$  means the degree as a polynomial in  $s$ . The Grassmann-Plücker identity implies the exchange property of  $f$ . This example was the motivation of valuated matroids in [2,3], which in turn can be identified with the negative of M-convex functions  $f$  with  $\text{dom } f \subseteq \{0, 1\}^V$ .

For  $p = (p(v))_{v \in V} \in \mathbb{Z}^V$  denote by  $D(p)$  the diagonal matrix of order  $n = |V|$  with diagonal elements  $s^{p(v)}$  ( $v \in V$ ). Then the function  $g: \mathbb{Z}^V \rightarrow \mathbb{Z}$  defined by

$$g(p) = \max \{ \deg_s \det(A \cdot D(p))[J] : J \in \mathcal{B} \}$$

is L-convex [16], where  $(A \cdot D(p))[J]$  means the  $m \times m$  submatrix of  $A \cdot D(p)$  with column indices in  $J$ . We have  $g = f^\bullet$ .

**L-Convex Sets**

An L-convex set  $D \subseteq \mathbb{Z}^V$  has ‘no holes’ in the sense that  $D = \overline{D} \cap \mathbb{Z}^V$ , where  $\overline{D}$  denotes the convex hull of  $D$  in  $\mathbb{R}^V$ . Hence it is natural to consider the polyhedral description of  $\overline{D}$ , ‘L-convex polyhedron’ (see [15,16]). For any function  $\gamma: V \times V \rightarrow \mathbb{Z} \cup \{+\infty\}$  with  $\gamma(v, v) = 0$  ( $v \in V$ ), define

$$\mathbf{D}(\gamma) = \left\{ p \in \mathbb{R}^V : \begin{array}{l} p(v) - p(u) \leq \gamma(u, v) \\ (\forall u, v \in V) \end{array} \right\}.$$

If  $\mathbf{D}(\gamma) \neq \emptyset$ ,  $\mathbf{D}(\gamma)$  is an integral polyhedron and  $D = \mathbf{D}(\gamma) \cap \mathbb{Z}^V$  is an L-convex set. If  $\gamma$  satisfies triangle inequality:

$$\gamma(u, v) + \gamma(v, w) \geq \gamma(u, w) \quad (u, v, w \in V),$$

then  $\mathbf{D}(\gamma) \neq \emptyset$  and

$$\begin{aligned} \gamma(u, v) &= \sup \{ p(v) - p(u) : p \in \mathbf{D}(\gamma) \} \\ & \quad (u, v \in V). \end{aligned}$$

Conversely, for any nonempty  $D \subseteq \mathbf{Z}^V$ ,

$$\gamma(u, v) = \sup \{p(v) - p(u) : p \in D\} \quad (u, v \in V),$$

satisfies triangle inequality as well as  $\gamma(v, v) = 0$  ( $v \in V$ ), and if  $D$  is L-convex, then  $\overline{D} = \mathbf{D}(\gamma)$ . Thus there is a one-to-one correspondence between L-convex set  $D$  and function  $\gamma$  satisfying triangle inequality. In particular,  $D \subseteq \mathbf{Z}^V$  is L-convex if and only if  $D = \mathbf{D}(\gamma) \cap \mathbf{Z}^V$  for some  $\gamma$  satisfying triangle inequality. For L-convex sets  $D_1, D_2 \subseteq \mathbf{Z}^V$ , it holds that  $D_1 + D_2 = \overline{D_1 + D_2} \cap \mathbf{Z}^V$  and  $\overline{D_1} \cap \overline{D_2} = \overline{D_1 \cap D_2}$ .

It is also true that a function  $\gamma$  satisfying triangle inequality corresponds one-to-one to a positively homogeneous M-convex function  $f$  (i. e.,  $f(\lambda x) = \lambda f(x)$  for  $x \in \mathbf{Z}^V$  and  $0 \leq \lambda \in \mathbf{Z}$ ). The correspondence  $f \mapsto \gamma$  is given by

$$\gamma(u, v) = f(\chi_v - \chi_u) \quad (u, v \in V),$$

whereas  $\gamma \mapsto f$  by

$$f(x) = \inf_{\lambda} \left\{ \sum_{u,v \in V} \lambda_{uv} \gamma(u, v) : \begin{array}{l} \sum_{u,v \in V} \lambda_{uv} (\chi_v - \chi_u) = x, \\ 0 \leq \lambda_{uv} \in \mathbf{Z} \\ (u, v \in V) \end{array} \right\} \quad (x \in \mathbf{Z}^V).$$

The correspondence between L-convex sets and positively homogeneous M-convex functions via functions with triangle inequality is a special case of the conjugacy relationship between L- and M-convex functions.

**M-Convex Sets**

An M-convex set  $B \subseteq \mathbf{Z}^V$  has ‘no holes’ in the sense that  $B = \overline{B} \cap \mathbf{Z}^V$ . Hence it is natural to consider the polyhedral description of  $\overline{B}$ , ‘M-convex polyhedron’. A set function  $\rho: 2^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  is said to be *submodular* if

$$\rho(X) + \rho(Y) \geq \rho(X \cup Y) + \rho(X \cap Y) \quad (X, Y \subseteq V),$$

where the inequality is satisfied if  $\rho(X)$  or  $\rho(Y)$  is equal to  $+\infty$ . It is assumed throughout that  $\rho(\emptyset) = 0$  and  $\rho(V)$

$< +\infty$  for any set function  $\rho: 2^V \rightarrow \mathbf{Z} \cup \{+\infty\}$ . For a set function  $\rho$ , define

$$\mathbf{P}(\rho) = \left\{ x \in \mathbf{R}^V : \begin{array}{l} x(X) \leq \rho(X) \\ (\forall X \subseteq V), \\ x(V) = \rho(V) \end{array} \right\},$$

where  $x(X) = \sum_{v \in X} x(v)$ . If  $\rho$  is submodular,  $\mathbf{P}(\rho)$  is a nonempty integral polyhedron,  $B = \mathbf{P}(\rho) \cap \mathbf{Z}^V$  is an M-convex set, and

$$\rho(X) = \sup \{x(X) : x \in \mathbf{P}(\rho)\} \quad (X \subseteq V).$$

Conversely, for any nonempty  $B \subseteq \mathbf{Z}^V$ , define a set function  $\rho$  by

$$\rho(X) = \sup \{x(X) : x \in B\} \quad (X \subseteq V).$$

If  $B$  is M-convex, then  $\rho$  is submodular and  $\overline{B} = \mathbf{P}(\rho)$ . Thus there is a one-to-one correspondence between M-convex set  $B$  and submodular set function  $\rho$ . In particular,  $B \subseteq \mathbf{Z}^V$  is M-convex if and only if  $B = \mathbf{P}(\rho) \cap \mathbf{Z}^V$  for some submodular  $\rho$ . The correspondence  $B \leftrightarrow \rho$  is a restatement of a well-known fact [4,8]. For M-convex sets  $B_1, B_2 \subseteq \mathbf{Z}^V$ , it holds that  $B_1 + B_2 = \overline{B_1 + B_2} \cap \mathbf{Z}^V$  and  $\overline{B_1} \cap \overline{B_2} = \overline{B_1 \cap B_2}$ .

It is also true that a submodular set function  $\rho$  corresponds one-to-one to a positively homogeneous L-convex function  $g$ . The correspondence  $g \mapsto \rho$  is given by the restriction

$$\rho(X) = g(\chi_X) \quad (X \subseteq V)$$

( $\chi_X$  is the characteristic vector of  $X$ ), whereas  $\rho \mapsto g$  by the Lovász extension (explained below). The correspondence between M-convex sets and positively homogeneous L-convex functions via submodular set functions is a special case of the conjugacy relationship between M- and L-convex functions.

For a set function  $\rho: 2^V \rightarrow \mathbf{Z} \cup \{+\infty\}$ , the *Lovász extension* [11] of  $\rho$  is a function  $\widehat{\rho}: \mathbf{R}^V \rightarrow \mathbf{R} \cup \{+\infty\}$  defined by

$$\widehat{\rho}(p) = \sum_{j=1}^n (p_j - p_{j+1}) \rho(V_j) \quad (p \in \mathbf{R}^V),$$

where, for each  $p \in \mathbf{R}^V$ , the elements of  $V$  are indexed as  $\{v_1, \dots, v_n\}$  (with  $n = |V|$ ) in such a way that  $p(v_1) \geq \dots \geq p(v_n)$ ;  $p_j = p(v_j)$ ,  $V_j = \{v_1, \dots, v_j\}$  for  $j = 1, \dots, n$ , and

$p_{n+1} = 0$ . The right-hand side of the above expression is equal to  $+\infty$  if and only if  $p_j - p_{j+1} > 0$  and  $\rho(V_j) = +\infty$  for some  $j$  with  $1 \leq j \leq n-1$ . The Lovász extension  $\widehat{\rho}$  is indeed an extension of  $\rho$ , since  $\widehat{\rho}(\chi_X) = \rho(X)$  for  $X \subseteq V$ .

The relationship between submodularity and convexity is revealed by the statement [11] that a set function  $\rho$  is submodular if and only if its Lovász extension  $\widehat{\rho}$  is convex.

The restriction to  $\mathbf{Z}^V$  of the Lovász extension of a submodular set function is a positively homogeneous L-convex function, and any positively homogeneous L-convex function can be obtained in this way [15].

**Properties of L-Convex Functions**

For any  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  and  $x \in \mathbf{R}^V$ , define  $g[-x]: \mathbf{Z}^V \rightarrow \mathbf{R} \cup \{+\infty\}$  by

$$g[-x](p) = g(p) - \langle p, x \rangle \quad (p \in \mathbf{Z}^V).$$

The set of the minimizers of  $g[-x]$  is denoted as  $\text{argmin}(g[-x])$ .

Let  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  be L-convex. Then  $\text{dom } g$  is an L-convex set. For each  $p \in \text{dom } g$ ,

$$\rho_p(X) = g(p + \chi_X) - g(p) \quad (X \subseteq V)$$

is a submodular set function with  $\rho_p(\emptyset) = 0$  and  $\rho_p(V) < +\infty$ .

An L-convex function  $g$  can be extended to a convex function  $\bar{g}: \mathbf{R}^V \rightarrow \mathbf{R} \cup \{+\infty\}$  through the Lovász extension of the submodular set functions  $\rho_p$  for  $p \in \text{dom } g$ . Namely, for  $p \in \text{dom } g$  and  $q \in [0, 1]^V$ , it holds [15] that

$$\begin{aligned} \bar{g}(p + q) &= g(p) + \sum_{j=1}^n (q_j - q_{j+1})(g(p + \chi_{V_j}) - g(p)), \end{aligned}$$

where, for each  $q$ , the elements of  $V$  are indexed as  $\{v_1, \dots, v_n\}$  (with  $n = |V|$ ) in such a way that  $q(v_1) \geq \dots \geq q(v_n)$ ;  $q_j = q(v_j)$ ,  $V_j = \{v_1, \dots, v_j\}$  for  $j = 1, \dots, n$ , and  $q_{n+1} = 0$ . The expression of  $\bar{g}$  shows that an L-convex function is an integrally convex function in the sense of [5].

An L-convex function  $g$  enjoys *discrete midpoint convexity*:

$$g(p) + g(q) \geq g\left(\left\lceil \frac{p+q}{2} \right\rceil\right) + g\left(\left\lfloor \frac{p+q}{2} \right\rfloor\right)$$

for  $p, q \in \mathbf{Z}^V$ , where  $\lceil p \rceil$  (or  $\lfloor p \rfloor$ ) for any  $p \in \mathbf{R}^V$  denotes the vector obtained by rounding up (or down) the components of  $p$  to the nearest integers.

The minimum of an L-convex function  $g$  is characterized by the local minimality in the sense that, for  $p \in \text{dom } g$ ,  $g(p) \leq g(q)$  for all  $q \in \mathbf{Z}^V$  if and only if  $g(p + \mathbf{1}) = g(p) \leq g(p + \chi_X)$  for all  $X \subseteq V$ .

The minimizers of an L-convex function, if nonempty, form an L-convex set. For any  $x \in \mathbf{R}^V$ ,  $\text{argmin}(g[-x])$ , if nonempty, is an L-convex set. Conversely, this property characterizes L-convex functions under an auxiliary assumption.

A number of operations can be defined for L-convex functions [15,16]. For  $x \in \mathbf{Z}^V$ ,  $g[-x]$  is an L-convex function. For  $a \in \mathbf{Z}^V$  and  $\beta \in \mathbf{Z}$ ,  $g(a + \beta p)$  is L-convex in  $p$ . For  $U \subseteq V$ , the projection of  $g$  to  $U$ :

$$g^U(p') = \inf \{g(p', p''): p'' \in \mathbf{Z}^{V \setminus U}\} \quad (p' \in \mathbf{Z}^U)$$

is L-convex in  $p'$ , provided that  $g^U > -\infty$ . For  $\psi_v \in \mathcal{C}_1$  ( $v \in V$ ),

$$\widetilde{g}(p) = \inf_{q \in \mathbf{Z}^V} \left[ g(q) + \sum_{v \in V} \psi_v(p(v) - q(v)) \right]$$

is L-convex in  $p \in \mathbf{Z}^V$ , provided that  $\widetilde{g} > -\infty$ . The sum of two (or more) L-convex functions is L-convex, provided that its effective domain is nonempty.

**Properties of M-Convex Functions**

Let  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  be M-convex. Then  $\text{dom } f$  is an M-convex set. For each  $x \in \text{dom } f$ ,

$$\gamma_x(u, v) = f(x - \chi_u + \chi_v) - f(x) \quad (u, v \in V)$$

satisfies [16] triangle inequality.

An M-convex function  $f$  can be extended to a convex function  $\bar{f}: \mathbf{R}^V \rightarrow \mathbf{R} \cup \{+\infty\}$ , and the value of  $\bar{f}(x)$  for  $x \in \mathbf{R}^V$  is determined by  $\{f(y): y \in \mathbf{Z}^V, \lfloor x \rfloor \leq y \leq \lceil x \rceil\}$ . That is, an M-convex function is an integrally convex function in the sense of [5].

The minimum of an M-convex function  $f$  is characterized by the local minimality in the sense that for  $x \in \text{dom } f$ ,  $f(x) \leq f(y)$  for all  $y \in \mathbf{Z}^V$  if and only if  $f(x) \leq f(x - \chi_u + \chi_v)$  for all  $u, v \in V$  [12,15,18].

The minimizers of an M-convex function, if nonempty, form an M-convex set. Moreover, for any

$p \in \mathbf{R}^V$ ,  $\text{argmin}(f[-p])$ , if nonempty, is an M-convex set. Conversely, this property characterizes M-convex functions, under an auxiliary assumption that the effective domain is bounded or the function can be extended to a convex function over  $\mathbf{R}^V$  (see [12,15]).

The level set of an M-convex function is not necessarily an M-convex set, but enjoys a weaker exchange property. Namely, for any  $p \in \mathbf{R}^V$  and  $\alpha \in \mathbf{R}$ ,  $S = \{x \in \mathbf{Z}^V : f[-p](x) \leq \alpha\}$  (the level set of  $f[-p]$ ) satisfies: For  $x, y \in S$  and for  $u \in \text{supp}^+(x - y)$ , there exists  $v \in \text{supp}^-(x - y)$  such that either  $x - \chi_u + \chi_v \in S$  or  $y + \chi_u - \chi_v \in S$ . Conversely, this property characterizes M-convex functions [25].

A number of operations can be defined for M-convex functions [15,16]. For  $p \in \mathbf{Z}^V$ ,  $f[-p]$  is an M-convex function. For  $a \in \mathbf{Z}^V$ ,  $f(a - x)$  and  $f(a + x)$  are M-convex in  $x$ . For  $U \subseteq V$ , the restriction of  $f$  to  $U$ :

$$f_U(x') = f(x', \mathbf{0}_{V \setminus U}) \quad (x' \in \mathbf{Z}^U)$$

(where  $\mathbf{0}_{V \setminus U}$  is the zero vector in  $\mathbf{Z}^{V \setminus U}$ ) is M-convex in  $x'$ , provided that  $\text{dom } f_U \neq \emptyset$ . For  $\varphi_v \in \mathcal{C}_1$  ( $v \in V$ ),

$$\tilde{f}(x) = f(x) + \sum_{v \in V} \varphi_v(x(v)) \quad (x \in \mathbf{Z}^V)$$

is M-convex, provided that  $\text{dom } \tilde{f} \neq \emptyset$ . In particular, a separable convex function  $\tilde{f}(x) = \sum_{v \in V} \varphi_v(x(v))$  with  $\text{dom } \tilde{f}$  being an M-convex set is an M-convex function. For two M-convex functions  $f_1$  and  $f_2$ , the integral convolution

$$\begin{aligned} & (f_1 \square f_2)(x) \\ &= \inf \left\{ f_1(x_1) + f_2(x_2) : \begin{array}{l} x = x_1 + x_2 \\ x_1, x_2 \in \mathbf{Z}^V \end{array} \right\} \\ & \hspace{15em} (x \in \mathbf{Z}^V) \end{aligned}$$

is either M-convex or else  $(f_1 \square f_2)(x) = \pm \infty$  for all  $x \in \mathbf{Z}^V$ .

Sum of two M-convex functions is not necessarily M-convex; such function with nonempty effective domain is called  $M_2$ -convex. Convolution of two L-convex functions is not necessarily L-convex; such function with nonempty effective domain is called  $L_2$ -convex.  $M_2$ - and  $L_2$ -convex functions are in one-to-one correspondence through the integral Fenchel-Legendre transformation.

### $L^{\natural}$ - and $M^{\natural}$ -Convexity

$L^{\natural}$ - and  $M^{\natural}$ -convexity are variants of, and essentially equivalent to, L- and M-convexity, respectively.  $L^{\natural}$ - and  $M^{\natural}$ -convex functions are introduced in [9] and [19], respectively.

