Seven financial and six non-financial variables, representing all dimensions of companies' performance, were selected for inclusion in the models that were developed through the MHDIS approach. The results indicated that ROA, CA/CL and Current Assets/Total Assets A were the important criteria for financial model. In additional, litigation, stock exchange, UTADISCR and CA/CL were the most important criteria for the non-financial model. Furthermore, the non-financial

MHDIS model provides higher overall classification accuracy indicating that the inclusion of non-financial variables resulted in a more accurate distinction between qualified and unqualified companies.

By using such models, auditors can simultaneously screen a large number of firms and direct their attention to the ones that are more likely to contain misstatements, saving time or money. These models can also be used by policy-makers in an attempt to stop tax evasion (i. e. the tax evasion consisting of filing fraudulent tax declarations in Italy is estimated to be between 3 and 10% of GNP [87]). In addition, these models can be useful to investors, managers, banks and others companies to identify 'red flags'.

The current research could be extended in several directions. First, future research could be extended towards the inclusion of additional variables such as managers' experience, market characteristics (i. e. industry concentration, industry growth), audit fees and non-audit fees, subsidiaries, and stock prices. Second, companies could be classified into more specific groups. Third, the inclusion of data from a longer time period, could allow the consideration of industry and macroeconomic effects. Finally, future research could be directed towards the comparison and integration of alternative or additional classification techniques, such as neural networks, rough sets, expert systems, support vector machine, and others. The integration of the models through additional techniques, such as bagging and boosting, could also be examined.

## Introduction/Background

Over the last 35 years there have been several studies which have attempted to develop classification models to predict takeover targets in various countries and regions of the world, such as the USA [7,8,10,11,12,15,23,30,34,37], the UK [2,3,4,5,13,28,36], Canada [9,20,29], Greece [31,38,39], and more recently the EU [26,27] and Asia [25]. This is not surprising, since the prediction of acquisitions can be of major interest to stockholders, investors, creditors, and generally anyone who has established a relationship with the acquired firm [35].

Most of these studies have used multivariate statistical and econometric techniques such as discriminant analysis (DA) and logit analysis and only more recently the parametric nature and the statistical assumptions and restrictions of those approaches have led researchers to the application of alternative techniques such as artificial neural networks (ANN) [10], rough sets (RS) [31], recursive partitioning algorithm [15], support vector machines [26], and nearest neighbors [26].

A few recent studies have also used multicriteria decision aid (MCDA, which is the designation usually used in Europe, or multiple criteria decision making, MCDM, which is the one usually used in the USA) techniques [13,25,26,27,36,39] which over the last few years have gained significant recognition among researchers and have been employed in several studies in banking, finance, accounting, and management. For example, Steuer and Na [33] identified 256 applications that combine MCDM and finance. One of the characteris-

tics of these techniques is that they are well suited for analyzing complex decision problems that involve multiple and usually conflicting criteria and/or goals. They can therefore prove particularly useful in the prediction of acquisitions, since there is often not one single reason but a number of reasons that lead management to the decision to merge with or acquire another firm. A further advantage of MCDA techniques is that they do not make any assumptions, as do the traditional techniques (see Barniv and McDonald [6] for a summary of the problems related to the use of discriminant, logit, and probit), about the normality of the variables or the group dispersion matrices (e.g., DA) and they are not sensitive to multicollinearity (e.g., logit analysis). In this paper we first present a brief review of the studies that have applied MCDA in the prediction of acquisition targets (Sect. “**Methods/Applications**”). Then, in Sect. “**Formulation**”, we outline one of the MCDA techniques, namely, *utilités additives discriminantes* (UTADIS), which is used for the development of our classifications models. “**Cases**” describes a case study and presents the results. Finally, Sect. “**Conclusions**” concludes our paper.

## Methods/Applications

Zopounidis and Doumpos [39] were the first to propose the use of MCDA in the prediction of acquisition targets. They developed a classification model with the multigroup hierarchical discrimination (MHDIS) method using a sample of 30 acquired and 30 nonacquired Greek firms and ten financial ratios covering various aspects of a firm’s financial condition. Data from 1 year prior to the acquisition (year  $-1$ ) were used for the development of the model, while years 2 (year  $-2$ ) and 3 (year  $-3$ ) before the acquisition were used to test its discrimination ability. The model classifies correctly 58.33 and 61.67% of the firms for years 2 and 3 prior to the acquisition, respectively. The authors argue that this poor classification could be attributed to the difficulty of predicting acquisition targets in general, and not necessarily to the inability of the proposed approach as a discrimination method. To test further the proposed technique, its classification accuracy was compared with that of DA and UTADIS. The correct classification accuracy obtained using the proposed method is better for all years than that obtained

using DA. As opposed to the UTADIS method, the classification accuracy under the proposed approach is significantly higher for year  $-1$ , the same for for year  $-2$ , and slightly higher for year  $-3$ . On the basis of these results the authors conclude that the iterative binary segmentation procedure is able to provide results that are at least favorably comparable with those provided by UTADIS and outperforms DA.

Tartari et al. [35] also used UTADIS in their study along with linear DA (LDA), probabilistic neural networks (PNN), and RS in an attempt to examine whether the integration of different methods using a stacked generalization approach could result in higher classification accuracies. Their sample consisted of 48 UK firms, selected from 19 industries/sectors, acquired during 2001, and 48 nonacquired firms matched by principal business activity, asset size, sales volume, and number of employees. Twenty-three financial ratios measuring profitability, liquidity and solvency, and managerial performance were initially calculated for each firm for up to 3 years prior to the acquisition (1998–2000); however, they finally used a set of nine ratios, selected on the basis of factor analysis. Their exercise consisted of two stages. First, UTADIS, LDA, PNN, and RS were used to develop individual models. The most recent year (i. e., 2000) was used as a training sample, while data from the other two years (i. e., 1998 and 1999) were used to test the generalizing performance of the proposed integration approach. An eightfold cross-validation approach was employed to develop the base models using the four methods. The classifications of the firms obtained were then used as a training sample for the development of a stacked generalization model. Finally, the development of the stacked model was performed using the UTADIS method that combines (at a metalevel) the group assignments of all the four methods considered in the analysis. The use of other methods to develop the combined model was also examined; nevertheless the results are inferior to those obtained with UTADIS. The stacked model performs better (in terms of the overall correct accuracy rate) than any of the four methods upon which it is based, throughout all the years of the analysis. Furthermore, the results indicate that the stacked model provides significant reductions in the overall error rate compared with LDA, RS, and UTADIS, although they were less significant compared with PNN.

In another UK study, Doumpos et al. [13] compared the classification ability of UTADIS against one of the models developed using DA, logistic regression (LR), and ANN. The sample included 76 UK firms acquired during 2000–2002, matched by industry and size with 76 nonacquired firms. Twenty-nine financial ratios were initial candidates for model development, representing profitability, efficiency, activity, financial leverage, liquidity, and growth; however, the authors finally selected six variables on the basis of a  $t$  test and correlation analysis. The UTADIS model was first developed using data drawn from the most recent year prior to the acquisition (i. e., year  $-1$ ). The model developed was then applied to data from 2 and 3 years prior to the acquisition (years  $-2$  and  $-3$ ). The average accuracies were 74.34 and 78.95%, respectively. These accuracies are higher than the ones obtained by both DA and LR, and are found to comparable to or better than those of ANN when tested using data from years  $-2$  and  $-3$ .

Pasiouras et al. [26] used both UTADIS and MHDIS, among several other classification techniques, to develop models specifically designed for the EU banking industry. They developed several models on the basis of equal and unequal training samples from the period 1998–2000, using both raw and country-adjusted variables. The models were tested in equal and unequal datasets from a future period (2001–2002). They also developed models that combine the predictions of the individual models developed in the first stage, using two integration techniques, namely, stacked generalization and majority voting. Their results were mixed and depended on the form of the variables used, the datasets, and the evaluation measure considered. Hence, they concluded that there is no clear winner technique that dominates all the others under all circumstances. However, UTADIS appears several times as one of the best techniques. Furthermore, the stacked model developed through UTADIS also performs relatively well.

Pasiouras et al. [27] also focused on the EU banking sector, but differentiated their study in two ways from that of Pasiouras et al. [26]. First, they considered an additional MCDA technique, namely, PAIRCLAS, that was applied for the first time in the prediction of acquisitions. Second, they followed a tenfold cross-validation resampling procedure for the development and eval-

uation of the models. Their sample consisted of 168 banks acquired between 1998 and 2002 matched with 168 nonacquired banks. MHDIS achieved the highest overall accuracy in the validation dataset, with 68% of the acquired and 63.3% of the nonacquired banks classified correctly (implying an overall classification rate of 65.7%). PAIRCLAS also achieves marginally better classification accuracies than UTADIS, and its ability to classify correctly the nonacquired banks (75%) is even higher than that of MHDIS (72.2%).

In another study, Pasiouras et al. [25] concentrated on the Asian banking sector. They used a sample of 52 targets and 47 acquirers that were involved in acquisitions in nine Asian banking markets during 1998–2004 and matched them by country and time with an equal number of banks not involved in acquisitions. The models were developed and validated through a tenfold cross-validation approach using UTADIS and MHDIS. In each case three versions of the model were developed. The first one distinguished between acquired and noninvolved banks. The second one distinguished between acquirers and noninvolved banks. The last one, was a three-outcome model that simultaneously distinguished between targets, acquirers, and noninvolved banks. For comparison purposes they also developed models through DA. The results indicate that the MCDA models are more efficient than the ones developed through DA. Furthermore, in all cases the models are more efficient in distinguishing between acquirers and noninvolved banks than between targets and noninvolved banks. Finally, the models with a binary outcome achieve higher accuracies than the ones which simultaneously distinguish between acquirers, targets, and noninvolved banks.

## Formulation

The problem considered in the present study is a classification one that in general involves the assignment of a set of  $m$  alternatives  $A = \{\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m\}$ , evaluated along a set of  $n$  criteria  $g_1, g_2, \dots, g_n$ , to a set of  $q$  classes  $C_1, C_2, \dots, C_q$ . In the case of acquisitions, the alternatives are the firms in the sample, the criteria can correspond to financial and nonfinancial variables, and there are usually two classes, the nonacquired firms (class  $C_1$ ) and the acquired firms (class  $C_2$ ). Hence, in what follows we consider the simple two-class case, while details

on the multiclass case can be found in Doumpos and Zopounidis [14] and Zopounidis and Doumpos [39].

The UTADIS approach, used in the present study, implies the development of an additive utility function that is used to score the firms and decide upon their classification. The utility function has the following general form:

$$U(\mathbf{a}) = \sum_{i=1}^n w_i u'_i(g_i) \in [0, 1], \tag{1}$$

where  $w_i$  is the weight of criterion  $g_i$  (the criteria weights sum up to 1) and  $u'_i(g_i)$  is the corresponding marginal utility function normalized between 0 and 1. The marginal utility functions provide a mechanism for decomposing the aggregate result (global utility) in terms of individual assessment to the criterion level. To avoid the estimation of both the criteria weights and the marginal utility functions, it is possible to use the transformation  $u_i(g_i) = w_i u'_i(g_i)$ . Since  $u'_i(g_i)$  is normalized between 0 and 1, it becomes obvious that  $u_i(g_i)$  ranges in the interval  $[0, w_i]$ . In this way, the additive utility function is simplified to the following form:

$$U(\mathbf{a}) = \sum_{i=1}^n u_i(g_i) \in [0, 1]. \tag{2}$$

The utility function developed provides an aggregate score  $U(\mathbf{a})$  of each firm along all criteria. In the case of acquisitions prediction, this score provides the basis for determining whether the firm could be classified in either the group of nonacquired ones or in the group of acquired ones. The classification rule in this case is the following ( $C_1$  and  $C_2$  denote the group of nonacquired and acquired firms, respectively, while  $u_1$  is a cutoff utility point defined on the global utility scale, i. e., between 0 and 1):

$$\left. \begin{aligned} U(\mathbf{a}) \geq u_1 &\Rightarrow \mathbf{a} \in C_1 \\ U(\mathbf{a}) < u_1 &\Rightarrow \mathbf{a} \in C_2 \end{aligned} \right\}. \tag{3}$$

The estimation of the additive value function and the cutoff threshold is performed using linear programming techniques so that the sum of all violations of the classification rule (3) for all the firms in the training sample is minimized. A detailed description and derivation of this mathematical programming formulation can be found in Doumpos and Zopounidis [14].

### Cases

In this section, our method is illustrated by a case study from the work of Pasiouras et al. [24]. The dataset considered in the study consists of 76 firms acquired between 2000 and 2002, and 76 nonacquired firms, which operate in manufacturing, construction, and mining-quarrying-extraction industries in the UK. The sample was constructed as follows. The acquired firms were first identified in the Hemscott M&As database and the financial data were collected from the Financial Analysis Made Easy database of Bureau van Dijk. After screening for data availability in FAME, 59 manufacturing, six construction, five production and six mining-quarrying-extraction firms had complete financial data for the 3 years prior to the acquisition and were included in the sample.

Although the year of acquisition is not common for all firms in the sample, they were all thought to be acquired in the “zero” year, considered as the year of reference. The years of activity prior to “zero” are coded as “year -1” (1 year prior), “year -2” (2 years prior), and “year -3” (3 years prior).

After the sample described above had been obtained, nonacquired firms were chosen to match the acquired firms. The firms were matched by industry and size (total assets) and financial data for the nonacquired companies were taken from the same calendar years as for the corresponding acquired companies.

Barnes [5] mentions that the problem for the analyst who attempts to forecast targets is simply a matter of identifying the best predictive (i. e., explanatory) variables. Unfortunately, financial theories do not offer much in selecting specific variables among the numerous ones regarded as potential candidates in model development. Given the large number of possible ratios, it is important to reduce the list of ratios that enter the final model selection process. Hence, a question that emerges when attempting to select accounting ratios for empirical research is which ones, among the hundreds, should be used? However, there is no easy way to determine how many ratios a particular model should contain. Too few and the model will not capture all the relevant information. Too many and the model will overfit the training sample, but underperform in a holdout sample, and will most likely have onerous data input requirements [21]. As Hamer [17]

points out, the variable set should be constructed on the basis of (1) minimizing the cost of data collection and (2) maximizing the model applicability. Huberty [18] suggests three variable screening techniques that could be used: logical screening (e. g., financial theory and human judgment), statistical screening (e. g., test of differences of two group means such as the  $t$  test), and dimension reduction (e. g., factor analysis). In the present study we follow the latermost approach as in Stevens [34], Barnes [2], Kira and Morin [20], Zanakis and Zopounidis [38], and Tartari et al. [35]. Hence, a total of 25 variables are initially considered on the basis of data availability and previous studies, covering several aspects of firms' performances such as profitability, efficiency, activity, financial leverage, liquidity, and growth. Factor analysis is then used to reduce the number of variables to a smaller number of factors that are linear combinations of the initial variables. The analysis results in the extraction of seven factors, with eigenvalues higher than 1. The variable with the highest loading is selected from each one of the seven components for inclusion in the classification models. Consequently, we use the following seven variables:

1. X1: Current assets/current liabilities,
2. X2: Total liabilities/shareholders' equity,
3. X3: Annual change of total assets,
4. X4: Annual change of current liabilities,
5. X5: Profits before taxes/total assets,
6. X6: Sales/stock,
7. X7: Sales/debtors.

X1 is an indicator of liquidity that has been used in many previous studies [2,12,20,38]. The views about liquidity are somewhat mixed. It is possible that firms with excess liquidity are more likely to be acquired because of their good short-term financial position and the availability of cash or near-cash assets [36]. In this case, there is also an opportunity for the acquirers to finance the acquisition with the target's own resources [32]. On the other hand, it can be argued that a firm in need of funds to finance its working capital requirements is likely to be an acquisition target because the acquirer, after the acquisition, expects to bring additional funds into the firm to improve its liquidity [29].

X2 is a measure of financial leverage that has been used as a proxy for financial leverage in Rege [29], Palepu [23], and Kim and Arbel [19] among others. Ac-

ording to the *financial leverage hypothesis* the likelihood of being acquired decreases with the increase in company debt. There are two reasons why firms with lower preexisting levels of debt are considered attractive acquisition targets. The first is that the low debt ratio of the target decreases the probability of future default of the joint firm, while at the same time it increases the debt capacity of the new firm. The second is that in some cases a firm has extremely low debt ratios, the value of the firm may not be maximized, and low leverage can be seen as a sign of inefficient management.

X3 and X4 are measures of annual changes in two basic elements of the firms (i. e., assets, liabilities). Firms whose growth rates, as measured by X3, are relatively high can experience problems because their management and/or structure will not be able to deal with and sustain exceptional growth. It is therefore possible that a firm which is constrained in this way will become an acquisition target of a firm with surplus resources or management available to help [14]. Furthermore, a firm with high levels of growth might be acquired by firms that want to take advantage of this increase in assets, and boost their own growth. Turning to X4, exceptional increases may indicate that the firm has problems in meeting its short-term liabilities and can therefore be acquired to avoid solvency.

Variables X5, X6, and X7 are related to the *inefficient management hypothesis*. This hypothesis argues that if the managers of a firm fail to maximize its market value, then the firm is likely to be an acquisition target and inefficient managers will be replaced. Thus, these takeovers are motivated by a belief that the acquiring firm's management can manage better the target's resources. This view is supported by two specific arguments. First, the firm might be poorly run by its current management, partly because the objectives of the management are at variance with those of the shareholders. In this case, the takeover threat can serve as a control mechanism limiting the degree of variance between management's pursuits for growth from shareholders' desire for wealth maximization. A merger may not be the only way to improve management, but if disappointed shareholders cannot accomplish a change in management that will increase the value of their investment within the firm, either because it is too costly or too slow, then a merger may be a simpler and more practical way of achieving their desired goals. Second,

**Multicriteria Methods for Mergers and Acquisitions, Table 1**  
Weights of the variables (percent) in the *utilités additives discriminantes* (UTADIS) model (averages over the ten replications)

	Year -1	Year -2	Year -3
X1	11.15	2.45	10.40
X2	23.28	34.04	31.99
X3	5.15	7.43	8.80
X4	15.79	5.71	8.59
X5	14.67	25.08	12.22
X6	14.40	11.31	14.77
X7	15.56	13.97	13.23

the acquirer may simply have better management experience than the target. There are always firms with unexploited opportunities to cut costs and increase sales and earnings, and that makes them natural candidates for acquisition by other firms with better management [1]. Therefore, if the management of the acquirer is more efficient than the management of the target firm, a gain could result through a merger if the management of the target is replaced.

Table 1 presents the contribution of the seven criteria in the UTADIS model. To ensure the proper development and validation of the models, we follow a ten-fold cross-validation. Hence, the total sample of 152 firms is randomly split into ten mutually exclusive subsamples (folds) of approximately equal size. Then ten models are developed, using each fold in turn for validation and the remaining folds for training. Therefore, in each of the ten replications, the training sample consists of 137 firms and the validation of 15 firms. The figures presented are the averages over the ten replications.

X2 (total liabilities/shareholders' equity) appears to be the most important criterion in all 3 years with an average weight that ranges between 23.28 (year -1) and 34.04% (year -3). The profitability and efficiency indicators (X5, X6, X7) also appear to be important in classifying firms within the two groups, with average weights between 11.31 and 25.08%. X1 (i. e., current assets ratio) carries a weight above 10% in years -1 and -3 but it is considerably reduced to 2.45% in year -2. Finally, X3, which corresponds to the annual growth of the firm in terms of total assets, is the least important criterion in all years.

**Multicriteria Methods for Mergers and Acquisitions, Table 2**  
Classification accuracies in percent (averages over ten replications)

	Acquired firms	Nonacquired firms	Overall accuracy
Classification accuracies of the UTADIS model in the development stage			
Year -1	80.1	71.8	75.9
Year -2	81.9	71.1	76.5
Year -3	81.1	70.3	75.7
Classification accuracies in the validation stage			
Year -1			
UTADIS	76.2	63.9	70.1
DA	77.9	54.0	65.9
Year -2			
UTADIS	75.3	65.5	70.4
DA	77.4	47.2	62.3
Year -3			
UTADIS	77.3	63.1	70.2
DA	65.5	50.4	58.0

By comparing the score  $U(a)$  of each firm with the cutoff threshold that was calculated through the estimation of the UTADIS model and rule (3), we can decide whether a firm can be classified as acquired or not acquired. Table 2 presents the classification results obtained by UTADIS during the development and validation process. In Table 2 we also present the classification results obtained by DA, used for benchmarking purposes.

The overall classification accuracy of the UTADIS model during the development stage is around 75%. Furthermore, the model appears to be quite robust, with classifications that do not deviate significantly from one year to another. Unsurprisingly, consistent with previous studies, the classification accuracy decreases in the validation stage; however, the decrease is relatively small and the overall classification accuracy is now around 70%. It should be mentioned that while our model misclassifies around 30% of the firms in the validation dataset, this is not uncommon for studies on the prediction of acquisitions targets.

Other studies that used resampling techniques obtained similar results. Bartley and Boardman [7] reported a classification accuracy of 64%, while in a later

study [8] they obtained classification accuracies between 69.9 and 79.9%. Similarly, the classification accuracy in the study of Kira and Morin [20] was 66.17%. The study of Pasiouras et al. [27] that focused on the EU banking industry also reported classification accuracies between 61.6 and 65.7%. As Barnes [14] notes, perfect prediction models are difficult to develop even for bankruptcy prediction, where failing firms have definitely inferior or abnormal performance compared with healthy firms. The problem with the identification of acquisition targets is not only that there are potentially many reasons for acquisitions, but also that at the same time managers do not always act in a manner which maximizes shareholders' returns owing to hybrid or agency motives.

While the comparison of the results obtained in the current study with the ones of previous studies gives a first indication for the performance of the model, a direct comparison is not appropriate because of differences in the datasets [16,21], the industry under investigation, the methods used to validate the models, and so on. Hence, the comparison of the UTADIS model with the one developed with DA using exactly the same dataset, variables, and development and validation procedures might provide a more accurate indication of the efficiency (in terms of classification accuracy) of the MCDA model. Looking at the results in Table 2, we see that UTADIS clearly achieves higher classification accuracies than DA. Furthermore, while the classification accuracies of DA decrease as we move back in time, the accuracies of UTADIS remain quite robust, even when we use data from 3 years prior to the acquisition. Finally, with the exception of acquired firms in year  $-1$ , UTADIS outperforms DA in classifying correct firms of both groups (i. e., acquired, nonacquired).

## Conclusions

In this paper we first discussed why MCDA could be useful in the prediction of acquisition targets and provided a review of relevant studies. Then, we presented the UTADIS technique and its application on a dataset of acquired and nonacquired UK firms.

The application indicates that UTADIS not only outperforms a model developed by DA, but it also achieves quite robust results, as we use data that move away from the period of the event.

Future applications of MCDA in the area of acquisitions prediction could focus on the incorporation of nonfinancial and qualitative data (e. g. managers' experience, managers' educational background) in the analysis. Although this has been mentioned in the literature in the past [22,38], there is still a lack of studies that use such variables in the analysis, usually owing to data availability. MCDA techniques, like UTADIS, can easily incorporate qualitative data, and it would be therefore interesting to perform such an exercise. Furthermore, it would also be worthwhile to investigate the classification of firms in more than two groups (e. g., acquired, acquirers, noninvolved) as in the study of Pasiouras et al. [25]. While the results of the later study were not promising, the study focused on the banking industry, which is a special case. Hence, results from nonfinancial sectors might lead to different conclusions. MCDA techniques, like MHDIS, which was developed with the multigroup discrimination in mind, might be useful in such applications.

Decision making problems, according to their nature, the policy of the decision maker, and the overall objective of the decision may require the choice of an alternative solution, the ranking of the alternatives from the best to the worst ones or the *sorting* of the alternatives in predefined homogeneous classes [30]. For instance, a decision regarding the location of a new power plant can be considered as a choice problem, since the objective is to select the most appropriate location according to environmental, social and investment criteria. On the other hand, an evaluation of the efficiency of the different units of a firm can be considered as a ranking problem, since the objective is to estimate the relative performance of each unit compared to the others. Finally, a credit granting decision is a sorting problem: a credit application can be accepted, rejected or submitted for further consideration, according to the business and personal profile of the applicant. Actually, a wide variety of decision problems, including financial and investment decisions, environmental decisions, medical decisions, etc., are better formulated and studied through the sorting approach.

The sorting problem, generally stated, involves the assignment of a set of observations (objects, alternatives) described over a set of attributes or criteria into predefined homogeneous classes. This type of problem can also be referred to as the '*discrimination*' problem or the '*classification*' problem. Although any of these three terms can be used to describe the general objective of the problem (i.e. the assignment of observa-

tions into groups), actually, they refer to two slightly different situations: the discrimination or classification problem refers to the assignment of observations into classes which are not necessarily ordered. On the other hand, sorting refers to the problem in which the observations should be classified into classes which are ordered from the best to the worst ones. For instance, in medical diagnosis the classification of patients according to their symptoms into several possible diseases is a discrimination (classification) problem, since it is impossible to establish a preference ordering between the diseases. On the contrary, the evaluation of bankruptcy risk is a sorting problem, since the non-bankrupt firms are preferred to the bankrupt ones. In this paper the terms 'discrimination', 'classification', and 'sorting' will be used without distinction to refer to the general problem of assigning observations, objects or alternatives into classes.

The major practical interest of the sorting problem, has motivated researchers in developing an arsenal of methods for studying such problems, with the aim being the development of quantitative models achieving the higher possible classification accuracy and predicting ability. In 1936, R.A. Fisher [8] was the first to propose a framework for studying classification problems taking into account their multidimensional nature. The linear discriminant analysis (LDA) that Fisher proposed has been used for decades as the main classification technique and it is still being used at least as a reference point for comparing the performance of new techniques that are developed. C. Smith in 1947 [34] extended Fisher's linear discriminant analysis proposing quadratic discriminant analysis (QDA) in order to overcome the restrictive assumption underlying LDA that groups have equal dispersion matrices. Later on, several other statistical classification approaches have been proposed. Among them logit and probit analysis are the most widely used techniques overcoming the multivariate normality assumption of discriminant analysis (both linear and quadratic). Although these techniques overcome most of the statistical restrictions imposed in discriminant analysis, their parameters are difficult to explain, especially in multigroup discriminant problems.

The continuous advances in other fields including operations research and artificial intelligence led many scientists and researchers to exploit the new capabili-

ties of these fields, in developing more efficient classification techniques. Among the attempts made one can mention neural networks, machine learning, fuzzy sets as well as *multicriteria decision aid* (MCDA). This article will focus on MCDA and its application in the study of classification problems with or without ordered classes. MCDA provides an arsenal of powerful and efficient nonparametric classification methods and approaches, which are free of statistical assumptions and restrictions, while furthermore they are able to incorporate the decision maker's preferences in a flexible and realistic way.

The remainder of the article is organized as follows. Section 2 provides a review of MCDA sorting approaches and techniques, outlining their basic characteristics, concepts and limitations. In section 3, a new MCDA sorting method is described and its operation is depicted through a simple illustrative example. Finally, section 4 concludes the paper and outlines some possible future research directions concerning the application of MCDA in sorting problems.

## Multicriteria Sorting Methods

The MCDA methods which have been proposed for the study of sorting problems can be distinguished either according to the approach from which they are originated (multi-objective/goal programming, multi-attribute utility theory, outranking relations, preference disaggregation), or according to the type of problem that they address (ordered or non-ordered classes). The review presented in this section will distinguish the methods according to their origination, but in the same time the type of problems that they address will also be discussed.

### Goal Programming Approaches

The work of A. Charnes and W.W. Cooper [4] set the foundations on goal/multi-objective programming, but it can also be considered as one of the pioneering studies in the field of MCDA in general. Since then, both multi-objective and *goal programming* constitute two major fields of interest from the theoretical and practical points of view in the MCDA and operations research communities. In particular, goal programming approaches, during the 1960s and the 1970s have been used to elicit attribute weights in multiple criteria rank-

ing decision problems [15,27,35,36]. N. Freed and F. Glover [9] were among the first to investigate the potentials of goal programming techniques in the discriminant problem. Their aim was to develop a linear discriminant model so that the minimum distance of the score of each alternative from a predefined cut-off point is maximized (maximize the minimum distance-MMD). To develop this model, they proposed the following goal programming formulation:

$$\begin{cases} \max & d \\ \text{s.t.} & \sum w_i x_{ij} + d \leq c, \quad \forall i \in \text{Group 1,} \\ & \sum w_i x_{ij} - d \geq c, \quad \forall i \in \text{Group 2,} \end{cases}$$

where  $w_i$  is the weight of attribute  $i$ ,  $x_{ij}$  is the evaluation of alternative  $j$  on attribute  $i$ , and  $c$  is the cut-off score ( $w_i$  and  $d$  are unrestricted in sign). Soon after proposing this model, the same authors proposed a variety of similar goal programming formulations incorporating several other discrimination criteria, such as the sum of deviations (optimize the sum of deviations-OSD), the sum of interior deviations (minimize the sum of interior deviations-MSID) and the maximum deviation [10].

These two studies attracted the interest of several operational researchers and management scientists. S.M. Bajgier and A.V. Hill [2] proposed a new goal programming approach in order to minimize the number of misclassifications using a mixed integer programming formulation (MIP) and conducted a first experimental study to compare the MMD model, the OSD model, and their MIP formulation with LDA. They concluded that the goal programming formulations are generally superior to LDA, except for the case of moderate to low overlap between groups and equal dispersion matrices, where LDA outperforms all the examined goal programming formulations.

The performance of goal programming approaches compared to statistical techniques was an issue that several researchers tried to investigate using mainly experimental data sets. Freed and Glover [11] compared MMD, MSID, OSD and LDA and they concluded that although the presence of outliers pose a greater problem for the two simpler goal programming formulations (MMD and MSID) than for LDA, generally the goal programming approaches outperform LDA.

E.A. Joachimsthaler and A. Stam [18] compared the LDA, QDA, logistic regression and OSD procedures and they concluded that these methodologies produce similar results although the misclassification rates for LDA and QDA tended to increase with highly kurtosis data and increased dispersion heterogeneity. C.A. Markowski and E.P. Markowski [22] examined the influence of qualitative attributes on the discriminating performance of MMD and LDA. Although the incorporation of qualitative attributes in LDA violates the normality assumption, the experimental study of the authors showed that the incorporation of qualitative variables improved the performance of LDA, while on the other hand MMD did not appear to be particularly well-suited for use with qualitative variables. In another experimental study conducted by P.A. Rubin [32], QDA outperformed 15 goal programming approaches, leading the author to indicate that 'if LP models are to be considered seriously as an alternative to conventional procedures, they must be shown to outperform QDA under plausible conditions, presumably involving non-Gaussian data'. These experimental studies clearly indicate the confusion concerning the discriminating performance of the goal programming formulations as opposed to well known multivariate statistical techniques. Except for this issue, the research on the field of goal programming approaches for discriminant problems, was also focus on the theoretical drawbacks which were often meet. Markowski and Markowski [23] were the first to identify two major drawbacks of the goal programming formulations (MMD and OSD) proposed by Freed and Glover [9,10]. More specifically, they proved that if each quadrant contains at least one case from the second group, unacceptable solutions will result in MMD (all coefficients in the discriminant function are zeros which leads all the observations to be classified in the same group), while furthermore they showed that the solutions (discriminant functions) obtained through the MMD and the OSD models are not stable when the data are transformed (when there is a shift from the origin). Except for these two problems, many goal programming formulations were found to suffer from two additional theoretical shortcomings [29]:

- a) they produce unbounded solutions, and
- b) they produce improper solutions.

A solution is considered *unbounded* if the objective function can be increased or decreased without limit,

in which case the discrimination rule (function) may be meaningless, whereas a solution is improper if all observations fall on the classification hyperplane.

To overcome these problems new goal programming formulations were proposed, including hybrid models [12,13], nonlinear programming formulations [37], as well as several mixed integer programming formulations [1,3,5,20,33,38,39].

In the light of this review of goal programming approaches for discriminant problems it is possible to identify the following three characteristics of the research in this field:

- 1) The majority of the proposed models aim at developing a linear discrimination rule (function). The extension of the models to develop a nonlinear discriminant function leads to nonlinear programming formulations which are generally computationally intensive and difficult to solve. Among the few alternative approaches is the MSM method (multisurface method) proposed by O.L. Mangasarian [21] that leads to the construction of a piecewise linear discrimination surface between two groups (see also [26] for a revision of the method using multi-objective programming and fuzzy mathematical programming techniques).
- 2) Little research has been made on extending the existing framework on the multigroup discriminant problem. E.-U. Choo and W.C. Wedley [5], W. Gochet et al. [14], as well as J.M. Wilson [39] applied goal programming approaches in multigroup discriminant problems, but generally most of the studies in this field were focused on two-group discrimination trying to extend the original goal programming models of Freed and Glover [9,10] in order to achieve higher classification accuracy and predicting ability.
- 3) The models based on the goal programming approach can be applied in any classification problem with or without ordered classes.

### Outranking Relations Approaches

In contrast to the goal programming approaches, *outranking relations* procedures study the classification problem on a completely different basis. The aim of such procedures is not to develop a discriminant function (linear or nonlinear), but instead their aim is to

model the decision makers' preferences and develop a global preference model which can be used to assign the alternatives (observations) into the predefined classes. To achieve the classification of the alternatives some reference profiles are determined which can be considered as representative examples of each class. Through the comparison of each alternative with these reference profiles the classification of the alternatives is accomplished.

A representative example of MCDA sorting method based on the outranking relations approach is the ELECTRE TRI method proposed by W. Yu [40]. The aim of ELECTRE TRI is to provide a sorting of the alternatives under consideration into two or more ordered categories. In order to define the categories ELECTRE TRI uses some reference alternatives (reference profiles)  $r_i, i = 1, \dots, k - 1$ , which can be considered as fictitious alternatives different from the alternatives under consideration. The profile  $r_i$  is the theoretical limit between the categories  $C_i$  and  $C_{i+1}$  ( $C_{i+1}$  is preferred to  $C_i$ ) and  $r_i$  is strictly better than  $r_{i-1}$  for each criterion. To provide a sorting of the alternatives in categories ELECTRE TRI makes comparisons of each alternative with the profiles.

For an alternative  $a$  and a profile  $r_i$  the concordance index  $c_j(a, r_i)$  is calculated. This index expresses the strength of the affirmation 'alternative  $a$  is at least as good as profile  $r_i$  on criterion  $j$ '. In order to compare the alternative to a reference profile on the basis of more than one criteria, a global concordance index  $C(a, r_i)$  is calculated. This index expresses the strength of the affirmation 'a is at least as good as  $r_i$  according to all criteria'. Setting  $w_j$  as the weight of the criterion  $j$ ,  $C(a, r_i)$  is constructed as the weighted average of all  $c_j(a, r_i)$ .

In contrast to the concordance index, the discordance index  $D_j(a, r_i)$  expresses the strength of the opposition to the affirmation 'alternative  $a$  is at least as good as profile  $r_i$  according to criterion  $j$ '. The calculation of the discordance index is based on the definition of a veto threshold  $v_j(r_i)$  for criterion  $j$  and the profile  $r_i$ . The veto threshold  $v_j(r_i)$  for criterion  $j$  defines the minimum accepted difference between the values of the profile  $r_i$  and alternative  $a$  on the specific criterion so that we can say that they have totally different preference according to criterion  $j$ .

Let  $\bar{F}(a, r_i)$  be the set consisted of all criteria for which the discordance index value is greater than the

value of global concordance index. For each affirmation of the type: 'alternative  $a$  outranks profile  $r_i$  according to all criteria', the credibility index  $\sigma_s(a, r_i)$  is calculated. If  $\bar{F}(a, r_i)$  is empty then  $\sigma_s(a, r_i) = C(a, r_i)$ , otherwise the credibility index is calculated as follows:

$$\sigma_s(a, r_i) = C(a, r_i) \cdot \prod_{j \in \bar{F}} \frac{1 - D_j(a, r_i)}{1 - C(a, r_i)}.$$

If the value of the credibility index of the affirmation 'alternative  $a$  outranks profile  $r_i$  according to all criteria' exceeds a predefined cut-off value  $\lambda$ , then the proposition 'a outranks  $r_i$ ' can be considered to be valid. Denoting the outranking relation as **S**, the preference (**P**), indifference (**I**) and incomparability (**R**) relations between alternative  $a$  and profile  $r_i$  can be defined as follows:

- $a\mathbf{I}r_i$  if and only if  $a\mathbf{S}r_i$  and  $r_i\mathbf{S}a$ ;
- $a\mathbf{P}r_i$  if and only if  $a\mathbf{S}r_i$  and no  $r_i\mathbf{S}a$ ;
- $r_i\mathbf{P}a$  if and only if no  $a\mathbf{S}r_i$  and  $r_i\mathbf{S}a$ ;
- $a\mathbf{R}r_i$  if and only if no  $a\mathbf{S}r_i$  and no  $r_i\mathbf{S}a$ .

According to these relations two sorting procedures are applied: the pessimistic and the optimistic one. The sorting procedure starts by comparing alternative  $a$  to the worst profile  $r_1$  and in the case where  $a\mathbf{P}r_1$ ,  $a$  is compared to the second profile  $r_2$ , etc., until one of the following two situations appears:

- i)  $a\mathbf{P}r_i$  and  $r_{i+1}\mathbf{P}a$  or  $a\mathbf{I}r_{i+1}$ ;
- ii)  $a\mathbf{P}r_i$  and  $a\mathbf{R}r_{i+1}, \dots, a\mathbf{R}r_{i+k}, r_{i+k+1}\mathbf{P}a$ .

If situation i) appears, then alternative  $a$  is assigned to category  $i + 1$  by both pessimistic and optimistic procedures. If situation ii) appears, then  $a$  is assigned to category  $i + 1$  by the pessimistic procedure and to category  $i + k + 1$  by the optimistic procedure.

It is clear that the ELECTRE TRI method is a powerful tool for analyzing the decision maker's preference in sorting problems involving multiple criteria where the classes are ordered. However, the major drawback of the method is the significant amount of information that it requires by the decision maker (weights of the criteria, preference and indifference thresholds, veto thresholds, etc.). This problem can be overcome using decision instances (assignment examples) as proposed in [25].

Other MCDA sorting methods based on the outranking relations approach have been proposed in [24] (N-TOMIC method), [31] and the PROMETHEE

method as it has been modified in [19]. Furthermore, P. Perny [28] extended the existing framework of the sorting methods based on the outranking relations approach in the case in which the groups are not ordered. More specifically, he proposed the construction of a fuzzy outranking relation in order to estimate the membership of each alternative for each group, and suggested two assignment procedures:

- a) filtering by strict preference (the assignment rule consists of testing whether an alternative is preferred or not to a reference profile reflecting the lower limit of a group), and
- b) filtering by indifference (the assignment rule consists of testing whether an alternative is indifferent or not to a reference profile representing a prototype of a group).

Overall the main characteristics of sorting methods based on the outranking relations approach of MCDA include their application to both sorting (ordered classes) as well as discrimination (non ordered classes) problems, and the significant amount of information that they require by the decision maker.

### Preference Disaggregation Approaches

The *preference disaggregation* approach refers to the analysis (disaggregation) of the global preferences of the decision maker to deduce the relative importance of the evaluation criteria, using ordinal regression techniques based mainly on linear programming formulations.

In contrast to the outranking relations approach the global preference model of the decision maker is not constructed through a direct interrogation procedure between the decision analyst and the decision maker. Instead, decision instances (e. g. past decisions) are used in order to analyze the decision policy of the decision maker, to specify his/her preferences and construct the corresponding global preference model as consistently as possible.

A well known preference disaggregation method is the UTA method (UTilités Additives) proposed in [17]. Given a predefined ranking of a reference set of alternatives, the aim of the UTA method is to construct a set of additive utility functions which are as consistent as possible with the pre-ordering of the alternatives (and consequently with the decision maker's preferences). The

form of the additive utility function is the following:

$$U(\bar{g}) = \sum_j u_j(g_j),$$

where  $U(\bar{g})$  denotes the global utility of an alternative described over a vector of criteria  $\bar{g}$ , while  $u_j(g_j)$  is the partial or marginal utility of an alternative on criterion  $g_j$ .

Except for the study of ranking problems, the methodological framework of the preference disaggregation approach using the UTA method is also applicable in sorting problems. The UTADIS method (UTilités Additives DIScriminantes) [6,16,17,42] is a representative example. In the UTADIS method, the sorting of the alternatives is accomplished by comparing the global utility (scores) of each alternative  $a$ , denoted as  $U(a)$ , with some thresholds ( $u_1, \dots, u_{q-1}$ ) which distinguish the classes  $C_1, \dots, C_q$  (the classes are ordered, so that  $C_1$  is the class of the best alternatives and  $C_q$  is the class of the worst alternatives).

$$\begin{aligned} U(a) \geq u_1 &\Rightarrow a \in C_1 \\ u_2 \leq U(a) < u_1 &\Rightarrow a \in C_2 \\ \dots & \\ u_k \leq U(a) < u_{k-1} &\Rightarrow a \in C_k \\ \dots & \\ U(a) < u_{q-1} &\Rightarrow a \in C_q. \end{aligned}$$

The objective of the UTADIS method is to estimate an additive utility function and the utility thresholds in order to minimize the classification error. The classification error is measured through two error functions denoted as  $\sigma^+(a)$  and  $\sigma^-(a)$ , representing the deviations of a misclassified alternative from the utility threshold. The estimation of both the additive utility model and the utility thresholds is achieved through linear programming techniques [6,42].

See [7] and [41] for three variants of the UTADIS method to improve the classification accuracy of the obtained additive utility models as well as their predicting ability. The first variant (UTADIS I) except for the classification errors also incorporates the distances of the correctly classified alternatives from the utility thresholds which have to be maximized. The second variant (UTADIS II) is based on a mixed integer programming formulation minimizing the number of

misclassifications instead of their magnitude, while the third variant (UTADIS III) combines UTADIS I and II, and its aim is to minimize the number of misclassifications and maximize the distances of the correctly classified alternatives from the utility thresholds.

Overall the main characteristics of the application of the preference disaggregation approach in the study of sorting problems, can be summarized in the following three aspects.

- 1) The information that is required is minimal, since, similarly to the goal programming approaches, only a predefined classification of a reference set of alternatives is required.
- 2) The preference disaggregation approach is focused only on decision problems where the classes are ordered, since it is assumed that there is a strict preference relation between the classes.
- 3) The classification/sorting models which are developed have a nonlinear form, since the marginal utilities of the evaluation criteria are piecewise linear and consequently the global utility model is also nonlinear, in contrast to the linear discriminant models used in the goal programming approaches.

### A Multigroup Hierarchical Discrimination Method

In this section a new method is presented for the study of discrimination problems with two or more ordered groups (multigroup discrimination). The proposed method is called M.H.DIS (Multigroup Hierarchical DIScrimination) and differs from most of the aforementioned MCDA approaches in two major aspects.

- 1) It employs a hierarchical discrimination approach: the method does not aim on the development of an overall global preference model (discriminant function) which will characterize all the observations (alternatives or objects). Instead the method is trying to distinguish the groups progressively, starting by discriminating the first group (best alternatives) from all the others, and then proceeding to the discrimination between the objects which belong to the other groups.
- 2) It accommodates three different discrimination criteria in a very flexible and efficient way. The most common discrimination criterion in the previous approaches is the minimization of the classification

error which is measured as the deviations of the scores of the misclassified alternatives from some cut-off points. However, such an objective does not necessarily yield the optimal classification rule. For instance, consider that in a discrimination problem, three alternatives are misclassified with the following deviations from the cut-off point: [0.25, 0.25, 0.25], with the overall objective of minimizing the total classification error being 0.75. It is obvious, that this classification result is not optimal, since a classification result [0, 0, 0.75] yields the same value for the overall classification error (0.75), but there is only one misclassified alternative instead of three. Several mixed integer programming formulations have been proposed to confront this issue, but their application in real world problems is prohibited by the significant amount of time required to solve such problems. M.H.DIS employs an efficient *mixed integer programming* (MIP) formulation for minimizing the number of misclassifications, once the minimization of the classification error has been achieved. Furthermore, M.H.DIS also considers a third criterion in order to achieve the higher possible discrimination. These three discrimination criteria have been used in previous studies separately, or in hybrid models [12,13], but they have never been used through a sequential procedure. Instead, in M.H.DIS initially the classification error is minimized. Then considering only the misclassified alternatives M.H.DIS tries to ‘re-arrange’ their classification error in order to minimize the number of misclassifications, and finally the maximum discrimination between the alternatives is attempted.

### Model Formulation

Let  $A = \{a_1, \dots, a_n\}$  be a set of  $n$  alternatives which should be classified into  $q$  ordered classes  $C_1, \dots, C_q$ . ( $C_1$  is preferred to  $C_2$ ,  $C_2$  is preferred to  $C_3$ , etc.) Each alternative is described (evaluated) along a set  $G = \{g_1, \dots, g_m\}$  of  $m$  evaluation criteria. The evaluation of each alternative  $a$  on criterion  $g_i$  is denoted as  $g_i(a)$ . According to the set  $A$  of alternatives,  $p_i$  different values for each criterion  $g_i$  can be distinguished. These  $p_i$  values are rank-ordered from the smallest value  $g_i^1$  to the largest value  $g_i^{p_i}$ . Furthermore, among the set of cri-

teria it is possible to distinguish two subsets: a subset  $G_1$  consisting of  $m_1$  criteria for which higher values indicate higher preference, and a second subset  $G_2$  consisting of  $m_2$  criteria for which the decision maker's preference is a decreasing function of the criterion's scale. For instance, in an investment decision problem  $G_1$  may include criteria related to the return of an investment project (projects with higher return are preferred), while  $G_2$  may include criteria related to the risk of the investment (projects with lower risk are preferred).

### The Hierarchical Discrimination Process

The method proceeds progressively in the classification of the alternatives into the predefined classes, starting from class  $C_1$  (best alternatives). Initially, the aim is to identify which alternatives belong in class  $C_1$ . The alternatives which are found to belong in class  $C_1$  (either correctly or incorrectly) are excluded from further consideration. In a second stage the objective is to identify which alternatives belong in class  $C_2$ . The alternatives which are found to belong in this class (either correctly or incorrectly) are excluded from further consideration, and the same procedure continues until all alternatives have been classified in the predefined classes.

Throughout this hierarchical classification procedure, it is assumed that the decision maker's preferences are monotone functions (increasing or decreasing) on the criteria's scale. This assumption implies that in the case of a criterion  $g_i \in G_1$ , as the evaluation of an alternative on this criterion increases, then the decision of classifying this alternative into a higher (better) class is more favorable to a decision of classifying the alternative into a lower (worst) class. For instance, in the credit granting problem as the profitability of a firm increases, the credit analyst will be more favorable in classifying the firm as a healthy firm, rather than classifying it as a risky one. A similar implication is also made for each criterion  $g_i \in G_2$ .

This preference relation between the several possible decisions of classifying a specific alternative  $a$  into one of the predefined classes, imposes the following general classification rule:

The decision concerning the classification of an alternative  $a$  into one of the predefined classes

should be made in such a way that the utility (value) of such a decision for the decision maker is maximized.

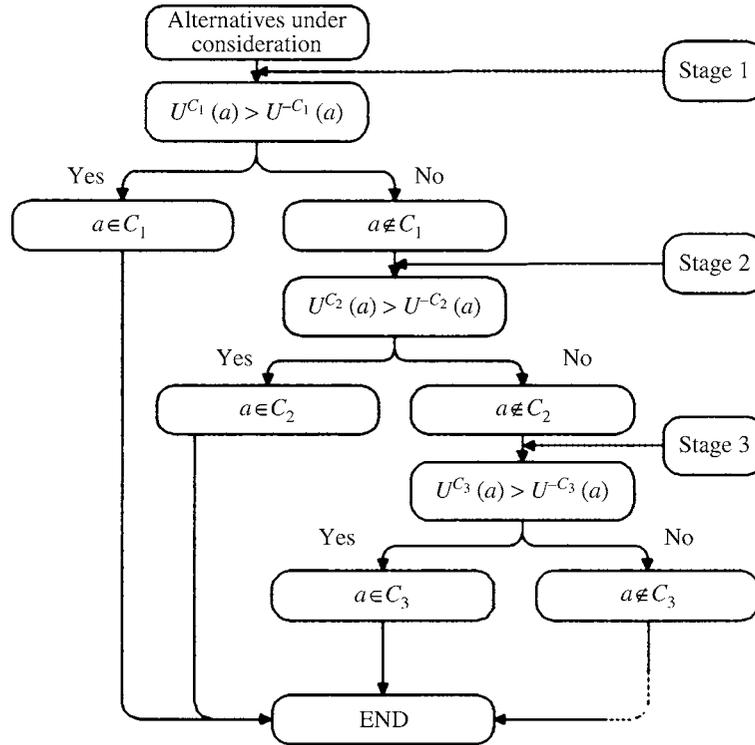

The utility of a decision concerning the classification of an alternative  $a$  into group  $C_j$  can be expressed in the form of additive utility function:

$$U^{C_j}(a) = \sum_{i=1}^m u_i^{C_j}[g_i(a)] \in [0, 1],$$

where  $u_i^{C_j}[g_i(a)]$  denotes the marginal (partial) utility of the decision concerning the classification of an alternative  $a$  into group  $C_j$  according to criterion  $g_i$ . If  $g_i \in G_1$ , then  $u_i^{C_j}(g_i)$  will be an increasing function on the criterion's scale. On the contrary, the marginal utility of a criterion  $g_i \in G_2$  regarding the classification of an alternative into a lower (worse) class  $C_k$  ( $k > j$ ) will be a decreasing function on the criterion's scale. For instance, consider once again the credit granting problem: since healthy firms are generally characterized by high profitability, the marginal utility for a profitability criterion for the group of healthy firms will be an increasing function, indicating that as profitability increases the preference of decision concerning the classification of a firm in the group of healthy firms is also increasing. On the other hand, for the group of risky firms the marginal utility will be a decreasing function of the criterion's (profitability) values, indicating that as profitability increases the preference of the decision concerning the classification of a firm in the group of risky firms is decreasing.

Consequently, at each stage of the hierarchical classification procedure that was described above, two utility functions are constructed. The first one corresponds to the utility of a decision concerning the classification of an alternative  $a$  into class  $C_k$  (denoted as  $U^{C_k}(a)$ ), while the second one corresponds to the utility of a decision concerning the nonclassification of an alternative  $a$  into class  $C_k$  (denoted as  $U^{-C_k}(a)$ ). Based on these two utility functions the aforementioned general classification rule can be expressed as follows:

$$\begin{cases} \text{if } U^{C_k}(a) > U^{-C_k}(a), & \text{then } a \in C_k, \\ \text{if } U^{C_k}(a) < U^{-C_k}(a), & \text{then } a \notin C_k. \end{cases} \quad (1)$$

Multicriteria Sorting Methods, Figure 1  
The hierarchical classification procedure

Following this rule, the overall hierarchical discrimination procedure is presented in Fig. 1.

**Estimation of Utility Functions**

According to the hierarchical discrimination procedure which was described above, to achieve the classification of the alternatives in  $q$  classes, the number of utility functions which must be estimated is  $2(q - 1)$ . The estimation of these utility functions in M.H.DIS is accomplished through linear programming techniques. More specifically, at each stage of the hierarchical discrimination procedure, two linear programs and one mixed integer program are solved to estimate ‘optimally’ the two utility functions.

**LP1: Minimizing the Overall Classification Error**

According to the classification rule (1), to achieve the correct classification of an alternative  $a \in C_k$  at stage  $k$  (cf. Fig. 1), the estimated utility functions should satisfy

the following constraint:

$$U^{C_k}(a) > U^{-C_k}(a).$$

Since, in linear programming it is not possible to use strict inequality constraints, a small positive real number  $s$  may be used as follows:

$$U^{C_k}(a) - U^{-C_k}(a) \geq s.$$

If for an alternative  $a \in C_k$  the classification rule at stage  $k$  yields  $U^{C_k}(a) < U^{-C_k}(a)$ , then this alternative is misclassified, since it should be classified in one of the lower classes (the specific classification of the alternative will be determined in the next stages of the hierarchical discrimination process). The classification error in this case is:

$$e(a) = U^{-C_k}(a) - U^{C_k}(a) + s.$$

Similarly, to achieve the correct classification of an alternative  $b \notin C_k$  at stage  $k$ , the estimated utility func-

tions should satisfy the following constraint:

$$U^{-C_k}(b) - U^{C_k}(b) \geq s.$$

If this constraint is not satisfied for an alternative  $b \notin C_k$  at stage  $k$ , then this fact implies that this alternative should be classified in class  $C_k$  and the classification error in this case is  $e(b) = U^{C_k}(b) - U^{-C_k}(b) + s$ .

Moreover, to achieve the monotonicity of the marginal utilities, the following constraints are imposed:

$$\text{if } g_i \in G_1 \begin{cases} u_i^{C_k}(g_i^1) = 0 \\ u_i^{-C_k}(g_i^{p_i}) = 0 \\ u_i^{C_k}(g_i^{j+1}) > u_i^{C_k}(g_i^j) \\ u_i^{-C_k}(g_i^{j+1}) < u_i^{-C_k}(g_i^j) \end{cases} \quad (2)$$

$$\text{if } g_i \in G_2 \begin{cases} u_i^{C_k}(g_i^{p_i}) = 0 \\ u_i^{-C_k}(g_i^1) = 0 \\ u_i^{C_k}(g_i^{j+1}) < u_i^{C_k}(g_i^j) \\ u_i^{-C_k}(g_i^{j+1}) > u_i^{-C_k}(g_i^j) \end{cases} \quad (3)$$

where  $g_i^j$  and  $g_i^{j+1}$  are two consecutive values of criterion  $g_i(g_i^{j+1} > g_i^j$  for all  $g_i \in G$ ). These constraints can be simplified by setting:

$$\text{if } g_i \in G_1 \begin{cases} w_{ij,j+1}^{C_k} = u_i^{C_k}(g_i^{j+1}) - u_i^{C_k}(g_i^j) \\ w_{ij,j+1}^{-C_k} = u_i^{-C_k}(g_i^j) - u_i^{-C_k}(g_i^{j+1}) \end{cases} \quad (4)$$

$$\text{if } g_i \in G_2 \begin{cases} w_{ij,j+1}^{C_k} = u_i^{C_k}(g_i^j) - u_i^{C_k}(g_i^{j+1}) \\ w_{ij,j+1}^{-C_k} = u_i^{-C_k}(g_i^{j+1}) - u_i^{-C_k}(g_i^j) \end{cases} \quad (5)$$

The marginal utility of criterion  $g_i$  at point  $g_i^j$  can then be calculated through the following formulas:

$$\begin{aligned} u_i^{C_k}(g_i^j) &= \sum_{l=1}^{j-1} w_{il,l+1}^{C_k}, \\ u_i^{-C_k}(g_i^j) &= \sum_{l=j}^{p_i-1} w_{il,l+1}^{-C_k}. \end{aligned} \quad (6)$$

Using these transformations, constraints (2) and (3) can be rewritten as follows (a small positive number  $t$  is used to ensure the strict inequality):

$$w_{ij,j+1}^{C_k} \geq t, \quad w_{ij,j+1}^{-C_k} \geq t, \quad \forall g_i.$$

Consequently, the initial linear program (LP1) to be solved can be formulated as follows:

$$\left\{ \begin{array}{l} \min \quad F = \sum_{a \in A} e(a) \\ \text{s.t.} \quad U^{C_k}(a) - U^{-C_k}(a) + e(a) \geq s, \\ \quad \quad \forall a \in C_k, \\ \quad \quad U^{-C_k}(b) - U^{C_k}(b) + e(b) \geq s, \\ \quad \quad \forall b \notin C_k, \\ \quad \quad w_{ij,j+1}^{C_k} \geq t \\ \quad \quad w_{ij,j+1}^{-C_k} \geq t \\ \quad \quad \sum_i \sum_j w_{ij,j+1}^{C_k} = 1 \\ \quad \quad \sum_i \sum_j w_{ij,j+1}^{-C_k} = 1 \\ \quad \quad e(a), s, t \geq 0. \end{array} \right.$$

**LP2: Minimizing the Number of Misclassifications**

If after the solution of (LP1), there exist some alternatives  $a \in A$  for which  $e(a) > 0$ , then obviously these alternatives are misclassified. However, as it has been already illustrated during the discussion of the main characteristics of M.H.DIS, it may be possible to achieve a ‘re-arrangement’ of the classification errors which may lead to the reduction of the number of misclassifications.

In M.H.DIS this is achieved through a mixed integer programming (MIP) formulation. However, since MIP formulations are difficult to solve, especially in cases where the number or integer or binary variables is large, the MIP formulation used in M.H.DIS considers only the misclassifications occurred by solving (LP1), while retaining all the correct classifications. Let  $C$  be the set of alternatives which have been correctly classified after solving (LP1), and  $M$  be the set of misclassified alternatives for which  $e(a) > 0$ . The MIP formulation used in

M.H.DIS is the following (LP2):

$$\left\{ \begin{array}{l}
 \min \quad F = \sum_{a \in A} I(a) \\
 \text{s.t.} \quad U^{C_k}(a) - U^{-C_k}(a) \geq s, \\
 \quad \forall a \in C_k \cap C, \\
 \quad U^{-C_k}(b) - U^{C_k}(b) \geq s, \\
 \quad \forall b \notin C_k, b \in C, \\
 \quad U^{C_k}(a) - U^{-C_k}(a) + I(a) \geq s, \\
 \quad \forall a \in C_k \cap M, \\
 \quad U^{-C_k}(b) - U^{C_k}(b) + I(a) \geq s, \\
 \quad \forall b \notin C_k, b \in M, \\
 \quad w_{ij,j+1}^{C_k} \geq t \\
 \quad w_{ij,j+1}^{-C_k} \geq t \\
 \quad \sum_i \sum_j w_{ij,j+1}^{C_k} = 1 \\
 \quad \sum_i \sum_j w_{ij,j+1}^{-C_k} = 1 \\
 \quad s, t, I(a) \text{ integer.}
 \end{array} \right.$$

The first set of constraints is used to ensure that all the correct classifications achieved by solving (LP1) are retained. The second set of constraints is used only for the alternatives which were misclassified by (LP1). Their meaning is similar to the constraints in LP1, with the only difference being the transformation of the continuous variables  $e(a)$  of LP1 (classification errors) into integer variables  $I(a)$  which indicate whether an alternative is misclassified or not. The meaning of the final two constraints has already been illustrated in the discussion of the LP1 formulation. The objective of LP2 is to minimize the number of misclassifications occurred through the solution of LP1.

**LP3: Maximizing the Minimum Distance**

Solving LP1 and LP2 the ‘optimal’ classification of the alternatives has been achieved, where the term ‘optimal’ refers to the minimization of the number of misclassified alternatives. However, the correct classification of some alternatives may have been ‘marginal’, that is although they are correctly classified, their global utilities according to the two utility functions developed may have been very close. The objective of LP3 is to maximize the minimum difference between the global util-

ities of the correctly classified alternatives achieved according to the two utility functions.

Similarly to LP2, let  $C$  be the set of alternatives which have been correctly classified after solving LP1 and LP2, and  $M$  be the set of misclassified alternatives. LP3 can be formulated as follows:

$$\left\{ \begin{array}{l}
 \max \quad d \\
 \text{s.t.} \quad U^{C_k}(a) - U^{-C_k}(a) - d \geq s, \\
 \quad \forall a \in C_k \cap C, \\
 \quad U^{-C_k}(b) - U^{C_k}(b) - d \geq s, \\
 \quad \forall b \notin C_k, b \in C, \\
 \quad U^{C_k}(a) - U^{-C_k}(a) \geq s, \\
 \quad \forall a \in C_k \cap M, \\
 \quad U^{-C_k}(b) - U^{C_k}(b) \geq s, \\
 \quad \forall b \notin C_k, b \in M, \\
 \quad w_{ij,j+1}^{C_k} \geq t \\
 \quad w_{ij,j+1}^{-C_k} \geq t \\
 \quad \sum_i \sum_j w_{ij,j+1}^{C_k} = 1 \\
 \quad \sum_i \sum_j w_{ij,j+1}^{-C_k} = 1 \\
 \quad d, s, t \geq 0.
 \end{array} \right.$$

The first set of constraints involves only the correctly classified alternatives. In these constraints  $d$  represents the minimum absolute difference between the global utilities of each alternative in the two utility functions. The second set of constraints involves the misclassified alternatives and it is used to ensure that they will be retained as misclassified.

**An Illustrative Example**

To illustrate the application of the method, consider a simple example consisting of six alternatives evaluated along three evaluation criteria [25] for which higher values are preferred. The alternatives must be classified in three ordered classes. Table 1, illustrates the evaluation of the alternatives on the criteria as well as the predefined classification.

**Distinguishing Between  $C_1$  and  $C_2$ - $C_3$**

In the first stage of the hierarchical discrimination procedure, the aim is to distinguish the alternatives belonging in class  $C_1$  from the alternatives belonging in

**Multicriteria Sorting Methods, Table 1**  
Data of the illustrative example (Source: [25])

	$g_1$	$g_2$	$g_3$	Class
$a_1$	70	64.75	46.25	$C_1$
$a_2$	61	62	60	$C_1$
$a_3$	40	50	37	$C_2$
$a_4$	66	40	23.125	$C_2$
$a_5$	20	20	20	$C_3$
$a_6$	15	15	30	$C_3$

classes  $C_2$  and  $C_3$ . To achieve this classification two utility functions are developed, denoted as  $U^{C_1}(a)$  and  $U^{-C_1}(a)$ .

The utility of the decision of classifying the alternative  $a_1$  in class  $C_1$  can be expressed as follows:

$$U^{C_1}(a_1) = u_1^{C_1}(70) + u_2^{C_1}(64.75) + u_3^{C_1}(46.25). \quad (7)$$

Since for all criteria higher values are preferred, it is possible to define the following rank-order on each criterion's scale ( $p_1 = p_2 = p_3 = 6$ ).

$$\begin{aligned} g_1) \quad & g_1^1 = 15 < 20 < 40 < 61 < 66 < 70 = g_1^{p_1}; \\ g_2) \quad & g_2^1 = 15 < 20 < 40 < 50 < 62 < 64.75 = g_2^{p_2}; \\ g_3) \quad & g_3^1 = 20 < 23.125 < 30 < 37 < 46.25 < 60 = g_3^{p_3}. \end{aligned}$$

According to relation (4), the following transformations are then applied (criterion  $g_1$ ):

$$\begin{aligned} w_{11,2}^{C_1} &= u_1^{C_1}(20) - u_1^{C_1}(15), \\ w_{12,3}^{C_1} &= u_1^{C_1}(40) - u_1^{C_1}(20), \\ w_{13,4}^{C_1} &= u_1^{C_1}(61) - u_1^{C_1}(40), \\ w_{14,5}^{C_1} &= u_1^{C_1}(66) - u_1^{C_1}(61), \\ w_{15,6}^{C_1} &= u_1^{C_1}(70) - u_1^{C_1}(66). \end{aligned}$$

The same transformations are also applied to criteria  $g_2$  and  $g_3$ . Then, according to (6), relation (7) can be re-written in the following way:

$$\begin{aligned} U^{C_1}(a) &= (w_{11,2}^{C_1} + w_{12,3}^{C_1} + w_{13,4}^{C_1} + w_{14,5}^{C_1} + w_{15,6}^{C_1}) \\ &+ (w_{21,2}^{C_1} + w_{22,3}^{C_1} + w_{23,4}^{C_1} + w_{24,5}^{C_1} + w_{25,6}^{C_1}) \\ &+ (w_{31,2}^{C_1} + w_{32,3}^{C_1} + w_{33,4}^{C_1} + w_{34,5}^{C_1}). \end{aligned}$$

On the other hand, if  $a_1$  is classified in class  $C_2$  then the utility of the decision maker will be:

$$\begin{aligned} U^{-C_1}(a_1) &= u_1^{-C_1}(70) + u_2^{-C_1}(64.75) + u_3^{-C_1}(46.25) \\ \Downarrow \\ U^{-C_1}(a_1) &= w_{35,6}^{-C_1}. \end{aligned}$$

Following the same methodology, the utilities concerning the classification of the rest of the alternatives are also formulated.

- Alternative  $a_2$ :

$$\begin{aligned} U^{-C_1}(a_2) &= u_1^{C_1}(61) + u_2^{C_1}(62) + u_3^{C_1}(60) \\ \Downarrow \\ U^{C_1}(a_2) &= (w_{11,2}^{C_1} + w_{12,3}^{C_1} + w_{13,4}^{C_1}) \\ &+ (w_{21,2}^{C_1} + w_{22,3}^{C_1} + w_{23,4}^{C_1} + w_{24,5}^{C_1}) \\ &+ (w_{31,2}^{C_1} + w_{32,3}^{C_1} + w_{33,4}^{C_1} + w_{34,5}^{C_1} + w_{35,6}^{C_1}), \\ U^{-C_1}(a_2) &= u_1^{-C_1}(61) + u_2^{-C_1}(62) + u_3^{-C_1}(60) \\ \Downarrow \\ U^{-C_1}(a_2) &= (w_{14,5}^{-C_1} + w_{15,6}^{-C_1}) + (w_{25,6}^{-C_1}). \end{aligned}$$

- Alternative  $a_3$ :

$$\begin{aligned} U^{-C_1}(a_3) &= u_1^{C_1}(40) + u_2^{C_1}(50) + u_3^{C_1}(37) \\ \Downarrow \\ U^{C_1}(a_3) &= (w_{11,2}^{C_1} + w_{12,3}^{C_1}) \\ &+ (w_{21,2}^{C_1} + w_{22,3}^{C_1} + w_{23,4}^{C_1}) \\ &+ (w_{31,2}^{C_1} + w_{32,3}^{C_1} + w_{33,4}^{C_1}), \\ U^{-C_1}(a_3) &= u_1^{-C_1}(40) + u_2^{-C_1}(50) + u_3^{-C_1}(37) \\ \Downarrow \\ U^{-C_1}(a_3) &= (w_{13,4}^{-C_1} + w_{14,5}^{-C_1} + w_{15,6}^{-C_1}) \\ &+ (w_{24,5}^{-C_1} + w_{25,6}^{-C_1}) + (w_{34,5}^{-C_1} + w_{35,6}^{-C_1}). \end{aligned}$$

- Alternative  $a_4$ :

$$\begin{aligned} U^{-C_1}(a_4) &= u_1^{C_1}(66) + u_2^{C_1}(40) + u_3^{C_1}(23.125) \\ \Downarrow \\ U^{C_1}(a_4) &= (w_{11,2}^{C_1} + w_{12,3}^{C_1} + w_{13,4}^{C_1} + w_{14,5}^{C_1}) \end{aligned}$$

$$\begin{aligned}
 &+ (w_{21,2}^{C_1} + w_{22,3}^{C_1}) + (w_{31,2}^{C_1}), \\
 U^{-C_1}(a_4) &= u_1^{-C_1}(66) \\
 &+ u_2^{-C_1}(40) + u_3^{-C_1}(23.125) \\
 \Updownarrow \\
 U^{-C_1}(a_4) &= (w_{15,6}^{-C_1}) \\
 &+ (w_{23,4}^{-C_1} + w_{24,5}^{-C_1} + w_{25,6}^{-C_1}) \\
 &+ (w_{32,3}^{-C_1} + w_{33,4}^{-C_1} + w_{34,5}^{-C_1} + w_{35,6}^{-C_1}).
 \end{aligned}$$

• Alternative  $a_5$ :

$$\begin{aligned}
 U^{-C_1}(a_5) &= u_1^{C_1}(20) + u_2^{C_1}(20) + u_3^{C_1}(20) \\
 \Updownarrow \\
 U^{C_1}(a_5) &= (w_{11,2}^{C_1}) + (w_{21,2}^{C_1}), \\
 U^{-C_1}(a_5) &= u_1^{-C_1}(20) \\
 &+ u_2^{-C_1}(20) + u_3^{-C_1}(20) \\
 \Updownarrow \\
 U^{-C_1}(a_5) &= (w_{12,3}^{-C_1} + w_{13,4}^{-C_1} + w_{14,5}^{-C_1} + w_{15,6}^{-C_1}) \\
 &+ (w_{22,3}^{-C_1} + w_{23,4}^{-C_1} + w_{24,5}^{-C_1} + w_{25,6}^{-C_1}) \\
 &+ (w_{31,2}^{-C_1} + w_{32,3}^{-C_1} + w_{33,4}^{-C_1} + w_{34,5}^{-C_1} + w_{35,6}^{-C_1}).
 \end{aligned}$$

• Alternative  $a_6$ :

$$\begin{aligned}
 U^{-C_1}(a_6) &= u_1^{C_1}(15) + u_2^{C_1}(15) + u_3^{C_1}(30) \\
 \Updownarrow \\
 U^{C_1}(a_6) &= (w_{31,2}^{C_1} + w_{32,3}^{C_1}), \\
 U^{-C_1}(a_6) &= u_1^{-C_1}(15) + u_2^{-C_1}(15) + u_3^{-C_1}(15) \\
 \Updownarrow \\
 U^{-C_1}(a_6) &= (w_{11,2}^{-C_1} + w_{12,3}^{-C_1} + w_{13,4}^{-C_1} + w_{14,5}^{-C_1} + w_{15,6}^{-C_1}) \\
 &+ (w_{21,2}^{-C_1} + w_{22,3}^{-C_1} + w_{23,4}^{-C_1} + w_{24,5}^{-C_1} + w_{25,6}^{-C_1}) \\
 &+ (w_{33,4}^{-C_1} + w_{34,5}^{-C_1} + w_{35,6}^{-C_1}).
 \end{aligned}$$

According to these expressions of the global utility of the decision to classify an alternative into class  $C_1$  or into one of the classes  $C_2$  and  $C_3$ , the LP1 formulation is used to minimize the classification error ( $s = 0.001$ ,  $t = 0.0001$ ).

$$\left\{ \begin{array}{l}
 \min \quad F = e(a_1) + e(a_2) + e(a_3) + e(a_4) \\
 \quad \quad \quad + e(a_5) + e(a_6) \\
 \text{s.t.} \quad U^{C_1}(a_1) - U^{-C_1}(a_1) + e(a_1) \geq 0.001 \\
 \quad \quad \quad U^{C_1}(a_2) - U^{-C_1}(a_2) + e(a_2) \geq 0.001 \\
 \quad \quad \quad U^{-C_1}(a_3) - U^{C_1}(a_3) + e(a_3) \geq 0.001 \\
 \quad \quad \quad U^{-C_1}(a_4) - U^{C_1}(a_4) + e(a_4) \geq 0.001 \\
 \quad \quad \quad U^{-C_1}(a_5) - U^{C_1}(a_5) + e(a_5) \geq 0.001 \\
 \quad \quad \quad U^{-C_1}(a_6) - U^{C_1}(a_6) + e(a_6) \geq 0.001 \\
 \quad \quad \quad w_{ij,j+1}^{C_1} \geq 0.0001, \quad w_{ij,j+1}^{-C_1} \geq 0.0001, \\
 \quad \quad \quad \sum_{i=1}^3 \sum_{j=1}^5 w_{ij,j+1}^{C_1} = 1, \\
 \quad \quad \quad \sum_{i=1}^3 \sum_{j=1}^5 w_{ij,j+1}^{-C_1} = 1, \\
 \quad \quad \quad \forall i = 1, 2, 3, \quad \forall j = 1, \dots, 6, \\
 \quad \quad \quad e(a_1), e(a_2), e(a_3) \geq 0, \\
 \quad \quad \quad e(a_4), e(a_5), e(a_6) \geq 0.
 \end{array} \right.$$

The obtained solution is presented in Table 2. According to this solution, the marginal utilities are calculated.

• Criterion  $g_1$ :

$$\begin{aligned}
 - \quad &u_1^{C_1}(15) = 0, \\
 - \quad &u_1^{-C_1}(15) = w_{11,2}^{-C_1} + w_{12,3}^{-C_1} + w_{13,4}^{-C_1} + w_{14,5}^{-C_1} + w_{15,6}^{-C_1} \\
 &= 0.25937,
 \end{aligned}$$

Multicriteria Sorting Methods, Table 3

Global utilities obtained through the solution of LP1 (stage 1)

	$U^{C_1}(a)$	$U^{-C_1}(a)$
$a_1$	0.8643	0.1110
$a_2$	0.8025	0.1852
$a_3$	0.2967	0.5924
$a_4$	0.0993	0.7034
$a_5$	0.0002	0.9258
$a_6$	0.0988	0.8889

According to these marginal utilities, the global utilities are calculated based on the expressions that have already been presented. Table 3, illustrates the obtained global utilities according to the two utility functions that were developed.

It is clear that  $a_1$  and  $a_2$  are classified in class  $C_1$ , since the global utility of a decision concerning the classification of these two alternatives in class  $C_1$  is greater than the utility concerning their classification in classes  $C_2$  or  $C_3$ . Similarly, alternatives  $a_3, a_4, a_5$  and  $a_6$  are not classified in class  $C_1$ , but instead they belong in one of the classes  $C_2$  or  $C_3$  (their specific classification will be determined in the next stage of the hierarchical discrimination process).

Since the correct discrimination between the alternatives belonging in class  $C_1$  and the alternative not belonging in this class has been achieved through LP1, it is not necessary to proceed in LP2 (minimization of the number of misclassifications). Hence, the procedure proceeds in the formulation and solution of LP3 in order to achieve the higher possible discrimination:

$$\left\{ \begin{array}{l} \max \quad d \\ \text{s.t.} \quad U^{C_1}(a_1) - U^{-C_1}(a_1) - d \geq 0.001 \\ \quad \quad U^{C_1}(a_2) - U^{-C_1}(a_2) - d \geq 0.001 \\ \quad \quad U^{-C_1}(a_3) - U^{C_1}(a_3) - d \geq 0.001 \\ \quad \quad U^{-C_1}(a_4) - U^{C_1}(a_4) - d \geq 0.001 \\ \quad \quad U^{-C_1}(a_5) - U^{C_1}(a_5) - d \geq 0.001 \\ \quad \quad U^{-C_1}(a_6) - U^{C_1}(a_6) - d \geq 0.001 \\ \quad \quad w_{ij,j+1}^{C_1} \geq 0.0001, \quad w_{ij,j+1}^{-C_1} \geq 0.0001 \\ \quad \quad \sum_{i=1}^3 \sum_{j=1}^5 w_{ij,j+1}^{C_1} = 1, \quad \sum_{i=1}^3 \sum_{j=1}^5 w_{ij,j+1}^{-C_1} = 1, \\ \quad \quad \forall i = 1, 2, 3, \quad \forall j = 1, \dots, 6, \quad d \geq 0. \end{array} \right.$$

According to the obtained solution and following the same procedure for calculating the marginal utili-

**Multicriteria Sorting Methods, Table 4**  
Global utilities obtained through the solution of LP3 (stage 1)

	$U^{C_1}(a)$	$U^{-C_1}(a)$
$a_1$	0.9985	0.0001
$a_2$	0.9987	0.0003
$a_3$	0.0008	0.9992
$a_4$	0.0009	0.9993
$a_5$	0.0002	0.9998
$a_6$	0.0002	0.9998

ties, the global utilities of Table 4 are obtained. Obviously, this new solution provides a better discrimination of the alternatives, compared to the initial solution obtained by LP1.

**Distinguishing Between  $C_2$  and  $C_3$**

After the solution of LP3, the first stage of the hierarchical discrimination process is completed, with the correct classification of  $a_1$  and  $a_2$  in class  $C_1$ . Consequently, these two alternatives are excluded from further consideration (second stage). In the second stage, the aim is to determine the specific classification of the alternatives  $a_3, a_4, a_5$  and  $a_6$ . The following rank-order is defined on the scale of the three evaluation criteria ( $p_1 = p_2 = p_3 = 4$ ).

- $g_1) g_1^1 = 15 < 20 < 40 < 66 = g_1^{p_1};$
- $g_2) g_2^1 = 15 < 20 < 40 < 50 = g_2^{p_2};$
- $g_3) g_3^1 = 20 < 23.125 < 30 < 37 = g_3^{p_2}.$

Then, following the procedure illustrated in the previous stage, the variables  $w_{ij,j+1}^{C_1}$  and  $w_{ij,j+1}^{-C_1}$  are formulated, and the new form of the LP1 problem is the fol-

$a_5$	0.2111	0.8000
$a_6$	0.1612	0.7500

lowing ( $s = 0.001, t = 0.0001$ ):

$$\left\{ \begin{array}{l} \min \quad F = e(a_3) + e(a_4) + e(a_5) + e(a_6) \\ \text{s.t.} \quad U^{C_2}(a_3) - U^{-C_2}(a_3) + e(a_3) \geq 0.001 \\ \quad \quad U^{C_2}(a_4) - U^{-C_2}(a_4) + e(a_4) \geq 0.001 \\ \quad \quad U^{-C_2}(a_5) - U^{C_2}(a_5) + e(a_5) \geq 0.001 \\ \quad \quad U^{-C_2}(a_6) - U^{C_2}(a_6) + e(a_6) \geq 0.001 \\ \quad \quad w_{ij,j+1}^{C_2} \geq 0.0001, \quad w_{ij,j+1}^{-C_2} \geq 0.0001 \\ \quad \quad \sum_{i=1}^3 \sum_{j=1}^3 w_{ij,j+1}^{C_2} = 1, \\ \quad \quad \sum_{i=1}^3 \sum_{j=1}^3 w_{ij,j+1}^{-C_2} = 1, \\ \quad \quad \forall i = 1, 2, 3, \quad \forall j = 1, \dots, 4, \\ \quad \quad e(a_3), e(a_4), e(a_5), e(a_6) \geq 0. \end{array} \right.$$

Table 5 presents the global utilities of the alternatives according to the solution obtained by LP1 in this second stage.

The alternatives are correctly classified in their original classes, and therefore, it is not necessary to proceed with LP2 (similarly to the first stage). Instead, the method proceeds in solving LP3 to achieve better discrimination of the alternatives.

$$\left\{ \begin{array}{l} \max \quad d \\ \text{s.t.} \quad U^{C_2}(a_3) - U^{-C_2}(a_3) - d \geq 0.001 \\ \quad \quad U^{C_2}(a_4) - U^{-C_2}(a_4) - d \geq 0.001 \\ \quad \quad U^{-C_2}(a_5) - U^{C_2}(a_5) - d \geq 0.001 \\ \quad \quad U^{-C_2}(a_6) - U^{C_2}(a_6) - d \geq 0.001 \\ \quad \quad w_{ij,j+1}^{C_2} \geq 0.0001, \quad w_{ij,j+1}^{-C_2} \geq 0.0001, \\ \quad \quad \sum_{i=1}^3 \sum_{j=1}^3 w_{ij,j+1}^{C_2} = 1 \\ \quad \quad \sum_{i=1}^3 \sum_{j=1}^3 w_{ij,j+1}^{-C_2} = 1, \\ \quad \quad \forall i = 1, 2, 3, \quad \forall j = 1, \dots, 4, \\ \quad \quad d \geq 0. \end{array} \right.$$

Table 6 presents the global utilities calculated according to the solution of LP3.

In this point the hierarchical discrimination procedure ends, since all the alternatives have been classified in the three predefined classes. Moreover, this classification is correct. In particular, in stage 1  $a_1$  and  $a_2$  have

**Multicriteria Sorting Methods, Table 6**  
Global utilities obtained through the solution of LP3 (stage 2)

	$U^{C_2}(a)$	$U^{-C_2}(a)$
$a_3$	0.9999	0.0005
$a_4$	0.9997	0.0003
$a_5$	0.0002	0.9996
$a_6$	0.0005	0.7949

been correctly classified in class  $C_1$ , while in stage 2  $a_3$  and  $a_4$  have been correctly classified in class  $C_2$ , and  $a_5$  and  $a_6$  have been classified into the final class  $C_3$  (cf. Table 6).

### Concluding Remarks and Future Perspectives

The focal point of interest in this article was the application of MCDA in the study of sorting or more generally discrimination (classification) problems. Such types of problems have major practical interest in several fields including finance, environmental and energy policy and planning, marketing, medical diagnosis, robotics (pattern recognition), etc. The multivariate statistical classification techniques have been used for decades to study such problems. However, their inability to provide a realistic and flexible approach to support real world decision making problems in situations where classification is required, led operational researchers, management scientists as well as practitioners towards the exploitation of the recent advances in the fields of operations research, management science, and artificial intelligence.

Among these 'alternative' approaches for the study of classification problem, MCDA provides an arsenal of tools and methods to develop classification (sorting) models within a realistic and flexible context. This article outlined the main MCDA classification techniques, both from the specific type of classification problems that they address (ordered or non-ordered classes), as well as from the MCDA approach that they employ (goal programming, outranking relations, preference disaggregation).

Furthermore, a new MCDA approach has been proposed. The M.H.DIS method, extends the common two-group classification framework, through a hierarchical multigroup discrimination procedure, taking into account three main discrimination criteria through a sequential process. In this way the classification prob-

lem is studied globally, in order to achieved the higher possible classification accuracy. Except for the illustrative example used in this paper, the M.H.DIS method has already been used in several financial classification problems, including the evaluation of bankruptcy risk, portfolio selection and management, the evaluation of bank branches efficiency, the assessment of country risk, company mergers and acquisitions, etc. [43], providing very encouraging results compared to well known statistical techniques (discriminant analysis, logit and probit analysis), and MCDA preference disaggregation techniques (family of UTADIS methods).

An interesting further research direction would be the exploration of a possible combination of M.H.DIS with artificial intelligence techniques such as fuzzy sets, in order to consider the fuzziness which may exist on the evaluation of alternatives on each evaluation criterion, or on the classification of the alternatives.

Multidimensional assignment problem; Zero-one integer programming; Combinatorial optimization

### Introduction

The multidimensional assignment problem (MAP) can be viewed as a higher-dimensional extension of the linear assignment problem (LAP). While the LAP is often explained as assigning each person in a group a specific job so that for each job there is only one person who does it, and for each person there is only one assigned job. The MAP generalizes evidently two-dimensional (people, jobs) LAP by allowing additional dimensions (space, time, etc.) Hence, the previous example of scheduling people to jobs can be extended to scheduling people to jobs at various time intervals in different locations, so that each specific parameter (say, time interval) is coupled with its own unique three other parameters (person, job, location) and none of them are in any other assignment (of a person, a job, a time slot and a person). Such a modified assignment problem is an example of a MAP in four dimensions.

Obviously, the LAP is a special case of the MAP in two dimensions. On the other hand, the MAP (sometimes referred to as multi-index assignment problem) is a special case of the multi-index transportation problem, just like the LAP is a particular instance of the more general transportation problem.

Interestingly, a broader class of multidimensional transportation problems was originally considered about a decade before the LAP was first given its multidimensional generalization. In fact, a three-dimensional case of the multi-index transportation problem was first introduced by Schell in 1955 [33], and later by Haley [19] in 1963. The MAP was initially presented by Pierskalla [26] in 1966, through first extending the LAP to its three-dimensional case, and then (in 1968) as a general formulation of MAP in  $n$  dimensions [27].

Despite the fact that the LAP can be solved in polynomial time, the MAP of dimensionality  $d \geq 3$  is known to be NP-hard in general (the latter statement follows from a reduction of the matching problem in three dimensions) [16]. In fact, the size of the MAP increases extremely fast with an increase in di-

mensions. To be more precise, the size of problem grows by products of factorials. As a result of the inherent complexity of the problem, only small to medium-sized instances of the MAP can be solved routinely at the moment. Most of the exact and heuristic algorithms developed for this problem are enumerative in nature and/or utilize some form of local neighborhood search. Although many real-life applications of the MAP, including the data association problem in target tracking, require solving general problems of dimensions higher than three, most of the proposed solution methods deal with widely studied three-dimensional versions such as axial 3-MAP and planar 3-MAP.

**Formulation**

Several alternative formulations of the MAP have been given since Pierskalla introduced it as a 0-1 integer programming problem as follows.

Given  $1 \leq p_1 \leq \dots \leq p_d \leq n$ , a finite sequence of positive integers, we want to

$$\begin{aligned}
 &\text{minimize} \quad \sum_{1 \leq i_1 \leq p_1} \dots \sum_{1 \leq i_d \leq p_d} c_{i_1 \dots i_d} \cdot x_{i_1 \dots i_d} \\
 &\text{subject to} \quad \sum_{1 \leq i_2 \leq p_2} \dots \sum_{1 \leq i_d \leq p_d} x_{i_1 \dots i_d} \\
 &\hspace{15em} = 1, \quad 1 \leq i_1 \leq p_1, \\
 &\quad \sum_{1 \leq i_1 \leq p_1} \dots \sum_{1 \leq i_{k-1} \leq p_{k-1}} \sum_{1 \leq i_{k+1} \leq p_{k+1}} \dots \\
 &\quad \quad \quad \sum_{1 \leq i_d \leq p_d} x_{i_1 \dots i_d} = 1, \\
 &\quad 1 \leq i_k \leq p_k, \quad 2 \leq k \leq d-1, \\
 &\quad \sum_{1 \leq i_1 \leq p_1} \dots \sum_{1 \leq i_{d-1} \leq p_{d-1}} x_{i_1 \dots i_d} = 1, \\
 &\quad 1 \leq i_d \leq p_d, \\
 &x_{i_1 \dots i_d} \in \{0, 1\}, \quad 1 \leq i_k \leq p_k, \quad 1 \leq k \leq d,
 \end{aligned} \tag{1}$$

where  $c_{i_1 \dots i_d}$  are the cost coefficients.

By introducing dummy variables, we can assume without loss of generality that  $p_1 = \dots = p_d = n$ ; then the  $d$ -dimensional assignment problem can be re-

formulated as follows:

$$\begin{aligned}
 &\text{minimize} \quad \sum_{1 \leq i_1 \leq n} \dots \sum_{1 \leq i_d \leq n} c_{i_1 \dots i_d} \cdot x_{i_1 \dots i_d} \\
 &\text{subject to} \quad \sum_{1 \leq i_2 \leq n} \dots \sum_{1 \leq i_d \leq n} x_{i_1 \dots i_d} = 1, \quad 1 \leq i_1 \leq n, \\
 &\quad \sum_{1 \leq i_1 \leq n} \dots \sum_{1 \leq i_{k-1} \leq n} \\
 &\quad \quad \quad \sum_{1 \leq i_{k+1} \leq n} \dots \sum_{1 \leq i_d \leq n} x_{i_1 \dots i_d} = 1, \\
 &\quad 1 \leq i_k \leq n, \quad 2 \leq k \leq d-1, \\
 &\quad \sum_{1 \leq i_1 \leq n} \dots \sum_{1 \leq i_{d-1} \leq n} x_{i_1 \dots i_d} = 1, \quad 1 \leq i_d \leq n, \\
 &x_{i_1 \dots i_d} \in \{0, 1\}, \quad 1 \leq i_k \leq n, \quad 1 \leq k \leq d.
 \end{aligned} \tag{2}$$

The MAP (2) also has an interesting interpretation as a problem of combinatorial optimization:

Given a  $d$ -dimensional cubic matrix, one must find the permutation of its columns and rows with the minimum sum of the diagonal elements. In other words, this is an equivalent characterization of (2) in terms of  $d-1$  permutations  $\pi_1, \pi_2, \dots, \pi_{d-1}$  of the set  $\{1, 2, \dots, n\}$ :

$$\begin{aligned}
 &\text{minimize} \quad \sum_{1 \leq i \leq n} c_{i \pi_1(i) \dots \pi_{d-1}(i)}, \\
 &\text{subject to} \quad \pi_1, \pi_2, \dots, \pi_{d-1} \in \Pi^n,
 \end{aligned} \tag{3}$$

where  $\Pi^n$  is the set of all permutations of  $\{1, 2, \dots, n\}$ .

Spieksma [34] gives an alternative compact formulation of the MAP as follows:

Given  $d$  sets  $A_1, A_2, \dots, A_d$ , each of size  $n$ , let  $A = \otimes_{i=1}^d A_i = A_1 \times A_2 \times \dots \times A_d$ . In other words,  $A$  is a set of all  $d$ -tuples  $a = (a(1), a(2), \dots, a(d)) \in A$ . Let  $x_a$  denote a variable for each  $a \in A$ . Then, given assignment costs  $c_a$  for all  $a \in A$ , the objective function is written as  $\sum_{a \in A} c_a x_a$ .

Given a positive integer  $k$ , such that  $1 \leq k \leq d-1$ , let  $Q$  denote the set of all  $(d-k)$ -element subsets of  $\{1, 2, \dots, d\}$ . Each subset  $F$  from  $Q$  corresponds to the set of “fixed” indices. Given such  $F$ , let  $A_F = \otimes_{f \in F} A_f$ . Next, given some  $g \in A_F$ , let  $A(F, g) = \{a \in A \mid a(f) = g(f), \forall f \in F\}$  denote the set of all  $d$ -tuples that coincide with  $g$  on the set  $F$  of “fixed” indices.

Then the multi-index assignment problem can be written as:

$$\begin{aligned} & \text{maximize/minimize } \sum_{a \in A} c_a x_a \\ & \text{subject to } \sum_{a \in A(F, g)} x_a = 1, \\ & \quad \text{for all } g \in A_F, F \in Q, \\ & \quad x_a \in \{0, 1\}, \text{ for all } a \in A. \end{aligned} \quad (4)$$

Similarly to the linear assignment formulation by means of a bipartite graph, the MAP can also be stated using the graph theory terminology in the subsequent fashion [7]:

Given a complete  $d$ -partite graph  $G = (V_1, V_2, \dots, V_d; E)$ , where  $V_i, |V_i| = n, i \in \{1, 2, \dots, d\}$ , denote mutually disjoint vertex sets, and  $E$  is the set of edges in the graph, a subset of the vertex set  $V = \cup_{i=1}^d V_i$  is said to be a *clique* if it meets every set  $V_i$  in exactly one vertex. A  $d$ -dimensional assignment is a partition of  $V$  into  $n$  pairwise disjoint cliques. Given a real-valued cost function  $c$  defined on the set of cliques of  $d$ -partite graph  $G$ , the  $d$ -dimensional assignment problem asks for a  $d$ -dimensional assignment, which minimizes  $c$ .

### Cases

A special case of the MAP that is based on the graph theory formulation for MAP was considered by Bandelt et al. [6]. The cost function in this particular case can be represented using some type of function of elementary costs defined on the edges of the  $d$ -partite graph, whereas a general formulation of the MAP using graphs allows for the cost function to be defined arbitrarily on the set of cliques. In particular, the clique costs can be decomposed using such functions of edge costs as a sum of costs (i. e., a sum of the lengths of all the edges in a given clique), a tour cost (i. e., minimum cost of a traveling salesman tour in a given clique), a star cost (i. e., minimum length of a spanning star in a given clique), and a tree cost (i. e., minimum cost of a spanning tree). By using the decomposed costs, one can construct the worst-case bounds on the ratio between the solution costs found by a simple heuristic, as well as find the cost of the optimal solution. Specifically, Crama and Spieksma [10] considered a case of three-dimensional assignment problem, where the lengths of the edges of the underlying three-partite graph satisfy the triangle

inequality, and the objective function is defined as the cost of the triangle formed by three vertices (each from a different mutually disjoint vertex subsets of the three-partite graph). When the triangle cost is defined as the length of the triangle (i. e., sum of the lengths of all its sides), then there exists a heuristic that gives a feasible solution that is within  $3/2$  from the optimum. The latter bound is decreased to  $4/3$  in the case when the triangle cost is defined as the sum of the two shortest sides.

As mentioned earlier, owing to the exponential increase in the size of the problem with an increase in the number of parameters, it becomes computationally difficult to solve MAP instances of higher dimensionality. As a result most solution methods for the MAP are constructed for three-dimensional versions of the problem. Two important types of the three-dimensional assignment problem are the *axial* three-dimensional assignment problem and the *planar* three-dimensional assignment problem. The distinction between two types lies in constraints and can be easily explained using the following simple geometric interpretation [7].

Let each solution be represented by a three-dimensional 0-1 array of size  $n \times n \times n$ . To visualize such an array of zeros and ones, let us fix a vertex and draw lines or axes along three dimensions. Next, we partition each axis into  $n$  intervals. This partition splits the array into  $n^3$  cells so that each cell contains either a 0 or a 1. Given an axis, say  $j$ , each of  $n$  intervals on  $j$  has a corresponding two-dimensional level surface that consists of  $n \times n$  cells and goes through a given interval of  $j$ . Alternatively, the interval partition of each axis divides a three-dimensional solution array into  $n$  two-dimensional surfaces or “slices” corresponding to each interval on the axis. The constraints imposed in the axial case guarantee that for each axis and all of its intervals, the  $n \times n$  cells in each two-dimensional slice through the interval sum up to 1. In other words, each axial interval is assigned a value of 1, which constitutes the sum of all cells that can be projected on that axial interval. This explains the name “axial.”

In contrast, the constraints of the planar MAP deal with three planes formed by each possible pair of axes. For example, consider the plane formed by axes  $j$  and  $k$ . Using the above partition, this plane is divided into  $n \times n$  squares. For each square on the plane, there is a corresponding stack of cells that goes along the  $i$  axis. Each cell in the stack is projected onto its square  $(j^*, k^*)$

by axis  $i$ . The planar constraints require that for each plane and every square the sum of the cells in an associated stack is equal to 1.

Integer programming formulations for each of type of three-index MAP are given below.

Given a set of  $n^3$  cost coefficients  $c_{ijk}$ , the axial three-dimensional assignment problem is defined as follows:

$$\begin{aligned}
 &\text{minimize } \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n c_{ijk} x_{ijk} \\
 &\text{subject to } \sum_{j=1}^n \sum_{k=1}^n x_{ijk} = 1, \quad 1 \leq i \leq n, \\
 &\quad \sum_{i=1}^n \sum_{k=1}^n x_{ijk} = 1, \quad 1 \leq j \leq n, \\
 &\quad \sum_{i=1}^n \sum_{j=1}^n x_{ijk} = 1, \quad 1 \leq k \leq n, \\
 &\quad x_{ijk} \in \{0, 1\}, \quad 1 \leq i, j, k \leq n.
 \end{aligned} \tag{5}$$

Given  $n^3$  cost coefficients  $c_{ijk}$ , the planar three-dimensional assignment problem can be written in the following fashion:

$$\begin{aligned}
 &\text{minimize } \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n c_{ijk} x_{ijk} \\
 &\text{subject to } \sum_{i=1}^n x_{ijk} = 1, \quad 1 \leq j, k \leq n, \\
 &\quad \sum_{j=1}^n x_{ijk} = 1, \quad 1 \leq i, k \leq n, \\
 &\quad \sum_{k=1}^n x_{ijk} = 1, \quad 1 \leq i, j \leq n, \\
 &\quad x_{ijk} \in \{0, 1\}, \quad 1 \leq i, j, k \leq n.
 \end{aligned} \tag{6}$$

The axial three-index MAP given by (5) can also be formulated using  $n$  permutations  $\sigma$  and  $\pi$  as a combinatorial optimization problem:

$$\text{minimize } \sum_{i=1}^n c_{i\sigma(i)\pi(i)}, \text{ subject to } \sigma, \pi \in \Pi_n. \tag{7}$$

Note that the planar three-dimensional assignment problem has a different combinatorial interpretation in terms of Latin squares of order  $n$ .

Although both axial and planar three-dimensional assignment problems (just as the general MAP) are

generally NP-hard, there exist a number of polynomially solvable special cases. Particularly, in the case when the cost coefficients form a so-called Monge array [8], the MAP is solved by  $d - 1$  identity- $n$  permutations  $\{1, 2, \dots, n\} \rightarrow \{1, 2, \dots, n\}$ . Another case of the polynomially solvable MAP is the axial three-dimensional assignment problem, where the cost coefficient can be represented as a product of nonnegative index factors  $c_{ijk} = p_i \cdot q_j \cdot r_k$ , and the objective function is maximized [9].

### Methods

All known exact methods for solving this generally NP-hard problem are enumerative in nature, and as a result of the inherent complexity of the problem such methods are too slow for practical applications of the MAP. Hence, researchers often use heuristic approaches to find suboptimal solutions of different MAPs. In fact, one of the earliest solution methods for the MAP was a suboptimal method of trisubstitution proposed by Pierskalla [26] in 1966 to solve a three-dimensional assignment problem. Later Frieze and Yadegar [15] developed a suboptimal procedure for the three-index MAP using Lagrangian relaxation. Their technique utilized information contained in the relaxed solution to recover a feasible solution. The key advantage of the Lagrangian relaxation approach is that it allows for computing both upper and lower bounds on the optimum solution, and therefore this method can be employed to evaluate solution quality. Consequently, the Lagrangian relaxation technique was widely used to propose numerous modifications of the original three-dimensional method by extending it to the general multidimensional case [12,28,29]. For example, one of such algorithms presented by Poore and Robertson [29] in 1997 works by relaxing a  $d$ -dimensional assignment problem to a two-dimensional problem, then maximizing with regard to the relaxed Lagrangian multipliers, and next formulating the recovery procedure as a  $(d - 1)$ -dimensional problem. These three steps are repeated successively until the recovery procedure can be formulated as a two-dimensional problem, which is solved optimally in polynomial time, and the algorithm terminates.

Most exact methods for solving the MAP are devised primarily for its three-dimensional case. One of

the earliest exact approaches for the axial three-dimensional assignment problem was suggested by Pierskalla [27] in 1968. His approach works by enumerating all feasible solutions using a tree structure, and utilizing the branch and bound method as follows. For a given node of the feasible solutions tree, a lower bound is calculated from the corresponding dual subproblem, before proceeding further on outgoing branches from the node. If the lower bound is greater than the known lowest bound, then the outgoing branches are eliminated, since it is impossible to obtain a better solution along such branches. Otherwise when the lower bound obtained is less than the known lowest bound, we continue further from this node, because it might still be possible to improve our solution in that direction. Although this branch and bound algorithm can easily be generalized to the multidimensional case, it is too slow to work effectively for the general MAP.

Since Pierskalla introduced his branch and bound procedure for the axial three-dimensional assignment problem, many other branch and bound based approaches have been developed. Most of them branch the current problem onto two subproblems by setting one variable  $x_{ijk} = 0$  or  $x_{ijk} = 1$ . Then the size of the subproblems is decreased. In contrast, a branch and bound scheme proposed by Balas and Saltzman [5] permits fixing several variables at once at each branching node by incorporating a special branching strategy that takes advantage of the problem structure.

The planar three-index MAP can also be solved using variations of branch and bound. One of the first applications of this method to the planar case was given by Vlach [35] in 1967. The algorithm obtains lower bounds by means of row and column reductions that are similar to the ones in the axial case. A method for solving the planar three-dimensional assignment problem based on a clever combination of branch and bound with a relaxation heuristic and Lagrangian relaxation was developed by Magos and Miliotis [24]. The upper bounds are calculated by first applying the relaxation heuristic and then decomposing the remaining problem into  $n$  linear sum assignment problems. The lower bounds are computed by either a heuristic or a Lagrangian relaxation depending on the current problem.

The method introduced by Hansen and Kaufman [20] for solving the axial three-dimensional as-

ignment problem employs a primal-dual method comparable to the well-known Hungarian method for the LAP.

There have been a number of investigations of a convex hull of feasible solutions of the three-dimensional assignment problem. Euler et al. [14] examined the polyhedral structure of the solution polytope for the planar three-index MAP through its connection to Latin squares. Euler [13] also studied the axial polytope by investigating the role of odd cycles for a class of facets of the polytope. The structure of the axial three-index assignment polytope was also analyzed by Balas et al. [3,4,32]. They developed linear-time separation algorithms for different classes of facets induced by specific cliques, and then constructed a polyhedral procedure for solving the axial three-index MAP.

Clemons et al. [11] applied a simulated annealing algorithm for solving the MAP. Several local neighborhood search procedures were implemented for the MAP. Greedy randomized adaptive search procedures (GRASP) were applied by Murphey et al. [25] for solving the general MAP and later by Lidstrom et al. [22] and by Aiex et al. [1] for finding solutions of the axial three-dimensional assignment problem. A tabu search for the planar three-dimensional assignment problem was employed by Magos [23] to obtain suboptimal solutions of the planar three-index assignment problem.

Grundel and Pardalos [18] developed a test problem generator for testing exact and suboptimal solution methods for the axial MAP. Several recent studies investigated various asymptotic properties of the MAPs with randomly generated assignment cost coefficients. In particular, Grundel et al. [17] established the lower and upper bounds for the expected number of local minima of the MAPs with random costs.

## Applications

The MAP can be used to solve various real-life problems arising in such important areas as capital investment, dynamic facility location, and satellite launching [30]. Other applications of the MAP include circuit board assembly and production planning of goods, which can be modeled using the axial three-dimensional assignment problem [34]. The planar three-dimensional assignment problem has also found many interesting applications, for instance, school timetables

and experimental design [21], as well as modeling of satellite launching [2].

Furthermore, it was shown that such a complex problem as tracking elementary particles can be investigated using the five-dimensional assignment problem as a mathematical model [31]. By solving this complex case of the MAP, one can reconstruct the paths of charged elementary particles produced by the Large Electron–Positron Collider.

Many important applications of the general MAP arise in data association, resource allocation, air traffic control, surveillance, etc. In particular, Poore [28] has shown that the data association problem arising in a large class of multiple target tracking and sensor fusion problems can be formulated as a MAP by partitioning the set of observations into false reports and tracks, and then maximizing the likelihood of selecting the true partition.

### Keywords

Multidimensional knapsack; Multiconstraint knapsack; Multiple choice knapsack; Combinatorial optimization

The *multidimensional knapsack problem* (MKP) can be formulated as:

$$\left\{ \begin{array}{l} \max \quad \sum_{j=1}^n p_j x_j \\ \text{s.t.} \quad \sum_{j=1}^n r_{ij} x_j \leq b_i, \quad i = 1, \dots, m, \\ \quad \quad x_j \in \{0, 1\}, \quad j = 1, \dots, n, \end{array} \right. \quad (1)$$

where  $b_i \geq 0$ ,  $i = 1, \dots, m$ , and  $r_{ij} \geq 0$ ,  $i = 1, \dots, m$ ,  $j = 1, \dots, n$ .

Each of the  $m$  constraints in (1) is called a *knapsack constraint*, so the MKP is also called the *m-dimensional knapsack problem*.

Other names given to this problem in the literature are the *multiconstraint knapsack problem*, the *multi-knapsack problem* and the *multiple knapsack problem*. Some authors also include the term ‘zero-one’ in their name for the problem, e.g., the *multidimensional zero-one knapsack problem*. Historically the majority of authors have used the name *multidimensional knapsack problem* and so we also use that phrase to refer to the problem. The special case corresponding to  $m = 2$  is known as the *bidimensional knapsack problem* or the *bi-knapsack problem*.

Many practical problems can be formulated as a MKP, for example, the capital budgeting problem where project  $j$  has profit  $p_j$  and consumes  $r_{ij}$  units of resource  $i$ . The goal is to find a subset of the  $n$  projects such that the total profit is maximised and all resource constraints are satisfied. Other applications of the MKP include allocating processors and databases in a distributed computer system [24], project selection and cargo loading [53], and cutting-stock problems [26].

The MKP can be regarded as a general statement of any zero-one integer programming problem with non-negative coefficients. Indeed much of the early work on the MKP (e.g., [32,35,52,59]) viewed the problem in this way.

Most of the research on knapsack problems deals with the much simpler single constraint version ( $m = 1$ ). For the single constraint case the problem is not

strongly *NP*-hard and effective approximation algorithms have been developed for obtaining near-optimal solutions. A good review of the single constraint knapsack problem and its associated exact and heuristic algorithms is given by S. Martello and P. Toth [42].

Below we give a very brief overview of the literature relating to the MKP. A more detailed literature review can be found in [10].

### Exact Algorithms

There have been relatively few exact algorithms presented in the literature.

W. Shih [53] presented a branch and bound algorithm (cf. also ► **Integer programming: Branch and bound methods**) for the MKP with an upper bound obtained by computing the objective function value associated with the optimal fractional solution for each of the  $m$  single constraint knapsack problems separately and selecting the minimum objective function value among those as the upper bound.

Another branch and bound algorithm was presented in [25] with various relaxations of the problem, including Lagrangian, surrogate and composite relaxations being used to compute bounds. Y. Crama and J.B. Mazzola [11] showed that although the bounds derived from these relaxations are stronger than the bounds obtained from the linear programming (LP) relaxation, the improvement in the bound that can be realized using these relaxations is limited.

### Statistical/Asymptotic Analysis

There have been a few papers considering a statistical/asymptotic analysis of the MKP.

An asymptotic analysis was presented by K.E. Schilling [51] who computed the asymptotic ( $n \rightarrow \infty$  with  $m$  fixed) objective function value for the MKP where the  $r_{ij}$ 's and  $p_j$ 's were uniformly (and independently) distributed over the unit interval and where  $b_i = 1$ . K. Szkatula [54] generalized that analysis to the case where  $b_i \neq 1$  (see also [55]).

A statistical analysis was conducted by J.F. Fontanari [18], who investigated the dependence of the objective function on  $b_i$  and on  $m$ , in the case when  $p_j = 1$  and the  $r_{ij}$ 's were uniformly distributed over the unit interval.

### Early Heuristic Algorithms

Early heuristic algorithms for the MKP were typically based upon simple constructive heuristics.

S.H. Zanakis [59] gave detailed results comparing three algorithms from [32,35] and [52]. R. Loulou and E. Michaelides [40] presented a greedy-like method based on *Toyoda's primal heuristic* [57]. Primal heuristics start with a zero solution, after which a succession of variables are assigned the value one, according to a given rule, as long as the solution remain feasible.

### Bound Based Heuristics

Bound based heuristics make use of an upper bound on the optimal solution to the MKP.

M.J. Magazine and O. Oguz [41] presented a heuristic algorithm that combines the ideas of S. Senju and Toyoda's dual heuristic [52] with *Everett's generalized Lagrange multiplier approach* [17]. Dual heuristics start with the all-ones solution, variables are then successively set to zero according to heuristic rules until a feasible solution is obtained. Their algorithm computes an approximate solution and uses the multipliers generated to obtain an upper bound.

H. Pirkul [45] presented a heuristic algorithm which makes use of surrogate duality. The  $m$  knapsack constraints were transformed into a single knapsack constraint using surrogate multipliers. A feasible solution was obtained by packing this single knapsack in decreasing order of profit/weight ratios. These ratios were defined as  $p_j / \sum_{i=1}^m \omega_i r_{ij}$ , where  $\omega_i$  is the surrogate multiplier for constraint  $i$ . Surrogate multipliers were determined using a descent procedure.

J.S. Lee and M. Guignard [36] presented a heuristic that combined Toyoda's primal heuristic [57] with variable fixing, LP and a complementing procedure from [6].

A. Volgenant and J.A. Zoon [58] extended the heuristic in [41] in two ways:

- 1) in each step, not one, but more, multiplier values are computed simultaneously; and
- 2) at the end of the procedure the upper bound is sharpened by changing some multiplier values.

A. Freville and G. Plateau [21] presented an efficient preprocessing algorithm for the MKP, based on [20], which provided sharp lower and upper bounds on the optimal value, and also a tighter equivalent represen-

tation by reducing the continuous feasible set and by eliminating constraints and variables.

They also [22] presented a heuristic for the bidimensional knapsack problem which includes problem reduction, a bound based upon surrogate relaxation and partial enumeration.

### Tabu Search Heuristics

Tabu search (TS) heuristics are based on tabu search concepts (see [1,29,46]).

F. Dammeyer and S. Voß [12] presented a TS heuristic based on reverse elimination. R. Aboudi and K. Jörnsten [2] combined TS with the pivot and complement heuristic [6] in a heuristic that they applied to the MKP (see also [39]). R. Battiti and G. Tecchiolli [7] presented a heuristic based on reactive TS (essentially TS but with the length of the tabu list varied over the course of the algorithm).

F. Glover and G.A. Kochenberger [28] presented a TS heuristic with a flexible memory structure that integrates recency and frequency information keyed to ‘critical events’ in the search process. Their method was enhanced by a strategic oscillation scheme that alternates between constructive (current solution feasible) and destructive (current solution infeasible) phases. See also [30].

A. Løkketangen and Glover [37] presented a heuristic based on probabilistic TS (essentially TS but with the acceptance/rejection of a potential move controlled by a probabilistic process). They also [38] presented a TS heuristic designed to solve general zero-one mixed integer programming problems which they applied to the MKP.

### Genetic Algorithm Heuristics

Genetic algorithm (GA) heuristics are based on genetic algorithm concepts (see [1,8,43,46]).

In the GA of [34] infeasible solutions were allowed to participate in the search and a simple fitness function which uses a graded penalty term was used. In [56] simple heuristic operators based on local search algorithms were used, and a hybrid algorithm based on combining a GA with a TS heuristic was suggested.

In [48,49] a GA was presented where parent selection is not unrestricted (as in a standard GA) but is restricted to be between ‘neighboring’ solutions. Infea-

sible solutions were penalized as in [34]. An adaptive threshold acceptance schedule (motivated by [14,15]) for child acceptance was used.

In the GA of [33] only feasible solutions were allowed. P.C. Chu and J.E. Beasley [10] presented a GA based upon a simple repair operator to ensure that all solutions were feasible.

### Analysed Heuristics

Analysed heuristics have some theoretical underlying analysis relating to their worst-case or probabilistic performance.

A.M. Frieze and M.R.B. Clarke [23] described a polynomial approximation scheme based on the use of the dual simplex algorithm for LP, and analysed the asymptotic properties of a particular random model.

In [47] a class of generalized greedy algorithms is proposed in which items are selected according to decreasing ratios of their  $p_j$ 's and a weighted sum of their  $r_{ij}$ 's. These heuristics were subjected to both a worst-case, and a probabilistic, performance analysis.

I. Averbakh [5] investigated the properties of several dual characteristics of the MKP for different probabilistic models. He also presented a fast statistically efficient approximate algorithm with linear running time complexity for problems with random coefficients.

### Other Heuristics

G.E. Fox and G.D. Scudder [19] presented a heuristic based on starting from setting all variables to zero(one) and successively choosing variables to set to one(zero). See [13] for a heuristic based upon simulated annealing (SA). See [27] for a heuristic based on ghost image processes. S. Hanafi and others [31] presented a simple multistage algorithm within which a number of different local search procedures (such as greedy, SA, threshold accepting [14,15] and noising [9]) can be used. They also presented two TS heuristics.

### Multiple-Choice Problems

One problem that is related to the MKP is the *multidimensional multiple-choice knapsack problem* (MMKP). Suppose that  $\{1, \dots, n\}$  is divided up into  $K$  sets  $S_k$ ,  $k = 1, \dots, K$ , which are mutually exclusive  $S_k \cap S_l = \emptyset$ ,  $\forall k \neq l$ , and exhaustive  $\cup_{k=1}^K S_k = \{1, \dots, n\}$ . If we then

add to the formulation of the MKP given previously the constraint

$$\sum_{j \in S_k} x_j = 1, \quad k = 1, \dots, K, \quad (2)$$

we obtain the MMKP. Equation (2) ensures that exactly one variable is chosen from each of the sets  $S_k$ ,  $k = 1, \dots, K$ .

See [44] for a heuristic for MMKP based on the MKP heuristic of Magazine and Oguz [41].

The special case of the MMKP corresponding to  $m = 1$  is known as the *multiple-choice knapsack problem* (MCKP) and its LP relaxation as the *linear multiple-choice knapsack problem* (LMCKP). Work on MCKP includes [16], which presented a hybrid dynamic programming tree search algorithm incorporating a Lagrangian relaxation bound; [4], which presented a heuristic based upon SA; and [3], which presented a tree search algorithm incorporating a Lagrangian relaxation bound. For work on LMCKP see [50]. Earlier work on MCKP and LMCKP is cited in [3, 4, 16, 50].

Modern large scale vehicle design (aircraft, ships, automobiles, mass transit) requires the interaction of multiple disciplines, traditionally processed in a sequential order. *Multidisciplinary optimization* (MDO), a formal methodology for the integration of these disciplines, is evolving toward methods capable of replacing the traditional sequential methodology of vehicle design by concurrent algorithms, with both an overall gain in product performance and a decrease in design time. The obstacles to MDO becoming a production methodology, in the same sense as quality control, are numerous and formidable. In aircraft design, for instance, typical disciplines involved would be aerodynamics, structures, thermodynamics, controls, propulsion, manufacture, and economics. Detailed analyses in each of these disciplines could involve tens to hundreds of subroutines and tens of thousands of lines of code. Managing the software libraries and data alone is a daunting task.

Codes from different disciplines typically are grossly incompatible, but even within disciplines, data structures and solution representations may be incompatible, requiring ‘translation’ routines or recoding. This incompatibility is particularly acute when stand-alone packages with interactive interfaces are involved. Most disciplinary codes, designed years ago for small serial computers, are very ill-suited to modern parallel architectures, even with a coarse grained approach.

Detailed, highly accurate disciplinary analyses are very expensive, requiring sometimes hours on a supercomputer, even when run in parallel. The import of this is that, regardless of the dimension of the design space, it can be sampled for accurate function values at only a relatively small number of points. Other obstacles to achieving true MDO include model verification, noisy function values, and flawed parallel optimization methodologies.

Almost every conceivable strategy for MDO has been proposed. A good recent summary of hierarchical approaches can be found in [4], and [9] pioneered nonhierarchical or concurrent approaches. The basic idea of concurrent methods, and a particular variant known as *concurrent subspace optimization* (CSSO), is to simultaneously and independently optimize each of the disciplines (or ‘contributing analyses’, as they are called), and then perform a global coordination that brings the entire system closer to a globally feasible and optimal point. *Collaborative optimization* differs from CSSO in how the global coordination is managed. An excellent discussion of these approaches is in the proceedings [2]. While concurrent methods are intuitively appealing and naturally parallelizable, they are not guaranteed to converge [8].

Trust region model management [1] is a rigorous approach to MDO that shows promise, and aspects of CSSO when combined with an extended Lagrangian and response surface approximations, can lead to a provably convergent MDO method (J.F. Rodríguez, J.E. Renaud and L.T. Watson, [6]). A noteworthy aspect of the *Rodríguez method* [6] is that the convergence proof covers variable fidelity data, which is crucial in practice.

In a taxonomy of MDO approaches, one distinction would be between hierarchic or nonhierarchic. Another distinction is whether parallelism is achieved between disciplines (concurrent disciplinary computation) or within disciplines (multipoint, response surface, local/global computation). If response surface approximations are used, two prevalent approximation methods are classical least squares and *DACE* (Design and Analysis of Computer Experiments).

S. Burgee, A.A. Giunta, V. Balabanov, B. Grossman, W.H. Mason, R. Narducci, R.T. Haftka, and Watson [3] has a detailed discussion of the multipoint, classical least squares approach to response surface construction, and of the use of parallelism within disciplines (the pipelined MDO paradigm of Burgee is also provably convergent). The tack of this approach is to use classical design of experiments theory, regression statistics, and low order polynomial approximation models.

The DACE [7] model posits that the output of a computer analysis program is

$$Y(x) = \beta + Z(x),$$

where  $Z(x)$  is a zero mean stationary Gaussian process. (This is clearly a fiction since computer output is deterministic. The issue is whether the model has predictive power.) Using Bayesian statistics, the best unbiased predictor is

$$\widehat{Y}(x) = \widehat{\beta} + r(x, S)R^{-1}(Y_S - 1 \cdot \widehat{\beta}),$$

where  $S$  is a set of observation sites,  $Y_S$  is the vector of observations at  $S$ ,  $r(x, S)$  is the correlation of  $x$  with sites  $S$ ,  $R$  is the correlation matrix between sites  $S$ , and  $\widehat{\beta}$  is the estimate of the mean. Some parametrized functional form for the correlation is assumed, and then these correlation parameters and  $\widehat{\beta}$  are computed as maximum likelihood estimates.

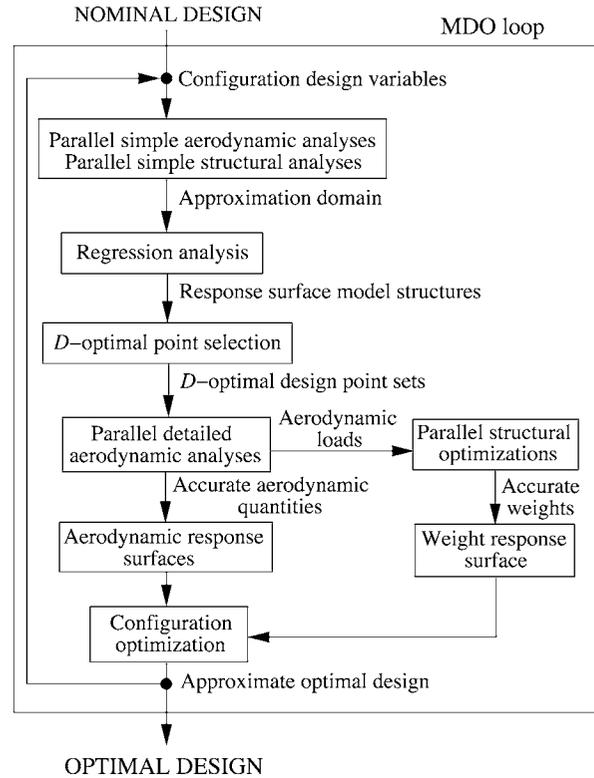

DACE models are more flexible than polynomial models, but with sparse data in high dimensions neither DACE nor polynomial models have much predictive power. To appreciate the problem, observe that a cube in 30 dimensions has  $2^{30} \approx 10^9$  vertices, and to even evaluate an algebraic formula at each vertex requires supercomputer power.

### MDO Paradigm Example

As an illustration, an MDO paradigm for aircraft design is presented here. The MDO algorithm is a repeat loop, with a nominal design as its starting point, approximate optimal designs as loop iterates, and an optimal design as its ending point (see Fig. 1). At the start of each loop, aerodynamic shape and mission variables are obtained from either the nominal starting design or the intermediate approximate optimal design. These shape and mission variables are then used in the parallel simple aerodynamic and structural analyses.

The simple aerodynamic analyses are performed on a regular grid of points in the design space. Simple aerodynamic calculations evaluate the (aerodynamic) feasibility of each grid point using tolerances on the constraints and move limits on the objective function, eliminating grossly infeasible points, and generating an approximation domain. The simple structural analyses use the aerodynamic shape and mission variables in basic weight equations to calculate approximate weights needed by the objective function and constraints, further refining the approximation domain.

Using the relatively abundant data from the simple analyses, regression analysis and analysis of variance

Multidisciplinary Design Optimization, Figure 1  
MDO paradigm

are used to identify less important terms in the polynomial response surface models. Once the less important terms are eliminated, the structure of the reduced-term polynomial regression models is known, and can be used later in the generation of response surface approximations of the optimal weight and necessary aerodynamic quantities over the approximation domain.

A genetic algorithm (GA; cf. ► [Genetic Algorithms](#)) is used to find sets of approximate  $D$ -optimal design points in the approximation domain obtained from the parallel simple analyses. The structure of a response surface model is embodied in the regression matrix  $\mathbf{X}$ , which defines the GA merit function  $|\mathbf{X}^T \mathbf{X}|$  (maximized by a set of points called  $D$ -optimal). These  $D$ -optimal design points are input to the detailed aerodynamic analysis code, which performs detailed analyses at each of the  $D$ -optimal design points in parallel. The analyses result in accurate aerodynamic quantities, such as wave drag and other drag components, and accurate aerodynamic loads.

The accurate aerodynamic quantities are used to generate reduced-term polynomial response surface models for each of the expensive quantities (such as wave drag). An aerodynamic load calculated in the detailed aerodynamic analyses is used in a detailed structural optimization to calculate an accurate optimal weight for that particular aerodynamic load. This structural optimization is done (in parallel) for each aerodynamic load generated in the detailed aerodynamic analyses. The accurate optimal weights calculated in the structural optimization are used to generate a reduced-term polynomial response surface model for the optimal weight.

All the response surface models are then used in a configuration optimization to generate an approximate optimal design, which will be used as the starting design for the next iteration of the MDO loop. The grid spacing may possibly be refined for the simple analyses. When some convergence criterion is satisfied, the MDO loop exits with an optimal design.

Note that the *source of parallelism in the present MDO paradigm is the multipoint approximations within each discipline*, where the disciplines are visited sequentially in a pipeline. This contrasts sharply with CSSO MDO paradigms, where the *source of the parallelism is processing the disciplines in parallel*.

Location theory; Weber problem; Weber–Rawls problem; multifacility Weber problem; multiWeber problem; Gauge; Convex polytope; Linear programming; NP-hard; Voronoi diagram; Restricted location problem; Finite dominating set; Discretization; Barrier location problems

In location planning one is typically concerned with finding a good location for one or several new facilities with respect to a given set of existing facilities (clients). The two most common models in planar location theory are the *Weber problem*, where the average (weighted) distance of the new to the existing facilities is taken into account and the *Weber–Rawls problem*, where the maximum (weighted) distance of the new to the existing facilities is taken into account.

More precisely, one is given a finite set  $Ex = \{Ex_1, \dots, Ex_M\}$  of existing facilities (represented by their geographical coordinates) in the plane  $\mathbf{R}^2$  and distance functions  $d_m$  assigned to each existing facility  $m \in \mathcal{M} := \{1, \dots, M\}$ . The set of locations for the  $N$  new facilities one is looking for is denoted  $X = \{X_1, \dots, X_N\}$ . The distance between the new facilities is measured by a common distance  $d$ . Additionally, a value  $w_{mn}$  is assigned to each pair  $(Ex_m, X_n)$ , for  $m \in \mathcal{M}, n \in \mathcal{N} := \{1, \dots, N\}$  and a value  $v_{rs}$  assigned to each pair  $(X_r, X_s)$ , for  $r, s \in \mathcal{N}, s > r$ , reflecting the *level of interaction*.

With these definitions the *multifacility Weber objective function* can be written as

$$\sum_{m \in \mathcal{M}} \sum_{n \in \mathcal{N}} w_{mn} d_m(Ex_m, X_n) + \sum_{\substack{r, s \in \mathcal{N} \\ s > r}} v_{rs} d(X_r, X_s) := f(X_1, \dots, X_N)$$

and the *multifacility Weber–Rawls objective function* can be written as

$$\max \left\{ \max_{\substack{m \in \mathcal{M} \\ n \in \mathcal{N}}} w_{mn} d_m(Ex_m, X_n), \max_{\substack{r, s \in \mathcal{N} \\ s > r}} v_{rs} d(X_r, X_s) \right\} := g(X_1, \dots, X_N).$$

In the corresponding optimization problems we may additionally assume a feasible region  $\mathcal{F}$  and we look for

$$\min_{\{X_1, \dots, X_N\} \subset \mathcal{F}} f(X_1, \dots, X_N),$$

and

$$\min_{\{X_1, \dots, X_N\} \subset \mathcal{F}} g(X_1, \dots, X_N).$$

In the first part of this survey it is assumed that  $\mathcal{F} = \mathbf{R}^2$  whereas  $\mathcal{F}$  will be a restricted set later on.

The models above implicitly assume that the new facilities can be distinguished, that the amount of interaction between each new and existing facility is known

and that the new facilities have mutual communication. Note, that problems without communication between the new facilities can be separated into  $N$  independent 1-facility problems which can be easily solved by suitable algorithms. Also, in many applications we want to locate a number of indistinguishable facilities to serve the overall demand. This implies that we are not only locating facilities, but we are also allocating existing facilities (clients) to the new ones. This variation of the problem is called *multiWeber* or *multiWeber–Rawls problem* and the objective functions can be written as

$$\sum_{m \in \mathcal{M}} w_m d_m(Ex_m, \{X_1, \dots, X_N\}) = \widehat{f}(X)$$

and

$$\max_{m \in \mathcal{M}} \{w_m d_m(Ex_m, \{X_1, \dots, X_N\})\} = \widehat{g}(X),$$

respectively, where  $d_m(Ex_m, \{X_1, \dots, X_N\}) := \min_{Y \in \{X_1, \dots, X_N\}} d_m(Ex_m, Y)$ .

In order to discuss solution methods, suitable types of distance functions  $d_m, m \in \mathcal{M}$ , are specified next.

Let  $B$  be a compact convex set in the plane containing the origin in its interior and let  $Y$  be a point in the plane. The *gauge* of  $Y$  (with respect to  $B$ ) is then defined as

$$\gamma_B(Y) := \inf \{ \lambda > 0 : Y \in \lambda B \}.$$

This definition dates back to [25]. The distance from  $Ex_m$  to  $Y$  induced by  $\gamma_B$  is

$$d_m(Ex_m, Y) := \gamma_{B_m}(Y - Ex_m) \quad \text{for } m \in \mathcal{M}.$$

In the case where all  $B_m$  are convex polytopes with extreme points  $\text{Ext}(B_m) := \{e_1^m, \dots, e_G^m\}$  we can define halflines  $l_i^m$  starting at  $Ex_m$  and going through  $e_i^m$ . For the 1-facility case it was proved in [6] for the Weber problem that there always exists an optimal solution in the set of intersection points of the halflines  $l_i^m$  for  $i = 1, \dots, G^m$  and  $m \in \mathcal{M}$ . This result carries over to multi-(facility) Weber problems when each  $B_m$  has no more than 4 extreme points [24]. For more than 4 extreme points it is in general wrong (see [24] for a counterexample).

In the case where all  $B_m$  are polytopes we can give linear programming formulations for the multifacility

Weber as well as the multifacility Weber–Rawls problem [34] using  $B_m^0$ , the polar set of  $B_m$ ,  $m \in \mathcal{M}$ .

$$\left\{ \begin{array}{l} \min \quad \sum_{m \in \mathcal{M}} \sum_{n \in \mathcal{N}} w_{mn} z_{mn} + \sum_{\substack{r, s \in \mathcal{N} \\ s > r}} v_{rs} z'_{rs} \\ \text{s.t.} \quad \langle Ex_m - X_n, e_m^0 \rangle \leq z_{mn}, \\ \quad \forall m \in \mathcal{M}, n \in \mathcal{N} \quad e_m^0 \in \text{Ext}(B_m^0), \\ \quad \langle X_s - X_r, e^0 \rangle \leq z'_{rs}, \\ \quad \forall s, r \in \mathcal{N}, s > r, e^0 \in \text{Ext}(B^0), \\ \\ \min \quad z \\ \text{s.t.} \quad w_{mn} \langle Ex_m - X_n, e_m^0 \rangle \leq z, \\ \quad \forall m \in \mathcal{M}, n \in \mathcal{N}, e_m^0 \in \text{Ext}(B_m^0), \\ \quad v_{rs} \langle X_s - X_r, e^0 \rangle \leq z, \\ \quad \forall s, r \in \mathcal{N}, s > r, e^0 \in \text{Ext}(B^0). \end{array} \right.$$

Even without polyhedral structure we still have a convex optimization problem for which several solution techniques are available (see [11,12,21,32] and references therein).

In the case where we also have to deal with the allocation problem we still can apply discretization results from the 1-facility case. The allocation part makes the problem however NP-hard (see [22,23]; cf. also ► **Complexity Theory**; ► **Complexity Classes in Optimization**). Nevertheless, constructs from computational geometry (e. g. Voronoi diagrams; cf. also ► **Voronoi Diagrams in Facility Location**) can be used to tackle the allocation part efficiently and allow iterative heuristics producing in general satisfactory results (see [2,30]).

Further extensions are possible and already investigated including location with attraction and repulsion, hub location, etc. (see [32] for further references).

A problem common to all forms of multi-(facility) location problems is, that in an optimal solution locations of different new facilities may coincide with each other or with existing facilities. This raises at least two issues:

- A priori detection of coincidences which result in a reduction of the dimension of the problem and allow the exploitation of differentiability are discussed in [7,20,31].
- If coincidence is excluded, the theory of restricted location can be used which is discussed next.

So far, the set  $\mathcal{F}$  for placing new facilities was the whole plane  $\mathbb{R}^2$ . Now, the feasibility set  $\mathcal{F} = \mathbb{R}^2 \setminus \text{int}(\mathcal{R})$  is con-

sidered, where  $\mathcal{R} \subseteq \mathbb{R}^2$  is the restricting set assumed to be connected in  $\mathbb{R}^2$ . This problem is more complicated than the unrestricted one, since  $\mathcal{F}$  is in general not convex. But from a practical point of view it is a necessary extension of the classical location model, since forbidden regions appear everywhere: nature reserves, lakes, exclusion of coincidence in multifacility, etc. These problems are called *restricted location problems* and have been developed in [1,12,14,15] and [26]. In the following we exclude the trivial case and assume that none of the optimal solutions of the unrestricted problem is a feasible solution of the restricted one.

If the objective function  $h$  of the location problem is convex it can be shown that optimal solutions of the restricted problem can be found on the boundary of  $\mathcal{R}$ . Therefore, level curves

$$L_=(z) := \{X \in \mathbb{R}^n : h(X) = z\}$$

and level sets

$$L_{\leq}(z) := \{X \in \mathbb{R}^n : h(X) \leq z\}$$

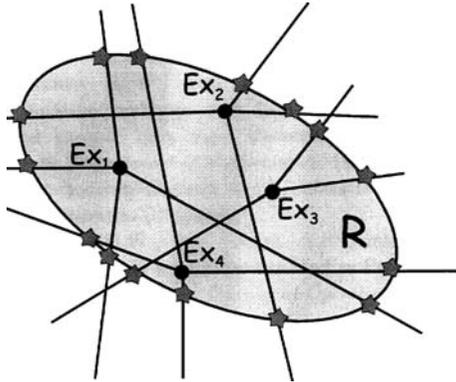

can be used to reformulate the restricted location problem as

$$\min \{z : L_=(z) \cap \partial\mathcal{R} \neq \emptyset \text{ and } L_{\leq}(z) \subseteq \mathcal{R}\}.$$

A resulting search algorithm was formulated in [11], but proved to be inefficient in practical applications.

An efficient approach originally presented in [12,14,15] identifies *finite dominating set* (FDS) on the boundary  $\mathcal{R}$ , i. e. a finite set of locations on  $\partial\mathcal{R}$  which contains an optimal solution. Using this discretization, problems with gauge distance and convex forbidden region can be solved by considering as FDS the intersection points of  $l_i^m$  and the boundary of  $\mathcal{R}$  (see [15,26,28] and the illustration in the following figure).

The discretization also works for restricted center problems [16] and can be extended to nonconvex forbidden regions (see [15,26]) and also to the case of attraction and repulsion (negative weights are allowed), see [29]. The concept of forbidden regions has been successfully applied to a problem in PCB assembly, where the bins holding the parts to be inserted into the PCB have to be stored [10]. Of course, the PCB itself has to be forbidden for placing a bin. A solution approach, where also the issue of space requirements in a multifacility setting is addressed can be found in [9,15]. A more gen-

**Multifacility and Restricted Location Problems, Figure 1**  
 Example of a restricted location problem with 4 existing facilities and an elliptic forbidden region

eral case where the new facility is a line has been considered in [33]. Algorithms for multifacility problems with forbidden regions can be found in [8,15,27].

Another type of restricted location problem is one, where not only placement, but also trespassing of regions is forbidden. These problems are called *barrier location problems*. The corresponding models are mathematically challenging, since the distance functions (and thus also the objective functions) are no longer convex. [17] considers Euclidean distances and one circle as forbidden region. [1] and [4] develop heuristics for  $l_p$  distances and barriers that are closed polygons. [19] and [3] obtain discretization results for  $l_1$  distances and arbitrary shaped barriers by showing an equivalence of the barrier problem to a network location problem. In the more general context of gauge distances an FDS is given in [13] for median problems and in [5] for center problems. Finally, [18] considers barrier problems if the distance is an arbitrary norm and the barrier consists of a line with finitely many passages.

### Keywords

Transportation problem; Three-dimensional transportation problem; Greedy algorithm; Monge property; Approximation algorithms

An ordinary *transportation problem* has variables with two indices, typically corresponding to sources (or origins, or supply points) and destinations (or demand points). A *multi-index transportation problem* (MITP) has variables with three or more indices, corresponding to as many different types of points or resources or other factors. Multi-index transportation problems were considered by T. Motzkin [22] in 1952; an application involving the distribution of different types of soap was presented by E. Schell [35] in 1955. MITPs are also known as *multidimensional transportation problems* [4]. There are several versions and special cases of MITPs:

- The number  $k$  of dimensions may be fixed to a small value; the resulting MITP is called a  $k$ -index transportation problem,  $k$  ITP. Quite naturally, the

best studied cases are the *three-index transportation problems* (3ITPs), also known as *three-dimensional*, or *3D transportation problems*.

- The type of constraints is determined by an integer  $m$  with  $0 < m < k$ , defining  $m$ -fold  $k$  ITPs (called *symmetric MITPs* in [16]; see also [41, Chapt. 8]). The most common cases are *axial MITPs*, when  $m = k - 1$ ; and *planar MITPs*, when  $m = 1$ ; see below for details.
- Integer solutions may or may not be required. Integrality requirements, which give rise to *integer MITPs*, may be necessary since MITPs lack the integrality property enjoyed by ordinary transportation problems (but see [22] for an exception).
- Unit right-hand sides, in conjunction with integrality requirements, give rise to *multi-index assignment problems* (MIAPs). (Some authors use this term for integer MITPs with integer right-hand sides; the present terminology, consistent with that for ordinary assignment and transportation problems, seems preferable.) MIAPs are hard to solve: the 3IAP is already NP-hard by reduction from the 3-dimensional matching problem [17]. Even worse [6]: no polynomial time algorithm for the 3IAP can achieve a constant performance ratio, unless  $P = NP$ .
- The objective function is usually a simple linear combination of the variables, normally a total cost to be minimized as in equation (1) below. Alternatives, not considered in this article, may include bottleneck objectives [11,36], more general nonlinear objectives such as in [34], or multicriteria problems [38].
- There may be additional constraints, such as upper bounds on the variables, (capacitated MITPs), variables fixed to the value zero (MITPs with forbidden cells), or constraints on certain partial sums of variables (MITPs with generalized capacity constraints).

MITPs with linear objectives and without integrality restrictions are linear programming problems with a special structure. The most extensively studied *integer MITPs* are *three-index assignment problems* (3IAPs); see also Three-index Assignment Problem.

**Formulations**

The following compact notation [31,34] avoids multiple summations and multiple layers of subindices. Let  $k$

$\geq 3$  denote the number of dimensions or indices, and  $K = \{1, \dots, k\}$ . For  $i \in K$  let  $A_i$  denote the set of values of the  $i$ th index. Let  $A = \otimes_{i \in K} A_i = A_1 \times \dots \times A_k$  denote the Cartesian product of these index sets, that is, the set of all joint indices ( $k$ -tuples)  $a = (a(1), \dots, a(k))$  with  $a(i) \in A_i$  for all  $i \in K$ . One variable  $x_a$  is associated with each joint index  $a \in A$ . Thus, for example in a 3ITP with index sets  $I, J$  and  $L$ , the variable  $x_a$  stands for  $x_{ij\ell}$  when the joint index is  $a = (i, j, \ell)$ .

Given unit costs  $c_a \in \mathbf{R}$  for all  $a \in A$ , a linear objective function is

$$\min \sum_{a \in A} c_a x_a \tag{1}$$

and the variables are usually restricted to be nonnegative:

$$x_a \geq 0 \quad \text{for all } a \in A. \tag{2}$$

Given the integer  $m$  with  $0 < m < k$ , the demand constraints of the  $m$ -fold  $k$  ITP are defined as follows. Let  $\binom{K}{k-m}$  denote the set of all  $(k - m)$ -element subsets of  $K$ ; an  $F \in \binom{K}{k-m}$  is interpreted as a set of  $k - m$  ‘fixed indices’. Given such an  $F$  and a  $(k - m)$ -tuple  $g \in A_F = \otimes_{f \in F} A_f$  of ‘fixed values’, let

$$A(F, g) = \{a \in A : a(f) = g(f), \forall f \in F\}$$

be the set of  $k$ -tuples which coincide with  $g$  on the fixed indices. The  $m$ -fold demand constraints are

$$\sum_{a \in A(F,g)} x_a = d_{Fg} \tag{3}$$

for all  $F \in \binom{K}{k-m}, g \in A_F,$

where the right-hand sides  $d_{Fg}$  are given positive demands associated with the values  $g$  for fixed index subset  $F$ . These ‘demands’ may also denote supplies or capacities when the indices represent sources or some other resource type. When some of these resources are in excess, the equality in constraints (3) may be replaced with inequalities. Problem (1)–(3) is a  $k$  ITP. Adding the integrality restrictions

$$x_a \in \mathbb{N} \quad \text{for all } a \in A, \tag{4}$$

yields an integer MITP.

As mentioned above, the most common cases are  $m = k-1$ , defining axial MITPs; and  $m = 1$ , defining planar MITPs. For the axial problems, the notation may be simplified by letting  $d_{ig} = d_{Fg}$  when  $F = \{i\}$ . Note that each variable  $x_a$  appears in the same number  $k$  of axial and planar demand constraints; however there are only  $\sum_{i \in K} |A_i|$  axial constraints, versus  $\sum_{i \in K} \prod_{f \in K \setminus \{i\}} |A_f|$  planar constraints. Of course, it is possible to combine demand constraints with different values of  $m$ , so as to formulate different types of restrictions (e. g., see [5] and [16]).

Reductions between MITPs are presented in [16], where it is shown in particular that an  $m$ -fold  $k$  ITP can be reduced to a 1-fold  $k$  ITP for any  $m$  (with  $0 < m < k$ ), thereby generalizing a result in [14]. Thus, an algorithm that solves planar  $k$  ITPs is in principle capable of solving  $m$ -fold  $k$  ITPs for any  $m$  (with  $0 < m < k$ ).

Notice that any MITP with arbitrary right hand sides can be transformed to a MITP with right hand sides 1. This is a (pseudopolynomial) transformation and simply involves duplicating a resource with a supply of  $q$  units by  $q$  unit-supply resources. There seems to be little advantage in doing so, except perhaps in converting an integer MITP into one with 0–1 variables.

Another issue is the existence of feasible solutions. For an axial MITP the requirement of equal total demands  $\sum_g d_{ig} = \sum_g d_{jg}$  for all  $i, j \in K$  is a necessary and sufficient condition for the existence of feasible solutions. Feasibility conditions are more complicated for nonaxial problems; see [40] for a review of results for planar problems. See also [41, Chapt. 8] for properties of polytopes associated with (integer) MITPs, including issues of degeneracy.

## Applications

### Transportation and Logistics

MITPs are used to model transportation problems that may involve different goods; such resources as vehicles, crews, specialized equipment; and other factors such as alternative routes or transshipment points. Thus index sets  $A_1$  and  $A_2$  may represent destinations and sources, respectively, and the other sets  $A_3, A_4, \dots$  these additional factors. The type of ‘demand’ constraints used will reflect the availability of these factors and their interactions. Thus, for example, an axial demand constraint (3) with right-hand side  $d_{3i}$  will be used for a ve-

hicle type  $i \in A_3$  of which  $d_{3i}$  units are globally available (at identical cost) to all sources and destinations, while a constraint with  $F = \{2, 3\}$  will be used if there are  $d_{Fg}$  vehicles of type  $g(3)$  available at the different sources  $g(2)$ .

Interesting cases arise when each resource or factor  $\ell \in A_i$  corresponds to a point  $P_{i,\ell}$  in a *metric space*, i. e., a set with a distance  $\delta$ , and the unit costs  $c_a$  are ‘decomposable’ as defined below. Each joint index  $a \in A$  may be interpreted as a *cluster* of points among which transportation and other activities are conducted. The unit cost  $c_a$  reflects the within-cluster transportation costs associated with these activities; it is *decomposable* if it can be expressed as a function of the distances between pairs of points in the cluster  $a$ . Examples include the *diameter*  $\max_{i,j} \delta(P_{i,a(i)}, P_{j,a(j)})$ , when all these activities are performed simultaneously; the sum costs  $\sum_{i,j} \delta(P_{i,a(i)}, P_{j,a(j)})$  when all activities are performed sequentially; and the *Hamiltonian path* or *path* costs, when all points  $P_{i,\ell}$  in the cluster have to be visited in a shortest sequence.

Other interesting cases arise when one of the indices denotes time. A simple *dynamic location problem* [27] may be modeled as an axial  $k$  ITP, where index set  $A_1$  may denote the set of facilities (say, warehouses) to be located;  $A_2$  that of candidate locations; and  $A_3$  that of time periods. The costs  $c_{ijt}$  may include discounted construction and operating costs of these facilities. See [38] and [33] for other applications of this type.

### Timetabling

Other problems involving time and which can be formulated as MITPs arise in timetabling or staffing applications. To illustrate, consider the following generic situation. Given are  $N$  employees (index  $i$ ), each of which can be assigned to one of  $M$  tasks (index  $j$ ) during each of  $T$  time periods (index  $k$ ). Moreover, for each pair consisting of a task and a time period a number  $r_{jk}$  is given denoting the number of employees required for task  $j$  in period  $k$ . Also, a number  $r_{ij}$  is given denoting the number of periods that task  $j$  requires employee  $i$ . An employee can only be assigned to one task during each time period. Finally, there is a cost-coefficient  $c_{ijk}$  which gives the cost of employee  $i$  performing task  $j$  in period  $k$ . This problem is called the *multi-period assignment problem* in [21] (see also the references contained

therein). To model this as a planar 3ITP, let  $A_1$  be the set of employees;  $A_2$  the set of tasks;  $A_3$  the set of time periods;

$$d_{Fg} = \begin{cases} r_{jk} & \text{for } F = \{2, 3\}, \quad \forall g = (j, k); \\ 1 & \text{for } F = \{1, 3\}, \quad \forall g = (i, k); \\ r_{ij} & \text{for } F = \{1, 2\}, \quad \forall g = (i, j); \end{cases}$$

and require the decision variables to be in  $\{0, 1\}$ . A special case arises when  $r_{jk} = 1$  for all  $j, k$  and  $N = M$ . The polyhedral structure of the resulting planar 3ITP is investigated in [7]. Other references dealing with timetabling problems formulated as MITPs are [10,15] and [12].

### Multitarget Tracking

Consider the following (idealized) situation.  $N$  objects move along straight lines in the plane. At each of  $T$  time instants a *scan* has been made, and the approximate position of each object is observed and recorded. From such a scan it is not possible to deduce which object generated which observation. Also, a small error may be associated with each observation. A *track* is defined as a  $T$ -tuple of observations, one from each scan. For each possible track a cost is computed based on a least squares criterion associated with the observations in the track. The problem is now to identify  $N$  tracks while minimizing the sum of the costs of these tracks. This problem is called the *data-association problem* in [25]. It can be modeled as an axial integer TIAP as follows: let  $A_i$  be the set of observations in scan  $i$ ,  $i = 1, \dots, T$ , and let  $d_{ig} = 1$ ,  $i = 1, \dots, T$ ,  $g = 1, \dots, N$ . Not surprisingly, this problem is NP-hard already for  $T = 3$  (see [37]; notice however that this does not follow from the NP-hardness of 3IAP due to the structure present in the cost-coefficients in the objective function of multitarget tracking problems). Other references dealing with target tracking problems formulated as axial MIAPs are [23] and [24]; see also [20].

### Tables with Given Marginals

Other statistical applications of MITPs require finding multidimensional tables with given sums across rows or higher-dimensional planes, as specified in constraints (3). The right-hand sides  $d_{Fg}$  of such constraints are

often known as *marginals*. In a simple application [3] arising in the *integration of surveys* and *controlled selection*, each index set represents a population from which a sample is to be drawn. A (joint) sample is a  $k$ -tuple, one from each population. The marginals are specified marginal probability distributions over each population, giving rise to axial demand constraints. Given sample costs  $c_a$ , the problem is to find a joint probability distribution, defined by  $(x_a)$ , of all the samples, consistent with these marginal distributions and of minimum expected cost (1).

In contrast, problems of *updating input-output matrices* (see [34] and references therein) typically have nonlinear objectives. In such problems, given are a  $k$ -dimensional array  $B$  of data (for example, past input-output coefficients) and arrays  $d$  of marginals (for example, forecast aggregate coefficients) with appropriate dimensions. The problem is to determine values  $x_a$ , the updated array entries, satisfying the demand constraints corresponding to the given marginals, and such that the resulting updated array  $X = (x_a)$  differs as little as possible from the given array  $B$ , as specified by an appropriate (nonlinear) objective function. A (nonlinear) MITP arises when the values  $x_a$  are constrained to be nonnegative, a natural requirement in many contexts.

### Other Applications

include an axial integer 3ITP model for planning the launching of weather satellites [27], and an axial integer 5IAP arising in routing meshes in circuit design [9].

### Solution Methods

As noted above, MITPs are linear programming problems with a special structure. There are several proposals for extensions of LP (transportation) algorithms to MITPs (e. g., [4,13] for 3ITPs and [1] for a 4ITP).

As also mentioned earlier, integer MITPs are hard to solve. Exact algorithms have been proposed for the axial integer 3IAP (see Three-index Assignment Problem) and for the planar integer 3IAP (see [39] and [19]). Other exact approaches for integer MITPs rely on structure that is present in the particular application considered (see, e. g., [12]).

Several methods have been proposed to obtain good approximate solutions to integer MITPs. In [21] results

are reported for a *rounding heuristic* on some medium-sized planar integer 3ITPs. A *tabu search* algorithm for this problem is described in [18]. Heuristic solution approaches based on *Lagrangian relaxation* are proposed in [26,28] and [29] for multitarget tracking problems.

One major difficulty with these exact or approximate solution methods may be the sheer size of MITP formulations; if, for example, all  $|A_i| = n$  then an  $m$ -fold  $k$  ITP has  $n^k$  variables and  $\binom{k}{m}n^{k-m}$  constraints. In contrast, the two approaches sketched below yield feasible solutions to *axial* MITPs much more quickly than simply writing down all the cost coefficients. In particular, these algorithms only produce the nonzero variables  $x_a$  and their values; all other variables are zero in the solution. In addition, this solution is integral if all demands are integral. Of course, the effectiveness of these methods relies on some assumptions on the cost coefficients  $c_a$ , assumptions which are verified in several applications.

### A Greedy Algorithm for Axial MITPs

The *greedy algorithm* below (a multi-index extension of the *North-West corner rule*) finds a feasible solution to axial MITPs in  $O(k \sum_i |A_i|)$  time, which is (for fixed  $k$ ) linear in the size of the demand data  $d_{ig}$ . This solution is in fact optimal if the cost coefficients are known to satisfy a ‘Monge property’ [3,31,32] defined below. (For  $k = 3$ , this greedy algorithm is already described in [4] to obtain a basic feasible solution).

Consider the axial  $k$  ITP with equality constraints (3) and assume that each  $A_i = \{1, \dots, |A_i|\}$ . Recalling that the demands are denoted  $d_{ig}$ , assume that  $\sum_{g \in A_i} d_{ig} = \sum_{g \in A_1} d_{1g}$  for all  $i \in K$ , a necessary and sufficient condition for the problem to be feasible.

```

PROCEDURE greedy MITP algorithm
  WHILE ( $\sum_{g \in A_i} d_{ig} > 0$  for all  $i \in K$ ) DO
    let  $a(i) = \min\{g \in A_i : d_{ig} > 0\}$ ;
    let  $\Delta = \min\{d_{i,a(i)} : i \in K\}$ ;
    let  $x_a = \Delta$ ;
    FOR  $i \in K$  DO let  $d_{i,a(i)} = d_{i,a(i)} - \Delta$ ;
  RETURN  $x$ 
END

```

### A greedy algorithm for axial MITPs

### A Monge Property

The *join*  $a \vee b$  and *meet*  $a \wedge b$  of  $a, b \in A$  are

$$(a \vee b)_i = \max\{a(i), b(i)\},$$

$$(a \wedge b)_i = \min\{a(i), b(i)\} \quad \text{for all } i \in K.$$

The cost coefficients  $(c_a)$  satisfy the *Monge property* if

$$c_{a \vee b} + c_{a \wedge b} \leq c_a + c_b \quad \text{for all } a, b \in A.$$

Note that this is just the *submodularity* of the function  $c: A \rightarrow \mathbf{R}$  defined on the product lattice  $A$ , see [3,31,32]. These references show that the above greedy algorithm returns an optimal solution for *all* feasible demands if and only if the cost function satisfies the Monge property. The latter two references also extend the greedy algorithm

- i) to the case of forbidden cells when the nonforbidden cells form a *sublattice* of  $A$ ; and
- ii) so that it returns an optimal dual solution.

They also show that optimizing a linear function over a *submodular polyhedron* is special case of the dual problem. It is shown in [32] that the primal problems are equivalent to the ‘submodular linear programs on forests’ of [8].

Cost functions  $c$  with the Monge property include typical decomposable costs (as defined above) when all the points are located on a same line or on parallel lines (one line for each factor type  $A_i$ ). For these problems, the greedy algorithm above amounts to a ‘left to right sweep’ across the points.

### Hub Heuristics for Axial MITPs

The basic idea ([30], extending earlier work on axial 3IAPs [6] and MIAPs [2] with decomposable costs) is to solve a small number of ordinary transportation problems and to expand their solutions into a feasible solution to the original MITP. For a large collection of decomposable costs arising from applications, the objective value of this feasible solution is provably within a constant factor of the optimum.

Given an index  $h$ , called the *hub*, determine, for each index  $i \neq h$ , a feasible solution to the ordinary transportation problem defined by supplies  $(d_{ij})_{j \in A(i)}$  and  $(d_{hg})_{g \in A(h)}$ . The Expand procedure below then takes as inputs these solutions  $y^{(h)} = (y^i)_{i \neq h}$  and expands them into a feasible solution  $x^{(h)}$  to the axial MITP. Its running time is  $O(|A_h| \sum_{i \neq h} |A_i|)$ .

```

FOR  $k = 1, \dots, n$ ,
PROCEDURE Expand( $h, y^{(h)}$ )
FOR  $g := 1$  TO  $n_h$  DO
   $q := 0$ ;
   $a(i) := 1$  for  $i \in K \setminus h$ ;
  WHILE( $q < d_{h,g}$ ) DO
    let  $\ell$  be such that
       $y_{a(\ell),g}^\ell = \min\{y_{a(r),g}^r : r \neq h\}$ ;
       $x_a^{(h)} := y_{a(\ell),g}^\ell$ ;
       $y_{a(r),g}^r := y_{a(r),g}^r - x_a^{(h)}$  for all  $r \in K \setminus h$ ;
       $a(\ell) := a(\ell) + 1$ ;
       $q := q + x_a^{(h)}$ ;
RETURN  $x^{(h)}$ 
END

```

### The Expand procedure for axial MITPs

In the hub heuristics for decomposable costs, the ordinary transportation problems use as cost coefficients the distances  $\delta(P_{ij}, P_{hg})$  between the corresponding points  $P_{ij}$  and  $P_{hg}$  in the metric space. The expanded MITP solution  $x^h$  would be optimum if the cost function was that of the star with center  $h$ , namely if  $c_a = \sum_{i \neq h} \delta(P_{i,a(i)}, P_{h,a(h)})$ . The *triangle-inequality* property of the distance  $\delta$  allows one to bound the cost penalty from using this  $h$ -star cost function instead of the actual decomposable cost function.

In the *single hub heuristic*, one chooses a hub  $h \in K$ ; solves these  $k - 1$  transportation problems; inputs their solutions  $y^{(h)}$  to Expand; and simply outputs the resulting MITP solution  $x^{(h)}$ . If the distance  $\delta$  satisfies the triangle inequality, the cost of this solution  $x^{(h)}$  is no more than  $k - 1$  times the optimal cost, in the worst case, for many common decomposable cost functions. The *multiple-hub heuristic* is an obvious extension whereby one performs the single-hub heuristic  $k$  times, once for each  $h \in K$ , and retains the best solution. This amounts to solving  $\binom{K}{2}$  ordinary transportation problems. Under the same assumptions as above and for many common decomposable cost functions, the cost of the resulting solution is less than twice the optimum cost in the worst case.

### Keywords

Nonlinear optimization; Multilevel; Bilevel;

Hierarchical; Multidisciplinary design

*Multilevel*, or *hierarchical*, programming problems (MLP) are constrained optimization programs in which subsets of the solution set are themselves solution sets of other, lower-level optimization programs. Several general MLP problem statements exist. They differ from one another in the specifics of optimization variable distribution among the levels and the definition of the objectives and constraints at particular levels.

Given a set of objectives  $\{f_i\}_{i=1, \dots, M}$  with  $f_i: \mathbf{R}^n \rightarrow \mathbf{R}$  and a vector of variables  $x \in \mathbf{R}^n$ , partitioned into subsets

$x = (x_1, \dots, x_M)$  for some integer  $M$  denoting the number of subsystems, a prototypical form of MLP may be stated as follows:

$$\begin{cases} \min_{x_1 \in S_1} & f_1(x) \\ \text{s.t.} & x_2 \in \operatorname{argmin}_{x_2 \in S_2} \{f_2(x)\} \\ & \vdots \\ & x_M \in \operatorname{argmin}_{x_M \in S_M} \{f_M(x)\}, \end{cases}$$

where the optimization problem at each level  $i$  controls its own subset of variables  $x_i$ , while the other subsets of variables  $x_1, \dots, x_{i-1}, x_{i+1}, x_M$  serve as parameters. The constraint set for each level is  $S_i \equiv \{x: h_i(x) = 0, g_i(x) \geq 0\}$  with  $h_i: \mathbf{R}^n \rightarrow \mathbf{R}^{m^{h_i}}$  and  $g_i: \mathbf{R}^n \rightarrow \mathbf{R}^{m^{g_i}}$  for some integers  $m^{h_i}, m^{g_i}$ .

This form of MLP inspired by the work of H. Stackelberg [92] can be viewed as an  $M$ -player Stackelberg game [18,84]. Its interpretation is that of  $M$  autonomous players or decision makers seeking to minimize their (possibly constrained) objective functions while manipulating subsets of decision or design variables disjoint from those of other decision makers. The higher-level problems are implicit in the variables of the lower-level problems. This formulation has been studied widely in the bilevel case. See, for example, [15] and the references therein. In general, all problem levels, but the outermost one, may contain a number of concurrent optimization problems.

A related variant of the problem, known as the *generalized bilevel programming problem*, represents the reaction of the lower-level problem to decisions made by the upper-level problem via a solution of an equilibrium problem stated as a variational inequality:

$$\begin{cases} \min_{\substack{x \in X, \\ y \in Y(x)}} & f_1(x, y) \\ \text{s.t.} & \langle f_2(x, y), y - z \rangle \leq 0 \quad \text{for all } z \in Y(x), \end{cases}$$

where the upper-level domain  $X$  is such that the lower-level domain  $Y(x)$  is not empty. This formulation was introduced by P. Marcotte in [63] and studied in [45,64], and [71].

Multilevel problems may be partitioned into two classes with respect to another criterion [100]. In one of the classes, upper-level optimization problems depend on the corresponding lower-level ones through

the *optimal value functions* (or the *marginal functions*) of the lower-level problems. An optimal value function represents the value of a lower-level objective function at a solution of that lower-level problem. In the other class, upper-level problems depend on the corresponding lower-level problems through the actual optimal solutions of the latter. An example of two such formulations in engineering design optimization will be given further.

Multilevel programming problems arise in numerous applications where the structure of the application involves hierarchical *decision making* or where the sheer size and complexity of the problem necessitates partitioning of the system and processing the subsystems in a hierarchical fashion. Information on applications of multilevel optimization in such varied areas as power systems, water resource systems, urban traffic systems, and river pollution control can be found in [36,50,51,52,62,69,70,85], and many other references. The use of multilevel algorithms in engineering control is well documented, for instance, in [46] and [57].

The broad area of *multidisciplinary design optimization* (MDO) – a term that denotes a large set of research subjects and practical techniques for the design of complex coupled engineering systems – is particularly amenable to the use of multilevel methods, due to the extreme computational expense and the organizational complexity of the field. For instance, the design of aircraft involves aerodynamics, structural analysis, control, weights, propulsion, and cost, to list a few disciplines. The complexity and expense of each discipline have assured that most disciplines have developed into vast, autonomous fields of study, so that practically feasible optimization methods that involve the contributing disciplines must take into account such an *autonomy* and the hierarchical organization. Maintaining disciplinary autonomy while accounting for interdisciplinary subsystem couplings and allowing for integrated system optimization with respect to system and interdisciplinary objectives is one of the tasks of MDO. Overviews of multidisciplinary optimization may be found in [6] and [90].

Practitioners of engineering have been using multilevel methods, in some form, since optimization algorithms made their appearance in engineering problems. The seminal works [60,65], and [98] contributed

to a systematic development and understanding of hierarchical optimization. Multilevel methods have been studied extensively in application to multidisciplinary design ([16,17,22,96,97]) and single-discipline design areas that give rise to large problems, such as structural optimization (e. g., [74,87,91]). Engineering multilevel optimization has always had a strong connection with *multi-objective optimization* (e. g., [53]).

### Problem Formulation

The procedure of formulating an engineering design problem as a multilevel or a bilevel problem is difficult and depends on the complexity and size of the problem. The general components in formulating a multilevel optimization problem are as follows:

- The original problem is studied to determine its structure. Structure is of paramount importance in deciding to adopt a particular formulation. For instance, most formulations assume that the problem subsystems share only a relatively small number of variables, i. e., that the *bandwidth of interdisciplinary coupling* is relatively small.
- The problem is partitioned into a system (or upper-level) problem and subsystem (or lower-level) problems. Decisions are made on inclusions of particular variables and constraints into the system and subsystems. Decisions are also made on the form of the system and subsystem objectives.
- Finally, algorithms are selected for solving the system and subsystem optimization problems. One must distinguish a formulation of the problem from the algorithm used to solve that formulation. While some of the multilevel formulations can be easily shown to be mathematically equivalent to the original problem with respect to solution sets, they may not be equivalent with respect to other attributes, such as constraint qualifications and optimality conditions. Hence the numerical properties of algorithms applied to different formulations vary widely [8,9,10].

Problem *decomposition* constitutes a special area of study. In general, decomposition techniques take advantage of the problem structure and depend on the strength and bandwidth of couplings among the subsystems. *Separable* and partially separable problems are particularly amenable to decomposition.

Two types of decomposition may be considered in design optimization. Coarse-grained decomposition with respect to disciplines presents no difficulty, because the design problem initially consists of autonomous parts. The difficulty at this level of problem formulation is in *integration* or *synthesis*. However, in realistic applications, even though the coarse-grained decomposition is frequently obvious, the complexity of the problem requires that a *dependence analysis* be performed in order to determine the most advantageous arrangement or sequencing of the disciplinary subsystems in the optimization procedure. Automatic techniques based on graph-theoretic foundations may be found in [78] and [79], for instance.

Finer-grained decomposition within a particular discipline may be addressed by a multitude of techniques for decomposition of mathematical programs. Extensive references on decomposition in general mathematical programming, beginning with [19] and [31], and extended in [49] and many others, can be found in [42] and [43]. Further references to decomposition techniques aimed specifically at design problems can be found in [95].

General multilevel programming presents an exceedingly difficult problem, and many multilevel formulations and algorithms of engineering design rely more on heuristics than on theoretically substantiated foundations. There are exceptions, for instance, such as those in [12,29,68], and [75]. While many engineering multilevel approaches have enjoyed success when applied to specific problems, insufficient analytical foundation and the difficulty of the problem usually mean that the approaches are not robust, and extensive ‘fine-tuning’ of heuristic parameters is required for each new problem or instance of a problem. Hence, recent years have seen renewed interest in systematic, analytically substantiated approaches to MLP. Many such developments have taken place in *bilevel optimization*.

### Bilevel Optimization

Although bilevel optimization problems (BLP) form the simplest case of multilevel optimization, they are very difficult to solve and constitute a fertile research area. A survey of the field can be found in [28]. A large bibliography with an emphasis on theoretical developments is also provided in [94].

The conventional general bilevel problem may be posed as follows:

$$\begin{cases} \min_{x \in X} & f_1(x, y) \\ \text{s.t.} & h_1(x, y) = 0 \\ & g_1(x, y) \geq 0, \end{cases}$$

where  $y$  solves for fixed  $x$ :

$$\begin{cases} \min_{y \in Y} & f_2(x, y) \\ \text{s.t.} & h_2(x, y) = 0 \\ & g_2(x, y) \geq 0. \end{cases}$$

The cases of linear and convex problem functions have been studied widely. A popular class of methods for the linear bilevel problem (extreme point algorithms) computes global solutions by enumerating extreme points of the lower-level feasible set (e. g., [27]). Convex bilevel problems are often solved by branch and bound methods (e. g., [15]). A survey of methods for linear and convex bilevel programming can be found in [11].

The considerably more difficult case of nonlinear and nonconvex problem functions has inspired much research activity as well but has, to date, led to few computationally successful algorithms. The existing approaches to nonlinear bilevel optimization can be classified into several categories.

### Penalty-Based Methods

This category uses penalty methods. In some algorithms (e. g., [1]), a barrier function penalizes the lower-level objective. In double-penalty methods, both the lower-level problem and the upper-level problem are approximated by sequences of unconstrained optimization problems [56,61,64]. Single or double-penalty methods are, in general, expected to converge slowly, especially for highly nonlinear problems. Thus using these methods for the usually large and nonlinear design optimization problems may be difficult.

### KKT-Based Methods

The algorithms of this category convert the bilevel problem into a nonconvex, single-level optimization problem by using the *Karush—Kuhn—Tucker conditions* (KKT conditions) of the lower-level problem as constraints on the upper-level problem [14,15,20,

37,44]. If the lower-level problem is convex, the KKT formulation is equivalent to the original formulation [14]. However, even in this case, the KKT conditions on the lower-level problem include the *complementarity slackness* condition as a constraint. The form of the complementarity condition makes the single-level problem difficult to solve. The KKT formulation suffers from an additional difficulty. Namely, it is well known from the study of the sensitivity and stability of nonlinear programming (e. g., [40]) that even if the lower-level problem behaves exceedingly well in that it satisfies such stringent assumptions as *strong second order sufficiency* and *regularity* as a *constraint qualification*, the *feasible set* of the single-level problem will generally not be differentiable with respect to  $x$ . Hence, the performance of gradient-based solvers on the transformed problem may be adversely affected.

### Descent-Based Methods

Another category of algorithms is based on solving subproblems that result in descent for the upper-level problem with gradient information of the lower-level problem used in a number of ways [34,39,59,83].

The remainder of the article will be devoted to a more detailed description of two specific approaches to nonlinear, nonconvex problems that arose from the need to solve engineering design problems. One approach is a bilevel formulation, the other is an algorithm for solving multilevel formulations.