Let  $v_0$  be a new element not in  $V$  and define  $\tilde{V} = \{v_0\} \cup V$ . A function  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  with  $\text{dom } g \neq \emptyset$  is called  $L^{\natural}$ -convex if it is expressed in terms of an L-convex function  $\tilde{g}: \mathbf{Z}^{\tilde{V}} \rightarrow \mathbf{Z} \cup \{+\infty\}$  as  $g(p) = \tilde{g}(0, p)$ . Namely, an  $L^{\natural}$ -convex function is a function obtained as the restriction of an L-convex function. Conversely, an  $L^{\natural}$ -convex function determines the corresponding L-convex function up to the constant  $r$  in the definition of L-convex function.

An  $L^{\natural}$ -convex function is essentially the same as a submodular integrally convex function of [5], and hence is characterized by discrete midpoint convexity [9]. An L-convex function, enjoying discrete midpoint convexity, is an  $L^{\natural}$ -convex function.

Quadratic function

$$g(p) = \sum_{i=1}^n \sum_{j=1}^n a_{ij} p_i p_j \quad (p \in \mathbf{Z}^n)$$

with  $a_{ij} = a_{ji} \in \mathbf{Z}$  is  $L^{\natural}$ -convex if and only if  $a_{ij} \leq 0$  ( $i \neq j$ ) and  $\sum_{j=1}^n a_{ij} \geq 0$  ( $i = 1, \dots, n$ ). For  $\{\psi_i \in \mathcal{C}_1 : i = 1, \dots, n\}$ , a separable convex function

$$g(p) = \sum_{i=1}^n \psi_i(p_i) \quad (p \in \mathbf{Z}^n)$$

is  $L^{\natural}$ -convex.

The properties of L-convex functions mentioned above are carried over, mutatis mutandis, to  $L^{\natural}$ -convex functions. In addition, the restriction of an  $L^{\natural}$ -convex function  $g$  to  $U \subseteq V$ , denoted  $g_U$ , is  $L^{\natural}$ -convex.

A subset of  $\mathbf{Z}^V$  is called an  $L^{\natural}$ -convex set if its indicator function is an  $L^{\natural}$ -convex function. A set  $E \subseteq \mathbf{Z}^V$  is an  $L^{\natural}$ -convex set if and only if

$$p, q \in E \Rightarrow \left\lceil \frac{p+q}{2} \right\rceil, \left\lfloor \frac{p+q}{2} \right\rfloor \in E.$$

A function  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  with  $\text{dom } f \neq \emptyset$  is called  $M^{\natural}$ -convex if it is expressed in terms of an M-convex function  $\tilde{f}: \mathbf{Z}^{\tilde{V}} \rightarrow \mathbf{Z} \cup \{+\infty\}$  as

$$\tilde{f}(x_0, x) = \begin{cases} f(x) & \text{if } x_0 + \sum_{u \in V} x(u) = 0 \\ +\infty & \text{otherwise.} \end{cases}$$

Namely, an  $M^{\natural}$ -convex function is a function obtained as the projection of an M-convex function. Conversely, an  $M^{\natural}$ -convex function determines the corresponding M-convex function up to a translation of  $\text{dom } f$  in the direction of  $v_0$ . A function  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  with  $\text{dom } f \neq \emptyset$  is  $M^{\natural}$ -convex if and only if (see [19]) it satisfies

- $M^{\natural}$ -EXC) For  $x, y \in \text{dom } f$  and  $u \in \text{supp}^+(x - y)$ ,
 
$$f(x) + f(y) \geq \min \left[ f(x - \chi_u) + f(y + \chi_u), \min_{v \in \text{supp}^-(x-y)} \{f(x - \chi_u + \chi_v) + f(y + \chi_u - \chi_v)\} \right].$$

Since M-EXC) implies  $M^{\natural}$ -EXC), an M-convex function is an  $M^{\natural}$ -convex function.

Quadratic function

$$f(x) = \sum_{i=1}^n a_i x_i^2 + b \sum_{i < j} x_i x_j \quad (x \in \mathbf{Z}^n)$$

with  $a_i \in \mathbf{Z}$  ( $1 \leq i \leq n$ ),  $b \in \mathbf{Z}$  is  $M^{\natural}$ -convex if  $0 \leq b \leq 2 \min_{1 \leq i \leq n} a_i$  (cf. [19]). For  $\{\varphi_i \in \mathcal{C}_1: i = 0, \dots, n\}$ , a function of the form

$$f(x) = \varphi_0 \left( \sum_{i=1}^n x_i \right) + \sum_{i=1}^n \varphi_i(x_i) \quad (x \in \mathbf{Z}^n)$$

is  $M^{\natural}$ -convex [19]; a separable convex function is a special case of this (with  $\varphi_0 = 0$ ). More generally, for  $\{\varphi_X \in \mathcal{C}_1: X \in \mathcal{T}\}$  indexed by a laminar family  $\mathcal{T} \subseteq 2^V$ , the function

$$f(x) = \sum_{X \in \mathcal{T}} \varphi_X(x(X)) \quad (x \in \mathbf{Z}^V)$$

is  $M^{\natural}$ -convex [1], where  $\mathcal{T}$  is called *laminar* if for any  $X, Y \in \mathcal{T}$ , at least one of  $X \cap Y, X \setminus Y, Y \setminus X$  is empty.

The properties of M-convex functions mentioned above are carried over, mutatis mutandis, to  $M^{\natural}$ -convex functions. In addition, the projection of an  $M^{\natural}$ -convex function  $f$  to  $U \subseteq V$ , denoted  $f^U$ , is  $M^{\natural}$ -convex.

A subset of  $\mathbf{Z}^V$  is called an  $M^{\natural}$ -convex set if its indicator function is an  $M^{\natural}$ -convex function. A set  $Q \subseteq \mathbf{Z}^V$  is an  $M^{\natural}$ -convex set if and only if  $Q$  is the set of integer points of an integral generalized polymatroid (cf. [7] for generalized polymatroids).

As a consequence of the conjugacy between L- and M-convexity,  $L^{\natural}$ -convex functions and  $M^{\natural}$ -convex functions are conjugate to each other under the integral Fenchel–Legendre transformation.

### Duality

Discrete duality theorems hold true for L-convex/concave and M-convex/concave functions. A function  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{-\infty\}$  is called L-concave (respectively,  $L^{\natural}$ -, M-, or  $M^{\natural}$ -concave) if  $-g$  is L-convex (respectively,  $L^{\natural}$ -, M-, or  $M^{\natural}$ -convex);  $\text{dom } g$  means the effective domain of  $-g$ . The concave counterpart of the discrete Fenchel–Legendre transform is defined as

$$g^\circ(p) = \inf \{ \langle p, x \rangle - g(x) : x \in \mathbf{Z}^V \} \quad (p \in \mathbf{Z}^V).$$

A discrete separation theorem for L-convex/concave functions, named *L-separation theorem* [15] (see also [9]), reads as follows. Let  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  be an  $L^{\natural}$ -convex function and  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{-\infty\}$  be an  $L^{\natural}$ -concave function such that  $\text{dom } f \cap \text{dom } g \neq \emptyset$  or  $\text{dom } f^\bullet \cap \text{dom } g^\circ \neq \emptyset$ . If  $f(p) \geq g(p)$  ( $p \in \mathbf{Z}^V$ ), there exist  $\beta^* \in \mathbf{Z}$  and  $x^* \in \mathbf{Z}^V$  such that

$$f(p) \geq \beta^* + \langle p, x^* \rangle \geq g(p) \quad (p \in \mathbf{Z}^V).$$

Since a submodular set function can be identified with a positively homogeneous L-convex function, the L-separation theorem implies *Frank's discrete separation theorem* for a pair of sub/supermodular functions [6], which reads as follows. Let  $\rho: 2^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  and  $\mu: 2^V \rightarrow \mathbf{Z} \cup \{-\infty\}$  be submodular and supermodular functions, respectively, with  $\rho(\emptyset) = \mu(\emptyset) = 0$ ,  $\rho(V) < +\infty$ ,  $\mu(V) > -\infty$ , where  $\mu$  is called *supermodular* if  $-\mu$  is submodular. If  $\rho(X) \geq \mu(X)$  ( $X \subseteq V$ ), there exists  $x^* \in \mathbf{Z}^V$  such that

$$\rho(X) \geq x^*(X) \geq \mu(X) \quad (X \subseteq V).$$

Another discrete separation theorem, *M-separation theorem* [12,15] (see also [9]), holds true for M-convex/concave functions. Namely, let  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  be an  $M^{\natural}$ -convex function and  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{-\infty\}$  be an  $M^{\natural}$ -concave function such that  $\text{dom } f \cap \text{dom } g \neq \emptyset$  or  $\text{dom } f^\bullet \cap \text{dom } g^\circ \neq \emptyset$ . If  $f(x) \geq g(x)$  ( $x \in \mathbf{Z}^V$ ), there exist  $\alpha^* \in \mathbf{Z}$  and  $p^* \in \mathbf{Z}^V$  such that

$$f(x) \geq \alpha^* + \langle p^*, x \rangle \geq g(x) \quad (x \in \mathbf{Z}^V).$$

The L- and M-separation theorems are conjugate to each other, while a self-conjugate statement can be made in the form of the *Fenchel-type duality* [12,15], as follows. Let  $f: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{+\infty\}$  be an  $L^{\natural}$ -convex function and  $g: \mathbf{Z}^V \rightarrow \mathbf{Z} \cup \{-\infty\}$  be an  $L^{\natural}$ -concave function

such that  $\text{dom } f \cap \text{dom } g \neq \emptyset$  or  $\text{dom } f^\bullet \cap \text{dom } g^\circ \neq \emptyset$ . Then it holds that

$$\begin{aligned} & \inf \{f(p) - g(p) : p \in \mathbb{Z}^V\} \\ & = \sup \{g^\circ(x) - f^\bullet(x) : x \in \mathbb{Z}^V\}. \end{aligned}$$

Moreover, if this common value is finite, the infimum is attained by some  $p \in \text{dom } f \cap \text{dom } g$  and the supremum is attained by some  $x \in \text{dom } f^\bullet \cap \text{dom } g^\circ$ .

*Example 3* Here is a simple example to illustrate the subtlety of discrete separation for discrete functions. Functions  $f: \mathbb{Z}^2 \rightarrow \mathbb{Z}$  and  $g: \mathbb{Z}^2 \rightarrow \mathbb{Z}$  defined by  $f(x_1, x_2) = \max(0, x_1 + x_2)$  and  $g(x_1, x_2) = \min(x_1, x_2)$  can be extended respectively to a convex function  $\bar{f}: \mathbb{R}^2 \rightarrow \mathbb{R}$  and a concave function  $\bar{g}: \mathbb{R}^2 \rightarrow \mathbb{R}$  according to the defining expressions. With  $\bar{p} = (\frac{1}{2}, \frac{1}{2})$ , we have  $\bar{f}(x) \geq \langle \bar{p}, x \rangle \geq \bar{g}(x)$  for all  $x \in \mathbb{R}^2$ , and a fortiori,  $f(x) \geq \langle \bar{p}, x \rangle \geq g(x)$  for all  $x \in \mathbb{Z}^2$ . However, there exists no integral vector  $p \in \mathbb{Z}^2$  such that  $f(x) \geq \langle p, x \rangle \geq g(x)$  for all  $x \in \mathbb{Z}^2$ . Note also that  $f$  is  $M^\natural$ -convex and  $g$  is L-concave.

**Network Duality**

A conjugate pair of M- and L-convex functions can be transformed through a network ([12,16]; see also [23]). Let  $G = (V, A)$  be a directed graph with arc set  $A$  and vertex set  $V$  partitioned into three disjoint parts as  $V = V^+ \cup V^0 \cup V^-$ . For  $\varphi_a \in \mathcal{C}_1$  ( $a \in A$ ) and M-convex  $f: \mathbb{Z}^{V^+} \rightarrow \mathbb{Z} \cup \{+\infty\}$ , define  $\tilde{f}: \mathbb{Z}^{V^-} \rightarrow \mathbb{Z} \cup \{\pm\infty\}$  by

$$\begin{aligned} \tilde{f}(y) &= \inf_{\xi, x} \\ & \left\{ f(x) + \sum_{a \in A} \varphi_a(\xi(a)) : \begin{array}{l} \partial \xi = (x, 0, -y) \\ \xi \in \mathbb{Z}^{V^+ \cup V^0 \cup V^-} \\ \xi \in \mathbb{Z}^A \end{array} \right\}. \end{aligned}$$

For  $\psi_a \in \mathcal{C}_1$  ( $a \in A$ ) and L-convex  $g: \mathbb{Z}^{V^+} \rightarrow \mathbb{Z} \cup \{+\infty\}$ , define  $\tilde{g}: \mathbb{Z}^{V^-} \rightarrow \mathbb{Z} \cup \{\pm\infty\}$  by

$$\begin{aligned} \tilde{g}(q) &= \inf_{\eta, p, r} \\ & \left\{ g(p) + \sum_{a \in A} \psi_a(\eta(a)) : \begin{array}{l} \eta = -\delta(p, r, q) \\ \eta \in \mathbb{Z}^A \\ (p, r, q) \in \mathbb{Z}^{V^+ \cup V^0 \cup V^-} \end{array} \right\}. \end{aligned}$$

Then  $\tilde{f}$  is M-convex, provided that  $\tilde{f} > -\infty$ , and  $\tilde{g}$  is L-convex, provided that  $\tilde{g} > -\infty$ . If  $g = f^\bullet$  and  $\psi_a =$

$\varphi_a^\bullet$  ( $a \in A$ ), then  $\tilde{g} = \tilde{f}^\bullet$ . A special case ( $V^+ = V$ ) of the last statement yields the network duality:

$$\begin{aligned} & \inf \left\{ \Phi(x, \xi) : \begin{array}{l} \partial \xi = x, \\ x \in \mathbb{Z}^V, \\ \xi \in \mathbb{Z}^A \end{array} \right\} \\ & = \sup \left\{ \Psi(p, \eta) : \begin{array}{l} \eta = -\delta p, \\ p \in \mathbb{Z}^V, \\ \eta \in \mathbb{Z}^A \end{array} \right\}, \end{aligned}$$

where  $\Phi(x, \xi) = f(x) + \sum_{a \in A} \varphi_a(\xi(a))$ ,  $\Psi(p, \eta) = -g(p) - \sum_{a \in A} \psi_a(\eta(a))$  and the finiteness of  $\inf \Phi$  or  $\sup \Psi$  is assumed. The network duality is equivalent to the Fenchel-type duality.

**Subdifferentials**

The subdifferential of  $f: \mathbb{Z}^V \rightarrow \mathbb{Z} \cup \{+\infty\}$  at  $x \in \text{dom } f$  is defined by  $\{p \in \mathbb{R}^V : f(y) - f(x) \geq \langle p, y - x \rangle (\forall y \in \mathbb{Z}^V)\}$ . The subdifferential of an  $L_2$ - or  $M_2$ -convex function forms an integral polyhedron. More specifically:

- The subdifferential of an L-convex function is an integral base polyhedron (an M-convex polyhedron).
- The subdifferential of an  $L_2$ -convex function is the intersection of two integral base polyhedra (M-convex polyhedra).
- The subdifferential of an M-convex function is an L-convex polyhedron.
- The subdifferential of an  $M_2$ -convex function is the Minkowski sum of two L-convex polyhedra.

Similar statements hold true with L and M replaced respectively by  $L^\natural$  and  $M^\natural$ .

**Algorithms**

On the basis of the equivalence of  $L^\natural$ -convex functions and submodular integrally convex functions, the minimization of an L-convex function can be done by the algorithm of [5], which relies on the ellipsoid method. The minimization of an M-convex function can be done by purely combinatorial algorithms; a greedy-type algorithm [2] for valuated matroids and a domain reduction-type polynomial time algorithm [24] for M-convex functions. Algorithms for duality of M-convex functions (in other words, for  $M_2$ -convex functions) are also developed; polynomial algorithms [14,22] for valuated matroids, and a finite primal algorithm [18] and a polynomial time conjugate-scaling algorithm [10] for the submodular flow problem.

## Applications

A discrete analog of the conjugate duality framework [21] for nonlinear optimization is developed in [15]. An application of M-convex functions to engineering system analysis and matrix theory is in [13,17]. M-convex functions find applications also in mathematical economics [1].

Linear complementarity problem; Mixed integer programming; Bimatrix games; Mixed integer problem; Minimum norm solution

In this article we consider the general *linear complementarity problem* (LCP) of finding a vector  $x \in \mathbf{R}^n$  such that

$$Mx + q \geq 0, \quad x \geq 0, \quad x^T Mx + q^T x = 0$$

(or proving that such an  $x$  does not exist), where  $M$  is an  $n \times n$  rational matrix and  $q \in \mathbf{R}^n$  is a rational vector. For given data  $M$  and  $q$ , the problem is generally denoted by  $\text{LCP}(M, q)$ . The LCP unifies a number of important problems in operations research. In particular, it generalizes the primal-dual linear programming problem, convex quadratic programming, and *bimatrix games* [1,2].

For the general matrix  $M$ , where  $S = \{x: Mx + q \geq 0, x \geq 0\}$  can be bounded or unbounded, the LCP can always be solved by solving a specific zero-one, linear, *mixed integer problem* with  $n$  zero-one variables. Consider the following mixed zero-one integer problem:

$$(\text{MIP}) \quad \begin{cases} \max_{\alpha, y, z} & \alpha \\ \text{s.t.} & 0 \leq My + \alpha q \leq e - z, \\ & \alpha \geq 0, \quad 0 \leq y \leq z, \\ & z \in \{0, 1\}^n. \end{cases}$$

**Theorem 1** *Let  $(\alpha^*, y^*, z^*)$  be any optimal solution of (MIP). If  $\alpha^* > 0$ , then  $x^* = y^*/\alpha^*$  solves the LCP. If in the optimal solution  $\alpha^* = 0$ , then the LCP has no solution.*

The equivalent mixed integer programming formulation (MIP) was first given in [3]. Every feasible point  $(\alpha, y, z)$  of (MIP), with  $\alpha > 0$ , corresponds to a solution of LCP. Therefore, solving (MIP), we may generate several solutions of the corresponding LCP. J.B. Rosen [4] proved that the solution obtained by solving (MIP) is the *minimum norm solution* to the linear complementarity problem.

### Keywords

Pivot rules; Anticycling; Least-index; Recursion;  
Oriented matroids

From the early days of mathematical optimization people were looking for simple rules that ensure that certain algorithms terminate in a finite number of steps. Specifically, on combinatorial structures the lack of finite termination imply that the algorithm cycles, i. e. periodically visits the same solutions. That is why rules ensuring finite termination of algorithms on finite structures are frequently referred to as *anticycling rules*.

One frequently used anticycling rule in linear optimization (cf. ► **Linear programming**) is the so-called *lexicographic pivoting rule* [9]. The other large class of anticycling procedures, the ‘least-index’ rules, is the subject of this paper. least-index rules were designed for network flow problems, linear optimization problems, linear complementarity problems and oriented matroid programming problems. These classes will be considered in the sequel.

### Consistent Labeling For the Max-Flow Problem

The *maximal flow problem* (see e. g. [11]; [24]) is one of the basic problems of mathematical programming. The problem is given as follows. A *directed capacitated net-*

*work*  $(N, A, u)$  is given, where  $N$ , the set of nodes, is a finite set;  $A \subset N \times N$  is the set of directed arcs; finally,  $u \in \mathbf{R}^A$  denotes the nonnegative capacity upper bound for flows through the arcs. Let further  $s, t \in N$  be specified as the source and the sink in the network. A vector  $f \in \mathbf{R}^A$  is a *flow* in the network, if the incoming flow at each node, different from the source and the sink, is equal to the flow going out from the node. The goal is to find a maximal flow, namely a flow for which the total flow flowing out of the source or, equivalently, flowing in to the sink is the largest possible. The *Ford–Fulkerson algorithm* is the best known algorithm to find such a maximal flow. It is based on generating augmenting path’s subsequently. A *path*  $P$  connecting the source  $s$  and the sink  $t$  is a finite subset of arcs, where the source is the tail of the first arc; the sink is the head of the last arc; finally, the tail of an arc is always equal to the head of its predecessor. For ease of simplicity let us assume that if  $(v^1, v^2) \in A$ , then  $(v^2, v^1) \in A$  as well. If the opposite arc were not present, we can introduce it with zero capacity.

0	Initialization. Let $f$ be equal to zero. Let a free capacity network $(N, \bar{A}, \bar{u})$ be defined. Initially let $\bar{A} = \{a \in A : u_a > 0\}$ and $\bar{u} = u$ .
1	Augmenting path. Let $P$ be a path from $s$ to $t$ in the free capacity network. IF no such path exists, THEN STOP; A maximal flow is obtained.
2	Augmenting the flow. Let $\vartheta$ be the minimum of the arc capacities along the path $P$ . Clearly $\vartheta > 0$ . Increase the flow $f$ on each arc of $P$ by $\vartheta$ .
3	Update the free-capacity network. Decrease (increase) $\bar{u}_a$ by $\vartheta$ if the (opposite) of arc $a$ is on the path $P$ . Let $\bar{A} = \{a \in A : \bar{u}_a > 0\}$ . Go to Step 1.

### The Ford–Fulkerson max-flow algorithm

At each iteration cycle the flow value strictly increases. Thus, if the vector  $u$  is integral and the max-flow problem is bounded, then the Ford–Fulkerson algorithm provides a maximal flow in a finite number of steps. However, if the vector  $u$  contains irrational com-

ponents, then the algorithm does not terminate in a finite number of steps and, even worse, it might converge to a nonoptimal flow. For such an example see [11,24]. An elegant solution for this problem is the *consistent labeling algorithm* of A.W. Tucker [28]. This most simple refinement reads as follows:

Be consistent at any time during the algorithm, specifically when building the augmenting path by using the *labeling procedure*. Whenever a labeled but unscanned subset of nodes is given during the procedure pick always the same from the same subset to be scanned. Particularly, if we assign an index to each node, then we are supposed to choose always the least-indexed node among the possibilities.

Tucker writes [28]: ‘Fulkerson (unpublished) conjectured that a consistent labeling procedure would be polynomially bounded; a proof of this conjecture appears to be very difficult.’

### Linear Optimization

Before discussing the general LO problem, first the linear *feasibility problem* is considered.

0	Initialization. Let $T(B)$ be an arbitrary basis tableau and fix an arbitrary ordering of the variables.
1	Leaving variable selection. Let $K_P$ be the set of the indices of the infeasible variables in the basis. IF $K_P = \emptyset$ , THEN STOP; the feasibility problem is solved. ELSE, let $p$ be the least-index in $K_P$ and then $x_p$ will leave the basis.
2	Entering variable selection. Let $K_D$ be the set of the column indices of the negative elements in row $p$ of $T(B)$ . IF $K_D = \emptyset$ , THEN STOP; Row $p$ of the tableau $T(B)$ gives an evidence that the feasibility problem is inconsistent and row $p$ of the inverse basis is a solution of the alternative system. ELSE, let $q$ be the least-index in $K_D$ and then $x_q$ will enter the basis.
3	Basis transformation. Pivot on $(p, q)$ . Go to Step 1.

Pivot rule

### Least-Index Rules for Feasibility Problem

The feasibility problem

$$Ax = b, \quad x \geq 0,$$

and its alternative pair

$$b^T y > 0, \quad A^T y \leq 0,$$

can be solved by a very simple least-index pivot algorithm. A fundamental result, the so-called *Farkas lemma* (cf. also ► **Farkas lemma**; ► **Farkas lemma: Generalizations**) [10] says that exactly one of the two alternative systems has a solution. This result is also known as the *theorem of the alternatives*. When a simple finite pivot rule gives a solution to either of the two alternatives, an elementary constructive proof for the Farkas lemma and its relatives is obtained. The above simple finite least-index pivot rule for the feasibility problem is a special case (see below) of Bland’s algorithm [5]. It is taken from [19] where the role of pivoting, and specifically the role of finite, least-index pivot rules in linear algebra is explored.

### The Linear Optimization Problem

The general linear optimization (LO), linear programming (cf. ► **Linear programming**), problem will be considered in the standard primal form

$$\min \{c^T x : Ax = b, x \geq 0\},$$

together with its standard dual

$$\max \{b^T y : A^T y \leq c\}.$$

One of the most efficient, and for a long time the only, practical method to solve LO problems was the simplex method of G.B. Dantzig. The *simplex method* is a *pivot algorithm* that traverses through feasible *basic solutions* while the objective value is improving. The simplex method is in practice one of the most efficient algorithms but it is theoretically a finite algorithm only for *nondegenerate problems*.

A basis is called *primal degenerate* if at least one of the basic variables is zero; it is called *dual degenerate* if the reduced cost of at least one nonbasic variable is zero. In general, the basis is degenerate if it is either primal or dual, or both primal and dual degenerate. The LO problem is degenerate, if it has a degenerate ba-

sis. A pivot is called degenerate when after the pivot the objective remains unchanged. When the problem is *degenerate* the objective might stay the same in subsequent iterations and the simplex algorithm may *cycle*, i. e. starting from a basis, after some iterations the same basis is revisited and this process is repeated endlessly. Because the simplex method produces a sequence with monotonically improving objective values, the objective stays constant in a cycle, thus each pivot in the cycle must be degenerate. The possibility of cycling was recognized shortly after the invention of the simplex algorithm. Cycling examples were given by E.M.L. Beale [2] and by A.J. Hoffman [17]. Recently (1999) a scheme to construct cycling LO examples is presented in [15]. These examples made evident that extra techniques are needed to ensure finite termination of simplex methods. The first and widely used such tool is the class of lexicographic pivoting rules (cf. ► **Lexicographic pivoting rules**). Other, more recent techniques are the *least-index anticycling rules* and some more general recursive schemes.

### Least-Index Pivoting Methods for LO

Cycling of the simplex method is possible only when the LO problem is degenerate. In that case not only many variables might be eligible to enter, but also to leave the basis. The least-index primal simplex rule makes the selection of both the entering and the leaving variable uniquely determined. Least-index rules are based on consistent selection among the possibilities. The first such rule for the simplex method was published by R.G. Bland [4,5].

The least-index simplex method is finite. The finiteness proofs are quite elementary. All are based on the simple fact that there is a finite number of different basis tableaus. Further, orthogonality of the primal and dual spaces on some recursive argumentation is used [4,5,27]

It is straightforward to derive the least-index dual simplex algorithm. The only restriction relative to the dual simplex algorithm is, that when there are more candidates to leave or to enter the basis, always the least-indexed candidate has to be selected.

An interesting use of least index-resolution is used in [18] by designing finite primal-dual type Hungarian methods for LO. Note that finite criss-cross rules (cf.

0	Initialization Let $T(B)$ be a given primal feasible basis tableau and fix an arbitrary ordering of the variables.
1	Entering variable selection. Let $K_D$ be the set of the indices of the dual infeasible variables, i.e. those with negative reduced cost. IF $K_D = \emptyset$ , THEN STOP; The tableau $T(B)$ is optimal and this way a pair of solutions is obtained. ELSE, let $q$ be the least-index in $K_D$ and $x_q$ , will enter the basis.
2	Leaving variable selection. Let $K_P$ be the set of the indices of those candidate pivot elements in column $q$ that satisfy the usual pivot selection conditions of the primal simplex method. IF $K_P = \emptyset$ , THEN STOP; the primal problem is unbounded, and so the dual problem is infeasible. ELSE, let $p$ be the least-index in $K_P$ and then $x_p$ will leave the basis.
3	Basis transformation. Pivot on $(p, q)$ . Go to Step 1.

### The least-index primal simplex rule

also ► **Criss-cross pivoting rules**) [14,26] make maximum possible use of least-index resolution.

Least-index simplex methods are not polynomial, they might require exponential number of steps to solve a LO problem, as it was shown by D. Avis and V. Chvátal [1]. Their example is essentially the Klee–Minty polytope [21]. Another example, again on the Klee–Minty polytope, is Roos’s exponential example [25] for the least-index criss-cross method. Here the initial basis is feasible and, although it is not required, feasibility happens to be preserved, thus the criss-cross method reduces to a least index simplex method.

### Linear Complementarity Problems

A linear complementarity problem (cf. ► **Linear complementarity problem**) (LCP) is given as follows:

$$-Mx + s = t, \quad x, s \geq 0, \quad x^T s = 0.$$

Pivot algorithms are looking for a *complementary basis* solution of the LCP. A basis is called complementary, if

exactly one of the complementary variables  $x_i$  and  $s_i$  for all  $i$  is in the basis.

The solvability of LCP depends on the properties of the matrix  $M$ . One of the simplest case is when  $M$  is a  $P$ -matrix. The matrix  $M$  is a  $P$ -matrix if all of its principal minors are positive. K.G. Murty [22] presented an utmost simple finite pivot algorithm for solving the  $P$ -matrix LCP. This algorithm is a least-index *principal pivot algorithm*.

Two extremal behaviors, exponential in the worst case and polynomial in average, of this finite pivot rule is studied in [13].

Finite least-index pivot rules are developed for larger classes of LCPs. All are least-index principal pivoting methods, some more classical feasibility preserving simplex type methods [7,8,23], others are least-index criss-cross pivoting rules (cf. ► [Criss-cross pivoting rules](#)) [6,16,20]. More details are given in ► [Principal pivoting methods for linear complementarity problems](#).

0	Initialization. Let $T(B)$ be complementary basis tableau and fix an arbitrary ordering of the variables. (We can choose $x = 0$ , $s = t$ i.e., $x$ nonbasic, $s$ basic.)
1	Leaving variable selection. Let $K$ be the set of the infeasible variables. IF $K = \emptyset$ , THEN STOP; a complementary solution for LCP is obtained. ELSE, let $p$ be the least-index in $K$ .
2	Basis transformation. Pivot on $(p, p)$ , i.e. replace the least-indexed infeasible variable in the basis by its complementary pair. Go to Step 1.

#### Murty's Bard-type schema

#### Least-Index Rules and Oriented Matroids

The least-index simplex method was originally designed for oriented matroid linear programming (cf. also ► [Oriented matroids](#)) [3,4]. It turned soon out, that this is *not* a finite algorithm in the oriented matroid context. The reason is the possibility of *nondegenerate cycling* [3,12], a phenomenon what is impossible in the linear case. An apparent difference between the linear

and the oriented matroid context is that for oriented matroids none of the finite-, recursive- or least-index-type rules yield a simplex method, i. e. a pivot method that preserves feasibility of the basis throughout. This discrepancy is also due to the possibility of nondegenerate cycling.

Orthogonal polynomials; Least squares; Padé-type approximation; Quadrature methods

Let  $c$  be the linear functional on the space of complex polynomials defined by

$$c(x^i) = \begin{cases} c_i \in \mathbb{C}, & i = 0, 1, \dots, \\ 0, & i < 0. \end{cases}$$

It is said that  $\{P_k\}$  forms a family of (formal) *orthogonal polynomials* with respect to  $c$  if  $\forall k$ :

- $P_k$  has the exact degree  $k$ ,
- $c(x^i P_k(x)) = 0$  for  $i = 0, \dots, k - 1$ .

Such a family exists if,  $\forall k$ , the Hankel determinant

$$H_k^{(0)} = \begin{vmatrix} c_0 & c_1 & \cdots & c_{k-1} \\ c_1 & c_2 & \cdots & c_k \\ \cdots & \cdots & \cdots & \cdots \\ c_{k-1} & c_k & \cdots & c_{2k-2} \end{vmatrix}$$

is different from zero. Such polynomials enjoy most of the properties of the usual orthogonal polynomials, when the functional  $c$  is given by

$$c(x^i) = \int_a^b x^i d\alpha(x),$$

where  $\alpha$  is bounded and non decreasing in  $[a, b]$  (see [1] for these properties). In this paper we study the polynomials  $R_k$  such that

$$\sum_{i=0}^m [c(x^i R_k(x))]^2$$

is minimized, where  $m$  is an integer strictly greater than  $k - 1$  (since, for  $m = k - 1$ , we recover the previous formal orthogonal polynomials) and which can possibly depend on  $k$ . They will be called *least squares (formal) orthogonal polynomials*. They depend on the value of  $m$  but for simplicity this dependence will not be indicated in our notations.

Such polynomials arise naturally in problems of *Padé approximation* for power series with perturbed

coefficients, and in *Gaussian quadrature* (as described in the last section). Some properties of these polynomials are derived, together with a recursive scheme for their computation.

**Existence and Uniqueness**

Since the polynomials  $R_k$  will be defined apart from a multiplying factor, and since it is asked that the degree of  $R_k$  is exactly  $k$  we shall write

$$R_k(x) = b_0 + b_1x + \dots + b_kx^k$$

with  $b_k = 1$ . We set

$$\Phi(b_0, \dots, b_{k-1}) = \sum_{i=0}^m [c(x^i R_k(x))]^2$$

and we seek for the values of  $b_0, \dots, b_{k-1}$  that minimize this quantity. That is, such that

$$\frac{\partial \Phi}{\partial b_j} = 0 \quad \text{for } j = 0, \dots, k - 1. \tag{1}$$

Setting  $\gamma_n = (c_n, \dots, c_{n+m})^T$ , this system can be written

$$b_0(\gamma_0, \gamma_j) + \dots + b_{k-1}(\gamma_{k-1}, \gamma_j) = -(\gamma_k, \gamma_j) \tag{2}$$

for  $j = 0, \dots, k - 1$ . Thus  $R_k$  exists and is unique if and only if the matrix  $A_k$  of this system is non singular. Setting  $X = (1, x, \dots, x^{k-1})$  and calling the right-hand side of the preceding system  $\gamma$  we see that

$$R_k(x) = \frac{\begin{vmatrix} A_k & \gamma \\ X & x^k \end{vmatrix}}{|A_k|}.$$

If we set

$$B_k = \begin{pmatrix} c_0 & \dots & c_{k-1} \\ \dots & \dots & \dots \\ c_m & \dots & c_{m+k-1} \end{pmatrix},$$

then  $A_k = B_k^T B_k$ ,  $\gamma = B_k^T \gamma_k$  and we recover the usual solution of a system of linear equations in the *least squares* sense.

**Computation**

The polynomials  $R_k$  can be recursively computed by inverting the matrix  $A_k$  of the above system (2) by the *bordering method*, see [5]. This method is as follows. Set

$$A_{k+1} = \begin{pmatrix} A_k & u_k \\ v_k & a_k \end{pmatrix}$$

where  $u_k$  is a column vector,  $v_k$  a row vector and  $a_k$  a scalar. We then have

$$A_{k+1}^{-1} = \begin{pmatrix} A_k^{-1} + A_k^{-1} u_k \beta_k^{-1} v_k A_k^{-1} & -A_k^{-1} u_k \beta_k^{-1} \\ -\beta_k^{-1} v_k A_k^{-1} & \beta_k^{-1} \end{pmatrix},$$

where  $\beta_k = a_k - v_k A_k^{-1} u_k$ .

Instead of choosing the normalization  $b_k = 1$  we could impose the condition  $b_0 = 1$ . In that case we have the system

$$b'_1(\gamma_1, \gamma_j) + \dots + b'_k(\gamma_k, \gamma_j) = -(\gamma_0, \gamma_j) \tag{3}$$

for  $j = 1, \dots, k$ , and the bordering method can be used not only for computing the inverses of the matrices of the system recursively but also for obtaining its solution, since the new right-hand side contains the previous one.