### Examples: Collaborative Optimization

Collaborative optimization (CO) is a general approach to solving multidisciplinary design optimization problems by formulating them as nonlinear bilevel programs of special structure. CO comprises a number of methods. Its antecedents can be traced to earlier hierarchical approaches, as in [60] and [98]. The underlying idea of CO appeared in [13,80,81,82,88] and [96,97]. The approach has recently received attention under the name of *collaborative optimization* [22,23,86,93].

Given that MDO problems are naturally partitioned into subsystems along disciplinary lines, CO suggests an intuitively attractive way to formulate the optimization problem so that the autonomy of the disciplinary subsystem computations is preserved. However, the approach presents a problem that is difficult to solve by

means of conventional nonlinear programming software [7,58]. The analytical and computational aspects of CO were addressed in [9], of which the following discussion is an abstract. As a complete description of CO is lengthy, only an abbreviated version is considered here.

It is assumed that the original system is composed of a number, say  $M$ , of interdependent but autonomous systems, each of which is described by a disciplinary analysis  $A_i$ ,  $i = 1, \dots, M$ , expressed in the form

$$A_i(x_i, y_i(x_i)) = 0,$$

where, given a vector of disciplinary design variables  $x_i$ , the analysis (frequently represented by a numerical differential equation solver or simulator) is performed to yield the vector of state variables or responses  $y_i(x_i)$ . The sets of disciplinary variables  $x_i$  are not necessarily disjoint. The disciplinary constraints are usually represented by inequalities

$$c_i(x_i, y_i(x_i)) \geq 0.$$

Once the system objective and variables and the subsystem constraints and variables are identified, the bilevel problem is formed as follows:

The constraints of the system problem comprise the ‘consistency’ (or ‘coupling’ or ‘matching’) conditions that are used to drive the discrepancy among the inputs and outputs shared by the subsystems to zero. The values of the constraints are computed by solving the subsystem optimization problems, and the number of *consistency constraints* is related to the number of subsystems and variables shared among the subsystems. The form of the consistency constraints determines a particular implementation of CO.

Let  $\xi$  and  $\eta$  represent system-level variables corresponding to inputs and outputs of subsystems, respectively. Then, given  $M$  subsystems, the abbreviated system program is

$$\begin{cases} \min & F(\xi, \eta) \\ \text{s.t.} & G(\xi, \eta) = 0, \end{cases} \quad (1)$$

where

$$G(\xi, \eta) = \begin{pmatrix} g_1(\xi, \eta) \\ \vdots \\ g_M(\xi, \eta) \end{pmatrix}$$

is the set of system consistency constraints obtained by solving lower-level subproblems, each of which is of the form

$$\begin{cases} \min & \frac{1}{2} [\|\xi_i - x_i\|^2 + \|\eta_i - y(x_i)\|^2] \\ \text{s.t.} & c_i(x_i, y(x_i)) \geq 0, \end{cases} \quad (2)$$

where  $i$  is the number of the subsystem. Thus, the objective of a subsystem optimization problem is always to minimize the discrepancy between the shared variables of the subsystems, in a least squares sense, subject to satisfying the disciplinary constraints, which do not depend explicitly on the system variables passed down to the subsystems as parameters. The subsystems remain feasible during optimization, while *interdisciplinary feasibility* is gradually attained at the system level via the consistency constraints. Maintaining disciplinary feasibility is extremely important from the design perspective.

The problem now consists of a set of decoupled subproblems that can be solved independently and in parallel.

One instance of the system-level consistency conditions gives rise to the form in which CO is usually presented: namely, the consistency condition is intended to drive to zero the value function of the subproblem (2). That is,

$$g_i(\xi, \eta) = \frac{1}{2} \|\xi - x_*\|^2 + \|\eta - y(x_*)\|^2, \quad (3)$$

where  $x_*$  solves the subsystem optimization problem.

Another instance of system-level consistency conditions matches the system-level variables with their subsystem counterparts computed in subproblem

$$g_i(\xi, \eta) = (\xi - x_*, \eta - y(x_*)). \quad (4)$$

The behavior of optimization algorithms applied to the original and CO formulations will differ greatly, as the formulations are not equivalent with respect to constraint qualifications or optimality conditions.

In general, value functions are not differentiable, and this may cause difficulties for optimization algorithms applied to the system-level problem. However, under a number of strong assumptions, the constraints are locally differentiable and can usually be computed.

Derivatives of the system-level constraints with respect to the system-level design variables are the sensi-

tivities of the minima or the solutions of the subsystem-level optimization problems to parameters. The area of *sensitivity in nonlinear programming* has been studied extensively. Relevant results can be found in [40] and [41]. In particular, under the assumptions of sufficient smoothness, *second order sufficiency*, regularity as constraint qualification, and *strict complementarity slackness*, the basic sensitivity theorem (BST) proves the existence of a unique, local, continuously differentiable solution-multiplier triple for the perturbed problem. Moreover, locally, the set of active constraints remains unchanged and regularity and strict complementarity hold, allowing one to compute derivatives locally. In fact, under a number of assumptions, stronger statements can be made about the differentiability of the value function [30,77].

Under the conditions of BST, local first order derivatives of the consistency constraints (3) have a particularly simple form because, in the case of CO, the constraints of the lower-level problems do not depend on parameters. On the other hand, the first order sensitivities of solutions of the lower-level problem that form the derivatives of the consistency constraints (4), while of closed form, are expensive to compute and involve second order derivatives of the subsystem Lagrangians.

There is another feature of the CO formulation with compatibility constraints (3) that will cause difficulties for nonlinear programming algorithms applied to the system-level problem: *Lagrange multipliers* will almost never exist for the equality constrained system level problem, with all the ensuing consequences. The nonexistence of Lagrange multipliers is due to the description of the feasible region that causes the Jacobian of the system-level constraints to vanish at a solution. The formulation with compatibility constraints (4) aims to address this problem. However, the computation of derivatives for this formulation is clearly expensive, as it not only involves solving a system of equations, but also requires the computation of second order information for the subsystems. The difficulties are addressed in detail in [9].

In summary, CO is an appealing approach to design optimization; however, the bilevel nature of the problem formulation will cause difficulties for conventional nonlinear programming algorithms applied to the system-level problem. Variations, special algo-

rithms for solution, and alternatives can be found in, e. g. [33,54,55].

### Example: MAESTRO, a Class of Multilevel Algorithms

As mentioned earlier, most multilevel formulations and algorithms for engineering design problems assume that the bandwidth of coupling among the subsystems comprised by the multilevel system is small. While many problems may be stated in this way, it is becoming increasingly important to consider problems with large bandwidth of coupling where, to use an MDO expression, ‘everything affects everything else’. MAESTRO (a class of multilevel algorithms for constrained optimization; [2]) is intended for solving large nonlinear programming problems with arbitrary couplings among the naturally occurring subsystems, i. e., a particular instance of MDO problems with a single objective. The class was extended in, e. g., [5] to include a large class of steps for the nonlinear programming problem and in [3,4] to incorporate general nonlinear objectives. The class makes no assumptions on the structure of the problem, such as convexity or separability.

The algorithms of the class are based on *trust region methodology* (see, e. g., [35,38,67]) and are proven to converge under reasonable assumptions.

The idea of the MAESTRO algorithms is to attain sequential predicted *sufficient decrease conditions* for all the constrained objectives, and is a direct extension of the multilevel ideas for the equality constrained optimization problem. The approach can be summarized as follows. Given an initial approximation to the solution of the multilevel problem, the *trial step* for the multilevel problem is computed as a sum of a sequence of substeps, each of which predicts sufficient (or optimal) decrease in the quadratic model of the objective of a given subproblem, subject to maintaining predicted decrease in the models of the previous objectives. For instance, in the case of the unconstrained bilevel problem, the trial step for the bilevel problem is a sum of two substeps. The first substep is computed to predict sufficient decrease, via the quadratic model of the innermost objective  $f_2$ , for the subproblem of approximately optimizing

$$m_{f_2}(s) \equiv f_2(x_c) + \nabla f_2(x_c)^\top s + \frac{1}{2} s^\top H_2(x_c) s,$$

in the trust region of size  $\delta_{f_2}$  to produce the substep  $s_{f_2}$ , where  $x_c$  is the current approximation to the solution and  $H_2$  is the current approximation to the Hessian of  $f_2$ . The second step  $s_{f_1}$  would then approximately minimize the quadratic model of the outermost objective  $f_1$ , constructed at  $x_c + s_{f_2}$ , in the trust region of size  $\delta_{f_1}$ , subject to constraints that enforce the preservation of the predicted sufficient or optimal decrease for  $f_1$ . The total trial step is evaluated by using the merit function designed to account for the sequential processing of the objectives. The algorithm is shown to converge to critical points of the bilevel or multilevel problem. Thus, the essential difference between this approach and the classical approaches to bilevel optimization is that instead of starting from the optimality conditions for the bilevel or multilevel problem, the approach attempts to obtain decrease on the sequence of subproblem models, while preserving predicted decrease for the previously processed subproblems, and to measure progress via the use of an appropriate merit function with rigorously updated penalty parameters. It is important to emphasize that the merit function is used only to evaluate the steps, and not to compute them.

The ongoing work is concerned with practical implementation issues and applications to engineering design problems.

## Summary

Multilevel optimization has been an active research field, both in applied mathematics and in engineering design. Many open questions remain, in particular, in the area of practical computational algorithms for bilevel and multilevel problems. Overviews of some recent developments can be found in [66].

Understanding the behavior of specific, nonlinear programming algorithms applied to the system-level problem of the bilevel or multilevel formulations will present an interesting and difficult area of inquiry, and would benefit from the techniques of *nonsmooth analysis and optimization* [32,36,47], unconventional notions of constraint qualifications [24,25], and optimality [99,100].

To facilitate research and testing in the area of algorithms, one may find automatic bilevel and multilevel problem generators, as well as other sources of multilevel problems, described in [26,72,73].

Parallel computation in mechanics

Multilevel optimization methods have been developed first in the period after 1960. The main scope was to facilitate the optimization of large scale systems in industrial processes and to solve trajectory determination and prediction problems using trajectory decomposition techniques. The reader may refer in this respect to the corresponding articles [3] and [26] and to the references given there but also to the books [27] and [12]. More recent works on this subject have been published in [4,14]. It should be mentioned that certain sources concerning the ideas of multilevel optimization may be found in well-known treatises of calculus of variations and theoretical mechanics, cf. e.g. [5,10]. Indeed, the well-known procedure of variational methods in Mechanics of ‘frozen’ variables or constraints has a great

relationship with the ideas of multilevel optimization. Also the well-known iterative methods of H. Cross and G. Kany of linear structural analysis used after 1940 and before the development of computer codes based on the *finite element method* (FEM), for the calculation of framed structures, are nothing than a formulation in the ‘language’ of structural analysis of a multilevel optimization algorithm for the minimization problem of the complementary energy of the structure, expressed in terms of the bending moments of the beam and column connections.

Among the pioneers in the application of the multilevel optimization methods in mechanics and especially concerning the calculation of structures involving inequality constraints was P.D. Panagiotopoulos [19,20]. The idea was the following: Most mechanical problems can be expressed as the minimum problems of an appropriately formulated energy function. The decomposition of this initial optimization problem into smaller subproblems corresponds to the energetic decomposition of the initial mechanical problem into smaller fictitious subproblems. The mutual interaction of these subproblems yields, after an iterative procedure, the solution of the initial problem. The aforementioned method leads to the following three main applications of the multilevel optimization techniques in the framework of Mechanics and more generally in engineering sciences.

- a) Calculation of large structures.
- b) Validation of the simplifying assumptions used for the calculation of complex structures. Accuracy testing.
- c) Accuracy improvement of simplified models used for the estimation of the behavior of complex structures.

Note that in the above, the term ‘structure’ can be replaced with the term ‘systems’, meaning systems whose behavior is characterized by the solution of a minimax problem.

Since most of the multilevel techniques developed in the early sixties for the trajectory determination problems in space science are also applicable to stationarity problems, and since recently it has been proved that in the dynamic problems involving impact phenomena the functional of the action is stationary [22,23] it results that there is also a further application of the multilevel optimization methods:

- d) Calculation of the dynamic behavior of structures involving impact effects.

To the aforementioned applications the following, classical one, can be added.

- e) Solution of optimal control (minimum of weight or cost, maximum of strength) in dynamic structural analysis problems.

This article deals mainly with static systems. Concerning the application d) and e) the reader is referred to [12,27] in relation with [22,23]. In dynamic problems analogous methods to the static problems can be developed.

The classical *decomposition techniques* which are applied to optimization problems (cf. in this respect also [20, pp. 355ff]) have been extended and they can be applied also to *substationarity problems* [25], i. e. to problems of the type

$$0 \in \bar{\partial}f(x),$$

where  $f$  is a nonconvex nonsmooth energy function and  $\bar{\partial}$  denotes the generalized gradient of F.H. Clarke [7] as it has been extended by R.T. Rockafellar [25] for nonLipschitzian functionals. In this case the *variational inequalities* of the convex energy problems are replaced by *hemivariational inequalities* (cf. e. g. [8,17,20,21]) and instead of a global minimum of the convex potential or complementary energy functionals, the local minima and maxima are searched and among them the global minimum as well. For the numerical treatment of hemivariational inequalities certain numerical methods have been developed (cf. e. g. [21]) and among them, the two methods described in [15] are extensions of the multilevel optimization methods to substationarity problems.

It should also be noted that most of the domain decomposition methods are special cases of the multilevel optimization algorithms, as it results easily if one considers the energy functionals corresponding to the partial differential equations studied. Then the domain decomposition leads to energy functionals which have to be minimized on the decomposed parts of the domain.

Finally, it should be mentioned that fractal geometries in optimization problems arising in Mechanics are treated by means of appropriate multilevel transformations of the problem as is will be shown further. It is evident that an optimization problem with many variables cannot always directly be decomposed into indepen-

dent optimization subproblems. The aim of the multilevel optimization is to define with respect to an optimization problem, appropriate mutually independent subproblems. Each of these when solved independently yields the optimum of the overall problem after an iterative procedure which is called second-level controller. The decomposition into subproblems is achieved by choosing some variables, called coordinating variables, which are freely manipulated by the second-level controller in such a way that the subproblems (first-level of the problem) have solutions which in fact yield the optimum of the initial problem, i. e. before its decomposition into subproblems. Here, the ideas of [3] are closely followed.

There are several different methods of transforming a given constrained optimization problem into a multilevel optimization problem. All these methods are basically combination of two methods: the *feasible decomposition method* or *model coordination method* and the *nonfeasible decomposition method* or *goal coordination method*.

Let us consider the problem

$$\begin{cases} \min_{\mathbf{x}, \mathbf{u}} & \Pi(\mathbf{x}, \mathbf{u}) \\ \text{s.t.} & \mathbf{f}(\mathbf{x}, \mathbf{u}) = 0 \\ & \mathbf{R}(\mathbf{x}, \mathbf{u}) \geq 0, \end{cases} \quad (1)$$

where  $\mathbf{x}$  is a vector in  $E_n$ ,  $\mathbf{u}$  is a vector in  $E_m$ ,  $\mathbf{f}$  is an  $n$  vector of  $C^2$  functions,  $\Pi$  is a twice continuously differentiable ( $C^2$ ) function, and  $\mathbf{R}$  is an  $r$  vector of  $C^2$  functions. To decompose, coordinating variables  $\mathbf{s}$  may be substituted not only for a single variable but also, for functions  $\mathbf{g}(\mathbf{x}, \mathbf{u})$ , so that  $\Pi$  is splitted into mutually disjoint parts and the  $\mathbf{f}$  and  $\mathbf{R}$  equations contain no common  $\mathbf{x}$ ,  $\mathbf{u}$ , or  $\mathbf{s}$  variables between the subproblems. Thus the following problem results:

$$\begin{aligned} \Pi(\mathbf{x}, \mathbf{u}, \mathbf{s}) &= \sum_{i=1}^N \Pi^{(i)}(\mathbf{x}^{(i)}, \mathbf{u}^{(i)}, \mathbf{s}^{(i)}) \\ \mathbf{f}^{(i)}(\mathbf{x}^{(i)}, \mathbf{u}^{(i)}, \mathbf{s}^{(i)}) &= 0, \quad i = 1, \dots, N, \\ \mathbf{R}^{(i)}(\mathbf{x}^{(i)}, \mathbf{u}^{(i)}, \mathbf{s}^{(i)}) &\geq 0, \quad i = 1, \dots, N. \end{aligned}$$

The  $(i)$  denotes to the  $i$ th subproblem or subsystem which must be optimized. For example in a control problem  $\mathbf{x}$  denotes the state,  $\mathbf{u}$  denotes the control and  $\mathbf{x}^{(1)}$  is the state vector for the first subsystem. Also the

coupling equations must be added:

$$\mathbf{s}^{(i)} = \mathbf{g}^{(i)}(\mathbf{x}^{(j)}, \mathbf{u}^{(j)}) \quad \text{for all } j \neq i.$$

The Lagrangian of the new problem reads

$$\begin{aligned} \widetilde{\Pi}(\mathbf{x}, \mathbf{u}, \mathbf{s}; \boldsymbol{\lambda}, \boldsymbol{\mu}, \boldsymbol{\rho}) &= \sum_{i=1}^N \Pi^{(i)} + \sum_{i=1}^N \boldsymbol{\lambda}^{(i)\top} \mathbf{f}^{(i)} + \sum_{i=1}^N \boldsymbol{\mu}^{(i)\top} (\mathbf{R}^{(i)} - \boldsymbol{\sigma}^{(i)}) \\ &\quad + \sum_{i=1}^N \boldsymbol{\rho}^{(i)\top} (\mathbf{g}^{(i)} - \mathbf{s}^{(i)}), \quad (2) \end{aligned}$$

where  $\boldsymbol{\sigma}^{(i)} \geq 0$  are additional slack variables such that

$$\mathbf{R}^{(i)} - \boldsymbol{\sigma}^{(i)} = 0.$$

$\widetilde{\Pi}$  is immediately separable into  $N$  individual subsystems, except for its last term.

In the method of nonfeasible decomposition it is assumed that  $\boldsymbol{\rho}^{(i)}$  has a known value. The term  $\boldsymbol{\rho}^{(i)\top} \mathbf{s}^{(i)}$  is put in the  $i$ th subsystem and all of the  $\boldsymbol{\rho}^{(i)\top} \mathbf{g}^{(i)}(\mathbf{x}^{(j)}, \mathbf{u}^{(j)})$  terms associated with the  $j$ th variables are put in the  $j$ th subsystem. On the other hand, in the feasible decomposition method it is assumed that  $\mathbf{s}^{(i)}$  has a known value. Moreover, all of the  $\boldsymbol{\rho}^{(i)\top} [\mathbf{g}^{(i)}(\mathbf{x}^{(j)}, \mathbf{u}^{(j)}) - \mathbf{s}^{(i)}]$  terms associated with the  $j$ th variables are put in the  $j$ th subsystem. In both cases, the optimization problem is separable and each subsystem can be optimized independently. Equation (2) is rewritten in more compact form as

$$\begin{aligned} \widetilde{\Pi}(\mathbf{x}, \mathbf{v}; \boldsymbol{\lambda}, \boldsymbol{\mu}, \boldsymbol{\rho}) &= F(\mathbf{x}, \mathbf{v}) + \boldsymbol{\lambda}^\top \mathbf{f}(\mathbf{x}, \mathbf{v}) + \boldsymbol{\mu}^\top [\mathbf{R}(\mathbf{x}, \mathbf{v}) - \boldsymbol{\sigma}] \\ &\quad + \boldsymbol{\rho}^\top \mathbf{h}(\mathbf{x}, \mathbf{v}), \quad (3) \end{aligned}$$

where  $\boldsymbol{\sigma} \geq 0$ ,  $\mathbf{v}$  represents  $\mathbf{u}$  and  $\mathbf{s}$  and  $\mathbf{h}(\mathbf{x}, \mathbf{v})$  denotes all  $\mathbf{g}^{(i)} - \mathbf{s}^{(i)}$ ,  $\boldsymbol{\rho}$  is a Lagrange multiplier vector of the same dimension as  $\mathbf{g}$ ,  $\boldsymbol{\mu}$  is an  $r$  vector including all Lagrange multipliers, and  $\boldsymbol{\lambda}$  is an  $n$  vector including all Lagrange multipliers.

The Kuhn–Tucker theory of nonlinear programming [9] implies that if  $\Pi(\mathbf{x}, \mathbf{v})$  has a critical point at  $(\mathbf{x}^0, \mathbf{v}^0)$  such that the constraint equations in (1), are satisfied, and if the rank of

$$\left[ \left( \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \right)^\top \left( \frac{\partial \mathbf{R}}{\partial \mathbf{y}} \right)^\top \left( \frac{\partial \mathbf{h}}{\partial \mathbf{y}} \right)^\top \right]$$

is full and equals the rank of

$$\left[ \left( \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \right)^\top \left( \frac{\partial \mathbf{R}}{\partial \mathbf{y}} \right)^\top \left( \frac{\partial \mathbf{h}}{\partial \mathbf{y}} \right)^\top \left( \frac{\partial \Pi}{\partial \mathbf{y}} \right)^\top \right], \quad (4)$$

where

$$\mathbf{y} \equiv \begin{pmatrix} \mathbf{x} \\ \mathbf{v} \end{pmatrix}$$

at  $(\mathbf{x}^0, \mathbf{v}^0)$ , then a set of unique Lagrange multipliers  $\lambda^0$ ,  $\mu^0$  and  $\rho^0$  exist at the critical point. The necessary conditions for a critical point (local minimum) are

$$\frac{\partial \tilde{\Pi}}{\partial \mathbf{x}} = \frac{\partial \tilde{\Pi}}{\partial \mathbf{v}} = 0, \quad \mu_i R_i = 0, \quad \mathbf{R} \geq 0, \quad \boldsymbol{\mu} \leq 0, \quad (5)$$

$$\frac{\partial \tilde{\Pi}}{\partial \boldsymbol{\lambda}} = \mathbf{f}^\top = 0, \quad \frac{\partial \tilde{\Pi}}{\partial \boldsymbol{\rho}} = \mathbf{h}^\top = 0. \quad (6)$$

If  $\Pi(\mathbf{x}, \mathbf{v})$  is convex, if  $f_i(\mathbf{x}, \mathbf{v})$  and  $h_i(\mathbf{x}, \mathbf{v})$  are convex for  $\lambda_i^0$  and  $\rho_i^0$  positive, or if  $f_i(\mathbf{x}, \mathbf{v})$ ,  $h_i(\mathbf{x}, \mathbf{v})$ ,  $R_i(\mathbf{x}, \mathbf{v})$  are concave for  $\lambda_i^0$ ,  $\rho_i^0$ ,  $\mu_i^0$  negative, and the above necessary conditions are satisfied, then  $\Pi(\mathbf{x}^0, \mathbf{v}^0)$  is the absolute minimum of (1) and  $\tilde{\Pi}$  has a global saddle point at  $(\mathbf{x}^0, \mathbf{v}^0)$ ; that is,

$$\begin{aligned} \tilde{\Pi}(\mathbf{x}, \mathbf{v}; \boldsymbol{\lambda}^0, \boldsymbol{\mu}^0, \boldsymbol{\rho}^0) &\geq \tilde{\Pi}(\mathbf{x}^0, \mathbf{v}^0; \boldsymbol{\lambda}^0, \boldsymbol{\mu}^0, \boldsymbol{\rho}^0) \\ &\geq \tilde{\Pi}(\mathbf{x}^0, \mathbf{v}^0; \boldsymbol{\lambda}, \boldsymbol{\mu}, \boldsymbol{\rho}) \end{aligned}$$

for all  $\mathbf{x}, \mathbf{v}, \boldsymbol{\lambda}, \boldsymbol{\mu}$ , and  $\boldsymbol{\rho}$ . These conditions can be relaxed to local convexity and concavity such that only a local minimum and saddle point are assured.

The *nonfeasible gradient controller* of L.C. Lasdon and J.D. Schoeffler [11] has the following form: Given (1), suppose that

- $\tilde{\Pi}$  has a global saddle point at  $(\mathbf{x}^0, \mathbf{v}^0; \boldsymbol{\lambda}^0, \boldsymbol{\mu}^0, \boldsymbol{\rho}^0)$ ; and
- for any given  $\boldsymbol{\rho}$ , a finite constrained (unique) minimum (constrained by  $\mathbf{f}$  and  $\mathbf{R}$ ) exists.

Then the iterative procedure given by

$${}^{i+1}\boldsymbol{\rho} = {}^i\boldsymbol{\rho} + \Delta\boldsymbol{\rho},$$

where

$$\Delta\boldsymbol{\rho} = +\kappa \mathbf{h}(\mathbf{x}^*, \mathbf{v}^*), \quad \text{with } \kappa > 0,$$

will converge to  $\boldsymbol{\rho}^0$  and the absolute minimum of (1). Note that a local saddle point can replace a), then the

initial guess on  $\boldsymbol{\rho}$  must be within this saddle region. However, then the algorithm leads only to a local minimum. This Lasdon gradient controller can be considered as a variant of the modified *Arrow-Hurwicz gradient method* of K. Arrow, L. Hurwicz and H. Uzawa [1].

The *feasible gradient controller* of C.B. Brosilow et al. [6] has the following form: Given (1), suppose that

- a finite minimum exists at  $(\mathbf{x}^0, \mathbf{v}^0)$ ; and
- all the conditions of (5) and (6) are fulfilled except for  $\partial \tilde{\Pi} / (\partial \mathbf{s}) = 0$ , (where  $\mathbf{v}$  denotes all  $\mathbf{s}$  and  $\mathbf{u}$ ).

Then the iterative procedure given by

$${}^{i+1}\mathbf{s} = {}^i\mathbf{s} + \Delta\mathbf{s},$$

where

$$\Delta\mathbf{s} = -\kappa \left( \frac{\partial \tilde{\Pi}}{\partial \mathbf{s}} \right), \quad \text{with } \kappa > 0,$$

will converge to  $\mathbf{s}^0 = \mathbf{x}^0$  and the minimum of (1).

The good choice of  $\kappa$  is important for the gradient calculations. Then at the second level of the feasible method, we may write ([3, p. 142]) that

$$d\Pi^* = \frac{\partial \tilde{\Pi}}{\partial \mathbf{s}} d\mathbf{s} = -\kappa \frac{\partial \tilde{\Pi}}{\partial \mathbf{s}} \left( \frac{\partial \tilde{\Pi}}{\partial \mathbf{s}} \right)^\top, \quad \kappa > 0.$$

An estimate of the expected improvement is written as  $-\alpha \tilde{\Pi}^*$ ,  $\alpha > 0$ , where  $\alpha$  is usually 10% or so. Then

$$\kappa = \frac{\alpha \tilde{\Pi}^*}{\left( \frac{\partial \tilde{\Pi}}{\partial \mathbf{s}} / \partial \mathbf{s} \right) \left( \frac{\partial \tilde{\Pi}}{\partial \mathbf{s}} / \partial \mathbf{s} \right)^\top}. \quad (7)$$

In the case of nonfeasible decomposition a similar equation may be obtained [3]:

$$\kappa = \frac{\alpha \tilde{\Pi}^*}{\mathbf{g}^\top \mathbf{g}}. \quad (8)$$

Note that  $\Delta\mathbf{s}$  and  $\Delta\boldsymbol{\rho}$  become singular at the optimum if (7) and (8) are used, respectively, and therefore these values of  $\Delta\mathbf{s}$  and  $\Delta\boldsymbol{\rho}$  are not appropriate to obtain exact solutions.

There is also the possibility to apply a Newton-Raphson controller both for the feasible and for the nonfeasible method in the second level (cf. in this context [3, p. 173]).

For instance examining (5) and (6), it is obvious that the only necessary condition not satisfied by the subsystems is  $\mathbf{g} = 0$  in the nonfeasible decomposition method. Thus the Newton–Raphson method has as task to solve  $\mathbf{g} = 0$  by an iterative method at the second level.

Note that the main characteristic of the aforementioned methods, i. e. the decomposition into subsystems and the separable optimization applies also to nonsmooth convex or nonconvex optimization problems.

### Large Cable Structures

Here a possibility offered in structural analysis by the multilevel optimization algorithms is presented. Certain subproblems do not contain inequalities, i. e. are bilateral, and thus they can be treated by the available classical (i. e. based only on inequalities) FEM programs.

In the majority of *cable structures* the number of cables and nodes is large, and so an optimization problem with a large number of unknowns and constraints must be solved. Here, a multilevel optimization technique suitable for the solution of this kind of optimization problem is proposed. The initial optimization problem is decomposed into a number of subproblems. In the ‘first level’ of the calculation, each subproblem is optimized separately, and in the ‘second level’ the solutions of these subproblems are combined to yield the overall optimum.

It is interesting to note that some of these subproblems constitute minimization problems without inequality constraints (corresponding to classical bilateral structures), and the algorithms for their numerical treatment are much faster. The initial problem is decomposed into two subproblems: the first involves only the displacement terms and corresponds to a structure resulting from the given one by considering that all the cables act as bars (capable of having compressive forces), and the second, including only the slackness terms, corresponds to a hypothetical slack structure. In order to perform the decomposition, the potential energy of the structure is written in the form

$$\Pi(\mathbf{u}, \mathbf{v}) = \Pi'(\mathbf{u}) + \Pi''(\mathbf{v}) + \mathbf{u}^\top \mathbf{G}\mathbf{K}_0\mathbf{v}, \quad (9)$$

where

$$\Pi'(\mathbf{u}) = \frac{1}{2}\mathbf{u}^\top \mathbf{K}\mathbf{u} - \mathbf{u}^\top (\mathbf{G}\mathbf{K}_0\mathbf{e}_0 + \mathbf{p}) \quad (10)$$

and

$$\Pi''(\mathbf{v}) = \frac{1}{2}\mathbf{v}^\top \mathbf{K}_0\mathbf{v} + \mathbf{v}^\top (\mathbf{a} - \mathbf{K}_0\mathbf{e}_0). \quad (11)$$

In the above equations  $\mathbf{u}$ ,  $\mathbf{v}$ ,  $\mathbf{p}$ ,  $\mathbf{e}_0$  are the displacements, slackness, loading and initial strain vectors respectively,  $\mathbf{K}_0$  is the natural stiffness matrix,  $\mathbf{K}$  is the stiffness matrix of the assembled structure and  $\mathbf{G}$  is the equilibrium matrix. Introducing the variable  $\mathbf{w}$  the minimization problem (9) takes the form

$$\min \Pi(\mathbf{u}, \mathbf{v}, \mathbf{w}) = \Pi'(\mathbf{u}) + \Pi''(\mathbf{v}) + \mathbf{u}^\top \mathbf{G}\mathbf{K}_0\mathbf{w}.$$

The Lagrangian of this problem is

$$\Pi_1(\mathbf{u}, \mathbf{v}, \mathbf{w}) = \Pi(\mathbf{u}, \mathbf{v}, \mathbf{w}) + \boldsymbol{\rho}^\top (\mathbf{v} - \mathbf{w}),$$

where  $\boldsymbol{\rho}$  is the vector of the Lagrange multipliers. The decomposition can be performed by means of two methods: the nonfeasible gradient controller method of Lasdon and Schoeffler and the feasible gradient controller method of Brosilow, Lasdon and Pearson [11]. In the nonfeasible gradient controller method the value of  $\boldsymbol{\rho}$  is supposed to be constant in the first level, say  $\boldsymbol{\rho}_1$ , and the minimization problem decomposes into the two subproblems

$$\min_{\mathbf{u}, \mathbf{w}} \{ \Pi'(\mathbf{u}) + \mathbf{u}^\top \mathbf{G}\mathbf{K}_0\mathbf{w} - \boldsymbol{\rho}_1^\top \mathbf{w} \}$$

and

$$\min_{\mathbf{v}} \{ \Pi''(\mathbf{v}) + \boldsymbol{\rho}_1^\top \mathbf{v} : \mathbf{v} + \mathbf{p} \geq 0 \}.$$

After performing the optimization, the values of  $\mathbf{u}$ ,  $\mathbf{v}$  and  $\mathbf{w}$ , e. g.  $\mathbf{u}_1$ ,  $\mathbf{v}_1$  and  $\mathbf{w}_1$ , result. It is obvious that  $\mathbf{v}_1 \neq \mathbf{w}_1$ . The task of the second level is to estimate a new value of  $\boldsymbol{\rho}$ , e. g.  $\boldsymbol{\rho}_2$  by means of the equation

$$\boldsymbol{\rho}_2 = \boldsymbol{\rho}_1 + \kappa(\mathbf{v}_1 - \mathbf{w}_1), \quad \kappa > 0,$$

where  $\kappa$  is a properly chosen constant (see, e. g., [11]), and to transmit this value to the first level. The optimization is performed again, new values  $\mathbf{u}_2$ ,  $\mathbf{v}_2$  and  $\mathbf{w}_2$  result, etc., until the differences  $\mathbf{v}_i - \mathbf{w}_i$  are made negligible. The algorithm converges in a finite number of steps, provided that the minima exist [11].

In the feasible gradient controller method, the value of  $\mathbf{w}$  is taken as constant in the first level, e. g.  $\mathbf{w}_1$ , and

thus the initial problem decomposes into the two sub-problems

$$\min_{\mathbf{u}} \{ \Pi'(\mathbf{u}) + \mathbf{u}^\top \mathbf{G} \mathbf{K}_0 \mathbf{w}_1 \}$$

and

$$\min_{\mathbf{v}, \boldsymbol{\rho}} \{ \Pi_1''(\mathbf{v}) + \boldsymbol{\rho}^\top (\mathbf{v} - \mathbf{w}_1'') : \mathbf{v} + b \geq 0 \}.$$

As a result of the optimization, the values of  $\mathbf{u}$ ,  $\mathbf{v}$  and  $\boldsymbol{\rho}$ , e. g.  $\mathbf{u}_1$ ,  $\mathbf{v}_1$  and  $\boldsymbol{\rho}_1$  are calculated. By means of the second level a new value of  $\mathbf{w}$ , e. g.  $\mathbf{w}_2$ , is estimated and transmitted to the first level. This value is given by the equation

$$\mathbf{w}_2 = \mathbf{w}_1 - \kappa \left( \frac{\partial \Pi_1(\mathbf{u}, \mathbf{v}, \mathbf{w})}{\partial \mathbf{w}} \right)_{\mathbf{w}=\mathbf{w}_1}, \quad \kappa > 0,$$

where  $\kappa$  is a properly chosen constant (see, e. g., [11]). The optimization yields a new set of values  $\mathbf{u}_2$ ,  $\mathbf{v}_2$  and  $\boldsymbol{\rho}_2$  and the procedure is continued until the difference between the consecutive values of vector  $\mathbf{w}$  becomes sufficiently small.

For numerical applications the reader is referred to [20].

### Large Elastoplastic Structures

We consider here the holonomic *plasticity* model [13], (extension to nonholonomic plasticity problems is straightforward) described by the following equations:

$$\begin{aligned} \mathbf{e} &= \mathbf{F}_0 \mathbf{s}, \\ \mathbf{e} &= \mathbf{e}_0 + \mathbf{e}_E + \mathbf{e}_P, \\ \mathbf{e}_P &= \mathbf{N} \boldsymbol{\lambda}, \\ \boldsymbol{\phi} &= \mathbf{N}^\top \mathbf{s} - \mathbf{k}, \\ \boldsymbol{\lambda} &\geq 0, \quad \boldsymbol{\phi} \leq 0, \quad \boldsymbol{\phi}^\top \boldsymbol{\lambda} = 0, \end{aligned}$$

where  $\mathbf{F}_0$  is the natural flexibility matrix of the structure,  $\mathbf{e}$  the respective strain vector consisting of three parts, the initial strain  $\mathbf{e}_0$ , the elastic strain  $\mathbf{e}_E$  and the plastic strain  $\mathbf{e}_P$ ,  $\boldsymbol{\lambda}$  are the plastic multipliers vector,  $\boldsymbol{\phi}$  the yield functions,  $\mathbf{N}$  is the matrix of the gradients of the yield functions with respect to the stresses and  $\mathbf{k}$  is a vector of positive constants. The potential energy of the structure is written in the form

$$\Pi(\mathbf{u}, \boldsymbol{\lambda}) = \Pi'(\mathbf{u}) + \Pi''(\boldsymbol{\lambda}) - \mathbf{u}^\top \mathbf{G} \mathbf{K}_0 \mathbf{N} \boldsymbol{\lambda}$$

where

$$\begin{aligned} \Pi'(\mathbf{u}) &= \frac{1}{2} \mathbf{u}^\top \mathbf{K} \mathbf{u} - \mathbf{e}_0^\top \mathbf{K}_0 \mathbf{G}^\top \mathbf{u} - \mathbf{p}^\top \mathbf{u}, \\ \Pi''(\boldsymbol{\lambda}) &= \frac{1}{2} \boldsymbol{\lambda}^\top \mathbf{N}^\top \mathbf{K}_0 \mathbf{N} \boldsymbol{\lambda} + \mathbf{e}_0^\top \mathbf{K}_0 \mathbf{N} \boldsymbol{\lambda} - \mathbf{k} \boldsymbol{\lambda}. \end{aligned}$$

Again,  $\mathbf{K}$  is the stiffness matrix of the structure and  $\mathbf{K}_0$  is the inverse of  $\mathbf{F}_0$ .

The solution of the problem can be obtained by minimizing the potential energy of the structure:

$$\min \{ \Pi(\mathbf{u}, \boldsymbol{\lambda}) : \boldsymbol{\lambda} \geq 0 \}. \quad (12)$$

By introducing a new variable  $\mathbf{w}$ , (12) takes the form

$$\min \{ \Pi(\mathbf{u}, \boldsymbol{\lambda}, \mathbf{w}) = \Pi'(\mathbf{u}) + \Pi''(\boldsymbol{\lambda}) - \mathbf{u}^\top \mathbf{G} \mathbf{K}_0 \mathbf{N} \mathbf{w} : \mathbf{w} = \boldsymbol{\lambda}, \boldsymbol{\lambda} \geq 0 \}. \quad (13)$$

As in the previous section, the decomposition can be performed by the two methods of the feasible and the nonfeasible gradient controller respectively. For the sake of brevity only the nonfeasible gradient method will be shown here. The Lagrangian of (13) is first considered

$$\Pi(\mathbf{u}, \boldsymbol{\lambda}, \mathbf{w}) = \Pi(\mathbf{u}, \boldsymbol{\lambda}, \mathbf{w}) + \boldsymbol{\rho}^\top (\boldsymbol{\lambda} - \mathbf{w})$$

and the minimization problem is decomposed in the following two subproblems

$$\min_{\mathbf{u}, \mathbf{w}} \{ \Pi'(\mathbf{u}) - \mathbf{u}^\top \mathbf{G} \mathbf{K}_0 \mathbf{N} \mathbf{w} - \boldsymbol{\rho}^\top \mathbf{w} \} \quad (14)$$

and

$$\min_{\boldsymbol{\lambda}} \{ \Pi_1''(\boldsymbol{\lambda}) + \boldsymbol{\rho}^\top \boldsymbol{\lambda} : \boldsymbol{\lambda} \geq 0 \}. \quad (15)$$

In the first step it is supposed that the value of  $\boldsymbol{\rho}$  is constant (say  $\boldsymbol{\rho}_1$ ) and we take as a result from (14) and (15) the values  $\mathbf{u}_1$ ,  $\boldsymbol{\lambda}_1$  and  $\mathbf{w}_1$ . Obviously  $\boldsymbol{\lambda}_1 \neq \mathbf{w}_1$ . Then the second level controller estimates the new value of  $\boldsymbol{\rho}$  from the equation

$$\boldsymbol{\rho}_2 = \boldsymbol{\rho}_1 + \kappa (\boldsymbol{\lambda}_1 - \mathbf{w}_1), \quad \kappa > 0,$$

and transmits it to the first level, and the procedure is continued until the differences  $\boldsymbol{\lambda}_i - \mathbf{w}_i$  become appropriately small.

The same procedure can be applied also to holonomic models including hardening and to nonholonomic plasticity models [13].

## Validation and Improvements of Simplified Models

In mechanics and engineering sciences as well as in economy, simplified models are often considered for the treatment of complicated problems, e. g. concerning the calculation of stresses in complex structures. In these models it is assumed that certain quantities do not influence considerably the solution of the problem. By means of the multilevel decomposition, a method which permits the *validation* of these models and the improvement of their accuracy can be developed. This idea is explained in the sequel.

A. Consider a large structure involving also some cables and assume that due to the pretension of the cables the structure is calculated as if the cables are rods, i. e. by ignoring the fact that a cable may become slack and then it has zero stresses. Then in the equations (9)–(11)  $\mathbf{v} = 0$  and the solution of the minimum problem is obtained by solving an unconstrained minimization problem, i. e. by a linear system solver. In order to check whether the solution of the simplified model is close to the solution of the initial problem, in which some cables, say  $r$ , may become *slack*, i. e.  $v_i > 0$ ,  $i = 1, \dots, r$ , it is enough to verify whether the second level controller which gives a value of the slackness of the cables causes a significant change in the solution of the first level problem which corresponds to the simplified structure. Also the algorithm offers an improvement of the solution of the simplified model.

B. Here, the investigation of the mutual influence of two subsystems is presented. Consider two substructures connected together, for instance a cylindrical shell with a hemispherical shell covering the one end of the cylinder. The solution of the whole linear elastic structural compound minimizes, for a given external loading, the potential (or the complementary) energy of the whole structure. Let  $\mathbf{x}_1$  (respectively,  $\mathbf{x}_2$ ) be the variables of the cylindrical (respectively, the hemispherical) shell and let  $\mathbf{z}$  be the common variables at the contact line which are common in both structures. In order to decompose the potential energy into two minimum problems, one containing the unknowns of the cylindrical shell and the other of the hemispherical shell, the common variables for the cylindrical (respectively, hemispherical) shell are denoted by  $\mathbf{z}_1$  (respectively,  $\mathbf{z}_2$ ) and

thus the initial problem

$$\min_{\mathbf{x}_1, \mathbf{x}_2, \mathbf{z}} \{ \Pi(\mathbf{x}_1, \mathbf{x}_2, \mathbf{z}) = \Pi_1(\mathbf{x}_1, \mathbf{z}) + \Pi_2(\mathbf{x}_2, \mathbf{z}) \}$$

is written as

$$\min_{\mathbf{x}_1, \mathbf{x}_2, \mathbf{z}_1, \mathbf{z}_2} \{ \Pi_1(\mathbf{x}_1, \mathbf{z}_1) + \Pi_2(\mathbf{x}_2, \mathbf{z}_2) : \mathbf{z}_1 - \mathbf{z}_2 = 0 \}.$$

Here  $\Pi_1$  (respectively,  $\Pi_2$ ) denotes the potential or the complementary energy of the cylindrical (respectively, the hemispherical) shell. Thus it can be tested by the nonfeasible controller method how the difference  $\mathbf{z}_1 - \mathbf{z}_2$  influences the solution of the problem. The procedure is similar in the case of elastoplastic structures with the difference that the minimum is constrained by inequalities.

The above procedure may find applications in estimating the influence of saddles on pipelines of rigidity rings on long tubes etc.

C. Note that in all the above cases the Lagrange multipliers have a precise meaning: they correspond in the sense of energy to the chosen coordinating variables, i. e., if the coordinating variables are stresses (respectively, strains) or forces (respectively, displacements) then the coordinating Lagrange multipliers are strains (respectively, stresses) or displacements (respectively, forces). Thus the feasible and the nonfeasible decomposition method have a precise mechanical meaning. In the first case the Lagrange multipliers, i. e. the strains (respectively, the stress) are controlled while in the second one the coordinating variables, i. e. the stress (respectively, the strain) of the links between the two substructures are controlled, in order to achieve the position of equilibrium of the whole structure.

D. Some of the resulting substructures may have a known analytical solution. Then this fact facilitates the calculation and may be applied as a test for the accuracy of the resulting solution via a numerical technique, e. g. by the FEM model. The procedure is described in [24].

E. The multilevel decomposition method can be used also as estimator of the sensitivity of the final solution to small changes of the system to be optimized [24]. This method may be used for example in estimating how a partial change in a structure influences the stress

and strain field of the structure without solving twice the structure.

### Decomposition Algorithms for Nonconvex Minimization Problems

In unilateral contact problems with friction, Panagiotopoulos proposed in 1975 an algorithm [18] called later PANA-algorithm for the decomposition of the *quasivariational inequality* problems into two classical variational inequality problems which are equivalent to two minimization problems. Analogous decomposition methods of complicated problems using an analogous to [18] fixed point procedure can be applied to the treatment of much more complicated problems today involving nonconvex energy functions. This section is devoted to the study of multilevel decomposition algorithms for problems belonging to the general framework of the substationarity problems.

It is known that the equilibrium of an elastic body  $\Omega$  in adhesive contact with a support  $\Gamma$  is governed by the following problem [17,21]: Find  $u \in V$  such as to satisfy the hemivariational inequality

$$\alpha(u, v - u) + \int_{\Gamma} j_N^0(u_N, v_N - u_N) d\Gamma + \int_{\Gamma} j_T^0(u_T, v_T - u_T) d\Gamma \geq (f, v - u), \quad \forall v \in V. \quad (16)$$

Here  $u, v$  are the displacement fields,  $f$  are all the applied forces,  $(f, v)$  – usually a  $L^2$  internal product – is the work of the applied forces,  $\alpha(u, v)$  is the elastic strain energy which is usually a coercive form,  $j_N$  (respectively,  $j_T$ ) denote the nonconvex, locally Lipschitz generally nonsmooth energy density functions of the adhesive forces in the normal (respectively, the tangential) direction to the interface  $\Gamma$ . It is assumed that the normal adhesive action is independent of the tangential adhesive action. Moreover,  $j_N^0, j_T^0$  denote the directional derivative in the sense of Clarke [7], and  $u_N, v_N$  (respectively,  $u_T, v_T$ ) denote the normal (respectively, tangential) component of the displacement with respect to  $\Gamma$ . The solution of the above problem can be obtained in most cases of practical interest (cf. [21]) under certain mild hypotheses which guarantee this equivalence, by

solving the substationarity problem

$$0 \in \bar{\partial} I(u) = \bar{\partial} \left\{ \frac{1}{2} \alpha(u, u) + \int_{\Gamma} j_N(u_N) d\Gamma + \int_{\Gamma} j_T(u_T) d\Gamma - (f, u) \right\},$$

where  $\bar{\partial}$  denotes the generalized gradient of Clarke.

In engineering problems the nonconvex superpotentials (cf. e.g. [16])  $j_N$  and  $j_T$  are not independent but they depend  $j_N$  (respectively,  $j_T$ ) on the vectors  $S_T$  (respectively,  $S_N$ ), where  $S_T, S_N$  are the reactions corresponding to  $u_T, u_N$  respectively. In this case a hemivariational inequality cannot be formulated. In order to solve this problem numerically one may apply the following procedure: In the first step it is assumed that  $S_N$  is given, say,  $S_N^{(0)}$  and the problem  $(S_N^{(0)})$  enters with its work into  $(f_1^{(0)}, u)$

$$0 \in \bar{\partial} \left\{ \frac{1}{2} \alpha(u, u) + \int_{\Gamma} j_T(S_N^{(0)}, u_T) d\Gamma - (f_1^{(0)}, u) \right\} \quad (17)$$

is solved. The above problem yields a value of  $S_T$ , say  $S_T^{(1)}$ . Then the problem

$$0 \in \bar{\partial} \left\{ \frac{1}{2} \alpha(u, u) + \int_{\Gamma} j_N(S_T^{(1)}, u_N) d\Gamma - (f_2^{(1)}, u) \right\} \quad (18)$$

is solved  $(S_T^{(1)})$  enters with its work into  $(f_2^{(1)}, u)$  yielding a new value of  $S_N$ , say  $S_N^{(1)}$ , and so on until the differences  $\|S_N^{(i)} - S_N^{(i+1)}\|$  and  $\|S_T^{(i)} - S_T^{(i+1)}\|$  at each point of the discretized interface  $\Gamma$  become appropriately small. Here  $\|\cdot\|$  denotes the  $\mathbf{R}^3$ -norm because the values are checked pointwise. The first (respectively, second) problem with  $j_N = 0$  (respectively, with  $j_T = 0$ ) corresponds to the first level (respectively, to the second level). Applications of the above procedure can be found in [15,20,21].

### Structures with Fractal Interfaces

In this section the attention is focused on the fractal geometry of interfaces where their behavior is modeled by means of an appropriate nonmonotone contact and friction mechanism. The interfaces of fractal geometry are analyzed here as a sequence of classical interface

subproblems. These classical subproblems result from the consideration of the *fractal interface* as the unique ‘fixed point’ of a given *iterative function system* (IFS), which consists of  $N$  contractive mappings  $w_i: \mathbf{R}^2 \rightarrow \mathbf{R}^2$  with contractivity factors  $0 \leq s_i < 1$ ,  $i = 1, \dots, N$  [2]. According to this procedure, a fractal set  $A$  is the ‘fixed point’ of a transformation  $W$  i. e.

$$A = W(A) = \bigcup_{i=1}^N W_i(A),$$

where  $W_i$  is defined

$$W_i(B) = \{w_i(x): x \in B\}, \quad \forall B \in H(\mathbf{R}^2).$$

Generally a *fractal set*  $A$  is given by the relation:

$$A = \lim_{n \rightarrow \infty} W^{(n)}(B), \quad \forall B \in H(\mathbf{R}^2),$$

where  $H(\mathbf{R}^2)$  is the space of all compact subsets of  $\mathbf{R}^2$ . Thus each level corresponds to a classical geometry approximating the fractal geometry. Within each level a new optimization problem is solved with the new data. Thus the multilevel character of the optimization problem results from the necessity to take into account the fractal geometry.

In the sequel a linear elastic structure occupying a subset  $\Omega$  of  $\mathbf{R}^3$  is considered. In its undeformed state the structure has a boundary  $\Gamma$  which is decomposed into two mutually disjoint parts  $\Gamma_U$  and  $\Gamma_F$ . It is assumed that on  $\Gamma_U$  (respectively,  $\Gamma_F$ ) the displacements (respectively, the tractions) are given. In the structure  $\Omega$  some cracks with interfaces  $\Phi$  of fractal type are formed. These cracks in brittle materials frequently propagate along one or more irregular ways. In this case the fracture system may be considered to be a cluster of branches propagating in such a way that new branches in the  $n + 1$  step are successively created from a former branch at the  $n$  step. In other words the fracture system can be modeled by an IFS procedure. Regarding now the boundary conditions on  $\Phi$ , it is assumed that nonmonotone, possibly multivalued laws describe the behavior of each interface in the normal and tangential directions. More specifically, it is assumed that the following boundary conditions hold:

$$\begin{aligned} -S_N &\in \bar{\partial} j_N(u_N, x), \\ -S_T &\in \bar{\partial} j_T(u_T, x). \end{aligned}$$

Then according to the previous section, an equilibrium position of  $\Omega$  is characterized by the hemivariational inequality (16).

In this case, where the fractured body  $\Omega$  with fractal interfaces  $\Phi$  is studied, it is necessary to substitute in (16) the domain  $\Gamma$  with  $\Phi$ . As it has been mentioned above,  $\Phi$  is the fixed point of a given transformation denoted by  $W$ , i. e.

$$\begin{aligned} \Phi &= W\Phi, \\ \Phi^{(n+1)} &= W\Phi^{(n)}, \\ \Phi_{n \rightarrow \infty}^{(n)} &\rightarrow \Phi. \end{aligned}$$

Thus, for each approximation  $\Phi^{(n)}$  of the fractal interface  $\Phi$  a structure  $\Omega^{(n)}$  must be solved. Since  $\Phi^{(n)}$  is an interface set with classical geometry the solutions  $u^{(n)}$  and  $\sigma^{(n)}$  (where  $u^{(n)}$  and  $\sigma^{(n)}$  are the corresponding displacement and stress fields) are obtained using numerical procedures for the solution of (17) and (18). This procedure is repeated several times by increasing  $n$ ; at the limit  $n \rightarrow \infty$ ,  $u^{(n)}$  and  $\sigma^{(n)}$  give the solution of the fractal interface problem.

Multi-objective programming; Combinatorial optimization

It is well known that, on the one hand, *combinatorial optimization* (CO) provides a powerful tool to formulate and model many optimization problems, on the

other hand, a multi-objective (MO) approach is often a realistic and efficient way to treat many real world applications. Nevertheless, until recently, Multi-objective combinatorial optimization (MOCO) did not receive much attention in spite of its potential applications. One of the reason is probably due to specific difficulties of MOCO models. We can distinguish three main difficulties. The first two are the same as those existing for multi-objective integer linear programming (MOILP) problem (cf. ► **Multi-objective Integer Linear Programming**), i. e.

- the number of *efficient solutions* may be very large;
- the nonconvex character of the feasible set requires to device specific techniques to generate the so-called ‘non-supported’ efficient solutions (cf. ► **Multi-objective Integer Linear Programming**).

A particular single CO problem is characterized by some specificities of the problem, generally a special form of the constraints; the existing methods for such problem use these specificities to define efficient ways to obtain an optimal solution. For MOCO problem, it appears interesting to do the same to obtain the set of efficient solutions. Consequently, and contrary to what is often done in MOLP and MOILP methods, a third difficulty is to elaborate methods avoiding to introduce additional constraints so that we preserve during all the procedure the particular form of the constraints.

The general form of a MOCO problem is

$$(P) \begin{cases} \min_{X \in S} & z_k(X) = c_k X, \\ & k = 1, \dots, K, \\ \text{where} & S = D \cap B^n \\ \text{with} & X(n \times 1), \\ & B = \{0, 1\} \end{cases}$$

and  $D$  is a specific polytope characterizing the CO problem: assignment problem, knapsack problem, traveling salesman problem, etc.

There exists several surveys on MOCO; some are devoted to specific problems (i. e., the particular form of  $D$ ): the shortest path problem [8], transportation networks [2], and the scheduling problem [6,7]; the survey [9] is more general examining successively the literature on MO assignment problems, knapsack problems, network flow problems, traveling salesman problems, location problems, set covering problems.

In the present article we put our attention on the existing methodologies for MOCO. First we examine how to determine the set  $E(P)$  of all the efficient solutions and we distinguish three approaches: direct methods, two-phase methods and heuristic methods. Subsequently we analyse interactive approaches to generate a ‘good compromise’ satisfying the decision maker.

## Generation of $E(P)$

### Direct Methods

The first idea is to use intensively classical methods for single objective problem (P) existing in the literature to determine  $E(P)$ . Of course, each time a feasible solution is obtained the  $k$  values  $z_k(X)$  are calculated and compared with the list  $\widehat{E(P)}$  containing all the feasible solutions already obtained and non dominated by another generated feasible solution. Clearly,  $\widehat{E(P)}$ , called the *set of potential efficient solutions*, plays the role of the so-called ‘incumbent solution’ in single objective methods. At each step,  $\widehat{E(P)}$  is updated and at the end of the procedure  $E(P) = \widehat{E(P)}$ . Such extension of single objective method is specially designed for enumerative procedure based on a *branch and bound* approach. Unfortunately, in a MO framework, a node of the branch and bound tree is less often fathomed than in the single objective case, so that logically such MO procedure is less efficient.

We describe below an example of such direct method, extending the well known Martello–Toth procedure, for the multi-objective *knapsack problem* formulated as

$$\begin{cases} \max & z_k(X) = \sum_{j=1}^n c_j^{(k)} x_j, \quad k = 1, \dots, K, \\ & \sum_{j=1}^n w_j x_j \leq W \quad x_j = (0, 1). \end{cases}$$

The following typical definitions are used ( $k = 1, \dots, K$ ):

- $O_k$ : variables order according to decreasing values of  $c_j^k/w_j$ .
- $r_j^{(k)}$ : the rank of variable  $j$  in order  $O_k$ .
- $\Theta$ : variables order according to increasing values of  $\sum_{k=1}^K r_j^{(k)}/K$ .

We assume that variables are indexed according to ordinal preference  $\Theta$ .

At any node of the branch and bound tree, variables are set to 0 or 1; let  $B_0$  and  $B_1$  denote the index sets of variables assigned to the values 0 and 1, respectively. Let  $F$  be the index set of free variables which always follow, in the order  $\mathcal{O}$ , those belonging to  $B_1 \cup B_0$ . If  $i - 1$  is the last index of fixed variables, we have  $B_1 \cup B_0 = \{1, \dots, i - 1\}$ ;  $F = \{i, \dots, n\}$ .

Initially,  $i = 1$ . Let

- $\overline{W} = W - \sum_{j \in B_1} w_j \geq 0$  be the leftover capacity of the knapsack.
- $\underline{Z} = (\underline{z}_k = \sum_{j \in B_1} c_j^{(k)})_{k=1, \dots, K}$  be the criteria values vector obtained with already fixed variables.

$\widehat{E(P)}$  contains nondominated feasible values  $\underline{Z}$  and is updated at each new step.

Initially,  $\underline{z}_k = 0, \forall k$ , and  $\widehat{E(P)} = \emptyset$ .

- $\overline{Z} = (\overline{z}_k)$  be the vector whose components are upper bounds of feasible values respectively for each objective at considered node. These upper bounds are evaluated separately, for instance as in the Martello–Toth method.

Initially,  $\overline{z}_k = \infty, \forall k$ .

A node is fathomed in the following two situations:

- $\{j \in F: w_j < \overline{W}\} = \emptyset$ ; or
- $\overline{z}$  is dominated by  $z^* \in \widehat{E(P)}$ .

When the node is fathomed, the backtracking procedure is performed: a new node is build up by setting to zero the variable corresponding to the last index in  $B_1$ . Let  $t$  be this index:

$$\begin{aligned} B_1 &\leftarrow B_1 \setminus \{t\}, \\ B_0 &\leftarrow (B_0 \cap \{1, \dots, t - 1\}) \cup \{t\}, \\ F &\leftarrow \{t + 1, \dots, n\}. \end{aligned}$$

When the node is nonfathomed, a new node of the branch and bound tree is build up for next iteration, as follows:

- Define  $s$  to be the index variable such that

$$\max \left\{ l \in F: \sum_{j=i}^l w_j < \overline{W} \right\}.$$

If  $w_i > \overline{W}$ , set  $s = i - 1$ .

- If  $s \geq i$ :

$$\begin{aligned} B_1 &\leftarrow B_1 \cup \{i, \dots, s\}, \\ B_0 &\leftarrow B_0, \\ F &\leftarrow F \setminus \{i, \dots, s\}. \end{aligned}$$

If  $s = i - 1$ ,

$$\begin{aligned} B_1 &\leftarrow B_1 \cup \{r\}, \\ B_0 &\leftarrow B_0 \cup \{i, \dots, r - 1\}, \\ F &\leftarrow F \setminus \{i, \dots, r\}, \end{aligned}$$

with  $r = \min \{j \in F: w_j < \overline{W}\}$ .

The procedure stops when the initial node is fathomed and then  $E(P) = \widehat{E(P)}$ . An illustration is given in [10].

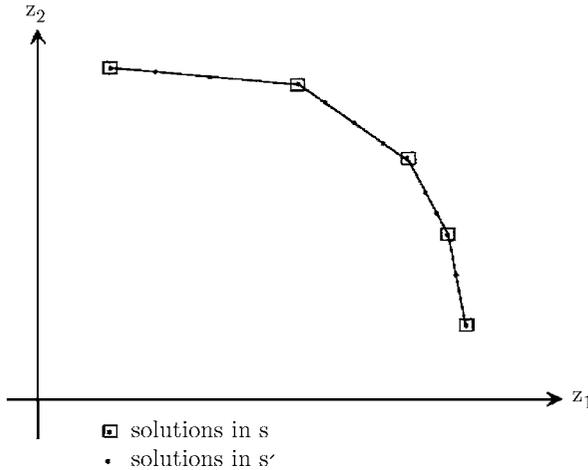

### Two-Phase Method

Such an approach is particularly well designed for bi-objective MOCO problems. The first phase consists to determine the set  $SE(P)$  of supported efficient solutions (see ► **Multi-objective Integer Linear Programming**). Let  $S \cup S'$  be the list of supported efficient solutions already generated;  $S$  is initialized with the two efficient optimal solutions respectively of objectives  $z_1$  and  $z_2$ . Solutions of  $S$  are ordered by increasing value of criterion 1; let  $X_r$  and  $X_s$  be two consecutive solutions in  $S$ , thus with  $z_{1r} < z_{1s}$  and  $z_{2r} > z_{2s}$ , where  $z_{kl} = z_k(X_l)$ . The following single-criterion problem is considered:

$$(P_\lambda) \quad \begin{cases} \min & z_\lambda(X) = \lambda_1 z_1(X) + \lambda_2 z_2(X) \\ & X \in S = D \cap B^{(n)} \\ & \lambda_1 \geq 0, \quad \lambda_2 \geq 0. \end{cases}$$

This problem is optimized with a classical single objective CO algorithm for the values  $\lambda_1 = z_{2r} - z_{2s}$  and  $\lambda_2 = z_{1s} - z_{1r}$ ; with these values the search direction  $z_\lambda(X)$  corresponds in the objective space to the line defined by  $Z_r$  and  $Z_s$ . Let  $\{X^t: t = 1, \dots, T\}$  be the set of optimal solutions obtained in this manner and  $\{Z_t: t = 1, \dots, T\}$  their images in the objective space. There are two possible cases:

- $\{Z_r, Z_s\} \cap \{Z_t: t = 1, \dots, T\} = \emptyset$ : Solutions  $X^t$  are new supported efficient solutions.  $X^1$  and  $X^T$ , provided  $T > 1$ , are put in  $S$  and, if  $T > 2$ ,  $X^2, \dots, X^{T-1}$  are put in  $S'$ . It will be necessary at further steps to consider the pairs  $(X^r, X^1)$  and  $(X^T, X^s)$
- $\{Z_r, Z_s\} \subset \{Z_t: t = 1, \dots, T\}$ : Solutions  $\{X^t: t = 1, \dots, T\} \setminus \{X^r, X^s\}$  are new supported efficient solutions giving the same optimal value as  $X^r$  and  $X^s$  for  $z_\lambda(X)$ ; we put them in list  $S'$ .

**Multi-objective Combinatorial Optimization, Figure 1**  
 $SE(P) = S \cup S'$

This first phase is continued until all pairs  $(X^r, X^s)$  of  $S$  have been examined without extension of  $S$ .

Finally, we obtain  $SE(P) = S \cup S'$  as illustrated in Fig. 1.

The purpose of the second phase is to generate the set  $NSE(P) = E(P) \setminus SE(P)$  of nonsupported efficient solutions. Each nonsupported efficient solution has its image inside the triangle  $\Delta Z_r Z_s$  determined by two successive solutions  $X^r$  and  $X^s$  of  $SE(P)$  (see Fig. 1). So each of the  $|SE(P)| - 1$  triangles  $\Delta Z_r Z_s$  are successively analysed. This phase is more difficult to manage and is dependent of the particular MOCO problem analysed; in general, this second phase is achieved using partly a classical single objective CO method. An example of such second phase is given in ► [Bi-objective Assignment Problem](#) and in [14] for the bi-objective knapsack problem.

### Heuristic Methods

As pointed out in [9,10,14], it is unrealistic to extend the exact methods describe above to MOCO problems with more than two criteria or more than a few hundred variables; the reason is that these methods are too consuming time. Because a *metaheuristic*, simulating annealing (SA), tabu search (TS), genetic algorithms (GA), etc., provide, for the single objective problem, excellent solutions in a reasonable time, it appeared logical to try to adapt these metaheuristics to a multi-objective framework.

The seminal work in this direction is the 1993 Ph.D. thesis of E.L. Ulungu, which gave rise to the so-called *MOSA method* to approximate  $E(P)$  (see, in particular, [11]). After this pioneer study, this direction has been tackled by other research teams: P. Czyzak and A. Jaszkiwicz ([3]) proposed another way to adapt simulating annealing to a MOCO problem; independently, [4,5] and [1] did the same with tabu search, the later combining also tabu search and genetic algorithms; genetic algorithms are also used in [13].

The principle idea of MOSA method can be resumed in short terms. One begins with an initial iterate  $X_0$  and initializes the set of potentially efficient points  $PE$  to just contain  $X_0$ . One then samples a point  $Y$  in the neighborhood of the current iterate. But instead of accepting  $Y$  if it is better than the current iterate on an objective: we now accept it if it is *not dominated* by any of the points currently in the set  $PE$ . If it is not dominated, we make  $Y$  the current iterate, add it to  $PE$ , and throw out any point in  $PE$  that are dominated by  $Y$ . On the other hand, if  $Y$  is dominated, we still make it the current iterate with some probability. In this way, as we move the iterate through the space, we simultaneously build up a set  $PE$  of potentially efficient points. The only complicated aspect of this scheme is the method for computing the acceptance probability for  $Y$  when it is dominated by a point in  $PE$ . The MOSA method is described in details in [11] and in ► [Bi-objective Assignment Problem](#).

### Interactive Determination of a Good Compromise

The general idea of *interactive methods* is described in ► [Multi-objective Integer Linear Programming](#). Two types of methods can be distinguished, which we treat in the following subsections.

### Goal Programming

As pointed out in [9], this methodology is often used by American researchers to treat several case studies. The general idea of *goal programming* method is to introduce for each objective  $k$  deviation variables  $d^+$  and  $d^-$ , respectively by excess and by default, with respect to a certain a priori goal  $g_k$ , so that goal constraints are defined. If some priorities expressed by some weights  $p_k$  are given, this results in a single-objective problem  $(P_g)$

defined by the global weighted deviation function:

$$(P_g) \quad \begin{cases} \min & \sum_{k=1}^K p_k d_k^- \\ \text{s.t.} & z_k(X) + d_k^+ - d_k^- = g_k, \quad \forall k, \\ & X \in S = D \cap B^n. \end{cases}$$

When a solution is obtained, the decision maker can possibly modify the values of the goals  $g_k$  before a new iteration is performed. One drawback is that the additional goal constraints induce the loss of the particular structure of the initial CO problem, so that a general ILP software must be used to solve problem  $(P_g)$ .

### Interactive Two-Phase Methods and MOSA Method

The two-phase methodology described above can easily be adapted to build interactively a good compromise. At each step of the first phase, the decision maker can indicate which pair  $(X_r, X_s)$  he prefers so that only a small subset of  $SE(P)$  is generated in the direction given by the decision maker; at the second phase, only one (or a few number of) triangles  $\Delta Z_r Z_s$  is (are) analysed to verify if there exists in it a more satisfying non-supported efficient solution. In the same spirit, an interactive MOSA method can be designed (see also [12]): the decision maker gives some goals  $g_k$  and only the solutions satisfying  $z_k(X) \leq g_k$  are putting in the list of potential efficient solutions. When this list contains a certain a priori fixed number of solutions, the decision maker indicates which one is preferred, modifies the goals  $g_k$  in a more restrictive sense before to continue the search with MOSA.

An example of such interactive procedure is given in [12] for a real case study.

## Introduction

A number of optimization problems are actually multiobjective optimization problems (MOPs), where the objectives are conflicting. As a result, there is usually no single solution which optimizes all objectives simultaneously. A number of techniques have been developed to find a compromise solution to MOPs. The reader is referred to the recent book by Miettinen [16] about the theory and algorithms for MOPs. Fractional programming problems (FPPs) arise from many applied areas such as portfolio selection, stock cutting, game theory, and numerous decision problems in management science. Many approaches for FPPs have been exploited in considerable details. See, for example, Avriel et al. [3], Craven [5], Schaible [24,25], Schaible and Ibaraki [26] and Stancu-Minasian [27,28].

In this paper, we consider the following multiobjective fractional programming problem:

(MFP)  $\min$

$$\frac{f(x)}{g(x)} \triangleq \left( \frac{f_1(x)}{g_1(x)}, \frac{f_2(x)}{g_2(x)}, \dots, \frac{f_p(x)}{g_p(x)} \right)^T,$$

s.t.

$$h(x) \leq 0, \quad x \in X,$$

where  $X \subset R^n$  is an open set,  $f_i, g_i$  ( $i = 1, 2, \dots, p$ ) are real-valued functions defined on  $X$ , and  $h$  is an  $m$ -dimensional vector-valued function defined on  $X$ . Suppose that  $f_i(x) \geq 0$  and  $g_i(x) > 0$  for  $x \in X$  and  $i = 1, 2, \dots, p$ . Moreover, let  $f_i, g_i$  ( $i = 1, 2, \dots, p$ ) and  $h_j$  ( $j = 1, 2, \dots, m$ ) be continuously differentiable over  $X$  and denote the gradients of  $f_i, g_i$  and  $h_j$  at  $x$  by  $\nabla f_i(x), \nabla g_i(x)$  and  $\nabla h_j(x)$ , respectively.

If the parameter  $p$  in the problem (MFP) is equal to 1, then (MFP) corresponds to the following single-objective fractional programming problem:

$$(FP) \min \frac{f(x)}{g(x)},$$

$$\text{s.t. } h(x) \leq 0, \quad x \in X,$$

where  $X \subset R^n$  is an open set,  $f, g$  are real-valued functions defined on  $X$ , and  $h$  is an  $m$ -dimensional vector-valued function defined on  $X$ ,  $f(x) \geq 0$  and  $g(x) > 0$  for all  $x \in X$ . Moreover, assume that  $f(x), g(x)$  and  $h_j(x)$  ( $j = 1, 2, \dots, m$ ) are continuously differentiable over  $X$ .

Khan and Hanson [10], and Reddy and Mukherjee [21] considered the optimality conditions and duality for (FP) with respect to the following generalized concepts of convexity, respectively.

**Definition 1** [6] Let  $f$  be a real function defined on an open set  $X \subseteq R^n$  and differentiable at  $x_0$ . Given a mapping  $\eta : X \times X \rightarrow R^n$ , the function  $f$  is said to be invex at  $x_0$  with respect to  $\eta$  if,  $\forall x \in X$ , the following inequality holds:

$$f(x) - f(x_0) \geq \nabla f(x_0)^T \eta(x, x_0).$$

**Definition 2** [7] Let  $f$  be a real function defined on an open set  $X \subseteq R^n$  and differentiable at  $x_0$ . Given a real number  $\rho$ , a mapping  $\eta : X \times X \rightarrow R^n$  and a scalar function  $d : X \times X \rightarrow R$ , the function  $f$  is said to be  $\rho$ -invex at  $x_0$  with respect to  $\eta$  and  $d$  if,  $\forall x \in X$ , the following inequality holds:

$$f(x) - f(x_0) \geq \nabla f(x_0)^T \eta(x, x_0) + \rho d^2(x, x_0).$$

The authors of references [10,21] imposed the corresponding generalized convexity on the numerator and denominator individually for the objective function in the problem (FP), and then derived some optimality conditions and duality results. How to extend these methods to the multiobjective case is still an open problem [21].

As far as the multiobjective fractional problem (MFP) is concerned, Jeyakumar and Mond [8] introduced a concept of  $\nu$ -invexity as follows.

**Definition 3** Let  $f : X \rightarrow R^p$  be a real vector function defined on an open set  $X \subseteq R^n$  and each component of  $f$  be differentiable at  $x_0$ . The function  $f$  is said to be  $\nu$ -invex at  $x_0 \in X$  if there exist a mapping  $\eta : X \times X \rightarrow R^n$  and a function  $\alpha_i : X \times X \rightarrow R_+ \setminus \{0\}$  ( $i = 1, 2, \dots, p$ ) such that,  $\forall x \in X$ ,

$$f_i(x) - f_i(x_0) \geq \alpha_i(x, x_0) \nabla f_i(x_0)^T \eta(x, x_0).$$

Jeyakumar and Mond [8] obtained some weak efficiency conditions and duality results for a nonconvex multiobjective fractional programming problem via the concept of  $\nu$ -invexity,  $\nu$ -pseudoinvexity and  $\nu$ -quasiinvexity.

Motivated by various concepts of generalized convexity, Liang et al. [12] introduced a unified formulation of the generalized convexity, which was called

$(F, \alpha, \rho, d)$ -convexity, and obtained some corresponding optimality conditions and duality results for the single-objective fractional problem (FP). In this paper, we will extend the methods adopted for the single-objective problem (FP) in [12] to the multiobjective problem (MFP).

**Definition 4** A function  $F : R^n \rightarrow R$  is said to be sublinear if for any  $\alpha_1, \alpha_2 \in R^n$ ,

$$F(\alpha_1 + \alpha_2) \leq F(\alpha_1) + F(\alpha_2), \quad (1)$$

and for any  $r \in R_+, \alpha \in R^n$ ,

$$F(r\alpha) = rF(\alpha). \quad (2)$$

Note that the concept of the sublinear function was given in Preda [20]. Now, a sublinear function is defined simply as a function that is subadditive and positively homogeneous, which is free of extraneous symbols in Preda [20]. It follows from (2) that  $F(0) = 0$ .

Based upon the concept of the sublinear function, we recall the unified formulation about generalized convexity, i. e.,  $(F, \alpha, \rho, d)$ -convexity, which was introduced in [12] as follows.

**Definition 5** Given an open set  $X \subset \Re^n$ , a number  $\rho \in R$ , and two functions  $\alpha : X \times X \rightarrow R_+ \setminus \{0\}$  and  $d : X \times X \rightarrow R$ , a differentiable function  $f$  over  $X$  is said to be  $(F, \alpha, \rho, d)$ -convex at  $x_0 \in X$  if for any  $x \in X$ ,  $F(x, x_0; \cdot) : \Re^n \rightarrow \Re$  is sublinear, and  $f(x)$  satisfies the following condition:

$$f(x) - f(x_0) \geq F(x, x_0; \alpha(x, x_0) \nabla f(x_0)) + \rho d^2(x, x_0). \quad (3)$$

The function  $f$  is said to be  $(F, \alpha, \rho, d)$ -convex over  $X$  if,  $\forall x_0 \in X$ , it is  $(F, \alpha, \rho, d)$ -convex at  $x_0$ ;  $f$  is said to be strongly  $(F, \alpha, \rho, d)$ -convex or  $(F, \alpha)$ -convex if  $\rho > 0$  or  $\rho = 0$ , respectively.

From Definition 5, there are the following special cases:

- (i) If  $\alpha(x, x_0) = 1$  for all  $x, x_0 \in X$ , then  $(F, \alpha, \rho, d)$ -convexity is  $(F, \rho)$ -convexity [20].
- (ii) If  $F(x, x_0; \alpha(x, x_0) \nabla f(x_0)) = \nabla f(x_0)^T \eta(x, x_0)$  for a certain mapping  $\eta : X \times X \rightarrow R^n$ , then  $(F, \alpha, \rho, d)$ -convexity is  $\rho$ -invexity defined in [7].
- (iii) If  $\rho = 0$  or  $d(x, x_0) \equiv 0$  for all  $x, x_0 \in X$  and  $F(x, x_0; \alpha(x, x_0) \nabla f(x_0)) = \nabla f(x_0)^T \eta(x, x_0)$

for a certain mapping  $\eta : X \times X \rightarrow R^n$ , then  $(F, \alpha, \rho, d)$ -convexity reduces to invexity [6].

In the following,  $\rho, \alpha$  and  $d$  are referred to as parameters of  $(F, \alpha, \rho, d)$ -convexity. Furthermore, we will adopt the following conventions.

Let  $R_+^n$  denote the nonnegative orthant of  $R^n$  and  $x^T$  denote the transpose of the vector  $x \in R^n$ . For any two vectors  $x = (x_1, x_2, \dots, x_n)^T, y = (y_1, y_2, \dots, y_n)^T \in R^n$ , we denote:

- $x = y$  implying  $x_i = y_i, \quad i = 1, 2, \dots, n;$
- $x < y$  implying  $x_i \leq y_i, \quad i = 1, 2, \dots, n,$   
but  $x \neq y;$
- $x < y$  implying  $x_i < y_i, \quad i = 1, 2, \dots, n;$
- $x \not< y$  implying  $y_i < x_i$  for at least one  $i$ .

A solution of the problem (MFP) is referred to as an efficient (Pareto optimal) solution, which is defined as follows.

**Definition 6** A feasible solution  $x_0 \in X$  of (MFP) is called an efficient solution of (MFP) if there exists no other feasible solution  $x \in X$  such that

$$\frac{f(x)}{g(x)} < \frac{f(x_0)}{g(x_0)}.$$

In [14], Maeda gave a kind of constraint qualification, which was called generalized Guignard constraint qualification (GGCQ), under which he derived the following Kuhn–Tucker type necessary conditions for a feasible solution  $x_0$  to be an efficient solution to the problem (MFP):

If  $x_0$  is an efficient solution of (MFP) and (GGCQ) holds at  $x_0$  [14], then there exist  $\tau = (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p, \tau > 0, \sum_{i=1}^p \tau_i = 1$  and  $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m)^T \in R_+^m$  such that

$$\sum_{i=1}^p \tau_i \nabla \frac{f_i(x_0)}{g_i(x_0)} + \sum_{j=1}^m \lambda_j \nabla h_j(x_0) = 0,$$

$$\lambda_j h_j(x_0) = 0, \quad j = 1, 2, \dots, m.$$

This paper is organized as follows. In Sect. “Efficiency Conditions”, efficiency conditions for the multiobjective fractional problem (MFP) involving  $(F, \alpha, \rho, d)$ -convexity are presented. The duality properties of the problem (MFP) are studied in Sect. “Duality”,

including several duals for (MFP) and some weak and strong duality theorems. Concluding remarks are given in the last section.

**Efficiency Conditions**

First, we present a lemma which indicates that  $(F, \alpha, \rho, d)$ -convexity can be preserved after taking division.

**Lemma 1** Let  $X \subset R^n$  be an open set. Assume that  $p, q$  are real-valued differentiable functions defined on  $X$  and  $p(x) \geq 0, q(x) > 0$  for all  $x \in X$ . If  $p$  and  $-q$  are  $(F, \alpha, \rho, d)$ -convex at  $x_0 \in X$ , then  $p/q$  is  $(F, \bar{\alpha}, \bar{\rho}, \bar{d})$ -convex at  $x_0$ , where  $\bar{\alpha}(x, x_0) = \frac{\alpha(x, x_0)q(x_0)}{q(x)}, \bar{\rho} = \rho \left(1 + \frac{p(x_0)}{q(x_0)}\right)$  and  $\bar{d}(x, x_0) = \frac{d(x, x_0)}{q^{\frac{1}{2}}(x)}$ .

In the following, we present some sufficient efficiency conditions for (MFP) under appropriate  $(F, \alpha, \rho, d)$ -convexity assumptions.

**Theorem 1** Let  $x_0$  be a feasible solution of (MFP). Suppose that there exist  $\tau = (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p, \tau > 0, \sum_{i=1}^p \tau_i = 1$  and  $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m)^T \in R_+^m$  such that

$$\sum_{i=1}^p \tau_i \nabla \frac{f_i(x_0)}{g_i(x_0)} + \sum_{j=1}^m \lambda_j \nabla h_j(x_0) = 0, \tag{4}$$

$$\lambda_j h_j(x_0) = 0, \quad j = 1, 2, \dots, m. \tag{5}$$

If  $f_i$  and  $-g_i$  ( $i = 1, 2, \dots, p$ ) are  $(F, \alpha_i, \rho_i, d_i)$ -convex at  $x_0, h_j$  ( $j = 1, 2, \dots, m$ ) is  $(F, \beta_j, \zeta_j, c_j)$ -convex at  $x_0$ , and

$$\sum_{i=1}^p \tau_i \bar{\rho}_i \frac{\bar{d}_i^2(x, x_0)}{\bar{\alpha}_i(x, x_0)} + \sum_{j=1}^m \lambda_j \zeta_j \frac{c_j^2(x, x_0)}{\beta_j(x, x_0)} \geq 0, \tag{6}$$

where  $\bar{\alpha}_i(x, x_0) = \frac{\alpha_i(x, x_0)g_i(x_0)}{g_i(x)}, \bar{\rho}_i = \rho_i \left(1 + \frac{f_i(x_0)}{g_i(x_0)}\right)$ , and  $\bar{d}_i(x, x_0) = \frac{d_i(x, x_0)}{g_i^{\frac{1}{2}}(x)}$ , then  $x_0$  is a global efficient solution for (MFP).

**Corollary 1** Let  $x_0$  be a feasible solution of (MFP). Suppose that there exist  $\tau = (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p, \tau > 0, \sum_{i=1}^p \tau_i = 1$ , and  $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m)^T \in R_+^m$  such that

$$\sum_{i=1}^p \tau_i \nabla \frac{f_i(x_0)}{g_i(x_0)} + \sum_{j=1}^m \lambda_j \nabla h_j(x_0) = 0,$$

$$\lambda_j h_j(x_0) = 0, \quad j = 1, 2, \dots, m.$$

If  $f_i$  and  $-g_i$  ( $i = 1, 2, \dots, p$ ) are strongly  $(F, \alpha_i, \rho_i, d_i)$ -convex (or  $(F, \alpha_i)$ -convex) at  $x_0$ ,  $h_j$  ( $j = 1, 2, \dots, m$ ) is strongly  $(F, \beta_j, \zeta_j, c_j)$ -convex (or  $(F, \beta_j)$ -convex) at  $x_0$ , then  $x_0$  is a global efficient solution for (MFP).

For  $i = 1, 2, \dots, p$ , if  $g_i(x) = 1$  for all  $x \in X$ ,  $f_i(x)$  need not be nonnegative, and the functions involved are assumed to be invex,  $\rho$ -invex with respect to  $\eta: X \times X \rightarrow R^n$ ,  $d: X \times X \rightarrow R$ ,  $(F, \rho)$ -convex, or generalized  $(F, \rho)$ -convex, respectively, then we can obtain the corresponding results presented in [1,2,9].

Next, we consider a special case of (MFP), in which the fractional objective functions have the same denominator. For  $i = 1, 2, \dots, p$ , let  $g_i(x) = g(x)$  in (MFP). The property about the efficient solution of this special (MFP) can be obtained similarly as that in Theorem 1, so we state the following theorem:

**Theorem 2** Let  $x_0$  be a feasible solution of (MFP). Suppose that there exist  $\tau = (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p$ ,  $\tau > 0$ ,  $\sum_{i=1}^p \tau_i = 1$ , and  $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m)^T \in R_+^m$  such that

$$\sum_{i=1}^p \tau_i \nabla \frac{f_i(x_0)}{g(x_0)} + \sum_{j=1}^m \lambda_j \nabla h_j(x_0) = 0,$$

$$\lambda_j h_j(x_0) = 0, \quad j = 1, 2, \dots, m.$$

If  $-g$  is  $(F, \alpha, \rho, d)$ -convex at  $x_0$ ,  $f_i$  ( $i = 1, 2, \dots, p$ ) is  $(F, \alpha, \rho_i, d)$ -convex at  $x_0$ ,  $h_j$  ( $j = 1, 2, \dots, m$ ) is  $(F, \bar{\alpha}, \zeta_j, \bar{d})$ -convex at  $x_0$ , and  $\sum_{i=1}^p \tau_i \bar{\rho}_i + \sum_{j=1}^m \lambda_j \zeta_j \geq 0$ , where  $\bar{\alpha}(x, x_0) = (\alpha(x, x_0)g(x_0))/g(x)$ ,  $\bar{\rho}_i = \rho_i + \rho(f_i(x_0))/g(x_0)$  and  $\bar{d}(x, x_0) = (d(x, x_0))/g(x)$ , then  $x_0$  is a global efficient solution for (MFP).

Finally, we present an equivalent formulation of the problem (MFP). Let  $G(x) = \prod_{i=1}^p g_i(x)$ ,  $G_i(x) = \frac{G(x)}{g_i(x)}$  ( $i = 1, 2, \dots, p$ ). Then (MFP) can be written in the following form:

$$\begin{aligned} & \text{(MFP)} \\ & \min \left( \frac{G_1(x)f_1(x)}{G(x)}, \frac{G_2(x)f_2(x)}{G(x)}, \dots, \frac{G_p(x)f_p(x)}{G(x)} \right)^T, \\ & \text{s.t. } h(x) \leq 0, \quad x \in X. \end{aligned}$$

By Theorem 2, we have the following corollary:

**Corollary 2** Let  $x_0$  be a feasible solution of (MFP). Suppose that there exist  $\tau = (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p$ ,

$\tau > 0$ ,  $\sum_{i=1}^p \tau_i = 1$ , and  $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m)^T \in R_+^m$  such that

$$\sum_{i=1}^p \tau_i \nabla \frac{f_i(x_0)}{g_i(x_0)} + \sum_{j=1}^m \lambda_j \nabla h_j(x_0) = 0,$$

$$\lambda_j h_j(x_0) = 0, \quad j = 1, 2, \dots, m.$$

If  $-G$  is  $(F, \alpha, \rho, d)$ -convex at  $x_0$ ,  $G_i f_i$  ( $i = 1, 2, \dots, p$ ) is  $(F, \alpha, \rho_i, d)$ -convex at  $x_0$ ,  $h_j$  ( $j = 1, 2, \dots, m$ ) is  $(F, \bar{\alpha}, \zeta_j, \bar{d})$ -convex at  $x_0$ , and  $\sum_{i=1}^p \tau_i \bar{\rho}_i + \sum_{j=1}^m \lambda_j \zeta_j \geq 0$ , where  $\bar{\rho}_i = \rho_i + \rho(f_i(x_0))/g_i(x_0)$ ,  $\bar{\alpha}(x, x_0) = (\alpha(x, x_0)G(x_0))/G(x)$ , and  $\bar{d}(x, x_0) = (d(x, x_0))/(G^{1/2}(x))$ , then  $x_0$  is a global efficient solution for (MFP).

Under the assumptions of Theorem 2 or Corollary 2, if  $\rho \geq \max_{1 \leq i \leq p} \rho_i$ ,  $\bar{\rho}_i = \rho_i(1 + f_i(x_0)/g(x_0))$ , or  $\bar{\rho}_i = \rho_i(1 + f_i(x_0)/g_i(x_0))$ , respectively, then the corresponding results still hold.

**Duality**

Many types of duals for a given mathematical programming problem. Two well-known duals are the Wolfe type dual [29] and the Mond-Weir type dual [17]. Recently, the mixed (or general type) dual has been considered for various optimization problems [1,2,11,13,18,19,20,30,31,32]. The mixed dual includes the Wolfe type dual and the Mond-Weir type dual as special cases. In the sequel, the generalized Mond-Weir dual are discussed first, and then three other types of duals are presented, which are based on  $(F, \alpha, \rho, d)$ -convexity for the problem (MFP).

Let  $M = \{1, 2, \dots, m\}$  and  $M_0, M_1, \dots, M_q$  be a partition of  $M$ , i. e.,  $\bigcup_{k=1}^q M_k = M$ ,  $M_k \cap M_l = \emptyset$  for  $k \neq l$ . The generalized Mond-Weir dual of (MFP) is as follows:

$$\begin{aligned} & \max \frac{f(u)}{g(u)} + \lambda_{M_0}^T h_{M_0}(u) e \triangleq \\ & \left( \frac{f_1(u)}{g_1(u)} + \lambda_{M_0}^T h_{M_0}(u), \dots, \right. \\ & \left. \frac{f_p(u)}{g_p(u)} + \lambda_{M_0}^T h_{M_0}(u) \right)^T, \\ & \text{s.t. } \sum_{i=1}^p \tau_i \nabla \frac{f_i(u)}{g_i(u)} + \sum_{j=1}^m \lambda_j \nabla h_j(u) = 0, \end{aligned}$$

$$\begin{aligned} \lambda_{M_k}^T h_{M_k}(u) &\geq 0, k = 1, 2, \dots, q, \\ \tau &= (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p, \tau > 0, \\ \sum_{i=1}^p \tau_i &= 1, \\ \lambda_{M_k} &\in R_+^{|M_k|}, k = 0, 1, 2, \dots, q, \\ u &\in X, \end{aligned}$$

where  $e = (1, 1, \dots, 1)^T$  and  $\lambda_{M_k}$  denotes the column vector whose subscripts of components belong to  $M_k$ . In particular, if  $M_0 = M, M_k = \emptyset, k = 1, 2, \dots, q$ , then the above dual becomes the Wolfe type dual; if  $M_0 = \emptyset$  and  $q = 1, M_1 = M$ , the Mond-Weir type dual is obtained. Since the Wolfe type dual is unsuitable for single objective fractional programming problems [15,22,23], the duals with  $M_0 \neq \emptyset$  are certainly unsuitable for (MFP). For the generalized Mond-Weir type dual, we only consider the case  $M_0 = \emptyset, M_1 = M$ , i. e., the Mond-Weir dual.

**Mond-Weir Dual**

The Mond-Weir dual of the problem (MFP) has the following form:

$$\begin{aligned} \text{(MFD1)} \\ \max \frac{f(u)}{g(u)} &= \left( \frac{f_1(u)}{g_1(u)}, \frac{f_2(u)}{g_2(u)}, \dots, \frac{f_p(u)}{g_p(u)} \right)^T \\ \text{s.t. } \sum_{i=1}^p \tau_i \nabla \frac{f_i(u)}{g_i(u)} &+ \sum_{j=1}^m \lambda_j \nabla h_j(u) = 0, \\ \lambda^T h(u) &\geq 0, \\ \tau &= (\tau_1, \tau_2, \dots, \tau_p)^T \in R^p, \tau > 0, \sum_{i=1}^p \tau_i = 1, \\ \lambda &= (\lambda_1, \lambda_2, \dots, \lambda_m)^T \in R_+^m, u \in X. \end{aligned}$$

**Theorem 3 (Weak Duality)** Assume that  $\bar{x}$  is a feasible solution of (MFP) and  $(\bar{u}, \bar{\tau}, \bar{\lambda})$  is a feasible solution of (MFD1). If  $f_i$  and  $-g_i$  ( $i = 1, 2, \dots, p$ ) are  $(F, \alpha_i, \rho_i, d_i)$ -convex at  $\bar{u}$ ,  $h_j$  ( $j = 1, 2, \dots, m$ ) is  $(F, \beta, \zeta_j, c_j)$ -convex at  $\bar{u}$ , and the inequality

$$\sum_{i=1}^p \bar{\tau}_i \bar{\rho}_i \frac{\bar{d}_i^2(\bar{x}, \bar{u})}{\bar{\alpha}_i(\bar{x}, \bar{u})} + \sum_{j=1}^m \bar{\lambda}_j \zeta_j \frac{c_j^2(\bar{x}, \bar{u})}{\beta(\bar{x}, \bar{u})} \geq 0 \tag{7}$$

holds, where  $\bar{\alpha}_i(\bar{x}, \bar{u}) = \alpha_i(\bar{x}, \bar{u})(g(\bar{u})) / (g(\bar{x}))$ ,  $\bar{\rho}_i = \rho_i(1 + (f_i(\bar{u})) / (g_i(\bar{u})))$ , and  $\bar{d}_i(\bar{x}, \bar{u}) = (d_i(\bar{x}, \bar{u})) /$

$(g_i^{\frac{1}{2}}(\bar{x}))$ , then we have

$$\frac{f(\bar{x})}{g(\bar{x})} \not\leq \frac{f(\bar{u})}{g(\bar{u})}.$$

**Corollary 3 (Weak Duality)** Assume that  $\bar{x}$  is a feasible solution of (MFP), and  $(\bar{u}, \bar{\tau}, \bar{\lambda})$  is a feasible solution of (MFD1). If  $f_i$  and  $-g_i$  ( $i = 1, 2, \dots, p$ ) are strongly  $(F, \alpha_i, \rho_i, d_i)$ -convex (or  $(F, \alpha_i)$ -convex) at  $\bar{u}$ , and  $h_j$  ( $j = 1, 2, \dots, m$ ) is strongly  $(F, \beta, \zeta_j, c_j)$ -convex (or  $(F, \beta)$ -convex) at  $\bar{u}$ , then

$$\frac{f(\bar{x})}{g(\bar{x})} \not\leq \frac{f(\bar{u})}{g(\bar{u})}.$$

**Theorem 4 (Strong Duality)** Assume that  $\bar{x}$  is an efficient solution of (MFP) and the constraint qualification (GGCQ) holds at  $\bar{x}$  [14]. Then there exists  $(\bar{\tau}, \bar{\lambda}) \in R_+^p \times R_+^m$  such that  $(\bar{x}, \bar{\tau}, \bar{\lambda})$  is a feasible solution of (MFD1), and the objective function values of (MFP) and (MFD1) at the corresponding points are equal. If the assumptions about the generalized convexity and the inequality (7) in Theorem 3 are also satisfied, then  $(\bar{x}, \bar{\tau}, \bar{\lambda})$  is an efficient solution of (MFD1).

**Schaible Dual**

In this subsection, we shall consider the following extended form of the Schaible dual for (MFP) [22,23]:

$$\begin{aligned} \text{(MFD2)} \\ \max \lambda &= (\lambda_1, \lambda_2, \dots, \lambda_p)^T \\ \text{s.t. } \sum_{i=1}^p \tau_i \nabla_u (f_i(u) - \lambda_i g_i(u)) &+ \sum_{j=1}^m v_j \nabla h_j(u) \\ &= 0, \\ f_i(u) - \lambda_i g_i(u) &\geq 0, i = 1, 2, \dots, p \\ v^T h(u) &\geq 0, \\ \tau > 0, \sum_{i=1}^p \tau_i &= 1, \\ \lambda \in R_+^p, \tau \in R_+^p, v \in R_+^m, u &\in X. \end{aligned}$$

**Theorem 5 (Weak Duality).** Assume that  $\bar{x}$  is a feasible solution of (MFP) and  $(\bar{u}, \bar{\tau}, \bar{\lambda}, \bar{v})$  is a feasible solution of (MFD2). If one of the following holds:

- (I)  $f_i$  and  $-g_i$  ( $i = 1, 2, \dots, p$ ) are  $(F, \alpha_i, \rho_i, d_i)$ -convex at  $\bar{u}$ ,  $h_j$  ( $j = 1, 2, \dots, m$ ) is  $(F, \beta, \zeta_j, c_j)$ -convex at  $\bar{u}$ , and

$$\sum_{i=1}^p \bar{\tau}_i \rho_i (1 + \bar{\lambda}_i) \frac{d_i^2(\bar{x}, \bar{u})}{\alpha_i(\bar{x}, \bar{u})} + \sum_{j=1}^m \bar{v}_j \zeta_j \frac{c_j^2(\bar{x}, \bar{u})}{\beta(\bar{x}, \bar{u})} \geq 0; \tag{8}$$

- (II)  $f_i$  and  $-g_i$  ( $i = 1, 2, \dots, p$ ) are  $(F, \alpha, \rho_i, d)$ -convex at  $\bar{u}$ ,  $h_j$  ( $j = 1, 2, \dots, m$ ) is  $(F, \alpha, \zeta_j, d)$ -convex at  $\bar{u}$ , and the vectors  $\bar{\tau}, \bar{\lambda}, \bar{v}$  satisfy:

$$\sum_{i=1}^p \bar{\tau}_i \rho_i (1 + \bar{\lambda}_i) + \sum_{j=1}^m \bar{v}_j \zeta_j \geq 0, \tag{9}$$

then

$$\frac{f(\bar{x})}{g(\bar{x})} \neq \bar{\lambda}.$$

**Theorem 6 (Strong Duality).** Assume  $\bar{x}$  is an efficient solution of (MFP), and the constraint qualification (GGCQ) holds at  $\bar{x}$  [14]. Then there exist  $\bar{\tau} \in R_+^p$ ,  $\bar{\lambda} \in R_+^p$ ,  $\bar{v} \in R_+^m$  such that  $(\bar{x}, \bar{\tau}, \bar{\lambda}, \bar{v})$  is a feasible solution of (MFD2) and  $\bar{\lambda} = \frac{f(\bar{x})}{g(\bar{x})}$ . Furthermore, if all assumptions in Theorem 5 are satisfied, then the corresponding  $(\bar{x}, \bar{\tau}, \bar{\lambda}, \bar{v})$  is an efficient solution of (MFD2).

### Extended Bector Type Dual

For a single-objective fractional programming problem in [4], Bector used the positivity of the denominator to transform the inequality constraints and add them to the objective by Lagrangian multipliers for establishing a kind of dual. Since the denominators in (MFP) need not be the same, we use the equivalent form ( $\overline{MFP}$ ) of (MFP) to establish the following dual, which is called the extended Bector type dual of (MFP):

(MFD3)

$$\begin{aligned} & \max \left( \begin{array}{c} \frac{G_1(u)f_1(u) + v_{M_0}^T h_{M_0}(u)}{G(u)} \\ \vdots \\ \frac{G_p(u)f_p(u) + v_{M_0}^T h_{M_0}(u)}{G(u)} \end{array} \right)^T \\ & \text{s.t. } \sum_{i=1}^p \tau_i \nabla_u \frac{G_i(u)f_i(u) + v_{M_0}^T h_{M_0}(u)}{G(u)} \end{aligned}$$

$$+ \sum_{k=1}^q \nabla_u v_{M_k}^T h_{M_k}(u) = 0,$$

$$v_{M_k}^T h_{M_k}(u) \geq 0, \quad k = 1, 2, \dots, q,$$

$$G_i(u)f_i(u) + v_{M_0}^T h_{M_0}(u) \geq 0,$$

$$i = 1, 2, \dots, p,$$

$$\sum_{i=1}^p \tau_i = 1, \tau = (\tau_1, \tau_2, \dots, \tau_p)^T \in R_+^p,$$

$$\tau > 0,$$

$$u \in X, \quad v_{M_k} \in R_+^{M_k}, \quad k = 0, 1, 2, \dots, q.$$

**Theorem 7 (Weak Duality)** Let  $x$  be a feasible solution of (MFP) and  $(u, \tau, v)$  be a feasible solution of (MFD3). Assume that  $-G$  is  $(F, \alpha, \rho, d)$ -convex at  $u$ ,  $G_i f_i$  ( $i = 1, \dots, p$ ) is  $(F, \alpha, \rho_i, d)$ -convex at  $u$  and  $h_j$  ( $j = 1, \dots, m$ ) is  $(F, \alpha, \zeta_j, d)$ -convex at  $u$ . If  $\rho \geq \max_{1 \leq i \leq p} \rho_i$  and the following inequality holds:

$$\begin{aligned} & \sum_{i=1}^p \tau_i \rho_i \left( 1 + \frac{G_i(u)f_i(u) + v_{M_0}^T h_{M_0}(u)}{G(u)} \right) \\ & + \sum_{j \in M_0} v_j \zeta_j + G(u) \sum_{k=1}^q \sum_{j \in M_k} v_j \zeta_j \geq 0, \tag{10} \end{aligned}$$

then we have

$$\frac{f(x)}{g(x)} \neq \frac{\overline{G}(u)f(u) + v_{M_0}^T h_{M_0}(u) e}{G(u)},$$

where  $\overline{G}(u) = \text{diag}\{G_1(u), \dots, G_p(u)\}$  and each component in  $e \in R^p$  is equal to 1.

**Theorem 8 (Strong Duality)** Assume that  $\bar{x}$  is an efficient solution of (MFP) and the constraint qualification (GGCQ) holds at  $\bar{x}$  [14]. Then there exists  $(\bar{\tau}, \bar{v})$  such that  $(\bar{x}, \bar{\tau}, \bar{v})$  is a feasible solution of (MFD3), and the objective function values of (MFP) and (MFD3) at  $\bar{x}$  and  $(\bar{x}, \bar{\tau}, \bar{v})$ , respectively, are equal. If the assumptions and conditions in Theorem 7 are also satisfied, then  $(\bar{x}, \bar{\tau}, \bar{v})$  is an efficient solution of (MFD3).

### Concluding Remarks

In this paper, a unified formulation of the generalized convexity defined in [12] is adopted, which includes many other generalized convexity concepts in optimization theory as special cases. Our concept of generalized convexity is suitable to analyze the efficiency

conditions and duality of multiobjective fractional programming problems. Efficiency conditions and duality for a class of multiobjective fractional programming problems are presented. We extend the methods, which were adopted for single-objective fractional programming problems in [10,12,21], to the case with multiple fractional objectives. We also present the extended Bector type dual by using an equivalent formulation of the primal problem. Note that we only consider (MFP) from a viewpoint of the efficient solution in this paper. The methods used here can be extended to the study of (MFP) from a viewpoint of the weak efficient solution.

## Keywords

Multi-objective programming; Integer; Linear programming

From the 1970s onwards, *multi-objective linear programming* (MOLP) methods with continuous solutions have been developed [8]. However, it is well known that discrete variables are unavoidable in the linear programming modeling of many applications, for instance, to represent an investment choice, a production level, etc.

The mathematical structure is then *integer linear programming* (ILP), associated with MOLP giving a MOILP problem. Unfortunately, MOILP cannot be solved by simply combining ILP and MOLP methods, because it has got its own specific difficulties.

The problem (P) considered is defined as

$$(P) \left\{ \begin{array}{l} \max_{X \in D} z_k(X) = \sum_{j=1}^n c_j^{(k)} x_j, \\ k = 1, \dots, K, \\ \text{where } D = \left\{ X \in \mathbb{R}^n : \begin{array}{l} TX \leq d, \\ X \geq 0, \\ x_j \text{ integer,} \\ j \in J \end{array} \right\} \\ \text{with } \begin{array}{l} T(m \times n), \\ d(m \times 1), \\ X(n \times 1), \\ J \subset \{1, \dots, n\}. \end{array} \end{array} \right.$$

If we denote  $LD = \{X: TX \leq d, X \geq 0\}$ , problem (LP) is the linear relaxation of problem (P):

$$(LP) \left\{ \begin{array}{l} \max' z_k(X), \quad k = 1, \dots, K, \\ X \in LD \end{array} \right.$$

A solution  $X^*$  in  $D$  (or  $LD$ ) is said to be *efficient* for problem (P) (or (LP)) if there does not exist any other solution in  $D$  (or  $LD$ ) such that  $z_k(X) \geq z_k(X^*)$ ,  $k = 1, \dots, K$ , with at least one strict inequality.

Let  $E(\cdot)$  denote the set of all efficient solutions of problem  $(\cdot)$ . It is well known (see [8]) that (LP) may be characterized by the optimal solutions of the single objective and parametrized problem:

$$(LP_\lambda) \left\{ \begin{array}{l} \max \sum_{k=1}^K \lambda_k z_k(X) \\ X \in LD \\ \text{with } \lambda_k > 0, \quad \forall k, \\ \sum_{k=1}^K \lambda_k = 1 \end{array} \right.$$

This fundamental principle – often called *Geoffrion's theorem* – is no longer valid in presence of discrete variables because the set  $D$  is not convex. The set of optimal solutions of problem  $(P_\lambda)$ , defined as problem  $(LP_\lambda)$  in which  $LD$  is replaced by  $D$ , is only a subset  $SE(P)$  of  $E(P)$ ; the solutions in  $SE(P)$  are called *supported efficient solutions*, while the solutions belonging to  $NSE(P) = E(P) \setminus SE(P)$  are called *nonsupported efficient solutions*.

The breakdown of Geoffrion's theorem for problem (P) can be illustrated by the following obvious example:

$$\begin{aligned} K &= 2, \\ z_1(X) &= 6x_1 + 3x_2 + x_3, \\ z_2(X) &= x_1 + 3x_2 + 6x_3, \\ D &= \{X: x_1 + x_2 + x_3 \leq 1, x_i \in \{0, 1\}\}. \end{aligned}$$

For this problem,

$$E(P) = \{(1, 0, 0); (0, 1, 0); (0, 0, 1)\}$$

while  $NSE(P) = \{(0, 1, 0)\}$ .

Nevertheless, V.J. Bowman [1] has given a theoretical characterization of  $E(P)$ : Setting

$$M_k = \max_{X \in D} z_k(X),$$

$$\bar{z}_k = M_k + \varepsilon_k, \quad \text{with } \varepsilon_k > 0,$$

$$\rho > 0,$$

then  $E(P)$  is characterized by the optimal solutions of the problem  $(P_\lambda^T)$ :

$$\min_{X \in D} \max_k \left( \lambda_k (\bar{z}_k - z_k(X)) + \rho \left( \sum_{k=1}^K (\bar{z}_k - z_k(X)) \right) \right),$$

consisting of minimizing the augmented weighted Tchebychev distance between  $z_k(X)$  and  $\bar{z}_k$ .

Let us note that another characterization of  $E(P)$  is given in [2] for the particular case of binary variables.

Two types of problems can be analysed:

- Generate  $E(P)$  explicitly. Several methods have been proposed; they are reviewed in [10]. below we will present two of them, which appear general, characteristic and efficient.
- To determine interactively with the decision maker a ‘best compromise’ in  $E(P)$  according to the preferences of the decision maker. Some of the existing approaches are reviewed in [11]; below we will describe three of these interactive methods.

**Generation of  $E(P)$**

**Klein–Hannan Method**

See [5]. This is an iterative procedure for sequentially generating the complete set of efficient solutions for problem  $(P)$  (we suppose that the coefficients  $c_j^{(k)}$  are integers); it consists in solving a sequence of progressively more constrained single objective ILP problems and can be implemented through use of any ILP algorithm.

- (Initialization: step 0) An objective function  $l \in \{1, \dots, K\}$  is chosen arbitrarily and the following single objective ILP problem is considered:

$$(P_0) \quad \max_{X \in D} z_l(X).$$

Let  $E(P_0)$  be the set of all optimal solutions of  $(P_0)$  and let  $E_0(P)$  be the set of solutions defined as  $E_0(P) = E(P_0) \cap E(P)$ . Thus,  $E_0(P)$  is the subset of non-dominated solutions in  $E(P_0)$ .

- (Step  $j$ , ( $j \geq 1$ )) The efficient solutions generated at the previous steps are denoted by  $X_r^*$ ,  $r = 1, \dots, R$ , i. e.  $\cup_{i=1}^{j-1} E_i(P) = \{X_r^* : r = 1, \dots, R\}$ . In this  $j$ th step, the following problem is solved

$$(P_j) \quad \begin{cases} \max_{X \in D} z_l(X) \\ \bigcap_{r=1}^R \left( \bigcup_{\substack{k=1 \\ k \neq l}}^K z_k(X) \geq z_k(X_r^*) + 1 \right) \end{cases}.$$

The new set of constraints represents the requirement that a solution to  $(P_j)$  be better on some objective  $k \neq l$  for each efficient solution  $X_r^*$  generated during the previous steps; an example of implementation of these constraints is given in [5]. The set of solutions  $E_j(P)$  is then defined as  $E_j(P) = E(P_j) \cap E(P)$ , where  $E(P_j)$  is the set of all optimal solutions of  $(P_j)$ .

The procedure continues until, at some iteration  $J$ , the problem  $(P_j)$  becomes infeasible; at this time  $E(P) = \cup_{j=0}^{J-1} E_j(P)$ .

**Kiziltan–Yucaoglu Method**

See [4]. This is a direct adaptation to a multi-objective framework of the well-known *Balas algorithm* for the ILP problem with binary variables.

At node  $S^r$  of the *branch and bound* scheme, the following problem is considered:

$$\left\{ \begin{array}{l} \max' \quad \sum_{j \in F^r} c_j x_j + \sum_{j \in B^r} c_j \\ \text{s.t.} \quad \sum_{j \in F} t_j x_j \leq d^r \\ \quad \quad x_j = (0, 1) \\ \text{where} \quad B^r \text{ is the index set of variables} \\ \quad \quad \text{assigned the value one} \\ \quad \quad F^r \text{ is the index of free variables} \\ \quad \quad d^r = d - \sum_{j \in B^r} t_j \\ \quad \quad t_j \text{ is the } j\text{th column of } T \\ \quad \quad c_j \text{ is the vector of components } c_j^{(k)}. \end{array} \right.$$

The node  $S^r$  is called *feasible* when  $d^r \geq 0$  and *infeasible* otherwise. The three *basic rules of the branch and bound* algorithm are:

- (bounding rule) A lower and upper bound vector,  $\underline{Z}^r$  and  $\overline{Z}^r$ , respectively, are defined as

$$\underline{Z}^r = \sum_{j \in B^r} c_j,$$

$$\overline{Z}^r = \underline{Z}^r + Y^r,$$

where  $Y_k^r = \sum_{j \in F^r} \max\{0, c_j^k\}$ . The vector  $\underline{Z}^r$  is added to a list  $\widehat{E}$  of existing lower bounds if  $\underline{Z}^r$  is not dominated by any of the existing vectors of  $\widehat{E}$ . At the same time, any vector of  $\widehat{E}$  dominated by  $\underline{Z}^r$  is discarded.

- (fathoming rules) In the multi-objective case, the feasibility of a node is no longer a sufficient condition for fathoming it. The three general fathoming conditions are:
  - $\overline{Z}^r$  is dominated by some vector of  $\widehat{E}$ ;
  - the node  $S^r$  is feasible and  $\underline{Z}^r = \overline{Z}^r$ ;
  - the node  $S^r$  is unfeasible and  $\sum_{j \in F^r} \min(0, t_{ij}) > d_i^r$  for some  $i = 1, \dots, m$ .

The usual backtracking rules are applied.

- (branching rule) A variable  $x_l \in F^r$  is selected to be the branching variable.
  - If the node  $S^r$  is feasible,  $l \in \{j \in F^r : c_j \not\leq 0\}$ .
  - Otherwise, index  $l$  is selected by the *minimum unfeasibility criterion*:

$$\min_{j \in F^r} \sum_{i=1}^m \max(0, -d_i^r + t_{ij}).$$

When the explicit enumeration is complete,  $E(P) = \widehat{E}$ .

### Interactive Methods

Such methods are particularly important to solve multi-objective applications. The general idea is to determine progressively a good compromise solution integrating the preferences of the decision maker.

The dialog with the decision maker consist of a succession of ‘calculation phase’ managed by the model and ‘information phase’ managed by the decision maker.

At each calculation phase, one or several new efficient solutions are determined taking into account the information given by the decision maker at the preceding information phase. At each information phase, a few number of easy questions are asked to the decision maker to collect information about its preferences in regard to the new solutions.

### Gonzalez–Reeves–Franz Algorithm

See [3]. In this method a set  $\widetilde{E}$  of  $K$  efficient solutions is selected and updated in each algorithm step according to the decision maker’s preferences. At the end of the procedure,  $\widetilde{E}$  will contain the most preferred solutions. The method is divided in two stages: in the first one, the supported efficient solutions are considered, while the second one deals with nonsupported efficient solutions.

- (Stage 1): Determination of the best supported efficient solutions.  $\widetilde{E}$  is initialized with  $K$  optimal solutions of the  $K$  single objective ILP problems. Let us denote by  $\widetilde{Z}$  the  $K$  corresponding points in the objective space of the solution of  $\widetilde{E}$ . At each iteration, a linear direction of search  $G(X)$  is build:  $G(X)$  is the inverse mapping of the hyperplane defined by the points of  $\widetilde{Z}$  in the objective space into the decision space. A new supported efficient solution  $X^*$  is determined by solving the single objective ILP problem  $\max_{X \in D} G(X)$  and  $Z^*$  is the corresponding point in the objective space. Then:
  - if  $Z^* \notin \widetilde{Z}$  and the decision maker prefers solution  $X^*$  to at least one solution of  $\widetilde{E}$ : the least preferred solution is replaced in  $\widetilde{E}$  by  $X^*$  and a new iteration is performed;
  - if  $Z^* \notin \widetilde{Z}$  and  $X^*$  is not preferred to any solution in  $\widetilde{E}$ :  $\widetilde{E}$  is not modified and the second stage is initiated;
  - if  $Z^* \in \widetilde{Z}$ :  $\widetilde{Z}$  defines a face of the efficient surface and the second stage is initiated.
- (Stage 2): Introduction of the best non supported solutions. We will not give details about this second stage (see [3] or [10]); let us just say that it is performed in the same spirit but considering the single objective problem

$$\begin{cases} \max & G(X) \\ & X \in D \\ & G(X) \leq \widetilde{G} - \varepsilon \quad \text{with } \varepsilon > 0 \end{cases}$$

where  $\widetilde{G}$  is the optimal value obtained for the last function  $G(X)$  considered.

### Steuer–Choo Method

See [9]. Several interactive approaches of MOLP problems can also be applied to MOILP; among them, we mention only the Steuer–Choo method, which is a very

general procedure based on problem  $(P_\lambda^T)$  defined in the introduction.

The first iteration uses a widely dispersed group of  $\lambda$  weighting vectors to sample the set of efficient solutions. The sample is obtained by solving problem  $(P_\lambda^T)$  for each of the  $\lambda$  values in the set. Then the decision maker is asked to identify the most preferred solution  $X^{(1)}$  among the sample. At iteration  $j$ , a more refined grid of weighting vectors  $\lambda$  is used to sample the set of efficient solution in the neighborhood of the point  $z_k(X^{(j)})$  ( $k = 1, \dots, K$ ) in the objective space. Again the sample is obtained by solving several problems  $(P_\lambda^T)$  and the most preferred solution  $X^{(j+1)}$  is selected. The procedure continues using increasingly finer sampling until the solution is deemed to be acceptable.

**The MOMIX Method**

(See [6].) The main characteristic of this method is the use of an interactive branch and bound concept – initially introduced in [7] – to design the interactive phase.

- (First compromise): The following minimax optimization, with  $m = 1$ , is performed to determined the compromise  $\tilde{X}^{(1)}$ :

$$(P^m) \quad \begin{cases} \min & \delta \\ \forall k & \Pi_k^{(m)}(M_k^{(m)} - z_k(X)) \leq \delta, \\ & X \in D^{(m)} \end{cases}$$

where

- $D^{(1)} \equiv D$ ;
- $[m_k^{(1)}, M_k^{(1)}]$  are the variation intervals of the criteria  $k$ , provided by the pay-off table (see [8]);
- $\Pi_k^{(1)}$  are certain normalizing weights taking into account these variation intervals (see [8]).

*Remark 1* If the optimal solution is not unique, an augmented weighted Tchebychev distance is required in order to obtain an efficient first solution.

- (Interactive phases): There are integrated in an interactive branch and bound tree; a first step (a *depth-first* progression in the tree) leads to the determination of a first good compromise; the second step (a *backtracking* procedure) confirms the degree of satisfaction achieved by the decision maker or it finds a better compromise if necessary.
- (Depth first progression): For  $m \geq 1$ , let at the  $m$ th iteration

- 1)  $\tilde{X}^{(m)}$  be the  $m$ th compromise;
- 2)  $z_k^{(m)}$  be the corresponding values of the criteria;
- 3)  $[m_k^{(m)}, M_k^{(m)}]$  be the variation intervals of the criteria; and
- 4)  $\Pi_k^{(m)}$  be the weight of the criteria.

The decision maker has to choose, at this  $m$ th iteration, the criterion  $l_m(1) \in \{k: k = 1, \dots, K\}$  he is willing to improve in priority. Then a new constraint is introduced so that the feasible set becomes  $D^{(m+1)} \equiv D^{(m)} \cap \{z_{l_m(1)}(X) > z_{l_m(1)}^{(m)}\}$  Further, the variation intervals  $[m_k^{(m+1)}, M_k^{(m+1)}]$  and the weights  $\Pi_k^{(m+1)}$  are updated on the new feasible set  $D^{(m+1)}$ . The new compromise  $\tilde{X}^{(m+1)}$  is obtained by solving the problem  $(P^{m+1})$ .

Different tests allow to terminate this first step. The node  $(m+1)$  is fathomed if one of the following conditions is verified:

- a)  $D^{(m+1)} = \emptyset$ ;
- b)  $M_k^{(m+1)} - m_k^{(m+1)} \leq \epsilon_k \forall k$ ;
- c) the vector  $\hat{Z}$  of the *incumbent values* (values of the criteria for the best compromise already determined) is preferred to the new ideal point (of component  $M_k^{(m+1)}$ ).

The first step of the procedure is stopped if either more than  $q$  successive iterations do not bring an improvement of the incumbent point  $\hat{Z}$  or more than  $Q$  iterations have been performed.

Note that the parameters  $\epsilon_k$ ,  $q$  and  $Q$  are fixed in the agreement with the decision maker.

- c) (Backtracking procedure): It can be hoped that the appropriate choice of the criterion  $z_{l_m(1)}$ , at each level  $m$  of the depth-first progression, has been made so that at the end of the first step, a good compromise has been found.

Nevertheless, it is worth examining some other parts of the tree to confirm the satisfaction of the decision maker. The complete tree is generated in the following manner: at each level,  $K$  subnodes are introduced by successively adding the constraints:

$$\begin{matrix} z_{l_m(1)}(X) > z_{l_m(1)}^{(m)}, \\ z_{l_m(2)}(X) > z_{l_m(2)}^{(m)}; & z_{l_m(1)}(X) \leq z_{l_m(1)}^{(m)}, \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ z_{l_m(K)}(X) > z_{l_m(K)}^{(m)}; & z_{l_m(k)}(X) \leq z_{l_m(k)}^{(m)}, \end{matrix}$$

for all  $k = 1, \dots, K - 1$ , where  $l_m(k) \in \{k: k = 1, \dots, K\}$  is the  $k$ th objective that the decision maker wants to improve at the  $m$ th level of the branch and bound tree.

At each level  $m$ , the criteria are thus ordered according to the priorities of the decision maker in regard with the compromise  $\widetilde{X}^{(m)}$ .

The usual backtracking procedure is applied; yet it seems unnecessary to explore the whole tree. Indeed, the subnode  $k > \overline{K}$  of each branching correspond to a simultaneous relaxation of those criteria  $l_m(k)$ ,  $k \leq \overline{K}$ , the decision maker wants to improve in priority!

Therefore, the subnodes  $k > \overline{K} = 2$  or  $3$ , for instance, do almost certainly not bring any improved solutions.

The fathoming tests and the stopping tests are again applied in this second step.

Multicriteria analysis; Interactive method

A multi-objective (multicriteria) mixed integer programming (MOMIP) problem is a mathematical programming problem that considers more than one objective

where  $X \subset \mathbf{R}^n$  denotes the nonconvex set of feasible solutions defined by a set of functional constraints,  $x \geq 0$  and  $x_j$  integer  $j \in J \subset \{1, \dots, n\}$ . It is assumed that  $X$  is compact (closed and bounded) and nonempty.

Although a MOMIP problem may be nonlinear, models with linear constraints and linear objective functions have been more often considered. In a multi-objective mixed integer linear programming (MOMILP) problem, the functional constraints can be defined as  $Ax \leq b$ , and the objective functions  $f_i(x) = c_i x$ ,  $i = 1, \dots, k$ , where  $A$  is a  $m \times n$  matrix,  $b$  is a  $m$ -dimensional column vector and  $c_i$ ,  $i = 1, \dots, k$ , are  $n$ -dimensional row vectors.

Multi-objective mixed integer programming is very useful for many areas of application such as communication, transportation and location, among others. Integer variables are required in a real-world model whenever it is sought to incorporate discrete phenomena; for instance, investment choices, production levels, fixed charges, logical conditions or disjunctive constraints. However, research on MOMIP has been rather limited. Concerning multi-objective mathematical programming, most research efforts have been so far devoted to linear programming with continuous variables (MOLP). The introduction of discrete phenomena into multi-objective models leads to all-integer or mixed integer problems that are more difficult to tackle. They can not be handled by most MOLP approaches because the feasible set is no longer convex. Also, there are multi-objective approaches designed for all-integer problems that do not apply to the mixed integer case. Therefore, even for the linear case, techniques for dealing with multi-objective mixed integer programming involve more than the combination of MOLP with multi-objective integer programming techniques.

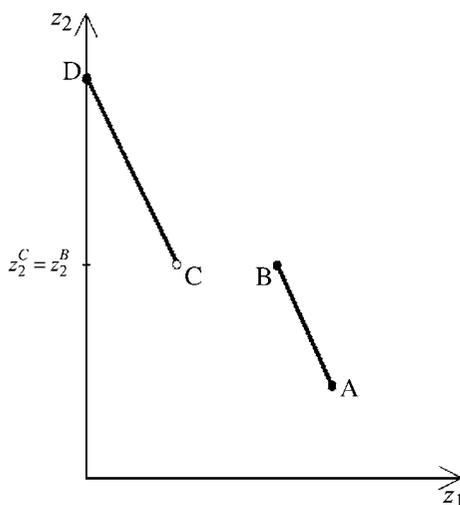

## Efficiency and Nondominance

The concept of *efficiency* (or *nondominance*) in MOMIP is defined as usually for multi-objective mathematical programming: A solution  $\bar{x} \in X$  is *efficient* if and only if it does not exist another  $x \in X$  such that  $f_i(x) \geq f_i(\bar{x})$  for all  $i \in \{1, \dots, k\}$  and  $f_i(x) > f_i(\bar{x})$  for at least one  $i$ . A solution  $\bar{x} \in X$  is *weakly efficient* if and only if it does not exist another  $x \in X$  such that  $f_i(x) > f_i(\bar{x})$  for all  $i \in \{1, \dots, k\}$ .

Let  $Z \subset \mathbb{R}^k$  be the image of the feasible region  $X$  in the criterion (objective function) space. A criterion point  $\bar{z} \in Z$  corresponding to a (weakly) efficient solution  $\bar{x} \in X$  is called (weakly) *nondominated*. The designations ‘efficient’, ‘nondominated’ and ‘Pareto optimal’ are often used as synonyms.

## Supported and Unsupported Nondominated Solutions

Since the feasible region is nonconvex, unsupported nondominated points/solutions may exist in a MOMIP problem. A nondominated point  $\bar{z} \in Z$  is *unsupported* if it is dominated by a convex combination (which does not belong to  $Z$ ) of other nondominated criterion points (belonging to  $Z$ ). In Fig. 1 the line segment from  $A$  to  $B$  plus  $D$  is the set of supported nondominated criterion points. The line segment from  $C$  to  $D$  excluding  $C$  and  $D$  is the set of unsupported nondominated criterion points. Note that convex combinations of  $B$  and  $D$

Multi-objective Mixed Integer Programming, Figure 1  
Nondominated criterion points of a MOMILP problem

dominate the line segment from  $C$  to  $D$ , excluding  $D$ .  $C$  is a weakly nondominated solution.

## Characterization of the Nondominated Set

Unlike MOLP, the nondominated (or efficient) set of MOMIP problems can not be fully determined by parameterizing on  $\lambda$  the weighted-sums program:

$$(P_\lambda) \quad \begin{cases} \max & \left\{ \sum_{i=1}^k \lambda_i f_i(x) : x \in X \right\} \\ \text{where} & \lambda \in \Lambda. \end{cases}$$

Here,

$$\Lambda = \left\{ \lambda \in \mathbb{R}^k : \begin{array}{l} \lambda_i > 0 \quad \forall i, \\ \sum_{i=1}^k \lambda_i = 1 \end{array} \right\}.$$

The unsupported nondominated solutions cannot be reached even if the complete parameterization on  $\lambda$  is attempted.

Researchers on multi-objective mathematical programming early recognized this fact and stated other characterizations for the nondominated set that fit MOMIP and, in particular, MOMILP problems. Basically, two main characterizations are defined. One consists of introducing additional constraints into the *weighted-sums program*. Generally, these constraints impose bounds on the objective function values. This form of characterization may be regarded as a particularization of the general characterization provided by R.M. Soland [13]. The other is based on the Tchebycheff theory whose theoretical foundation originated from V.J. Bowman [3]. More details about these characterizations and on how they provide the computation of nondominated solutions will be given later. Although providing very important theoretical results, the characterizations of the nondominated set do not offer an explicit means to provide decision support for MOMIP problems. However, some authors have developed decision support methods for these problems.

## Interactive Versus Noninteractive Methods

Methods may be either *noninteractive* (in general, generating methods designed to find the whole or a subset of the nondominated solutions) or *inter-*

*active* (characterized by phases of human intervention alternated with phases of computation). Generating methods for MOMIP problems usually require an excessive amount of computational resources, both in processing time and storage capacity. Even specialized generating algorithms developed just for bi-objective problems, which profit from graphical representations on the criterion space, tend to be inadequate to deal with large problems. Nevertheless, the distinction between interactive and generating methods is not always clear. Some approaches attempt to find a representative subset of the nondominated set (generating methods according to the above definition) and would be easily embodied in an interactive framework. The bi-objective method of R. Solanki [14] may be regarded as an example of such an approach.

Taking into account the difficulties mentioned above, and the large number of nondominated solutions in many problems, special attention to interactive methods will be paid. First of all, a short remark is made about the major paradigms followed by the authors of interactive methods. Some authors admit that the decision maker's (DM) preferences can be represented by an *implicit utility function*. The interactive process consists in building a protocol of interaction aiming to discover the optimum (or an approximation of it) of that implicit utility function. The convergence to this optimum requires no contradictions in the DM's responses given throughout the interactive process.

In contrast with implicit utility function approaches, the *open communication* approaches are based on a progressive and selective learning of the nondominated set. The terminology of open communication is inspired on the concept of open exchange, defined by P. Feyerabend [6]. Such multi-objective approaches are not intended to converge to any 'best' compromise solution but to help the DM to avoid the search for nondominated solutions he/she is not at all interested in. There are no irrevocable decisions during the whole process and the DM is always allowed to go 'backwards' at a later interaction. So, at each interaction, the DM is only asked to give some indications on what direction the search for nondominated solutions must follow, or occasionally to introduce additional constraints. The process only finishes when the DM considers to have gained sufficient insight into the

nondominated solution set. Using the terminology of B. Roy [12], 'convergence' must give place to 'creation'. The interactive process is a constructive process, not the search for something 'pre-existent'.

Although we personally prefer the open communication methods, we will include in the next section a tentative classification of both, drawing out some differences and similarities between them. We adopt this perspective because this question is not specific to mixed integer programming and arguments pro or against each approach, besides being subjective, are the same as in other multi-objective programming fields. Furthermore, since MOMIP is still in its early steps, no behavioral studies exist addressing the use of procedures within this context.

As we have mentioned before, research on MOMIP has been rather scarce in comparison to other fields of the multi-objective mathematical programming, namely in MOLP. We will mention herein some well-known methods specially designed for MOMIP or far more generally applicable.

## Computing Processes and Their Use in Interactive Methods

### Weighted-Sums Programs with Additional Constraints

The introduction of bounds on the objective function values into the *weighted-sums program*  $(P_\lambda)$  enables this program to also compute unsupported nondominated solutions:

$$(P_{\lambda,g}) \quad \max \left\{ \sum_{j=1}^k \lambda_j f_j(x) : x \in X, f(x) \geq g \right\},$$

where  $f(x) = (f_1(x), \dots, f_k(x))$ ,  $\lambda \in \Lambda$  and  $g$  is a vector of objective bounds. Besides the fact that every solution obtained by  $(P_{\lambda,g})$  is nondominated, there always exists a  $g \in \mathbf{R}^k$  such that  $(P_{\lambda,g})$  yields a particular nondominated solution. Other types of additional constraints can also be used.

A scalarizing program which consists of the weighted-sums program combined with additional constraints is used for computing nondominated solutions in the interactive branch and bound method of B. Villarreal et al. [18]. The additional constraints are bounds imposed on integer variables by the branching

process. This method, which is devoted to MOMILP problems, received later improvements in [8] and [11]. Starting by applying the well-known (MOLP) *Zionts-Wallenius procedure* to the linear relaxation of the MOMILP problem, the method then employs a branch and bound phase until an integer solution that satisfies the DM is achieved. An implicit utility function is assumed and the DM's preferences are assessed using pairwise evaluations of decision alternatives and trade-off analysis. In light of the DM's underlying utility function, decisions on whether to apply again the Zionts-Wallenius procedure to the linear relaxation of a candidate multi-objective subproblem, or to continue to branch by appending a constraint on a variable, are successively made.

Another method that uses particular forms of  $(P_{\lambda, g})$  to compute nondominated solutions is due to Y. Aksoy [1]. This is an interactive method for bicriterion mixed integer programs that employs a branch and bound scheme to divide the subset of nondominated solutions considered at each node into two disjoint subsets. The branching process seeks to bisect the range of nondominated values for  $z_2$  at the node under consideration, checking whether a nondominated point exists whose value for  $z_2$  is in the middle of the range. If no such solution exists, that subset is divided using two nondominated points whose values for  $z_2$  are the closest (one up and the other down) to the middle value. These nondominated solutions are obtained by solving  $(P_{\lambda, g})$  optimizing one objective function and bounding the other. The interactive process requires the DM to make pairwise comparisons in order to determine the branching node and to adjust the incumbent solution to the preferred nondominated solution. It is assumed that the DM's preferences are consistent, transitive and invariant over the process aiming to optimize the DM's implicit utility function.

C. Ferreira et al. [5] proposed a decision support system for bicriterion mixed integer programs. The interactive process follows an open communication protocol asking the DM to specify bounds for the objective function values. These bounds are input into  $(P_{\lambda, g})$  defining subregions to carry on the search for nondominated solutions. Some objective space regions are progressively eliminated either by dominance or infeasibility.

### Tchebycheff and Achievement Scalarizing Programs

Bowman [3] proved that the parameterization on  $w$  of  $\min_{x \in X} \|\bar{f} - f(x)\|_w$  generates the nondominated set, where  $w_i \geq 0$  for all  $i$ ,  $\sum_{i=1}^k w_i = 1$ ,  $\bar{f}$  is a criterion point such that  $\bar{f} > f(x)$  for all  $x \in X$  and  $\|\bar{f} - f(x)\|_w$  denotes the  $w$ -weighted Tchebycheff metric, that is,  $\max_{1 \leq i \leq k} \{w_i |\bar{f}_i - f_i(x)|\}$ . This scalarizing program is equivalent to

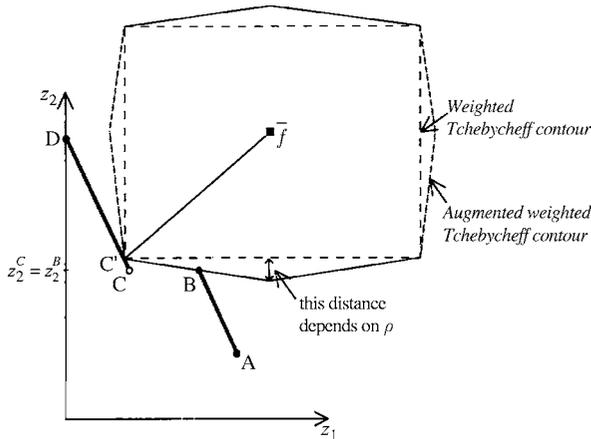

$$(T_w) \quad \begin{cases} \min & \alpha \\ \text{s.t.} & w_i (\bar{f}_i - f_i(x)) \leq \alpha, \quad 1 \leq i \leq k, \\ & x \in X, \quad \alpha \geq 0. \end{cases}$$

$(T_w)$  may yield weakly nondominated solutions (for instance, point C in Fig. 1). Replacing the objective function in  $(T_w)$  by  $\alpha - \rho \sum_{i=1}^k f_i(x)$  with  $\rho$  a small positive value, all the solutions returned by this augmented weighted Tchebycheff program are nondominated. R.E. Steuer and E.-U. Choo [16] proved that there are always  $\rho$  small enough that enable to reach all the nondominated set for the finite-discrete and polyhedral feasible region cases.

Concerning the MOMIP case, although there may be portions of the nondominated set that the program is unable to compute, even considering  $\rho$  very small (for example, the line segment from C to C' in Fig. 2, for a given  $\rho$ ), this characterization is still possible in practice. Note that  $\rho$  can be set so small that the DM is unable to discriminate between those solutions and a nearby weakly nondominated solution (this corresponds to C' getting closer to C in Fig. 2).

In [16] and [15] a lexicographic weighted Tchebycheff program is proposed for the nonlinear and infinite-discrete feasible region cases to overcome this drawback of the augmented weighted Tchebycheff program. The lexicographic approach can also be applied to the mixed integer (linear) case. However, it is more difficult to implement since two stages of optimization are employed. At the first stage only  $\alpha$  is minimized. When the first stage results in alternative optima, a second stage is required. It consists of minimizing  $-\sum_{i=1}^k f_i(x)$  over the solutions that minimize  $\alpha$  in order to eliminate the weakly nondominated solutions.

Besides  $(T_w)$  (either the augmented or the lexicographic forms), there are other similar approaches that also allow to characterize the nondominated set of

**Multi-objective Mixed Integer Programming, Figure 2**  
**Illustration of the augmented weighted Tchebycheff metric**

multi-objective mixed integer programs. An approach of this type consists in discarding the  $w$ -vector or fixing it and varying  $\bar{f}$ , the criterion reference point that represents the DM's aspiration levels. This scalarizing program can be denoted by  $(T_{\bar{f}})$ . There always exist reference points satisfying  $\bar{f} > f(x)$  for all  $x \in X$ , such that  $(T_{\bar{f}})$  produces a particular nondominated solution  $\bar{z} = f(\bar{x})$ . The variation of  $\bar{f}$  can be done according to a vector direction  $\theta$ , leading to  $(T_{\bar{f}+\theta})$ . The reference points are thus projected onto the nondominated set. Reference points that do not satisfy the condition  $\bar{f} > f(x)$  for all  $x \in X$  may also be considered provided that the  $\alpha$  variable is defined without sign restriction. This corresponds to the minimization of a distance from  $Z$  to the reference point if the latter is not attainable and to the maximization of such a distance if the reference point is attainable. If reference or aspiration levels are used as controlling parameters, the (weighted) Tchebycheff metric changes its form of dependence on controlling parameters and should be interpreted as an *achievement function* [9].

Like  $(T_w)$ , the simplest form of  $(T_{\bar{f}})$  may produce weakly nondominated solutions. The augmented form is a good substitute in practice and the lexicographic approach guarantees that all nondominated solutions can be reached. In what follows, let  $(T.)$  denote either the simplest, the augmented or the lexicographic form.

Scalarizing programs  $(T_w)$ ,  $(T_{\bar{f}})$  and their extensions or slight different formulations are used to generate nondominated solutions in several (interactive)

methods proposed in literature, namely in the following ones.

Steuer and Choo [16] proposed a general purpose multi-objective programming interactive method that assumes an implicit DM's utility function without any special restriction on shape. The strategy of the interactive procedure is to sample series of progressively smaller subsets of nondominated solutions. At each interaction, the DM selects his/her preferred solution from a sample of nondominated solutions obtained from  $(T_w)$  with several  $w$ -vectors and the ideal criterion point in the role of  $\bar{f}$ . The solution preferred by the DM provides information to tighten the set of  $w$ -vectors for the next interaction. The procedure terminates when a nondominated criterion point sufficiently close to the optimal criterion point of the underlying utility function is found.

*Solanki's method* [14], which is designed for bi-objective mixed integer linear programs, is an adaptation of the noninferior set estimation (NISE) method developed by J.L. Cohon for bi-objective linear programs. It seeks to generate a representative subset of nondominated solutions by combining the NISE's key features with weighted Tchebycheff scalarizing programs. At each iteration, a new nondominated solution, say  $z^3$ , is computed by solving  $(T_w)$  for specific  $w$  and  $\bar{f}$ , assuring that  $z^3$  belongs to the region between a pair of nondominated criterion points previously determined, say  $(z^1, z^2)$ . This pair is then replaced by  $(z^1, z^3)$  and  $(z^3, z^2)$ . The approximation of the nondominated surface is progressively improved, thus decreasing the 'errors' associated with the approximate representation of the pairs. This 'error' is measured by the largest range of the two objectives for the points forming the pair. The algorithm finishes when the maximum 'error' is lower than a predefined maximum allowable 'error'.

Another interactive method capable of solving MOMIP problems was developed by A. Durso [4]. This method employs a branching scheme considering progressively smaller portions of the nondominated set by imposing lower bounds on the criterion values. At each interaction, the  $k$  nondominated solutions that define the (quasi)ideal criterion point for each new node are calculated. The DM is then asked to select the node for branching by choosing the preferred ideal point. The branching process begins by solving an equally weighted augmented Tchebycheff program to deter-

mine a ‘centralized’ nondominated point for the subset of the node under exploration. Once the DM chooses the most preferred of the  $k + 1$  nondominated points already known for this node, say  $\widehat{z}$ , up to  $k$  new nodes (children) are created. Each child inherits its parent’s bounding constraints and uses  $\widehat{z}$  to further restrict one of them. Thus, the  $i$ th child restricts the  $i$ th criterion by imposing  $f_i(x) \geq \widehat{z}_i + \delta$  with  $\delta$  small positive. This approach may be regarded as an open communication procedure that terminates when the DM is satisfied with the incumbent solution (the preferred nondominated solution obtained so far).

M.J. Alves and J. Clímaco [2] proposed a MOMILP open communication interactive approach. It combines the Tchebycheff theory with the traditional branch and bound technique for solving single-objective mixed integer programs. At each interaction, the DM specifies either a reference point  $\bar{f}$ , which is input in  $(T_{\bar{f}})$  to compute a nondominated solution via branch and bound, or just selects an objective function, say  $f_j$ , he/she wants to improve with respect to the previous nondominated solution. In the latter case, the reference point is automatically adjusted by increasing the  $j$ th component of  $\bar{f}$  keeping the others equal, in order to produce new nondominated solutions (directional search) more suited to the DM’s preferences. This involves an iterative process of sensitivity analysis and operations to update the branch and bound tree. The sensitivity analysis takes advantage of the special behavior of the parametric scalarizing program  $(T_{\bar{f}+\theta})$ . It returns a value  $\bar{\theta}_j > 0$  such that the structure of the previous branch and bound tree remains unchanged for variations in  $\bar{f}_j$  up to  $\bar{f}_j + \bar{\theta}_j$ . Therefore, reference points  $\bar{f} + \theta = (\bar{f}_1, \dots, \bar{f}_j + \theta_j, \dots, \bar{f}_k)$  with  $\theta_j \leq \bar{\theta}_j$  lead to nondominated solutions that may be obtained in a straightforward way. If the DM wishes to continue the search in the same direction, a slight increase over  $\bar{\theta}_j$ , say  $\bar{\theta}_j + \epsilon$ , is first considered. In this case, the previous sensitivity analysis also returns the best candidate node, i. e., an ancestor of the node that will produce the next nondominated solution. The previous branch and bound tree is thus used to proceed to the next computations. Since further branching is usually required, an attempt is made to simplify the tree before enlarging it. The underlying idea is to avoid an evergrowing tree. This simplification means cutting off parts of the tree linked by branching constraints no

longer active. In sum, this approach brings together sensitivity analysis phases meant to adjust the reference point and simplification/branching operations of the search tree to compute nondominated solutions. This process is repeated as long as the DM wishes to continue the directional search or if the reference point has not been adjusted enough to yield a nondominated solution different from the previous one (a situation that occurs more often in all-integer programs than in mixed integer models). Computational experiments have shown that this multi-objective approach succeeds in performing directional searches. The times of computing phases using simplification/branching operations have been significantly reduced by this strategy.

Some researchers have developed other methods for multi-objective integer programming that are also applicable to the mixed integer case. Good examples of such approaches are those in [10,17] and [7]. In our opinion, they all are open communication procedures that share some key features, namely the concept of projecting a reference direction onto the nondominated surface (although this procedure is used in different ways) and the type of information required about the DM’s preferences. This information lies fundamentally in the specification of aspiration levels for the objective function values (reference points). Some of these approaches are continuous/integer ([7,10]) working almost all the time with nondominated continuous solutions of the linear relaxation of the problem. Whenever the DM finds a satisfactory continuous solution, an integer nondominated solution close to it is then computed.

## Conclusions and Future Developments

Most methods developed so far for MOMIP problems require an excessive amount of computational effort, or require too much cognitive load from the DM, or only address bi-objective problems. In addition, computational experience with real-world applications is lacking. Although interesting or promising approaches have been developed, further research efforts must be made in order to build effective interactive methods able to handle real-sized problems.

*Multiple criteria decision making (MCDM)* refers to the explicit incorporation of more than one evaluation criteria into a decision problem. MCDM has been a very active field of research roughly since the 1970s. Although boundaries might be fuzzy and overlapping, multicriteria decision analysis (studying the problem of identifying the ‘most-preferred’ among a finite discrete set of alternatives), multi-attribute utility theory (using utility functions explicitly to model a decision maker’s preferences) and multi-objective optimization (modeling the decision problem within a mathematical programming framework) have emerged as major fields of interest under MCDM. For more information on the general field of MCDM, see [21].

Multi-objective mathematical programming provides a flexible modeling framework that allows for simultaneous optimization of more than one objective function over a feasible set. Mathematically, the multi-objective optimization problem can be expressed as:

$$(MOO) \quad \begin{cases} \max & f(x), \\ \text{s.t.} & x \in X, \end{cases}$$

where  $X \subseteq \mathbf{R}^n$  is the set of feasible alternatives and  $f = (f_1, \dots, f_p): \mathbf{R}^n \rightarrow \mathbf{R}^p$ ,  $p \geq 2$ , is a vector-valued function. Note that  $X$  can be any set, continuous or discrete, expressed through constraints, and the objective function  $f$  can be of any form.

The increased flexibility provided by (MOO) also raises the question of what constitutes a solution to it.

The definition of optimality is no longer valid, as each objective function would possibly yield a different optimal solution. Therefore solving the (MOO) problem is about studying the inherent trade-offs among conflicting objectives. Efficient solutions are the ones that possess the relevant trade-off information. An  $x^o \in \mathbf{R}^n$  is called an *efficient solution* for the (MOO) problem if  $x^o \in X$  and there exists no  $x \in X$  such that  $f(x) \geq f(x^o)$  with strict inequality holding for at least one component. The set of all efficient solutions of the (MOO) problem is usually denoted by  $X_E$ . As per the above definition, the most-preferred solution of the decision maker should belong to  $X_E$ , as solutions that are not efficient, the dominated ones, can be improved upon in at least one objective without worsening the others.

Since  $X_E$  is usually a big set, confining the most-preferred solution to  $X_E$  does not help identify the most-preferred solution immediately. In particular, the difficulty of defining and obtaining the most-preferred solution, the one that the decision maker would identify as the solution to the decision-making problem, and the need for the inevitable involvement of the decision maker in the solution procedure has resulted in very different solution approaches to the (MOO) problem.

## Traditional Classification

The timing of the involvement of the decision maker in the solution procedure has been a crucial factor that distinguishes among various approaches to the (MOO) problem [13]. *A priori methods*, methods that use prior articulation of preferences, ask the decision maker to specify preference information prior to the application of an optimization routine. The elicitation of preference information can be directed towards deriving a utility function that describes the decision maker’s preferences [14], or as in goal programming [7] and compromise programming [23], a standard model can be imposed upon the decision maker. As these methods reduce the (MOO) problem to a single-objective optimization problem and they aspire to find a single solution to it, they have received considerable recognition although their assumptions are usually restrictive.

The *interactive methods* require the interaction of the decision maker with the computer while solving a particular (MOO) problem. Usually, the idea is to construct a model that proposes solutions to the

(MOO) problem based on some initial input. The decision maker is then invited to reply to the solution by providing additional preference information. The interaction between the computer program and the decision maker continues until a satisfying solution is obtained.

Interactive methods are important in more than one way. First, they have introduced the means for practically solving a (MOO) problem [12]. Second, they help a decision maker learn about the inherent trade-offs of a problem during the solution process [5]. Third, the idea underlying the interactive methods constitutes the major motivation behind the contemporary *decision support systems*. Although interactive algorithms have encountered a certain level of acceptance from practitioners [1,20], they are not without disadvantages. They usually rely too much on the information provided by the decision maker, are not able to provide a global look at  $X_E$ , and thus at the trade-offs inherent in a problem, and they focus on finding a single solution whereas a number of solutions may be compatible with the decision maker's preferences. Moreover, their information requests may be overwhelming for the decision maker. It has been discussed that interactive methods need to address behavioral aspects of decision making [16] and concentrate on interfacing the decision maker [15] as well as broadening their model base [10]. Although they do not encompass all the raised issues, some of the interactive (MOO) algorithms have already evolved into decision support systems that provide a friendly environment for modeling as well as problem solving [17]. It can be expected that more decision support systems to solve problem (MOO) will appear in the near future.

Perhaps the most straight-forward way of approaching the (MOO) problem is as in *vector optimization* methods. Also referred to as *posterior methods*, these methods are based on the sole assumption that the decision maker prefers more to less in each objective function in (MOO) hence they propose identifying all of the efficient solutions of (MOO) and presenting them to the decision maker for the identification of the most-preferred solution. Along with theoretical findings [2,11], some vector optimization methods have been proposed; however, the methods have not gained practical recognition in general. The failure in the implementation of the proposed methods can be explained by the heavy computational requirements

of these methods. Perhaps a more important factor is the difficulty of presenting the efficient set in a 'legible' way to the decision maker. Furthermore, as the efficient set is usually continuous when the feasible region is, the task of identifying the most-preferred solution is a monstrous one attributed to the decision maker.

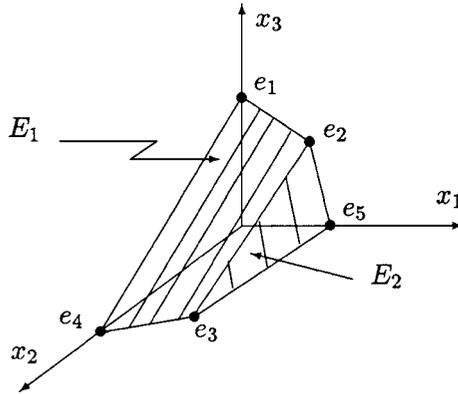

### Multi-Objective Linear Programming

When (MOO) has linear objective functions and a polyhedral feasible set, the resulting problem is called a *multiple objective linear programming* (MOLP) problem. The MOLP problem has mathematical features that make it easier to characterize and obtain the efficient set compared to the more general case. More specifically, it has been shown that the efficient set of the MOLP problem consists of a collection of efficient faces of the feasible region. As faces of a polyhedron can be characterized in a number of ways, for instance as the convex hull of its extreme points if its compact, as the optimal solution set to a particular optimization problem, or as a polyhedron itself, it becomes possible to obtain and present the efficient set [9,18,22].

Yet the computational effort increases with problem size, and the (MOO) problem cannot be considered truly solved at this stage without some mechanism that helps the decision maker identify the most-preferred solution in this huge and hard-to-explore set. Most of the vector optimization methods have concentrated on finding the set of efficient extreme points of the multiple objective linear programming problem. These are usually methods that rely on simplex-like procedures or parametric searches that incorporate book-keeping mechanisms based on the fact that the set of efficient extreme points is connected. A well-known procedure that solves (MOLP) for all of its extreme points is AD-BASE which was developed by R.E. Steuer [19].

*Example 1* Consider the MOLP problem [18]:

$$\begin{cases} \max & x_1, x_2, x_3, \\ \text{s.t.} & 2x_1 + 3x_2 + 4x_3 \leq 12 \\ & 4x_1 + x_2 + x_3 \leq 8 \\ & x_1, x_2, x_3 \geq 0. \end{cases} \quad (1)$$

The efficient set is the union of the two shaded efficient faces  $E_1$  and  $E_2$ . There are 5 efficient extreme points:  $e_1 = (0, 0, 3)$ ,  $e_2 = (10/7, 0, 16/7)$ ,  $e_3 = (12/10, 32/10, 0)$ ,  $e_4 = (0, 4, 0)$ ,  $e_5 = (2, 0, 0)$ . If  $X$  denotes the feasible region, The face marked  $E_1$  can be characterized as the polyhedron that forces the first constraint in (1) to equality in the definition of  $X$ . It can also be defined as the convex hull of its four extreme points  $e_1, e_2, e_3, e_4$ . Finally, it is the optimal solution set to the optimization problem

$$\begin{cases} \max & \lambda_1 x_1 + \lambda_2 x_2 + \lambda_3 x_3 \\ \text{s.t.} & x \in X \end{cases}$$

for  $(\lambda_1, \lambda_2, \lambda_3) = (2, 3, 4)$ , and its positive multiples.

In large problems, the set of efficient extreme points may still contain too many points to be studied by the decision maker. Moreover, extreme efficient points may not carry the trade-off information well since some portions of the efficient set may end up being over-emphasized whereas some regions are highly missed. Indeed, there is no reason for a decision maker to be solely interested in extreme point efficient solutions. The attractiveness of efficient extreme points mostly lies in their mathematical properties. With this motivation, a method that applies to a general set of (MOO) problems has been suggested to find globally-representative subsets of the efficient set [6].

### Working in the Outcome Space

The outcome set  $Y = \{ y \in \mathbb{R}^p: y = f(x) \exists x \in X \}$  helps redefine an equivalent problem to (MOO) in  $p$ -dimensional *outcome space*:

$$\text{(MOOO)} \quad \begin{cases} \max & y \\ \text{s.t.} & y \in Y. \end{cases}$$

As the number of objectives  $p$  is usually much less than the number of variables  $n$ , the structure of  $Y$  is simpler than that of  $X$  [4,8]. The ability to work directly with (MOOO) thus has the potential of providing significant computational benefits that vector optimization algorithms have tried to realize [3].

### Reflections on Optimization Trends

As a field within the general field of optimization, multi-objective optimization is naturally affected by the trends that become dominant in optimization. Consequently, interior point methods, genetic algorithms, neural networks have been applied to the (MOO) problem in various ways. As there are difficult problems under (MOO) that cannot be yet practically solved, new developments in the general field of optimization constitute a potential to solve these problems.

### Nonlinear and Integer Problems

Most of the algorithms proposed to solve problem (MOO) concentrate on the fully linear case. In general, when nonlinearities are introduced, the efficient solutions and the efficient set become difficult to characterize. There are some algorithms that allow for nonlinearities in the objective functions, and in the constraints that define the feasible region, but usually in a conservative way so as to retain some computational tractability. Similarly, the multiple objective integer programming problem is a very difficult one to solve due to the additional complications related to integrality.

### Applications

Along with what one can call ‘case studies’, certain applications that are more generic than a case study but more specific than problem (MOO) itself have appeared. Typical examples include, but are not limited to, bicriteria network optimization problems, bicriteria knapsack problems, and multicriteria scheduling problems. Since usually these are problems that naturally involve multiple criteria, the methods developed for these problems have practical implications. Most of the methods developed can be categorized under a priori methods. A typical approach is to form a weighted combination of the objective functions. Recently, interactive and vector optimization approaches that deal with similar problems have also appeared.

### A Related Optimization Problem

A related problem is the problem of optimizing a function  $g: \mathbf{R}^n \rightarrow \mathbf{R}^p$  over the efficient set  $X_E$ . This can be a difficult *global optimization* problem depending on the properties of the objective function  $g$ . The problem is motivated in different ways. Sometimes, in certain settings, a function that is to serve as a pseudo utility function is available. Then optimizing this pseudo utility function over the efficient set in a sense corresponds to solving problem (MOO) itself. In addition, when  $g$  becomes one of the objective functions, then solving this problem provides the range of values the objective function takes over the efficient set. This information is valuable for a decision maker who is trying to make assessments to solve a problem and is used in some of the interactive algorithms. The difficulty of the problem has also resulted in heuristic solution approaches.

### Trends

The advances in information technology affect the field of multiple criteria decision making heavily. Faster computers and parallel processing opportunities make it timewise feasible to solve optimization problems that would be deemed impractical in the past. Improved graphical capabilities make it feasible to accommodate sophisticated user interfaces to invite the decision maker in the problem solving process more actively and reliably. The developments in the World Wide Web present many opportunities to explore for individual and group decision support. At this point in time, there is still a need to solve the MOO problem in a rigorous, user-friendly and creative way. The decision support systems that enable the involvement of the decision maker in modeling and problem solving practically seem to be the way of solving (MOO) problems. The vector optimization approaches can also benefit from a decision support framework in their effort to help the decision maker identify a most-preferred solution.

### Keywords

Interaction of design and control; Multi-objective optimization; Mixed integer nonlinear optimization; Pareto optimal solution

Traditionally, *process design* and *process control* are treated sequentially. Dynamics are not considered during the design phase, and flowsheet changes can not be made during the control phase. The problem with this approach is that the two are inherently connected as the design of the process affects its controllability. Thus, the steady state design and the dynamic operability issues should be treated simultaneously. Analyzing the *interaction of design and control* addresses the issue of quantitatively determining the *trade-offs* between the steady state economics and the dynamic controllability.

The interaction of design and control problem is to determine the process flowsheet which is both the economically optimal and controllable. There are different methods for addressing this problem. One common approach is to use overdesign where, once the economic steady state design is determined, surge tanks are added or equipment sizes are increased in order to handle any dynamic problems which may arise. This overdesign is usually based on heuristic rules and will likely move the design away from its economic optimum. There is no guarantee that the measures taken will even improve the controllability of the process. Other methods may examine the dynamic operation of several designs to determine which has the best controllability aspects.

There are very few methods which address the interaction of design and control in a quantitative manner.

The interaction of design and control can be addressed through a *process synthesis* approach involving optimization. This approach involves the representation of design alternatives through a process superstructure, the mathematical modeling of the superstructure, and the development of an algorithm to extract the optimal flowsheet from the superstructure. The simultaneous optimization of the design and control of the process is handled through multiple objectives representing the steady state economics and dynamic controllability. This naturally leads to a multi-objective framework.

### Multi-objective Optimization

In any decision making process, the goal is to reach the best compromise solution among a number of competing objectives. Many examples of competing objectives exist in the field of engineering. For example, in the design of a process, one may have to consider safety and operational issues as well as economic issues. A decision making process is necessary when the most economic design is not the safest or most operable.

The best compromise solution depends on the relative importance of the conflicting objectives. This relative importance is not easily determined and is usually a subjective decision. The one responsible for making this decision is the decision maker (DM) whose choice can be based on a number of factors. Since subjective measures and decisions do not translate well into mathematics, a quantitative way of determining the trade-offs and relative importance among the the objectives is necessary for a multi-objective optimization framework.

### Multi-objective Framework for the Interaction of Design and Control

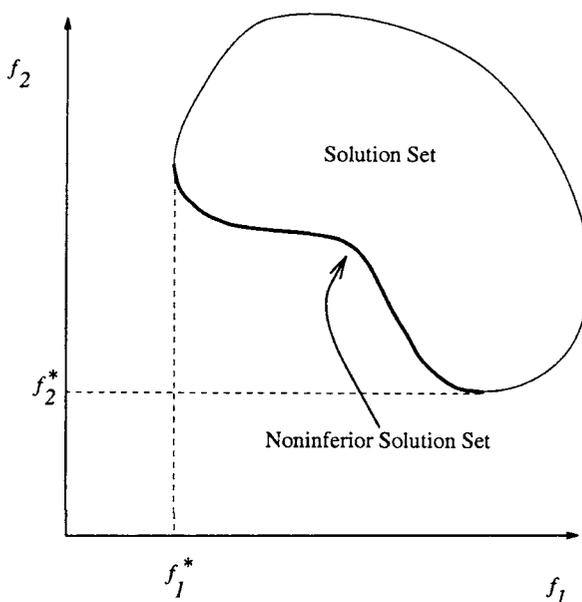

In analyzing the interaction of design and control, the objectives that are considered measure the steady state economics and the dynamic controllability of the process. The optimization approach in process synthesis serves as the basis for the multi-objective framework for the interaction of design and control. The procedure involves four steps:

- 1) Process representation;
- 2) Mathematical modeling;

- 3) Generation of noninferior solution set (determine trade-offs);
- 4) Best-compromise examination.

The first step is the representation of all the possible design alternatives through a process superstructure. In this step, all the units and possible connections of interest are incorporated into the superstructure such that all designs of interest are included as a subset of the superstructure.

Next, a mathematical model of the superstructure is developed for the superstructure as well as for objective functions. The mathematical formulation is determined by the structure of the process flowsheet and must include all information needed to evaluate the objective functions. The objective functions must measure the economics of the process as well as the controllability of the process. Since the objective related to the economic performance is determined by steady state operation and the objective for the controllability is determined by its dynamic operation, the mathematical model must contain both steady state and dynamic information. The mathematical formulation involves both continuous and discrete variables where discrete variables are used to indicate the existence of units and connections within the flowsheet.

Multi-objective Optimization: Interaction of Design and Control, Figure 1  
Noninferior solution set for a problem with two objectives

Once the model has been formulated, an algorithm is developed and used to determine the quantitative trade-offs among the competing objectives. Individually, each objective can be optimized, but together, they will be in conflict. This means that there is a set of solutions where one objective can be improved only at the expense of the other objectives. This set of solutions is called the *noninferior solution set* which is visually depicted for a two objective problem in Fig. 1. This solution set is also referred to as *nondominated* and *Pareto optimal* and the surface of noninferior solutions implicitly defines a function  $G(\mathbf{J})$ .

Using the information about the trade-offs among the competing objectives, a strategy for determining the best compromise solution is developed. This strategy is based on information from the DM and depends on the relative weights given to the objectives. These weights are varied systematically to locate the solution which the DM prefers the most. How to determine these weights is one of the more interesting aspects of the problem.

Note that the multi-objective problem can be reduced if some of the objectives (presumably those with very low weights) need not be optimized but simply brought to a satisfactory level. In this case, these objectives can be incorporated into the problem as constraints.

### General Mathematical Formulation

The mathematical model is a multi-objective *mixed integer nonlinear programming* problem which has the following form:

$$\left\{ \begin{array}{ll} \text{OPTIMIZE} & \mathbf{J}(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbb{R}^p \\ & \mathbf{y} \in \{0, 1\}^q. \end{array} \right. \quad (1)$$

In this formulation,  $\mathbf{J}$  is a vector of objectives which includes the economic and controllability objectives. The expressions  $\mathbf{h}$  and  $\mathbf{g}$  represent material and energy balances, thermodynamic relations, and other constraints. The controllability measures are included in the formulation as  $\boldsymbol{\eta}$ . The variables in this problem are partitioned as continuous  $\mathbf{x}$  and binary  $\mathbf{y}$ .

### Solution of the MOP

One way to address the solution of the MOP is to formulate it using a utility function  $U$  which implicitly relates the multiple objectives in terms of some common basis:

$$\left\{ \begin{array}{ll} \min & U[\mathbf{J}(\mathbf{x}, \mathbf{y})] \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbb{R}^p \\ & \mathbf{y} \in \{0, 1\}^q. \end{array} \right. \quad (2)$$

By introducing the utility function, the vector optimization problem has been reduced to a scalar optimization problem and MINLP techniques can be applied to solve the problem. These MINLP techniques include *generalized Benders decomposition* (GBD) [4,14], *outer approximation* (OA) [2], *outer approximation with equality relaxation* (OA/ER) [8], and *outer approximation with equality relaxation and augmented penalty* (OA/ER/AP) [16]. These methods are discussed in detail in [3].

With the definition of the noninferior solution set, the optimization problem can be formulated as

$$\left\{ \begin{array}{ll} \min & U[\mathbf{J}(\mathbf{x}, \mathbf{y})] \\ \text{s.t.} & G(\mathbf{J}) = 0. \end{array} \right. \quad (3)$$

The challenging aspect of the problem is determining the explicit form of the utility function. One possible form of the utility function is a weighted linear sum of the objectives:

$$U[\mathbf{J}(\mathbf{x}, \mathbf{y})] = \sum_{i \in I} w_i J_i,$$

where  $I$  is the set of objective functions and  $w_i$  are the weights for the objective functions whose value is determined by the DM. The difficulty that arises is that the utility function is generally not known. It is, however, assumed to be convex and continuously differentiable.

The issues surrounding the solution of the multi-objective optimization problem are determining the noninferior solution set, determining the utility function based on information from the DM, and determining the best-compromise solution.

Different techniques have been developed in order to assess the trade-offs among the objectives quantita-

tively. See [7] for a tutorial in multi-objective optimization. A review is also available in [17]. Much of the fundamental aspects of multi-objective optimization can be found in [1].

### Noninferior Solution Sets

The noninferior solution set can be determined in a number of ways. One approach is to formulate the problem as

$$\left\{ \begin{array}{l} \min \sum_{i \in I} w_i J_i(\mathbf{x}, \mathbf{y}) \\ \text{s.t. } \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \mathbf{x} \in \mathbb{R}^p \\ \mathbf{y} \in \{0, 1\}^q, \end{array} \right. \quad (4)$$

where the weights  $w_i$  are selected such that  $w_i \geq 0$  for all  $i$  and  $\sum_{i \in I} w_i = 1$ . Through a suitable choice of the weights, the noninferior solution set can be found. This approach can miss some points in the noninferior solution set if the solution region is nonconvex. In order to address this problem, a weighted norm can be used as follows:

$$\left\{ \begin{array}{l} \min \left\{ \sum_{i \in I} [w_i J_i(\mathbf{x}, \mathbf{y})]^p \right\}^{1/p} \\ \text{s.t. } \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \mathbf{x} \in \mathbb{R}^p \\ \mathbf{y} \in \{0, 1\}^q. \end{array} \right. \quad (5)$$

By increasing the size of  $p$ , the curvature of the supporting function is increased and more noninferior points can be found. In the extreme of  $p = \infty$ , all the noninferior points can be located. Using the  $\infty$ -norm, the problem becomes

$$\left\{ \begin{array}{l} \min \max_{i \in I} w_i J_i(\mathbf{x}, \mathbf{y}) \\ \text{s.t. } \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \mathbf{x} \in \mathbb{R}^p \\ \mathbf{y} \in \{0, 1\}^q. \end{array} \right. \quad (6)$$

The advantage of this formulation is that the weights have a physical meaning for the DM. If the DM knows

the desired values for each objective for a given noninferior point, the weights can be set to the reciprocal of these values. The noninferior solution will be the one that is most like the one with the values specified by the DM. The disadvantage of this formulation is that it can be difficult to solve.

Another way to determine the noninferior solution set is through the  $\epsilon$ -constraint method [6]. In this approach, all but one of the objectives is incorporated into the problem as a constraint less than  $\epsilon$ . This results in the following formulation:

$$\left\{ \begin{array}{l} \min J_1(\mathbf{x}, \mathbf{y}) \\ \text{s.t. } J_i(\mathbf{x}, \mathbf{y}) \leq \epsilon_i, \quad i = 2, \dots, q, \\ \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \mathbf{x} \in \mathbb{R}^p \\ \mathbf{y} \in \{0, 1\}^q. \end{array} \right. \quad (7)$$

By varying the values of  $\epsilon_i$ , the points of the noninferior solution set can be found.

### Choosing the Best-Compromise Solution

To this point, the focus has been on determining the noninferior solution set. Only one of the points can be chosen as the best solution for the problem, and the task of the DM is to determine this point. Once the noninferior solution set is determined, it is presented to the DM who will choose the solution point he prefers. The selection of this point is based on the relative importance of the objectives in the eyes of the decision maker.

Instead of assigning arbitrary weights to the various objectives, a systematic approach can be applied which uses the trade-off information in the noninferior solution set. The slope of the noninferior solution set at any point reveals how much one objective will be improved at the expense of another objective. This information is used in an interactive, iterative *cutting plane algorithm* to determine the best compromise solution.