Let  $A'_k$  be the matrix of (3) and  $d'_k$  be the right-hand side. We then have

$$A'_{k+1} = \begin{pmatrix} A'_k & u'_k \\ v'_k & a'_k \end{pmatrix}, \quad d'_{k+1} = \begin{pmatrix} d'_k \\ f'_k \end{pmatrix}$$

with

$$\begin{aligned} u'_k &= ((\gamma_{k+1}, \gamma_1), \dots, (\gamma_{k+1}, \gamma_k))^T; \\ v'_k &= ((\gamma_1, \gamma_{k+1}), \dots, (\gamma_k, \gamma_{k+1})); \\ a'_k &= (\gamma_{k+1}, \gamma_{k+1}); \\ d'_k &= ((\gamma_0, \gamma_1), \dots, (\gamma_0, \gamma_k))^T; \\ f'_k &= (\gamma_0, \gamma_{k+1}). \end{aligned}$$

Setting  $z'_k = (b'_1, \dots, b'_k)^T$  we have

$$z'_{k+1} = \begin{pmatrix} z'_k \\ 0 \end{pmatrix} + \frac{f'_k - v'_k z'_k}{\beta'_k} \begin{pmatrix} -A'^{-1}_k u'_k \\ 1 \end{pmatrix}$$

with  $\beta'_k = a'_k - v'_k A'^{-1}_k u'_k$ .

Of course the bordering method can only be used if  $\beta_k$  (or  $\beta'_k$  in the second case) is different from zero. If it is not the case, instead of adding one new row and one new column to the system it is possible to add several rows and columns until a non singular  $\beta_k$  (which is now a square matrix) has been found (see [3] and [4]).

**Location of the Zeros**

We return to the normalization  $b_k = 1$ . As

$$c(x^i R_k(x)) = b_0 c_i + \dots + b_k c_{i+k}$$

and  $\partial c(x^i R_k(x))/\partial b_j = c_{i+j}$ , from (1) we obtain

$$\sum_{i=0}^m c(x^i R_k(x))c_{i+j} = 0 \quad \text{for } j = 0, \dots, k-1. \quad (4)$$

This relation can be written as

$$c(R_k(x)(c_i + c_{i+1}x + \dots + c_{i+m}x^m)) = 0,$$

for  $i = 0, \dots, k-1$ . Let us now assume that

$$c_i = \int_a^b x^i d\alpha(x), \quad i = 0, 1, \dots,$$

with  $\alpha$  bounded and nondecreasing in  $[a, b]$ . We have

$$\begin{aligned} & c_i + c_{i+1}x + \dots + c_{i+m}x^m \\ &= \sum_{j=0}^m \left[ \int_a^b y^{i+j} d\alpha(y) \right] x^j \\ &= \int_a^b y^i \left( \sum_{j=0}^m x^j y^j \right) d\alpha(y). \end{aligned}$$

Set

$$w(x, \mu) = \int_a^b y^\mu \left( \sum_{j=0}^m x^j y^j \right) d\alpha(y).$$

Thus

$$w(x, i) = c_i + c_{i+1}x + \dots + c_{i+m}x^m$$

and it follows that

$$c(R_k(x)w(x, i)) = \int_a^b R_k(x)w(x, i) d\alpha(x) = 0$$

for  $i = 0, \dots, k-1$ , which shows that the polynomial  $R_k$  is *biorthogonal* in the sense of [7,8]. Let us now study the location of the zeros of  $R_k$ . For that purpose we shall apply [7, Thm. 3], also given as [8, Thm. 5]. Set

$$d\Phi(x, \mu) = w(x, \mu)d\alpha(x)$$

and

$$I_k(\mu) = \int_a^b x^k d\Phi(x, \mu), \quad k = 0, 1, \dots$$

In our case,  $\mu$  takes the values  $\mu_i = i-1, i = 1, 2, \dots$ . Thus

$$\det [I_i(\mu_j)] = \det [(\gamma_{j-1}, \gamma_i)]$$

and the condition of regularity of [7,8] is equivalent to our condition for the existence and uniqueness of  $R_k$ . According to [7,8], we now have to look at the interpolation property of  $w$ . We have

$$w(x_i, \mu_j) = (\gamma_{j-1}, X_i)$$

where  $X_i = (1, x_i, \dots, x_i^m)^\top$ , the  $x_i$ 's being arbitrary distinct points in  $[a, b]$ , and thus

$$\begin{vmatrix} (\gamma_0, X_1) & \dots & (\gamma_{k-1}, X_1) \\ \dots & \dots & \dots \\ (\gamma_0, X_k) & \dots & (\gamma_{k-1}, X_k) \end{vmatrix} = \det(X_k \Gamma_k)$$

with

$$X_k = \begin{pmatrix} X_1^\top \\ \vdots \\ X_k^\top \end{pmatrix} \quad \text{and} \quad \Gamma_k = (\gamma_0, \dots, \gamma_{k-1}).$$

The interpolation property holds if and only if  $\det(X_k \Gamma_k) \neq 0$ , that is, if and only if the matrix  $X_k \Gamma_k$  has rank  $k$ . Thus, using the theorem of [7,8], we have proved the following result:

**Theorem 1** *If  $A_k$  is regular and if  $X_k \Gamma_k$  has rank  $k$ , then  $R_k$  exists and has  $k$  distinct zeros in  $[a, b]$ .*

*Remark 2* When  $0 \leq a < b$ , it can be proved that  $\det(X_k \Gamma_k) \neq 0$  (see [2] for the details).

### Applications

Our first application deals with *Padé-type approximation*. Let  $v_k$  be an arbitrary polynomial of degree  $k$  and let  $w_k(t) = a_0 + \dots + a_{k-1}t^{k-1}$  be defined by

$$a_i = c(x^{-i-1}v_k(x)), \quad i = 0, \dots, k-1.$$

We set

$$\tilde{v}_k(t) = t^k v_k(t^{-1}) \quad \text{and} \quad \tilde{w}_k(t) = t^{k-1} w_k(t^{-1}).$$

Let  $f$  be the formal power series

$$f(t) = \sum_{i=0}^{\infty} c_i t^i.$$

Then it can be proved that

$$f(t) - \frac{\tilde{w}_k(t)}{\tilde{v}_k(t)} = O(t^k) \quad (t \rightarrow 0).$$

The rational function  $\frac{\widetilde{w}_k(t)}{\widetilde{v}_k(t)}$  is called a Padé-type approximant of  $f$  and it is denoted by  $(k - 1/k)_f(t)$ , [1]. Moreover it can also be proved that

$$f(t) - \frac{\widetilde{w}_k(t)}{\widetilde{v}_k(t)} = \frac{t^k}{\widetilde{v}_k(t)} c \left( \frac{v_k(x)}{1 - xt} \right) = \frac{t^k}{\widetilde{v}_k(t)} \cdot c \left( \left( 1 + xt + \dots + x^{k-1}t^{k-1} + \frac{x^k t^k}{1 - xt} \right) v_k(x) \right).$$

That is,

$$f(t)\widetilde{v}_k(t) - \widetilde{w}_k(t) = t^k \sum_{i=0}^{\infty} c(x^i v_k(x)) t^i.$$

Thus if the polynomial  $v_k$ , which is called the *generating polynomial* of  $(k - 1/k)$ , satisfies

$$c(x^i v_k(x)) = 0 \quad \text{for } i = 0, \dots, k - 1,$$

then

$$f(t) - \frac{\widetilde{w}_k(t)}{\widetilde{v}_k(t)} = O(t^{2k}).$$

In this case  $v_k$  is the formal orthogonal polynomial  $P_k$  of degree  $k$  with respect to  $c$  and  $\frac{\widetilde{w}_k(t)}{\widetilde{v}_k(t)}$  is the usual Padé approximant  $[k - 1/k]$  of  $f$ .

As explained in [10], Padé approximants can be quite sensitive to perturbations on the coefficients  $c_i$  of the series  $f$ . Hence the idea arises to take as  $v_k$  the least squares orthogonal polynomial  $R_k$  of degree  $k$  instead of the usual orthogonal polynomial, an idea which in fact motivated our study. Of course such a choice decreases the degree of approximation, since the approximants obtained are only of the Padé-type, but it can increase the stability properties of the approximants and also their precision since  $\sum_{i=0}^m [c(x^i v_k(x))]^2$  is minimized by the choice  $v_k = R_k$ . We give a numerical example that illustrates this fact.

We consider the function

$$f(z) = \frac{\ln(1 + z)}{z} = \sum_{i=0}^{\infty} c_i z^i$$

and we assume that we know the coefficients  $c_i$  with a certain precision. For example, we know approximate values  $c_i^*$  such that

$$|c_i - c_i^*| \leq 10^{-8}, \quad i = 0, 1, \dots$$

In the following table we compare the number of exact figures given by the Padé approximant with those of the least squares Padé-type approximant, both computed with the same number of coefficients  $c_i^*$ . We can see that the least squares Padé-type approximant has better stability properties.

$z$	Padé approx [7/8]	LS Padé-type approx [6/7] ( $m = 8$ )
1.5	6.7	7.7
1.9	5.7	7.0
2.1	5.2	6.7

Another application concerns quadrature methods. We have already shown that if the functional  $c$  is given by

$$c_i = \int_a^b x^i d\alpha(x), \quad i = 0, 1, \dots, \quad 0 \leq a < b,$$

with  $\alpha$  bounded and nondecreasing, then the corresponding least squares orthogonal polynomial of degree  $k$ ,  $R_k$ , has  $k$  distinct zeros in  $[a, b]$ . We can then construct quadrature formulas of the interpolatory type.

If  $\lambda_1, \dots, \lambda_k$  are the zeros of  $R_k$ , we can approximate the integral

$$I = \int_a^b f(x) d\alpha(x)$$

by

$$I_k = A_1 f(\lambda_1) + \dots + A_k f(\lambda_k) \tag{5}$$

where

$$A_i = \int_a^b \frac{\pi(x)}{\pi'(\lambda_i)(x - \lambda_i)} d\alpha(x)$$

and

$$\pi(x) = \prod_{j=1}^k (x - \lambda_j).$$

This corresponds to replacing the function  $f$  by its interpolating polynomial at the knots  $\lambda_1, \dots, \lambda_k$ . The truncation error of (5) is given by

$$I - I_k = E_T = \int_a^b f[\lambda_1, \dots, \lambda_k, x] R_k(x) d\alpha(x).$$

Expanding the divided difference we see

$$f[\lambda_1, \dots, \lambda_k, x] = \sum_{i=1}^k f[\lambda_1, \dots, \lambda_{k+i}](x - \lambda_{k+1}) \cdots (x - \lambda_{k+i-1}) + f[\lambda_1, \dots, \lambda_{k+m+1}, x](x - \lambda_{k+1}) \cdots (x - \lambda_{k+m+1})$$

for  $\lambda_{k+1}, \dots, \lambda_{k+m+1}$  any points in the domain of definition  $\mathcal{D}_f$  of  $f$ . If  $0 \in \mathcal{D}_f$ , then we can choose

$$\lambda_{k+1} = \dots = \lambda_{k+m+1} = 0.$$

Setting

$$M_i = f[\lambda_1, \dots, \lambda_{k+i}]$$

we get

$$f[\lambda_1, \dots, \lambda_k, x] = \sum_{i=1}^{m+1} M_i x^{i-1} + x^{m+1} f[\lambda_1, \dots, \lambda_{k+m+1}, x]$$

and hence, for the truncation error

$$E_T = \sum_{i=0}^m M_{i+1} \left( \int_a^b R_k(x) x^i d\alpha(x) \right) + \int_a^b f[\lambda_1, \dots, \lambda_{k+m+1}, x] x^{m+1} R_k(x) d\alpha(x)$$

with

$$\sum_{i=0}^m \left( \int_a^b R_k(x) x^i d\alpha(x) \right)^2$$

minimised. Moreover, if  $f \in C^{k+m+1}([a, b])$  and, since  $x^{m+1}$  is positive over  $[a, b]$ , we obtain

$$\int_a^b f[\lambda_1, \dots, \lambda_{k+m+1}, x] x^{m+1} R_k(x) d\alpha(x) = \frac{c_{m+1}}{(k+m+1)!} R_k(\lambda) f^{(k+m+1)}(\eta)$$

with  $\lambda, \eta \in [a, b]$ , and, for the error,

$$E_T = \sum_{i=0}^m \frac{f^{(k+i)}(\eta_i)}{(k+i)!} \left( \int_a^b R_k(x) x^i d\alpha(x) \right) + \frac{c_{m+1}}{(k+m+1)!} R_k(\lambda) f^{(k+m+1)}(\eta) \quad (6)$$

with  $\eta_i \in [a, b], i = 0, \dots, m, \lambda, \eta \in [a, b]$ . We remark that in the case where  $m = k - 1, R_k$  is the orthogonal polynomial with respect to the functional  $c$  and so (5) corresponds to a Gaussian quadrature formula. An advantage of the quadrature formulas (5) is that they are less sensitive to perturbations on the sequence of moments  $c_i$ , as is shown in the following numerical example. Such a case can arise in some applications where the formula giving the moments  $c_i$  is sensitive to rounding errors, see [11] for example.

Consider the functional  $c$  defined by

$$c_i = \int_0^1 x^i dx = \frac{1}{i+1}$$

and perturb the coefficients in the following way

$i$	$c_i^*$	$i$	$c_i^*$
0	1.00000011	6	0.14285700
1	0.50000029	7	0.12500000
2	0.33333340	8	0.11111109
3	0.25000101	9	0.10000000
4	0.20000070	10	0.09090899
5	0.16666600	11	0.08333300

We can construct from these coefficients the least squares orthogonal polynomials and the corresponding quadrature formulas (5). The precision of the numerical approximations of  $I = \int_0^1 f(x) dx$  is given in the following table

$f(x)$	$k = 5; m = 4$ Gauss quad.	$k = 5; m = 6$ least sq. quad.
$1/(x + 0.5)$	$-2.2 * 10^{-5}$	$-6.2 * 10^{-6}$
$1/(x + 0.3)$	$-2.1 * 10^{-4}$	$-1.2 * 10^{-5}$

We can obtain other applications from the following generalization. Instead of minimizing  $\sum_{i=0}^m [c(x^i R_k(x))]^2$  we can introduce weights and minimize

$$\Phi^*(b_0, \dots, b_{k-1}) = \sum_{i=0}^m p_i [c(x^i R_k^*(x))]^2$$

with  $p_i > 0, i = 0, \dots, m$ . If we choose the inner product

$$(\gamma_i, \gamma_j)^* = \sum_{k=0}^m p_k c_{i+k} c_{j+k}$$

the solution of this problem can be computed as in the previous case and all the properties of the polynomials are still true. It can be seen, from numerical examples, that if the sequence of moments  $c_i$  has a decreasing precision, we can expect that the least squares Padé-type approximants constructed with a decreasing sequence of weights will give a better result. In the same way, for the quadrature formulas (5), from the expression (6) of the truncation error and the knowledge of the magnitude of the derivatives, we can reduce this error by choosing appropriate weights. Some other possible applications of least squares orthogonal polynomials will be studied in the future.

## Introduction

### Historical Remarks

The linear least squares problem originally arose from the need to fit a linear mathematical model to given observations. In order to reduce the influence of errors in the observations one uses a greater number of measurements than the number of unknown parameters in the model.

The algebraic procedure of the method of least squares was first published by A.M. Legendre [25]. It was justified as a statistical procedure by C.F. Gauss [13]. A famous example of the use of the least squares principle is the prediction of the orbit of the asteroid Ceres by Gauss in 1801. After this success, the method of least squares quickly became the standard procedure for analysis of astronomical and geodetic data.

Gauss gave the method a sound theoretical basis in two memoirs: 'Theoria Combinationis' [11,12]. In them, Gauss proves the optimality of the least squares estimate without any assumptions that the random variables follow a particular distribution.

### Statistical Models

In the *general univariate linear model* the vector  $b \in \mathbf{R}^m$  of observations is related to the unknown parameter vector  $x \in \mathbf{R}^n$  by a linear relation

$$Ax = b + \epsilon, \quad (1)$$

where  $A \in \mathbf{R}^{m \times n}$  is a known matrix of full column rank. Further,  $\epsilon$  is a vector of random errors with zero means and covariance matrix  $\sigma^2 W \in \mathbf{R}^{m \times m}$ , where  $W$  is known but  $\sigma^2 > 0$  unknown. The standard linear model is obtained for  $W = I$ .

**Theorem 1 (Gauss–Markoff theorem)** Consider the standard linear model (1) with  $W = I$ . The best linear unbiased estimator of any linear function  $c^\top x$  is  $c^\top \hat{x}$ , where  $\hat{x}$  is obtained by minimizing the sum of the squared residuals,

$$\|r\|_2^2 = \sum_{i=1}^m r_i^2, \quad (2)$$

where  $r = b - Ax$  and  $\|\cdot\|_2$  denotes the Euclidean vector norm. Furthermore,  $E(s^2) = \sigma^2$ , where  $s^2$  is the quadratic form

$$s^2 = \frac{1}{m-n} (b - A\hat{x})^\top (b - A\hat{x}). \quad (3)$$

The variance-covariance matrix of the least squares estimate  $\hat{x}$  is given by

$$V(\hat{x}) = \sigma^2 (A^\top A)^{-1}. \quad (4)$$

The residual vector  $\hat{r} = b - A\hat{x}$  satisfies  $A^\top \hat{r} = 0$ , and hence there are  $n$  linear relations among the  $m$  components of  $\hat{r}$ . It can be shown that the residuals  $\hat{r}$ , and therefore also the quadratic form  $s^2$ , are uncorrelated with  $\hat{x}$ , i. e.,  $\text{cov}(\hat{r}, \hat{x}) = 0$ ,  $\text{cov}(s^2, \hat{x}) = 0$ .

If the errors in  $\epsilon$  are uncorrelated but not of equal variance, then the covariance matrix  $W$  is diagonal. Then the least squares estimator is obtained by solving the *weighted least squares problem*

$$\min \|D(Ax - b)\|_2, \quad D = W^{-\frac{1}{2}}. \quad (5)$$

For the general case with no restrictions on  $A$  and  $W$ , see [23].

The assumption that  $A$  is known made in the linear model is frequently unrealistic since sampling or modeling errors often also affect  $A$ . In the *errors-in-variables model* one instead assumes a linear relation

$$(A + E)x = b + r, \quad (6)$$

where  $(E, r)$  is an error matrix whose rows are independently and identically distributed with zero mean and the same variance. An estimate of the parameters  $x$  in the model (6) is obtained from the total least squares (TLS) problem.

### Characterization of Least Squares Solutions

Let  $\mathcal{S}$  be set of all solutions to a least squares problem,

$$\mathcal{S} = \{x \in \mathbf{R}^n : \|Ax - b\|_2 = \min\}. \quad (7)$$

Then  $x \in \mathcal{S}$  if and only if  $A^\top(b - Ax) = 0$  holds. Equivalently,  $x \in \mathcal{S}$  if and only if  $x$  satisfies the *normal equations*

$$A^\top Ax = A^\top b. \quad (8)$$

Since  $A^\top b \in \mathcal{R}(A^\top) = \mathcal{R}(A^\top A)$  the normal equations are always consistent. It follows that  $\mathcal{S}$  is a nonempty, convex subset of  $\mathbf{R}^n$ . Any least squares solution  $x$  uniquely decomposes the right-hand side  $b$  into two orthogonal components

$$b = Ax + r, \quad Ax \in \mathcal{R}(A) \perp r \in \mathcal{N}(A^\top),$$

where  $\mathcal{R}(A)$  and  $\mathcal{N}(A^\top)$  denote the range of  $A$  and the nullspace of  $A^\top$ , respectively.

When  $\text{rank } A < n$  there are many least squares solutions  $x$ , although the residual  $b - Ax$  is still uniquely determined. There is always a unique least squares solution in  $\mathcal{S}$  of minimum length. The following result applies to both overdetermined and underdetermined linear systems.

**Theorem 2** Consider the linear least squares problem

$$\min_{x \in \mathcal{S}} \|x\|_2, \quad \mathcal{S} = \{x \in \mathbb{R}^n : \|b - Ax\|_2 = \min\}, \quad (9)$$

where  $A \in \mathbb{R}^{m \times n}$  and  $\text{rank}(A) = r \leq \min(m, n)$ . This problem always has a unique solution, which is distinguished by the property that

$$x \perp \mathcal{N}(A).$$

**Pseudo-inverse and Conditioning**

**Singular Value Decomposition and Pseudo-inverse**

A matrix decomposition of great theoretical and practical importance for the treatment of least squares problems is the singular value decomposition (SVD) of  $A$ ,

$$A = U \Sigma V^\top = \sum_{i=1}^n u_i \sigma_i v_i^\top. \quad (10)$$

Here  $\sigma_i$  are the singular values of  $A$  and  $u_i$  and  $v_i$  the corresponding left and right singular vectors.

Using this decomposition the solution to problem (9) can be written  $x = A^\dagger b$ , where

$$A^\dagger = V \begin{pmatrix} \Sigma_r^{-1} & 0 \\ 0 & 0 \end{pmatrix} U^\top \in \mathbb{R}^{n \times m}. \quad (11)$$

Here  $A^\dagger$  is called the *pseudo-inverse* of  $A$ . It is the unique matrix which minimizes  $\|AX - I\|_F$ , where  $\|\cdot\|_F$  denotes the Frobenius norm. Note that the pseudo-inverse  $A^\dagger$  is not a continuous function of  $A$ , unless one allows only perturbations which do not change the rank of  $A$ .

The pseudo-inverse was first introduced by E.H. Moore in 1920. R. Penrose [30] later gave the following elegant algebraic characterization.

**Theorem 3 (Penrose’s conditions)** The pseudo-inverse  $X = A^\dagger$  is uniquely determined by the four conditions:

- 1)  $AXA = A$ ;
- 2)  $XAX = X$ ;
- 3)  $(AX)^\top = AX$ ;
- 4)  $(XA)^\top = XA$ .

It can be directly verified that  $A^\dagger$  given by (11) satisfies these four conditions.

The *total least squares problem* (TLS problem) involves finding a perturbation matrix  $(E, r)$  having minimal Frobenius norm, which lowers the rank of the matrix  $(A, b)$ . Consider the singular value decomposition of the augmented matrix  $(A, b)$ :

$$(A, b) = U \Sigma V^\top, \quad \Sigma = \text{diag}(\sigma_1, \dots, \sigma_{n+1}),$$

where  $\sigma_1 \geq \dots \geq \sigma_{n+1} \geq 0$ . Then, in the generic case,  $(x, -1)^\top$  is a right singular vector corresponding to  $\sigma_{n+1}$  and  $\min \|(E, r)\|_F = \sigma_{n+1}$ .

An excellent survey of theoretical and computational aspects of the total least squares problem is given in [22].

**Conditioning of the Least Squares Problem**

Consider a *perturbed least squares problem* where  $\tilde{A} = A + \delta A$ ,  $\tilde{b} = b + \delta b$ , and let the perturbed solution be  $\tilde{x} = x + \delta x$ . Then, assuming that  $\text{rank}(A) = \text{rank}(A + \delta A) = n$  one has the first order bound

$$\|\delta x\|_2 \leq \frac{1}{\sigma_n} (\|\delta b\|_2 + \|\delta A\|_2 \|x\|_2) + \frac{1}{\sigma_n^2} \|\delta A\|_2 \|r\|_2.$$

The *condition number* of a matrix  $A \in \mathbb{R}^{m \times n}$  ( $A \neq 0$ ) is defined as

$$\kappa(A) = \|A\|_2 \|A^\dagger\|_2 = \frac{\sigma_1}{\sigma_r}, \quad (12)$$

where  $\sigma_1 \geq \dots \geq \sigma_r > 0$ , are the nonzero singular values of  $A$ . Hence, the *normwise relative condition number* of the least squares problem can be written as

$$\kappa_{LS}(A, b) = \kappa(A) + \kappa(A)^2 \frac{\|r\|_2}{\|A\|_2 \|x\|_2}. \quad (13)$$

For a *consistent problem* ( $r = 0$ ) the last term is zero. However, in general the condition number depends on the size of  $r$  and involves a term proportional to  $\kappa(A)^2$ .

A more refined perturbation analysis, which applies to both overdetermined and underdetermined systems, has been given in [34]. In order to prove any meaningful result it is necessary to assume that  $\text{rank}(A + \delta A) = \text{rank}(A)$ . If  $\text{rank}(A) = \min(m, n)$ , the condition  $\eta \equiv \|A^\dagger\|_2 \|\delta A\|_2 < 1$  suffices to ensure that this is the case.

## Numerical Methods of Solution

### The Method of Normal Equations

The first step in the method of normal equations for the least squares problem is to form the cross-products

$$C = A^T A \in \mathbb{R}^{n \times n}, \quad d = A^T b \in \mathbb{R}^n. \quad (14)$$

Since the matrix  $C$  is symmetric, it is only necessary to compute and store its upper triangular part. When  $m \gg n$  this step will result in a great reduction in the amount of data.

The computation of  $C$  and  $d$  can be performed either using an inner product form (operating on columns of  $A$ ) or an outer product form (operating on rows of  $A$ ). Row-wise accumulation of  $C$  and  $d$  is advantageous if the matrix  $A$  is sparse or held in secondary storage. Partitioning  $A$  by rows, one has

$$C = \sum_{i=1}^m a_i a_i^T, \quad d = \sum_{i=1}^m b_i a_i, \quad (15)$$

where  $\tilde{a}_i^T$  denotes the  $i$ th row of  $A$ . This expresses  $C$  as a sum of matrices of rank.

Gauss solved the symmetric positive definite system of normal equation by elimination, preserving symmetry, and solving for  $x$  by back-substitution. A different sequencing of this algorithm is to compute the *Cholesky factorization*

$$C = R^T R, \quad (16)$$

where  $R$  is upper triangular with positive diagonal elements, and then solve the two triangular systems

$$R^T z = d, \quad Rx = z, \quad (17)$$

by forward- and back-substitution, respectively. The Cholesky factorization, named after the French officer A.L. Cholesky, who worked on geodetic survey problems in Africa, was published by C. Benoit [1]. (In statistical applications this method is often known as the *square-root method*, although the proper square root of  $A$  should satisfy  $B^2 = A$ .)

The method of normal equations is suitable for moderately ill-conditioned problems but is not a backward stable method. The accuracy can be improved by using fixed precision iterative refinement in solving the normal equations.

Set  $x_0 = 0$ ,  $r_0 = 0$ , and for  $s = 0, 1, \dots$  until convergence do

$$\begin{aligned} r_s &= b - Ax_s, \\ R^T(R\delta x_s) &= A^T r_s, \\ x_{s+1} &= x_s + \delta x_s. \end{aligned}$$

(Here,  $x_1$  corresponds to the unrefined solution of the normal equations.)

The method of normal equations can fail when applied to weighted least squares problems. To see this consider a problem with two different weights  $\gamma$  and 1,

$$\min_x \left\| \begin{pmatrix} \gamma A_1 \\ A_2 \end{pmatrix} x - \begin{pmatrix} \gamma b_1 \\ b_2 \end{pmatrix} \right\|_2, \quad (18)$$

for which the matrix of normal equations is  $A^T A = \gamma^2 A_1^T A_1 + A_2^T A_2$ . When  $\gamma \gg 1$  this problem is called *stiff*. In the limit  $\gamma \rightarrow \infty$  the solution will satisfy the subsystem  $A_1 x = b_1$  exactly. If  $\gamma > u^{-1/2}$  ( $u$  is the unit roundoff), the information in the matrix  $A_2$  may completely disappear when forming  $A^T A$ . For possible ways around this difficulty, see [4, Chap. 4.4].

### Least Squares by QR Factorization

The *QR factorization* and its extensions are used extensively in modern numerical methods for solving least squares problems. Let  $A \in \mathbb{R}^{m \times n}$  with  $\text{rank}(A) = n$ . Then there are an orthogonal matrix  $Q \in \mathbb{R}^{m \times m}$  and an upper triangular  $R \in \mathbb{R}^{n \times n}$  such that

$$A = Q \begin{pmatrix} R \\ 0 \end{pmatrix} \quad (19)$$

Since orthogonal transformations preserve the Euclidean length, it follows that

$$\|Ax - b\|_2 = \|Q^T(Ax - b)\|_2 \quad (20)$$

for any orthogonal matrix  $Q \in \mathbb{R}^{m \times m}$ . Hence using the QR factorization (19) the solution to the least squares problem can be obtained from

$$Q^T b = \begin{pmatrix} d_1 \\ d_2 \end{pmatrix}, \quad Rx = d_1. \quad (21)$$

An algorithm based on the QR decomposition by Householder transformations was first developed in a seminal paper by G.H. Golub [18]. Here,  $Q$  is compactly represented as a product of Householder ma-

trices  $Q = P_1 \cdots P_n$ , where  $P_k = I - \beta_k u_k u_k^T$ . Only the Householder vectors  $u_k$  are stored, and advantage is taken of the fact that the first  $k - 1$  components of  $u_k$  are zero.

Golub’s method for solving the standard least squares problem is normwise backward stable, see [24, pp. 90ff]. Surprisingly, this method is stable also for solving the weighted least squares problems (5) provided only that the equations are sorted after decreasing row norms in  $A$ , see [8].

Due to storage considerations the matrix  $Q$  in a QR decomposition is often discarded when  $A$  is large and sparse. This creates a problem, since then it may not be possible to form  $Q^T b$ . If the original matrix  $A$  is saved one can use the *corrected seminormal equations* (CSNE)

$$R^T R \bar{x} = A^T b, \quad \bar{r} = b - A \bar{x},$$

$$\bar{R}^T \bar{R} \delta x = A^T \bar{r}, \quad x_c = \bar{x} + \delta x.$$

(Note that unless the correction step is carried out the numerical stability of this method is no better than the method of normal equations.) An error analysis of the CSNE method is given in [2]. A comparison with the bounds for a backward stable method shows that in most practical applications the corrected seminormal equations is forward stable.

Applying the *Gram–Schmidt orthogonalization* process to the columns of  $A$  produces  $Q_1$  and  $R$  in the factorization

$$A = (a_1, \dots, a_n) = Q_1 R, \quad Q_1 = (q_1, \dots, q_n),$$

where  $Q_1$  has orthogonal columns and  $R$  is upper triangular. There are two computational variants of Gram–Schmidt orthogonalization, the *classical Gram–Schmidt orthogonalization* (CGS) and the *modified Gram–Schmidt orthogonalization* (MGS). In CGS there may be a catastrophic loss of orthogonality unless re-orthogonalization is used. In MGS the loss of orthogonality can be shown to occur in a predictable manner.

Using an equivalence between MGS and Householder QR applied to  $A$  with a square matrix of zeros on top, backward stable algorithm based on MGS for solving least squares problems have been developed, see [3].

### Rank-Deficient and Ill-Conditioned Problems

The mathematical notion of rank is not always appropriate in numerical computations. For example, if

a matrix  $A \in \mathbf{R}^{n \times n}$ , with (mathematical) rank  $k < n$ , is randomly perturbed by roundoff, the perturbed matrix most likely has full rank  $n$ . However, it should be considered to be ‘numerically’ rank deficient.

When solving rank-deficient or ill-conditioned least squares problems, correct assignment of the ‘numerical rank’ of  $A$  is often the key issue. The *numerical rank* should depend on a tolerance which reflects the error level. Overestimating the rank may lead to a computed solution of very large norm, which is totally irrelevant. This behavior is typical in problems arising from discretizations of ill-posed problems, see [21].

Assume that the ‘noise level’  $\delta$  in the data is known. Then a numerical rank  $k$ , such that  $\sigma_k > \delta \geq \sigma_{k+1}$ , can be assigned to  $A$ , where  $\sigma_i$  are the singular values of  $A$ . The approximate solution

$$x = \sum_{i=1}^k \frac{c_i}{\sigma_i} v_i, \quad c = U^T b,$$

is known as the *truncated singular value decomposition solution* (TSVD). This solution solves the related least squares problem  $\min_x \|A_k x - b\|_2$ , where

$$A_k = \sum_{i=1}^k u_i \sigma_i v_i^T, \quad \|A - A_k\|_2 \leq \delta,$$

is the best rank  $k$  approximation of  $A$ , The subspace

$$\mathcal{R}(V_2), \quad V_2 = (v_{k+1}, \dots, v_n),$$

is called the *numerical nullspace* of  $A$ .

An alternative to TSVD is *Tikhonov regularization*, where one considers the regularized problem

$$\min_x \|Ax - b\|_2^2 + \tau^2 \|Dx\|_2^2, \tag{22}$$

for some positive diagonal matrix  $D = \text{diag}(d_1, \dots, d_n)$ . The problem (22) is equivalent to the least squares problem

$$\min_x \left\| \begin{pmatrix} \tau D \\ A \end{pmatrix} x \begin{pmatrix} \tau 0 \\ b \end{pmatrix} \right\|_2, \tag{23}$$

where the matrix  $A$  has been modified by appending the matrix  $\tau D$  on top. An advantage of using the regularized problem (23) instead of the TSVD is that its solution can be computed from a QR decomposition. When  $\tau > 0$  this problem is always of full column rank and has

a unique solution. For  $D = I$  it can be shown that  $x(\tau)$  will approximately equal the TSVD solution for  $\tau = \delta$ .

Problem (23) also appears as a subproblem in trust region algorithms for solving nonlinear least squares, and in interior point methods for constrained linear least squares problems. A more difficult case is when the noise level  $\delta$  is unknown and has to be determined in the solution process. Such problems typically arise in the treatment of discrete ill-posed problems, see [21].

### Rank Revealing QR Factorizations

In some applications it is too expensive to compute the SVD. In such cases so called ‘rank revealing’ QR factorizations, often are a good substitute.

It can be shown that for any  $0 < k < n$  a column permutation  $\Pi$  exists such that the QR decomposition of  $A\Pi$  has the form

$$A\Pi = Q \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix}, \quad (24)$$

where

$$\sigma_k(R_{11}) \geq \frac{1}{c}\sigma_k, \quad \|R_{22}\|_2 \leq c\sigma_{k+1}, \quad (25)$$

and  $c < (n + 1)/2$ . In particular, if  $A$  has numerical  $\delta$ -rank equal to  $k$ , then there is a column permutation such that  $\|R_{22}\|_2 \leq c\delta$ . Such a QR factorization is called a *rank revealing QR factorization* (RRQR). No efficient numerical method is known which can be guaranteed to compute an RRQR factorization satisfying (25), although in practice *Chan’s method* [7] often gives satisfactory results.

A related rank revealing factorization is the complete orthogonal decomposition of the form

$$A = U \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix} V^T, \quad (26)$$

where  $U$  and  $V$  are orthogonal matrices,  $R_{11} \in \mathbf{R}^{k \times k}$ ,  $\sigma_k(R_{11}) \geq \sigma_k/c$ , and

$$(\|R_{12}\|_F^2 + \|R_{22}\|_F^2)^{\frac{1}{2}} \leq c\sigma_{k+1}.$$

This is also often called a *rank revealing URV factorization*. (an alternative lower triangular form ULV is sometimes preferable to use.) If  $V = (V_1 V_2)$  is partitioned conformably the orthogonal matrix  $V_2$  can be taken as an approximation to the numerical nullspace  $\mathcal{N}(A)$ .