### Cutting Plane Algorithm

The cutting plane algorithm described in [11] is based on [5] and [10]. Marginal rates of substitution were used to solve problems of the form (2) where  $U$  is unknown, convex, and continuously differentiable. Due to

convexity, the partial derivatives of  $U$  with respect to each of the arguments in the objective space are positive. This is expressed mathematically as

$$\frac{\partial U(\mathbf{J})}{\partial J_i} > 0.$$

Thus, a decrease in  $J_i$  will lead to a decrease in  $U$ . In the interactive scheme, the DM is asked for the positive trade-off weights,  $w_i^k$ , for a given solution  $k$ . This weight is defined as the ratio of the change in the utility function with respect to one function divided by the change in the utility function with respect to another. This is expressed mathematically as

$$w_i^k = \frac{\partial U(\mathbf{J}^k) / \partial J_i}{\partial U(\mathbf{J}^k) / \partial J_1}$$

where  $\mathbf{J}^k = [J_1(\mathbf{x}^k, \mathbf{y}^k), \dots, J_1(\mathbf{x}^k, \mathbf{y}^k)]$ . A line search along a feasible direction of steepest descent locates an improved solution for the next iteration.

By exploiting the fact that the utility function is convex, cutting planes can be introduced to reduce the search to improving directions [10]. Since  $U$  is convex,

$$\begin{aligned} 0 &\geq U(\mathbf{J}^*) - U(\mathbf{J}^k) \\ &\geq \nabla_f U(\mathbf{J}^k)(\mathbf{J}^* - \mathbf{J}^k) \\ &\geq \begin{cases} \min & \nabla_f U(\mathbf{J}^k)(\mathbf{J} - \mathbf{J}^k) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbb{R}^p \\ & \mathbf{y} \in \{0, 1\}^q. \end{cases} \end{aligned} \quad (8)$$

This involves the linearization in the objective space around the point  $\mathbf{J}^k$ . If the solution to the minimization is zero, then the optimal solution  $\mathbf{J}^*$  has been found. If the solution has a negative value, then the direction leads to an improvement in the objective space. This minimization can be performed over a number of points  $k = 1, \dots, K$  to find a direction which improves all of them. Cutting planes in the objective space are formed to find new values of the objectives which improve the utility function according to the trade-off weights,  $\nabla U$ , which the DM provides. At each iteration

of the algorithm, the following problem must be solved:

$$\left\{ \begin{array}{l} \min \quad z \\ \text{s.t.} \quad z \geq \sum_{i=1}^p w_i^k (J_i(\mathbf{x}, \mathbf{y}) - J_i(\mathbf{x}^k, \mathbf{y}^k)), \\ \quad \quad \quad \forall k = 1, \dots, K. \\ \quad \quad \quad \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ \quad \quad \quad \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \quad \quad \quad \mathbf{x} \in \mathbb{R}^p \\ \quad \quad \quad \mathbf{y} \in \{0, 1\}^q. \end{array} \right. \quad (9)$$

The steps of the cutting plane algorithm are the following:

- 1 Determine the initial solution point  $k = 1$  and determine the values of all the objective functions. Assign the values of the weights  $w_i^k$ .
- 2 Solve (9) to find new values of  $\mathbf{x}$  and  $\mathbf{y}$ . Determine the values of the objective functions for the new values of  $\mathbf{x}$  and  $\mathbf{y}$ .
- 3 IF the solution to (9) is zero, THEN go to Step 4 ELSE set  $k = k + 1$ , update the values  $\mathbf{x}^k$ ,  $\mathbf{y}^k$ , and  $\mathbf{J}^k$ , generate new weights, and go to Step 2.
- 4 Terminate with  $\mathbf{x}^k$  and  $\mathbf{y}^k$  as the best-compromise solution.

#### Cutting plane algorithm

This algorithm requires the DM to provide only trade-off weights at each iteration. These weights can be estimated by knowledge of the relative importance of the objectives or by information from the noninferior solution set.

### Multi-objective Optimization in the Interaction of Design and Control

The interaction of design and control has been recognized as a multi-objective problem by many researchers as the objectives representing the steady-state economic design and dynamic controllability are regarded as non-commensurable. One of the first challenges in this problem is determining a suitable controllability objective. The choice of the controllability objective will dictate the required elements of the mathematical formulation of the problem.

One of the early works which addressed the multi-objective nature of the interaction of design and control was that of [9]. A given set of alternative steady-state designs was assumed to be known. Bounds on the dynamic measures of the designs were determined and used to screen designs and determine the noninferior solution set. No method was provided for determining the best-compromise solution.

In the work of [13], singular value decomposition is used to determine dynamic operability measures. The controllability is formulated through the linearization of the model and is given in terms of the singular values of the transfer function. This modeling leads to an infinite-dimensional problem as all frequencies must be considered for the controllability measure. For the multi-objective optimization, the  $\epsilon$ -constraint method was used to determine the noninferior solution set. The scalar optimization was addressed by approximating the infinite-dimensional problem and using an gradient-based algorithm to solve the optimization problem and determine the operating parameters for the process.

The previous methods did not take into account that the structure of the process flowsheet as well as the design parameters determine its inherent controllability. In order to consider structural alternatives in the process flowsheet such as the existence of units in the flowsheet, discrete variables are used in the process modeling. This aspect of the process design was considered by [11,12] in the interaction of design and control by using the optimization approach to process synthesis. In this approach, the structure of the process flowsheet and the design parameters are considered simultaneously with the dynamic controllability of the process. The controllability measures employed were the open-loop linear controllability measures (singular value, condition number, relative gain array). The noninferior solution set was determined using the  $\epsilon$ -constraint method, and the best-compromise solution was found using the cutting plane method described above.

Further development of the above technique was addressed by [15] where nonlinear dynamic models were considered. The problem was formulated as a multi-objective *mixed integer optimal control problem*. The multi-objective problem was again solved using the  $\epsilon$ -constraint method. The mixed integer optimal con-

trol problem was solved by extending the methods for solving mixed integer nonlinear optimization to handle dynamic systems.

## Conclusions

Analyzing the interaction of design and control leads to a multi-objective optimization problem. The key issue in solving this problem is quantitatively determining the trade-offs between the steady-state economics and the dynamic controllability. By using multi-objective optimization techniques, these characteristics of the process can be traded off in a systematic manner.

By following the optimization approach to process synthesis, a mathematical framework can be developed. This involves developing a superstructure of design alternatives and effective mathematical models for the different criteria. The algorithmic procedure for solving the multi-objective problem involves the successive solution of scalar optimization problems to determine the noninferior solution set. The final step in the approach is to determine the best-compromise solution from those in the noninferior solution set.

Multi-objective optimization; Multiple criteria decision making; Interactive method; Preference value function; Value function

The *multi-objective optimization (multiple criteria decision making)* problem is the problem of choosing a most preferred solution when two or more incommensurate, conflicting objective functions (criteria) are to be simultaneously maximized. Interest in multi-objective optimization has risen sharply during the past 30 years. There are at least three reasons for this. First, and most importantly, is the increasing recognition that most applied problems in both the private and public sectors involve multiple objectives rather than one objective. Second, a variety of solution algorithms for multi-objective optimization are now available. Finally, the enormous improvements in the speed and storage of computers make it practical to apply these algorithms to the solution of realistically-sized problem applications.

Formally, the statement of the multi-objective optimization problem of interest here is

$$(V) \quad \begin{cases} \text{VMAX} & f(x) = [f_1(x), \dots, f_p(x)], \\ \text{s.t.} & x \in X. \end{cases}$$

Here,  $p \geq 2$ ,  $X$  is a nonempty subset of  $\mathbf{R}^n$ , each  $f_j, j = 1, \dots, p$ , is a real-valued function defined on  $X$  or on some suitable set containing  $X$ , and VMAX indicates that, in some unspecified sense, we are to 'vector maximize' the vector  $f(x)$  of *objective functions (criteria)* over  $X$ . The set  $X$  is called the set of *decision alternatives* or the *decision set*, and  $\{f(x) \in \mathbf{R}^p: x \in X\}$ , is called the *outcome set*.

There are a large number of diverse solution algorithms for problem (V). All are intended to help the *decision maker (DM)* find a most preferred solution to the problem. In the majority of these algorithms, the notion of efficiency plays an indispensable role. An *efficient (nondominated, noninferior, Pareto optimal)* solution for problem (V) is a solution  $\bar{x} \in X$  such that there exists no other solution  $x \in X$  that satisfies  $f(x) \geq f(\bar{x})$  and  $f(x) \neq f(\bar{x})$ . Let  $X_E$  denote the set of efficient solutions for problem (V). Notice that if  $\bar{x} \in X_E$ , then there is no other feasible solution for problem (V) that achieves at least as large a value as  $\bar{x}$  in each criterion of the problem and a strictly larger value than  $\bar{x}$  in at least one criterion of the problem.

In the great majority of instances of problem (V), the *preference value function (value function)*  $v$  of the DM is unknown. This is a function  $v: \mathbf{R}^p \rightarrow \mathbf{R}$  that maps

the outcomes of problem V to real numbers in such a way that for any two outcomes  $y^1$  and  $y^2$ , the DM prefers  $y^1$  to  $y^2$  if and only if  $v(y^1) > v(y^2)$ . Although  $v$  is unknown, what is known is that for each objective function  $f_j$ , the DM prefers more of  $f_j$  to less of  $f_j$ . Mathematically, this means that  $v$  is *coordinatewise increasing*, i. e., that whenever  $\bar{z}, z \in \mathbf{R}^p$  satisfy  $\bar{z} \geq z$  and  $\bar{z}_j > z_j$  for some  $j = 1, \dots, p$ , then  $v(\bar{z}) > v(z)$ . It is easy to show that when  $v$  is coordinatewise increasing, any maximizer  $x^*$  of  $v[f(x)]$  over  $X$  must satisfy  $x^* \in X_E$ . In other words, as long as the DM prefers more to less, the search for a most preferred solution to problem (V) can be confined to  $X_E$ . This is one of the key reasons that the concept of efficiency is so important to the majority of the algorithms for problem (V).

The interactive methods constitute one of the most popular categories of algorithms for solving problem (V). An *interactive method* for problem (V) consists of a sequence of DM-computer interactions designed to create a sequence of decision alternatives that terminates with a most preferred solution to the problem. In a majority of cases, the generated alternatives are efficient. Each iteration of the interactive process consists of three steps. First, an initial solution is found with the aid of the computer. Typically, this solution is found by solving a single-objective optimization problem that generates either an efficient point or, at worst, a feasible point. Next, the DM is asked to react to the generated point by answering one or more questions involving his preferences for it. Last, based upon the answers given, the computer generates a new point, typically by modifying parameters in the single-objective optimization problem. This process continues until either the computer or the DM identifies a most preferred solution. The value function  $v$  of the DM is never needed and, in fact, is assumed to be unavailable.

There are several advantages to using interactive methods as compared to other categories of methods for problem (V). For instance, the preference information asked of the DM at each iteration is not difficult to supply. Furthermore, the DM thereby learns about his value function, which is often initially vague or mostly unknown. As the search continues, the DM also learns about the decision or efficient decision alternatives available and the trade-offs in the objective functions across these decision alternatives. The optimizations required of the computer are also usually

not difficult to perform. Finally, because the DM is highly involved in the process, his confidence in the most preferred solution that is eventually found is enhanced.

A frequent criticism of the interactive methods is that, in practice, the work required of the DM during the iterations seems to be burdensome for him in many cases. This may cause the DM to prematurely terminate the search so that a most preferred solution is not found.

There are literally hundreds of interactive algorithms for problem (V). Many are limited to cases where problem (V) is a multiple objective linear programming problem. Others apply when problem (V) is a multiple objective convex, nonlinear programming problem, a multiple objective integer programming problem, or some other type of multiple objective optimization problem. Instead of examining these algorithms individually, we will describe them by groups according to the characteristics that they possess.

One of the key characteristics of the interactive algorithms concerns the type of information required of the DM at each iteration. For instance, at each iteration, the DM may be asked to intuitively assign or reassign *weights* to the criteria according to his current assessment of their relative importance. R.E. Steuer [13] has shown some important stumbling blocks to this approach, however. Other algorithms may instead elicit *relaxation quantities* from the DM. In these cases, the DM is asked how much he would be willing to relax the level of one objective function in order to obtain possible improvements in the levels of other objective functions. Some of the oldest interactive algorithms use this approach [1,9]. Still other types of algorithms ask the DM various types of *trade-off questions*. The trade-off questions are designed to obtain an estimate of the gradient of the value function of the DM at the current solution. This approach is also relatively old, but difficult for the DM to accomplish [5,14]. Finally, a number of algorithms call for the DM to make *paired comparisons* at each iteration. In a paired comparison, the DM is given two solutions to compare and must give his preference for one or the other. Usually, the DM can accomplish this. But when the two solutions are quite similar, difficulties can arise [15]. In addition, algorithms that use paired comparisons can sometimes call for excessive numbers of these comparisons [12].

A second dimension where the interactive algorithms differ is in the approach used to explore the feasible region  $X$  or the efficient set  $X_E$ . Some algorithms use *feasible direction methods* [2]. In these algorithms, at each iteration, the direction to move from a point that was last found and the distance to move along the direction are determined with the aid of the DM. By moving along the direction by the specified amount, the next solution point is found. In many algorithms, all such points are efficient. In another group of algorithms, *feasible region reduction* is used to explore  $X$  or  $X_E$ . As points in  $X$  or in  $X_E$  are examined in these methods, portions of  $X$  are removed, usually via linear cuts. Another set of algorithms uses *weighting space reduction*. In these algorithms, a weighted sum of  $f_j$ ,  $j = 1, \dots, p$ , is maximized at each iteration, thereby yielding a point in  $X_E$ . Based upon the DM's responses to these maximizations, portions of the weighting space are removed. Eventually, the portion of the weighting space remaining is so small that the DM can pick out the set of weights associated with a most preferred solution.

Other approaches used to explore  $X$  or  $X_E$  include the *trade-off cutting plane* method [10], *Lagrange multiplier* methods, *visual interactive* methods (see, e.g. [7]), and the *branch and bound* method [8], among others. For further reading concerning these methods, see [3,4,6,11,12,13].

Another way to group the interactive algorithms for problem (V) is according to whether or not they handle inconsistencies in the DM's preference responses. As human beings, DM's are prone to giving preference responses over the course of the solution procedure that imply inconsistencies such as asymmetries or intransitivities of preference. Some algorithms take no account of these possible inconsistencies and have been criticized for this [12]. Others attempt to reduce inconsistency by either minimizing the DM's cognitive burden or by incorporating tests for inconsistency that are used as the interactive solution process proceeds.

W.S. Shin and A. Ravindran [12] have compared various of the classes of interactive algorithms according to four criteria that are important in practice. These criteria are the DM's cognitive burden, the ease with which the single-objective optimizations called for can be used, implemented and solved, the handling of inconsistency, and the overall quality of the solution process and the answers obtained. Although preliminary,

these comparisons seem to show the relative superiority of the weighting space reduction and other criterion weight space search methods, and of the visual interactive methods. Readers should note, however, that the rankings in the study are subjectively-obtained by the authors [7].

For further general reading on interactive methods, see [2,3,4,6,11,12,13,14].

## Keywords

Vector inequality; Efficient point; Vector valued Lagrangian

As is well known, duality in mathematical programming is based on the property that any closed convex set can be also represented by the intersection of closed half spaces including it. Let the multi-objective optimization problem to be considered here be given by

$$(P) \quad \begin{cases} \min & f(x) := (f_1(x), \dots, f_p(x)) \\ \text{over} & x \in X, \end{cases}$$

where

$$X = \left\{ x \in X' : \begin{array}{l} g_i(x) \leq 0, \\ i = 1, \dots, m, X' \subset \mathbb{R}^n \end{array} \right\}.$$

Note here that vector inequalities are commonly used: for any  $n$ -vectors  $a$  and  $b$ ,  $a > b$  means  $a_i > b_i$  ( $i = 1, \dots, n$ ). Also,  $a \geq b$  means  $a_i \geq b_i$  ( $i = 1, \dots, n$ ). On the other hand,  $a \geq b$  means  $a \geq b$  but  $a \neq b$ . Hereafter, vector inequalities such as  $g(x) \leq 0$  will be used instead of  $g_i(x) \leq 0$  ( $i = 1, \dots, m$ ).

Defining a dual problem (D) in some appropriate way associated with the problem (P), our aim is to show the property  $\min(P) = \max(D)$ . Here  $\min(P)$  denotes the set of efficient points of the problem (P) in the objective function space  $\mathbf{R}^p$ , and similarly  $\max(D)$  the one of the dual problem (D).

Unlike the usual mathematical programming, the optimal value of the primal problem (and the dual problem) are not necessarily determined uniquely in multi-objective optimization. Hence, there have been developed several kinds of formulation of dual problem in order to get the desirable property  $\min(P) = \max(D)$ . Regarding Lagrange duality, three typical dualizations can be seen in linear cases, nonlinear cases and geometric approaches [6].

## Linear Cases

The first result on duality for multi-objective optimization seems the one given in [1] for linear cases. This is formulated as a matrix optimization including the vector optimization as a special case. Although there have been several related works, the probably most attractive one is given in [2] because it is formulated as a natural

extension of traditional linear programming: Let  $A$  be an  $m \times n$  matrix,  $C$  a  $p \times n$  matrix, and  $b$  an  $m$ -vector. Then the *primal problem* (P) in linear cases is formulated as

$$(P_1) \quad \begin{cases} \min & Cx \\ \text{s.t.} & Ax \geq b \\ & x \geq 0. \end{cases}$$

Associated with (P<sub>1</sub>), H. Iserman [2] defined the *dual problem* as

$$(D_1) \quad \begin{cases} \max & \Lambda b \\ \text{s.t.} & \Lambda A \not\geq C \\ & \Lambda \geq 0. \end{cases}$$

Here, the multiplier  $\Lambda \geq 0$  is a  $p \times m$  matrix whose elements are all nonnegative.

Then Isermann's duality is given by

- i)  $\Lambda b \not\geq Cx$  for all feasible  $x$  and  $\Lambda$ .
- ii) Suppose that  $\bar{\Lambda}b = C\bar{x}$  for some feasible  $\bar{x}$  and some feasible  $\bar{\Lambda}$ . Then  $\bar{\Lambda}$  is an efficient solution to (D<sub>1</sub>) and  $\bar{x}$  is an efficient solution to (P<sub>1</sub>).
- iii)  $\min(P_1) = \max(D_1)$ .

## Nonlinear Cases

The most natural dualization in nonlinear multi-objective optimization seems to be the one given in [10].

Consider the problem (P), and assume the following:

- i)  $X'$  is a nonempty compact convex set.
- ii)  $f$  is continuous, and  $f(X) + \mathbf{R}_+^p$  is convex in  $\mathbf{R}^p$ .
- iii)  $g_i$  ( $i = 1, \dots, m$ ) are continuous and convex.

Under these assumptions, it can be readily shown that for every  $u \in \mathbf{R}^m$ , both sets  $X(u) = \{x \in X' : g(x) \leq u\}$  and  $Y(u) = f[X(u)] = \{y \in \mathbf{R}^p : y = f(x), x \in X', g(x) \leq u\}$  are compact and convex.

The primal problem (P) can be embedded as (P<sub>0</sub>) in a family of perturbed problems (P<sub>u</sub>) given by

$$(P_u) \quad \min Y(u).$$

Defining  $\Gamma = \{u \in \mathbf{R}^m : X(u) \neq \emptyset\}$ , the set  $\Gamma$  is convex. Now in a similar fashion to the ordinary mathematical programming, the perturbed map can be defined by

$$W(u) = \min \{f(x) : x \in X', g(x) \leq u\}.$$

It is known that for every  $u \in \Gamma$ ,  $W(u) + \mathbb{R}_+^p$  is convex and

$$W(u) + \mathbb{R}_+^p = Y(u) + \mathbb{R}_+^p.$$

In addition, the map  $W$  is monotone and convex on  $\Gamma$ .

Now, define the vector valued Lagrangian function with a  $p \times m$  matrix multiplier  $\Lambda$  as

$$L(x, \Lambda) = f(x) + \Lambda g(x).$$

Associated with this definition, the dual map can be defined as

$$\Phi(\Lambda) = \min \Omega(\Lambda),$$

where

$$\Omega(\Lambda) = \{L(x, \Lambda) : x \in X'\}.$$

Under the terminology, the dual problem associated with the primal problem (P) can be given by

$$(D_{TS}) \quad \max \bigcup_{\Lambda \in \mathcal{L}} \Phi(\Lambda).$$

It can be shown that  $\Phi$  is concave point-to-set map on  $\Gamma$ , namely

$$\begin{aligned} &\Phi(\alpha\Lambda^1 + (1-\alpha)\Lambda^2) \\ &\subset \alpha\Phi(\Lambda^1) + (1-\alpha)\Phi(\Lambda^2) + \mathbb{R}_+^p \end{aligned}$$

and  $\Phi(\Lambda) + \mathbb{R}_+^p$  is a convex set in  $\mathbb{R}^p$  for each  $\Lambda \in \mathcal{L}$ . Here  $\mathcal{L}$  is the set of all  $p \times m$  matrices whose components are all positive.

T. Tanino and Y. Sawaragi [10] presented the following as duality in multi-objective optimization:

**Theorem 1**

i) For any  $x \in X$  and  $y \in \Phi(\Lambda)$

$$y \not\preceq f(x).$$

ii) Suppose that  $\hat{x} \in X$ ,  $\hat{\Lambda} \in \mathcal{L}$  and  $f(\hat{x}) \in \Phi(\hat{\Lambda})$ . Then  $\hat{y} = f(\hat{x})$  is an efficient point to the primal problem (P) and also to the dual problem (D<sub>TS</sub>).

iii) Suppose that any efficient solutions to (P) are all proper and that Slater's constraint qualification is satisfied. Then

$$\min(P) \subset \max(D_{TS}).$$

*Remark 2* The above theorem is not complete in the sense that the relation  $\min(P) = \max(D)$  does not hold. Regarding conjugate duality, there have been reports presenting  $w\text{-min}(P) = w\text{-max}(D)$  (see, e.g., [4] and [9]). Several studies based on geometric consideration have been made for deriving the relation  $\min(P) = \max(D)$  using vector valued Lagrangian. This will be stated in the following

**Geometric Duality**

Geometric considerations are made in [3], based on the supporting hyperplanes for  $\text{epi}W$ , and in [5], based on the supporting conical varieties for  $\text{epi}W$ , which is denoted by  $G$  here.

Define

$$G = \left\{ (u, y) \in \mathbb{R}^p \times \mathbb{R}^p : \begin{array}{l} y \geq f(x), \\ u \geq g(x) \\ \text{for some } x \in X' \end{array} \right\},$$

$$Y_G = \{y : (0, y) \in G, 0 \in \mathbb{R}^m, y \in \mathbb{R}^p\}.$$

Associates with the primal problem (P), we consider the following two kinds of dual problems:

$$(D_N) \quad \max \bigcup_{\Lambda \in \mathcal{L}} Y_{S(\Lambda)},$$

where

$$Y_{S(\Lambda)} = \{y \in \mathbb{R}^p : f(x) + \Lambda g(x) \not\preceq y, \forall x \in X'\}$$

and

$$(D_J) \quad \bigcup_{\substack{\mu > 0 \\ \lambda \geq 0}} Y_{H^-(\lambda, \mu)},$$

where

$$\begin{aligned} &Y_{H^-(\lambda, \mu)} \\ &= \left\{ y \in \mathbb{R}^p : \begin{array}{l} \langle \mu, f(x) \rangle + \langle \lambda, g(x) \rangle \geq \langle \mu, y \rangle \\ \forall x \in X' \end{array} \right\}. \end{aligned}$$

**Theorem 3**

i) For any feasible  $x$  in (P) and for any feasible  $y$  in (D<sub>N</sub>) or (D<sub>J</sub>),

$$y \not\preceq f(x).$$

ii) Assume that  $G$  is closed, that there exists at least an efficient solution to the primal problem, and that

these solutions are all proper. Then, under the condition of Slater's constraint qualification, the following holds:

$$\min(P) = \max(D_N) = \max(D_J).$$

**Remark 4** In the above duality, we assumed that the convex set  $G$  is closed and that Slater's constraint qualification is satisfied, which seem relatively restrictive. Instead of these conditions, J. Jahn [3] assumed that  $Y_G$  is closed and some normality condition.

Define

$$A_{G(\mu)} = \{\alpha: (0, \alpha) \in G(\mu), 0 \in \mathbb{R}^m, \alpha \in \mathbb{R}^1\}$$

$$Y_G = \{y: (0, y) \in G, 0 \in \mathbb{R}^m, y \in \mathbb{R}^m\}.$$

**Definition 5** The primal problem (P) is said to be  $J$ -normal, if for every  $\mu > 0$

$$\text{cl}(A_{G(\mu)}) = A_{\text{cl}G(\mu)}.$$

The primal problem (P) is said to be  $J$ -stable, if it is  $J$ -normal and for an arbitrary  $\mu > 0$  the problem

$$\sup_{\lambda \geq 0} \inf_{x \in X} \langle \mu, f(x) \rangle + \langle \lambda, g(x) \rangle$$

has at least one solution.

On the other hand, J.W. Nieuwenhuis [7] suggested another normality condition:

**Definition 6** The primal problem (P) is said to be  $N$ -normal, if

$$\text{cl} Y_G = Y_{\text{cl}G}.$$

**Lemma 7** Slater's constraint qualification ( $\exists \hat{x}, g(\hat{x}) > 0$ ) yields  $J$ -stability and  $N$ -normality.

**Theorem 8** Suppose that  $Y_G$  is closed,  $\min_D(P) \neq \emptyset$ , and the efficient solutions to (P) are all proper. Then, under the condition of  $J$ -stability,

$$\min(P) = \max(D_N) = \max(D_J).$$

## Duality for Weak Efficiency

Define

$$Y_{S'(\Lambda)} = \{y \in \mathbb{R}^p: f(x) + \Lambda g(x) \not\prec y, \forall x \in X'\}.$$

**Theorem 9** Suppose that  $Y_G$  is a nonempty subset in  $\mathbb{R}^p$  and  $Y_G + \mathbb{R}_+^p$  is bounded. Then under the condition of  $N$ -normality

$$w\text{-min cl } Y_G = w\text{-max cl } \bigcup_{\Lambda \in \mathcal{L}} Y_{S'(\Lambda)}$$

$$= w\text{-max cl } \bigcup_{\substack{\mu \in \mathbb{R}_+^p \setminus \{0\} \\ \lambda \geq 0}} Y_{H^-(\lambda, \mu)}.$$

**Remark 10** As can be readily seen, by defining  $\inf A$ , for a set  $A \in \mathbb{R}^p$ , as essentially  $\min \text{cl}(A + \mathbb{R}_+^p)$  and similarly  $\sup A$  as essentially  $\min \text{cl}(A - \mathbb{R}_+^p)$ , we can have  $\inf(P) = \sup(D_{TS}) = \sup(D_N) = \sup(D_J)$  under some appropriate stability condition [9].

### Keywords

Multi-objective optimization; Multiple criteria decision making; Efficient solution; Pareto optimal solution; Noninferior solution; Nondominated solution; Weakly efficient solution; Weakly Pareto optimal solution; Weakly noninferior solution; Weakly nondominated solution; Properly efficient solution

The *multi-objective optimization (multiple criteria decision making)* problem is the problem of choosing a most preferred solution when two or more incommensurate, conflicting objective functions (criteria) are to be simultaneously maximized. A central difficulty in such problems is that, unlike in single objective maximization problems, there is no obvious or simple way to define the concept of a most preferred solution. Nevertheless, because the applications of multi-objective optimization abound, there has been great interest during the past 30 years in seeking appropriate definitions for a most preferred solution and in developing algorithms that aid the decision maker (DM) to find such a solution. These applications are in a wide variety of areas, including, for example, production planning, finance, environmental conservation, academic planning, nutrition planning, advertising, facility location, auditing, blending techniques, transportation planning, and scheduling, to name just a few.

There are several alternate mathematical formulations of the multi-objective optimization problem [13]. For purposes of modeling the deterministic multiple objective optimization problems found in management science/operations research, however, the most popular form of the problem is denoted

$$(V) \quad \begin{cases} \text{VMAX} & [f_1(x), \dots, f_p(x)] \\ \text{s.t.} & x \in X. \end{cases}$$

Here,  $p \geq 2$ ,  $X$  is a nonempty subset of  $\mathbf{R}^n$ , each  $f_j, j = 1, \dots, p$ , is a real-valued function defined on  $X$  or on a suitable set containing  $X$ , and VMAX indicates that we are to, in some as-yet unspecified sense, ‘vector maximize’ the vector

$$f(x) = [f_1(x), \dots, f_p(x)]$$

of *objective functions (criteria)* over  $X$ . The set  $X$  is called the set of *alternatives* or the *decision set*.

Of all of the solution concepts proposed for helping the DM find a most preferred solution for problem (V), the concept of efficiency has proven to be of overriding importance. An *efficient (Pareto optimal, noninferior, nondominated) solution* for problem (V) is a point  $\bar{x} \in X$  such that there exists no other point  $x \in X$  that satisfies  $f(x) \geq f(\bar{x})$  and  $f(x) \neq f(\bar{x})$ . Letting  $X_E$  denote the set of all efficient points for problem (V), we see that whenever  $\bar{x} \in X_E$ , there is no other feasible

point that does at least as well as  $\bar{x}$  in all of the criteria for problem (V) and strictly better in at least one criterion. A point  $\bar{x} \in X$  is called *dominated* when for some other point  $x \in X$ ,  $f(x) \geq f(\bar{x})$  and, for at least one  $j = 1, \dots, p$ ,  $f_j(x) > f_j(\bar{x})$ . Thus, we have the alternate definition for efficiency that states that a point  $\bar{x}$  is an *efficient* solution for problem (V) when  $\bar{x} \in X$  and there are no other points in  $X$  that dominate  $\bar{x}$ .

One of the reasons for the fundamental importance of the efficiency concept is that it has proven to be highly useful in a variety of algorithms for problem (V). Among these algorithms are the *satisficing* methods, *compromise programming*, most *interactive methods*, and the *vector maximization method*. The latter method, for instance, seeks to generate either all of  $X_E$  or key parts of  $X_E$ . The generated set is shown to the DM. Then, based upon the DM's internal utility (or value) function, the DM chooses from the generated set a most preferred solution. For details concerning these methods for problem (V), see [7,10,12,13,14].

In some cases, it is useful to consider a slightly relaxed concept of efficiency called weak efficiency. A point  $\bar{x} \in X$  is called a *weakly efficient* (*weakly Pareto optimal*, *weakly noninferior*, *weakly nondominated*) solution for problem (V) when there is no other point  $x \in X$  such that  $f(x) > f(\bar{x})$ . Let  $X_{WE}$  denote the set of all weakly efficient points for problem (V). Notice that  $X_E$  is a subset of  $X_{WE}$ . In some cases of problem (V), such as when the objective functions are ratios of linear functions, it is easier to analyze and generate points in  $X_{WE}$  than points in  $X_E$ .

Let  $U$  represent a utility function defined on the space  $\mathbb{R}^p$  of the objective functions of problem (V). Suppose that  $U$  is *coordinatewise increasing*, i. e., that whenever  $\bar{z}, z \in \mathbb{R}^p$  satisfy  $\bar{z} \geq z$  and  $\bar{z}_j > z_j$  for some  $j = 1, \dots, p$ , then  $U(\bar{z}) > U(z)$ . Suppose that  $x^*$  is an optimal solution to the single objective problem

$$(S) \quad \max_{x \in X} U[f_1(x), \dots, f_p(x)].$$

Then  $x^*$  must be an efficient solution for problem (V) (cf. [11]).

The property in the previous paragraph explains to a great extent why the concept of efficiency is of such fundamental value. The assumption that the utility function  $U$  in the above paragraph is coordinatewise increasing implies that in problem (S), for each  $j = 1, \dots,$

$p$ , more of  $f_j$  is preferred to less of  $f_j$ . Thus, if we imagine that  $U$  is the utility (or value) function of the DM over the objective function space of problem (V), then the previous paragraph implies that whenever the DM prefers more to less in each objective function of problem (V), any point that maximizes the DM's utility for  $f(x)$  over  $X$  must be an efficient point in problem (V). In short, as long as we know that the DM prefers more to less, we can confine the search for a most preferred solution to  $X_E$ . Although the utility function of the DM is generally not actually available, in virtually all applications the DM does, indeed, prefer more to less in each objective function of problem (V). Thus, in essentially all cases, any most preferred solution for problem (V) will be found in  $X_E$ .

Because of the central importance of efficiency, a great deal of effort has been made by researchers to delineate the properties of the efficient points and of the efficient set for problem (V). In what follows, we shall briefly highlight some of the most important of these properties.

Consider the single-objective optimization problem

$$(W) \quad \begin{cases} \max & \sum_{j=1}^p w_j f_j(x), \\ \text{s.t.} & x \in X. \end{cases}$$

Here,  $w_j$ ,  $j = 1, \dots, p$ , are parameters, which are often thought of as weights associated with the objective functions  $f_j$ ,  $j = 1, \dots, p$ , of problem (V). A number of so-called *scalarization properties* for efficient points of problem (V) are expressed in terms of problem (W). To present some of these, another efficiency concept, called proper efficiency, is needed. A point  $x^\circ$  is said to be a *properly efficient solution* for problem (V) when  $x^\circ \in X_E$  and, for some sufficiently large number  $M$ , whenever  $f_i(x) > f_i(x^\circ)$  for some  $i = 1, \dots, p$  and some  $x \in X$ , there exists some  $j = 1, \dots, p$  such that  $f_j(x) < f_j(x^\circ)$  and

$$\frac{f_i(x) - f_i(x^\circ)}{f_j(x^\circ) - f_j(x)} \leq M.$$

In words, for each properly efficient solution of problem (V), for each criterion, the possible marginal gains in that criterion relative to the losses in the criteria that have losses *cannot all* be unbounded from above. Let

$X_{PRE}$  denote the set of properly efficient solutions for problem (V), and let  $w^T = (w_1, \dots, w_p)$ . Then some key scalarization properties are as follows.

- 1) If  $\bar{x}$  is the unique optimal solution to problem (W) for some  $w \geq 0, w \neq 0$ , then  $\bar{x} \in X_E$ .
- 2) If  $\bar{x}$  is an optimal solution to problem (W) for some  $w \geq 0, w \neq 0$ , then  $\bar{x} \in X_{WE}$ .
- 3) Assume that for each  $j = 1, \dots, p, f_j$  is a concave function on the convex set  $X$ . Then  $\bar{x} \in X_{PRE}$  if and only if  $\bar{x}$  is an optimal solution to problem (W) for some  $w > 0$ .
- 4) Under the assumptions in property 3),  $\bar{x} \in X_{WE}$  if and only if  $\bar{x}$  is an optimal solution to problem (W) for some  $w \geq 0, w \neq 0$ .
- 5) Under the assumptions of property 3), if  $\bar{x} \in X_E$  but  $\bar{x} \notin X_{PRE}$ , then there exists a  $w \geq 0, w \neq 0$  with  $w_j = 0$  for at least one  $j = 1, \dots, p$  such that  $\bar{x}$  is an optimal solution to problem (W).
- 6) If each  $f_j, j = 1, \dots, p$ , is a linear function and  $X$  is a polyhedron,  $X_{PRE} = X_E$ .

The scalarization properties can be used for various purposes, including the generation of points in  $X_E, X_{WE}$  and  $X_{PRE}$ . For instance, when each  $f_j, j = 1, \dots, p$ , is a linear function and  $X$  is a polyhedron, from properties 3) and 6), points in  $X_E$ , including, at least potentially, all of  $X_E$ , can be generated by solving problem (W) as the parameter  $w > 0$  is varied. Under the assumptions of property 3), the same process will generate points in  $X_{PRE}$ , including, at least potentially, all of  $X_{PRE}$ . However, from properties 3)–5), it is apparent that no such simple process for generating  $X_E$  exists, even under the assumptions of property 3). This is another motivation for the proper efficiency concept.

Another important issue in efficiency concerns testing. One may want to test a given point for efficiency in problem (V), and one may want to test whether  $X_E$  and  $X_{PRE}$  are empty or not. We will present several of the properties of efficiency that provide some of the theory for these tests. These properties all utilize the single-objective problem

$$(T) \begin{cases} \max & \sum_{j=1}^p f_j(x), \\ \text{s.t.} & f_j(x) \geq f_j(x^\circ), \\ & j = 1, \dots, p, \\ & x \in X. \end{cases}$$

Here,  $x^\circ$  is an arbitrary element of  $\mathbf{R}^n$ . The properties are as follows.

- 7) The point  $x^\circ \in \mathbf{R}^n$  belongs to  $X_E$  if and only if  $x^\circ$  is an optimal solution to problem (T).
- 8) Suppose that  $x^\circ \in X$  in problem (T), and that problem (T) has no finite maximum value. Then  $X_{PRE} = \emptyset$  [1].
- 9) Suppose that the assumptions of property 3) hold, that  $x^\circ \in X$  in problem (T), and that problem (T) has no finite maximum value. Then, if the set
 
$$Z = \{z \in \mathbf{R}^p : z \leq f(x) \text{ for some } x \in X\}$$
 is closed,  $X_E = \emptyset$ .
- 10) Assume that each  $f_j, j = 1, \dots, p$ , is a linear function and that  $X$  is a polyhedron. Suppose that  $x^\circ \in X$  in problem (T), and that problem (T) has no finite maximum value. Then  $X_E = \emptyset$ .
- 11) Any optimal solution to problem (T) belongs to  $X_E$ .

Notice from these properties that solving problem (T) is a useful tool for both testing a point for efficiency and for investigating the issues of whether  $X_E$  and  $X_{PRE}$  are empty or not. In the case of testing a point  $x^\circ$  for efficiency, property 7) shows that problem (T) can be used to obtain a definitive answer, i. e., using property 7), we will always detect whether or not  $x^\circ \in X_E$ . Furthermore, when property 7) shows that  $x^\circ \notin X_E$ , but problem (T) has an optimal solution  $x^*$ , then, by property 11),  $x^* \in X_E$ . Notice also that in this case,  $x^*$  dominates  $x^\circ$ .

In the case of investigating whether or not  $X_E$  and  $X_{PRE}$  are empty, however, definitive answers cannot usually be obtained by using these properties. This is because none of the properties addresses the issue of whether or not  $X_E$  and  $X_{PRE}$  are empty when, instead of having an optimal solution or having no finite maximum value, problem (T) has a finite but unattained maximum value. The one case where the properties can be used to definitely detect whether or not  $X_E$  and  $X_{PRE}$  are empty is the case where the objective functions of problem (V) are all linear and  $X$  is a polyhedron. In that case, problem (T) cannot have a finite but unattained maximum value. Therefore, properties 7), 10) and 11) can be used to detect whether or not  $X_E = X_{PRE}$  is empty in such cases.

One of the main challenges computationally to generating all or parts of  $X_E$  or  $X_{WE}$  for the DM to consider

is that both  $X_E$  and  $X_{WE}$  are, except for trivial cases, *nonconvex sets*. Although some researchers have suggested ways to mitigate this problem [5], it generally remains a major stumbling block for algorithm development. In many common cases, however,  $X_E$  or  $X_{WE}$  possesses a useful, although less valuable, property than convexity upon which algorithms can be based. This property is called *connectedness*. In particular, a set  $Z \subseteq \mathbf{R}^n$  is *connected* if, whenever  $A$  and  $B$  are nonempty subsets of  $\mathbf{R}^n$  such that  $A$  has no points in common with the closure of  $B$ , and  $B$  has no points in common with the closure of  $A$ ,  $Z \neq A \cup B$ . Some common cases of problem (V) where  $X_E$  or  $X_{WE}$  is connected are given in the following properties.

- 12) Assume that for each  $j = 1, \dots, p$ ,  $f_j$  is a quasiconcave function on  $X$ , and that  $X$  is a compact convex set. Then  $X_{WE}$  is connected.
- 13) Assume that for each  $j = 1, \dots, p$ ,  $f_j$  is a concave function on  $\mathbf{R}^n$ , and that  $X$  is a compact convex set. Then  $X_E$  is connected.

Recall that a concave function on a convex set is also quasiconcave on the set. Therefore, from property 12), it follows that  $X_{WE}$  is connected when each objective function in problem (V) is a concave function on  $X$ , and  $X$  is a compact, convex set.

There are a variety of other properties of efficient points and of the efficient set for problem (V). These include, for instance, density properties, stability-related properties, the *domination property* [2,3,8], and complete efficiency-related properties [4,6]. For further reading, see [5,7,9,10,12,13,14].

Sensitivity analysis with respect to right-hand side changes; Critical region

In this article we will describe some results for sensitivity analysis and parametric programming for linear models. The solution approach that is described here is based upon the extension of simplex algorithm for linear programs (LP) [3,5]. Here we mention some references ([1,2,6,7,8,9,10,11,12,13,14,15,16,18,19,20,21], and [17]); however [3] is recommended for an extensive list of references and [4] for a historical outline on parametric linear programming.

We will consider right-hand side (RHS) multiparametric linear programming problems, where uncertain parameters are assumed to be bounded in a convex region. The solution algorithm is based upon characterizing the given initial convex region by a number of nonoverlapping smaller convex regions and obtaining

optimal solutions associated with each of these regions. The basic assumptions for the application of the algorithm are:

- The given region must be finite and connected.
- One should be able to characterize at least one (smaller) region.
- One should be able to identify all regions that are adjacent to a given region.

Consider the following multiparametric linear programming problem, when parameters are present on the right-hand side of the constraints:

$$\begin{cases} z(\theta) = \min_x & c^\top x \\ \text{s.t.} & Ax = b + F\theta \\ & x \geq 0 \\ & x \in \mathbb{R}^n, \quad \theta \in \mathbb{R}^s, \end{cases} \quad (1)$$

where  $x$  is a vector of continuous variables;  $A$  and  $F$  are constant matrices, and  $c$  and  $b$  are constant vectors of appropriate dimensions;  $\theta$  is a vector of uncertain parameters, such that for each  $\theta \in K$ ,  $\theta \in \mathbb{R}^s$ , (1) has a finite optimal solution, and has no optimal solution for  $\theta \in \mathbb{R}^s - K$ . Further, consider the following restriction on  $\theta \in \mathcal{E}$ ,  $\mathcal{E} = \{\theta: G\theta \leq g\}$ , where  $G$  is a constant matrix and  $g$  is a constant vector; see Fig. 1 for a graphical interpretation for the two parametric case where  $\theta$  is bounded in the region given by PQRST.

The simplex tableau associated with (1) is given as follows:

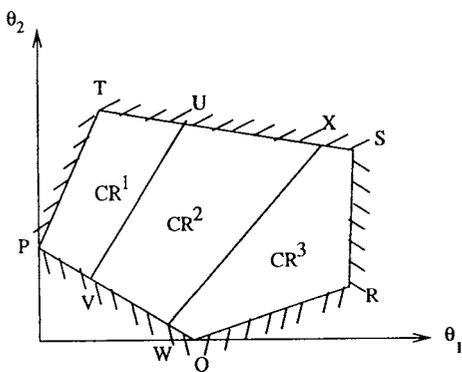

$$\begin{aligned} Yx - \rho F\theta &= x_B, \\ z + \rho z^\top x - f_{m+1}\theta &= z^{(\rho)}, \end{aligned}$$

where

$$\begin{aligned} Y &= B^{-1}A, \quad \rho F = B^{-1}F, \quad x_B = B^{-1}b, \\ z &= c^\top x, \quad \rho z = c_B^\top Y - c^\top, \\ f_{m+1}^\top &= c_B^\top \rho F, \quad z^{(\rho)} = c_B^\top x_B, \end{aligned} \quad (2)$$

where  $\rho$  corresponds to the index of basic variables and  $B$  is the corresponding matrix. The (critical) region within which the above (optimal) tableau is valid can then be derived as follows. The *critical region*, CR, where an optimal solution,  $z^{(\rho)}(\theta) = c_B^\top x_B(\theta)$ , preserves its optimality, is given by the initial conditions on  $\theta$ :

$$G\theta \leq g \quad (3)$$

Multiparametric Linear Programming, Figure 1  
Definition of critical regions

together with the conditions of *primal feasibility*. The conditions of primal feasibility are derived as follows. The basis  $B$  is said to be *primal feasible* if the condition:

$$B^{-1}b(\theta) = x_B(\theta) \geq 0, \tag{4}$$

where  $b(\theta) = b + F\theta$  and  $x_B(\theta) = x_B + \rho F\theta$ , is satisfied. Then using (2) and (4), the condition of primal feasibility is given by:

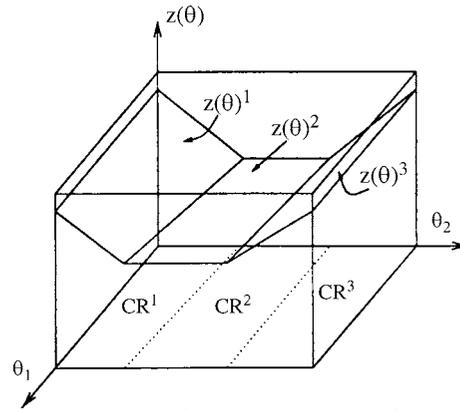

$$-\rho F\theta \leq x_B. \tag{5}$$

Thus, the critical region corresponding to  $\rho$  is given by (5) and (3). For illustration purposes, say in Fig. 1, the initial region of  $\theta$  (condition (3)) is given by PQRST and the condition of primal feasibility is given by UVWX (condition (5)), then  $CR^2$  is the corresponding critical region. Note that  $CR^2$  is obtained by removing the redundant constraints, PT, QR and RS. In order to devise a procedure to obtain ‘all’ the critical regions ( $CR^1$  and  $CR^3$ ), and optimal solutions associated with them, we first state the following:

- Two optimal bases are said to be *neighbors* if
  - there exists some  $\theta^* \in K$  such that both the bases are optimal, and,
  - it is possible to pass from one basis to another by one dual step.
- The critical regions associated with two different optimal bases are said to be *neighbors* if their corresponding bases are neighbors.
- Two neighboring critical regions lie in opposite half spaces.
- The optimal value function,  $z(\theta)$ , is continuous and convex; see Fig. 2 for a graphical interpretation for the case of two parameters.

Based upon the above statements, the solution algorithm for identifying all the critical regions can now be described. The algorithm consists of two major parts. In the first part, an initial feasible solution is obtained and the critical region which corresponds to the initial solution is characterized. The second part then starts with this critical region and identifies all the regions and corresponding optimal solutions. The major steps of the algorithm are as follows:

- 1) Find a feasible solution:
  - Solve (1) by treating  $\theta$  as a free variable to obtain  $\theta^*$ . If no feasible solution exists, stop; (1) is infeasible.

**Multiparametric Linear Programming, Figure 2**  
 $z(\theta)$  is a continuous and convex function of  $\theta$

- Fix  $\theta = \theta^*$  and solve (1) to obtain an initial basis  $B$  and corresponding critical region.
- 2) Find all optimal solutions:
  - Construct two lists  $V$  and  $W$ , where  $V$  consists of those optimal bases whose neighboring bases have been identified, and  $W$  consists of those bases whose neighbors have yet not been identified.
  - Select any basis from  $W$  and identify all its neighboring bases. From all the identified bases, insert in  $W$  those bases which are neither in  $V$  nor in  $W$ . The optimal solutions (and corresponding critical regions) are then determined by moving from the basis to its neighbors by one dual step.
  - Repeat the procedure until  $W = \{\emptyset\}$ .

Parametric bounds; Branch and bound; Comparison of parametric solutions

In this article we describe theoretical and algorithmic developments in the field of parametric programming for linear models involving 0–1 integer variables. We will consider two cases of the problem: single parametric (when a single uncertain parameter is present) and multiparametric (when more than one uncertain parameters are present in the model). For the case when a single uncertain parameter is present, solution approaches are based upon

- enumeration [11,12,13];
- cutting planes [6]; and
- branch and bound techniques [8,10].

For the multiparametric case, solution algorithm that has been proposed is based upon branch and bound fundamentals [1,2]. While most of the work on single parametric problems has been reviewed in the two excellent papers [5] and [7], and has been borrowed here for the sake of completeness, the work on multiparametric problems, the focus of this article, is quite recent and is described in detail. It may be mentioned that while solution approaches for single parametric case are available for uncertainty in objective function coefficients or right-hand side of constraints, for the case of more than one uncertain parameter the solution ap-

proach is available only for the right-hand side case. Next we will describe solution approaches for

- a) single parametric mixed integer linear programs for objective function coefficients parametrization; and
- b) single parametric pure integer programs when the uncertain parameter is present on the right-hand side of the constraints.

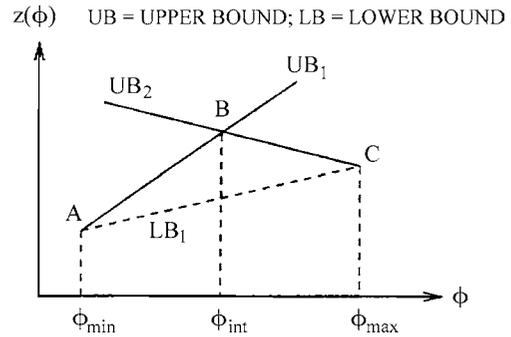

These illustrate some concepts which are based upon some basic observations. For other solution approaches, see the literature cited above. Finally we will present a solution approach for right-hand side multiparametric mixed integer linear programs.

**Mixed Integer Linear Programming Problems Involving a Single Uncertain Parameter in Objective Function Coefficients**

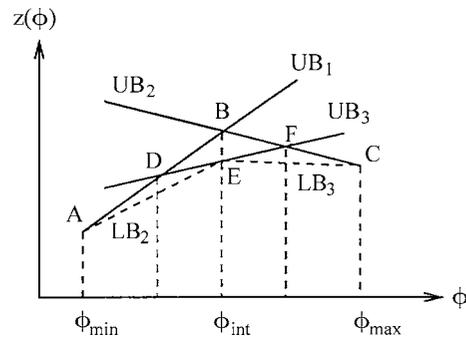

These can be stated as follows:

$$\begin{cases} z(\phi) = \min_{x,y} (c^T + c'\phi)x + d^T y \\ \text{s.t. } Ax + Ey \leq b, \\ x \in \mathbb{R}^n, \quad y \in \{0, 1\}^l, \\ \phi_{\min} \leq \phi \leq \phi_{\max}, \end{cases} \quad (1)$$

where  $x$  is a vector of continuous variables;  $y$  is the vector of 0–1 integer variables;  $\phi$  is a scalar uncertain parameter bounded between its lower and upper bounds  $\phi_{\min}$  and  $\phi_{\max}$  respectively;  $A$  is an  $(m \times n)$  matrix;  $E$  is an  $(m \times l)$  matrix;  $c, c', d$  and  $b$  are vectors of appropriate dimensions. Solution procedure for (1) is based upon following two features of the formulation in (1). First feature of this formulation is that, since the uncertain parameter is present in the objective function only, the feasible region of (1) remains constant for all the fixed values of  $\phi$  in  $[\phi_{\min}, \phi_{\max}]$ . And the second feature is that, the optimal value of (1) for  $\phi_{\min} \leq \phi \leq \phi_{\max}$  is piecewise linear, continuous, and concave on its finite domain. The solution is then approached by deriving valid upper and lower bounds, using the concavity property of the objective function value, and sharpening these bounds until they converge to the same value, as described next. Solving (1) for  $\phi$  fixed at its endpoints  $\phi_{\min}$  and  $\phi_{\max}$ , gives upper bounds  $AB$  and  $BC$  respectively (see Fig. 1); and a linear interpolation,  $AC$ , between the endpoints provides a lower bound to the solution. The region  $ABC$  within which the solution will

**Multiparametric Mixed Integer Linear Programming, Figure 1**  
Derivation of bounds

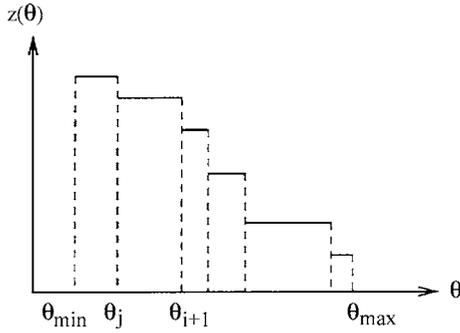

**Multiparametric Mixed Integer Linear Programming, Figure 2**  
Sharpening of bounds

lie is then reduced by solving (1) at  $\phi_{\text{int}}$ , the intersection point of two upper bounds  $AB$  and  $BC$ . This results (see Fig. 2) in two smaller regions,  $ADE$  and  $EFC$ , within which the solution will exist. This procedure is continued until the difference between upper and lower bounds becomes zero.

Integer programming problem involving a single uncertain parameter on the right-hand side of the constraints can be stated as follows:

$$\begin{cases} z(\theta) = \min_y d^T y \\ \text{s.t. } Ey \leq b + r\theta, \\ \theta_{\min} \leq \theta \leq \theta_{\max} \\ y \in \{0, 1\}^l, \end{cases} \quad (2)$$

where  $r$  is a scalar constant and  $\theta$  is a scalar uncertain parameter bounded between  $\theta_{\min}$  and  $\theta_{\max}$  respectively. For a special case of (2) when  $r \geq 0$ , it may be

**Multiparametric Mixed Integer Linear Programming, Figure 3**  
**Step function nature of objective function value**

noted that as  $\theta$  is increased from  $\theta_{\min}$  to  $\theta_{\max}$ , the feasible region will enlarge, and hence the objective function value will decrease or remain the same, i. e.,  $z(\theta_i) \geq z(\theta_{i+1})$  for  $\theta_i \leq \theta_{i+1}$ . Further, since only integer variables are present in (2), a solution will remain optimal for some interval of  $\theta$  and then suddenly another solution will become optimal, and remain so for the next interval (see Fig. 3). The problem thus reduces to solving (2) at an end point, say  $\theta_{\min}$ , and then finding a point  $\theta_i$  at which the current solution becomes infeasible. Solving (2) at  $\theta_i + \epsilon$  will give another integer solution. This procedure is continued until we hit the other end point,  $\theta_{\max}$ .

Consider a multiparametric mixed integer linear programming problem (mp-MILP) of the following form:

$$\begin{cases} z(\theta) = \min_{x,y} c^T x + d^T y \\ \text{s.t.} & Ax + Ey \leq b + F\theta, \\ & G\theta \leq g, \\ & x \in \mathbb{R}^n, \quad y \in \{0, 1\}^l, \quad \theta \in \mathbb{R}^s, \end{cases} \quad (3)$$

where  $\theta$  is a vector of uncertain parameters;  $F$  is an  $(m \times s)$  matrix,  $G$  is an  $(r \times s)$  matrix, and  $g$  is a constant vector. Solving (3) implies obtaining the optimal solution to (3) for every  $\theta$  that lies in  $\mathcal{E} = \{\theta: G\theta \leq g, \theta \in \mathbb{R}^s\}$ . The algorithm for the solution of (3) proposed in [1] is based upon simultaneously using the concepts of

- branch and bound method for solving mixed integer linear programming (MILP) problems (see, e. g., [9]); and,

- simplex algorithm for solving multiparametric linear programming (mp-LP) problems [4].

While a solution of (3) by relaxing the integrality condition on  $y$  (at the root node) represents a *parametric lower bound*, a solution where all the  $y$  variables are fixed (e. g., at a terminal node) represents a *parametric upper bound*. The algorithm proceeds from the root node (lower bound) towards terminal nodes (upper bound) by fixing  $y$  variables at the intermediate nodes. The complete enumeration of the tree is avoided by fathoming those intermediate nodes which guarantee a suboptimal solution.

At the root node, by relaxing the integrality condition on  $y$ , i. e., considering  $y$  as a continuous variable bounded between 0 and 1, (3) is transformed to an mp-LP of the following form:

$$\begin{cases} \check{z}(\theta) = \min_{x,\check{y}} c^T x + d^T \check{y} \\ \text{s.t.} & Ax + E\check{y} \leq b + F\theta, \\ & G\theta \leq g, \\ & 0 \leq \check{y} \leq 1, \\ & x \in \mathbb{R}^n, \quad \theta \in \mathbb{R}^s. \end{cases} \quad (4)$$

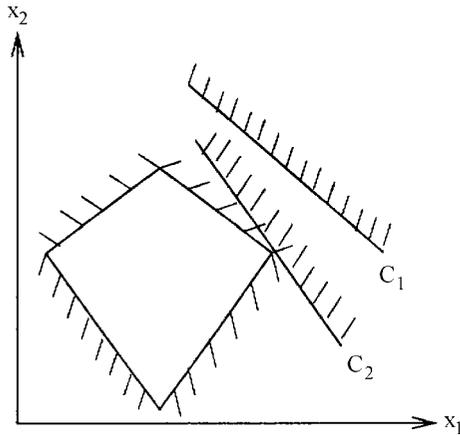

The solution of (4), given by linear parametric profiles,  $\check{z}(\theta)^i$ , valid in their corresponding *critical regions*,  $\check{CR}^i$ , represents a parametric lower bound.

Similarly, at a node where all  $y$  are fixed,  $y = \hat{y}$ , (3) is transformed to an mp-LP of the following form:

$$\begin{cases} \widehat{z}(\theta) = \min_{x,\hat{y}} c^T x + d^T \hat{y} \\ \text{s.t.} & Ax + E\hat{y} \leq b + F\theta, \\ & G\theta \leq g, \\ & \hat{y} = \{0, 1\}^l, \\ & x \in \mathbb{R}^n, \quad \theta \in \mathbb{R}^s. \end{cases} \quad (5)$$

The solution of (5),  $\widehat{z}(\theta)^i$ , valid in its corresponding critical regions,  $\widehat{CR}^i$ , represents a parametric upper bound.

Starting from the root node, some of the  $y$  variables are systematically fixed (to 0 and 1) to generate intermediate nodes of the branch and bound tree. At an intermediate node, where some  $y$  are fixed and some are

**Multiparametric Mixed Integer Linear Programming, Figure 4**  
Redundant constraints

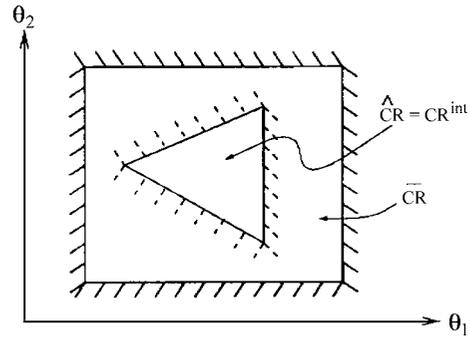

relaxed, an mp-LP of the following form is formulated:

$$\left\{ \begin{array}{l} \bar{z}(\theta) = \min_{x,y} c^T x + d_j^T \hat{y}_j + d_k^T \check{y}_k \\ \text{s.t. } Ax + E_j \hat{y}_j + E_k \check{y}_k \leq b + F\theta, \\ G\theta \leq g, \\ \hat{y}_j = \{0, 1\}, \\ 0 \leq \check{y}_k \leq 1, \\ x \in \mathbb{R}^n, \quad \theta \in \mathbb{R}^s, \end{array} \right. \quad (6)$$

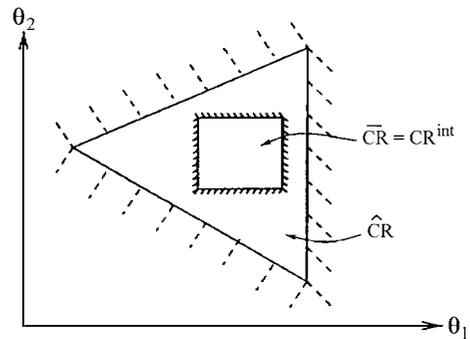

where the subscripts  $j$  and  $k$  correspond to  $y$  that are fixed and  $y$  that are free, respectively. The solution at an intermediate node,  $\bar{z}(\theta)^i$ , valid in its corresponding critical regions,  $\overline{CR}^i$ , is then analyzed, to decide whether to explore subnodes of this intermediate node or not, by using the following fathoming criteria. A given space in any node can be discarded if one of the following holds:

- (*infeasibility criterion*) Problem (6) is infeasible in the given space.
- (*integrality criterion*) An integer solution is found in the given space.
- (*dominance criterion*) The solution of the node is greater than the current upper bound in the same space.

If all the regions of a node are discarded the node can be fathomed. While the first two fathoming criteria (Infeasibility and Integrality) are easy to apply, in order to ap-

**Multiparametric Mixed Integer Linear Programming, Figure 5**  
Definition of  $CR^{int}$ ; Case 1

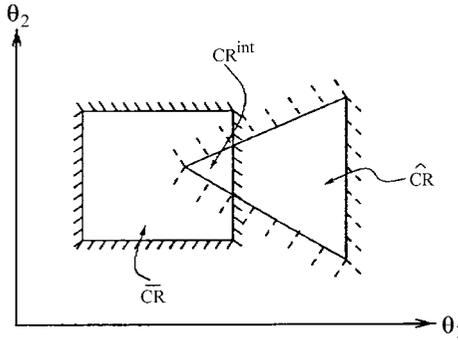

**Multiparametric Mixed Integer Linear Programming, Figure 6**  
Definition of  $CR^{int}$ ; Case 2

ply the third one (dominance criteria) we need a comparison procedure, which is described next.

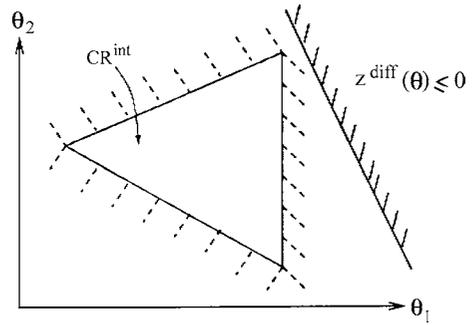

The comparison procedure consists of two steps. In the first step, a region,  $CR^{int} = \widehat{CR} \cap \overline{CR}$ , where the solution of the intermediate node and the current upper bound are valid is defined. This is achieved by removing the redundant constraints from the set of constraints which define  $\widehat{CR}$  and  $\overline{CR}$  (for a procedure to eliminate redundant constraints see [3]); graphical interpretation of redundant constraints is given in Fig. 4, where  $C_1$  is a strongly redundant constraint and  $C_2$  is a weakly redundant constraint.

The results of this *redundancy test*, which belong to one of the following 4 cases, are then analyzed as follows:

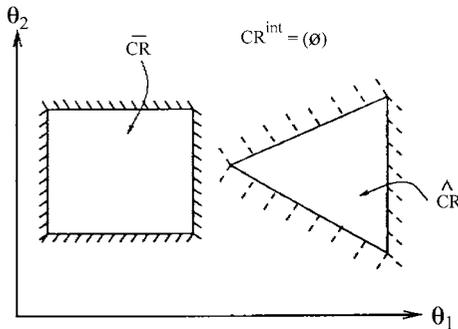

- (case 1; Fig. 5) All constraints from  $\overline{CR}$  are redundant. This implies that  $\overline{CR} \supseteq \widehat{CR}$ , and therefore  $CR^{int} = \widehat{CR}$ .

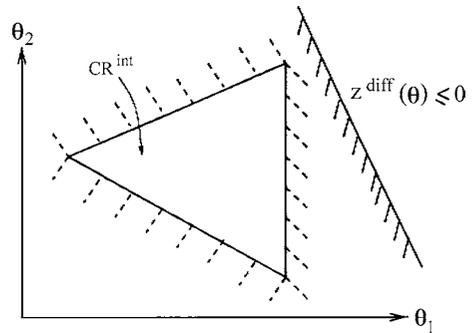

Multiparametric Mixed Integer Linear Programming, Figure 7  
Definition of  $CR^{int}$ ; Case 3

Multiparametric Mixed Integer Linear Programming, Figure 9  
Compare  $\bar{z}(\theta) : \hat{z}(\theta)$ ; Case 1

Multiparametric Mixed Integer Linear Programming, Figure 8  
Definition of  $CR^{int}$ ; Case 4

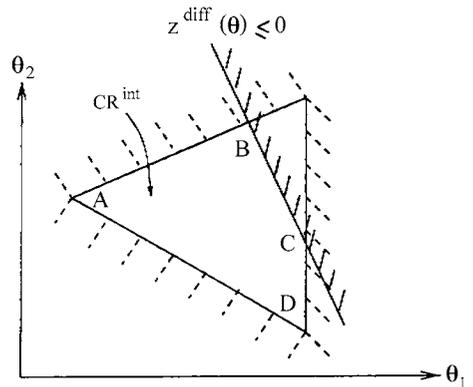

Multiparametric Mixed Integer Linear Programming, Figure 10  
Compare  $\bar{z}(\theta) : \hat{z}(\theta)$ ; Case 2

- (case 2; Fig. 6) All constraints from  $\widehat{CR}$  are redundant. This implies that  $\widehat{CR} \supseteq \overline{CR}$ , and therefore  $CR^{int} = \overline{CR}$ .
- (case 3; Fig. 7) Constraints from both regions are nonredundant. This implies that two spaces intersect with each other, and  $CR^{int}$  is given by the space delimited by the nonredundant constraints.
- (case 4; Fig. 8) The problem is infeasible. This implies that two spaces are apart from each other and  $CR^{int} = \{\emptyset\}$ .

Once  $CR^{int}$  has been defined, the second step is to compare  $\bar{z}$  to  $\hat{z}$ , so as to find which of the two is lower. This is achieved by defining a new constraint:

$$z^{diff}(\theta) = \bar{z}(\theta) - \hat{z}(\theta) \leq 0$$

and checking for redundancy of this constraint in  $CR^{int}$ . This redundancy test results in following 3 cases:

Multiparametric Mixed Integer Linear Programming, Figure 11  
Compare  $\bar{z}(\theta) : \hat{z}(\theta)$ ; Case 3

- (case 1; Fig. 9) The new constraint is redundant. This implies that  $\bar{z}(\theta) \leq \hat{z}(\theta)$  and therefore the space must be kept for further analysis.

- (case 2; Fig. 10) The problem is infeasible. This implies that  $\bar{z}(\theta) \geq \hat{z}(\theta)$  and therefore the space can be discarded from further analysis.
- (case 3; Fig. 11) The new constraint is non-redundant. This implies that  $\bar{z}(\theta) \leq \hat{z}(\theta)$  in  $ABCD$ , and therefore the rest of the space can be discarded from further analysis.

Based upon the above theoretical framework, the steps of the algorithm can be summarized as follows:

- 1 Set an upper bound of  $\hat{z}(\theta) = \infty$ .
- 2 Solve the fully relaxed problem (4).  
IF an integer solution is found in a critical region, THEN update the upper bound and discard the region from further analysis.
- 3 Fix one of the  $y$  variables to 0 and 1 to create two new nodes.  
IF no new nodes can be generated, THEN stop.
- 4 Solve the resulting problem (6).  
IF the problem is infeasible THEN go back to Step 3,  
ELSE compare the solution to the current upper bound.
- 5 IF all regions from a node have been analyzed, THEN go to Step 3.

### Motivation

Proteins are arguably the most complex molecules in nature. This complexity arises from an intricate balance of intra- and inter-molecular interactions that define the native three-dimensional structure of the system, and subsequently its biological functionality. The underlying goal of *protein folding* research is to understand the formation of these native tertiary structures. Genetic engineering can be used to produce proteins with specific amino acid sequences. The next step involves developing the link between the primary protein sequence and the native structure. The ability to predict the folding of proteins promises to have important practical and theoretical ramifications, especially in the areas of medicinal and biophysical chemistry.

Experimental studies have shown that proteins, under native physiological conditions, spontaneously re-fold to their unique, native structure after denaturation. This implies that the formation of the native structure is controlled primarily by the amino acid sequence. According to Anfinsen's hypothesis the native structure is in a state of thermodynamic equilibrium corresponding to the conformation with the lowest free energy. Through mathematical modeling of protein interaction energies, the protein folding problem can be addressed as a *conformational search* for the global minimum energy.

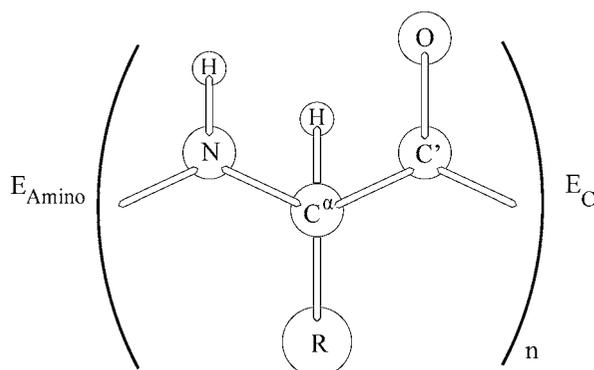

There exists two fundamental problems associated with protein folding in the context of a conformational search. The first is the ability to correctly model protein interactions using detailed mathematical equations. The second is associated with searching the highly nonconvex energy hypersurface that describes a given protein. This complexity, coupled with an exponential growth in the number of local minima as the size of protein increases, has become known as the *multiple minima* problem. There exists an obvious need for the development of efficient global optimization techniques. An efficient method which has been successfully applied to detailed atomistic models of protein folding is the  $\alpha$ BB [1,2,3,17] global optimization algorithm.

### Mathematical Description

Proteins are essentially polymer chains composed of a predefined set of amino acid residues in which neighboring residues are linked by peptidic bonds. Naturally occurring proteins consist of only 20 different amino acid residues, and the form of the side chain  $R$  (e.g., methyl, butyl, benzoic, etc.) defines the differences between these constituent groups. The chemical structure of a generic protein is illustrated in Fig. 1. The repeating unit  $-NC^\alpha C'$  defines the backbone of the protein. The protein also possesses amino and carboxyl end groups, denoted by  $E_{\text{Amino}}$  and  $E_{\text{Carboxyl}}$ , respectively.

The geometry of a protein can be fully described by assigning a three-dimensional coordinate vector  $r_i$ :

$$r_i = \begin{pmatrix} x_i \\ y_i \\ z_i \end{pmatrix}.$$

**Multiple Minima Problem in Protein Folding:  $\alpha$ BB Global Optimization Approach, Figure 1**  
Generic primary protein structure

These  $r_i$  specify the position of each atom in the protein molecule. The bond vector between two atoms ( $i, j$ ) connected with a covalent bond is defined as:

$$r_{ij} = \begin{pmatrix} x_j - x_i \\ y_j - y_i \\ z_j - z_i \end{pmatrix}.$$

The corresponding bond length is then equal to the Euclidean distance between these two atoms:

$$|r_{ij}| = \sqrt{(x_j - x_i)^2 + (y_j - y_i)^2 + (z_j - z_i)^2}$$

A covalent bond angle,  $\theta_{ijk}$ , formed by the two adjacent bond vectors  $r_{ij}$  and  $r_{jk}$  can be computed by the following formulas:

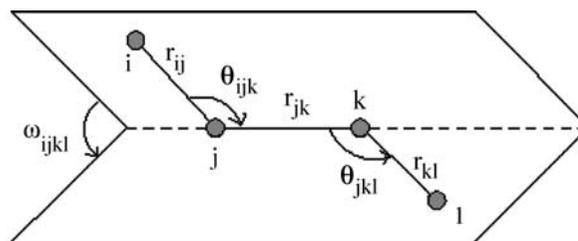

$$\cos(\theta_{ijk}) = \frac{r_{ij} \cdot r_{jk}}{|r_{ij}| |r_{jk}|}, \quad \sin(\theta_{ijk}) = \frac{r_{ij} \times r_{jk}}{|r_{ij}| |r_{jk}|}.$$

Here,  $r_{ij} \cdot r_{jk}$  is the dot product of the bond vectors  $r_{ij}$  and  $r_{jk}$  and  $r_{ij} \times r_{jk}$  is the cross product.

The dihedral angle  $\omega_{ijkl}$  measures the relative orientation of two adjacent covalent angles  $\theta_{ijk}$  and  $\theta_{jkl}$ . This angle is defined as the angle between the normals through the planes defined by atoms  $i, j, k$  and  $j, k, l$  respectively, and can be calculated from the following relations:

$$\cos(\omega_{ijkl}) = \frac{(r_{ij} \times r_{jk}) \cdot (r_{jk} \times r_{kl})}{|r_{ij} \times r_{jk}| |r_{jk} \times r_{kl}|},$$

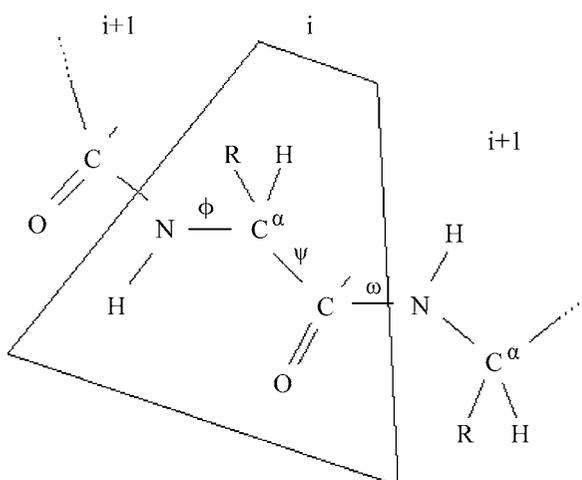

$$\sin(\omega_{ijkl}) = \frac{(r_{kl} \times r_{ij}) \cdot r_{jk} |r_{jk}|}{|r_{ij} \times r_{jk}| |r_{jk} \times r_{kl}|}.$$

**Multiple Minima Problem in Protein Folding:  $\alpha$ BB Global Optimization Approach, Figure 2**  
Illustration of dihedral angle

An alternative to specifying the coordinate vector for all atoms in a protein molecule is to set bond lengths, covalent bond angles and independent dihedral angles. A common approximation is to assume rigid bond lengths and bond angles so that the dihedral angles can be used to fully characterize the shape of the protein molecule.

The names of the dihedral angles of a protein chain follow a standard nomenclature. The dihedral angle between the normals of the planes formed by atoms  $C_{i-1}N_iC_i^\alpha$  and  $N_iC_i^\alpha C_i'$  respectively, is called  $\phi_i$ , where  $i-1$  and  $i$  are two adjacent amino acid residues. The angle defined by the planes  $N_iC_i^\alpha C_i'$  and  $C_i^\alpha C_i' N_{i+1}$ , respectively, is called  $\psi_i$ , where  $i$  and  $i+1$  are two adjacent amino acid residues. Also,  $\omega_i$  is the dihedral angle defined by the planes  $C_i^\alpha C_i' N_{i+1}$  and  $C_i' N_{i+1} C_{i+1}^\alpha$ .

**Multiple Minima Problem in Protein Folding:  $\alpha$ BB Global Optimization Approach, Figure 3**  
Dihedral angle conventions

The letter  $\chi$  is utilized to denote the dihedral angles which are associated with the side groups  $R_i$ . Finally, the letter  $\theta$  is used to name the dihedral angles associated with the two end groups. These conventions are illustrated in Fig. 3.

### Potential Energy Modeling

A number of empirically based *molecular mechanics* models have been developed for protein systems, including AMBER [24], CHARMM [7], ECEPP/3 [19], GROMOS [11], MM3 [4]. These models, also known as *force fields*, are typically expressed as summations of several potential energy components, with the mathematical form of individual energy terms based on the phenomenological nature of that term. A general total potential energy equation should include terms for bond stretching ( $E_{\text{bond}}$ ), angle bending ( $E_{\text{angle}}$ ), torsion ( $E_{\text{tor}}$ ) and nonbonded ( $E_{\text{nb}}$ ) interactions:

$$E_{\text{potential}} = E_{\text{bond}} + E_{\text{angle}} + E_{\text{tor}} + E_{\text{nb}}$$

When rigid body approximations are employed, bond stretching and angle bending energies can be neglected. For these force fields, torsion angles define a set of independent variables that effectively describe any protein conformation. This approximately reduces the number of variables by a factor of 3 over those force fields that use a Cartesian coordinate system to describe flexible molecular geometries.

One example of a rigid body atomistic level potential energy model is the ECEPP/3 force field. In this case, the nonbonded energy terms,  $E_{\text{nb}}$ , include electrostatic,  $E_{\text{elec}}$ , van der Waals,  $E_{\text{vdw}}$ , and hydrogen bonding,  $E_{\text{hbond}}$ , interactions. These energies are calculated for those atoms that are separated by more than two atoms; that is, the atoms possess at least a 1–4 relationship. Electrostatic energies,  $E_{\text{elec}}$ , are calculated as Coulombic forces based on atomic point charges:

$$E_{\text{elec}} = \frac{Q_i Q_j}{\epsilon R_{ij}}$$

Here,  $Q_i$  and  $Q_j$  represent the two point charges, while  $R_{ij}$  equals the distance between these two points. The  $\epsilon$  term describes the dielectric nature of the protein environment.

General nonbonded van der Waals interactions,  $E_{\text{vdw}}$ , are modeled using a 6–12 Lennard–Jones poten-

tial energy term, which consists of a repulsion and attraction term:

$$E_{\text{vdw}} = \epsilon_{ij} \left[ \left( \frac{R_{ij}^*}{R_{ij}} \right)^{12} - 2 \left( \frac{R_{ij}^*}{R_{ij}} \right)^6 \right].$$

The energy minimum for a given atomic pair is described by the potential depth,  $\epsilon_{ij}$ , and position,  $R_{ij}^*$ . For those atomic pairs that may form a hydrogen bond, the 6–12 potential energy term is replaced by a modified 10–12 Lennard–Jones type term:

$$E_{\text{hbond}} = \epsilon_{ij} \left[ 5 \left( \frac{R_{ij}^*}{R_{ij}} \right)^{12} - 6 \left( \frac{R_{ij}^*}{R_{ij}} \right)^{10} \right].$$

Finally, corrective torsional energies,  $E_{\text{tor}}$ , which are represented by a three term Fourier series expansion, are also added:

$$E_{\text{tor}} = \frac{E_1}{2}(1 - \cos \phi) + \frac{E_2}{2}(1 - \cos 2\phi) + \frac{E_3}{2}(1 - \cos 3\phi).$$

Each term can be interpreted physically. The 1- $x$  ( $\cos \phi$ ) symmetry term accounts for those nonbonded interactions not included in general nonbonded terms. The 2- $x$  ( $\cos 2\phi$ ) symmetry term is related to the interactions of orbitals, while the 3- $x$  ( $\cos 3\phi$ ) symmetry term describes steric contributions.

Other specific potential energy terms may also be added to the general energy equation depending on the exact protein sequence. For example, the formation of disulfide bridges can be enforced by adding a penalty term to constrain the values of particular atomic distances. Correction terms have also been used to adjust conformational energies according to the configurations of proline and hydroxyproline residues.

### Solvation Energy Modeling

In general, the energetic description of a protein must also include *solvation effects*. A theoretically simple approach would be to explicitly surround the peptide with solvent molecules and compute potential energy contributions for intra- and inter-molecular interactions. These explicit calculations tend to greatly increase the computational cost of the simulation. In addition, solvent configurations are not rigid, so these calcula-

tions must consider an average solvent-peptide configuration, which is typically generated by a number of *Monte-Carlo* (MC) or molecular dynamics (MD) simulations [14]. Therefore, most simulations of this type are limited to restricted conformational searches.

An alternative way for effectively considering average solvent effects is to use implicit solvation models. One complication involves the solvent's influence on electrostatic interaction energies because of the implicit relationship between dielectric effects and solvation. A simple solution has been to modify the representation of the dielectric term. In reality, however, the rigorous treatment of electrostatic interactions involves the solution of the Poisson–Boltzmann equation.

Other simple and computationally feasible implicit solvation models are based on empirical representations of the solvation energy. In these cases, the solvation energy of each functional group is related to the interaction of the solvent with a hydration shell for the particular group. The individual terms are then summed together to provide a total solvation energy for the system. These solvation contributions can be described by the following general equation:

$$E_{\text{solv}} = \sum_{i=1}^N S_i \sigma_i.$$

Typically,  $S_i$  represents either the solvent-accessible surface area,  $A_i$ , or the solvent-accessible volume of hydration layer,  $VHS_i$ , for the functional group, and  $\sigma_i$  is an empirically derived free energy density parameter.

A number of algorithms have been developed for calculating solvent-accessible surface areas [8,9,22]. Although several of these are relatively efficient, the appearance of discontinuities has been one complication in considering solvent accessible surface areas. In addition, a large number of parameterization strategies (JRF, OONS, WE, etc.) have been used to derive appropriate  $\sigma_i$  parameters [21,23,25]. In the case of the JRF parameter set, discontinuities can be avoided because the surface-accessible solvation energies are only included at local minimum conformations [23]. This is because the parameters were derived from low energy solvated configurations of actual tetrapeptides.

Several methods have also been developed for calculating the hydration volumes and corresponding free energy parameters [6,12]. A recent and computation-

ally inexpensive method, RRRIGS, is based on a Gaussian approximation for the volume of a hydration layer [6]. This method also inherently avoids numerical problems associated with possible discontinuities so that the solvation energy contributions can easily be added at every step of local minimizations.

### Problem Formulation

For protein folding, the *energy minimization* problem can be formulated as a nonconvex, nonlinear global optimization problem in which the energy,  $E$ , must be globally minimized with respect to the dihedral angles of the protein:

$$\left\{ \begin{array}{l} \min \quad E(\phi_i, \psi_i, \omega_i, \chi_i^k, \theta_j^N, \theta_j^C) \\ \text{subject to} \quad -\pi \leq \phi_i \leq \pi \\ \quad \quad \quad -\pi \leq \psi_i \leq \pi \\ \quad \quad \quad -\pi \leq \omega_i \leq \pi \\ \quad \quad \quad -\pi \leq \chi_i^k \leq \pi \\ \quad \quad \quad -\pi \leq \theta_j^N \leq \pi \\ \quad \quad \quad -\pi \leq \theta_j^C \leq \pi. \end{array} \right.$$

The index  $i = 1, \dots, N_{\text{RES}}$  defines the number of residues,  $N_{\text{RES}}$ , in the protein. In addition,  $k = 1, \dots, K^i$  denotes the number of dihedral angles in the side chain of the  $i$ th residue, and  $j = 1, \dots, J^N$  and  $j = 1, \dots, J^C$  indicates the indices of the amino and carboxyl end groups, respectively. The energy,  $E$ , represents the total potential energy function,  $E_{\text{potential}}$ , plus the free energy of solvation,  $E_{\text{solv}}$ . In most cases, this is the exact formulation; that is, energetic and gradient contributions can be added at each step of the minimization. However, in the case of surface-accessible hydration using the JRF parameters, the potential energy function is minimized before adding the hydration energy contributions. In other words, gradient contributions from solvation are not considered.

Even after reducing this optimization problem to a function of internal variables, the multidimensional surface that describes the energy function possesses an astronomically large number of local minima. In addition, evaluation of the energy, especially with the addition of solvation, is computationally expensive, which makes even local minimization slow. A large number of techniques have been developed to search this nonconvex conformational space. Many methods employ

stochastic search procedures, while others rely on simplifications of the potential model and/or mathematical transformations. In addition, the use of statistical and/or heuristic conformational information is often required. In general, the major limitation is that there is no guarantee for convergence to the global minimum energy structure. A number of recent reviews have focused on global optimization issues for these systems [10,20].

The  $\alpha$ BB global optimization approach has been extremely effective in identifying global minimum energy conformations of peptides described by detailed atomistic models. The development of this deterministic *branch and bound* method was motivated by the need for an algorithm that could guarantee convergence to the global minimum of nonlinear optimization problems with twice-differentiable functions. The application of this algorithm to the minimization of potential energy functions was first introduced for microclusters [16]. The algorithm has also been shown to be successful for isolated [5,15], as well as solvated peptide systems [13].

### Global Minimization Using $\alpha$ BB

The  $\alpha$ BB global optimization algorithm effectively brackets the global minimum solution by developing converging sequences of lower and upper bounds. These bounds are refined by iteratively partitioning the initial domain. Upper bounds on the global minimum are obtained by local minimizations of the original energy function,  $E$ . Lower bounds belong to the set of solutions of the convex lower bounding functions, which are constructed by augmenting  $E$  with the addition of separable quadratic terms. By using  $\phi_i^L, \psi_i^L, \omega_i^L, \chi_i^{k,L}, \theta_j^{N,L}, \theta_j^{C,L}$  and  $\phi_i^U, \psi_i^U, \omega_i^U, \chi_i^{k,U}, \theta_j^{N,U}, \theta_j^{C,U}$  to refer to lower and upper bounds on the corresponding dihedral angles, the lower bounding function,  $L$ , of the energy hypersurface can be expressed in the following manner:

$$L = E + \sum_{i=1}^{N_{\text{RES}}} \alpha_{\phi,i} (\phi_i^L - \phi_i) (\phi_i^U - \phi_i) + \sum_{i=1}^{N_{\text{RES}}} \alpha_{\psi,i} (\psi_i^L - \psi_i) (\psi_i^U - \psi_i)$$

$$+ \sum_{i=1}^{N_{\text{RES}}} \alpha_{\omega,i} (\omega_i^L - \omega_i) (\omega_i^U - \omega_i) + \sum_{i=1}^{N_{\text{RES}}} \sum_{k=1}^{K^i} \alpha_{\chi,i,k} (\chi_i^{k,L} - \chi_i^k) (\chi_i^{k,U} - \chi_i^k) + \sum_{j=1}^{J^N} \alpha_{j,\theta^N} (\theta_j^{N,L} - \theta_j^N) (\theta_j^{N,U} - \theta_j^N) + \sum_{j=1}^{J^C} \alpha_{j,\theta^C} (\theta_j^{C,L} - \theta_j^C) (\theta_j^{C,U} - \theta_j^C).$$

The  $\alpha$  represent nonnegative parameters which must be greater or equal to the negative one-half of the minimum eigenvalue of the Hessian of  $E$  over the defined domain. The overall effect of these terms is to overpower the nonconvexities of the original nonconvex terms by adding the value of  $2\alpha$  to the eigenvalues of the Hessian of  $E$ . The convex lower bounding functions,  $L$ , possess a number of important properties which guarantee global convergence [18]:

- i)  $L$  is a valid underestimator of  $E$ ;
- ii)  $L$  matches  $E$  at all corner points of the current box constraints;
- iii)  $L$  is convex in the current box constraints;
- iv) the maximum separation between  $L$  and  $E$  is bounded. This property ensures that feasibility and convergence tolerances can be reached for a finite size partition element;
- v) the underestimators  $L$  constructed over supersets of the current set are always less tight than the underestimator constructed over the current box constraints for every point within the current box constraints.

Once solutions for the upper and lower bounding problems have been established, the next step is to modify the problem for the next iteration. This is accomplished by successively partitioning the initial domain into smaller subdomains. One obvious strategy is to subdivide the original hyper-rectangle by bisecting the longest dimension. In order to ensure nondecreasing lower bounds, the hyper-rectangle to be bisected is chosen by selecting the region which contains the infimum of the minima of lower bounds. A nonincreasing sequence for the upper bound is found by solving the nonconvex problem locally and selecting it to be the minimum over all the previously recorded up-

per bounds. If the single minimum of  $L$  for any hyper-rectangle is greater than the current upper bound, this hyper-rectangle can be discarded because the global minimum cannot be within this subdomain (fathoming step).

The computational requirement of the  $\alpha$ BB algorithm depends on the number of variables (global) on which branching occurs. Therefore, these global variables need to be chosen carefully. Qualitatively, the branching variables should correspond to those variables which substantially influence the nonconvexity of the surface and the location of the global minimum. In terms of the protein folding problem, it is generally accepted that the backbone dihedral angles ( $\phi$  and  $\psi$ ) are the most influential variables. Therefore, in larger problems, the global variable set should include only the set of  $\phi$  and  $\psi$  variables. In this case, the dihedral angles associated with the peptide bond ( $\omega$ ) and the side chains ( $\chi$ ) are treated as local variables.

### Algorithmic Description

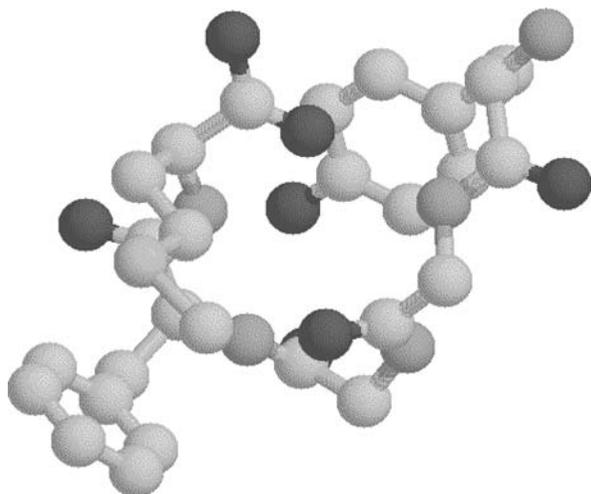

The basic steps of the algorithm are as follows:

- 1) The initial best upper bound is set to an arbitrarily large value. The original domain is partitioned along one of the global variable dimensions.
- 2) A convex function  $L$  is constructed in each hyper-rectangle and minimized using a local nonlinear solver, with function calls to potential and solvation models. If a solution is greater than the best upper bound the entire subregion can be fathomed, otherwise the solution is stored.
- 3) The local minima for  $L$  are used as initial starting points for local minimizations of the upper bounding function  $E$  in each hyper-rectangle. In solving the upper bounding problems, all variable bounds are expanded to  $(-\pi, \pi)$  domain. These solutions are upper bounds on the global minimum solution in each hyper-rectangle.
- 4) The current best upper bound is updated to be the minimum of those thus far stored. If a new upper bound (from step 3) is selected, a separate module is called to ensure that the absolute value of each gradient in the objective function gradient vector is below a specified tolerance (kcal/mol/deg). The second derivative matrix is also evaluated to verify that the upper bound solution is a local minimum.
- 5) The hyper-rectangle with the current minimum value for  $L$  is selected and partitioned along one of the global variables.
- 6) If the best upper and lower bounds are within an  $\epsilon$  tolerance the program will terminate, otherwise it will return to Step 2.

A novel approach has also been proposed for the initialization of the  $\alpha$ BB algorithm [5]. Specifically, an analysis of 98 proteins from the Brookhaven X-ray data bank was used to develop dihedral angle distributions in the form of histograms from  $-\pi$  to  $\pi$  for each dihedral angle of each of the naturally occurring amino acids. Using this information, a set of reduced domains can be defined for every dihedral angle of every residue in the peptide sequence. Overall initialization domains correspond to the Cartesian products of all the sub-domains of individual residues in the protein. This approach maintains the guarantee of global optimality over the considered search space of the reduced domains, and is deterministic in those subdomains that possess convex underestimators. In addition, all variable bounds are expanded to the  $[-\pi, \pi]$  when solving the upper bounding problem. Therefore, although the initial point of an upper bounding minimization is restricted to the search space of the corresponding lower bounding problem, the solution may lie outside the original subdomain.

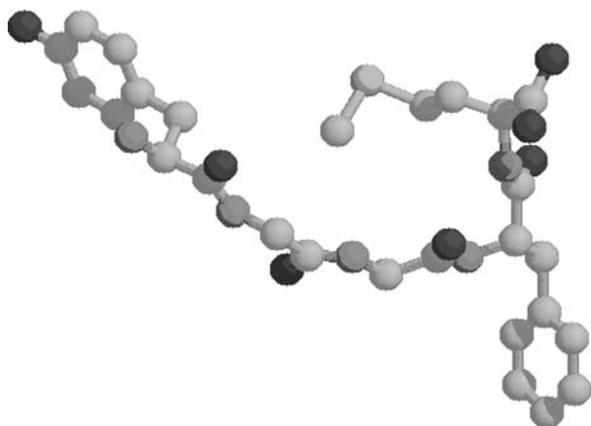

*Example 1* Met-enkephalin (H-Tyr-Gly-Gly-Phe-Met-OH) is an endogenous opioid pentapeptide found in the human brain, pituitary, and peripheral tissues. Its biological function involves a large variety of physiological processes, most notably the endogenous response to pain. The peptide consists of 24 dihedral angles and a total of 75 atoms, and has played the role of a benchmark molecular conformation problem. The energy hypersurface is extremely complex with the number of local minima estimated on the order of  $10^{11}$ . The unsolvated global minimum energy conformation, which is efficiently located using the  $\alpha$ BB algorithm, has been shown to exhibit a type II'  $\beta$ -bend along the N-C' peptidic bond of Gly<sup>3</sup> and Phe<sup>4</sup> [5], as shown in Fig. 4.

The algorithm has also successfully predicted global minimum energy structures of met-enkephalin using both solvent-accessible surface area (JRF) and volume of hydration (RRIGS) models [13]. In both cases, extended structures were identified, which qualitatively

agrees with experimental results. However, differences in the role of nonbonded energies and the side chain conformations have been identified. The global minimum energy conformations of the surface area and volume of hydration models are shown in Fig. 5 and Fig. 6, respectively.

Dynamic programming; Multiple objective programming; Efficient set

Dynamic programming has been an area of active research since its introduction by R. Bellman [1]. More recently, with the recognition that many applied optimization problems require more than one objective, the study of multicriteria optimization has become a growing area of research. Included in this area of multicriteria optimization is the study of multiple objective dynamic programming (MODP). MODP was

first used to replace multiple objective linear programming (MOLP) where it was not applicable, such as in problems with discrete variables. Many of the techniques used are extensions of classical dynamic programming. The following is a discussion of some of the research that has been developed in the area of MODP.

Using multiple objective dynamic programming to find the ‘shortest’ path through a network with constant costs is one of the more straightforward uses of MODP. Work has been done on both forward and backward MODP in this area. First, we consider a general network containing a set of nodes  $N = \{1, \dots, n\}$  and a set of arcs  $A = \{(i_0, i_1), (i_2, i_3), (i_4, i_5), \dots\} \subset N \times N$  which indicates connections between nodes. Each arc  $(i, j)$  has an associated cost vector,  $c_{ij} = (c_{ij1}, \dots, c_{ijm}) \in \mathbf{R}^m$ . A path from node  $i_0$  to  $i_p$  is the sequence of arcs  $P = \{(i_0, i_1), \dots, (i_{p-1}, i_p)\}$  where the first node of each arc is the same as the terminal node of the preceding arc and each node in the path is unique. Let  $\Pi_i$  be the set of all paths from node 1 to node  $i$ . The cost to traverse a path  $p$  in  $\Pi_i$  is  $[c(p)] = \sum_{(i,j) \in p} [c_{ij}]$ . A path in  $\Pi_i$  is *nondominated* if there is no other path  $p^*$  in  $\Pi_i$  with  $[c(p^*)]_r \leq [c(p)]_r$  for  $r = 1, \dots, m$  and  $[c(p^*)]_r < [c(p)]_r$  for some  $r \in \{1, \dots, m\}$ .

```

0 | k = 1.
1 | Evaluate  $S_i^k$  for all nodes using  $S_i^k = \{c_{ij} + S_i^{k-1}\}$ .
2 | If  $k < N$ , set  $k = k + 1$  and return to step 1; otherwise:
3 | For each nondominated solution at each node determined in step 1 and for each  $r$ ,  $r = 1, \dots, m$ , define  $T^r$  as  $T^r = \min_{i_n, \dots, i_0} \sum_n c_{i_n}^r j_{n-1}$ , where  $i_n$  is the originated node at stage  $n$  and  $I_n$  is the set of nodes that can be reached from node  $n$ .
4 | Given weights  $W^m \in \mathbf{R}_+^m$ , compute the MIN-SUM as
   |  $\min \left[ \sum_{r=1}^m \left\{ W^r \frac{\sum_{k=1}^N c_{ij} - T^r}{T^r} \right\} \right]$ .

```

H.G. Daellenbach and C.A. DeKluyver [5] gave one of the earliest algorithms for backward MODP with constant costs, which finds nondominated paths from all nodes to the destination node. Their method is ba-

sically an extension of the principle of optimality to a multicriteria context. They state a *principle of Pareto optimality of MODP*: ‘A nondominated policy has the property that regardless of how the process entered a given state, the remaining decisions must belong to a nondominated subpolicy.’ Let  $S_i^k$  be the nondominated vector of objective values for a node  $i$ , exactly  $k$  links from its destination,  $t$ . Then the algorithm is given above.

The resulting  $S_i^k$  vectors give nondominated solutions for the network, but maybe not all of them. They solve an example in which the weights are not specified.

A few years later, R. Hartley [6] proposed a similar algorithm that also uses backward MODP to find all Pareto paths from all nodes in the network to a specified node. The algorithm is as follows:

Let  $V_0(i) = \{\infty, \dots, \infty\}$  for  $k = 0, 1, \dots$ , and let  $V_k(t) = \{0, \dots, 0\}$ .

$V_k(i) = \text{eff}[\cup \{c_{ij} + V_{k-1}(j) : j \in \Gamma(i)\}]$  for  $i \in N$  ( $i \neq t$ ) and  $k = 1, 2, \dots$ , where  $\Gamma(i)$  is the set of nodes such that  $(i, j) \in A$ . The ‘eff’ operator finds all nondominated vectors in the set. The associated paths must be handled separately.

H.W. Corley and I.D. Moon [4] used forward MODP to find all nondominated paths from a specified node to all other nodes in a network with multiple constant costs. They assumed that the network contains no loops and that  $c_{ij} \neq \{0, \dots, 0\}$  for any  $(i, j) \in A$ . Letting  $G_i^{(k)}$  be the set of vector costs of all Pareto paths from node 1 to node  $i$  containing  $k$  or fewer arcs, the algorithm follows:

```

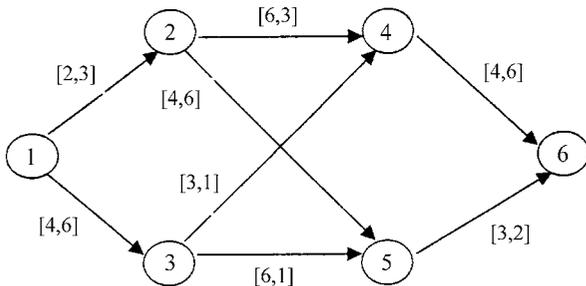

1 | Set  $c_{ii} = (0, \dots, 0)$ ,  $i = 1, \dots, n$  and  $c_{ij} = (\infty, \dots, \infty)$ ,  $i \neq j$ , if no arc exists from  $i$  to  $j$ . Set  $k = 1$  and let  $G_i^{(1)} = \{c_{1i}\}$ ,  $i = 1, \dots, n$ .
2 | For  $i = 1, \dots, n$ , set  $G_i^{k+1} = \text{Vmin} \cup_{j=1}^n \{c_{ij} + g_j^k : g_j^k \in G_j^{(k)}\}$ .
3 | If  $G_i^{(k+1)} = G_i^{(k)}$ ,  $i = 1, \dots, n$ , stop, otherwise go to step 4.
4 | If  $k = n - 1$ , stop. Else,  $k = k + 1$  and go to step 2.

```

Vmin is an operation that computes the vector costs of all nondominated paths in a set of vector costs. An algorithm for Vmin is given in their paper.

Multiple Objective Dynamic Programming, Figure 1

Table 1 gives the results of the algorithm. The resulting Pareto optimal paths from node 1 to node 6 are  $\{(1, 2), (2, 5), (5, 6)\}$  and  $\{(1, 3), (3, 5), (5, 6)\}$ .

The following example uses the *Corley-Moon algorithm* to solve a dynamic routing problem for the network in Fig. 1.

Using multiple objective dynamic programming to find the shortest path through a network with time-dependent costs is considerably more complicated than MODP with constant costs. The monotonicity assumptions necessary for the principle of optimality in dynamic programming can easily be broken when dealing with time-dependent costs. Reaching a node later may be less costly than reaching it earlier. M.M. Kostreva

and M.M. Wiecek [7] extended the work done by K.L. Cooke and E. Halsey [3] on dynamic programming with one time-dependent cost (travel time) to dynamic programming with multiple time-dependent costs. This method uses backward dynamic programming on a discrete time grid to find all nondominated paths from every node in the network to the destination node.

Assume the discrete time grid  $S_T = \{t_0, \dots, t_0 + T\}$ ,  $t_0 > 0$  and the cost functions  $[c_{ij}(t)]_k > 0$ ,  $(i, j) \in A$ , for all  $t \in S_T$ .  $T$  is the upper bound on total time to travel from any node in the network to the destination node,  $N_d$ . Also assume that  $[c_{ij}(t)]_1$  is the time to travel from node  $i$  to node  $j$  when the arrival time at node  $i$  is time  $t$ . For all  $i \in N \setminus N_d$  and all  $t \in S_T$ , define  $\{[F_i(t)]\}$  as the set of nondominated vectors associated with the paths that leave node  $i$  at time  $t$  and reach node  $N_d$  and define  $\{[F_i(t)(k)]\}$  as the set of nondominated vectors associated with the paths that leave node  $i$  at time  $t$  and reach node  $N_d$  in at most  $k + 1$  links before time  $t_0 + T$ , where  $k = 0, 1, \dots$ . The following is the principle of optimality used for this algorithm: ‘A nondominated path  $p$ , leaving node  $i$  at time  $t \in S_T$  and reaching node  $N$  at or before time  $t_0 + T$ , has the property that for each node  $j$  lying on this path, a subpath  $p_1$ , that leaves node  $j$  at time  $t_j \in S_T$ ,  $t_j > t$ , and arrives at node  $N$  at or before

time  $t_0 + T$ , is nondominated.’ The algorithm is as follows:

- 1 Find a time grid of discrete values  $S_T = \{t_0, \dots, t_0 + T\}$ ,  $t_0 > 0$  and compute  $[c_{ij}(t)]$  for all  $t \in S_T$  and all  $(i, j) \in A$ .
- 2 Modify  $[c_{ij}(t)]$  for all  $t \in S_T$  and all  $(i, j) \in A$  as follows:  

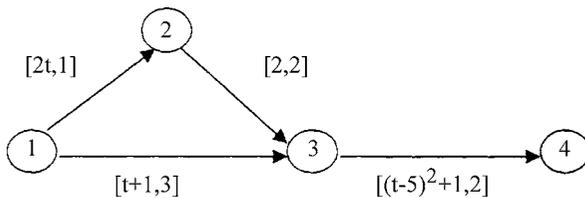

$$[c_{ij}(t)]' = \begin{cases} [c_{ij}(t)] & \text{if } t + [c_{ij}(t)]_l \leq t_0 + T, \\ \infty & \text{if } t + [c_{ij}(t)]_l > t_0 + T. \end{cases}$$
- 3 Find the initial array  $\{[F_i(t)(0)]\}$ ,  $i = 1, \dots, N$ , for all  $t \in S_T$ , where  $\{[F_{N_d}(t)(0)]\} = \{0\}$ , and  $\{[F_i(t)(0)]\} = [c_{iN_d}(t)]'$  for  $i \in N \setminus N_d$ .
- 4 Find the arrays  $\{[F_i(t)(k)]\}$ ,  $i = 1, \dots, N$ , for all  $t \in S_T$ , for  $k = 1, 2, \dots$  as follows:  

$$\begin{aligned} & \{[F_i(t)(k)]\} \\ &= \text{VMIN}\{[c_{ij}(t)]' + \{[F_j(t + [c_{ij}(t)]'_1)^{(k-1)}]\}, \\ & \quad i \in N \setminus \{N_d\}, \\ & \{[F_i(t)(k)]\} = \{0\}. \end{aligned}$$
- 5 The sequence of sets  $\{[F_i(t_0)(k)]\}$ ,  $k = 1, 2, \dots$ , converges to the set  $\{[F_i(t_0)]\}$ , the set of nondominated vectors associated with the paths that leave node  $i$  at time  $t_0$  and reach node  $N_d$ .

The following example uses Algorithm One [7] to solve a dynamic routing problem for the network in Fig. 2. A grid of discrete values of time  $S_{19} = \{1, 2, \dots, 20\}$  for  $t_0 = 1$  is established.

Table 2 shows the initial array and the two subsequent arrays. So, the set  $\{\text{Eff}(E_i(t_0))\}$  of all nondominated paths that leave node 1, 2, and 3 at time  $t_0 = 1$  are  $\{(1, 2), (2, 3), (3, 4)\}$ ,  $\{(2, 3), (3, 4)\}$ , and  $\{(3, 4)\}$ .

Kostreva and Wiecek [7] also developed an algorithm which uses forward dynamic programming to

Multiple Objective Dynamic Programming, Figure 2

find all nondominated paths from an origin node to every other node in the network without using a time grid. Thus, assume  $t$  is a continuous variable,  $t \geq 0$ , and  $[c_{ij}(t)]_1 > 0$ . An assumption must be made about the cost functions so that the principle of optimality will hold for these networks: For any arc  $(i, j) \in A$  and all  $t_1, t_2 \geq 0$ , if  $t_1 \leq t_2$ , then:

- a)  $t_1 + [c_{ij}(t_1)]_1 \leq t_2 + [c_{ij}(t_2)]_1$ , and
- b)  $[c_{ij}(t_1)]_r \leq [c_{ij}(t_2)]_r$  for all  $r \in \{2, \dots, m\}$ . Assuming the cost functions are monotone increasing with respect to time satisfies this assumption.

- 1 Find the initial vector  $\{[G_j^{(0)}]\}$ ,  $j = 1, \dots, N$ , where  $\{[G_1^{(0)}]\} = \{0\}$  and  $\{[G_j^{(0)}]\} = [c_{1j}(0)]$ ,  $j = 2, \dots, N$ .
- 2 Calculate the vectors  $\{[G_j^{(k)}]\}$ ,  $j = 1, \dots, N$ , for  $k = 1, 2, \dots$ , as follows:  

$$\begin{aligned} & \{[G_j^l(t_l)^{(k)}], l = 1, \dots, N_j\} \\ &= \text{VMIN}\{[G_i^n(t^n)^{(k-1)}] + [c_{ij}(t^n)], \\ & \quad n = 1, \dots, N_i\}, \\ & \quad j = 2, \dots, N, \\ & \{[G_1^l(t^l)^{(k)}], l = 1\} = \{0\}. \end{aligned}$$
- 3  $\{[G_j^{(k)}]\}$ ,  $k = 1, 2, \dots$ , converges to  $\{[G_j]\}$ , the set of vector costs of all nondominated paths which leave the origin node at time  $t = 0$  and lead to node  $j$ .

Assume that node 1 is the origin node. For nodes  $j = 2, \dots, N$ , let  $[G_j^u(t^u)^{(k)}]$  be the vector cost of the nondominated path  $u$  which is of at most  $k$  links leaving the origin node at time  $t = 0$  and leading to node  $j$ , where  $t^u$  is the arrival time of this path at node  $j$ . Also, let  $\{[G_j^{(k)}]\}$  be the set of vector costs of all nondominated paths which are of at most  $k$  links leaving the origin node at time  $t = 0$  and leading to node  $j$ , where  $N_j$  is the number of nondominated paths. Let  $\{[G_j]\}$  be the set of vector costs of all nondominated paths which leave the origin node at time  $t = 0$  and lead to node  $j$ . The algorithm is as listed above.

Another way to get around the monotonicity assumption of dynamic programming is to use generalized dynamic programming techniques. See [2] for

a way to use generalized DP with a multicriteria preference function. Basically, generalized DP uses a weaker principle of optimality than Bellman’s famous version [1]. Generalized DP finds partial solutions that may lead to optimal solutions even though locally they are not optimal solutions according to the preference function.

In [2] generalized DP is applied to the multicriteria best path problem. Assuming node 1 to be the origin and node  $N$  to be the destination, let  $\Pi$  be the set of all paths in the network. Let

$$P(j) = \{p \in \Pi : i_1 = 1, i_n = j\}$$

be the set of all paths from the origin to node  $j$ . Let

$$X(j) = \{p \in \Pi : i_1 = j, i_n = N\}$$

be the set of all paths from node  $j$  to the destination node. The vector cost along each arc is called an *arc length vector*,  $l_{ij} = (l_{ij}^1, \dots, l_{ij}^m) \in \mathbf{R}^m$ . A path length function  $z: \Pi \rightarrow \mathbf{R}^m$  assigns a path length vector to every path  $p \in \Pi$  where  $\circ$  is a binary operator on  $\mathbf{R}^m$ :

$$z(p) = l_{1,2} \circ \dots \circ l_{i_{n-1},i_n}$$

Thus, each different objective can have a different binary operation. For example, distance would have an additive binary operator and probabilities would have

a multiplicative binary operator. Let

$$Z(j) = \{z(p) : p \in P(j)\}$$

be the set of all length vectors of all paths from the origin to node  $j$ . A multicriteria preference function  $u: \mathbf{R}^m \rightarrow \mathbf{R}$  is defined on the set of path length vectors. The objective is to maximize this preference function. The monotonicity assumption says that for all  $z, z' \in Z(j)$ ,  $u(z) \leq u(z') \Rightarrow u(z \circ l_{jk}) \leq u(z' \circ l_{jk})$  for all  $j, k \in S$  such that  $(j, k) \in T$ . Unfortunately, with multi-objective problems this assumption is easily violated. Generalized DP tries to get around this monotonicity assumption by having local preference relations defined as  $\rho_j \subseteq Z(j) \times Z(j)$ : for  $z, z' \in Z(j)$ , where  $z \rho_j z'$  implies that any subpath from the origin to node  $j$  whose length is  $z$  cannot be used in a path to produce a better overall path from the origin to the destination node than using the subpath from the origin to node  $j$  whose length is  $z'$ . So, subpath length vector  $z'$  is more locally preferred even though subpath length vector  $z$  may be globally preferred,  $u(z') \leq u(z)$ . So, for  $z, z' \in Z(j)$ ,  $z \rho_j z'$  if and only if  $\exists p' \in X(j)$  such that  $u(z \circ z(p)) \leq u(z' \circ z(p'))$  for all  $p \in X(j)$ . These local preference relations are used to form the *weak principle of optimality*. An optimal path must be composed of subpaths that can be part of an optimal path.

Unfortunately, in order to get these preference relations one would have to complete all paths from every node in the network. Since this is too computationally intense, the preference relations are relaxed to the refining local preference relations  $<_j$  where  $z <_j z'$  implies  $z \rho_j z'$ . Using  $<_j$  avoids having to find the entire relation  $\rho_j$ . Using this relation means that a larger set of maximal path length vectors will be kept by using  $\rho_j$  than if  $\rho_j$  were used. A maximal path length vector is a vector where there does not exist another vector at that state that is strictly more preferred. Let

$$\max_l(X, \rho) = \{x \in X : \exists x' \in X : x \rho x' \text{ and } x' \rho x\}.$$

The following are the equations of generalized DP:

$$\begin{aligned} f(1) &= \{z_1\}, \\ f(j) &= \max_l \left( \bigcup_{(i,j) \in A} (f(i) \circ l_{ij}) <_j \right) \\ \text{for } j &= 2, \dots, N, \end{aligned}$$

where  $\{f(i) \circ l_{ij}\} = \{z \circ l_{ij} : z \in f(i)\}$ .

When the monotonicity assumptions are satisfied, the  $<_j$  relation can be replaced with the multicriteria preference function,  $u$ , thus reducing to the conventional DP problem. However, when the monotonicity assumption does not hold the  $<_j$  relation must be defined by trying exploit any special structures of each individual problem. Also, using dynamic programming to find the entire Pareto optimal set can be seen as another special case of generalized DP where  $z_k \geq z'_k$  for all  $k = 1, \dots, m \Rightarrow z <_j z'$  (assuming minimization of each criteria).

The subject of multiple objective dynamic programming has developed into a viable body of knowledge capable of providing solutions to applied problems in which trade-offs among objectives is important. Among the multiple objective techniques, it is distinctive in its ability to provide the entire Pareto optimal set. To gain such an advantage, one must be willing to perform computationally intensive operations on large sets of vectors.

### Keywords

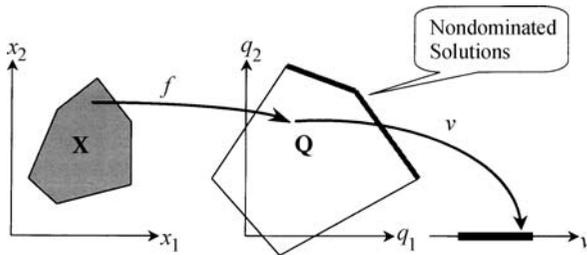

Multiple criteria decision making; Multiple objective programming; Multiple objective programming support; Scalarizing function; Value function

This article gives a brief introduction into multiple objective programming support. We will overview basic concepts, formulations, and principles of solving multiple objective programming problems. To solve those problems requires the intervention of a decision-maker. That's why behavioral assumptions play an important role in multiple objective programming. Which assumptions are made affects which kind of support is given to a decision maker. We will demonstrate how a free search type approach can be used to solve multiple objective programming problems.

### Introduction

Before we can consider the concept of *multiple objective programming support* (MOPS), we have to first explain the concept of *multiple criteria decision making* (MCDM). Even if there is a variation of different definitions, most researchers working in the field might accept the following general definition: Multiple Criteria Decision Making (MCDM) refers to the solving of decision and planning problems involving multiple (generally conflicting) criteria. 'Solving' means that a decision-maker (DM) will choose one 'reasonable' alternative from among a set of available ones. It is also meaningful to define that the choice is irrevocable. For an MCDM problem it is typical that no unique solution for the problem exists. Therefore to find a solution for MCDM problems requires the intervention of a decision-maker (DM). In MCDM, the word 'reasonable' is replaced by the words 'efficient/nondominated'. They will be defined later on.

Actually the above definition is a strongly simplified description of the whole (multiple criteria) decision making process. In practice, MCDM problems are not often so well-structured, that they can be considered just as a choice problem. Before a decision problem is ready to be 'solved', the following questions require a lot of preliminary work: How to structure the problem? How to find essential criteria? How to handle uncertainty? These questions are by no means outside the interest area of MCDM-researchers. The outranking method by B. Roy [17] and the AHP (the analytic hierarchy process) developed by T.L. Saaty [18] are examples of the MCDM-methods, in which a lot of effort is devoted to problem structuring. Both methods are well known and widely used in practice. In both methods,

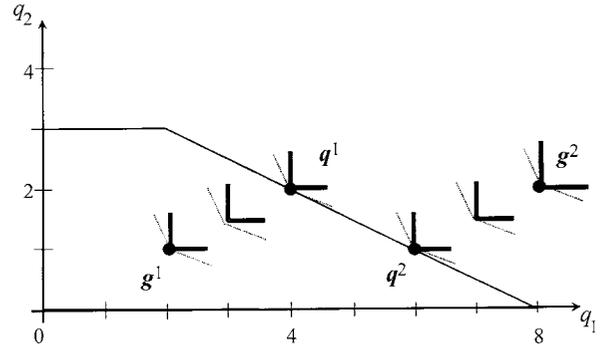

**Multiple Objective Programming Support, Figure 1**  
A variable, criterion, and value space

the presence of multiple criteria is an essential feature, but the structuring of a problem is an even more important part of the solution process.

When the term ‘support’ is used in connection with MCDM, we may adopt a broad perspective and refer with the term to all research associated with the relationship between the problem and the decision-maker. In this article we take a narrower perspective and focus on a very essential supporting problem in multiple criteria decision making: How to assist a DM to find the ‘best’ solution from among a set of available ‘reasonable’ alternatives, when the alternatives are evaluated by using several criteria? Available alternatives are assumed to be defined explicitly or implicitly by means of a mathematical model. The term *multiple objective programming* is usually used to refer to dealing with this kind of model.

The following considerations are general in the sense that usually it is not necessary to specify how the alternatives are defined. It is enough to assume that they belong to set  $Q$ . However, in Fig. 1 and Fig. 2 and the numerical example we consider a multiple objective linear programming model in which all constraints and objectives are defined using linear functions.

The article consists of seven sections. In Sect. “**A Multiple Objective Programming Problem**”, we give a brief introduction to some foundations of multiple objective programming. How to generate potential ‘reasonable’ solutions for a DM’s evaluation is considered in Sect. “**Generating Nondominated Solutions**”, and in Sect. “**Solving Multiple Objective Problems**”, we will review general principles to solve a multiple objective programming problem. In Sect. “**Example of a Decision Support System: VIG**”, a multiple criteria decision support system VIG is introduced, and a numerical ex-

**Multiple Objective Programming Support, Figure 2**  
Illustrating the projection of a feasible and an infeasible aspiration level point onto the nondominated surface

ample is solved in Sect. “**Numerical Illustrations**”. Concluding remarks are given in Sect. “**Conclusion**”.

### A Multiple Objective Programming Problem

A multiple objective programming (MOP) problem in a so-called *criterion space* can be defined as follows:

$$\begin{cases} \text{‘max’} & q \\ \text{s.t.} & q \in Q, \end{cases} \quad (1)$$

where set  $Q \subset \mathbf{R}^k$  is a so-called *feasible region* in a  $k$ -dimensional criterion space  $\mathbf{R}^k$ . The set  $Q$  is of special interest. Most considerations in multiple objective programming are made in a criterion space.

Set  $Q$  may be convex/nonconvex, bounded/unbounded, precisely known or unknown, consist of finite or infinite number of alternatives, etc. When  $Q$  consists of a finite number of elements which are explicitly known in the beginning of the solution process, we have an important class of problems which may be called e.g. (multiple criteria) *evaluation problems*. Sometimes those problems are referred to as *discrete multiple criteria problems* or *selection problems* (for a survey see for example [16]).

When the number of alternatives in  $Q$  is infinite and not countable, the alternatives are usually defined using a mathematical model formulation, and the problem is called continuous. In this case we say that the alternatives are only implicitly known. This kind of problem is referred as a *multiple criteria design problem* (the terms ‘evaluation’ and ‘design’ are adopted from A. Arbel) or a *continuous multiple criteria problem*. In this case, the

set  $Q$  is not specified directly, but by means of decision variables as usually done in single optimization problems:

$$\begin{cases} \max & q = f(x) = (f_1(x), \dots, f_k(x)) \\ \text{s.t.} & x \in X, \end{cases} \quad (2)$$

where  $X \subset \mathbf{R}^n$  is a *feasible set* and  $f : \mathbf{R}^n \rightarrow \mathbf{R}^k$ . The space  $\mathbf{R}^n$  is called a *variable space* (see Fig. 1). The functions  $f_i, i = 1, \dots, k$ , are *objective functions*. The feasible region  $Q$  can now be written as  $Q = \{q : q = f(x), x \in X\}$ .

The MOP-problem has seldom a unique solution, i.e. an optimal solution that simultaneously maximizes all objectives. Conceptually the multiple objective mathematical programming problem may be regarded as a *value (utility) function* maximization program:

$$\begin{cases} \max & v(q) \\ \text{s.t.} & q \in Q, \end{cases} \quad (3)$$

where  $v$  is a real-valued function, which is strictly increasing in the criterion space and defined at least in the feasible region  $Q$ . It is mapping the feasible region into a one-dimensional value space (see Fig. 1). Function  $v$  specifies the DM's preference structure over the feasible region. However, the key assumption in multiple objective programming is that  $v$  is unknown. Generally, if the value function is estimated explicitly, the system is considered to be in the MAUT category, see for example [7], (MAUT stands for multiple attribute utility theory) and can then be solved without any interaction of the DM. Typically, MAUT-problems are not even classified under the MCDM-category. If the value function is implicit (assumed to exist but is otherwise unknown) or no assumption about the value function is made, the system is usually classified under MCDM [2] or MOP.

Solutions of the MOP-problems are all those alternatives which can be the solutions of some value function  $v : Q \rightarrow \mathbf{R}$ . Those solutions are called *efficient* or *nondominated* depending on the space where the alternatives are considered. The term *nondominated* is used in the criterion space and *efficient* in the variable space. (Some researchers use the term *efficient* to refer to *efficient* and *nondominated* solutions without making any difference.) Any choice from among the set of *efficient* (*nondominated*) solutions is an acceptable and 'reason-

able' solution, unless we have no additional information about the DM's preference structure.

*Nondominated* solutions are defined as follows:

**Definition 1** In (1),  $q^* \in Q$  is *nondominated* if and only if there does not exist another  $q \in Q$  such that  $q \geq q^*$  and  $q \neq q^*$ .

**Definition 2** In (1),  $q^* \in Q$  is *weakly nondominated* if and only if there does not exist another  $q \in Q$  such that  $q > q^*$ .

Correspondingly, *efficient* solutions are defined as follows:

**Definition 3** In (2),  $x^* \in X$  is *efficient* if and only if there does not exist another  $x \in X$  such that  $f(x) \geq f(x^*)$  and  $f(x) \neq f(x^*)$ .

**Definition 4** In (2),  $x^* \in X$  is *weakly efficient* if and only if there does not exist another  $x \in X$  such that  $f(x) > f(x^*)$ .

The final ('best') solution  $q \in Q$  of the problem (1) is called the *most preferred solution*. It is a solution preferred by the DM to all other solutions. At the conceptual level, we may think it is the solution maximizing an (unknown) value function in problem (3). How to find it? That is the problem we now proceed to consider.

Unfortunately, the above characterization of the most preferred solution is not very operational, because no system can enable the DM to simultaneously compare the final solution to all other solutions with an aim to check if it is really the most preferred or not. It is also as difficult to maximize a function we do not know. Some properties for a good system are, for example, that it makes the DM convinced that the final solution is the most preferred one, does not require too much time from the DM to find the final solution, to give reliable enough information about alternatives, etc. Even if it is impossible to say which system provides the best support for a DM for his multiple criteria problem, all proper systems have to be able to recognize, generate and operate with *nondominated* solutions. To generate *nondominated* solutions for the DM's evaluation is thus one key issue in multiple objective pro-

gramming. In the next section, we will consider some principles.

### Generating Nondominated Solutions

Despite many variations among different methods of generating nondominated solutions, the ultimate principle is the same in all methods: a single objective optimization problem is solved to generate a new solution or solutions. The objective function of this single objective problem may be called a *scalarizing function*, according to [25]. It typically has the original objectives and a set of parameters as its arguments. The form of the scalarizing function as well as what parameters are used depends on the assumptions made concerning the DM's preference structure and behavior.

Two classes of parameters are widely used in multiple objective optimization:

- 1) weighting coefficients for objective functions; and
- 2) reference/aspiration/reservation levels for objective function values.

Based on those parameters, there exist several ways to specify a scalarizing function. An important requirement is that this function completely characterizes the set of nondominated solutions:

for each parameter value, all solution vectors are nondominated, and for each nondominated criterion vector, there is at least one parameter value, which produces that specific criterion vector as a solution

(see, for theoretical considerations, e. g. [26]).

### A Linear Scalarizing Function

A classic method to generate nondominated solutions is to use the weighted-sums of objective functions, i. e. to use the following linear scalarizing function:

$$\max \{ \lambda' f(x) : x \in X \}. \quad (4)$$

If  $\lambda > 0$ , then the solution vector  $x$  of (4) is efficient, but if we allow that  $\lambda \geq 0$ , then the solution vector is weakly-efficient. (see, e. g. [21, p. 215; 221]). Using the parameter set  $\Lambda = \{ \lambda : \lambda > 0 \}$  in the weighted-sums linear program we can completely characterize the efficient set provided the constraint set is convex.

However,  $\Lambda$  is an open set, which causes difficulties in a mathematical optimization problem. If we use  $\text{cl}(\Lambda) = \{ \lambda : \lambda \geq 0 \}$  instead, the efficiency of  $x$  cannot be guaranteed anymore. It is surely weakly-efficient, and not necessarily efficient. When the weighted-sums are used to specify a scalarizing function in multiple objective linear program (MOLP) problems, the optimal solution corresponding to nonextreme points of  $X$  is never unique. The set of optimal solutions always consists of at least one extreme point, or the solution is unbounded. In early methods, a common feature was to operate with weight vectors  $\lambda \in \mathbf{R}^k$ , limiting considerations to efficient extreme points (see, e. g., [29]).

### A Chebyshev-Type Scalarizing Function

Currently, most solution methods are based on the use of a so-called Chebyshev-type scalarizing function first proposed by A. Wierzbicki [25]. We will refer to this function by the term *achievement (scalarizing) function*. The achievement (scalarizing) function projects any given (feasible or infeasible) point  $g \in \mathbf{R}^k$  onto the set of nondominated solutions. Point  $g$  is called a *reference point*, and its components represent the desired values of the objective functions. These values are called *aspiration levels*.

The simplest form of achievement function is:

$$s(g, q, w) = \max_{k \in K} \frac{g^k - q^k}{w_k}, \quad (5)$$

where  $w > 0 \in \mathbf{R}^k$  is a (given) vector of weights,  $g \in \mathbf{R}^k$ , and  $q \in Q = \{ f(x) : x \in X \}$ . By minimizing  $s(g, q, w)$  subject to  $q \in Q$ , we find a weakly nondominated solution vector  $q^*$  (see, e. g. [25,26]). However, if the solution is unique for the problem, then  $q^*$  is nondominated. If  $g \in \mathbf{R}^k$  is feasible, then  $q^* \in Q$ ,  $q^* \geq g$ . To guarantee that only nondominated (instead of weakly nondominated) solutions will be generated, more complicated forms for the achievement function have to be used, for example:

$$s(g, q, w, \rho) = \max_{k \in K} \left[ \frac{g^k - q^k}{w_k} \right] + \rho \sum_{i=1}^k (g_i - q_i), \quad (6)$$

where  $\rho > 0$ . In practice, we cannot operate with a definition 'any positive value'. We have to use a pre-specified value for  $\rho$ . Another way is to use a lexicographic formulation [10].

The applying of the scalarizing function (6) is easy, because given  $g \in \mathbf{R}^k$ , the minimum of  $s(g, v, w, \rho)$  is found by solving the following LP-problem:

$$\begin{cases} \min & \epsilon + \rho \sum_{i=1}^k (g_i - q_i) \\ \text{s.t.} & x \in X \\ & \epsilon \geq \frac{g_i - q_i}{w_i}, \quad i = 1, \dots, k. \end{cases} \quad (7)$$

Problem (7) can be further written as:

$$\begin{cases} \min & \epsilon + \rho \sum_{i=1}^k (g_i - q_i) \\ \text{s.t.} & x \in X \\ & q + \epsilon w - z = g \\ & z \geq 0. \end{cases} \quad (8)$$

To illustrate the use of the achievement scalarizing function, consider a two-criteria problem with a feasible region having four extreme points (0, 0), (0, 3), (2, 3), (8, 0), as shown in Fig. 2. In Fig. 2, the thick solid lines describe the indifference curves when  $\rho = 0$  in the achievement scalarizing function. The thin dotted lines stand for the case  $\rho > 0$ . Note that the line from (2, 3) to (8, 0) is nondominated and the line from (0, 3) to (2, 3) (excluding the point (2, 3)) is weakly-nondominated, but dominated. Let us assume that the DM first specifies a feasible aspiration level point  $g^1 = (2, 1)$ . Using a weight vector  $w = [2, 1]'$ , the minimum value of the achievement scalarizing function ( $-1$ ) is reached at a point  $v^1 = (4, 2)$  (cf. Fig. 2). Correspondingly, if an aspiration level point is infeasible, say  $g^2 = (8, 2)$ , then the minimum of the achievement scalarizing function ( $+1$ ) is reached at point  $v^2 = (6, 1)$ . When a feasible point dominates an aspiration level point, then the value of the achievement scalarizing function is always negative; otherwise it is nonnegative. It is zero, if an aspiration level point is weakly-nondominated.

### Solving Multiple Objective Problems

Several dozen procedures and computer implementations have been developed from the 1970s onwards to address both *multiple criteria evaluation* and *design*

*problems*. The multiple objective decision procedures always requires the intervention of a DM at some stage in the solution process. A popular way to involve the DM in the solution process is to use an interactive approach.

The specifics of these procedures vary, but they have several common characteristics. For example, at each iteration, a solution, or a set of solutions, is generated for a DM's examination. As a result of the examination, the DM inputs information in the form of trade-offs, pairwise comparisons, aspiration levels, etc. (see [20] for a more detailed discussion). The responses are used to generate a presumably, improved solution. The ultimate goal is to find the most preferred solution of the DM. Which search technique and termination rule is used is heavily dependent on the underlying assumptions postulated about the behavior of the DM and the way in which these assumptions are implemented. In MCDM-research there is a growing interest in the behavioral realism of such assumptions.

Based on the role that the value function (3) is supposed to play in the analysis, we can classify the assumptions into three categories:

- 1) Assume the existence of a value function  $v$ , and assess it explicitly.
- 2) Assume the existence of a stable value function  $v$ , but do not attempt to assess it explicitly. Make assumptions of the general functional form of the value function.
- 3) Do not assume the existence of a stable value function  $v$ , either explicitly, or implicitly.

The first assumption is adopted in multi-attribute utility or decision analysis (see, e. g. [7]). Interactive software implementing such approaches on personal computers exists.

The second assumption was a basic paradigm used in interactive multiple criteria approaches in the 1970s. A classical example is the GDF-method [3]. DM's responses to specific questions were used to guide the solution process towards an 'optimal' or 'most preferred' solution (in theory), assuming that the DM behaves according to some specific (but unknown) underlying value function (see for surveys, e. g. [5,20,21], and [24]). Interactive software that implements such systems for a computer have often been developed by the authors of the above procedures for experimental purposes.

Pareto race interface for the search, embedded in the VIG software [8].

Thus Pareto race is a visual, dynamic, search procedure for exploring the nondominated frontier of a multiple objective linear programming problem. The user sees the objective function values on a display in numeric form and as bar graphs, as he/she travels along the nondominated frontier. The keyboard controls include an accelerator, gears, brakes, and a steering mechanism. The search on the nondominated frontier is like driving a car. The DM can, e. g., increase/decrease the speed, make a turn and brake at any moment he/she likes.

To implement those features, Pareto race uses certain control mechanisms, which are controlled by the following keys:

- (SPACE) BAR, an ‘accelerator’: Proceed in the current direction at constant speed.
- F1, ‘gears (backward)’: Increase speed in the backward direction.
- F2, ‘gears (forward)’: Increase speed in the forward direction.
- F3, ‘fix’: Use the current value of objective  $i$  as the worst acceptable value.
- F4, ‘relax’: Relax the ‘bound’ determined with key F3.
- F5, ‘brakes’: Reduce speed.
- F10, ‘exit’.
- num, ‘turn’: Change the direction of motion by increasing the component of the reference direction corresponding to the goal’s ordinal number  $i \in [1, k]$  pressed by DM.

An example of the Pareto race screen is given in Fig. 3. The screen is associated with the numerical example described in the next section.

Pareto race does not specify restrictive behavioral assumptions for a DM. He/she is free to make a search on the nondominated surface, until he/she believes that the solution found is his/her most preferred one.

Pareto race is only suitable for solving moderate size problems. When the size of the problem becomes large, computing time makes the interactive mode inconvenient. To solve large scale problems [13] proposed a method based on Pareto race. An (interactive) free search is performed to find the most preferred direction. Based on the direction, an nondominated curve can be generated in a batch mode if desired.

## Numerical Illustrations

For illustrative purposes, we will consider the following production planning problem, where a decision maker (DM) tries to find the ‘best’ product-mix for three products: Product 1, Product 2, and Product 3. The production of these products requires the use of one machine (mach. hours), man-power (man hours), and two critical materials (crit. mat. 1 and crit. mat. 2). Selling the products results in profit (profit). Assume that the DM describes his/her decision problem as follows:

Of course, I would like to make as much profit as possible. Because it is difficult and quite expensive to obtain critical materials, I would like to use them as little as possible, but never more than I have presently in storage (96 units of each). Only one machine is used to produce the products. It operates without any problems for at least 9 hours. The length of the regular working day is 10 hours. People are willing to work overtime which is costly and they are tired the next day. Therefore, if possible, I would like to avoid it. Finally, product 3 is very important to a major customer, and I cannot totally exclude it from the production plan.

The traditional single objective programming considers the problem as a profit maximization problem. The other ‘requirements’ are taken as constraints. The multiple objective programming takes a ‘softer’ perspective. We may, for instance, consider the problem as a four objective problem. The DM would like to make as much profit as possible, but simultaneously, he/she would like to use those two critical materials as little as possible, and in addition to maximize the use of product 3. Machine hours and man hours are considered as constraints, but during the search process the role of

**Multiple Objective Programming Support, Table 1**  
The coefficient matrix of the production planning problem

	Prod. 1	Prod. 2	Prod. 3
mach. hours	1.5	1	1.6
man hours	1	2	1
crit. mat. 1	9	19.5	7.5
crit. mat. 2	7	20	9
profit	4	5	3

**Multiple Objective Programming Support, Table 2**  
A sample of solutions for the multiple criteria problem

	I	II	III	IV
Objectives:				
crit. mat. 1	91.46	94.50	93.79	90.00
crit. mat. 2	85.44	88.00	89.15	84.62
profit	30.27	31.00	30.42	29.82
product 3	0.23	0.00	0.50	0.44
Constraints:				
mach. hours	9.00	9.00	9.00	9.00
man hours	9.73	10.00	10.00	9.62
Decision Variables:				
product 1	3.88	4.00	3.45	3.71
product 2	2.81	3.00	3.03	2.74
product 3	0.23	0.00	0.50	0.44

constraints and objectives may also be changed, if necessary.

We assume that the problem can be modeled as an MOLP-model. The coefficient matrix of the problem is given in Table 1.

Thus, we have the following multiple objective linear programming model:

$$\begin{aligned}
 \text{crit. mat. 1: } & 9P_1 + 19.5P_2 + 7.5P_3 \rightarrow \min \\
 \text{crit. mat. 2: } & 7P_1 + 20P_2 + 9P_3 \rightarrow \min \\
 \text{profit: } & 4P_1 + 5P_2 + 3P_3 \rightarrow \max \\
 \text{product 3: } & P_3 \rightarrow \max
 \end{aligned}$$

subject to:

$$\begin{aligned}
 \text{mach. hours: } & 1.5P_1 + P_2 + 1.6P_3 \leq 9 \\
 \text{man hours: } & P_1 + 2P_2 + P_3 \leq 10
 \end{aligned}$$

The problem has no unique solution. Using the Pareto race (see Fig. 3) or any other software developed for multiple objective programming enables a DM to search nondominated solutions. Which solution he/she will choose as a final one depends entirely on his/her own preferences. Actually, all sample solutions except solution II are somehow consistent with his/her statement above. In solution II, product 3 is excluded from the production plan.

## Conclusion

In this article, we have provided an overview on multiple objective programming support. The emphasis was

how to find the most preferred alternative from among a set of reasonable (nondominated) alternatives. This kind of the approach is unique for the multiple criteria decision making. We have left other features like structuring the problem, finding relevant criteria etc. beyond this presentation. They are important, but also relevant in the considerations of any decision support system.

Optimization; Nonconvex minimization; Low-rank nonconvexity

Multiplicative programming refers to a class of optimization problems containing products of real-valued functions in the objective and/or in the constraints. A product of convex functions is called a *convex multiplicative function*; similar definitions hold for *concave* and *linear* multiplicative functions. Multiplicative functions appear in various areas, including microeconomics [4], VLSI chip design [10] and modular design [2]. Especially in multiple objective decision making, they play important roles [3]. A typical example is a bond portfolio optimization studied in [7],

where a number of performance indices such as average coupon rate, average terminal yields and average length of maturity associated with a portfolio (a bundle of assets) are to be optimized (either minimized or maximized) subject to a number of constraints. One handy approach to simultaneously optimizing multiple objectives without a common scale is to optimize the geometric mean, or equivalently the product of these objectives. Thus, we are led to consider a multiplicative programming problem.

The simplest subclass of multiplicative programming problems is a *linear multiplicative program*, which is a quadratic program of minimizing a product of two affine functions  $\mathbf{c}_1^\top \mathbf{x} + c_{10}$ ,  $i = 1, 2$ , over a polytope  $D \subset \mathbb{R}^n$ :

$$\begin{cases} \min & f(\mathbf{x}) = (\mathbf{c}_1^\top \mathbf{x} + c_{10})(\mathbf{c}_2^\top \mathbf{x} + c_{20}) \\ \text{s.t.} & \mathbf{x} \in D. \end{cases} \quad (1)$$

This problem was first studied by K. Swarup [13] many years ago, but had attracted little attention until the late 1980s when an intensive research was undertaken [8,12,14]. In general, the objective function  $f$  is indefinite; it is quasiconcave on a region where the signs of  $\mathbf{c}_i^\top \mathbf{x} + c_{i0}$ s are the same, but quasiconvex on a region where the signs are different [1,8]. Therefore, to solve (1), we need to solve a quasiconcave minimization problem:

$$\begin{cases} \min & f(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D \cap S, \end{cases} \quad (2)$$

and a quasiconcave maximization problem:

$$\begin{cases} \max & f(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D \cap S, \end{cases} \quad (3)$$

where  $S = \{\mathbf{x} \in \mathbb{R}^n: \mathbf{c}_i^\top \mathbf{x} + c_{i0} \geq 0, i = 1, 2\}$ . While (2) belongs to multi-extremal global optimization [6] and is known to be NP-hard [11] (cf. also ► **Complexity Classes in Optimization**; ► **Computational Complexity Theory**), problem (3) can be solved using a standard convex minimization technique because maximizing  $f(\mathbf{x})$  amounts to minimizing a convex function  $-\log(\mathbf{c}_1^\top \mathbf{x} + c_{10}) - \log(\mathbf{c}_2^\top \mathbf{x} + c_{20})$ . For the same reason as (3), certain linear programs with additional linear multiplicative constraints, e. g. the modular design problem

with  $x_i y_j \geq b_{ij}$  [2], can be handled within the framework of convex programming, if  $x_i, y_j \geq 0$ .

A generalization of (1) is a *convex multiplicative program*, which minimizes a product of several convex functions  $f_i(\mathbf{x})$ ,  $i = 1, \dots, p$ , over a compact convex set  $D \subset \mathbb{R}^n$ :

$$\begin{cases} \min & f(\mathbf{x}) = \prod_{i=1}^p f_i(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D. \end{cases} \quad (4)$$

In most of the existing solutions to (4), the convex functions  $f_i$  are assumed to be nonnegative-valued on  $D$ . When  $f_i(\mathbf{x}') = 0$  for some  $i$  and for some  $\mathbf{x}' \in D$ , the minimum value of (4) is zero; and  $\mathbf{x}'$  is a globally optimal solution. We may therefore assume for each  $i$  that  $f_i(\mathbf{x}) > 0$  for all  $\mathbf{x} \in D$ . If  $f$  is a concave multiplicative function instead of a convex one, the problem is equivalent to a concave minimization problem because  $\log f(\mathbf{x}) = \sum_{i=1}^p \log f_i(\mathbf{x})$  is concave. The convex multiplicative program (4) itself can also be transformed into a concave minimization problem (cf. ► **Concave Programming**), though  $f$  is not a concave function. For example, introducing additional variables  $y_i$ ,  $i = 1, \dots, p$ , we have an equivalent problem:

$$\begin{cases} \min & \sum_{i=1}^p \log y_i \\ \text{s.t.} & \mathbf{x} \in D \\ & f_i(\mathbf{x}) \leq y_i, \quad i = 1, \dots, p, \\ & \mathbf{y} \geq 0. \end{cases} \quad (5)$$

The number  $p$  of  $f_i$ s is often very small in comparison with the dimension  $n$  of  $\mathbf{x}$ ; e. g. five or so in applications to multiple objective optimization. Owing to this *low-rank nonconvexity* [9], problem (5) can be solved far more efficiently than the usual concave minimization problem of the same size.

In addition to (1) and (4), there are a number of studies on problems with *generalized convex multiplicative functions* of the forms  $f(\mathbf{x}) = \prod_{i=1}^p f_i(\mathbf{x}) + g(\mathbf{x})$  and  $f(\mathbf{x}) = \sum_{i=1}^p f_{2i-1}(\mathbf{x}) f_{2i}(\mathbf{x}) + g(\mathbf{x})$ , where the  $f_i$ s and  $g$  are convex functions. These are all nonconvex minimization problems, each of which has an enormous number of local minima. Nevertheless, algorithms de-

veloped in the 1990s can locate a globally optimal solution in a reasonable amount of time, by exploiting special structures of  $f$  such as low-rank nonconvexity. A comprehensive review of the algorithms are given by H. Konno and T. Kuno in [5].

### Introduction

In this contribution, we consider Multi-Quadratic Programming (MQP) problems, where the objective function is a quadratic function and the feasible region is defined by a finite set of quadratic and linear constraints. They can be formulated as follows:

$$\begin{aligned} \min & x^T Qx + c^T x \\ \text{s.t.} & x^T A_j x + B_j x \leq b_j, \quad j = 1, \dots, m \quad x \geq 0, \end{aligned} \quad (1)$$

where  $A_j$  is an  $(n \times n)$  matrix corresponding to the  $m$ th quadratic constraint, and  $B_j$  is the  $j$ th row of the  $(m \times n)$  matrix  $B$ .

MQP plays an important role in modeling many diverse problems. The MQP encompasses many other optimization problems since it provides a much improved model compared to the simpler linear relaxation of a problem. Indeed, linear mixed 0-1, fractional, bilinear, bilevel, generalized linear complementarity, and many more programming problems are or can easily be reformulated as special cases of MQP. However, there are theoretical and practical difficulties in the process of solving such problems. However, very large linear models can be solved efficiently; whereas MQP problems are in general  $\mathcal{NP}$ -hard and numerically intractable. The problem of finding a feasible solution is also  $\mathcal{NP}$ -hard. This is because MQP is a generalization of the linear complementarity problem [29]. The nonlinear constraints in MQP define a feasible region which is in general neither convex nor connected. Moreover, even if the feasible region is a polyhedron, optimizing the quadratic objective function is strongly  $\mathcal{NP}$ -hard as the resulting problem is considered to be the disjoint bilinear programming problem. Therefore, finding a finite and exact algorithm that solves large MQP problems is impractical. Even for the convex case (when  $Q$  and  $A_j$  are positive semidefinite), there are very few algorithms for solving MQP problems. However, the MQP constitutes an important part of mathematical programming problems, arising in various practical applications including facility location, production planning, VLSI chip design, optimal design of water distribution networks, and most problems in chemical engineering design.

The MQP was first introduced in the seminal paper of Kuhn and Tucker [31]. Later on, the case of MQP with a single quadratic constraint in the problem was discussed in [55,56]. The first general approach for solving MQP problems was proposed in [12], where the following two Lagrange functions for MQP are considered:

$$L_1(x, \mu) = x^T Q x + c^T x + \sum_{j=1}^m \mu_j (x^T A_j x - B_j x - b_j),$$

$$L_2(x, \mu, \lambda) = L_1(x, \mu) - \lambda_i x_i,$$

where  $\mu$  and  $\lambda$  are the multipliers for the quadratic and bound constraints respectively. A cutting plane algorithm was applied to solve this problem; that is, the

algorithm solves a sequence of linear master problems that minimize a piecewise linear function constructed from the Lagrange functions for constant  $x$ , and a primal problem with either an unconstrained quadratic function (using  $L_2(x, \mu, \lambda)$ ) or a quadratic function over the nonnegative orthant (using  $L_1(x, \mu)$ ) [21].

### Multi-Quadratic Integer Program

In this contribution we consider a multi-quadratic integer programming (MQIP) problem with bilevel variables. This problem is a more specific case of MQP. Recently, multi-quadratic zero-one programming problems were proved equivalent to mixed-integer programming problems [16]. In that work, a quadratic zero-one programming was initially proved equivalent to a mixed integer programming problem. Then, the result was extended to the case multi-quadratic programming case.

Throughout this paper, we consider a multi-quadratic zero-one programming problem, which has following form:

$$P_1 :: \min f(x) = x^T A x, \text{ s.t. } Bx \geq b, x^T Cx \geq \alpha, \\ x \in \{0, 1\}^n, \alpha \text{ is a constant.}$$

Notice  $x^T Cx \geq \alpha$  essentially represent the same the quadratic constraints as  $x^T A_j x + B_j x \leq b_j$  in problem (1), due to the binary variables' property  $x_i x_i = x_i$ .

### Applications

#### Bilinear Problem

Each  $n$ -dimensional MQP problem can be easily transformed to a  $2n$ -dimensional bilinear problem. A strategy for reducing the necessary dimension of the resulting bilinear program is also proposed [7,28]. However, on the other hand, bilinear optimization problems are nothing else but a special instance of MQP. Pooling problems in petrochemistry, the modular design problem introduced in [17], in particular the multiple modular design problem [7,18] or the more general modularization of product sub-assemblies [46], and special classes of structured stochastic games [20] are only some examples of the wide range of applications of bilinear programming problems. Another large class of optimization problems are problems with linear or quadratic functions additionally involving Boolean

variables (i.e., variables  $x_i \in \mathbb{R}$  with the constraint  $x_i \in \{0, 1\}$ ). Another widely explored problem is the problem of packing  $n \in \mathbb{N}$  equal circles in a square, which can be transformed to a MQP problem. One looks for the maximum radius  $r$  of  $n$  non-overlapping circles contained in the unit square. This problem is equivalent to a MQP problem with a linear objective function and concave quadratic constraints.

### Minimax Problem

A related class of global optimization problems are minimax location problems [42], which also lead to quadratic constraints. Production planning and portfolio optimization are examples where so-called chance constrained linear programs occur. These are problems, looking similar to linear programs. However, the matrix describing the linear constraints of such problems is not deterministic, it is a stochastic one. Under certain restrictive assumptions it is possible to transform these stochastic constraints to deterministic quadratic constraints [42], such that in general a problem of type MQP is obtained. In [8] it is shown that nonconvex MQP problems can be used for the examination of special instances of nonlinear bilevel programming problems. Other applications of MQP include the fuel mixture problem encountered in the oil industry [43] and also placement and layout problems in integrated circuit design [9,10].

### Mixed Integer Problem

As described in the previous section, MQP problem can be easily linearized to a mixed integer zero-one problem with the same problem size. In theory and practice, the linearization technique proposed in [16] has been shown to be superior than other conventional linearization techniques. In medical applications, multi-quadratic zero-one problems were used to model epileptic brains for electrode selection problems. Basically, multi-quadratic zero-one problems were solved to identify the location (electrode) sites of the brain that can detect seizure precursors (predict seizures) [30,34,36]. In order to operate in real time, multi-quadratic zero-one problems were linearized to a mixed integer zero-one problem, which is much faster to solve in practice.

Hence there are many applications of MQP. Whether the MQP is in practice applicable for solving, for example, problems resulting from integer programming problems, depends on the numerical efficiency of the solution method that is used. Up to now only few methods for solving the considered general case of MQP were proposed in the literature. Most of them result from methods being developed for other more general problem classes. In the next section we will discuss some of the solution techniques.

### Solution Techniques

There are many different techniques proposed for solving this type of problems, most of them are of branch and bound type or some type of linearization techniques [4,25,26,27,37,38,39,57]. A disadvantage of the standard linearization technique is the additional variables for each product  $x_i x_j$ , in which the number of new variables is  $O(n^2)$ , where  $n$  is the number of initial 0-1 variables [4,25,26,57]. The method proposed in [16] needs only  $O(kn)$  additional continuous variables, where  $k$  is the number of quadratic constraints, and the number of initial 0-1 variables remains the same. A branch-and-bound algorithm for solving MQP problems (and other more general problems), when the objective function is separable and the constraint set is linear, was introduced in [19]. The method evolves solving bounding convex envelope approximating problems over successive partitions of the feasible region. This method was later extended to deal with nonconvex constraints but it generates a number of infeasible solutions and does not, in general, converge in a finite number of iterations [53]. An algorithm for the solution to linear problems with an additional reverse convex constraint was proposed in [15]. The algorithm involves partitioning the feasible region into subsets contained in cones originating at an infeasible vertex of the polytope formed by the linear constraints while ensuring that an interior point of the feasible region is contained in each partition. Later on, an algorithm for the solution to problems with concave objective functions and separable quadratic constraint was proposed in [8]. The algorithm uses piecewise linear approximation for the quadratic constraints and solves a MQP problem as a mixed 0-1 linear problem. This algorithm is similar to the solu-

tion approaches for concave quadratic problems [40] and for indefinite quadratic problems [35]. During the last decade, several authors are interested in some special cases of MQP. Also, many extensions of MQP have been discussed in the literature. The problem of minimizing an indefinite quadratic objective subject to two-sided indefinite quadratic constraints was discussed in [54]. Under suitable assumptions, they derived necessary and sufficient optimality conditions and gave some conditions for the existence of solutions for this nonconvex program. While several methods have been suggested for solving MQP problems, numerical solutions of the general problem are still rarely available in the literature. By using a double duality argument, under suitable assumptions, the MQP is proved to be equivalent to a convex program [6]. In addition, a problem with a concave quadratic function is proved to be equivalent to a minimax convex problem, and thus can be solved in polynomial time via interior-points methods. The property is no longer true when  $Q$  is an indefinite quadratic function [6].

### Linear Forms of MQIP

As aforementioned, MQP problems have a close relationship with mixed integer zero-one problem by applying linearization schemes, which have been explored for decades. Although the existing linearization schemes originally were developed for QP instead of MQP, they could be easily applied to MQP, since the quadratic constraints in MQP could be reformulated by using the same technique in linearization considered for the quadratic objective. This section will provide a brief view of major linearization schemes and their applications on MQP problems.

No matter what specific reformulation of the linearization schemes, the ideas are the same as replacing the quadratic product  $x_i x_j$  by additional variables. Currently existing linearization schemes were developed in four phases.

The prototype of linearization technique arose in 1960s, proposed by Watters [57] and Zangwill [58] (see also Fortet [22,23]). This approach introduces additional binary variables  $w_{ij}$  for replacement of the products  $x_i x_j$  and additional constraints,  $x_i + x_j - w_{ij} \leq 1$  and  $x_i + x_j \geq 2w_{ij}$ ,  $\forall i, j$ , for a guarantee of correct replacement. Taken this approach, the MQP  $P_1$  is trans-

formed as following form:

$$\begin{aligned} MIP_1 :: \min f(x, w) = & \sum_i a_{ii} x_i \\ & + \sum_i \sum_{j>i} (a_{ij} + a_{ji}) w_{ij}, \text{ s.t. } Bx \geq b, \\ & \sum_i c_{ii} x_i + \sum_i \sum_{j>i} (c_{ij} + c_{ji}) w_{ij} \geq \alpha, \\ & x_i + x_j - w_{ij} \leq 1, \forall i, j, x_i + x_j \geq 2w_{ij}, \\ & \forall i, j, x \in \{0, 1\}^n, w_{ij} \in \{0, 1\} \alpha \text{ is a constant} \\ & \text{and } A = (a_{ij}), C = (c_{ij}). \end{aligned}$$

In this formulation, the quadratic products  $x_i x_j$  in objective and constraints,  $x^T A x$  and  $x^T C x$ , have been similarly replaced by additional binary variables  $w_{ij}$ , and the formulation is consistent with original  $P_1$  by additional constraints,  $x_i + x_j - w_{ij} \leq 1$  and  $x_i + x_j \geq 2w_{ij}$ ,  $\forall i, j$ . Following this seminal work, Glover and Woolsey [25] provided more concise zero-one linear programming formulations, where reformulation rules are given under difference conditions to reduce the numbers of additional constraints and additional variables.

In the second phase development of linearization techniques, researchers recognized the additional binary variables  $w_{ij}$  in  $MIP_1$  could be relaxed by continuous ones. Such linearization schemes include the models developed in Glover [24], Glover and Woolsey [26], and Rhys [45]. One scheme with close relationship of the linearization prototype was provided in Glover and Woolsey [26], which introduces additional cut constraints  $x_i \geq w_{ij}$  and  $x_j \geq w_{ij}$ ,  $\forall i, j$  enforcing the additional continuous variables  $w_{ij}$  to be binary. However, this technique doubles the number of additional constraints added and thereafter enlarges the size of original MQP problems. A straightforward generalization of  $x_i \geq x_i x_j$ ,  $\forall j$  generated their further improvement of this technique in [26] that used alternative concise constraints  $(n - i)x_j \geq \sum_{(j>i)} w_{ij}$ ,  $\forall i$  to enforce the additional variables to be binary, with somewhat fewer constraints. Applying such linearization technique, the MQP  $P_1$  has the following representation:

$$\begin{aligned} MIP_2 :: \min f(x, w) = & \sum_i a_{ii} x_i \\ & + \sum_i \sum_{j>i} (a_{ij} + a_{ji}) w_{ij}, \text{ s.t. } Bx \geq b, \end{aligned}$$

$$\sum_i c_{ii}x_i + \sum_i \sum_{j>i} (c_{ij} + c_{ji})w_{ij} \geq \alpha,$$

$$\begin{aligned} x_i + x_j - w_{ij} &\leq 1, \forall i, j, (n-i)x_j \\ &\geq \sum_{(j>i)} w_{ij}, \forall i, x \in \{0, 1\}^n, w_{ij} \geq 0 \end{aligned}$$

$\alpha$  is a constant and  $A = (a_{ij}), C = (c_{ij})$ .

The main difference between  $MIP_1$  and  $MIP_2$  is the continuity of  $w_{ij}$  and the smaller number of additional constraints.

Beyond the linearization technique in [26], Glover first noticed Petersen's work [41], where the cross products in the model are considered by their upper and lower bounds. Following this idea, Glover, in [24], firstly proposed a linearization technique introducing different continuous variables  $w_i$  to the pioneer research. In his linearization scheme, the additional continuous variables are defined by  $w_i = x_i \sum_j a_{ij}x_j$ , where  $x_i$  are binary variables in original model and  $a_{ij}$  are quadratic coefficients in the objective function. Further define the lower and upper bounds of  $\sum_j a_{ij}x_j$  by  $A_i^- = \sum_j \{a_{ij} | a_{ij} < 0\}$  and  $A_i^+ = \sum_j \{a_{ij} | a_{ij} > 0\}$ , respectively. Taking the cross products and binary variables into consideration, the additional inequalities  $A_i^+ x_i \geq w_i \geq A_i^- x_i$  and  $\sum_j a_{ij}x_j - A_i^-(1-x_i) \geq w_i \geq \sum_j a_{ij}x_j - A_i^+(1-x_i)$  provide the equivalence of original QP model. Applied such linearization technique, the MQP  $P_1$  has a different structure as follows:

$$MIP_3 :: \min f(w) = \sum_i w_i, \text{ s.t. } Bx \geq b,$$

$$A_i^+ x_i \geq w_i \geq A_i^- x_i, \forall i, \sum_j a_{ij}x_j - A_i^-(1-x_i)$$

$$\geq w_i \geq \sum_j a_{ij}x_j - A_i^+(1-x_i) \forall i, \sum_i v_i \geq \alpha,$$

$$C_i^+ x_i \geq v_i \geq C_i^- x_i, \forall i, \sum_j c_{ij}x_j - C_i^-(1-x_i)$$

$$\geq v_i \geq \sum_j c_{ij}x_j - C_i^+(1-x_i) \forall i, x \in \{0, 1\}^n,$$

$\alpha$  is a constant.

Notice, in  $MIP_3$ , the quadratic constraint  $x^T C x \geq \alpha$  is replaced by a series of inequalities  $\sum_i v_i \geq \alpha, C_i^+ x_i \geq v_i \geq C_i^- x_i, \forall i, \sum_j c_{ij}x_j - C_i^-(1-x_i) \geq v_i \geq \sum_j c_{ij}x_j - C_i^+(1-x_i) \forall i$ , which follow the definitions in [24] as:  $v_i = x_i \sum_j c_{ij}x_j, C_i^- = \sum_j \{c_{ij} | c_{ij} < 0\}$ ,

and  $C_i^+ = \sum_j \{c_{ij} | c_{ij} > 0\}$ . Compared  $MIP_3$  with  $MIP_1$  and  $MIP_2$ , the most important improvement of this linearization technique is that the numbers of additional variables and constraints reduce from  $O(n^2)$  to  $O(n)$ . Some recent papers [1,2] proposed further-improved linearization techniques based on the strategy of Glover's technique, either providing concise formulation or generating tighter upper/lower bounds.

The linearization techniques in the third phase development considered the transformation from the direction of tightness instead of problem size. One typical technique included in this category is the famous Sherali-Adams Reformulation-Linearization Technique (as RLT in short) [3,4,5,50,51,52] which provides wide-range applications. The development milestones of RLT can be found in a recent memorial paper written by Sherali [47]. Interested readers could follow this paper to find the development details of the linearization scheme.

Some practical applications of linearization technique in early 1980s (e.g. [13] considered for solving notorious quadratic assignment problem) generated the experiences that the linearization techniques are practically inefficient although they may have small problem size. Such experience intrigued some researchers to provide better LP structures with tighter bounds, which offer better computational efficiencies, rather than to pursue smaller problem size. The linearization technique shown in [3] provides a structure having tighter bounds for zero-one QP. The transformation happens not only replacing the cross products  $x_i x_j$  in the model but also reconstructing the constraints to obtain the tightness. The example given in [3] not only includes the additional constraints and continuous variables, but reconstructs the linear constraints by multiplying  $x_j$  and  $1-x_j$ , respectively. Applying this linearization technique to MQP,  $P_1$  is transformed as follows:

$$MIP_4 :: \min f(x, w) = \sum_i a_{ii}x_i$$

$$+ \sum_i \sum_{j>i} (a_{ij} + a_{ji})w_{ij}, \text{ s.t. } \sum_i B_{ki}x_i - \beta_k$$

$$\geq \sum_{i<j} B_{ki}w_{ij} + \sum_{i>j} B_{ki}w_{ji} + (B_{kj} - \beta_k)x_j$$

$$\geq 0,$$

$$\forall j, k, \sum_i c_{ii}x_i + \sum_i \sum_{j>i} (c_{ij} + c_{ji})w_{ij} \geq \alpha,$$

$$x_i + x_j - w_{ij} \leq 1, \forall i, j, x_i \geq w_{ij}, x_j \geq w_{ij}$$

$$\forall i, j, x \in \{0, 1\}^n, w_{ij} \geq 0,$$

where  $\alpha$  is a constant and  $A = (a_{ij})$ ,  
 $C = (c_{ij})$ ,  
 $B = (B_{ij}), b = (\beta_k)$ .

Notice the linear constraints  $Bx \geq b$  are reconstructed as by multiplying  $x_j$  and  $1 - x_j$  and then have much more complicated but tighter representations. The authors also provided the rigorous proof that the construction is tighter than the linearization provided by Glover [24]. Other than that, this formulation uses the inequalities  $x_i \geq w_{ij}$  and  $x_j \geq w_{ij}$  instead of  $(n - i)x_j \geq \sum_{(j>i)} w_{ij}$  which will weaken the model's tightness as pointed out by the authors.

Using this idea of multiplying  $x_j$  and  $1 - x_j$  to the feasible set Adams and Sherali [4] provided a linearization strategy to more general MIP with cross products between continuous and binary variables. Comparisons were also provided between the RLT strategy and the linearization techniques in Watters [57], Zangwill [58], Petersen [41], Glover and Woolsey [25,26], and Glover [24]. Along with this direction, Sherali and Adams [49,50,51] generated a hierarchy of relaxations for zero-one polynomial problems. This relaxation strategy generalizes the idea in [3] by introducing a select set of  $d$ -degree polynomial terms or factors, where  $d$  is an integer less than the number of binary variables. Multiplying the feasible set by  $d$ -degree polynomial terms, as the authors showed, obtains an equivalent reformulation, for each  $d = 1, \dots, n$ , which can enforce the binary restrictions on the original  $x$  variables. And these papers also proved that, when  $d = n$ , the resulting linear system characterizes the convex hull of feasible solutions, and therefore is tighter than any other linearization techniques.

The most recent development, as the final phase, of linearization technique is proposed by Chaovalitwongse et al. [16]. The authors took the dual variables into account, and proposed a new linearization technique based on KKT optimality conditions. Their approach was originally considered for MQP, and is not hard to be utilized for zero-one QP problems. The transformation of MQP  $P_1$  using this linearization

strategy can be shown as follows.

$$MIP_5 :: \min g(s, x) = e^T s - Me^T x, \text{ s.t.}$$

$$Ax - y - s + Me = 0, Bx \geq b,$$

$$y \leq 2M(e - x), Cx - z + M'e \geq 0,$$

$$e^T z - M'e^T x \geq \alpha, z \leq 2M'x,$$

$$x \in \{0, 1\}^n, y_i, s_i, z_i \geq 0,$$

where  $M' = \|C\|_\infty$  and  $M = \|A\|_\infty$ .

Notice the additional variables including  $s, y$  and  $z$ , which are introduced from the Lagrangian function of MQP.

**Theorem 1**  $P_1$  has an optimal solution  $x^0$  iff there exist  $y^0, s^0, z^0$  such that  $(x^0, y^0, s^0, z^0)$  is an optimal solution of  $MIP_5$ .

*Proof 1* See [16]. □

To conclude all the linearization schemes shown herein, we provide a table aggregating the numbers of additional variables and constraints for these techniques as a brief comparison. Assuming we have  $k$  linear constraints  $\sum_i B_{ji}x_i \geq b_j, j = 1, \dots, k$  and  $m$  quadratic constraints  $x^T C_j x \geq \alpha_j, j = 1, \dots, m$ , in an MQP. Also assume that the number of binary variables  $n \gg k$  and  $n \gg m$ . Then the number of additional variables and constraints of the linearized forms applying different techniques can be shown in the table as follows:

Models	$P_1$	$MIP_1$	$MIP_2$	$MIP_3$	$MIP_4$	$MIP_5$
Additional constraints	0	$O(n^2)$	$O(n^2)$	$O(nm)$	$O(n^2)$	$O(nm)$
Additional variables	0	$O(n^2)$	$O(n^2)$	$O(nm)$	$O(n^2)$	$O(nm)$
Total constraints	$O(m + k)$	$O(n^2)$	$O(n^2)$	$O(nm)$	$O(n^2)$	$O(nm)$
Total variables	$O(n)$	$O(n^2)$	$O(n^2)$	$O(nm)$	$O(n^2)$	$O(nm)$

Notice that the problem size is not the only reason of computational efficiencies. The tightness of linearization schemes, as pointed out by [47], may significantly change the effectiveness of the techniques for MQP.

In terms of solution methods, there are many studies in the literature dealing with the MQP. Most of them apply a technique called semidefinite programming to

solve the problem. Specifically, these approaches include special branch-and-bound [9,10,32,44], branch-and-cut [11], lift-and-project [11], and the state-of-the-art Interior Point method [14,33]. Some of them have been applied in the commercial software package, e. g., the solvers BARON and CPLEX in GAMS.