### Updating Least Squares Solutions

It is often desired to solve a sequence of modified least squares problems

$$\min_x \|Ax - b\|_2, \quad A \in \mathbf{R}^{m \times n}, \quad (27)$$

where in each step rows of data in  $(A, b)$  are added, deleted, or both. This need arises, e. g., when data are arriving sequentially. In various time-series problems a window moving over the data is used; when a new observation is added, an old one is deleted as the window moves to the next step in the sample. In other applications columns of the matrix  $A$  may be added or deleted. Such modifications are usually referred to as updating (downdating) of least squares solutions.

Important applications where modified least squares problems arise include statistics, optimization, and signal processing. In statistics an efficient and stable procedure for adding and deleting rows to a regression model is needed; see [6]. In regression models one may also want to examine the different models, which can be achieved by adding or deleting columns (or permuting columns).

### Recursive Least Squares

Applications in signal processing often require near real-time solutions. It is then critical that the modification should be performed with as few operations and as little storage requirement as possible.

Methods based on the normal equations and/or updating of the Cholesky factorization are still often used in statistics and signal processing, although these algorithms lack numerical stability. Consider a least squares problem where an observation  $w^T x = \beta$  is added. The updated solution  $\tilde{x}$  then satisfies the modified normal equations

$$(A^T A + w w^T) \tilde{x} = A^T b + \beta w. \quad (28)$$

A straightforward method for computing  $\tilde{x}$  is based on updating the (scaled) covariance matrix  $C = (A^T A)^{-1}$ . By the *Sherman–Morrison formula* one obtains  $\tilde{C}^{-1} = C^{-1} + w w^T$ , and

$$\tilde{C} = C - \frac{1}{1 + w^T u} u u^T, \quad u = C w. \quad (29)$$

From this follows the updating formula

$$\tilde{x} = x + (\beta - w^T x) \tilde{u}, \quad \tilde{u} = \tilde{C} w. \quad (30)$$

The equations (29), (30) define a *recursive least squares* (RLS) algorithm. They can, with slight modifications, also be used for ‘deleting’ observations. The simplicity of this updating algorithm is appealing, but a disadvantage is its serious sensitivity to roundoff errors.

**Modifying Matrix Factorizations**

The first area where algorithms for *modifying matrix factorizations* seems to have been systematically used is optimization. Numerous aspects of updating various matrix factorizations are discussed in [17].

There is a simple relationship between the problem of updating matrix factorizations and that of updating least squares solutions. If  $A$  has full column rank and the  $R$ -factor of the matrix  $(A, b)$  is

$$\begin{pmatrix} R & z \\ 0 & \rho \end{pmatrix}, \tag{31}$$

then the solution to the least squares problem (27) is given by

$$Rx = z, \quad \|Ax - b\|_2 = \rho. \tag{32}$$

Hence updating algorithms for the QR or Cholesky factorization can be applied to  $(A, b)$  in order to give updating algorithms for least squares solutions.

Backward stable algorithms, which require  $O(m^2)$  multiplications, exist for updating the QR decomposition for three important kinds of modifications:

- General rank one change of  $A$ .
- Deleting (adding) a column of  $A$ .
- Adding (deleting) a row of  $A$ .

In these algorithms,  $Q \in \mathbf{R}^{m \times m}$  is stored explicitly as an  $m \times m$  matrix. In many applications it suffices to update the ‘Gram–Schmidt’ QR decomposition

$$A = Q_1 R, \quad Q_1 \in \mathbf{R}^{m \times n}, \tag{33}$$

where  $Q_1 \in \mathbf{R}^{m \times n}$  consists of the first  $n$  columns of  $Q$ , [10,31]. These only require  $O(mn)$  storage and operations.

J.R. Bunch and C.P. Nielsen [5] have developed methods for updating the SVD

$$A = U \begin{pmatrix} \Sigma \\ 0 \end{pmatrix} V^T,$$

where  $U \in \mathbf{R}^{m \times m}$  and  $V \in \mathbf{R}^{n \times n}$ , when  $A$  is modified by adding or deleting a row or column. However, their algorithms require  $O(mn^2)$  flops.

Rank revealing QR factorizations can be updated more cheaply, and are often a good alternative to use. G.W. Stewart [33] has shown how to compute and update a rank revealing complete orthogonal decomposition from an RRQR decomposition.

Most updating algorithms can be modified in a straightforward fashion to treat cases where a block of rows/columns are added or deleted, which are more amenable to efficient implementation on vector and parallel computers.

**Sparse Problems**

The gain in operations and storage in solving the linear least squares problems where the matrix  $A$  is sparse can be huge, making otherwise intractable problems possible to solve. *Sparse least squares problems* of huge size arise in a variety of applications, such as geodetic surveys, photogrammetry, molecular structure, gravity field of the earth, tomography, the force method in structural analysis, surface fitting, and cluster analysis and pattern matching.

Sparse least squares problems may be solved either by direct or iterative methods. Preconditioned iterative methods can often be considered as hybrids between these two classes of solution. Below direct methods are reviewed for some classes of sparse problems.

**Banded Least Squares Problems**

A natural distinction is between sparse matrices with regular zero pattern (e.g., banded structure) and matrices with an irregular pattern of nonzero elements.

A rectangular *banded matrix*  $A \in \mathbf{R}^{m \times n}$  has the property that the nonzero elements in each row lie in a narrow band.  $A$  is said to have *row bandwidth*  $w$  if

$$w(A) = \max_{1 \leq i \leq m} (l_i(A) - f_i(A) + 1). \tag{34}$$

where

$$f_i(A) = \min \{j: a_{ij} \neq 0\},$$

$$l_i(A) = \max \{j: a_{ij} \neq 0\}$$

are column subscripts of the first and last nonzeros in the  $i$ th row of  $A$ . For this structure to have practical significance one needs to have  $w \ll n$ . Note that, although the row bandwidth is independent of the row ordering, it will depend on the column ordering. To permute the

columns in  $A$  so that a small bandwidth is achieved the method of choice is the reverse Cuthill–McKee ordering, see [15].

It is easy to see that if the row bandwidth of  $A$  is  $w$  then the matrix of normal equations  $C = A^T A$  has at most upper bandwidth  $p = w - 1$ , i. e.,

$$|j - k| \geq w \quad \Rightarrow \quad (A^T A)_{jk} = \sum_{i=1}^m a_{ij} a_{ik} = 0.$$

If advantage is taken of the band structure, the solution of a least squares problem where  $A$  has bandwidth  $w$  by the method of normal equations requires a total of

$$\frac{1}{2}(mw(w + 3) + n(w - 1)(w + 2)) + n(2w - 1)$$

flops.

Similar savings can be obtained for methods based on Givens QR decomposition used to solve banded least squares problem. However, then it is essential that the rows of  $A$  are sorted so that the column indices  $f_i(A)$ ,  $i = 1, \dots, m$ , of the first nonzero element in each row form a nondecreasing sequence, i. e.,

$$i \leq k \quad \Rightarrow \quad f_i(A) \leq f_k(A).$$

A matrix whose rows are sorted in this way is said to be in *standard form*. Since the matrix  $R$  in the QR factorization has the same structure as the Cholesky factor, it must be a banded matrix with nonzero elements only in the first  $p = w - 1$  superdiagonals. In the *sequential row orthogonalization scheme* an upper triangular matrix  $R$  is initialized to zero. The orthogonalization then proceeds row-wise, and  $R$  is updated by adding a row of  $A$  at a time.

If  $A$  has constant bandwidth and is in standard form then in the  $i$ th step of reduction the last  $(n - l_i(A))$  columns of  $R$  have not been touched and are still zero as initialized. Further, the first  $(f_i(A) - 1)$  rows of  $R$  are already finished at this stage and can be read out to secondary storage. Thus, as with the Cholesky method, very large problems can be handled since primary storage is needed only for the active part of  $R$ . The complete orthogonalization requires about  $2mw^2$  flops, and can be performed in  $w(w + 3)/2$  locations of primary storage.

The Givens rotations could also be applied to one or several right-hand sides  $b$ . Only if right-hand sides

which are not initially available are to be treated, need the Givens rotations be saved. The algorithm can be modified to also handle problems with variable row bandwidth  $w_i$ .

For the case when  $m \gg n$  a more efficient schemes uses Householder transformations, see [24, Chap. 11]. Let  $A_k$  consist of the rows of  $A$  for which the first nonzero element is in column  $k$ . Then, in step  $k$  of this algorithm, the  $A_k$  is merged with  $R_{k-1}$ , by computing the QR factorization

$$Q_k^T \begin{pmatrix} R_{k-1} \\ A_k \end{pmatrix} = R_k.$$

Note that this and later steps will not involve the first  $k - 1$  rows and columns of  $R_{k-1}$ . Hence the first  $k - 1$  rows of  $R_{k-1}$  are rows in the final matrix  $R$ .

The reduction using this algorithm takes about  $w(w + 1)(m + 3n/2)$  flops, which is approximately half as many as for the Givens method. As in the Givens algorithm the Householder transformations can also be applied to one or several right-hand sides  $b$  to produce  $c = Q^T b$ . The least squares solution is then obtained from  $Rx = c_1$  by back-substitution.

It is essential that the Householder transformations be subdivided as outlined above, otherwise intermediate fill will occur and the operation count increase greatly, see the example in [32].

### Block Angular Form

There is often a substantial similarity in the structure of large sparse least squares problems. The matrices possess a block structure, perhaps at several levels, which reflects a 'local connection' structure in the underlying physical problem. In particular, the problem can often be put in the following bordered block diagonal or *block angular form*:

$$A = \begin{pmatrix} A_1 & & B_1 \\ & \ddots & \vdots \\ & & A_M & B_M \end{pmatrix}, \quad (35)$$

$$x = \begin{pmatrix} x_1 \\ \vdots \\ x_{M+1} \end{pmatrix}, \quad b = \begin{pmatrix} b_1 \\ \vdots \\ b_M \end{pmatrix}. \quad (36)$$

From (35) it follows that the variables  $x_1, \dots, x_M$  are coupled only to the variables  $x_{M+1}$ . Some applications

where the form (35) arises naturally are photogrammetry, Doppler radar positioning [27], and geodetic survey problems [20].

Problems of block angular form can be efficiently treated either by using normal equations or by QR factorization. It is easily seen that the matrix  $R$  from Cholesky or QR will have a block structure similar to that of  $A$ ,

$$R = \begin{pmatrix} R_1 & & S_1 \\ & \ddots & \vdots \\ & & R_M & S_M \\ & & & R_{M+1} \end{pmatrix}, \tag{37}$$

where the  $R_i \in \mathbf{R}^{n_i \times n_i}$  are upper triangular. This factor can be computed by first performing a sequence of orthogonal transformations yielding

$$Q_i^T(A_i, B_i) = \begin{pmatrix} R_i & S_i \\ 0 & T_i \end{pmatrix}, \quad Q_i^T b_i = \begin{pmatrix} c_i \\ d_i \end{pmatrix}.$$

Any sparse structure in the blocks  $A_i$  should be exploited. The last block row  $R_{M+1}, c_{M+1}$  is obtained by computing the QR decomposition

$$\tilde{Q}_{M+1}^T (T \quad d) = \begin{pmatrix} R_{M+1} & c_{M+1} \\ 0 & d_{M+1} \end{pmatrix},$$

where

$$T = \begin{pmatrix} T_1 \\ \vdots \\ T_M \end{pmatrix}, \quad d = \begin{pmatrix} d_1 \\ \vdots \\ d_M \end{pmatrix}.$$

The unknown  $x_{M+1}$  is determined from the triangular system  $R_{M+1} x_{M+1} = c_{M+1}$ . Finally  $x_M, \dots, x_1$  are computed by back-substitution in the sequence of triangular systems  $R_i x_i = c_i - S_i x_{M+1}, i = M, \dots, 1$ . Note that a large part of the computations can be performed in parallel on the  $M$  subsystems.

Several modifications of this basic algorithm have been suggested in [19] and [9].

### General Sparse Problems

If  $A$  is partitioned by rows, then (15) can be used to compute the matrix  $C = A^T A$ . Make the ‘no-cancellation assumption’ that whenever two nonzero numerical quantities are added or subtracted, the result

is nonzero. Then it follows that the nonzero structure of  $A^T A$  is the direct sum of the nonzero structures of  $a_i \cdot a_i^T, i = 1, \dots, m$ , where  $a_i^T$  denotes the  $i$ th row of  $A$ . Hence the undirected graph  $G(A^T A)$  representing the structure of  $A^T A$  can be constructed as the direct sum of all the graphs  $G(a_i \cdot a_i^T), i = 1, \dots, m$ . The nonzeros in row  $a_i^T$  will generate a subgraph, where all pairs of nodes are connected. Such a subgraph is called a *clique*.

From the graph  $G(A^T A)$  the structure of the Cholesky factor  $R$  can be predicted by using a graph model of Gaussian elimination. The fill under the factorization process can be analyzed by considering a sequence of undirected graphs  $G_i = G(A^{(i)}), i = 0, \dots, n-1$ , where  $A^{(0)} = A$ . These *elimination graphs* can be recursively formed in the following way. Form  $G_i$  from  $G_{(i-1)}$  by removing the node  $i$  and its incident edges and adding fill edges. The fill edges in eliminating node  $v$  in the graph  $G$  are

$$\{(j, k): (j, k) \in \text{Adj}_G(v), j \neq k\}.$$

Thus, the fill edges correspond to the set of edges required to make the adjacent nodes of  $v$  pairwise adjacent. The filled graph  $G_F(A)$  of  $A$  is a graph with  $n$  vertices and edges corresponding to all the elimination graphs  $G_i, i = 0, \dots, n-1$ . The filled graph bounds the structure of the Cholesky factor  $R$ ,

$$G(R^T + R) \subset G_F(A). \tag{38}$$

This also gives an upper bound for the structure of the factor  $R$  in the QR decomposition.

A reordering of the columns of  $AP$  of  $A$  corresponds to a symmetric reordering of the rows and columns of  $A^T A$ . Although this will not affect the number of nonzeros in  $A^T A$ , only their positions, it may greatly affect the number of nonzeros in the Cholesky factor  $R$ . Before carrying out the Cholesky or QR factorization numerically, it is therefore important to find a permutation matrix  $P$  such that  $P^T A^T A P$  has a sparse Cholesky factor  $R$ .

By far the most important local ordering method is the *minimum degree ordering*. In terms of the Cholesky factorization this ordering is equivalent to choosing the  $i$ th pivot column as one with the minimum number of nonzero elements in the unreduced part of  $A^T A$ . This will minimize the number of entries that will be modified in the next elimination step. Remarkably fast

symbolic implementations of the minimum degree algorithm exist, which use refinements of the elimination graph model of the Cholesky factorization. See [16] for a survey of the extensive development of efficient versions of the minimum degree algorithm.

Another important ordering method is *substructuring* or *nested dissection*, which results in a nested block angular form. Here the idea is to choose a set of nodes  $\mathcal{B}$  in the graph  $G(A^T A)$ , which separates the other nodes into two sets  $\mathcal{A}_1$  and  $\mathcal{A}_2$  so that node variables in  $\mathcal{A}_1$  are not connected to node variables in  $\mathcal{A}_2$ . The variables are then ordered so that those in  $\mathcal{A}_1$  appear first, those in  $\mathcal{A}_2$  second, and those in  $\mathcal{B}$  last. Finally the equations are ordered so that those including  $\mathcal{A}_1$  come first, those including  $\mathcal{A}_2$  next, and those only involving variables in  $\mathcal{B}$  come last. This dissection can be continued recursively, first dissecting the regions  $\mathcal{A}_1$  and  $\mathcal{A}_2$  each into two subregions, and so on.

An algorithm using the normal equations for solving sparse linear least squares problems is usually split in a symbolical and a numerical phase as follows.

- 1) Determine symbolically a column permutation  $P_c$  such that  $P_c^T A^T A P_c$  has a sparse Cholesky factor  $R$ .
- 2) Perform the Cholesky factorization of  $P_c^T A^T A P_c$  symbolically to generate a storage structure for  $R$ .
- 3) Compute  $B = P_c^T A^T A P_c$  and  $c = P_c^T A^T b$  numerically, storing  $B$  in the data structure of  $R$ .
- 4) Compute the Cholesky factor  $R$  numerically and solve  $R^T z = c$ ,  $Ry = z$ , giving the solution  $x = P_c y$ .

Here, steps 1 and 2 involve only symbolic computation and apply also to a sparse QR algorithm. For details of the implementation of the numerical factorization see [15, Chap. 5]. For moderately ill-conditioned problems a sparse Cholesky factorization, possibly used with iterative refinement, is a satisfactory choice.

Orthogonalization methods are potentially more accurate since they work directly with  $A$ . The number of operations needed to compute the QR decomposition depends on the row ordering, and the following heuristic row ordering algorithm should be applied to  $A$  before the numerical factorization takes place:

First sort the rows after increasing  $f_i(A)$ , so that  $f_i(A) \leq f_k(A)$  if  $i < k$ . Then for each group of rows with  $f_i(A) = k$ ,  $k = 1, \dots, \max_i f_i(A)$ , sort all the rows after increasing  $L_i(A)$ .

In the sparse case, applying the usual sequence of Householder reflections may cause a lot of *intermedi-*

*ate fill-in*, with consequent cost in operations and storage. In the row sequential algorithm by J.A. George and M.T. Heath [14], this problem is avoided by using a row-oriented method employing Givens rotations. Even more efficient are *multifrontal methods*, in which Householder transformations are applied to a sequence of small dense subproblems.

Note that in most sparse QR algorithms the orthogonal factor  $Q$  is not stored. The corrected seminormal equations are used for treating additional right-hand sides. The reason is that for rectangular matrices  $A$  the matrix  $Q$  is usually much less sparse than  $R$ . In the multifrontal algorithm, however,  $Q$  can efficiently be represented by the Householder vectors of the frontal orthogonal transformations, see [26].