### Introduction

Many problems in optimization involve multiple length and time scales. Perhaps the most commonly stud-

ied problems in this area are configurational molecular modeling problems such as phase transitions in wax formation, the structure of Lennard-Jones (LJ) clusters, and protein folding. This class of optimization problems is generally characterized by the presence of many, many stationary points (i. e., minima, first-order saddles, second-order saddles, etc.) that give the appearance of roughness at the small length scale and quite different geometric structure at the large length scale. A good example of the disparity in different length scales is described in Onuchic et al. [28] who illustrate the small-scale geometry of the protein free energy landscape showing many stationary points (or roughness or frustration) at the small length scale and a funnel shaped geometry for the large length scale. This is the multi-scale description we adopt in this expose. It is often acknowledged that finding all stationary points on these multi-scale objective function surfaces is all but impossible [8] for many problems of practical interest and in most cases it is irrelevant. What is of primary interest from a computational chemistry perspective is finding the relatively few important stationary points that describe important physical phenomena – without finding everything else. These important stationary points include global minima, strong local minima and important transitions states that describe rate limiting behavior.

There are many deterministic and/or stochastic methods that can be used to solve multi-scale global optimization problems. See, for example, [1,2,3,4,5,6,7,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,29,30,31,32,33,34,35,36]. These methodologies run the gambit from branch and bound methods, to homotopy-continuation and interval methods, to simulated annealing and genetic algorithms, to terrain and funneling methods, to specialized techniques.

In this chapter, a deterministic terrain/funneling approach for multi-scale global optimization is described. This approach considers two distinct length scales and assumes that the geometry of the larger length scale is funnel shaped. Terrain methods are used to explore the objective function landscape at small length scales and gather point-wise and average gradient and curvature information while funneling methods are used to make large-scale, monotonically decreasing moves at the large length scale and ‘funnel’ iterates to the global minimizer.

## Formulation

The formulation of the problem under consideration is straightforward. It is to find the

$$\text{global min } f(z) : \text{ subject to } z \leq c(z) \quad (1)$$

where  $f = f(z)$  is a  $C^3$  objective function defined on  $\mathbb{R}^n$  subject to bounds on variables,  $c(z)$ , and where  $z$  are the optimization variables. It is assumed that  $f$  has two distinct length scales – a small length scale of considerable roughness and a large length scale where  $f$  has non-quadratic behavior. For the discussions that follow, it is convenient to denote the gradient of  $f$  by  $g = g(z)$  and the Hessian matrix of  $f$  by  $h = h(z)$ .

Generally, formulations based on second-order Taylor series expansion are adequate to describe behavior at the small length scale, and methods based on quadratic approximations of  $f$  are well known. However, since it is assumed that the behavior of the objective function,  $f$ , is non-quadratic at the large length scale, funneling methods are used to build approximations to the large-scale geometry of  $f$  using the funnel function given by

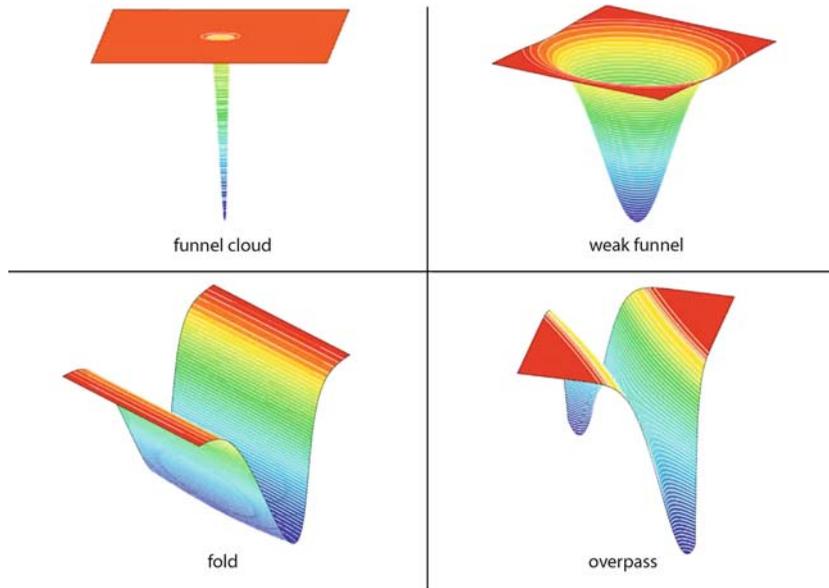

$$F(z) = F_0 - \Gamma \exp[-q(z)] \quad (2)$$

where  $q(z) = \frac{1}{2}z^T A z + b^T z + c$ , and where  $\Gamma > 0$ ,  $F_0$  and  $c$  are scalar parameters,  $b$  is an  $n$ -dimensional vector, and  $A$  is an  $n \times n$  symmetric matrix. The functional form of Eq. (2) is interesting because it is non-convex, has a unique global minimum when  $A$  is positive definite, and contains certain inherent self-scaling characteristics. Figure 1 gives an illustration of the funnel geometries that can be represented by the functionality of Eq. (2).

The funnels at the top and the bottom left in Fig. 1 each have unique minimum because  $A$  is positive definite while the one at the bottom right has two minima since  $A$  is indefinite.

## Methods

In this sub-section, the global terrain method, a funneling algorithm, and a multi-scale global optimization method are described.

Multi-Scale Global Optimization Using Terrain/Funneling Methods, Figure 1  
Various Funnel Geometries

### A Global Terrain Method for Optimization at the Small Length Scale

Terrain methods [18,19,20] have been described in detail in a separate chapter in this encyclopedia and are briefly summarized in this chapter for the purpose of continuity of presentation. Terrain methods are used to locate sets of stationary and singular points of the objective function. They do this by following valleys and moving up and down the landscapes of  $g^T g$  and  $f$ . Key among the equations used in terrain methods is the characterization of valleys as solutions,  $V$ , to a sequence of general nonlinearly constrained optimization problems

$$V = \{ \min h^T g^T h \text{ such that } g^T g = L, \text{ for all } L \in \Lambda \} \quad (3)$$

where  $g$  and  $h$  are defined as before, where  $L$  is any given value (or level) of the least-squares objective function, and where  $\Lambda$  is some collection of contours. Terrain methods require

- 1) Reliable downhill equation solving
- 2) Reliable and efficient computation of singular points
- 3) Efficient uphill movement comprised of predictor-corrector calculations
- 4) Reliable and efficient eigenvalue-eigenvector computations

- 5) Effective bookkeeping
- 6) A termination criterion to decide when the computations have finished.

In this chapter, a terrain methodology is used to find sets of stationary and singular points and to determine *average* gradient and *average* curvature (or Hessian matrix) information along a given terrain path. Average gradient and curvature information is calculated from the mean value theorem using the following equations.

$$\langle g \rangle = (1/\alpha) \int g[z(\alpha)] d\alpha \quad (4)$$

$$\langle h \rangle = (1/\alpha) \int h[z(\alpha)] d\alpha \quad (5)$$

where  $\alpha$  is some relevant length of the smooth terrain path connecting any set of stationary and singular points. It is important for the reader to understand that it is the set of stationary and singular points as well as average gradient and Hessian matrix information that are communicated from the small length scale to the large length scale. This will be discussed again a little later in this chapter.

### A Funneling Method for Optimization at the Large Length Scale

To build iterative global funnel approximations of the objective function we match function, gradient, and second derivative information of the true objective function,  $f$ ,  $g$  and  $h$ , with the function, gradient, and Hessian matrix information,  $F$ ,  $G$  and  $H$  respectively, of the funnel function at various points, where  $G = G(z)$  and  $H = H(z)$  are given by

$$G(z) = \Gamma \exp[-q(z)][Az + b] \quad (6)$$

$$H(z) = \Gamma \exp[-q(z)][A - (Az + b)(Az + b)^T] \quad (7)$$

Note that if  $f(z)$  is used in place of  $F(z)$  in Eq. (2), then it follows that

$$\gamma(z) = F_0 - f(z) = \Gamma \exp[-q(z)] \quad (8)$$

where  $\gamma > 0$  is a positive scaling factor that depends on a single numerical measurement,  $f(z)$ , and the scalar parameter,  $F_0$ . Moreover, replacing  $G(z)$  with  $g(z)$  and  $H(z)$  with  $h(z)$  in Eqs. (6) and (7) respectively give the equations

$$[Az + b] = g(z)/\gamma \quad (9)$$

$$A = [\gamma h + g g^T]/\gamma^2 \quad (10)$$

Equations (8), (9), and (10) show that it is possible to estimate  $A$  and  $b$  from values of  $f(z)$ ,  $g(z)$ , and  $h(z)$  using interpolation formula at two or more iterates.

**Interpolating Formulae** Let  $z_k$  be any value of the unknown optimization variables with corresponding objective function, gradient and Hessian matrix values  $f_k$ ,  $g_k$  and  $h_k$  respectively. Also let  $z_{k+1}$  be some other arbitrary but not necessarily nearby or successive iterate with corresponding function, gradient and Hessian matrix values  $f_{k+1}$ ,  $g_{k+1}$  and  $h_{k+1}$ . Writing Eq. (8) for  $z_k$  and  $z_{k+1}$  and then subtracting the latter from the former, eliminates  $F_0$  and gives

$$\gamma_{k+1} - \gamma_k = f_k - f_{k+1} \quad (11)$$

Repeating the same algebra using Eq. (10) yields

$$\gamma_k^2[\gamma_{k+1}h_{k+1} + g_{k+1}g_{k+1}^T] - \gamma_{k+1}^2[\gamma_k h_k + g_k g_k^T] = 0 \quad (12)$$

Equations (11) and (12) form a set of  $[1 + n(n + 1)/2]$  nonlinear equations in the two unknowns  $\gamma_k$  and  $\gamma_{k+1}$  when the symmetry of the associated matrices is taken into account. This together with Eq. (11) gives a total of  $[1 + n(n + 1)/2]$  nonlinear equations. For  $n = 1$ , there are two equations and two unknowns. When  $n > 1$  there are more equations than unknown variables. However, irrespective of this, two equations for which  $\gamma_k$  and  $\gamma_{k+1} > 0$  can be determined using the Routh criterion.

**Estimating Funnel Parameters** Calculated values of  $\gamma_k$  and  $\gamma_{k+1}$  can be used to determine the matrix  $A$  from Eq. (10) – using gradient and Hessian matrix information either at  $z_k$  or  $z_{k+1}$ . Following this, the parameter  $b$  can be computed by simply rearranging Eq. (9) to give

$$b = g(z)/\gamma - Az \quad (13)$$

while  $F_0$  can be calculated from  $F_0 = f(z) + \gamma$ . Like  $A$ , the values of  $b$  and  $F_0$  can be determined using function and gradient values at either  $z_k$  or  $z_{k+1}$ .

**Finding the Funnel Minimum** It is then straightforward to estimate the unique global minimizer of the *funnel approximation*, say  $y$ , by simply solving

$$Ay = -b \quad (14)$$

Note that Eq. (10) shows that the matrix  $A$  is generated from a rank-one, positive semi-definite correction to  $h(z)$ , that the sign definiteness of  $A$  can be controlled by the parameter  $\gamma$ , and that  $\gamma$  appears to also play the role of a self-scaling factor.

**Communication Between Length Scales** One of the keys to success in any multi-scale global optimization methodology is the communication between length scales. In the terrain/funneling approach to multi-scale global optimization, small-scale calculations communicate *average* gradient and Hessian matrix information at two distinct points to the large length scale. The large length scale optimizations, on the other hand, communicate an estimate of the values of the optimization variables at a converged minimum of the funnel approximation to the small length scale and identify the next region on the objective function surface on which small-scale optimizations should be conducted.

## A Multi-Scale Global Optimization Method

The details of a multi-scale global optimization methodology based on the terrain and funneling methods is as follows.

- 1 Perform two sets of small-scale optimization calculations using the terrain methodology starting from two different points on the objective function surface. Calculate *average* gradient, and *average* Hessian information along the resulting terrain paths. Thus at the  $k$ th funnel iteration the following information is available –  $z_k, f_k, g_k$  and  $h_k$  and  $z_{k+1}, f_{k+1}, g_{k+1}$  and  $h_{k+1}$  such that  $f_{k+1} < f_k$ .
- 2 Conduct iterative large-scale optimization calculations with the funneling methodology initialized using the objective function, average gradient and average Hessian information from the small-scale optimization calculations to find a funnel minimum that also corresponds to a stationary point on the true objective function surface. To do this,
  - a) Solve Eqs. (11) and (12) for  $\gamma_k$  and  $\gamma_{k+1}$ .
  - b) Using  $\gamma_{k+1}$ , calculate  $A$  and  $b$  from Eqs. (10) and (13) respectively.
  - c) Determine an estimate of funnel minimum,  $y$ , from Eq. (14).
  - d) Evaluate  $f(y)$ ,  $g(y)$  and  $h(y)$ .
  - e) Test  $f(y)$  against  $f_{k+1}$ . If  $f(y) < f_{k+1}$ , then go to step 2f for the next funnel iteration. Else set  $\gamma_k = \gamma_k/2$  and return to step 2a.
  - f) Set  $z_{k+1} = y$ ,  $f_{k+1} = f(y)$ ,  $g_{k+1} = g(y)$ , and  $h_{k+1} = h(y)$ .
  - g) If  $\|g(z_{k+1})\| < \varepsilon$ , set  $y = y^*$ , and go to step 3; else go to step 2a.
- 3 Conduct a new set of small-scale terrain calculations using the funnel minimum from step 2. Calculate *average* gradient and *average* Hessian information along the resulting terrain path such that new values of  $z_{k+1}, f_{k+1}, g_{k+1}$  and  $h_{k+1}$  satisfy the condition  $f_{k+1} < f_k$ .
- 4 Repeat step 2 using the new small-scale information and  $z_k, f_k, g_k$  and  $h_k$  from step 1.
- 5 Repeat steps 2 and 3 until there is no further decrease in the objective function.

Here we describe step 2 of the multi-scale algorithm. The most effective way to determine  $\gamma_{k+1}$  in step 2a is to rearrange Eq. (11) for  $\gamma_{k+1}$  in terms of  $\gamma_k$  and then substitute the resulting expression into Eq. (12) This

gives a cubic polynomial equation in  $\gamma_k$  and shows that there are *three* possible values of  $\gamma_k$  and thus three possible sets of scaling factors  $(\gamma_k, \gamma_{k+1})$ . Using an equation solver like Newton's method, it is easy to find one solution for  $\gamma_k$ . The other two values of  $\gamma_k$  can be determined by deflation of the cubic equation to a quadratic equation and by using the quadratic formula. The correct value of  $\gamma_k$  is the smallest *real* valued  $\gamma_k > 0$  such that  $\gamma_{k+1} > \gamma_k$ , where  $\gamma_{k+1} = f_k - f_{k+1} + \gamma_k$ . Step 2b is straightforward and step 2c requires the solution of a system of linear equations. Step 2d evaluates the *actual* function, gradient, and Hessian matrix at the funnel iterate  $y$ . Step 2e is used to ensure monotonic decreasing objective function values by halving  $\gamma_{k+1}$  until  $f(y) < f_{k+1}$  while step 2f replaces the information associated with  $z_{k+1}$  with that for the funnel iterate  $y$ . Finally, step 2g checks the norm of the gradient of the objective function and terminates the funnel iterations once that norm of the gradient falls below the specified tolerance. Note that any point,  $y^*$ , that satisfies the convergence condition in step 2g is simultaneously a stationary point of  $f(z)$  and a minimizer of the funnel function  $F(z)$ .

The proposed multi-scale optimization algorithm is very robust. The reason for this is because if the funneling algorithm gets trapped at a local minimum, the methodology returns to the small-scale terrain calculations to get average gradient and average Hessian information around that local minimum. Replacing point-wise zero-valued gradient information at a local minimum with averaged non-zero valued gradient information forces the optimizer to look for a minimizer that is deeper in funnel. By forcing movement further down the funnel in this way, the multi-scale algorithm will continue to improve the value of the objective function in a monotonic fashion until it reaches the global minimum at the bottom of the funnel.

## Application

In this sub-section, a simple illustration of the multi-scale global optimization methodology is given using the classical thirteen-particle Lennard-Jones (LJ<sub>13</sub>) problem. This example was selected because it is the first in the series of Lennard-Jones clusters that truly has a single funnel based on the Mackay icosahedron structure with the global minimum lying at the bot-

tom of the funnel [8]. The  $LJ_{13}$  cluster has 33 unknown Cartesian coordinates, 1509 minima, 116,835 first-order and second-order transition states, and many higher order transition states [9].

### Small Scale Terrain Optimization

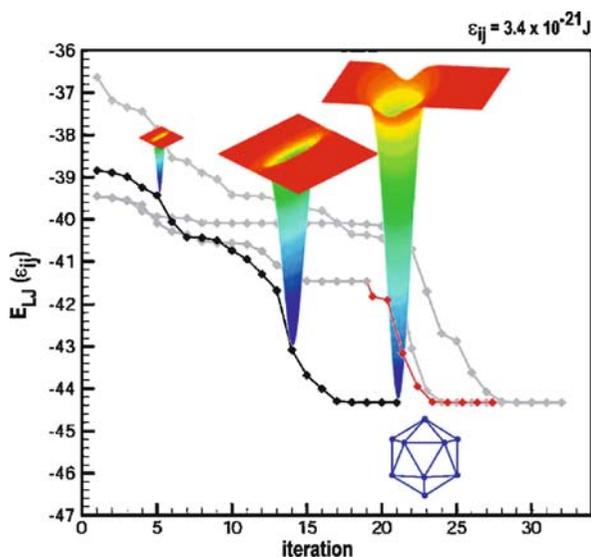

Small-scale optimization calculations were performed using the terrain methodology from two different starting points. From the first starting point, which corresponds to an energy of  $E = -38.8572$ , six (6) stationary and singular points along a terrain path were calculated requiring 4832 function and gradient evaluations and 616.68 s of computer time. Average gradient and Hessian information was accumulated along the terrain path defined the path integrals given by Eqs. (4) and (5). From a second and quite different starting point on the objective function surface another set of small-scale optimization calculations was performed using the terrain methodology. The energy at this second starting point was  $E = -38.4246$ , and five (5) stationary and singular points were calculated requiring 1415 function and gradient evaluations and 214.25 s of computer time. Again, average gradient and Hessian information was accumulated along the terrain path using the path integrals using Eqs. (4) and (5).

### Large Scale Funneling Optimization

To build an approximation of the large-scale geometry, two singular points – one from each of the two sets of terrain calculations – were selected. Using the function values at these singular points as well as average gradient and average Hessian information, funnel parameters were determined and a first estimate of the funnel minimum was calculated. We then replaced one of the singular points with this estimate of the funnel minimum and repeated the funnel optimization calculations until  $\|g\| < \varepsilon = 1 \times 10^{-4}$ . Figure 2 summarizes these results, which are shown by the curve of dark or black diamonds. The resulting structure for  $LJ_{13}$  is also shown in Fig. 2. Twenty (20) funneling iterations were required for convergence to the global minimum at  $E = -44.3268$  on the  $LJ_{13}$  energy surface.

### Robustness

Terrain/funnel calculations were performed using many other arbitrary starting points on the potential

Multi-Scale Global Optimization Using Terrain/Funneling Methods, Figure 2  
Multi-Scale Terrain/Funneling Calculations for the  $LJ_{13}$  Cluster

energy surface for the  $LJ_{13}$  cluster to illustrate the robustness of this multi-scale optimization method. Results for some of these calculations are also shown in Fig. 2 by the two light gray curves with diamonds. Note that these multi-scale optimization calculations using the terrain/funneling approach also converge easily and monotonically to the global minimum in 32 and 27 funnel iterations respectively from these starting points. In all cases, the funneling portion of the overall multi-scale algorithm finds the global minimum in less than 0.35 s.

### Reliability – Avoiding Traps at Local Minima

To show that the proposed optimization approach does not get trapped at local minima, terrain/funneling calculations were repeated from a different set of initial terrain calculations. In particular, small-scale terrain calculations starting from points on the energy surface corresponding to energy values of  $E_1 = -39.1597$  and  $E_2 = -38.4246$  were performed and average gradient and average Hessian information gathered along the resulting terrain paths. Using this information, the funneling algorithm converged to a *local* minimum on the potential energy surface at  $E_3 = -41.4445$  in 18 funnel iterations. The results of these calculations correspond to the gray curve that terminates at  $E = -41.4445$  in

Fig. 2. This local minimum was then used as a starting point to perform a third set of small-scale terrain calculations and to gather average gradient and average Hessian information in the valley around the local minimum. Using this average information around the local minimum,  $E_3$ , together with average information around  $E_1$ , a second set of iterative funneling calculations was performed. In this case, the funneling calculations located the global minimum at  $E = -44.3268$  on the energy surface in 16 funnel iterations. This second set of funnel iterations is shown by the red curve in Fig. 2.

Those readers interested in the numerical details of the  $LJ_{13}$  illustration are encouraged to contact the author, who is quite willing to provide all computer-generated numerical results for this example.

Stochastic programming; Approximation

Many problems in finance, economics and other applications require that decisions  $x_t \in \mathbf{R}_t^n$  are made periodically over time, depending on observations of uncertain data  $(\eta_t, \xi_t)$  in future periods  $t = 1, \dots, T$ . Here, it is distinguished between random data  $\eta_t \in \Theta_t \subset \mathbf{R}_t^K$  that influence prices in the objective function and random data  $\xi_t \in \Xi_t \subset \mathbf{R}_t^L$  that affect the demand on the right-hand side of constraints in an optimization problem.

Once an observation  $(\eta_t, \xi_t)$  becomes available, the decision maker has to determine a policy  $x_t$  that minimizes the costs  $\rho_t(x^{t-1}, x_t, \eta^t)$  in  $t$  plus the expected costs in the subsequent periods  $t + 1, \dots, T$ , subject to

a set of constraints  $f_t(x^{t-1}, x_t) \leq h(\xi^t)$ . Both the objective function and the constraints may depend on the sequences of observations  $\eta^t = (\eta_1, \dots, \eta_t)$ ,  $\xi^t = (\xi_1, \dots, \xi_t)$  up to  $t$  and earlier decisions  $x^{t-1} = (x_0, \dots, x_{t-1})$ . Obviously, an action  $x_t$  must be selected after  $(\eta_t, \xi_t)$  is observed but before the future outcomes  $\eta_{t+1}, \dots, \eta_T$  and  $\xi_{t+1}, \dots, \xi_T$  are known, i. e. the decision is based only on information available at time  $t$ . Hence, one obtains a sequence of decisions with the property  $x_0, x_1(\eta^1, \xi^1), \dots, x_T(\eta^T, \xi^T)$ , called *nonanticipativity*. This results in a *multistage stochastic program*, which may be written in its dynamic representation as a series of nested two-stage programs (with  $\phi_{T+1}(\cdot) := 0$ , see [4]):

$$\begin{aligned} \phi_t(x^{t-1}, \eta^t, \xi^t) := \min & \left\{ \rho_t(x^{t-1}, x_t, \eta^t) \right. \\ & \left. + \int \phi_{t+1}(x^{t-1}, x_t, \eta^t, \eta_{t+1}, \xi^t, \xi_{t+1}) dP_{t+1} \right\}, \\ & t = 0, \dots, T, \quad (1) \end{aligned}$$

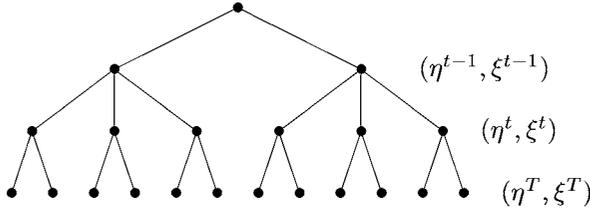

where the expectation is taken w.r.t. the probability measure  $P_{t+1}(\eta_{t+1}, \xi_{t+1} | \eta^t, \xi^t)$  of the joint distribution of  $(\eta_{t+1}, \xi_{t+1})$ , subject to

$$f_t(x^{t-1}, x_t) \leq h(\xi^t), \quad x_t \geq 0. \quad (2)$$

In case of discrete distributions, it is well known that one can immediately transform the stochastic multistage program given by (1) and (2) into a (large) deterministic equivalent problem which can be solved by standard optimization tools, possibly combined with *decomposition techniques* to exploit the special structure of the problem (see e. g. [1,9,10]). However, if the distribution is continuous with some density function, it is in general impossible to do the integration in (1) exactly. One way to overcome this difficulty is to approximate the (continuous) probability measure  $P_t$  by a discrete one  $Q_t$ . In MSP, this is usually done by constructing a *scenario tree* which can be illustrated as follows:

Together with the associated scenario probabilities, this tree is defined formally as

$$\begin{aligned} \mathcal{A} := & \left\{ (\eta^T, \xi^T) : \begin{array}{l} (\eta_t, \xi_t) \in \mathcal{A}_t(\eta^{t-1}, \xi^{t-1}) \\ \forall t > 0 \end{array} \right\}, \\ q(\eta^T, \xi^T) := & \prod_{t=1}^T q_t(\eta_t, \xi_t | \eta^{t-1}, \xi^{t-1}). \end{aligned} \quad (3)$$

**Multistage Stochastic Programming: Barycentric Approximation, Figure 1**

The scenario tree represents an approximation of the discrete-time process  $(\eta_t, \xi_t; t = 1, \dots, T)$ , and  $\mathcal{A}_t(\cdot)$  denotes the set of finitely many outcomes for  $(\eta_t, \xi_t)$  conditioned on the history  $(\eta^{t-1}, \xi^{t-1})$ . Again, this results in a sparse large scale program. Naturally, the question arises how good the accuracy of the associated (deterministic) optimization problem is, and if the set of scenarios can be improved w.r.t. the accuracy.

For convex optimization problems where the random data are decomposable in two groups, one that determines the cost function and the second one affecting the demand, it can be shown (see [4] for details) that the *value function* (1) is a saddle function for all  $t = 1, \dots, T$  under the following conditions:

- i)  $\rho_t(\cdot)$  is concave in  $\eta_t$ ,
- ii) the left-hand sides of the constraints are deterministic, and
- iii) the distribution function of  $P_t(\cdot | \eta^{t-1}, \xi^{t-1})$  depends linearly on the past.

Then, (1) is concave in  $\eta_t$  and convex in  $(x_t, \xi_t)$ . The situation where assumptions i)–iii) are fulfilled is called the entire convex case.

This underlying saddle property of the value function motivates the application of *barycentric approximation* which derives two scenario trees  $\mathcal{A}^u$  and  $\mathcal{A}^l$ . The associated approximate deterministic programs provide upper and lower bounds to the original problem. In this sense, barycentric approximation is a generalization of the inequalities due to H.P. Edmundson [2] and A. Madansky [8] (see e.g. **► Stochastic Programs with Recourse: Upper Bounds**) and J.L. Jensen [6] that is applicable to saddle functions of correlated random data. Here, it is assumed that  $\Theta_t \subset R_t^K$  and  $\mathcal{E}_t \subset R_t^L$  are regular simplices whose vertices are denoted by  $u_{v_t}, v_t = 0, \dots, K_t$ , and  $v_{\mu_t}, \mu_t = 0, \dots, L_t$ . Both  $\Theta_t$  and  $\mathcal{E}_t$  may depend on prior observations  $(\eta^{t-1}, \xi^{t-1})$  although this is not stressed in the notation for simplicity.

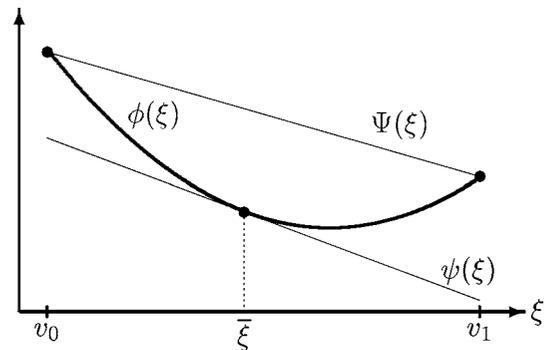

To illustrate the way the discretization is performed, assume that a two-stage problem is given (the time index is omitted here) with deterministic objective, i.e. only the right-hand side coefficients  $h(\xi)$  are random (see e.g. [7]). For any  $\xi \in \mathcal{E}$ , the *barycentric weights*  $\tau_0(\xi), \dots, \tau_L(\xi)$  w.r.t. the simplex  $\mathcal{E}$  are given by

$$\begin{aligned} \tau_0 + \dots + \tau_L &= 1, \\ \tau_0 v_0 + \dots + \tau_L v_L &= \xi. \end{aligned} \quad (4)$$

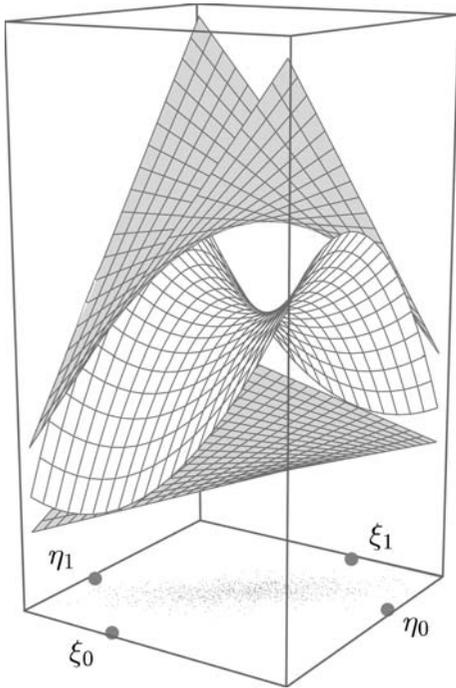

Since  $\phi(x, \xi)$  is convex in  $\xi$  for all  $x$ ,  $\varphi(\xi) := \phi(\hat{x}, \xi)$  is a convex function for any fixed first-stage decision  $\hat{x}$ . Due to convexity,  $\varphi(\xi)$  is bounded from above for all  $\xi \in \mathcal{E}$  by a linear function  $\Psi(\xi) = \sum_{\mu=0}^L \tau_\mu(\xi) v_\mu$ . To construct the ‘classical’ *Edmundson–Madansky upper bound* (EM) for  $\int \varphi(\xi) dP$  over the simplex  $\mathcal{E}$ ,  $\xi$  is replaced by a discrete random variable with the same expectation, attaining values  $v_0, \dots, v_L$ . To obtain the corresponding probabilities,  $\xi$  has to be replaced by  $\overline{\xi} = \int \xi dP$  in (4), and the system must be solved for  $\tau_0, \dots, \tau_L$ . Then,  $\int \varphi(\xi) dP \leq \sum_{\mu=0}^L \tau_\mu(\overline{\xi}) v_\mu$ , and the weights may be interpreted as the probabilities of the discrete outcomes.

On the other hand, a lower bound can be found using *Jensen’s inequality*:  $\varphi(\overline{\xi}) \leq \int \varphi(\xi) dP$ , i.e. by evaluation of the function for the expectation of  $\xi$ , and the tangent  $\psi(\xi)$  to  $\varphi(\xi)$  at  $\overline{\xi}$  is a lower bound to the original function. Both linear approximations  $\psi(\xi)$  and  $\Psi(\xi)$  to the convex value function for a given policy are shown in Fig. 2.

From a computational viewpoint, the original function  $\varphi(\xi)$  is replaced by two linear affine functions. Clearly,  $\psi(\xi)$  and  $\Psi(\xi)$  can be integrated easily over the support of  $\xi$ . If there is only randomness in the objec-

**Multistage Stochastic Programming: Barycentric Approximation, Figure 2**

**Multistage Stochastic Programming: Barycentric Approximation, Figure 3**

tive with deterministic right-hand sides, a lower and an upper bound can be constructed by applying the same procedure to the dual concave (maximization) problem, deriving an upper bound from Jensen’s inequality and a lower approximation with the EM-rule.

Barycentric approximation combines these concepts for stochastic objective and right-hand sides [3] and extends them to the multistage case [4,5]. It derives distinguished points, so-called *generalized barycenters*, where the value function (1) must be supported by two bilinear functions to minimize the error induced by the approximation. This is shown in Fig. 3 for  $K_t = L_t = 1$ , where the minorant is supported at  $\xi_0$  and  $\xi_1$  and the majorant at  $\eta_0$  and  $\eta_1$ .

Let  $\lambda_{t,0}(\eta_t), \dots, \lambda_{t,K_t}(\eta_t), \tau_t, 0(\xi_t), \dots, \tau_t, L_t(\xi_t)$  be the barycentric weights w.r.t.  $\Theta_t$  and  $\Xi_t$  defined analogously to (4). For both simplices, the generalized barycenters and their probabilities are given by

$$\eta_{\mu_t} = [q(\eta_{\mu_t})]^{-1} \cdot \sum_{\nu_t=0}^{K_t} u_{\nu_t} \int \lambda_{\nu_t}(\eta_t) \tau_{\mu_t}(\xi_t) dP_t,$$

$$q(\eta_{\mu_t}) = \int \tau_{\mu_t}(\xi_t) dP_t, \quad \mu_t = 0, \dots, L_t,$$

$$\xi_{\nu_t} = [q(\xi_{\nu_t})]^{-1} \cdot \sum_{\mu_t=0}^{L_t} \nu_{\mu_t} \int \lambda_{\nu_t}(\eta_t) \tau_{\mu_t}(\xi_t) dP_t,$$

$$q(\xi_{\nu_t}) = \int \lambda_{\nu_t}(\eta_t) dP_t, \quad \nu_t = 0, \dots, K_t.$$

Note that the integrand  $\lambda_{\mu_t}(\eta_t) \cdot \tau_{\nu_t}(\xi_t)$  is a bilinear function in  $(\eta_t, \xi_t)$  since the barycentric weights  $\lambda_{\mu_t}$  and  $\tau_{\nu_t}$  are linear in their components. Obviously, a bilinear function is easy to integrate which was the intention of the approximation.

The generalized barycenters  $\xi_{\nu_t}, \nu_t = 0, \dots, K_t$ , are supporting points of the minorant. They are combined with the vertices  $u_{\nu_t}$  and weighted with the corresponding probabilities  $q(\xi_{\nu_t})$  to obtain discrete outcomes for the lower approximation of the original measure  $P_t$ . This way, one derives a discrete probability measure  $Q_t^l$  with support

$$\text{supp } Q_t^l = \{(u_{\nu_t}, \xi_{\nu_t}) : \nu_t = 0, \dots, K_t\}.$$

Analogously,  $\eta_{\mu_t}, \mu_t = 0, \dots, L_t$ , are supporting points for the majorant with assigned probabilities  $q(\eta_{\mu_t})$ . This induces a discrete measure  $Q_t^u$  for the upper approximation with

$$\text{supp } Q_t^u = \{(\eta_{\mu_t}, \nu_{\mu_t}) : \mu_t = 0, \dots, L_t\}.$$

Both measures represent the solutions of two corresponding moment problems. The advantageous feature from a computational viewpoint is that the generalized barycenters and their probabilities are completely determined by the first moments of  $\eta_t$  and  $\xi_t$ , and by the bilinear cross moments  $E(\eta_{\nu_t} \cdot \xi_{\mu_t}), \nu_t = 0, \dots, K_t, \mu_t = 0, \dots, L_t$ . Note that the covariance of two random variables is derived from the first moments and the corresponding cross moments. Therefore, the measures  $Q_t^u$  and  $Q_t^l$  incorporate implicitly a correlation between  $\eta_t$  and  $\xi_t$ . However, cross moments (or covariances, respectively) between different elements of  $\eta_t$  are not taken into account (the same holds for the components of  $\xi_t$ ). Hence, the formulae given above are applicable without the assumption of independent random variables.

Applying the approximation scheme dynamically over time, one obtains two *barycentric scenario trees*  $\mathcal{A}^l$  and  $\mathcal{A}^u$  with their path probabilities of type (3). The set of outcomes at stage  $t = 1, \dots, T$  is given by  $\mathcal{A}^l(\eta^{t-1}, \xi^{t-1}) = \text{supp } Q_t^l(\cdot | \eta^{t-1}, \xi^{t-1})$  and  $\mathcal{A}^u(\eta^{t-1}, \xi^{t-1}) = \text{supp } Q_t^u(\cdot | \eta^{t-1}, \xi^{t-1})$ . Substituting  $P_t$  in (1) by the discrete measures  $Q_t^l$  and  $Q_t^u$  yields two value functions

$$\begin{aligned} \psi_t(x^{t-1}, \eta^t, \xi^t) &:= \min \left\{ \rho_t(x^{t-1}, x_t, \eta^t) \right. \\ &\quad \left. + \int \psi_{t+1}(x^{t-1}, x_t, \eta^t, \eta_{t+1}, \xi^t, \xi_{t+1}) dQ_{t+1}^l \right\}, \\ \Psi_t(x^{t-1}, \eta^t, \xi^t) &:= \min \left\{ \rho_t(x^{t-1}, x_t, \eta^t) \right. \\ &\quad \left. + \int \Psi_{t+1}(x^{t-1}, x_t, \eta^t, \eta_{t+1}, \xi^t, \xi_{t+1}) dQ_{t+1}^u \right\} \end{aligned}$$

for  $t = 0, \dots, T$  with  $\psi^{T+1}(\cdot) = \Psi^{T+1}(\cdot) := 0$ . According to [4], these are lower and upper bounds to the original value function, i. e.

$$\psi_t(x^{t-1}, \eta^t, \xi^t) \leq \phi_t(x^{t-1}, \eta^t, \xi^t) \leq \Psi_t(x^{t-1}, \eta^t, \xi^t).$$

In the entire convex case, the accuracy of the approximation is quantifiable by the difference between the upper and lower bound. If required, the approximation can be improved by partitioning the simplices  $\Theta_t$  and  $\mathcal{E}_t$ . In case that the subsimplices become arbitrarily small, the extremal measures converge to  $P_t$ , and the convergence of the upper and lower bounds to the expectation of the value function is guaranteed (see [5] for details).

### Introduction

The *nested partitions* (NP) method is a powerful optimization method that has been found to be very effective for solving large-scale discrete optimization problems. Such problems are common in many practical applications and the NP method is hence useful in diverse application areas. It can be applied to both operational and planning problems and has been demonstrated to effectively solve complex problems in both manufacturing and service industries.

The NP method was first introduced in [4] and application examples include diverse areas such as optimization of beam orientation in radiation therapy [1], feature selection in data mining [3], and product design [5].

### Formulation

The NP method is particularly well suited for complex large-scale discrete optimization problems where traditional methods experience difficulty. It is, however, very broadly applicable and can be used to solve any optimization problem that can be stated mathematically in the following generic form:

$$\min_{x \in X} f(x), \quad (1)$$

where the solution space or feasible region  $X$  is either a discrete or a bounded set of feasible solutions.

An important special type of problem that can be effectively addressed using the NP method is *mixed integer programs* (MIP) [6]. For such problems there may be one set of discrete variables and one set of continuous variables and the objective function and constraints are both linear. A general MIP can be stated as follows:

$$z_{\text{MIP}} = \min_{x, y \in X} c^1 x + c^2 y, \quad (2)$$

where  $X = \{x \in Z_+^n, y \in R^n : A^1 x + A^2 y \leq b\}$  and we use  $z_{\text{MIP}}$  to denote any linear objective function, that is,  $z_{\text{MIP}} = f(x) = cx$ . While some large-scale MIPs can be solved efficiently using exact mathematical programming methods, complex applications often give rise to MIPs where exact solutions can only be found for relatively small problems. When dealing with such complex large-scale problems the NP method provides an attractive alternative. However, even in such cases it may be possible to take advantage of exact mathematical programming methods by incorporating them into the NP framework. The NP method therefore provides a framework for combining the complementary bene-

fits of two optimization approaches that have traditionally been studied separately, namely, mathematical programming and metaheuristics.

Another important class of problems are *combinatorial optimization problems* (COP) where the feasible region is finite but its size typically grows exponentially with the number of input parameters of the problem. A general COP can be stated as follows:

$$\min_{x \in X} f(x), \quad (3)$$

where  $|X| < \infty$ , but the objective function  $f: X \rightarrow \mathbf{R}$  may be a complex nonlinear function. Sometimes it may have no analytic expression and must be evaluated through a model, such as a simulation model, a data mining model, or other application-dependent models. One advantage of the NP method is that it is effective for optimization when  $f$  is known analytically (deterministic optimization), when it is noisy (stochastic optimization), or even when it must be evaluated using an external process.

## Methods

The NP method is best viewed as a metaheuristic framework, and it has similarities to branching methods in that like branch-and-bound it creates partitions of the feasible region. However, it also has some unique features that make it well suited for very hard large-scale optimization problems.

Metaheuristics have emerged as the most widely used approach for solving difficult large-scale combinatorial optimization problems [2]. A metaheuristic provides a framework to guide application-specific heuristics, such as a greedy local search, by restricting which solution or set of solutions should or can be visited next. For example, the tabu search metaheuristic disallows certain moves that might otherwise be appealing by making the reverse of recent moves tabu or forbidden. At the same time it always forces the search to take the best nontabu move, which enables the search to escape local optima. Similar to tabu search, most metaheuristics guide the search from solution to solution or possibly from a set of solutions to another set of solutions. In contrast, the NP method guides the search by determining where to concentrate the search effort. Any optimization method, such as an application-specific lo-

cal search, other general purpose heuristic, or a mathematical programming method, can then be integrated within this framework.

The development of metaheuristics and other heuristic search methods has been made largely in isolation from the recent advancements in the use of mathematical programming methods for solving large-scale discrete problems. It is a very important and novel characteristic of the NP method that it provides a natural metaheuristic framework for combining the use of heuristics and mathematical programming and taking advantage of their complementary nature. Indeed, as far as we know, the NP method is the first systematic search method that enables users to simultaneously realize the full benefits of incorporating lower bounds through various mathematical programming methods and using any domain knowledge or heuristic search method for generating good feasible solutions. It is this flexibility that makes the NP method so effective for practical problems.

To concentrate the search effort, the NP method employs a decomposition approach similar to that of branch-and-bound. Specifically, in each step the method partitions the space  $X$  of feasible solutions into the *most promising region* and the *complementary region*, namely, the set of solutions not contained in the most promising region. The most promising region is then partitioned further into subregions. The partitioning can be done exactly as branching for a branch-and-bound algorithm, but instead of focusing on obtaining lower bounds and comparing those bounds with a single primal feasible solution, the NP methods focuses on generating primal feasible solution from each of the subregions and the complementary region. This results in an upper bound on the performance of each of these regions. The region with the best feasible solution is judged the most promising and the search is focused accordingly. A best upper bound does not guarantee that the corresponding subset contains the optimal solution, but since the NP method also finds primal feasible solutions for the complementary region it is able to recover from incorrect moves. Specifically, if the best solution is found in one of the subregions this becomes the new most promising region, where if it is in the complementary region the NP method backtracks. This focus on generating primal feasible solutions and the global perspective it achieves

through backtracking are distinguishing features of the NP method that set it apart from similar branching methods.

Unlike exact optimization methods such as branch-and-bound the NP method does not guarantee that the correct region is selected in each move of the algorithm. Incorrect moves can be corrected through backtracking, but for the method to be both effective and efficient, the correct move must be made frequently. How this is accomplished depends on how the feasible solutions are generated.

In what we refer to as the *pure NP method* feasible solutions are generated using simple uniform random sampling. To increase the probability of making the correct move the number of samples should be increased. A purely uniform random sampling is rarely efficient, however, and the strength of the NP method is that it can incorporate application-specific methods for generating feasible solutions. In particular, for practical applications domain knowledge can often be utilized to very effectively generate good feasible solutions. We call such implementations *knowledge-based NP methods*. We will also see examples of what we refer to as *hybrid NP methods* where feasible solutions are generated using either general heuristic methods such as greedy local search, genetic algorithm, or tabu search, or mathematical programming methods. If done effectively, incorporating such methods into the NP framework makes it more likely that the correct move is made and hence makes the NP method more efficient. Indeed, such hybrid and knowledge-based implementations are often an order of magnitude more efficient than uniform random sampling.

In addition to the method for generating feasible solutions, the probability of making the correct move depends heavily on the partitioning approach. A generic method for partitioning is usually straightforward to implement but by taking advantage of special structure and incorporating this into intelligent partitioning the efficiency of the NP method may be improved by an order of magnitude. The strength of the NP method is indeed in this flexibility. Special structure, local search, any heuristic search, and mathematical programming can all be incorporated into the NP framework to develop optimization algorithms that are more effective in solving large-scale optimization problems than when these methods are used alone.

## Cases

Here we introduce three application examples that illustrate the type of optimization problems for which the NP method is particularly effective. For each application the optimization problem has a complicating aspect that makes it difficult for traditional optimization methods. For the first of these problems, resource-constrained project scheduling, the primary difficulty is in a set of complicating constraints. For the second problem, the feature selection problem, the difficulty lies in a complex objective function. The third problem, radiation treatment planning, has both difficult-to-satisfy constraints and a complex objective function that cannot be evaluated through an analytical expression. Each of the three problems can be solved effectively by the NP method by incorporating our understanding of the application into the framework.

### Resource-Constrained Project Scheduling

Planning and scheduling problems arise as critical challenges in many manufacturing and service applications. One such problem is the resource-constrained project scheduling problem that can be described as follows. A project consists of a set of tasks to be performed and given precedence requirements between some of the tasks. The project scheduling problem involves finding the starting time of each task so that the overall completion time of the project is minimized. It is well known that this problem can be solved efficiently using what is called the critical path method that uses forward recursion to find the earliest possible completion time for each task. The completion time of the last task defines the makespan or the completion time of the entire project.

Now assume that one or more resources are required to complete each task. The resources are limited so if a set of tasks requires more than the available resources they cannot be performed concurrently. The problem now becomes NP-hard and cannot be solved efficiently to optimality using any traditional methods. To state the problem we need the following notation:  $V$  is the set of all tasks,  $E$  is the set of precedence constraints,  $p_i$  is the processing time of task  $i \in V$ ,  $R$  is the set of resources,  $R_k$  are the available resources of type  $k \in R$ , and  $r_{ik}$  are resources of type  $k$  required by task  $i$ .

The decision variables are the starting times for each task:  $x_i$  is the starting time of task  $i \in V$ .

Finally, for notational convenience we define the set of tasks processed at time  $t$  as

$$V(t) = \{i: x_i \leq t \leq x_i + p_i\} . \quad (4)$$

With this notation, we now formulate the resource-constrained project scheduling problem mathematically as follows:

$$\min \max_{i \in V} x_i + p_i , \quad (5)$$

$$x_i + p_i \leq x_j, \quad \forall (i, j) \in E , \quad (6)$$

$$\sum_{i \in V(t)} r_{ik} \leq R_k, \quad \forall k \in R, t \in \mathbf{Z}_+^1, x_i \in \mathbf{Z}_+^1 . \quad (7)$$

Here the precedence constraints (6) are easy, whereas the resource constraints (7) are hard. By this we mean that if the constraints (7) are dropped then the problem becomes easy to solve. Such problems, where complicating constraints transform the problem from easy to very hard, are common in large-scale optimization. Indeed the classic job shop scheduling problem can be viewed as a special case of the resource-constrained project scheduling problem where the machines are the resources. Without the machine availability constraints the job shop scheduling problem reduces to a simple project scheduling problem. Other well-known combinatorial optimization problems have similar properties. For example, without the subset elimination constraints the classic traveling salesman problem reduces to a simple assignment problem that can be solved efficiently.

The flexibility of the NP method allows us to address such problems effectively by taking advantage of special structure when generating feasible solutions. It is important to note that it is very easy to use sampling to generate feasible solutions that satisfy very complicated constraints. Therefore, when faced with a problem with complicating constraints we want to use random sampling to generate partial feasible solutions that resolve the difficult part of the problem and then complete the solution using the appropriate efficient optimization method.

For example, when a feasible solution for the resource-constrained-project scheduling problem is generated, the resource allocation should be generated

using random sampling and the solution can then be completed by applying the critical path method to determine the starting times for each task. This requires reformulating the problem so that the resource and precedence constraints can be separated, but such a reformulation is rather easily achieved by noting that the resource constraints can be resolved by determining a sequence between the tasks that require the same resource(s) at the same time. Once this sequence has been determined it can be added as precedence constraints and the remaining solution can be generated using the critical path method. Feasible solutions can therefore be generated in the NP method by first randomly sampling a sequence to resolve resource conflicts and then applying the critical path method. Both procedures are very fast, so complete sample solutions can be generated rapidly.

We also note that constraints that are difficult for optimization methods such as mathematical programming are sometimes very easily addressed in practice by incorporating domain knowledge. For example, a domain expert may easily be able to specify priorities among tasks requiring the same resource(s) in the resource-constrained project scheduling problem. The domain expert can therefore, perhaps with some assistance from an interactive decision support system, specify some priority rules to convert a very complex problem into an easy-to-solve problem. The NP method can effectively incorporate such domain knowledge into the optimization framework by using the priority rules when generating feasible solutions. This is particularly effective because the domain expert would not need to specify priority rules to resolve all resource conflicts. Rather, any available priority rule or other domain knowledge can be incorporated to guide the sampling.

The same structure can be used to partition intelligently. Instead of partitioning directly using the decision variables ( $x_i$ ), we note that it is sufficient to partition to resolve the resource conflicts. Once those are resolved then the problem is solved. This approach is applicable to any problem that can be decomposed in a similar manner.

### Feature Selection

Knowledge discovery and data mining is a relatively new field that has experienced rapid growth owing to

its ability to extract meaningful knowledge from very large databases. One of the problems that must usually be solved as part of practical data mining projects is the feature selection problem, which involves selecting a good subset of variables to be used by subsequent inductive data mining algorithms. The problem of selecting a best subset of variables is well known in the statistical literature as well as in machine learning. The recent explosion of interest in data mining for addressing various business problems has led to a renewed interest in this problem. From an optimization point of view, feature selection can clearly be formulated as a COP where binary decision variables determine if a feature (variable) is included or excluded. The solution space can therefore be stated very simply as all permutations of a binary vector of length  $n$ , where  $n$  is the number of variables. The size of this feasible region is  $2^n$ , so it experiences exponential growth, but typically there are no additional constraints to complicate its structure.

On the other hand, there is no consensus objective function that measures the quality of a feature or a set of features. Tens of alternatives have been proposed in the literature, including both functions that measure the quality of individual features and functions that measure the quality of a set of features. However, no single measure is satisfactory in all cases and the ultimate measure is therefore: Does it work? In other words, when the features selected are used for learning does it result in a good model being induced? The most effective feature selection approach in terms of solution quality is therefore the wrapper approach, where the quality of a set of features is evaluated by applying a learning algorithm to the set and evaluating its performance. Specifically, an inductive learning algorithm, such as decision tree induction, support vector machines or neural networks, are applied to training data containing only the features selected. The performance of the induced model is evaluated and this performance is used to measure the quality of the feature subset. This objective function is not only nonlinear, but since a new model must be induced for every feature subset it is also very expensive to evaluate.

Mathematically, the feature selection can be stated as the following COP:

$$\min_{x \in \{0,1\}^n} f(x), \tag{8}$$

that is,  $X = \{0, 1\}^n$ . Feature selection is therefore a very hard COP not because of the complexity of the feasible region, although it does grow exponentially, but owing to the complexity of an objective function that is very expensive to evaluate. However, this is also an example where application-specific heuristics can be effectively exploited by the NP method.

Significant research has been devoted to methods for measuring the quality of features. This includes information-theoretic methods such as using Shannon's entropy to measure the amount of information contained in each feature: the more information, the more valuable the feature. The entropy is measured for each feature individually and it can hence be used as a very fast local search or a greedy heuristic, where the features with the highest information gain are added one at a time. While such a purely entropy based feature selection will rarely lead to satisfactory results, the NP method can exploit this by using the entropy measure to define an intelligent partitioning.

We let  $X(k) \subseteq X$  denote the most promising region in the  $k$ th iteration and partition the set into two disjoint subsets (note that  $X(0) = X$ ):

$$X_1(k) = \{x \in X(k) : x_i = 1\}, \tag{9}$$

$$X_2(k) = \{x \in X(k) : x_i = 0\}. \tag{10}$$

Hence, a partition is defined by a sequence of features  $x_1, x_2, \dots, x_n$ , which determines the order in which the features are either included ( $x_i = 1$ ) or excluded ( $x_i = 0$ ).

We calculate the information gain  $\text{Gain}(i)$  of feature  $i$ , which is the expected reduction in entropy that would occur if we knew the value of feature  $i$ , that is,

$$\text{Gain}(i) = I - E(i), \tag{11}$$

where  $I$  is the expected information that is needed to classify a given instance and  $E(i)$  is the entropy of each feature. The maximum information gain, or equivalently the minimum entropy, determines a ranking of the features. Thus, we select

$$i_1 = \arg \min_{i \in \{1,2,\dots,n\}} E(i),$$

$$\begin{aligned}
 i_2 &= \arg \min_{i \in \{1, 2, \dots, n\} \setminus \{i_1\}} E(i), \\
 &\vdots \\
 i_n &= \arg \min_{i \in \{1, 2, \dots, n\} \setminus \{i_1, \dots, i_{n-1}\}} E(i).
 \end{aligned}$$

The feature order  $i_1, i_2, \dots, i_n$  defines an intelligent partition for the NP method and this has been found to be an order of magnitude more efficient than an average arbitrary partitioning [3]. We can use a similar idea to generate feasible solutions from each region using a sampling strategy that is biased towards including features with high information gain. A very fast greedy heuristic can thus greatly increase the efficiency of the NP method while resulting in much higher quality solutions that the greedy heuristic is able to achieve on its own.

### Radiation Treatment Planning

Health care delivery is an area of immense importance where optimization techniques have been used increasingly in recent years. Radiation treatment planning is an important example of this and intensity-modulated radiation therapy (IMRT) is a recently developed complex technology for such treatment. It employs a multileaf collimator to shape the beam and to control, or modulate, the amount of radiation that is delivered from each of the delivery directions (relative to the patient). The planning of the IMRT is very important because it needs to achieve the treatment goal while incurring the minimum possible damage to other organs. Because of its complexity the treatment planning problem is generally divided into several subproblems. The first of these is termed the *beam angle selection* (BAS) problem. In essence, BAS requires the determination of roughly four to nine angles from 360 possible angles subject to various spacing and opposition constraints.

Designing an optimal IMRT plan requires the selection of beam orientations from which radiation is delivered to the patient. These orientations, called beam angles, are currently manually selected by a clinician on the basis of his/her judgment. The planning process proceeds as follows. A dosimetrist selects a collection of angles and waits 10–30 min while a dose pattern is calculated. The resulting treatment is likely to be unacceptable, so the angles and dose constraints are adjusted, and the process is repeated. Finding a suitable

collection of angles often takes several hours. The goal of using optimization methods to identify quality angles is to provide a better decision support system to replace the tedious repetitive process just described. An integer programming model of the problem contains a large number of binary variables and the objective value of a feasible point is evaluated by solving a large, continuous optimization problem. For example, in selecting five to ten angles, there are between  $4.9^{10}$  and  $8.9 \times 10^{19}$  subsets of  $0, 1, 2, \dots, 359$ .

The BAS problem is complicated by both an objective function with no analytical expression and constraints that are hard to satisfy. In the end an IMRT plan is either acceptable or not and the considerations for determining acceptability are too complex for a simple analytical model. Thus, the acceptability and hence the objective function value for each plan must be evaluated by a qualified physician. This makes evaluating the objective not only expensive in terms of time and effort, but also introduces noise into the objective function because two physicians may not agree on the acceptability of a particular plan. The constraints of the BAS problem are also complicated since each beam angle will result in radiation of organs that are not the target of the treatment. There are therefore two types of constraints: the target should receive the minimum amount of radiation and other organs should receive no more than some maximum amount of radiation. Since these bounds need to be specified tightly the constraints are hard to satisfy.

The BAS problem illustrates how mathematical programming can be effectively incorporated into the NP framework. Since the evaluation of even a single IMRT plan must be done by an expert and is hence both time-consuming and expensive, it is imperative to impose a good structure on the search space that reduces the number of feasible solutions that need to be generated. This can be accomplished through an intelligent partitioning, and specifically by computing the optimal solution of an integer program with a much simplified objective function [1]. The output of the integer program then serves to define an intelligent partitioning. For example, suppose a good angle set ( $50^\circ, 80^\circ, 110^\circ, 250^\circ, 280^\circ, 310^\circ, 350^\circ$ ) is found by solving the integer program. We can then partition on the first angle in the set, which is  $50^\circ$  in this example. Then one subregion includes angle  $50^\circ$ , and the other excludes  $50^\circ$ .

## Conclusions

The NP method is a powerful metaheuristic for solving large-scale discrete optimization problems. The method systematically partitions the feasible region into subregions and moves from one region to another on the basis of information obtained by randomly generating feasible sample solutions from each of the current regions. The method keeps track of which part of the feasible region is the most promising in each iteration and the number of feasible solutions generated, and hence the computational effort is always concentrated in this most promising region.

The efficiency of the NP algorithm depends on making the correct move frequently. This success probability depends in turn on both the partitioning and the method for generating feasible solutions. For any practical application it is therefore important to increase the success probability by developing intelligent partitioning methods, incorporating special structure into weighted sampling, and applying randomized heuristics to generate high-quality feasible solutions.

The NP method has certain connections to standard mathematical programming techniques such as branch-and-bound. However, the NP method is primarily useful for problems that are either too large or too complex for mathematical programming to be effective. But even for such problems mathematical programming methods can often be used to solve either a relaxed problem or a subproblem of the original and these solutions can be effectively incorporated into the NP framework.

The three application examples presented here illustrate the broad usefulness of the NP method in both manufacturing and service industries, and how it can take advantage of special structure and application-specific heuristics to improve the efficiency of the search.

Network; Shortest path; Minimum spanning trees; Steiner minimal tree; Network flows

Scientific or engineering applications usually require solving mathematical problems. Such applications in accordance with networks span a wide range, from modeling the evolution of species in biology to modeling soap films for grids of wires; from the design of collections of data to the design of heating or air-conditioning systems in buildings; and from the creation of oil and gas pipelines to the creation of communication networks, road and railway lines. These are all network design problems of significant importance and nontrivial complexity. The network topology and design characteristics of these systems are classical examples of optimization problems.

I. Intuitively speaking, a *network* is a set of points and a set of connections where each connection joins one point to another and has a certain length. The combinatorial structure of such a network is described as a graph  $G$  which is defined to be a pair  $(V, E)$  where

- $V$  is any finite set of elements, called *vertices*, and
- $E$  is a finite family of elements which are unordered pairs of vertices, called *edges*.

Additionally, assume that a function  $l: E \rightarrow \mathbf{R}$  is given for the edges of the graph  $G$ . Usually, assume that  $l$

has only positive values and call it a length-function. A (connected) graph equipped with a length-function is called a *network*.

The *length of a subgraph*  $G' = (V', E')$ ,  $V' \subseteq V$ ,  $E' \subseteq E \cap \binom{V'}{2}$ , of the network  $G$  is defined as

$$L(G') := \sum_{e \in E'} l(e).$$

Each network  $G = (V, E)$  with the length-function  $l: E \rightarrow \mathbf{R}$  is a metric space  $(V, \rho)$  by defining the distance function in the way that  $\rho(v, v')$  is the length of a shortest path between the vertices  $v$  and  $v'$  in  $G$ . That means that  $\rho: V \times V \rightarrow \mathbf{R}$  is a real-valued function satisfying:

- i)  $\rho(v, v') \geq 0$  for all  $v, v'$  in  $V$ ;
- ii)  $\rho(v, v') = 0$  if and only if  $v = v'$ ;
- iii)  $\rho(v, v') = \rho(v', v)$  for all  $v, v'$  in  $V$ ; and
- iv)  $\rho(v, v') \leq \rho(v, w) + \rho(w, v')$  for all  $v, v', w$  in  $V$  (*triangle inequality*).

The *problem of finding shortest paths* in a graph with a length-function is an important and well-studied problem. Such a path is easy to find by an algorithm created by E.W. Dijkstra [7]:

#### PROCEDURE shortest path

```

InputInstance();
Start with the vertex  $v$ ;
Label the vertex  $v$  with 0 :  $L(v) = 0$ ;
REPEAT
    Select an edge  $ww'$  between a labeled vertex  $w$  and an unlabeled vertex  $w'$  such that the quantity  $L(w) + l(ww')$  is minimal as possible;
    Label  $w'$  :  $L(w') = L(w) + l(ww')$ 
UNTIL  $v'$  is achieved
END shortest path;
```

#### A pseudocode for a procedure finding a shortest path between two vertices $v$ and $v'$ in a network

Assume that the procedure runs if all vertices of the network are achieved then the procedure creates a spanning tree rooted at the vertex  $v$  containing shortest paths from  $v$  to every vertex. Moreover, the label  $L(w)$  denotes the distance from  $v$  to  $w$ , in other terms,  $\rho(v, w) = L(w)$ .

Conversely, each finite metric space can be represented as a graph with a nonnegative length-function [23].

Graphs lend themselves as natural models of transportation as well as communication networks. Consequently, it is natural to study network design problems such as optimal facility location problems for graphs and as graphs in metric spaces.

The core network design problem is the *minimum spanning tree problem*, where one wish to design a minimum cost network contains a path from each vertex to each other. Such a network must be a tree, which is called a *minimum spanning tree* (MST). Creating a minimum spanning tree is the problem one has the longest history of all ND problems, starting with O. Borůvka [2] in 1926. See [19] for an excellent historical survey.

All the known efficient minimum spanning tree algorithms are special cases of a general greedy method, in which one builds up an MST edge-by-edge, including appropriate short edges and excluding appropriate long edges ones. Perhaps the simplest method to find an MST is due to J.B. Kruskal [30]:

#### PROCEDURE minimum spanning tree

```

InputInstance();
Start without any edge;
REPEAT
    Choose the shortest edge that does not form form a circle with edges already chosen
UNTIL  $|V| - 1$  edges are chosen
END minimum spanning tree;
```

#### A pseudocode for a procedure finding a minimum spanning tree in a network $G = (V, E)$

About an efficient implementation of Kruskal's algorithm and several more effective procedures compare [3].

**II.** A general ND problem is for a given configuration of vertices and/or edges to find a network which contains these objects, fulfilling some predetermined requirements and minimizes a given objective function. This is quite general and models a wide variety of problems.

J. McGregor Smith [40] presents a classification of applications for network design problems. Generalizing this is

- *Large region networks.* The metric in large geographic regions is given by the shortest great circle distance between the points on the (Euclidean)

sphere. Large region location problems arise when the difference between the Euclidean and the great circle metrics is considerable. Location of international headquarters or distribution centers and planning oil or natural gas pipelines or long distance telephone lines are examples [27] and [38].

- *Regional networks.* Consider inter-urban networks, like communication networks, railway lines and interstate highway networks. R.F. Love and J.G. Morris [33] study a variety of mathematical forms as samples for intercity, urban and rural road distances. Moreover, they found that the  $p$ -norms, and linear combinations of these, are the best possible. Recent surveys are [4] and [34].
- *Macro scale networks.* Chemical processing plants, urban arterial systems and similar intra-urban systems are typical applications. In these situations the rectilinear metric is often used. If the structure of the possible connections is predetermined it is also possible to formulate the problem as a network design problem in graphs.
- *Intermediate scale networks.* Electric, heating and air-conditioning systems in buildings are examples of network optimization problems where Steiner points can reduce the overall minimum cost solution of the network. The rectilinear metric is the most frequent measure of the distance in these applications. For models and methods see [26].
- *Micro scale networks.* The design of very large scale integration (VLSI) networks is an example of Steiner's problem where the overall interconnecting length of the network is crucial for the solution. In this class of applications, the rectilinear metric is again the most frequent metric. It is also conceivable to use a linear combination of rectilinear and maximum norm [26] and [32].
- *Evolutionary networks.* Molecular sequences are used to reconstruct the course of the evolution. Since the evolution is assumed to have proceed from a common ancestral species in a tree-like branching of species, this process is generally modeled by a tree. The key question is the reconstruction of this tree based on the contemporary data. Molecular data comes as either DNA sequences (composed of nucleotides from an alphabet of four letters; namely the four nucleic acids Adenine, Guanine, Thymine and Cytosine) or sequences of pro-

teins (composed of amino acids from an alphabet of 20 letters; namely Alanine, Arginine, Asparagine, ..., Valine). As the metric often the Hamming distance is used. Surveys are given in [13] and [39].

III. Considering a group of ND problems which are the problems with connectivity requirements one finds:

- The *bounded degree minimum spanning tree problem* (abbreviated: BDMST-problem), which is defined as follows: Given a finite set  $N$  of points in a metric space and an integer  $\beta > 1$ . Find a spanning tree  $T = (N, E)$  such that  $T$  has minimal length among all candidates with a maximum degree of the vertices less or equal than  $\beta$ . Finding a BDMST of maximum degree  $\beta = 2$  is equivalent to solving the *traveling salesman problem*, which is known to be NP-hard. The borderline which divides the classes NP-hard and  $\mathcal{P}$  for the BDMST problem depending on the space and the quantity  $\beta$  are described in [5] and [37].
- Many modified (minimum) spanning tree problems are presented in the literature, for instance
  - find a spanning tree interconnecting all vertices with minimal maximum degree;
  - find a spanning tree interconnecting all vertices with at least  $k$  leaves in the tree;
  - find a spanning tree  $T = (V, E)$  such that the quantity

$$\sum_{v, v' \in V} L(\text{the path from } v \text{ to } v' \text{ in } T)$$

is minimal;

- find a spanning tree isomorphic to a given tree;
- These problems are NP-complete in general, but it is shown that they can be solved more easily in several specific cases, [15,17], and [28].
- The *Steiner minimal tree problem*, where one seek a minimum network that connects a set  $N$  of designated terminal points. Any network solving this problem must be a tree, which is called a *Steiner minimal tree* (SMT). It may contain vertices different from the points which are to be connected. Such points are called *Steiner points*. In other terms; an SMT for  $N$  is a minimum spanning tree on  $N \cup Q$ , where  $Q$  is a set of additional vertices inserted into the metric space in order to achieve a minimal solution. In general, however, it is impossible to compute the number of Steiner points in an easy way

independently from the determination of an SMT. Additionally, Steiner point locations in the space are not prespecified from a candidate list of point locations.

Steiner’s problem for graphs was originally formulated by S.B. Hakimi [22] in 1971. Since then, the problem has received considerable attention in the literature. Several exact algorithms and heuristics have been suggested and discussed.

R.M. Karp [29] showed that Steiner’s problem is NP-complete. An algorithm which finds a solution in exponential time is given in [8]. The algorithm is based on the dynamic programming methodology using a decomposition property. On the other hand, Hakimi [22] remarked that an SMT for  $N$  in a network  $G = (V, E)$  can be found by the enumeration of minimum spanning trees of subgraphs of  $G$  induced by supersets of  $N$ . E.L. Lawler [31] suggested a modification of this algorithm, using the fact that the number of Steiner points is bounded by  $|N| - 2$  which shows that not all subsets  $V'$  must be considered.

A recent survey about Steiner minimal trees in networks is given in [26].

Algorithmic problems on arbitrary graphs often remain NP-complete even when restricted to special classes of graphs, yet may become solvable in polynomially bounded time on others. For instance, Steiner’s problem remains NP-complete even for planar graphs [14]; yet, it can be solved in linear time in several specific graphs [41,43,44].

The geometric version of the Steiner minimal tree problem was originated by P. Fermat [10] early in the 17th century and by C.F. Gauss [16] in 1836. Perhaps starting with the book [6], in 1941, the *Gauss problem* became popularized under the name of *Steiner’s problem*. That is: Given finite set of points in a Euclidean space, find a network which connects all points of the set with minimal length.

A classical survey of Steiner’s problem in the Euclidean plane is [18] and is termed ‘Steiner minimal tree’ for the shortest interconnecting network and ‘Steiner points’ for the additional vertices.

Without loss of generality, the following is true for any SMT for a finite set  $N$  of points:

1) the degree of each vertex is at most three;

2) the degree of each Steiner point equals three; and two edges incident to a Steiner point meet at an angle of  $120^\circ$ ;

3) there are at most  $|N| - 2$  Steiner points.

In the Euclidean plane one has a geometric construction by ruler and compass originated in [35] and [42]. Recent (1999) surveys about Steiner minimal trees, also in other geometries than the Euclidean ones, are given in [4] and [26].

Clearly, an MST is an approximation of an SMT. More exactly: One can find a tree interconnecting a finite set of points in a metric space in fast time (namely,  $O(n^2)$ -time, where  $n$  is the number of given points or the number of vertices in  $N$ , respectively) with a length at most twice the length of a shortest possible tree, namely an SMT. Hence, it is of interest to consider the quantity

$$\inf \left\{ \frac{L(\text{SMT for } N)}{L(\text{MST for } N)} : \begin{array}{l} N \text{ a finite set} \\ \text{of points} \end{array} \right\},$$

which is called the *Steiner ratio* of the space and says how much the total length of an MST can be decreased by allowing Steiner points.

space	Steiner ration	source
Plane with rectangular norm	$2/3 = 0.66666\dots$	[25]
Euclidean norm	$\sqrt{3}/2 = 0.86602\dots$	[9]
Plane with $p$ -norm	$2/3 \leq m \leq \sqrt{3}/2$	[4]

IV. Most of the ND problems can be modeled by an integer program.

Let  $G = (V, E)$  be a graph. A cut  $S$  in  $G$  is a partition of the vertex-set  $V$  into two nonempty parts,  $S$  and  $V \setminus S$ . An edge  $e$  crosses the cut  $S$ , written by  $e \in \gamma(S)$ , if it has exactly one endpoint in each part. Now, let  $l: E \rightarrow \mathbf{R}$  be a length-function. Define the following integer linear program:

$$\begin{cases} \min & \sum_{e \in E} l(e) \cdot x_e \\ \text{s.t.} & \sum_{e \in \gamma(S)} x_e \geq p(S), \quad \emptyset \neq S \subset V, \\ & x_e \in \{0, 1\}, \quad e \in E, \end{cases}$$

whereby  $p: 2^V \rightarrow \mathbf{N}$  is a function parametrizing the ND problem which is to solve. If one has two vertices  $v$  and  $v'$ , and sets  $p(S) = 1$  when  $S$  contains  $v$  but not  $v'$ , then the program models the shortest path problem (between  $v$  and  $v'$ ). If  $p(S) = 1$  for all cuts  $S$ , then the program models the minimum spanning tree problem. Other ND problems with connectivity constraints discussed by integer linear programs are mentioned in [20] and [21].

V. The second group of ND problems are the problems with capacity constraints.

Let  $G = (V, E)$  be a directed graph, usually called a *digraph*, that is

- $V$  is a finite set of elements, called *vertices*, and
  - $E \subseteq V \times V$  is a finite family, called the *set of edges*.
- Assume, that there are two distinguished vertices, a source  $v_0$  and a sink  $v_1$  in  $G$ , and that there is a (directed) path from  $v_0$  to  $v_1$ . Additionally, assume that there is a nonnegative capacity-function  $c: E \rightarrow \mathbf{R}$ .

A flow  $f$  on the digraph  $G$  is a nonnegative function on the edges such that

- 1)  $f$  does not exceed the capacities:  $0 \leq f(e) \leq c(e)$  for every edge  $e$ ; and
- 2)  $f$  satisfies the so-called *Kirchhoff-condition*

$$\sum_{(u,v) \in E} f(u, v) = \sum_{(v,w) \in E} f(v, w)$$

for every vertex  $v \in V \setminus \{v_0, v_1\}$ .

The quantity

$$\sum_{(v_0,v) \in E} f(v_0, v) = \sum_{(v,v_1) \in E} f(v, v_1)$$

is called the *value of the flow*  $f$ . The problem is to find a flow of maximum value, called a *maximum flow*.

The fundamental theory of network flows was developed by L.R. Ford Jr. and D.R. Fulkerson [11,12]: Similarly as above, a cut is defined to be a vertex partition  $S$  and  $V \setminus S$  such that  $v_0 \in S$  and  $v_1 \in V \setminus S$ . The capacity of the cut is

$$c(S) = \sum_{e \in \gamma(S)} c(e).$$

Ford and Fulkerson's main result, the *max-flow min-cut theorem*, states that the maximum flow value equals the minimum cut capacity.

Ford and Fulkerson proved this theorem by devising an algorithm that, given a flow  $f$ , either finds a cut

whose capacity equals the flow value or finds a way to increase the the flow value along an augmenting path from  $v_0$  to  $v_1$ .

```

PROCEDURE maximum flow
  InputInstance();
  Start with the zero flow;
  REPEAT
    find an augmenting path from  $v_0$  to  $v_1$ ;
    increase the flow value by altering the flows
    along the edges of the path
  UNTIL it no longer applies
END maximum flow;
    
```

A pseudocode for a procedure finding a maximum flow from a source  $v_0$  to a sink  $v_1$  in a graph  $G = (V, E)$  equipped with a capacity-function

If all capacities are integers this procedure produces a maximum flow. Note, if the capacities are arbitrary real numbers the algorithm need never terminate, and successive flow values, though they will converge, need not converge to the maximum flow value.

Surveys for network flow algorithms, including classical work and a discussion of complexity, are [1] and [36].

VI. Combining ND problems with connectivity and capacity constraints there is the minimum cost flow problem, which is to determine a least cost shipment of a commodity through a network in order to satisfy the network possibilities.

Let  $G = (V, E)$  be a digraph. Associated with each vertex  $v$  there is a number  $b(v) \in \mathbf{R}$ , satisfying  $\sum_{v \in V} b(v) = 0$ . A vertex  $v$  is called a *source*, a *sink* or a *transshipment vertex* if  $b(v)$  is positive, negative or zero, respectively. Additionally, assume that there is a nonnegative capacity-function  $c: E \rightarrow \mathbf{R}$  and a positive cost-function (i. e., length-function)  $l: E \rightarrow \mathbf{R}$ . Then the *minimum cost flow problem* is formulated as

$$\left\{ \begin{array}{l} \min \sum_{e \in E} l(e) \cdot x_e \\ \text{s.t.} \sum_{(w,v) \in E} x_{(w,v)} - \sum_{(v,w) \in E} x_{(v,w)} = b(v), \\ v \in V, \\ 0 \leq x_e \leq c(e), \quad e \in E, \\ x_e \in \{0, 1\}, \quad e \in E. \end{array} \right.$$

This problem is discussed in the literature many times; one of several available good sources is [1] which includes several polynomial time algorithms. A general background is [24].

Maximum coverage location problem; Uncapacitated facility location problem

The *covering problem on a network* involves the decision problem of determining the location of one or more ‘facilities’ or ‘centers’ to provide service to several clients located at known points on the network. To provide service to a client, a facility must be located ‘close enough’ to the client. In a more general version of the problem, there may be fixed costs associated with locating facilities, and also there may be penalty costs associated with not serving clients (not locating a facility close enough to the client). In this situation, to mini-

mize total cost there is a trade-off between establishing facilities and not serving clients.

Let  $N(V, A)$  be a connected undirected network with node set  $V = \{v_1, \dots, v_m\}$  and arc set  $A$ . Each arc  $a \in A$  has a given length  $l_a \geq 0$ . If we consider  $a = [v_i, v_j]$  as a line segment with length  $l_a$ , then any point on  $a$  can be defined by its distance from  $v_i$  (or from  $v_j$ ). We denote by  $d(x, y)$  the shortest path distance on the arcs of  $N$  between the points  $x$  and  $y$  on  $N$ . If  $X$  is a set of points on  $N$ , then  $D(X, y)$  denotes the distance between  $y$  and a point in  $X$  which is closest to  $y$ .

Without loss of generality, we assume that the clients are located at the nodes of  $N$ . Furthermore, we assume that each node  $v_i \in V$  is the site of exactly one client. To specify the notion of ‘coverage’, for  $i = 1, \dots, m$ , let the ‘covering radius’  $r_i \geq 0$  be associated with  $v_i$ . In order for client  $i$  to be covered, we require that at least one facility  $x$  be located so that  $d(x, v_i) \leq r_i$ . Equivalently, if  $X$  is a set of located facilities,  $D(X, v_i) \leq r_i$ .

In our version of the problem, we assume that facilities can only be located at members of a subset  $V'$  of  $V$ , where  $V' = \{v_1, \dots, v_n\}$ ,  $n \leq m$ . Since both clients and facilities are located at nodes of  $N$ , we can define an  $m \times n$  (0–1) covering matrix  $A$ , where  $a_{ij} = 1$  if and only if  $d(v_j, v_i) \leq r_i$ . Thus if  $a_{ij} = 1$  and if there is a facility located at  $v_j$ , then client  $i$  is covered. Let  $c_j > 0$  be the cost of locating a facility at node  $v_j$ ,  $j = 1, \dots, n$ , and let  $b_i > 0$  be the penalty cost associated with not covering client  $i$ . Finally, let  $z_i$ ,  $i = 1, \dots, m$  be a (0–1) variable. Also, let  $x_j$ ,  $j = 1, \dots, n$  be a (0–1) variable. Then with the above, we can formulate the covering problem as the following (0–1) integer programming problem:

$$(P) \quad \min \sum_{j=1}^n c_j x_j + \sum_{i=1}^m b_i z_i$$

subject to:

$$\begin{cases} \sum_{j=1}^n a_{ij} x_j + z_i \geq 1, & i = 1, \dots, m, \\ x_j \in \{0, 1\}, & j = 1, \dots, n, \\ z_i \in \{0, 1\}, & i = 1, \dots, m. \end{cases}$$

In an optimal solution to problem (P), note that  $z_i = 1$  only when client  $i$  is not covered. That is, only when  $x_j = 0$  for every  $j$  where  $d(v_j, v_i) \leq r_i$ .

For some versions of the problem there is a ‘budget constraint’ imposed on the facilities. This constraint usually takes the form:

$$\sum_{j=1}^n c_j x_j \leq M. \quad (1)$$

In the special case where each  $c_j = 1$ , the budget constraint simply limits the number of facilities that can be located (to a total of  $M$ ). This problem, when each  $b_i = 1$  and the cost of locating facilities is eliminated from the objective function, is often called the *maximum coverage location problem*, since when the objective function is minimized, a minimum number of clients are not covered and so a maximum number of clients are are covered. Henceforth, we will only consider versions of problem (P) that do not include (1).

Several applications of problem (P) and its variants have been reported in the literature (see [11] for a partial list of applications). Besides direct applications of the problem, in [9] it is shown that the *p-center problem on a network* (the problem of locating no more than  $p$  facilities to minimize the maximum distance between any client and its closest facility) can be solved by solving a sequence of covering problems. As further evidence of its applicability, in [7] it is shown that the *uncapacitated facility location problem* can be formulated as a covering problem. Thus, the covering problem is one of the very fundamental network location problems.

On a general network, the covering problem is known to be *NP-hard*. Heuristics for general (0–1) covering problems have been well-studied ([3,4,5,8,10]).

A popular heuristic is the greedy heuristic which works as follows. (For notational convenience, in the following discussion of the heuristic we assume that each client must be covered. Thus the  $z_i$  variables can be removed from (P). If this is not the case, modifications to the heuristic are obvious.) At each iteration  $t$ , let  $A^t$  be the submatrix of  $A$  that consists of rows and columns of  $A$  that have not been removed thus far. For each column  $j$  of  $A^t$  compute  $r_j^t = c_j/I_j^t$ , where  $I_j^t$  is the number of nonzero entries in column  $j$  of  $A^t$ . Set  $x_{j^*}$  to 1 where  $j^*$  is an index  $j$  for which  $r_j^t$  is minimum.

Remove  $j^*$  from  $A^t$  as well as every row  $i$  where  $a_{ij^*} = 1$ . The resulting matrix is  $A^{t+1}$  and the heuristic con-

tinues until there are no nonzero entries remaining in the matrix.

Thus the heuristic chooses the column of  $A^t$  for which the corresponding facility covers uncovered clients at ‘least cost per coverage’. The procedure continues until all clients are covered.

There is a performance guarantee of the greedy heuristic that is independent of the cost coefficients, but does depend upon the entries in the matrix  $A$ . It can be shown that the ratio of the objective function value derived via the greedy approach to the optimal objective function value will not exceed  $H(d) = \sum_{k=1}^d 1/k$ , where  $d$  is the maximum number of nonzero entries in any column of  $A$ .

When the underlying network,  $N(V, A)$ , is a tree,  $T$  (a connected undirected network without cycles), problem (P) can be solved in polynomial time. A. Kolen and A. Tamir [7] have shown that in the case of a tree network, the rows and columns of  $A$  can be permuted (in polynomial time) so that the matrix  $A$  is in *standard greedy form* (does not contain the submatrix  $\begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ ).

They then show that any covering problem (P) where  $A$  is in standard greedy form can be solved in  $O(mn)$ . See [1] for the existence of covering problems where  $A$  is standard greedy, but where the problem cannot be derived from a tree network location problem. Thus, the Kolen–Tamir approach may be applicable to a broader class of covering problems on networks.

In the special case of (P) on a tree, where each  $c_j = 1$  and every client must be covered ( $b_i$  is sufficiently large to prohibit noncoverage), even more efficient solution methods are possible (see [2,6], and [12]). With each  $c_j = 1$ , problem (P) reduces to the problem of minimizing the number of facilities located subject to the condition that every client is covered.

The procedure of B.C. Tansel, R.L. Francis, T.J. Lowe, and M.L. Chen [12] involves a physical ‘string model’. Their approach does not involve direct use of the formulation (P) and facilities can be located anywhere (on nodes or arcs) on the tree  $T$ . The procedure begins by inscribing straight-line segments on a planar surface such that each segment represents an arc of  $T$ . Next, a string of length  $r_i$  is fastened to each node  $v_i$  of the inscribed tree.

The procedure involves pulling the strings toward the interior of the tree by first considering strings fas-

tened to nodes at the tips of the tree. Facilities are located at points on the tree where the ends of tight strings reach. Once a facility is located each remaining string that reaches the facility is removed from the model, since the corresponding client is covered by that facility.

Combinatorial optimization; Neural networks; Nonlinear programming; Global optimization

Most of the engineering design problems and applications can be formulated as a nonlinear programming problem in which the objective function to be optimized is nonlinear and has many local optima in its feasible region. It is desirable to find a local optimum that corresponds to a near global optimum. The problem of finding a global minimum or maximum is known as the *global optimization problem*. The main difficulties in finding a global optimum are that there are no operationally useful optimality conditions for identifying whether a point is indeed a global optimum, except in cases of special structured problems [16].

In this article, one class of global optimization problems, specifically combinatorial optimization problems will be mainly discussed. The combinatorial optimization problems deal with problems of maximizing or minimizing an objective function subject to inequality and/or equality constraints over a set of combinatorial alternatives. Finding optimal solutions to such problems where the decision variables are combinatorial or discrete is known as *combinatorial optimization problems*. A naive way to solve combinatorial optimization problems is to list all of the feasible solutions of a given problem, then evaluate its objective function, and choose the best one as an optimum solution. However, even though it is possible in principle to solve the problem in this way, in practice it is not, because of the large number of possible feasible solutions to any problem of a reasonable size. Most of the combinatorial optimization problems are *NP*-complete [34]. Because of the combinatorial structure of these problems the time needed to solve them grows exponentially with the size of the problem. For *NP*-complete problems, there is no algorithm that provides an exact solution to the problem in polynomial time.

Over the last three decades, the combinatorial optimization problem is one of the most challenging problems that has received considerable attention. The traditional solution methodologies for combinatorial optimization problems can be categorized into three groups as exact, heuristic, and approximation methods [50]. Exact methods guarantee to obtain an optimum solution, but the computational time for obtaining an optimum solution is usually an exponential function of the number of variables. The simplex method and branch and bound methods are some examples of exact methods. The heuristic methods are problem-specific methods based on success without formal analysis of performance. Simulated annealing (SA), tabu search, and genetic algorithms are some examples of heuristic methods [45]. On the other hand, the approximation methods generate feasible solutions that are near optimal solutions. Neural networks based methods are perceived as approximation methods.

This article reviews the use of NNs for combinatorial optimization problems and provides a survey of most of the NN approaches that have been applied to combinatorial optimization problems. In Section 2, basic definitions, classifications and applications of NNs are introduced. In Section 3, the mathematical basis of problem formulation for NNs based on an energy function is explained. In Section 4, various combinatorial optimization problems studied on NNs are presented. Finally, Section 5 is the conclusion.

## Neural Networks

Neural Network (NN) models are algorithms for intellectual tasks such as learning and optimization that are based on the concept of how the human brain works. A NN model is composed of a large number of processing elements called *neurons*. Each neuron is connected to other neurons by links, each with an associated weight. Neurons without links toward them are called *input neurons* and with no link leaving away from them are called *output neurons*. The neurons are represented by state variables. State variables are functions of the weighted-sum of input variables and other state variables. Each neuron performs a simple transformation at the same time in a parallel-distributed manner. The input-output relation of the transformation in a neuron is characterized by an *activation function*.

Some examples of activation functions are the threshold function, linear, and sigmoidal functions. The combination of input neurons, output neurons, and links between neurons with associated weights constitute the architecture of the NN.

Mathematically, a NN model is a directed graph with the following properties [12]:

- 1) Each neuron (node) is associated with a state variable  $S_i$  and an activation threshold (bias)  $v_i$ .
- 2) Each link (edge) between two neurons  $i$  and  $j$  associates with it a weight  $w_{ij}$ .
- 3) Each neuron (node) defines a transfer function  $f_i(S_i, w_{ij}, v_i)$ , which determines the state of the neuron.

The classification of NNs can be done in different ways. According to the nature of activation, they can be categorized as deterministic and stochastic NNs. *Deterministic NNs* activate their states by using deterministic activation functions such as the threshold, linear, or sigmoidal functions. Most of the existing NN models are deterministic. *Stochastic NNs* activate their states according to a probability distribution. A typical example of stochastic NNs is the Boltzmann Machine (BM). According to the nature of the connectivity, NNs can be categorized as feed-forward and recurrent NNs. If a directed graph has no closed paths, then it is called a *feed-forward NN*. A typical example of the feed-forward NN is the popular multilayer perceptron. Conversely, if a directed graph has closed paths, then it is called a *recurrent NN*. A typical example of the recurrent NN is the Hopfield NN ([9,12]).

Modern era of NNs is said to have begun with the introductory work of W.S. McCulloch and W. Pitts [28]. They have proposed a general theory of information processing based on networks of neurons. Each one of these neurons can only take the output values 1 or 0 by representing the active and resting states of neurons respectively. NNs have come a long way from the early days of McCulloch and Pitts. NNs have established themselves as an interdisciplinary subject with rich connections in the neuroscience, psychology, physical sciences, mathematics and engineering.

NNs have very close ties with optimization and the ties are manifested mainly into two aspects. On one aspect, a lot of learning algorithms have been developed based on optimization techniques to train NNs to perform modeling tasks ([2,9,12,37,39]). On the other aspect, NNs have been developed for solving optimization

problems ([4,6,12,26,36,40,44,50,51]). Because of the inherent nature of parallel and distributed information processing in NNs, they are promising computational models for solving large scale optimization problems in real-time ([3,5,21,22,23,49]).

## Neural Networks and Combinatorial Optimization Problems

NNs have been proposed as a model of computation to solve combinatorial optimization problems. To solve combinatorial optimization problems using NNs requires a mapping of the problem onto the NNs in such a way that one can identify a solution from outputs of the neurons. In other words, to solve the combinatorial optimization problems using NNs, the key is to map the problem into the architecture of the NN for which the stable state represents the solution of the combinatorial optimization problem.

Combinatorial optimization problems can be solved using NNs by following two approaches.

- 1) By formulating a combinatorial optimization problem in terms of minimizing an energy function of either discrete or continuous variables ([1,3,4,5,8,13,15,35,36,40]).
- 2) By designing competition based NNs in which neurons are allowed to compete to become active under certain conditions ([7,9]).

These two approaches suggest that NNs are an alternative for solving combinatorial optimization problems as compared to other optimization techniques. Motivations for using NNs include the improvement in the speed of the operation through massively parallel computation and possible hardware design advantages. One of the main advantages of NN approaches to classical optimization approaches is the inherently parallel and distributed nature of the dynamic solution procedure. Therefore, NNs are capable to solve large scale optimization problems in real time ([3,5,21,22,23,49]).

NNs have been used to solve many combinatorial optimization problems since the pioneering work of J.J. Hopfield and D.W. Tank [15]. They formulated the traveling salesman problem (TSP) on a highly interconnected NN and made exploratory numerical studies on a 10-city and 30-city TSP. They showed that an energy function can be defined for an analog Hopfield NN and the NN always converges to a local min-

imum of this function. To find the (near) global minimum of the energy function, the Boltzmann Machine (BM) was proposed [2]. The BM was the first attempt to combine SA and NN architectures to solve combinatorial optimization problems. However, BM is designed for discrete variables with the disadvantage of being so slow. Another approach by combining SA and NNs was proposed in [24]. In this study, a noise term has been added to the neural dynamics. The intensity of that noise term has been shown to depend on the state of the neuron as well as on a temperature parameter  $T$ . By selecting an appropriate temperature schedule  $T(t)$ , the resulting NN converged to a near global minimum of the NN energy function that is in the neighborhood of the global minimum of the combinatorial optimization problem. The Hopfield NN was extended to handle inequality constraints and simplified its convergence characteristics by the eigenvalue analysis [1]. The mathematical basis of the behavior of the Hopfield NN by means of an idealization of the Hopfield network was given in [47]. This study helped to give a better understanding of the relationship between NNs and the combinatorial optimization. The analog neural solution of the combinatorial optimization problem was considered [48]. The solution method was analyzed based on the Lagrange multiplier for the continuous relaxation problem of 0-1 integer programming. The theory and methodology of the deterministic NNs for the combinatorial optimization were presented in [50]. This study was extended to the convex programming [51]. The use of NN methods for the combinatorial optimization problems was reviewed ([13,26,44]). A systematic approach to design competition based NNs for the combinatorial optimization was presented in [7]. The competition based NNs were studied in detail [9].

The procedure of NN approaches to the combinatorial optimization mostly begins with the formulation of an energy function. Ideally, the minimum of this energy function corresponds to the optimal solution of the combinatorial optimization problem. Most of the existing NN approaches to combinatorial optimization problems formulate an energy function by incorporating an objective function and constraints through functional transformation and numerical weighting. A functional transformation is usually used to convert constraints to a penalty function to penalize the

violations of constraints. Numerical weighting is often used to balance constraint satisfaction and objective minimization. In the NN formulation for combinatorial optimization problem, constraint violations enter to the energy function in an explicit way. In general, such an energy function will have the following form:

$$E = \sum_i A_i (\text{constraint violation})_i + \text{cost} \quad (1)$$

where  $A_i > 0$  and cost is an objective function that is independent from the constraint violations. By minimizing the energy function  $E$ , we attempt to minimize the cost while at the same time minimize the constraint violations.

The second step in designing NNs for combinatorial optimization problems is to derive a dynamic equation (also known as state equation or motion equation). The dynamic equation of the NN prescribes the motion of the activation states of the NN. A properly derived dynamic equation can ensure that the state of the NN reaches equilibrium and the equilibrium-state of the NN satisfies the constraints and optimizes the objective function of the problem. Currently, the dynamic equations of most NNs for optimization problems are derived by letting the time derivative of a state vector to be directly proportional to the negative gradient of an energy function. The dynamic equations and energy functions for a wide variety of combinatorial optimization problems were studied [28]. The last step is to determine the architecture of the NN in terms of neurons and connections based on the derived dynamic equation in such a way that one can identify a solution from the outputs of the neurons.

The success of optimization using NNs lies in the formulation of an energy function, based on the objective function and constraints of the given optimization problem, and the derivation of a dynamic equation of NNs, based on the formulated energy function.

The NN approaches to optimization problems have been started with [14]. He has pioneered an approach for solving minimization problems by utilizing the collective computational capabilities of NNs. He has mapped the objective function and the problem constraints onto a quadratic energy function of the neural states that presents the energy of the system of neurons.

The energy function had the following form:

$$E(S) = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N C_{ij} S_i S_j - \sum_{i=1}^N S_i I_i, \quad (2)$$

where  $S_i$  represents the output state of neurons.  $C_{ij}$  represents the strength of the link between neurons  $i$  and  $j$ .  $I_i$  represents the input bias; the input of neurons is denoted as  $x_i$ . The motion equations of neurons is defined by

$$\frac{dx_i}{dt} = -x_i + \sum_{j \neq i}^N C_{ij} S_j + I_i, \quad (3)$$

where  $S_i = f_i(x_i)$ .

Hopfield showed that for a NN with symmetric connections and nonnegative elements on the diagonal of the  $C$  matrix, the NN will always converge by performing the gradient descent to a stable state, which is a local minimum of the energy function. Many difficult optimization problems can be formulated as the minimization of a quadratic form and thus can be mapped onto the NN model. Hopfield and Tank [15] extended the discrete model to an analog model where  $0 \leq S_i \leq 1$ . The modified energy function is:

$$E(S) = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N C_{ij} S_i S_j - \sum_{i=1}^N S_i I_i + \sum_{i=1}^N \frac{1}{R_i} \int_0^{v_i} g_i^{-1}(S) dS, \quad (4)$$

where  $R_i$  is the input resistance to unit  $i$ , and  $g_i$  is the activation function. The dynamics of the neuron update is defined by

$$\frac{dx_i}{dt} = -x_i + \sum_{j \neq i}^N C_{ij} S_j + I_i, \quad (5)$$

where  $S_i = \frac{1}{2}(1 + \tanh(x_i))$ .

This model is synchronous, continuous and deterministic.

NNs to minimize the energy function are composed of either discrete or continuous neurons. The possibilities of using different types of NNs such as discrete-state

and discrete-time, continuous-state and discrete-time, and continuous-state and continuous-time networks to solve combinatorial optimization problems were investigated [29]. One usually prefers to use continuous neurons rather than discrete ones for two reasons. First, a continuous network tends to avoid oscillations between stable states. Second, solutions are much better than those provided by discrete NNs, because the valley of energy landscapes are wider and neuron outputs are not restricted to corners of the hypercube during convergence. NNs do not guarantee globally optimal solutions but they compute locally optimal solutions.

In the last two decades, spin glass theories of statistical physics have been extensively studied because of their applications to other areas like optimization and neural networks ([10,30,46]). A similarity between an NN of the type proposed in [28] and a system of elementary magnetic spins was pointed in [25]. These ideas were developed further [14] by studying how such a NN or a spin system can store and retrieve information. The idea of an energy function was used to formulate a new way of understanding the computation performed by NNs.

To solve combinatorial optimization problems using NNs and the mean field theory (MFT) of the statistical physics ([3,4,5,17,18,20,31,40]) was introduced by C. Peterson and J.R. Anderson [38]. This was the first detailed attempt to use the MFT and NNs for solving combinatorial optimization problems after a brief description by Hopfield and Tank [15]. The problem was mapped onto the NN such that a neuron being 'on' corresponded to a certain decision and then relaxed the system using the MFT in order to escape from local minima. In this study, the problem was mapped onto an *Ising glass model* ([10,11,31,40]). Another method for finding approximate solutions to combinatorial optimization problems within NNs and the MFT concept was presented [40]. The problem was mapped onto a *Potts glass model* ([19,31,40,46,52]) in this study. A mean field annealing (MFA) was described based on the MFT and SA. Similar studies based on the MFT of statistical physics to solve combinatorial optimization problems have been studied ([4,5,49]). A general framework for the MFA algorithm was derived and its relationship with to Hopfield NNs was shown [4]. A NN mapping and the MFT solution method for finding good solutions to combinatorial optimization prob-

lems containing inequality constraints like the knapsack problem were developed ([32,33]).

A method to solve combinatorial optimization problems was proposed ([17,18]) based on ‘two-layer random field model’ using the technique of the MFA. This method determined the appropriate values of the weights of two kinds of terms in objective function; a cost term that should be minimized and a constraint term that expresses constraints imposed on solutions. A parallel MFT method and a new temperature scheduling method named as maximum entropy cooling schedule were proposed [43]. The relationship between the MFT NN model and the continuous-time Hopfield NN was analyzed [20] by using the theory of dynamical systems. This study showed that the asynchronous MFT model was equivalent to the continuous-time Hopfield NN on the nature of the fixed points and hence guaranteed theoretically usage of the MFT model for solving combinatorial optimization problems in place of the continuous-time Hopfield NN.

### Combinatorial Optimization Problems

In this section, we list some of the combinatorial optimization problems that have been studied to be solved using NNs. Most of these problems are *NP*-complete [34]. The mapping of combinatorial optimization problems onto NNs by focusing graph problems such as graph *K*-partitioning, maximum graph matching, and maximum clique problems was studied [13]. The use of NNs for combinatorial optimization problems was reviewed [26]. A number of interesting combinatorial optimization problems such as graph partitioning, traveling salesman problem, vertex cover, maximum clique, maximum independent set, number partitioning, maximum matching, set cover, and graph coloring were studied to show how to map these problems into NNs [44]. A NN mapping and the MFT solution method for finding good solutions to combinatorial optimization problems containing inequality constraints like the knapsack problem were developed [32]. The MFT approach to the knapsack problem was extended to multiple knapsacks and generalized assignment problems [33]. The following three problems have been studied mostly by several researchers using different approaches.

### Quadratic Assignment Problem

The quadratic assignment problem (QAP) represents a large class of combinatorial optimization problems arising in a variety of planning and designing contexts. The QAP seeks to minimize a quadratic cost function for assignment of a number of objects to positions that can be mathematically described as follows [50]:

$$\left\{ \begin{array}{l} \min \quad f(x) = \sum_{i=1}^N \sum_{j=1}^N \sum_{k=1}^N \sum_{l=1}^N c_{ijkl} x_{ij} x_{kl} \\ \text{s.t.} \quad \sum_{i=1}^N x_{ij} = 1, \quad j = 1, \dots, N, \\ \sum_{j=1}^N x_{ij} = 1, \quad i = 1, \dots, N, \\ x_{ij} \in \{0, 1\}, \quad i, j = 1, \dots, N, \end{array} \right. \quad (6)$$

where  $c_{ijkl}$  denotes the cost associated with assigning object  $i$  to position  $j$  and object  $k$  to position  $l$  for  $i, j, k, l = 1, \dots, N$ .

An energy function for this problem can be written as follows [8]:

$$E(S) = \frac{A}{2} \sum_{i=1}^n \sum_{j \neq i}^m \sum_{k=1}^m \sum_{l \neq k}^m c_{ijkl} S_{ik} S_{jl} + \frac{B}{2} \sum_{i=1}^n \sum_{k=1}^m \sum_{l \neq k}^m S_{ik} S_{il} + \frac{C}{2} \sum_{k=1}^m \left( 1 - \sum_{i=1}^n S_{ik} \right)^2. \quad (7)$$

The first term is the just cost function. The second term specifies the constraint that at most one position can be assigned to each object and the third term specifies the constraint that every object must be assigned by exactly one assignment. This term prevents the solution of no assignments. The QAP was studied in ([6,7,8,50]).

### Graph Partitioning Problem

The graph partitioning (GP) problem can be defined as follows: Given a set of  $N$  nodes with a given connectivity, partition them into  $K$  sets each with  $N/K$  nodes such that the net connectivity (cut-size) is minimal between each set. If  $K = 2$ , then this problem is known as the *graph bipartitioning problem*.

An energy function for this problem can be written as follows [42]: For each vertex  $i$ , a binary unit  $S_i = +1$  or  $-1$  is assigned, and for each pair of vertices  $S_i, S_j, i \neq j$

$j$ , a value  $T_{ij} = 1$  if they are connected, and  $T_{ij} = 0$  if they are not connected is assigned:

$$E(S) = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N T_{ij} S_i S_j + \frac{\alpha}{2} \left( \left( \sum_{i=1}^N S_i \right)^2 - \sum_{i=1}^N S_i^2 \right), \tag{8}$$

where  $\alpha$  is an imbalance parameter. The first term corresponds to the cost function and the second term corresponds to the constraints of the problem that guarantee equal partition.  $T_{ij} S_i S_j$  is 0 whenever vertices  $i$  and  $j$  are not connected at all, positive whenever connected vertices  $i$  and  $j$  are in the same partition and negative when they are in separate partition. The GP was studied in ([5,6,38,40,41,42,44,49]). The graph bipartitioning was studied in ([4,6,36,40,41,42]). The graph K-partitioning was studied in ([13,44]).

**Traveling Salesman Problem**

The traveling salesman problem (TSP) can be defined as follows: Given a list of  $N$  cities and the distances,  $d_{ij}$ , among them, find the shortest possible tour through a set of  $N$  cities, visiting each one exactly once. Note that the TSP is a special case of the GP problem where  $K = N$ . For the  $n$ -city TSP, the number of possible tours are  $n!$ . However, a tour describes an order in which cities are visited. For the  $n$ -city TSP, there are  $2n$  tours of equal path-length. Therefore, there are  $2!/2n$  distinct paths for closed TSP tours. The total of  $N = n^2$  neurons required to map the  $n$ -city TSP to NNs. To enable the  $N$  neurons in the TSP network, to compute a solution to the problem, the network must be described by an energy function in which the lowest energy state correspond to the best path. Hopfield and Tank [15] used the following energy function to solve the TSP problem. The output  $S_{ij}$  indicates whether city  $i$  is assigned to position  $j$  in the tour or not.

$$E(S) = \frac{A}{2} \sum_X \sum_i \sum_{j \neq i} S_{Xi} S_{Xj} + \frac{B}{2} \sum_i \sum_X \sum_{X \neq Y} S_{Xi} S_{Yi}$$

$$+ \frac{C}{2} \left( \sum_X \sum_i S_{Xi} - N \right)^2 + \frac{D}{2} \sum_X \sum_{X \neq Y} \sum_i d_{XY} S_{Xi} (S_{Y,i+1} + S_{Y,i-1}). \tag{9}$$

The first three terms characterize the general problem constraints. The first triple sum is zero if and only if each city row  $X$  contains no more than ‘1’, (the rest of the entries being zero). The second triple sum is zero if and only if each ‘position in tour’ column contains no more than ‘1’, (the rest of the entries being zero). The third triple sum is zero if and only if there are  $n$  entries of ‘1’ in the entire matrix. The last triple sum is the cost term, the length of the path corresponding to a given tour. The TSP was studied in ([6,15,17,18,26,27,35,40,41,42,43,50]).

In addition to these problems, the following problems have been also studied:

- The Airline Crew Scheduling [21].
- The Constraint Satisfaction Problem [26].
- The Generalized Assignment Problem ([7,33]).
- The Graph Coloring Problem [44].
- The Job Scheduling [7].
- The Knapsack Problem ([1,7,32,33,36,41,42]).
- The Maximum Clique Problem ([13,22,23,44]).
- The Maximum Independent Set Problem [44].
- The Maximum Matching Problem ([13,44]).
- The Morphism Problems [13].
- The Number Partitioning [44].
- The Satellite Broadcasting Scheduling [3].
- The School Scheduling ([41,42]).
- The Set Cover Problem [44].
- The Vertex Cover Problem [44].

**Conclusions**

The use of NNs for the combinatorial optimization problems and the NN approaches that have been applied to combinatorial optimization problems were reviewed. These approaches suggest that NNs are an alternative for solving combinatorial optimization problems as compared to other optimization techniques. Motivations for using NNs include the improvement in the speed of the operation through massively parallel computation, and possible hardware design advan-

tages. One of the main advantages of NN approaches to classical optimization approaches is the inherently parallel and distributed nature of the dynamic solution procedure. Therefore, NNs are capable to solve large scale optimization problems in real time. This is essential in many engineering design, control, and optimization problems. Because of the inherent nature of parallel and distributed information processing in NNs, they are promising computational models for solving large scale optimization problems in real-time.

Dynamic programming; Optimization; Reinforcement learning; Simulation; Neural networks

Neuro-dynamic programming (NDP for short) is a relatively new class of dynamic programming methods for control and sequential decision making under uncertainty. These methods have the potential of dealing with problems that for a long time were thought to be intractable due to either a large state space or the lack of an accurate model. The methods discussed combine ideas from the fields of neural networks, artificial intelligence, cognitive science, simulation, and approximation theory. In this article, we delineate the major conceptual issues, we survey a number of recent developments, we describe some computational experience, and we address a number of open questions.

We consider systems where decisions are made in stages. The outcome of each decision is not fully predictable but can be anticipated to some extent before the next decision is made. Each decision results in some immediate cost but also affects the context in which future decisions are to be made and therefore affects the cost incurred in future stages. *Dynamic programming* (DP for short) provides a mathematical formalization of the trade-off between immediate and future costs.

Generally, in DP formulations there is a discrete-time dynamic system whose state evolves according to given transition probabilities that depend on a decision/control  $u$ . In particular, if we are in state  $i$  and we choose decision  $u$ , we move to state  $j$  with given probability  $p_{ij}(u)$ . Simultaneously with this transition, we incur a cost  $g(i, u, j)$ . In comparing, however, the available decisions  $u$ , it is not enough to look at the magnitude of the cost  $g(i, u, j)$ ; we must also take into account how desirable the next state  $j$  is. We thus need a way to rank or rate states  $j$ . This is done by using the optimal cost (over all remaining stages) starting from state  $j$ , which is denoted by  $J^*(j)$ . These costs can be shown to satisfy some form of *Bellman's equation*

$$J^*(i) = \min_u E \{g(i, u, j) + J^*(j)|i, u\},$$

for all  $i$ ,

where  $j$  is the state subsequent to  $i$ , and  $E\{ \cdot |i, u\}$  denotes expected value with respect to  $j$ , given  $i$  and  $u$ . Generally, at each state  $i$ , it is optimal to use a control  $u$  that attains the minimum above. Thus, decisions are ranked based on the sum of the expected cost of the present period, and the optimal expected cost of all subsequent periods.

The objective of DP is to calculate numerically the optimal cost function  $J^*$ . This computation can be done off-line, i. e., before the real system starts operating. An optimal policy, that is, an optimal choice of  $u$  for each  $i$ , is computed either simultaneously with  $J^*$ , or in real time by minimizing in the right-hand side of Bellman's equation. It is well known, however, that for many important problems the computational requirements of DP are overwhelming, mainly because of a very large number of states and controls (Bellman's 'curse of dimensionality'). In such situations a suboptimal solution is required.

## Cost Approximations in Dynamic Programming

NDP methods are suboptimal methods that center around the approximate evaluation of the optimal cost function  $J^*$ , possibly through the use of neural networks and/or simulation. In particular, we replace the optimal cost  $J^*(j)$  with a suitable approximation  $\tilde{J}(j, r)$ , where  $r$  is a vector of parameters, and we use at state  $i$  the (suboptimal) control  $\tilde{\mu}(i)$  that attains the minimum in the (approximate) right-hand side of Bellman's equation

$$\tilde{\mu}(i) = \arg \min_u E \{g(i, u, j) + \tilde{J}(j, r)|i, u\}.$$

The function  $\tilde{J}$  will be called the *scoring function*, and the value  $\tilde{J}(j, r)$  will be called the *score* of state  $j$ . The general form of  $\tilde{J}$  is known and is such that once the parameter vector  $r$  is determined, the evaluation of  $\tilde{J}(j, r)$  of any state  $j$  is fairly simple.

We note that in some problems the minimization over  $u$  of the expression

$$E \{g(i, u, j) + \tilde{J}(j, r)|i, u\}$$

may be too complicated or too time-consuming for making decisions in real-time, even if the scores  $\tilde{J}(j, r)$  are simply calculated. In such problems we may use a related technique, whereby we approximate the expression minimized in Bellman's equation,

$$Q(i, u) = E \{g(i, u, j) + J^*(j)|i, u\},$$

which is known as the  $Q$ -factor corresponding to  $(i, u)$ . In particular, we replace  $Q(i, u)$  with a suitable approximation  $\tilde{Q}(i, u, r)$ , where  $r$  is a vector of parameters. We then use at state  $i$  the (suboptimal) control that minimizes the approximate  $Q$ -factor corresponding to  $i$ :

$$\tilde{\mu}(i) = \arg \min_u \tilde{Q}(i, u, r).$$

Much of what will be said about approximation of the optimal cost function also applies to approximation of  $Q$ -factors. We thus focus primarily on approximation of the optimal cost function  $J^*$ .

We are interested in problems with a large number of states and in scoring functions  $\tilde{J}$  that can be described with relatively few numbers (a vector  $r$  of small dimension). Scoring functions involving few parameters are called *compact representations*, while the tabular description of  $J^*$  are called the *lookup table represen-*

tion. Thus, in a lookup table representation, the values  $J^*(j)$  are stored in a table for all states  $j$ . In a typical compact representation, only the vector  $r$  and the general structure of the scoring function  $\tilde{J}(\cdot, r)$  are stored; the scores  $\tilde{J}(j, r)$  are generated only when needed. For example,  $\tilde{J}(j, r)$  may be the output of some neural network in response to the input  $j$ , and  $r$  is the associated vector of weights or parameters of the neural network; or  $\tilde{J}(j, r)$  may involve a lower-dimensional description of the state  $j$  in terms of its ‘significant features’, and  $r$  is the associated vector of relative weights of the features. Thus determining the scoring function  $\tilde{J}(j, r)$  involves two complementary issues:

- 1) deciding on the general structure of the function  $\tilde{J}(j, r)$ ; and
- 2) calculating the parameter vector  $r$  so as to minimize in some sense the error between the functions  $J^*(\cdot)$  and  $\tilde{J}(\cdot, r)$ .

Approximations of the optimal cost function have been used in the past in a variety of DP contexts. Chess playing programs represent a successful example. A key idea in these programs is to use a position evaluator to rank different chess positions and to select at each turn a move that results in the position with the best rank. The *position evaluator* assigns a numerical value to each position, according to a heuristic formula that includes weights for the various features of the position (material balance, piece mobility, king safety, and other factors). Thus, the position evaluator corresponds to the scoring function  $\tilde{J}(j, r)$  above, while the weights of the features correspond to the parameter vector  $r$ . Usually, some general structure of position evaluator is selected (this is largely an art that has evolved over many years, based on experimentation and human knowledge about chess), and the numerical weights are chosen by trial and error or (as in the case of the champion program Deep Thought) by ‘training’ using a large number of sample grandmaster games.

As the chess program paradigm suggests, intuition about the problem, heuristics, and trial and error are all important ingredients for constructing cost approximations in DP. However, it is important to supplement heuristics and intuition with more systematic techniques that are broadly applicable and retain as much as possible the nonheuristic aspects of DP.

NDP aims to develop a methodological foundation for combining dynamic programming, compact repre-

sentations, and simulation to provide the basis for a rational approach to complex stochastic decision problems.

### Approximation Architectures

An important issue in function approximation is the *selection of architecture*, that is, the choice of a parametric class of functions  $\tilde{J}(\cdot, r)$  or  $\tilde{Q}(\cdot, r)$  that suits the problem at hand. One possibility is to use a neural network architecture of some type. We should emphasize here that in this article we use the term ‘neural network’ in a very broad sense, essentially as a synonym to ‘approximating architecture’. In particular, we do not restrict ourselves to the classical multilayer perceptron structure with sigmoidal nonlinearities. Any type of universal approximator of nonlinear mappings could be used in our context. The nature of the approximating structure is left open in our discussion, and it could involve, for example, radial basis functions, wavelets, polynomials, splines, etc.

Cost approximation can often be significantly enhanced through the use of *feature extraction*, a process that maps the state  $i$  into some vector  $f(i)$ , called the *feature vector* associated with the state  $i$ . Feature vectors summarize, in a heuristic sense, what are considered to be important characteristics of the state, and they are very useful in incorporating the designer’s prior knowledge or intuition about the problem and about the structure of the optimal controller. For example in a queueing system involving several queues, a feature vector may involve for each queue a three-value indicator, that specifies whether the queue is ‘nearly empty’, ‘moderately busy’, or ‘nearly full’. In many cases, analysis can complement intuition to suggest the right features for the problem at hand.

Feature vectors are particularly useful when they can capture the ‘dominant nonlinearities’ in the optimal cost function  $J^*$ . By this we mean that  $J^*(i)$  can be approximated well by a ‘relatively smooth’ function  $\hat{J}(f(i))$ ; this happens for example, if through a change of variables from states to features, the function  $J^*$  becomes a (nearly) linear or low-order polynomial function of the features. When a feature vector can be chosen to have this property, one may consider approximation architectures where both features and (relatively simple) neural networks are used together. In partic-

ular, the state is mapped to a feature vector, which is then used as input to a neural network that produces the score of the state. More generally, it is possible that both the state and the feature vector are provided as inputs to the neural network.

A simple method to obtain more sophisticated approximations, is to partition the state space into several subsets and construct a separate cost function approximation in each subset. For example, by using a linear or quadratic polynomial approximation in each subset of the partition, one can construct piecewise linear or piecewise quadratic approximations over the entire state space. An important issue here is the choice of the method for partitioning the state space. Regular partitions (e. g., grid partitions) may be used, but they often lead to a large number of subsets and very time-consuming computations. Generally speaking, each subset of the partition should contain ‘similar’ states so that the variation of the optimal cost over the states of the subset is relatively smooth and can be approximated with smooth functions. An interesting possibility is to use features as the basis for partitioning. In particular, one may use a more or less regular discretization of the space of features, which induces a possibly irregular partition of the original state space. In this way, each subset of the irregular partition contains states with ‘similar features’.

### Simulation and Training

Some of the most successful applications of neural networks are in the areas of pattern recognition, nonlinear regression, and nonlinear system identification. In these applications the neural network is used as a universal approximator: the input-output mapping of the neural network is matched to an unknown nonlinear mapping  $F$  of interest using a least squares optimization. This optimization is known as *training the network*. To perform training, one must have some training data, that is, a set of pairs  $(i, F(i))$ , which is representative of the mapping  $F$  that is approximated.

It is important to note that in contrast with these neural network applications, in the DP context there is no readily available training set of input-output pairs  $(i, J^*(i))$ , which can be used to approximate  $J^*$  with a least squares fit. The only possibility is to evaluate (exactly or approximately) by simulation the cost functions of

given (suboptimal) policies, and to try to iteratively improve these policies based on the simulation outcomes. This creates analytical and computational difficulties that do not arise in classical neural network training contexts. Indeed the use of simulation to evaluate approximately the optimal cost function is a key new idea, that distinguishes the methodology of this presentation from earlier approximation methods in DP.

Using simulation offers another major advantage: it allows the methods of this article to be used for systems that are hard to model but easy to simulate; that is, in problems where an explicit model is not available, and the system can only be observed, either as it operates in real time or through a software simulator. For such problems, the traditional DP techniques are inapplicable, and estimation of the transition probabilities to construct a detailed mathematical model is often cumbersome or impossible.

There is a third potential advantage of simulation: it can implicitly identify the ‘most important’ or ‘most representative’ states of the system. It appears plausible that if these states are the ones most often visited during the simulation, the scoring function will tend to approximate better the optimal cost for these states, and the suboptimal policy obtained will perform better.

### Neuro-Dynamic Programming

The name ‘neuro-dynamic programming’ expresses the reliance of the methods of this article on both DP and neural network concepts. In the artificial intelligence community, where the methods originated, the name *reinforcement learning* is also used. In common artificial intelligence terms, the methods allow systems to ‘learn how to make good decisions by observing their own behavior, and use built-in mechanisms for improving their actions through a reinforcement mechanism’. In less anthropomorphic DP terms, ‘observing their own behavior’ relates to simulation, and ‘improving their actions through a reinforcement mechanism’ relates to iterative schemes for improving the quality of approximation of the optimal cost function, or the  $Q$ -factors, or the optimal policy. There has been a gradual realization that reinforcement learning techniques can be fruitfully motivated and interpreted in terms of classical DP concepts such as value and policy iteration; see the survey [1], and the book [6], which

point out the connections between the artificial intelligence/reinforcement learning viewpoint and the control theory/DP viewpoint, and give many references.

The currently most popular methodology in NDP iteratively adjusts the parameter vector  $r$  of the scoring function  $\tilde{J}(j, r)$  as it produces sample state trajectories  $(i_0, \dots, i_{k+1}, \dots)$  by using simulation. These trajectories correspond to either a fixed stationary policy, or to a ‘greedy’ policy that applies, at state  $i$ , the control  $u$  that minimizes the expression

$$E \{g(i, u, j) + \tilde{J}(j, r) | i, u\},$$

where  $r$  is the current parameter vector. A central notion here is the notion of a *temporal difference*, defined by

$$d_k = g(i_k, u_k, i_{k+1}) + \tilde{J}(i_{k+1}, r) - \tilde{J}(i_k, r),$$

and expressing the difference between our expected cost estimate  $\tilde{J}(i_k, r)$  at state  $i_k$  and the predicted cost estimate  $g(i_k, u_k, i_{k+1}) + \tilde{J}(i_{k+1}, r)$  based on the outcome of the simulation. If the cost approximations were exact, the average temporal difference would be zero by Bellman’s equation. Thus, roughly speaking, the values of the temporal differences can be used to make incremental adjustments to  $r$  so as to bring about an approximate equality (on the average) between expected and predicted cost estimates along the simulated trajectories. This viewpoint, formalized by R.S. Sutton in [5], can be implemented through the use of gradient descent/stochastic approximation methodology. Sutton proposed a family of methods of this type, called TD( $\lambda$ ), and parameterized by a scalar  $\lambda \in [0, 1]$ . One extreme, TD(1), is closely related to Monte-Carlo simulation and least squares parameter estimation, while the other extreme, TD(0), is closely related to stochastic approximation. A related method is Q-learning, introduced by C.J.C.H. Watkins [9], which is a stochastic approximation-like method that iterates on the Q-factors. While there is convergence analysis of TD( $\lambda$ ) and Q-learning for the case of lookup table representations (see [8,4]), the situation is much less clear in the case of compact representations. A number of results have been derived for approximate policy and value iteration methods, which are obtained from the traditional DP methods after compact representations of the various cost functions involved are introduced.

While the theoretical support for the NDP methodology is only now emerging, there have been quite a few reports of successes with problems too large and complex to be treated in any other way. A particularly impressive success is the development of a backgammon playing program as reported by G. Tesauro [7]. Here a neural network provided a compact representation of the optimal cost function of the game of backgammon by using simulation and TD( $\lambda$ ). The training was performed by letting the program play against itself. After training for several months, the program nearly defeated the human world champion. Variations of the method used by Tesauro have been used with success in a variety of applications.

The recent experience of several researchers, involving several engineering applications, has confirmed that NDP methods can be impressively effective in problems where traditional DP methods would be hardly applicable and other heuristic methods would have a limited chance of success. We note, however, that the practical application of NDP is computationally very intensive, and often requires a considerable amount of trial and error. Fortunately, all the computation and experimentation with different approaches can be done off-line. Once the approximation is obtained off-line, it can be used to generate decisions fast enough for use in real time. In this context, we mention that in the machine learning literature, reinforcement learning is often viewed as an ‘on-line’ method, whereby the cost approximation is improved as the system operates in real time. This is reminiscent of the methods of traditional adaptive control.

Extensive references for the material of this article are the research monographs [3,6]. A more limited textbook discussion is given in [2]. The survey [1], and the overviews [10,11], and other papers in the edited volume [12] point out the connections between the artificial intelligence/reinforcement learning viewpoint and the control theory/DP viewpoint, and give many references.

Unconstrained optimization; Hybrid conjugate gradient method; Conjugacy condition; Numerical comparisons; Dolan–Moré profile

New hybrid conjugate gradient algorithms are proposed and analyzed. In these hybrid algorithms the famous parameter  $\beta_k$  is computed as a convex combination of the Polak–Ribière–Polyak and Dai–Yuan conjugate gradient algorithms. In one hybrid algorithm the parameter in convex combination is computed in such a way that the conjugacy condition is satisfied, independent of the line search. In the other, the parameter in convex combination is computed in such a way that the conjugate gradient direction is the Newton direction. The algorithm uses the standard Wolfe line search conditions. Numerical comparisons with conjugate gradient algorithms using a set of 750 unconstrained optimization problems, some of them from the CUTE library, show that the hybrid computational scheme based on the conjugacy condition outperforms the known hybrid conjugate gradient algorithms.

**Introduction**

Let us consider the nonlinear unconstrained optimization problem

$$\min \{f(x) : x \in R^n\}, \tag{1}$$

where  $f : R^n \rightarrow R$  is a continuously differentiable function, bounded from below. For solving this problem, starting from an initial guess  $x_0 \in R^n$ , a nonlinear conjugate gradient method generates a sequence  $\{x_k\}$  as

$$x_{k+1} = x_k + \alpha_k d_k, \tag{2}$$

where  $\alpha_k > 0$  is obtained by line search, and the directions  $d_k$  are generated as

$$d_{k+1} = -g_{k+1} + \beta_k s_k, \quad d_0 = -g_0. \tag{3}$$

In (3)  $\beta_k$  is known as the conjugate gradient parameter,  $s_k = x_{k+1} - x_k$  and  $g_k = \nabla f(x_k)$ . Consider  $\|\cdot\|$  the Euclidean norm and define  $y_k = g_{k+1} - g_k$ . The line search in the conjugate gradient algorithms is often based on the standard Wolfe conditions:

$$f(x_k + \alpha_k d_k) - f(x_k) \leq \rho \alpha_k g_k^T d_k, \tag{4}$$

$$g_{k+1}^T d_k \geq \sigma g_k^T d_k, \tag{5}$$

where  $d_k$  is a descent direction and  $0 < \rho \leq \sigma < 1$ . Plenty of conjugate gradient methods are known, and an excellent survey of these methods, with special attention to their global convergence, was given by Hager and Zhang [19]. Different conjugate gradient algorithms correspond to different choices for the scalar parameter  $\beta_k$ . Some of these methods, such those of Fletcher and Reeves (FR) [16], Dai and Yuan (DY) [12] and conjugate descent (CD) proposed by Fletcher [15], have strong convergence properties, but they may have modest practical performance owing to jamming:

$$\beta_k^{FR} = \frac{g_{k+1}^T g_{k+1}}{g_k^T g_k}, \quad \beta_k^{DY} = \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k},$$

$$\beta_k^{CD} = \frac{g_{k+1}^T g_{k+1}}{-g_k^T s_k}.$$

On the other hand, the methods of Polak and Ribière [23] and Polyak (PRP) [24], Hestenes and Stiefel (HS) [20] or Liu and Storey (LS) [22] in general may

not be convergent, but they often have better computational performances:

$$\beta_k^{PRP} = \frac{g_{k+1}^T y_k}{g_k^T g_k}, \quad \beta_k^{HS} = \frac{g_{k+1}^T y_k}{y_k^T s_k}, \quad \beta_k^{LS} = \frac{g_{k+1}^T y_k}{-g_k^T s_k}.$$

In this contribution we focus on hybrid conjugate gradient methods. These methods are combinations of different conjugate gradient algorithms; mainly they are proposed to avoid the jamming phenomenon. One of the first hybrid conjugate gradient algorithms was introduced by Touati-Ahmed and Storey [28], where the parameter  $\beta_k$  is computed as

$$\beta_k^{TS} = \begin{cases} \beta_k^{PRP} = \frac{g_{k+1}^T y_k}{\|g_k\|^2}, & \text{if } 0 \leq \beta_k^{PRP} \leq \beta_k^{FR}, \\ \beta_k^{FR} = \frac{\|g_{k+1}\|^2}{\|g_k\|^2}, & \text{otherwise.} \end{cases}$$

The PRP method has a built-in restart feature that directly addresses jamming. Indeed, when the step  $s_k$  is small, then the factor  $y_k$  in the numerator of  $\beta_k^{PRP}$  tends to zero. Therefore,  $\beta_k^{PRP}$  becomes small and the search direction  $d_{k+1}$  is very close to the steepest descent direction  $-g_{k+1}$ . Hence, when the iterations jam, the method of Touati-Ahmed and Storey uses the PRP computational scheme.

Another hybrid conjugate gradient method was given by Hu and Storey [21], where  $\beta_k$  in (3) is

$$\beta_k^{HuS} = \max \{0, \min \{\beta_k^{PRP}, \beta_k^{FR}\}\}.$$

As above, when the method of Hu and Storey is jamming, then the PRP method is used instead.

The combination of LS and CD conjugate gradient methods leads to the following hybrid method:

$$\beta_k^{LS-CD} = \max \{0, \min \{\beta_k^{LS}, \beta_k^{CD}\}\}.$$

The CD method of Fletcher [15] is very similar to the FR method. With an exact line search, the CD method is identical to the FR method. Similarly, for an exact line search, the LS method is identical to the PRP method. Therefore, the hybrid LS-CD method with an exact line search has similar performances as the hybrid method of Hu and Storey.

Gilbert and Nocedal [17] suggested a combination between PRP and FR methods as

$$\beta_k^{GN} = \max \{-\beta_k^{FR}, \min \{\beta_k^{PRP}, \beta_k^{FR}\}\}.$$

Since  $\beta_k^{\text{FR}}$  is always nonnegative, it follows that  $\beta_k^{\text{GN}}$  can be negative. The method of Gilbert and Nocedal has the same advantage of avoiding jamming.

Using the standard Wolfe line search, the DY method always generates descent directions and if the gradient is Lipschitz-continuous the method is globally convergent. In an effort to improve their algorithm, Dai and Yuan [13] combined their algorithm with other conjugate gradient algorithms, and proposed the following two hybrid methods:

$$\beta_k^{\text{hDY}} = \max \{-c\beta_k^{\text{DY}}, \min \{\beta_k^{\text{HS}}, \beta_k^{\text{DY}}\}\},$$

$$\beta_k^{\text{hDYz}} = \max \{0, \min \{\beta_k^{\text{HS}}, \beta_k^{\text{DY}}\}\},$$

where  $c = (1 - \sigma)/(1 + \sigma)$ . For the standard Wolfe conditions (4) and (5), under the Lipschitz continuity of the gradient, Dai and Yuan [13] established the global convergence of these hybrid computational schemes.

In the following we propose another hybrid conjugate gradient as a convex combination of PRP and DY conjugate gradient algorithms. We selected these two methods for combination in a hybrid conjugate gradient algorithm because the PRP algorithm has good computational properties, on one hand, and the DY algorithm has strong convergence properties, on the other hand. Often the PRP method performs better in practice than the DY method and we speculate this in order to have a good practical conjugate algorithm. The structure of this chapter is as follows. In Sect. “**New Hybrid Conjugate Gradient Algorithms**” we introduce our hybrid conjugate gradient algorithm and prove that it generates descent directions satisfying in some conditions the sufficient descent condition. Section “**The New Hybrid Algorithms (CCOMB, NDOMB)**” presents the algorithms and in Sect. “**Convergence Analysis**” we show the convergence analysis. In Sect. “**Numerical Experiments**” some numerical experiments and performance profiles of Dolan–Moré [14] corresponding to this new hybrid conjugate gradient algorithm and some other conjugate gradient algorithms are presented. The performance profiles corresponding to a set of 750 unconstrained optimization problems in the CUTE test problem library [6] as well as some other unconstrained optimization problems presented in [1] show that this hybrid conjugate gradient algorithm outperforms the known hybrid conjugate gradient algorithms.

## New Hybrid Conjugate Gradient Algorithms

The iterates  $x_0, x_1, x_2, \dots$  of our algorithm are computed by means of recurrence (2) where the step size  $\alpha_k > 0$  is determined according to the Wolfe conditions (4) and (5), and the directions  $d_k$  are generated by the rule:

$$d_{k+1} = -g_{k+1} + \beta_k^{\text{N}} s_k, \quad d_0 = -g_0, \quad (6)$$

where

$$\begin{aligned} \beta_k^{\text{N}} &= (1 - \theta_k)\beta_k^{\text{PRP}} + \theta_k\beta_k^{\text{DY}} \\ &= (1 - \theta_k) \frac{g_{k+1}^T y^k}{g_k^T g_k} + \theta_k \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} \end{aligned} \quad (7)$$

and  $\theta_k$  is a scalar parameter satisfying  $0 \leq \theta_k \leq 1$ , which needs to be determined. Observe that if  $\theta_k = 0$ , then  $\beta_k^{\text{N}} = \beta_k^{\text{PRP}}$ , and if  $\theta_k = 1$ , then  $\beta_k^{\text{N}} = \beta_k^{\text{DY}}$ . On the other hand, if  $0 < \theta_k < 1$ , then  $\beta_k^{\text{N}}$  is a convex combination of  $\beta_k^{\text{PRP}}$  and  $\beta_k^{\text{DY}}$ .

Referring to the PRP method, Polak and Ribière [23] proved that when function  $f$  is strongly convex and the line search is exact, then the PRP method is globally convergent. In an effort to understand the behavior of the PRP method, Powell [25] showed that if the step length  $s_k = x_{k+1} - x_k$  approaches zero, the line search is exact and the gradient  $\nabla f(x)$  is Lipschitz-continuous, then the PRP method is globally convergent. Additionally, assuming that the search direction is a descent direction, Yuan [29] established the global convergence of the PRP method for strongly convex functions and a Wolfe line search. For general nonlinear functions the convergence of the PRP method is uncertain. Powell [26] gave a three-dimensional example, in which the function to be minimized is not strongly convex, showing that even with an exact line search the PRP method may not converge to a stationary point. Later on Dai [7] presented another example, this time with a strongly convex function for which the PRP method fails to generate a descent direction. Therefore, theoretically the convergence of the PRP method is limited to strongly convex functions. For general nonlinear functions the convergence of the PRP method is established under restrictive conditions (Lipschitz continuity, exact line search and the step size tends to zero). However, the numerical experiments presented, for example, by Gilbert and Nocedal [17] proved that the PRP method is one of the best conjugate

gradient methods, and this was the main motivation to consider it in (7).

On the other hand, the DY method always generates descent directions, and in [8] Dai established a remarkable property for the DY conjugate gradient algorithm, relating the descent directions to the sufficient descent condition. It was shown that if there exist constants  $\gamma_1$  and  $\gamma_2$  such that  $\gamma_1 \leq \|g_k\| \leq \gamma_2$  for all  $k$ , then for any  $p \in (0, 1)$  there exists a constant  $c > 0$  such that the sufficient descent condition  $g_i^T d_i \leq -c \|g_i\|^2$  holds for at least  $\lfloor pk \rfloor$  indices  $i \in [0, k]$ , where  $\lfloor j \rfloor$  denotes the largest integer  $\leq j$ . Therefore, this property is the main reason we consider the DY method in (7).

It easy to see that

$$d_{k+1} = -g_{k+1} + (1 - \theta_k) \frac{y_k^T g_{k+1}}{g_k^T g_k} s_k + \theta_k \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} s_k. \tag{8}$$

Supposing that  $d_k$  is a descent direction ( $d_0 = -g_0$ ), then for the algorithm given by (2) and (8) we can prove the following result.

**Theorem 1** Assume that  $\alpha_k$  in algorithm (2) and (8) is determined by Wolfe line search (4) and (5). If  $0 < \theta_k < 1$ , and

$$\left| \frac{g_k^T s_k}{y_k^T s_k} \right| \|g_{k+1}\|^2 \geq \frac{(g_{k+1}^T y_k)(g_{k+1}^T s_k)}{\|g_k\|^2}, \tag{9}$$

then direction  $d_{k+1}$  given by (8) is a descent direction.

*Proof* Since  $0 < \theta_k < 1$ , from (8) we get

$$\begin{aligned} g_{k+1}^T d_{k+1} &= -\|g_{k+1}\|^2 + (1 - \theta_k) \frac{y_k^T g_{k+1}}{g_k^T g_k} g_{k+1}^T s_k \\ &\quad + \theta_k \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} g_{k+1}^T s_k \\ &\leq -\|g_{k+1}\|^2 + \frac{y_k^T g_{k+1}}{g_k^T g_k} g_{k+1}^T s_k \\ &\quad + \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} g_{k+1}^T s_k \\ &= \left( -1 + \frac{g_{k+1}^T s_k}{y_k^T s_k} \right) \|g_{k+1}\|^2 \\ &\quad + \frac{y_k^T g_{k+1}}{g_k^T g_k} g_{k+1}^T s_k \\ &= \frac{g_k^T s_k}{y_k^T s_k} \|g_{k+1}\|^2 + \frac{y_k^T g_{k+1}}{g_k^T g_k} g_{k+1}^T s_k. \end{aligned}$$

But,  $y_k^T s_k > 0$  by (5) and since  $g_k^T s_k \leq 0$ , it follows that

$$\frac{g_k^T s_k}{y_k^T s_k} \|g_{k+1}\|^2 \leq 0.$$

Therefore, from (9), it follows that  $g_{k+1}^T d_{k+1} \leq 0$ , i.e., the direction  $d_{k+1}$  is a descent one.  $\square$

**Theorem 2** Suppose that  $(g_{k+1}^T y_k)(g_{k+1}^T s_k) \leq 0$ . If  $0 < \theta_k < 1$ , then the direction  $d_{k+1}$  given by (8) satisfies the sufficient descent condition

$$g_{k+1}^T d_{k+1} \leq - \left( 1 - \theta_k \frac{g_{k+1}^T s_k}{y_k^T s_k} \right) \|g_{k+1}\|^2. \tag{10}$$

*Proof* From (8) we have

$$\begin{aligned} g_{k+1}^T d_{k+1} &= -\|g_{k+1}\|^2 + (1 - \theta_k) \frac{g_{k+1}^T y_k}{g_k^T g_k} g_{k+1}^T s_k \\ &\quad + \theta_k \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} g_{k+1}^T s_k \\ &= -\|g_{k+1}\|^2 + \theta_k \frac{g_{k+1}^T s_k}{y_k^T s_k} \|g_{k+1}\|^2 \\ &\quad + (1 - \theta_k) \frac{(g_{k+1}^T y_k)(g_{k+1}^T s_k)}{g_k^T g_k} \\ &\leq - \left( 1 - \theta_k \frac{g_{k+1}^T s_k}{y_k^T s_k} \right) \|g_{k+1}\|^2 \leq 0. \end{aligned}$$

Observe that since  $y_k^T s_k > 0$  by (5) and since  $g_{k+1}^T s_k = y_k^T s_k + g_k^T s_k < y_k^T s_k$ , then  $y_k^T s_k / g_{k+1}^T s_k > 1$ . Therefore, if  $0 < \theta_k < 1$ , it follows that  $\theta_k < y_k^T s_k / g_{k+1}^T s_k$ . Therefore,

$$1 - \theta_k \frac{g_{k+1}^T s_k}{y_k^T s_k} > 0,$$

proving the theorem.  $\square$

To select the parameter  $\theta_k$  we consider the following two possibilities. In the first hybrid conjugate gradient algorithm the parameter  $\theta_k$  is selected in such a manner that the *conjugacy condition*  $y_k^T d_{k+1} = 0$  is satisfied at every iteration, independent of the line search. Hence,

from  $y_k^T d_{k+1} = 0$  after some algebra, using (8), we get

$$\theta_k = \theta_k^{\text{CCOMB}} \equiv \frac{(y_k^T g_{k+1})(y_k^T s_k) - (y_k^T g_{k+1})(g_k^T g_k)}{(y_k^T g_{k+1})(y_k^T s_k) - \|g_{k+1}\|^2 \|g_k\|^2}. \tag{11}$$

In the second algorithm the parameter  $\theta_k$  is selected in such a manner that the direction  $d_{k+1}$  from (8) is the Newton direction, i. e.,

$$-\nabla^2 f(x_{k+1})^{-1} g_{k+1} = -g_{k+1} + (1 - \theta_k) \frac{y_k^T g_{k+1}}{g_k^T g_k} s_k + \theta_k \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} s_k. \tag{12}$$

Having in view that  $\nabla^2 f(x_{k+1}) s_k = y_k$ , from (12) we get

$$\theta_k = \theta_k^{\text{NDOMB}} \equiv \frac{(y_k^T g_{k+1} - s_k^T g_{k+1}) \|g_k\|^2 - (g_{k+1}^T y_k)(y_k^T s_k)}{\|g_{k+1}\|^2 \|g_k\|^2 - (g_{k+1}^T y_k)(y_k^T s_k)}. \tag{13}$$

Observe that the parameter  $\theta_k$  given by (11) or (13) can be outside the interval  $[0, 1]$ . However, in order to have a real convex combination in (7) the following rule is considered: if  $\theta_k \leq 0$ , then set  $\theta_k = 0$  in (7), i. e.,  $\beta_k^N = \beta_k^{\text{PRP}}$ ; if  $\theta_k \geq 1$ , then take  $\theta_k = 1$  in (7), i. e.,  $\beta_k^N = \beta_k^{\text{DY}}$ . Therefore, under this rule for  $\theta_k$  selection, the direction  $d_{k+1}$  in (8) combines the properties of the PRP and DY algorithms.

**The New Hybrid Algorithms (CCOMB, NDOMB)**

- Step 1 Initialization.** Select  $x_0 \in R^n$  and the parameters  $0 < \rho \leq \sigma < 1$ . Compute  $f(x_0)$  and  $g_0$ . Consider  $d_0 = -g_0$  and set the initial guess:  $\alpha_0 = 1/\|g_0\|$ .
- Step 2 Test for continuation of iterations.** If  $\|g_k\|_\infty \leq 10^{-6}$ , then stop.
- Step 3 Line search.** Compute  $\alpha_k > 0$  satisfying the Wolfe line search conditions (4) and (5) and update the variables  $x_{k+1} = x_k + \alpha_k d_k$ . Compute  $f(x_{k+1})$ ,  $g_{k+1}$  and  $s_k = x_{k+1} - x_k$ ,  $y_k = g_{k+1} - g_k$ .
- Step 4.  $\theta_k$  parameter computation.** If  $(y_k^T g_{k+1})(y_k^T s_k) - \|g_{k+1}\|^2 \|g_k\|^2 = 0$ , then set  $\theta_k = 0$ , otherwise compute  $\theta_k$  as follows:

*CCOMB algorithm* ( $\theta_k$  from the conjugacy condition):  $\theta_k = \theta_k^{\text{CCOMB}}$ .

*NDOMB algorithm* ( $\theta_k$  from the Newton direction):  $\theta_k = \theta_k^{\text{NDOMB}}$ .

- Step 5  $\beta_k^N$  conjugate gradient parameter computation.** If  $0 < \theta_k < 1$ , then compute  $\beta_k^N$  as in (7). If  $\theta_k \geq 1$ , then set  $\beta_k^N = \beta_k^{\text{DY}}$ . If  $\theta_k \leq 0$ , then set  $\beta_k^N = \beta_k^{\text{PRP}}$ .
- Step 6 Direction computation.** Compute  $d = -g_{k+1} + \beta_k^N s_k$ . If the restart criterion of Powell,

$$|g_{k+1}^T g_k| \geq 0.2 \|g_{k+1}\|^2, \tag{14}$$

is satisfied, then set  $d_{k+1} = -g_{k+1}$ ; otherwise define  $d_{k+1} = d$ . Compute the initial guess  $\alpha_k = \alpha_{k-1} \|d_{k-1}\| / \|d_k\|$ , set  $k = k + 1$  and continue with step 2.

It is well known that if  $f$  is bounded along the direction  $d_k$  then there exists a step size  $\alpha_k$  satisfying the Wolfe line search conditions (4) and (5). In our algorithm when the Powell restart condition is satisfied, we restart the algorithm with the negative gradient  $-g_{k+1}$ . More sophisticated reasons for restarting the algorithms have been proposed in the literature [10], but we are interested in the performance of a conjugate gradient algorithm that uses this restart criterion, associated with a direction satisfying the conjugacy condition or that is equal to the Newton direction. Under reasonable assumptions, conditions (4), (5) and (14) are sufficient to prove the global convergence of the algorithm. We consider this aspect in the next section.

The first trial of the step length crucially affects the practical behavior of the algorithm. At every iteration  $k \geq 1$  the starting guess for step  $\alpha_k$  in the line search is computed as  $\alpha_{k-1} \|d_{k-1}\|_2 / \|d_k\|_2$ . This selection was considered for the first time by Shanno and Phua [27] in CONMIN. It is also considered in the packages SCG by Birgin and Martínez [5] and in SCALCG by Andrei [2,3,4].

**Convergence Analysis**

Throughout this section we assume that

1. *The level set  $S = \{x \in R^n : f(x) \leq f(x_0)\}$  is bounded.*
2. *In a neighborhood  $N$  of  $S$ , the function  $f$  is continuously differentiable and its gradient is Lipschitz-continuous, i. e., there exists a constant  $L > 0$*

such that  $\|\nabla f(x) - \nabla f(y)\| \leq L \|x - y\|$ , for all  $x, y \in N$ .

Under these assumptions for  $f$ , there exists a constant  $\Gamma \geq 0$  such that  $\|\nabla f(x)\| \leq \Gamma$ , for all  $x \in S$ .

It was proved in [11] that for any conjugate gradient method with strong Wolfe line search the following lemma holds.

**Lemma 1** Suppose that assumptions 1 and 2 hold and consider any conjugate gradient method (2) and (3), where  $d_k$  is a descent direction and  $\alpha_k$  is obtained by the strong Wolfe line search. If

$$\sum_{k \geq 1} \frac{1}{\|d_k\|^2} = \infty, \tag{15}$$

then

$$\liminf_{k \rightarrow \infty} \|g_k\| = 0. \tag{16}$$

For uniformly convex functions which satisfy the above assumptions we can prove that the norm of  $d_{k+1}$  generated by (8) is bounded above. Thus, by Lemma 1 we have the following result.

**Theorem 3** Suppose that assumptions 1 and 2 hold. Consider the algorithm (2) and (8), where  $d_{k+1}$  is a descent direction and  $\alpha_k$  is obtained by the strong Wolfe line search.

$$f(x_k + \alpha_k d_k) - f(x_k) \leq \rho \alpha_k g_k^T d_k, \tag{17}$$

$$|g_{k+1}^T d_k| \leq -\sigma g_k^T d_k. \tag{18}$$

If for  $k \geq 0$ ,  $\|s_k\|$  tends to zero and there exist the non-negative constants  $\eta_1$  and  $\eta_2$  such that

$$\|g_k\|^2 \geq \eta_1 \|s_k\|^2 \text{ and } \|g_{k+1}\|^2 \leq \eta_2 \|s_k\|, \tag{19}$$

and the function  $f$  is a uniformly convex function, i.e., there exists a constant  $\mu \geq 0$  such that for all  $x, y \in S$

$$(\nabla f(x) - \nabla f(y))^T(x - y) \geq \mu \|x - y\|^2, \tag{20}$$

then

$$\lim_{k \rightarrow \infty} g_k = 0. \tag{21}$$

*Proof* From (20) it follows that  $y_k^T s_k \geq \mu \|s_k\|^2$ . Now, since  $0 \leq \theta_k \leq 1$ , from uniform convexity and (19) we

have

$$\begin{aligned} |\beta_k^N| &\leq \left| \frac{g_{k+1}^T y_k}{g_k^T g_k} \right| + \left| \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} \right| \\ &\leq \frac{\|g_{k+1}\| \|y_k\|}{\eta_1 \|s_k\|^2} + \frac{\eta_2 \|s_k\|}{\mu \|s_k\|^2}. \end{aligned}$$

But  $\|y_k\| \leq L \|s_k\|$ ; therefore,

$$|\beta_k^N| \leq \frac{\Gamma L}{\eta_1 \|s_k\|} + \frac{\eta_2}{\mu \|s_k\|}.$$

Hence,

$$\|d_{k+1}\| \leq \|g_{k+1}\| + |\beta_k^N| \|s_k\| \leq \Gamma + \frac{\Gamma L}{\eta_1} + \frac{\eta_2}{\mu},$$

which implies that (15) is true. Therefore, by Lemma 1 we have (16), which for uniformly convex functions is equivalent to (21).  $\square$

Powell [25] showed that for general functions the PRP method is globally convergent if the step lengths  $\|s_k\| = \|x_{k+1} - x_k\|$  tend to zero, i.e.,  $\|s_k\| \leq \|s_{k-1}\|$  is a condition of convergence. For convergence of our algorithms from (19) we see that along the iterations, for  $k \geq 1$ , the gradient must be bounded as  $\eta_1 \|s_k\|^2 \leq \|g_k\|^2 \leq \eta_2 \|s_{k-1}\|$ . If the Powell condition is satisfied, i.e.,  $\|s_k\|$  tends to zero, then  $\|s_k\|^2 \ll \|s_{k-1}\|$  and therefore the norm of the gradient can satisfy (19). In the numerical experiments we observed that (19) is always satisfied in the last part of the iterations.

For general nonlinear functions the convergence analysis of our algorithm exploits insights developed by Gilbert and Nocedal [17], Dai and Liao [9] and Hager and Zhang [18]. Global convergence proof of these new hybrid conjugate gradient algorithms is based on the Zoutendijk condition combined with the analysis showing that the sufficient descent condition holds and  $\|d_k\|$  is bounded. Suppose that level set  $S$  is bounded and function  $f$  is bounded from below.

**Lemma 2** Assume that  $d_k$  is a descent direction and  $\nabla f$  satisfies the Lipschitz condition  $\|\nabla f(x) - \nabla f(x_k)\| \leq L \|x - x_k\|$  for all  $x$  on the line segment connecting  $x_k$  and  $x_{k+1}$ , where  $L$  is a constant. If the line search satisfies the second Wolfe condition (5), then

$$\alpha_k \geq \frac{1 - \sigma}{L} \frac{|g_k^T d_k|}{\|d_k\|^2}. \tag{22}$$

*Proof* Subtracting  $g_k^T d_k$  from both sides of (5) and using the Lipschitz condition, we have

$$(\sigma - 1)g_k^T d_k \leq (g_{k+1} - g_k)^T d_k \leq L\alpha_k \|d_k\|^2. \quad (23)$$

Since  $d_k$  is a descent direction and  $\sigma < 1$ , (22) follows immediately from (23).  $\square$

**Theorem 4** *Suppose that assumptions 1 and 2 hold,  $0 < \theta_k \leq 1$ ,  $(g_{k+1}^T y_k)(g_{k+1}^T s_k) \leq 0$ , for every  $k \geq 0$  there exists a positive constant  $\omega$ , such that  $1 - \theta_k(g_{k+1}^T s_k)/(y_k^T s_k) \geq \omega > 0$ , and there exist the constants  $\gamma$  and  $\Gamma$ , such that for all  $k$ ,  $\gamma \leq \|g_k\| \leq \Gamma$ . Then for the computational scheme (2) and (8), where  $\alpha_k$  is determined by the Wolfe line search (4) and (5), either  $g_k = 0$  for some  $k$  or*

$$\liminf_{k \rightarrow \infty} \|g_k\| = 0. \quad (24)$$

*Proof* By the Wolfe condition (5) we have

$$y_k^T s_k = (g_{k+1} - g_k)^T s_k \geq (\sigma - 1)g_k^T s_k = -(1 - \sigma)g_k^T s_k. \quad (25)$$

By Theorem 2, and the assumption  $1 - \theta_k(g_{k+1}^T s_k)/(y_k^T s_k) \geq \omega$ , it follows that

$$g_k^T d_k \leq -\left(1 - \theta_{k-1} \frac{g_k^T s_{k-1}}{y_{k-1}^T s_{k-1}}\right) \|g_k\|^2 \leq -\omega \|g_k\|^2.$$

Therefore,

$$-g_k^T d_k \geq \omega \|g_k\|^2. \quad (26)$$

Combining (25) with (26), we get

$$y_k^T s_k \geq (1 - \sigma)\omega\alpha_k\gamma^2.$$

On the other hand  $\|y_k\| = \|g_{k+1} - g_k\| \leq L \|s_k\|$ ; hence,

$$|g_{k+1}^T y_k| \leq \|g_{k+1}\| \|y_k\| \leq \Gamma L \|s_k\|.$$

With these, from (7) we get

$$|\beta_k^N| \leq \left| \frac{g_{k+1}^T y_k}{g_k^T g_k} \right| + \left| \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} \right|.$$

But

$$\left| \frac{g_{k+1}^T y_k}{g_k^T g_k} \right| \leq \frac{\|g_{k+1}\| \|y_k\|}{\gamma^2} \leq \frac{\Gamma L \|s_k\|}{\gamma^2} \leq \frac{\Gamma L D}{\gamma^2},$$

where  $D = \max \{\|y - z\| : y, z \in S\}$  is the diameter of the level set  $S$ .

On the other hand,

$$\left| \frac{g_{k+1}^T g_{k+1}}{y_k^T s_k} \right| \leq \frac{\Gamma^2}{(1 - \sigma)\omega\alpha_k\gamma^2}.$$

Therefore,

$$|\beta_k^N| \leq \frac{\Gamma L D}{\gamma^2} + \frac{\Gamma^2}{(1 - \sigma)\omega\alpha_k\gamma^2} \equiv E. \quad (27)$$

Now, we can write

$$\|d_{k+1}\| \leq \|g_{k+1}\| + |\beta_k^N| \|s_k\| \leq \Gamma + E D. \quad (28)$$

Since the level set  $S$  is bounded and the function  $f$  is bounded from below, using Lemma 2, from (4) it follows that

$$0 < \sum_{k=0}^{\infty} \frac{(g_k^T d_k)^2}{\|d_k\|^2} < \infty, \quad (29)$$

i. e., the Zoutendijk condition holds. Therefore, from Theorem 2 using (29), the descent property yields

$$\sum_{k=0}^{\infty} \frac{\gamma^4}{\|d_k\|^2} \leq \sum_{k=0}^{\infty} \frac{\|g_k\|^4}{\|d_k\|^2} \leq \sum_{k=0}^{\infty} \frac{1}{\omega^2} \frac{(g_k^T d_k)^2}{\|d_k\|^2} < \infty,$$

which contradicts (28). Hence,  $\gamma = \liminf_{k \rightarrow \infty} \|g_k\| = 0$ .  $\square$

Therefore, when  $0 < \theta_k \leq 1$  our hybrid conjugate gradient algorithms are globally convergent, meaning that either  $g_k = 0$  for some  $k$  or (24) holds. Observe that in the conditions of Theorem 2 the direction  $d_{k+1}$  satisfies the sufficient descent condition independent of the line search.

### Numerical Experiments

In this section we present the computational performance of a Fortran implementation of the CCOMB and NDOMB algorithms for a set of 750 unconstrained optimization test problems. The test problems are the unconstrained problems in the CUTE [6] library, along with other large-scale optimization problems presented in [1]. We selected 75 large-scale unconstrained optimization problems in extended or generalized form. Each problem was tested ten times for a gradually increasing number of variables:  $n = 1000, 2000, \dots$ ,

10000. At the same time we present comparisons with other conjugate gradient algorithms, including the performance profiles of Dolan and Moré [14].

All algorithms implement the Wolfe line search conditions with  $\rho = 0.0001$  and  $\sigma = 0.9$ , and the same stopping criterion  $\|g_k\|_\infty \leq 10^{-6}$ , where  $\|\cdot\|_\infty$  is the maximum absolute component of a vector.

The comparisons of algorithms are given in the following context. Let  $f_i^{ALG1}$  and  $f_i^{ALG2}$  be the optimal values found by ALG1 and ALG2, for problem  $i = 1, \dots, 750$ , respectively. We say that, in the particular problem  $i$ , the performance of ALG1 was better than the performance of ALG2 if

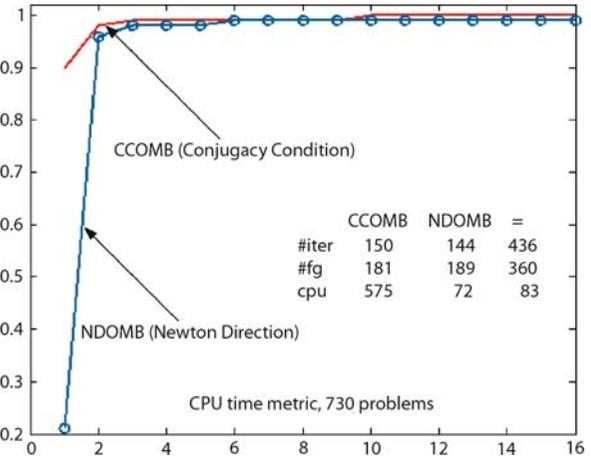

$$|f_i^{ALG1} - f_i^{ALG2}| < 10^{-3} \tag{30}$$

and the number of iterations, or the number of function-gradient evaluations, or the CPU time of ALG1 was less than the number of iterations, or the number of function-gradient evaluations, or the CPU time corresponding to ALG2, respectively.

All codes were written in double-precision Fortran and compiled with f77 (default compiler settings) on an Intel Pentium 4, 1.8 GHz workstation. All these codes were authored by Andrei. The performances of these algorithms were evaluated using the profiles of Dolan and Moré [14]. That is, for each algorithm we plotted the fraction of problems for which the algorithm is within a factor of the best CPU time. The left side of these figures gives the percentage of the test problems, out of 750, for which an algorithm is more performant; the right side gives the percentage of the test problems that were successfully solved by each of the algorithms. Mainly, the right side represents a measure of an algorithm's robustness.

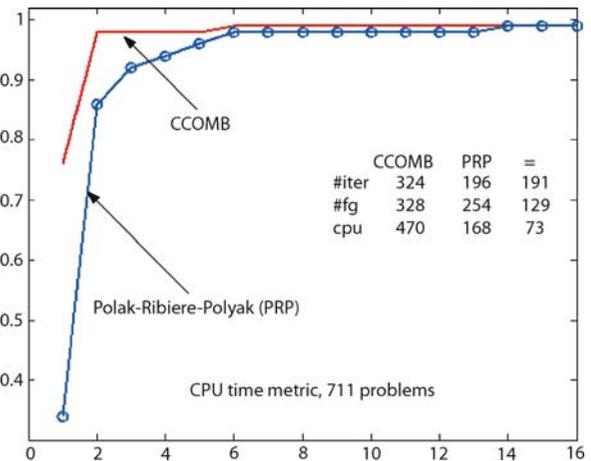

In the first set of numerical experiments, we compared the performance of the CCOMB algorithm with the performance of the NDOMB algorithm. Figure 1 shows the Dolan and Moré CPU performance profile of the CCOMB algorithm compared with that of the NDOMB algorithm.

Observe that the CCOMB algorithm outperforms the NDOMB algorithm in the vast majority of problems. Only 730 problems out of 750 satisfy criterion (30). Referring to the CPU time, the CCOMB algorithm was better in 575 problems, in contrast to the NDOMB algorithm, which solved only 72 problems in a better CPU time.

Performance based on CPU time: CCOMB algorithm compared with the NDOMB algorithm

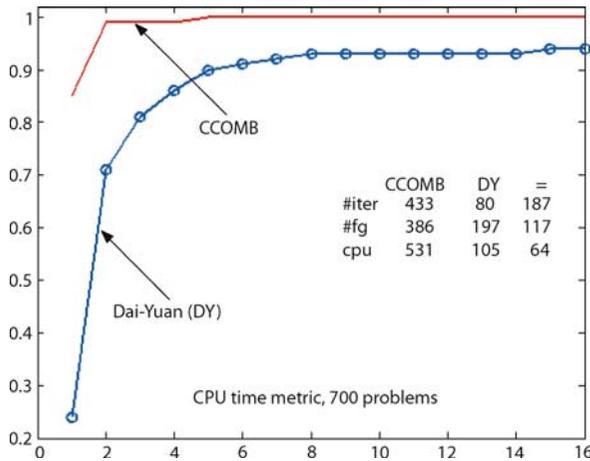

New Hybrid Conjugate Gradient Algorithms for Unconstrained Optimization, Figure 2

Performance based on CPU time: CCOMB algorithm compared with the Polak-Ribiere-Polyak (PRP) algorithm

In the second set of numerical experiments we compared the performance of the CCOMB algorithm with the performances of the PRP and DY conjugate gradient algorithms. Figures 2 and 3 show the Dolan and Moré CPU performance profiles of the CCOMB algorithm compared with those of the PRP and DY algorithms, respectively.

When comparing the CCOMB and PRP algorithms (Fig. 2), subject to the number of iterations, we see that the CCOMB algorithm was better in 324 problems (i. e.,

New Hybrid Conjugate Gradient Algorithms for Unconstrained Optimization, Figure 3

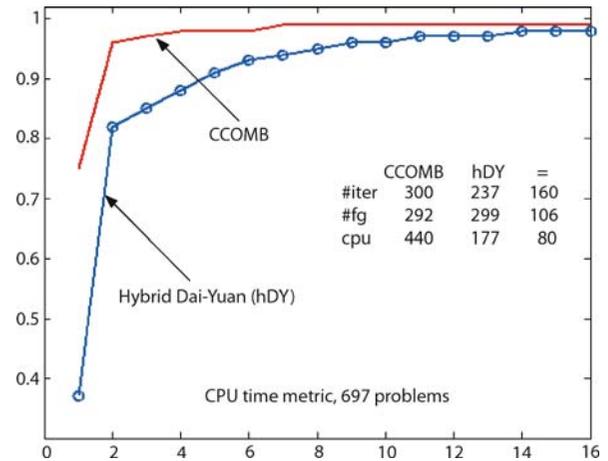

Performance based on CPU time: CCOMB algorithm compared with the Dai-Yuan (DY) algorithm

it achieved the minimum number of iterations in 324 problems), the PRP algorithm was better in 196 problems and they achieved the same number of iterations in 191 problems, etc. Out of 750 problems, only for 711 problems does criterion (30) holds. Similarly, in Fig. 3 we see the number of problems for which the CCOMB algorithm was better than the DY algorithm. Observe that the convex combination of the PRP and DY algorithms, expressed as in (7), is far more successful than the PRP or the DY algorithm.

The third set of numerical experiments refers to the comparisons of the CCOMB algorithm with hybrid conjugate gradient algorithms: hDY, hDYz, GN, HuS, TS and LS-CD. Figures 4-9 presents the Dolan and Moré CPU performance profiles of these algorithms, as well as the number of problems solved by each algorithm in the minimum number of iterations, the minimum number of function evaluations and the minimum CPU time, respectively.

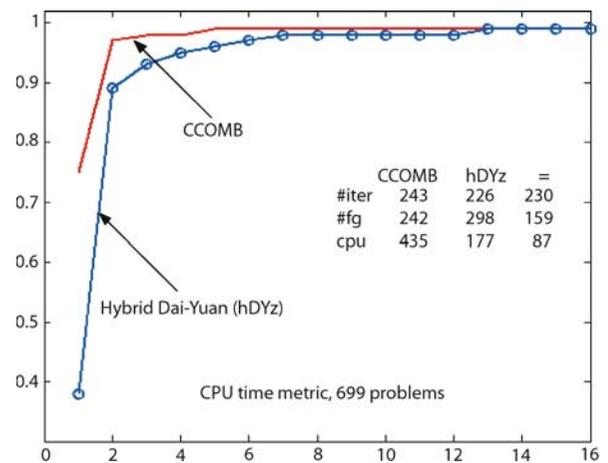

From these figures we see that the CCOMB algorithm is the top performer. Since these codes use the same Wolfe line search and the same stopping criterion they differ in their choice of the search direction. Hence, among these conjugate gradient algorithms we considered here, the CCOMB algorithm appears to generate the best search direction.

In the fourth set of numerical experiments we compared the CCOMB algorithm with the CG\_DESCENT

conjugate gradient algorithm of Hager and Zhang [18]. The computational scheme implemented in the CG\_DESCENT algorithm is a modification of the HS method which satisfies the sufficient-descent condition, independent of the accuracy of the line search. The CG\_DESCENT code, authored by Hager and Zhang, contains the variant CG\_DESCENT (HZw) implementing the Wolfe line search and the variant CG\_DESCENT (HZaw) implementing an approximate Wolfe line search. There are two main points associated

Performance based on CPU time: CCOMB algorithm compared with the Liu–Storey–conjugate descent (LS-CD) algorithm

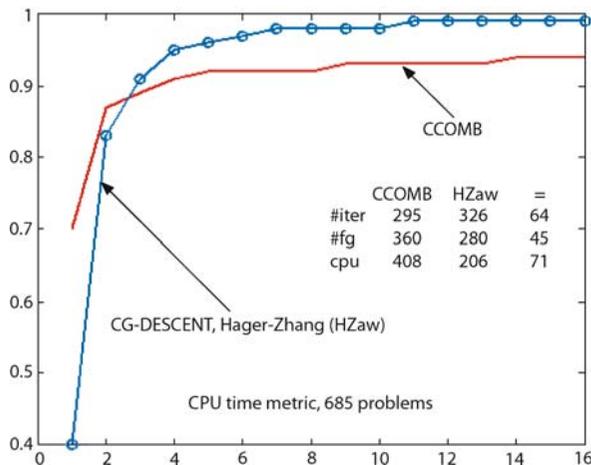

with the CG\_DESCENT algorithm. Firstly, the scalar products are implemented using the loop unrolling of depth 5. This is efficient for large-scale problems (over  $10^6$  variables). Secondly, the Wolfe line search is implemented using a very fine numerical interpretation of the first Wolfe condition (4). The Wolfe conditions implemented in the CCOMB and CG\_DESCENT (HZw) algorithms can compute a solution with accuracy of the order of the square root of the machine epsilon.

In contrast, the approximate Wolfe line search implemented in the CG\_DESCENT (HZaw) algorithm can compute the solution with accuracy of the order of machine epsilon. Figures 10 and 11 present the performance profile of these algorithms in comparison with that of the CCOMB algorithm. We see that the CG\_DESCENT algorithm is more robust than the CCOMB algorithm.

## Conclusion

We know a large variety of conjugate gradient algorithms. The known hybrid conjugate gradient algorithms are based on projection of classical conjugate gradient algorithms. In this chapter we have proposed new hybrid conjugate gradient algorithms in which the famous parameter  $\beta_k$  is computed as a con-

vex combination of  $\beta_k^{\text{PRP}}$  and  $\beta_k^{\text{DY}}$ , i.e.,  $\beta_k = (1 - \theta_k)\beta_k^{\text{PRP}} + \theta_k\beta_k^{\text{DY}}$ . The parameter  $\theta_k$  is computed in such a manner that the conjugacy condition is satisfied, or the corresponding direction in the hybrid conjugate gradient algorithm is the Newton direction. For uniformly convex functions if the step size  $s_k$  approaches zero, the gradient is bounded in the sense that  $\eta_1 \|s_k\|^2 \leq \|g_k\|^2 \leq \eta_2 \|s_{k-1}\|^2$  and the line search satisfies the strong Wolfe conditions, then our hybrid conjugate gradient algorithms are globally convergent. For general nonlinear functions if the parameter  $\theta_k$  from the  $\beta_k^{\text{N}}$  definition is bounded, i.e.,  $0 < \theta_k < 1$ , then our hybrid conjugate gradient is globally convergent. The Dolan and Moré CPU performance profile of the hybrid conjugate gradient algorithm based on the conjugacy condition (CCOMB algorithm) is better than the performance profile corresponding to the hybrid algorithm based on the Newton direction (NDOOMB algorithm). The performance profile of the CCOMB algorithm was better than those of the well-established conjugate gradient algorithms (hDY, hDYZ, GN, HuS, TS and LS-CD) for a set consisting of 750 unconstrained optimization test problems, some of them from CUTE library. Additionally the proposed hybrid conjugate gradient algorithm CCOMB is more robust than the PRP and DY conjugate gradient algorithms. However, subject to robustness the CCOMB algorithm is outperformed by the CG\_DESCENT algorithm.

### Keywords

Hemivariational inequalities; Nonsmooth modeling; Generalized subdifferential of F.H. Clarke; Nonconvex energy function

A large number of problems in mechanics, engineering and economics can be defined by means of appropriate differentiation of an *energy function*. This function is sometimes called a *potential*. On the assumption of

differentiability one may write the first order optimality condition that the gradient of the function is equal to zero at some point. All points which satisfy this condition are called *critical points*. The set of nonlinear equations derived this way are the governing equations (the model) of the studied problem. Equivalently, one may consider the requirement that the directional derivative of the function at this critical point and in all directions emanating from this point is equal to zero, or that all possible small variations of the energy function around the critical point is equal to zero. This way the critical point is described by a *variational inequality* and one speaks about a variational formulation of the problem. Whether a critical point is also a minimum of the considered energy function, or, for example, a maximum or a saddle point requires the consideration of second order optimality conditions. One should mention in passing that (possibly local) minima are of outmost importance in applications. For instance, in mechanics they provide stable equilibria of the studied mechanical systems. Convexity and coercivity of the energy function guarantees that a critical point is a minimum while strict convexity ensures its uniqueness as well.

Lack of differentiability of the energy function, or the consideration of inequality constraints in the minimization problem changes the picture. As far as the convexity property holds, one may use the powerful tools of *convex analysis* to study the problem. The gradient of the nonsmooth but convex function is replaced by the subgradient, the differential by a set-valued *subdifferential* (in the sense of J.-J. Moreau and R.T. Rockafellar) and the critical point equation by the differential inclusion: zero must be an element of the subdifferential of the energy function at minimum. Accordingly, in the variational formulation a variational equation is replaced by a variational inequality. Analogous considerations hold true for the case of inequality constraints. Here, one has, in principle, two ways to study the problem. Either all admissible variations are taken into account in the derivation of the optimality conditions, or the inequality constraints are included by means of the indicator function of the admissible set in the set of the problem's variables. Following Moreau, who introduced and studied convex analysis and applied it for the solution of mechanical problems, a convex nondifferentiable potential energy function is called a *superpotential*.

Admittedly, convexity is a convenient assumption too good to be true in real life applications. The study of nonconvex energy functions requires new tools and methods, which are being developed within the area of nonconvex analysis. Among them, the notion of the generalized gradients in the sense of F.H. Clarke, Rockafellar [2] has found several applications. Concerning the search for minima of a nonconvex energy function one may formulate critical point problems. Under certain assumptions the generalized gradient of Clarke provides a useful tool for the formulation and the study of nonconvex and nonsmooth energy function problems. In the area of mechanics, P.D. Panagiotopoulos has been the first to introduce and use this notion. He called the resulting nonconvex variational inequalities *hemivariational inequalities*. Initially, the notion of Clarke, which is suitable for locally Lipschitz energy functions, has been used. Later, the extended notion of Rockafellar, which roughly speaking includes infinite vertical branches, has been considered. Later, he extended this analysis by incorporating inequality constraints or convex superpotential terms (as in the case of convex problems), which have been inspired from the engineering applications he studied. Thus, he formulated and studied *variational-hemivariational inequality* problems. On the analogy of convex analysis, the nonconvex and possibly nondifferentiable energy functions have been called by Panagiotopoulos *nonconvex superpotentials*. Once more, it should be emphasized here that hemivariational inequalities are not equivalent to minimum problems but to substationarity problems. Nevertheless, they constitute a consistent extension of variational inequalities, and they include them for the case of convex energy functions. Furthermore, and this is important for some numerical algorithms, as with the subdifferential of convex analysis the generalized subdifferential of Clarke involves one convex set in the set-valued approximation of the differential of a nonconvex and nonsmooth energy function. Consequently, the development of theory and algorithms runs in parallel with the ones developed for problems of convex analysis and of variational inequalities. It should be mentioned that propositions of substationary potential and complementary energy generalize the classical minimum energy propositions of mechanics (where, for historical reasons, they are known as principles). Moreover, following the example of *nonsmooth analy-*

sis, Panagiotopoulos named the whole area of mechanics which deals with nondifferentiable functions *nonsmooth mechanics*.

In this article the notions of generalized derivative of Clarke and Rockafellar and the definition of the substationarity points are first given. After that, the hemivariational and the variational-hemivariational inequalities of Panagiotopoulos are presented. Short comments on the theoretical tools which are used for their study, examples of applications and numerical algorithms which have been proposed for their solution complete the paper. Details on all previous issues can be found in the cited publications. See also ► **hemivariational inequalities: applications in mechanics**.

**Clarke’s Generalized Derivative**

Let a function  $f$  be locally Lipschitz at  $x \in X$  and let  $y$  be a vector in  $X$ . The *directional differential in the sense of Clarke* of  $f$  at  $x$  in the direction  $y$ , denoted by  $f^0(x, y)$ , is defined by the relation:

$$f^0(x, y) = \limsup_{\substack{\mu \rightarrow 0+ \\ h \rightarrow 0}} \frac{f(x + h + \mu y) - f(x + h)}{\mu}.$$

$f^0(x, y)$  is also called a *generalized directional differential*.

By means of the directional differential  $f^0(x, y)$  one can now define the *generalized gradient*  $\bar{\partial}f(x): X \rightarrow X^*$ :

$$\bar{\partial}f(x) = \left\{ x^* \in X^* : \begin{matrix} f^0(x, x_1 - x) \geq (x^*, x_1 - x) \\ \forall x_1 \in X \end{matrix} \right\}. \quad (1)$$

One may also use the definition

$$\bar{\partial}f(x) = \{x^* \in X^* : (x^*, -1) \in N_{\text{epi} f}(x, f(x))\}, \quad (2)$$

where  $N_C(x)$  denotes the normal cone to a set  $C$  at point  $x$  and  $\text{epi} f$  is the epigraph of the function  $f$ .

Note that  $\bar{\partial}f(\cdot)$  is a multivalued mapping; it is a nonempty convex, closed and bounded subset of  $X^*$  and the following relation holds true:

$$f^0(x, y) = \max \{ \langle y, x^* \rangle : x^* \in \bar{\partial}f(x) \}. \quad (3)$$

For didactical reasons the notation  $\bar{\partial}$  is used here (and in most of the work of Panagiotopoulos). In honor of

Clarke who proposed it, the notation  $\partial_{\text{CL}}$  is sometimes used. When misunderstanding is not expected, the notation  $\partial$ , which is usually reserved for the convex analysis subdifferential, is also used. It should also be noted here that  $\bar{\partial}$  should not be confused with the superdifferential used in the theory of quasidifferentiability in the sense of V.F. Demyanov.

Relation (1) can be used to define the generalized gradient  $\bar{\partial}f(x)$  for any type of function  $f: X \rightarrow \overline{\mathbb{R}}$  which is finite at the point  $x$ . Note that  $\bar{\partial}f(x)$  may be empty. The above definition of  $\bar{\partial}f(x)$  for any function  $f: X \rightarrow \overline{\mathbb{R}}$  makes sense, because the normal cone  $N_C(x)$  can be defined with respect to any set  $\text{epi} f$ . The generalized directional differential  $f^\uparrow(x; y)$  at  $x$  in the direction  $y$  is defined by the relation:

$$f^\uparrow(x, y) = \sup \{ \langle y, x^* \rangle : x^* \in \bar{\partial}f(x) \}. \quad (4)$$

Thus one may write the relation:

$$\bar{\partial}f(x) = \left\{ x^* \in X^* : \begin{matrix} f^\uparrow(x, x_1 - x) \geq (x^*, x_1 - x) \\ \forall x_1 \in X \end{matrix} \right\}. \quad (5)$$

The directional differential  $f^\uparrow(x; y)$  is also called *directional differential in the sense of Rockafellar* [15]. Note that  $\bar{\partial}f(x) = \emptyset$  if  $f^\uparrow(x, 0) = -\infty$ , while if  $f^\uparrow(x, y)$  is finite for every  $y$ , then  $\bar{\partial}f(x) \neq \emptyset$ .

It should be noted that for a convex function  $f$  one has

$$f^\uparrow(x, y) = \liminf_{y \rightarrow y} f'(x, \tilde{y}), \quad \forall y \in X, \quad (6)$$

where  $f'(\cdot, \cdot)$  denotes the one-sided directional Gâteaux differential. Moreover, for a locally Lipschitz function  $f$  at point  $x$  one has

$$f^\uparrow(x, y) = f^0(x, y), \quad \forall y \in X, \quad (7)$$

and for a continuously differentiable  $f$ :

$$\bar{\partial}f(x) = \{\text{grad} f(x)\}. \quad (8)$$

**Examples**

For a convex function  $f$  one has

$$\bar{\partial}f(x) = \partial f(x), \quad (9)$$

and for a concave and bounded below on a neighborhood of  $x$  function  $f$ :

$$\bar{\partial}f(x) = -\partial(-f)(x) \tag{10}$$

at every point  $x$  where  $f$  is finite. The *indicator function*  $I_C$  of a (generally nonconvex) set  $C$  is defined by  $I_C(x) = 0$  if  $x \in C$ , and  $I_C(x) = \infty$  otherwise. It can be proved that

$$\bar{\partial}I_C(x) = N_C(x) \tag{11}$$

and

$$I_C^\uparrow(x, y) = I_{T_C(x)}(y). \tag{12}$$

In the finite-dimensional case  $X \equiv \mathbf{R}^n$ , for a locally Lipschitz function  $f$  at a point  $x$ ,  $\bar{\partial}f(x)$  is the convex hull of all points  $y \in \mathbf{R}^n$  of the form

$$y = \lim_{i \rightarrow \infty} \text{grad } f(x_i), \tag{13}$$

where  $x_i$  converges as  $i \rightarrow \infty$  to  $x$ , avoiding the non-differentiability points and any other points of a set of measure zero (in the sense of Lebesgue) and such that  $\text{grad } f(x_i)$  converges.

For a *maximum-type function*  $f$ , i. e., when the function is defined by means of continuously differentiable functions  $\varphi_i = \varphi_i(x)$ ,  $i = 1, \dots, m$ ,  $x \in \mathbf{R}^n$  by the relation:  $f = \max \{\varphi_1, \dots, \varphi_m\}$ , one has

$$\bar{\partial}f(x) = \text{co} \{ \text{grad } \varphi_i(x) : i \in I(x) \}, \tag{14}$$

where  $I(x) = \{i: \varphi_i(x) = f(x)\}$  is the active index set.

The *normal cone* to a set defined by:  $C = \{x \in \mathbf{R}^n: f(x) \leq 0\}$  at a point  $x_0$  with  $f(x_0) = 0$  is described by the relation

$$N_C(x_0) \subset \left\{ \lambda x^* : x^* \in \mathbf{R}^n, \lambda \geq 0, x^* \in \bar{\partial}f(x_0) \right\},$$

whenever  $f$  is Lipschitzian on a neighborhood of  $x_0$  and  $0 \notin \bar{\partial}f(x_0)$ . The notion of  $\bar{\partial}$ -regularity assures that directional derivative information can be regained from the Clarke's notion. For a locally Lipschitz function one requires that  $f^0(x, y) = f'(x, y)$ ,  $\forall y \in X$ , holds at  $x$ . This definition is equivalent to the statement that  $\text{epi } f$  is regular at  $(x, f(x))$ . For instance, a convex function and a maximum type function are  $\bar{\partial}$ -regular at a point

$x$  where they are finite. For example, for the max-type function  $f = \max \{\varphi_1, \dots, \varphi_m\}$  one has

$$N_C(x_0) = \bar{\partial}I_C(x_0) = \left\{ z = \sum_{i=1}^m \lambda_i \text{grad } \varphi_i(x_0) : \begin{array}{l} \lambda_i \geq 0, \\ \varphi_i(x_0) \leq 0, \\ \lambda_i \varphi_i(x_0) = 0 \end{array} \right\}, \tag{15}$$

if  $0 \notin \bar{\partial}f(x_0)$ . The above relation permits the extension of the Lagrange multiplier rule for optimization problems subjected to the nonconvex inequality constraints  $\varphi_i(x) \leq 0$ ,  $i = 1, \dots, m$ . This becomes obvious, e. g. if one considers the search for a local minimum problem of a continuously differentiable function  $g: \mathbf{R}^n \rightarrow \mathbf{R}$  over  $C = \{x \in \mathbf{R}^n: \varphi_i(x) \leq 0, i = 1, \dots, m\}$ . A necessary condition is  $0 \in \bar{\partial}(g + I_C)(x)$ , which implies that

$$-\text{grad } g(x) \in \bar{\partial}I_C(x), \tag{16}$$

which together with (15) leads to the Lagrange multiplier rule.

### Critical Points and Substationarity

The notion of *substationarity* plays an important role in the theory of hemivariational inequalities because it permits the formulation of the propositions of substationary potential and complementary energy which generalize the corresponding classical minimum energy propositions in mechanics [12,13,14]. Point  $x_0$  is a *substationarity point of a functional*  $f: X \rightarrow \overline{\mathbf{R}}$  if

$$0 \in \bar{\partial}f(x_0). \tag{17}$$

Equivalently one has:

$$f^\uparrow(x_0, y) \geq 0, \quad \forall y \in X. \tag{18}$$

Substationarity points are all the classical stationarity points, all the local minima, a large class of local maxima, as well as all the saddle points. Point  $x$  is said to be a *substationarity point of  $f$  with respect to a set  $C$* , if  $f + I_C$  is substationary at  $x$ .

### Nonconvex Energy Functions

The nonconvex superpotentials resulting by integrating discontinuous functions  $\beta \in L_{loc}^\infty(\mathbf{R})$  play an important

role in the formulation of hemivariational inequalities for several types of mechanical problems. After some technical details about filling in gaps in a multifunction, nonmonotone laws in mechanics which admit a nonconvex energy function will be introduced.

**Filling the Gaps in a Multifunction**

Suppose that  $\beta: \mathbf{R} \rightarrow \mathbf{R}$  is a function such that  $\beta \in L^\infty_{\text{loc}}(\mathbf{R})$ , i. e. a function which is essentially bounded on any bounded interval of  $\mathbf{R}$ . For any  $\rho > 0$  and  $\xi \in \mathbf{R}$  let us define

$$\bar{\beta}_\rho(\xi) = \operatorname{ess\,inf}_{\|\xi_1 - \xi\| \leq \rho} \beta(\xi_1) \tag{19}$$

and

$$\bar{\bar{\beta}}_\rho(\xi) = \operatorname{ess\,sup}_{\|\xi_1 - \xi\| \leq \rho} \beta(\xi_1). \tag{20}$$

Obviously, the monotonicity properties of  $\rho \rightarrow \bar{\beta}_\rho(\xi)$  and  $\rho \rightarrow \bar{\bar{\beta}}_\rho(\xi)$  imply that the limits as  $\rho \rightarrow 0_+$  exist. Therefore one may write that:  $\bar{\beta}(\xi) = \lim_{\rho \rightarrow 0_+} \bar{\beta}_\rho(\xi)$ . Furthermore, one defines the multivalued function:

$$\widetilde{\beta}(\xi) = [\bar{\beta}(\xi), \bar{\bar{\beta}}(\xi)], \tag{21}$$

where  $[\cdot, \cdot]$  denotes an interval between the two given arguments. Then, a locally Lipschitz function  $j$  can be determined, up to an additive constant, by the relation

$$j(\xi) = \int_0^\xi \beta(\xi_1) d\xi_1, \tag{22}$$

such that  $\bar{\partial}j(\xi) \subset \widetilde{\beta}(\xi)$ . If moreover  $\beta(\xi_\pm)$  exist for each  $\xi \in \mathbf{R}$ , then one has  $\bar{\partial}j(\xi) = \widetilde{\beta}(\xi)$ .

**Superpotential Nonmonotone Laws**

Let us assume that one has an one-dimensional mechanical law which is described by the graph of a discontinuous function. For instance, a force-displacement law ( $S - u$ ) is considered, which may correspond to an one-dimensional nonlinear spring law, to a nonlinear boundary condition, etc. The law is con-

sidered to be of the form  $\beta: u \rightarrow -S$  where  $u \in \mathbf{R}$  and  $S \in \mathbf{R}$ . The procedure of (19)–(22) is used in order to define a locally Lipschitz nonconvex superpotential energy function  $j(u)$ . The mechanical law is produced, in turn, by using the previously introduced generalized subdifferential operator  $\partial_{CL} = \bar{\partial}$  and the nonconvex superpotential  $j$  as follows:

$$-f \in \partial_{CL}j(u). \tag{23}$$

By definition, (23) is equivalent to the inequality

$$j^\uparrow(u, u^* - u) \geq \langle -f, u^* - u \rangle, \quad \forall u^* \in U, \tag{24}$$

for  $u \in U$ , which Panagiotopoulos has called a hemivariational inequality, and to the inclusion

$$(-f, -1) \in N_{\operatorname{epi} j}(u, j(u)). \tag{25}$$

For  $j$  Lipschitzian,  $j^\uparrow$  in (23) is replaced by  $j^0$ . Obviously, if  $j$  is a convex superpotential, one has superpotential laws which can be described by monotone graphs with complete vertical branches. The procedure would be identical in that case as well, where  $\partial_{CL}$  is replaced by the subdifferential of convex analysis. The result would be a variational inequality. Note also that extensions to multidimensional laws (e. g., material constitutive relations) can be considered within this formulation.

**Hemivariational Inequalities**

An abstract coercive hemivariational inequality is written first. Let  $V$  be a real Hilbert space with the property that  $V \subset [L^2(\Omega)]^n \subset V^*$ , where  $V^*$  denotes the dual space of  $V$ , and the injections are continuous and dense. Let moreover a boundary value problem be defined in an open, bounded subset  $\Omega$  of  $\mathbf{R}^n$ . Here  $(\cdot, \cdot)$  denotes the  $[L^2(\Omega)]^n$  inner product and the duality pairing,  $\|\cdot\|$  is the norm of  $V$  and  $|\cdot|_2$  is the  $[L^2(\Omega)]^n$ -norm. One should recall that the form  $(\cdot, \cdot)$  extends uniquely from  $V \times L^2[(\Omega)]^n$  to  $V \times V^*$ . Moreover let  $L: V \rightarrow L^2(\Omega)$ ,  $Lu = \widehat{u}, \widehat{u}(x) \in \mathbb{R}$  be a linear continuous mapping. Further, assume that  $l \in V^*$ , that  $L: V \rightarrow L^2(\Omega)$  and that  $\widetilde{V} = \{v \in V: \widehat{v} \in L^\infty(\Omega)\}$  is dense in  $V$  for the  $V$ -norm, and has a Galerkin base in  $V$ . It is also assumed that  $a(\cdot, \cdot): V \times V \rightarrow \mathbf{R}$  is a bilinear symmetric continuous form which is *coercive*, i. e. there exists a constant  $c$

$> 0$  such that

$$a(v, v) \geq c \|v\|^2, \quad \forall v \in V. \quad (26)$$

A *coercive hemivariational inequality problem* reads: Find  $u \in V$  such that

$$a(u, v - u) + \int_{\Omega} j^0(\widehat{u}, \widehat{v} - \widehat{u}) \, d\Omega \geq (l, v - u), \quad (27)$$

$$\forall v \in V.$$

For example, a linear elastostatic structural analysis problem with additional nonlinear elements of non-monotone type which admit a nonconvex superpotential  $j(u)$  can be written in the hemivariational inequality form (25). In this context  $u$  are the displacements at the various points of the structure, which occupies  $\Omega$  in its undeformed configuration. For a plate problem one has  $\Omega \subset \mathbf{R}^2$ , for a three-dimensional continuum  $\Omega \subset \mathbf{R}^3$ , etc. Moreover the functional space  $V$  is dictated from the kind of the assumed application and from the (natural, support) boundary conditions of the structure. The operator  $L$  and the energy form  $(u, u)$  depend on the mechanical theory used for the elastic part of the structure, while  $l$  denotes the external loading. Finally, coercivity usually means that a well-defined mechanical theory has been assumed and sufficient boundary conditions are assigned so that, for example, no rigid body motions of the structure are allowed. Finally, one should note that the familiar form of the principle of virtual work (i. e., a variational equality) can be obtained back from the hemivariational inequality (27) if the effect of the nonlinear terms is neglected, i. e., if the second term on the left-hand side of (27) is absent and if an equality is assumed in the place of the inequality.

### Theoretical Studies

One recalls that the theory of the existence of solution of variational inequalities is a well-developed theory in mathematics which is closely connected with the convexity of the energy functionals involved. Indeed the existence theory of variational inequalities is based on monotonicity arguments. On the contrary the study of hemivariational inequalities, due to the absence of convexity is based on compactness arguments. Existence and approximation results for hemivariational inequalities have been studied for several applications.

See [11,14] for details and citations to related references.

### Semicoercive Case

Noncoercive problems arise in mechanics, for example, when the existing classical boundary conditions are not sufficient to prevent (even infinitesimal) rigid body displacements and rotations of the structure. In classical, equality mechanics, one may write conditions that guarantee the existence of a solution to the considered boundary value problem. Nevertheless, uniqueness of some quantities may be lost. One may consider, as an example, a free elastic body subjected to self-equilibrated external forces. In this case stresses and deformations of the elastic body can be determined, but its displacements are only determined modulo some rigid body displacements and rotations. In the presence of inequality (e. g., unilateral contact) constraints analogous relations have also been provided by G. Fichera (see, e. g., [13, Chap. 4]). It is interesting to observe that some inequality constraints may be activated and stabilize the body, a result that has certain applications in robotics [1].

For hemivariational inequalities, analogous results have been obtained by Panagiotopoulos and coworkers (see also [4]). One such result for an abstract hemivariational inequality is given here, without proof. Here  $a(\cdot, \cdot)$  is assumed to be *semicoercive*, i. e.,  $a(\cdot, \cdot)$  is continuous and symmetric but it has a nonzero kernel, i. e.  $\ker a(\cdot, \cdot) = \{q: a(q, q) = 0\} \neq \{0\}$ . Moreover let  $\ker a$  be finite dimensional. Let us assume that the norm  $\|v\|$  on  $V$  is equivalent to  $\| \|v\| \| = p(\widetilde{v}) + \|q\|_2$ , where  $v = \widetilde{v} + q$ ,  $q \in \ker a$ ,  $\widetilde{v} \in \ker a^\perp$  (i. e.  $(\widetilde{v}, q) = 0$ ,  $\forall q \in \ker a$ ) and  $p(\widetilde{v})$  is a seminorm on  $V$  such that  $p(v) = p(v + q)$ ,  $\forall v \in V$ ,  $q \in \ker a$ , and let  $a(v, v) \geq c(p(v))^2$ ,  $\forall v \in V$ ,  $c = \text{const} > 0$ . This semicoercivity inequality replaces (26) for the coercive case. Moreover, let  $q_+$  and  $q_-$  be the positive and negative parts of  $\widehat{q}$ , where  $\widehat{q} = Lq$ , i. e.  $q_+ = \max\{0, \widehat{q}\}$ ,  $q_- = \max\{0, -\widehat{q}\}$ . The following quantities will also be used:  $\beta(-\infty) = \limsup_{\xi \rightarrow -\infty} \beta(\xi)$  and  $\beta(\infty) = \liminf_{\xi \rightarrow \infty} \beta(\xi)$ . On the assumption that

$$\beta(-\infty) \leq \beta(\xi) \leq \beta(\infty), \quad \forall \xi \in \mathbb{R}, \quad (28)$$

a necessary condition for the existence of a solution  $u \in V$  of a semicoercive hemivariational inequality problem

is the following inequality:

$$\begin{aligned} \int_{\Omega} [\beta(-\infty)q_+ - \beta(\infty)q_-] d\Omega &\leq (l, q) \\ &\leq \int_{\Omega} [\beta(\infty)q_+ - \beta(-\infty)q_-] d\Omega, \end{aligned} \quad (29)$$

$\forall q \in \ker a.$

If (28) holds strictly (with  $<$  instead of  $\leq$ ), then (29) also holds strictly.

### Substationarity of the Energy

Equivalent to the hemivariational inequality is the following *substationarity problem*: Find  $u \in V$  such that the superpotential energy functional

$$\Pi(v) = \frac{1}{2}a(v, v) + \int_{\Omega} j(\widehat{v}) d\Omega - (l, v) \quad (30)$$

is substationary at  $v = u$ . Here, the integral  $\int_{\Omega} j(\widehat{v}) d\Omega$  is set equal to  $\infty$  if it is not defined.

Recall that the latter problem is, by definition, equivalent to: Find  $u \in V$  which is a solution of the inclusion

$$0 \in \partial\Pi(u). \quad (31)$$

The equivalence of the above defined substationarity problem with the hemivariational inequality can be proved, on the assumption that  $j$  is locally Lipschitz and  $\partial$ -regular

### Applications

Several types of hemivariational inequalities have already been studied (see, for example, [13,14], and the references given there) with respect to certain engineering problems, e. g. in nonmonotone semipermeability problems, in the theory of multilayered plates (delamination), in the theory of composite structures, in the theory of partial debonding of adhesive joints etc.

### Numerical Algorithms

Till now (1998), the following methods have been investigated for the numerical solution of hemivariational inequality problems in mechanics.

- Nonsmooth optimization algorithms (in particular, of the *bundle algorithm* optimization type), for the solution of the inclusion (31). See [6,9] and, for the bundle nonsmooth optimization concept, e. g., [7].

- Decomposition into a series of convex subproblems (for instance, into a number of variational inequalities). For the numerical treatment of problems in elastostatics this approach has been the most fruitful, according to the experience of the authors. The decomposition has been based either on engineering motivated methods and heuristics (cf., [8]), or on mathematical programming techniques. In the last case results from the theory of quasidifferentiability [3], of difference-convex optimization [10] and of enumeration-type or branch and bound procedures [16] have been tested. More details can be found in [3,5,10,14].

### Keywords

Economy of scale; Global optimization; Nonconvex programming; Flows in networks; Fixed charge networks; Network design

The basic *network flow problem* can be formulated as

$$\left\{ \begin{array}{l} \min \quad \sum_{(i,j) \in A} \phi_{ij}(x_{ij}) \\ \text{s.t.} \quad \sum_{(n,j) \in A} x_{nj} - \sum_{(i,n) \in A} x_{in} = b_n, \\ \quad \quad \quad \forall n \in N, \\ \quad \quad \quad l_{ij} \leq x_{ij} \leq u_{ij}, \quad \forall (i,j) \in A, \end{array} \right. \quad (1)$$

where  $A$  is the (directed) arc set with generic element  $(i, j)$ ;  $N$  is the node set with generic element  $n$ ;  $b_n$  is the *net supply* (if  $b_n > 0$ ) or *net demand* (if  $b_n < 0$ ) at node  $n$ ;  $u_{ij}$  (respectively,  $l_{ij}$ ) is the flow upper (respectively, lower) bound for arc  $(i, j)$ ;  $x_{ij}$  is the *flow decision variable* for arc  $(i, j)$ ; and  $\phi_{ij}(x_{ij})$  is the *cost function* for arc  $(i, j)$ .

It is assumed that  $\sum_{n \in N} b_n = 0$  (otherwise, a dummy supply node or demand node can be added to  $N$  to enforce this condition). The *objective function* in (1) minimizes total costs in the network; the first constraints are *node flow balance equations*; and the second constraints are *arc flow bounds*. Extensions to the basic network flow problem given above include *multicommodity networks*, *generalized networks* (i. e., networks with arc flow gains or losses), and *augmented networks* (i. e., formulations with additional constraints and/or decision variables in addition to  $x_{ij}$ ) (see, for example, [1]).

If the cost function  $\phi_{ij}(x_{ij})$  is a *nonconvex function* for one or more of the arcs in set  $A$ , then (1) is referred to as a *nonconvex network flow problem* (NNFP). The most commonly used cost function in a NNFP is a *fixed charge function*, of the form

$$\phi_{ij}(x_{ij}) = \begin{cases} 0 & \text{if } x_{ij} = 0, \\ \alpha_{ij} + \beta_{ij} \cdot x_{ij} & \text{if } x_{ij} > 0, \end{cases} \quad (2)$$

where  $\alpha_{ij}$  and  $\beta_{ij}$  are coefficients with  $\alpha_{ij} \geq 0$  (and  $l_{ij} = 0$ ). By incurring the quantum of cost  $\alpha_{ij}$  before flow can be carried on arc  $(i, j)$ , fixed charge NNFPs can be used to model a variety of network design and expansion [29], lot sizing [17], and facility location [6,30] problems. Classical combinatorial problems, such as traveling salesperson and 0–1 knapsack problems, can also be represented as fixed charge NNFPs. In fact, any mathematical programming problem that can be formulated as an integer program with integer coefficients can be recast as a fixed charge NNFP [28].

Another common form of cost function in a NNFP is a concave quadratic function, of the form

$$\phi_{ij}(x_{ij}) = \alpha_{ij} + \beta_{ij} \cdot (x_{ij} - \gamma_{ij})^2, \quad (3)$$

where  $\alpha_{ij}$ ,  $\beta_{ij}$ , and  $\gamma_{ij}$  are coefficients with  $\beta_{ij} \leq 0$ . Concave quadratic NNFPs are used to model arc flow economies of scale which are present in many communication [32], water resource [10], and physical distribution [22] problems.

A third type of cost function used in NNFPs is the ‘sawtooth’ function. A simple two-piece sawtooth function is given by

$$\phi_{ij}(x_{ij}) = \begin{cases} \alpha_{ij} \cdot x_{ij} & \text{if } x_{ij} < \gamma_{ij}, \\ \beta_{ij} \cdot x_{ij} & \text{if } x_{ij} \geq \gamma_{ij}, \end{cases} \quad (4)$$

where  $\alpha_{ij}$ ,  $\beta_{ij}$ , and  $\gamma_{ij}$  are coefficients with  $\alpha_{ij} \geq \beta_{ij}$  and  $l_{ij} \leq \gamma_{ij} \leq u_{ij}$ . Functions of the form (4) are used to represent price-breaks and other types of all-units discounting [7] that occur, for instance, in network representations of inventory [33] and cash flow management problems [24].

The NNFP is in the class of NP-hard problems [14]. Thus, determining the *global minimum* to an NNFP is challenging because of the existence of many feasible points that are locally, but not globally, optimal. G.M. Guisewite [18] distinguishes between NNFPs with concave cost functions (such as (2) and (3)) and indefinite cost functions (that is, functions that are neither concave nor convex, such as (4)). For concave NNFPs, if the constraints in (1) are feasible, then there exists an optimal extreme point solution. Further, if the coefficients  $b_n$ ,  $l_{ij}$ , and  $u_{ij}$  in (1) are integer-valued, then the optimal arc flows  $x_{ij}^*$  will also be integer-valued [4].

One of the earliest solution methods for concave NNFPs was proposed by B. Yaged [32]. This method uses successive linearizations of the concave cost function. It quickly converges to a local (but not necessarily global) minimum. Other approximate methods for concave NNFPs involve dual ascent [2,9], Lagrangian relaxation [11], local extreme point search techniques [13,21], and tabu search methods [16].

Exact methods for concave NNFPs generally rely on the underlying network topology. For problems with an arbitrary network topology, branch and bound procedures using rectangular partitioning are the most widely used techniques [3,5,26,30]. If the number of supply nodes or demand nodes in the set  $N$  is limited, then dynamic programming approaches are tractable [8,17,20]. Alternatively, if there are only a small number of arcs in the set  $A$  with a nonlinear cost function, then parametric programming techniques may be employed [25].

For the second type of NNFP – with an indefinite form of cost function – the optimal solution to (1) is not necessarily at an extreme point of the feasible region. For cases where the indefinite cost function is piecewise-linear but not necessarily continuous (as is the case in (4)), then the problem can be formulated and solved as a mixed integer program. If the indefinite function is continuous (and satisfies certain regularity properties), then it can be converted to a difference convex function (d.c. function) and the indefinite NNFP

can be solved as a specialized difference convex programming problem [31]. For more general functions, the indefinite NNFP can be converted (at least in principle) to a concave NNFP on an expanded network. Then, the concave NNFP solution techniques can be applied the problem on the expanded network [27].

See [12,15,18,19,22,23] for additional discussion of applications and solution methods for NNFPs.

Variational-hemivariational inequality; Generalized critical point; Unilateral mechanics

Problems in *unilateral mechanics* involving both monotone and nonmonotone unilateral boundary conditions have as variational formulations the so-called variational-hemivariational inequalities [5]. Solutions of these mathematical models can be determined as the critical points of some energy functionals which can usually be expressed as the sum of a locally Lipschitz function  $\Phi: X \rightarrow \mathbf{R}$  and a proper, convex and lower semicontinuous function  $\Psi: X \rightarrow \mathbf{R} \cup \{+\infty\}$ . The critical points of  $I := \Phi + \Psi$  are here defined as the solutions of the *variational-hemivariational inequality*:

$$u \in X : \Phi^o(u; v - u) + \Psi(v) - \Psi(u) \geq 0, \quad \forall v \in X. \quad (1)$$

For example, let us consider a linear elastic body identified with an open bounded subset  $\Omega \subset \mathbf{R}^3$ . The boundary  $\Gamma$  of the body  $\Omega$  is assumed to consist of three open disjoint parts  $\Gamma_1, \Gamma_2$  and  $\Gamma_3$ , i.e.  $\Gamma = \overline{\Gamma}_1 \cup \overline{\Gamma}_2 \cup \overline{\Gamma}_3$ . Let us denote by  $u = (u_i), \sigma = (\sigma_{ij}), \varepsilon = (\varepsilon_{ij}), S = (S_i)$  the displacement vector, the stress tensor, the strain tensor and the stress vector, respectively. It is supposed that the body is subject to a body density force  $f \in L^2(\Omega; \mathbf{R}^3)$ . Moreover, one compels the part  $\Gamma_1$  of the body to satisfy the constraint

$$u(x) \in Q(x), \quad \forall x \in \Gamma_1, \quad (2)$$

where  $Q(x)$  is defined as follows:

$$Q(x) := \{y \in \mathbf{R}^3 : g(x, y) \leq 0\}, \quad (3)$$

where  $g: \Gamma_1 \times \mathbf{R}^3 \rightarrow \mathbf{R}$  is continuous and convex in the second variable. Moreover, we assume that  $g(x, 0) \leq 0, \forall x \in \Gamma_1$ . Thus  $Q(x)$  is a nonempty, closed and convex subset for all  $x \in \Gamma_1$ . The formulation of these unilateral constraints has to encompass the associated forces of constraints  $r(x)$ . We assume a normal reaction law of the form

$$-r(x) \in N_{Q(x)}(u(x)), \quad \forall x \in \Gamma_1, \quad (4)$$

where for a vector  $v \in \mathbf{R}^3, N_{Q(x)}(v)$  denotes the normal cone of  $Q(x)$  at  $v$ . Note that the system (2–4) is equivalent to the variational inequality

$$u(x) \in Q(x) : r(x)^T(v - u(x)) \geq 0, \quad \forall v \in Q(x), \quad \forall x \in \Gamma_1. \quad (5)$$

The part  $\Gamma_2$  (it is assumed that  $\text{meas}(\Gamma_2) > 0$ ) of the boundary is assumed to be fixed, that is,

$$u(x) = 0, \quad \forall x \in \Gamma_2. \tag{6}$$

On  $\Gamma_3$ , we consider conditions of a unilateral contact between the body and a Winkler-type support which may sustain only limited values of traction, that is (we consider the usual decompositions  $v = v_N n + v_T$ ,  $S = S_N n + S_T$ ,  $v_N, S_N \in \mathbf{R}$ ,  $v_T, S_T \in \mathbf{R}^3$ , where  $n$  denotes the unit outward normal vector on  $\Gamma$ ):

$$-S_N \in \partial j(x, u_N(x)), \quad \forall x \in \Gamma_3, \tag{7}$$

where

$$j(x, y) := \begin{cases} 0 & \text{if } y < 0, \\ \frac{k_\sigma(x)y^2}{2} & \text{if } 0 \leq y < \varepsilon, \\ \frac{k_\sigma(x)\varepsilon^2}{2} & \text{if } y \geq \varepsilon, \end{cases}$$

and

$$S_T = C_T \quad \text{on } \Gamma_3 \tag{8}$$

with  $C_T$  given in  $L^2(\Gamma_3; \mathbf{R}^3)$ . We refer the reader to [4] for the details concerning the formulation of the subdifferential law (7). From (7), (8) and the orthogonality between  $S_N n$  and  $u_T$  and between  $S_T$  and  $u_{Nn}$ , we obtain the hemivariational inequality

$$\begin{aligned} S^\top v + j_y^0(x, u_N(x); v_N) - C_T^\top v_T &\geq 0, \\ \forall v \in \mathbf{R}^3, \quad \forall x \in \Gamma_3. \end{aligned}$$

Here  $\partial j(x, \cdot)$  stands for the Clarke subdifferential of  $j$  with respect to the second variable while  $j_y^0(x, u; v)$  denotes the generalized directional derivative of  $j$  at  $u$  in the direction  $v$  [2]. In the framework of a small deformation theory, one has the equilibrium equations

$$\sigma_{ij,j} + f_i = 0, \tag{9}$$

$$\varepsilon_{ij}(u) = \frac{1}{2}(u_{i,j} + u_{j,i}), \tag{10}$$

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl}(u), \tag{11}$$

where  $C_{ijkl} \in L^\infty(\Omega)$  denotes the elasticity tensor assumed to satisfy the usual symmetry and ellipticity properties. Suppose now that all the data are sufficiently

smooth to justify the following computations. From (9) and for a virtual displacement  $v - u$  we obtain the equation

$$-\int_{\Omega} \sigma_{ij,j}(v_i - u_i) \, dx = \int_{\Omega} f^\top(v - u) \, dx.$$

Using the Green–Gauss theorem and relations (10) and (11), we get

$$\begin{aligned} &\int_{\Omega} C_{ijkl}\varepsilon_{ij}(u)\varepsilon_{kl}(v - u) \, dx \\ &= \int_{\Omega} f^\top(v - u) \, dx + \int_{\Gamma} S^\top(v - u) \, ds. \end{aligned}$$

Using now the boundary conditions, we derive for  $v$  and  $u$  satisfying (6):

$$\begin{aligned} &\int_{\Omega} C_{ijkl}\varepsilon_{ij}(u)\varepsilon_{kl}(v - u) \, dx \\ &= \int_{\Omega} f^\top(v - u) \, dx + \int_{\Gamma_3} S_N(v_N - u_N) \, ds \\ &\quad + \int_{\Gamma_3} C_T^\top(v_T - u_T) \, ds + \int_{\Gamma_1} r^\top(v - u) \, ds. \end{aligned}$$

A combination of this last expression expressing the principle of virtual work with the mechanical laws (4) and (7), we obtain the variational-hemivariational inequality problem: Find  $u$  satisfying (2) and (6) such that

$$\begin{aligned} &\int_{\Omega} C_{ijkl}\varepsilon_{ij}(u)\varepsilon_{kl}(v - u) \, dx \\ &+ \int_{\Gamma_3} j^0(x, u_N; v_N - u_N) \, ds \\ &- \int_{\Omega} f^\top(v - u) \, dx - \int_{\Gamma_3} C_T^\top(v_T - u_T) \, ds \geq 0, \end{aligned}$$

for all  $v$  satisfying (2) and (6). This mathematical model expresses the principle of virtual works in its inequality form. Let us now present a suitable framework to formulate this last inequality model. The boundary  $\Gamma$  of the body is assumed sufficiently regular and we denote by  $\gamma: H^1(\Omega; \mathbf{R}^3) \rightarrow H^{1/2}(\Gamma; \mathbf{R}^3)$ ,  $\gamma_N: H^1(\Omega; \mathbf{R}^3) \rightarrow H^{1/2}(\Gamma)$  and  $\gamma_T: H^1(\Omega; \mathbf{R}^3) \rightarrow H_T$  (see e. g., [6] for the notations) the usual trace mapping, normal trace mapping and tangential trace mapping, respectively. We set

$$X = \{u \in H^1(\Omega; \mathbf{R}^3) : \gamma(u(x)) = 0 \text{ a.e. } x \in \Gamma_2\}$$

and

$$C = \{u \in X : \gamma(u(x)) \in Q(x) \text{ a.e. } x \in \Gamma_1\}.$$

We define the operator  $A: X \rightarrow X'$ , the element  $h \in X'$  and the functional  $J: X \rightarrow \mathbf{R}$  by the formulas:

$$\begin{aligned} \langle Au, v \rangle &:= \int_{\Omega} C_{ijkl}(x) \varepsilon_{ij}(u) \varepsilon_{kl}(v) \, dx, \\ &\quad \forall u, v \in X, \\ \langle h, v \rangle &:= \int_{\Omega} f_i v_i \, dx + \int_{\Gamma_3} C_T^\top v_T \, ds, \\ &\quad \forall v \in X, \\ J(v) &:= \int_{\Gamma_3} j(x, \gamma_N(v(x))) \, ds, \\ &\quad \forall v \in X. \end{aligned}$$

Using the rules concerning the subdifferentiation of integral functionals and composite mappings [2], we can show that

$$\begin{aligned} J^o(u, v) &\leq \int_{\Gamma_3} j^o(x, \gamma_N(u(x)); \gamma_N(u(x))) \, ds, \\ &\quad \forall u, v \in X. \end{aligned} \tag{12}$$

Setting

$$\Phi(u) = \frac{1}{2} \langle Au, u \rangle - \langle h, u \rangle + J(u)$$

and using the relation (12) we see that the equilibriums of our system can be determined by means of the variational-hemivariational inequality:

$$u \in C : \quad \Phi^o(u; v - u) \geq 0, \quad \forall v \in C,$$

or equivalently

$$u \in X : \quad \Phi^o(u; v - u) + \Psi_C(v) - \Psi_C(u) \geq 0, \quad \forall v \in X, \tag{13}$$

where  $\Psi_C$  denotes the indicator function of  $C$ . It is now natural to introduce a concept of *generalized critical point* of the energy functional  $I = \Phi + \Psi_C$  as a solution of the variational-hemivariational inequality (13) (which is a particular case of the general model given in (1)).

Various other examples in mechanics leading to a variational-hemivariational inequality like (1) are described in [5]. As a rule, the formulation of concrete problems involving both monotone and nonmonotone boundary conditions introduces a general nonsmooth and nonconvex energy functional (expressed as the sum

of a locally Lipschitz function  $\Phi: X \rightarrow \mathbf{R}$  and a proper, convex and lower semicontinuous function  $\Psi: X \rightarrow \mathbf{R} \cup \{+\infty\}$ ) whose critical points are defined as the solutions of the variational-hemivariational inequality (1). If  $\Phi \in C^1(X; \mathbf{R})$  then problem (1) reduces to a classical variational inequality. A critical point theory to deal with such case has been developed by A. Szulkin [7]. Defining a compactness condition of Palais–Smale type related to the variational inequality model and using the famous Ekeland principle, Szulkin provided a deformation lemma and extended the well-known mountain pass theorem, the saddle point theorem, the main results for even functionals, etc. Several examples including variational inequalities are given in [7]. If  $\Psi = 0$ , the problem (1) reduces to the problem studied by K.-C. Chang [1]. Motivated by the study of partial differential equations involving discontinuous nonlinearities, Chang extended the concept of critical point, the Palais–Smale condition and the deformation lemma so as to be applicable to locally Lipschitz functionals. The minimax method developed by Chang is now one of the most efficient and appreciated tools to deal with hemivariational inequalities arising in unilateral mechanics and partial differential equations involving discontinuous nonlinearities. It has been in particular extensively used by D. Goeleven, D. Motreanu, and P.D. Panagiotopoulos [3] so as to develop in several directions the theory of hemivariational inequalities (see for instance the references cited in [3]). So, the theory of Szulkin and the one of Chang has been shown very efficient to deal with problems in unilateral mechanics involving some given classes of boundary conditions. However, one has seen it above, to deal efficiently with problems in unilateral mechanics involving both monotone and nonmonotone boundary conditions it is necessary to deal with a critical point theory for functions which can be written as the sum of a locally Lipschitz function and a proper, convex and lower semicontinuous function. Such theory has now recently been developed by Goeleven, Motreanu, and Panagiotopoulos [3]. The approach combines the approach of Szulkin and the one of Chang in a nontrivial way. A general linking theorem is obtained and then used to generalize the mountain pass theorem, the saddle point theorem and the main results for even functionals. This last theory constitutes a contribution in the field of nonconvex-nonsmooth calculus of variations that unifies the theory of Szulkin

and Chang. Moreover it can be used to develop the theory of variational-hemivariational inequalities and consequently to study various concrete problems in mechanics involving different types of unilateral boundary conditions.

Nondifferentiable optimization; Nonsmooth optimization

Nondifferentiable, or nonsmooth, optimization (NDO) is concerned with problems where the smoothness assumption on the functions involved is relaxed. ‘Nondifferentiability’ means that the gradient does not exist, implying that the function may have kinks or corner points. Consequently, the function cannot be approximated locally by a tangent hyperplane, or by a quadratic approximation. In NDO, the smoothness assumption is usually replaced by weaker ones, which at least guarantees the existence of directional derivatives.

NDO problems arise in a variety of contexts, and methods designed for smooth optimization may fail to solve them. This justifies developing specialized theory and methods that are the object of this short introduction. In the sequel, we will often refer to *convex NDO*, a subclass of nondifferentiable optimization, in which functions are further assumed to be convex. Due to its global property, convexity allows stronger convergence results and finer analyses. Yet, the difficulties linked with the presence of kinks remain an important aspect, justifying special interest for this class of problems.

In the following Section, we give some basic definitions, then discuss examples of nondifferentiable optimization problems and finally, describe a few different solution techniques.

**Basic Definitions**

The basic nondifferentiable optimization problem takes the form

$$[\text{NDP}] \quad \min_{x \in \mathbf{R}^n} f(x), \quad (1)$$

where  $f$  is a real valued, continuous, nondifferentiable function. Convexity of  $f$  implies that it has at least one supporting hyperplane at every point of  $\mathbf{R}^n$ . The slopes of such hyperplanes form the set of *subgradients*, which is known as the *subdifferential set* or the *generalized gradient* [7]. At differentiable points there is a unique

supporting hyperplane whose slope is the gradient. At nondifferentiable points, there is an infinite set of subgradients and, hence, an infinite set of supporting hyperplanes.

A supporting hyperplane to  $f$  at a point  $x_0$  is given by

$$y = f(x_0) + \xi_0^\top (x - x_0),$$

where  $\xi_0$  is any element of the subdifferential  $\partial f(x_0)$  of  $f$  at  $x_0$ . Recalling the fact that it is a supporting hyperplane leads to the *subgradient inequality*

$$f(x_0) + \xi_0^\top (x - x_0) \leq f(x). \quad (2)$$

Subgradients are defined by this inequality.

Determining the whole subdifferential set is generally an extremely difficult, or impossible, task. If the function  $f$  is polyhedral, the number of extreme points of the subdifferential may be exponential in the dimension of the underlying space. A complete description of the subdifferential can be accomplished for simple situations, such as the one when  $f$  is the maximum of a finite number of convex differentiable functions:  $f(x) = \max_{i \in I} f_i(x)$ . The subdifferential  $\partial f(x_0)$  is then given by

$$\partial f(x_0) = \left\{ \sum_{i \in I(x_0)} \alpha_i \nabla f_i(x_0) : \begin{array}{l} \sum_{i \in I(x_0)} \alpha_i = 1, \\ \alpha_i \geq 0 \end{array} \right\}$$

$$I(x_0) = \{i : f_i(x_0) = f(x_0)\} .$$

When  $f$  is a Lipschitz function, the subdifferential set can be defined as being the set of cluster points of the gradients  $\nabla f(x_i)$  as a sequence of differentiable points  $x_i$  approaches  $x$  [7]. The precise definition of  $\partial f(x_0)$  is given by

$$\text{conv} \{ \lim \nabla f(x_i) : x_i \rightarrow x_0 : \nabla f(x_i) \text{ exists} \} .$$

In nondifferentiable optimization, the whole subdifferential set is never calculated. Subgradients are calculated when needed and often a single element suffices. It is common practice to isolate the procedures for calculating subgradients into an oracle. The number of calls to the oracle can be a basis for comparing different NDO methods.

A natural solution method in nonsmooth analysis is an iterative method, where a search is done following descent directions. A descent direction is one along

which a small movement of  $f$  leads to a strict improvement. In other words

$$f'(x_0; d) = \lim_{t \rightarrow 0} \frac{f(x_0 + td) - f(x_0)}{t}$$

should be strictly negative.  $f'(x_0; d)$  is called the *directional derivative* and it is related to the subgradient through the relation

$$f'(x_0; d) = \sup \{ \xi^\top d : \xi \in \partial f(x_0) \}. \quad (3)$$

This relation implies that for  $d$  to be a descent direction,  $-d$  has to make an acute angle with every subgradient of  $f$  at  $x_0$ .

### Sources of NDO Problems

Nonsmooth problems are encountered in many disciplines. In some instances, they occur naturally and in others they result from mathematical transformations.

In statistics, for example, rectilinear data fitting, which was long discovered to be superior to the Euclidean one – it has the advantage of overcoming the effect of outliers, [25] – results directly in an NDO problem. Similarly, functions involving  $\ell_1$  or  $\ell_\infty$  norms, Euclidean or Chebyshev distances, a maximum of convex functions are typical NDO problems. As an example, the  $\ell_\infty$  solution of an overdetermined linear system is found by solving the nondifferentiable convex function:

$$\min_{x \in \mathbf{R}^n} \|Ax - b\|_\infty = \min_{x \in \mathbf{R}^n} \max_{i=1, \dots, m} |a_i^\top x - b_i|, \quad (4)$$

where  $x \in \mathbf{R}^n$ ,  $b \in \mathbf{R}^m$  and  $A \in \mathbf{R}^{m \times n}$  with rows  $a_i^\top$ . This problem can be traced back to the Russian mathematician P.L. Chebyshev who studied it in the 1850s [25].

Among the mathematical transformations that lead to NDO problems is the technique that changes constrained problems into unconstrained ones through the use of exact penalty functions [11] (cf. also ► **Quasidifferentiable optimization: Exact penalty methods**). Equality constraints,  $\phi(x) = 0$  and inequality constraints  $\varphi(x) \leq 0$  are placed in the objective using penalty parameters and nondifferentiable functions  $|\phi(x)|$  and  $\max \{0, \varphi(x)\}$ , respectively. In other words, a solution to the constrained problem

$$\begin{cases} \min & f(x) \\ \text{s.t.} & \phi(x) = 0, \\ & \varphi(x) \leq 0, \end{cases} \quad (5)$$

is determined by solving

$$\min f(x) + t_1 |\phi(x)| + t_2 \max\{0, \varphi(x)\}$$

for large enough values of  $t_1$  and  $t_2$ .

Still, the major source of optimization problems are master problems resulting from the application of relaxation/restriction techniques such as Lagrangian relaxation [14] (cf. also ► **Integer programming: Lagrangian relaxation**), [12], Benders decomposition (cf. also ► **Generalized Benders decomposition**) [4,13] and Dantzig–Wolfe decomposition [9,10].

These different approaches are conceptually similar, at least in the linear case, and end up solving the same NDO problem. To show that, let us consider the linear program

$$[LP] \begin{cases} \min & c^\top x \\ \text{s.t.} & Ax \geq b, \\ & Dx \geq d, \\ & x \geq 0. \end{cases}$$

Where, we assume for the ease of exposition that  $\{x: Ax \geq b; x \geq 0\}$  is a bounded, nonempty polytope. The dual of [LP] is

$$[LD] \begin{cases} \max & b^\top u + d^\top v \\ \text{s.t.} & A^\top u + D^\top v \leq c, \\ & u, v \geq 0. \end{cases}$$

Applying Lagrangian relaxation to [LP] is equivalent to relaxing  $Dx \geq d$  using positive dual multipliers  $v$ , leading to

$$\max_{v \geq 0} \left\{ \min_{x \geq 0} c^\top x + v^\top (d - Dx) : Ax \geq b \right\}. \quad (6)$$

Benders decomposition applied to [LD] results in

$$\max_{v \geq 0} \left\{ \max_{u \geq 0} b^\top u + d^\top v : A^\top u \leq c - D^\top v \right\},$$

where  $v$  is assumed to be the complicating variable. Replacing the inside problem by its dual leads to

$$\max_{v \geq 0} \left\{ \min_{x \geq 0} c^\top x + v^\top (d - Dx) : Ax \geq b \right\}. \quad (7)$$

Dantzig–Wolfe decomposition replaces [LP] by its convex representation in terms of the convex points of

$\{x: Ax \geq b; x \geq 0\}$  that is indexed by  $\mathcal{E}$ , to get

$$\begin{cases} \min & \sum_{h \in \mathcal{E}} \alpha_h (c^\top x^h) \\ \text{s.t.} & \sum_{h \in \mathcal{E}} \alpha_h (Dx^h) \geq d, \\ & \sum_{h \in \mathcal{E}} \alpha_h = 1, \\ & \alpha_h \geq 0, \quad h \in \mathcal{E}. \end{cases}$$

Taking the dual results in

$$\begin{cases} \max_{v \geq 0, v_0} & v_0 + d^\top v \\ \text{s.t.} & c^\top x^h + v^\top Dx^h \geq v_0, \quad \forall h \in \mathcal{E}, \end{cases}$$

which is equivalent to

$$\max_{v \geq 0} \left\{ \min_{h \in \mathcal{E}} c^\top x^h + v^\top (d - Dx^h) \right\}. \tag{8}$$

The equivalence between (6) and (7) is obvious. Using the fact that there is always an extreme point solution to a linear program, the equivalence between (6), (7) and (8) is established. Therefore, Lagrangian relaxation applied to the primal is exactly Benders decomposition applied to the dual, and is equivalent by duality to Dantzig–Wolfe decomposition. Furthermore, all three solve (8), which is the maximum of a concave piecewise linear function that is nondifferentiable at intersection points.

F.H. Clarke [7] and [8] discusses further examples from physics, engineering, economics and optimal control. Other mathematical problems leading to NDO optimization include semi-infinite programming, eigenvalue optimization and variational inequalities [16].

### Solution Approaches

Due to the existence of successful solution methods for differentiable optimization, one other solution approach tries to transform nonsmooth problem into smooth ones. As an example, the absolute value function  $|x|$ , which is nondifferentiable at zero can be approximated by

$$\begin{cases} -x, & x \geq t, \\ \frac{x^2}{t}, & -t \leq x \leq t, \\ x, & x \leq -t, \end{cases}$$

for small values of the parameter  $t$ . For these transformations to be successful, the right transformation should be found and the the nondifferentiable points should be known. A solution approach based on this transformation is discussed in [21].

Other solution approaches that try to eliminate nondifferentiability, do so by transforming an unconstrained nonsmooth problem into a constrained smooth one. This approach is highly efficient for problems that can be transformed into easily solvable constrained problems such as linear programs. The  $\ell_\infty$  optimization problem described in (4) is equivalent to the linear program

$$\begin{cases} \min & y \\ \text{s.t.} & Ax - ye \leq b, \\ & Ax + ye \geq b, \end{cases}$$

where  $e$  is the appropriate dimension vector whose entries are all ones. Being a linear program with a special type of matrix, most linear programming techniques were modified to solve (4). This includes the simplex-like algorithm in [3] and the interior point algorithms in [23] and [27].

### Subgradient Methods

The first methods for nondifferentiable optimization tried to extend the gradient-based methods that were successful for smooth optimization. The transition from gradients to subgradients is not straightforward as some subgradient-based search direction are not necessarily improving directions. P. Wolfe [26] gives an example where the extension of the steepest descent method fails. To overcome that, some designed methods [18,20] will only take a serious step when the next iterate is a better one.

Subgradient methods (cf. also ► **Nondifferentiable optimization: Subgradient optimization methods**) were developed by N.Z. Shor [24] in the 1960s. They are basically an iterative technique where iterates are updated using a current subgradient and a carefully-chosen stepsize. Applied to (1), iterates are given by

$$x_{k+1} = x_k + t_k \xi_k,$$

where  $x_k$  is the current point,  $\xi_k$  is a subgradient of  $f$  at  $x_k$  and  $t_k$  is a stepsize. Shor [24] states that a constant

stepsize does not converge, even for the simple function  $|x|$ . He proposes the use of a stepsize that satisfies

$$\sum_{k=0}^{\infty} t_k = \infty, \quad t_k \rightarrow 0.$$

In practice, the most widely used stepsize is  $\theta[f(x_k) - f^*] / \|\xi_k\|$  where  $\theta \in (0, 2]$  and  $f^*$  is the best estimate of the optimal value  $f(x^*)$ .

### Steepest Descent and $E$ -Subgradient Methods

Subgradient methods are not monotonic, as they do not guarantee to improve the value of the minimized function. Descent methods are designed to overcome this drawback. As an example we discuss the steepest descent method which chooses its search direction by solving

$$\min_{\|d\| \leq 1} f'(x; d).$$

Using relation (3), the steepest descent direction, at a point  $x_k$ , is given by

$$d_k = \frac{\xi_k}{\|\xi_k\|}; \quad \xi_k = \arg \max_{\xi \in \partial f(x_k)} \|\xi\|.$$

The method proceeds iteratively, updating the iterates by

$$x_{k+1} = x_k + \alpha_k \xi_k$$

and choosing the steplength  $\alpha_k$  so that  $f(x_{k+1}) < f(x_k)$ .

The main difficulty with the steepest descent resides in the calculation of the direction  $d_k$  which necessitates the knowledge of the whole differential set  $\partial f(x)$ . To overcome that,  $\epsilon$ -subgradient methods prefer to calculate approximate steepest descent direction by searching through subgradients of neighboring points through the use of the  $\epsilon$ -subdifferential set

$$\begin{aligned} & \partial_{\epsilon} f(x) \\ &= \{\xi: f(x_0) + \xi(x - x_0) + \epsilon \leq f(x), \forall x\}. \end{aligned}$$

Details of the method can be found in [5].

### Cutting Plane Methods

J.E. Kelley [17] and W. Cheney and A.A. Goldstein [6] were the first to realize the potential of such methods

for convex programming. Applied to (1), cutting plane algorithms use the subgradient inequality to approximate  $f$  by

$$f(x) \cong \max_{i \in I} f(x_i) + \xi_i^T(x - x_i),$$

where  $\xi_i^f$ ,  $i \in I$  are subgradients of  $f$  at  $x_i$ ,  $i \in I$ . Thus, (1) is replaced by

$$\min_x \left\{ \max_{i \in I} f(x_i) + \xi_i^T(x - x_i) \right\},$$

which is equivalent to,

$$\begin{cases} \min & v \\ \text{s.t.} & f(x_i) + \xi_i^T(x - x_i) \leq v, \quad \forall i \in I. \end{cases} \quad (9)$$

Problem (9) is a linear program that is easier to deal with than the original problem. It is to note, however, that this is only an approximation of (1), which gets better as more constraints are added. Let us denote by  $[MP_k]$  the relaxed master problem (9) with index set  $I_k$ .

By transforming (1) to (9), a nondifferentiable problem is replaced by a constrained problem having a large number of constraints. Cutting plane methods use only a subset of these constraints and generate the rest as needed. In fact, they would solve a series of relaxed master problems  $[MP_k]$  and stop when an optimal (satisfactory) solution to (1) is reached.

Various cutting plane methods were proposed over the years. Each variant generates cuts at a different point called the *query point*. Kelley's classical cutting plane method [17] chooses the minimum of the relaxed master problem  $[MP_k]$  as a query point. Although, it may work well for some problems, this method suffers from slow convergence [22]. The analytic center cutting plane method (ACCPM) [15,16], on the other hand, chooses the analytic center as its query point. Its calculation makes use of interior point concepts and has shown promising results for a number of applications [1,2]. Bundle methods [19,20], choose the query point by solving a quadratic program that contains a small number of cutting planes. The information (bundle of cutting planes) is updated regularly and kept moderately small.

### Conclusion

Nondifferentiable optimization tackles a class of problems that are intractable to classical optimization meth-

ods. Most of the theory is based on the notion of subgradients and most of the work is done for the convex case. It has an abundance of applications in real life, because the nondifferentiability aspect captures some of the inherent complexity in real-life problems. Like all disciplines, favoring an easily implementable and understood method will not necessarily lead to a good solution method. This corresponds to the subgradient method in NDO. Although it is easily implementable, it has slow convergence. More sophisticated methods, such as bundle methods or ACCPM are more promising from a computational point of view but require more knowhow of the method and of numerical linear algebra.

### Keywords

Nondifferentiable optimization; Nonsmooth optimization; Cutting planes

Cutting plane methods were proposed independently by J.E. Kelley [27] and W. Cheney and A.A. Goldstein [5] as a solution technique for constrained convex optimization problems. Although they may not compete with some of the efficient methods for smooth optimization, they are one of the first and fundamental

solution approaches for nondifferentiable optimization (cf. ► [Nondifferentiable optimization](#)).

The fact that they rely on polyhedral approximations of convex functions, makes the technique suitable for nondifferentiable optimization. It forms with subgradient optimization [38] the two major solution approaches for nondifferentiable problems. The cutting plane algorithms that are being designed over the years are getting more sophisticated and ultimately, showing promising computational results and stable numerical properties.

In this article, we give an overview of cutting plane methods for nondifferentiable optimization problems. We start with a brief introduction to cutting planes. We then give a generic cutting plane algorithm, that will be used to describe some of the main variants.

### A Generic Cutting Plane Algorithm

To describe the general cutting plane approach, we consider the following nondifferentiable problem

$$[NDP] \begin{cases} \min & f(x) \\ \text{s.t.} & g(x) \leq 0, \end{cases}$$

where  $f$  and  $g$  are real-valued, continuous, nondifferentiable, convex functions. Convexity implies that there is at least one supporting hyperplane to  $f$  at every point  $x_0$  of the domain, whose equation is given by

$$y = f(x_0) + \xi_0^f(x - x_0),$$

where  $\xi_0^f$  is any element of the subdifferential  $\partial f(x_0)$  of  $f$  at  $x_0$ . (For ease of notation we assume that subgradients are row vectors.) Recalling that a supporting hyperplane gives an under-estimate of  $f$ , the *subgradient inequality*

$$f(x_0) + \xi_0^f(x - x_0) \leq f(x) \tag{1}$$

can be used to approximate  $f$  by the maximum of a set of piecewise linear functions. Therefore, given a set of points  $x_i$ ,  $i \in I$  and their corresponding subgradients  $\xi_i^f$ ,  $f$  is tangentially approximated by

$$\bar{f}(x) = \max_{i \in I} \left\{ f(x_i) + \xi_i^f(x - x_i) \right\}. \tag{2}$$

Inequality (1) implies that  $\bar{f}(x) \leq f(x)$  for any index set  $I$ . Larger sets will give better approximations.

The same can be said about  $g$ , leading to the polyhedral approximation

$$\bar{g}(x) = \max_{j \in J} g(x_j) + \xi_j^g(x - x_j),$$

where  $\xi_j^g$  are subgradients of  $g$  at a collection of points  $x_j$  indexed by  $J$ . Thus, [NDP] can be approximated by,

$$\begin{cases} \min & \left\{ \max_{i \in I} f(x_i) + \xi_i^f(x - x_i) \right\} \\ \text{s.t.} & \max_{j \in J} g(x_j) + \xi_j^g(x - x_j) \leq 0, \end{cases}$$

which is equivalent to,

$$\begin{cases} \min & v \\ \text{s.t.} & f(x_i) + \xi_i^f(x - x_i) \leq v, \quad \forall i \in I, \\ & g(x_j) + \xi_j^g(x - x_j) \leq 0, \quad \forall j \in J. \end{cases} \quad (3)$$

Problem (3) is a linear program that is easier to deal with than the original problem. It is to note, however, that this is only an approximation of [NDP], that gets better as more constraints are added. Let us denote by  $[MP_k]$  the *relaxed master problem* (3) with index sets  $I_k$  and  $J_k$  whose optimal solution is denoted by  $(x_k, v_k)$ .

By transforming [NDP] into (3), nondifferentiability is eliminated at the cost of having a problem with a very large number of constraints. To get around that, cutting plane methods use only a subset of these constraints and generate the rest as needed. In fact, they would handle a series of relaxed master problems  $[MP_k]$  and stop when an optimal (satisfactory) solution to [NDP] is reached.  $[MP_k]$  is a relaxation of [NDP] as, by convexity of  $g$ ,

$$\left\{ x : \max_{j \in J_k} \left\{ g(x_j) + \xi_j^g(x - x_j) \right\} \leq 0 \right\}$$

contains  $\{x : g(x) \leq 0\}$ , while, by convexity of  $f$ ,

$$\max_{i \in I_k} \left\{ f(x_i) + \xi_i^f(x - x_i) \right\} \leq f(x)$$

for all  $x \in \{x : g(x) \leq 0\}$ . This implies that the optimal value  $v_k$  is a lower bound on the optimal value  $f(x^*)$ . The relaxation gets tighter as more points are included in the index sets  $I$  and  $J$ . The hope is that termination occurs before the sets  $I$  and  $J$  get enormously big.

The idea described above can be put into the generic cutting plane algorithm below.

In the course of the cutting plane algorithm, upper bounds are usually achieved through the objective evaluation at a feasible point. Lower bounds are either given by the optimal solution of the relaxed master problem, or by evaluating the dual objective at a feasible dual solution. For the stopping criteria, the algorithm may be stopped if the bound on the duality gap drops below a certain threshold. This is given by the difference between the best known upper and lower bounds.

*Initialize:*

- 1 Get an initial upper bound  $v_u$  and a lower bound  $v_l$  for the optimal solution  $f(x^*)$ .
- 2 Get an initial relaxed master problem  $[MP_0]$ .

*Iterate* ( $k$ )

- 1 Get a *query point*  $x_k$  and a corresponding lower bound  $v_l^+$ .
- 2 If  $x_k$  is infeasible to [NDP] ( $g(x_k) > 0$ ), then the oracle of  $g$  generates a *feasibility cut* of type  $g(x_k) + \xi_j^g(x - x_k) \leq 0$ .
- 3 If  $x_k$  is feasible to [NDP] ( $g(x_k) \leq 0$ ), then the oracle of  $f$  generates an *optimality cut* of type  $f(x_k) + \xi_i^f(x - x_k) \leq v$  and an upper bound  $v_u^+$ .
- 4 Update the bounds:
  - a) if  $x_k$  is feasible to [NDP], then  $v_u = \max\{v_u, v_u^+\}$ .
  - b)  $v_l = \min\{v_l, v_l^+\}$
- 5 Update index sets:
  - a) If a feasibility cut is added then  $I_{k+1} := I_k$  and  $J_{k+1} := J_k \cup \{k\}$ .
  - b) If an optimality cut is added then  $I_{k+1} := I_k \cup \{k\}$  and  $J_{k+1} := J_k$ .
- 6 Either STOP or  $k := k + 1$ .

At each iteration of the method, we can construct a bounded polyhedral set, namely the *localization set*. Given an upper bound  $v_u^k$  to  $[MP_k]$ , it is given by

$$F_k(v_u^k) = \left\{ (x, v) : \begin{cases} v \leq v_u^k; \\ f(x_i) + \xi_i^f(x - x_i) \leq v, \\ i \in I_k; \\ g(x_j) + \xi_j^g(x - x_j) \leq 0, \\ j \in J_k \end{cases} \right\}.$$

The localization set  $F_k(v_u)$  is a bounded polyhedral subset of the feasible region of  $[MP_k]$  that contains any optimal solution  $(x^*, f(x^*))$  to [NDP]. To see that,  $f(x^*)$

$\leq v_u^k$  as  $v_u^k$  is an upper bound on the optimal value. Furthermore, by the feasibility of  $x^*$  and the subgradient inequality  $g(x_j) + \xi_j^g(x^* - x_j) \leq g(x^*) \leq 0$  for all  $j \in J_k$  and by the fact that  $[MP_k]$  is a relaxation of  $[NDP]$ ,  $f(x_i) + \xi_i^f(x^* - x_i) \leq v_k \leq f(x^*)$  for all  $i \in I_k$ .

Although every cutting plane method follows the above general scheme, different query point choices produce different algorithms. Prior to discussing a few of them, we would like to stress that some methods are explicitly based on the localization set, and require that this set be bounded. This might not hold in particular in the initialization phase, since no cut is yet present, and no upper and lower bounds on the objective are known. Therefore, one has to introduce box constraints. This may not even suffice if the first generated cut is not an optimality one, because the localization set remains unbounded in the  $z$  variable. One must then proceed with an auxiliary phase I problem.

### Kelley's Cutting Plane Method

This is the classical cutting plane method that was originally described in [27] and is present in the original *Dantzig–Wolfe decomposition* [7,8] and Benders decomposition [4]. At iteration  $k$ , the method solves the relaxed master  $[MP_k]$  and uses its solution  $x_k$  to generate further cuts.

As  $[MP_k]$  is a relaxation of  $[NDP]$ ,  $v_k$  gives a lower bound to  $f(x^*)$  which is monotonically increasing. In addition, when  $x_k$  is feasible,  $f(x_k)$  gives an upper bound that, unfortunately, is not monotonically decreasing. The difference between the updated bounds gives an estimate of the duality gap and can be used as a practical stopping criteria. The exact optimal solution of  $[NDP]$  is detected when  $x_k$  is feasible and  $f(x_k) = v_k$ , which is equivalent to having  $0 \in \partial f(x_k)$ .

This optimal point strategy assumes that the relaxation is a good approximation of the original problem, but this is only true when a big number of cuts has been generated. The method is globally convergent [47], but in practice, it sometimes shows a slow pattern of convergence [35].

### Center of Gravity Method

This method was first proposed in [32] as the first cutting plane method that generates query points at the center of the localization set. Choosing the *center of*

*gravity* to generate query points seems to be the natural choice. In fact cutting through the center of gravity of the a localization set of volume  $V$  and dimension  $n$  produces two sets, each with a volume of at least

$$\left[1 - \left(1 - \frac{1}{n+1}\right)^n\right] V.$$

Therefore, after  $k$  iterations the volume of the localization set shrinks at a constant rate of  $1/(1 - \exp(-1))$ . This rate of convergence is the best that can be obtained [46]. Unfortunately, finding a single center of gravity could be as difficult as solving the original problem.

For some simple convex bodies such as ellipsoids, cubes or spheres, calculating the center of gravity is relatively easy. This idea is the motivation behind the largest inscribed sphere method of [11], the volumetric method of [43] and the analytic center cutting plane method (ACCPM) of [18,19,21].

### Largest Inscribed Sphere Method

The query point of this method is chosen as the center of the largest inscribed sphere in the localization set. Its calculation is based on work of G.L. Nemhauser and W.B. Widhelm [34], who showed that the minimization of the simple linear program

$$\begin{cases} \min & \sigma \\ \text{s.t.} & a_i^\top x + \|a_i^\top\| \sigma \leq b_i, \quad i \in I, \end{cases}$$

gives the radius  $\sigma$  and the center  $x$  of the largest inscribed sphere in the bounded polyhedron  $\{x: a_i^\top x \leq b_i, i \in I\}$ . The method is detailed in [11].

### Volumetric Method

P.M. Vaidya [43] proposed the volumetric center as a query point. It is the maximizer of the determinant of the Hessian matrix of the logarithmic barrier function. This choice is motivated by the observation that for every point of the localization set, an inscribed ellipsoid can be constructed. The point that gives the maximum-volume inscribed ellipsoid is the minimizer of

$$\frac{1}{2} \log \left( \det \left( \sum \frac{a_i a_i^\top}{(b_i - a_i^\top x)^2} \right) \right),$$

where  $a_i$  are the columns of the matrix defining the localization set.

### Bundle Methods

These methods were first proposed by C. Lemaréchal [30]. The method has developed over the years, [28,31], building upon the pioneering work [30].

The method adds a regularization term to the estimation of  $f$  and solves

$$\begin{cases} \min & \left\{ \max_{i \in I_k} f(x_i) + \xi_i^f(x - x_i) \right. \\ & \left. + \frac{1}{2\alpha_k} \|x - x_{k-1}\|^2 \right\} \\ \text{s.t.} & \max_{j \in J_k} \left\{ g(x_j) + \xi_j^g(x - x_j) \right\} \leq 0, \end{cases} \quad (4)$$

to get the next query point  $x_k$ . The main idea is based on the fact that (2) is a good approximation of  $f$  when the next iterate is not far from the previous ones. Problem (4) is equivalent to the quadratic program

$$\begin{cases} \min & v + \frac{1}{2\alpha_k} \|x - x_{k-1}\|^2 \\ \text{s.t.} & f(x_i) + \xi_i^f(x - x_i) \leq v, \quad i \in I_k, \\ & g(x_j) + \xi_j^g(x - x_j) \leq 0, \quad j \in J_k. \end{cases}$$

The nice feature of bundle methods is that they limit the number of hyperplanes that are used to approximate  $f$ . The set of subgradients (the bundle) is updated at each iteration and kept moderately small. As a result, (4) is solved very quickly.

Techniques to estimate  $\alpha_k$  are treated in [28] where three different values are proposed.

### Analytic Center Cutting Plane Method (ACCPM)

To overcome the difficulty associated with the calculation of centers of polyhedrons and still use a central point strategy, ACCPM uses concepts from the interior point literature that have proven to be highly efficient.

The query point for ACCPM is the *analytic center* of the localization set  $F_k(v_u)$ . This new notion of center was first introduced in [40,41,42] as the the unique pair  $(x_a^k, v_a^k)$  that minimizes

$$\begin{aligned} \log(v_u^k - v) + \sum_{i \in I_k} \log[v - f(x_i) - \xi_i^f(x - x_i)] \\ + \sum_{j \in J_k} \log[-g(x_j) - \xi_j^g(x - x_j)]. \end{aligned}$$

This function is a *potential function* similar to the one used by N.K. Karmarkar [26] when presenting the first interior point algorithm. Its minimization is equivalent to the solution of a linear program by any interior point method. The primal projective algorithm (cf. also ► **Linear programming: Karmarkar projective algorithm**) is favored due to its ability to deal with dual infeasibilities when new cuts are added. It is, in principle, a modified Newton method applied to the minimization of the potential function [16].

The *Newton procedure* for computing a central point  $(x_a^k, v_a^k)$  of  $F_k(v_u)$  identifies, upon termination, a dual feasible solution to  $[MP_k]$ . Evaluating the dual objective at this point, gives a lower bound to the optimal solution of  $[NDP]$ . In addition, if  $x_a^k$  is feasible to  $[NDP]$ , i. e.  $g(x_a^k) \leq 0$ , then  $f(x_a^k)$  is an upper bound. Unfortunately,  $x_a^k$  never coincides with the original optimizer  $x^*$ , as it can never be a vertex, so the stopping criteria can only be based on the difference between the upper a lower bounds. The algorithm would stop if that gap is sufficiently small.

The convergence analysis of the method is done in [20] and [36]. ACCPM is readily implemented [25] and has shown promising results in solving different large scale problems [2,3,17,33]. The method was modified to use weighted analytic centers as a query point [22], to add multiple cuts at once [24], to use a primal-dual interior point algorithm for the calculation of analytic centers [9] and to accommodate quadratic cuts [10].

### Concluding Remarks

Cutting plane methods are an effective solution approach for nondifferentiable optimization. This has proven to be true when advanced methods such as bundle and analytic center methods were designed. Not only they make use of recent advances in optimization theory, they also resulted in efficient computer implementations.

Manipulating the set of cuts is an important enhancement factor to cutting plane methods. In the addition of cuts, introducing a whole set at once is more effective than introducing single cuts as it allows the fast accumulation of information about the problem. This is possible for certain classes of problems where disaggregation is possible. This is true for Dantzig–Wolfe and

Benders decompositions with primal and dual block diagonal matrices respectively.

The second improvement is in the manipulation of number of cuts in the relaxed master problem. Keeping all cuts may lead to a better approximation but it also requires huge amounts of storage space and solution time. Thus well defined cut-dropping strategies will considerably improve the performance of the method.

A final remark concerns the use of heuristics with cutting planes. They can be used to initialize the method so that sufficient cutting planes are obtained to start the method, or take over the search for optimal solutions when the method stalls.

### Max-Type Functions

Let  $S \subset \mathbf{R}^n$  be an open set. A standard *minimax problem* (MMP) is the problem of minimizing a function

$$f(x) = \max_{y \in G} \varphi(x, y), \quad (1)$$

where  $G$  is a compact set of some space  $Y$ , the function  $\varphi: S \times G \rightarrow \mathbf{R}$  is continuous jointly in  $[x, y]$  on  $S \times G$  and continuously differentiable in  $x$  (the function  $\varphi'_x(x, y)$  is continuous in  $[x, y]$  on  $S \times G$ ). The function  $f$  is, in general, nonsmooth though  $\varphi$  is smooth in  $x$ .

*Remark 1* The function

$$f(x) = \max_{y \in G} |\varphi(x, y)|$$

can be rewritten in the form (1) since

$$\begin{aligned} f(x) &= \max_{y \in G} \max\{\varphi(x, y), -\varphi(x, y)\} \\ &= \max_{\bar{y} \in \bar{G}} \bar{\varphi}(x, \bar{y}), \end{aligned}$$

where

$$\begin{aligned} \bar{G} &= \{[1, y]: y \in G\} \cup \{-1, y]: y \in G\} \\ &\subset \mathbf{R} \times Y = \bar{Y}, \\ \bar{\varphi}(x, \bar{y}) &= \begin{cases} \varphi(x, y), & \bar{y} = [1, y], \\ -\varphi(x, y), & \bar{y} = -[1, y]. \end{cases} \end{aligned}$$

The first serious study of minimax problems was performed by P.L. Chebyshev who may be considered as Godfather of nonsmooth analysis. He treated the problem of minimizing the function

$$f(x) = \max_{y \in [a, b]} |\Psi(y) - P(x, y)|, \tag{2}$$

where  $x = (x_0, \dots, x_{n-1}) \in \mathbf{R}^n$ ,  $P(x, y) = \sum_{i=0}^{n-1} x_i y^i$ . The function  $P(x, y)$  is a polynomial (in  $y$ ). If  $x^* \in \mathbf{R}^n$  and

$$f(x^*) = \min_{x \in \mathbf{R}^n} f(x)$$

then  $P(x^*, y)$  is called the *polynomial of best approximation* (for the function  $\Psi(y)$ ). If  $\Psi(y) = y^n$ ,  $[a, b] = [-1, 1]$  then

$$P_n^*(y) = y^n - P(x^*, y) = \frac{1}{2^{n-1}} T_n(y),$$

where  $T_n(y)$  is the famous *Chebyshev polynomial*:

$$\begin{aligned} T_0(y) &= 1, \quad T_1(y) = y, \\ T_{m+1}(y) &= 2yT_m(y) - T_{m-1}(y), \quad \forall m \geq 2. \end{aligned}$$

On the interval  $[-1, 1]$  the relation  $T_n(y) = \cos(n \arccos y)$  holds.

Let  $\varphi_1(x, y) = \Psi(y) - P(x, y)$ . The following condition holds (see [4,9]): For a point  $x^* \in \mathbf{R}^n$  to be a minimizer of  $f$  (see (2)) it is necessary and sufficient that  $n + 1$  points  $y_0, \dots, y_n$  exist such that

$$\begin{aligned} y_i &\in G, \quad \forall i \in 0, \dots, n; \\ y_0 &< \dots < y_n, \end{aligned}$$

$$\varphi_1(x^*, y_{i+1}) = -\varphi_1(x^*, y_i), \tag{3}$$

$$\forall i \in 0, \dots, n - 1, \tag{4}$$

$$|\varphi_1(x^*, y_{i+1})| = \varphi(x^*, y_i) = f(x^*). \tag{5}$$

The set  $\{y_0, \dots, y_n\}$  satisfying (3)–(5) is called a *Chebyshev alternation* (or *alternance*).

The following properties of a max-function will be used in the sequel (see [1,4,5]).

- 1) Let a function  $f$  be described by (1). Then it is directionally differentiable at any point  $x \in S$  and

$$\begin{aligned} f'(x, g) &= \lim_{\alpha \downarrow 0} \frac{f(x + \alpha g) - f(x)}{\alpha} \\ &= \max_{v \in \partial f(x)} (v, g), \end{aligned} \tag{6}$$

where

$$\begin{aligned} \partial f(x) &= \text{co} \{ \varphi'(x, y) : y \in R(x) \}, \\ g &\in \mathbf{R}^n, \\ R(x) &= \{ y \in G : \varphi(x, y) = f(x) \}. \end{aligned}$$

(6) means that  $f$  is subdifferentiable,  $\partial f(x)$  is the *subdifferential* of  $f$  at  $x$  (it is a convex compact set). The subdifferential mapping  $\partial f$  is not, in general, Hausdorff continuous.

- 2) For a point  $x^* \in S$  to be a (local or global) minimizer of  $f$  on  $S$  it is necessary that

$$0_n \in \partial f(x^*). \tag{7}$$

Here  $0_n = (0, \dots, 0) \in \mathbf{R}^n$ .

A point  $x^* \in S$  satisfying (7) is called an *inf-stationary point* of  $f$ .

*Remark 2* Note that for a point  $x^{**} \in S$  to be a (local or global) maximizer of  $f$  on  $S$  it is necessary that

$$\partial f(x^{**}) = \{0_n\}. \tag{8}$$

If the function  $f$  is convex (it is the case, e. g., if  $\varphi$  is convex in  $x$  for any  $y \in G$ ), then condition (7) is also sufficient for  $x^*$  to be a global minimizer of  $f$  on an open set  $S$ . Therefore condition (8) implies that a convex function  $f$  does not attain its maximal value on an open convex set  $S$ .

- 3) If  $x_0$  is not inf-stationary then the direction

$$g(x_0) = -\frac{v_0}{\|v_0\|}, \tag{9}$$

where

$$\|v_0\| = \max_{v \in \partial f(x_0)} \|v\|,$$

is the steepest descent direction of  $f$  at  $x_0$ , i. e.

$$f'(x_0, g(x_0)) = \min_{\|g\|=1} f'(x_0, g).$$

4) The following expansion holds

$$f(x + \Delta) = f(x) + \max_{y \in G} [\varphi(x, y) - f(x) + (\varphi'_x(x, y), \Delta)] + o_x(\Delta),$$

where

$$\frac{o_x(\Delta)}{\|\Delta\|} \xrightarrow{\|\Delta\| \rightarrow 0} 0.$$

This expression can be rewritten as

$$f(x + \Delta) = f(x) + \max_{[a, v] \in df(x)} [a + (v, \Delta)] + o_x(\Delta), \tag{10}$$

where

$$df(x) = \text{co} \left\{ [a, v] \in \mathbf{R} \times \mathbf{R}^n : \begin{matrix} a = \varphi(x, y) - f(x), \\ v = \varphi'_x(x, y), \\ y \in G \end{matrix} \right\} \tag{11}$$

is the *hypodifferential* of  $f$  at  $x$ . Note that  $a \geq 0$  and  $\max_{[a, v] \in df(x)} a = 0$ . The mapping  $df$  is Hausdorff-continuous on  $S$ .

5) Necessary condition (7) is equivalent to

$$0_{n+1} \in df(x^*). \tag{12}$$

6) If  $x_0$  is not inf-stationary, then let us find

$$\min_{z \in df(x^*)} \|z\| = \|z_0\|,$$

where  $z_0 = [a_0, v_0]$ . In this case  $v_0 \neq 0_n$ . The direction

$$\tilde{g}(x_0) = -\frac{v_0}{\|v_0\|} \tag{13}$$

is a descent (not necessary steepest descent) direction of  $f$  at  $x_0$ .

The vector-function  $\tilde{g}(x)$  (see (13)) is continuous.

7) If the function  $\varphi$  in (1) is twice continuously differentiable at  $x$  then the following relation holds:

$$f(x + \Delta) = f(x) + \max_{y \in G} [\varphi(x, y) - f(x) + (\varphi'_x(x, y), \Delta) + \frac{1}{2}(\varphi_{xx}(x, y)\Delta, \Delta)] + o_x(\Delta^2), \tag{14}$$

where

$$\frac{o_x(\Delta^2)}{\|\Delta\|^2} \xrightarrow{\|\Delta\| \rightarrow 0} 0.$$

(14) can be rewritten as

$$f(x + \Delta) = f(x) + \max_{[a, v, A] \in d^2f(x)} \left[ a + (v, \Delta) + \frac{1}{2}(A\Delta, \Delta) \right] + o_x(\Delta^2), \tag{15}$$

where

$$d^2f(x) = \text{co} \left\{ [a, v, A] \in \mathbf{R} \times \mathbf{R}^n \times \mathbf{R}^{n \times n} : \begin{matrix} a = \varphi(x, y) - f(x), \\ v = \varphi'_x(x, y), \\ A = \varphi_{xx}(x, y), \\ y \in G \end{matrix} \right\}. \tag{16}$$

Here  $\mathbf{R}^{n \times n}$  is the space of real  $(n \times n)$ -matrices. The set  $d^2f(x)$  is called the *second hypodifferential* of  $f$  at  $x$ . It is closed, bounded and convex. The mapping  $d^2f$  is Hausdorff continuous on  $S$ . In this case  $f$  is twice continuously hypodifferentiable.

### Algorithms for Unconstrained Minimization

Assume that in (1)  $S = \mathbf{R}^n$ . Then the problem of minimizing  $f$  is an unconstrained minimax problem. There are a lot of numerical methods to solve this problem based on the properties of max-functions.

### Method of Steepest Descent

Let  $x_0 \in \mathbf{R}^n$  be arbitrary. Assume that  $x_k$  has already been defined. If  $0_n \in \partial f(x_k)$  then  $x_k$  is an inf-stationary point and the process terminates. If  $0_n \notin \partial f(x_k)$  then let us take  $g_k = g(x_k)$  (see (9)) and find

$$\min_{\alpha \geq 0} f(x_k + \alpha g_k) = f(x_k + \alpha_k g_k). \tag{17}$$

Now, put  $x_{k+1} = x_k + \alpha_k g_k$ . Continuing in the same manner we construct a sequence  $\{x_k\}$  such that

$$f(x_{k+1}) < f(x_k). \tag{18}$$

If this sequence  $\{x_k\}$  is finite, then, by construction, the last point is a stationary one.

Let  $\{x_k\}$  be not finite. Assume that the set  $Q(x_0) = \{x \in \mathbf{R}^n: f(x) \leq f(x_0)\}$  is bounded (then it is closed). Due to (18)  $x_k \in Q(x_0)$  and, hence, there exist a point  $x^* \in Q(x_0)$  and a subsequence  $\{x_{k_s}\}$  such that  $x_{k_s} \rightarrow x^*$ . One may expect that  $x^*$  is inf-stationary. However, in general, this is not the case and the reason is the discontinuity of the mapping  $\partial f$ .

To ensure the convergence it is necessary to overcome the discontinuity of  $\partial f$ .

Let us introduce the set  $R_\varepsilon(x) = \{y \in G: f(x) - \varphi(x, y) \leq \varepsilon\}$  where  $\varepsilon \geq 0$ . Put

$$L_\varepsilon(x) = \text{co} \{ \varphi'_x(x, y): y \in R_\varepsilon(x) \}.$$

Find

$$\min_{v \in L_\varepsilon(x)} \|v\| = \|v_\varepsilon(x)\|.$$

If  $\|v_\varepsilon(x)\| = 0$ , the point  $x$  is called an  $\varepsilon$ -stationary point. Choose any  $\varepsilon > 0$ . Let us construct the following method. Take any  $x_0 \in \mathbf{R}^n$ . Let  $x_k$  have already been found. If  $\|v_\varepsilon(x_k)\| = 0$  then  $x_k$  is  $\varepsilon$ -stationary. If  $\|v_\varepsilon(x_k)\| > 0$  then let us find

$$\min_{\alpha \geq 0} f(x_k - \alpha v_\varepsilon(x_k)) = f(x_k - \alpha_k v_\varepsilon(x_k))$$

and put  $x_{k+1} = x_k - \alpha_k v_\varepsilon(x_k)$ . Continuing analogously we get a sequence  $\{x_k\}$ .

**Proposition 3** *If the set  $Q(x_0)$  is bounded then in a finite number of steps we arrive at a point  $x_k$  such that*

$$0_n \in L_{2\varepsilon}(x_k).$$

Thus, in a finite number of steps we shall find a  $2\varepsilon$ -stationary point.

Now it is not difficult to modify this method to get an inf-stationary point of  $f$ .

Choose any  $\varepsilon_0 > 0$  and  $x_0 \in \mathbf{R}^n$ . Assume that  $Q(x_0)$  is bounded. Applying the above method, in a finite number of steps we shall find a point  $\bar{x}_0$  such that  $0_n \in L_{2\varepsilon_0}(\bar{x}_0)$ . Let  $\bar{x}_k \in Q(x_0)$  be found such that  $0_n \in L_{2\varepsilon_k}(\bar{x}_k)$  where  $\varepsilon_k = 2^{-k}\varepsilon_0$ . Take  $\varepsilon_{k+1} = \varepsilon_k/2$  and  $x_k = \bar{x}_k$ . Applying the above method, in a finite number of steps a point  $\bar{x}_{k+1} \in Q(x_0)$  will be found such that  $0_n \in L_{2\varepsilon_{k+1}}(\bar{x}_{k+1})$ . Clearly,  $\bar{x}_{k+1} \in Q(x_0)$ . The sequence  $\{\bar{x}_k\}$  is bounded.

**Proposition 4** *Any limit point of the sequence  $\{x_k\}$  is an inf-stationary point of  $f$ .*

### Hypodifferential Descent

Another method is based on expansion (10). Take  $x_0 \in \mathbf{R}^n$ . Let  $x_k$  have been found. Compute

$$\min_{z \in df(x_k)} \|z\| = \|z_k\|,$$

where  $z_k = [a_k, v_k]$ . If  $\|z_k\| = 0$  then the point  $x_k$  is inf-stationary and the process terminates.

If  $\|z_k\| > 0$  then  $v_k \neq 0_n$  and let us find

$$\min_{\alpha \geq 0} f(x_k - \alpha v_k) = f(x_k - \alpha_k v_k)$$

and put  $x_{k+1} = x_k - \alpha_k v_k$ .

If the sequence  $\{x_k\}$  thus constructed is finite then the last point is inf-stationary. If  $\{x_k\}$  is infinite then the following result holds:

**Proposition 5** *If the set  $Q(x_0)$  is bounded then any limit point of the sequence  $\{x_k\}$  is inf-stationary.*

*Remark 6* The two algorithms described above are ‘conceptual’ (according to the terminology of E. Polak). These algorithms are computationally effective in the case where the set  $G$  (see (1)) contains only a finite number of points. Different practical implementations of the above ideas can be found in [2,4,10,11,12].

### Newton-Type Method

If the function  $\varphi$  in (1) is twice continuously differentiable, one can employ the expansion (14)–(15).

Take any  $x_0 \in \mathbf{R}^n$ . Let  $x_k$  have already been defined.

Find

$$\min_{\Delta \in \mathbf{R}^n} F_k(\Delta) = F_k(\Delta_k),$$

where

$$F_k(\Delta) = \max_{[a, v, A] \in d^2 f(x_k)} \left[ a + (v, \Delta) + \frac{1}{2}(A\Delta, \Delta) \right].$$

Now put  $x_{k+1} = x_k + \Delta_k$ .

Under some additional conditions (see [3]) the sequence  $\{x_k\}$  thus constructed converges at least to a local minimizer of  $f$  (and the rate of convergence is quadratic).

### A Convex Max-Function

#### Extremal Basis Method

Now let us consider the case where  $f$  is described by (1) and the function  $\varphi$  in (1) is strongly convex in  $x$  with

a constant  $m > 0$  for every fixed  $y \in G$ , i. e.

$$\begin{aligned} \varphi(x + \Delta, y) &\geq \varphi(x, y) \\ &+ (\varphi'_x(x, y), \Delta) + m\|\Delta\|^2, \\ \forall [x, y] \in \mathbf{R}^n \times G, \quad \forall \Delta \in \mathbf{R}^n. \end{aligned} \tag{19}$$

The function  $f$  is also strongly convex and has a unique minimizer.

Choose an arbitrary set of  $n + 2$  points from  $G$ :

$$\begin{aligned} \tau_0 &= \{y_{01}, \dots, y_{0,n+2}\}, \\ y_{0i} &\in G, \quad \forall i \in 1, \dots, n + 2. \end{aligned}$$

The set  $\tau_0$  will be called a *basis*.

Assume that the points  $x_0, \dots, x_{k-1}$  and the basis  $\tau_k = \{y_{k1}, \dots, y_{k,n+2}\}$  have already been found.

Let us define the function

$$f_k(x) = \max_{i \in 1, \dots, n+2} \varphi(x, y_{ki})$$

and choose a point  $x_k \in \mathbf{R}^n$  such that

$$f_k(x_k) = \min_{x \in \mathbf{R}^n} f_k(x). \tag{20}$$

If  $f(x_k) = f_k(x_k)$  then  $x_k$  is the minimizer of  $f$ , and the process terminates.

The minimization problem in (20) is simpler than that of minimizing  $f$ .

Consider the case  $f(x_k) > f_k(x_k)$ . By the necessary and (in our convex case) sufficient condition (7)

$$0_n \in L_k, \tag{21}$$

where  $L_k = \text{co } H_k$ ,  $H_k = \{\varphi'_x(x_k, y_{ki}) : i \in R_k\}$ ,  $R_k = \{i \in 1, \dots, n + 2 : \varphi(x_k, y_{ki}) = f_k(x_k)\}$ . By the Carathéodory theorem [7] every point of  $L_k$  can be represented as a convex combination of not more than  $n + 1$  points of  $H_k$ . Therefore, there exists at least one index  $i_k \in 1, \dots, n + 2$  such that either  $i_k \notin R_k$  or the origin in (21) may be ‘constructed’ without the vector  $\varphi'_x(x_k, y_{ki_k})$ .

Let  $\bar{y}_k \in G$  be such that

$$\varphi(x_k, \bar{y}_k) = f(x_k) = \max_{y \in G} \varphi(x_k, y).$$

Now let us construct a new basis

$$\tau_{k+1} = \{y_{k+1,1}, \dots, y_{k+1,n+2}\}$$

where

$$y_{k+i,i} = \begin{cases} y_{ki}, & i \neq i_k, \\ \bar{y}_k, & i = i_k. \end{cases}$$

The basis  $\tau_{k+1}$  differs from  $\tau_k$  by one point and also contains  $n + 2$  points. For the basis  $\tau_{k+1}$  again define the function  $f_{k+1}(x)$  and the point  $x_{k+1}$ .

As a result, a sequence  $\{x_k\}$  is constructed. If this sequence is finite, its last point is the minimizer. If not, the following property holds.

**Proposition 7 (See [6 Sect. III.10].)** *The sequence  $\{x_k\}$  converges to the minimum point of  $f$ .*

*Remark 8* The extremal basis method can be extended (with necessary adjustments) to the case where  $\varphi$  is just convex at  $x$ , not necessarily strongly convex.

*Remark 9* If the function  $\varphi$  in (1) is not convex then condition (7) and the Carathéodory theorem produce the following properties:

- 1) There exist points  $y_1, \dots, y_{k+1}$  such that  $y_i \in Y$  for any  $i \in 1, \dots, k + 1$  and a minimizer  $x^*$  of  $f$  is an inf-stationary point of the function

$$F(x) = \max_{i \in 1, \dots, k+1} \varphi(x, y_i).$$

- 2) There exist points  $y_1, \dots, y_{k+1}$  and coefficients  $\alpha_1, \dots, \alpha_{k+1}$  such that

$$\begin{aligned} y_i &\in Y, \quad \alpha_i \geq 0, \\ \forall i \in 1, \dots, k + 1, \quad \sum_{i \in 1, \dots, k+1} \alpha_i &= 1, \end{aligned}$$

and a minimizer  $x^*$  is a stationary point of the smooth function

$$L(x) = \sum_{i \in 1, \dots, k+1} \alpha_i \varphi(x, y_i).$$

These properties can be used to derive corresponding numerical algorithms.

**Constrained Minimax Problems**

Let  $f$  be defined by (1) on an open set  $S \subset \mathbf{R}^n$  and  $\Omega \subset S$  be a closed set. The problem is to find

$$\min_{x \in \Omega} f(x) = f^*.$$

Take  $x \in \Omega$ . The set

$$\Gamma(x, \Omega) = \left\{ g \in \mathbf{R}^n : \begin{aligned} &\exists \{[\alpha_k, g_k]\} : \\ &[\alpha_k, g_k] \rightarrow [+0, g], \\ &x + \alpha_k g_k \in \Omega, \\ &\forall k \end{aligned} \right\}$$

is the *Bouligand cone* to  $\Omega$  at  $x$ . It is nonempty and closed.

The function  $f$  is subdifferentiable (see (6)).

The following necessary condition holds ([4,5]):

For a point  $x^* \in \Omega$  to be a minimizer of  $f$  on  $\Omega$  it is necessary that

$$f'(x^*, g) \geq 0, \quad \forall g \in \Gamma(x^*, \Omega). \tag{22}$$

The cone  $\Gamma(x^*, \Omega)$  may be represented in the form

$$\Gamma(x^*, \Omega) = \bigcup_{i \in I} A_i, \tag{23}$$

where the  $A_i$  are closed convex cones,  $I$  is some set (e. g.,  $\Gamma(x^*, \Omega)$  can always be given as the union of all its rays). Of course, from practical considerations we are interested to have as few elements in  $I$  as possible (the best case is the one where  $\Omega$  is convex, then  $\Gamma(x^*, \Omega)$  is also convex).

Taking into account (6), condition (22) can be rewritten in the equivalent form

$$\partial f(x^*) \cap A_i^+ \neq \emptyset, \quad \forall i \in I, \tag{24}$$

where  $A_i^+$  is the cone conjugate to  $A_i$ :

$$A_i^+ = \{v \in \mathbf{R}^n : (v, g) \geq 0, \forall g \in A_i\}.$$

A point  $x^* \in \Omega$  satisfying (24) is called an *inf-stationary point* of  $f$  on  $\Omega$ .

Let  $x \in \Omega$  be not inf-stationary. For every  $i \in I$  let us find

$$\min_{\substack{v \in \partial f(x) \\ w \in A_i^+}} \|v - w\| = \|v_i - w_i\| = \rho_i \tag{25}$$

and

$$\max_{i \in I} \rho_i = \rho_{i_0} = \|v_{i_0} - w_{i_0}\|. \tag{26}$$

Then the direction

$$g_{i_0}(x_0) = \frac{w_{i_0} - v_{i_0}}{\rho_{i_0}}$$

is a direction of steepest descent of the function  $f$  at the point  $x_0$  (on the set  $\Omega$ ):

$$f'(x, g_{i_0}(x_0)) = \min_{\substack{g \in \Gamma(x_0, \Omega) \\ \|g\|=1}} f'(x, g).$$

It may happen that there exist several steepest descent directions (s.d.d.). If  $\Gamma(x_0, \Omega)$  is convex then such a direction is unique.

Many numerical methods for minimizing  $f$  on  $\Omega$  employ condition (24) (see [2,6,10,11,12]).

Let us discuss in detail the case where  $\Omega$  is described in the form

$$\Omega = \{x \in S : h(x) \leq 0\}, \tag{27}$$

where

$$h(x) = \max_{z \in G_1} \psi(x, z),$$

$G_1$  is a compact set of some space  $Z$ ,  $\psi: S \times G_1 \rightarrow \mathbf{R}^n$  is continuous jointly in  $x$  and  $z$  on  $S \times G_1$  and is continuously differentiable in  $x$ . Assume that  $\Omega$  is nonempty. Note that  $\Omega$  is closed.

The function  $h$  is also subdifferentiable and

$$\begin{aligned} \partial h(x) &= \text{co} \{ \psi'_x(x, z) : z \in Q(x) \}, \\ Q(x) &= \{ z \in G_1 : \psi(x, z) = h(x) \}. \end{aligned}$$

Note that if  $h(x) = 0$  and  $0_n \notin \partial h(x)$  then

$$\Gamma^+(x, \Omega) = \{v = \lambda w : \lambda \leq 0, w \in \partial h(x)\}.$$

If  $h(x) < 0$  the  $\Gamma^+(x, \Omega) = \{0_n\}$ .

The cone  $\Gamma(x, \Omega)$  is convex and closed and, hence, there exists only one steepest descent direction.

The following necessary condition is true: Let  $x^* \in \Omega$ ,  $h(x^*) = 0$ . For a point  $x^*$  to be a minimizer of  $f$  on  $\Omega$  it is necessary that

$$0_n \in \text{co}\{\partial f(x^*), \partial h(x^*)\} = L(x^*). \tag{28}$$

If  $0_n \notin \partial h(x^*)$  then conditions (22) and (28) are equivalent. If  $0_n \in \partial h(x^*)$  then (28) holds automatically but (22) does not.

If  $0_n \notin L(x_0)$ ,  $h(x_0) = 0$  then the direction

$$g(x_0) = - \frac{v(x_0)}{\|v(x_0)\|}$$

where

$$\|v(x_0)\| = \min_{v \in L(x_0)} \|v\|$$

is a descent direction and it is an admissible direction, i. e. there exists  $\alpha_0 > 0$  such that  $x_0 + \alpha g(x_0) \in \Omega, \forall \alpha$

$\in [0, \alpha_0]$ . Observe that the steepest descent direction is not necessarily admissible.

Note also that for any  $\lambda > 0$  condition (28) is equivalent to

$$0_n \in \text{co}\{\partial f(x^*), \lambda \partial h(x^*)\} = L_\lambda(x^*).$$

**Method of Hypodifferential Descent**

The function  $h$  (as well as  $f$ ) is continuously hypodifferentiable with the hypodifferential (cf. (11))

$$dh(x) = \text{co} \left\{ [a, v]: \begin{array}{l} a = \psi(x, z) - h(x), \\ v = \psi'_x(x, z), \\ z \in G_1 \end{array} \right\}. \quad (29)$$

Let

$$L(x) = \text{co}\{df(x), dh(x) + [h(x), 0_n]\}.$$

**Proposition 10** For a point  $x^* \in \Omega$  to be a minimizer of  $f$  on  $\Omega$  it is necessary that

$$0_{n+1} \in L(x^*). \quad (30)$$

A point  $X^* \in \Omega$  satisfying (30) is an inf-stationary point of  $f$  on  $\Omega$ .

If  $x \in \Omega$  is not inf-stationary, then

$$\rho(x) = \min_{\bar{z} \in L(x)} \|\bar{z}\| = \|\bar{z}(x)\| > 0.$$

Here

$$\begin{aligned} \bar{z}(x) &= [\eta(x), z(x)], \\ \eta(x) &\in \mathbf{R}, \quad z(x) \in \mathbf{R}^n, \quad z(x) \neq 0_n. \end{aligned}$$

The direction  $g(x) = -z(x)/\|z(x)\|$  is an admissible descent direction. The vector-function  $z(x)$  is continuous on  $\Omega$ .

Let us describe the following method (see [5, Chap. 5, Sect. 5]):

Take any  $x_0 \in \Omega$ . Let  $x_k \in \Omega$  have already been defined. If  $\rho(x_k) = 0$  then  $x_k$  is inf-stationary. If  $\rho(x_k) > 0$  then let us find

$$\begin{aligned} &\min_{\substack{\alpha \geq 0, \\ (x_k - \alpha z(x_k)) \in \Omega}} f(x_k - \alpha z(x_k)) \\ &= f(x_k - \alpha_k z(x_k)). \end{aligned}$$

Now put

$$x_{k+1} = x_k - \alpha_k z(x_k).$$

By construction  $x_k \in \Omega, \forall k$ .

If the sequence  $\{x_k\}$  is finite, its last point is an inf-stationary one. If it is infinite the following result holds:

**Proposition 11** If the set

$$\{x \in \Omega: f(x) \leq f(x_0)\}$$

is bounded, then any limit point of the sequence  $\{x_k\}$  is inf-stationary.

*Remark 12* The method described is ‘conceptual’. For its practical implementation it is necessary to avoid the computation of  $df$  and  $dh$  (by (11) and (29)) and take some smaller sets (since the hypodifferential mapping is not uniquely defined).

*Remark 13* If both functions  $\varphi$  and  $\psi$  are convex in  $x$  then the extremal basis method (given above) can be extended for minimizing  $f$  on  $\Omega$  (see [6]).

**The Kelley Method**

Let us consider the problem of minimizing a function

$$\begin{aligned} f(x) &= \max_{y \in G} \varphi(x, y) \\ &= \max_{y \in G} [\varphi_1(x, y) + f_1(x)] \end{aligned}$$

on a convex compact set  $\Omega \in \mathbf{R}^n$ , where  $\varphi_1: \Omega \times G \rightarrow \mathbf{R}$  is convex in  $x$  on  $\Omega$  for any  $y \in G$  and continuous in  $y$  on  $G$  and  $f_1: \Omega \rightarrow \mathbf{R}$  is continuous on  $\Omega$ . Then the following modification of the Kelley cutting plane method [8] can be used:

Choose any  $x_0 \in \Omega$  and find  $y_0 \in G$  such that  $\varphi(x_0, y_0) = f(x_0)$ . Take any  $v_0 \in \partial\varphi_1(x_0, y_0)$  (where  $\partial\varphi_1(x_0, y_0)$  is the subdifferential of the convex function  $\varphi_1(x, y_0)$  at  $x_0$ ). Put

$$\begin{aligned} B_0(x) &= f_1(x) \\ &\quad + \varphi_1(x_0, y_0) + (v_0, x - x_0). \end{aligned}$$

Let  $x_k \in \Omega$  have already been defined. Find  $y_k \in G$  such that  $\varphi(x_k, y_k) = f(x_k)$ , take any  $v_k \in \partial\varphi_1(x_k, y_k)$  and put

$$\begin{aligned} B_k(x) &= f_1(x) \\ &\quad + \varphi_1(x_k, y_k) + (v_k, x - x_k). \end{aligned}$$

Let

$$\begin{aligned} f_k(x) &= \max_{i \in 0, \dots, k} B_i(x) \\ &= f_1(x) + \max_{i \in 0, \dots, k} [\varphi_1(x_i, y_i) + (v_i, x - x_i)]. \end{aligned}$$

Find

$$\min_{x \in \Omega} f_k(x) = f_k(x_k^*).$$

If  $f_k(x_k^*) = f(x_k^*)$  then  $x_k^*$  is a minimizer of  $f$  on  $\Omega$  and the process terminates. Otherwise, take  $x_k^* = x_{k+1}$  and proceed as above. If the sequence  $\{x_k\}$  thus constructed is finite, its last point is a minimizer. If not, the following statement holds.

**Proposition 14** *Any limit point of the sequence  $\{x_k\}$  is a minimizer of  $f$  on  $\Omega$ .*

Newton method; Variational inequality problem; Nonlinear complementary problem; Smoothing; Approximation of nonsmooth mappings; Semismooth mapping; Superlinear convergence

One of the main approaches to solving equations and unconstrained optimization problems with differentiable functions involved is based on the *Newton*

method (NM). The classical version of this method (in a finite-dimensional setting) deals with an equation

$$F(x) = 0 \tag{1}$$

with a differentiable mapping  $F$ . Having an approximate solution  $x_k$  ( $k = 0, 1, \dots$ ) we wish to find a new one  $x_{k+1} = x_k + y$  which is ‘better’ than  $x_k$ . Since there exists the derivative  $\nabla F$ , we can approximate the mapping  $y \mapsto F(x_k + y)$  by the mapping  $y \mapsto F(x_k) + \nabla F(x_k)y$  and hence approximate the equation  $F(x_k + y) = 0$  by the equation

$$F(x_k) + \nabla F(x_k)y = 0. \tag{2}$$

It is assumed that the linear mapping  $\nabla F(x_k)$  is invertible. A new approximation  $x_{k+1}$  to the solution has a form  $x_{k+1} = x_k + y_k$  where  $y_k = -(\nabla F(x_k))^{-1} F(x_k)$  is a solution of the equation (2). (Sometimes it is more convenient to add a degree of freedom and consider a vector  $x_{k+1} = x_k + t_k y_k$  with  $t_k > 0$  as a new approximation.) Thus a classical smooth version of the NM has a form

$$x_{k+1} = x_k - (F'(x_k))^{-1} F(x_k). \tag{3}$$

There are many methods for solving an unconstrained minimization problem

$$f(x) \rightarrow \min \tag{4}$$

based on the scheme (3) and its modifications. The simplest scheme:

$$x_{k+1} = x_k - [\nabla^2 f(x_k)]^{-1} \nabla f(x_k) \tag{5}$$

is suitable for twice-continuously differentiable ( $C^2$ ) functions  $f$ . This scheme allows us to find critical points of the function  $f$ .

As it turns out many optimization and related problems even with smooth objective functions and constraints can be reduced to the solution of special kinds of nonsmooth equations (see, for example, [20]).

We shall consider as an example a variational inequality problem (VIP): find a vector  $x \in D$  such that

$$(y - x)^\top F(x) \geq 0 \quad \text{for all } y \in K, \tag{6}$$

where  $K$  is a closed convex subset of  $\mathbf{R}^n$  and  $F$  is a continuously differentiable ( $C^1$ ) mapping defined on an

open set  $D \supset K$ . Let  $P_K$  be the metric projection onto the set  $C$  (that is  $\|x - P_K x\| = \min_{y \in K} \|x - y\|$  with the Euclidean norm  $\|\cdot\|$ ) and

$$\begin{aligned} \widetilde{F}_K(x) &= x - P_K(x - F(x)), \\ F_K(z) &= F(P_K(z)) + (z - P_K(z)). \end{aligned} \tag{7}$$

It can be shown (see, for example, [20]) that a vector  $x$  satisfies (6) if and only if  $x$  is a solution of the equation  $\widetilde{F}_K(x) = 0$  and if and only if  $z = x - F(x)$  is a solution of the equation  $F_K(z) = 0$ . Since  $P_K$  is not necessarily a smooth mapping it follows that both mappings  $\widetilde{F}_K$  and  $F_K$  are not necessarily smooth.

A special case of VIP (6) with  $K = \mathbf{R}_+^n$  is a nonlinear complementary problem (NCP): find a vector  $x \in D$  such that

$$x \geq 0, \quad F(x) \geq 0, \quad x^\top F(x) = 0, \tag{8}$$

where  $D \subset \mathbf{R}^n$  is an open set containing the nonnegative orthant  $\mathbf{R}_+^n$  and  $F$  is a continuously differentiable ( $C^1$ ) function defined on  $D$ . Since  $P_{\mathbf{R}_+^n}(x) = x^+$ , the mappings (7) have the following form:

$$\begin{aligned} \widetilde{F}_K(x) &= \min(x, F(x)), \\ F_K(z) &= F(x^+) - x^-, \end{aligned} \tag{9}$$

where  $x^+ = \max(x, 0)$  and  $x^- = \min(x, 0)$ ; max and min stand for componentwise maximum and minimum, respectively. Thus NCP reduces to equations with max and min operators.

The following properties of the function  $m(b, c) = \min(b, c)$  are important for application to NCP:  $m$  is positive homogeneous of the first degree and the set  $\{x = (x_1, x_2): x_1 \geq 0, x_2 \geq 0, m(x) = 0\}$  coincides with the union of two positive semi-axes. Sometimes it is more convenient to consider functions with the same properties and also being  $C^1$  on  $\mathbf{R}^2$  except the origin. One example from this large class of functions is the so-called Fischer-Burmeister function [8]

$$\phi(b, c) = (b^2 + c^2)^{1/2} - (b + c). \tag{10}$$

If

$$H(x) = (\phi(x_1, F_1(x)), \dots, \phi(x_n, F_n(x)))^\top, \tag{11}$$

then  $x$  is a solution of NCP if and only if  $H(x) = 0$ .

Thus it became necessary to extend the NM to enable the efficient solution of nonsmooth equations.

Note that this extension is not generally possible. B. Kumer [15] has found an example of a function  $F$  defined on the real line, which enjoys very good properties ( $F$  is Lipschitz, strictly monotone, directionally differentiable everywhere and Fréchet differentiable at the solution of the equation (1)) and such that NM alternates for almost all starting points.

One of the first contributions to nonsmooth NM was given by S.M. Robinson [27] for solving feasibility problems involving inequality constraints and by M. Kojima and S. Shindo [14] for solving (1) with a piecewise smooth mapping  $F$ . Various versions and modifications of the NM for nonsmooth equations have been developed during the last decade. In particular *damped NM* and *smoothing NM* enjoy global convergence under certain monotonicity assumptions. There are finite-dimensional and infinite-dimensional settings of this problem. Here we consider only finite-dimensional versions of the nonsmooth NM. For infinite-dimensional problems see for example [7,16].

The first problem which arises in the study of nonsmooth NM is to find suitable *approximations of nonsmooth mappings*. Many authors suggested various versions of such approximations. Two types of approximations are mainly considered. One of them is an approximation by a certain set-valued mapping  $x \rightarrow V(x)$  where  $V(x)$  is a set of invertible matrices. In this case the equation (2) is replaced by a linear equation  $F(x_k) + A_k y = 0$ , where  $A_k$  is an arbitrary matrix from  $V(x_k)$ . Thus NM in such a setting has a form

$$x_{k+1} = x_k - A_k^{-1} F(x_k). \quad (12)$$

The second type is based on an approximation by means of a certain nonlinear mapping  $F'$ . In such a case the method can be presented in the following form:  $x_{k+1} = x_k + y_k$ , where  $y_k$  is a solution of the nonlinear equation

$$F(x_k) + F'(x_k)(y) = 0. \quad (13)$$

It is assumed that the auxiliary nonlinear equation (13) can be solved relatively easily.

There is a general approach [16] based on the set-valued approximation  $\mathcal{F}(x, y)$  of a single-valued locally Lipschitz mapping  $F$  which includes both of the above mentioned types. This approach clarifies two conditions which lead to convergence of NM: first the

uniform injectivity (invertibility) of the approximating mapping at a neighborhood  $Y$  of a solution  $x^*$ : there exists  $c > 0$  such that

$$\|u\| \geq c \|y\| \quad \text{for all } y \in Y, u \in \mathcal{F}(x, y), \quad (14)$$

and secondly, that the mapping  $F$  should accomplish a relatively good approximation at this neighborhood:

$$F(x) + \mathcal{F}(x, y) \subset \mathcal{F}(x, y + (x - x^*) + o(\|x - x^*\|), \quad (15)$$

where  $o(y)/\|y\| \rightarrow 0$  as  $\|y\| \rightarrow 0$ .

It can be shown (see [16]) that for many concrete situations (15) is equivalent to

$$F(x) + \mathcal{F}(x, x^* - x) \subset o(\|x - x^*\|)B, \quad (16)$$

where  $B$  is the unit ball. The local speed of convergence is determined by the number  $c$  and the function  $o$  in (15). Conditions (14) and (15) are necessary for convergence of NM under some additional assumptions ([16]).

We now turn to the first type of approximation. If  $F$  is a locally Lipschitz mapping then the *B-subdifferential*  $\partial_B F(x)$  and *Clarke generalized Jacobian*  $\partial_{Cl} F(x)$  are considered as approximations. By definition

$$\partial_B F(x) = \left\{ \lim_{x_k \rightarrow x} \nabla F(x_k): \begin{array}{l} F \text{ differentiable} \\ \text{at } x_k \end{array} \right\}$$

and  $\partial_{Cl} F(x)$  is the convex hull of  $\partial_B F(x)$ . L. Qi suggested another approximation, the *C-differential* [23], which can be applied to all continuous (not just Lipschitz) mappings. By definition the *C-subdifferential*  $T$  is a compact-valued upper-semicontinuous mapping such that  $F(x + u) = F(x) + A(u) + o(u)$  for any  $A \in T(x + u)$ . (It is important that  $T$  is a mapping, not an individual set at the point  $x$ ; approximation near the point  $x$  is accomplished by matrices from the sets  $T(y)$  for all  $y$  sufficiently close to  $x$ .) Close construction of point-based set-valued approximation is studied in [30], where connections with constructions from [16,28] are mentioned. There exist exact calculus rules for *C-differentials* which allow their relatively easy computation. An interesting example of approximation is given by *approximate Jacobians* (see, for example, [10]). This construction is again applicable for all continuous mappings and allows the unification of various approaches to approximation.

Local convergence based on a matrix approximation  $V(x)$  can be proved only if all matrices  $A$  belonging to  $V(x)$  with  $x$  sufficiently close to a solution  $x^*$ , accomplish a sufficiently good approximation (compare with [16]). Convergence can be, in particular, proved if the mapping  $F$  is semismooth (see [25]) at the point  $x^*$  or enjoys some properties close to semismoothness (see, for example, [10]). The mapping  $F$  is called *semismooth* with respect to a matrix approximation  $V(x)$  at a point  $x^*$  if the directional derivative  $F'(x, \cdot)$  exists at all points  $x$  close to  $x^*$  and

$$\begin{aligned} Au - F'(x, u) &= o(\|u\|), \\ A &\in T(x + u), \quad u \rightarrow 0, \end{aligned} \tag{17}$$

that is, each matrix  $A \in T(x + u)$  approximates the directional derivative at the point  $x$  in the direction  $u$ . (Semismoothness was originally introduced by R. Mifflin for real-valued functions in 1977.) In some applications strong semismoothness is required. The mapping  $F$  is called *strongly semismooth* at a point  $x$  if there exists a number  $K$  such that

$$\begin{aligned} \|Au - F'(x, u)\| &\leq K \|u\|^2, \\ A &\in T(x + u), \quad u \rightarrow 0. \end{aligned} \tag{18}$$

Semismoothness and strongly semismoothness can be easily verified in many concrete situations. The simplest example of a strongly semismooth mapping is a coordinatewise maximum (or minimum) of a finite number of  $C^2$  mappings.

It is well known that the NM produces for differentiable mappings a sequence which converges to a solution very fast. As it turns out this property holds also in nonsmooth setting under some regularity conditions. Qi and J. Sun demonstrated that for semismooth mappings the rate of convergence is *Q-superlinear* [25], that is

$$\lim_{k \rightarrow +\infty} \frac{\|x_{k+1} - x^*\|}{\|x_k - x^*\|} = 0.$$

Under some additional assumptions (for example, strong semismoothness) [25] it can be shown that the rate of convergence is *Q-quadratic*:

$$\lim_{k \rightarrow +\infty} \frac{\|x_{k+1} - x^*\|}{\|x_k - x^*\|^2} < +\infty.$$

The so-called *Kantorovich scheme* [12] in the study of NM can also be extended for nonsmooth equations

(see for example [16,25,27,29]). This scheme allows one to prove not only the convergence of the NM but also the existence of a solution in a small neighborhood of the starting point  $x_0$  if some combinations of such parameters as  $\|F(x_0)\|$  and the uniform boundary of norm of inverse matrices, the value  $K$  in (18), the radius of neighborhood, are sufficiently small.

Various kinds of nonlinear approximation are used for setting the NM in the framework of the second approach.

The *B-derivative* [19,22], that is uniformly (with respect to direction) directional derivative, is often used as a nonlinear approximation. One more tool for such an approximation is the *codifferential* [5]. One of the difficult tasks arising under application of the NM based on nonlinear approximation is to solve the auxiliary subproblem (13). For *B-derivative* based NM, J.S. Pang [19] proposed solving this problem inexactly. A version of NM under the assumption that each matrix of  $\partial_B F(x)$  is invertible (the so-called *BD-regularity*) was studied in [22]. This assumption is weaker than invertibility of *B-derivative* and also nonsingularity of all matrices of  $\partial_{Cl} F(x)$ . A different approach to nonlinear approximation was proposed by Robinson [28], who introduced the so-called *point-based approximation*. This approach is convenient in the study of equations with mappings  $F_K$  (see (7)) generated by the projection  $P_K$  on a convex set  $K$ . *Q-superlinear* convergence and (for strong approximations) *Q-quadratic* convergence can be proved for various kinds of nonlinear approximations.

An abstract version of the second approach, based on the Kantorovich scheme, was proposed in [29]. The mapping  $F^\circ(x, \nu)$  is called an *approximator* for the mapping  $F$  at the point  $x$  in the direction  $\nu$  if  $F(x + \nu) = F(x) + F^\circ(x, \nu) + o(\nu)$  where  $\lim_{t \rightarrow +0} t^{-1} o(t\nu) = 0$ . Assume that an approximator  $F^\circ$  accomplishes a strong approximation: there exist a number  $K$  such that  $\|F(x + u) - F(x) - F^\circ(x, u)\| \leq K \|u\|^2$  for all  $x$  close to the starting point  $x_0$ , and  $F^\circ$  enjoys the following property (which is weaker than the pseudo-Lipschitz property [1]): there exists a number  $L$  such that the equation  $F^\circ(x, u) = y$  has a solution  $\bar{u}$  with  $\|\bar{u}\| \leq L \|y\|$  for all sufficiently small  $y$ . Then the convergence of the NM based on  $F^\circ$  can be proved [29] by means of the Kantorovich scheme under some typical for this scheme assumptions. The inequality  $\|x^* - x_k\| \leq \gamma$

$2^{-k}$  holds for the Newton sequence  $(x_k)$  with a number  $\gamma > 0$ .

As a rule NM converges to a solution (even in the smooth setting) only if a starting point is sufficiently close to this solution. Thus the question arises: is it possible to find modifications of NM which provide *global convergence* for some equations, that is convergence from an arbitrary initial point? One of such modifications is the *damped Newton method*. For instance, if the NM uses a positively homogeneous approximation  $F'(x_k, u)$ , such as a Jacobian in the smooth case, or directional derivative [7,13,15,19], then  $x_{k+1}$  is chosen as  $x_k + \lambda_k y_k$  for some  $\lambda_k \in (0, 1]$  such that

$$\|F(x_{k+1})\| \cong (1 - \lambda_k) \|F(x_k)\| < \|F(x_k)\|. \quad (19)$$

This can be generalized to nonpositively homogeneous approximations such as point based approximations [3,21] by setting up a path  $p_k(\lambda)$  joining  $x_k = p_k(0)$  to  $x_k + y_k = p_k(1)$ , where  $y_k$  is found by the NM, such that  $F(p_k(\lambda)) = (1 - \lambda) F(x_k) + o(\lambda)$ . Then it is easy to determine  $\lambda_k \in (0, 1]$  such that for  $x_{k+1} = p_k(\lambda_k)$ , (19) holds.

There is a close connection between the damped NM and the so-called *list square merit function* of the operator  $F$ :

$$\theta(x) = \frac{1}{2} \|F(x)\|^2.$$

For some nonsmooth operators  $F$  arising from NCP and related problems the function  $\theta$  is continuously differentiable. This property is very useful in the study of NM and damped NM [11].

One of modifications of the nonsmooth NM is the so-called *smoothing Newton method*, which is also called *splitting NM* or *homotopy NM*. This method based on an approximation of the operator  $F$  in (1) by a smooth function  $G$ . Usually a smoothing damped NM is studied. This method has the following form

$$x_{k+1} = x_k - t_k \nabla G_x(x_k, \varepsilon_k)^{-1} F(x_k), \quad (20)$$

where  $G(x, \varepsilon)$  is a smoothing approximation of the mapping  $F$ , that is for any  $\varepsilon > 0$  the function  $x \mapsto G(x, \varepsilon)$  is continuously differentiable and  $\|F(x) - G(x, \varepsilon)\| \rightarrow 0$  as  $\varepsilon \rightarrow 0$ .

Various types of *smoothing functions* are used in optimization for a long time (see, for example, [13]). Some

of them can be constructed by means of the so-called *Chen–Harker–Kanzow–Smale function*:

$$\xi(u, \varepsilon) = \frac{1}{2} \left( (u^2 + 4\varepsilon^2)^{\frac{1}{2}} + u \right), \quad (u, \varepsilon) \in \mathbb{R}^2,$$

which serves for an approximation of  $\max(0, u)$  (see, for example, [24]). In particular, it is possible to find smoothing operators for operators defined by (9) by means of the function  $\xi$ . An interesting approach to the smoothing methods can be found in [3]. Global convergence of the method (20) can be proved under some assumptions. If the gradient of the smoothing function  $G$  is fairly close to some approximations of the operator  $F$  then the method converges Q-superlinearly (quadratically) [4,24].

There is a close connection between smoothing NM and *interior point methods* (see, for example, [21]).

For some special classes of problems it is possible to obtain stronger results than in the general setting (see, for example, [6,11,18,26]). On the other hand there are modifications of the nonsmooth Newton method for the solution of generalized equations of the form  $y \in F(x)$  with a set-valued mapping  $F$  (see, for example, [2,7,16]).

Parametric programming model; Sensitivity; Stability; Optimal parameter; Parameter identification; Point-to-set mapping

Mathematical descriptions of real-life problems are typically stated in terms of *decision variables*  $x$  and parameters  $\theta$ . These objects may be related through a system of equations and inequalities such as

$$x \in \mathcal{F}(\theta) = \left\{ x \in \mathbf{R}^n : \begin{array}{l} g^i(x, \theta) \leq 0, \quad i \in I, \\ h^j(x, \theta) = 0, \quad j \in J \end{array} \right\},$$

where  $g^i, h^j: \mathbf{R}^n \times \mathbf{R}^p \rightarrow \mathbf{R}$ ,  $i \in I, j \in J$ , are some functions, and  $I$  and  $J$  are finite index sets. Problems of the form

$$\left\{ \begin{array}{ll} \min_{(x)} & f(x, \theta) \\ \text{s.t.} & x \in \mathcal{F}(\theta), \end{array} \right.$$

where  $\theta$  is allowed to vary over some set  $F$  in  $\mathbf{R}^p$ , are termed *parametric programming models* (PPM). *Parametric programming* (PP) is the study of parametric programming models. A local analysis of these models, around a fixed  $\theta$ , is referred to as *sensitivity analysis* (SA). In particular, SA is concerned with changes of the minimal value subject to small perturbations of the parameter. Parametric programming is a huge area containing, or closely related to, many topics, such as path following methods (cf. ► [Parametric optimization: Embeddings, path following and singularities](#)), sensitivity in semi-infinite programming, constraint qualifications (cf. also ► [First order constraint qualifications](#); ► [Second order constraint qualifications](#)), bilevel programming (cf. ► [Bilevel programming: Introduction, history and overview](#)), etc. We will refer to some of these topics hereby only in passing. Since every equality constraint can be replaced by two inequalities, one can assume that  $J = \emptyset$ . Then the model is said to be *linear* (resp. *convex*) if the functions  $f(\cdot, \theta), g^i(\cdot, \theta): \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $i \in I$ , are linear (resp. convex) for every  $\theta \in \mathbf{R}^p$ .

## Historical Outline

Parametric programming has its roots in the study of linear programs:

$$\text{LP} \left\{ \begin{array}{ll} \min & c^\top x \\ \text{s.t.} & Ax \leq b, \quad x \geq 0, \end{array} \right.$$

where one or more coefficients of the vectors  $b$  and  $c$ , or the matrix  $A$ , are considered as parameters and allowed to vary. The study can be traced to the 1950s literature. According to [16], the right-hand side changes in a linear program were investigated by W. Orchard-Hays in his unpublished Master's thesis (1952). The term 'parametric' LP was used in [41]. The classical problems of SA and PPM dealt mainly with pivoting and the simplex method. A different approach that uses polyhedral structures rather than the simplex method was developed in [46,47,48,49]. A classical parametric problem in LP is to determine the range of perturbations for specific parameters in  $b$  and  $c$ , that preserve optimal bases. A related problem is to determine the range for which an optimal solution exists. This range is called the 'critical set'. Various approaches to solving these problems have been successfully implemented in commercial software packages and adjusted to particular situations, e.g., data envelopment analysis [45]. It is well known that difficulties may arise when the problem under consideration is degenerate (i.e., when optimal basis is not unique). In that case the commercial packages may provide essentially different results, that is to say, the information could be 'confusing and hardly allows a solid interpretation'; see, e.g., [5], where the claim is demonstrated on a transportation problem. The study of changes of the parameters in [5] is a departure from the classical approach. Instead of employing local analysis and pivoting, the authors make use of the strict complementarity condition and optimal partitioning in order to construct and study the behavior of the *optimal value function* for the right-hand side and objective-function perturbations. They do it for both LP and convex quadratic programming and obtain sharp intervals. Other approaches used to study the effect of perturbations of parameters in LP, including the 'tolerance approach' (where variations may occur simultaneously and independently), are described in [63,64]. The classical texts on sensitivity analysis and *parametric linear programming* include [9,15,37,48,49].

([15] lists 1031 references.) Almost 1000 items only on degeneracy in LP are listed in [17].

A major obstacle to using linear algebra and calculus methods in the study of linear models is that these methods are not suited to explain continuity properties of the model. Indeed, the model does not generally react ‘continuously’ to continuous changes of the parameters in the coefficient matrix. Let us illustrate such a situation.

*Example 1* Consider the model

$$\begin{cases} \min & x \\ \text{s.t.} & \theta x = 0, \\ & -1 \leq x \leq 1. \end{cases}$$

When  $\theta = 0$ , then the feasible set  $\mathcal{F}(\theta)$  is the segment  $-1 \leq x \leq 1$ , the optimal solution is  $x = -1$ , and the optimal value is  $-1$ . For any perturbation  $\theta \neq 0$ , all three objects jump to zero.

An example of a linear model where the critical set is disjoint and not closed is given in [9, pp. 114–116]. Another one with a matrix of full row rank where both the feasible set and the set of optimal solutions experience jumps under continuous perturbations of the *parameter* in the interior of the critical set is given in [42]. We extend this example to an LP in canonical form with a full row rank matrix below.

*Example 2* Consider the model

$$\begin{cases} \min & -x_2, \\ \text{s.t.} & x_1 + x_2 + x_3 = 1, \\ & x_1 + \theta x_2 - x_4 = 1, \\ & x_i \geq 0, \quad i = 1, \dots, 4. \end{cases}$$

A unique optimal solution at  $\theta = 1$  is  $x = (x_i) = (0, 1, 0, 0)$  and the optimal value is  $-1$ . However, for any perturbation  $\theta = 1 - \epsilon$ ,  $\epsilon > 0$ , the solution jumps to another unique optimal solution  $(1, 0, 0, 0)$ , and the optimal value becomes zero.

In order to study reactions of a model to continuous perturbations of data, the feasible set and the optimal solutions set can be viewed as images of *point-to-set mappings* with a domain in the space of parameters. Hence the study of continuity of these and related objects, such as *Lagrange multiplier sets*, requires

basic tools of point-to-set topology. These tools have been used in mathematical programming sporadically and in different contexts, e.g., in an analysis of convergence of numerical algorithms in [50,65]. After papers such as [26], the point-to-set approach to the study of parametric programming has become standard. The first text on the theory of *nonlinear parametric optimization* is [4], written by several authors from the ‘Berlin school of parametric optimization’ initiated by F. Nožička. (Twenty nine students obtained doctorates under his supervision.) This text contains 30 pages of bibliography on PP. A classical text on methodology used in perturbation analyses in nonlinear programming is [13], and one on path following methods in PP is [25]. A unified approach to general perturbations with applications to system analysis and numerical optimization is given in [34]. Since the late 1970s there has been an outburst of research activities in PP. For instance, to date (1998) there have been 20 annual symposia on mathematical programming with data perturbations held at the George Washington Univ., and the International Conference on Parametric Optimization and Related Topics is being held bi-annually since 1985. There have been at least 15 books written on parametric programming.

The study of parametric programming can be roughly divided into three general areas: *stability*, optimality and numerical methods, and applications.

### Stability

In this area one mainly studies continuity properties of the feasible set  $\mathcal{F}(\theta)$ , the set of all optimal solutions  $\mathcal{F}^\circ(\theta) = \{x^\circ(\theta)\}$ , the set of all Lagrange multipliers  $U = U(\theta)$ , and the optimal value  $f^\circ(\theta) = f(x^\circ(\theta), \theta)$ , as the parameter  $\theta$  varies. Here  $f^\circ$  is a function, while  $\mathcal{F}: \theta \rightarrow \mathcal{F}(\theta)$ ,  $\mathcal{F}^\circ: \theta \rightarrow \mathcal{F}^\circ(\theta)$ , and  $U \rightarrow U(\theta)$  are point-to-set mappings. If the constraints in a *parametric programming model* are continuous functions, then  $\mathcal{F}$  is a closed mapping. In order to guarantee continuity of the mapping  $\mathcal{F}$  one requires an extra condition, e.g., that  $\mathcal{F}$  be lower-semicontinuous (or, equivalently, open). If the PPM is convex and  $\mathcal{F}^\circ(\theta^*) \neq \emptyset$  and bounded, at some  $\theta^*$ , then continuity of  $\mathcal{F}$  locally implies both the existence of optimal solutions and continuity of the *optimal value function*, and the mapping  $\mathcal{F}^\circ$  is closed. However, continuity of  $\mathcal{F}$  does not imply continuity of  $U$ .

Conditions for the existence of a differentiable path of solutions  $x^\circ(\theta)$  in a general model, as the parameter  $\theta$  varies, are given in [14]. They are extended to a continuously differentiable path of saddle points in [13]; see also [19,20]. The results are established by applying an appropriate implicit function theorem to a necessary condition for optimality. The reference [14] also contains an explicit formula for the partial derivatives, as well as approximations based on classical penalty functions. For a state-of-the-art about *Lipschitz stability* for linear and quadratic (also nonconvex) programs up to 1987, see [30]. For a recent (1998) guided tour of sensitivity analysis that yields lower and upper estimates for the optimal value function see [6].

If the feasible set mapping  $\mathcal{F}$  is continuous and the set of optimal solutions is nonempty and bounded, then such models are often termed stable. In *convex parametric programming* continuity of  $\mathcal{F}$  is implied by *Slater's condition*. In the fundamental paper [51], stability for linear systems in the canonical form, subject to perturbations of all data, is characterized by the existence of a positive feasible solution  $x > 0$ . The result is stated for linear inequalities in partially ordered Banach spaces. It is extended in [52] to nonlinear inequalities over a closed convex set. When perturbations of specific coefficients are considered, then the existence of a positive solution is not a necessary, but it is rather a sufficient condition for stability. Also, in this case, chunks (regions) of the parameter space attached to a fixed parameter  $\theta^*$ , where  $\mathcal{F}$  is lower semicontinuous, are termed *regions of stability* at  $\theta^*$  see [73,74]. (In the model from Example 2, a region of stability at  $\theta^* = 1$  is  $\theta \geq 1$ .) Such regions can often be calculated globally; one of these is the set of all paths emanating from  $\theta^*$  on which the constraints satisfy Slater's condition. For a list of regions of stability and a necessary condition for stability in convex PP see [69]. These regions are of independent interest in, e.g., the study of random decision systems with complete connections [66] and linear programming [7]. The radius of the largest ball centered at  $\theta^*$ , with the property that the model is stable at its every interior point  $\theta$ , is the *radius of stability* at  $\theta^*$ , e.g., [69]. It is a measure of how much the system can be uniformly strained from  $\theta^*$  before it starts breaking down. In a linear parametric programming model in canonical form with a full row rank coefficient matrix, stability is implied by the existence of

a nondegenerate basic feasible solution. On the other hand, *instability* (i. e., loss of continuity of the feasible set mapping) typically occurs in situations of 'enforced optima' such as lexicographic and multilevel programming, including *von Stackelberg games* of market economy. For example, in bilevel programming, instability occurs when the optimal solutions set of the follower (lower level decision maker) loses its lower semicontinuity. The leader's (upper level decision maker's) model is then unstable, because its feasible set is the set of optimal solutions of the follower. In this situation the leader's optimal value function typically experiences a discontinuity even if the follower's model is globally stable; see [43, Chapt. 13; 16]. The notion of stability is not uniquely defined, see, e.g. [4,13,21,31,34]. *Structural stability* and continuous deformations of nonlinear programs have been studied in, e.g., [22,28,29,33]. In particular, the '*topological stability*' of the feasible set (i. e., homeomorphy with respect to all sufficiently small perturbations up to second order of the involved functions) is proved to be equivalent to the Mangasarian–Fromovitz constraint qualification being satisfied at the feasible points; see [24]. Characterizations of stability (local existence and uniqueness) of stationary points and Karush–Kuhn–Tucker points with respect to all sufficiently small perturbations up to second order are given, respectively, in [32,53]. For a study of stability with nondifferentiable data see [3,44], also [57]. Some difficulties with an abstract formulation of parametric programming are mentioned in [43, Chapt. 14]; see also [2,58,75]. Stability in optimal control is studied in, e.g., [38,39].

## Optimality and Numerical Methods

A parameter  $\theta$  is said to be *locally* (resp. *globally*) optimal if it locally (resp. globally) optimizes the optimal value function  $f^\circ(\theta)$  over its feasible set  $F = \{\theta: \mathcal{F}(\theta) \neq \emptyset\}$ . Calculation and characterization of *optimal parameters* are basic problems of parametric programming. For convex PPM one can formulate necessary and sufficient conditions for local (and global) optimality of the parameter, e.g., [68,69,70,71]. These conditions are expressed in terms of *saddle-point inequalities* and local results typically require conditions such as uniqueness of the optimal solution in the  $x$  component and lower semicontinuity of the feasible set mapping. They

are simplified under *input constraint qualifications* [55]. The optimal value function is not generally known analytically, it is generally nondifferentiable, nonconvex (nonconcave), and discontinuous even for linear models. However, for the right-hand side and objective-function perturbations in linear models it can be constructed, e. g., [5].

Calculation of optimal parameters is often achieved by using the so-called '*marginal value formula*'. This formula gives the derivative of the optimal value function on a prescribed path in terms of the derivatives of the Lagrangian function relative to  $x$  and  $\theta$ . At each iteration the calculation consists of two parts: first, an improvable feasible path is determined and then a step-size problem is solved on the path by a search method. Optimization of the optimal value function by stable perturbations of the parameters (also called *input optimization*) in convex PP is a challenging problem and no satisfactory theory or numerical methods presently seem to exist, e. g., [71]. In contrast, the theory of path following methods, based on nonlinear programming optimality conditions and used when data depend on one scalar parameter, is well developed, although 'not successful in every case' see, e. g., [23,25]. In order to improve the *path following approach* these authors propose jumps between connected components in the sets of local minimizers and generalized critical points.

## Applications

Classical sensitivity analysis, when applied to the right-hand side perturbations in linear programming, provides interpretation of Lagrange multipliers as *shadow prices*. The results have been extended to convex programming using the marginal value formula, e. g., in [12]. Genuine applications of parametric programming extend far beyond classical sensitivity analysis. Some of them are related to the fundamental notion of a *well-posed problem* in the sense of Hadamard. These are problems in applied mathematics which have a unique solution and the solution changes continuously when the parameters (e. g., boundary conditions in differential equations) change continuously. Problems that are not well-posed are called *ill-posed*. According to Fritz John (see [62, p. ix]) 'the majority of applied problems are, and always have been, ill-posed, partic-

ularly when they require numerical answers'. There is a more general notion of well-posedness (for problems with nonunique solutions); see [10]. Many problems of mathematical physics can be formulated as optimization problems and continuous dependence of the solution on the boundary conditions can be studied using PP. In the context of mathematical programming, some of the first applications of PP included the study of convergence of numerical algorithms. The rate of convergence can be determined using continuity properties of point-to-set mappings; see, e. g., [14,50,54,65]. Some of the ambiguities that occur while solving ordinary LP can be understood and resolved by PP. For example, in some models describing real-life problems, such as the one reported in [62, pp. 212–213], significant *jumps of optimal solutions* occur when some data are perturbed, while the respective values of the objective function are comparatively close. This is a typical behavior of stable linear programming models when the optimal solutions mapping is not continuous. The authors of [62] suggest a method for stabilization of optimal solutions of such programs by 'Tikhonov regularization'.

The results on optimal parameters in parametric programming have many applications including machine scheduling [61,67], restructuring of the work force in a textile mill [71,72], ranking of efficiently administered university libraries by their robustness of data [40,72], the study of systems of differential equations under matrix perturbations in robust analysis and control [27], as well as approximation theory, especially in the problems of *best fitting to data*. These problems are formulated as follows: given a set of points, one wishes to determine a function (from a prescribed class of functions, e. g., linear) that best approximates these points. After forcing the points to satisfy the function, the problem generally reduces to an inconsistent system of equations for which one determines a best approximate solution. The solution is given in terms of *decision variables* (such as the slope of the line and its intersection with the  $y$ -axis, in the linear cases of two-dimensional data in the  $(x, y)$ -plane). If the Euclidean norm is used then the solutions are called the *least squares solutions*. However, the problem can also incorporate estimates of errors made in measuring data. The errors may fall within some known lower and upper bounds. One can consider the data vector as a pa-

parameter in which case the best approximation problem assumes a more general form. It consists of finding perturbations of data, within specified boundaries, for which one achieves the best fit. The problem is called the *generalized least squares problem* in the context of the Euclidean space. If the analytic form of the function that approximates data is known, and if it contains some ‘parameters’ to be determined, then the best approximation problem is called the *parameter identification problem*.

*Example 3* One may wish to determine the constant of gravity  $g$ , the initial position  $s_0$ , and the initial velocity  $v_0$  of a falling object. It is known that the object is governed by Newton’s second law of motion  $s = s_0 + v_0 t + gt^2/2$ . Measuring  $s = s(t)$  at various times  $t$ , one obtains a generally inconsistent system of linear equations in the ‘parameters’  $s_0$ ,  $v_0$ , and  $g$ . After minimizing a norm of the residual vector one identifies the parameters. However, one may also take into consideration relative errors that have been made in reading  $t$  and  $s(t)$ . The generalized parameter identification problem is to determine the best fit within the allowable errors. This approach typically gives more accurate results. In the context of parametric programming models, the optimal errors are optimal values of the parameter, while the ‘parameters’ to be identified, like  $s_0$ ,  $v_0$ , and  $g$ , are actually decision variables.

Parameter identification problems are used in many areas. For example, in the biological sciences they are used in attempts to find kinetic constants which can quantitatively describe certain *biochemical processes*. Typically, experiments are performed with tracers (labeled with radioactive or stable isotopes), then experimental tissue radioactivity curves are fitted to a biological model to find kinetic parameters. On the basis of these kinetic parameters one can calculate regional glucose utilization in the brain [60], serotonin synthesis [8], aromatic amino acid activity [18] and receptor densities [36].

Optimal parameters are also important for *post-optimality analyses* of linear programs. Using PP one can answer basic questions like: Given an optimal solution of an LP, for what perturbations of data does the solution remain optimal? The following example exposes the problem.

*Example 4* Consider the linear program in one variable with zero-value objective function:

$$\begin{cases} \min & 0 \cdot x \\ \text{s.t.} & -1 \leq x \leq 1. \end{cases}$$

A (global) *minimizer* is  $x^* = -1$ . Now suppose that this program belongs to the class of perturbed programs

$$\begin{cases} \min & \theta^2 \cdot x, \\ \text{s.t.} & -1 \leq x \leq 1, \end{cases}$$

when  $\theta$  is fixed at  $\theta^* = 0$ . Then, for perturbations  $\theta \neq 0$ , the point  $(x^*, \theta^*)$  is actually a local *maximizer*! In situations like these some optimal solutions of linear programs may be ‘better’ than others. Here, say,  $x = 1$  is ‘better’ than  $x^* = -1$ , because its local optimality is not affected by perturbations of  $(x, \theta)$ .

The optimality-preserving problems, at the global optimality level, are solved for linear models using the saddle-point optimality conditions along  $\theta$ -paths and after setting the terms corresponding to the components of the  $x$  variable equal to zero. Two closely related problems are:

- i) given an infeasible point  $x$  (e. g., a prescribed profile of production that one wishes to achieve), find perturbations of data  $\theta$  that make the point feasible; and
- ii) given a feasible but nonoptimal point, find perturbations that make the point optimal.

Many results from convex parametric programming can be adjusted to work for partly convex programs (PC) and more general mathematical programs, e. g., [1,23,70]. Partly convex programs are programs which, after ‘freezing’ some of the coordinates in  $x$ , become convex programs in the remaining variables. The program from Example 4, with the objective function  $x_2^2 \cdot x_1$  and the constraint  $-1 \leq x_1 \leq 1$ , is a PC program. (Identify  $x_2 = \theta$ .) Since every mathematical program with twice continuously differentiable functions can be formulated as a *partly convex program*, see [35], one can in principle study (and solve) many mathematical programs by studying PC programs and convex parametric programming models.

Numerous *applications of parametric programming* are mentioned in the classical texts [4,14,15,34]. Parametric programming has found many applications in discrete optimization, transportation problems (e. g.,

[59]), economics and finance (e. g., [11,56]), approximation, as well as in multi-objective, multilevel, stochastic and global optimization (e. g., ► **Parametric global optimization: Sensitivity**). Some of the recent research in parametric programming has been focused on connections between polynomial complexity and perturbation theory, stability results for nonunique solutions, control, semi-infinite programs (e. g., [28]), and nonsmooth problems.

Relaxation methods for convex nondifferentiable optimization have their origin in relaxation methods for finding a solution to a system of linear inequalities, see [1] and [6]. In mathematical terms, one wants to find a vector  $x \in \mathbf{R}^n$  such that  $a_i^\top x - b_i \leq 0$  for  $i = 1, \dots, m$ . In the simplest form, such a relaxation method iterates an initial guess  $x_0 \in \mathbf{R}^n$  with the iteration scheme

$$x_{k+1} = x_k - \gamma^k \frac{a_{i_k}^\top x_k - b_{i_k}}{\|a_{i_k}\|_2^2} a_{i_k}, \quad (1)$$

where  $i_k \in \text{Argmax}_{i=1, \dots, m} a_i^\top x_k - b_i$ , and  $\gamma^k \in [\delta, 2 - \delta]$  and  $\delta \in (0, 1)$ . The iterations stop once a feasible solution is found. With  $\gamma^k = 1$  the iteration formula (1) corresponds to a projection of  $x_k$  onto the most violated hyperplane at  $x_k$ .

The problem of finding a solution to an inequality system can be cast into a convex nondifferentiable optimization problem with known optimal value, namely the following

$$\min_x f(x) = \min_x \max \left\{ \max_{i=1, \dots, m} a_i^\top x - b_i, 0 \right\},$$

which has optimal solution value equal to zero if the system is consistent.

The iteration scheme (1) can be generalized to convex nondifferentiable minimization with known optimal value in the following manner. Suppose that we want to find  $x \in \mathbf{R}^n$  such that  $f(x) \leq f_{\text{lev}}$ , where  $f_{\text{lev}} \geq f^* = \inf f(x)$  is known. Let  $m_f$  denote the set of affine functions minorizing  $f$ ,

$$m_f = \left\{ (a, b) \in \mathbf{R}^n \times \mathbb{R} : \begin{array}{l} a^\top y - b \leq f(y) \\ \text{for all } y \in \mathbf{R}^n \end{array} \right\}.$$

Assume as is customary in nondifferentiable optimization that we at  $x \in \mathbb{R}^n$  can evaluate  $f(x)$  and one arbitrarily chosen *subgradient*

$$g \in \partial f(x) \\ = \left\{ g \in \mathbb{R}^n : \begin{array}{l} f(y) \geq f(x) + g^\top(y-x) \\ \text{for all } y \in \mathbb{R}^n \end{array} \right\}.$$

Then,  $(g, g^\top x - f(x)) \in \mathfrak{m}_f$  and by definition of  $\mathfrak{m}_f$ ,

$$f(x) \geq \sup_{(a,b) \in \mathfrak{m}_f} \{a^\top x - b\} \\ \geq g^\top x - (g^\top x - f(x)) = f(x).$$

Hence  $f(x) = \sup_{(a,b) \in \mathfrak{m}_f} \{a^\top x - b\}$ .

Thus, finding an  $x$  such that  $f(x) \leq f_{\text{lev}}$  can be seen as solving an infinite system of inequalities,  $a^\top x - b - f_{\text{lev}} \leq 0$  for all  $(a, b) \in \mathfrak{m}_f$ . The analog of (1) then becomes

$$x_{k+1} = x_k - \gamma^k \frac{f(x_k) - f_{\text{lev}}}{\|g_k\|_2^2} g_k, \quad (2)$$

where  $g_k \in \partial f(x_k)$ . It can be shown that if  $X^* = \{x: f(x) \leq f_{\text{lev}}\} \neq \emptyset$  then  $x_k \rightarrow x_{\text{lev}} \in X^*$ .

This steplength rule has often in the literature been called the *Polyak II rule* perhaps since it appears as the second numbered equation in B.T. Polyak's classical paper [8], where its convergence properties are studied. It is shown there that, under certain mild conditions on  $f$ , the convergence rate is linear to an optimal solution, should it exist.

The step (2) corresponds to a projection onto a hyperplane. With  $\gamma^k = 1$ ,  $x_{k+1}$  solves the quadratic programming problem

$$\begin{cases} \min & \|x - x_k\|_2^2, \\ \text{s.t.} & f_{\text{lev}} \geq f(x_k) + g_k^\top(x - x_k). \end{cases} \quad (3)$$

One may in this framework add previously generated subgradients in order to obtain faster convergence, i. e. let  $x_{k+1}$  solve

$$\begin{cases} \min & \|x - x_k\|_2^2, \\ \text{s.t.} & f_{\text{lev}} \geq f(x_j) + g_j^\top(x - x_j), \\ & j \in J^k, \end{cases} \quad (4)$$

where  $J^k$  is a subset of  $\{1, \dots, k\}$  including  $k$ .

## Constraints on the Variables

The classical way to handle constraints on the variables, i. e. when  $x$  has to be in some closed and *convex set*  $X$  as well as in the set  $\{x: f(x) \leq f_{\text{lev}}\}$ , is to let

$$x_{k+1} = P_X \left( x_k - \gamma^k \frac{f(x_k) - f_{\text{lev}}}{\|g_k\|_2^2} g_k \right), \quad (5)$$

where  $P_X(y) = \operatorname{argmin}_{x \in X} \|y - x\|_2$  denotes the *projection* of  $y$  onto the feasible set  $X$ .

However, it is often better to let  $x_{k+1}$  be the projection of  $x_k$  onto the set  $X \cap \{x: \gamma^k(f_{\text{lev}} - f(x_k)) \geq g_k^\top(x - x_k)\}$ , i. e. for  $\gamma^k = 1$  to add  $x \in X$  to the constraint set of (3). If  $X$  consists of simple bounds or the unit-simplex then it can be shown that this latter way results in a new iteration point which is closer to the desired set  $\{x \in X: f(x) \leq f_{\text{lev}}\}$  than does (5) (see [2]). In these two cases the computational burden of solving this one projection problem does not need to be larger, than solving the two very simple projections involved in (5).

## Finding a Minimum Point

Suppose one wants to find a minimum point  $x^*$  of a convex function  $f$ . Then if the optimal value  $f^*$  is known a priori then the algorithms mentioned above can be successfully used with  $f_{\text{lev}} = f^*$ . But, prior knowledge of  $f^*$  is not usually the case. However, when solving the dual problem in applications of *Lagrangian relaxation* to obtain upper bounds on a primal maximization problem, it is often the case that a (good) lower bound,  $f_{\text{low}}$ , on  $f^*$  is known from a primal feasible solution. In these applications, iterations schemes as the ones above can be applied heuristically and often successfully by replacing  $f_{\text{lev}}$  in (2) by  $f_{\text{low}}$ .

To be specific, one such heuristic goes as follows. Suppose that at iteration  $k$  a lower bound  $f_{\text{low}}^k$  on  $f^*$  is known, which is used in place of  $f_{\text{lev}}$  in (2). Initially,  $\gamma_0 = 2$  and at iteration  $k$ ,  $\gamma_k$  is reduced by a constant factor  $\alpha \in (0, 1)$ , if there has been no decrease in terms of the function values for the last  $K_{\text{max}}$  iterations (which could indicate that too large steps are taken). Here  $\alpha$  and  $K_{\text{max}}$  are parameters which need to be chosen appropriately for the application in question. Typical values are  $\alpha = 0.5$  and  $K_{\text{max}} = 5$ .

- 0 (Initialization)  
 Select a point  $x_1 \in \mathbf{R}^n$  and  $\delta^1 > 0$  and  $\sigma_{\max} > 0$ .  
 Set  $\sigma_1 = 0$  and  $f_{\text{rec}}^0 = \infty$ . Set  $k = 1$ ,  $l = 1$  and  $k(1) = 1$ .
- 1 (Function call)  
 Calculate  $f(x_k)$  and  $g_k \in \partial f(x_k)$ .  
 IF  $\|g_k\| = 0$   
 THEN terminate ( $x_k \in \text{Argmin } f$ ). Set  $f_{\text{rec}}^k = \min\{f(x_k), f_{\text{rec}}^{k-1}\}$  and update  $x_{\text{rec}}^k$  correspondingly.
- 2 (Sufficient Descendent?)  
 If  $f(x_k) \leq f_{\text{rec}}^{k(l)} - \delta_l/2$ , set  $k(l+1) = k$ ,  $\sigma_k = 0$ ,  $\delta_{l+1} = \delta_l$ ,  $l = l+1$  and skip next step.
- 3 (Oscillation?)  
 If  $\sigma_k > \sigma_{\max}$ , set  $k(l+1) = k$ ,  $\sigma_k = 0$ ,  $\delta_{l+1} = \delta_l/2$ , replace  $x_k$  by  $x_{\text{rec}}^k$  and  $g_k$  correspondingly.
- 4 (New point)  
 Set  $f_{\text{lev}}^k = f_{\text{rec}}^{k(l)} - \delta_l$ ,
- $$x_{k+1} = x_k - \frac{f(x_k) - f_{\text{lev}}^k}{\|g_k\|_2} g_k.$$
- 5 (Path update)  
 Set  $\sigma_k = \sigma_{k+1} + \|x_{k+1} - x_k\|$ . Set  $k = k+1$  and return to Step 1.

A simple convergent method, [2] and [4], based on (2) for minimizing  $f$  with no assumption on prior knowledge of the optimal value is motivated as follows. It is a fact that if the set  $\{x \in \mathbf{R}^n : f(x) \leq f_{\text{lev}}\}$  is empty then the iteration scheme (2) generates a path whose length  $\sum_{k=1}^{\infty} \|x_{k+1} - x_k\|$  is unbounded, and if the set is nonempty then the path length is bounded. If the former seems to be occurring then  $f_{\text{lev}}$  should be increased and if the algorithm seems to be converging to  $f_{\text{lev}}$  then a lower  $f_{\text{lev}}$  could be used. The mechanics of the algorithm should be clear from the following description. Let  $f_{\text{rec}}^k = \min_{i=1, \dots, k} f(x_i)$  denote the best function value found up to iteration  $k$  and let  $x_{\text{rec}}^k$  be the point at which this occurs. Let  $f_{\text{lev}}^k$  denote the 'level' which we are aiming for. The number  $k(l)$  denotes the iteration of the  $l$ th change of  $f_{\text{lev}}^k$ . The number  $\sigma_k$  is the length of the path since the last update of  $f_{\text{lev}}$ .

Note that the level  $f_{\text{lev}}^k$  remains fixed in between the iterations  $k(l)$  and  $k(l+1) - 1$ . For this algorithm it is possible to derive so called efficiency estimates. In par-

ticular, it can be shown that for 'small'  $\epsilon > 0$  the algorithm produces  $f_{\text{rec}}^k - f^* < \epsilon$  for  $k \geq K/\epsilon^3$ , where  $K$  is a positive constant.

Of course, one may in Step 4 use (4) instead of (2) to obtain a new iteration point. However, when using (4) in Step 4, more sophisticated schemes to adjust the aiming level  $f_{\text{lev}}^k$  are possible. A scheme suggested in [3] uses ideas from so called *proximal point bundle methods*, in which sufficient descent in terms of function values is enforced by means of so called null steps. Another method by C. Lemaréchal, A.S. Nemirovsky and Yu.E. Nesterov, [5], for the case when  $x$  is constrained to a compact set  $X$ , uses  $f_{\text{lev}}^k = \alpha f_{\text{rec}}^k + (1 - \alpha)f_{\text{low}}^k$ , where  $f_{\text{low}}^k$  is the best lower bound possible, that is

$$f_{\text{low}}^k = \min_{x \in X} \max_{j=1, \dots, k} f(x_j) + g_j^T(x - x_j).$$

This algorithm has a complexity estimate given by  $f_{\text{rec}}^k - f^* < \epsilon$  for  $k \geq K/\epsilon^2$ , where  $K$  is a positive constant. Such a complexity estimate is optimal in the sense that it can not be improved uniformly with respect to the dimension by more than an absolute constant factor (for details, see [7]).

Subgradient; Subdifferential; Convex function

*Subgradient methods* for minimization of a *convex function*  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  over a closed *convex set*  $X$  have proven to be an efficient mean to solve large scale optimization problems. In particular, this is the case when  $X$  is a simple set, such as  $\mathbf{R}^n$  or the positive orthant and when high accuracy of the solution is not required, e. g. in the context of Lagrangian relaxation of integer programming problems (cf. ► [Integer programming: Lagrangian relaxation](#)).

A *subgradient* at a point  $x \in \mathbf{R}^n$  of a convex function  $f$  is a vector  $g \in \mathbf{R}^n$  satisfying  $f(y) \geq f(x) + g^\top(y - x)$  for all  $y \in \mathbf{R}^n$ . The set of subgradients at a point  $x$  is known as the *subdifferential*  $\partial f(x)$ . At points where the function is differentiable, the gradient is the sole member of the subdifferential.

Gradient based iterative methods, e. g. the steepest descent method designed for minimization of a smooth functions fail when one attempts to use their analogs,

i. e. replacing gradients by subgradients, for minimization of convex nonsmooth functions. This is because the negative subgradient may not be a descent direction and even if it were at all points generated along the path, the sequence of iterates would not necessarily minimize  $f$ .

The basic subgradient algorithm takes the following form:

```

0 (Initialize)
  Choose a point  $x_0 \in \mathbf{R}^n$  and set  $k = 0$ .
1 (Function call)
  Calculate  $g_k \in \partial f(x_k)$ .
  IF  $\|g_k\| = 0$  THEN terminate since  $x_k \in \text{Argmin} f$ .
2 (New point)
  Set
     $x_{k+1/2} = x_k - t_k \frac{g_k}{\|g_k\|}$ ,
  and
     $x_{k+1} = \underset{y \in X}{\text{argmin}} \|y - x_{k+1/2}\|$ ,
  replace  $k$  by  $k + 1$ . Return to Step 1.
```

It can be shown, see [4], that if

$$t_k \downarrow 0 \quad \text{and} \quad \sum_{k=0}^{\infty} t_k = \infty, \quad (1)$$

then  $\liminf f(x_k) = \inf_{x \in X} f(x) = f^*$  and furthermore, if also

$$\sum_{k=0}^{\infty} t_k^2 < \infty,$$

then  $x^k$  converges to a minimum point, if there is one (see [2]).

As can be expected, the rate of convergence for the above algorithm with the *divergent series rule* (1) is very slow. In fact, it can be shown that the algorithm can not have so-called geometric convergence rate. An algorithm is said to have *geometric convergence rate*, or *linear convergence rate*, if for any convex function and any starting point there exist  $M$  and  $q \in (0, 1)$  such that  $\|x_k - x^*\| \leq Mq^k$ , where  $x^*$  is an optimal point. J.-L. Goffin has [3] shown that it is possible to obtain geometric convergence rate with the *geometric series rule*

$$t_k = M\rho^k \|g_k\|,$$

if  $M$  and  $\rho \in (0, 1)$  are chosen large enough. In practice, though, for a particular  $f$  and starting point  $x_0$  it is impossible to know what sufficiently large is.

Another often used steplength rule is the so-called *relaxation rule*, or *Polyak II rule*, where  $t^k$  is chosen according to

$$t_k = \gamma_k \frac{f(x_k) - f_{\text{lev}}^k}{\|g_k\|},$$

where  $f_{\text{lev}}^k$  is an estimate of the minimum value value  $f^*$  and  $\gamma_k \in [\delta, 2 - \delta]$ , and  $\delta \in (0, 1)$ . See also ► **Nondifferentiable optimization: Relaxation methods.**

Pure subgradient methods have a tendency to zig-zag, i. e. a step in the direction  $-g_k$  tends to be followed by a step which is almost parallel with  $g_k$ . Several solutions to overcome this behavior have been proposed. One such solution is the concept of *space dilation* of N.Z. Shor (see [5]). This approach is related to quasi-Newton methods for differentiable optimization. Another solution to the zig-zagging problem is the method proposed in [1], in which a step is taken in a direction which is a sum of the previous direction and the current subgradient. This approach is analogous to conjugate gradient methods for differentiable optimization.

Newton method; Full-step Gauss–Newton method; Quasi-Newton methods; Adaptive methods; Global convergence; Local convergence rate

Nonlinear least squares problems can be phrased in terms of minimizing a real valued function that is a sum of some nonlinear functions of several variables. Efficient solution for unconstrained nonlinear least squares is important. Though some problems that arise in practical areas usually have constraints placed upon the variables and special techniques are required to handle these constraints, eventually the numerical techniques used rely upon the efficient solution of unconstrained nonlinear least squares problems.

The *unconstrained nonlinear least squares problems* have the form

$$\min f(x) = \frac{1}{2} \sum_{i=1}^m [r_i(x)]^2 = \frac{1}{2} r(x)^\top r(x),$$

where  $r(x) = (r_1(x), \dots, r_m(x))^\top$  and  $r_i(x)$ ,  $i = 1, \dots, m$  are nonlinear functions of  $x \in \mathbf{R}^n$ . When  $r(x)$ , hence  $f(x)$  is twice continuously differentiable, the gradient

and the Hessian matrix of  $f(x)$  are given by

$$\begin{aligned} g(x) &= \nabla f(x) = A(x)r(x), \\ G(x) &= \nabla^2 f(x) \\ &= A(x)A(x)^\top + \sum_{i=1}^m r_i(x)\nabla^2 r_i(x) \end{aligned}$$

where  $A(x) = [\nabla r_1(x) \cdots \nabla r_m(x)]$ . The special structures of these derivatives had been exploited in developing effective solution methods for nonlinear least squares.