A Fortran multifrontal sparse QR subroutine, called QR27, has been developed by P. Matstoms [28]. He [29] has also developed a version of this to be used with MATLAB, implemented as four M-files and available from netlib.

Gottfried Wilhelm Leibniz; Integration; Differentiation; Theory of envelopes; Infinitesimal calculus

G.W. Leibniz (1646–1716) was a well-known German philosopher and mathematician. He is considered a de-

scendant of German idealism and a pioneer of the Enlightenment. Leibniz is known as the inventor of the differential and integral calculus [7].

Leibniz's contribution in philosophy is as significant as in mathematics. In philosophy Leibniz is known for his fundamental philosophical ideas and principles including truth, necessary and contingent truths, possible worlds, the principle of sufficient reason (i. e., there is a reason behind everybody's action), the principle of pre-established harmony (i. e., the universe is created in such a way that corresponding mental and physical events occur simultaneously), and the principle of noncontradiction (i. e., if a contradiction can be derived from a proposition, this proposition is false). Leibniz was fond on the idea that the principles of reasoning could be organized into a formal symbolic system, an algebra or calculus of thought, where disagreements could be settled by calculations [4].

Leibniz was the son of a professor of moral philosophy at Leipzig Univ. Leibniz learned to read from his father before going to school. He taught himself Latin and Greek by age 12, so that he could read the books in his father's library. He studied law at the Univ. of Leipzig from 1661 to 1666. In 1666 he was refused the degree of doctor of laws at Leipzig. He went to the Univ. of Altdorf, which awarded him doctorate in jurisprudence in 1667 [1].

Leibniz started his career at the courts of Mainz where he worked until 1672. The Elector of Mainz promoted him to diplomatic services. In 1672 he visited Paris to try to dissuade Louis XIV from attacking German areas. Leibniz remained in Paris until 1676, where he continued to practice law. In Paris he studied mathematics and physics under Chr. Huygens. During this period he developed the basic features of his version of the calculus. He spent the rest of his life, from 1676 until his death (November 14, 1716) at Hannover [6].

Leibniz's most important achievement in mathematics was the discovery of *infinitesimal calculus*. The significance of calculus is so important that it was marked as the starting point of modern mathematics. Leibniz's formulations were different from previous investigation by I. Newton. Newton was mainly concentrated in the geometrical representation of calculus, while Leibniz took it towards analysis. Newton considered variables changing with time. Leibniz thought of variables  $x$ ,  $y$  as ranging over sequences of infinitely

close values. For Newton integration and differentiation were inverses, while Leibniz used *integration* as a summation. At that time, neither Leibniz nor Newton thought in terms of functions, both always thought in terms of graphs.

In November 1675 he wrote a manuscript using the notation  $\int f(x) dx$  for the first time [5]. In the same manuscript he presented the product rule for *differentiation*. The quotient rule first appeared two years later, in July 1677. In 1676 Leibniz arrived in the conclusion that he was in possession of a method that was highly important because of its generality. Whether a function was rational or irrational, algebraic or transcendental (a word that Leibniz coined), his operations of finding sums and differences could always be applied.

In November 1676 Leibniz discovered the familiar notation  $d(x^n) = nx^{n-1} dx$  for both integral and fractional  $n$ . Newton claimed that: 'not a single previously unsolved problem was solved here', but the formalism of Leibniz's approach proved to be vital in the development of the calculus. Leibniz never thought of the derivative as a limit. This does not appear until the work of J. d'Alembert. Leibniz was convinced that good mathematical notations were the key to progress so he experimented with different notation for coefficient systems. His language was fresh and appropriate, incorporating such terms as *differential*, *integral*, *coordinate* and *function* [8]. His notations which we still use today, were clear and elegant. His unpublished manuscripts contain more than 50 different ways of writing coefficient systems, which he worked on during a period of 50 years beginning in 1678.

Leibniz used the word *resultant* for certain combinatorial sums of terms of a determinant. He proved various results on resultants including what is essentially Cramer's rule. He also knew that a determinant could be expanded using any column, what is now called Laplace expansion. As well as studying coefficient systems of equations which led him to determinants, Leibniz also studied coefficient systems of quadratic forms which led naturally towards matrix theory [9]. He thought about continuity, space and time [2].

In 1684 Leibniz published details of his differentiable calculus in 'Acta Eruditorum', a journal established in Leipzig two years earlier. He described a general method for finding *maxima* and *minima*, and drawing tangents to curves. The paper contained the

rules for computing the derivatives of powers, products and quotient.

In 1686 Leibniz published a paper on the principles of new calculus [3] in 'Acta Eruditorum'. Leibniz emphasized the inverse relationship between differentiation and integration in the fundamental theorem of calculus.

In 1692 Leibniz wrote a paper that set the basis of the *theory of envelopes*. This was further developed in another paper published on 1694 where he introduced for the first time the terms *coordinates* and *axes of coordinates*.

Leibniz published many papers on mechanical subjects as well [1]. In 1700 Leibniz founded the Berlin Academy and was its first president.

Leibniz's principal works are:

- 1) 'De Arte Combinatoria' (On the Art of Combination), 1666;
- 2) 'Hypothesis Physica Nova' (New Physical Hypothesis), 1671;
- 3) 'Dicours de Metaphysique' (Discourse on Metaphysics), 1686;
- 4) Unpublished Manuscripts on the Calculus of Concepts, 1690;
- 5) 'Nouveaux Essais sur L'entendement Humaine' (New Essays on Human Understanding), 1705;
- 6) 'Theodicee' (Theodicy), 1710;
- 7) 'Monadologia' (The Monadology), 1714.

Linear complementarity; Pivoting

The *linear complementarity problem* (LCP) is a well known problem in mathematical programming. Applications of the LCP to engineering, game theory, economics, and many other scientific fields have been found. The monograph of K.G. Murty [8] is a compendium of LCP developments. One of the most significant approaches to the solution of the linear complementarity problem is called Lemke's method or Lemke's algorithm. Two descriptions of the algorithm [6,7] provide many algorithmic proofs and details for the interested reader. Our treatment here is a sketch of the algorithm, together with pointers to related work in the literature.

There are some important related works for those who wish to solve LCP. A. Ravindran [10] provided a FORTRAN implementation of Lemke's algorithm in a set-up similar to the revised simplex method. C.B. Garcia [2] described some classes of matrices for which the associated LCPs can be solved by Lemke's algorithm. J.J.M. Evers [1] enlarged the range of application

of Lemke's algorithm, and showed that it could solve the bimatrix game. P.M. Pardalos and J.B. Rosen [9] presented a global optimization approach to LCP. D. Solow and P. Sengupta [11] proposed a finite descent theory for the linear complementarity problem. M.M. Kostreva [4] showed that without the *nondegeneracy assumption*, Lemke's algorithm may *cycle*, and showed that the minimum length of such a cycle is four.

The linear complementarity problem considered is: Given an  $(n \times n)$ -matrix  $M$  and an  $(n \times 1)$  column vector  $q$ , problem  $LCP(q, M)$  is to find  $x$  (or prove that no such  $x$  exists) in  $\mathbf{R}^n$  satisfying

$$y = Mx + q, \quad (1)$$

$$y_i \geq 0, \quad (2)$$

$$x_i \geq 0, \quad (3)$$

$$y_i \cdot x_i = 0, \quad (4)$$

for all  $i, i = 1, \dots, n$ .

Clearly these conditions are equivalent to  $y^T x = 0$ . The variables  $(y_i, x_i)$  are called a *complementary pair of variables*. Lemke's algorithm is organized relative to the following extended system of equations:

$$y = Mx + q + x_0 d, \quad (5)$$

where  $d$  is an  $(n \times 1)$  column vector, and  $x_0 \geq 0$ . Relative to the vector  $d$ , it is only required that  $(q + x_0 d) \geq 0$  for some  $x_0 \geq 0$ . It is assumed that the system of equations (5) is nondegenerate, that is, any solution has at most  $n + 1$  zero values among the variables  $(y, x, x_0)$ .

### Lemke's Algorithm

If  $q > 0$ , terminate with a complementary feasible solution,  $y = q, x = 0$ .

If  $q$  has some negative component, then on the first pivot  $x_0$  is increased until for the first time  $y = q + x_0 d \geq 0$ . When this occurs, some  $y$  variable, say  $y_r$  becomes zero. The first pivot is to exchange the variables  $x_0$  and  $y_r$ . Now the variable  $x_0$  is basic, and the variables  $y_r$  and  $x_r$  are two complementary non basic variables. If a pivot can be made on variable  $x_r$  (complement of the most recently pivoted member of the complementary pair), then it leads to another similar situation with an-

other pair of complementary variables. If a pivot cannot be made, the sequence is terminated. If the variable  $x_0$  becomes non basic (zero), a solution is at hand. If not, the pivoting continues uniquely, with each new set of equations containing a non basic complementary pair of variables, one of which is most recently made non basic. Due to the unique choices of pivot row and pivot column, finite termination must occur.

Under certain conditions, including the positive semidefinite matrices, the condition of termination without finding a pivot (also called secondary ray termination) can be shown to imply that the set  $\{x: y = Mx + q \geq 0, x \geq 0\}$  is empty. Under such conditions, Lemke's algorithm is said to *process the LCP*: either it is solved, or it is shown not to have a feasible solution. The set of all LCPs which Lemke's algorithm will process is unknown, but some recent papers shed light on its processing domain. Kostreva and M.M. Wiecek [5] use a multiple objective optimization approach which eventually results in a larger dimensioned LCP, while G. Isac, Kostreva and Wiecek [3] point out a set of problems which is impossible for Lemke's method to process.

*Example 1* Consider the LCP corresponding to the quadratic programming problem

$$\begin{cases} \min & x_1^2 - 2x_1x_2 + x_2^2 + 3x_1 + x_2 \\ \text{s.t.} & 3x_1 + x_2 \geq 4 \\ & x_1 \geq 0, x_2 \geq 0. \end{cases}$$

Then  $q = (-4, 3, 1)^T$  and  $M = [(0, -3, -1)^T, (3, 2, -2)^T, (1, -2, 2)^T]$ , and Lemke's algorithm requires four pivots to obtain the solution  $x^* = (1, 1)^T$ , using the vector  $d = (1, 1, 1)^T$ . It is noteworthy that the nondegeneracy assumption is not satisfied in this example, but Lemke's algorithm works anyway.

The general linear optimization (LO), linear programming (cf. ► [Linear programming](#)), problem will be considered in the standard primal form

$$\min \{c^T x : Ax = b, x \geq 0\},$$

together with its standard dual

$$\max \{b^T y : A^T y \leq c\}.$$

One of the most efficient, and for a long time the only, practical method to solve LO problems was the simplex method of G.B. Dantzig. The *simplex method* is a *pivot algorithm* that traverses through feasible *basic solutions* while the objective value is improving. The simplex method is practically one of the most efficient algorithms but it is theoretically a finite algorithm only for *nondegenerate problems*.

A basis is called *primal degenerate* if at least one of the basic variables is zero; it is called *dual degenerate* if the reduced cost of at least one nonbasic variable is zero. In general, the basis is degenerate if it is either primal or dual, or both primal and dual degenerate. The LO problem is degenerate, if it has a degenerate basis. A pivot is called degenerate when after the pivot the objective remains unchanged. When the problem is *degenerate* the objective might stay the same in subsequent iterations and the simplex algorithm may *cycle*, i. e. starting from a basis, after some iterations the same basis is revisited and this process is repeated endlessly. Because the simplex method produces a sequence with monotonically improving objective values, the objective stays constant in a cycle, thus each pivot in the cycle must be degenerate. The possibility of cycling was recognized shortly after the invention of the simplex algorithm. Cycling examples were given by E.M.L. Beale [2] and by A.J. Hoffman [10]. Recently (1999) a scheme to construct cycling LO examples is presented in [9]. These examples made evident that extra techniques are needed to ensure finite termination of simplex methods. The first and widely used such tool is the *lexico-*

graphic simplex rule. Other techniques, like the least-index anticycling rules (cf. ► **Least-index anticycling rules**) and more general recursive schemes were developed more recently.

### Lexicographic Simplex Methods

First we need to define an ordering, the so-called *lexicographic ordering* of vectors.

#### Lexicographic Ordering

An  $n$ -dimensional vector  $u = (u_1, \dots, u_n)$  is called *lexicographically positive* or, in other words, *lexico-positive* if its first nonzero coordinate is positive, i. e. for a certain  $j \leq n$  one has  $u_i = 0$  for  $i < j$  and  $x_u > 0$ . Observe, that the zero vector is the only lexico-nonnegative vector which is not lexico-positive. The vector  $u^0$  is said to be lexicographically smaller than a vector  $u^1$  when the difference  $u^1 - u^0$  of the two vectors is lexico-positive. Further, if a finite set of vectors  $\{u^0, \dots, u^k\}$  is given, then the vector  $u^0$  is said to be lexico-minimal in the given set, when  $u^0$  is lexicographically smaller than  $u^i$  for all  $1 \leq i \leq k$ .

#### The Lexicographic Primal Simplex Method

Cycling of the simplex method is possible only when the LO problem is degenerate. In that case possibly many variables are eligible to enter and to leave the basis. The lexicographic primal simplex rule makes the selection of the leaving variable uniquely determined when the entering variable is already chosen.

#### The Use of Lexicographic Ordering

At start a feasible *lexico-positive basis tableau* is given. A basis tableau is called lexico-positive if, except the reduced cost row, all of its row vectors are lexico-positive. Any feasible basis tableau can be made lexico-positive by a simple rearrangement of its columns. Specifically, we can take the solution column as the first one, and then take the current basic variables, in an arbitrary order, followed by the nonbasic variables, again in an arbitrary ordering.

The following lexicographic simplex pivot selection rule was first proposed by Dantzig, A. Orden and P. Wolfe [7].

- |   |   |
|---|---|
| 0 | Initialization.<br>Let $T(B)$ be a given primal feasible lexico-positive basis tableau.<br>(Fix the order of the variables.)  |
| 1 | Entering variable selection.<br>Choose a dual infeasible variable, i.e. one with negative reduced cost. Let its index be $q$ .<br>IF no such variable exists, THEN STOP;<br>The tableau $T(B)$ is optimal and this way a pair of optimal solutions is obtained.   |
| 2 | Leaving variable selection.<br>Collect in column $q$ all the candidate pivot elements that satisfy the usual pivot selection conditions of the primal simplex method.<br>Let $K = \{i_1, \dots, i_k\}$ be the set of the indices of the candidate leaving variables.<br>IF there is no pivot candidate, THEN STOP;<br>The primal problem is unbounded, and so the dual problem is infeasible.<br>IF there is a unique pivot candidate $\{p\} = K$ to leave the basis, THEN go to Step 3.<br>IF there are more pivot candidates, THEN look at the row vectors $t^i$ , $i \in K$ , of the basis tableau (note that by construction $x_i$ is the first coordinate of $t^i$ ).<br>Let $p$ be the pivot row if $t^p$ is lexico-minimal in this set of row vectors. |
| 3 | Basis transformation.<br>Pivot on $(p, q)$ . Go to Step 1.  |

#### The lexicographic primal simplex rule

The following two observations are important. First note that lexicographic selection plays role only when the leaving variable is selected. In that case some rows of the tableau are compared in the lexicographic ordering. If the basis variables were originally out right after the solution column, as proposed in order to get a lexico-positive initial tableau, then this comparison is already decided when one considers only the columns corresponding to the initial basis. This claim holds, because those columns form a basis, thus the related row vectors are linearly independent as well.

On the other hand, when the initial basis is the unit matrix, then at each pivot the basis inverse can be found, in the place of the initial unit matrix. When these

two observations are put together, it can be concluded that instead of using the rows of the basis tableau, the rows of the basis inverse headed by the corresponding solution coordinate, can be used in Step 2. to determine the unique leaving variable. As a consequence one do not need to calculate and store the complete basis tableau when implementing the lexicographic pivot rule. The solution and the basis inverse provide all the necessary information.

The lexicographic simplex method is finite. The finiteness proof is based on the following simple properties: There is a finite number of different basis tableaus. The first row of the tableau, i. e. the vector, having the objective value as its first coordinate followed by the reduced cost vector, strictly increases lexicographically at each iteration. This fact ensures that no basis can be revisited, thus cycling is impossible.

### Lexicographic Ordering and Perturbation

Independent of [7], A. Charnes [4] developed a technique of *perturbation*, that resulted in a finite simplex algorithm. This algorithm turned out to be equivalent to the lexicographic rule. The perturbation technique is as follows. Let  $\epsilon$  be a sufficiently small number. Let us replace  $b_i$  by  $b_i + \sum_j a_{ij}\epsilon^j$  for all  $i$ . If  $\epsilon$  is small enough then the resulted problem is nondegenerate. Moreover, starting from a given primal feasible basis, the primal simplex method applied to the new problem produces exactly the same pivot sequence as the lexicographic simplex method on the original problem.

In particular, when the problem is initialized with a feasible basis solution, it suffices to use the perturbation  $b_i + \epsilon^i$ . This way only the basis part of the coefficient matrix is used in Charnes' perturbation technic.

An appealing property of the perturbation technique is that actually it is not needed to perform the perturbation with a concrete  $\epsilon$ . It can be done symbolically.

### Lexicographic Dual Simplex Method

The dual simplex method is nothing else, than the primal simplex method applied to the dual problem, when the dual problem is brought in the primal standard form. This way it is straightforward to develop the lexi-

cographic, or the equivalent perturbation technique for the dual simplex method.

### Extensions

The lexicographic rule is extensively used in proving finiteness of pivot algorithms, see e. g. [1] for an application in a monotonic build-up scheme, [14] for further references in LO and [5] for references when lexicographic degeneracy resolution is applied for complementarity problems.