As a general unconstrained minimization problem, the *Newton method* plays a central role in the development of numerical methods for nonlinear least squares solution. Most commonly used nonlinear least squares methods can be viewed as variations on Newton's method. The Newton method for general optimization is derived based upon the quadratic model

$$q_k(\delta) = f_k + g_k^\top \delta + \frac{1}{2} \delta^\top G_k \delta,$$

where  $f_k = f(x^{(k)})$ ,  $g_k = g(x^{(k)})$ ,  $G_k = G(x^{(k)})$ ,  $\delta = x - x^{(k)}$ , and  $x^{(k)}$  is an approximation to a local minimizer  $x^*$  of the objective function  $f(x)$ .  $q_k(\delta)$  is a local approximation to  $f(x)$  at  $x^{(k)}$  obtained from the *truncated Taylor approximation*. If this approximation is appropriate, then a presumably better approximation  $x^{(k+1)} = x^{(k)} + \delta^{(k)}$  can be obtained by requiring that the step  $\delta^{(k)}$  be a minimizer of  $q_k(\delta)$ . Thus the Newton method takes an initial approximation  $x^{(1)}$  to  $x^*$  and attempts successively to improve the approximation through the iteration

- Solve the system  $G_k \delta = -g_k$  for  $\delta = \delta^{(k)}$ .
- Set  $x^{(k+1)} = x^{(k)} + \delta^{(k)}$ .

If  $G_k = M_k + C_k$  with  $M_k = A_k A_k^\top$ ,  $C_k = C(x^{(k)}) = \sum_{i=1}^m r_i(x^{(k)})\nabla^2 r_i(x^{(k)})$  is positive definite, the solution  $\delta^{(k)}$  of the system is the global minimizer of  $q_k(\delta)$ , and if the starting point  $x^{(1)}$  is sufficiently close to  $x^*$  at which  $g(x^*) = 0$  and  $G(x^*)$  is positive definite, the Newton method is well defined and converges at a quadratic rate.

Unfortunately, the basic Newton method as it stands is not suitable for a general purpose use since  $G_k$  may not be positive definite when  $x^{(k)}$  is remote from  $x^*$  and even if  $G_k$  is positive definite, the convergence may

not occur since  $\{f_k\}$  may not decrease. Though both the possibilities can be eliminated by incorporating either *trust region technique* for the former case or *line search technique* for the later case, the main disadvantage of the Newton method is the demand for evaluation of second order derivatives of problem functions.

Since  $r(x)$  is being minimized in the least squares sense, it may be the case that  $r_i(x^*)$ ,  $i = 1, \dots, m$  are zero or very small. Thus when  $x^{(k)}$  is close to  $x^*$ , compared with  $M_k$ , the second part  $C_k$  in  $G_k$  may be negligible. This suggests that  $M_k$  is a good approximation to  $G_k$  and gives the well known *full-step Gauss–Newton method*

- Solve the system  $M_k \delta = -A_k r_k$  for  $\delta = \delta^{(k)}$ .
- Set  $x^{(k+1)} = x^{(k)} + \delta^{(k)}$ .

An important feature of the Gauss–Newton method is that the approximation to the Hessian  $G_k$  is directly obtained only from the first order derivatives of the problem functions. The approximation will be exact when the functions  $r_i(x)$ ,  $i = 1, \dots, m$ , are all either linear or zeros. Since the Gauss–Newton method is obtained from the Newton method by neglecting the part  $C_k$  of  $G_k$ , the convergence property of the method greatly depends on the size of the omitted part. If  $C(x^*)$  is large relative to  $M(x^*)$  in the sense  $\eta_m(x^*) = \|M(x^*)^{-1} C(x^*)\| > 1$  which is regarded as *combined relative measure* of the nonlinearity and residual size of the problem (assuming  $A(x^*)$  is full rank), then the method does not converge. If  $\eta_m(x^*) \leq \theta < 1$  and the initial point  $x^{(1)}$  is close to  $x^*$  enough, the Gauss–Newton method converges. In case convergence occurs, the rate of convergence also depends upon the size of  $\eta_m(x^*)$ . If  $C(x^*) = 0$ , the method is rather satisfactory in the sense that the method converges quadratically for zero residual problems, and if  $C(x^*) \neq 0$ , the convergence rate of the method is linear and the speed of convergence decreases as the relative nonlinearity or the residual size increases.

Since the matrix  $M_k$  is at worst positive semidefinite, the solution, denoted now by  $s^{(k)}$ , determined in the Gauss–Newton system is not uphill on  $f(x)$ . A possible modification to force the Gauss–Newton method to converge is to incorporate line search techniques. If the matrix  $A_k$  has full rank, then  $M_k$  is positive definite and the solution  $s^{(k)}$  in the Gauss–Newton system is a descent direction of  $f(x)$  at  $x^{(k)}$ . A line search along the direction  $s^{(k)}$  determines a steplength  $\alpha_k$  such that  $f(x^{(k)})$

$+ \alpha_k s^{(k)} < f(x^{(k)})$  and a new approximation to  $x^*$  is then obtained as  $x^{(k+1)} = x^{(k)} + \alpha_k s^{(k)}$ . This modification was first suggested by H.O. Hartley [7] and is generally referred as *damped Gauss–Newton method*. This method does prevent divergence and usually have a larger domain of convergence than the full-step Gauss–Newton method. In fact convergence follows if the *condition number*  $\mathcal{K}(A_k A_k^\top)$  is uniformly bounded above. Since  $A_k$  will usually be bounded above, this essentially requires that  $A_k$  does not loss rank in limit. Unfortunately this can happen [11] and convergence to a noncritical point can occur. Also when  $A_k$  is rank deficient, the solution  $s^{(k)}$  of the Gauss–Newton system becomes numerically orthogonal to  $g_k$  at some distance from a local minimizer  $x^*$  and no further progress can be made by line searches.

A further modification to the full-step Gauss–Newton method is to incorporate the trust region technique. In this modification, the trust region subproblem

$$\begin{cases} \min & q_k(\delta) = f_k + r_k^\top A_k^\top \delta + \frac{1}{2} \delta^\top M_k \delta \\ \text{s.t.} & \|\delta\| \leq \Delta_k \end{cases}$$

is solved for  $\delta^{(k)}$  with properly adjusted radius  $\Delta_k$  and the new point is obtained as  $x^{(k+1)} = x^{(k)} + \delta^{(k)}$ . The trust region radius is adjusted in such a way that the model function  $q_k(\delta)$  is believed to have adequately approximated the function  $f(x)$  in the region  $\|\delta\| \leq \Delta_k$ . This modification with a different form was first suggested by K. Levenberg [8] and D.W. Marquardt [9]. J.J. Moré used the modification in the above form [10].

An aspect of the Gauss–Newton method is the efficient solution of the Gauss–Newton system. It must be emphasized here that the solution of the system can not be done by first forming the product  $A_k A_k^\top$  and then performing a factorization on the product, because this will worsen the conditioning of the system and lead to substantial loss in precision. A stable and efficient way is to factorize the augmented matrix  $[A_k^\top \ r_k]$  using either *Householder transformation* or *Given’s transformation*.

Regarded as a general optimization problem, another way to obtain approximations to the Hessian matrix  $G_k$  from first order derivative information of problem functions is to use *quasi-Newton updates* and the resulting Newton type methods are called *quasi-Newton methods*. Let  $B_k$  denote an approximation to the

Hessian  $G_k$  in the quadratic model  $q_k(\delta)$ . Any Newton type method with line searches has the following basic framework.

- Solve the system  $B_k s = -g_k$  for a descent direction  $s^{(k)}$ .
- Determine a steplength  $\alpha_k$  along the direction  $s^{(k)}$  by line searches.
- Set  $x^{(k+1)} = x^{(k)} + \alpha_k s^{(k)}$ .

In order to ensure *global convergence* and to have a rapid *local convergence rate*, quasi-Newton updates require the matrix  $B_k$  to satisfy the following conditions:

- since  $G_k \delta_k \approx \gamma_k$ ,  $B_k$  should satisfy the so-called quasi-Newton equation

$$B_{k+1} \delta^{(k)} = \gamma^{(k)},$$

where

$$\delta^{(k)} = x^{(k+1)} - x^{(k)}, \gamma^{(k)} = g_{k+1} - g_k.$$

- $B_k$  is symmetric.
- $B_{k+1}$  is effectively obtained from  $B_k$  using lower rank updating

$$B_{k+1} = B_k + E_k$$

so that the calculation of  $B_{k+1}$  is less expensive.

- $B_k$  is positive definite so that the solution  $s^{(k)}$  obtained as the minimizer of  $q_k(\delta)$  is a descent direction of  $f(x)$  at  $x^{(k)}$ .

There exist numerous updating formulas to achieve these conditions and the *Broyden family* with single parameter

$$\begin{aligned} B_{k+1}(\theta) = B_k &- \frac{B_k \delta^{(k)} \delta^{(k)\top} B_k}{\delta^{(k)\top} B_k \delta^{(k)}} \\ &+ \frac{\gamma^{(k)} \gamma^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}} + \theta w^{(k)} w^{(k)\top} \end{aligned}$$

is the most important, where

$$\begin{aligned} w^{(k)} &= (\delta^{(k)\top} B_k \delta^{(k)})^{1/2} \\ &\times \left[ \frac{\gamma^{(k)}}{\delta^{(k)\top} \gamma^{(k)}} - \frac{B_k \delta^{(k)}}{\delta^{(k)\top} B_k \delta^{(k)}} \right] \end{aligned}$$

and  $\theta$  is a parameter [3]. If  $\delta^{(k)\top} \gamma^{(k)} > 0$  for all  $k$ , then  $B_{k+1}(\theta)$  preserves positive definiteness for all values

$$\theta > \bar{\theta} = \frac{1}{1 - a_k b_k} (< 0),$$

where

$$a_k = \frac{\gamma^{(k)\top} H_k \gamma^{(k)}}{\delta^{(k)\top} \gamma^{(k)}}, \quad b_k = \frac{\delta^{(k)\top} B_k \delta^{(k)}}{\delta^{(k)\top} \gamma^{(k)}}$$

and  $H_k = B_k^{-1}$ . The  $\bar{\theta}$  is the value which causes  $B_{k+1}(\theta)$  to be singular. The condition  $\delta^{(k)\top} \gamma^{(k)} > 0$  is realistic and can always be achieved when the steplength  $\alpha_k$  either is determined from exact line search or satisfies the *Goldstein conditions*. The Broyden family includes the famous BFGS ( $\theta = 0$ ) formula

$$B_{k+1}^{\text{BFGS}} = B_k + \frac{\gamma^{(k)} \gamma^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}} - \frac{B_k \delta^{(k)} \delta^{(k)\top} B_k}{\delta^{(k)\top} B_k \delta^{(k)}},$$

DFP ( $\theta = 1$ ) formula

$$B_{k+1}^{\text{DFP}} = B_k + \left( 1 + \frac{\delta^{(k)\top} B_k \delta^{(k)}}{\delta^{(k)\top} \gamma^{(k)}} \right) \times \frac{\gamma^{(k)} \gamma^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}} - \frac{\gamma^{(k)} \delta^{(k)\top} B_k + B_k \delta^{(k)} \gamma^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}}$$

and the *selfdual rank one formula* ( $\theta = 1/(1-b_k)$ )

$$B_{k+1} = B_k + \frac{y_k y_k^\top}{\delta^{(k)\top} y_k}, \quad y_k = \gamma^{(k)} - B_k \delta^{(k)}.$$

Both the DFP and BFGS methods was found to work well in practice and have been widely used. These two methods have a number of important properties as follows:

- 1) For quadratic functions (with exact line searches)
  - terminate in at most  $n$  iterations with ( $B_{n+1} = G$ );
  - preserve the *hereditary property*

$$B_i \delta^{(j)} = \gamma^{(j)}, \quad j = 1, \dots, i - 1;$$

- generate conjugate directions, and conjugate gradients (when  $B_1 = I$ )
- 2) For general functions
    - preserve positive definite  $B_k$ ;
    - global convergence for strictly convex functions (with exact line searches);
    - local superlinear convergence rate.

The BFGS method is even better than the DFP method and has usually been used with low accuracy line searches. In fact, global convergence and superlinear convergence rate of the BFGS method with inexact line searches have been proved [12]. The Broyden family is important in that many of the properties of the BFGS and DFP formulas are common to whole family. L.C.W. Dixon showed that when applied to any continuously differentiable function, all Broyden methods generate the same sequence  $\{x^{(k)}\}$  from the same starting point, assuming that the multiple local minima in line search are resolved consistently, degenerate values of  $\theta$  are avoided and the algorithm is well-defined.

When any above quasi-Newton updating formula is used in a method, the system  $B_k s = -g_k$  needs solved to get the direction  $s^{(k)}$  and this needs  $O(n^3)$  arithmetic operations. In early versions of quasi-Newton methods, the search direction  $s^{(k)}$  is obtained as a product of a matrix and a vector from

$$s^{(k)} = -H_k g_k$$

and the matrix  $H_k$  is an inverse approximation to  $G_k$  ( $H_k \approx G_k^{-1}$  obtained from an *inverse quasi-Newton updating* formula. This avoids the solution of the system and only requires  $O(n^2)$  arithmetic operations. The inverse updating formulas can be similarly derived from the quasi-Newton equation

$$H_{k+1} \gamma^{(k)} = \delta^{(k)}.$$

or can be derived from above updating formulas using the *Sherman–Morrison formula*. For example, the Broyden family of inverse updating is given by

$$H_{k+1}(\phi) = H_k - \frac{H_k \gamma^{(k)} \gamma^{(k)\top} H_k}{\gamma^{(k)\top} H_k \gamma^{(k)}} + \frac{\delta^{(k)} \delta^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}} + \phi v^{(k)} v^{(k)\top},$$

where

$$v^{(k)} = \left( \gamma^{(k)\top} H_k \gamma^{(k)} \right)^{1/2} \times \left[ \frac{\delta^{(k)}}{\delta^{(k)\top} \gamma^{(k)}} - \frac{H_k \gamma^{(k)}}{\gamma^{(k)\top} H_k \gamma^{(k)}} \right]$$

and  $\phi$  is a parameter related to  $\theta$  by

$$\phi = \frac{1 - \theta}{1 + \theta(a_k b_k - 1)}.$$

The corresponding inverse BFGS, DFP and rank one updating formulas can be obtained by setting  $\phi = 1$ ,  $\phi = 0$  and  $\phi = 1/(1 - a_k)$ . It can be seen that one kind of updating formulas is obtained from another kind by simply making interchanges  $B_k \leftrightarrow H_k$  and  $\delta^{(k)} \leftrightarrow \gamma^{(k)}$ . Although, the matrix  $H_k$  preserves the positive definiteness in theory when  $\delta^{(k)\top} \gamma^{(k)} > 0$ , the loss of the positive definiteness may occur in practical calculations due to round-off errors and it can not be easily recognized whether the matrix  $H_k$  is positive definite or not. Now the widely used versions of quasi-Newton methods is to represent the matrix  $B_k$  in a factorized form  $L_k D_k L_k^\top$  and to update the factors in  $O(n^2)$  operations to obtain the factors  $L_{k+1} D_{k+1} L_{k+1}^\top$  of the matrix  $B_{k+1}$  where  $L$  is a unit lower triangular matrix and  $D$  is a diagonal matrix with positive diagonals [5]. The solution of the system  $B_k s = -g_k$  is then obtained in  $O(n^2)$  operations by using forward and backward substitutions. The positive definiteness of the matrix  $B_k$  is indicated by the diagonal elements of  $D_k$  and can be maintained by controlling round-off errors. Methods with quasi-Newton updating in  $LDL^\top$  form preserve the convergence properties of quasi-Newton methods and reduce the arithmetic operations at each iteration.

When quasi-Newton updating formulas are used to generate approximations to the Hessian matrices or their inverses for nonlinear least squares problems,  $A_1 A_1^\top$  can be selected as the initial matrix  $B_1$  if  $A_1 A_1^\top$  is positive definite. One more modification to the quasi-Newton updateings for nonlinear least squares is the definition of the vector  $\gamma^{(k)}$ . Let  $\gamma_o^{(k)}$  denote previous defined vector  $\gamma^{(k)}$ . From the Taylor expansion of  $g(x)$ , a new definition of  $\gamma^{(k)}$

$$\gamma_n^{(k)} = M_{k+1} \delta^{(k)} + (A_{k+1} - A_k) r_{k+1}$$

can be used to replace  $\gamma_o^{(k)}$  in any quasi-Newton updating formula. This idea is essentially suggested by

M.C. Bartholomew-Biggs [2]. However, the condition  $\delta^{(k)\top} \gamma_n^{(k)} > 0$ , required for maintaining the positive definite approximations, may not be guaranteed by line searches. This difficulty can be avoided by using a safeguarded value

$$\max \left\{ \delta^{(k)\top} \gamma_n^{(k)}, 0.01 \delta^{(k)\top} \gamma_o^{(k)} \right\}$$

in place of  $\delta^{(k)\top} \gamma^{(k)}$  in updating formulas [1].

For nonlinear least squares problems, both the quasi-Newton and Gauss-Newton methods generate approximations to Hessian matrices of objective functions only from their first order derivative information. The convergence rate is superlinear when any quasi-Newton, such as BFGS method is used to any differentiable nonlinear least squares problem, but the special structure of the problem functions is not taken into account and many iterations are required to build up a satisfactory approximation to the Hessian. The Gauss-Newton method takes the advantage of the special form of nonlinear least squares and better approximations to Hessian matrices are directly obtained from the Jacobian matrix  $A(x)$  of  $r(x)$  for zero and small residual problems. The damped Gauss-Newton method converges at a quadratic rate for zero residual problems and at a fast linear rate for small residual problems, which in limited precision may be preferable to superlinear convergent methods. However, the method converges slowly for large residual problems, even fails on singular problems. Hence, the damped Gauss-Newton method is generally preferred for zero and small residual problems, but should be avoided for large residual and singular problems. Attempts have been made to combine the best features of both kind of methods. These include *adaptive methods* [4,13], *hybrid methods* [1,6], and *factorized quasi-Newton methods* [14,15].

In adaptive methods approximations to Hessian  $G(x)$  are obtained by approximating the nonlinear term  $C_k$  in  $G_k$  by a symmetric matrix  $S_k$  and keeping the Gauss-Newton matrix  $M_k$  unchanged, that is, to define

$$B_k = M_k + S_k$$

and to develop updating formulas for the matrix  $S_k$ . This idea was first suggested by K.M. Brown and J.E. Dennis in 1973. In their method  $S_k = \sum_{i=1}^m r_i(x^{(k)}) S_i^{(k)}$  and  $S_i^{(k)}$  approximates  $\nabla^2 r_i(x^{(k)})$  obtained from  $S_i^{(k-1)}$  using certain quasi-Newton updating formula. In

methods of C.G. Broyden and Dennis (1973), J.T. Bett (1976), Bartholomew-Biggs (1977), P.E. Gill and W. Murray (1978), and Dennis, D.M. Gay and R.E. Welsch (1981) the formulas for updating  $S_k$  are defined by using certain quasi-Newton-like updating formulas, for example, Gill and Murray used the BFGS-like formula

$$S_{k+1} = S_k + \frac{\gamma^{(k)}\gamma^{(k)\top}}{\delta^{(k)\top}\gamma^{(k)}} - \frac{W_k\delta^{(k)}\delta^{(k)\top}W_k}{\delta^{(k)\top}W_k\delta^{(k)}},$$

where  $W_k = M_{k+1} + S_k$ , while Dennis, Gay and Welsch developed an updating formula for  $S_k$ :

$$S_{k+1} = S_k - \frac{\eta^{(k)}\gamma^{(k)\top} + \gamma^{(k)}\eta^{(k)\top}}{\delta^{(k)\top}\gamma^{(k)}} + \frac{\eta^{(k)\top}\delta^{(k)}}{(\delta^{(k)\top}\gamma^{(k)})^2}\gamma^{(k)}\gamma^{(k)\top},$$

where  $\eta^{(k)} = S_k\delta^{(k)} - \gamma^{(k)}$  and  $\gamma^{(k)} = (A_{k+1} - A_k)r_{k+1}$ . These methods attempt to get better approximations to  $G_k$  from first order derivative information by using the special structure of nonlinear least squares. However, since the positive definiteness of the resulting approximation  $B_k = M_k + S_k$  can not be guaranteed, these methods must be incorporated with trust region techniques. This increases the complexity of methods. Theoretical analysis and practical calculations show that the Dennis–Gay–Welsch adaptive method is superlinearly convergent and effective.

At each iteration of a hybrid method, the approximation  $B_k$  is simply chosen either the Gauss–Newton matrix  $M_k$  or a quasi-Newton matrix, for example BFGS matrix, by defining a test  $T_k$ , that is,

$$B_{k+1} = \begin{cases} \text{BFGS}(B_k, \delta^{(k)}, \gamma^{(k)}) & \text{if } T_k \text{ holds,} \\ M_{k+1} & \text{otherwise,} \end{cases}$$

where  $\text{BFGS}(B_k, \delta^{(k)}, \gamma^{(k)})$  denotes the BFGS updating formula. Thus each step of a hybrid method is either a Gauss–Newton step or a BFGS step. In developing a hybrid method, a test must be derived to distinguish between these two steps. A reasonable test should have the capability to differentiate problems so that the method ultimately takes the damped Gauss–Newton method for zero and small residual problems or the BFGS method for large residual and singular problems. M. Al-Baali and R. Fletcher [1] proposed a test

$$T_k : \Delta(B_k, \delta^{(k)}, \gamma^{(k)}) \leq \Delta(M_{k+1}, \delta^{(k)}, \gamma^{(k)}),$$

based on the quantity

$$\Delta(A, \delta^{(k)}, \gamma^{(k)}) = \left( a_k^2 - 2\frac{1}{b_k} + 1 \right)^{1/2},$$

which is regarded as a measure of the approximation error of the matrix  $A$  to  $G_{k+1}$ , where

$$a_k = \frac{\gamma^{(k)\top}A^{-1}\gamma^{(k)}}{\delta^{(k)\top}\gamma^{(k)}}, \quad b_k = \frac{\delta^{(k)\top}A\delta^{(k)}}{\delta^{(k)\top}\gamma^{(k)}}.$$

Though the resulting hybrid method is robust and effective, the test needs extra  $O(n^2)$  arithmetic operations at each iteration and the resulting method is only linearly convergent [6]. Fletcher and C.X. Xu [6] proposed a simple test

$$T_k : \frac{f_k - f_{k+1}}{f_k} \leq \epsilon,$$

where  $\epsilon \in (0, 1)$  is a preset parameter. Numerical experiences show that the method is not sensitive to the choice of the value  $\epsilon$ , but the value  $\epsilon = 0.2$  is recommended. The test is simple and theoretical analysis shows that the method ultimately takes the Gauss–Newton method for zero residual problems and the BFGS method for nonzero residual problems. Therefore, the method maintains the convergence properties of BFGS method and combines the best features of both the Gauss–Newton and BFGS methods. Practical calculations show that the later hybrid method is better than the Fletcher–Al-Baali hybrid method.

Factorized quasi-Newton methods for nonlinear least squares take the approximations  $B_k$  in the form

$$B_k = (A_k + L_k)(A_k + L_k)^\top$$

and develop updating formulas for the matrix  $L_k$  such that  $L_kL_k^\top + A_kL_k^\top + L_kA_k^\top$  approximates the second part  $C_k$  of  $G_k$ . If the matrix  $(A_k + L_k)$  is of full rank, the search direction  $s^{(k)}$  obtained from the system  $B_k s = -g_k$  is guaranteed to be descent. The updating formulas for  $L_k$  can similarly derived from the quasi-Newton equation

$$(A_{k+1} + L_{k+1})(A_{k+1} + L_{k+1})^\top \delta^{(k)} = \gamma^{(k)}.$$

Using the theory of *generalized inverses* of matrices, Xu, X.F. Ma and M.Y. Kong derived a class of updating for-

mulas for  $L_k$

$$L_{k+1} = L_k + (a - d) \frac{V_k \delta^{(k)} \gamma^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}} + b \frac{V_k W_k^{-1} \gamma^{(k)} \gamma^{(k)\top}}{\delta^{(k)\top} \gamma^{(k)}} - c \frac{V_k \delta^{(k)} \delta^{(k)\top} W_k}{\delta^{(k)\top} W_k \delta^{(k)}}$$

where

$$V_k = A_{k+1} + L_k, \quad W_k = V_k V_k^\top$$

$a, b, c$  and  $d$  are parameters satisfying the following equations:

$$\frac{\delta^{(k)\top} W_k \delta^{(k)}}{\delta^{(k)\top} \gamma^{(k)}} a^2 + 2ab + \frac{\gamma^{(k)\top} W_k^{-1} \gamma^{(k)}}{\delta^{(k)\top} \gamma^{(k)}} = 1,$$

$$\frac{ad}{\delta^{(k)\top} \gamma^{(k)}} = \frac{bc}{\delta^{(k)\top} W_k \delta^{(k)}},$$

$$c + d = 1.$$

The resulting approximation  $B_{k+1} = (A_{k+1} + L_{k+1})(A_{k+1} + L_{k+1})^\top$  are a class of Broyden-like updating formulas

$$B_{k+1} = \alpha B_{k+1}^{BFGS} + \beta B_{k+1}^{DFP},$$

where  $\alpha = c^2 + 2cd$ ,  $\beta = d^2$  and  $\alpha + \beta = (c+d)^2 = 1$ ,  $B_{k+1}^{BFGS}$  and  $B_{k+1}^{DFP}$  are in previous forms with  $B_k$  being replaced by  $W_k$ . Both these formulas for BFGS-like and DFP-like are first obtained by H. Yabe and T. Takahashi [15] from their proposed updating formulas for  $L_{k+1}$  which can be obtained in the above updating formulas of  $L_{k+1}$  by setting  $c = 0, d = 1, b = (\delta^{(k)\top} \gamma^{(k)} / \gamma^{(k)\top} W_k^{-1} \gamma^{(k)})^{1/2}$  for BFGS-like and  $c = 1, d = 0, a = (\delta^{(k)\top} \gamma^{(k)} / \delta^{(k)\top} W_k \delta^{(k)})^{1/2}$  for DFP-like, respectively.

Nonlinear least squares; Residuals; Kuhn–Tucker optimality condition; Descent method; Line search; Trust region

Nonlinear least squares problems are among the most commonly occurring and important applications of optimization techniques. The problem is to find minima of a real valued function that has the form of a sum of some nonlinear functions of several independent variables

$$\min f(x) = \frac{1}{2} \sum_{i=1}^m [r_i(x)]^2 = \frac{1}{2} r(x)^T r(x),$$

where  $r_i(x)$ ,  $i = 1, \dots, m$ , are  $m$  nonlinear functions defined on  $\mathbf{R}^n$ ,  $r(x)$  is the vector representation of  $r_i(x)$ ,  $i = 1, \dots, m$ ,  $m \geq n$ , and the real number  $1/2$  is generally placed for convenience.

Approaches for least squares can be traced back to more than two hundred years ago. It is well-known that C.F. Gauss proposed the method, called *Gauss–Newton method*, in 1809 to estimate motion orbits of planets

from observation data. However, early in the 1750s some methods had been suggested by P.S. Laplace, L. Euler, etc. to deal with measuring data in astronomical observations. In 1805, A.M. Legendre proposed a method to determine the orbit of comets and the meridian of the earth. He called it least squares method, but did not demonstrate its optimality in theory. The advent of computer promoted the development and applications of numerical analysis including optimization methods and nonlinear least squares solutions.

Nonlinear least squares problems arise in various practical areas such as scientific computing, scientific experiments, engineering designs, survey and observations, geological prospecting, physical science, mathematics and so on. It is particularly useful in data processing and error estimations. Here are a few examples to illustrate the applications of nonlinear least squares problems.

### Solution of Simultaneous Equations

It is frequently concerned with in scientific computing to find a solution of a system of nonlinear equations

$$f_1(x_1, \dots, x_n) = 0,$$

...

$$f_m(x_1, \dots, x_n) = 0,$$

where  $x_1, \dots, x_n$  are unknowns. The system is *underdetermined* if  $m < n$ , *well-determined* if  $m = n$  and *overdetermined* if  $m > n$ . It is usually not possible to obtain an exact solution for an overdetermined system and one possibility is to seek a best least squares solution, that is, to find  $x^*$  such that the function

$$f(x) = \frac{1}{2} \sum_{i=1}^m [f_i(x)]^2$$

is minimized at  $x^*$ .

### Curve (Data) Fitting

Perhaps the most frequently solved of all nonlinear least squares problems are data fitting problems. In scientific researches, for example chemical or physical experiments, it is often encountered that the dependence of some observable quantity  $y$  on some independent variable(s)  $t$  is predicted, based on theoretical ground, to

have the form

$$y = h(x, t)$$

and  $m$  values  $y_1, \dots, y_m$  are measured for points  $t_1, \dots, t_m$  where  $x \in \mathbf{R}^n$  is an adjustable parameter vector. We are required to choose an optimal parameter vector  $x^*$  such that the function  $h(x, t)$  best fits the data in the least squares sense, that is, define the function  $f(x)$  by

$$f(x) = \frac{1}{2} \sum_{i=1}^m [h(x, t_i) - y_i]^2 = \frac{1}{2} r(x)^T r(x),$$

and  $x^*$  is found by minimizing the function  $f(x)$  where  $r_i(x) = h(x, t_i) - y_i, i = 1, \dots, m$  are called *residuals*.

In practice, both the values  $y_1, \dots, y_m$  and  $t_1, \dots, t_m$  are usually subject to measured errors. In the above conventional approach, implicit assumptions are made that only the values  $y_1, \dots, y_m$  are subject to measured errors and that the values  $t_1, \dots, t_m$  are either exact or contain negligible errors. In many applications, however, this is an oversimplification and the use of the above nonlinear least squares problems may lead to bias in the estimated parameters and variance values. It is then necessary to take proper account of errors in all variable values. The function of the resulting problem has the form

$$\begin{aligned} f(x, \tau) &= \frac{1}{2} \sum_{i=1}^m [(h(x, \tau_i) - y_i)^2 + (\tau_i - t_i)^2] \\ &= \frac{1}{2} [r(x, \tau)^T r(x, \tau) + e(\tau)^T e(\tau)], \end{aligned}$$

where  $\tau = (\tau_1, \dots, \tau_m)^T$  and  $r(x, \tau), e(\tau)$  are  $m$ -vectors with components  $r_i(x, \tau) = h(x, \tau_i) - y_i$  and  $e_i(\tau) = \tau_i - t_i, i = 1, \dots, m$ , respectively. Taking errors in all variables into account increases the complexity of the problem. For example, the simplest linear problem  $h(x, t) = x_1 + x_2 t$  is no longer a linear problem when errors in all variables are taken into account.

### Optimal Designs

Let us consider the optimal design of a coaxial cable circuit. Let  $x_1, \dots, x_n$  be the design parameters. For a given circuit, its performance index is a function of  $x_1, \dots, x_n$  and  $\omega$

$$h(x_1, \dots, x_n, \omega),$$

where  $\omega$  is the frequency of the circuit. The aim of the circuit optimal design is to determine the circuit parameters  $x_1, \dots, x_n$  such that the performance index of the circuit best approximates a given characteristic function  $\psi(\omega)$  in a given interval  $[\alpha, \beta]$  of the frequency  $\omega$ . This can be expressed as to find  $x^* \in \mathbf{R}^n$  which minimizes the function

$$\begin{aligned} f(x) &= \frac{1}{2} \sum_{i=1}^m [r_i(x)]^2 \\ &= \frac{1}{2} \sum_{i=1}^m [h(x_1, \dots, x_n, \omega_i) - \psi(\omega_i)]^2 \end{aligned}$$

where  $\alpha \leq \omega_1 < \dots < \omega_m \leq \beta$ . Meanwhile the circuit parameters are generally subject to some restricted factors of supplied cables such as geometric shapes, diameters, medium materials and so on. These subjects can be expressed as constrained conditions in the form

$$c_j(x_1, \dots, x_n) \geq 0, \quad j = 1, \dots, p.$$

Therefore, the mathematical model of the optimal design of a circuit generally has the form

$$\begin{cases} \min & f(x) = \frac{1}{2} \sum_{i=1}^m [r_i(x)]^2 \\ \text{s.t.} & c_j(x) \geq 0, \quad j = 1, \dots, p. \end{cases}$$

Nonlinear least squares problems can be classified into unconstrained and constrained ones depending on whether there exist constraints on variables  $x \in \mathbf{R}^n$ . For example, the resulting problem in the optimal design of the coaxial cable circuit is a constrained nonlinear least squares problem while the problem formed in the solution of simultaneous equations is an unconstrained nonlinear least squares problem. In some situations, the solution of a unconstrained nonlinear least squares problem may be unacceptable. To avoid such a situation, some restrictions on parameter vector  $x$  can be imposed in the form of constraints. For example, some variables are required to be nonnegative, some may be bounded by lower and/or upper bound(s), and some dependent relationships among variables must be satisfied. This also results in constrained nonlinear least squares problem. When errors in all variables are taken into account, the resulting problem is generally called a *generalized nonlinear least squares problem*. This increases not only the problem complexity, but also the

problem dimension. An advantage of the generalized nonlinear least squares problems that can be exploited is that the problem variables are *separable*. An optimization problem is called separable if the optimization with respect to some of the variables is easier than with respect to the others. Of course, there are other separable nonlinear least squares problems such as arose in curve fitting, component analysis and orthogonal regression (see [14]).

When  $r(x)$ , and hence  $f(x)$  is twice continuously differentiable, the gradient and the Hessian matrix of  $f(x)$  are given by

$$\begin{aligned}\nabla f(x) &= A(x)r(x), \\ \nabla^2 f(x) &= A(x)A(x)^T + \sum_{i=1}^m r_i(x)\nabla^2 r_i(x),\end{aligned}$$

where  $A(x) = [\nabla r_1(x), \dots, \nabla r_m(x)]$ . Let  $x^*$  be a minimizer of a NLS problem. The problem is called a *zero residual problem* if  $r(x^*) = 0$  and hence  $f(x^*) = 0$  and a *nonzero residual problem* if  $r(x^*) \neq 0$ . A nonzero residual problem is called *small residual* if  $r(x^*)$  is small or the second part of  $\nabla^2 f(x^*)$  is relatively small compared with the first part of  $\nabla^2 f(x^*)$ , otherwise it is called *large residual*.

Methods for nonlinear least squares are iterative type and are based upon trying to find a point  $x^*$  at which the so-called *Kuhn–Tucker optimality condition* is satisfied. These methods are generally of *descent* type. From a given initial point, these methods generate a sequence  $\{x^{(k)}\}$  such that either one point of the sequence or any accumulation point of  $\{x^{(k)}\}$  is a *Kuhn–Tucker point* (referred to as a *KT point*). The typical behavior of a method is that if the iteration is not terminated at some point  $x^{(k)}$ , the values  $\phi(x^{(k)})$  of a *merit function* for the problem are monotonically decreased so that the iterates  $x^{(k)}$  move steadily towards a neighborhood of a KT point  $x^*$ , and then converges rapidly to the point  $x^*$ . The basic structure of the  $k$ th iteration of such a method has the form

- Check if  $x^{(k)}$  is a KT point.
- If  $x^{(k)}$  is not a KT point, determine a  $\delta^{(k)}$  such that

$$\phi(x^{(k)} + \delta^{(k)}) < \phi(x^{(k)}).$$

- $x^{(k+1)} = x^{(k)} + \delta^{(k)}$ .

The information of second order derivatives of problem functions are required to determine if a KT

point is a local minimizer. Since the evaluation of second order derivatives are time consuming and sometimes the second order derivatives of functions are not available, most nonlinear least squares methods do not evaluate second order derivatives and just try to locate a KT point. A KT point may not be a local minimizer. However, there exist other features of methods such as the monotonic decreasing property of the sequence  $\{\phi(x^{(k)})\}$ , which usually imply that a KT point is a local minimizer, except in rare cases. A descent method with this property is called globally convergent, that is, the method does not require the initial point  $x^{(1)}$  close to  $x^*$ .

A globally convergent method for optimization usually defines a merit function  $\phi$  to force convergence from poor starting points. For unconstrained nonlinear least squares problems, the choice of  $\phi$  is simple. It is natural to choose the objective function  $f$  as  $\phi$ . For constrained nonlinear least squares problems, the choice of  $\phi$  is complicated by the fact that  $x^{(k)} + \delta^{(k)}$  should move closer to satisfying the constraints than  $x^{(k)}$  and  $\delta^{(k)}$  yields a reasonable decrease in the objective function. A number of merit functions are available for constrained nonlinear least squares problems solution. These include the  $\ell_1$  *penalty function* proposed by S.P. Han [11] and used by R. Fletcher [9], the *augmented Lagrange functions* of M.R. Hestenes [12] and Fletcher [7], the *merit function* of G. Di Pillo and L. Grippo [6] and the *merit function* of P.T. Boggs and J.W. Tolle [2].

Strategies are available to achieve the descent property in nonlinear least squares methods. These are: *line search* strategy and *trust region* strategy. Line search strategy transfers a multivariable minimization problem into a series of sub-minimization problems with single variable, and are the most commonly used in practice. In line search methods,  $\delta^{(k)}$  is obtained in the form  $\delta^{(k)} = \alpha_k s^{(k)}$  where  $s^{(k)}$  is a descent direction of the merit function  $\phi(x)$  at  $x^{(k)}$  and  $\alpha_k > 0$  is a steplength along the direction  $s^{(k)}$ . The descent direction  $s^{(k)}$  is generally obtained as a minimizer of some model problem which is a local approximation to the original problem at  $x^{(k)}$  and the steplength  $\alpha_k$  is determined by some line search method so that  $x^{(k)} + \alpha_k s^{(k)}$  gives a sufficient decrease in a chosen merit function from  $x^{(k)}$ . Specifically,  $\alpha_k$  is determined such that  $\phi(x^{(k)} + \alpha_k s^{(k)}) < \phi(x^{(k)})$ . For methods with line search, the convergence and the convergence rate depend upon the reduction on the merit

function at each iteration, which relies on the choices of the descent direction  $s^{(k)}$  and the steplength  $\alpha_k$ . Theoretically, exact line searches satisfying  $\alpha_k = \operatorname{argmin} \phi(x^{(k)} + \alpha s^{(k)})$  usually gives the maximal reduction on the function  $\phi(x^{(k)} + \alpha s^{(k)})$ . But determining  $\alpha_k$  by exact line search is not necessary and inefficient when iterate  $x^{(k)}$  is remote from  $x^*$ . Practical line search methods search for a steplength satisfying certain conditions. These conditions are readily satisfied so that the steplength can be effectively determined and guarantee the convergence of a method when the search direction  $s^{(k)}$  is sufficient descent [1]. Among various conditions, *Goldstein's conditions* are widely used in practice. These conditions require the steplength  $\alpha_k$  to satisfy

$$\begin{aligned} \phi(x^{(k)} + \alpha s^{(k)}) &\leq \phi(x^{(k)}) + \rho \alpha \nabla \phi(x^{(k)})^\top s^{(k)}, \\ \phi(x^{(k)} + \alpha s^{(k)}) &\geq \phi(x^{(k)}) + \sigma \alpha \nabla \phi(x^{(k)})^\top s^{(k)}, \end{aligned}$$

where  $0 < \rho < \sigma < 1$ . Usually, these two conditions define an interval of acceptable  $\alpha$ -values. A disadvantage of the second condition is that the minimum of  $\phi(x^{(k)} + \alpha s^{(k)})$  may be excluded to the left of the interval. A remedy to avoid this case is to use

$$\nabla \phi(x^{(k)} + \alpha s^{(k)})^\top s^{(k)} \geq \sigma \nabla \phi(x^{(k)})^\top s^{(k)}$$

to replace that condition. Numerous line search methods are available. Strategies used in line search methods generally consist of *bracketing* and *sectioning*. The simplest line search methods are pattern searches such as *golden section search* and *Fibonacci section search* [1]. These pattern searches use only evaluated function values. When the first order derivative information are available, the simplest line search is the *backtracking* which seeks the smallest integer  $i$  satisfying

$$\phi(x^{(k)} + t^i \alpha_0 s^{(k)}) \leq \phi(x^{(k)}) + \rho t^i \alpha_0 \nabla \phi(x^{(k)})^\top s^{(k)}$$

and set  $\alpha_k = t^j \alpha_0$  if  $j$  is such an integer. Effective line search methods to determine  $\alpha_k$  satisfying the Goldstein conditions are also available [1]. These methods employ sectioning schemes and interpolations.

Trust region strategy generates  $\delta^{(k)}$  by solving some model subproblem with a trust region constraint. The trust region defined by  $\|\delta\| \leq \Delta_k$  is a neighborhood about the current point  $x^{(k)}$  and is adjusted in such a way that the subproblem model is believed to have adequately approximated the chosen merit function in

that region. For a given trust region radius  $\Delta_k$ , the solution  $\delta^{(k)}$  of minimizing the subproblem model within the region  $\|\delta\| \leq \Delta_k$  is sought. If a satisfactory reduction on the merit function is obtained at  $x^{(k)} + \delta^{(k)}$ ,  $x^{(k)} + \delta^{(k)}$  is accepted as  $x^{(k+1)}$ . If the computed step  $\delta^{(k)}$  is not acceptable, the sub-problem model is not accurate enough in that region and the radius of the trust region is reduced to improve the accuracy of the approximation and the step is recomputed. The trust region radius may be increased after an acceptable step. Methods with trust region converge globally. An obstacle preventing the trust region methods from common use is the effective solution of trust region subproblems. Repeated solution of system of linear equations with modified coefficient matrices are required to obtain a satisfactory  $\delta^{(k)}$  and increase the complexity of trust region methods. Now effective approximate solution methods for the solution of trust region subproblems exist. These include positive definite *dogleg path* method [5,13], indefinite dogleg path methods [19], optimal path method in two-dimensional subspaces [3] and conjugate gradient method [15].

Subproblem models are generally local approximations to a chosen merit function at current iterate point  $x^{(k)}$ . These approximations are generally linear or quadratic. A linear approximation is the simplest function and a quadratic approximation is usually more accurate than linear approximation in certain neighborhood of  $x^{(k)}$ . The quadratic function is one of the simplest smooth functions and the minimum of a model problem with quadratic function is well-determined and is relatively easy to determine.

As an important class of optimization problems, any method for general minimization can be used to solve nonlinear least squares problems. However, special methods which take the advantage of the special structure of the objective function in nonlinear least squares are available. Most special methods are based on the well-known Gauss–Newton (G-N) method which requires only the first order derivatives of problem functions. In the G-N method, the matrix  $A(x^{(k)}) A(x^{(k)})^\top$  is used to approximate the Hessian matrix  $\nabla^2 f(x^{(k)})$ . Since  $r(x^*)$  may be small or zero as  $f(x)$  is minimized, this may be a good approximation when  $x^{(k)}$  is close to  $x^*$ . It is well known that for zero residual problems, the local convergence rate of the G-N method is quadratic, but for small residual problems,

the convergence of the method is at most linear and even not converge for large residual problems. According to the information used in a method, methods for nonlinear least squares can be divided into first order derivative methods, second order derivative methods and methods without derivatives. Among them the first order derivative methods are the most commonly used. These include (damped) G-N method, quasi-Newton methods, hybrid methods [1,10], adaptive method [4], factorized quasi-Newton methods [17,18] and methods with quasi-Newton corrections to Gauss–Newton matrix. As for second order derivative methods, the Newton method is the most famous. However, the disadvantages of the Newton method such as the evaluation of second order derivatives and convergence only local make the method rarely used in practice. As for methods without using derivatives, one can make a choice among the direction set methods [8] and the hybrid Gauss–Newton–Broyden method [16]. Theoretical analysis and numerical results show that these methods have good convergence properties and are robust and trust.

*Descent methods* for nonlinear least squares problems generate a sequence  $\{x^{(k)}\}$  such that  $f(x^{(k+1)}) < f(x^{(k)})$  and  $x^{(k)}$  converges to a local minimizer of the objective function  $f(x)$ . Methods with *line searches* generate the sequence using the iteration

$$x^{(k+1)} = x^{(k)} + \alpha_k s^{(k)},$$

where  $s^{(k)}$  is a descent direction of  $f(x)$  at  $x^{(k)}$  and  $\alpha_k$  is a steplength along the direction  $s^{(k)}$  determined by line searches. The search direction  $s^{(k)}$  is obtained as the solution of the system

$$B_k s = -g_k,$$

where  $g_k$  is the gradient of  $f(x)$  at  $x^{(k)}$  and  $B_k$  is either the Hessian  $G_k$  of  $f(x)$  at  $x^{(k)}$  or its approximation. The matrix  $B_k$  is required to be positive definite, so that the solution  $s^{(k)}$  which is the unique minimizer of the quadratic model

$$q_k(\delta) = f_k + g_k^T \delta + \frac{1}{2} \delta^T B_k \delta$$

is guaranteed to be a descent direction, where  $q_k(\delta)$  is a local approximation to  $f(x)$  at  $x^{(k)}$ ,  $f_k = f(x^{(k)})$  and  $\delta = x - x^{(k)}$ .

When the matrix  $B_k$  is not positive definite that are often encountered in practical calculation, the quadratic model does not have a unique minimizer and methods with line searches may not be defined. A more realistic approach is to take  $x^{(k+1)} = x^{(k)} + \delta^{(k)}$ . The  $\delta^{(k)}$  minimizes the quadratic model within a neighborhood  $N(x^{(k)}, \Delta_k)$  of the point  $x^{(k)}$  in which the quadratic function is believed adequately to approximate the function  $f(x)$ . The neighborhood  $N(x^{(k)}, \Delta_k)$  is generally called a *trust region* and methods having this framework are called *trust region methods*. These methods can retain the rapid rate of convergence of Newton type methods, but are also generally applicable and *globally convergent*.

The development of trust region methods can be traced back to the work of K. Levenberg [8] and D.W. Marquardt [9] on unconstrained *nonlinear least squares*

problems

$$\min f(x) = \frac{1}{2} \sum_{i=1}^m [r_i(x)]^2 = \frac{1}{2} r(x)^T r(x),$$

where  $r(x) = (r_1(x), \dots, r_m(x))^T$  and  $r_i(x)$ ,  $i = 1, \dots, m$ , are nonlinear functions of  $x \in \mathbf{R}^n$ . Assuming that  $r_i(x)$ ,  $i = 1 \dots, m$ , hence  $f(x)$  is twice continuously differentiable, the gradient and the Hessian matrix of  $f(x)$  are defined by

$$\begin{aligned} g(x) &= \nabla f(x) = A(x)r(x), \\ G(x) &= \nabla^2 f(x) \\ &= A(x)A(x)^T + \sum_{i=1}^m r_i(x)\nabla^2 r_i(x). \end{aligned}$$

The *Levenberg–Marquardt method* is a modification of the well-known *Gauss–Newton method* and is based upon the idea that when the full Gauss–Newton step fails, a proper bias towards the steepest descent direction may generate a satisfactory reduction on the function  $f(x)$ . Thus the step  $\delta^{(k)}$  between iterates of the Levenberg–Marquardt method is a solution of the system

$$(A_k A_k^T + \mu_k I)\delta = -g_k$$

for some properly chosen  $\mu_k \geq 0$ . The application of the Levenberg–Marquardt method to general unconstrained minimization is given by S.M. Goldfeld, R.E. Quandt and H.F. Trotter [6], in which the matrix  $A_k A_k^T$  in the above system is just replaced by the matrix  $B_k$ , that is,

$$(B_k + \mu_k I)\delta = -g_k.$$

Let  $\delta^{(k)}$  be the solution of the system. Then  $\delta^{(k)}$  solves the trust region subproblem

$$\begin{cases} \min & q_k(\delta) = f_k + g_k^T \delta + \frac{1}{2} \delta^T B_k \delta \\ \text{s.t.} & \|\delta\| \leq \Delta_k \end{cases}$$

with  $\Delta_k = \|\delta^{(k)}\|$ . Also for any given  $\Delta_k$ , the solution  $\delta^{(k)}$  of the trust region subproblem usually satisfies the system

$$(B_k + \mu_k I)\delta = -g_k, \quad \|\delta^{(k)}\| = \Delta_k,$$

where  $\mu_k \geq 0$  such that  $B_k + \mu_k I$  is at least positive semidefinite, except for the case when  $B_k$  is positive definite and  $\|B_k^{-1}g_k\| \leq \Delta_k$ , then the solution is  $\delta^{(k)} = -$

$B_k^{-1}g_k$ . It can be seen that the solution  $\delta^{(k)}$  can be obtained by controlling either the value  $\mu_k$  or the radius  $\Delta_k$ .

Early versions of the Levenberg–Marquardt and Goldfeld–Quandt–Trotter methods determined  $\delta^{(k)}$  from the system by controlling  $\mu_k$  and recently used trust region methods determined  $\delta^{(k)}$  by controlling the radius  $\Delta_k$ . Direct control of  $\mu_k$  has a number of disadvantages. One is that there does not seem to have a reasonable and automatic initial choice for the value  $\mu_1$ , while a reasonable value for initial  $\Delta_1$  can be a small fraction of the size  $\|x^{(1)}\|$  of the starting point  $x^{(1)}$ . One more problem occurs when  $x^{(k)} + \delta^{(k)}$  leads to an increase in the objective function  $f(x)$ . In this case, the function and derivative information evaluated at  $x^{(k)}$  and  $x^{(k)} + \delta^{(k)}$  can be used to estimate a required decrease in radius  $\Delta_k$ , but it is not clear how these information are used to estimate a reasonable increase for  $\mu_k$ .

In implementing recent forms of trust region methods, there are two main problems. One problem is how the trust region radius  $\Delta_k$  shall be chosen. To prevent undue restriction of the step  $\delta^{(k)}$ , the trust region radius  $\Delta_k$  should be as large as possible under the condition that  $q_k(\delta)$  adequately approximates  $f(x)$  in that region. Let  $\delta^{(k)}$  be the solution of the trust region subproblem for given  $\Delta_k$ , the agreement between  $q_k(\delta)$  and  $f(x)$  in the neighborhood  $N(x^{(k)}, \Delta_k)$  can be measured by the comparison between the actual reduction in  $f(x)$

$$\text{ared}(\delta^{(k)}) = f(x^{(k)}) - f(x^{(k)} + \delta^{(k)})$$

and the reduction predicted by the quadratic model

$$\begin{aligned} \text{pred}(\delta^{(k)}) &= f(x^{(k)}) - q_k(\delta^{(k)}) \\ &= -g_k^\top \delta^{(k)} - \frac{1}{2} \delta^{(k)\top} B_k \delta^{(k)}, \end{aligned}$$

where  $B_k$  is either the Hessian matrix  $G_k$  of  $f(x)$  or its approximation, for example  $A_k A_k^\top$ . If  $\text{ared}(\delta^{(k)})$  is satisfactory compared with the  $\text{pred}(\delta^{(k)})$ , which implies a good reduction in  $f$ , the trust region is referred to as proper. Then  $x^{(k)} + \delta^{(k)}$  is accepted as a new iterate point  $x^{(k+1)}$  and the trust region radius may either keep unchanged or be increased in case the reduction in  $f$  is sufficient and the trust region constraint is active. If the computed step  $\delta^{(k)}$  is not acceptable, which occurs when  $q_k(\delta)$  is not accurate enough in  $N(x^{(k)}, \Delta_k)$ , then

the radius  $\Delta_k$  is reduced to improve accuracy of the approximation and the step is recomputed from the trust region subproblem with reduced  $\Delta_k$ . A model trust region method with direct control of  $\Delta_k$  can now be described as follows:

- 1) Give parameters  $0 < \gamma_1 < 1 < \gamma_2$ ,  $0 < \eta_1 < \eta_2 < 1$  and  $\Delta_{\max} > 0$ , initial point  $x^{(1)}$  and  $\Delta_1 (\leq \Delta_{\max})$  and set  $k = 1$ .
- 2) Calculate  $f_k, g_k$ . If  $g_k = 0$  then terminate, else form  $B_k$ .
- 3) Solve the trust region subproblem for  $\delta^{(k)}$ .
- 4) Compute  $\theta_k = \text{ared}(\delta^{(k)})/\text{pred}(\delta^{(k)})$ .
- 5) If  $\theta_k < \eta_1$ , then  $\Delta_k = \gamma_1 \Delta_k$  and go to step 3).
- 6)  $x^{(k+1)} = x^{(k)} + \delta^{(k)}$ ,

$$\Delta_{k+1} = \begin{cases} \bar{\Delta} & \text{if } \theta_k \geq \eta_2 \\ & \text{and } \|\delta^{(k)}\| = \Delta_k, \\ \Delta_k & \text{otherwise,} \end{cases}$$

set  $k = k + 1$ , where  $\bar{\Delta} = \min\{\gamma_2 \Delta_k, \Delta_{\max}\}$

The most important issue to implement a trust region method is the efficient solution of the trust region subproblem. There are three possible cases to determine the solution of the trust region subproblem:

- a) *Newton step case*:  $B_k$  is positive definite and  $\|B_k^{-1}g_k\| \leq \Delta_k$ . The solution is  $\delta^{(k)} = -B_k^{-1}g_k$ .
- b) *General case*:  $B_k$  is positive definite and  $\|B_k^{-1}g_k\| > \Delta_k$  or  $B_k$  is indefinite and  $\|(B_k - \mu_1^{(k)}I)^+ g_k\| \geq \Delta_k$  where  $(A)^+$  denotes the generalized inverse of the matrix  $A$  and  $\mu_1^{(k)}$  is the smallest eigenvalue of  $B_k$ . The solution is  $\delta^{(k)} = -(B_k + \mu_k I)^{-1}g_k$  with  $\mu_k > \mu_\ell = \max\{0, -\mu_1^{(k)}\}$ ,  $\|\delta^{(k)}\| = \Delta_k$ .
- c) *Hard case* [11]:  $B_k$  is indefinite and  $\|(B_k - \mu_1^{(k)}I)^+ g_k\| < \Delta_k$ . The solution is  $\delta^{(k)} = -(B_k - \mu_1^{(k)}I)^+ g_k + t_k u_1^{(k)}$  where  $u_1^{(k)}$  is the eigenvector of  $B_k$  corresponding to  $\mu_1^{(k)}$  and  $t_k$  is determined from the equation  $\|(B_k - \mu_1^{(k)}I)^+ g_k + t u_1^{(k)}\| = \Delta_k$ .

Since the hard case rarely occurs, the solution of trust region subproblem is closely related to the solution of the equation

$$\begin{aligned} \phi_k(\mu) &= \|\delta_k(\mu)\| - \Delta_k \\ &= \|(B_k + \mu I)^{-1}g_k\| - \Delta_k = 0. \end{aligned}$$

This is a nonlinear equation with respect to  $\mu$  and there is generally no finite method to find its exact solution. Since  $\phi_k(\mu_\ell) > 0$  and  $\phi_k(\infty) = -\Delta_k$ , it is clear that the

solution can be found in the interval  $(\mu_\ell, \infty)$ . Since  $\phi_k(\mu)$  is a convex and continuous monotonic decreasing function in the interval  $(\mu_\ell, \infty)$ , the solution of the equation is unique. M.D. Hebden [7] used the practical structure of the function  $\phi_k(\mu)$  to propose a method that generates a sequence  $\{\mu^{(j)}\}$  such that  $\mu^{(j)} \rightarrow \mu_k$ . Let  $\mu^{(j)}$  be a current estimation to  $\mu_k$ , a fractional function

$$\psi_k(\mu) = \frac{\alpha}{\mu + \beta} - \Delta_k$$

is used to approximate the function  $\phi_k(\mu)$  such that

$$\psi_k(\mu^{(j)}) = \phi_k(\mu^{(j)}), \quad \psi'_k(\mu^{(j)}) = \phi'_k(\mu^{(j)})$$

where

$$\alpha = -\frac{(\phi_k(\mu^{(j)}) + \Delta_k)^2}{\phi'_k(\mu^{(j)})},$$

$$\beta = -\frac{\phi_k(\mu^{(j)}) + \Delta_k}{\phi'_k(\mu^{(j)})} - \mu^{(j)}.$$

Setting  $\psi_k(\mu) = 0$  and substituting  $\alpha$  and  $\beta$  give the iteration

$$\mu^{(j+1)} = \mu^{(j)} + \xi(\mu^{(j)}) \left[ \frac{\|\delta_k(\mu^{(j)})\|}{\Delta_k} - 1 \right],$$

$$\xi(\mu^{(j)}) = \frac{\|\delta_k(\mu^{(j)})\|^2}{\delta_k(\mu^{(j)})^T (B_k + \mu^{(j)}I)^{-1} \delta_k(\mu^{(j)})}.$$

J.J. Moré and D.C. Sorensen [11] also derived the iteration by applying the Newton method to the equation

$$h_k(\mu) = \frac{1}{\Delta_k} - \frac{1}{\|\delta_k(\mu)\|}.$$

The iteration can be calculated in the following way.

- i) Factorize the matrix  $(B_k + \mu^{(j)}I) = R^T R$  with  $R$  an upper triangular matrix.
- ii) Solve  $R^T R \delta = -g_k$  for  $\delta_k(\mu^{(j)})$  using forward and backward substitutions.
- iii) Solve  $R^T z = \delta_k(\mu^{(j)})$  for  $z_j$  using forward substitution.
- iv)  $\mu^{(j+1)} = \mu^{(j)}$

$$+ \frac{\|\delta_k(\mu^{(j)})\|^2}{\|z_j\|^2} \left[ \frac{\|\delta_k(\mu^{(j)})\|}{\Delta_k} - 1 \right].$$

To start the iteration, an initial value for  $\mu^{(1)}$  is required. A natural choice is the value  $\mu^{(1)} = \mu_\ell$ . This choice

needs the calculation of the smallest eigenvalue of the matrix  $B_k$  and will cause numerical difficulties when  $B_k$  is not positive definite. Moré [10] used the choice

$$\mu^{(1)} = \mu_{k-1} \frac{\Delta_{k-1}}{\Delta_k}$$

as the initial value of  $\mu_k$  at the  $k$ th iteration where  $\mu_{k-1}$  is the accepted value of the equation  $\phi_{k-1}(\mu) = 0$  at the  $(k - 1)$ th iteration. J.E. Dennis and R.B. Schnabel [4] proposed the choice

$$\mu^{(1)} = \mu_{k-1} + \xi(\mu_{k-1}) \left[ \frac{\|\delta_{k-1}(\mu_{k-1})\|}{\Delta_k} - 1 \right],$$

$$\xi(\mu_{k-1}) = \frac{\|\delta_{k-1}(\mu_{k-1})\|^2}{\delta_{k-1}(\mu_{k-1})^T (B_{k-1} + \mu_{k-1}I)^{-1} \delta_{k-1}(\mu_{k-1})},$$

which is an analog to the iteration for  $\mu^{(j+1)}$ . Of course, a safeguard strategy is imposed to force convergence, that is, lower and upper bounds for  $\mu^{(j)}$  are provided and updated in iteration process. The iteration finds an approximate solution  $\delta^{(k)}$  satisfying the *Hebden conditions* [7]

$$\text{pred}(\delta^{(k)}) \geq \tau(f_k - q_k^*),$$

$$\left| \|\delta^{(k)}\| - \Delta_k \right| \leq \rho \Delta_k,$$

where  $\tau$  and  $\rho$  are positive constants and  $q_k^*$  is the optimal value of the trust region subproblem for given  $\Delta_k$ . Then strong convergence result can be obtained (see [5]).

In the general case, the repeated solution of the system  $(B_k + \mu^{(j)}I)\delta = -g_k$  for different values of  $\mu^{(j)}$  to determine a satisfactory approximate solution  $\delta^{(k)}$  of the trust region subproblem for given value  $\Delta_k$  and the recomputation of  $\delta^{(k)}$  for reduced values  $\Delta_k$  may be required at each iteration. It is this complication that prevent trust region methods from wide use in past two decades. Most practical trust region methods attempt to find an approximate solution of the trust region subproblem in a reasonable amount of computational effort. G.A. Shultz, Schnabel and R.H. Byrd [13] proposed general conditions on the approximate solution  $\delta^{(k)}$  to ensure a satisfactory reduction on  $q_k(\delta)$  so that resulting trust region methods have strong convergence properties. These conditions are as follows:

A) There exist constants  $\beta_1 > 0$  and  $\sigma_1 > 0$  such that for all  $\Delta_k$  and  $B_k$

$$\text{pred}(\delta^{(k)}) \geq \beta_1 \|g_k\| \min \left\{ \Delta_k, \sigma_1 \frac{\|g_k\|}{\|B_k\|} \right\} .$$

B) There exists a  $\beta_2 > 0$  such that for all  $\Delta_k$  and  $B_k$

$$\text{pred}(\delta^{(k)}) \geq -\beta_2 \mu_1^{(k)} \Delta_k^2 .$$

C) If the matrix  $B_k$  is positive definite and  $\|B_k^{-1}g_k\| \leq \Delta_k$ , then

$$\delta^{(k)} = -B_k^{-1}g_k .$$

Condition A) ensures the global convergence of a trust region method to a point satisfying the first order necessary condition and a trust region method satisfying condition B) will converge to a point at which the second order necessary conditions are satisfied. When condition C) is satisfied, a convergent trust region method converges at a quadratic rate if  $G(x^*)$  is positive definite at the limit point  $x^*$ .

Let  $\Delta_k$  vary in the interval  $(0, \infty)$ , then the solution  $\delta_k(\mu)$  of the trust region subproblem forms a continuous optimal path  $\Gamma^{(k)}(\tau)$  in the space  $\mathbf{R}^n$ . The optimal path can be expressed as

$$\Gamma^{(k)}(\tau) = \Gamma_1^{(k)}(t(\tau)) + \Gamma_2^{(k)}(\theta(\tau))$$

where

$$\Gamma_1^{(k)}(t(\tau)) = - \sum_{i \in I} \frac{t(\tau)}{\mu_i^{(k)} t(\tau) + 1} v_i^{(k)} - t(\tau) \sum_{i \in N} v_i^{(k)} ,$$

$$\Gamma_2^{(k)}(\theta(\tau)) = \theta(\tau) u_1^{(k)} ,$$

$$t(\tau) = \begin{cases} \tau & \text{if } \tau < \frac{1}{\mu_\ell} , \\ \frac{1}{\mu_\ell} & \text{if } \tau \geq \frac{1}{\mu_\ell} , \end{cases}$$

$$\theta(\tau) = \begin{cases} 0 & \text{if } \mu_\ell = 0 , \\ \max \left\{ \tau - \frac{1}{\mu_\ell} , 0 \right\} & \text{if } \mu_\ell > 0 , \end{cases}$$

$$I = \left\{ i: \mu_i^{(k)} \neq 0 \right\} , \quad N = \left\{ i: \mu_i^{(k)} = 0 \right\}$$

$$v_i^{(k)} = u_i^{(k)\top} g_k u_i^{(k)} , \quad i = 1, \dots, n ,$$

and  $\mu_1^{(k)} \leq \dots \leq \mu_n^{(k)}$  are eigenvalues of  $B_k$  and  $u_i^{(k)}$ ,  $i = 1, \dots, n$ , are corresponding orthonormal eigenvectors. The optimal path has two properties. As a point  $x$  proceeds from  $x^{(k)}$  along the path: i) the distance to  $x^{(k)}$  is

monotonically increasing, and ii) the value of  $q_k(\delta)$  is monotonically decreasing. These properties guarantee that for any given  $\Delta_k$ , the solution of the trust region subproblem is  $\delta^{(k)} = \Gamma^{(k)}(\tau_k)$  where  $\tau_k$  is uniquely determined from the equation  $\|\Gamma^{(k)}(\tau)\| = \Delta_k$ . The formulation of the path  $\Gamma^{(k)}(\tau)$  needs the calculation of all eigenvalues and eigenvectors of the matrix  $B_k$ . This is time consuming and is unrealistic. J.P. Bulteau and J.-Ph. Vial [1] restrict the solution of the trust region subproblem in a two-dimensional subspace  $S = \text{span}[a_1 a_2]$  and choose the solution of the problem

$$\begin{cases} \min & q_k(\delta) = f_k + g_k^\top \delta + \frac{1}{2} \delta^\top B_k \delta , \\ \text{s.t.} & \|\delta\| \leq \Delta_k , \delta \in S , \end{cases}$$

as an approximate solution of the subproblem. The vectors  $a_1$  and  $a_2$  are chosen in such a way that  $A = [a_1 a_2]$ ,  $A^\top A = I$ . Then any  $\delta \in S$  can be expressed as  $\delta = Az$  for any  $z \in \mathbf{R}^2$  and the restricted subproblem can be simplified as

$$\begin{cases} \min & q_k(z) = f_k + g_k^\top Az + \frac{1}{2} z^\top A^\top B_k A z , \\ \text{s.t.} & \|z\| \leq \Delta_k . \end{cases}$$

This is a trust region subproblem in the space  $\mathbf{R}^2$  and can be easily solved using the optimal path method, since we only need calculate the whole eigensystem of a  $(2 \times 2)$ -matrix  $A^\top B_k A$  to form the optimal path  $\Gamma_S^{(k)}(\tau)$ . The subspace  $S$  is generally chosen in the following way:

$$S = \begin{cases} \text{span}[-g_k, -B_k^{-1}g_k] & \text{if } B_k \text{ P.D.} , \\ \text{span}[-g_k, u_1^{(k)}] & \text{if } B_k \text{ I.D.} , \end{cases}$$

where P.D. and I.D. denote positive definite and indefinite, respectively. In fact the path  $\Gamma_S^{(k)}(\tau)$  can be regarded as a projection of the optimal path  $\Gamma^{(k)}(\tau)$  in the subspace  $S$  and is an approximation of the path  $\Gamma^{(k)}(\tau)$ . Based on this idea, the recent efficient solution methods for trust region subproblems first form an approximate path  $\Gamma_a^{(k)}(\tau)$  and then choose  $\delta^{(k)} = \Gamma_a^{(k)}(\tau_k)$  with  $\|\Gamma_a^{(k)}(\tau_k)\| = \Delta_k$ . This greatly reduce the complication for the solution of the trust region subproblem, since for any given  $\Delta_k$  the solution is obtained from the solution of the equation  $\|\Gamma_a^{(k)}(\tau)\| = \Delta_k$  and the reformulation of the path for any reduced  $\Delta_k$  is not required. When formulating an approximate path, it is required

to satisfy the two properties i) and ii) that the optimal path has.

*Dogleg path* methods are most effective and are first suggested by M.J.D. Powell and modified by Dennis and H.H.W. Mei [3] for positive definite matrices and extended to indefinite matrices by J.Z. Zhang and C.X. Xu [15]. Powell’s method uses a single dogleg path in the form

$$\Gamma_{ps}^{(k)} = [0, \delta_{cp}^{(k)}, \delta_{np}^{(k)}]$$

to approximate the optimal path, where

$$\delta_{cp}^{(k)} = -\frac{g_k^\top g_k}{g_k^\top B_k g_k} g_k$$

is the minimizer of  $q_k(\delta)$  in the steepest descent direction and

$$\delta_{np}^{(k)} = -B_k^{-1} g_k$$

is the global minimizer of  $q_k(\delta)$ . Then the solution  $\delta^{(k)}$  of the problem

$$\min \left\{ q_k(\delta) : \|\delta\| \leq \Delta_k, \delta \in \Gamma_{ps}^{(k)} \right\}$$

is taken as an approximate solution of the trust region subproblem. The solution  $\delta^{(k)}$  can be obtained in the following way

$$\delta^{(k)} = \begin{cases} -B_k^{-1} g_k & \text{if } \left\| \delta_{np}^{(k)} \right\| \leq \Delta_k, \\ -\frac{\Delta_k}{\|g_k\|} g_k & \text{if } \left\| \delta_{cp}^{(k)} \right\| \geq \Delta_k, \\ \delta_{cp}^{(k)} + t_k(\delta_{np}^{(k)} - \delta_{cp}^{(k)}) & \text{otherwise,} \end{cases}$$

where  $t_k \in (0, 1)$  is determined from the equation  $\|\delta_{cp}^{(k)} + t(\delta_{np}^{(k)} - \delta_{cp}^{(k)})\| = \Delta_k$ . Dennis and Mei modified the single dogleg path to form a double dogleg path

$$\Gamma_{dm}^{(k)} = [0, \delta_{cp}^{(k)}, \delta_\eta^{(k)}, \delta_{np}^{(k)}],$$

where

$$\delta_\eta^{(k)} = \eta \delta_{np}^{(k)}, \quad \frac{\|g_k\|^4}{g_k^\top B_k g_k \cdot g_k^\top B_k^{-1} g_k} < \eta < 1.$$

The solution  $\delta^{(k)}$  in both the methods satisfies the general conditions A) and C). Hence both the methods are global convergent and convergence rate is quadratic if  $G(x^*)$  is positive definite at limit point  $x^*$ .

Both the single and double dogleg path methods do work well when all the matrices  $B_k$  are positive definite. But they are unable to deal with the nonpositive definite case which occurs very often in practice. Zhang and Xu proposed indefinite dogleg paths for indefinite matrices  $B_k$ . One of these indefinite dogleg paths has the form

$$\Gamma_{ip}^{(k)} = [0, \delta_{\mu p}^{(k)}, \delta_\mu^{(k)}, d],$$

where

$$\delta_{\mu p}^{(k)} = -\frac{g_k^\top g_k}{g_k^\top (B_k + \mu_k I) g_k} g_k,$$

$$\delta_\mu^{(k)} = -(B_k + \mu_k I)^{-1} g_k,$$

$d$  is a *negative curvature* direction of the matrix  $B_k$  and  $\mu_k$  is chosen such that  $(B_k + \mu_k I)$  is positive definite. Since the optimal path  $\Gamma^{(k)}(\tau)$  is infinite when  $B_k$  is indefinite, this is an infinite dogleg path. The solution  $\delta^{(k)}$  obtained in the path has the following form

$$\delta^{(k)} = \begin{cases} -\frac{\Delta_k}{\|g_k\|} g_k & \text{if } \left\| \delta_{\mu p}^{(k)} \right\| \geq \Delta_k, \\ \delta_\mu^{(k)} + t_k d, t_k > 0 & \text{if } \left\| \delta_\mu^{(k)} \right\| \leq \Delta_k, \\ \delta_{\mu p}^{(k)} + t_k(\delta_\mu^{(k)} - \delta_{\mu p}^{(k)}), & \\ t_k \in (0, 1) & \text{otherwise,} \end{cases}$$

where both  $t_k$  are determined from the equation  $\|\delta^{(k)}(t)\| = \Delta_k$ . When this indefinite dogleg path is combined with either the single or the double dogleg path, the resulting trust region method generates the solution  $\delta^{(k)}$  satisfying all the three general conditions A)–C).

The negative curvature direction  $d$  can be effectively obtained from the Bunch–Parlett factorization

$$PB_k P^\top = LDL^\top$$

for symmetric matrices [2], where  $P$  is a permutation matrix,  $L$  a unit lower triangular matrix and  $D$  a block diagonal matrix with  $1 \times 1$  and  $2 \times 2$  diagonal blocks. Since matrices  $B_k$  and  $D$  have the same *inertia*, the negative curvature directions of  $B_k$  can be directly obtained from the eigenvectors of  $D$  corresponding to its negative eigenvalues. Let  $v_1$  be the eigenvector corresponding to the smallest eigenvalue of  $D$  and  $v = (v_1^\top L^\top P g_k) v_1$ . Then

$$d = -\text{sgn}(g_k^\top P^\top L^{-1} v) P^\top L^{-1} v$$

is a satisfactory negative curvature direction of  $B_k$  [15].

For large scale problems, methods with matrix factorizations generally are not suitable. T. Steihaug [14] proposed to use a *conjugate gradient method* for the system  $B_k \delta = -g_k$  to find an approximate solution of the trust region subproblem. After  $\delta_1$ ,  $h_1$  and  $d_1$  are given, the iteration of the conjugate gradient method has the form:

$$\begin{aligned}\delta_{j+1} &= \delta_j + \alpha_j d_j, \\ \alpha_j &= \frac{h_j^\top h_j}{d_j^\top B_k d_j}, \\ h_{j+1} &= h_j - \alpha_j B_k d_j, \\ d_{j+1} &= h_{j+1} + \beta_j d_j, \\ \beta_j &= \frac{h_{j+1}^\top h_{j+1}}{h_j^\top h_j}, \\ j &= 1, \dots, n.\end{aligned}$$

When this iteration is used to generate an approximate solution to the trust region subproblem, the solution is obtained in the following way. Assume that  $d_j^\top B_k d_j > 0$  for  $j = 1, \dots, i - 1$  and  $\|\delta_i\| < \Delta_k$  and that  $h_i$  and  $d_i$  have been calculated. In case either  $d_i^\top B_k d_i < 0$  or  $d_i^\top B_k d_i > 0$  but  $\|\delta_i + \alpha_i d_i\| \geq \Delta_k$ ,  $\delta_i + t_i d_i$  is chosen as  $\delta^{(k)}$  where the value  $t_i$  is determined from the equation  $\|\delta_i + t d_i\| = \Delta_k$ . If  $d_j^\top B_k d_j > 0$  for all  $j = 1, \dots, n$  and  $\|\delta_{n+1}\| \leq \Delta_k$ , then it follows from the properties of the conjugate gradient method that the matrix  $B_k$  is positive definite,  $h_{n+1} = 0$  and  $\delta_{n+1} = -B_k^{-1} g_k$  is the exact solution of the system  $B_k \delta = -g_k$ . Therefore,  $\delta_{n+1}$  is the desired solution of trust region subproblem. The conjugate gradient method for the solution of the trust region subproblem has the form.

- 1) Give  $\delta_1 = 0$ ,  $h_1 = -g_k$ ,  $d_1 = h_1$ ,  $\eta_k \in (0, 1)$ ,  $j = 1$ .
- 2) If  $d_j^\top B_k d_j < 0$  then go to 6) below, else calculate  $\alpha_j = h_j^\top h_j / d_j^\top B_k d_j$  and  $\delta_{j+1} = \delta_j + \alpha_j d_j$ .
- 3) If  $\|\delta_{j+1}\| \geq \Delta_k$ , go to 6) below.
- 4) Calculate  $h_{j+1} = h_j - \alpha_j B_k d_j$ . If  $\|h_{j+1}\| \leq \eta_k \|g_k\|$ , choose  $\delta^{(k)} = \delta_{j+1}$ .
- 5)  $\beta_j = h_{j+1}^\top h_{j+1} / h_j^\top h_j$ ,  $d_{j+1} = h_{j+1} + \beta_j d_j$ ,  $j = j + 1$ , then go to 2).
- 6) Determine  $t_j$  such that  $\|\delta_j + t_j d_j\| = \Delta_k$  and choose  $\delta^{(k)} = \delta_j + t_j d_j$ .

In fact, the conjugate gradient method for the approximate solution of the trust region subproblem is essentially a *multiple dogleg path* method. When the matrix

$B_k$  is positive definite, the multiple dogleg path is

$$\Gamma_{mp}^{(k)} = [0, \delta_1, \dots, \delta_{n+1}]$$

and when the matrix  $B_k$  is indefinite, the multiple dogleg path is

$$\Gamma_{mi}^{(k)} = [0, \delta_1, \dots, \delta_i, d_i]$$

where  $d_i$  is the first calculated negative curvature direction in the iteration process. Then the solution  $\delta^{(k)}$  is obtained either in the path  $\Gamma_{mp}^{(k)}$  or in the path  $\Gamma_{mi}^{(k)}$ .

Thermodynamics; Heterogeneous; Homogeneous; Azeotrope

An *azeotrope* occurs when a liquid mixture boils at a constant temperature, producing a vapor with the same composition as the liquid. This is a significant phenomenon in *distillation* processes. An azeotrope represents a barrier to distillation, beyond which further separation of the components in the mixture is not possible. Therefore, the problem of locating all azeotropes in a chemical mixture is more than simply a thermodynamic curiosity, it is important for a number of reasons. First, the task of locating *all* azeotropes in a chemical mixture is essential for the *synthesis of separation processes*. A separation process that is designed without complete knowledge about the azeotropes in the system is likely to be infeasible.

In addition, many thermodynamic models have been proposed which can predict the phase behavior of nonideal mixtures. Unfortunately, the accuracy of these models is not uniform over a wide range of mixtures. One useful way of testing the accuracy of a model for a given mixture is to compare the compositions of the azeotropes predicted by the model with those determined by experiment.

Despite the considerable interest in the area of predicting phase equilibria for chemical mixtures, relatively few methods for enumerating the azeotropes for a given system have been reported. The thermodynamic conditions for azeotropy constitute a nonlinear system of equations. This problem presents the additional challenge of finding all of the solutions to the nonlinear system of equations where the number of solutions is not known.

### Nonlinear System of Equations

The most common type of azeotropes studied to date are called homogeneous azeotropes and occur when a single liquid phase is in equilibrium with the vapor phase. The thermodynamic conditions for homogeneous azeotropy are therefore gives,

- 1) equilibrium between the vapor phase and a single liquid phase, and
- 2) composition of the vapor phase is identical to the composition of the liquid phase.

Two other classifications of azeotropes, heterogeneous and reactive, will be discussed later in this article.

### Condition 1: Phase Equilibrium

The equilibrium condition requires that the chemical potential of each component must be the same in the liquid and the vapor phases. If we consider a mixture of  $N$  components,

$$\mu_i^V = \mu_i^L, \quad \forall i \in N,$$

where  $\mu_i^V$  and  $\mu_i^L$  represent the *chemical potential* of component  $i$  in the vapor and liquid phases. From the definition of the fugacity of component  $i$  in a mixture,  $\widehat{f}_i$ ,

$$\widehat{f}_i^V = \widehat{f}_i^L, \quad \forall i \in N,$$

hence,

$$y_i \widehat{\phi}_i^V P = x_i \gamma_i^L f_i^L, \quad \forall i \in N. \quad (1)$$

The symbol  $\widehat{\phi}_i^V$  represents the mixture *fugacity coefficient* of component  $i$  in the vapor phase. For the liquid phase,  $\gamma_i^L$  is the *activity coefficient*, and  $f_i^L$  is the fugacity of component  $i$  in the liquid phase. Rearranging (1) gives,

$$\frac{y_i}{x_i} = \frac{\gamma_i^L f_i^L}{\widehat{\phi}_i^V P}, \quad \forall i \in N.$$

A common simplification is to assume that at low pressure the vapor phase can be modeled as an ideal gas, for which  $\widehat{\phi}_i^V = 1$ . For the liquid phase the fugacity is equal to  $f_i^L = \phi_i^{sat} P_i^{sat} (PF)_i$ . But, for an ideal gas,  $\phi_i^{sat} = 1$ , and  $(PF)_i = 1$ . Therefore,

$$\frac{y_i}{x_i} = \frac{\gamma_i^L P_i^{sat}}{P}. \quad (2)$$

### Condition 2: Equality of Phase Compositions

The azeotropy condition requires that the composition of the vapor phase is identical to the composition of the liquid phase.

$$y_i = x_i, \quad \forall i \in N. \quad (3)$$

Equations must also be added to require that the mole fractions in each phase sum to unity and have values between 0 and 1.

$$\begin{cases} \sum_{i \in N} y_i = \sum_{i \in N} x_i = 1, \\ 0 \leq y_i, x_i \leq 1, \end{cases} \quad \forall i \in N. \quad (4)$$

Equations (2), (3), (4) constitute the nonlinear system of equations that are satisfied by a homogeneous azeotrope. Typical nonlinear equation solvers cannot be used robustly to find all of the solutions to this system of equations, since it is a nonlinear, constrained problem with multiple solutions. Many systems contain multiple azeotropes, each of which is a solution to the system. In addition, each pure component is a solution, giving at least  $N$  solutions.

### Solution Methodologies

Most of the previous work reported in the literature has been limited to calculating homogeneous azeotropes using local nonlinear equation solvers. This means that the ability of these methods to predict azeotropes is dependent upon choosing good starting points for the solution technique. These methods cannot guarantee that all of the azeotropes have been located in a particular system. [1] calculated ternary homogeneous azeotropes using the Wilson model under isothermal conditions. [10] calculated homogeneous azeotropes of binary mixtures using an equation of state as the thermodynamic model. Their approach was to fix temperature and vary composition and volume until thermodynamic equilibrium conditions were satisfied. [12] also used an equation of state to calculate homogeneous azeotropes for binary mixtures.

[2] presented a search method for finding homogeneous and heterogeneous azeotropes which uses a *Levenberg-Marquardt algorithm* to find homogeneous azeotropes and then checks the stability of each solution with the tangent plane criterion described by [8]. A solution which is found to be unstable is then used as the starting point for a new search for an heterogeneous azeotrope. Again, this technique relies on local solution techniques and cannot guarantee that all azeotropes are located.

[4] proposed a method for locating all homogeneous azeotropes in multicomponent systems. This method uses a homotopy continuation technique for tracking branches of solutions to the nonlinear system of equations. They demonstrated that the technique performed robustly for systems containing up to five components using the Wilson activity coefficient equation. Recently, [3] have extended this method for heterogeneous azeotropes, and [9] have used it to predict

reactive azeotropes. [7] have formulated the problem of locating all homogeneous azeotropes as a global optimization problem in which each global minimum solution corresponds to an azeotrope. They applied this approach robustly using the Wilson, NRTL, UNIQUAC and UNIFAC activity coefficient equations for systems containing up to five components.

An excellent review on nonideal distillation, including a discussion on the computation of azeotropes has recently been published in [13].

### Global Optimization Approach

In order to find all azeotropes, one must find all solutions to the system of nonlinear equations constituted by (2), (3), and (4). The method proposed in [6] reformulates the problem of enclosing all solutions of nonlinear systems of constrained equations into a global optimization problem in which the task is to enclose all global minimum solutions. In this approach, each nonlinear equality is replaced by two inequalities and a single slack variable is introduced. For the location of all homogeneous azeotropes, this corresponds to employing equations (2), (3), and (4) and reformulating them as the following global optimization problem:

$$\left\{ \begin{array}{l} \min_{\mathbf{x}, T, s} \quad s \\ \text{s.t.} \quad \ln P - \ln P_i^{\text{sat}} - \ln \gamma_i - s \leq 0, \quad \forall i, \\ \quad \quad -\ln P + \ln P_i^{\text{sat}} + \ln \gamma_i - s \leq 0, \quad \forall i, \\ \quad \quad \sum_{i \in N} x_i = 1, \\ \quad \quad 0 < \mathbf{x} < 1, \\ \quad \quad s \geq 0. \end{array} \right. \quad (5)$$

Problem (5) may have multiple global minima. Each global minimum of Problem (5) (where the solution  $s^* = 0$ ) corresponds to an homogeneous azeotrope since when  $s = 0$  the constraints (2), (3), and (4) are satisfied. Note that the first two sets of constraints of (5) correspond to the nonlinear equations (2) of the equilibrium constraint written as two inequalities. In addition, note that the nonlinear term  $P_i^{\text{sat}} \gamma_i x_i$  appears as both a positive and a negative term. Thus, this term must be nonconvex in at least one of the two constraints. This means that if a local optimization approach is used to solve Problem (5), some or all of the global solutions may be missed.

For azeotropes in which less than  $N$  of the components participate (a  $k$ -ary azeotrope where  $k \leq N$ ), the case where  $x_i = 0$  for one or more component must be accounted for. This can be done by multiplying the equilibrium constraints used in (5) by  $x_i$ . The general search for all  $k$ -ary homogeneous azeotropes is formulated as:

$$\left\{ \begin{array}{l} \min_{\mathbf{x}, T, s} \quad s \\ \text{s.t.} \quad x_i(\ln P - \ln P_i^{\text{sat}} - \ln \gamma_i) - s \leq 0, \\ \quad \quad \forall i \in N, \\ \quad \quad x_i(-\ln P + \ln P_i^{\text{sat}} + \ln \gamma_i) - s \leq 0, \\ \quad \quad \forall i \in N, \\ \quad \quad \sum_{i \in N} x_i = 1, \\ \quad \quad 0 \leq \mathbf{x} \leq 1, \\ \quad \quad s \geq 0. \end{array} \right. \quad (6)$$

- 0 Start with an initial guess for a solution (this does not affect the convergence of the algorithm).
- 1 Determine if the current solution satisfies the original nonlinear system of equation. IF it does, THEN store the solution, it corresponds to an azeotrope.
- 2 Is the current region smaller than the minimum size tolerance? IF it is, THEN fathom the region.
- 3 Partition the region into two subdomains.
- 4 Solve a lower bounding problem in each subdomain. IF the solution is greater than zero, THEN fathom the region. ELSE the solution is stored in the list of lower bounding solutions.
- 5 Choose among the active regions the one with the minimum lower bounding solution and update the current solution point. Return to Step 1. IF there are no regions remaining, THEN terminate.

### Global optimization procedure

In [7], the authors have applied a global optimization approach to enclose all of the solutions to Problems (5) and (6). In this approach, each nonconvex term

is identified, and replaced by a convex underestimator. The solution of the convexified problem is then a lower bound on the solution to the original nonconvex problem. A *branch and bound* procedure is used to improve the lower bound. Regions that cannot contain an azeotrope have a positive lower bound and can be fathomed. Regions whose lower bound is less than or equal to zero are refined further until all of the azeotropes have been located. [7] have analyzed the Wilson, NRTL, UNIQUAC, and UNIFAC equations and have developed tight convex underestimators for all of the nonconvex terms for these thermodynamic functions.

*Example 1* In this quaternary system (methanol, benzene, i-propanol, n-propanol) three binary azeotropes have been reported in the literature, as shown in Table 1. No experimental data was found for the ternary and quaternary systems.

Using the global optimization approach of [7], both the Wilson and NRTL equations predicted only the three reported azeotropes. The results for the Wilson equation are very close to the reported compositions and temperatures of the azeotropes. The results for the NRTL equation are also close to the reported values, with the exception of the Methanol-Benzene azeotrope.

### Homotopy Continuation Approach

The method proposed in [4] is based on tracking branches of solutions to nonlinear systems of equations that are perturbed from the original system. The key idea is to start with an equilibrium surface, on which all of the solutions are known a priori. The postulation is that every solution is connected to one of the branches of the initial surface. This surface is then gradually deformed, and the solution branches are tracked, ending with the actual nonideal equilibrium surface.

If the original equilibrium condition, (2), is rearranged so that the vapor mole fraction,  $y_i$ , is represented as a function of  $x_i$ , we obtain an equation of the form

$$y_i = \frac{\gamma_i^L P_i^{\text{sat}}}{P} x_i .$$

The ideal system can be represented by *Raoult's law*:

$$y_i^{\text{id}} = \frac{P_i^{\text{sat}}}{P} x_i .$$

2 – 4	–	0.776	–	0.224	77.131

One of the most convenient ways to represent the gradual deformation of the equilibrium surface is to use the linear convex combination of the ideal and nonideal equilibrium surfaces, where the homotopy parameter,  $t$ , determines the degree of deformation.

$$\tilde{y}_i = [(1 - t) + t\gamma_i^L] \frac{P_i^{\text{sat}}}{P} x_i .$$

The problem now is to find the roots of

$$\mathbf{h}(\mathbf{x}, t) = 0 , \quad (7)$$

where

$$\mathbf{h}(\mathbf{x}, t) = \tilde{\mathbf{y}} - \mathbf{x} .$$

In [4], the authors use a *homotopy continuation* method to find the roots of (7). At  $t = 0$ , the pure components are used at the initial solutions to the ideal equilibrium equation. The homotopy parameter is then increased by a small amount and the solution branches are tracked. At each step, the determinant of  $\mathbf{h}_x$  is calculated, where

$$\mathbf{h}_x = \left[ \frac{\partial h_i}{\partial x_j} \right]$$

$$i = 1, \dots, N - 1, \quad j = 1, \dots, N - 1 .$$

**Nonlinear Systems of Equations: Application to the Enclosure of All Azeotropes, Table 2**  
**Solution for acetone (1) – chloroform (2) – methanol (3)**

Azeo	$x_1$	$x_2$	$x_3$	$T$ (deg C)
experimental data from [5]				
1 – 2	0.360	0.640	–	64.50
1 – 3	0.800	–	0.200	55.70
2 – 3	–	0.653	0.347	53.35
1 – 2 – 3	0.318	0.241	0.441	57.67
Wilson equation				
1 – 2	0.3437	0.6563	–	65.47
1 – 3	0.7944	–	0.2056	55.34
2 – 3	–	0.6481	0.3519	53.91
1 – 2 – 3	0.3234	0.2236	0.4530	57.58

If  $\det[\mathbf{h}_x] = 0$ , then a bifurcation may occur, and an additional solution branch is started, which corresponds to an azeotrope.

[4] applied this method to a range of well-understood systems using the Wilson activity coefficient equation. Even though the homotopy continuation approach does not offer theoretical guarantee of locating all azeotropes, [4] observed that the method predicted all of the azeotropes that have been verified experimentally for these systems.

*Example 2 [4] examined the ternary system of acetone, chloroform, and methanol* They found that their homotopy continuation approach predicted all three binary azeotropes that are reported in the literature, using the Wilson equation. Their results are shown in Table 2.

**Heterogeneous Azeotropes**

Azeotropy is not limited to systems with a single liquid phase. In the more general case, where multiple liquid phases exist in equilibrium, a liquid mixture that boils at a constant temperature is called a heterogeneous azeotrope. Heterogeneous azeotropes can be of two different types. Type I heterogeneous azeotropes occur when the overall liquid composition is identical to the vapor composition. Conversely, Type II heterogeneous azeotropes occur when the overall liquid composition is not equal to the vapor composition. Type II heterogeneous azeotropes are possible theoretically, but have never been verified experimentally.

The phase equilibrium condition for a heterogeneous azeotrope in a system with  $M$  liquid phases is written:

$$\mu_i^V = \mu_i^{L_j}, \quad \forall i \in N, \forall j \in M.$$

When the definitions of the chemical potentials are applied and simplifications are made, the expression becomes,

$$\frac{y_i}{x_i^j} = \frac{\gamma_i^{L_j} P_i^{\text{sat}}}{P}.$$

In Type I heterogeneous azeotropes, the overall composition of the liquid is equal to the composition of the vapor,

$$y_i = \sum_{j=1}^M \psi^j x_i^j, \quad \forall i \in N,$$

where  $\psi^j$  is the mole fraction of liquid phase  $j$  in the liquid mixture. The additional constraints are:

$$\begin{aligned} \sum_{i=1}^N y_i &= 1, \\ \sum_{i=1}^N x_i^j &= 1, \quad \forall j \in M, \\ \sum_{j=1}^M \psi^j &= 1, \end{aligned}$$

An extension of the homotopy continuation method for homogeneous azeotropes of [4] was developed by [3] in order to examine the problem of finding all Type I heterogeneous azeotropes.

**Reactive Azeotropes**

Azeotropic behavior can also occur in reacting mixtures, [11]. The authors derived necessary and sufficient conditions for reactive azeotropes. These are:

$$Y_i - X_i = 0, \quad i = 1, \dots, N - 1,$$

where

$$\begin{aligned} X_i &= \frac{v_k x_i - v_i x_k}{v_k - v_T x_k}, \\ Y_i &= \frac{v_k y_i - v_i y_k}{v_k - v_T y_k}, \end{aligned}$$

where  $v_i$  is the vector of reaction stoichiometric coefficients for component  $i$ , the index  $k$  refers to the reference component, and  $v_T$  is the vector of the sum of the stoichiometric coefficients for each reaction.

In addition to this requirement, the system must also be in phase equilibrium, and in chemical equilibrium. The chemical equilibrium expression for each reaction  $r$  is written,

$$\left(\frac{K_{eq}^r}{K_{eq}^r + 1}\right) \prod_{i \in \text{react}} (x_i \gamma_i)^{|v_{\text{react}}^r|} - \left(\frac{1}{K_{eq}^r + 1}\right) \prod_{i \in \text{prod}} (x_i \gamma_i)^{|v_{\text{prod}}^r|} = 0,$$

where  $K_{eq}^r$  is the equilibrium coefficient for reaction  $r$ .

[9] have applied an arc-length continuation approach to search for all reactive azeotropes at fixed  $K_{eq}$  for systems with a single chemical reaction.

### Basic Problem Formulation

Sensitivity analysis problems typically reduce to determining the response of a vector  $x^* = (x_1^*, \dots, x_n^*)$  to changes in a scalar  $\alpha^*$ , where  $x^*$  and  $\alpha^*$  are required to satisfy an  $n$ -dimensional system of nonlinear equations of the form

$$0 = \psi(x, \alpha) \equiv (\psi^1(x, \alpha), \dots, \psi^n(x, \alpha))^T. \quad (1)$$

This problem formulation, with a scalar parameter  $\alpha$ , is more general than it might first appear. For example, suppose an analyst wishes to investigate the surface of function values  $x = f(z)$  taken on by some function  $f: \mathbf{R}^m \rightarrow \mathbf{R}^n$  as  $z$  ranges over a specified region  $Z$  in  $\mathbf{R}^m$ . One approach is to consider a suitably smooth curve  $s: [0, 1] \rightarrow Z$  which roughly fills this region, of the form  $z = s(\alpha)$ , and to define a new function of the form  $\psi(x, \alpha) \equiv x - f(s(\alpha))$ . Solving the system of equations  $\psi(x, \alpha) = 0$  for  $x$  as a function of  $\alpha$  as  $\alpha$  ranges from 0 to 1 then yields a curve of points  $x(\alpha)$  on the function surface which gives some idea of the shape of this surface over the region  $Z$ .

Assuming  $\psi: \mathbf{R}^{n+1} \rightarrow \mathbf{R}^n$  is twice continuously differentiable and has a nonsingular Jacobian matrix  $\psi_x(x^*, \alpha^*)$ , the implicit function theorem guarantees the existence of a continuously differentiable function  $x(\alpha)$  taking some neighborhood  $N(\alpha^*)$  of  $\alpha^*$  into  $\mathbf{R}^n$  such that

$$0 = \psi(x(\alpha), \alpha), \quad \alpha \in N(\alpha^*), \tag{2}$$

with  $x(\alpha^*) = x^*$ . From (2) one obtains the fundamental equation for sensitivity analysis,

$$\frac{dx(\alpha)}{d\alpha} = -\psi_x(x(\alpha), \alpha)^{-1} \psi_\alpha(x(\alpha), \alpha), \tag{3}$$

$$\alpha \in N(\alpha^*).$$

As it stands, (3) is an analytically incomplete system of ordinary differential equations. That is, a closed form representation for the Jacobian inverse  $J(\alpha)^{-1} \equiv \psi_x(x(\alpha), \alpha)^{-1}$  as a function of  $\alpha$  is often not obtainable for  $n \geq 3$ . Thus, the integration of (3) from initial conditions would typically require the supplementary algebraic determination of the Jacobian inverse  $J(\alpha)^{-1}$  at each step in the integration process.

Why not simply incorporate a linear equation solver to accomplish the needed matrix inversions? Two reasons can be given. First, the Jacobian matrix might have one or more eigenvalues which are small in absolute value. Consequently, as can be seen using a singular value decomposition, the inverse matrix can be highly ill-conditioned in the sense that its elements have large absolute values and take on both positive and negative values. In this case, small roundoff and truncation errors can cause large errors in the resulting numerically determined component values of the sensitivity vector

$dx(\alpha)/d\alpha$ . Second, there exists an alternative approach [14] that has proven its reliability and efficiency in numerous contexts over the past twenty years: replace the algebraic operation of matrix inversion by an initial value problem highly suited for modern digital computers.

The latter approach is taken in [10]. The differential system (3) is extended by the incorporation of ordinary differential equations for the Jacobian inverse. More precisely, letting  $A(\alpha)$  and  $\delta(\alpha)$  denote the adjoint and the determinant of the Jacobian matrix  $J(\alpha)$ , and recalling that the inverse of any nonsingular matrix can be represented as the ratio of its adjoint to its determinant, the following differential system is validated for  $x(\alpha)$ ,  $A(\alpha)$ , and  $\delta(\alpha)$ :

$$\frac{dx(\alpha)}{d\alpha} = -A(\alpha) \frac{\psi_\alpha(x(\alpha), \alpha)}{\delta(\alpha)}; \tag{4}$$

$$\frac{dA(\alpha)}{d\alpha} = \frac{A(\alpha) \text{Trace}(A(\alpha)B(\alpha)) - A(\alpha)B(\alpha)A(\alpha)}{\delta(\alpha)}; \tag{5}$$

$$\frac{d\delta(\alpha)}{d\alpha} = \text{Trace}(A(\alpha)B(\alpha)). \tag{6}$$

The  $ij$ th component of the matrix  $B(\alpha) \equiv dJ(\alpha)/d\alpha$  appearing in equations (5) and (6) is

$$\sum_{k=1}^n \left( \psi_{jk}^i(x(\alpha), \alpha) \frac{dx_k(\alpha)}{d\alpha} \right) + \psi_{j,n+1}^i(x(\alpha), \alpha), \tag{7}$$

where  $\psi_{jk}^i$  denotes the second partial of  $\psi^i$  with respect to  $x_j$  and  $x_k$ , and  $\psi_{j,n+1}^i$  denotes the second partial of  $\psi^i$  with respect to  $x_j$  and  $\alpha$ . Given (4), note that each of the components (7) is expressible as a known function of  $x(\alpha)$ ,  $A(\alpha)$ ,  $\delta(\alpha)$ , and  $\alpha$ . Initial conditions for equations (4)–(6) must be provided at a parameter point  $\alpha^*$  by specifying values for  $x(\alpha^*)$ ,  $A(\alpha^*)$  satisfying  $0 = \psi(x(\alpha^*), \alpha^*)$ ,  $A(\alpha^*) = \text{Adj}(J(\alpha^*))$ , and  $\delta(\alpha^*) = \text{Det}(J(\alpha^*)) \neq 0$ .

In summary, the system of equations (4)–(6) provides an analytically complete system of ordinary differential equations for the *nonlocal sensitivity analysis* of the original system of interest,  $0 = \psi(x, \alpha)$ . That is, it permits the *tracking* of the solution vector  $x(\alpha)$  and the sensitivity vector  $dx(\alpha)/d\alpha$ , together with the adjoint  $A(\alpha)$  and the determinant  $\delta(\alpha)$  of the Jacobian matrix  $J(\alpha)$ , over any  $\alpha$ -interval  $[\alpha^*, \alpha^{**}]$  where the determinant remains nonzero.

### Fully Automated Implementation

The complete differential system (4)–(6) was initially implemented in [10] by means of a Fortran program incorporating a fourth-order Adams–Moulton integration method with a Runge–Kutta start and hand-coded partial derivatives. High numerical accuracy was obtained in illustrative applications, even near critical points  $\alpha$  where the determinant  $\delta(\alpha)$  became zero. Nevertheless, hand-coding of partial derivatives was clearly an undesirable feature of the program. The partial derivative expressions in (7) involve the second order partial derivatives of  $\psi(\cdot)$ ; and  $\psi(\cdot)$  in turn could involve the partial derivatives of some still more basic function, such as the criterion function for an optimization problem. This is indeed the typical case for economic problems (e. g., the profit maximization problem handled in [10]), since such problems invariably incorporate the decision-making processes of various types of economic agents.

In consequence, a more fully *automated Fortran program for nonlocal sensitivity analysis* was eventually developed in [11]. This program is referred to as *Nasa* (an acronym for Nonlocal Automated Sensitivity Analysis); it is available for downloading as free-ware from the Web site <http://www.econ.iastate.edu/tesfatsi/>. *Nasa* incorporates a fairly substantial library for the forward-mode automatic evaluation of partial derivatives through order three [13] as well as an adaptive homotopy method [12] for automatically obtaining all required initial conditions. The following sections briefly describe these features. A recent example of how *Nasa* has been applied to an applied general equilibrium problem in economics is detailed in [2].

### Incorporation of Automatic Differentiation

Four basic approaches (see Jerrell [8] for an interesting comparative discussion of these four alternative approaches) can be used to obtain computer-generated numerical values for derivatives: hand-coding; numerical differentiation; symbolic differentiation; and automatic derivative evaluation, or *automatic differentiation* for short. Recently, *computational differentiation* has come to be the preferred term for automatic differentiation; see [1]. To avoid confusion, the more traditional term is used here. Numerical differentia-

tion methods substitute discrete approximate forms for derivative expressions. For example, finite difference methods involve the approximation of derivatives by ratios of discrete increments; e. g.,  $f'(t) \approx [f(t+h) - f(t)]/h$  for some suitably small  $h$ . Symbolic differentiation methods generate exact symbolic expressions for derivatives that can be manipulated algebraically as well as evaluated numerically. In contrast, automatic differentiation methods do not generate explicit derivative expressions, either approximate or symbolic. Rather, these methods focus on the generation of derivative evaluations by breaking down the evaluation of a derivative at a given point into a sequence of simpler evaluations for functions of at most one or two variables. These evaluations are exact up to roundoff and truncation error.

For the nonlocal sensitivity analysis problem outlined above, the primary requirement is for partial derivative evaluations through order three to be obtained in a reliable and efficient manner. The use of numerical differentiation methods such as finite difference introduces systematic approximation errors into applications that can be reduced but not eliminated entirely due to the risk of catastrophic floating point error. Symbolic differentiation software packages such as *Macsyma*, *Mathematica*, and *Maple* produce analytical expressions for derivatives but are notorious for ‘expression swell’, that is, for the great many lines of code they produce for the derivative expressions of even relatively simple functional forms despite repeated use of reduction routines; see [5] for explicit examples (note that automatic differentiation has now been introduced into *Maple*, see [6]). Thus, an automatic derivative evaluation routine would seem to be the preferred alternative for the application at hand.

Automatic differentiation appears to have been independently developed by R.E. Moore [16] and R. Wengert [20]. The key idea of Moore and Wengert was to decompose the evaluation of complicated functions of many variables into a sequence of simpler evaluations of special functions of one or two variables, referred to below as a ‘function list’. Total differentials of the special functions could be automatically evaluated along with the special function values, and partial derivatives could then be recovered from the total differentials by solving certain associated sets of linear algebraic equations.

**Nonlocal Sensitivity Analysis with Automatic Differentiation, Table 1**  
**Illustrative application of the Feed algorithm**

Function List	$\partial/\partial x$	$\partial/\partial y$	$\partial^2/\partial x^2$	$\partial^3/\partial x^3$
$a = x$	1	0	0	0
$b = y$	0	1	0	0
$c = ab$	$a_x b + ab_x$	$a_y b + ab_y$	$a_{xx} b + 2a_x b_x + ab_{xx}$	$a_{xxx} b + 3a_{xx} b_x + 3a_x b_{xx} + ab_{xxx}$
$d = \log(c)$	$c^{-1} c_x$	$c^{-1} c_y$	$-c^{-2} c_x^2 + c^{-1} c_{xx}$	$2c^{-3} c_x^3 - 3c^{-2} c_x c_{xx} + c^{-1} c_{xxx}$
$z = a + d$	$a_x + d_x$	$a_y + d_y$	$a_{xx} + d_{xx}$	$a_{xxx} + d_{xxx}$

As detailed in [1] and [4], great strides have been made over the past thirty years in developing fast and reliable automatic differentiation algorithms. The Nasa program incorporates one such algorithm, originally developed in [13], that is now referred to as *Feed* (an acronym for Fast Efficient Evaluation of Derivatives). A detailed discussion of the use of this automatic differentiation algorithm for both optimization and sensitivity analysis can be found in [9]. Total differentials are replaced by derivative arrays in order to avoid repeated function evaluations and the need to recover partial derivatives from total differentials for each successively higher-order level of differentiation.

As a simple illustration of Feed, consider the function  $F: \mathbb{R}_{++}^2 \rightarrow \mathbb{R}$  defined by

$$z = F(x, y) \equiv x + \log(xy). \tag{8}$$

Suppose one wishes to evaluate the function value  $z$  and the partial derivatives  $z_x, z_y, z_{xx}$  and  $z_{xxx}$  at a given domain point  $(x, y)$ . Consider Table 1.

The first column of Table 1 constitutes the function list for the function (8); it sequentially evaluates the function value  $z = x + \log(xy)$  at the given domain point  $(x, y)$ . The remaining entries in each row give the indicated derivative evaluations of the first entry in the row, using only algebraic operations. The first two rows initialize the algorithm, one row being required for each independent variable. The only input required for the first two rows is the domain point  $(x, y)$ . Each subsequent row outputs a one-dimensional array of the form  $(p, p_x, p_y, p_{xx}, p_{xxx})$ , using the arrays obtained from previous row calculations as inputs. The final row yields the desired evaluations  $(z, z_x, z_y, z_{xx}, z_{xxx})$ . Note that the limitation to this collection of partial derivative evaluations is for expositional simplicity only. The evaluation of any additional desired partial derivative of  $z$ , say  $z_{xyy}$

or  $z_{xxx}$ , can be obtained in a similar manner by suitably augmenting Table 1 with an additional column of algebraic operations.

The elements in each of the rows in Table 1 can be numerically evaluated by means of sequential calls to Feed calculus subroutines. These evaluations are exact up to roundoff and truncation error. For expositional simplicity, Table 1 only depicts evaluations for partial derivatives through order three. However, Feed calculus subroutines can in principle be constructed to evaluate the function value and the distinct partial derivatives through order  $k$  of any real-valued multivariable function that can be sequentially evaluated in a finite number of steps by means of the two-variable functions

$$\begin{aligned} w &= u + v, & w &= u - v, & w &= uv, \\ w &= \frac{u}{v}, & w &= u^v \end{aligned} \tag{9}$$

and arbitrary nonlinear one-variable  $k$ th-order differentiable functions such as

$$\begin{aligned} \cos(u), \quad \sin(u), \quad \exp(u), \quad c^u, \\ \log(u), \quad au^b + c, \end{aligned} \tag{10}$$

for arbitrary constants  $a, b$ , and  $c$ . Systematic rules for constructing general  $k$ th-order calculus subroutines for special functions such as (10) are derived in [13]. References to other work focusing on recurrence relations for the derivatives of special functions such as (10) can be found, for example, in [15]. A detailed discussion of the library of Feed calculus subroutines currently incorporated into Nasa is given in [11].

The Feed algorithm thus envisions the successive transformation of arrays of partial derivatives through any specified order  $k$  into similarly-configured arrays as one forward sweep is taken through the function list for a specified  $k$ th-order differentiable function. A similar approach is proposed in [15] and [18, p. 280]. In

contrast, the partial derivative evaluation methods proposed in [17, Chapter VI, pp. 91–111] and [21] have a tree structure; that is, gradient operations are used to generate evaluations for each successively higher-order collection of partial derivatives using the results of previous gradient operations as inputs. Another approach that has attracted a great deal of interest is reverse-mode differentiation; see [3] and [7].

### Automatic Initialization via Adaptive Homotopy Continuation

The initial conditions needed to integrate the complete differential system (4)–(6) from a given initial parameter point  $\alpha^*$  consist of a solution vector  $x(\alpha^*)$  together with evaluations for the adjoint  $A(\alpha^*)$  and determinant  $\delta(\alpha^*)$  of the Jacobian matrix  $\psi_x(x(\alpha^*), \alpha^*)$ . For many nonlinear problems, finding an initial solution vector is a difficult matter in and of itself.

Nasa incorporates an adaptive homotopy method [12] for automating these needed initializations. A standard (linear) homotopy method applied to the problem of finding a solution  $x^*$  for a system of equations  $0 = F(x)$  proceeds by introducing a homotopy of the form

$$0 = tF(x) + [1 - t][x - c] \quad (11)$$

and solving for  $x$  as a function of  $t$  as  $t$  varies from 0 to 1 along the real line, where  $c$  represents any initial guess for the solution vector  $x^*$ . In contrast, an *adaptive homotopy* is a homotopy for which the usual continuation parameter  $t$  varying from 0 to 1 on the real line is replaced by an adaptive continuation ‘agent’ that makes its way by trial and error from  $0 + 0i$  to  $1 + 0i$  in the complex plane in accordance with certain stated objectives.

Specifically, the continuation agent designed in [12] adaptively selects a path of  $\beta$  values from  $0 + 0i$  to  $1 + 0i$  in the complex plane for the homotopy

$$0 = [F(x) - F(c)] + \beta F(c), \quad (12)$$

where  $c$  again represents any initial guess for the solution vector  $x^*$ . The path for  $\beta$  is selected in accordance with the following multiple objective optimization problem: Reach the point  $1 + 0i$  starting from the point  $0 + 0i$  by taking as few steps as possible along a spider-web (spoke/hub) grid centered at  $1 + 0i$  in the

complex plane, but do so in a way that avoids regions where the Jacobian matrix becomes ill-conditioned.

The adaptive homotopy method introduced in [12] and incorporated into Nasa is thus an example of what might more generally be called an *adaptive computational method*, i. e., a computational method that embodies the following principle important for applied researchers: Let the computational algorithm adapt to the physical problem at hand instead of requiring users to reformulate their physical problems to conform to algorithmic requirements. For sufficiently smooth functions  $F(\cdot)$ , a properly constructed homotopy (e. g., a probability one homotopy as formulated in [19]) is theoretically guaranteed to have no singular points along the real continuation path from 0 to 1 for almost all initial starting points  $c$ . However, successful implementation of such homotopy methods can require a mathematically sophisticated reformulation of the user’s original problem.

The homotopy (12) is solved for  $x$  as a function of  $\beta$  as  $\beta$  varies from  $0 + 0i$  to  $1 + 0i$  in the complex plane by making use of a complete system of ordinary differential equations analogous to the system set out in the basic problem formulation above. At each  $\beta$  point one obtains a solution vector  $x^*(\beta)$  together with evaluations  $A^*(\beta)$  and  $\delta^*(\beta)$  for the adjoint and determinant of the homotopy Jacobian matrix  $J^*(\beta) = F_x(x^*(\beta))$ . Note that the homotopy Jacobian matrix coincides with the Jacobian matrix for the original function of interest  $F(\cdot)$ , implying that singularities are not artificially induced into the problem by the homotopy method per se. In principle, the solution vector  $x^*(1 + 0i)$  obtained for (12) at  $\beta = 1 + 0i$  yields a solution vector for the original system of interest,  $0 = F(x)$ . In particular, letting  $F(x) \equiv \psi(x, \alpha^*)$ , one obtains complete initial conditions for the original problem of interest, the nonlocal sensitivity analysis of the system  $0 = \psi(x, \alpha)$  over an interval of  $\alpha$  values starting at  $\alpha^*$ .

### Keywords

Network; Multicommodity flow; Decomposition algorithms

The routing of traffic requirements is one of the important problems that have to be solved when designing a telecommunication network. Another important

problem is the computation of standby capacities that must be set up to enable the rerouting of the traffic requirements affected by any network failure of some given types. Both problems can be formulated as nonoriented multicommodity network flow models sometimes also called *undirected multicommodity network flow models*. The routing problem captures the main aspects of such models and is therefore considered in more details hereafter. The reader interested in the computation of standby capacities is referred to [11,12].

A transmission network can be viewed as an undirected graph. An edge (i. e. a link of the network) is characterized by a pair of nodes, a transmission cost per circuit and a transmission capacity in the number of circuits. The *routing problem* is the determination of the most economical way of using the available transmission capacities to route a traffic matrix (a number of circuits between various pairs of nodes) through the network. This problem can be expressed as follows:

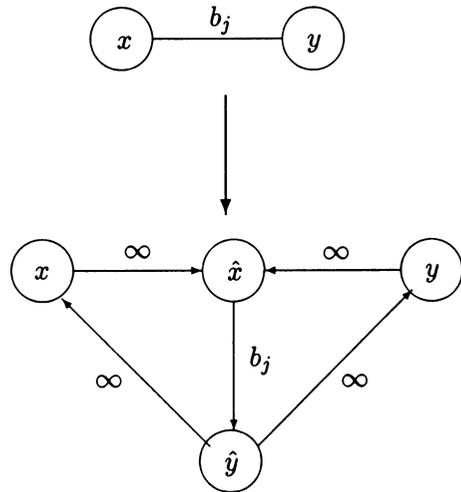

$$\begin{cases} \min & \sum_{k,j} c_j^k |x_j^k| \\ \text{s.t.} & Ax^k = r^k, \quad k \in K, \\ & \sum_k |x_j^k| \leq b_j, \quad j \in J, \end{cases}$$

where:

- $A$  is the node-arc incidence matrix corresponding to an arbitrary orientation of the network graph (i. e.  $A_{ij} = +1$  if arc  $j$  is directed away from node  $i$ ,  $A_{ij} = -1$  if arc  $j$  is directed towards node  $i$ ,  $A_{ij} = 0$  otherwise);
- $J = \{1, \dots, \bar{J}\}$  is the set of arcs of the network;
- $k$  is a commodity characterized by a number of circuits,  $d^k$ , to be routed through the network between a given pair of nodes,  $s^k$  and  $t^k$ ;
- $K = \{1, \dots, \bar{K}\}$  is the set of commodities to be routed;
- $r^k$  is the requirement vector for commodity  $k$  (i. e.  $r_{s^k}^k = d^k$ ,  $r_{t^k}^k = -d^k$  and  $r_l^k = 0$  when  $l \notin \{s^k, t^k\}$ );
- $x^k$  is the flow vector for a given commodity  $k$  (i. e.  $x_j^k$  is the flow on arc  $j = (s, t)$  with  $x_j^k > 0$  if the flow goes from  $s$  to  $t$  and  $x_j^k < 0$  if the flow goes from  $t$  to  $s$ );
- $b_j$  is the capacity of link  $j$ ;
- $c_j^k$  is the cost per unit of flow on link  $j$  for commodity  $k$ .

The first group of constraints contains one block of constraints per commodity. These so-called *flow constraints* specify that  $x$  is a routing of the traffic requirements. The second group of constraints ties together the various commodities. These *coupling constraints* specify that only a limited number of circuits can be routed through any given edge of the network. The above formulation is called a *node-arc formulation of the problem*.

If we assume that cost coefficient  $c_j^k$  are non negative, this nonlinear problem can be replaced with an equivalent standard (linear) multicommodity flow problem by using the transformation of the network graph depicted in the following figure where the figures over edges and arcs denote capacities.

The structure of the resulting model is similar to that of the original model except that absolute values are removed and nonnegativity restrictions on the flow variables are introduced. The transformation is justified by the fact that the support of the flow associated with any given commodity does not contain any directed cycle in the optimal solution of the transformed problem. The transformed model could be solved by any code designed for the solution of directed multicommodity flow problems. However, as this model is much larger than the original nonlinear model a better approach has to be devised when a computationally efficient solution method is sought for. Assuming that  $c_j^k > 0$ , one can introduce nonnegative variables,  $x_j^{k+}$  and  $x_j^{k-}$ , such that  $x_j^k = x_j^{k+} - x_j^{k-}$  and  $|x_j^k| = x_j^{k+} + x_j^{k-}$  to obtain an equiv-

alent linear formulation [11]:

$$\left\{ \begin{array}{l} \min \sum_{k,j} c_j^k (x_j^{k+} + x_j^{k-}) \\ \text{s.t. } A(x^{k+} - x^{k-}) = r^k, \quad \forall k, \\ \sum_k (x_j^{k+} + x_j^{k-}) \leq b_j, \quad \forall j \in J, \\ x_j^{k+} \geq 0, \quad \forall k \in K, \quad \forall j \in J, \\ x_j^{k-} \geq 0, \quad \forall k \in K, \quad \forall j \in J. \end{array} \right.$$

For real networks such as the Paris district transmission network, the number of nodes,  $\bar{I}$ , can be larger than 100 and the number of links larger than 300. If one assumes that there can be a traffic requirement between any pair of nodes, the size of the problem can be larger than approximately  $M \approx 5 \times 10^5$  constraints and  $N \approx 3 \times 10^6$  variables, since  $\bar{K} = \bar{I}(\bar{I} - 1)/2$  in this case. However, the formulation can be often simplified and an equivalent smaller problem solved. In fact, when the cost per unit of flow on a given link does not depend on the commodity (i. e.  $c_j^k = c_j^l$  for any  $k$ ) all the commodities which have a common endpoint can be ‘merged’. More precisely, consider a particular node,  $i$ , and the set,  $K_i$ , of commodities,  $k$ , such that  $s_k = i$  or  $t_k = i$ . As the orientation of the commodities is arbitrary the commodities in  $K_i$  can be replaced with a single commodity characterized by a requirement vector,  $r$ , of components,  $r_i = \sum_{k \in K_i} d_k$ ,  $r_j = -d^k$  for all  $j \in \cup_{k \in K_i} \{s_k, t_k\} - \{i\}$  and  $r_j = 0$  for all  $j \notin \cup_{k \in K_i} \{s_k, t_k\}$ . A merging of commodities that minimizes the number of merged commodities can be found by solving a minimum node cover problem in a nondirected graph (cf. **► Network location: Covering problems**) where the vertices correspond to the endpoints of the commodities and the edges correspond to the commodities. In practice a satisfactory solution to this problem can be obtained by a greedy algorithm where at each iteration the node that covers the larger number of edges not yet covered is selected. In any case, the problem reduces to a number of commodities not larger than  $\bar{I}$ . Assuming that  $\bar{K} = \bar{I}$ , one obtains  $M \approx 10,000$  constraints and  $N \approx 60,000$  variables. This size of problem is within the reach of modern general purpose linear programming codes. However, if extra constraints were to be included in the initial formulation the merging of the commodities might not be any longer possible. For example, this would be the case if quality of service constraints were introduced to impose

that no more than  $p$  percent of any traffic requirement is routed on any link. Constraints of the form  $x_j^{k+} + x_j^{k-} \leq p d_k / 100$  would have to be added to the above formulation. The size of this new model would be huge.

Fortunately, specialized algorithms that exploit both the block structure of the problem and the structure of each block of flow constraints can be designed to provide efficient solution methods. A primal partitioning simplex algorithm specialization is presented in [3]. Specializations based on price-directive decomposition (cf. **► Branch and price: Integer programming with column generation**), resource-directive decomposition and partitioning of linear systems (simplex and dual affine scaling algorithm) are reviewed in [5]. Technical details on specializations as well as comparative experiments are presented in [4].

It is worth giving more details on one of the most attractive specialization method obtained by applying the Dantzig–Wolfe decomposition principle to the above formulation. The advantage of this specialization is threefold. First, it leads to a reformulation of the problem that appeals to network planners (as the concept of routing path is more directly part of the model) and is easily understood without any references to the Dantzig–Wolfe decomposition principle. Secondly, it can be easily implemented using modern linear programming libraries. Thirdly, and more importantly it is computationally efficient for real-life instances that are usually weakly constrained (no more than 10% edges saturated at optimality) (see [4]).

By applying the Dantzig–Wolfe decomposition principle it can be shown that the routing problem can be reformulated as follows [5]:

$$\left\{ \begin{array}{l} \min \sum_{k,l} [c^k]^T v_l^k \alpha_l^k \\ \text{s.t. } \sum_l \alpha_l^k = d^k, \quad k \in K, \\ \sum_{k,l} \alpha_l^k v_l^k \leq (b_1, \dots, b_{\bar{J}})^T, \\ \alpha_l^k \geq 0, \quad k \in K. \end{array} \right.$$

$v_l^k$  is the characteristic vector of a path,  $p_l^k$ , that connects  $s_k$  to  $t_k$  in the undirected network graph, i. e. the components  $j$  of  $v_l^k$  is 1 if link  $j$  belongs to  $p_l^k$  and is 0 otherwise.  $[c^k]^T v_l^k$  is the cost of  $p_l^k$  per unit of flow routed on that path (i. e. the sum of the costs  $c_j^k$  of its links) and

$\alpha_i^k$  is the amount of traffic routed on path  $p_i^k$ . The first set of constraints expresses that  $d_k$  units of traffic have to be routed between  $s_k$  and  $t_k$  whereas the second set of constraints expresses the limitation on the capacity available on the links to route the traffic. The formulation above is known as the *node-path formulation* of the multicommodity flow problem.

This formulation has an exponential number of columns but it is not necessary to express all the columns of this linear program. Indeed, the reduced cost of variable  $\alpha_i^k$  is  $w_i^k = [c^k + \lambda]^T v_i^k - \pi_k$ , where  $-\lambda$  is the vector of simplex multipliers associated with the capacity constraints and  $\pi_k$  is the vector of simplex multipliers associated with the constraint corresponding to commodity  $k$  in the first group of constraints. Therefore  $\min_i w_i^k$  can be obtained by computing a shortest path between  $s_k$  and  $t_k$  in the undirected network graph where the edge lengths are given by the vector  $c^k + \lambda$ .

In the decomposition algorithm the formulation given above is called the (*full*) *master program*. The  $\bar{K}$  shortest path problems which are solved to generate columns of the master program are called the *satellite problems*. At each stage of the algorithm a *reduced master program*, i. e. a program that contains a subset of the columns of the master program, is solved. The first reduced master program is initialized with a set of columns corresponding to a basic matrix and the columns corresponding to the slack variables. If no such initial set of columns is available, artificial variables are added to the formulation and a first phase or a big- $M$  method have to be used to drive the program to a feasible basis. After solving a reduced master program to optimality, the  $\bar{K}$  satellite problems are solved to check whether the solution obtained is optimal for the full master program. If the reduced costs corresponding to the solution of the satellite problems are nonnegative the solution to the reduced master program is an optimal solution to the full master program, otherwise the master program is increased with the new columns candidate for basis entry and the simplex algorithm goes on. After the solution of a reduced master program the reduced cost of all variables in that program are nonnegative. Hence, as  $\lambda$  is the reduced cost vector associated with the slack variables of the coupling constraints we deduce that  $\lambda \geq 0$  and that in turn the edge lengths in the satellite problems are nonnega-

tive. The satellite problems can therefore be solved using the Dijkstra algorithm (see [9] and [13] for details of efficient implementations).

The solution of each master program can be made more efficient by using a refinement of the GUB specialization of the simplex algorithm (see [4] for details). Some variations of the algorithm may be also applied. For example, some columns generated may be discarded from the reduced master program at later stages, the generation of new columns may be carried out before optimality is reached provided that the simplex multipliers  $\lambda$  are nonnegative.

Finally it is worth mentioning that a new cutting plane technique based on interior point method and called the *analytic center cutting plane method* (AC-CPM) was recently proposed to solve large scale convex optimization problems [8]. Its application to the dual of the above formulation gives performances that are roughly similar to those of the Dantzig–Wolfe decomposition algorithm [4] but ACCPM is much more efficient for highly nonlinear problems [7].

Further details on network programming and modeling can be found in [1,2,6,10].

### Introduction

Being natural generalizations of the classical Fréchet derivative and the subdifferential in the sense of convex analysis, *Fréchet subdifferentials* have been known for more than 30 years. They were probably first introduced in finite dimensions in [1] (under the name “lower semidifferentials”). Some of their properties in the infinite-dimensional setting were investigated in [18,21]. During the first decade Fréchet subdifferentials were not widely used because of rather poor (direct) calculus. They mostly served as building blocks for more sophisticated *limiting (Fréchet) subdifferentials* [19,23,30,31].

The discovery of the “fuzzy rules” in the 1980s [11,12,15,29] revitalized interest in Fréchet subdifferentials. It was shown that calculus results and optimality conditions can be formulated in terms of Fréchet and other “simple” subdifferentials computed not at the given point, but at some points arbitrarily close to it, thus incorporating “differential” properties of the function at nearby points. Such results are actually at the core of the corresponding statements for limiting subdifferentials.

Being the smallest among all “simple” subdifferentials with reasonable properties, the Fréchet subdifferentials have proved to be convenient tools for the analysis of nondifferentiable functions on *Asplund* spaces, a very important subclass of general Banach spaces. Furthermore, the main fuzzy results in terms of Fréchet subdifferentials present characterizations of *Asplund* spaces themselves [6,12,13,34,35,38,45].

The article contains no proofs. A more detailed survey of Fréchet subdifferentials can be found in [25].

Mostly standard notations are used throughout the article.  $X$  and  $Y$  denote normed linear spaces and  $X^*$  and  $Y^*$  denote their topological duals.  $\langle \cdot, \cdot \rangle$  is a bilinear form defining a canonical pairing between a space and its dual.  $B_\rho(x)$  stands for a closed ball with center  $x$  and radius  $\rho$ . We write  $B_\rho$  instead of  $B_\rho(0)$  and just  $B$  if  $\rho = 1$  (unit ball).

**Definitions**

**Fréchet Subdifferentials**

Let  $f : X \rightarrow \mathbb{R}_\infty = \mathbb{R} \cup \{+\infty\}$ ,  $f(x) < \infty$ . The set

$$\partial f(x) = \left\{ x^* \in X^* : \liminf_{u \rightarrow x} \frac{f(u) - f(x) - \langle x^*, u - x \rangle}{\|u - x\|} \geq 0 \right\} \tag{1}$$

is called the *Fréchet subdifferential* of  $f$  at  $x$ . This set is (norm) closed and convex. The next proposition shows that it generalizes the notions of the Fréchet derivative and the subdifferential in the sense of convex analysis.

**Proposition 1**

1. If  $f$  is Fréchet-differentiable at  $x$  with the derivative  $\nabla f(x)$  then  $\partial f(x) = \{\nabla f(x)\}$ .
2. If  $f$  is convex then

$$\partial f(x) = \left\{ x^* \in X^* : f(u) - f(x) \geq \langle x^*, u - x \rangle, \forall u \in X \right\}.$$

Note that the Fréchet subdifferential does not change if another equivalent norm on  $X$  is used in (1).

*Example 1* The set (1) can be empty. Take  $f : \mathbb{R} \rightarrow \mathbb{R} : f(u) = -|u|$ ,  $u \in \mathbb{R}$ .

One can also consider the *Fréchet superdifferential*

$$\partial^+ f(x) = \left\{ x^* \in X^* : \limsup_{u \rightarrow x} \frac{f(u) - f(x) - \langle x^*, u - x \rangle}{\|u - x\|} \leq 0 \right\}. \tag{2}$$

While the set (1) consists of linear continuous functionals “supporting”  $f$  from below, the functionals from (2) “support”  $f$  from above. Unlike the classical case, the existence of two different derivative-like objects is quite natural for nonsmooth analysis: “differential” properties of a function “from below” and “from above” could be essentially different.

Subdifferentials and superdifferentials are related by the equality

$$\partial(-f)(x) = -\partial^+ f(x). \tag{3}$$

Surely, in the nondifferentiable case at least one of the sets (1) and (2) must be empty.

**Proposition 2**  $\partial f(x) \neq \emptyset$  and  $\partial^+ f(x) \neq \emptyset$  if and only if  $f$  is Fréchet-differentiable at  $x$ . In this case one has  $\partial f(x) = \partial^+ f(x) = \{\nabla f(x)\}$ .

*Example 2* Both sets (1) and (2) can be empty simultaneously. Take  $f : \mathbb{R} \rightarrow \mathbb{R} : f(u) = u \sin(1/u)$  if  $u \neq 0$ , and  $f(0) = 0$ .

*Example 3* The fact that the set (1) is a singleton does not imply differentiability. Take  $f : \mathbb{R} \rightarrow \mathbb{R} : f(u) = \max(u \sin(1/u), 0)$  if  $u \neq 0$ , and  $f(0) = 0$ . Then  $f$  is nondifferentiable at 0, although one evidently has  $\partial f(0) = \{0\}$ .

*Example 4* Fréchet differentiability is essential in Proposition 1 Gâteaux differentiable functions can be nonsubdifferentiable in the Fréchet sense. Take  $f : \mathbb{R}^2 \rightarrow \mathbb{R} : f(u_1, u_2) = -\sqrt{|u_1|^2 + |u_2|^2}$  if  $u_2 = u_1^2$ ,  $f(u_1, u_2) = 0$  otherwise. The Gâteaux derivative of  $f$  is 0, while  $\partial f(0) = \emptyset$ .

*Remark 1* One can define the *Gâteaux subdifferential* on the basis of the notion of the Gâteaux differentiability. For this subdifferential, the analogs of Propositions 1 and 2 and some other results hold true. Considering Gâteaux (and other types of) “simple” subdifferentials can be useful in some applications. The Gâteaux subdifferential always contains the Fréchet subdifferential.

If  $\dim X < \infty$  the Fréchet subdifferential can be expressed equivalently in terms of certain generalized directional derivatives [1,16,18,39,42,43].

**Fréchet Normal Cone**

Now consider a set  $\Omega \subset X$  and let  $x \in \Omega$ . Similarly to definition (1) of the Fréchet subdifferential one can define the *Fréchet normal cone*

$$N(x|\Omega) = \left\{ x^* \in X^* : \limsup_{u \xrightarrow{\Omega} x} \frac{\langle x^*, u - x \rangle}{\|u - x\|} \leq 0 \right\} \tag{4}$$

to  $\Omega$  at  $x$ . Here  $u \xrightarrow{\Omega} x$  means that  $u \rightarrow x$  with  $u \in \Omega$ .

It is a norm closed and convex cone closely related to the subdifferential defined above. It is actually the Fréchet subdifferential  $\partial \delta_\Omega(x)$  of the indicator function

$\delta_\Omega$  of  $\Omega$  ( $\delta_\Omega(u) = 0$  if  $u \in \Omega$  and  $\delta_\Omega(u) = \infty$  otherwise).

This fact allows one to deduce some properties of normal cones from the corresponding statements about subdifferentials. Thus, it follows from Proposition 1, that the normal cone (4) generalizes the corresponding notion of convex analysis.

In finite dimensions the Fréchet normal cone coincides with the polar of the *tangent (contingent, Bouligand tangent)* cone to  $\Omega$  at  $x$ . If  $X$  is reflexive it coincides with the polar of the *weak tangent* cone [1,2,9,14,43].

The relationship between Fréchet subdifferentials and normal cones is bilateral. For a function  $f : X \rightarrow \mathbb{R}_\infty$  one can consider its *epigraph*  $\text{epif} = \{(u, \mu) \in X \times \mathbb{R} : f(u) \leq \mu\}$ . If the norm on  $X \times \mathbb{R}$  is compatible with that on  $X$  (that is,  $\|(x, 0)\| = \|x\|$ ), then the following equivalent definition of the Fréchet subdifferential holds true:

$$\partial f(x) = \left\{ x^* \in X^* : (x^*, -1) \in N(x, f(x)|\text{epif}) \right\}. \tag{5}$$

“Horizontal” normals to the epigraph can also be of interest. They define the *singular Fréchet subdifferential* of  $f$  at  $x$ :

$$\partial^\infty f(x) = \left\{ x^* \in X^* : (x^*, 0) \in N(x, f(x)|\text{epif}) \right\}.$$

Of course, if  $f$  is *calm* at  $x$  [7,42], that is,  $\|f(u) - f(x)\| \leq l\|u - x\|$  for some  $l > 0$  and for all  $u$  in a neighborhood of  $x$ , then the latter set is empty.

**Strict Fréchet  $\delta$ -Subdifferentials**

As mentioned in “Introduction,” Fréchet subdifferentials have poor calculus and their direct application has been rather limited. There exists a way of enriching the properties of the subdifferentials. It consists in considering differential properties of a function at nearby points.

Consider a new derivative-like object based on the Fréchet subdifferential:

$$\hat{\partial}_\delta f(x) = \bigcup_{\substack{u \in B_\delta(x) \\ |\text{cl}f(u) - f(x)| \leq \delta}} \partial(\text{cl}f)(u). \tag{6}$$

It depends on some positive  $\delta$ .  $\text{cl}f$  denotes here the lower semicontinuous envelope of  $f$  (its epigraph is the closure of the epigraph of  $f$  in  $X \times \mathbb{R}$ ). Unlike (1) the set (6) can be nonconvex. It is called the *strict Fréchet  $\delta$ -subdifferential* of  $f$  at  $x$  [24].

The *strict Fréchet  $\delta$ -superdifferential*  $\hat{\partial}_\delta^+ f(x)$  of  $f$  at  $x$  can be defined in a similar way. The equality  $\hat{\partial}_\delta^+ f(x) = -\hat{\partial}_\delta(-f)(x)$  holds true. The strict subdifferentials and superdifferentials can be nonempty simultaneously and can be essentially different. The set  $\hat{\partial}_\delta^0 \varphi(x) = \hat{\partial}_\delta f(x) \cup \hat{\partial}_\delta^+ f(x)$  can be useful in some situations. It is called the *strict Fréchet  $\delta$ -differential* of  $f$  at  $x$ .

The *strict Fréchet  $\delta$ -normal cone* to a set  $\Omega$  at  $x \in \Omega$  is defined similarly:

$$\hat{N}_\delta(x|\Omega) = \bigcup_{u \in \text{cl}\Omega \cap B_\delta(x)} N(u|\text{cl}\Omega).$$

The goal of introducing strict Fréchet  $\delta$ -subdifferentials is mainly notational. They are convenient for formulating “fuzzy” results, but such results can certainly be formulated in terms of ordinary Fréchet subdifferentials.

**Limiting Subdifferentials**

The limiting Fréchet subdifferentials are defined as limits of “simple” ones [23,30,31,34]. To simplify the definitions we assume in this subsection that  $f : X \rightarrow \mathbb{R}_\infty$  is lower semicontinuous in a neighborhood of  $x$ .

The *limiting Fréchet subdifferential* of  $f$  at  $x$  is defined as

$$\begin{aligned} \bar{\partial}f(x) = \{ &x^* \in X^* : \exists \text{ sequences} \\ &\{x_k\} \subset X, \{x_k^*\} \subset X^* \text{ such that} \\ &x_k \xrightarrow{f} x, x_k^* \xrightarrow{w^*} x^* \text{ and } x_k^* \in \partial f(x_k), k = 1, 2, \dots \}. \end{aligned} \tag{7}$$

The notations  $x_k \xrightarrow{f} x$  and  $x_k^* \xrightarrow{w^*} x^*$  here mean, respectively, that  $x_k \rightarrow x$  with  $f(x_k) \rightarrow f(x)$  (*f-attentive convergence* [42]), and  $x_k^*$  converges to  $x^*$  in the *weak\* topology* of  $X^*$ .

$\bar{\partial}f(x)$  is a weakly\* sequentially closed set in  $X^*$ . In general it is nonconvex. If  $f$  is strictly differentiable at  $x$  the set (7) reduces to the derivative.

Using strict  $\delta$ -subdifferentials, one can rewrite (7) in the following way:

$$\bar{\partial}f(x) = \bigcap_{\delta>0} \text{cl}^* \hat{\partial}_\delta f(x),$$

where  $\text{cl}^*$  denotes the weak\* sequential closure.

Other limiting objects (the *limiting superdifferential*, the *limiting differential*, the *limiting normal cone*, the *singular limiting subdifferential*, and the *limiting coderivative*) can be defined in a similar way.

Thus, the limiting normal cone to a closed set  $\Omega$  is defined by the equality

$$\bar{N}(x|\Omega) = \bigcap_{\delta>0} \text{cl}^* \hat{N}_\delta(x|\Omega).$$

It coincides with the limiting subdifferential of the indicator function of  $\Omega$ . The analog of (5) is also valid:

$$\bar{\partial}f(x) = \{x^* \in X^* : (x^*, -1) \in \bar{N}(x, f(x)|\text{epi}f)\}.$$

The limiting subdifferentials and normal cones have been well investigated. They possess good calculus (which is the consequence of the fuzzy calculus of Fréchet subdifferentials; see [19,23,30,31,32,34,36,42] for the properties of these objects and some examples). They have proved to be very efficient for formulating optimality conditions in nonsmooth optimization [20,22,29,30,31,32,34,36], especially in finite dimensions. When applying limiting subdifferentials in infinite dimensional spaces, one must be careful about nontriviality of the limits in the weak\* topology. Additional regularity conditions are needed (*compact epi-Lipschitzness, sequential normal compactness, partial sequential normal compactness* [4,34,36], etc.)

### Fréchet $\varepsilon$ -Subdifferentials and $\varepsilon$ -Normals

In some cases it can be convenient to use  $\varepsilon$ -extensions of the Fréchet subdifferentials and normal cones [21,23,29,44]. For instance, the *Fréchet  $\varepsilon$ -subdifferential* and the *Fréchet  $\varepsilon$ -superdifferential* of  $f$  at  $x$  are defined as

$$\text{partial}_\varepsilon f(x) = \left\{ x^* \in X^* : \liminf_{u \rightarrow x} \frac{f(u) - f(x) - \langle x^*, u - x \rangle}{\|u - x\|} \geq -\varepsilon \right\},$$

$$\partial_\varepsilon^+ f(x) = \left\{ x^* \in X^* : \limsup_{u \rightarrow x} \frac{f(u) - f(x) - \langle x^*, u - x \rangle}{\|u - x\|} \leq \varepsilon \right\}.$$

Unlike (1) and (2), these sets depend on the specific norm on  $X$  (when  $\varepsilon > 0$ ).

The next two propositions extend Propositions 1 and 2 respectively.

**Proposition 3** *If  $f$  is convex then*

$$\partial_\varepsilon f(x) = \partial f(x) + \varepsilon B^* = \{x^* \in X^* : f(u) - f(x) \geq \langle x^*, u - x \rangle - \varepsilon \|u - x\|, \forall u \in X\}.$$

*Remark 2* Note that the above  $\varepsilon$ -subdifferential differs from the corresponding notion of convex analysis, which is usually defined [41] as the set of all  $x^* \in X^*$ , such that  $f(u) - f(x) \geq \langle x^*, u - x \rangle - \varepsilon$  for all  $u \in X$ .

**Proposition 4** *If  $x_1^* \in \partial_{\varepsilon_1} f(x)$ ,  $x_2^* \in \partial_{\varepsilon_2}^+ f(x)$ ,  $\varepsilon_1 \geq 0$ ,  $\varepsilon_2 \geq 0$  then  $\|x_1^* - x_2^*\| \leq \varepsilon_1 + \varepsilon_2$ .*

### Formulation

#### Direct Calculus

The propositions below present some simple calculus results for Fréchet subdifferentials. Most of them follow directly from the definitions. More advanced statements of fuzzy calculus are presented in the next subsections.

**Proposition 5** *If  $f$  attains a local minimum at  $x$  then  $0 \in \partial f(x)$ .*

**Proposition 6**  $\partial(\lambda f)(x) = \lambda \partial f(x)$  for any  $\lambda > 0$ .

**Proposition 7** *Let  $f_1, f_2 : X \rightarrow \mathbb{R}_\infty$  be finite at  $x$ . Then*

$$\partial(f_1 + f_2)(x) \supset \partial f_1(x) + \partial f_2(x). \tag{8}$$

The above proposition presents an example of a *Sum Rule*. Usually the sum rule is the central result of any subdifferential calculus. Unfortunately, the inclusion (8) is almost useless: it does not allow one to decompose elements of the subdifferential of the sum of functions in terms of elements of subdifferentials of the original functions. Simple examples show that inclusion (8) can be strict even in the convex case. The next proposition gives two important cases when the equality holds true in (8).

**Proposition 8** Let  $f_1, f_2 : X \rightarrow \mathbb{R}_\infty$  be finite at  $x$ .

1. If  $f_1$  and  $f_2$  are convex and one of them is continuous at  $x$  then

$$\partial(f_1 + f_2)(x) = \partial f_1(x) + \partial f_2(x).$$

2. If  $f_1$  is Fréchet-differentiable at  $x$  then

$$\partial(f_1 + f_2)(x) = \nabla f_1(x) + \partial f_2(x). \tag{9}$$

Part 1 of Proposition 8 is known as the Moreau–Rockafellar theorem [41]. Part 2 is a simple corollary of Proposition 7. It is an interesting example, when an inclusion implies an equality. Indeed, applying Proposition 7 to the sum of the functions  $f_1 + f_2$  and  $-f_2$  and making use of (3), one gets

$$\partial f_2(x) \supset \partial(f_1 + f_2)(x) - \partial^+ f_1(x). \tag{10}$$

Taking into account Proposition 2, the inclusions (8) and (10) imply (9).

Proposition 8 yields a simple necessary optimality condition generalizing Proposition 5.

**Proposition 9** Let  $f_1 : X \rightarrow \mathbb{R}$  be Fréchet-differentiable at  $x$  where  $f_2 : X \rightarrow \mathbb{R}_\infty$  is finite. If  $f_1 + f_2$  attains a local minimum at  $x$  then  $-\nabla f_1(x) \subset \partial f_2(x)$ .

The next two assertions are corollaries of Propositions 7 and 9.

**Proposition 10** Let  $x \in \Omega_1 \cap \Omega_2$ . Then  $N(x|\Omega_1 \cap \Omega_2) \supset N(x|\Omega_1) + N(x|\Omega_2)$ .

**Proposition 11** Let  $f$  be Fréchet-differentiable at  $x$ . If  $f$  attains at  $x$  a local minimum on  $\Omega$  then  $-\nabla f(x) \in N(x|\Omega)$ .

For a set  $\Omega \subset X$  and  $u \in X$  consider the distance  $d_\Omega(u) = \inf_{\omega \in \Omega} \|u - \omega\|$ .

**Proposition 12 ([18])** For any  $x \in \Omega$  one has  $\partial d_\Omega(x) = \{x^* \in N(x|\Omega) : \|x^*\| \leq 1\}$ .

### Strict Differentiability

Recall that  $f$  is called *strictly differentiable* [34,42] at  $x$  (with the strict derivative  $\nabla f(x)$ ) if

$$\lim_{\substack{u \rightarrow x, u' \rightarrow x \\ u \neq u'}} \frac{f(u') - f(u) - \langle \nabla f(x), u' - u \rangle}{\|u' - u\|} = 0.$$

In the case of a strictly differentiable function the Fréchet subdifferentials and superdifferentials at nearby points cannot differ much from the strict derivative.

**Proposition 13 ([25])** If  $f$  is strictly differentiable at  $x$  with the derivative  $\nabla f(x)$  then for any  $\varepsilon > 0$  there exists a  $\delta > 0$  such that:

1.  $\hat{\partial}_\delta^0 f(x) \subset \nabla f(x) + \varepsilon B^*$ .
2.  $\nabla f(x) \in \partial_\varepsilon f(u) \cap \partial_\varepsilon^+ f(u)$  for all  $u \in B_\delta(x)$ .

The rest of the section is devoted to “fuzzy” results in terms of Fréchet subdifferentials and strict Fréchet  $\delta$ -differentials.

### Variational Principles

The *variational principles* by Ekeland [10], Borwein and Preiss [3] as well as their subsequent followers [6,8,34,40,42] are very powerful tools of modern variational analysis. They make it possible to substitute an “almost minimal” point (up to  $\varepsilon$ ) by another point, arbitrarily close to the initial one, which is the local minimizer for a slightly perturbed (usually by adding a small term) function. Thus, such principles can be viewed as fuzzy results.

The next assertion is valid for an arbitrary Asplund space. It is known as the *Subdifferential Variational Principle*. Let us recall that a Banach space is called *Asplund* [6,8,34,40] if any continuous convex function on it is Fréchet-differentiable on a dense  $G_\delta$  set of points. Asplund spaces form a rather broad subclass of Banach spaces. It includes, for instance, all spaces which admit Fréchet-differentiable bump functions (in particular, Fréchet smooth spaces). Reflexive spaces are examples of Fréchet smooth spaces.

Asplund spaces provide a very convenient framework for investigating “differential” properties of non-smooth functions. Actually the Asplund property of a Banach space is not only sufficient but also a necessary condition for the fulfillment of some basic results in nonsmooth analysis involving Fréchet normals and subdifferentials (see [6,13,34,35,38] and the statements below).

**Theorem 1 (Mordukhovich and Wang [38])** Let  $X$  be Asplund,  $f : X \rightarrow \mathbb{R}_\infty$  be lower semicontinuous and bounded below,  $\varepsilon > 0$ ,  $\lambda > 0$ . Suppose that  $f(x) < \inf f + \varepsilon$ . Then there exists a  $u \in B_\lambda(x)$  and an  $x^* \in \partial f(u)$ , such that  $f(u) \leq f(x)$  and  $\|x^*\|_* < \varepsilon/\lambda$ .

The following theorem states that the class of Fréchet subdifferentiability spaces [15] coincides with Asplund spaces.

**Theorem 2** *The following assertions are equivalent:*

1.  $X$  is an Asplund space.
2. For any lower semicontinuous function  $f : X \rightarrow \mathbb{R}_\infty$  the set  $\{u \in X : \partial f(u) \neq \emptyset\}$  is dense in  $\text{dom} f$ .
3. For any lower semicontinuous function  $f : X \rightarrow \mathbb{R}_\infty$  there exists an  $x \in \text{dom} f$  such that  $\partial f(x) \neq \emptyset$ .

### Sum Rules

After the sum rule was first established in the limiting form in [19] (see [23,31]) the fuzzy versions were derived in [12,15] (see also [6,17,37]). Now two main versions of the fuzzy sum rule are known. For simplicity they are formulated below in terms of strict  $\delta$ -subdifferentials.

**Rule 1 Weak Fuzzy Sum Rule** *Let  $f_1, f_2 : X \rightarrow \mathbb{R}_\infty$  be finite at  $x$  and lower semicontinuous near  $x$ . Then  $\partial(f_1 + f_2)(x) \subset \hat{\partial}_\delta f_1(x) + \hat{\partial}_\delta f_2(x) + U^*$  for any  $\delta > 0$  and any weak\* neighborhood  $U^*$  of 0 in  $X^*$ .*

**Rule 2 Strong Fuzzy Sum Rule** *Let  $f_1 : X \rightarrow \mathbb{R}_\infty$  be finite at  $x$  and lower semicontinuous near  $x$  and  $f_2 : X \rightarrow \mathbb{R}$  be Lipschitz continuous near  $x$ . Then  $\partial(f_1 + f_2)(x) \subset \hat{\partial}_\delta f_1(x) + \hat{\partial}_\delta f_2(x) + \delta B^*$  for any  $\delta > 0$ .*

A Banach space is called a *trustworthy space* [15] (for some kind of a subdifferential) if Rule 1 is valid in it. The following theorem proved by Fabian [12] states that for the Fréchet subdifferential the class of trustworthy spaces coincides with Asplund spaces.

**Theorem 3** *The following assertions are equivalent:*

1.  $X$  is an Asplund space.
2. The Weak Fuzzy Sum Rule is valid in  $X$ .
3. The Strong Fuzzy Sum Rule is valid in  $X$ .

The Weak Fuzzy Sum Rule yields the following representation of Fréchet normals to the intersection of closed sets.

**Proposition 14** *Let  $\Omega_1, \Omega_2$  be closed subsets in an Asplund space  $X$  and  $x \in \Omega_1 \cap \Omega_2$ . Then  $N(x, \Omega_1 \cap \Omega_2) \subset \hat{N}_\delta(x, \Omega_1) + \hat{N}_\delta(x, \Omega_2) + U^*$  for any  $\delta > 0$  and any weak\* neighborhood  $U^*$  of 0 in  $X^*$ .*

Other fuzzy calculus results (chain rules, formulas for maximum-type functions, mean value theorems, etc.)

for functions and multifunctions can be deduced from (some form of) the sum rule [5,16,24,37].

### Extremal Principle

The *Extremal Principle* continues the line of variational principles discussed above and is in a sense equivalent to them as well as to the sum rules.

Let  $\Omega_1, \Omega_2$  be closed subsets in  $X$ . They are called *locally extremal* [29,30] near  $x \in \Omega_1 \cap \Omega_2$  if there exists a neighborhood  $U$  of  $x$  and sequences  $\{a_{ik}\} \in X, i = 1, 2, k = 1, 2, \dots$ , such that  $a_{ik} \rightarrow 0$  when  $k \rightarrow \infty$  and  $(\Omega_1 - a_{1k}) \cap (\Omega_2 - a_{2k}) \cap U = \emptyset, k = 1, 2, \dots$

This means that by an arbitrarily small shift the sets can be made unintersecting in a neighborhood of  $x$ . The definition represents a rather general notion of extremality: some locally extremal system corresponds to a local solution of any optimization problem (see various examples in [22,29,31,33]).

The *Extremal Principle*, first established in [29] (see also [22,30,31]) for the case of a Fréchet smooth space (and in terms of  $\varepsilon$ -normals) and in [35] (see [34]) in the Asplund space setting, provides a dual space characterization of locally extremal systems in terms of Fréchet normals. It can be viewed as a fuzzy form of the *separation* property.

**Extremal Principle** *If a system of sets  $\Omega_1, \Omega_2$  is locally extremal near  $x \in \Omega_1 \cap \Omega_2$  then for any  $\delta > 0$  there exist elements  $x_1^* \in \hat{N}_\delta(x|\Omega_1), x_2^* \in \hat{N}_\delta(x|\Omega_2)$  such that  $\|x_1^* + x_2^*\| < \delta, \|x_1^*\| + \|x_2^*\| = 1$ .*

The following theorem proved in [35] shows that the Extremal Principle provides an extremal characterization of Asplund spaces.

**Theorem 4** *The following assertions are equivalent:*

1.  $X$  is an Asplund space.
2. The Extremal Principle is valid in  $X$ .

Due to Theorems 3 and 4 the Extremal Principle is equivalent to the Sum Rules. It is also equivalent to some other basic results of nonsmooth analysis [6,34,45].

The Extremal Principle can be viewed as a certain extension of the classical separation theorem for convex sets. It was used in [22,29,30,31,36] and in many other papers as a main tool for deducing calculus formulas and necessary optimality conditions.

The local extremality assumption in the Extremal Principle can be replaced by a weaker *stationarity* condition [26,27,28]. The resulting *Extended Extremal Principle* is formulated as a necessary and sufficient condition and is also equivalent to the asplundity of the space.

As noticed in [35], considering the extremal system provided by the pair  $\{x\}, \Omega$ , where  $x$  is a boundary point of a closed set  $\Omega$  makes it possible to deduce from Theorem 4 the following nonconvex generalization of the well-known *Bishop–Phelps theorem* [40].

**Corollary 1** *Let  $\Omega$  be a closed subset in an Asplund space  $X$  and let  $x \in \text{bd}\Omega$ . Then for any  $\delta > 0$  there exists  $x^* \in \hat{N}_\delta(x|\Omega)$  such that  $\|x^*\| = 1$ .*

### Introduction

The article considers different stationarity and regularity concepts for extended real-valued functions on metric spaces.

All the properties can be characterized in terms of certain local constants. A function is said to be stationary at a point (in some sense) if the corresponding constant is zero (a critical point). Otherwise the function is said to be regular at this point (in the same sense), and the constant provides a quantitative estimate of regularity.

Traditionally the stationary behavior of a function at a point (*stationary point*) means that it is arbitrarily close to a constant near this point, that is the rate of change of the function is infinitely small compared to the increment of the variable. Of course, this is equivalent to the derivative being equal to zero (dual characterization of stationarity). The classical examples of the stationary behavior of a function, found in the textbooks, are given by the functions  $y = x^2$ ,  $y = -x^2$ , and  $y = x^3$ . These three examples characterize the three possible types of stationary behavior in the differentiable case.

Stationarity arises naturally in optimization theory: a point of minimum or maximum is necessarily a stationary point. At the same time it is easy to see that weaker stationarity concepts are applicable to optimization problems. For instance, when dealing with minimizing a real-valued function, only its decrement must be infinitely small at a stationary point, and the function itself does not need to be arbitrarily close to a constant or even differentiable at the point. Of course, if

it is differentiable, one has the same classical stationarity concept. In the nondifferentiable case more types of the stationary behavior are possible. The examples are:  $y = |x|$  and  $y = \max(x, -x^2)$  (both functions are considered near the point  $x = 0$ ). One can speak about *inf-stationarity* (the term suggested by Vladimir F. Demianov). From the point of view of maximization a concept of *sup-stationarity* can be considered in a similar way. Thus in the nondifferentiable case the stationarity splits into two “semi-stationarity” concepts.

Another pair of stationarity concepts can be of interest in optimization theory: the point itself may not be stationary (inf or sup), but in any of its neighborhood there exists another point in which the behavior of the function is arbitrarily close to stationary (a “fuzzy” condition). We will speak about *weak stationarity* (inf or sup). The exact definitions will be given below.

An example of this type of stationary behavior is given by the function  $y = x \sin(1/x)$  if  $x \neq 0$ , and  $y = 0$  if  $x = 0$ . One can easily see that this function is differentiable on  $\mathbb{R} \setminus \{0\}$ , and there exists a sequence  $\{x_k\}$  such that  $x_k \rightarrow 0$  and  $x_k$  is a point of local minimum,  $k = 1, 2, \dots$ . Another example:  $y = x + x^2 \sin(1/x)$  if  $x \neq 0$ , and  $y = 0$  if  $x = 0$ . This function is everywhere differentiable,  $y'(0) = 1$ , and there exists a sequence  $\{x_k\}$  such that  $x_k \rightarrow 0$  and  $y'(x_k) = 0$ ,  $k = 1, 2, \dots$

Stationarity concepts can also be defined in terms of dual space elements (subdifferentials). The relations between primal and dual definitions provide dual characterizations of (primal space concepts of) stationarity.

This article contains no proofs. A more detailed description of the stationarity and regularity concepts for real-valued functions can be found in [11].

Mostly standard notations are used throughout this article.  $X$  denotes a metric space with distance  $d$ .  $B_\rho(x)$  stands for a closed ball with center  $x$  and radius  $\rho$ .

**Definitions**

**Inf- $\theta$ -Stationarity and Inf- $\theta$ -Regularity**

Let  $f$  be a function on a metric space  $X$  with values in the extended real line  $\mathbb{R}_\infty = \mathbb{R} \cup \{+\infty\}$ . It is assumed to be finite at some point  $x^\circ \in X$ .

For  $\rho > 0$  define the constant

$$\theta_\rho[f](x^\circ) = \inf_{x \in B_\rho(x^\circ)} f(x) - f(x^\circ). \tag{1}$$

Note that  $\theta_\rho[f](x^\circ) \leq 0$  and the equality  $\theta_\rho[f](x^\circ) = 0$  for some  $\rho > 0$  (for all  $\rho > 0$ ) means that  $x^\circ$  is a point of local (global) minimum of  $f$ .

Of course, the infimum in (1) can be limited to the set  $\{x \in B_\rho(x^\circ) : f(x) \leq f(x^\circ)\}$ , or even to the set  $\{x \in B_\rho(x^\circ) : f(x) < f(x^\circ)\}$  under the additional agreement that the infimum over the empty subset of  $\mathbb{R}_-$  is 0.

The function  $\rho \rightarrow \theta_\rho[f](x^\circ)$  is nonincreasing on  $\mathbb{R}_+$  and  $\lim_{\rho \rightarrow +0} \theta_\rho[f](x^\circ) \leq 0$ . The equality  $\lim_{\rho \rightarrow +0} \theta_\rho[f](x^\circ) = 0$  means that  $f$  is lower semicontinuous at  $x^\circ$ . In the latter case it can be important to know how quickly  $\theta_\rho[f](x^\circ)$  approaches 0 compared to  $\rho$ .

Define two more “derivativelike” constants based on (1):

$$\theta[f](x^\circ) = \limsup_{\rho \rightarrow +0} \frac{\theta_\rho[f](x^\circ)}{\rho}, \tag{2}$$

$$\hat{\theta}[f](x^\circ) = \limsup_{x \xrightarrow{f} x^\circ, \rho \rightarrow +0} \frac{\theta_\rho[f](x)}{\rho}, \tag{3}$$

where  $x \xrightarrow{f} x^\circ$  means that  $x \rightarrow x^\circ$  with  $f(x) \rightarrow f(x^\circ)$ . Due to the variations of  $x$  in (3),  $\hat{\theta}[f](x^\circ)$  gains some properties of the strict derivative.

The constants (2) and (3) are nonpositive too, and “zero cases” correspond to certain kinds of stationary behavior of  $f$  near  $x^\circ$ . If a constant is strictly negative, this can be considered as a kind of regularity.

**Definition 1**  $f$  is

- (i) *inf- $\theta$ -stationary* at  $x^\circ$  if  $\theta[f](x^\circ) = 0$ ;
- (ii) *weakly inf- $\theta$ -stationary* at  $x^\circ$  if  $\hat{\theta}[f](x^\circ) = 0$ ;
- (iii) *inf- $\theta$ -regular* at  $x^\circ$  if  $\theta[f](x^\circ) < 0$ ;
- (iv) *strongly inf- $\theta$ -regular* at  $x^\circ$  if  $\hat{\theta}[f](x^\circ) < 0$ .

The purpose of the “inf” prefix in this definition is to emphasize that minimization problems are addressed here. Unlike the classical case, stationarity-regularity properties of nondifferentiable functions “from below” and “from above” can be essentially different.

**Inf- $\tau$ -Stationarity and Inf- $\tau$ -Regularity**

Another way of defining stationarity-regularity is based on using slightly modified versions of (2) and (3):

$$\tau[f](x^\circ) = \liminf_{x \rightarrow x^\circ} \frac{[f(x) - f(x^\circ)]_-}{d(x, x^\circ)}, \tag{4}$$

$$\hat{\tau}[f](x^\circ) = \limsup_{x \rightarrow x^\circ, \rho \rightarrow +0} \inf_{u \in B_\rho(x) \setminus \{x\}} \frac{[f(u) - f(x)]_-}{d(u, x)}. \tag{5}$$

The notation  $[\alpha]_- = \min(\alpha, 0)$  is used here. Again, only the points  $x \in B_\rho(x^\circ)$  with  $f(x) < f(x^\circ)$  and  $u \in B_\rho(x)$  with  $f(u) < f(x)$  are of interest in (4) and (5), respectively. The role of the notation is to handle the case where the set of such points is empty. Similarly to (2) and (3), these constants are nonpositive.

*Remark 1*  $\tau[f](x^\circ)$  coincides up to a sign with the strong slope  $|\nabla f|(x^\circ)$  of  $f$  at  $x^\circ$  [1] (see also [5]).

**Definition 2**  $f$  is

- (i) *inf- $\tau$ -stationary* at  $x^\circ$  if  $\tau[f](x^\circ) = 0$ ;
- (ii) *weakly inf- $\tau$ -stationary* at  $x^\circ$  if  $\hat{\tau}[f](x^\circ) = 0$ ;
- (iii) *inf- $\tau$ -regular* at  $x^\circ$  if  $\tau[f](x^\circ) < 0$ ;
- (iv) *strongly inf- $\tau$ -regular* at  $x^\circ$  if  $\hat{\tau}[f](x^\circ) < 0$ .

The relations between the constants (2), (3) and (4), (5), as well as between the corresponding stationarity and regularity concepts will be discussed in the next section.

**Sup-Stationarity and Sup-Regularity**

Similarly to (1)–(5) corresponding “maximization” constants can be defined. To do this one has to replace “inf,” “lim inf,” “lim sup,” and  $[\cdot]_-$  by “sup,” “lim sup,” “lim inf,” and  $[\cdot]_+$ , respectively, in the corresponding definitions. The resulting constants are nonnegative. They are related to (1)–(5) by the following equalities:

$$\begin{aligned} \theta_\rho^+[f](x^\circ) &= -\theta_\rho[-f](x^\circ), \\ \theta^+[f](x^\circ) &= -\theta[-f](x^\circ), \\ \hat{\theta}^+[f](x^\circ) &= -\hat{\theta}[-f](x^\circ), \\ \tau^+[f](x^\circ) &= -\tau[-f](x^\circ), \\ \hat{\tau}^+[f](x^\circ) &= -\hat{\tau}[-f](x^\circ) \end{aligned}$$

and lead to similar *sup-stationarity* and *sup-regularity* concepts.

Of course, for a function  $f$  the set of sup-stationary (sup-regular) points is different in general from that of inf-stationary (inf-regular) points.

The “combined” concepts can also be of interest. It is natural to say that a function is stationary (in some sense) at a point if it is either inf-stationary or sup-stationary at this point. In contrast, the regularity prop-

erty for a function is satisfied when this function is both inf-regular and sup-regular at the point.

**Definition 3**  $f$  is

- (i)  *$\theta$ -stationary* at  $x^\circ$   
if  $\max(\theta[f](x^\circ), \theta[-f](x^\circ)) = 0$ ;
- (ii) *weakly  $\theta$ -stationary* at  $x^\circ$   
if  $\max(\hat{\theta}[f](x^\circ), \hat{\theta}[-f](x^\circ)) = 0$ ;
- (iii)  *$\theta$ -regular* at  $x^\circ$   
if  $\max(\theta[f](x^\circ), \theta[-f](x^\circ)) < 0$ ;
- (iv) *strongly  $\theta$ -regular* at  $x^\circ$   
if  $\max(\hat{\theta}[f](x^\circ), \hat{\theta}[-f](x^\circ)) < 0$ ;
- (v)  *$\tau$ -stationary* at  $x^\circ$   
if  $\max(\tau[f](x^\circ), \tau[-f](x^\circ)) = 0$ ;
- (vi) *weakly  $\tau$ -stationary* at  $x^\circ$   
if  $\max(\hat{\tau}[f](x^\circ), \hat{\tau}[-f](x^\circ)) = 0$ ;
- (vii)  *$\tau$ -regular* at  $x^\circ$   
if  $\max(\tau[f](x^\circ), \tau[-f](x^\circ)) < 0$ ;
- (viii) *strongly  $\tau$ -regular* at  $x^\circ$   
if  $\max(\hat{\tau}[f](x^\circ), \hat{\tau}[-f](x^\circ)) < 0$ .

Strong inf-regularity can be interpreted in the following way: all points in a neighborhood of a given point have “descent sequences,” and the rate of descent is uniform. In contrast to that, strong regularity is equivalent to the existence of both descent and ascent sequences with the uniformity property.

**Dual Stationarity and Regularity**

All definitions in the preceding subsections are primal space definitions. As in the classical analysis, dual characterizations of stationarity and regularity concepts are important. In the case of a normed linear space, such characterizations can be formulated in terms of *Fréchet subdifferentials*.

Let  $X$  be a normed linear space. Its (topological) dual is denoted  $X^*$ .  $\langle \cdot, \cdot \rangle$  is the bilinear form defining the duality pairing. Recall that the Fréchet subdifferential of  $f$  at  $x^\circ$  is defined as

$$\partial f(x^\circ) = \left\{ x^* \in X^* : \liminf_{x \rightarrow x^\circ} \frac{f(x) - f(x^\circ) - \langle x^*, x - x^\circ \rangle}{\|x - x^\circ\|} \geq 0 \right\}. \tag{6}$$

**Definition 4**  $f$  is

- (i) *inf-d-stationary* at  $x^\circ$  if  $0 \in \partial f(x^\circ)$ ;
- (ii) *inf-d-regular* at  $x^\circ$  if  $0 \notin \partial f(x^\circ)$ .

It follows immediately from the definitions that in the normed space setting inf- $\tau$ -stationarity (inf- $\tau$ -regularity) is equivalent to inf- $d$ -stationarity (inf- $d$ -regularity).

Somewhat more complicated constructions are needed for the characterization of weak stationarity and strong regularity.

Let us assume for simplicity that  $f$  is lower semicontinuous near  $x^\circ$ .

In the general nonconvex setting the subdifferential mapping  $\partial f(\cdot)$  fails to possess good (semi-)continuity properties. In fact, the set  $\partial f(x)$  can be empty rather often. Based on (6) one can define a more robust derivativelike object:

$$\hat{\partial}_\delta f(x^\circ) = \bigcup_{\substack{x \in B_\delta(x^\circ) \\ |f(x) - f(x^\circ)| \leq \delta}} \partial f(x). \tag{7}$$

This object depends on a positive parameter  $\delta$  and accumulates information on “differential” properties of  $f$  at nearby points, thus attaining some properties of the strict derivative. The set (7) is called the *strict* $\delta$ -subdifferential of  $f$  at  $x^\circ$  (see [7,8,9]). In contrast to (6), set (7) can be nonconvex. However, it possesses certain subdifferential calculus.

Using (7) one more constant can be defined for characterizing stationarity/regularity properties of  $f$ :

$$\eta[f](x^\circ) = \liminf_{\delta \rightarrow 0} \{ \|x^*\| : x^* \in \hat{\partial}_\delta f(x^\circ) \}. \tag{8}$$

Unlike the constants considered in the preceding subsections, this constant is nonnegative.

**Definition 5**  $f$  is

- (i) *inf- $\eta$ -stationary* at  $x^\circ$  if  $\eta[f](x^\circ) = 0$ ;
- (ii) *inf- $\eta$ -regular* at  $x^\circ$  if  $\eta[f](x^\circ) > 0$ .

Note that the inf- $\eta$ -stationary condition  $\eta[f](x^\circ) = 0$  does not imply the inclusion  $0 \in \hat{\partial}_\delta f(x^\circ)$ .

*Example 1* Take  $f(x) = x$ , if  $x < 0$ , and  $f(x) = x^2$  otherwise. One has  $\partial f(0) = \emptyset$ ,  $0 \notin \hat{\partial}_\delta f(0)$  for any  $\delta > 0$ , while  $\eta[f](0) = 0$ .

Fortunately (8) happens to be closely related to (3) and (5).

Sup- $d$ -stationarity and sup- $\eta$ -stationarity as well as the corresponding regularity concepts can be defined in a similar way.

**Formulation**

**Relations Between the “Elementary” Constants**

**Proposition 1** *The following assertions hold true:*

- (i)  $\tau[f](x^\circ) \leq \theta[f](x^\circ)$ ;
- (ii) If  $\theta_\rho[f](x^\circ) = 0$  for some  $\rho > 0$ , then  $\tau[f](x^\circ) = \theta[f](x^\circ) = 0$ .

Proposition 1 (i) implies the relations between the corresponding stationarity and regularity concepts:

- inf- $\tau$ -stationarity  $\Rightarrow$  inf- $\theta$ -stationarity;
- inf- $\theta$ -regularity  $\Rightarrow$  inf- $\tau$ -regularity.

Proposition 1 (ii) means that at a point of local minimum a function is both inf- $\tau$ -stationary and inf- $\theta$ -stationary.

Inequality (i) in Proposition 1 can be strict even for functions from  $\mathbb{R}$  to  $\mathbb{R}$ .

*Example 2* Take  $f(x) = -|x|$ , if  $|x| = 1/2^n$ ,  $n = 1, 2, \dots$ , and  $f(x) = 0$  otherwise. Obviously  $\tau[f](0) = -1$ . At the same time, for any  $\rho \in \mathcal{E}_n = \{\rho: 1/2^n \leq \rho < 1/2^{n-1}\}$  one has  $\theta_\rho[f](0) = -1/2^n$  and

$$\sup_{\rho \in \mathcal{E}_n} \frac{\theta_\rho[f](0)}{\rho} = \frac{-1/2^n}{1/2^{n-1}} = -\frac{1}{2}.$$

Thus,  $\theta[f](0) = -1/2$ .

It is possible to modify the above example to make  $\theta[f](0)$  equal zero.

*Example 3* Take  $f(x) = -|x|$ , if  $|x| = 1/n^n$ ,  $n = 1, 2, \dots$ , and  $f(x) = 0$  otherwise. One still has  $\tau[f](0) = -1$  while  $\theta[f](0) = 0$ .

Thus, in the above example  $f$  is inf- $\tau$ -regular at 0 while being inf- $\theta$ -stationary at this point.

It is possible to modify the example further to make  $f$  continuous and even differentiable near 0 (but not strictly differentiable!) while keeping the inequality (i) in Proposition 1 strict.

**Relations Between the “Strict” Constants**

The relations between the elementary constants and their “strict” counterparts, as well as between the two “strict” constants, are given by the following theorem.

**Theorem 1** *The following assertions hold true:*

- (i)  $\hat{\theta}[f](x^\circ) \geq \limsup_{x \xrightarrow{f} x^\circ} \theta[f](x)$ ,

- (ii)  $\hat{\tau}[f](x^\circ) = \limsup_{x \xrightarrow{f} x^\circ} \tau[f](x)$ ;
- (iii)  $\hat{\tau}[f](x^\circ) \leq \hat{\theta}[f](x^\circ)$ ;
- (iv) If  $X$  is complete and  $f$  is lower semicontinuous near  $x^\circ$ , then  $\hat{\tau}[f](x^\circ) = \hat{\theta}[f](x^\circ)$ .

Parts (i) and (ii) of Theorem 1 imply the inequalities

$$\theta[f](x^\circ) \leq \hat{\theta}[f](x^\circ), \quad \tau[f](x^\circ) \leq \hat{\tau}[f](x^\circ),$$

and both of them can be strict.

*Example 4* Take the function  $f$  from Example 1. Evidently,  $f$  attains a local minimum at  $x_n = 1/2^n$  for any  $n = 1, 2, \dots$ , and consequently,  $\theta_\rho[f](x_n) = 0$  for some  $\rho > 0$ . It follows from Proposition 1 (ii) that  $\tau[f](x_n) = \theta[f](x_n) = 0$ . Consequently,  $\hat{\tau}[f](0) = \hat{\theta}[f](0) = 0$ . Recall that  $\tau[f](0) = -1$  and  $\theta[f](0) = -1/2$ .

Inequalities (i) and (iii) in Theorem 1 can be strict, too.

*Example 5* Define the function  $f : \mathbb{R} \rightarrow \mathbb{R}$  in the following way:  $f(x) = x$  if  $x \leq 0$ ,  $f(x) = x - 1/n$  if  $1/n < x \leq 1/(n-1)$ ,  $n = 2, 3, \dots$ ,  $f(x) = x - 1/2$  if  $x > 1/2$ . It is easy to see that  $\theta[f](x) = \tau[f](x) = -1$  for any  $x \in \mathbb{R}$ . Then  $\hat{\tau}[f](0) = -1$ . On the other hand, take  $x_n = 1/n + 1/n^2$ ,  $\rho_n = 1/n$ ,  $n = 1, 2, \dots$ . Then  $f(x_n) = 1/n^2$ , and consequently,  $\theta_{\rho_n}[f](x_n) \geq -1/n^2$ . It follows immediately that  $\hat{\theta}[f](0) = 0$ .

Due to part (iv) of Theorem 1, in the case of a lower semicontinuous function on a complete metric space two weak stationarity concepts as well as two strong regularity concepts coincide and the prefixes  $\theta$  and  $\tau$  can be omitted.

**Corollary 1** *The following assertions hold true:*

- (i) *Inf- $\theta$ -stationarity  $\Rightarrow$  weak inf- $\theta$ -stationarity;  
strong inf- $\theta$ -regularity  $\Rightarrow$  inf- $\theta$ -regularity;*
- (ii) *Inf- $\tau$ -stationarity  $\Rightarrow$  weak inf- $\tau$ -stationarity;  
strong inf- $\tau$ -regularity  $\Rightarrow$  inf- $\tau$ -regularity;*
- (iii) *Weak inf- $\tau$ -stationarity  $\Rightarrow$  weak inf- $\theta$ -stationarity;  
strong inf- $\theta$ -regularity  $\Rightarrow$  strong inf- $\tau$ -regularity;*
- (iv) *If  $X$  is complete and  $f$  is lower semicontinuous near  $x^\circ$ , then  
weak inf- $\tau$ -stationarity  $\Leftrightarrow$  weak inf- $\theta$ -stationarity;  
strong inf- $\theta$ -regularity  $\Leftrightarrow$  strong inf- $\tau$ -regularity.*

The next ‘‘fuzzy’’ characterization of weak inf- $\tau$ -stationarity can be convenient for applications. It follows directly from definition (5).

**Proposition 2**  *$f$  is weakly inf- $\tau$ -stationary at  $x^\circ$  if and only if for any  $\varepsilon > 0$  there exists an  $x \in B_\varepsilon(x^\circ)$  such that  $|f(x) - f(x^\circ)| \leq \varepsilon$  and*

$$f(u) + \varepsilon d(u, x) \geq f(x) \quad \text{for all } u \text{ near } x. \quad (9)$$

*Remark 2* A point  $x$  satisfying (9) is referred to in [12] (see also [6]) as a *local Ekeland point* of  $f$  (with factor  $\varepsilon$ ). If all the conditions in Proposition 2 are satisfied, then  $x^\circ$  is said to be a *stationary point* of  $f$  with respect to minimization [12]. Thus, stationarity with respect to minimization is equivalent to weak inf- $\tau$ -stationarity and, in the case of a lower semicontinuous function on a complete metric space, also to weak inf- $\theta$ -stationarity.

**Relations Between the Primal and Dual Constants**

Henceforth  $X$  is assumed to be a normed linear space. The next assertion is straightforward and has already been mentioned in the previous section.

**Proposition 3**

- (i) *inf- $\tau$ -stationarity  $\Leftrightarrow$  weak inf- $d$ -stationarity;*
- (ii) *inf- $\tau$ -regularity  $\Leftrightarrow$  inf- $d$ -regularity.*

*Remark 3* Due to Propositions 1 and 3 the inclusion  $0 \in \partial f(x^\circ)$  is sufficient for inf- $\theta$ -stationarity of  $f$  at  $x^\circ$ . The opposite implication is not true in general (see Examples 2 and 3).

In what follows  $f$  is assumed to be lower semicontinuous near  $x^\circ$ .

**Theorem 2**

- (i)  $\hat{\theta}[f](x^\circ) + \eta[f](x^\circ) \geq 0$ .
- (ii) *If  $X$  is Asplund, then*

$$\frac{\hat{\theta}[f](x^\circ)}{[1 + \hat{\theta}[f](x^\circ)]_+} + \eta[f](x^\circ) \leq 0.$$

This theorem follows from [10], Theorem 2. The first part of the theorem is elementary. The proof of the second part is based on the application of the two fundamental results of variational analysis: the *Ekeland variational principle* [2] and the *fuzzy sum rule* due to Fabian [3].

Thus, in an Asplund space the constants  $\hat{\theta}[f](x^\circ)$  and  $\eta[f](x^\circ)$  can be zero or nonzero only simultaneously. Recall that a Banach space is called *Asplund* (see [4,13,14]) if any continuous convex function on it

is Fréchet differentiable on a dense  $G_\delta$  subset. Note that in a Banach space  $\hat{\theta}[f](x^\circ) = \hat{\tau}[f](x^\circ)$  due to Theorem 1.

**Corollary 2**

- (i)  $\text{inf-}\eta\text{-stationarity} \Rightarrow \text{weak inf-}\theta\text{-stationarity}$ ;
- (ii)  $\text{strong inf-}\theta\text{-regularity} \Rightarrow \text{inf-}\eta\text{-regularity}$ ;
- (iii) If  $X$  is Asplund, then
  - $\text{weak inf-}\theta\text{-stationarity} \Leftrightarrow \text{weak inf-}\tau\text{-stationarity}$
  - $\Leftrightarrow \text{inf-}\eta\text{-stationarity}$ ;
  - $\text{strong inf-}\theta\text{-regularity} \Leftrightarrow \text{strong inf-}\tau\text{-regularity}$
  - $\Leftrightarrow \text{inf-}\eta\text{-regularity}$ .

**Differentiable Functions**

The constants and corresponding stationarity/regularity concepts defined above take quite a traditional form when the function is assumed differentiable or convex. Fortunately, the number of different constants and concepts reduces significantly.

**Theorem 3** *If  $f$  is Fréchet differentiable at  $x^\circ$  with the derivative  $\nabla f(x^\circ)$ , then*

$$\begin{aligned} \theta[f](x^\circ) &= \tau[f](x^\circ) = -\theta^+[f](x^\circ) \\ &= -\tau^+[f](x^\circ) = -\|\nabla f(x^\circ)\|. \end{aligned}$$

*If, additionally, the derivative is strict, then*

$$\begin{aligned} \hat{\theta}[f](x^\circ) &= \hat{\tau}[f](x^\circ) = -\hat{\theta}^+[f](x^\circ) \\ &= -\hat{\tau}^+[f](x^\circ) = -\|\nabla f(x^\circ)\|. \end{aligned}$$

Recall that  $f$  is called *strictly differentiable* [13,15] at  $x^\circ$  (with the derivative  $\nabla f(x^\circ)$ ) if

$$\lim_{x \rightarrow x^\circ, u \rightarrow x^\circ} \frac{f(u) - f(x) - \langle \nabla f(x^\circ), u - x \rangle}{\|u - x\|} = 0.$$

This condition is stronger than the traditional Fréchet differentiability. Thus, condition  $\nabla f(x^\circ) \neq 0$  does not guarantee strong regularity in the sense of Definition 1 (or Definition 2) unless  $f$  is strictly differentiable at  $x^\circ$ .

*Example 6* Take  $f(x) = x + x^2 \sin(1/x)$ , if  $x \neq 0$  and  $f(0) = 0$ . This function is everywhere Fréchet differentiable and  $\nabla f(0) = 1$ . Thus,  $f$  is regular at zero. At the same time  $\hat{\tau}[f](0) = \hat{\tau}^+[f](0) = 0$ : there exists a sequence  $x_k \rightarrow 0$  such that  $\nabla f(x_k) \rightarrow 0$ , and the assertion follows from Theorem 1, part (ii). Consequently,  $f$

is both weakly inf-stationary and weakly sup-stationary at zero.

**Corollary 3** *If  $f$  is Fréchet differentiable at  $x^\circ$  with the derivative  $\nabla f(x^\circ)$ , then the following conditions are equivalent:*

- (i)  $f$  is  $\text{inf-}\theta\text{-stationary}$  at  $x^\circ$ ;
- (ii)  $f$  is  $\text{inf-}\tau\text{-stationary}$  at  $x^\circ$ ;
- (iii)  $f$  is  $\theta\text{-stationary}$  at  $x^\circ$ ;
- (iv)  $f$  is  $\tau\text{-stationary}$  at  $x^\circ$ ;
- (v)  $\nabla f(x^\circ) = 0$ .

*If, additionally, the derivative is strict, then the above conditions are also equivalent to the following ones:*

- (vi)  $f$  is  $\text{weakly inf-}\theta\text{-stationary}$  at  $x^\circ$ ;
- (vii)  $f$  is  $\text{weakly inf-}\tau\text{-stationary}$  at  $x^\circ$ ;
- (viii)  $f$  is  $\text{weakly } \theta\text{-stationary}$  at  $x^\circ$ ;
- (xi)  $f$  is  $\text{weakly } \tau\text{-stationary}$  at  $x^\circ$ .

*Remark 4* Stationarity and weak stationarity in the above corollary can be replaced with regularity and strong regularity, respectively, if one replaces the equality in (v) with the inequality  $\nabla f(x^\circ) \neq 0$ .

**Convex Functions**

In the convex case, as one might expect, all versions of inf-stationarity coincide and appear to be equivalent to just (local and global) minimality.

**Theorem 4** *Let  $f$  be convex.*

- (i) *If  $\theta_\rho[f](x^\circ) < 0$  for some  $\rho > 0$ , then  $\theta_\rho[f](x^\circ) < 0$  for all  $\rho > 0$ .*
- (ii) *The functions  $\rho \rightarrow \theta_\rho[f](x^\circ)/\rho$  and  $\rho \rightarrow \theta_\rho^+[f](x^\circ)/\rho$  are nondecreasing on  $\mathbb{R}_+ \setminus \{0\}$ .*
- (iii) *The following equalities hold true:*

$$\begin{aligned} \hat{\theta}[f](x^\circ) &= \hat{\tau}[f](x^\circ) = \theta[f](x^\circ) = \tau[f](x^\circ) \\ &= \inf_{\rho > 0} \frac{\theta_\rho[f](x^\circ)}{\rho} = \inf_{x \neq x^\circ} \frac{[f(x) - f(x^\circ)]_-}{\|x - x^\circ\|}, \end{aligned}$$

$$\begin{aligned} \theta^+[f](x^\circ) &= \tau^+[f](x^\circ) = \inf_{\rho > 0} \frac{\theta_\rho^+[f](x^\circ)}{\rho} \\ &= \inf_{\rho > 0} \sup_{\|x - x^\circ\| = \rho} \frac{[f(x) - f(x^\circ)]_+}{\rho}. \end{aligned}$$

- (iv)  $\tau[f](x^\circ) + \tau^+[f](x^\circ) \geq 0$ .
- (v)  $\hat{\tau}[f](x^\circ) + \hat{\tau}^+[f](x^\circ) \geq 0$ .

(vi) If  $\tau[f](x^\circ) + \tau^+[f](x^\circ) = 0$  and  $\{x_k\} \subset X$  is a sequence defining  $\tau[f](x^\circ)$ , that is  $x_k \rightarrow 0$  and

$$\tau[f](x^\circ) = \lim_{k \rightarrow \infty} \frac{f(x^\circ + x_k) - f(x^\circ)}{\|x_k\|}$$

then  $\{-x_k\}$  is a sequence defining  $\tau^+[f](x^\circ)$ :

$$\tau^+[f](x^\circ) = \lim_{k \rightarrow \infty} \frac{f(x^\circ - x_k) - f(x^\circ)}{\|x_k\|}.$$

**Corollary 4** If  $f$  is convex, then the following conditions are equivalent:

- (i)  $f$  attains a global minimum at  $x^\circ$ ;
- (ii)  $f$  attains a local minimum at  $x^\circ$ ;
- (iii)  $f$  is  $\inf$ - $\theta$ -stationary at  $x^\circ$ ;
- (iv)  $f$  is  $\inf$ - $\tau$ -stationary at  $x^\circ$ ;
- (v)  $f$  is  $\theta$ -stationary at  $x^\circ$ ;
- (vi)  $f$  is  $\tau$ -stationary at  $x^\circ$ ;
- (vii)  $f$  is weakly  $\inf$ - $\theta$ -stationary at  $x^\circ$ ;
- (viii)  $f$  is weakly  $\inf$ - $\tau$ -stationary at  $x^\circ$ ;
- (ix)  $f$  is weakly stationary at  $x^\circ$ .

**Remark 5** The conditions  $\tau[f](x^\circ) = \tau^+[f](x^\circ) = 0$  imply Fréchet differentiability of  $f$  at  $x^\circ$  (with the derivative equal to zero). The weaker condition  $\tau[f](x^\circ) + \tau^+[f](x^\circ) = 0$  in Theorem 4, (vi) implies linearity of the directional derivative of  $f$  along the direction of steepest descent (if the latter exists) with the opposite direction being automatically the direction of steepest ascent. This condition is not sufficient for differentiability of  $f$  at  $x^\circ$  unless  $X = \mathbb{R}$ . Note also that the direction opposite to the direction of steepest ascent does not need to be a direction of steepest descent.

**Example 7** <sup>(1)</sup> Take the function  $f(x, y) = \max(x, y)$  on  $\mathbb{R}^2$  and assume that  $\mathbb{R}^2$  is equipped with the max type norm:  $\|x, y\| = \max(|x|, |y|)$ .  $f$  is obviously not differentiable at 0. At the same time  $\tau[f](0) = -1$ ,  $\tau^+[f](0) = 1$ . The vector  $(-1, -1)$  defines the (unique) direction of steepest descent. The opposite vector  $(1, 1)$  defines the direction of steepest ascent and  $f$  is linear along the line defined by these vectors. Note that the direction of steepest ascent is not unique. For instance, the vector  $(1, 0)$  also defines the direction of steepest ascent, while the opposite vector does not define the direction of steepest descent and  $f$  is not linear along this line.

<sup>1</sup>The example was suggested by Alexander Rubinov (personal communication).

**Remark 6** Stationarity and weak stationarity in assertions (iii)–(ix) of the above corollary can be replaced with regularity and strong regularity, respectively, if one replaces (i) and (ii) with the opposite assertions:  $x^\circ$  is not a point of (local or global) minimum of  $f$ .

## Introduction

Clustering is the *unsupervised* classification of the patterns. Cluster analysis deals with the problems of organization of a collection of patterns into clusters based on similarity. It has found many applications, including information retrieval, document extraction, image segmentation etc.

In cluster analysis we assume that we have been given a set  $A$  of a finite number of points of  $n$ -dimensional space  $\mathbb{R}^n$ , that is

$$A = \{a^1, \dots, a^m\}, \text{ where } a^i \in \mathbb{R}^n, \quad i = 1, \dots, m.$$

The subject of cluster analysis is the partition of the set  $A$  into a given number  $q$  of overlapping or disjoint subsets  $C_i, i = 1, \dots, q$  with respect to predefined criteria such that

$$A = \bigcup_{i=1}^q C_i.$$

The sets  $C_i, i = 1, \dots, q$  are called clusters. The clustering problem is said to be *hard clustering* if every data point belongs to one and only one cluster. Unlike hard clustering in the *fuzzy clustering* problem the clusters are allowed to overlap and instances have degrees of appearance in each cluster. In this paper we will

exclusively consider the hard unconstrained clustering problem, that is we additionally assume that

$$C_i \cap C_k = \emptyset, \quad \forall i, k = 1, \dots, q, \quad i \neq k.$$

and no constraints are imposed on the clusters  $C_i, i = 1, \dots, q$ . Thus every point  $a \in A$  is contained in exactly one and only one set  $C_i$ .

Each cluster  $C_i$  can be identified by its center (or centroid). Then the clustering problem can be reduced to the following optimization problem (see [12,26]):

$$\begin{aligned} \text{minimize } \varphi(C, x) &= \frac{1}{m} \sum_{i=1}^q \sum_{a \in C_i} \|x^i - a\|^2 \quad (1) \\ \text{subject to } C &\in \bar{C}, \quad x = (x^1, \dots, x^q) \in \mathbb{R}^{n \times q} \end{aligned}$$

where  $\|\cdot\|$  denotes the Euclidean norm,  $C = \{C_1, \dots, C_q\}$  is a set of clusters,  $\bar{C}$  is a set of all possible  $q$ -partitions of the set  $A$ ,  $x^i$  is the center of the cluster  $C_i, i = 1, \dots, q$ :

$$x^i = \frac{1}{|C_i|} \sum_{a \in C_i} a,$$

and  $|C_i|$  is a cardinality of the set  $C_i, i = 1, \dots, q$ . The problem (1) is also known as the minimum sum-of-squares clustering. The combinatorial formulation (1) of the minimum sum-of-squares clustering is not suitable for direct application of mathematical programming techniques. The problem (1) can be rewritten as the following mathematical programming problem:

$$\begin{aligned} \text{minimize } \psi(x, w) &= \frac{1}{m} \sum_{i=1}^m \sum_{j=1}^q w_{ij} \|x^j - a^i\|^2 \quad (2) \\ \text{subject to } \sum_{j=1}^q w_{ij} &= 1, \quad i = 1, \dots, m, \end{aligned}$$

and

$$w_{ij} \in \{0, 1\}, \quad i = 1, \dots, m, \quad j = 1, \dots, q.$$

Here

$$x^j = \frac{\sum_{i=1}^m w_{ij} a^i}{\sum_{i=1}^m w_{ij}}, \quad j = 1, \dots, q$$

and  $w_{ij}$  is the association weight of pattern  $a_i$  with cluster  $j$  (to be found), given by

$$w_{ij} = \begin{cases} 1 & \text{if pattern } a^i \text{ is allocated to cluster } j \\ 0 & \text{otherwise.} \end{cases}$$

$w$  is an  $m \times q$  matrix.

There exist different approaches to clustering including agglomerative and divisive hierarchical clustering algorithms as well as algorithms based on mathematical programming techniques. Descriptions of many of these algorithms can be found, for example, in [15,20,21,26].

Problem (2) is a global optimization problem. Therefore different algorithms of mathematical programming can be applied to solve this problem. Some review of these algorithms can be found in [16]. However, most of these algorithms are applicable for clustering on small data sets.

Different heuristics can be used for solving clustering problems on large data sets and  $k$ -means is one such algorithm. Different versions of this algorithm have been studied by many authors (see [26]). This is a fast algorithm.  $k$ -means gives good results when there are few clusters but deteriorates when there are many [16]. This algorithm achieves a local minimum of problem (1) (see [24]), however results of numerical experiments presented, for example, in [19] show that the best clustering found with  $k$ -means may be more than 50% worse than the best known one.

Much better results have been obtained with metaheuristics, such as simulated annealing, tabu search and genetic algorithms [23]. The simulated annealing approaches to clustering have been studied, for example, in [13,25,27]. Application of tabu search methods for solving clustering problem is studied in [1]. Genetic algorithms for clustering have been described in [23]. The results of numerical experiments, presented in paper [2] show that even for small problems of cluster analysis when the number of entities  $m \leq 100$  and the number of clusters  $q \leq 5$  these algorithms take 500–700 (sometimes several thousands) times more CPU time than the  $k$ -means algorithms. For relatively large data sets one can expect that this difference will increase. This makes metaheuristic algorithms of global optimization ineffective for solving many clustering problems.

The paper [18] develops variable neighborhood search algorithm and the paper [17] presents  $j$ -means algorithm which extends  $k$ -means by adding a jump move. The global  $k$ -means heuristic, which is an incremental approach to minimum sum-of-squares clustering problem, is developed in [22]. The incremental approach is also studied in the paper [19]. Results of

numerical experiments presented show the high effectiveness of these algorithms for many clustering problems.

As mentioned above the problem (2) is the global optimization problem and the objective function in this problem is multimodal. However, global optimization techniques are highly time-consuming for solving many clustering problems. It is very important, therefore, to develop clustering algorithms that compute near global minimizers of the objective function. We propose the clustering algorithms based on nonsmooth optimization approach. The algorithms provide the capability of calculating clusters step-by-step, gradually increasing the number of data clusters until termination conditions are met, that is it allows one to calculate as many cluster as a data set contains with respect to some tolerance.

### Formulation

The problems (1) and (2) can be reformulated as the following mathematical programming problem [7,8,12]

$$\begin{aligned} & \text{minimize } f(x^1, \dots, x^q) \\ & \text{subject to } x = (x^1, \dots, x^q) \in \mathbb{R}^{n \times q}, \end{aligned} \quad (3)$$

where

$$f(x^1, \dots, x^q) = \frac{1}{m} \sum_{i=1}^m \min_{j=1, \dots, q} \|x^j - a^i\|^2. \quad (4)$$

It is shown in [12] that problems (2) and (3) are equivalent. However, there are some differences between these two formulations:

- The number of variables in problem (2) is  $(m+n) \times q$  whereas in problem (3) this number is only  $n \times q$  and the number of variables does not depend on the number of instances. It should be noted that in many real-world databases the number of instances  $m$  is substantially greater than the number of attributes  $n$ .
- In the hard clustering problem (2) the coefficients  $w_{ij}$  are integer, that is the problem (2) contains both integer and continuous variables. In the nonsmooth optimization formulation variables are only continuous.
- Nonsmooth optimization formulation of the clustering problem allows one to easily consider different similarity measures.

All these circumstances can be considered as advantages of the nonsmooth optimization formulation (3).

If  $q > 1$ , the objective function (4) in problem (3) is nonconvex and nonsmooth. If the number  $q$  of clusters and the number  $n$  of attributes are large, we have a large-scale global optimization problem. Moreover, the form of the objective function in this problem is complex enough not to be amenable to the direct application of general purpose global optimization methods. Therefore, in order to ensure the practicality of the nonsmooth optimization approach to clustering, proper identification and use of local optimization methods is very important. Clearly, such an approach does not guarantee a globally optimal solution to problem (3). On the other hand, this approach provides a “near” global minimum of the objective function that, in turn, provides a good enough clustering description of the data set under consideration.

Note also that a meaningful choice of the number of clusters is very important for clustering analysis. It is difficult to define *a priori* how many clusters represent the set  $A$  under consideration. In order to avoid this difficulty, a step-by-step calculation of clusters is implemented in algorithms discussed in the next section.

**Methods**

In this section we will describe two incremental clustering algorithms. Both algorithms are based on nonsmooth optimization approach to clustering. In the first algorithm nonsmooth optimization approach is used to find starting points for  $k$ -means algorithm. This algorithm is a modification of the global  $k$ -means algorithm proposed in [22]. The second algorithm is an optimization based clustering algorithm.

**Modified Global  $k$ -Means Algorithm**

$k$ -means algorithm and its different variations are known to be fast algorithms for clustering and they are applicable to large data sets. In this subsection we propose a new version of  $k$ -means algorithm: the modified global  $k$ -means algorithm, which in its turn is the modification of the global  $k$ -means algorithm. First we briefly describe  $k$ -means and the global  $k$ -means algorithms.

$k$ -means algorithm proceeds as follows

*Step 1.* Choose a seed solution consisting of  $k$  centroids (not necessarily belonging to  $A$ ).

*Step 2.* Allocate data points  $a^i \in A$  to its closest centroid and obtain  $k$ -partition of  $A$ .

*Step 3.* Recompute centroids for this new partition and go to to Step 2 until no more data points change their clusters.

**Nonsmooth Optimization Approach to Clustering, Algorithm 1**

**$k$ -means algorithm**

*Step 1.* Compute the centroid  $x^1$  of the set  $A$ :

$$x^1 = \frac{1}{m} \sum_{i=1}^m a^i$$

and set  $k = 1$ .

*Step 2.* Set  $k = k + 1$  and consider the centers  $x^1, x^2, \dots, x^{k-1}$  from the previous iteration.

*Step 3.* Consider each point  $a$  of  $A$  as a starting point for the  $k$ -th cluster center, thus obtaining  $m$  initial solutions with  $k$  points  $(x^1, x^2, \dots, x^{k-1}, a)$ ; apply  $k$ -means algorithm starting from each of them; keep the best  $k$ -partition obtained and its center  $(x^1, x^2, \dots, x^{k-1}, x^k)$ .

*Step 4.* If  $k = q$  stop, otherwise go to Step 2.

**Nonsmooth Optimization Approach to Clustering, Algorithm 2**

**The global  $k$ -means algorithm**

The effectiveness of this algorithm highly depends on a starting point. It converges only to a local solution which can significantly differ from the global one in large data sets.

The global  $k$ -means algorithm proposed in [22] is the modification of  $k$ -means algorithm and it computes clusters successively that is in order to compute  $k$ -th cluster centroid this algorithm uses centroids of  $k - 1$  clusters from the previous iteration. To compute  $q \leq m$  clusters this algorithm proceeds as follows.

This version of the algorithm is not applicable for clustering on middle sized and large data sets. Two

procedures were introduced to reduce its complexity (see [22]). We mention here only one of them. Let

$$d_{k-1}^i = \min \left\{ \|x^1 - a^i\|^2, \dots, \|x^{k-1} - a^i\|^2 \right\}. \quad (5)$$

For each  $a^i \in A$  we compute:

$$r_i = \sum_{j=1}^m \min \{0, \|a^i - a^j\|^2 - d_{k-1}^j\}$$

and we take the data point  $a^l \in A$  for which

$$l = \operatorname{argmin}_{i=1, \dots, m} r_i.$$

Then  $k$ -means algorithm is applied starting from the point  $(x^1, x^2, \dots, x^{k-1}, a^l)$  to find  $k$  cluster centers.

Now we will describe a new version of the global  $k$ -means algorithm where a starting point for  $k$ -th cluster center is computed using nonsmooth optimization approach. Let us consider the problem of finding  $k$  cluster center assuming that the centers  $x^1, \dots, x^{k-1}$  for  $(k-1)$ -clustering problem are known. We introduce the following function:

$$\bar{f}^k(y) = \frac{1}{m} \sum_{i=1}^m \min \{d_{k-1}^i, \|y - a^i\|^2\} \quad (6)$$

where  $y \in \mathbb{R}^n$  stands for  $k$ -th cluster center and  $d_{k-1}^i$  is defined as in (5). Consider a set

$$\bar{D} = \{y \in \mathbb{R}^n : \|y - a^i\|^2 \geq d_{k-1}^i\}.$$

This is a set where the distance from any point  $y$  to any data point is no less than the distance between this data point and its cluster center. We also consider the following set

$$D_0 = \mathbb{R}^n \setminus \bar{D} \equiv \left\{ y \in \mathbb{R}^n : \exists I \subset \{1, \dots, m\}, \right. \\ \left. I \neq \emptyset : \|y - a^i\| < d_{k-1}^i \forall i \in I \right\}.$$

The function  $\bar{f}^k$  is a constant on the set  $\bar{D}$  and its value over this set is

$$\bar{f}^k(y) = d_0 \equiv \frac{1}{m} \sum_{i=1}^m d_{k-1}^i, \quad \forall y \in \bar{D}.$$

It is clear that  $x^j \in \bar{D}$  for all  $j = 1, \dots, k-1$  and  $a^i \in D_0$  for all  $a^i \in A$ ,  $a^i \neq x^j$ ,  $j = 1, \dots, k-1$ . It is also clear that  $f(y) < d_0$  for all  $y \in D_0$ .

*Step 1.* For any  $a^i \in D_0 \cap A$  calculate the set  $S_2(a^i)$ , the centroid  $c^i$  of this set and calculate the value  $\bar{f}^k(c^i)$  of the function  $\bar{f}^k$  at this point.

*Step 2.* Compute

$$\bar{f}_{min}^k = \min_{a^i \in D_0 \cap A} \bar{f}^k(c^i), \\ a^j = \operatorname{argmin}_{a^i \in D_0 \cap A} \bar{f}^k(c^i).$$

and the corresponding center  $c^j$ .

*Step 3.* Compute the set  $S_2(c^j)$  and its centroid.

*Step 4.* Recompute the set  $S_2(c^j)$  and its centroid until no more data points escape this set or return to this set.

### Nonsmooth Optimization Approach to Clustering, Algorithm 3

#### An algorithm for finding the initial point

Any point  $y \in D_0$  can be taken as a starting point for the  $k$ -th cluster center. Probably more preferably among them is a global minimizer of the function  $\bar{f}^k$ . This function is a nonconvex and nonsmooth and its minimization is difficult task. We consider a scheme for finding its local minimizer.

For any  $y \in D_0$  we consider the following sets:

$$S_1(y) = \{a^i \in A : \|y - a^i\|^2 = d_{k-1}^i\}, \\ S_2(y) = \{a^i \in A : \|y - a^i\|^2 < d_{k-1}^i\}, \\ S_3(y) = \{a^i \in A : \|y - a^i\|^2 > d_{k-1}^i\}.$$

Since  $y \in D_0$  the set  $S_2(y) \neq \emptyset$ . We suggest the following algorithm to find a starting point for the  $k$ -th cluster center.

Now we can describe the modified global  $k$ -means algorithm.

It is clear that  $f^{k*} \geq 0$  for all  $k \geq 1$  and the sequence  $\{f^{k*}\}$  is decreasing, that is,

$$f^{k+1,*} \leq f^{k,*} \text{ for all } k \geq 1.$$

The latter implies that after  $\bar{k} > 0$  iterations the stopping criterion in Step 4 will be satisfied.

*Step 1.* (Initialization). Select a tolerance  $\varepsilon > 0$ . Calculate the centroid  $x^{1*} \in \mathbb{R}^n$  of the set  $A$ . Let  $f^{1*}$  be the corresponding value of the objective function (4). Set  $k = 1$ .

*Step 2.* (Computation of the next cluster center). Let  $x^{1*}, \dots, x^{k*}$  be the cluster centers for  $k$  clustering problem. Apply Algorithm 3 to find an initial point  $y^{k+1,0} \in \mathbb{R}^n$  for the  $k + 1$ -th cluster center.

*Step 3.* (Refinement of all cluster centers). Take  $x^{k+1,0} = (x^{1*}, \dots, x^{k*}, y^{k+1,0})$  as a new starting point, apply  $k$ -means algorithm to solve clustering problem for  $q = k + 1$ . Let  $x^{1*}, \dots, x^{k+1,*}$  be a solution to this problem and  $f^{k+1,*}$  be the corresponding value of the objective function (4).

*Step 4.* (Stopping criterion). If

$$\frac{f^{k*} - f^{k+1,*}}{f^{1*}} < \varepsilon$$

then stop, otherwise set  $k = k + 1$  and go to Step 2.

**Nonsmooth Optimization Approach to Clustering, Algorithm 4**  
**Modified global  $k$ -means algorithm**

**Nonsmooth Optimization Clustering Algorithm**

In this subsection we propose an algorithm for clustering where nonsmooth optimization techniques are used to find a starting point for the  $k$  cluster center and to solve  $k$ -clustering problems.

It is clear that  $f^{k*} \geq 0$  for all  $k \geq 1$  and the sequence  $\{f^{k*}\}$  is decreasing that is,

$$f^{k+1,*} \leq f^{k,*} \text{ for all } k \geq 1.$$

The latter implies that after  $\bar{k} > 0$  iterations the stopping criterion in Step 4 will be satisfied.

*Remark 1* One of the important questions when one tries to apply Algorithms 4 and 5 is the choice of the tolerance  $\varepsilon > 0$ . Large values of  $\varepsilon$  can result in the appearance of large clusters whereas small values can produce small and artificial clusters.

*Remark 2* Algorithms 2, 4 and 5 are incremental clustering algorithms. Main difference between Algorithms 2 and 4 is in the way they compute starting

*Step 1.* (Initialization). Select a tolerance  $\varepsilon > 0$ . Calculate the centroid  $x^{1*} \in \mathbb{R}^n$  of the set  $A$ . Let  $f^{1*}$  be the corresponding value of the objective function (4). Set  $k = 1$ .

*Step 2.* (Computation of the next cluster center). Select a point  $y^0 \in \mathbb{R}^n$  and solve the following minimization problem:

$$\text{minimize } \bar{f}^k(y) \text{ subject to } y \in \mathbb{R}^n \quad (7)$$

where  $\bar{f}^k$  is defined by (6).

*Step 3.* (Refinement of all cluster centers). Let  $\bar{y}^{k+1,*}$  be a solution to problem (7). Take  $x^{k+1,0} = (x^{1*}, \dots, x^{k*}, \bar{y}^{k+1,*})$  as a new starting point and solve the following minimization problem:

$$\begin{aligned} &\text{minimize } f^{k+1}(x) \text{ subject to} \\ &x = (x^1, \dots, x^{k+1}) \in \mathbb{R}^{n \times (k+1)} \end{aligned} \quad (8)$$

where

$$f^{k+1}(a) = \frac{1}{m} \sum_{i=1}^m \min_{j=1, \dots, k+1} \|x^j - a^i\|^2.$$

*Step 4.* (Stopping criterion). Let  $x^{k+1,*}$  be a solution to the problem (8) and  $f^{k+1,*}$  be the corresponding value of the objective function. If

$$\frac{f^{k*} - f^{k+1,*}}{f^{1*}} < \varepsilon$$

then stop, otherwise set  $k = k + 1$  and go to Step 2.

**Nonsmooth Optimization Approach to Clustering, Algorithm 5**  
**Nonsmooth optimization clustering algorithm**

points for the next cluster center. Algorithm 2 uses data points whereas Algorithm 4 uses local minimizers of the function  $\bar{f}^k$ . Algorithm 5 uses nonsmooth optimization techniques for the finding of both starting points and  $k$ -partition of a data set.

*Remark 3* Computational results on gene expression data sets presented in [6] demonstrate that Algorithm 4 is more efficient than Algorithm 2. However, the former requires more computational time.

*Remark 4* Results of numerical experiments presented in [11] demonstrate that Algorithm 5 is efficient for solving large scale clustering problems in a reasonable CPU time. Moreover, its success to locate global solutions is higher than that for Algorithms 2 and 4. However, this algorithm requires significantly more CPU time than other algorithms.

### Solving Optimization Problems

The objective functions in problems (7) and (8) are nonsmooth and nonconvex. If the number of attributes and clusters are large then the problem (8) is large scale problem. Both objective functions are non-regular and the computation of even one their subgradient may become very difficult problem (for the definition of non-regular function, see [14]). Therefore, subgradient-based methods are not always efficient for solving problems (7) and (8). We use the discrete gradient method to solve these problems [3,4,5]. This is a derivative free method.

The objective functions in problems (7) and (8) are piecewise partially separable (for the definition of piecewise partially separable functions, see [9]). The discrete gradient method was modified taking into account this special structure of the objective functions. This modified discrete gradient method is described in [10].

### Conclusions

In this paper we discussed a nonsmooth optimization approach to clustering problems. Many clustering problems are large scale global optimization problems. The nonsmooth optimization approach allows one to significantly reduce the number of variables in this problem. It also can easily handle different similarity measures.

We introduced two algorithms based on the nonsmooth optimization approach. Both algorithms are incremental clustering algorithms. As these algorithms compute clusters step by step, they allow the decision maker to easily vary the number of clusters according to the criteria suggested by the nature of the decision making situation not incurring the obvious costs of the increased complexity of the solution procedure. The suggested approach utilizes a stopping criterion that prevents the appearance of small and artificial clusters. Nonsmooth optimization problems from cluster anal-

ysis have special structure which allows one to design efficient algorithms for their solution.

the *variational inequalities* (abbreviated: VI) are to find an  $x^* \in X$  such that

$$(x - x^*)^\top F(x^*) \geq 0, \quad \forall x \in X. \tag{1}$$

When  $X = \mathbf{R}_+^n$  (the positive orthant), (1) is equivalent to the *nonlinear complementarity problem* (abbreviated: NCP): Find  $x^* \in \mathbf{R}^n$  such that

$$x^* \geq 0, \quad F(x^*) \geq 0, \quad x^{*\top} F(x^*) = 0. \tag{2}$$

Usually,  $X$  is represented by several inequalities and equalities. By considering the Karush–Kuhn–Tucker (KKT) conditions of (1) if necessary,  $X$  is assumed to be a closed convex subset of  $\mathbf{R}^n$  here. It has been proved by B.C. Eaves in [9] that solving (1) is equivalent to finding a solution of the equation

$$H(x) := x - \Pi_X[x - F(x)] = 0, \tag{3}$$

where  $\Pi_X$  is the orthogonal projection onto  $X$ . When  $X = \mathbf{R}_+^n$ , (3) becomes

$$H(x) = \min(x, F(x)) = 0, \tag{4}$$

where the operation  $\min$  is taken componentwisely. This means that finding a solution of NCP is equivalent to finding a root of (4). It also has been shown by A. Fischer in [10] that finding a solution of NCP is equivalent to finding a root of another equation, namely of:

$$H_i(x) := \phi(x_i, F_i(x)) = 0, \quad i = 1, \dots, n, \tag{5}$$

where  $\phi$  is called the *Fischer–Burmeister function* (FB function), defined in [10] as

$$\phi(a, b) = \sqrt{a^2 + b^2} - (a + b), \quad a, b \in \mathbf{R}.$$

Due to the nonsmoothness of the orthogonal projection operator  $\Pi_X$ , the  $\min$  function and the FB function, the function  $H$  defined either in (3), in (4) or in (5) is, in general, not smooth (i. e. continuously differentiable) no matter how smooth  $F$  is. This prevents one from using classical Newton methods to find solutions of these (nonsmooth) equations.

Suppose that  $H: \mathbf{R}^n \rightarrow \mathbf{R}^n$  is a locally Lipschitz function (the function  $H$  defined in either (3), (4) or (5) is a locally Lipschitz function) but is not necessarily smooth. By Rademacher’s theorem,  $H$  is almost everywhere differentiable. Let

$$D_H = \{x: H \text{ is differentiable at } x\}.$$

## Nonsmooth and Smoothing Methods for Nonlinear Complementarity Problems and Variational Inequalities

Given a nonempty closed set  $X \subset \mathbf{R}^n$  and a mapping  $F: \mathbf{R}^n \rightarrow \mathbf{R}^n$ , assumed to be continuously differentiable,

Then the generalized Jacobian of  $H$  at  $x$  in the sense of F.H. Clarke [6] can be defined by

$$\partial H(x) = \text{conv } \partial_B H(x),$$

where  $\partial_B H(x)$  [20] is defined by

$$\partial_B H(x) = \left\{ \lim_{\substack{x^j \rightarrow x \\ x^j \in D_H}} H'(x^j) \right\}.$$

The nonsmooth Newton method for solving

$$H(x) = 0, \quad x \in \mathbf{R}^n, \tag{6}$$

can be defined as follows: Having the vector  $x^k \in \mathbf{R}^n$ , compute  $x^{k+1}$  by

$$x^{k+1} = x^k - V_k^{-1} H(x^k), \tag{7}$$

where  $V_k \in \partial H(x^k)$ . The nonsmooth Newton method (7) reduces to the classical Newton method for a system of equations if  $H$  is continuously differentiable. The classical Newton method has the favorable feature that the sequence  $\{x^k\}$  generated by (7) is locally superlinearly (quadratically) convergent to a solution  $x^*$  of  $H(x) = 0$  if  $H'(x^*)$  is nonsingular (and  $H'$  is Lipschitz continuous) [8,18]. However, in general the iterative method (7) is not convergent for nonsmooth equations (6). See [16] for a counterexample.

In order to establish some superlinearly convergent results for the nonsmooth Newton method (7), we use the concept of *semismoothness*. Let  $H$  be directionally differentiable at  $x$ .  $H$  is said to be *semismooth* at  $x$  if

$$Vd - H'(x; d) = o(\|d\|), \quad d \rightarrow 0,$$

and  $H$  is called *strongly semismooth* at  $x$  if

$$Vd - H'(x; d) = O(\|d\|^2), \quad d \rightarrow 0,$$

where  $V \in \partial H(x + d)$ . Semismoothness was originally introduced by R. Mifflin [17] for functionals. L. Qi and J. Sun [24] extended the concept of semismoothness to vector-valued functions. See [19] for several forms of semismooth equations. Using semismoothness, they [24] presented the following convergence theorem for the generalized Newton method (7):

**Theorem 1** *Suppose that  $H(x^*) = 0$  and that all  $V \in \partial H(x^*)$  are nonsingular. Then the generalized Newton*

*method (7) is Q-superlinearly convergent in a neighborhood of  $x^*$  if  $H$  is semismooth at  $x^*$ , and quadratically convergent if  $H$  is strongly semismooth at  $x^*$ .*

Note that the nonsingularity of  $\partial H(x^*)$  in the above theorem is somewhat restrictive in some cases. Qi [20] presented a modified version of (7), which may be stated as follows

$$x^{k+1} = x^k - V_k^{-1} H(x^k), \tag{8}$$

where  $V_k \in \partial_B H(x^k)$ . The difference of this version from (7) is that  $V_k$  is chosen from  $\partial_B H(x^k)$  rather than the convex hull of  $\partial_B H(x^k)$ . Analogous to the above theorem, Qi [20] established the following result:

**Theorem 2** *Suppose that  $H(x^*) = 0$  and that all  $V \in \partial_B H(x^*)$  are nonsingular. Then the generalized Newton method (8) is Q-superlinearly convergent in a neighborhood of  $x^*$  if  $H$  is semismooth at  $x^*$ , and quadratically convergent at  $x^*$  if  $H$  is strongly semismooth at  $x^*$ .*

In general, neither (7) nor (8) can be globalized because  $\theta$  is not necessarily continuously differentiable, where for any  $x \in \mathbf{R}^n$ ,  $\theta(x) = \|H(x)\|^2/2$ . However, if  $\theta$  is continuously differentiable (e. g.,  $\theta$  is defined via (5); [14]), the nonsmooth Newton direction is a descent direction of  $\theta$  and thus globalized methods can be designed. See [7] for a line search model and [13] for a trust region model.

The feature of *smoothing methods* is to construct a smoothing approximation function  $G: \mathbf{R}^n \times \mathbf{R}_{++} \rightarrow \mathbf{R}^n$  of  $H$  such that for any  $\varepsilon > 0$  and  $x \in \mathbf{R}^n$ ,  $G(\varepsilon, \cdot)$  is continuously differentiable on  $\mathbf{R}^n$  and satisfies

$$\|H(x) - G(\varepsilon, x)\| \rightarrow 0 \quad \text{as } \varepsilon \downarrow 0, \tag{9}$$

and then to find a solution of  $H(x) = 0$  by (inexactly) solving the following problems for a given positive sequence  $\{\varepsilon^k\}$  with  $\varepsilon^k \rightarrow 0$  as  $k \rightarrow \infty$ ,

$$G(\varepsilon^k, x) = 0. \tag{10}$$

It was suggested in [21] to use the convolution to construct smooth approximations of the nonsmooth function  $H$ . A function  $\Phi: \mathbf{R}^n \rightarrow \mathbf{R}_+$  is called a *kernel function* if

$$\int_{\mathbf{R}^n} \Phi(x) \, dx = 1.$$

Suppose  $\Phi$  is a smooth kernel function. Define  $\Theta: \mathbf{R}_{++} \times \mathbf{R}^n \rightarrow \mathbf{R}_+$  by

$$\Theta(\varepsilon, x) = \varepsilon^{-n} \Phi(\varepsilon^{-1}x),$$

where  $(\varepsilon, x) \in \mathbf{R}_{++} \times \mathbf{R}^n$ . Then a smooth approximation of the projection operator  $\Pi_X$  can be described by

$$P(\varepsilon, x) = \int_{\mathbf{R}^n} \Pi_X(x - y)\Theta(\varepsilon, y) dy, \tag{11}$$

where  $(\varepsilon, x) \in \mathbf{R}_{++} \times \mathbf{R}^n$ . Suppose that

$$\kappa := \int_{\mathbf{R}^n} \|y\| \Phi(y) dy < +\infty.$$

Then for any  $x \in \mathbf{R}^n$  and  $\varepsilon > 0$  one has

$$\|P(\varepsilon, x) - \Pi_X(x)\| \leq \kappa \varepsilon.$$

In general,  $P(\varepsilon, x)$  is intractable because a multidimensional integration is involved. However, it can be written explicitly if  $X$  is of special structure (for example,  $X$  is a rectangular) and  $\Phi$  is chosen particularly (see [3,12]). In fact, already in 1986 S. Smale [26] gave a smooth function  $\frac{(w + \sqrt{w^2 + \varepsilon^2})}{2}$  to approximate  $\max(0, w)$ ,  $w \in \mathbf{R}$ , and used it to study linear complementarity problems. Also see [2,15]. The paper [1] stimulates much recent study about smoothing methods for solving NCP and VI. For the convenience of discussion, for any  $\varepsilon < 0$ , define  $P(\varepsilon, x) = P(-\varepsilon, x)$  and  $P(0, x) = \Pi_X(x)$ ,  $x \in \mathbf{R}$ . Then the smooth approximation  $G: \mathbf{R}^{n+1} \rightarrow \mathbf{R}^n$  of  $H$  defined in (6) can be described by

$$G(\varepsilon, x) = x - P(\varepsilon, x - F(x)), \tag{12}$$

where  $(\varepsilon, x) \in \mathbf{R} \times \mathbf{R}^n$ . Thus, for any  $(\varepsilon, x) \in \mathbf{R} \times \mathbf{R}^n$ ,

$$\|G(\varepsilon, x) - H(x)\| \leq \kappa \varepsilon.$$

See [21] for a general case if  $H$  is not of the form defined in (3).

Note that, for variational inequalities, if the function  $F$  is only defined on  $X$  and not well defined outside  $X$ , then the function  $H$  defined in (3) is not well defined on  $\mathbf{R}^n$ . In this case, one can use the normal map introduced by S.M. Robinson [25] to overcome this difficulty. It is also noted that solving (1) is equivalent to finding a solution of the equation

$$H(x) := x - \Pi_X[x - F(\Pi_X(x))] = 0, \tag{13}$$

where  $x \in \mathbf{R}^n$ . The above-defined  $H$  only requires  $F$  being defined on  $X$  instead of on  $\mathbf{R}^n$  as required by the function defined in (3). Unlike Robinson's normal map, the above map does not need to work on a transformed space, it works on the original space directly. By using the definition of  $P$ , the smoothing approximation  $G: \mathbf{R}^{n+1} \rightarrow \mathbf{R}^n$  of  $H$  defined in (13) can be described by

$$G(\varepsilon, x) = x - P(\varepsilon, x - F(P(\varepsilon, x))), \tag{14}$$

where  $(\varepsilon, x) \in \mathbf{R} \times \mathbf{R}^n$ .

The first globally and superlinearly (quadratically) convergent smoothing Newton method was proposed by X. Chen, Qi and D. Sun in [4], where the authors exploited a *Jacobian consistency property* and applied this property to an infinite sequence of smoothing approximation functions to get high-order convergent methods. The smoothing function defined by (12) satisfies the Jacobian consistency property while the one defined in (14) does not satisfy this property. The method in [4] was further studied by Chen and Y. Ye in [5].

Suppose that  $G: \mathbf{R}^{n+1} \rightarrow \mathbf{R}^n$  is a smoothing approximation of  $H$ . Define  $E: \mathbf{R}^n \rightarrow \mathbf{R}^n$  by

$$E(z) := \begin{pmatrix} \varepsilon \\ G(\varepsilon, x) \end{pmatrix}, \tag{15}$$

where  $z := (\varepsilon, x) \in \mathbf{R} \times \mathbf{R}^n$ . Then solving  $H(x) = 0$  is equivalent to finding a solution of  $E(z) = 0$ . Note that  $E$  is continuously differentiable at any  $(\varepsilon, x) \in \mathbf{R} \times \mathbf{R}^n$  with  $\varepsilon \neq 0$  and is possibly nonsmooth at  $(0, x) \in \mathbf{R} \times \mathbf{R}^n$ . We call  $E$  a *smoothing-nonsmooth reformulation* of  $H$ . Then classical Newton methods for solving smoothing equations can be used to solve  $E(z) = 0$  with one additional requirement:  $\varepsilon$  must be positive during the process of iteration. The latter can be done by solving a slightly modified Newton equation:

$$E(z) + E'(z)\Delta z = \beta \bar{z}, \tag{16}$$

where  $\beta \in (0, \infty)$  and  $\bar{z} := (\bar{\varepsilon}, 0)$  with  $\bar{\varepsilon} > 0$ . It is obvious that one should control  $\varepsilon$  such that it neither converges too fast (no stronger global convergence results guaranteed) nor too slow (no fast local convergence results guaranteed). A special line search model involving  $\beta$  and  $\bar{z}$  was designed in [23] to achieve this: Choose  $\bar{\varepsilon} \in \mathbf{R}_{++}$  and  $\gamma \in (0, 1)$  such that  $\gamma \bar{\varepsilon} < 1$ . Choose constants  $\delta, \sigma \in (0, 1)$ . Let  $\varepsilon^0 := \bar{\varepsilon}$ ,  $x^0 \in \mathbf{R}^n$  be an arbitrary point. For  $k = 0, 1, \dots$ , find a solution  $\Delta z^k$  of (16) with

$z := z^k$  and  $\beta := \gamma \min\{1, e(z)\}$ , where for any  $y \in \mathbf{R}^{n+1}$ ,  $e(y) = \|E(y)\|^2$ . Let  $l_k$  be the smallest nonnegative integer  $l$  satisfying

$$e(z^k + \delta^l \Delta z^k) \leq [1 - 2\sigma(1 - \gamma\bar{\varepsilon})\delta^l]e(z^k).$$

Define  $z^k := z^k + \delta^{l_k} \Delta z^k$ . It is often verified that  $G$  is also semismooth everywhere jointly with  $\varepsilon$  and  $x$  [23]. So the semismooth theory of nonsmooth Newton methods for solving nonsmooth equations can be used to obtain superlinear (quadratic) convergence of  $(\varepsilon, x)$  for the above smoothing Newton method while the global convergence is based on the particular designed line search. See [23] for details.

## Conclusion

In this paper semismooth Newton methods and smoothing Newton methods for solving NCP and VI based on nonsmooth equations have been briefly reviewed. These topics are still undergoing a very fast development. See [22] for an up-to-date review. Another nonsmooth approach for solving NCP and VI is to reformulate these problems as unconstrained optimization problems whose objective functions are once but not twice differentiable, (see [11]).

Computational complexity; Reducibility; Polynomial time reduction; NP-hard problem; NP-complete problem; strong NP-completeness; ordinary NP-completeness

Given a combinatorial problem, one tries to exploit its structure so as to develop a solution algorithm that guarantees identifying an optimal solution for every instance of the problem. For some problems, the inherent structure is such that one can develop an algorithm that progressively builds an optimal solution, or selects among a small number of candidate solutions. Such algorithms are quite desirable as their computer time requirements are small, and often a bounded polynomial function of the number  $n$  of parameters needed to specify the problem (e. g.  $\mathcal{O}(n)$  or  $\mathcal{O}(n^2)$ ; see [9] for details on algorithmic *complexity*). Thus, such algorithms are called *polynomial algorithms*. Problems solv-

able by a polynomial algorithm may be solved quickly on a computer.

Unfortunately, not all combinatorial problems possess enough structure to allow for a polynomial algorithm. Hence, when we encounter a new problem for which we cannot identify enough structure, we would like to know whether this lack of structure is due to the problem itself, or to incomplete analysis. To address this issue, one idea is to compare the structure of the problem at hand with the structure of other well known and notoriously hard problems; such problems are known in literature as *NP-complete problems*. Specifically, if we can show that our problem is 'equivalent' to an NP-complete problem, then any algorithm that solves our problem can be used to solve the hard one and vice versa. Then, we can justifiably suggest that our problem is very difficult. With this information, we can either continue focusing our efforts in finding a *polynomial time optimal algorithm* (admitting that our chances for success are low) or consider heuristics or enumeration techniques.

If we are ever able to find a polynomial time algorithm for a NP-complete problem, we will make one of the most important discoveries in human knowledge. This will mean that we are able to solve all hard combinatorial problems very quickly (for details about the relationship between the class of polynomially solvable problems and the class of NP-complete problems see [4]). If we believe that this is unlikely, then we focus our analyses on enumeration techniques. Hence, in the latter case, the equivalence between the problem at hand and the NP-complete problem have dictated our approach towards the problem at hand. Since 1971 when the foundations of complexity theory were developed by S.A. Cook in [2], all the papers that have appeared in the literature have taken the latter route – namely, they focus on heuristics and/or enumeration techniques. In this sense, complexity theory is a very useful tool for determining our approach towards solving difficult combinatorial problems. In this article, we present some of the fundamental techniques that have been used in the literature to prove equivalence among problems. We start in the next section by presenting a list of combinatorial optimization problems. Then, we describe some basic methodology for theorem proving in complexity theory, and conclude with a few illustrative example proofs.

### Some Known NP-Complete Problems

In what follows we present some problems commonly used in the literature to prove equivalence between problems. All of these problems are notoriously hard, they belong to the class of NP-complete problems, and hence, no polynomial algorithm is known for them. In the rest of this article we present methods for proving the equivalence between selected pairs among of these problems. Our selected problems span a sample of areas in combinatorial optimization including set partition, logic, graph theory, network theory, and scheduling theory.

The following two problems are representative of problems in set partition. The problems are stated in their decision form, i. e., we only require a ‘yes/no’ answer to resolve them. Each *instance* is described by the input data required to define the problem, and each *question* requires a ‘yes/no’ answer. This presentation of combinatorial problems follows the presentation form adopted in [4] which was the first text devoted to a systematic compilation of hard combinatorial problems.

**Definition 1 (Partition)** INSTANCE: Set  $A = \{a_1, \dots, a_n\}$  of elements, and a set function  $s: A \rightarrow Z^+$ .

QUESTION: Does there exist a set  $A' \subset A$  such that

$$\sum_{a \in A'} s(a) = \frac{1}{2} \sum_{a \in A} s(a) ?$$

**Definition 2 (3-Partition)** INSTANCE: Set  $A = \{a_1, \dots, a_{3n}\}$  of elements, set function  $s: A \rightarrow Z^+$ , and threshold value  $B$ .

QUESTION: Are there subsets  $A_k \subset A$ ,  $k = 1, \dots, n$ , such that

$$\sum_{a \in A_i} s(a) = B \text{ and } |A_k| = 3 \text{ for } 1 \leq i \leq n ?$$

These problems are among the most popular problems found in complexity theory. Note that in ‘Partition’,  $A$  is partitioned in two sets with no restriction on the number of elements per set. For this reason, ‘Partition’ is often referred to in the literature as *2-partition*. In contrast, ‘3-partition’ involves the partition of  $A$  in  $n$  sets each consisting of precisely three elements.

**Definition 3 (3-Satisfiability)** INSTANCE: A Boolean expression  $B$  in literals  $x_i$ ,  $i = 1, \dots, q$ ,

$$\begin{aligned} B &= (p_{11} \vee p_{12} \vee p_{13}) \wedge \dots \wedge (p_{n1} \vee p_{n2} \vee p_{n3}) \\ &= \bigwedge_{i=1}^n \bigvee_{j=1}^3 p_{ij} \end{aligned}$$

where each  $p_{ij}$  is either  $x_k$  or its negation  $\bar{x}_k$  for some  $1 \leq k \leq q$ .

QUESTION: Is there an assignment for the literals  $x_k$  such that  $B$  is true?

This problem is also referred to in the literature as *3-Sat*. The related problem where every clause has an arbitrary number of literals (rather than precisely three) is known in the literature as the *satisfiability* problem, or *Sat*, and has the distinction of being the first NP-complete problem (see [2]). Note that, if we were able to solve ‘Sat’ in polynomial time, then we would be able to determine the truth value of all possible statements in propositional calculus. Effectively, we could cast every imaginable theorem in propositional form, and let a computer answer it. This would be equivalent to theorem proving using computers.

**Definition 4 (Maximum clique)** INSTANCE: Graph  $G = (V, E)$  and positive integer  $k$ .

QUESTION: Does there exist a complete subgraph of  $G$  on  $k$  vertices?

The ‘maximum clique’ is a very important problem in graph theory with applications in diverse fields. The following problem is encountered when one wants to identify a path (with certain properties) in a given network.

**Definition 5 (Impossible pairs constrained path problem (IPP))** INSTANCE: Directed graph  $G = (V, A)$  with source  $s$  and sink  $t$ , and pairs of nodes  $(a_i, b_i)$  for  $i = 1, \dots, n$ .

QUESTION: Does there exist a directed  $s - t$  path containing at most one node from each pair  $(a_i, b_i)$  for  $i = 1, \dots, n$ ?

The following problems are found in scheduling theory where a set of jobs is to be processed in a production system so as to optimize a given objective. We use the standard 3-field notation  $\alpha/\beta/\gamma$  (see [6]) where  $\alpha$  denotes the number and type of processors,  $\beta$  describes the job characteristics, and  $\gamma$  the objective function. For example,  $\alpha = 1$  indicates a single processor, and  $\alpha$

=  $Pm$  denotes  $m$  identical processors operated in parallel. Job characteristics include completion deadlines, start times, precedence constraints among jobs, or processing characteristics. A popular scheduling objective is the minimization of the *makespan*,  $C_{\max}$  – the maximum completion time, where the maximum is taken over all jobs. Evidently,  $C_{\max}$  may be the preferred objective when a manager wants to maximize the utilization of processors.

**Definition 6**  $1/r_i, d_i/C_i \leq d_i$  INSTANCE: Set  $J = \{J_1, \dots, J_n\}$  of jobs, each with a processing time  $p_i$ , a due date  $d_i$ , and a release time  $r_i$ ,  $1 \leq i \leq n$ .

QUESTION: Is there a schedule of the jobs in  $J$  such that each job starts after time  $r_i$  and completes at time  $C_i \leq d_i$ ?

In the above problem one wants a single processor schedule where every job  $J_i$  starts no earlier than time  $r_i$  and finishes no later than time  $d_i$ . Such schedule would allow on time delivery of jobs to the customers.

**Definition 7**  $Pm//C_{\max}$  INSTANCE: Set  $M = \{M_1, \dots, M_m\}$  of parallel identical processors, set  $J = \{J_1, \dots, J_n\}$  of jobs each with a processing time  $p_i$ , and threshold value  $B$ .

QUESTION: Is there a nonpreemptive assignment of the  $n$  jobs to the  $m$  processors so that at any time every machine processes at most one job, and the completion time of  $J_i$  is  $C_i \leq B$  for every  $1 \leq i \leq n$ ?

Here we seek a schedule of the  $n$  jobs on the  $m$  processors so as to minimize the completion time of the last job. Every processor can process at most one job at a time, and every job must be processed in its entirety without being interrupted by any of the processors.

**Definition 8**  $P//\text{prec}, p_i = 1/C_{\max}$  INSTANCE: Set  $J = \{J_1, \dots, J_n\}$  of jobs with processing time  $p_i = 1$  for  $1 \leq i \leq n$ , and set  $A$  of precedence constraints between jobs in  $J$ . Also, set  $P$  of parallel identical processors, and a threshold value  $B$ .

QUESTION: Is there a nonpreemptive assignment of jobs to processors so that at any time every machine processes at most one job, the job precedence constraints are satisfied, and the completion time of  $J_i$  is  $C_i \leq B$  for every  $1 \leq i \leq n$ ?

Unlike the previous problem, the number of parallel identical processors is not specified in this problem, i. e.,  $\alpha = P$ . Every job has unit processing time. These unit jobs must satisfy a set of precedence constraints. Among all nonpreemptive schedules that satisfy these constraints, we seek one that minimizes the completion time of the last job.

The following section presents a general methodology for NP-completeness proofs with the problems described above as examples.

### Methodology for NP-Completeness Proofs

We start by presenting the four basic steps of a complexity proof. Such proofs demonstrate that a new problem  $\Pi$  can be transformed to a known NP-complete problem  $P \in \mathcal{NPC}$ . To indicate this reduction we use the notation  $P \propto \Pi$ .

- 1) Show that  $\Pi \in \mathcal{NP}$ .
- 2) Construct a transformation from  $P$  to  $\Pi$ .
- 3) Show that the transformation in step 2 can be effected by a polynomial time algorithm.
- 4) Show that there exists a solution  $S_P$  for  $P$ , if and only if there exists a solution  $S_\Pi$  for  $\Pi$ , and that the transformations  $S_P$  to  $S_\Pi$  and vice versa is done by a pseudopolynomial algorithm for *strong NP-complete reductions*, and by a polynomial algorithm for *ordinary NP-complete reductions*.

Step 1 requires that, given a solution  $S_\Pi$  of  $\Pi$  we can check whether  $S_\Pi$  provides a ‘yes’ or ‘no’ answer for  $\Pi$ , using a polynomial algorithm. Given an arbitrary instance  $I$  of  $P$ , step 2 requires constructing an instance  $I'$  of  $\Pi$ . Step 3 requires that the construction of  $I'$  from  $I$  is polynomial on the number of input data required to specify  $I$ . Finally, Step 4 requires proving that, given a solution  $S_P$  for the instance  $I$ , we can construct a solution  $S_\Pi$  for  $I'$  and vice versa. In almost all reductions that have appeared in literature, steps 1–3 are quite simple and usually straightforward, while step 4 often requires considerable creativity.

Step 4 refers to strong and ordinary NP-complete problems. In a nutshell, this is one of many classifications of NP-complete problems into smaller subclasses. For a detailed description of these classes see [4]. In practical terms, an ordinary NP-complete problem can be solved using implicit enumeration algorithms like dynamic programming. In this case, the complexity of

the algorithm is not polynomial on the *length of input data*, but it is polynomial on the *size* of these data. For instance, Partition is a NP-complete problem solvable by dynamic programming in  $\mathcal{O}(n \sum_i s(a_i))$  time (see [8]). Evidently, this complexity is polynomial on the size  $\sum_i s(a_i)$  of the data. To see that this complexity bound is not polynomial on the length of the data, consider the binary encoding scheme. In this scheme each  $s(a_i)$  can be represented by a string of length  $\mathcal{O}(\log s(a_i))$ , and hence  $s(a_1), \dots, s(a_n)$  can be described by a string of length  $\mathcal{O}(\sum_i \log s(a_i))$  which is no greater than  $\mathcal{O}(n \log B)$  where  $B = \sum_i s(a_i)$ . We see that the time complexity  $\mathcal{O}(nB)$  of the dynamic program (DP)

- is polynomial on the size  $B$  of the data.
- but not polynomial on the length of the input data for the instance  $I$  of ‘partition’, where  $\text{length}(I) = \mathcal{O}(n \log B)$ .

Notice that the complexity of this DP,  $\mathcal{O}(nB)$ , is not bounded by any polynomial function of  $n \log B$ . When the complexity of an algorithm is polynomial on the size of the data, but not the length of the input, we refer to the algorithm as a *pseudopolynomial algorithm*. A NP-complete problem solvable by a pseudopolynomial algorithm is called *ordinary NP-complete*. Else, the problem is *strongly NP-complete*.

As indicated by its complexity, solving ‘partition’ is easier than solving any problem not solvable by implicit enumeration. Such problems require explicit enumeration algorithms like branch and bound. In the list of problems given earlier, ‘partition’ is the only problem solvable by dynamic programming.

Given the complexity status of the known NP-complete problem  $P$ , we can determine whether a new problem  $\Pi$  is strongly or ordinary NP-complete, if one of the following happens:

- $P$  is strongly NP-complete, and  $P \propto \Pi$ . Then,  $\Pi$  is strongly NP-complete.
- $P$  is ordinary NP-complete,  $P \propto \Pi$ , and a pseudopolynomial algorithm exists for  $\Pi$ . Then,  $\Pi$  is ordinary NP-complete.

As indicated in the following tree, all other outcomes result to incomplete determination of the exact complexity status of problem  $\Pi$ .

### Example Proofs

In this section we present some simple applications of the four step reduction process outlined previously.

*Example 9* Partition  $\propto P2//C_{\max}$ . Step 1 requires us to show that  $P2//C_{\max} \in \mathcal{NP}$ , i. e., given a schedule  $S$  of the  $n$  jobs, we can check whether the associated makespan  $C_{\max}(S) \leq B$  in polynomial time. To perform the check, we need to find the completion time of the last job processed by each of the processors. This requires no more than  $n$  additions involving the processing times of the jobs in  $J$ . Hence,  $C_{\max}(S)$  can be computed in  $\mathcal{O}(n)$  time, and subsequently, whether  $C_{\max}(S) \leq B$  or not can be established in  $\mathcal{O}(1)$  time. Hence,  $P2//C_{\max} \in \mathcal{NP}$ . This completes step 1.

For step 2 we must construct an instance of  $P2//C_{\max}$ , given an instance of ‘partition’. Let  $I$  be an instance of ‘partition’, and  $s(a_1), \dots, s(a_n)$  be the values of the  $n$  elements  $a_1, \dots, a_n$  in  $I$ . We construct an instance  $I'$  of  $P2//C_{\max}$  as follows. Let  $p_i = s(a_i)$ ,  $i \in \{1, \dots, n\}$ . The number of processors is  $m = 2$  and the number of jobs is  $n$ . The threshold value  $B$  is set to  $B = (1/2) \sum_i p_i$ . This completes Step 2.

This construction of  $I'$  required  $n + 2$  assignments, and  $n + 1$  basic operations to compute  $B$ . Evidently, the total amount of effort required to construct  $I'$  is  $\mathcal{O}(n)$ . This concludes step 3.

In step 4, we need to show that, there exists a solution for the instance  $I$  of ‘partition’ if and only if there exists a solution for the instance  $I'$  of  $P2//C_{\max}$ . Indeed, let  $A_1, A_2$  be a partition of  $A$  such that

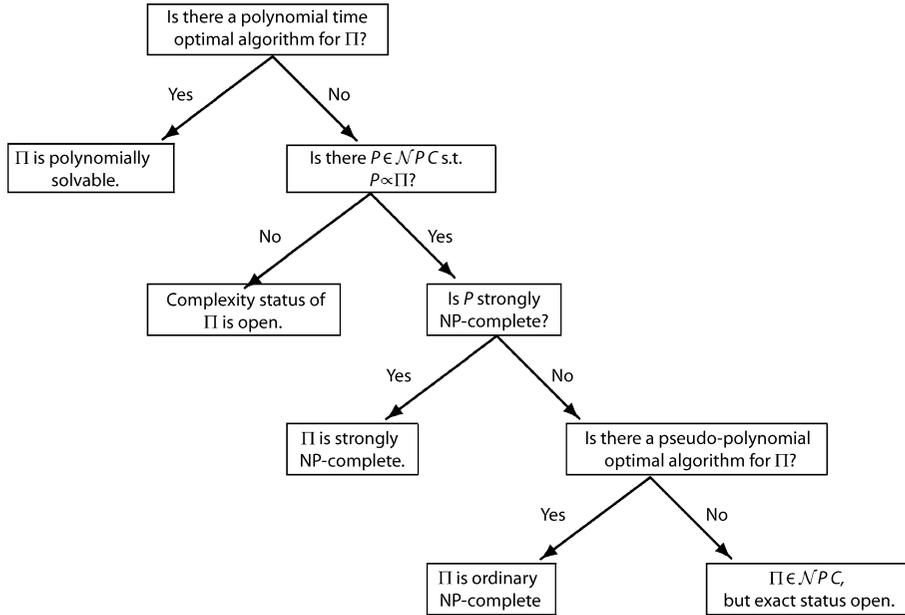

$$\sum_{a_i \in A_1} s(a_i) = \sum_{a_i \in A_2} s(a_i) = \frac{1}{2} \sum_{a_i \in A} s(a_i).$$

From this, we can construct a solution for  $I'$  by assigning all jobs in  $J^1 = \{J_i: a_i \in A_1\}$  to be processed (in any order) by processor  $M_1$ , and all jobs in  $J^2 = \{J_i: a_i \in A_2\}$  to be processed (in any order) by processor  $M_2$ . Let  $S$  be the resulting schedule for  $P2//C_{\max}$ . By definition of  $A_1$  and  $A_2$ ,

$$\sum_{J_i \in J^1} p_i = \sum_{J_i \in J^2} p_i = \frac{1}{2} \sum_i p_i = B.$$

Clearly, the schedule  $S$  is constructed from  $A_1, A_2$  in  $\mathcal{O}(n)$  time. Similarly, given a schedule  $S$  that solves  $P2//C_{\max}$  one can construct the partition  $A_1, A_2$  in  $\mathcal{O}(n)$  time as well.

Since ‘partition’ is an ordinary NP-complete problem, to completely determine the status of  $P2//C_{\max}$ , we will have to develop a pseudopolynomial algorithm for

**NP-complete Problems and Proof Methodology, Figure 1**  
**Establishing the complexity status of a problem  $\Pi$**

it. Such algorithm can in fact be developed (see [1]) which means that  $P2//C_{max}$  belongs to the class of ordinary NP-complete problems.

*Example 10 3-partition  $\propto 1/r_i, d_i/C_i \leq d_i$*  For Step 1, consider a given schedule  $S$  for  $1/r_i, d_i/C_i \leq d_i$ . By scanning the  $n$  jobs of  $S$  in sequence, we can obtain the start and completion times of the  $n$  jobs in  $\mathcal{O}(n)$  time. Then, we can perform the  $n$  comparisons  $r_i \leq C_i \leq d_i$  in  $\mathcal{O}(n)$  time. Hence,  $1/r_i, d_i/C_i \leq d_i \in \mathcal{NP}$ . This completes step 1.

For Step 2, suppose we are given an instance  $I$  of 3-partition, that is, a set  $A = \{a_1, \dots, a_{3n}\}$  with associated values  $s(a_1), \dots, s(a_{3n})$ , and threshold value  $B$ . For reasons that will become clear later, we make the following assumptions. Firstly,  $s(a_i) < B$  for every  $1 \leq i \leq 3n$ , otherwise we can immediately conclude that there is no solution for the instance  $I$  of 3-partition. Secondly, we assume that the elements  $a_1, \dots, a_{3n}$  possess the property

$\ast) \quad B/4 < s(a_i) < B/2 \text{ for } i = 1, \dots, 3n.$

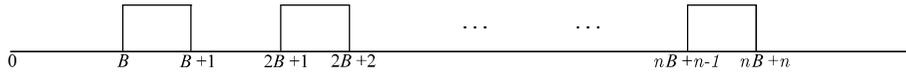

Indeed, if this condition does not hold, we can replace the value of each element  $a_i$  by  $s'(a_i) = s(a_i) + B$ , and the threshold value  $B$  by  $B' = 4B$ . Then, it is easy to see that,  $B < s'(a_i) < 2B$  (because  $s(a_i) < B$ ), and hence  $B'/4 < s'(a_i)$

$< B'/2$  for  $i = 1, \dots, 3n$ . In this case, the elements  $a_1, \dots, a_{3n}$  possess the required property with respect to the values  $s'(a_i)$  and the threshold  $B'$ . Hence, without loss of generality, we assume that the elements of the instance  $I$  of 3-partition satisfy property  $\ast$ ). This ensures that, if  $\sum_{a_i \in A_k \subset A} s(a_i) = B$ , then  $|A_k| = 3$ .

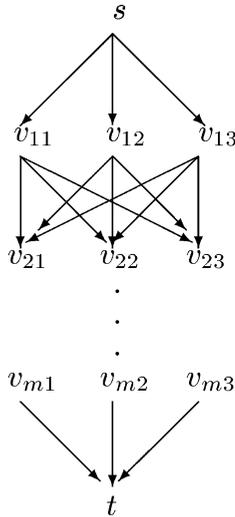

From  $I$ , we construct the instance  $I'$  of  $1/r_i, d_i/C_i \leq d_i \in \mathcal{NP}$  with  $4n$  jobs as follows. Set,  $p_i = s(a_i)$ ,  $r_i = 0$  and  $d_i = nB + n - 1$  for  $i = 1, \dots, 3n$ . Also include in  $I'$   $n$  'filler' jobs,  $F_1, \dots, F_n$  with processing times  $p_{F_i} = 1$ , start times  $r_{F_i} = iB + i - 1$  and due-dates  $d_{F_i} = iB + i$  for  $i = 1, \dots, n$ . Note that  $p_{F_i} = d_{F_i} - r_{F_i} = 1$  so the filler jobs have no slack. This completes step 2.

Clearly, The construction of  $I'$  is done in  $\mathcal{O}(n)$  time. To prove step 4, let  $A_k, k = 1, \dots, n$  be a solution of  $I$ . By definition of the 3-partition problem, each set  $A_k$  is such that  $|A_k| = 3$ , and  $\sum_{a \in A_k} s(a) = B, k = 1, \dots, n$ . From this, construct a schedule  $S$  for  $I'$  as follows. Let  $J^k = \{J_i : a_i \in A_k\}$  for  $k = 1, \dots, n$ , and schedule the jobs in  $J^k$  to be processed (in any order) starting at time  $(k - 1)B + k - 1$  and finishing at time  $kB + k - 1$  as in Fig. 2.

Evidently, the schedule  $S$  is constructed in  $\mathcal{O}(n)$  time. Alternatively, if  $S$  is a schedule that solves  $I'$ , then the filler jobs should partition the  $3n$  regular jobs in  $n$  distinct sets, say  $J^k = \{J_i : J_i \text{ starts after } F_{k-1} \text{ and is com-}$

NP-complete Problems and Proof Methodology, Figure 2  
Instance of  $1/r_i/C_j$

NP-complete Problems and Proof Methodology, Figure 3  
Instance of IPP

pleted before  $F_k$  for  $k = 1, \dots, n$ . Note that for  $k = 1$ ,  $J^1$  contains jobs that start after time  $t = 0$  ( $F_0$  is not defined) and complete prior to  $F_1$ . As the filler jobs have no slack, in each  $J_k$  the sum of the processing times must be precisely  $B$  units. By construction of the instance  $I$ , each  $J^k$  must contain precisely 3 jobs. Therefore, the sets  $A_k = \{a_i \in A : J_i \in J^k\}$  for  $k = 1, \dots, n$  partition  $A$  into  $n$  triplets such that  $\sum_{a_i \in A_k} s(a_i) = \sum_{J_i \in J^k} p_i = B$  for  $k = 1, \dots, n$ , i. e., the collection  $\{A_k\}_{k=1}^n$  solves  $I$ . Hence, given a schedule  $S$  that solves  $I'$ , we can construct a partition  $\{A_k\}_{k=1}^n$  that solves  $I$ , in  $\mathcal{O}(n)$  time. This completes step 4.

This example demonstrates that we can often construct the instance  $I$  so that it satisfies certain properties that may become handy in proving step 4. As seen so far, quite often steps 1 and 3, as well as parts of step 4 are trivial, in such cases the details are often omitted. A typical example is provided next.

*Example 11*  $3\text{-Sat} \propto \text{IPP}$  Given a Boolean expression  $B$ , construct a digraph  $G$  as indicated in Fig. 3.

Specifically, the arc set of  $G$  is

$$E = \{(s, v_{1j}) : j = 1, 2, 3\} \cup \{(v_{ij}, v_{i+1,k}) : 1 \leq i \leq m - 1; 1 \leq j, k \leq 3\} \cup \{(v_{mj}, t) : j = 1, 2, 3\}.$$

Also, let the set of restricted pairs be  $M = \{(v_{ij}, v_{kl}) : p_{ij} = \bar{p}_{kl}\}$ .

Let  $P = sv_{1l_1} \dots v_{ml_m}t$  be a constrained path. By making  $p_{il_i}$  true for  $i = 1, \dots, m$ , we force  $B$  to be true. Since  $P$  satisfies the constraints in  $M$ , these assignments do not conflict. Therefore the existence of a path  $P$  implies the satisfiability of  $B$  and vice versa. This construction took only  $\mathcal{O}(m)$  time, and the reduction is complete.

Our last example demonstrates how complexity theory can be used to derive approximation results.

*Example 12*  $\text{Max Clique} \propto P/\text{prec}$ ,  $p_j = 1/C_{\max}$  Given  $G = (V, E)$  construct a digraph  $D$  as follows. Introduce a job  $J_v$  for every  $v \in V$ , a job  $J_e$  for every  $e \in E$ , and an arc  $J_v \rightarrow J_e$  whenever  $v$  is an endpoint of  $e$ . Let  $l = \binom{k}{2}$  be the number of edges in a  $k$ -clique,  $k' = |V| - k$  the number of nodes not in the clique and  $l' = |E| - l$ , the number of edges not in the clique.

Let the number of processors be  $m = \max(k, l+k', l') + 1$ . Introduce three sets of dummy nodes

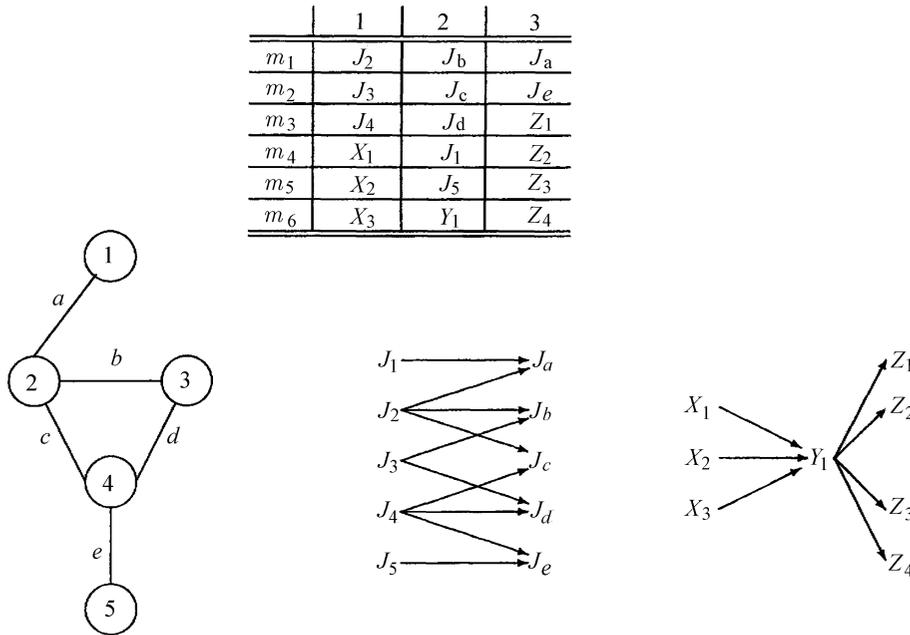

$$\begin{aligned} X_x, & \quad x = 1, \dots, m - k, \\ Y_y, & \quad y = 1, \dots, m - l - k', \\ Z_z, & \quad z = 1, \dots, m - l'. \end{aligned}$$

and the arcs  $X_x \rightarrow Y_y \rightarrow Z_z$ . Note that the total number of jobs is  $3m$ .

We will show that there exists a feasible schedule for the instance  $I$  of  $P/\text{prec}$ ,  $p_j = 1/C_{\max} = 3$  if and only if there exists a clique of size  $k$ . Or, in other words, there is a clique of size  $k$  if and only if we can complete the jobs in 3 periods.

( $\Leftarrow$ ). Suppose a  $k$ -clique exists. Then,

- Schedule the jobs corresponding to the  $k$  clique vertices in period 1 (see Fig. 4).

**NP-complete Problems and Proof Methodology, Figure 4**  
 Instance of  $P/prec, p = 1/C_{max}$

- Schedule the  $m-k$  jobs corresponding to each  $X_x$  in the remaining processors in the first period.
- Schedule the  $l$  jobs corresponding to the clique edges in period 2, schedule the  $k' = m - k$  remaining vertex jobs in period 2, and the  $m - l - k'$  jobs from  $Y_y$  in period 2.
- Finally, schedule the  $l' = |E| - l$  remaining edge jobs in period 3 and the  $m - l'$  jobs from  $Z_z$  in period 3 (see Fig. 4).

This is a feasible schedule on three periods.

( $\Rightarrow$ ). We prove this by contradiction. Suppose no  $k$ -clique exists. We will demonstrate that no 3-period schedule can exist either. Since there are  $m$  machines and  $3m$  jobs, in a three period schedule all machines must be busy for all the three periods. Certainly, due to the precedence constraints  $X_x \rightarrow Y_y \rightarrow Z_z$ , all  $m - k$  jobs must be done in period 1, all  $Y_y$  in period 2 and all the  $Z_z$  in period 3. Then, the remaining  $k$  slots in period 1 must be taken by vertex jobs. Since no  $k$ -clique exists, the edge jobs that can be scheduled in period 2 is no greater than  $l - 1$ . Then the jobs scheduled in period 2 are the  $l - 1$  edge jobs, all the  $Y_y$  jobs and the  $m - k$  remaining vertex jobs. The total number of these jobs does not exceed  $m - 1$ . Hence, there must be at least one machine that stays idle for a period. Hence no

schedule on three periods can exist, which is a contradiction.

This completes the reduction, and since ‘Max Clique’ is strongly NP-complete, so is  $P/prec, p_j = 1/C_{max}$ .

Observe that, in Example 12, the number  $m$  of processors is not fixed. Therefore, Example 12 does not settle the complexity status for the problem in which  $m$  is specified beforehand. For example, it does not resolve the complexity status of  $P3/prec, p_j = 1/C_{max}$ . A careful examination of Example 12 can enable us to construct error bounds. Suppose we develop a heuristic  $H$  to solve  $P/prec, p_j = 1/C_{max}$ . Then, given an instance of Max Clique, we generate the associated instance of  $P/prec, p_j = 1/C_{max}$  described in Example 12, and apply  $H$  on it. Since  $H$  cannot always solve  $P/prec, p_j = 1/C_{max}$  optimally (unless  $\mathcal{P} = \mathcal{NP}$ ), there will be instances where an optimal schedule on three periods exists, but our heuristic  $H$  fails to find it. Since the instance of  $P/prec, p_j = 1/C_{max}$  produced in Example 12 uses integer processing times, whenever  $H$  fails to produce an optimal solution, its makespan  $C_H$  will be  $C_H \geq 4$  rather than 3. Equivalently, the worst-case error bound for  $H$  must be  $p = C_H/C^* \geq 4/3$ . This observation is true for any pos-

sible heuristic for  $P/\text{prec}$ ,  $p_j = 1/C_{\max}$ . Therefore, unless  $\mathcal{P} = \mathcal{NP}$ , no heuristic algorithm can exist with worst-case error bound  $p < 4/3$ . Therefore, research efforts for worst-case analyses for  $P/\text{prec}$ ,  $p_j = 1/C_{\max}$  must be focused on values of  $p = 4/3$  or larger.

## Conclusion

In this article we presented some basic techniques used in proving  $\mathcal{NP}$ -completeness results. Following Cook's seminal paper [2], the first list of reductions for combinatorial problems was compiled in [5]. The four examples described in this article are illustrative of diverse optimization areas. They can be found in [3,4,7], and [6], respectively.

## Keywords

Unary optimization; Partial-update Newton method; Goldfarb–Wang algorithm; Inexact Newton method

We give a survey of numerical methods for the *unary optimization* problem:  $\min f(x) = \sum_{i=1}^m U_i(\alpha_i(x))$ ,  $x \in \mathbf{R}^n$ , where  $U(\cdot)$  is a function of a single argument and  $\alpha_i(x) = a_i^\top x$ ,  $a_i \in \mathbf{R}^n$ ,  $i = 1, \dots, m$ .

**Introduction**

Consider the unconstrained optimization problem:

$$\min f(x), \quad x \in \mathbf{R}^n. \tag{1}$$

If  $f(x)$  takes the form

$$f(x) = \sum_{i=1}^m U_i(\alpha_i(x)), \quad x \in \mathbf{R}^n, \tag{2}$$

where  $U_i(\cdot)$  is a smooth function of a single argument and  $\alpha_i(x) = a_i^\top x$ ,  $a_i \in \mathbf{R}^n$ ,  $i = 1, \dots, m$ , then we call problem (1) a *unary optimization problem*. Usually  $m \geq n$ . Unary optimization problems appear in many practical fields such as linear robust regression, portfolio selection and chemical equilibrium, see, e.g. [1,2,9].

The unary optimization problem was first proposed by G.P. McCormick and A. Sofer [9]. They exploited the special structure of derivatives of the unary function and applied the resulting algorithm to the solution of the classical chemical equilibrium problem. D. Goldfarb and S. Wang [7] first proposed an implementable algorithm specially for the unary optimization problem. Using the special structure of unary functions, in order to save computation cost, they modified the regular Newton method to develop a *partial-update Newton method*. In recent years some Chinese scholars worked on this subject and published several papers. We will review the state of art in this new interesting field.

**Goldfarb–Wang Algorithm GW**

If the unary functions  $U_i(\cdot)$ ,  $i = 1, \dots, m$ , in (2) are all differentiable and the Hessian matrix  $\nabla^2 f(x)$  is nonsingular for all  $x \in \mathbf{R}^n$ , then we can use Newton method to solve the problem (1), i. e., starting from the current point  $x^k$ , we compute the new iterate by

$$x^{k+1} = x^k + s^k,$$

where the increment  $s^k$  is obtained by solving the Newton equation

$$\nabla^2 f(x^k)s = -\nabla f(x^k). \tag{3}$$

Goldfarb and Wang noticed that the Hessian  $\nabla^2 f(x)$  of the unary function has the following form:

$$\nabla^2 f(x) = \sum_{i=1}^m \phi_i(x) a_i a_i^\top, \tag{4}$$

where

$$\phi_i(x) = d^2 U_i \frac{\alpha_i(x)}{d\alpha_i^2}. \tag{5}$$

Let  $\Phi(x) = \text{diag}(\phi_1(x), \dots, \phi_m(x))$ , and  $A^\top = (a_1, \dots, a_m)$ . Then we can write

$$\nabla^2 f(x) = A^\top \Phi(x) A. \tag{6}$$

Notice that only  $\phi_i(x)$  on the right-hand side of (4) or (6) may vary when  $x$  changes and the rank of the matrix  $\phi_i(x) a_i a_i^\top$  is one for any nonzero value  $\phi_i$ . Suppose that only the  $j$ th diagonal element of  $\Phi(x^k)$  and  $\Phi(x^{k-1})$  differs at iteration  $k$ , i. e.,

$$A^\top \Phi(x^k) A = A^\top \Phi(x^{k-1}) A + (\phi_j(x^k) - \phi_j(x^{k-1})) a_j a_j^\top, \tag{7}$$

or equivalently,

$$\nabla^2 f(x^k) = \nabla^2 f(x^{k-1}) + (\phi_j(x^k) - \phi_j(x^{k-1})) a_j a_j^\top. \tag{8}$$

Therefore,  $\nabla^2 f(x^k)^{-1}$  can be obtained from  $\nabla^2 f(x^{k-1})^{-1}$  by the well-known *Sherman–Morrison rank-one update formula*, and the next iteration can be obtained in only  $O(n^2)$  arithmetic operations after evaluating  $\nabla f$  and  $\phi_i$ ,  $i = 1, \dots, m$ .

The essential point of the GW algorithm is, in the  $k$ th iteration, to construct an approximation  $B^k$  to the Hessian  $\nabla^2 f(x^k)$ . Goldfarb and Wang compute the increment  $s^k$  by solving the approximate Newton equation

$$B^k s = -\nabla f(x^k), \tag{9}$$

where  $B^k = A^\top \Phi^k A$ , and  $\Phi^k = \text{diag}(\phi_1^k, \dots, \phi_m^k)$ . So their method can be viewed as a special type of *inexact Newton method*. The diagonal matrix  $\Phi^k$  is introduced to approximate  $\Phi(x^k)$ , and is defined by setting, for  $i = 1, \dots, m$ ,  $\phi_i^0 = \phi_i(x^0)$ , and

$$\phi_i^{k+1} = \phi_i^k, \tag{10}$$

if  $\phi_i(x^{k+1})$  is ‘replaceable’ by  $\phi_i^k$ ; and

$$\phi_i^{k+1} = \phi_i(x^{k+1}) \quad \text{otherwise}, \tag{11}$$

for  $k \geq 0$ . Choleski factorization is then used to solve (9). Notice that

$$B^{k+1} = B^k + \sum_{i \in S^k} (\phi_i^{k+1} - \phi_i^k) a_i a_i^\top. \tag{12}$$

where  $S^k$  is the set of indices  $i$  such that  $\phi_i(x^{k+1})$  is not ‘replaceable’ by  $\phi_i^k$ ,  $i = 1, \dots, m$ . We can exploit rank-one updates starting from the Choleski factorization of  $B^k$ , which needs  $O(|S^k|n^2)$  operations, where  $|S^k|$  is the number of elements in  $S^k$ . So it is possible to save computation cost if  $|S^k|$  is not very large.

Consider the assumptions:

- A1) there exists a point  $x^* \in \mathbf{R}^n$  with  $\nabla f(x^*) = 0$ ;
- A2)  $\nabla^2 f(x^*)$  is nonsingular;
- A3)  $\Phi(x)$  is continuous in a neighborhood of  $x^*$ .

Goldfarb and Wang proved the following

**Theorem 1** *Let assumptions A1)–A3) hold. Then there exists  $\delta > 0$  such that if  $\|x^0 - x^*\| \leq \delta$ , the sequence  $x^k$  generated by the partial-update Newton method converges to  $x^*$ . Moreover, the convergence is linear, i. e.,*

$$\|x^{k+1} - x^k\| \leq t \|x^k - x^*\|, \quad \forall k \tag{13}$$

where  $0 < t < 1$ .

In order to get a higher rate of convergence, they proposed two ‘replacement’ criteria for the method:

- Criterion 1: For  $i = 1, \dots, m$ ,  $\phi_i^k$  is replaceable by  $\phi_i^{k-1}$  if

$$\frac{|\phi_i(x^k) - \phi_i^{k-1}|}{|\phi_i(x^k) - \phi_i^{k-1}| + \|\nabla f(x^k)\|} < \eta, \tag{14}$$

where  $0 < \eta < 1$ .

- Criterion 2: For  $i = 1, \dots, m$ ,  $\phi_i^k$  is replaceable by  $\phi_i^{k-1}$  if  $k \leq p$  or

$$\frac{|\phi_i(x^k) - \phi_i^{k-1}|}{\max_{k-p+1 \leq j \leq k} |\phi_i(x^k) - \phi_i(x^{j-1})|} \leq 1, \tag{15}$$

where  $p$  is a given positive integer.

Consider the additional assumption

- A4)  $\Phi(x)$  is Lipschitz continuous at  $x^*$ .

The authors proved the following

**Theorem 2** *Let assumptions A1), A2) and A4) hold and let  $x^k$  be the sequence generated by GW algorithm. Then*

- 1)  $x^k$  is locally quadratically convergent to  $x^*$  if Criterion 1 is used;
- 2)  $x^k$  is locally superlinearly convergent to  $x^*$  with  $R$ -order at least  $r_p$ , where  $r_p$  is the unique positive root of  $t^{p+1} - t^p - 1 = 0$  if Criterion 2 is used.

In order to obtain global convergence of the method, the authors modified the ‘working approximation’  $\Phi^k$

of  $\Phi(x)$  to a  $\widehat{\Phi}^k$ , i. e., they modified the replacement criterion to ensure  $A^\top \widehat{\Phi}^k A$  to be positive definite. But the modified globally convergent algorithm is only  $R$ -linearly convergent.

The authors’ numerical results show the method takes less time to solve some types of problems than the modified Newton methods, but not always so.

### Analysis of the Replacement Criterion

The GW algorithm opened a new field for unary optimization, but, to our knowledge, during nearly five years no more papers in this field were published. Recently (as of 1999), J.Z. Zhang, N.Y. Deng and L.H. Chen [10] discussed the efficiency of the GW algorithm. They asked whether it was more efficient than Newton’s method when  $x^k$  approaches the solution  $x^*$ . They showed that, generally speaking, we can not expect the number  $\|S^k\|$  to be small enough such that the computation cost to factorize  $B^{k+1}$  by rank-one updates is less than that to factorize  $\nabla^2 f(x^{k+1})$  directly. The efficiency of GW algorithm heavily depends on the magnitude of the number  $|S^k|$ , so the frequency by which the replacement takes place is a key point. Based on this idea, the authors extended the Criterion 1 of GW algorithm to the so-called

- Criterion  $R_\alpha$ : For  $i = 1, \dots, m$  we replace  $\phi_i(x^{k+1})$  by  $\phi_i^k$  if

$$|\phi_i(x^{k+1}) - \phi_i^k| < \sigma \|\nabla f(x^{k+1})\|^\alpha, \tag{16}$$

where  $\sigma$  and  $\alpha$  are two constants satisfying  $\sigma > 0$  and  $\alpha \in (0, 1]$ .

It is easy to see that the GW’s Criterion 1 is a special case of Criterion  $R_\alpha$  with  $\alpha = 1$  and  $\sigma = \eta/(1 - \eta)$ .

Consider the assumptions

- A1) For  $i = 1, \dots, m$ ,  $U_i(\cdot)$  is three times continuously differentiable;
- A2) problem (1) has a solution  $x^*$  and  $\nabla^2 f(x^*)$  is positive definite;
- A3) the initial point  $x^0$  is close enough to the solution  $x^*$ .

They proved two theorems:

**Theorem 3** *Let assumptions A1)–A3) hold. Consider the sequence  $x^k$  generated by Algorithm  $R_\alpha$  with  $\alpha > \bar{\alpha}_{J+1}$ , where  $J$  is a nonnegative integer and  $\bar{\alpha}_{J+1}$  is the*

unique positive root of the equation

$$(1 + \alpha)^{J+1} \alpha = 1. \tag{17}$$

Suppose that for a fixed  $i$ , we have

- 1)  $d^3 U_i(\alpha_i(x^*)/d\alpha_i^3 \neq 0$ , and
- 2) there exists  $\bar{K} > 0$  such that

$$\phi_i^k \neq \phi_i(x^*), \forall k > \bar{K}. \tag{18}$$

Then

- a) for any  $K' > 0$ , there exists an integer  $k > K'$  such that

$$\phi_i^k = \phi_i(x^k); \tag{19}$$

- b) for any  $\epsilon > 0$ , there exists a  $K > 0$  such that if

$$\bar{k} > K, \tag{20}$$

$$\phi_i^{\bar{k}} = \phi_i(x^{\bar{k}}), \tag{21}$$

and

$$\left| a_i^\top \frac{s^{\bar{k}}}{\|s^{\bar{k}}\|} \right| > \epsilon. \tag{22}$$

Then, for  $x^k = x^{\bar{k}+1}, x^{\bar{k}+2}, \dots, \phi_i(x^k)$  is replaceable by  $\phi_i^{k-1}$  successively for at most  $J$  times.

**Theorem 4** The conditions are the same as Theorem 3. Suppose there exist  $M_1, M_2 > 0$  such that when  $k$  is large enough,

$$M_1 \|x^k - x^*\|^{1+\alpha} \leq \|x^{k+1} - x^*\| \tag{23}$$

$$\leq M_2 \|x^k - x^*\|^{1+\alpha}. \tag{24}$$

Then there exists  $\bar{K} > 0$ , such that if

$$\bar{k} > \bar{K} \tag{25}$$

and

$$\phi_i^{\bar{k}} = \phi_i(x^{\bar{k}}). \tag{26}$$

Then for  $x^k = x^{\bar{k}+1}, x^{\bar{k}+2}, \dots, \phi_i(x^k)$  is replaceable by  $\phi_i^{k-1}$  successively for at least  $J$  times.

When  $J = 0$ , then the positive root of  $(1 + \alpha)\alpha = 1$  is  $\bar{\alpha}_1 = \frac{(\sqrt{5}-1)}{2}$ . For GW's Criterion 1,  $\alpha = 1 > \bar{\alpha}_1$ ,

so from Theorem 3,  $\phi_i(x^k)$  will never be replaceable by  $\phi_i^{k-1}$  when  $k$  is large enough. So the GW algorithm with Criterion 1 cannot be expected to be more efficient than Newton method. The authors' numerical results also supported this conclusion.

But the authors pointed out, the idea of the GW algorithm to use the approximate Hessian  $B^k$  is promising, and efficient algorithms can hopefully be constructed.

### Using the Trust Region Approach

In GW algorithm, in order to ensure global convergence, the authors modified the criteria such that the approximate Hessian  $B^k$  be positive definite. However, this prevents the algorithms from having a locally superlinear convergence, may lead to  $B^k$  being a poor approximation and may increase the computation cost. Motivated by this observation, Chen, Deng and Zhang [3] removed the requirement for  $B^k$  to be positive definite, and proposed two modified partial-update algorithms based on trust region stabilization. They also improved the replacement criteria of GW algorithm and constructed the matrix  $B^k$  in a different way such that it may be a better approximation to the Hessian.

Besides the replacement of the line search technique by the trust region strategy, the main differences between their algorithms and the GW algorithm are as follows:

- a) As mentioned above, in order to get a better approximation to  $\nabla^2 f(x^k)$ , they abandoned the positive definiteness requirement for  $B^k$ . This change requires an efficient method to handle a trust region subproblem with indefinite matrix, so they used the indefinite dogleg method suggested in [11]. The main feature of the method is that it solves the TR subproblem approximately. It first uses a Bunch-Parlett (B-P) factorization for  $B^k$ , and then forms a dogleg curve. Instead of minimizing the objective function within the whole trust region, it makes a curvilinear search along the dogleg curve in the region.
- b) They introduced a threshold value  $l \approx n/6$  to control the algorithm to get the B-P factorization directly or to use a rank-one update, this motivated by the fact that the number of multiplications of the two methods is

$$c_n = \frac{1}{6}n^3 + O(n^2)$$

- 1 Set parameters  $p > 0$ , positive integers  $w$  and  $l$ . Choose the initial point  $x^0 \in \mathbf{R}^n$ . Set  $k = 0$ .
- 2 IF  $\nabla f(x^k) = 0$ , stop.
- 3 IF  $k = 0$ , go to Step 4; ELSE, define the set

$$S^k = \left\{ i : |\phi_i(x^k) - \phi_i^{k-1}| > \|\nabla f(x^k)\|^{1/p} \right\}. \quad (30)$$

IF

$$|S^k| \leq w, \quad (31)$$

where  $|S^k|$  is the number of elements in the set  $S^k$ , go to Step 5; otherwise go to Step 4.

- 4 Set

$$\phi_i^k = \phi_i(x^k), \quad i = 1, \dots, m, \quad B^k = \nabla^2 f(x^k). \quad (32)$$

Compute the Choleski factorization  $\nabla^2 f(x^k) = L_k D_k L_k^\top$  and the increment  $s^k$  by solving the Newton equation

$$\nabla^2 f(x^k) s = -\nabla f(x^k).$$

Set  $x^{k+1} = x^k + s^k$ . Go to Step 7.

- 5 Set

$$\phi_i^k = \begin{cases} \phi_i(x^k), & i \in S^k; \\ \phi_i^{k-1}, & i \notin S^k, \end{cases} \quad (33)$$

and

$$B^k = B^{k-1} + \sum_{i \in S^k} (\phi_i(x^k) - \phi_i^{k-1}) a_i a_i^\top. \quad (34)$$

Compute the Choleski factorization  $B^k = L_k D_k L_k^\top$  which is obtained by successive  $|S^k|$  rank-one corrections from the Choleski factorization

$$B^{k-1} = L_{k-1} D_{k-1} L_{k-1}^\top.$$

- 6 The increment  $\tilde{s}^k$  is given by

$$\tilde{s}^k = \psi(\nabla^2 f(x^k), \nabla f(x^k), B^k, l), \quad (35)$$

where  $\psi(\nabla^2 f(x^k), \nabla f(x^k), B^k, l)$  is a mapping defined by solving approximately the Newton equation

$$\nabla^2 f(x) s = -\nabla f(x) \quad (36)$$

with preconditioned conjugate gradient inner iterations, and the preconditioner is given by the inverse of  $B$ . The initial point is selected as  $s = 0$ . The number of inner iterations is  $l$ . The PCG method used here is a standard one, e.g. see [8, Algorithm 2.5.1]. Set  $x^{k+1} = x^k + \tilde{s}^k$ .

- 7 Set  $k = k + 1$ , and then go to Step 2.

#### ◀ Numerical Methods for Unary Optimization, Algorithm 1 Deng-Wang-Zhang algorithm

and

$$c_1 = n^2 + O(n)$$

respectively, and  $c_n/c_1 = n/6$ . That is, if  $k = 1$  or  $|S^k| > l$ , one performs the B-P factorization of  $B^k$  directly; otherwise, one uses the rank-one updates of the B-P factorization  $|S^k|$  times to get the factorization of the matrix

$$B^k = B^{\tau_k} + \sum_{i \in S^k} (\phi_i^k - \phi_i^{\tau_k}) a_i a_i^\top$$

where  $\tau_k$  is the index of the iteration at which the latest B-P factorization was performed.

- c) They considered the effect of  $a_i$  on the replacement criteria. From the expression

$$\nabla^2 f(x) = \sum_{i=1}^m [\|a_i\|^2 \phi_i(x)] \left( \frac{a_i}{\|a_i\|} \right) \left( \frac{a_i}{\|a_i\|} \right)^\top \quad (27)$$

they define  $S^k$  by

$$S^k = \{i :$$

$$\frac{\|a_i\|^2 |\phi_i(x^k) - \phi_i^{\tau_k}|}{[\|a_i\|^2 |\phi_i(x^k) - \phi_i^{\tau_k}| + \min\{\gamma, \|\nabla f(x^k)\|\}]} > \eta, \\ 1 \leq i \leq m\}, \quad (28)$$

where  $\gamma > 0$  is a constant. Then they gave two modified replacement criteria:

- Modified replacement criterion 1: For  $k = 1$  and  $i \in \{1, \dots, m\}$ , set  $\phi_i^1 = \phi_i(x^1)$ . For  $k > 1$ , define  $\phi_i^k$  as follows:

- 1) If  $|S^k| \leq l$ , set

$$\phi_i^k = \begin{cases} \phi_i(x^k) & \text{if } i \in S^k, \\ \phi_i^{\tau_k} & \text{if } i \notin S^k. \end{cases}$$

- 2) Otherwise, set

$$\phi_i^k = \phi_i(x^k).$$

- 2) Modified replacement criterion 2: The same as modified replacement criterion 1 except choose

an extra integer parameter  $p > 0$  and if  $k \leq p$ ,  $S^k$  is the same; otherwise, define

$$S^k = \{i : \left| \phi_i(x^k) - \phi_i^{T_k} \right| \geq \max_{k-p+1 \leq j \leq k} \left| \phi_i(x^k) - \phi_i(x^{j-1}) \right|, 0 \leq i \leq m\} . \tag{29}$$

Consider the assumptions

- [A1] For  $i = 1, \dots, m$ ,  $U(\cdot)$  is twice continuously differentiable;
- [A2] For any real constant  $\bar{f}$ , the level set  $\{x : f(x) \leq \bar{f}\}$  is compact;
- [A3] For  $i = 1, \dots, m$ , the function  $\phi_i(x)$  is Lipschitz continuous.

Under these assumptions the authors proved that the two algorithms are globally convergent, and if  $x^k$  converges to  $x^*$  and  $\nabla^2 f(x^*)$  is positive definite, then the convergence rate of the first algorithm is quadratic, while for the second algorithm,  $x^k$  is locally superlinearly convergent to  $x^*$  with  $R$ -order at least  $r_p$ , where  $r_p$  is the unique positive root of  $t^{p+1} - t^p - 1 = 0$ .

The authors' numerical experiments showed that the two algorithms outperform the trust region method which uses GW's criteria 1 and 2.

### An Inexact Newton Method Using Preconditioned Conjugate Gradient Techniques

More recently (1999), Deng, Wang and Zhang [6] developed Goldfarb and Wang's idea further and exploited the preconditioned conjugate gradient technique proposed in [5] and [4] to derive a new inexact Newton method. They showed that, when  $n \geq 31$ , the local behavior of this algorithm is superior to that of both the GW algorithms and the algorithm mentioned in the above section [3] from the efficiency point of view. Their algorithm model is given below.

Suppose problem (1) has a solution  $x^*$  and the following conditions are valid in a neighborhood of  $x^*$ :

- [A1] For  $i = 1, \dots, m$ , the second derivative  $\phi_i(x)$  of  $U_i(\cdot)$  defined by (5) is Lipschitz continuous with the constant  $L$ ;
- [A2]  $\nabla^2 f(x^*) > 0$ , i. e. the Hessian is symmetric positive definite.

The authors proved the following *local quadratic convergence theorem* about the Deng–Wang–Zhang algorithm.

**Theorem 5** *Let Assumptions A1)–A2) hold. If  $l \geq p$ , then there are positive scalars  $\delta$  and  $M$  such that if  $\|x^0 - x^*\| \leq \delta$ , the Deng–Wang–Zhang Algorithm (Algorithm 1) is well-defined and, furthermore, the sequence  $\{x^k\}$  generated by it satisfies*

$$\|x^{k+1} - x^*\| \leq M \|x^k - x^*\|^2 .$$

*In other words, the sequence  $\{x^k\}$  converges to  $x^*$  with  $q$ -order at least 2.*

The authors also studied the precisely quadratic convergence of the Deng–Wang–Zhang Algorithm, that is essential for the estimation of its computation cost. Consider the following additional assumption:

- [A3] For any nonzero  $h \in \mathbf{R}^n$ , we have

$$\sum_{i=1}^m \phi'_i(x^*) (a_i^\top h)^2 a_i \neq 0 . \tag{37}$$

The authors proved

**Theorem 6** *Consider the sequence  $\{x^k\}$  generated by the Deng–Wang–Zhang Algorithm with  $l > p$ . Let Assumptions (A1)–(A3) hold. Then there is a positive scalar  $\delta_1$  and  $M_1 > 0$  such that if  $\|x^0 - x^*\| \leq \delta_1$ , then for any  $k = 0, 1, \dots$*

$$M_1 \|x^k - x^*\|^2 \leq \|x^{k+1} - x^*\| \leq M \|x^k - x^*\|^2 , \tag{38}$$

*where  $M$  is defined in Theorem 5. In other words, the sequence  $\{x^k\}$  converges to  $x^*$  with  $Q$ -order equal to 2.*

In order to obtain an implementable algorithm, the authors specified the values of the parameters  $l, p$  and  $w$  in the Algorithm with the following purposes in mind:

- 1) retain the quadratic convergence;
- 2) keep the computation cost per iteration as little as possible.

Here the computation cost is only concerned with the arithmetic operations in solving the Newton equation in Step 4 and Steps 5–6. For simplicity, they only considered the number of multiplicative operations. For example, for Step 4, the arithmetic operations refer to the number  $Q_N$  of multiplications to compute the solution  $s^k$  to (36) by a direct Choleski factorization, which is

$$Q_N = Q_N(n) = \frac{n^3}{6} + \frac{3n^2}{2} - \frac{2n}{3} . \tag{39}$$

$p =$	(2, 3)	(4, 5)	(4, 5)	(8, 9)	(8, 9)	(8, 9)	(16, 17)
$l =$	3	5	5	9	9	9	17
$\frac{\bar{Q}(n)}{Q_N(n)} \leq$	0.67	0.53	0.43	0.41	0.35	0.33	0.28

Similarly, the arithmetic operations in one conjugate gradient inner iteration in Step 6 refers to the number of multiplications, denoted by  $Q_{CG}$ , in calculating the right-hand side of (35), but with  $l$  there being replaced by 1:

$$Q_{CG} = Q_{CG}(n) = 2n^2 + 6n + 2. \quad (40)$$

Using the minimization of an upper bound of the average computation cost per iteration, the authors obtained the optimal parameter values of  $w$ ,  $p$  and  $l$ , then established an implementable algorithm for problem (1) with  $n \geq 9$  as follows.

The same as the Deng-Wang-Zhang algorithm, except that the parameters are specified as follows:

- 1 The parameter  $w$ : set  $w = 0$ .
- 2 The parameter  $p$ : when  $19 \geq n \geq 9$ , set  $p \in (0, 1)$ ; when  $30 \geq n \geq 20$ , set  $p \in (0, 2)$ ; when  $n \geq 31$ , set  $p \in (2^{i^*}, 2^{i^*} + 1)$ , where the integer  $i^*$  can be determined as follows: Let  $N = [Q_N/Q_{CG}]$ , divide interval  $(0, N)$  by the points  $2^i$ ,  $i = 1, \dots$ , into subintervals  $(0, 2]$ ,  $(2^1, 2^{1+1}]$ ,  $\dots$ ,  $(2^{j-1}, 2^j]$ ,  $(2^j, N]$ , where  $2^j + 1 \leq N \leq 2^{j+1}$ , then compare the values

$$u(i) = \frac{Q_N}{1+i} + \frac{i(2^i + 1)Q_{CQ}}{1+i}$$

for  $i = 1, \dots, j$ . The integer  $i^*$  is defined as the index corresponding to the smallest value  $u^*$  of  $u(i)$ :  $u(i^*) = u^*$ .

- 3 The parameter  $l$ : set  $l = l(p)$ , where  $l(p)$  is defined by  $p + 1 \geq l(p) > p$ .

Then the authors proved the following theorem about the computation cost:

**Theorem 7** Let A1)–A3) hold. Then compared with the corresponding number  $Q_N = Q_N(n)$  of Newton's method with Choleski factorization, the average arithmetic operations per iteration  $\bar{Q} = \bar{Q}(n)$  of the improved Deng-Wang-Zhang algorithm has the following properties:

- 1) When  $30 \geq n \geq 9$ ,  $\bar{Q}(n) \leq Q_N(n)$ ;
- 2) when  $n \geq 31$ ,  $\bar{Q}(n) < Q_N(n)$ ;
- 3)  $\lim_{n \rightarrow \infty} \frac{\bar{Q}(n)}{Q_N(n)} \rightarrow 0$ .

Corresponding to the theoretical result in Theorem 7, some numerical values are listed in Table 1. For example, for  $n = 200$ , we have  $i^* = 2$ ,  $p \in (4, 5)$ ,  $l = 5$  and  $u^* = u(2) = 0.53Q_N$ , which means that the average cost per iteration of the improved Deng-Wang-Zhang algorithm is no more than  $0.53Q_N$ .

The authors also pointed out that the parameter selection problem in the Deng-Wang-Zhang algorithm is worth of further study from both theoretical and numerical points of view. Better performance than the one listed in Table 1 is expected due to a better parameter selection method.

Imperfect competition; Nash equilibrium; Game theory; Noncooperative behavior; Aspatial and spatial markets; Variational inequality formulations

An *oligopoly* consists of a finite number (usually few) firms involved in the production of a good. Oligopolies are a basic economic market structure, with examples ranging from large firms in automobile, computer, chemical, or mineral extraction industries to small firms with local markets. Oligopolies are examples of *imperfect competition* in that the producers or firms are sufficiently large that they affect the prices of the goods. A *monopoly*, on the other hand, consists of a single firm which has full control of the market.

Oligopoly theory dates to A. Cournot [1], who considered competition between two producers, the so-called *duopoly* problem, and is credited with being the first to study *noncooperative* behavior, in which the

agents act in their own self-interest. In his study, the decisions made by the producers or firms are said to be in equilibrium if no producer can increase his income by unilateral action, given that the other producer does not alter his decision.

J.F. Nash [18,19] generalized Cournot's concept of an equilibrium for a behavioral model consisting of several agents or players, each acting in his own self-interest, which has come to be called a *noncooperative game*. Specifically, consider  $m$  players, each player  $i$  having at his disposal a strategy vector  $x_i = \{x_{i1}, \dots, x_{in}\}$  selected from a closed, convex set  $K^i \subset \mathbf{R}^n$ , with a utility function  $u_i: K \rightarrow \mathbf{R}^1$ , where  $K = K^1 \times \dots \times K^m \subset \mathbf{R}^{mn}$ . The rationality postulate is that each player  $i$  selects a strategy vector  $x_i \in K^i$  that maximizes his utility level  $u_i(x_1, \dots, x_{i-1}, x_i, x_{i+1}, \dots, x_m)$  given the decisions  $(x_j)_{j \neq i}$  of the other players. In this framework one then has:

**Definition 1 (Nash equilibrium)** A Nash equilibrium is a strategy vector  $x^* = (x_1^*, \dots, x_m^*) \in K$ , such that

$$u_i(x_i^*, \widehat{x}_i^*) \geq u_i(x_i, \widehat{x}_i^*), \quad \forall x_i \in K^i, \quad \forall i,$$

where  $\widehat{x}_i^* = (x_1^*, \dots, x_{i-1}^*, x_{i+1}^*, \dots, x_m^*)$ .

It has been shown (cf. [6,10]) that Nash equilibria satisfy variational inequalities. In the present context, under the assumption that each  $u_i$  is continuously differentiable on  $K$  and concave with respect to  $x_i$ , one has

**Theorem 2 (variational inequality formulation)** Under the previous assumptions,  $x^*$  is a Nash equilibrium if and only if  $x^* \in K$  is a solution of the variational inequality

$$\langle F(x^*), x - x^* \rangle \geq 0, \quad \forall x \in K,$$

where  $F(x) \equiv (-\nabla_{x_1} u_1(x), \dots, -\nabla_{x_m} u_m(x))$ , and is assumed to be a row vector, where  $\nabla_{x_i} u_i(x)$  denotes the gradient of  $u_i$  with respect to  $x_i$ .

If the feasible set  $K$  is compact, then existence is guaranteed under the assumption that each utility function  $u_i$  is continuously differentiable. J.B. Rosen [22] proved existence under similar conditions. S. Karamardian [12] relaxed the assumption of compactness of  $K$  and provided a proof of existence and uniqueness of Nash equilibria under the strong monotonicity condition. As shown by D. Gabay and H. Moulin [6], the imposition of a coercivity condition on  $F(x)$  will guarantee existence of a Nash equilibrium  $x^*$  even if the feasible set is no longer compact. Moreover, if  $F(x)$  satisfies the strict monotonicity condition then uniqueness of  $x^*$  is guaranteed, provided that the equilibrium exists.

We begin with the presentation of a classical oligopoly model and then present a spatial oligopoly model which is related to the spatial price equilibrium problem.

**The Classical Oligopoly Problem**

We now describe the classical oligopoly problem (cf. [1,4], [5,6,7,13,20,21]) in which there are  $m$  producers involved in the production of a homogeneous commodity. The quantity produced by firm  $i$  is denoted by  $q_i$ , with the production quantities grouped into a column vector  $q \in \mathbb{R}^m$ . Let  $f_i$  denote the cost of producing the commodity by firm  $i$ , and let  $\rho$  denote the demand price associated with the good. Assume that

$$f_i = f_i(q_i)$$

and

$$\rho = \rho \left( \sum_{i=1}^m q_i \right).$$

The profit for firm  $i$ ,  $u_i$ , which is the difference between the revenue and cost, can then be expressed as

$$u_i(q) = \rho \left( \sum_{i=1}^m q_i \right) q_i - f_i(q_i).$$

Given that the competitive mechanism is one of noncooperative behavior, one can write down immediately:

**Theorem 3 (variational inequality formulation)** Assume that the profit function  $u_i(q)$  for each firm  $i$  is concave with respect to  $q_i$ , and that  $u_i(q)$  is continuously differentiable. Then  $q^* \in \mathbb{R}_+^m$  is a Nash equilibrium if and only if it satisfies the variational inequality:

$$\sum_{i=1}^m \left[ \frac{\partial f_i(q_i^*)}{\partial q_i} - \frac{\partial \rho(\sum_{i=1}^m q_i^*)}{\partial q_i} q_i^* - \rho \left( \sum_{i=1}^m q_i^* \right) \right] \times [q_i - q_i^*] \geq 0, \quad \forall q \in \mathbb{R}_+^m.$$

*Example 4* In this oligopoly example there are three firms. The data are as follows: the producer cost functions are given by:

$$\begin{aligned} f_1(q_1) &= q_1^2 + q_1 + 10, \\ f_2(q_2) &= \frac{1}{2}q_2^2 + 4q_2 + 12, \\ f_3(q_3) &= q_3^2 + \frac{1}{2}q_3 + 15, \end{aligned}$$

and the inverse demand or price function is given by:  $\rho(\sum_{i=1}^3 q_i) = -\sum_{i=1}^3 q_i + 5$ .

The equilibrium production outputs are as follows:

$$\begin{aligned} q_1^* &= \frac{23}{30}, & q_2^* &= 0, \\ q_3^* &= \frac{14}{15}; & \sum_{i=1}^3 q_i^* &= \frac{17}{10}. \end{aligned}$$

We now verify that the variational inequality is satisfied:  $-\partial u_1(q^*)/\partial q_1$  is equal to zero, as is  $-\partial u_3(q^*)/\partial q_3$ , whereas  $-\partial u_2(q^*)/\partial q_2 = 7/10$ . Since both  $q_1^*$  and  $q_3^*$  are greater than zero, and  $q_2^* = 0$ , one sees that, indeed, the above variational inequality is satisfied.

Computational approaches can be found in [2,4,8,14,16,17], and the references therein.

In the special case where the production cost functions are quadratic (and separable) and the inverse demand or price function is linear, one can reformulate the Nash equilibrium conditions of the Cournot oligopoly problem as the solution to an optimization problem (see [16,23]).

**A Spatial Oligopoly Model**

We now describe a generalized version of the oligopoly model due to S.C. Dafermos and A. Nagurney [3] (see, also, [11]), which is *spatial* in that the firms are now

located in different regions and there are transportation costs associated with shipping the commodity between the producers and the consumers. For the relationship between this model and the perfectly competitive spatial price equilibrium problem, see [3]. For algorithms for the computation of solutions to this model, see [15] (see, also, e. g., [9,16]). For additional background, including qualitative properties and references, see [16]. In [17] dynamic oligopolistic models are presented both spatial and aspatial (see also [4] and [20]) and stability analysis results given.

Assume that there are  $m$  firms and  $n$  demand markets that are generally spatially separated. Assume that the homogeneous commodity is produced by the  $m$  firms and is consumed at the  $n$  markets. As before, let  $q_i$  denote the nonnegative commodity output produced by firm  $i$  and now let  $d_j$  denote the demand for the commodity at demand market  $j$ . Let  $Q_{ij}$  denote the nonnegative commodity shipment from supply market  $i$  to demand market  $j$ . Group the production outputs into a column vector  $q \in \mathbf{R}_+^m$ , the demands into a column vector  $d \in \mathbf{R}_+^n$ , and the commodity shipments into a column vector  $Q \in \mathbf{R}^{mn}_+$ .

The following *conservation of flow* equations must hold:

$$q_i = \sum_{j=1}^n Q_{ij}, \quad \forall i,$$

$$d_j = \sum_{i=1}^m Q_{ij}, \quad \forall j,$$

where  $Q_{ij} \geq 0, \forall i, j$ .

As before, we associate with each firm  $i$  a production cost  $f_i$ , but allow now for the more general situation where the production cost of a firm  $i$  may depend upon the entire production pattern, that is,

$$f_i = f_i(q).$$

Similarly, allow the demand price for the commodity at a demand market to depend, in general, upon the entire consumption pattern, that is,

$$\rho_j = \rho_j(d).$$

Let  $c_{ij}$  denote the transaction cost, which includes the transportation cost, associated with trading (shipping) the commodity between firm  $i$  and demand market  $j$ . Here we permit the transaction cost to depend, in

general, upon the entire shipment pattern, that is,

$$c_{ij} = c_{ij}(Q).$$

The profit  $u_i$  of firm  $i$  is then given by:

$$u_i = \sum_{j=1}^n \rho_j c_{ij} - f_i - \sum_{j=1}^n c_{ij} Q_{ij},$$

which, in view of the conservation of flow equations and the functions, one may write as

$$u = u(Q).$$

Now consider the usual oligopolistic market mechanism, in which the  $m$  firms supply the commodity in a noncooperative fashion, each one trying to maximize his own profit. We seek to determine a nonnegative commodity distribution pattern  $Q$  for which the  $m$  firms will be in a state of equilibrium as defined below.

**Definition 5 (spatial Cournot–Nash equilibrium)**

A commodity shipment distribution  $Q^* \in \mathbf{R}_+^{mn}$  is said to constitute a Cournot–Nash equilibrium if for each firm  $i, i = 1, \dots, m$ ,

$$u_i(Q_i^*, \widehat{Q}_i^*) \geq u_i(Q_i, \widehat{Q}_i^*), \quad \forall Q_i \in \mathbf{R}_+^n,$$

where

$$Q_i \equiv \{Q_{i1}, \dots, Q_{in}\},$$

$$\widehat{Q}_i^* \equiv (Q_1^*, \dots, Q_{i-1}^*, Q_{i+1}^*, \dots, Q_m^*).$$

The variational inequality formulation of the Cournot–Nash equilibrium is given in the following theorem.

**Theorem 6 (variational inequality formulation; [3])**

Assume that for each firm  $i$  the profit function  $u_i(Q)$  is concave with respect to the variables  $\{Q_{i1}, \dots, Q_{in}\}$ , and continuously differentiable. Then  $Q^* \in \mathbf{R}_+^{mn}$  is a Cournot–Nash equilibrium if and only if it satisfies the variational inequality

$$-\sum_{i=1}^m \sum_{j=1}^n \frac{\partial u_i(Q^*)}{\partial Q_{ij}} \times (Q_{ij} - Q_{ij}^*) \geq 0,$$

$$\forall Q \in \mathbf{R}_+^{mn}.$$

Using the expressions for the utility functions for this model and the conservation of flow equations this varia-

tional inequality may be rewritten as:

$$\begin{aligned} & \sum_{i=1}^m \frac{\partial f_i(q^*)}{\partial q_i} \times (q_i - q_i^*) \\ & + \sum_{i=1}^m \sum_{j=1}^n c_{ij}(Q^*) \times (Q_{ij} - Q_{ij}^*) \\ & - \sum_{j=1}^n \rho_j(d^*) \times (d_j - d_j^*) \\ & - \sum_{i=1}^m \sum_{j=1}^n \sum_{l=1}^n \left[ \frac{\partial \rho_l(d^*)}{\partial d_j} - \frac{\partial c_{il}(Q^*)}{\partial Q_{ij}} \right] \\ & \times Q_{il}^*(Q_{ij} - Q_{ij}^*) \geq 0, \\ & \forall (q, Q, d) \in K, \end{aligned}$$

where  $K \equiv \{(q, Q, d): Q \geq 0, \text{ and the conservation of flow equations hold}\}$ .

Note that, in the special case, where there is only a single demand market and the transaction costs are identically equal to zero, this variational inequality collapses to the variational inequality governing the *aspatial* or the classical oligopoly problem.

Operations research

Operations research originated circa 1945. The Webster's Ninth New Collegiate Dictionary (1989) defines it as: The application of scientific and especially mathematical methods to the study and analysis of problems involving complex systems (as firm management, economic planning, and the waging of war).

Case Institute of Technology (presently part of Case Western Reserve Univ.) located in Cleveland, Ohio, USA, was the first institution of higher learning in the world to establish a graduate program in Operations Research leading towards the MSc and PhD degrees. The first PhD degree in operations research in the USA was awarded to L. Friedman circa 1957, at Case. In the 1950s and early 1960s, Case was one of the leading institutions in the field of operations research. The famous operations research group at Case was well established and reputed internationally. The operations research philosophy at Case was essentially based on the premise that operations research is science. An appropriate definition of operations research is: The application of scientific methods to analyze, model, solve, and control human-created or management problems using mainly quantitative techniques [2]. Operations research provides the decision maker either with an optimum option from among a set of feasible alternative courses of action or with an optimum allocation of limited resources so as to minimize or maximize a given criterion or objective function [1]. The seven steps used in order to carry on an operations research study are:

1) Observation.

2) Analysis of the present systems. This includes:

- a) qualitative analysis, quantitative analysis and data collection;
- b) components to be incorporated such as: man, machine, material, management, money, consumer, competitors, public, government, safety, reliability, aesthetics, ethics.

3) Definition and formulation of the problem. These must involve:

- a) the decision-maker;
- b) the objectives or criteria used;
- c) the environmental or system constraints;
- d) the feasible alternative courses of action.

4) Construction of a model (synthesis/design). Four models are possible:

- a) mathematical (or symbolic or abstract) model;
- b) iconic model (e. g. CAD, graphics, drawings);
- c) analog model;
- d) simulation model.

As an example, the construction of a mathematical model involves abstracting the operation of the system including:

- a) defining and quantifying
  - i) the decision or control variables;
  - ii) the parameters or uncontrollable variables;
- b) establishing functional relationships between variables and parameters;
- c) developing a mathematical function for the criterion (objective function to be minimized or maximized). One must specify:
  - i) the horizon period;
  - ii) the units;
  - iii) the measures used such as: cost or profit (e. g. average, total, discounted), reliability, availability;
- d) setting up the constraints.

5) Derivation of a solution to the problem. This typically consists in selecting the best from among the set of feasible alternative courses of action to meet the defined objective function and satisfy the constraints through optimization techniques and tools using analytic or numerical procedures.

6) Testing and/or Validation. This involves:

- a) validation of data;
- b) validation of the model;
- c) testing the solution. The testing methodology uses:
  - i) retrospective testing;
  - ii) prospective testing;
  - iii) simulation (accelerated testing);
  - iv) others.

7) Control and implementation of the solution. The control methodology uses, for example:

- a) sensitivity analysis;

b) statistical quality control.

The implementation methodology uses, for example:

- a) statistical inference;
- b) sampling techniques.

Let me say that the above definition of operations research and the outlined methodology were not exactly the ones proposed in the late 1950s. However, they may be considered close enough for all practical purposes. One may consider to what extent the definition and the methodology have been altered throughout the years. In my opinion very little! In the foreword [3] Aristotle is quoted: ‘And the science which knows to what end each thing must be done is the most authoritative of the sciences, and more authoritative than any ancillary science; and the end is the good of that thing, and in general the supreme good in the whole of nature’.

Finance; Mathematical programming; Simulation; Modeling; Applications; challenges for OR; Data envelopment analysis; Dynamic programming; Fractional programming; Goal programming; Linear programming; Markov chains; Monte-Carlo sampling and variance reduction; Nonlinear programming; Portfolio theory; Mean-variance; Quadratic programming; Stochastic programming

From the 1950s onwards, a strong relationship between operations research, OR, and finance has developed, resulting in a large and rapidly growing literature. Although most applications have been of OR techniques to finance, finance problems have also stimulated the development and refinement of OR techniques.

Finance problems, and especially those relating to financial markets, are particularly well suited to analysis using OR techniques. These problems are generally separable and well defined, have a clear objective (often to maximise profit or minimise risk), and have variables which are quantified in monetary terms. The relationships between the variables in finance models are usually stable and well defined, so that the resulting OR model is a good representation of the problem. As there are few concerns about human behavior ruling out the implementation of some solutions, the solutions produced by the analysis can usually be implemented. In addition, large amounts of data, both historic and real time, are readily available and can be used in OR models. Some finance problems involve very large sums of money, so that even a very small improvement in the quality of the solution is profitable to implement.

This review describes the application of OR to problems in the analysis of financial markets (e. g., the markets for debt, equity and foreign exchange markets and the corresponding derivatives markets). For a review of the application of OR to other areas of finance, such as: the management of the firm's finances: working capital management, capital investment, multinational taxation, and financial planning models (such as those developed for banks) see [3].

### Portfolio Theory

A seminal application of OR techniques to finance was by H.M. Markowitz [67,68] when he specified the portfolio problem in terms of optimization over the means and variances of the assets available, and proposed the solution of this problem through quadratic programming, see [11] for a survey. In addition to specifying the portfolio problem in terms of OR techniques, Markowitz also developed solution algorithms for more general quadratic programming problems. This provides an example of the interaction between OR techniques and finance, with the former sometimes being adapted to meet the needs of the latter.

Although the most obvious application of portfolio theory is to the choice of equity portfolios, and empirical papers, e. g., [10,81] have used quadratic programming to compute efficient equity portfolios, the technique can be applied more widely (e. g., to portfolios of currencies, bonds, or commercial loans). Multiperiod portfolio problems have been specified as dynamic programming problems [35], while [75], uses a stochastic generalized network model.

OR researchers have also modified or replaced the quadratic programming approach to portfolio problems, often by explicitly specifying the relevant utility function and using stochastic linear programming with recourse to model risk in a multiperiod framework. For example, in [15] forming bond portfolios is proposed to maximize their expected value, using stochastic linear programming to allow for interest rate risk. Early references in this area are [50,59,109,110]. The scenarios included in portfolio models may be generated by Monte-Carlo simulation, prior to the use of stochastic programming to maximise expected utility, e. g., [37,97,102,103] and [105], where this approach is applied to form portfolios of mortgage backed securities.

The investment policy of a pension fund can be formulated using asset-liability management models that allow for the correlations between the values of the fund's assets and liabilities. While these problems can be formulated using quadratic programming, they have usually been solved in other ways (see [113]). For example, in [74] it is assumed that the objective was to maximise the expected value of a nonlinear utility of wealth function, and specified the problem as a nonlinear network problem, with the simulation of future pension fund liabilities. Similar asset-liability problems are also faced by insurance companies, for example [19,20,21] formulate this problem for a Japanese insurance company. See also [50,59,76]. In [52] it is pointed out that the use of Monte-Carlo simulation can bias the results by including arbitrage opportunities in the sampled scenarios. To avoid this, an arbitrage-free event tree is aggregated before its inclusion in a multistage stochastic programming model of the asset-liability problem.

Another application of quadratic programming is generalized hedging, in which the objective is usually to minimise the variance of a portfolio of a given set of assets and the chosen hedging instruments. If the hedging instruments include options, this introduces a nonlinearity into the hedging decision, and [77] devises a nonlinear programming model to hedge foreign currency exposure using a mixture of currency forward and options contracts. Similarly, quadratic programming has been used to construct index tracking portfolios, where the purpose is to select a portfolio of assets (e. g., equities or bonds) which, when combined with a matching short position in the index to be tracked, has minimum risk [69,70,86,88]. Multistage stochastic programming with recourse, in conjunction with Monte-Carlo simulation to generate the scenarios, has been used in [97] and [105] to track an index of mortgage backed securities.

A related problem is that of portfolio immunization in which the objective is to construct a portfolio of interest rate dependent securities whose value is the same as some target asset (usually another interest rate dependent asset). (There is also a literature on managing the assets and liabilities held by banks (which are taken to exclude equities), where the objective is usually to maximise the value (or expected value) of the portfolio over one (or many) time periods (net of penalty costs from constraint target violations), subject to re-

strictions of the total investment, maximum capital loss and various bank regulations.) By matching the duration of the portfolio with that of the target asset, the portfolio is immunized against small parallel shifts in the yield curve (which shows the interest rates for different maturities), [36,55,78] and [2]. These immunization studies use a risk measure which does not involve squares or cross products of the decision variables, and so linear programming, not quadratic programming, is the solution technique.

In some applications of portfolio theory, the decision variables must be integer. Quadratic integer programming is used to compute hedging strategies involving futures in [82] and [89]. A. Shapiro, 1988, used stochastic integer programming with recourse to construct bond portfolios that allow for some of the bonds being called (or redeemed early) if interest rates are low.

Some authors have argued that formulation and solving quadratic programming portfolio problems is too onerous, and proposed simplified solution techniques. W.F. Sharpe [91] proposed a single index model which can be solved by the use of special purpose quadratic programming algorithms. When each asset represents only a small proportion of the portfolio, he [92] showed that his single index model can be treated as having a linear objective function. In 1971, he suggested using a piecewise linear approximation to the quadratic objective function, enabling the application of linear programming to solve portfolio problems. Another proposal is to minimize the mean absolute deviation (MAD), which can be solved using linear programming, rather than quadratic programming (e. g., [53,54,101,106], and [100]). Another approach is to specify the problem as choosing between a range of pre-specified equity portfolios using data envelopment analysis [84]. A further approach is to reformulate the portfolio problem as a nonlinear generalized network model for which efficient solution algorithms exist [73].

Portfolio problems, with the twin objectives of maximising returns and minimising risk, can also be viewed as goal programming problems with two goals. Additional goals can be introduced, and a number of authors have solved portfolio problems using goal programming, among them [57,58], and [61]. Capital growth theory, see [40] for a survey, has been used in a number of applications for the optimal investment of repeated investments over time, see e. g. [64,65,66,111].

## Pricing Derivatives

It is very important when trading in financial markets to have a good model for valuing the asset being traded, and OR techniques have made a substantial contribution in this area. Indeed, the very rapid growth of these markets is partly due to the application of OR techniques in pricing models.

P.P. Boyle [12] proposed the use of Monte-Carlo simulation as an alternative to the binomial model for pricing options for which a closed form solution is not readily available. Monte-Carlo simulation has the advantage over the binomial model that its convergence rate is independent of the number of state variables (e. g., the number of underlying asset prices and interest rates), while that of the binomial model is exponential in the number of state variables. Simulation is used to generate paths for the price of the underlying asset until maturity. The cash flows from the option for each path, weighted by their risk neutral probabilities, are discounted back to the present using the risk free rate, allowing the average present value across all the sample paths to be computed, thus yielding the current price of the option [14]. Risk neutral probabilities are inferred from prices assuming that investors have linear utility functions. Monte-Carlo simulation can also be used to compute various option price sensitivities, which include the hedge ratio. These sensitivities, or 'Greeks', are essential for many trading strategies [17].

Until recently it was thought that Monte-Carlo simulation could not be used to price American style options which can be exercised at any time before the option expires, because no closed form solutions for their price exist. This is a major problem, as the majority of options are American style. However, progress is being made in developing Monte-Carlo simulation techniques for pricing American style options [18,39]. Options have also been priced using finite difference approximations, and it has been proposed, [27] and [28], to use of linear programming to solve the finite difference approximations to the price of American style put options. In addition, American style options can be priced using dynamic programming, [29].

Provided a price history is available, a neural network can be trained to produce prices using a specified set of inputs, which can then be used for the out-of-sample pricing [49] of securities.

Mortgage backed securities (MBS) are created by the securitization of a pool of mortgages. For any specific mortgage, the borrower has the right to repay the loan early – the prepayment option, or may default on the payments of capital and interest. Thus MBS are hybrid securities, as they are variable interest rate securities with an early exercise option. Monte-Carlo simulation can be used to generate interest rate paths for future years. Forecasts of the mortgage prepayment rates then permit the computation of the cash flows from each interest rate path, and these sequences of cash flows are used to value the MBS [6,13,104]. This procedure, which can be used to identify mispriced MBS in real time, is computationally demanding and parallel (and massively parallel) and distributed processing have been used in the solution of the problem. Simulation has also been used to price collateralized mortgage obligations or CMOs [80]. Other hybrid securities, such as callable and puttable bonds and convertible bonds face similar valuation problems to MBS and require similarly intensive solution methods.

There is an active secondary market in loan portfolios which may carry a significant default risk. In [26] a Markov chain analysis with 14 loan performance states is used and Monte-Carlo simulation is performed to generate the probability distribution of the present value of loan portfolios.

### Trading Tactics

Besides pricing financial securities, traders are interested in finding imperfections in financial markets which can be exploited to make profits. See [51] for a survey of equity anomalies. One aspect of this is the search for weak form inefficiency (i. e. that an asset's past prices can be used as the basis of a profitable trading rule). An early attempt to find such exploitable regularities in stock prices is the use of Markov chains [30,31]. Such strategies have been found in horserace betting markets, see [42,43,44,45], and the survey book [41].

Arbitrageurs seek to exploit small price discrepancies to give riskless profits. Network models have been used to find arbitrage opportunities between sets of currencies ([22,55,73,75]). This problem can be specified as a maximal flow network, where the aim is to maximise the flow of funds out of the network, or as

a shortest path network. A risk arbitrage, convergence type hedgefund trade on discrepancies between various markets for Nikkei puts is described in [94].

There has been a growing interest in using artificial intelligence based techniques (expert systems, neural networks, genetic algorithms, fuzzy logic and inductive learning) to develop trading strategies for financial markets (e. g., [38,85,96,99]). Such approaches have the advantage that they can pick up nonlinear dynamics, and require little prior specification of the relationships involved.

### Funding Decisions

OR techniques have also been used to help firms determine the most appropriate method by which to raise capital from the financial markets. In [16] a chance constrained linear programming model is put forward to compute the values of the debt-equity ratio each period that maximize the value of the firm. Other studies have specified the choice between various types of funding as a linear goal programming problem [48,60].

A different approach to the debt problem is to assume that the firm has found its desired debt-equity ratio, and is purely concerned with raising the requisite debt as cheaply as possible. In this case, debt can be treated like any other input to the productive process, and inventory models used to determine the optimal 'reorder' times and quantities [9,62].

The design of callable bonds has been addressed in [23,24], using nonlinear programming, while [47] uses a simulated annealing algorithm. Firms which have issued callable debt face the bond-scheduling problem, in which they must decide when to call (repay) the existing debt and refinance it with a new issue, presumably at a lower cost. This dynamic programming problem has been modeled in [35,56] and [98].

Finally, the problem facing borrowers of choosing between alternative mortgage contracts (e. g., fixed rate, variable rate and adjustable rate mortgages) has been modeled using decision trees [46,63].

### Strategic Problems

In recent years, some of the decisions facing traders and market makers in financial markets have been analysed using game theory [32,79]. Traders in stock markets seek to trade at the most attractive prices and large

trades are often broken up into a sequence of smaller trades in an effort to minimise the price impact. This can be viewed as a strategic problem, and [8] uses stochastic dynamic programming to compute an optimal trading strategy.

In [83] game theory is applied to the situation where a company has two major shareholders, and a large number of very small shareholders. This can be modeled as an oceanic game, in which the two large players behave strategically while the many small shareholders (the ocean) do not. This approach can be used to derive the highest price a large shareholder will pay in the market for corporate control.

### Regulatory and Legal Problems

Financial regulators have become increasingly concerned about financial markets with their very large and rapid international financial flows. OR techniques have proved useful in regulating the capital reserves held by banks and other financial institutions to cover their risk exposure. OR techniques have also been used to ensure compliance with various legal requirements by designing appropriate strategies, and to solve other legal problems relating to financial markets.

A key regulatory issue is determining the capital required by financial institutions to underpin their activities in financial markets. An increasingly popular approach to this problem is the value at risk (VAR), which involves quantification of the lower tail of the probability distribution of outcomes from the firm's portfolio. Portfolios usually include options (or financial securities with option-like characteristics), and these have highly asymmetric payoffs. For such securities, analytical solutions to finding the probabilities in the lower tail of the payoff distribution are unreliable. Riskmetrics<sup>TM</sup> uses approximations based on 'the Greeks' for options that are at or near the money (i. e. the current price of the underlying asset is close to the price at which the option can be exercised), and Monte-Carlo simulation for other options positions [72]. (A related application of Monte-Carlo simulation is stress testing, which quantifies the sensitivity of a portfolio to specified, often adverse, market scenarios.) Some securities are also subject to credit risk, which has a highly nonnormal distribution for all instruments. Therefore, Monte-Carlo simulation is rele-

vant to modeling the credit risk of portfolios of financial instruments (e. g., loans, letters of credit, bonds, trade credit, swaps, forwards) as in CreditMetrics<sup>TM</sup> [71]. Y. Zhao and Ziemba [107,108] discuss how to model downsized risk in continuous and discrete time models.

Data envelopment analysis has been used to assist in bank regulation by measuring bank efficiency, which is then used to predict bank failure [4,5].

Traders are required to put up margin when they trade options, see [87] for a linear programming model in which the problem was modeled as a transportation problem.

An extensive set of rules governs the way in which a 'to-be-announced' MBS can be structured, leading to a complex problem in devising a feasible solution. This can be specified as a complicated integer programming problem (with the objective of maximising the originator's profit). Collateralized mortgage obligations (CMOs) also involve the securitization of a mortgage pool, but in this case the pool is structured into a series of bonds (or tranches), each with a different maturity and risks. See [25] for a complex zero-one programming model for solving this problem, with the objective of maximizing the proceeds from the issue.

In [90] a linear programming formulation is proposed to establish the maximum loss that investors could have sustained from trading in a company's shares. This figure can then be used by the company's lawyers in lawsuits claiming damages from a misleading statement by the company.

In August 1982, the Kuwait Stock Market collapsed leaving \$94 billion of debt to be resolved. This led to the problem of devising a fair method for distributing the assets seized from insolvent brokers among the other brokers and private investors. This problem was solved using linear programming, which reduced the total unresolved debt to \$20 billion, saving an estimated \$10.34 billion in lawyer's fees [33,34,95].

### Economic Understanding

OR can help in trying to understand the economic forces shaping the finance sector. Using a linear programming model of a bank, [7] employs annual data to compute movements in the shadow prices of the various constraints. They suggested that a rise in the

shadow price of the deposits constraint led to the financial innovation of negotiable CDs.

Arbitrage pricing theory (APT) seeks to identify the factors which affect asset returns. Most tests of the APT use factor analysis, and have difficulty in determining the number and definition of the factors that influence asset returns. To overcome these problems [1] suggests using a neural network, which also has the advantage that the results are distribution free.

## Conclusions

Mathematical programming is the OR technique that has been most widely applied in financial markets. Most types of mathematical programming have been employed – linear, quadratic, nonlinear, integer, goal, chance constrained, stochastic, fractional, DEA and dynamic. Monte-Carlo simulation is also widely used in financial markets – mainly to value exotic options and securities with embedded options, and to estimate the VAR for various financial institutions. In some cases the use of OR techniques has influenced the way financial markets function since they permit traders to make better decisions in less time. For example, exotic options would trade with much wider bid-ask spreads, if they traded at all, in the absence of the accurate prices computed using Monte-Carlo simulation.

Other OR techniques are less used in financial markets. Arbitrage and multiperiod portfolio problems have been formulated as network models, while market efficiency has been tested using neural networks. Game theory has been applied to battles for corporate control, decision trees to analyse mortgage choice, inventory models to set the size and timing of corporate bond issues, and Markov chains to valuing loan portfolios and testing market efficiency. One important OR technique – queueing theory – has found little application in financial markets

This review has shown that OR techniques have been usefully applied to portfolio problems and the accurate pricing of complex financial instruments. They are also used by financial regulators and financial institutions in setting capital adequacy standards. It is clear from this that OR techniques play an important role in financial markets and that this role is likely to increase over time.

Supply chain management; Logistics management; Distribution systems

A *supply chain* is ‘a connected series of activities which is concerned with planning, coordinating and controlling materials, parts, and finished goods from supplier to customer. It is concerned with two distinct flows (material and information) through the organization’, [67]. *Supply chain management* (SCM) is the coordination and integration of these activities with the goal of achieving a sustainable competitive advantage. SCM therefore encompasses a wide range of strategic, financial, and operational issues.

With the emergence of supply chain management as a new discipline, the role of operations research (OR) models in effective SCM has become significant. From 1985 onwards the performance, design, and analysis of the supply chain has received increased attention. Optimizing the performance of an entire supply chain is one of the most comprehensive strategic problems facing managers today. See [63] for 23 different kinds of OR models for logistics activities in supply chain management and strong arguments that OR/MS techniques are essential for supporting the redesign of logistics processes. They suggest, however, that these various models must be coordinated effectively to properly model a multistage supply chain.

This entry considers past literature encompassing both *strategic* and *operational* issues in supply chain management and design. Our goal is to highlight many of the recent (and some not so recent, as of 2000) papers that have led to the current increased level of activity in supply chain research. Due to the volume of work done over from 1985 onwards we limit ourselves to a discussion of papers that use OR modeling techniques in both the overall design of the supply chain and the design of operations coordination and control systems within the supply chain. We do not consider work done in the growing areas of supply chain negotiation and contracts (except where such contracts may be driven by production and transportation system models) or in the value of information in the supply chain; for a detailed discussion on these and many other developments in the field of supply chain management, see [68], which provides a comprehensive view of the field of quantitative modeling applications in supply chain management. Other recent reviews of the literature in supply chain modeling include [72] and [9]. Our work complements these reviews by including the evolution of models for

combined location-routing and inventory-routing decisions.

The *strategic design of a supply chain* requires managers to determine:

- 1) which suppliers and vendors to select for supplying raw materials;
- 2) the number, location, and capacity of manufacturing plants and warehouses;
- 3) specific transportation channels and modes for material movement between facilities;
- 4) raw material and end-item production amounts and control mechanisms for flows between suppliers, plants, warehouses, and customers; and
- 5) strategies for managing raw material, intermediate product, and finished goods inventory at each of the various locations.

*Operational decisions* in the supply chain, which are often constrained by choices made in the strategic design phase, include deciding short-term distribution and *logistics flows* between locations and production planning and inventory control policies at each location. Such decisions include determining the amount and timing of material flows from suppliers to plants, through plants and warehouses, and to retailers and customers. At the more detailed level, production and logistics operations planners must create detailed production sequencing and product delivery schedules.

We classify the literature we review into three broad categories:

- strategic supply chain design models;
- production and logistics coordination and control models; and
- supply chain simulation models.

The next three Sections consider models in each of these three areas. Note that within each section we have attempted to present past papers in chronological order of publication with a few exceptions to maintain continuity of presentation.

### Strategic Design Models

This Section summarizes the evolution of OR models in the broad area of *supply chain design*. We first consider approaches that decide important long-term strategic factors such as location of facilities and assignment of products and/or customers to these facilities. Note that these models attempt to determine the supply chain de-

sign that provides the best combination of service and cost performance from an overall system view. That is, in these approaches, a central planner determines the best overall system configuration. We then take a look at models that combine location and transportation decisions in the subsection on *location-routing models*.

### Distribution System Design

A.M. Geoffrion and G.W. Graves [36] present the first comprehensive supply chain design model for Hunt-Wesson foods. They develop a Benders decomposition-based algorithm that successfully solves a multicommodity production and distribution system design problem. This system contains several plants (with known and fixed capacities), distribution centers with limits on throughput, and retailer zones (each of which must be sourced to a single distribution center). The model finds the optimal distribution center configuration by considering fixed plus variable costs for operating warehouses as well as detailed production and transportation costs.

J.E. Hodder and M.C. Dincer [43] describe an international *plant location model* and develop a large scale nonlinear programming model. The objective function captures the difference between the expected value of profit and the variance of profit, which is scaled by a risk aversion factor. The model incorporates constraints on plant capacities, market demands, and financial investment limits. Their formulation considers the impacts of market prices, international interest rates, exchange rate fluctuations, production and transportation costs, import tariffs, and export taxes.

M.A. Cohen and H.L. Lee [22] present a single-period, multicommodity, nonlinear programming model to develop a global resource deployment policy. This paper provides a good initial effort to create a fully integrated logistics chain model by linking a set of distinct stochastic submodels. The objective function maximizes the total after-tax profit for the manufacturing facilities and distribution centers in all countries. The submodels incorporate plant production capacity limits, plant material requirements constraints, inventory balance constraints at both the plants and distribution centers, demand and supply capacity limits, and offset trade requirements. The model decides the assignment of products and subassemblies to plants,

vendors to distribution centers, and distribution centers to market regions. It also determines the amounts of components, subassemblies, and final products to produce at each plant and how to ship these items between vendors, manufacturing facilities, and distribution centers.

J.H. Bookbinder and K.E. Reece [10] extend the Geoffrion–Graves [36] model to consider multicommodity *distribution system design* with *vehicle routing* and transportation fleet-sizing decisions. They combined the Geoffrion–Graves [36] *Benders decomposition* approach with the vehicle routing approach of M.L. Fisher and R. Jaikumar [33]. The master problem in their algorithm determines the number and locations of warehouses. The subproblems then determine the best set of vehicle routes (including the number and sizes of vehicles used by location), given the warehouse configuration specified by the master problem.

Cohen and Lee [23] built on their prior work by creating a deterministic model for designing a large scale distribution network. This model also incorporates offset trade requirements and estimates before and after tax profits. Although they provide a comprehensive formulation of the global supply chain design problem, no detailed solution procedure for determining the optimal configuration is provided.

Cohen and S. Moon [24] formulate a mixed integer, multicommodity model that determines the assignment of product lines and production volumes to plants. For each plant they determine inbound raw material flows and outbound finished product flows. This research provides a restricted optimization algorithm to solve production-distribution problems with piecewise linear concave production costs. The objective function consists of fixed and variable production and transportation costs. The model includes supply, capacity, assignment, demand, and raw material requirements constraints. A variant of the Benders decomposition technique is applied to solve each problem instance.

Cohen and P.R. Kleindorfer [21] present a normative model for global manufacturing operations that directs plant location and capacity decisions as well as product mix, material flow, and cash flow amounts. The model consists of several submodels (a stochastic supply chain network model, a financial flow model, a stochastic exchange rate model, and a price-demand model). The submodels link a multiperiod stochastic

master problem to a set of single-period stochastic sub-problems. See [23] for a description of an implementation of this model framework.

B.C. Arntzen et al. [3] present one of the most comprehensive supply chain design models to date, which they use to redesign Digital Equipment Corporation's (DEC's) supply chain. They develop a multiperiod, multicommodity, mixed integer programming model called GSCM (Global Supply Chain Model) to optimize the configuration of DEC's global supply chain. The model accommodates multiple facilities, stages (echelons), time periods, and transportation modes. GSCM minimizes a composite function of activity days and the total cost of production, inventory, material handling, overhead, and transportation. The constraints enforce requirements on meeting customer demands, production and throughput capacity limits at each facility, and bounds on decision variables. GSCM encodes the global bill-of-materials (BOM) for each product and enforces inventory balance constraints for every product and location. Their formulation reflects offset trade and local content restrictions as well as duty payment and drawback for flows through various countries. The model decides the number and location of distribution centers, the customer-to-distribution center assignments, and product-to-plant assignments. Arntzen et al. [3] describe how DEC used GSCM to evaluate global supply chain alternatives and develop worldwide manufacturing and distribution strategies. DEC used GSCM to guide a worldwide restructuring that saved the company over \$100 million.

J.D. Camm et al. [15] develop an integer programming model using an uncapacitated *facility location* formulation for Procter & Gamble's distribution network. The model minimizes the total cost of distribution center location selection and distribution center-to-customer assignments, subject to assignment constraints and a maximum number of distribution centers in operation. This model chooses the best location and scale of operation for producing items in Procter & Gamble's product line.

H. Pirkul and V. Jayaraman [58] propose a mixed integer programming model for designing a three-level distribution network. The model defines the physical flows of commodities from plants to warehouses and from warehouses to customer zones. Their method determines the locations of plants and warehouses that

result in the minimum total operating plus fixed costs for the distribution network. They [58] develop a Lagrangian relaxation-based heuristic that assigns customers to open warehouses based on their demand for products, and then assigns open warehouses to open plants.

Recent approaches (as of 2000) for dynamic distribution system design, in which customer demands vary over a finite planning horizon, have been developed in [60,61] and [34]. These papers consider a set of capacitated plants with associated (uncapacitated) warehouses that must distribute products to a set of customers in each period. Each of these models requires assigning every customer to a single source, or warehouse, and hence employs heuristics for generalized assignment formulations of the problem. H.E. Romeijn and D. Romero Morales [60,61] show the asymptotic optimality of specific greedy heuristic procedures for the cyclic (repeating demand patterns) and acyclic demand cases. R. Freling et al. [34] apply a branch and price algorithm to the single sourcing problem under seasonal demands.

L.M.A. Chan and D. Simchi-Levi [17] consider a transportation-inventory-routing design problem and provide a model and algorithm for a three-level distribution system. The system contains a single vendor, multiple cross-docking warehouses, and multiple retailers with constant demand rates. We include this paper in the design section because, unlike the inventory-routing problems covered in the following section, this work develops insights regarding distribution system design strategy. The authors argue that this system corresponds closely to the Wal-Mart distribution system, which has proven immensely successful over the past decade. Their algorithm assigns each retailer to a warehouse using a bin-packing scheme, and partitions the assigned retailers into clusters using a capacitated concentrator location algorithm. They then combine retail clusters into groups that share the same reorder interval. The model minimizes asymptotic long-run average transportation plus inventory costs, and the authors show an optimal solution that forces each warehouse to receive fully loaded trucks from the vendor, but never to hold inventory. The warehouse therefore serves only as a coordinator of the frequency, time, and size of deliveries to retailers, i. e., as a cross-docking facility.

## Location-Routing Models

Next we briefly summarize work done on so-called location-routing models. This research area has received vast attention starting in the 1970s and we therefore highlight a few of the more significant developments. For a detailed summary of location-routing models, see [8] and [53]. Since traditional facility location models consider only the cost of assigning customers or markets to facilities (see, for example, [25]), many researchers have shown the value of explicitly considering integrated location models that incorporate detailed vehicle routing decisions.

Perhaps the earliest work to take such an integrated view was done by I.R. Webb [73], who randomly generates depot locations and considers the impact of using straight-line distances as a substitute for route distances in a deterministic setting with vehicle capacity restrictions. The paper concludes that a significant loss of accuracy can result from using straight-line models. S.K. Jacobsen and O.B.G. Madsen [45] subsequently use sophisticated heuristic approaches to solve a two-level newspaper distribution system design problem in practice.

G. Laporte and Y. Nobert [47] and Laporte et al. [48] give exact integer programming approaches for the location-routing problem in the absence of vehicle capacity restrictions (the first paper considers a single depot, while the second extends this to multiple depots). To solve a set of randomly generated problems they employ a branch and bound algorithm with the addition of violated subtour constraints.

J. Perl and M.S. Daskin [55,56] use optimization-based heuristic approaches for solving the multiple-depot routing problem with depot throughput costs and capacities. Their heuristic initially opens all depots and solves a routing problem for each. They then use fixed cost and depot capacity considerations to determine which depots to keep open and heuristically reallocate customers to open facilities.

Laporte et al. [46] extend the analysis to consider the location of a depot that collects goods from customers and returns them to the depot. In this model customer supplies are random variables and a vehicle must return to the depot once it is filled to capacity. The problem is modeled as a two-stage stochastic program with recourse.

R. Srivastava and W.C. Benton [65] consider the impact of environmental and operational factors on solutions to location-routing problems. These factors include the customers' spatial distribution and the ratio of location cost to routing costs. The authors apply several combinations of well-known routing and location heuristics to determine the effects of specific factors on heuristic performance.

Other recent heuristics and case studies in the location-routing literature include [4,41,54,64], and [52]. The following section considers shorter-term operations decisions in supply chain management.

## Production and Logistics Control Models

This Section considers models that decide more detailed operational decisions such as the timing and quantities of flows between facilities. These issues and decisions have been addressed for many years within the context of single-stage models. We focus on models that consider the impacts such decisions have on multiple entities in a supply chain. These entities may or may not belong to the same firm and may have either the same or conflicting objectives. With a few exceptions we have not summarized the voluminous literature in the area of multi-echelon inventory control. Papers in this area tend to develop cost models of multistage *inventory systems* under various cost, demand, and operational assumptions. They then seek to minimize overall production and inventory related costs. With the exception of the paper [20] noted in the following paragraph, we focus on models that consider inventory costs in conjunction with distribution and logistics related costs. For a detailed discussion of multi-echelon inventory analysis, see [39,49,68].

This Section first focuses on models that combine inventory and transportation decisions. (For in-depth analyses of general vehicle routing and inventory-routing models, see [30] and [11].) We then look at papers that consider the coordination of material flows and inventory placement in the supply chain. Finally we look at the phenomenon known as the 'bullwhip effect', (which describes the commonly observed increased demand variance at upstream stages in a supply chain) and models that have attempted to mitigate this effect.

## Combined Inventory and Transportation Decisions

A.J. Clark and H. Scarf [20] provide perhaps the earliest work considering the operational interaction between two separate members of a distribution chain. They develop a periodic review inventory management model for a serial distribution system. They use a simple system consisting of a single distribution center and a single retailer to show the optimality of modified base-stock policies for the retailer's inventory control. Modified base-stock policies require a fixed base-stock level that the retailer attempts to bring inventory up to at the beginning of each period. If the retailer cannot reach its target base-stock level (because the distribution center has insufficient stock), the retailer attempts to get as close to the base-stock level as possible by exhausting distribution center stock.

In one of the initial efforts to provide an exact model that incorporates combined inventory and transportation costs with stochastic demands, A. Federgruen and P. Zipkin [31] consider a single-period problem in which a central depot must allocate its inventory among multiple retailers. Their model minimizes expected inventory holding and shortage costs plus vehicle routing costs. Each of a set of vehicles has a fixed capacity and incurs a cost equal to  $c_{ij}$  for travel between locations  $i$  and  $j$ . The model determines vehicle routes and the allocation of inventory among the retailer locations that minimizes combined inventory and routing costs.

L.B. Burns et al. [12] present the model behind a system developed in a streamlining effort for GM's Delco Electronics Division distribution network. The model examines the trade-offs between inventory and transportation costs and determines which plants should supply a variety of assembly facilities in North America. The key decision involved was between the current practice of straight-line deliveries to a single centralized warehouse versus a peddling strategy that delivers parts directly to the assembly plants. The model recommended a new peddling strategy for Delco components and resulted in a 26.9% logistics savings opportunity.