### Lexicography and Oriented Matroids

Based on the perturbation interpretation, analogous lexicographic techniques and lexicographic pivoting rules were developed for oriented matroid programming [3] (cf. also ► **Oriented matroids**). These techniques were particularly interesting, because nondegenerate cycling [3,8] is possible in oriented matroids. An apparent difference between the linear and the oriented matroid context is that for oriented matroids none of the finite – recursive or least index type – rules yield a simplex method, i. e. a pivot method that preserves feasibility of the basis throughout. This discrepancy is also due to the possibility of nondegenerate cycling.

Interestingly, in the case of oriented matroid programming the finite lexicographic method of M.J. Todd [15,16] is the only one which preserves feasibility of the basis and therefore yields a finite simplex algorithm for oriented matroids.

The equivalence of Dantzig's self—dual parametric algorithm [6] and Lemke's complementary pivot algorithm [11,12] applied to the linear complementarity problem (cf. also ► **Linear complementarity problem**) defined by the primal and dual LO problem was proved by I. Lustig [13]. Todd's lexicographic pivot rule is essentially a lexicographic Lemke method (or the parametric perturbation method), when applied to the specific linear complementary problem defined by the primal-dual pair of LO problems. Hence, using the equivalence mentioned above a simplex algorithm for LO can be derived. However, it is more complicated to present this method in the linear optimization than in the complementarity context. Now Todd's rule will be sketched for the linear case.

0	Initialization. Let a lexico-positive feasible tableau $T(B)$ be given.
1	Entering variable selection. Collect all the dual infeasible variables as the set of candidate entering variables. Let their set of indices be denoted by $K_D$ . IF no such variable exists, THEN STOP; The tableau $T(B)$ is optimal and this way a pair of optimal solutions is obtained. IF there is a unique $\{q\} = K_D$ candidate to enter the basis, THEN go to Step 2. IF there are more pivot candidates, THEN let $q$ be the index of that variable whose column is lexico-minimal in the set $K_D$ . (Analogous to the dual lexicographic simplex selection rule).
2	Leaving variable selection. Collect in column $q$ all the candidate pivot elements that satisfy the usual pivot selection conditions of the primal simplex method. Let $K_p$ be the set of the indexes of the candidate leaving variables. IF there is no pivot candidate, THEN STOP; the primal problem is unbounded, and so the dual problem is infeasible. IF there is a unique $\{p\} = K_p$ pivot candidate to leave the basis, THEN go to Step 3. IF there are more pivot candidates, THEN let $p$ be the index of that variable whose row is lexico-minimal in the set $K_p$ . (Analogous to the primal lexicographic simplex selection rule.)
3	Basis transformation. Pivot on $(p, q)$ . Go to Step 1.

#### Todd's lexicographic Lemke rule (Phase II)

In Todd's rule the perturbation is done first in the right-hand side and then in the objective (with increasing order of the perturbation parameter  $\epsilon$ ). It finally gives a two phase simplex method. For illustration only the second phase [14] is presented here. Complete description of the algorithm can be found in [3,16].

This algorithm is not only a unique simplex method for oriented matroids, but it is a novel application of lexicography in LO as well.

### Synonyms

LCP

### Definition

In its standard form, a linear complementarity problem (LCP) is an inequality system stated in terms of a mapping  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$  where  $f(x) = q + Mx$ . Given  $f$ , one seeks a vector  $x \in \mathbf{R}^n$  such that for  $i = 1, \dots, n$ ,

$$x_i \geq 0, \quad f_i(x) \geq 0, \quad \text{and} \quad x_i f_i(x) = 0. \quad (1)$$

Because the affine mapping  $f$  is specified by the vector  $q \in \mathbf{R}^n$  and the matrix  $M \in \mathbf{R}^{n \times n}$ , the problem is ordinarily denoted  $\text{LCP}(q, M)$  or sometimes just  $(q, M)$ . A system of the form (1) in which  $f$  is not affine is called a *nonlinear complementarity problem* and is denoted  $\text{NCP}(f)$ . The notation  $\text{CP}(f)$  is meant to cover both cases.

If  $\bar{x}$  is a solution to (1) satisfying the additional *nondegeneracy condition*  $\bar{x}_i + f_i(\bar{x}) > 0$ ,  $i = 1, \dots, n$ , the indices  $i$  for which  $\bar{x}_i > 0$  or  $f_i(\bar{x}) > 0$  form complementary subsets of  $\{1, \dots, n\}$ . This is believed to be the

origin of the term *complementary slackness* as used in linear and nonlinear programming. It was this terminology that inspired the name *complementarity problem*.

### Sources of Linear Complementarity Problems

The linear complementarity problem is associated with the Karush–Kuhn–Tucker necessary conditions of local optimality found in quadratic programming. This connection (as well as the more general connection of nonlinear complementarity problems with other types of nonlinear programs) was brought out in [1,2] and later in [3]. Finding solutions to such systems was one of the original motivations for studying the subject. Another was the finding of equilibrium points in bimatrix and polymatrix games. This kind of application was emphasized in [16] and [22]. These early contributions also included essentially the first algorithms for this class of problems. There are numerous applications of the linear and nonlinear complementarity problems in computer science, economics, various engineering disciplines, finance, game theory, and mathematics. One application of the LCP is in algorithms for the nonlinear complementarity problem. Descriptions of (and references to) these applications can be found in [5,27] and [17]. The survey article [10] is a rich compendium on engineering and economic applications of linear and nonlinear complementarity problems.

### Equivalent Formulations

Whether linear or nonlinear, the complementarity problem expressed by the system (1) can be formulated in several equivalent ways. An obvious one calls for a solution  $(x, y)$  to the system

$$y - f(x) = 0, \quad x \geq 0, \quad x^\top y = 0. \quad (2)$$

Another is to find a zero  $x$  of the mapping

$$g(x) = \min\{x, f(x)\}, \quad (3)$$

where the symbol  $\min\{a, b\}$  denotes the component-wise minimum of the two  $n$ -vectors  $a$  and  $b$ . A third equivalent formulation asks for a fixed point of the mapping

$$h(x) = x - g(x),$$

that is, a vector  $x \in \mathbf{R}^n$  such that  $x = h(x)$ .

The formulation given in (3) is related to the (often nonconvex) optimization problem:

$$\begin{cases} \min & x^\top f(x) \\ \text{s.t.} & f(x) \geq 0 \\ & x \geq 0. \end{cases} \quad (4)$$

In such a problem, the objective is bounded below by zero, thus any feasible solution of (4) for which the objective function  $x^\top f(x) = 0$  must be a global minimum as well as a solution of (1). As it happens, there are circumstances (for instance, the monotonicity of the mapping  $f$ ) under which all the local minima for the mathematical programming problem (4) must in fact be solutions of (3). See [28] for an extended discussion of this matter.

Also noteworthy is a result in [8] showing that the LCP is equivalent to solving a system of equations  $y = \varphi(x)$  where the mapping  $\varphi: \mathbf{R}^n \rightarrow \mathbf{R}^n$  is piecewise linear. In particular,  $\text{LCP}(q, M)$  is equivalent to finding a vector  $u$  such that

$$q + Mu^+ - u^- = 0,$$

where (for  $i = 1, \dots, n$ ,  $u_i^+ = \max\{0, u_i\}$  and  $u_i^- = -\min\{0, u_i\}$ ).

### The Importance of Matrix Classes

The extensive literature of the LCP exhibits several main directions of study: the existence and uniqueness (or number of) solutions, mathematical properties of the problem, generalizations of the problem, algorithms, applications, and implementations.

Much of the theory of the linear complementarity problem is intimately linked in various ways to matrix classes. For instance, one of the earliest theorems on the existence of solutions to LCPs is due H. Samelson, R.M. Thrall and O. Wesler [30]. Motivated by a problem in structural mechanics, they showed that the  $\text{LCP}(q, M)$  has a unique solution for every  $q \in \mathbf{R}^n$  if and only if the matrix  $M$  has positive principal minors. (That is, the determinant of every principal submatrix of  $M$  is positive.) The class of such matrices has come to be known as  $\mathbf{P}$ , and its members are called  $\mathbf{P}$ -matrices. (The Samelson–Thrall–Wesler theorem characterizes this class of matrices in terms of the LCP.) The class  $\mathbf{P}$  includes all *positive definite* ( $\mathbf{PD}$ ) matrices, i.e., those square matrices  $M$  for which  $x^\top Mx > 0$  for all  $x \neq 0$ . In

the context of the LCP, the term  $\mathbf{PD}$  does not require symmetry. An analogous definition (and usage) holds for *positive semidefinite* ( $\mathbf{PSD}$ ) matrices, namely,  $M$  is  $\mathbf{PSD}$  if  $x^\top Mx \geq 0$  for all  $x$ . Some authors refer to such matrices as *monotone* because of their connection with monotone mappings.  $\mathbf{PSD}$ -matrices have the property that associated LCPs  $(q, M)$  are solvable whenever they are feasible, whereas LCPs  $(q, M)$  in which  $M \in \mathbf{PD}$  are always feasible and (since  $\mathbf{PD} \subset \mathbf{PSD}$ ) are always solvable. This distinction is given a more general matrix form in [25,26]. There  $\mathbf{Q}$  is defined as the class of all square matrices for which  $\text{LCP}(q, M)$  has a solution for all  $q$  and  $\mathbf{Q}_0$  as the class of all square matrices for which  $\text{LCP}(q, M)$  has a solution whenever it is feasible. Although the goal of usefully characterizing the classes  $\mathbf{Q}$  and  $\mathbf{Q}_0$  has not yet been realized, much is known about some of their special subclasses. Indeed, there are now literally dozens of matrix classes for which LCP existence theorems have been established. See [5,27] and [17] for an abundance of information on this subject.

From the theoretical standpoint, the class of ‘sufficient matrices’ [6] illustrates the intrinsic role of matrix classes in the study of the LCP. A matrix  $M \in \mathbf{R}^{n \times n}$  is *column sufficient* if

$$[x_i(Mx)_i \leq 0 \quad \forall i] \implies [x_i(Mx)_i = 0 \quad \forall i]$$

and *row sufficient* if  $M^\top$  is column sufficient. When  $M$  is both row and column sufficient, it is called *sufficient*. Row sufficient matrices always have nonnegative principal minors, hence so do (column) sufficient matrices. These classes include both  $\mathbf{P}$  and  $\mathbf{PSD}$  as distinct subclasses. The row sufficient matrices form a subclass of  $\mathbf{Q}_0$ ; this is not true of column sufficient matrices however. The column sufficient matrices  $M \in \mathbf{R}^{n \times n}$  are characterized by the property that the solution set of  $\text{LCP}(q, M)$  is convex for every  $q \in \mathbf{R}^n$ . In the same spirit, a real  $n \times n$  matrix  $M$  is row sufficient if and only if for every  $q \in \mathbf{R}^n$ , the solutions of the  $\text{LCP}(q, M)$  are precisely the optimal solutions of the associated quadratic program (4). Rather surprisingly, the class of sufficient matrices turns out to be identical to the matrix class  $\mathbf{P}_*$  introduced in [19]. See [13] and [34].

### Algorithms for Solving LCPs

The algorithms for solving linear complementarity problems are of two major types: pivoting (or, direct)

and iterative (or, indirect). Algorithms of the former type are finite procedures that attempt to transform the problem  $(q, M)$  to an equivalent system of the form  $(q', M')$  in which  $q' \geq 0$ . Doing this is not always possible; it depends on the problem data, usually on the matrix class (such as **P**, **PSD**, etc.) to which  $M$  belongs. When this approach works, it amounts to carrying out a *principal pivotal transformation* on the system of equations

$$w = q + Mz.$$

To such a transformation there corresponds an index set  $\alpha$  (with complementary index set  $\bar{\alpha} = \{1, \dots, n\} \setminus \alpha$ ) such that the *principal submatrix*  $M_{\alpha\alpha}$  is nonsingular. When this (block pivot) operation is carried out, the system

$$\begin{aligned} w_\alpha &= q_\alpha + M_{\alpha\alpha}z_\alpha + M_{\alpha\bar{\alpha}}z_{\bar{\alpha}}, \\ w_{\bar{\alpha}} &= q_{\bar{\alpha}} + M_{\bar{\alpha}\alpha}z_\alpha + M_{\bar{\alpha}\bar{\alpha}}z_{\bar{\alpha}} \end{aligned}$$

becomes

$$\begin{aligned} z_\alpha &= q'_\alpha + M'_{\alpha\alpha}w_\alpha + M'_{\alpha\bar{\alpha}}z_{\bar{\alpha}}, \\ w_{\bar{\alpha}} &= q'_{\bar{\alpha}} + M'_{\bar{\alpha}\alpha}w_\alpha + M'_{\bar{\alpha}\bar{\alpha}}z_{\bar{\alpha}}, \end{aligned}$$

where

$$\begin{aligned} q'_\alpha &= -M_{\alpha\alpha}^{-1}q_\alpha, \\ q'_{\bar{\alpha}} &= q_{\bar{\alpha}} - M_{\bar{\alpha}\alpha}M_{\alpha\alpha}^{-1}q_\alpha, \\ M'_{\alpha\alpha} &= M_{\alpha\alpha}^{-1}, \\ M'_{\bar{\alpha}\alpha} &= M_{\bar{\alpha}\alpha}M_{\alpha\alpha}^{-1}, \\ M'_{\alpha\bar{\alpha}} &= -M_{\alpha\bar{\alpha}}M_{\alpha\alpha}^{-1}, \\ M'_{\bar{\alpha}\bar{\alpha}} &= M_{\bar{\alpha}\bar{\alpha}} - M_{\bar{\alpha}\alpha}M_{\alpha\alpha}^{-1}M_{\alpha\bar{\alpha}}. \end{aligned}$$

There are two main pivoting algorithms used in processing LCPs. The more robust of the two is due to C.E. Lemke [21]. *Lemke's method* embeds the LCP  $(q, M)$  in a problem having an extra 'artificial' nonbasic (independent) variable  $z_0$  with coefficients specially chosen so that when  $z_0$  is sufficiently large, all the basic variables become nonnegative. At the least positive value of  $z_0$  for which this is so, there will (in the nondegenerate case) be (exactly) one basic variable whose value is zero. That variable is exchanged with  $z_0$ . Thereafter the method executes a sequence of (almost complementary) simple pivots. In each case, the variable *becoming* basic is the complement of the variable that be-

came nonbasic in the previous exchange. The method terminates if either  $z_0$  decreases to zero (in which case the problem is solved) or else there is no basic variable whose value decreases as the incoming nonbasic variable is increased. The latter outcome is called *termination on a secondary ray*. For certain matrix classes, termination on a secondary ray is an indication that the given LCP has no solution. Lemke's method is studied from this point of view in [7].

The other pivoting algorithm for the LCP is called the *principal pivoting method* (PPM), expositions of which are given in [3] and [5]. The algorithm has two versions: symmetric and asymmetric. The former executes a sequence of principal (block) pivots of order 1 or 2, whereas the latter does sequences of almost complementary pivots, each of which results in a block principal pivot of order potentially larger than 2.

*Iterative methods* are often favored for the solution of very large linear complementarity problems. In such problems, the matrix  $M$  tends to be sparse (i. e., to have a small percentage of nonzero elements) and structured. Since iterative methods do not modify the problem data, these features of large scale problems can be used to advantage. Ordinarily, however, an iterative method does not terminate finitely; instead, it generates a convergent sequence of trial solutions. The older iterative LCP algorithms are based on equation-solving methods (e. g., *Gauss-Seidel*, *Jacobi*, and *successive over-relaxation*); the more contemporary ones are varieties of the *interior point* type. In addition to the usual concerns about practical performance, considerable interest attaches to the development of polynomial time algorithms. Not unexpectedly, the allowable analysis and applicability of iterative algorithms depend heavily on the matrix class to which  $M$  belongs. Details on several such algorithms are presented in [36,37], and the monographs [5,27] and [17].

## Software

For decades researchers have experimented with computer codes for various linear (and nonlinear) complementarity algorithms. By the late 1990s, this activity reached the stage where the work could be distributed as something approaching commercial software. An overview of available software for complementarity problems (mostly nonlinear), is available as [35].

## Some Generalizations

Both linear and nonlinear complementarity problems have been generalized in numerous ways. One of the earliest generalizations, given in [14] and [18], is the problem  $CP(K, f)$  of finding a vector  $x$  in the closed convex cone  $K$  such that  $f(x) \in K^*$  (the dual cone) and  $x^\top f(x) = 0$ . Through this formulation, a connection can be made between complementarity problems and *variational inequality problems*, that is, problems  $VI(X, f)$  wherein one seeks a vector  $x^* \in X$  (a nonempty subset of  $\mathbf{R}^n$ ) such that

$$f(x^*)^\top (y - x^*) \geq 0 \quad \text{for all } y \in X.$$

It was established in [18] that when  $X$  is a closed convex cone, say  $K$ , with dual cone  $K^*$ , then  $CP(K, f)$  and  $VI(X, f)$  have exactly the same solutions (if any). See [15] for connections with variational inequalities, etc.

In [29] the generalized complementarity problem  $CP(K, f)$  defined above is considered as an instance of a *generalized equation*, namely to find a vector  $x \in \mathbf{R}^n$  such that

$$0 \in f(x) + \partial \psi_K(x),$$

where  $\psi_K$  is the indicator function of the closed convex cone  $K$  and  $\partial$  denotes the subdifferential operator as used in convex analysis.

Among the diverse generalizations of the linear complementarity problem, the earliest appears in [30]. There, for given  $n \times n$  matrices  $A$  and  $B$  and  $n$ -vector  $c$ , the authors considered the problem of the finding  $n$ -vectors  $x$  and  $y$  such that

$$Ax + By = c, \quad x, y \geq 0 \quad \text{and} \quad x^\top y = 0.$$