C.A. Yano and Y. Gerchak [76] consider a two-stage system where a manufacturing plant supplies an assembly plant with Just-in-time (JIT) shipments of a high-volume part. The model assumes that the retailer observes stochastic, periodic demand of a single product. They allow for emergency shipments of parts when in-

sufficient vehicle capacity exists. They determine the order-up-to point (base-stock level) for the part, the time between successive deliveries of the part, and the number of vehicles contracted for deliveries between the supplier and assembly plant. The model minimizes the sum of assembly plant expected inventory costs, contracted shipment costs, and emergency shipment costs. R. Ernst and Pyke [29] build on the work of Yano and Gerchak [76] by including the manufacturer's (or, in their case, the warehouse's) expected inventory costs plus per unit shipping costs (as opposed to a per truck shipping cost only).

We find a more detailed treatment of the trade-off between vehicle routing and inventory costs in [2], which considers a system with a central depot and multiple geographically dispersed retailers. All stock enters the system through the depot and each retailer observes deterministic demand that occurs at a constant rate. The model minimizes inventory costs at the retailers (the depot holds no stock) plus distribution costs incurred by combining retailer deliveries into routes served by a set of vehicles with fixed capacities. The authors develop bounds on both the optimal solution and solutions from a class of heuristics they develop. They then show the asymptotic optimality of their heuristics (within a class of strategies that partitions retailers into regions, and if a vehicle visits a region it must visit all retailers in the region). For other algorithms for and extensions to the inventory-routing model see [19,27,28], and [74].

P. Chandra and Fisher [18] consider the problem of coordinating production runs with vehicle routing decisions for a single facility with multiple customers. They compared the case of separately optimizing production planning and vehicle routing decisions to a coordinated approach that attempts to minimize the total combined cost of production and routing. They found increased value in coordinating these decisions under higher production capacity, longer time horizons, and low holding and setup costs (i. e., the more flexible and less constrained the production planning situation).

M. Henig et al. [42] consider the problem of determining the optimal inventory replenishment policy structure and truck capacity when a distribution center imposes a variable cost for each unit ordered in excess of distribution center truck capacity,  $R$ . They show that the optimal periodic ordering policy under such a cost

contains two base-stock levels,  $S_1$  and  $S_2$  ( $S_2 \geq S_1$ ). The policy structure requires that if initial inventory position before ordering is less than  $S_2$ , we either order up to  $S_1$ , order exactly  $R$  units, or order up to  $S_2$ , depending on the value of the initial inventory position; otherwise we do not order. The paper also specifies a method to determine the best level of truck capacity under the given cost structure.

Due to the increased reliance by manufacturers on third party less-than-truckload (LTL) carriers, Chan et al. [16] consider a multiperiod distribution model with LTL shipments. Their model assumes that a set of customers observe periodic, deterministic demand for multiple products over a finite planning horizon. The distribution network contains both suppliers and warehouses and the model allows for backlogging customer demands. The authors pose the problem as a fixed-charge minimum concave cost network flow problem over an equivalent distribution network, where the costs include LTL shipping costs plus inventory holding and shortage costs. The paper develops properties of optimal solutions and shows conditions under which the linear programming (LP) relaxation (under piecewise-linear concave costs) value equals the optimal mixed integer solution value. The heuristic solution algorithm proposed is based on effectively characterizing the cost of modifying a fractional integer variable found in the LP relaxation solution. Their results compare favorably to an original solution approach for the problem proposed in [7].

### Material Flows and Inventory Placement

We next consider several papers that deal with more effectively managing material flows and inventory placement in the supply chain.

Lee and C. Billington [50] develop a stochastic model for managing material flows in Hewlett-Packard's deskjet printer supply chain. They assume that each site observes stochastic demand and employs a periodic, order-up-to inventory system and that a predetermined value is set for either a target service level or base-stock level (for each site). Their model characterizes the demand transmission process (whereby a site translates its demand into orders on its' suppliers) and the availability transfer process, which describes the availability of goods at the supplier location. They de-

termine the review period and order quantity for each product type and location and address the trade-offs between inventory investment and service level in a multistage supply chain.

Pyke and Cohen [59] develop a stochastic model for managing material flows in an integrated three-level production-distribution system. The system contains multiple products, a single manufacturing facility, one warehouse, and a single retailer. The retailer promises its customers a minimum service level and the model minimizes total cost under constant setup and processing times at the factory. Although the transportation time from factory to retailer is constant, an option exists for the retailer to receive an expedited shipment if the finished goods stockpile at the factory cannot satisfy retailer demand. The model assumes stochastic production times and lead times between the factory and its finished goods stockpile, and approximates key inventory and service time distributions necessary for expressing expected total system cost. The outputs of the model include the economic reorder interval and replenishment batch size for each product type.

T. Altiok and R. Ranjan [1] analyze a multistage pull-type production system containing one final product, FIFO (first in, first out) processing rules, intermediate buffers, and Poisson demand. Each stage follows an  $(R, r)$  inventory policy (when inventory position falls below  $r$ , order up to  $R$ ) and backorders when stock is insufficient to meet demand. They develop an iterative procedure that separately considers the flow in each two-node subsystem as a function of the policy parameters. The procedure terminates when the average throughput values of all subsystems are approximately equal. The outputs include the inventory level in each buffer and the backorder probability,  $P$ . The authors show that when  $P$  does not exceed 0.3, their approximation method provides acceptable results.

S.C. Graves and S. Willems [40] consider the placement (location) of safety stock in a multistage supply chain. They represent the supply chain as a network and assume that each stage follows a base-stock policy (a stage represents a processing function, such as procurement of raw material, component production, assembly, testing, etc.). Demand occurs only at nodes that have no successors and each stage provides a guaranteed service time for meeting downstream demand. The

model minimizes system-wide safety stock costs while meeting the guaranteed service times (which constitute the decision variables). They [40] validated their model through a successful implementation in Eastman Kodak's digital camera supply chain.

Graves et al. [38] study *requirements planning* in multistage production systems. They begin with a single-stage model that produces one (aggregated) product to stock for a finished goods stockpile. They assume that each stage forecasts demand  $H$  periods in advance and revises forecasts in each period. These forecasts drive the production plan, which is also planned  $H$  periods in advance and is revised each period. They measure three significant parameters: the smoothness of the production plan, the stability of the production plan, and the safety stock level (smoothness of the production plan differs from stability in that smoothness characterizes the variability of actual production output while stability characterizes the variability of the production schedule). The paper captures the trade-off between production capacity and inventory requirements. The authors show how to extend the single-stage model to a multiple-stage dynamic requirements planning (DRP) model by replicating single-stage models. An application of the model to film manufacturing at Kodak resulted in a 60% decrease in inventory requirements for two items, while increasing one item's inventory by 20%, with a significant net savings reported for the business line.

### The Bullwhip Effect

Several recent papers (as of 2000) have described and quantified the phenomenon known as the *bullwhip effect* in supply chains – the tendency for demand variability to increase at upstream stages in the chain. This demand variability places a burden on suppliers because of the increased safety stock and excess vehicle capacity requirements.

C.C. Holt, F. Modigliani, and J.P. Shelton [44] first showed evidence that the variation in orders can increase at upstream points in the television manufacturing chain. J.D. Sterman's [66] documentation of experience with supply chain simulation experiments shows how rational decision making can lead to the bullwhip effect in the absence of full information about partners in the chain.

Lee, V. Padmanabhan, and S. Whang [51] offer four factors to explain the existence of the bullwhip effect (demand forecast updating, order batching, price fluctuation, and shortage gaming), along with mathematical models of these phenomena. They provide insights on how coordination between channel partners can diminish the bullwhip effect. Z. Drezner et al. [26] specifically consider the impact of forecast errors on the bullwhip effect. Their model shows that even in supply chains with perfect information shared among all members, errors in demand forecasts can still create a bullwhip effect.

M.P. Baganha and Cohen [5] consider conditions under which demand stabilization (or damping) becomes economically attractive in a two-echelon distribution system containing a warehouse and multiple retailers. Their model assumes that each retailer incurs a fixed order cost, which results in the optimality of  $(s, S)$  inventory policies at each retailer (when inventory position falls below  $s$ , order up to  $S$ ). Following an  $(s, S)$  policy results in autocorrelated orders from each retailer since we can expect that a retailer will not place an order in a period immediately following one in which an order was placed. Baganha and Cohen [5] therefore apply an autoregressive model to describe the distribution of retailer orders (which constitutes warehouse demand) and show situations in which retailer order damping can lead to lower system cost.

G.P. Cachon [13] studies supply chain demand variability in a model with one supplier and  $N$  retailers that face stochastic demand. Retailers follow a periodic  $(R, nQ)$  policy (order up to  $R$  using integer multiples of some base quantity,  $Q$ ). The model develops exact expressions for supply chain (inventory) costs under stationary retailer demand distributions. The results show how the supplier's demand variance declines as the retailers' order intervals are lengthened or as batch size increases. The main result of the paper shows that a balanced ordering strategy (when the same number of retailers order in each period) can lead to significant savings in supply chain inventory costs.

Cachon and Zipkin [14] consider competition and cooperation in a two-stage serial supply chain. The model assumes stationary stochastic demand occurs at a single retailer who then orders from a supplier. They consider both the competitive and cooperative scenarios: in the competitive case each firm minimizes its own

cost, while a coordinated approach minimizes system costs (both firms follow a base-stock policy). The paper shows how the competitive approach reduces efficiency by leading to a Nash Equilibrium point that differs from the system optimal solution. A sequence of linear transfer payments allows the firms to achieve the system optimal solution while operating independently.

A. Balakrishnan et al. [6] consider a two-echelon supply chain with a single-distribution center, multiple retailers, and multiple products. Like Cachon and Zipkin [14], they compare expected chain costs under autonomous decisions (competitive scenario) to those under coordination mechanisms. The model differs from that of Cachon and Zipkin [14] since it considers inventory plus transportation costs, and the coordination mechanisms differ from linear transfer payments. Balakrishnan et al. [6] offer both cost- and policy-driven mechanisms that effectively use the retailer order variability as a decision variable. By tuning to the best level of order variability they show that the coordination mechanisms can lead to better system costs than under autonomous decisions by damping retailer demand variation.

### Supply Chain Simulation Models

Because of the large number of decision variables and the complexity of the constraints required in developing exact cost models of large scale distribution systems, many researchers have used *simulation models* to provide valuable insight into complex supply chain dynamics. We next briefly consider models that have used simulation to derive such insights.

J. Wikner et al. [75] examine five supply chain improvement strategies using a simulation model for a three-level supply chain that includes one factory, multiple distribution centers and retailers, and carries inventory at each facility. The five strategies include

- 1) reducing system delays;
- 2) fine tuning order policy parameters;
- 3) removing the distribution center echelon from the system;
- 4) changing different echelon decision rules; and
- 5) improving information integration between stages.

They conclude that integrating information flow between channel partners is the most effective strategy for minimizing supply chain operating costs.

D.R. Towill et al. [70] then extend the simulation model to consider a just-in-time (JIT) delivery strategy. The JIT strategy combined with the removal of the distribution center echelon was shown to be more effective than the integration of information flow or modification of the order policy parameters. Towill and A. Del Vecchio [69] use methods from filter theory combined with a simulation model to analyze the effects of demand variability in the supply chain. They liken each stage in the chain to an electrical filter (with a response function) and analyze various supply chain responses to randomness in demand patterns. The simulated responses determine the minimum safety stock required to achieve a desired service level.

S. Tzafestas and G. Kapsiotis [71] present a mathematical programming based approach to optimize a portion of the supply chain and use simulation techniques to numerically analyze the performance of the optimized model. They consider a two-echelon system in which a manufacturer supplies multiple assembly plants. They then consider three decision scenarios. In scenario I the manufacturer minimizes its cost and its customers must accept the deliveries imposed by the manufacturer. Scenario II incorporates a central decision-maker that attempts to minimize overall system costs. Scenario III presents a decentralized decision framework where the supplier minimizes its cost subject to the demand imposed by the assembly plants under their optimal decisions. They perform the simulation under three scenarios: manufacturing facility optimization, global supply chain optimization, and decentralized optimization at each level. The numerical examples chosen by the authors do not result in significant differences in cost performance under any of the three tested scenarios.

D. Petrovic et al. [57] use fuzzy modeling to determine order-up-to levels at various stages in a supply chain. They develop a supply chain simulator that analyzes the effects of order-up-to levels on cost and the dynamic behavior of the chain in an uncertain environment. The fuzzy model handles uncertainty in both customer demand and external supply of raw materials. The model attempts to determine the stock levels and order quantities at each stage in the chain that give acceptable delivery performance at a reasonable total cost.

R. Ganeshan [35] presents a near optimal  $(s, Q)$  inventory policy (when inventory position falls below

s, order  $Q$  units) for a production/distribution network with multiple suppliers, a central warehouse, and multiple retailers. This model develops a system-wide cost equation (by describing the demand process at the warehouse) that includes warehouse and retailer inventory costs and uses a conjugate gradient method to find the best policy parameters. The paper verifies the costs implied by the prescribed policy parameters using a SLAM-based supply chain simulation model.

### Summary

Fisher [32] notes that the performance of supply chains today is extremely poor despite advances in the areas of quick response systems, mass customization, lean manufacturing, and new technologies. As firms increase their operations throughout the world, they will have even greater need for tools that integrate operations and information among geographically dispersed locations.

The key to success in SCM requires an emphasis on integrating activities through cooperation, coordination, and information sharing throughout the entire chain. To have the greatest benefit, the supply chain must be managed as a single entity, which requires improved OR models and tools so that supply chain managers can solve problems that reflect the relationships among all supply chain activities.

Many research opportunities exist for developing global supply chain models that take into account elements necessary for providing a complete and integrated view of the system. New areas for research include the following:

- modeling the effects of a greater number of stochastic elements;
- accounting for international economic issues (including exchange rate fluctuations and risks);
- incorporating and modeling detailed BOM relationships;
- product differentiation and mass customization strategies;
- capitalizing on advances in information technologies; and
- the value of important strategic global alliances.

We have commented on many significant developments and applications of OR models. Despite these advances, Geoffrion and Powers [37] report that many of the most popular commercial software packages still

use simple heuristic approaches that result in significantly suboptimal cost performance. Because of the proliferation of desktop computers and software packages with sophisticated graphical user interfaces, logistics executives have almost exclusively selected overly simplified heuristic-based software for the design and analysis of the supply chain.

Shapiro et al. [62] note that now is the perfect time for developing sophisticated OR supply chain models for personal computers and describe their success in doing so for a large consumer products company. The OR/MS profession has recently created many powerful decision tools that provide opportunities for improved SCM. It is important that these tools continue to find widespread application in industry through the development of comprehensive and user-friendly SCM systems.

## Mechanical Model

Considered is the rotation of a *flexible arm* in a horizontal plane around an axis through the arm's fixed end and driven by a motor whose torque is controlled. The equations of motion of the motor are given by

$$\begin{cases} \dot{\Theta}(t) = \omega(t), \\ \dot{\omega}(t) = u(t) = \frac{\tau(t)}{J}, \end{cases} \quad (1)$$

where  $\Theta$  is the angle of rotation,  $\omega$  is the angular velocity,  $\tau$  is the torque generated by the motor, and  $J$  is the moment of inertia of the motor and the arm.  $J$  is assumed to be constant, since the displacement of the arm due to the vibration caused by the rotation is assumed to be small.

In addition, we assume the arm to be homogeneous and of length 1. Following [6] the displacement  $y = y(t, x)$  of the arm from the rotating zero line is modeled by the differential equation

$$\begin{aligned} y_{tt}(t, x) + \alpha y_{xxxx}(t, x) \\ - \frac{\omega(t)^2}{2} \frac{\partial}{\partial x} [(1-x^2)y_x(t, x)] - \omega(t)^2 y(t, x) = -xu(t) \end{aligned}$$

for all  $t \in (0, T)$  and  $x \in (0, 1)$ , (2)

where  $T > 0$  is some given time and  $\alpha = EI\rho$  with  $E$  being Young's modulus of the arm material,  $I$  being the moment of inertia of the cross-section of the arm, and  $\rho$  being the mass per unit length.

The left end of the arm is clamped, and the right end is free. This leads to the boundary conditions

$$y(t, 0) = y_x(t, 0) = y_{xx}(t, 1) = y_{xxx}(t, 1) = 0 \quad (3)$$

for all  $t \in [0, T]$ .

At the beginning of the motion the arm is assumed to be in rest which leads to the initial conditions

$$\begin{aligned} y(0, x) = y_t(0, x) = 0 \\ \text{for all } x \in (0, 1) \end{aligned} \quad (4)$$

and

$$\Theta(0) = \dot{\Theta}(0) = 0. \quad (5)$$

## The Problem of Controllability and Minimum Norm Controllability

Let some angle  $\Theta_T \in \mathbf{R}$  with  $\Theta_T \neq 0$  be prescribed. Then we look for some control function  $u \in L^2(0, T)$  such that the solution  $y = y(t, x)$ ,  $t \in [0, T]$ ,  $x \in [0, 1]$  of (2), (3) and (4) satisfies the end conditions

$$\begin{aligned} y(T, x) = y_t(T, x) = 0 \\ \text{for all } x \in (0, 1) \end{aligned} \quad (6)$$

and the angle  $\Theta = \Theta(t)$ ,  $t \in [0, T]$ , of rotation satisfies the end conditions

$$\Theta(T) = \Theta_T \quad \text{and} \quad \dot{\Theta}(T) = 0. \quad (7)$$

If this problem of *controllability* is solvable, then a control function  $u \in L^2(0, T)$  is looked for which solves the problem of controllability and whose norm

$$\|u\|_{L^2(0, T)} = \left( \int_0^T u(t)^2 dt \right)^{\frac{1}{2}}$$

is as small as possible.

On using (1) and (5) we get

$$\begin{aligned} \dot{\Theta}(t) = \omega(t) &= \int_0^t u(s) ds, \\ \Theta(t) &= \int_0^t (t-s)u(s) ds \end{aligned}$$

for  $t \in [0, T]$  so that the differential equation (2) can be rewritten in the form

$$\begin{aligned} y_{tt}(t, x) + \alpha y_{xxxx}(t, x) - \left( \int_0^T u(s) ds \right)^2 \\ \times \left\{ \frac{1}{2} \frac{\partial}{\partial x} [(1-x^2)y_x(t, x)] + y(t, x) \right\} = -xu(t) \end{aligned} \quad (8)$$

for  $t \in (0, T)$  and  $x \in (0, 1)$

and the end conditions (7) are equivalent to

$$\begin{cases} -\int_0^T tu(t) dt = \Theta_T, \\ \int_0^T u(t) dt = 0. \end{cases} \quad (9)$$

### Solvability of the Problem of Controllability

At first we consider the special case where the cross-section areas behave like rigid bodies, i. e., they stay plane, do not change their measurements and do not rotate around their centers. Further, it is assumed that they stay orthogonal to the zero line. Then the differential equation (2) can be replaced by

$$y_{tt}(t, x) + \alpha y_{xxxx}(t, x) = -xu(t) \quad (10)$$

for  $t \in (0, T)$  and  $x \in (0, 1)$

(see [1] and [2]).

In this case it can be shown that the problem of controllability is solvable for every  $T > 0$  and the problem of *controllability with minimum norm* has a unique solution (see, for instance [3]). The main tool in the proof of this result is linear moment theory (see [4]).

In the general case where the displacement  $y = y(t, x)$  of the arm from the rotating zero line is modeled by the differential equation (2), the problem of controllability is not exactly solvable as being shown in [5]. The main tool in the proof of this result is nonlinear moment theory. However, if one determines the unique control  $u = u^1 \in L^2(0, T)$  which satisfies (9) with minimal norm such that the corresponding solution  $y = y^1 = y^1(t, x)$  of (10), (3) and (4) satisfies the end conditions (6) and then determines the unique control  $u = u^2 \in L^2(0, T)$  which satisfies (9) with minimum norm such that the solution  $y = y^2 = y^2(t, x)$  of the differential equation

$$y_{tt}^2(t, x) + \alpha y_{xxxx}^2(t, x) = \left( \int_0^t u^1(s) ds \right)^2 \times \left\{ \frac{1}{2} \frac{\partial}{\partial x} [(1-x^2)y_x^1(t, x)] + y^1(t, x) \right\} - xu^2(t)$$

for  $t \in (0, T)$ ,  $x \in (0, 1)$  the boundary conditions (4), and the initial conditions (3) satisfies the end conditions (4),

then the solution  $y = y^* = y^*(t, x)$  of

$$y_{tt}^*(t, x) + \alpha y_{xxxx}^*(t, x) - \left( \int_0^t u^2(t) dt \right)^2 \times \left\{ \frac{1}{2} \frac{\partial}{\partial x} [(1-x^2)y_x^*(t, x)] + y^*(t, x) \right\} = -xu^2(t)$$

for  $t \in (0, T)$ ,  $x \in (0, 1)$ , the boundary conditions (3), and the initial conditions (4) satisfies the end conditions (6) up to a very small error.

Global optimization; Random search algorithms; Simulated annealing; Improving hit and run; Hit and run methods; Mixed discrete-continuous global optimization; Design of composite structures; Structural optimization

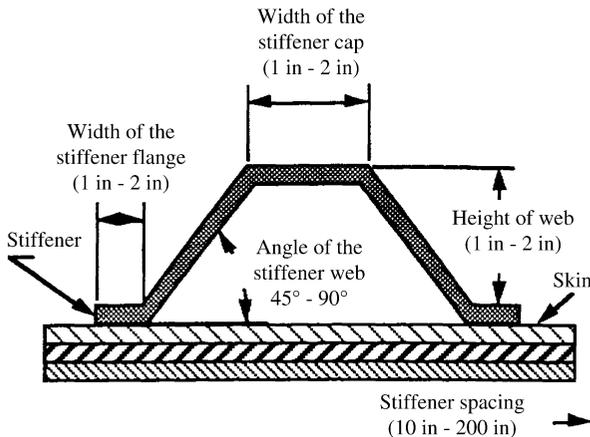

Designing a composite stiffened panel is a complicated process, and optimization techniques are proving helpful to engineers in designing a cost-effective, practical structure. Random search algorithms (cf. also ► [Random search methods](#)), such as simulated annealing and genetic algorithms, are being used in the *design of composite structures* [3]. A benefit of these algorithms is that they can optimize functions that cannot be handled with traditional optimization techniques. In this

article, a *structural design* problem for composite fuselage is described which involves solving a mixed integer global optimization problem. The objective function may be discontinuous, have many local optima, and the feasible region may be disconnected. The random search algorithm, *improving hit and run* [23], that is used to solve these composite structural optimization problems is also described in ► [Global optimization: Hit and run methods](#). Although a *random search algorithm* can only provide a probabilistic guarantee of finding the global optimum, the benefits of having a more realistic formulation outweigh the disadvantage of not having a 100% guarantee of finding the global optimum. The near optimal solutions found using this approach have been well-received by Boeing engineers and have demonstrated significant reductions in weight and cost [15].

Three optimization formulations for a composite design problem will be described, each increasing in complexity and incorporating more realism. The first two formulations are point designs, where a single cross-section of a composite panel is optimized. The first formulation assumes a fixed number of plies, while the second one allows the number of plies to be a variable in the optimization. The third formulation extends a ‘point’ optimization to a ‘blended’ panel optimization, by dividing a panel into elements. This third formulation is applied to the design of a large panel with varying cross-sections. Manufacturing considerations lead to constraints in the third formulation to ensure a practical, consistent, panel. A sample problem is also presented.

### Point Design

The first formulation optimizes a laminated composite structure, with skin and stiffeners. Laminated composites are composed of several thin layers, called plies, which are bonded together to form a composite laminate. A single ply consists of long reinforcing fibers (e.g., graphite fibers), embedded within a relatively weak matrix material (e.g., epoxy). Composite laminates are usually fabricated such that all fibers within an individual ply are oriented in one direction, however the angle may vary from ply to ply. The angle of the fibers in the  $i$ th ply is denoted by  $\theta_i$ . The design variables for the first formulation include: the fiber an-

**Optimal Design of Composite Structures, Figure 1**  
Design variables for a hat stiffened composite laminate

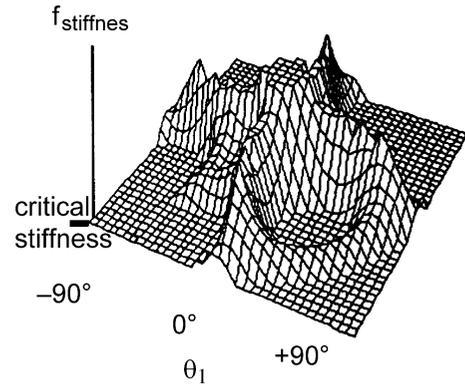

gles for each ply in the skin and stiffeners, denoted  $\theta_i^{\text{skin}}$  for  $i = 1, \dots, n^{\text{skin}}$  and  $\theta_i^{\text{stiffener}}$  for  $i = 1, \dots, n^{\text{stiffener}}$ , and stiffener geometry variables; height, width of cap, width of flange, angle of web, and stiffener spacing, as shown schematically in Fig. 1. In the first formulation, it is assumed that the numbers of plies in the skin and stiffeners,  $n^{\text{skin}}$  and  $n^{\text{stiffener}}$ , are fixed. This assumption is relaxed in the second formulation, where the number of plies will also be allowed to vary.

The first optimization formulation is stated as:

$$\begin{cases} \min & f(x) \\ \text{s.t.} & g_j(x) \geq 0 \quad \text{for } j = 1, \dots, m, \\ & x_i^l \leq x_i \leq x_i^u \quad \text{for } i = 1, \dots, n, \end{cases} \quad (1)$$

where the  $n$  variables consist of the  $n^{\text{skin}} + n^{\text{stiffener}}$  fiber angles and five stiffener geometry variables, and are real-valued,  $x \in \mathbf{R}^n$ . The objective function,  $f(x)$ , may be cost, weight, or a combination of cost and weight,  $f(x) = \delta_{\text{cost}} * f_{\text{cost}}(x) + \delta_{\text{weight}} * f_{\text{weight}}(x)$ . An alternate objective may be to maximize performance, such as maximize margin of safety.

The constraints are composed of simple upper and lower bounds on the variables,  $x_i^l \leq x_i \leq x_i^u$ , and the more complicated structural mechanics constraints,  $g_j(x) \geq 0$ . The structural mechanics constraints are composed of margins of safety for strain, strength, damage tolerance and buckling analyses [16]. The inequality constraints are formed so that a feasible design has a positive margin of safety. This first formulation has been described in [1,2,4,20].

**Optimal Design of Composite Structures, Figure 2**  
Graph of in-plane stiffness for a four ply symmetric laminate,  $[\theta_1, \theta_2, \theta_2, \theta_1]$

The margin-of-safety functions to be used as constraints and/or the objective function can be described as black-box functions where the functions often are only available in the form of a computer subroutine. For example, stiffness of a composite laminate can be calculated using classical lamination theory [5] or it could involve a finite element analysis [10,12].

To illustrate the global nature of these equations, a plot of the in-plane stiffness of a four ply, symmetric laminate,  $[\theta_1, \theta_2, \theta_2, \theta_1]$ , using classical lamination theory, is shown in Fig. 2. The greatest in-plane stiffness occurs when the fiber angles are all 0 degrees, as makes sense intuitively. See [20] for the equations used to generate the plot. The plateau in the graph represents infeasible designs, with a stiffness that is less than a prescribed critical value. If stiffness is used as an objective function, it can be seen to be nonlinear and nonconvex. If stiffness is used in the constraints to allow only those design above a threshold of critical stiffness, the feasible region itself is nonconvex and even has holes in it. This indicates what a difficult problem even attaining feasibility can be.

It is also possible to define a hierarchy of objectives. For example, we might minimize cost and when there is a tie on cost, we minimize weight, and when there is a tie on weight, then maximize margin of safety. This hierarchy is natural to the formulation because weight is not directly affected by the fiber angles, but varying the fiber angles can increase margin of safety while maintaining a low cost and weight. A two phase approach was used, where phase 1 maximized the min-

imum margin of safety until a positive value was obtained, and then phase 2 maintained feasibility while optimizing the hierarchy of cost, weight and margin of safety. A contrasting approach using a penalty method with a variable penalty factor was compared numerically in [10,11]. Numerically the penalty method was better than the hierarchical approach, although the hierarchical approach was more intuitive to the engineers.

An improvement to the first formulation involves relaxing the requirement to specify the numbers of plies in the skin and stiffener. Since the composite laminate is manufactured by laying down individual plies, it is realistic to treat the number of plies as an integer variable. Other optimization techniques have treated thickness of a ply as a continuous variable, and then rounded to the appropriate number of plies [3,17]. This is not as accurate as treating the number of plies as integer variables directly. The second formulation is very similar to the first, with additional binary variables to indicate whether a ply exists in the laminate;  $t_i^{\text{skin}}$  for  $i = 1, \dots, n^{\text{skin}}$  and  $t_i^{\text{stiffener}}$  for  $i = 1, \dots, n^{\text{stiffener}}$ , where  $t_i = 1$  if ply  $i$  exists and takes on fiber angle  $\theta_i$ , and  $t_i = 0$  if ply  $i$  is dropped from the laminate. The upper bounds on the number of plies needed in the skin and stiffener,  $n^{\text{skin}}$  and  $n^{\text{stiffener}}$  are now easier to provide and not a critical aspect of the inputs.

The complete second optimization formulation, including the binary variables is summarized as:

$$\begin{cases} \min & f(x, t) \\ \text{s.t.} & g_j(x, t) \geq 0 \quad \text{for } j = 1, \dots, m, \\ & x_i^l \leq x_i \leq x_i^u \quad \text{for } i = 1, \dots, n, \\ & t_i \in \{0, 1\} \quad \text{for } i = 1, \dots, n', \end{cases} \quad (2)$$

where  $n$  is the total number of continuous variables, including fiber angles and geometry variables, and  $n'$  is the largest number of plies,  $n' = n^{\text{skin}} + n^{\text{stiffener}}$ .

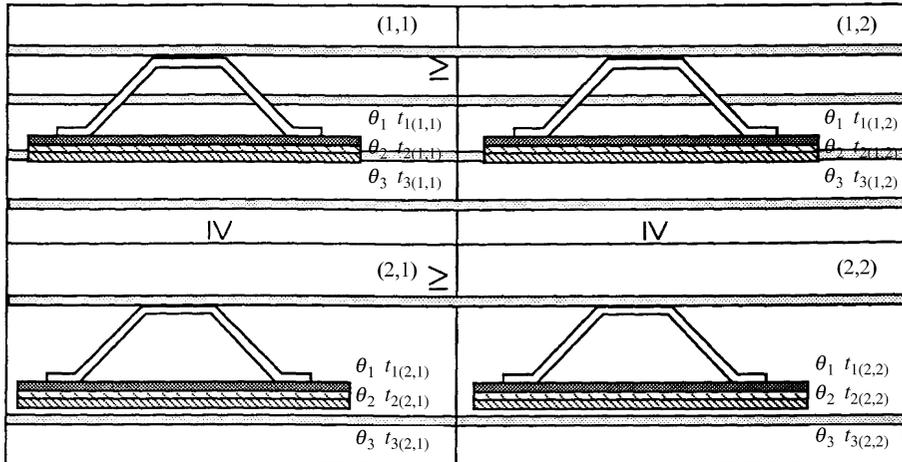

The random search algorithm had to be modified in order to solve the second formulation. See ► **Global optimization: Hit and run methods**, or [10,11,13] for details on the algorithm for *mixed discrete-continuous global optimization*. Once this capability was available, it was possible to create other discrete variables. The most interesting are the fiber angles, which may take on continuous values between +90 and -90 degrees, but for practical purposes are often restricted to dis-

crete values, such as 0,  $\pm 45$ , or 90 degrees. This flexibility in the formulation provides the ability to investigate manufacturing considerations. For example, running the optimization problem allowing the fiber angles to be continuous values may not be practical for manufacturing, but can provide a lower bound on weight. Then the problem can be run again to investigate the additional weight associated with using a discrete set of fiber angles. In this way, trade-offs can be carefully evaluated early in the design process.

### Blended Panel

The third formulation expands the optimization problem beyond considering a single point to include an entire panel. In the point optimization, it is assumed that the loads are constant and uniformly distributed over the section, and the design is also constant over the section. To be more realistic, the loads over a large panel such as a crown panel in a fuselage, are not evenly distributed. We could use the second formulation for the entire panel using the heaviest loads, but then we would essentially overdesign parts of the panel where the loads are much lighter. Therefore, in the third formulation, the panel is divided up into elements, where the loads are assumed constant for each element, but the loads may vary between different elements [16,19]. The elements cannot be point-optimized individually because the result may be impractical for manufacturing. For example, the stiffener spacing could increase and decrease in adjacent elements, or a 45° ply could change to a -30° in adjacent elements. This would not be considered manufacturable, since it is assumed that once a ply is in place, the orientation of the fiber angle cannot change, although the ply may be dropped off. The third formulation must ensure that the elements can be produced into a consistent panel, or what we call a 'blended' panel. By including binary variables for each ply in each element, 'blending rules' are established to reflect these manufacturing considerations.

Figure 3 illustrates the main blending rule for a panel divided into four elements. Consider any ply as it passes through the four elements. The fiber orientation of ply  $i$  is  $\theta_i$ , and there are also four binary integer variables associated with the ply. As described in

**Optimal Design of Composite Structures, Figure 3**  
**Design variables for a blended panel**

the second formulation, if the binary variable  $t_{i(j,k)} = 1$  then ply  $i$  in element  $(j,k)$  exists with fiber angle  $\theta_i$ , and if  $t_{i(j,k)} = 0$  then ply  $i$  has been dropped in element  $(j,k)$ . By adding constraints on the binary variables, we can force plies to be dropped in such a way that the panel is manufacturable. We assume that the heaviest load on the panel exists in the upper left corner, and we want to be able to drop a ply, but once it is dropped we do not allow it to be added back into the panel. Thus the main blending rule is nicknamed the ‘less-than-or-equal-to rule’, and includes the following constraints:

$$t_{i(j,k)} \geq t_{i(j,k+1)},$$

$$t_{i(j,k)} \geq t_{i(j+1,k)}$$

for all plies  $i$ , and for all rows  $j$  and columns  $k$  of the panel.

For the panel illustrated in Fig. 3, the above constraints would be:

$$t_{i(1,1)} \geq t_{i(1,2)},$$

$$t_{i(2,1)} \geq t_{i(2,2)}$$

and

$$t_{i(1,1)} \geq t_{i(2,1)},$$

$$t_{i(1,2)} \geq t_{i(2,2)}.$$

In the example, if ply  $i$  exists in element  $(1,1)$  but is dropped in element  $(1,2)$ , then it must also be dropped in element  $(2,2)$ . Ply  $i$  may exist or be dropped in element  $(2,1)$  and still satisfy the blending rule. This

blending rule has been very useful in structuring the optimization over a panel where the loads are allowed to vary, and a realistic design would make use of ply drops.

To summarize the third formulation, the second formulation is expanded to span several elements, and the blending rule is introduced as additional constraints:

$$\left\{ \begin{array}{l} \min \quad f(x, t) \\ \text{s.t.} \quad g_j(x, t) \geq 0, \quad j = 1, \dots, m, \\ \quad \quad x_i^l \leq x_i \leq x_i^u, \quad i = 1, \dots, n', \\ \quad \quad t_{i(j,k)} \geq t_{i(j,k+1)}, \quad i = 1, \dots, n, \\ \quad \quad t_{i(j,k)} \geq t_{i(j+1,k)}, \quad i = 1, \dots, n, \\ \quad \quad t_{i(j,k)} \in \{0, 1\}, \quad i = 1, \dots, n, \end{array} \right. \quad (3)$$

for all defined elements  $(j,k)$ .

Another aspect in blending of a panel has to do with the variation allowed in stiffener geometry across elements. For example, stiffener spacing cannot vary in the axial direction, but is allowed to vary across elements in the hoop direction. In the third formulation, we include a design variable for stiffener spacing,  $x_j^{stsp}$  that is only subscripted by row of the elements, which corresponds to the hoop direction. For example, in the illustration in Fig. 3 the stiffeners are one unit apart in the first row where the loads are heaviest, and two units apart in the second row which has lighter loads. No additional constraints are needed to incorporate this re-

striction, since the definition of the variable has ensured that stiffener spacing is constant in the axial direction. The other geometry variables are also allowed to vary across rows in the hoop direction, but remain constant in the axial direction. For example, as the stiffeners get spaced farther apart, they may also become shorter. In the sample problem presented here, it was assumed that the height of a stiffener remained constant for its entire length.

The main difference between the second and third formulation is the difference between a point design and a 'blended' panel design. The panel design is of greater use to the engineers, but there is a penalty in computational complexity. The addition of elements for a *blended panel* greatly increases the number of design variables for the optimization problem. Suppose the panel is divided into  $P * Q$  elements. Then there will be  $(n^{\text{skin}} + n^{\text{stiffener}}) * P * Q$  binary integer variables. There will be  $(n^{\text{skin}} + n^{\text{stiffener}})$  continuous variables for the fiber angles, and  $5 * P$  continuous geometry variables. An alternative formulation has been developed to reduce the number of variables by using integer variables that capture the number of elements, or distance, for which a ply is runs. Details of this formulation and numerical results are presented in [6,14,22].

We next present a sample problem and discuss the differences between a point design and a 'blended' panel design.

### Sample Problem

The sample problem presented here is taken from [18], and is intended to demonstrate the difference between the point formulation and the blended panel formulation. It uses two sets of loading conditions for each element as shown in Table 1., and uses the material properties associated with AS4-3501 graphite/epoxy, as in [1]. There are  $2 * 3$  elements with a maximum number of 16 plies (symmetric) in the skin and stiffeners. For this sample problem there are 96 binary integer variables, and 26 continuous variables, and the computer algorithm used 25,000 function evaluations.

For the sample problem we first did a point by point optimization for each element independently to obtain a lower bound on weight, and to observe the trends of the designs. The point by point optimization results for this sample problem are presented in Table 2. Notice

**Optimal Design of Composite Structures, Table 1**  
Loading conditions for the sample problem, where  $N_x$ ,  $N_y$ , and  $N_{xy}$  are in lb and  $M_x$ ,  $M_y$ ,  $M_{xy}$  are in lb-in

$N_x$	3000	3000	2500	2500	2500	2500
$N_y$	2000	2000	1500	1500	1000	1000
$N_{xy}$	1500	-1500	1500	-1500	1000	-1000
$M_x$	2000	2000	2000	2000	2000	2000
$M_y$	0	0	0	0	0	0
$M_{xy}$	0	0	0	0	0	0
$N_x$	2500	2500	2000	2000	2000	2000
$N_y$	2000	2000	1500	1500	1000	1000
$N_{xy}$	1000	-1000	1000	-1000	500	-500
$M_x$	2000	2000	2000	2000	2000	2000
$M_y$	0	0	0	0	0	0
$M_{xy}$	0	0	0	0	0	0

that fiber angles vary in a way that would be impractical for manufacturing. For example, the fiber angles vary drastically between adjacent elements, such as between element (1, 1) and element (1, 2). Also notice that stiffener spacing also varies in an impractical fashion. In the first row, stiffener spacing changes from 21 inches, to 22 inches, and then up to 30 inches. This is not a manufacturable design. Table 3 depicts the optimal design of the blended panel using the third formulation. Although the overall weight increased, the optimal design is now considered a practical design. Notice that the first ply in the first element of  $35^\circ$  stays in the entire panel, while the second ply in the first element of  $26^\circ$  gets dropped immediately. This type of tailored ply dropoffs is manufacturable, and makes use of the ability to tailor composite materials. Also, the stiffener spacing is fixed in the axial direction at 20.6 inches in the first row, as desired, and has a slight change to 20.8 inches in the second row. This also satisfies the blending rule.

The formulations presented thus far have been for a stiffened composite panel, but the point and the blended panel formulations have also been extended to a sandwich composite panel, as depicted in Fig. 4. A sandwich panel consists of an inner core, with plies on the outside. Typically the depth of the entire panel is constant, but the core increases to compensate for plies that are dropped. The sandwich formulation was used to design a fuselage keel panel in [7].

- The stiffener geometry variables were always at their upper and lower bounds: Height: 2 inches; Width of flange: 1 inch; Width of cap: 2 inches, and Angle of web: 90 degrees.

## COSTADE

Through the collective efforts of Boeing, NASA, the University of Washington and others, a prelimi-

nary design software package called *COSTADE* (Cost/Composite Optimization Software for Transport Aircraft Design Evaluation) has been developed [7,8,9]. The three optimization formulations described here are

**Optimal Design of Composite Structures, Figure 4**  
Design variables for a sandwich composite panel

available in the software. The optimization software has been applied to the design of aircraft composite panels, including a crown panel [15], a keel panel [7], a window belt [9], and most recently to a full fuselage barrel [10]. Research continues in defining more general blending rules [6], and more accurately reflecting the manufacturing considerations. The modified hit and run algorithm has been robust enough to solve the mixed integer-continuous global optimization problem with a hierarchy of objective functions efficiently. The design optimization has proved to be an effective aid in the design process of composite structures.

two-point boundary value problem; Nonlinear optics

Over the past two decades, significant technology advances have been made in *nonlinear optics* due to rapid developments of laser technology and nonlinear optical materials. Applications of nonlinear optics are everywhere, for example, lasers, spectroscopy, optical switching, parametric amplifiers and oscillators, optical com-

puting, and communications. A remarkable application is to generate powerful coherent radiation at a frequency that is twice that of available lasers, so-called second harmonic generation (SHG). However, nonlinear optical effects are generally very weak. In order to obtain useful nonlinear optical effects, several methods may be employed. First, extremely high intensity laser beams or materials with very high nonlinearities could be used. Unfortunately, limited by the availability of technology and high costs of such lasers/materials, this method is often impractical. Another method is to increase the effective nonlinearity of the medium by using composite materials. Such a method is currently an active research topic in material sciences. The third method is a structure assisted method. The idea is to enhance the nonlinear interaction between the material and the light by using gratings, waveguide, or other diffractive structures. The advantage is that the method is very practical and can make good use of available lasers and materials [10].

This work is devoted to *optimal design* or *parameter identification* problems that arise in modeling of nonlinear optical thin films [2]. We shall restrict our attention to second order nonlinear effects, which are the simplest and representative to other nonlinear effects. The following problems are of particular interest: From the measured transmittance and reflectance at both frequencies, what kind of information might be retrieved about the medium? Given nonlinear films and coating materials in a multi-layered form, maximize the transmittance of the second harmonic field, i. e., maximize the nonlinear optical effects. Note that in the simplest setting, the problem may be formulated as a *two-point boundary value problem* for first order nonlinear system of ordinary differential equations (ODEs). One goal of this research is to identify physical properties of the medium by probing the medium with light or other energy sources. Another goal is to design new materials with desirable properties, i. e., solving an optimal design problem.

Throughout we shall view the optimal design problem as a parameter identification problem. Because of important applications in diverse areas of science and engineering, parameter identification problems for nonlinear systems of ODEs have been studied extensively. The advent of computers and parallel machines has greatly accelerated activity in this area and has

driven the need for efficient computational methods and algorithms. For closely related parameter identification for nonlinear ODE initial value problems, three general approaches have been developed. We refer to [5] for a detailed discussion. Among them, the black box approach is the simplest one which essentially separates the numerical solution of differential equations from the optimization process. The ODE solver is treated as a ‘black box’ with a minimum communication with the optimization procedure. However, there is a severe drawback of the approach. Due to the nonlinearity of the problem, the model often does not have a solution for all parameters. Without the necessary communication, the optimization algorithm may ask for a solution to the ODE with parameter values for which the ODE solver fails. The second approach, the all-together approach, first discretizes the ODE system and then formulates the identification problem as an optimization problem with equality constraints resulting from the ODE discretization. The third approach often referred to as the domain decomposition or in-between approach divides the interval into a number of subintervals, and uses a black box procedure to solve the problem on each subinterval. In order to solve the ODE system over the entire interval, matching conditions are introduced to patch together solutions over subintervals. Recently, J.E. Dennis, G. Li, and K.A. Williamson [5] have developed two families of algorithms, the in-between and altogether approaches, for solving ODE inverse problems. Their model problem is a nonlinear initial value problem. Efficient algorithms are introduced by a nonlinear programming formulation of the problem coupled with an orthogonal collocation scheme for solving the model ODE. The general idea is to tailor the algorithm to best fit the level of interaction between the optimization algorithm and the ODE solution technique.

In this article, we propose a domain decomposition approach for solving the parameter identification problem of nonlinear ODE two-point boundary value problems. We introduce an in-between approach for solving the parameter identification problems for nonlinear ODE two point boundary value problems, which has the following distinct features:

- 1) The problem is formulated as a constrained optimization problem as opposed to the standard data fitting least squares problem. The set of variables is decomposed into two parts: a set of explicit variables and a set of implicit variables, which is shown to be efficient through a complexity analysis. The continuity and boundary conditions are treated as explicit constraints for the optimization problem. Hence, the parameters and the function values at the subdivision points are EXPLICIT variables only need to be satisfied and determined at the solution or the final step. At each iteration step, the differential equation (the IMPLICIT variables) is solved over each subinterval independently. Furthermore, the extremely large number of linear systems for computing the Jacobian, the gradient of the constraints, and the Hessian of the Lagrangian, which account for more than 95% of the total computation, are all solved completely independently over each of the subintervals.
- 2) The optimization approach adopted from [4] and [5] is a much refined version of the successive quadratic programming (SQP) together with a globalization strategy. The basic idea of the optimization approach together with a discussion on sparsity structures may be found in [5]. We point out that the approach is very complicated which involves computations of Jacobians and Hessians with respect to the implicit variables. Since our goal in this article is to present the main ideas of the in-between approach, the tedious technical details of the optimization techniques will be left out.

We follow the general idea of Dennis, Li, and Williamson [5]. However, the situation here is more complicated for the following reasons:

- 1) Unlike in [5], we do not assume availability of the data in the interior of the interval. This feature is essential in many practical applications, for example, in nondestructive testing. On the other hand, we use a set of samples that correspond to a set of experiments. The samples are taken, only on the boundary, by varying the sources.
- 2) Because the boundary value varies from sample to sample, the size of the system of differential equations is a multiple of the samples. Unlike in the initial value problem case where the unknowns are independent of the number of data points, the number of unknowns in our case is the number of sources (or experiments) multiplied by the number of unknowns introduced in the domain decomposition approach. As a result, the number of nonlinear equa-

tions and linear systems needed to be solved for implicit differentiations and computing the Hessian of the Lagrangian is a multiple of the square of the number of sources. Consequently, even with a moderate number of experiments, the computational and spatial cost may be so high that even main frame computers may not be able to solve it unless special efforts are taken to take advantage of the sparsity structures of the gradient of the constraints and the Hessian of the Lagrangian to reduce the number and the size of the resulting systems of linear and nonlinear equations.

Our approach has the flavor of the multiple or parallel shooting method for solving ODE two point boundary value problems [9]. We point out that a straightforward modification of the approach gives rise to a variant of the multiple shooting method. However, our emphasis here is not on solving the direct problem but rather on solving the parameter identification problem or the inverse problem.

### Model Formulation

We make the following assumptions: the fields are transverse; the medium is stratified; and the surface is flat. Since the medium is stratified, the fields vary only in one direction. The transversality assumption allows us to reduce the Maxwell system to a system of Helmholtz equations.

Let us specify the geometry of the model. Assume that a slab of stratified nonlinear material (say, composed of many layers of different nonlinear media) is placed between two linear homogeneous materials, say in the domain  $\Omega = (0, 1)$ . Suppose that the whole space is filled with material in such a way that the indexes of refraction  $q_1(x)$  and  $q_2(x)$  at frequencies  $\omega_1$  and  $\omega_2 = 2\omega_1$ , respectively, satisfy

$$q_j(x) = \begin{cases} q_{j1}, & x \geq l, \\ q_{j0}, & x \in \Omega, \\ q_{j2}, & x \leq 0, \end{cases}$$

for  $j = 1, 2$ , where  $q_{j1}$  and  $q_{j2}$  are fixed constants, and  $q_{j0}$  may be some piecewise constant.

Assume that a plane wave with electric field  $(0, E_I e^{iq_{11}x}, 0)$  is incident on  $\Omega$  from the above. Using the jump conditions, we can derive the following two-point

boundary value problem

$$\begin{aligned} \left( \frac{d^2}{dx^2} + q_1^2 \right) E_1 &= \chi_1 \bar{E}_1 E_2 \quad \text{in } \Omega, \\ \left( \frac{d^2}{dx^2} + q_2^2 \right) E_2 &= \chi_2 E_1^2 \quad \text{in } \Omega \\ E_1'(l) + iq_{11}E_1(l) &= 2iq_{11}e^{iq_{11}l}E_I, \\ E_2'(l) + iq_{21}E_2(l) &= 0, \\ E_1'(0) - iq_{12}E_1(0) &= 0, \\ E_2'(0) - iq_{22}E_2(0) &= 0, \end{aligned}$$

where  $E_1 = E_1(x, \omega_1)$ ,  $E_2 = E_2(x, \omega_2)$ , and  $\chi_1, \chi_2$  characterize the nonlinearity of the medium at frequencies  $\omega_1, \omega_2$ , respectively. The most striking feature of second harmonic generation is that new frequency components (at  $\omega_2$ ) are present.

By introducing new variables, the system may be simplified as a first order system of ODEs. From now on, we shall consider the following two point boundary value problem for a general system of nonlinear ODEs

$$\begin{aligned} y' &= F(x, y, p, k), \\ Ay(l) + By(0) &= g(k), \end{aligned}$$

where  $x \in (0, 1)$  is the independent variable,  $y = y(x) \in \mathbf{R}^{ny}$  is the solution,  $p \in \mathbf{R}^{np}$  denotes the parameters,  $k \in \mathbf{R}^{nd}$  represents the source terms,  $A$  and  $B$  are matrices possibly depending on the parameters  $p$ . Here  $ny$  is the number of dependent variables,  $np$  is the number of parameters, and  $nd$  is the number of samples or sources.

The direct problem is to determine solutions  $y = y(x, p, k)$ , given the parameters  $p$  and source terms  $g(k)$ . Mathematically, the problem is well understood. It is well known that due to the nonlinearities, existence of solutions is not obvious. Roughly speaking, it depends on the regularity of  $F$ . Further, even a solution does exist, because of the boundary conditions, it may not be unique. Throughout the article, we assume that the two-point boundary value problem has a unique solution.

The parameter identification problem or inverse problem is to determine the parameters  $p$  from the additional boundary data. We consider the data set:  $ydata(0)_s, ydata(l)_s, s = 1, \dots, nd$ , where once again  $nd$

is the number of samples by varying  $k$ . Define

$$\Phi(p) = \frac{1}{2} \sum_{s=1}^{nd} \|y(0; p; k_s) - ydata(0)_s\|^2 + \frac{1}{2} \sum_{s=1}^{nd} \|y(l; p; k_s) - ydata(l)_s\|^2,$$

where  $\|\cdot\|$  is the vector norm defined by  $\|u\|^2 = u^T \cdot u$ .

We are interested in identifying the parameters in the least squares sense, i. e., to find a  $p^*$  which best fits:

$$\begin{cases} \min & \Phi(p) \\ \text{s.t.} & y' = F(x, y; p, k_s); \\ \text{b.c.} & Ay(l; k_s) + By(0; k_s) = g(k_s), \\ & s = 1, \dots, nd. \end{cases}$$

### Collocation Scheme

We next describe a collocation scheme for solving the nonlinear system of ODEs. Here, we follow the general procedure given in [5]. Let us begin by dividing the interval  $(0, 1)$  into  $ns$  subintervals:  $[x_i, x_{i+1})$ , for  $i = 1, \dots, ns$ , and  $x_1 = 0, x_{ns} = 1$ . On the  $i$ th subinterval, the function  $y(x)$  may be approximated by a polynomial:  $y(x) \approx \sum_{j=0}^{nc} z_{ij} \Psi_{ij}(x)$ , where  $nc$  is the number of collocation points in one subinterval,  $\{\Psi_{ij}(x)\}$  is a basis of Lagrange polynomials of degree  $nc$  at the points  $t_{ij}$ ,  $z_{ij}$  are the collocation coefficients to be determined, and  $t_{ij}$  is the  $j$ th collocation point on the  $i$ th subinterval.

The collocation method requires the above piecewise polynomial approximation to satisfy the ODE at the collocation points on each of the subintervals. For the  $s$ th sample,  $s = 1, \dots, nd$ , solving for  $\{z_{ij}^s\}$  leads to an approximation to  $y$  at the collocation points. This step leads to the following *collocation conditions*:

$$h_1^s(p, z) = 0,$$

where for  $s = 1, \dots, nd, j = 1, \dots, nc, i = 1, \dots, ns,$

$$h_2^s(p, z) = \sum_{k=0}^{nc} \frac{d\Psi_{ik}(t_{ij})}{dx} z_{ik}^s - F(t_{ij}, z_{ij}^s; p).$$

In order to approximate the solution  $y(x)$  over the interval  $(0, 1)$ , we need to patch together approximations over subintervals. This can be done by enforcing *continuity conditions* at all end points of the subintervals except the two end points  $x_1 = 0, x_{ns} = 1$ . The conti-

nuity conditions are natural by assuming that the solution is continuous:

$$h_2^s(p, z) = 0, \text{ where for } s = 1, \dots, nd, i = 2, \dots, ns,$$

$$h_2^s(p, z) = z_{i0}^s - \sum_{k=0}^{nc} z_{i-1,k}^s \Psi_{i-1,k}(t_{i0}).$$

In addition, we want to enforce the *boundary value conditions*:

$$h_3^s(p, z) = 0, \text{ where for } s = 1, \dots, nd,$$

$$h_3^s(p, z) = Az_{00}^s + B \sum_{k=0}^{nc} z_{ns,k}^s \Psi_{ns,k}(l).$$

Set for  $q = 1, 2, 3$ ,

$$h_q = (h_q^1, \dots, h_q^{nd}).$$

We then have by combining the above conditions, that

$$h(p, z) = 0, \quad h = (h_1, h_2, h_3)^T. \quad (1)$$

### Domain Decomposition

It follows that the parameter identification problem may be formulated as a nonlinear programming problem:

$$\begin{cases} \min_{p,z} & \Phi(p, z) \\ \text{s.t.} & h(p, z) = 0. \end{cases}$$

If both the parameters and the collocation coefficients are treated as independent variables, i. e., the variables are treated all together, then the approach is called all together or all-at-once. In this approach, the nonlinear system of equations  $h(p, z) = 0$  gives rise to a set of explicit constraints. Thus,  $p, z$  only need to satisfy the constraints at the solution. Readily, one can verify that the dimension of the problem or number of unknowns in this case is  $np + (ns + nc \times ns) \times ny \times nd$ . There are two potential drawbacks for this approach. First, by treating all of the variables as independent variables, the size of the resulting nonlinear programming problem can be very large. Sophisticated optimization techniques are impractical for large size problems. Also, the approach does not support parallel structures. It is difficult to make it efficient in a parallel environment.

In order to exploit parallelism and reduce the size of the nonlinear programming problem, we propose a domain decomposition or in-between approach which

follows in principle [5]. The basic idea of the domain decomposition approach is to identify a set of implicit constraints, i.e., constraints that are satisfied at every iteration. More specifically, for each sample, this approach allows us to treat only the model parameters  $p$  and a subset of collocation coefficients corresponding to the ends of subintervals  $z_{i0}^s$ ,  $i = 0, \dots, ns-1$ , as the independent variables of the nonlinear programming problem. Thus the dimension of the problem is reduced to  $np + ns \times ny \times nd$ .

We decompose the set of collocation coefficients into a set of explicit variables

$$z_E \equiv \{z_{10}^s, \dots, z_{ns,0}^s\},$$

and a set of implicit variables

$$z_I \equiv \{z_{11}^s; \dots; z_{1,nc}^s; z_{21}^s; \dots; z_{ns,nc}^s\},$$

where again  $z_{ij}^s, j \neq 0$ , are determined by the collocation conditions.

Given  $p$  and  $z_{i0}^s$ , we then solve the nonlinear system  $h_1(p, z_{ij}^s) = 0$  for the implicit variables, independently on each subinterval. The dimension of the system is  $ny \times nc \times nd$  on a subinterval. The special structure of the problem allows us to break the nonlinear system into  $nd$  independent systems, where the dimension of each system is  $ny \times nc$ . Note that the continuity conditions and the boundary conditions are constraints of the nonlinear programming problem. They are satisfied only at the final solution  $(p^*, z^*)$  of the optimization problem.

Therefore, the problem becomes:

$$\begin{cases} \min_{p, z_E} & \Phi(p, z_E, z_I(p, z_E)) \\ \text{s.t.} & h_2(z_E, z_I(p, z_E)) = 0, \\ & h_3(z_E, z_I(p, z_E)) = 0, \end{cases}$$

where  $z_I(p, z_E)$  solves  $h_1(z_I; p, z_E) = 0$ .

*Remark 1* A simple calculation indicates that the dimension of the new nonlinear programming problem is  $np + ny \times nd$  and the number of constraints is  $ns \times ny \times nd$ .

We now briefly discuss some implementation issues for the domain decomposition approach. The number of nonlinear systems on one subinterval is  $(np + ny \times nd + 1) \times nd$ . Implicit differentiation should be used to compute the first order partial derivatives of the implicit

variables with respect to the explicit variables. The total number of linear systems to be solved for the implicit differentiation on one subinterval is  $(np + ny \times nd + 1) \times nd \times (ny + np)$ . This number is usually quite large. However, the linear systems are independent not only on each of the subintervals but also for each of the samples. Furthermore, for one sample on one interval, the coefficient matrices of the linear systems are all the same. Therefore, only one LU factorization is necessary. The rest are hundreds of independent triangular solvers. The second order derivatives are computed by using the finite-difference technique. The main advantage of this approach is that the resulting nonlinear systems are independent on each of the subintervals. Thus, there is no communication between the subintervals – an ideal feature for parallel computation.

### Optimization

We have formulated the problem as a nonlinear programming problem by using the domain decomposition approach. We next describe a general method developed originally in [5] for solving this type of optimization problems. The optimization algorithm is based on the successive quadratic programming (SQP) with a trust region globalization. The idea is to adopt different techniques based on how close the current approximate is from the solution. If it is ‘close’ to the solution, we choose a step to be the solution of the quadratic program:

$$\begin{cases} \text{minimize} & \text{A Quadratic Model} \\ \text{subject to} & \text{Linearized Constraints.} \end{cases}$$

Otherwise, if it is ‘far’ from the solution, we choose the step to be the solution to a trust region subproblem.

The algorithm for the QP is robust. It forms the reduced Hessian and determines whether a solution exists. Note that if the reduced Hessian is not positive definite, then the QP may have infinite number of solutions or no solution at all. If a solution does exist, the algorithm will find it. The algorithm will calculate a descent direction when the QP does not have a solution. The trust region globalization technique of [4] is employed to deal with the possible lack of positive definiteness of the reduced Hessian. Thus the algorithm handles degeneracies in the linearized constraints by using eigen decomposition.

## Numerical Experiment

Our test problem is based on a simplified model of the system of nonlinear Maxwell's equations that arises in modeling second harmonic generation of nonlinear optical thin films. Under some assumptions [2]. Let  $Y = (y_1, y_2, y_3, y_4)^T$ . The model problem takes the following form:

$$Y' = (y_2, -p_1 y_1 + p_3 y_1 y_3, y_4, p_4 y_1^2 - p_2 y_3),$$

with the boundary condition

$$AY(l) + BY(0) = g,$$

where

$$A = \begin{pmatrix} a_{11} & 1 & 0 & 0 \\ 0 & 0 & a_{21} & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

$$B = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ a_{12} & 1 & 0 & 0 \\ 0 & 0 & a_{22} & 1 \end{pmatrix},$$

and  $g = (g_k, 0, 0, 0)^T$ .

In this over-simplified case, the inverse problem is to determine the parameters  $p = (p_1, p_2, p_3, p_4)$  from the measured  $Y(0)$  and  $Y(l)$  for a given source term  $g_k$ . Since  $p$  which characterizes the physical properties of the medium is independent of  $g_k$ , it is natural to expect better reconstruction of  $p$  by performing a set of experiments or using a number of  $g_k$ . Here the constant  $g_k$  represents the intensity (power) of the incident light, which may vary with  $k$  in a given range.

In our experiment, the known constants were chosen in the following way:  $a_{11} = 5$ ,  $a_{21} = 4$ ,  $a_{12} = -2$  and  $a_{22} = -3$ . We used five pairs of sample boundary data at the end points. These data were generated by using the fixed parameters  $p_1 = 0.005$ ,  $p_2 = 0.003$ ,  $p_3 = 0.0015$  and  $p_4 = 0.025$ . We used five samples  $g_k$ ,  $k = 1, \dots, 5$ , where  $g_1 = 2$ ,  $g_2 = 5$ ,  $g_3 = -2$ ,  $g_4 = -3$  and  $g_5 = -5$ . We chose the number of collocation points  $nc = 4$ . It is obvious that in this example,  $np = 4$  and  $ny = 4$ . From the data, we then tried to recover the parameters  $p$ . The experiment was done on a Cray J916 which is a 16 CPU shared memory computer. The results are shown in the following three tables where  $ns$  is the number of sub-intervals,  $nd$  is the number of samples,  $n_x$  is the number of variables of the NLP problem,  $n_h$  is the number of

Optimal Design in Nonlinear Optics, Table 1

Accuracy improvement with increasing number of samples ( $ns = 20$ ,  $ncpu = 4$ )

nd	$n_x$	$n_h$	nit	error	CPU time
1	84	80	8	1.36e-2	6.16
2	164	160	5	1.12e-6	12.17
3	244	240	5	8.16e-7	26.43
4	324	320	5	6.29e-7	47.76
5	404	400	5	6.12e-7	69.04

Optimal Design in Nonlinear Optics, Table 2

Convergence effect on different number of sub-intervals ( $nd = 4$ ,  $ncpu = 4$ )

ns	$n_x$	$n_h$	nit	error	CPU time
8	100	96	12	1.28e-5	19.18
16	260	256	5	8.81e-6	31.97
32	516	512	5	3.65e-7	93.45

constraints, nit is the number of iterations for the algorithm to converge, error is the  $l_2$ -norm of the relative error between the estimated parameter and the exact parameter,  $ncpu$  is the number of CPUs used for solving the problem.

Table 1. shows the accuracy improvement when the number of samples is increased from one to five. One may observe that after some point, additional data make very little difference in terms of reconstruction of the parameters. This is largely due to the fact that the accuracy for solving nonlinear systems of equations has already been reached. In Table 2., we demonstrate the effect of increasing the number of sub-intervals, i. e., refining the grids. Finally, we show in Table 3. the total CPU time and the speed up with different number of CPUs.

## Discussion

We present a general approach on parameter identification for nonlinear ODE two-point boundary value problems that arise in optimal design of nonlinear optics. The data for our parameter identification problems are only given at the boundary points. Consequently, the problem size is a multiple of the number of

**Optimal Design in Nonlinear Optics, Table 3**

Speed-up on different number of CPUs ( $n_x = 644$ ,  $n_h = 640$ ,  $nd = 5$ ,  $ns = 32$ )

ncpu	Total CPU time	Speed-up

14	136.1	12.21
16	140.4	13.53

boundary data pairs. Our approach is based on ideas of nonlinear programming and domain decompositions. It generalizes [5] to a more general setting. Our preliminary numerical results indicate that the methods not only efficient on parallel machines but also effective on sequential machines. We also develop a technique to reduce the size of linear and nonlinear systems resulting from the approach.

A new research topic is to use the general approach developed in this article and [5] to solve inverse scattering and diffraction (PDE) problems. A crucial step is to develop a fast and efficient domain decomposition solver for the direct problem. Similar ideas have recently been used by Dennis and R.M. Lewis [6] for solving an inverse conductivity problem. The interested reader is referred to [1] [3] [8] for other results on related optimal design problems.

The multiphase, multireaction *chemical equilibrium problem* (the CEP) is a *nonlinear optimization problem* in chemical thermodynamics that is of interest in many fields. Some examples of application areas include biochemistry [23], chemical engineering [32], chemistry [2], geochemistry [3], metallurgy [21], and plasma science [10]. The CEP has a number of special features arising from its unique structure [9,28]. This makes its numerical solution especially challenging, leading to difficulties associated with multiple local minima and numerical scaling. General references to the CEP include [8,27], and [33]. A recent review of aspects of the CEP has been given in [24].

The CEP may be expressed in two general ways. The one more commonly encountered is formulated as a *global optimization problem*, when the objective function is specified at a ‘macroscopic level’ in terms of its analytical dependence on the underlying composition variables and an appropriate set of parameters. The other is formulated at a ‘molecular level’, in terms of an underlying intermolecular force model, and the optimization problem solved by means of a Monte-Carlo simulation method based in statistical mechanics [30]. In this article, we consider only the former viewpoint, and aspects of its formulation and solution.

The formulation and numerical solution of the CEP require, first, an assumption about which chemical substances are to be considered; and, second, about their distribution over possible phases. The latter may take two forms. One form of the CEP assumes that all substances are represented in all possible phases, and is referred to as the *universally accessible form* (UAF). The other form prohibits at least one substance from being present in all phases, and is referred to as the *restricted accessibility form* (RAF). Distinguishing these two forms has important consequences, as discussed below.

A special case of the CEP is the *phase equilibrium problem* (PEP), which involves a set of chemical substances which can distribute themselves among two or more phases, in the absence of chemical reaction. An example of UAF-PEP is the system *n*-butanol + water + *n*-butyl acetate [5]. This type of problem is important in the chemical processing industry, and there is much current interest in the development of efficient algorithms for its numerical solution. Elementary examples of RAF-PEP are ‘simple eutectic’ systems and ‘steam distillation’, as usually modeled.

UAF and RAF forms also arise in the general CEP in which chemical reactions occur, complicating their formulation and numerical solution. Examples of RAF-CEP include multiphase problems involving condensed phases, and multiphase problems involving ionic species accessible to only a single phase.

### Problem Formulation

Defining a CEP requires specifying two thermodynamic variables from the set  $\{P, V, T, U, H, S, G, A\}$ .  $\{T, P\}$  is a common choice and is primarily considered here; this choice implies that the objective function to be optimized is the *Gibbs function*,  $G$ . Other choices can be formulated in terms of this choice (see the section ‘Sensitivity Analysis’ below).

One of the most general problem formulations has been given in [25], which we summarize here. We assume the following are given:

- 1) a substance formula matrix,  $\mathbf{A}_S \in E^M \times S$ , where  $M$  is the number of elements and  $S$  is the number of substances, each of which is described by a formula vector  $\mathbf{a}_i$  with entries  $a_{ji}$ , which is a column of  $\mathbf{A}_S$  (electric charge is considered to be an element; in the unusual situation in which ionic species are accessible to more than one phase, a ‘charge row’ must be included in  $\mathbf{A}_S$  for each phase); we assume here that  $(\mathbf{A}_S) < S$  and is usually given by  $M$  (as assumed herein);
- 2) an elemental-abundance vector,  $\mathbf{b} \in E^M$ , with entries  $b_j \geq 0$  and  $\mathbf{b} \neq \mathbf{0}$ ;
- 3) a set of  $\pi$  *chemical potential models* or *phase classes*,  $\boldsymbol{\mu}^\beta (T, P, \mathbf{x}^\beta, \boldsymbol{\alpha}^\beta); \beta = 1, \dots, \pi$ , where:
  - $\boldsymbol{\mu}^\beta : E^{2+\tilde{T}^\beta+\alpha^\beta} \tilde{E}^{\tilde{T}^\beta}$
  - $\mathbf{x}^\beta \in E^{I^\beta}$  is the composition (e. g., mole-fraction) vector for  $\boldsymbol{\mu}^\beta$ ;

- $\alpha^\beta$  is the vector of parameters for  $\mu^\beta$ ;
- $I^\beta$  is the substance index set for phase class  $\beta$ , containing the set of subscripts of substances that are accessible to the phase class. For a UAF,  $I^\beta = \{1, \dots, S\}$  for all  $\beta$ . For an RAF, at least one substance subscript is absent from at least one  $I^\beta$ .  $\tilde{I}^\beta$  denotes the number of substances deemed to be accessible to any phase consistent with  $\mu^\beta$ ;
- $\tilde{\alpha}^\beta$  is the number of chemical potential model parameters given by  $\alpha^\beta$ ;
- each phase class satisfies the Gibbs–Duhem equation, as well as the limiting law  $\lim_{x_i^\beta \rightarrow 0} \mu_i^\beta = -\infty$ .

To elaborate on the term ‘phase class’ and to relate it to the term ‘phase’, we note that:

- 3.1) every substance in the system is represented in at least one phase class; i. e.,  $\cup_\beta = 1^\pi I^\beta = \{1, \dots, S\}$ ; we emphasize that all substances need not be represented in every phase class.
- 3.2) there may be more than one phase accessible to a given phase class  $\beta$ ; for each such phase  $k$  arising from a particular chemical potential model  $\mu^\beta$ , we have  $\mu^{\beta,k} \equiv \mu^\beta(T, P, \mathbf{x}^{\beta,k}, \alpha^\beta)$ , where  $\mathbf{x}^{\beta,k} \in E^{I^\beta}$  is the composition vector for the phase.
- 3.3) although the number of phase classes,  $\pi$ , is specified a priori, the number of phases,  $\pi^\beta$ , ‘accessible’ to the phase class  $\mu^\beta$ , may not be known a priori; furthermore,  $\pi$  and  $\pi^\beta$  are distinct from the total number of phases present at equilibrium in nonzero amounts,  $\Pi$ , which is also not known a priori, but is a result of the equilibrium computation.
- 3.4) The term *species* refers to a substance in a specific phase. Since  $\pi^\beta$  is generally unknown, construction of a *species index set* is not always possible.

The general statement of the chemical equilibrium problem at specified  $T$ ,  $P$  and  $\mathbf{b}$  is given by (omitting the dependence of  $\mu^\beta$  on  $T, P, \alpha^\beta$ ):

$$\min_{\tilde{n}^{\beta,k}, \mathbf{x}^{\beta,k}} G = \sum_{\beta=1}^{\pi} \sum_{k=1}^{\pi^\beta} \tilde{n}^{\beta,k} \sum_{i \in I^\beta} x_i^{\beta,k} \mu_i^\beta(\mathbf{x}^{\beta,k}), \quad (1)$$

subject to

$$\tilde{n}^{\beta,k} \geq 0; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (2)$$

$$x_i^{\beta,k} \geq 0; \quad i \in I^\beta; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (3)$$

$$\sum_{\beta=1}^{\pi} \sum_{k=1}^{\pi^\beta} \tilde{n}^{\beta,k} \sum_{i \in I^\beta} a_{ji} x_i^{\beta,k} - b_j = 0; \quad j = 1, \dots, M, \quad (4)$$

$$\sum_{i \in I^\beta} x_i^{\beta,k} - 1 = 0; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (5)$$

where  $\tilde{n}^{\beta,k}$  is the total number of moles in phase  $\beta$ ,  $k$ . In all cases we assume that at least one feasible solution exists.

### The Special Case of Phase Equilibrium (PEP)

In the PEP case, the problem statement is given by (1)–(3) and (5), with the element-balance equations (4) replaced by the substance balance:

$$\sum_{\beta=1}^{\pi} \sum_{k=1}^{\pi^\beta} \tilde{n}^{\beta,k} x_i^{\beta,k} - q_i = 0; \quad i = 1, \dots, S, \quad (6)$$

where  $q_i (\geq 0)$  is the (constant) total number of moles of substance  $i$  in the system.

### Kuhn–Tucker (KT) Conditions

We call a solution  $\{\tilde{n}^{\beta,k}, \mathbf{x}^{\beta,k}, \lambda, \theta\}$  ( $\lambda$  and  $\theta$  are Lagrange multipliers) of the following equations a *Kuhn–Tucker point* (KT point):

$$\tilde{n}^{\beta,k} \left( \mu_i^\beta(\mathbf{x}^{\beta,k}) - \sum_{j=1}^M \lambda_j a_{ji} \right) = 0; \quad i \in I^\beta; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (7)$$

$$\theta^{\beta,k} = \sum_{i \in I^\beta} x_i^{\beta,k} \left( \mu_i^\beta(\mathbf{x}^{\beta,k}) - \sum_{j=1}^M \lambda_j a_{ji} \right) \geq 0; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (8)$$

$$\theta^{\beta,k} \tilde{n}^{\beta,k} = 0; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (9)$$

$$\sum_{\beta=1}^{\pi} \sum_{k=1}^{\pi^\beta} \tilde{n}^{\beta,k} \sum_{i \in I^\beta} a_{ji} x_i^{\beta,k} - b_j = 0; \quad j = 1, \dots, M. \quad (10)$$

### Alternative Form of KT Conditions

Kuhn–Tucker conditions The KT conditions given above are referred to as the *nonstoichiometric form* of the equilibrium conditions [27, pp. 46–48]. These conditions may be expressed in an alternative form, the *stoichiometric form* [27, pp. 45–46]. These arise from expressing the element abundances in terms of *component species* ([27, Chap. 2], [29]). Equations (7), (8), and (10) are replaced, respectively, by

$$\tilde{n}^{\beta,k} \left( \mu_i^\beta(\mathbf{x}^{\beta,k}) - \sum_{j=1}^M \mu_j v_{ij} \right) = 0; \quad i \in I^\beta; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (11)$$

$$\theta^{\beta,k} = \sum_{i \in I^\beta} x_i^{\beta,k} \left( \mu_i^\beta(\mathbf{x}^{\beta,k}) - \sum_{j=1}^M \mu_j v_{ij} \right) \geq 0; \quad \beta = 1, \dots, \pi; \quad k = 1, \dots, \pi^\beta, \quad (12)$$

$$\sum_{\beta=1}^{\pi} \sum_{k=1}^{\pi^\beta} \tilde{n}^{\beta,k} \sum_{i \in I^\beta} v_{ij} x_i^{\beta,k} - q_j = 0; \quad j = 1, \dots, M, \quad (13)$$

where  $v_{ij}$  is a stoichiometric coefficient for species  $i$  with respect to component species  $j$ , and  $q_j$  is the total amount of component  $j$ .

### Global Optimality Conditions (Reaction Tangent-Plane Criterion, RTPC)

A necessary and sufficient condition for global optimality of a KT point is that the objective function is nowhere smaller than its value at that point. This may be expressed as:

$$\Delta G^\dagger \equiv \sum_{\beta=1}^{\pi} \sum_{k=1}^{\pi^\beta} \tilde{n}^{\beta,k} \sum_{i \in I^\beta} x_i^{\beta,k} \times \left( \mu_i^{\beta,k}(\mathbf{x}^{\beta,k}) - \sum_{j=1}^M \lambda_j^\dagger a_{ji} \right) \geq 0 \quad (14)$$

over all  $\{\tilde{n}^{\beta,k}, \mathbf{x}^{\beta,k}\}$  satisfying 2–(5), where  $\lambda^\dagger$  is the Lagrange multiplier at the KT point.

The above criterion takes different special forms for a UAF and for an RAF. If formation of a potential new phase is feasible in terms of the element-balance equations (which is always the case for a UAF, but not necessarily for an RAF), then we may consider the phase class individually, and obtain a simpler set of conditions involving only the mole fraction variables for the phase class from the inner summation in relation (14):

$$\sum_{i \in I^\beta} x_i^\beta \left( \mu_i^\beta(\mathbf{x}) - \sum_{j=1}^M \lambda_j^\dagger a_{ji} \right) \geq 0 \quad (15)$$

over all  $\{\tilde{n}^{\beta,k}, \mathbf{x}^{\beta,k}\}$  satisfying equations (2) to (6). This is called the *reaction tangent-plane criterion* (RTPC) [9,25].

For a UAF, all  $I^\beta$  contain the complete set of substances, which means, from equation (7), that each summation involving the Lagrange multipliers  $\lambda_j^\dagger$  in the above gives the chemical potential  $\mu_i^\dagger$  at the KT point. Criterion (15) then becomes

$$\sum_{i=1}^S x_i \left( \mu_i^\beta(\mathbf{x}) - \mu_i^\dagger \right) \geq 0. \quad (16)$$

This is the *tangent-plane criterion* (TPC) for a PEP [4] (see also [15,18]).

For an RAF, criterion (15) is not equivalent to criterion (16). A simple example arises in the system containing  $\{\text{CO}(\text{g}), \text{CO}_2(\text{g}), \text{O}_2(\text{g}), \text{C}(\text{s})\}$ . There are two phase classes, with index sets  $I^1 = \{1, 2, 3\}$  and  $I^2 = \{4\}$ . Consider a KT point at which only the gas phase is present, and denote the Lagrange multipliers as  $\lambda_C^\dagger$ ,  $\lambda_O^\dagger$ . To test for the presence of the solid phase, criterion (15) is

$$\mu_4 - \lambda_C^\dagger \geq 0. \quad (17)$$

If this criterion is satisfied, C(s) is not present at equilibrium; otherwise C(s) is present in nonzero amount at equilibrium.

Similar, but more involved, RAF problems often arise in metallurgical applications [12]. More complex RAF problems, in which a test must be made for the simultaneous presence of multiple phases, have been considered in [7].

### Chemical Potential Models

The *chemical potential* of substance  $i$  in phase class  $\beta$ ,  $\mu_i^\beta$ , may be expressed in terms of activity,  $a_i$ , or fugac-

ity  $f_i$ , or activity coefficient,  $\gamma_i$  (for ease of notation we omit the superscript  $\beta$ ):

$$\mu_i(T, P, \mathbf{x}) = \mu_i^*(T, P^*, \mathbf{x}^*) + RT \ln a_i(T, P, \mathbf{x}), \quad (18)$$

$$\mu_i(T, P, \mathbf{x}) = \mu_i^*(T, P^*, \mathbf{x}^*) + RT \ln \left( \frac{f_i(T, P, \mathbf{x})}{f_i^*(T, P^*, \mathbf{x}^*)} \right), \quad (19)$$

$$\mu_i(T, P, \mathbf{x}) = \mu_i^*(T, P^*, \mathbf{x}^*) + RT \ln \gamma_i(T, P, \mathbf{x}) x_i, \quad (20)$$

where  $R$  is the universal gas constant,  $8.3145 \text{ mol}^{-1} \text{ K}^{-1}$  (see also [27, pp. 48–57, 62–73]).

Each form consists of two parts on the right side,  $\mu_i^*(T, P^*, \mathbf{x}^*)$  and a logarithmic term (which has its origins in the use of the ideal-gas equation of state).  $\mu_i^*(T, P^*, \mathbf{x}^*)$  is the chemical potential in a *standard state* at  $(T, P^*, \mathbf{x}^*)$ , as a reference state. The superscript  $*$  denotes the requirement to specify the standard-state conditions  $P^*$  and  $\mathbf{x}^*$ . Methods of obtaining  $\mu_i^*(T, P^*, \mathbf{x}^*)$  are discussed in the next section.

The logarithmic term is obtained from an equation of state (EOS), or a specific model (e. g., a particular  $\gamma$  model), or a free-energy model (e. g., [17]). A simple phase-class model is the ideal-solution model

$$\mu_i(T, P, \mathbf{x}) = \mu_i^*(T, P^*, \mathbf{x}^*) + RT \ln x_i. \quad (21)$$

In this case, the objective function  $G$  is convex. More generally,  $G$  may be nonconvex, leading to multiple local minima.

## Methods of Obtaining

$\mu_i^*$ . Analysis of (11), together with (18)–(20), reveals that the equilibrium composition is determined not by the set of individual values of  $\mu_i^*(T, P^*, \mathbf{x}^*)$ , but by the linear combinations  $\{\Delta G_j^*(T): j = 1, \dots, R\}$ , where  $R = N - M$  is the maximum number of linearly independent stoichiometric vectors (or chemical equations),  $\nu_j$ , with elements  $\nu_{ij}$  ( $R$  as defined here is not to be confused with the universal gas constant  $R$ ), and  $N$  is the number of chemical species [27, p. 17]. For a single-phase system,  $N = S$ ; for a multiphase system,  $N > S$ .  $\Delta G_j^*$  is defined by

$$\Delta G_j^* \equiv -RT \ln K_j^* \equiv \sum_{i=1}^S \nu_{ij} \mu_i^* \quad (22)$$

and  $\mu_i^*$  is the standard chemical potential of substance  $i$  in a particular (specified) phase.

In order to give rise to the same set of equilibrium solutions, any choice of  $\{\mu_i^*\}$  in (7) and (8) must yield an invariant value of  $\Delta G_j^*(T)$  for any possible chemical equation  $j$  involving the system substances. This means that [27, p. 73] for any two choices  $\mu_i^*(1)$  and  $\mu_i^*(2)$ ,

$$\sum_{i=1}^S \nu_{ij} (\mu_i^*(2) - \mu_i^*(1)) = 0. \quad (23)$$

Equation (22) may be viewed as an undetermined set of  $R$  linearly independent equations in the  $N$   $\mu_i^*$  values, in terms of a specified  $\{\Delta G_j^*\}$ . A set of  $\mu_i^*$  may then be constructed by assigning arbitrary values (zero is the most convenient) to  $M$  substances with linearly independent formula vectors [6,27, pp. 214–217]. This approach *must* be followed if values of  $\mu_i^*$  are required in cases for which data are only available in the form of  $\Delta G_j^*$  (as, for example, in many situations involving biochemical and/or ionic systems).

Values of  $\mu_i^*$  obtained for a particular system using equation (22) cannot normally be used for other chemical systems. A *universal* set of  $\mu_i^*$  values that can be used for any chemical system requires assigning  $\{\mu_j^*\}$  to a set of species containing all possible chemical elements and whose formula vectors are linearly independent, and then assigning all  $\mu_i^*$  values relative to these as a datum. The minimum number of such species is equal to the number of chemical elements; thus, the simplest and most common choice is the set of elements themselves.

Even using the elements as a reference chemical state, various routes to obtaining a universal  $\{\mu_i^*\}$  are possible, and one must take great care when combining data from different sources.

For a given standard-state pressure, the temperature dependence of the thermochemical properties  $h$  (enthalpy),  $s$  (entropy), and  $\mu$  is given by

$$h_i^*(T) = h_i^*(T_r) + \int_{T_r}^T C_{Pi}(T) dT, \quad (24)$$

$$s_i^*(T) = s_i^*(T_r) + \int_{T_r}^T \frac{C_{Pi}(T)}{T} dT,$$

$$\mu_i^*(T) = h_i^*(T) - T s_i^*(T),$$

$$s_i^*(T) = s_i^*(T_r) + \int_{T_r}^T \frac{C_{Pi}(T)}{T} dT, \quad (25)$$

$$\mu_i^*(T) = h_i^*(T) - Ts_i^*(T), \quad (26)$$

where  $T_r$  is an arbitrary reference temperature, and  $C_p$  is molar heat capacity at constant pressure. An alternative route to  $\mu_i^*(T)$  is equation (24) together with integration of

$$\frac{\partial[\frac{\mu_i^*(T)}{T}]}{\partial T} = -\frac{h_i^*(T)}{T^2}. \quad (27)$$

Other routes to  $\mu_i^*(T)$  are described in [27, pp. 65–73].

The above equations require a choice of  $T_r$ , values of  $h_i^*(T_r)$ , one of  $\{s_i^*(T_r), \mu_i^*(T_r)\}$ , and values of  $C_{pi}(T)$ . Common choices of  $T_r$  are 0K and 298.15K. The former is a convenient choice when the quantities are determined from statistical mechanical considerations, and the latter is convenient from an ambient temperature consideration.

Given any set of data,  $\{\mu_i^*(1)(T)\}$ , another set may be formed via

$$\mu_i^{*(2)}(T) = \mu_i^{*(1)}(T) - \sum_{j=1}^M a_{ji}c_j(T), \quad (28)$$

where  $\{c_j(T)\}$  is a set of arbitrary constants for the elements; such a set ensures that (23) is satisfied. The choice

$$c_j(T) = \mu_j^{*(1)}(T) \quad (29)$$

for each element in some specified (standard) state at  $T$  gives  $\mu_j^{*(2)}(T) \equiv 0$  for each element.  $\{\mu_i^{*(2)}(T)\}$  is then called the *set of formation values* of  $\mu_i^*$ . This choice is often used, but is not computationally convenient, since its calculation at an arbitrary  $T$  requires an agreed-upon set of choices of the element standard states at each  $T$ , as well as information for the elements concerning  $C_p(T)$  and possible phase transition values of enthalpy.

Some sources of  $\mu_i^*$  and other thermochemical data are listed at the web site [34].

### Sensitivity Analysis

In many cases, it is desired to calculate the rate of change of the optimal solution with respect to one or more than one member of the set of underlying parameters,  $\{T, P, \mu_i^*, b_j\}$ . The set of *sensitivity parameters* of interest are the first order derivatives  $\partial n_i / \partial p_j$ , and the second order derivatives  $\partial^2 n_i / \partial p_j \partial p_k$ , where  $p_j$  denotes a parameter. These quantities can be used in the calcu-

lation of:

- 1) the solution of problems with specified thermodynamic variables other than  $(T, P)$ ;
- 2) the effect of inaccurate  $\mu_i^*$  data on the equilibrium composition;
- 3) *thermodynamic properties* of the equilibrium reacting mixture (e. g.,  $H^{eq}, C_p^{eq}, C_v^{eq}, \dots$ );
- 4) the effect of changes in the specified overall (initial) composition on the equilibrium composition (e. g., buffer capacity of aqueous systems).

These topics are discussed in ([26]; [27, Chap. 8]), and an application is described in [19].

### Stoichiometric Restrictions

Stoichiometric restrictions for a CEP arise when not all solutions of the element-balance equations, (4) and (5), are allowed. Stoichiometric restrictions typically arise from kinetics. The CEP can be solved by increasing the ‘effective number’ of component species, removing the restrictions [27, pp. 27–36, 218–219]). A simple illustration is provided by the permanganate-peroxide reaction [16].

### Equilibrium Constraints

Equilibrium constraints for a CEP result from the a priori specification of some function of the equilibrium composition. Examples include fixed pH problems and solubility calculations in aqueous chemistry. Additional examples are explored in [6,20], and [1].

### Numerical Implementation

Phase-class models giving rise to a convex  $G$  are important in many areas, including rocket propellant evaluation, aqueous speciation, gas-phase chemical processing, and metallurgical operations. Solution of such problems and implementation of the RTPC when necessary (in the case of pure condensed phases or of ideal-solution phases) is relatively straightforward in such cases ([27, pp. 58–59, 204–212], [28]).

In the case of nonconvex  $G$ , most workers have focused on numerical algorithms for the UAF, and in particular the PEP. See [31] for an implementation of a *homotopy continuation method* for the PEP. Global optimization algorithms have been applied in [11,13], and [22]. See [14] for the use of an algorithm based

on interval analysis. Numerical implementation of the RTPC has not yet been fully developed.

Some computer software packages to solve certain types of chemical reaction equilibrium problems are listed at the web site [34].

### Introduction

Offshore oilfield infrastructure planning is a challenging problem encompassing both complex physical con-

straints and intricate economical specifications. An offshore oilfield infrastructure consists of Production Platforms (PP), Well Platforms (WP), wells and connecting pipelines (see Fig. 1), and is constructed for the purpose of producing oil and/or gas from one or more oilfields. Each oilfield (F) consists of a number of reservoirs (R), while each reservoir in turn contains a number of potential locations for wells (W) to be drilled.

Offshore oilfield facilities are often in operation over several decades and it is therefore important to take future conditions into consideration when designing an initial infrastructure. This can be incorporated by dividing the operating horizon into a number of time periods and allowing planning decisions in each period, while design decisions are made for the horizon as a whole. The corresponding optimization model is then run periodically with updated information on the oilfields in order to reoptimize the planning decisions of the offshore oilfield facilities.

Design decisions involve the capacities of the PPs and WPs, as well as decisions regarding *which* PPs, WPs and wells to install over the whole operating horizon. Planning decisions involve the production profiles in each period, as well as decisions regarding *when* to install PPs, WPs, and wells included in the design. Decision variables can also be grouped into discrete variables, for example those representing the installation of PPs, WPs and wells in each period, and continuous

Optimal Planning of Offshore Oilfield Infrastructure, Figure 1 Configuration of fields, well platforms and production platforms

variables, for example those representing the production profiles and pressures in each period.

Iyer and Grossmann [7] proposed a multi-period MILP model that optimizes the planning and scheduling of investment and operation decisions that include the selection of reservoirs to develop, selection of well sites and the production rates from wells at each time period. The model incorporates the nonlinear reservoir through piecewise linear approximations. Van den Heever and Grossmann [14] proposed a multi-period MINLP model for oil field infrastructure planning. As opposed to Iyer and Grossmann [7], a non-linear reservoir model was incorporated directly into the formulation. Meister, Clark and Shah [9] proposed a model for selecting the optimal information-gathering process during the exploration phase, and simultaneously optimizing the operating policies. Jonsbraten [8] presented an MILP model for optimal development of an oil field under oil price uncertainty. The author uses progressive hedging algorithm that is very similar to Lagrangean decomposition to solve the problem. Ahmed, Gorman and Bagajewicz [1] discuss the financial risk management in the planning and scheduling of offshore oil infrastructure. They introduce uncertainty, risk management and budgeting constraints to the model by Iyer and Grossmann [7] employing a sampling average algorithm to overcome the numerical difficulties and compare the results with optimum results found using upper bound risk curves. Goel and Grossmann [4,5] extended this research to gas field development planning under uncertainty. The major uncertainties were in the size and initial deliverability of the fields. The authors assumed that the uncertainty in the size and initial deliverability of the fields resolve immediately when a well platform is built on the field. Linear reservoir models were used, which provide a reasonable approximation for gas fields. The authors proposed a multistage stochastic programming model and a solution algorithm based on the problem structure. Ulstein, Nygreen and Sagli [13] presented a model for tactical planning of Norwegian petroleum production. The model maximizes the net income before taxes from the production and sale of petroleum products. Different cases with demand variations, varying quality constraints and system breakdowns are considered. The model is solved for different scenarios and solutions are compared with the base case scenario. The benefit of the model is to

identify feasible ways to satisfy the demand for varying network configurations.

We describe in this chapter the deterministic model proposed by Van den Heever and Grossmann [14] which incorporates nonlinearities directly into the optimization model. Specifically, these are the reservoir pressures, gas to oil ratio, and cumulative gas produced expressed as nonlinear functions of the cumulative oil produced.

### Problem Statement

The design and planning of an offshore oilfield infrastructure (refer to Fig. 1) is considered over a planning horizon of  $Y$  years, divided into  $T$  time periods (e. g. quarterly time periods). An oilfield layout consists of a number of fields, each containing one or more reservoirs and each reservoir contains one or more wellsites. After the decision has been made to produce oil from a given well site, it is drilled from a WP using drilling rigs. A network of pipelines connects the wells to the WPs and the WPs to the PPs. For our purposes, we assume that the location/allocation problem has been solved, i. e. the possible locations of the PPs and WPs, as well as the assignment of wells to WPs and WPs to PPs, are fixed. In the model, one can easily relax the assumption of fixed allocation of each well to a WP and consider that each well may be allocated to two or more WPs. However, this will clearly increase the computational effort significantly. A more practical option might be to consider allocating each well to up to two WPs. In this case, the two different allocations are treated as two choices of identical wells of which only one can be selected.

The design decisions we consider are valid for the whole planning horizon and are:

- 1 whether or not to include each PP, WP, and well in the infrastructure over the planning horizon
- 2 the capacities of the PPs and WPs

The planning decisions are made in each time period and are:

- 1 whether or not to install each PP and WP
- 2 whether or not to drill each well
- 3 the production profile of each well

These decisions are made under the assumption that operating conditions are constant during a given time period.

## Optimization Model

The following is a complete Generalized Disjunctive Programming [6] model of the offshore oilfield infrastructure planning problem. Please refer to the list of nomenclature at the end of this chapter.

## Objective Function

The objective function is to maximize the Net Present Value (NPV) which includes sales revenues, investment costs and depreciation.

$$\begin{aligned} \max \Psi = & \sum_{t=1}^T \left\{ Rev_t - \sum_{p \in PP} \left[ CI_t^p \right. \right. \\ & \left. \left. + \sum_{\pi \in WPP(p)} \left\{ CI_t^{\pi,p} + \sum_{w \in WWP(\pi)} CI_t^{w,\pi,p} \right\} \right] \right\} \end{aligned} \quad (1)$$

The cost of exploration and appraisal drilling is not included in the objective, seeing that this model will be used after the results from exploration and appraisal have become available. Costs related to taxes, royalties and tariffs are not included in this model. The treatment of complex economic objectives is described in [15]. Costs that we have not included are the costs of decommissioning and well maintenance.

## Constraints Valid for the Whole Infrastructure

In (2) the sales revenue in each time period is calculated from the total oil produced, which is in turn calculated in (3) as the sum of the oil produced from all production platforms. (4) calculates the amount of oil flow from each reservoir in each time period to be the sum of all oil flowrates from wells associated with that reservoir times the duration of the time period. The cumulative flow of oil from each reservoir is calculated in (5). Note that (5) is one of the linking constraints that links the time periods together and thus prevents a solution procedure where each period is solved individually. The cumulative flow of oil is used in (6) to calculate the reservoir pressure through the exponential function which is obtained by fitting a nonlinear curve to the linear interpolation data used by Iyer et al. [7].

$$Rev_t = c_{1t} x_t^{\text{total}} \quad (2)$$

$$\sum_{p \in PP} x_t^p = x_t^{\text{total}} \quad (3)$$

$$I_t^{r,f} = \Delta t \sum_{(w,\pi,p) \in W_{F,R}(f,r)} x_t^{w,\pi,p} \quad \forall r \in R(f), f \in F \quad (4)$$

$$x c_{\theta}^{r,f} = \sum_{t=1}^{\theta-1} I_t^{r,f} \quad \forall r \in R(f), f \in F \quad (5)$$

$$v_t^{r,f} = \gamma_{p_1}^{r,f} \exp(\gamma_{p_2}^{r,f} x c_t^{r,f}) \quad \forall r \in R(f), f \in F \\ \text{for } t = 1 \dots T \quad (6)$$

## Disjunction for each PP, WP and Well

We exploit the hierarchical structure of the oilfield to formulate a disjunctive model. The production platforms are at the highest level of the hierarchy, and the disjunction includes all constraints valid for that PP, as well as the disjunction for the next hierarchical level, i. e. for all WPs associated with that PP. In turn, the disjunction for each WP, which is located within the disjunction of a PP, contains all constraints valid for that WP, as well as the disjunctions for all wells associated with that WP. We present the disjunctions here with numbers indicating the constraints present, and follow with the explanation of the individual constraints contained in each disjunction (Fig. 2)

The outer disjunction is valid for each PP in each time period and can be interpreted as follows: If production platform  $p$  has been installed during or before period  $t$  (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^p = \text{true}$ ), then all constraints in the largest bracket are applied:

$$\left[ \begin{array}{l} z_t^p = 1 \\ CI_t^p = c_{2t}^p + c_{3t}^p e_t^p \quad (7) \\ e_t^p \leq U \quad (8) \end{array} \right] \vee \left[ \begin{array}{l} z_t^p = 0 \\ CI_t^p, e_t^p = 0 \end{array} \right]$$

$$x_t^p \leq d_t^p \quad (9)$$

$$d_t^p = d_{t-1}^p + e_t^p \quad (10)$$

$$\sum_{\pi \in WPP(p)} x_t^{\pi,p} = x_t^p \quad (11)$$

$$\sum_{\pi \in WPP(p)} g_t^{\pi,p} = g_t^p \quad (12)$$

$$\left[ \begin{array}{c} \bigvee_{\theta=1}^t z_{\theta}^p \\ \left[ \begin{array}{c} z_t^p \\ (7), (8) \end{array} \right] \bigvee \left[ \begin{array}{c} \neg z_t^p \\ CI_t^p, e_t^p = 0 \\ (9), (10), (11), (12) \end{array} \right] \\ \left[ \begin{array}{c} z_t^{\pi,p} \\ (13), (14) \end{array} \right] \bigvee \left[ \begin{array}{c} \bigvee_{\theta=1}^t z_{\theta}^{\pi,p} \\ \neg z_t^{\pi,p} \\ CI_t^{\pi,p}, e_t^{\pi,p} = 0 \\ (15), (16), (17), (18), (19) \end{array} \right] \\ \left[ \begin{array}{c} z_t^{w,\pi,p} \\ (20) \end{array} \right] \bigvee \left[ \begin{array}{c} \bigvee_{\theta=1}^t z_{\theta}^{w,\pi,p} \\ \neg z_t^{w,\pi,p} \\ CI_t^{w,\pi,p} = 0 \\ (21), (22), (23), (24), (25), \\ (26), (27), (28), (29) \\ \forall w \in W_{WP}(\pi) \\ \forall \pi \in WP(p) \\ \forall p \in PP, t \in T \end{array} \right] \bigvee \left[ \begin{array}{c} \neg \bigvee_{\theta=1}^t z_{\theta}^{w,\pi,p} \\ x_t^{w,\pi,p} = 0 \\ g_t^{w,\pi,p} = 0 \\ xc_t^{w,\pi,p} = 0 \\ gc_t^{w,\pi,p} = 0 \end{array} \right] \bigvee \left[ \begin{array}{c} \neg \bigvee_{\theta=1}^t z_{\theta}^{\pi,p} \\ x_t^{\pi,p} = 0 \\ g_t^{\pi,p} = 0 \end{array} \right] \bigvee \left[ \begin{array}{c} \neg \bigvee_{\theta=1}^t z_{\theta}^p \\ x_t^p = 0 \\ g_t^p = 0 \end{array} \right] \end{array} \right]$$

Optimal Planning of Offshore Oilfield Infrastructure, Figure 2

First, the smaller nested disjunction is used to calculate the discounted investment cost (including depreciation) of the production platform in each time period. This cost is calculated if production platform  $p$  is installed in period  $t$  ( $z_t^p = True$ ), otherwise it is set to zero. (7) relates the cost as a function of the expansion capacity, which is set to zero if the production platform is not installed ( $z_t^p = False$ ), while (8) sets an upper bound on the expansion. (9) determines the design capacity to be the maximum flow among all time periods, and this is modeled linearly by defining the expansion variable which can take a non-zero value in only one time period. (11) and (12) are mass balances calculating the oil/gas flow from the PP as the sum of the flow from all WPs associated with that PP. If the production platform has not been installed yet (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^p = false$ ), the oil/gas flows, as well as investment cost, are set to zero.

The middle disjunction is valid for all well platforms associated with production platform  $p$  and is only applied if the discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^p$  is true. This disjunction states that if well platform  $\pi$  has been installed before or during period  $t$  (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^{\pi,p}$

= true), then the constraints present in that disjunction are applied:

$$\left[ \begin{array}{c} z_t^{\pi,p} \\ CI_t^{\pi,p} = c_{2t}^{\pi,p} + c_{3t}^{\pi,p} e_t^{\pi,p} \quad (13) \\ e_t^{\pi,p} \leq U \quad (14) \\ \bigvee \left[ \begin{array}{c} \neg z_t^{\pi,p} \\ CI_t^{\pi,p}, e_t^{\pi,p} = 0 \end{array} \right] \end{array} \right]$$

$$x_t^{\pi,p} \leq d_t^{\pi,p} \quad (15)$$

$$d_t^{\pi,p} = d_{t-1}^{\pi,p} + e_t^{\pi,p} \quad (16)$$

$$\sum_{\pi \in W_{WP}(\pi)} x_t^{w,\pi,p} = x_t^{\pi,p} \quad (17)$$

$$\sum_{\pi \in W_{WP}(\pi)} g_t^{w,\pi,p} = g_t^{\pi,p} \quad (18)$$

$$v_t^p = v_t^{\pi,p} - \alpha x_t^{\pi,p} - \beta g_t^{\pi,p} - \delta_t^{\pi,p} \quad (19)$$

Again, the smaller nested disjunction is used to calculate the discounted investment cost (including depreciation) of the well platform in each time period. This

cost is calculated if well platform  $\pi$  is installed in period  $t$  ( $z_t^{\pi,p} = True$ ), otherwise it is set to zero. (13) relates the cost as a function of the expansion capacity, which is set to zero if the well platform is not installed ( $z_t^{\pi,p} = False$ ), while (14) sets an upper bound on the expansion. (15) and (16) determine the design capacity as described in the case of the production platform. (17) and (18) are mass balances calculating the oil/gas flow from the WP as the sum of the flow from all wells associated with that WP. (19) relates the pressure at the WP to the pressure at the PP it is associated with. The pressure at the PP is the pressure at the WP minus the pressure drop in the corresponding pipeline, which is given by the remaining terms in (19). If the production platform has not been installed yet (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^{\pi,p} = false$ ), the oil/gas flows, as well as investment cost, are set to zero.

The innermost disjunction is valid for each well  $w$  associated with well platform  $\pi$ , and is only included if well platform  $\pi$  has already been installed (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^{\pi,p} = true$ ). If well  $w$  has been drilled during or before period  $t$  (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^{w,\pi,p} = true$ ), then the following constraints are applied:

$$\left[ \begin{array}{c} z_t^{w,\pi,p} \\ CI_t^{w,\pi,p} = c_{2t}^{w,\pi,p} \end{array} \right] \vee \left[ \begin{array}{c} \neg z_t^{w,\pi,p} \\ CI_t^{w,\pi,p} = 0 \end{array} \right] \quad (20)$$

$$v_t^{\pi,p} = v_t^{w,\pi,p} - \alpha x_t^{w,\pi,p} - \beta g_t^{w,\pi,p} - \delta_t^{w,\pi,p} \quad (21)$$

$$x_t^{w,\pi,p} = \rho^{w,\pi,p} (v_t^{r,f} - v_t^{w,\pi,p}) \quad (22)$$

$$g_t^{w,\pi,p} \leq x_t^{w,\pi,p} GOR_{\max} \quad (23)$$

$$x_t^{w,\pi,p} \leq \rho^{w,\pi,p} P_{\max} \quad (24)$$

$$x_t^{w,\pi,p} = \sum_{\theta=1}^{t-1} x_{\theta}^{w,\pi,p} \Delta t \quad (25)$$

$$g_t^{w,\pi,p} = \sum_{\theta=1}^{t-1} x_{\theta}^{w,\pi,p} \Delta t \quad (26)$$

$$x_t^{w,\pi,p} \geq x_{t+1}^{w,\pi,p} \quad (27)$$

$$g c_t^{w,\pi,p} = \gamma_{g1}^{r,f} + \gamma_{g2}^{r,f} x c_t^{w,\pi,p} + \gamma_{g3}^{r,f} (x c_t^{w,\pi,p})^2 \quad (28)$$

$$\forall (w, \pi, p) \in W_{F,R}(f, r)$$

$$GOR_t^{w,\pi,p} = \gamma_{gor1}^{r,f} + \gamma_{gor2}^{r,f} x c_t^{w,\pi,p} + \gamma_{gor3}^{r,f} (x c_t^{w,\pi,p})^2$$

$$\forall (w, \pi, p) \in W_{F,R}(f, r)$$

$$(29)$$

The smaller nested disjunction is used to calculate the discounted investment cost (including depreciation) of the well in each time period. This cost is calculated in (20) if well  $w$  is drilled in period  $t$  ( $z_t^{w,\pi,p} = True$ ), otherwise it is set to zero. (21) relates the pressure at the well to the pressure at the WP it is associated with. The pressure at the WP is the pressure at the well minus the pressure drop in the corresponding pipeline, which is given by the remaining terms. (22) states that the oil flowrate equals the productivity index times the pressure differential between reservoir and well bore. (23) restricts the gas flowrate to be the oil flow times the GOR, while (24) restricts the maximum oil flow to equal the productivity index times the maximum allowable pressure drop. The productivity index and the reservoir pressure determine the oil production rate from a well in a given time period. The well is usually capped when the GOR (gas to oil ratio) exceeds a certain threshold limit or when the pressure of the reservoir is lower than a minimum pressure. (25) and (26) calculate the cumulative flow to be the sum of flows over all periods up to the current one. Note that (25) and (26) are linking constraints that link the time periods together and prevent a solution procedure where every time period is solved separately. (27) denotes a specification by the oil company which restricts the flow profile to be non-increasing. While this company does not require a lower bound on the quantity of oil flowing through a pipeline, one could consider adding such a lower bound in the form of a threshold constraint where the flow is either zero or above some minimum, in order to address concerns that the pipeline may seize up if the flow rate were to drop below a certain level. The linear interpolation to calculate cumulative gas and GOR as functions of cumulative oil, are replaced by the nonlinear constraints (28) and (29). These quadratic equations are obtained from a curve fit of the linear interpolation data from Iyer et al. [7]. If the well has not been drilled yet (discrete expression  $\bigvee_{\theta=1}^t z_{\theta}^{w,\pi,p} = false$ ), the oil/gas flows, cu-

mulative flows, as well as investment cost, are set to zero.

**Logical Constraints**

These represent logical relationships between the discrete decisions. (30)–(32) specify that each well, WP and PP can be drilled/installed in only one period. (33) states that if a WP has not been installed by  $t$ , then any well  $w$  associated with that WP cannot be drilled in  $t$ . Likewise, (34) states that if a PP has not been installed by period  $t$ , then any WP associated with that PP cannot be installed in  $t$ . The restriction that only  $M_w$  wells can be drilled in any given time period, is given by (35).

$$\bigvee_{t=1}^T z_{\theta}^{w,\pi,p} \quad \forall w \in W_{WP(\pi)}, \pi \in WP(p), p \in PP \quad (30)$$

$$\bigvee_{t=1}^T z_{\theta}^{\pi,p} \quad \forall \pi \in WP(p), p \in PP \quad (31)$$

$$\bigvee_{t=1}^T z_{\theta}^p \quad \forall p \in PP \quad (32)$$

$$\neg \bigvee_{\theta=1}^t z_{\theta}^{\pi,p} \Rightarrow \neg z_t^{w,\pi,p} \quad (33)$$

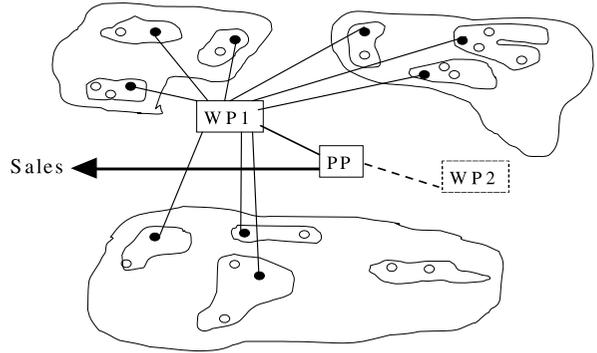

$\forall w \in W_{WP(\pi)}, \pi \in WP(p), p \in PP$

$$\neg \bigvee_{\theta=1}^t z_{\theta}^p \Rightarrow \neg z_t^{\pi,p} \quad \forall \pi \in WP(p), p \in PP \quad (34)$$

$$\bigvee_{(w,\pi,p)} z_t^{w,\pi,p} \leq M_w \quad (35)$$

**Solution Method**

Van den Heever and Grossmann [14] proposed an iterative aggregation/disaggregation algorithm, where the time periods are aggregated in the design problem, and subsequently disaggregated when the planning problem is solved for the fixed infrastructure obtained from the design problem. Both of these subproblems are described with the logic-based outer approximation method [6,12]. The solution from the planning problem is used to update the aggregation scheme after each iteration. This is done through a dynamic programming subproblem which determines how time periods should be aggregated to yield an aggregate problem that resembles the disaggregate problem as close as possible. Convex envelopes are used to deal with non-convexities arising from non-linearities.

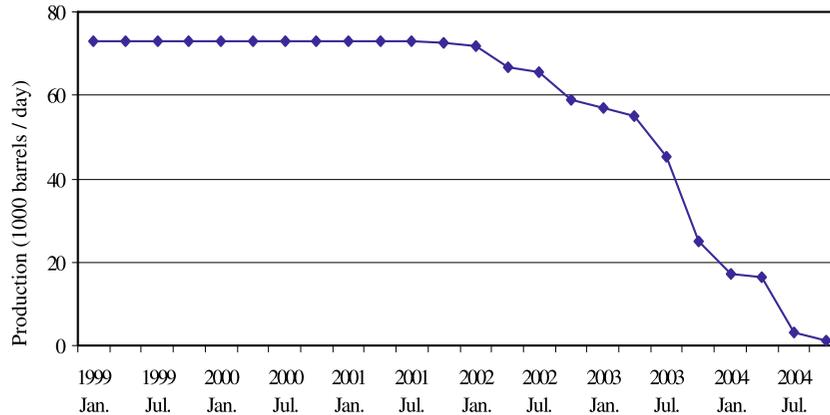

**Optimal Planning of Offshore Oilfield Infrastructure, Figure 3**  
The final configuration

**Optimal Planning of Offshore Oilfield Infrastructure, Table 1**  
The optimal investment plan

Item		Period invested

4	2	Apr. 1999
7	1	Jul. 1999
6	2	Oct. 1999
1	2	Jan. 2000
9	2	Jan. 2000
10	1	Jan. 2000

Figures 3 and 4, together with Table 1 show the optimal solution obtained for the largest problem instance of 25 wells in Fig. 1 for the planning horizon of 24 periods. The final configuration is shown in Fig. 2. Note that only 9 of the potential 25 wells are drilled over the 24 periods. Of these, 3 are drilled in the first period, 1 in the second, 1 in the third, 1 in the fourth, and 3 in the fifth period as shown in Table 1.

Figure 4 shows the production profile for the whole infrastructure over the 24 time periods encompassing the six years from January 1999 up to December 2004. The net present value obtained for the profit is \$67.99 million. This final solution is found in less than 25 min by the proposed algorithm, whereas a traditional solution approach such as the OA algorithm needs more than 5 h to find the solution. Due to the short solution

**Optimal Planning of Offshore Oilfield Infrastructure, Figure 4**  
Production profile over six years

time, the model can quickly be updated and resolved periodically as more information about the future becomes available. Also, different instances of the same problem can be solved in a relatively short time to determine the effect of different reservoir simulations on the outcome.

## Nomenclature

### Sets and Indices

$PP$	set of production platforms
$p$	production platform $p \in PP$
$WP(p)$	set of well platforms associated with platform $p$
$\pi$	well platform $\pi \in WP(p)$
$F$	set of fields
$f$	field $f \in F$
$R(f)$	set of reservoirs associated with field $f$
$r$	reservoir $r \in R(f)$
$W_{WP}(\pi)$	set of wells associated with well platform $\pi$
$W_R(r)$	set of wells associated with reservoir $r$
$W_{WP,R}(r, \pi)$	set of wells associated with reservoir $r$ and well platform $\pi$
$w$	well $w \in W_{(\cdot)}(\cdot)$
$t$	time periods
$T$	aggregated time periods
$T$	disaggregate time periods
$TA$	aggregate time periods
$t$	disaggregate time period $t \in T$
$\tau$	aggregate time period $\tau \in TA$

To denote a specific well  $w$  that is associated with a specific well platform  $\pi$ , which is in turn associated with a specific production platform  $p$ , we use the index combination  $(w, \pi, p)$ . Similarly, the index  $(\pi, p)$  applies to a specific well platform  $\pi$  associated with a specific production platform  $p$ . We omit superscripts in the variable definition for the sake of simplicity.

### Continuous Variables

$x_t$	oil flow rate in period $t$
$xc_t$	cumulative oil flow up to period $t$
$g_t$	gas flow rate (volumetric) in period $t$
$gc_t$	cumulative gas flow up to period $t$
$l_t$	oil flow (mass) in period $t$
$\phi_t$	gas-to-oil ratio (GOR) in period $t$
$v_t$	pressure in period $t$
$\delta_t$	pressure drop at choke in period $t$
$d_t$	design variable in period $t$
$e_t$	design expansion variable in period $t$
$Rev_t$	sales revenue in period $t$
$CI_t$	investment cost in period $t$ (including depreciation)
$s_\tau$	state at the end of aggregate period $\tau$ , i. e. number of disaggregate periods available for assignment at the end of aggregate period $\tau$
$m_\tau$	length of aggregate period $\tau$

### Boolean Variables

$z_t = \text{true}$	if facility (well, WP or PP) is drilled/installed in period $t$
---------------------	---

## Parameters

$\rho$	productivity index of well
$P_{\max}$	maximum pressure drop from well bore to well head
$GOR_{\max}$	maximum GOR
$m_{\tau}$	number of periods in aggregate time period $\tau$
$T_a$	number of aggregate time periods, $\tau = 1..T_a$
$M_w$	maximum number of wells drilled in a time period
$\Delta t$	length of time period $t$
$U$	upper bound parameter (defined by the respective constraint)
$\alpha$	pressure drop coefficient for oil flow rate
$\beta$	pressure drop coefficient for GOR
$c_{1t}$	discounted revenue price coefficient for oil sales
$c_{2t}$	discounted fixed cost coefficient for capital investment
$c_{3t}$	discounted variables cost coefficient for capital investment
$\gamma_{p1}$	first coefficient for pressure vs. cumulative oil
$\gamma_{p2}$	second coefficient for pressure vs. cumulative oil
$\gamma_{g1}$	first coefficient for cumulative gas vs. cumulative oil
$\gamma_{g2}$	second coefficient for cumulative gas vs. cumulative oil
$\gamma_{g3}$	third coefficient for cumulative gas vs. cumulative oil
$\gamma_{gor1}$	first coefficient for GOR vs. cumulative oil
$\gamma_{gor2}$	second coefficient for GOR vs. cumulative oil
$\gamma_{gor3}$	third coefficient for GOR vs. cumulative oil
$f_{inv,t}$	discounting factor for investment in period $t$
$f_{dpr,t}$	discounting factor for depreciation in period $t$
$f_{rev,t}$	discounting factor for revenue in period $t$
$I_t$	investment costs in period $t$
$R_t$	revenue in period $t$

## Superscripts

$(w, \pi, p)$	variables associated with well $w \in W$ , with well platform $\pi$ and production platform $p$
$(\pi, p)$	variables associated with well platform $\pi$ and production platform $p$
$(p)$	variables associated with production platform $p$
$(r)$	variables associated with reservoir $r$

### Background

Sensor networks are a collection of devices designed to detect and/or measure characteristics of targets within an environment or traits of an environment itself. These measurements are then used to estimate states within the system as modeled by the designer. The design goal is to provide an optimal estimate of these states against predetermined measures of goodness. The combining of all available measurements into optimal estimates of a dynamic system is a well-studied problem and is widely implemented in variants of Kalman filters throughout many current applications (see the Analytical Science Corporation, [10]).

However; in many applications, practical limitations preclude the collection of data by all sensors at any given instance in time. In fact, systems are often limited to collecting information from a single sensor at each instance. [1,7]. For example, radar or sonar systems may be precluded from simultaneously transmitting pulses due to inter-pulse interference, or data transmission rates may exceed system bandwidth capabilities. Under these conditions, the question is no longer how to combine the measurements to obtain an optimal state estimate, but instead is in what order should the sensors be visited in order to obtain an optimal estimate. The determination of this visitation order is called the sensor scheduling problem. A variant is the single sensor, multiple-site problem, where a sensor is moved between discrete locations while maintaining an estimate of a dynamic physical attribute at each site.

Numerous optimization techniques have been used to address the sensor scheduling problem. In general, sensor scheduling has been shown to be a combinatorial optimization problem, but with certain simplifying assumptions, several successful approaches employing dynamic, linear modeling techniques have been developed. These techniques have the benefit of the extensive development of filter theory and are often incorporated directly into existing filter designs or immediate extensions to their application. In this paper, selected techniques are presented in chronological order of their development. Each is presented with a brief overview of its theoretical development followed by observations on its significant implications and application.

### Methods

#### Linear Plant Control Model

In an early and oft cited publication, Meier et al. [8] posed the sensor selection problem as an adaptive plant control problem, in which a sequence of plant control vectors,  $u_k^P$  and measurement control vectors,  $u_k^M$  are sought to optimize plant performance. The measurement control vector selects which sensor (or sensors, in the more general case), if any, that the measurement subsystem would collect, creating a measurement matrix,  $Z_k = \{z_0, z_1, \dots, z_k\}$ , where  $z_k$  is a  $n$ -dimensional column vector. Initial development is for the general discrete case. Since, in the general case, the problem is of undetermined dimensionality and unbounded in many cases of practical interest, further development is made under the assumptions that the plant and measurement subsystem are *linear* in nature and that both the system disturbance and measurement noise are *Gaussian* processes. It is also assumed that the cost function is quadratic in nature. The examination of this special case allows more definitive results to be obtained. The resulting dynamic linear system is modeled as follows.

$$\begin{aligned} \overline{x_{k+1}} &= F_k \overline{x_k} + G_k u_k^P + \overline{w_k} \\ \overline{z_k} &= H_k (u_k^M) \overline{x_k} + \overline{v_k} \\ J &= E \left\{ \sum_{k=0}^N \left[ x_k^T Q_k x_k + u_k^{PT} R_k u_k^P + l_k^M (u_k^M) \right] \right. \\ &\quad \left. + x_{N+1}^T P_{N+1} x_{N+1} \right\} \end{aligned}$$

where  $x_k$  is the state of the system at time  $k$ ,  $F_k$  is the state transition matrix,  $G_k$  is the input matrix,  $w_k$  is zero-mean, Gaussian system noise with a covariance of  $Q_k$ ,  $z_k$  is the measurement vector,  $H_k$  is the observation matrix, and  $v_k$  is zero-mean, Gaussian measurement noise with covariance  $R_k$ , which is uncorrelated with  $Q_k$ . The system state and its associated error covariance matrix are optimally propagated in accordance with the following equations.

$$u_k^p = -K_k \hat{x}_k|_k$$

where  $\hat{x}_k|_k$  is the optimal state estimate and

$$\begin{aligned} K_k &= [G_k^T P_{k+1} G_k + R_k]^{-1} G_k^T P_{k+1} F_k \\ P_k &= Q_k + F_k^T P_{k+1} F_k + P_{k+1}^* \\ P_{k+1}^* &= F_k^T P_{k+1} G_k (G_k^T P_{k+1} G_k + R_k)^{-1} G_k^T P_{k+1} F_k, \\ &k = 0, 1, \dots, N; \end{aligned}$$

where a superscript\* indicates a variable that has been updated with the current measurement and lack thereof indicates the value as propagated through the model with prior to the measurement update.

Noting that the gain matrix,  $K_k$ , and the covariance matrices,  $P_k$  and  $P_k^*$ , are independent of  $R_k$  and  $H_k$  indicates that they are also independent of the measurement control vector,  $u_k^M$ . This leads to a major conclusion, that the measurement control vector,  $u_k^M$ , can be solved separately from the plant control vector,  $u_k^p$ , and can in fact be determined *a priori*. This allows the computation of the measurement control matrix to be performed through the following equivalent nonlinear, deterministic control problem:

$$\text{Minimize } J^* = \sum_{k=0}^N \{tr[P_{k+1}^* \hat{P}_k|_k] + l_k^M(u_k^M)\}.$$

Once in this form the problem can be solved employing dynamic programming or gradient method techniques, with examples of each presented by Meier, et al. In the presence of possible local minima, the dynamic programming approach is preferred to ensure a global minimum obtained. The inclusion of a cost for taking the measurement as part of the cost function allows for the dropping of unnecessarily expensive measurements. All following techniques focus on the minimization of the error covariance,  $P$ , and assume that

exactly one measurement will always be made each iteration.

### Bounded Open-Looped Covariance Propagation Model

A technique for a weighted random sampling of sensors is proposed by Gupta, et al. and developed in a series of publications [4,5,6]. Here a discrete linear system is assumed and the error covariance matrix is allowed to propagate open looped (that is without measurement updates) for a predetermined number of iterations,  $k$ . Dropping the plant portion of the model used in the above model, we have the following equations.

$$\begin{aligned} \bar{x}_k &= F_{k-1} \bar{x}_{k-1} + B \bar{w}_{k-1} \\ \bar{z}_k &= H_k \bar{x}_k + \bar{v}_k \\ P_{k+1} &= F_k P_k^* F_k^T + Q_k \end{aligned}$$

where  $x_k$  is the state of the system at time  $k$ ,  $F_k$  is the state transition matrix,  $w_k$  is zero-mean, Gaussian system noise with a covariance of  $Q_k$ ,  $B$  is the noise input matrix,  $z_k$  is the measurement vector,  $H_k$  is the observation matrix, and  $v_k$  is zero-mean, Gaussian measurement noise with covariance  $R_k$ , which is uncorrelated with  $Q_k$ . (Note that the lack of the  $G_k u_k^p$  term in this model reflects the pure sensor approach taken here vice the plant control approach taken by Meier, et al.). The error covariance matrix propagates in accordance with the following equations.

$$\begin{aligned} f_H(P) &= F P F^T + Q B B^T \\ &\quad - F P H^T (H P H^T + R)^{-1} H P F^T \\ f_H^k(P) &= f_H(f_H(\dots f_H(P))); \\ &\quad f_H \text{ is applied } k \text{ times.} \end{aligned}$$

While a general solution to this equation appears intractable, the concept is developed further by proving the existence of both upper and lower bounds under certain conditions. Requirements for the existence of these bounds include that  $P$  is positive semi-definite,  $R$  is positive definite, and the selection of sensor  $i$  for the  $j$ th measurement independent of all other selections. The upper bound is

$$\begin{aligned} X &= B Q B^T + A X A^T \\ &\quad - \sum_{i=0}^N q_i A [X C_i^T (R_i + C_i X C_i^T) C_i X] A^T \end{aligned}$$

and lower bound is

$$q_i |\lambda_{\max}(\bar{A}_j)|^2 \leq 1.$$

The final step in the development of this technique is to show that sensors chosen according to a Markov chain fall within these bounds, which in terms of the Markov chain parameters are

$$\begin{aligned} X_{k+1} &= \sum_{j=1}^N \pi_k^j X_{k+1}^j, \\ \pi_k^j X_{k+1}^j &= \sum_{i=1}^N f_{C_j}(X_k^i) q_{ij} \pi_k^i \\ Y_k &= \sum_{i=1}^k q_{jj}^{i-1} (\pi_{k+1-i}^j - q_{jj} \pi_{k-i}^j) f_{C_j}^i \\ &\quad \cdot (BQB^T) + q_{jj}^{k-1} \pi_0^j f_{C_0}^k(P_0). \end{aligned}$$

The bounds provided by this technique are loose and a designer has the opportunity to fine tune the system's performance by adjusting  $q_i$ . Selection of this parameter is known to also create a thresholding effect where use of a particular sensor is disallowed. Once implemented, this algorithm has a computational burden that is orders of magnitude less than a tree-search algorithm and finds a near-optimal solution in the steady state.

### Branch-and-Bound Search Method

The next technique, developed by Feng, et al. [3], is a branch-and-bound method, also built on a discrete time, time-varying model. The sensor schedule is represented by vector  $u$ , where element  $u_k = i$  means sensor  $i$  is in use at time  $k \in \{1, 2, \dots, N\}$  and  $U$  is the set of all possible  $u$  vectors. Since  $U$  is a finite set, at least one vector  $u$  will provide an optimal solution. To avoid an exhaustive search, a lower bound is developed for the propagation of the error covariance matrix and the algorithm performs a tree search for the optimal solution, pruning branches based on this lower bound. While the system model is similar to the previous model, the cost function is modified as following to reflect use of the  $u$  vector.

$$J(u) = \sum_{k=0}^{N-1} \text{Tr} \{ \Sigma(k) P_u(k) \} dt + c \cdot \text{Tr} \{ P_u(N) \}$$

where  $\Sigma$  is an  $n \times n$  positive definite matrix-valued function with

$$\begin{aligned} |\Sigma_{ij}(k)| &\leq L, k \in \{1, 2, \dots, N\}, \\ i, j &= 1, 2, \dots, n, \end{aligned}$$

where  $L$  and  $c$  are positive constants, and

$$P_u(k) = E \{ (x(k) - \hat{x}(k))(x(k) - \hat{x}(k))^T | \mathcal{F}_u \}$$

is the error covariance matrix and  $\mathcal{F}_u$  is the smallest  $\sigma$ -algebra for which  $z$  is measurable for  $u \in U$ .

For two symmetric matrices  $P_1$  and  $P_2$  of similar dimension, the notation  $P_1 \geq P_2$  was used to indicate  $P_1 - P_2$  is a positive semi-definite matrix. Feng, et al. [3] proceeded to prove the lower bound on the covariance matrix exists by showing if

$$\begin{aligned} P_{u_1}^*(k) &\leq P_{u_2}^*(k) \text{ for } k \in \{1, 2, \dots, N\}, \\ \text{then } J(u_1) &\leq J(u_2), \end{aligned}$$

and if

$$2P_{ii} \geq \sum_{j=1}^n |P_{ij}|, \quad \forall i = 1, 2, \dots, n,$$

then  $P$ , a  $n \times n$  positive matrix, is positive semi-definite. Hence, choosing

$$\Psi(k) = \max_{i=1,2,\dots,N} \Psi_i(k),$$

where  $\Psi_i(k)$  is a diagonal matrix chosen such that

$$H_i^T(k)(D_i(k)D_i^T(k))^{-1}C_i(k) \leq \Psi_i(k)$$

then the lower bound is given by

$$\begin{aligned} LB(u(1), u(2), \dots, u(i)) \\ = \sum_{k=0}^{N-1} \text{Tr} \{ \Sigma(k) P_u^*(k) \} dt + c \cdot \text{Tr} \{ P_u^*(N) \}, \end{aligned}$$

subject to the system propagation equations,

$$\begin{aligned} x_k(k) &= F_{k-1}(k) x_{k-1} + B(k) w_{k-1} \\ z_k &= H_k(k) x_k + D(k) v_k \end{aligned}$$

where  $k \in \{0, 1, \dots, T-1\}$  and  $Q_k$  and  $R_k$  are uncorrelated covariance matrices for  $w_k$  and  $v_k$ , respectively.

Branching is now implemented by noting, if  $\Upsilon_i(k) \leq \Upsilon_j(k)$ , then for any sequences,

$$\{u(1), u(2), \dots, u(k-1), i, u(k+1), \dots, u(T)\},$$

and  $\{u(1), u(2), \dots, u(k-1), j, u(k+1), \dots, u(T)\}$ ,

the solution for the covariance matrix will also be less than or equal to the solution for the second sequence, where  $H_i^T(k)(D_i(k)D_i^T(k))^{-1}C_i(k) = \Upsilon_i(k)$ .

Feng, et al. [3] present the associated algorithm and provide an illustrative example. An exhaustive search of the solution space for the example would have taken  $10^{12}$  checks, while the branch and bound approach found the solution after branching 6842 times and examining 435 solutions.

### Multi-site Problem Overview

In the multi-site single-sensor version of the sensor scheduling problem, the objective is for a single sensor to maintain an estimate of a dynamic physical attribute (e.g., position) of multiple targets. Tiwari, et al. [11] present a feasibility criterion for a single sensor to maintain a bounded estimate of an attribute at  $n$  locations. Yerrick, et al. [13] demonstrates by simulation the feasibility criterion presented in Tiwari, et al. [11] and develops a heuristic to find a good sensor motion model given the dynamics of the system under observation. Yerrick, et al. [14] provide an optimal sensor coverage solution for two sensor motion models given a model of the observed system's dynamics. The first model they study is based on i.i.d. transition probabilities among the sites. That is, the next site to be visited by the sensor is chosen according to a stationary probability distribution that is independent of the previously visited site. Their second model is more sophisticated as the moves are chosen according to a transition probability matrix.

All these mentioned works investigate probabilistic strategies for the motion of the single sensor among the sites. A deterministic approach overcomes one disadvantage of probabilistic motion: with any random motion strategy, there is nonzero probability that a particular site will not be visited at all in any finite time horizon. Yavuz and Jeffcoat [12] build an optimization model and show that it is NP-Hard. The authors also develop valid lower and upper bounds for the objective function of their model. This paper also exploits the relationships between the sensor scheduling prob-

lem and periodic scheduling problems. In particular, pinwheel scheduling and just-in-time manufacturing scheduling literatures are exploited and useful results are incorporated to sensor scheduling. The authors propose two constructive heuristic procedures to solve the sensor scheduling problem and evaluate their performance through a computational study.

### Conclusions

The three approaches presented demonstrate the power of using a dynamic linear model to address the sensor scheduling problem. These approaches also integrate easily into existing linear filter algorithms and systems. As with linear filtering schemes, small system nonlinearities are masked by the system and measurement noises. Should system non-linearities, prevent achieving the required level of performance needed, a filter-type of approach may still be achievable with nonlinear filters and potential approaches to the sensor scheduling problem using nonlinear filters are presented by Oshman [9] and Baras, et al. [2].

The recent contributions to multi-site single-sensor scheduling explore both probabilistic and deterministic solution approaches. The formulation of the problem is relatively new and in fact a wide range of different versions of the problem remain to be studied. Such versions should consider multiple sensors or relax one or more of the underlying assumptions; e.g., statistically independent sites, uniform transition times, no cost of movement or measurement, or time-invariant models of system dynamics and measurement.

### Introduction/Background

Solvents find widespread use throughout the chemical industry, from separations in bulk chemical processing to reactions, transport and separations in the fine chemicals and pharmaceutical industries. Solvents are useful for dissolving solid materials in order to enhance reaction rates, to facilitate the transport of solid materials, to provide a heat sink during highly exothermic reactions and to allow difficult separations to take place (liquid–liquid separations, absorption or extractive distillation). The choice of solvent has an impact on the economic performance of a given process, and on the quality of the products manufactured. For instance, different solvents can lead to different crystal structures being formed during crystallization; the regeneration of a solvent leaving a separation unit can be more or less energy-intensive, as in the case of chemical absorption versus physical absorption, leading to different operating costs; the amount of solvent required to process a certain amount of material may vary significantly, leading to different equipment sizes and hence capital investment.

The identification of an optimal solvent is a difficult task for several reasons. First of all, solvent design is a very complex problem in which many trade-offs must be considered. In absorption, for instance, a solvent which has a high capacity for the compound it must remove may be comparatively expensive to regenerate, and may be lost with the separated compound in larger quantities during regeneration. In reactions, a solvent which leads to a high product yield may also favor side reactions and thus result in the loss of valuable reactants. In addition, the optimal solvent is closely linked to the choice of operating conditions for a process. Thus, the decoupling of the choice of solvent and of operating conditions can lead to suboptimal solvent designs. Early methods for the computer-aided selection of solvents were based on enumeration or “generate-and-test” techniques [3,7]. However, because of the complexity of the problem, optimization

provides a natural framework for solvent design. In its most complete form, the solvent design problem is in fact an integrated plant-wide process and solvent design problem. The plant-wide aspect is required as a solvent which is optimal for a reactor may cause problems in separations (e. g., difficult recovery, poor behavior in crystallization) and vice versa. The design variables to be considered include equipment sizes and operating conditions (continuous variables), as well as the molecular structure of the solvent (integer or binary variables). The general problem structure is therefore a mixed-integer program. Usually, this problem is nonlinear in nature and, depending on the type of process model used, it may involve differential and algebraic equations.

From a practical point of view, it is not yet feasible to tackle the integrated plant-wide design problem for processes including both reaction and separation. The first publications on the use of optimization in solvent design focused on the optimization of physical property metrics such as solvent capacity and heat of vaporization [25,29]. There has since been steady progress on extensions of the problem formulation, with more direct measures of performance being used. The design of solvents for gas–liquid and liquid–liquid separations is a well-studied problem and some of the techniques developed are now used in industry. Much remains to be done on solvent design for reactions and solid–liquid separations (crystallization). For these unit operations, solvents are often chosen on the basis of intuition, similarity with other known systems and experimentation. The choices being made are thus often suboptimal. One major hurdle remains problem formulation because meaningful relations between solvent structure and solvent properties do not exist, or existing relations are very complex (e. g., Monte Carlo simulations or quantum-mechanical calculations).

In this article, the state-of-the-art in problem formulation is reviewed, and methods used to solve the problem are briefly discussed. There has been extensive and successful work on solvent selection based on “generate-and-test” approaches [3,15]. This approach is particularly well suited to the case where all decisions are integer and can therefore be enumerated but is not considered here because it does not usually rely on the formulation and solution of an optimization problem, but rather on matching certain property constraints [26].

Perspectives for further developments of optimization-based solvent design are considered at the end of this article.

## Formulation

### General Problem Formulation

The general formulation of the optimal solvent design problem is given by

$$\begin{aligned} \min_{\mathbf{x}, \mathbf{y}} \quad & f(\mathbf{x}, \mathbf{y}) \\ \text{subject to} \quad & h_{sp}(\mathbf{x}, \mathbf{y}) = 0, \\ & g_{sp}(\mathbf{x}, \mathbf{y}) \leq 0, \\ & h_{cf}(\mathbf{x}, \mathbf{y}) = 0, \\ & g_{cf}(\mathbf{x}, \mathbf{y}) \leq 0, \\ & h_p(\mathbf{x}, \mathbf{y}) = 0, \\ & g_p(\mathbf{x}, \mathbf{y}) \leq 0, \\ & \mathbf{x} \in \mathbb{R}^m, \\ & \mathbf{y} \in \{0, 1\}^q, \end{aligned} \quad (1)$$

where  $f$  is the objective function;  $h_{sp}$  is a set of structure–property equality constraints, which relate solvent molecular structure to physical properties;  $h_{cf}$  is a set of chemical feasibility and complexity equality constraints, which ensure that only meaningful solvent molecules are designed;  $h_p$  is a set of equality constraints describing the process, such as mass balances, energy balances and sizing constraints;  $g_{sp}$  is a set of structure–property inequality constraints;  $g_{cf}$  is a set of chemical feasibility, complexity and solvent property inequality constraints, such as limits on the solvent boiling point;  $g_p$  is a set of process performance constraints;  $\mathbf{x}$  is an  $m$ -dimensional vector of continuous variables denoting operating conditions, physical properties or process variables; and  $\mathbf{y}$  is a  $q$ -dimensional vector of binary variables describing the solvent structure.

### Representation of the Solvent

**Atom Groups** The solvent is usually represented as a set of atom groups which are commonly used in group contribution methods [34], such as  $\text{CH}_3$ ,  $\text{CH}_2$ ,  $\text{OH}$  and  $\text{COOH}$ . Any given molecule can thus be represented by a vector of integer variables,  $\mathbf{n}$ , where the  $i$ th element corresponds to the number of groups of type  $i$ . Thus,  $n$ -butanol is represented by  $n_{\text{CH}_3} = 1$ ,  $n_{\text{CH}_2} = 3$  and

$n_{\text{OH}} = 1$ . In order to allow the solution of the problem by mixed-integer programming algorithms such as the outer approximation [12,42], the integer variables are mapped onto a set of binary variables with the following constraints:

$$\sum_{k=0}^K 2^k y_{i,k} - n_i = 0, \quad \forall i \in G, \quad (2)$$

where  $G$  denotes the set of groups, each  $y_{i,k}$  denotes a binary variable and  $K$  is such that  $\sum_{k=0}^K 2^k$  is equal to the maximum number of groups of any given type allowed in the optimal solvent. This allows the variable vector  $\mathbf{n}$  to be treated as a vector of continuous variables. This approach has been used extensively in the optimal solvent design literature.

**Atom Groups and Connectivity Information** An alternative approach, which allows a more detailed representation of the molecule and the use of alternative structure–property relations such as second-order group contribution techniques [1,28] or connectivity indices [20], is based on a graph-theoretic representation of the compound via an adjacency matrix or similar tools. This has been proposed in the context of computer-aided molecular design by a number of authors [4,9,10,35].

**Chemical Feasibility Constraints** In order to ensure that the solvent designed is indeed physically meaningful, a number of constraints must be imposed to limit the combinations of binary variables. On the basis of typical boiling point constraints on solvents, it is first noted that solvents are usually acyclic, monocyclic aromatic or, more rarely, bicyclic aromatic molecules. This can be represented by three binary variables.  $y_a = 1$  for an acyclic molecule,  $y_b = 1$  for a bicyclic solvent molecule and  $y_m = 1$  for a monocyclic molecule [29]:

$$y_a + y_b + y_m = 1. \quad (3)$$

Furthermore, a continuous variable,  $m$ , is defined to represent the type of molecule. For a monocyclic molecule,  $m = 0$ , for an acyclic molecule,  $m = 1$  and for a bicyclic molecule,  $m = -1$ . This is expressed in terms of the binary variables as

$$m - (y_a - y_b) = 0. \quad (4)$$

The octet rule [29] ensures that the solvent molecule designed is structurally feasible and that there are no remaining free attachments in the molecule. It is based on the valency ( $v_i$ ) of different structural groups:

$$\sum_{i \in G} (2 - v_i) n_i - 2m = 0. \quad (5)$$

To prevent any group being bonded to itself, the formation of a double bond or the formation of more than one molecule, the following constraint can be included [29]:

$$n_j(v_j - 1) + 2m - \sum_{i \in G} n_i \leq 0 \quad \forall j \in G. \quad (6)$$

The following constraint ensures that the molecule contains at least two groups:

$$2 - \sum_{i \in G} n_i \leq 0. \quad (7)$$

In an aromatic molecule, the number of aromatic groups must be 6 if the molecule is monocyclic or 10 if it is bicyclic:

$$\sum_{i \in G_A} n_i - 6y_m - 10y_b = 0, \quad (8)$$

where  $G_A$  is the set of aromatic groups.

In a bicyclic molecule the number of aromatic carbon groups ( $n_{\text{ac}}$ ) must be greater than or equal to 2:

$$2y_b - n_{\text{ac}} \leq 0. \quad (9)$$

Chemical complexity constraints can be imposed to describe the presence of side chains on cyclic molecules [13]. Finally, limits can be placed on the total number of groups in the molecule, on the number of specific functional groups and on particular combinations of groups. This reduces the solvent design space, making the problem more tractable and it also accounts for the fact that group contribution methods typically work well for medium-sized compounds with a few functional groups.

**Design of Solvent Mixtures** Several authors have expanded the size of the solvent design space by considering solvent mixtures, in which the solvents in the mixture and its composition are determined as part of the problem solution [8,38]. The presence of continuous variables to describe composition makes the use of optimization techniques, as opposed to enumeration techniques, especially suitable.

## Methods/Applications

Having introduced some general concepts on the formulation of the optimal solvent design problem, we now turn our attention to the specific problems which have been tackled to date, and to the solution methods which have been employed. The applications are classified in terms of the type of objective function used. Most applications are in the area of fluid–fluid separations, but there have been a few publications on reactions and on solid–fluid separations.

### Design for Property Targets

**Properties from Group Contribution and Correlations** Initial work in the area of solvent design was focused on identifying solvents that maximize property performance measures. In a separation process, solvent capacity and selectivity could be taken as metrics for the effectiveness of the separation and solvent loss as a metric for the difficulty of the solvent regeneration. This approach was adopted in [29], where the following function was considered as an objective:

$$\text{Capacity} \times \text{selectivity} - 100 \times \text{solvent loss}. \quad (10)$$

This early work on optimal solvent design was applied to multicomponent gas absorption and liquid–liquid extraction using a mixed-integer nonlinear programming (MINLP) formulation, thus extending an earlier approach based on a nonlinear programming (NLP) formulation [25]. The required physical properties were calculated using group contribution techniques and similar correlations. In particular, phase equilibria was predicted using the UNIFAC approach [21]. This activity coefficient model has found many applications in solvent design thanks to its versatility.

The use of group contribution techniques and correlations allows many important selection criteria to be taken into account. Issues such as toxicity and environmental impact as deduced from octanol–water partition coefficients can be incorporated in the formulation as constraints [2]. Correlations provide a route to extending the scope of solvent design formulations. The design of solvents for crystallization can be considered by incorporating effects such as the influence of solvent choice on crystal shape [18]. Solvent choice for an extractive fermentation process can be considered by incorporating issues such as biocompatibility, inertness

and ability to cause phase splitting [43]. This captures the effect of the solvent on yield in terms of its ability to promote product extraction from the mixture. The impact of solvent on reaction rate constants can be taken into account via a combination of group contribution techniques and the solvatochromic equation of [11], as shown in [13]. In all these cases, the MINLP formulation provides a single integrated framework to consider the trade-offs between the different solvent properties.

**Properties from More Detailed Models** Group contribution techniques are usually most accurate for medium-sized molecules which contain few functional groups [34]. While this is often appropriate for the solvent being designed, the solutes considered are often more complex and this may result in a poor representation of the solvent–solute interactions. This has repercussions on the quality of the phase equilibria predictions and can have a significant impact on the design. To address this issue, recent work has been aimed at incorporating more realistic representations of the solute and of the solvent–solute systems.

In [22,36] it was shown how continuum solvation models, in which the solvent is modeled as a continuum but the solute is modeled at the quantum-mechanical level, can be used in solvent design. Lehmann and Maranas [22] used the model of [24] to predict activity coefficients for solvent–solute pairs. This information was used to optimize the capacity and selectivity of the solvent, while taking environmental considerations into account. The use of such models poses additional difficulties in the context of optimization-based solvent design, because the evaluation of the quantum-mechanical quantities requires the solution of an optimization problem (energy minimization). This naturally leads to a bilevel formulation with a very expensive inner problem. Lehmann and Maranas [22] successfully applied their approach to a small case study, using a genetic algorithm to solve the outer solvent design problem. However, they concluded that the presence of adjustable parameters in the solvation model limited the applicability of the method because these parameters are hard to determine reliably. Sheldon et al. [36] used a different solvation model [23] and focused on minimizing the free energy of solvation. This particular problem can be formulated as a single-level problem and the authors applied this formula-

tion to a set of case studies, using the outer-approximation algorithm [12,42]. A solvent design space of over 3000 molecules was considered in each case study and the algorithm systematically converged to the optimal solution after evaluating less than 12% of the candidate molecules. Despite the high computational cost of quantum-mechanical calculations, the best solvents were identified in reasonable CPU time. However, work remains to be done to incorporate such detailed property models into more realistic solvent design problems.

Another possibility to improve the quality of property prediction is to resort to group contribution equations of state which provide a description of gas and liquid phases, in contrast to activity coefficient models which are limited to the liquid phase. This allows the representation of nonideal vapor phases, which is especially relevant for high-pressure processes. Tamouza et al. [40] and Thi et al. [41] have proposed a group contribution version of the statistical associating fluid theory (SAFT) equation of state which takes into account molecular shape and hydrogen bonding and can thus be used to model complex fluid mixtures reliably. Recently, Keskes et al. [19] have shown that a solvent for a high-pressure absorption process for CO<sub>2</sub> removal from natural gas can be designed based on a group contribution version of the SAFT equation of state. A limited solvent design space was used, but this opens the way for further uses of equations of state in solvent design.

### Design for Process Targets

Since the mid-1990s, the formulation of the solvent design problem has become increasingly sophisticated as researchers have attempted to capture the complex trade-offs that are necessary to design an optimal process-solvent system. Two main classes of techniques have been developed: sequential approaches, in which some features of the solvent are preselected before turning to the process optimization problem, and integrated solvent and process design approaches.

**Sequential Approaches** In sequential approaches, a first step consists in identifying candidate solvents, or features of “good” solvents on the basis of property targets. In a second step, an optimal process is designed for the solvents selected in the first step. Such an approach

was proposed by Pistikopoulos et al. [33,39] based on a multiobjective framework which accounts for economic and environmental considerations. A list of solvents is first generated on the basis of environmental and property-based criteria. The solvents chosen are then verified in different process flowsheets/designs.

In a series of papers, Papadopoulos and Linke [30,31,32] proposed an approach in which candidate solvents are first designed on the basis of property targets. A clustering algorithm is then used to extract information from the set of high-performance candidates. This information is then incorporated into a multiobjective process design problem. Both optimization problems (initial solvent design and process design) are solved using a stochastic optimization algorithm. This approach has been applied to several separation process design problems.

### Integrated Solvent Design and Process Operation

The simultaneous optimization of the operation of a dynamic separation process and of the solvent was considered in [14]. In this case, the process equations  $h_p$  and  $g_p$  in formulation (1) are given by a set of differential and algebraic equations, resulting in a mixed-integer dynamic optimization (MIDO) problem. The authors applied the MIDO algorithm of [5,6] and a decomposition approach based on the work of [33], in which feasibility of key property constraints is tested before solving the computationally intensive MIDO primal problem. The system considered in this work was a batch extractive distillation process, with the objective to debottleneck existing equipment.

### Integrated Process and Solvent Design

*Single-Objective Framework* Hostrup et al. [16] proposed an MINLP formulation of the integrated process synthesis and solvent design problem. They used a series of analysis steps to explore the properties of candidate compounds and the properties of mixtures including candidate compounds. This allowed them to eliminate some candidate compounds on the basis of heuristics or on the basis of specific process constraints. Depending on the number of solvent candidates remaining after this study, a set of NLP process design problems or an MINLP is solved to identify the optimal process/solvent combination.

*Multiobjective Framework* Buxton et al. [8] extended the approach of [33]. Their approach is based on formulating a multiobjective problem in which economic and environmental criteria are taken into account. An approach to life-cycle analysis has been included in the formulation [17]. The large and highly nonlinear mixed-integer problem which results from this formulation is solved using a decomposition-based approach.

### Solution Techniques

Several solution techniques have been brought to bear on the range of problem formulations developed so far. Many researchers have focused on formulation rather than solution technique, and have applied local optimization algorithms such as the outer-approximation [12,42] and MIDO [5,6] algorithms. Others have used decomposition-based approaches [33] or sequential approaches [30] to reduce the complexity of the problem and avoid unnecessary evaluations of large sets of equations.

The solvent design problem is inherently nonconvex: whenever phase equilibria are considered, as is always the case for separation design, highly nonlinear constraints are introduced in the problem formulation. To address this issue, there have been a few attempts at deploying and adapting global optimization techniques. Sinha et al. [37] have developed a specialized branch-and-bound algorithm. They later developed an approach based on interval analysis to tackle the same problem [38]. Wang and Achenie [44] proposed a hybrid stochastic/deterministic approach based on a combination of simulated annealing and local MINLP (outer approximation). Marcoulaki and Kokossis [27] demonstrated the use of a simulated annealing algorithm to solve solvent design problems in separation process design (liquid–liquid extraction, extractive distillation, gas absorption). Finally, genetic algorithms have been used, for instance, by Lehmann and Maranas [22].

### Conclusions

The solvent design problem can naturally be framed as a mixed-integer optimization problem in which trade-offs between different properties can be considered through property targets or, more realistically, by measuring their effect on process metrics such as

environmental impact or economic performance. The main difficulties in the formulation and solution arise from the complexity of the performance–structure relationships, which can be highly nonlinear, as in the case of phase-equilibrium models, or very expensive to evaluate, as in the case of detailed process models or quantum-mechanical calculations. Although much progress has been made in formulating problems for fluid–fluid separations, much remains to be done for reactive processes and solid–fluid separations. In particular, reliable property–structure relations must be developed and incorporated into the formulation of the problem. This may require new solution techniques to be developed, especially when the property–structure model requires an optimization problem to be solved. Furthermore, the nonconvexity of the problem must be addressed more generally so that reliable solutions can be guaranteed.

### Introduction

A *triangulation* of a given set  $S$  of  $n$  points in the Euclidean plane is a maximal set of non-crossing straight line segments (called *edges*) which have both endpoints in  $S$ . As an equivalent definition, a triangulation of  $S$  is a partition of the convex hull of  $S$  into triangular faces whose vertex set is exactly  $S$ . Triangulations are a versatile means for partitioning and/or connecting geometric objects. They are used in many areas of engineering and scientific applications such as finite element methods, approximation theory, numerical computation, computer-aided geometric design, computational geometry, etc. Many of their applications are surveyed in [8,11,20,61].

A triangulation of  $S$  can be viewed as a planar graph whose vertex set is  $S$  and whose edge set is a subset of  $S \times S$ . The Eulerian relation for planar graphs implies that the number  $e(S)$  of edges, and the number  $t(S)$  of triangles, do not depend on the way of triangulating  $S$ . In particular

$$e(S) = 3n - 3 - h$$

$$t(S) = 2n - 2 - h$$

where  $h$  denotes the number of edges bounding the convex hull of  $S$ . The number of different triangulations of  $S$  is, however, an exponential function of  $n$ . More precisely, the number of triangulations *every* set of  $n$  points (in general position) must have is  $\Omega(2.63^n)$  [57]. A general upper bound is  $O(43^n)$  [68], and point sets can be constructed that exhibit  $\Theta(\sqrt{72}^n)$  triangulations [6]. All these bounds are very recent, and various prior bounds have been given; see the citations listed in [6,57,68].

The problem of automatically generating *optimal triangulations* for a point set  $S$  has been a subject of research since decades. Enumerating all possible triangulations and selecting an optimal one (exhaustive search) is too time-consuming even for small  $n$ . In fact, constructing optimal triangulations in polynomial time is a challenging task. This becomes more apparent as greedy methods, such as deleting candidate triangles or edges from worst to best, are doomed to fail by the NP-completeness of the following problem; see Lloyd [56]: Given a point set  $S$  and some set  $E$  of edges on  $S$ , decide whether  $E$  contains a triangulation of  $S$ .

Results on optimizing *combinatorial properties* of triangulations, such as their degree (Jansen [39]) or connectivity (Dey et al. [21] and Dillencourt [25]) are rare. Most optimization criteria for which efficient algorithms are known concern *geometric* properties of the edges and triangles.

### Delaunay Triangulations

The most commonly constructed and maybe the most famous triangulation for a point set  $S$  is the *Delaunay triangulation*,  $DT(S)$ . See [8,27,34,45] for extensive treatments and surveys.  $DT(S)$  contains – for each triple of points in  $S$  – the corresponding triangle provided its circumcircle is empty of points in  $S$ . Sib-

son [70] proved that  $DT(S)$  can be constructed from any given triangulation  $T$  of  $S$  by applying any sequence of *good edge flips*. These are exchanges of diagonals in one of  $T$ 's convex quadrilaterals  $Q$  such that – after the flip – the two new triangles are locally Delaunay, i. e., have circumcircles empty of vertices of  $Q$ .

Various global optimality properties of  $DT(S)$  can be proved by observing that every good flip gives a *local improvement* of the respective optimality measure. Lawson [47] observed that *equiangularity* of a triangulation, which is the sorted list of its angles, increases lexicographically in this way.  $DT(S)$  thus maximizes the minimum angle. *Coarseness* of a triangulation is measured by the largest circumcircle that arises for its triangles. D'Azevedo and Simpson [19] showed that  $DT(S)$  minimizes coarseness in this sense, and also if smallest enclosing circles are taken rather than circumcircles. The latter property – unlike others – generalizes to higher-dimensional Delaunay triangulations; see Rajan [64]. Similarly, *fatness* may be defined as the sum of triangle inradii. Lambert [46] pointed out that  $DT(S)$  maximizes fatness or, equivalently, the mean inradius. Triangular surfaces obtained from lifting  $DT(S)$  to 3-space (for any given heights at triangle vertices) minimize *roughness*, which is the integral of the squared gradient; see Ripka [66]. It is also known that a variant of  $DT(S)$  minimizes the minimum angle; see Epstein [31].

The Delaunay triangulation is a special instance of *regular triangulations*, which are obtained by projecting the lower boundary part of a convex polytope in 3-space; see e. g. Edelsbrunner and Shah [28]. Regular triangulations are, thus, obviously optimal in the sense that they allow for a convex lifting surface. Some more optimality properties of  $DT(S)$  can be derived from this fact; see Musin [60]. Delaunay and regular triangulations can be constrained to live in nonconvex polygons (rather than in the convex hull of the underlying point set  $S$ ), see [48] and [1], respectively. Equiangularity and, with it, various other optimality properties carry over to constrained Delaunay triangulations [48].

$DT(S)$  is the geometric dual of the famous *Voronoi diagram* of a point set  $S$  and can be computed in  $O(n \log n)$  time and  $O(n)$  space by various different approaches; see e. g. [8,27,34]. Su and Drysdale [71] gave a thorough experimental comparison of available Delaunay triangulation algorithms.

On the negative side,  $DT(S)$  fails to fulfill optimization criteria similar to those mentioned above, such as minimizing the maximum angle, or minimizing the longest edge. Edelsbrunner et al. [29,30] gave  $O(n^2 \log n)$  time and  $O(n^2)$  time algorithms, respectively, for computing triangulations optimal in these respects. The former algorithm is based on an *edge insertion paradigm* which is shown in Bern et al. [10] to lead – in polynomial time – to triangulations with maxmin triangle height, minmax triangle eccentricity, and minmax gradient surface, respectively.

### Minimum Weight Triangulations

Most longstanding open was another optimal triangulation problem, the *minimum weight triangulation*. Here the criterion is *weight*, which is defined as the sum of all edge lengths. The complexity of computing a minimum weight triangulation,  $MWT(S)$ , for arbitrary planar point sets  $S$  was open since 1975 when it was mentioned in Shamos and Hoey [67]. Minimum weight triangulation is included in Garey and Johnson's [35] list of problems neither known to be NP-hard, nor known to be solvable in polynomial time. Very recently, its complexity status has been resolved; Mulzer and Rote [59] proved that minimum weight triangulation is NP-hard.

Earlier attempts to prove the minimum weight triangulation problem NP-hard have resulted in some related NP-completeness results; they are listed in [38]. Several *heuristic algorithms* have been proposed to solve this problem; see Lingas [53], Plaisted and Hong [63], and Heath and Pemmaraju [38]. None of these is known to produce a constant approximation in weight, although progress in this respect has been made later, see below.

It is well known that the Delaunay triangulation  $DT(S)$  may exceed  $MWT(S)$  in weight by a factor of  $\Theta(n)$ ; see Kirkpatrick [42]. Another popular triangulation, the *greedy triangulation*,  $GT(S)$ , also may fail to approximate  $MWT(S)$  well.  $GT(S)$  is obtained by a greedy algorithm intended to yield small weight: Edges are inserted in increasing length order unless previously inserted edges are crossed and until the triangulation is completed. Several fast implementations have been proposed, e. g. by Dickerson et al. [22] who also give a brief history. Levkopoulos [49] showed

a lower bound of  $\Omega(\sqrt{n})$  on the approximation factor. A matching upper bound has been given in Levcopoulos and Krznaric [50]. The same paper introduces an interesting modification of  $GT(S)$  that achieves a *constant* weight approximation for  $MWT(S)$  in polynomial time, though with a very large constant. Very recently, Remy and Steger [65] developed an algorithm that finds an  $(1 + \epsilon)$ -approximation of  $MWT(S)$  in quasi-polynomial time,  $n^{O(\log^8 n)}$ .

For uniformly distributed point sets  $S$ , both triangulations  $GT(S)$  and  $DT(S)$  yield satisfactory approximations for  $MWT(S)$ ; see e. g. Lingas [54]. In fact,  $GT(S)$  seems to perform slightly better, as reported in Dickerson et al. [23].  $GT(S)$  can be constructed in  $O(n)$  expected time in this case, by an algorithm in Drysdale et al. [26] or by a modification of the algorithm in Levcopoulos and Lingas [52].

The weight of a triangulation may decrease when additional points (so-called *Steiner points*) are admitted. Eppstein [32] showed that the weight of a *minimum weight Steiner triangulation* for  $S$  may be  $\Omega(n)$  times smaller than the weight of  $MWT(S)$ . The same paper gives efficient triangulation algorithms that approximate the weight of the former within a constant factor, thus improving over previous results in Bern et al. [12]. No polynomial-time algorithms are known for the exact minimum weight Steiner triangulation problem.

*Dynamic programming* is a powerful tool to deal with discrete optimization problems which are decomposable in a certain sense. It leads to polynomial-time solutions for some restricted instances of the minimum weight triangulation problem. For example, if  $S$  is the vertex set of a convex polygon then  $MWT(S)$  can be computed in  $O(n^3)$  time and  $O(n^2)$  space. The basic observation used is that – once some triangle of the triangulation has been fixed – the problem splits into subproblems (subpolygons) whose solutions can be found recursively, thereby avoiding recomputation of common subproblems. The triangulation method, first proposed by Gilbert [36] and Klincsek [44], does not really exploit convexity. It works as well for nonconvex polygons, and in fact for any interior face of a planar straight line graph. It is worth mentioning that, in the convex polygon case,  $MWT(S)$  is approximated by  $GT(S)$  up to a constant factor; see Levcopoulos and Lingas [51]. Anagnostou and Corneil [7] consider the case where  $S$  gives rise to a small number  $k$  of convex layers (nested

convex hulls). Their dynamic programming approach works in time  $O(n^{3k+1})$  and thus is polynomial for constant  $k$ . Meijer and Rappaport [58] later improved the bound to  $O(n^k)$  when  $S$  is restricted to lie on  $k$  non-intersecting line segments.

The minimum weight triangulation problem can also be formulated as a *linear programming* problem. To this end, a variable  $x_i$  is assigned to each of the  $\binom{n}{2}$  edges  $e_i$  defined by  $S$ . The objective is to minimize

$$\sum_{e_i} x_i |e_i|$$

subject to the constraints

$$\begin{aligned} 0 &\leq x_i \leq 1 \\ x_i + x_j &\leq 1 \text{ for } e_i \cap e_j \neq \emptyset \\ x_i + \sum_{e_j \cap e_i \neq \emptyset} x_j &\geq 1. \end{aligned}$$

The last two constraints express the property that a triangulation is a maximal set of non-crossing edges. An integer solution of this linear program yields a minimum weight triangulation: For each edge  $e_i$ , inclusion into, or exclusion from  $MWT(S)$  is indicated by  $x_i = 1$  or  $x_i = 0$ , respectively. An optimal solution need not be integer, however, and insisting on an integer solution results in an *integer programming* problem whose general version is known to be NP-complete [35]. Using a modified version of this approach, Ono et al. [62] were able to compute  $MWT(S)$  for up to a hundred points.

The afore-mentioned polynomial-time results for triangulating polygonal domains (rather than point sets) give motivation for the following *subgraph approach* to compute  $MWT(S)$ , proposed e. g. in Xu [73] and Cheng et al. [14]: Find a (suitable) subgraph  $G$  of  $MWT(S)$ . If  $G$  contains  $k$  connected components, try all possibilities to add  $k - 1$  edges to make it a connected graph  $C$ . Complete each of these graphs  $C$  to a triangulation by optimally triangulating its faces, and select a triangulation with minimum weight, which gives  $MWT(S)$ . This approach, which basically is exhaustive search, can be implemented to run in  $O(n^{k+2})$  time. The problem, of course, is to find candidates for  $G$  with  $k$  small.

The subgraph approach should be distinguished from the heuristic approaches in [38,53,63] we mentioned before, which also first fix some graph  $G$  for  $S$

(for example, the minimum spanning tree) and then triangulate out its faces. The difference is that  $G$  will *not* be a subgraph of  $MWT(S)$  in general, and thus does not lead to an exact solution.

### Locally Defined Subgraphs of MWT

Many efforts have been put into the study of subgraphs of  $MWT(S)$ . Gilbert [36] pointed out that the *shortest edge* defined by  $S$  always belongs to  $MWT(S)$ . Another simple observation is that *unavoidable edges*, which are edges not being crossed by any other edge in  $S \times S$ , have to appear in any triangulation of  $S$  and thus are in  $MWT(S)$ . For example, all edges of the convex hull of  $S$  are unavoidable. The number of unavoidable edges does not exceed  $2n - 2$ , see Xu [74], and usually is very small.

Only in recent years, several more substantial subgraphs of  $MWT(S)$  have been identified. One of them arises from a class of *empty neighborhood graphs* introduced by Kirkpatrick and Radke [43]. Let  $p, q \in S$  and  $\beta \geq 1$ . The edge  $\overline{pq}$  is included in the  $\beta$ -skeleton,  $\beta(S)$ , if the two discs of diameter  $\beta|pq|$  and passing through both  $p$  and  $q$  are empty of points in  $S$ . It is not hard to see that  $\beta(S)$  always is a subgraph of the Delaunay triangulation  $DT(S)$ . In fact,  $\beta(S)$  can be constructed from  $DT(S)$  in  $O(n)$  time; see Lingas [55] or Jaromczyk et al. [40].

Interestingly,  $\beta(S)$  is a subgraph of  $MWT(S)$  for  $\beta$  large enough. The original bound  $\beta \geq \sqrt{2}$  in Keil [41] has been improved later in Cheng and Xu [17] to  $\beta > 1.1768$ , which is close to the largest value  $2/\sqrt{3}$  for which a counterexample is available [41]. Only for point sets  $S$  in convex position it is known that  $\beta > 2/\sqrt{3}$  always implies inclusion of  $\beta(S)$  in  $MWT(S)$ ; see Hainz et al. [37]. Whereas  $\beta(S)$  is a connected graph for  $\beta = 1$  (known as the *Gabriel graph* of  $S$ ), it may be highly disconnected for larger  $\beta$ -values. Cheng et al. [14] prove that – for uniformly distributed point sets  $S$  – the number of components is expected to be  $\Theta(n)$ .

Yang et al. [76] formulated and proved a different inclusion region: If the union of the two disks with radius  $|pq|$  and centered at  $p$  and  $q$ , respectively, is empty of points in  $S$ , then  $\overline{pq}$  is an edge of  $MWT(S)$ . That is, points  $p$  and  $q$  are mutual nearest neighbors. The skeleton generated in this way and the  $\beta$ -skeleton do not

contain each other for  $\beta > 2/\sqrt{3}$ , but for smaller  $\beta$ -values the  $\beta$ -skeleton contains the former as a subgraph. Note that both graphs are defined via a symmetric and local condition. A sufficient asymmetric condition can be found in Wang et al. [72]. We refer to Eppstein [33] for a survey paper on geometric graphs.

A distinct attempt to find a sufficient local condition defines an edge  $e$  as a *light edge* [2] if there is no edge in  $S \times S$  crossing  $e$  and shorter than  $e$ . Let  $L(S)$  denote the graph formed by the light edges for  $S$ .  $L(S)$  obviously contains all unavoidable edges, and in fact contains both Cheng and Xu's 1.1768-skeleton and the skeleton in Yang et al. [76]. By construction,  $L(S)$  is a subgraph of the greedy triangulation  $GT(S)$ , as light edges cannot be blocked by any edge previously inserted by the greedy strategy. On the other hand,  $L(S)$  is no subgraph of  $MWT(S)$  in general. However, if  $L(S)$  happens to be a full triangulation of  $S$ , then  $L(S) = MWT(S) = GT(S)$ . This allows for a fast computation of  $MWT(S)$  for a certain class of point sets  $S$ , using greedy triangulation algorithms.

These results are observed in Aichholzer et al. [2] as a consequence of the following matching theorem for planar triangulations, proved in Aichholzer et al. [4] and in Cheng and Xu [16]: For any two triangulations  $T_1$  and  $T_2$  of a fixed point set  $S$ , there is a perfect matching between the edge set of  $T_1$  and the edge set of  $T_2$  such that matched edges either cross or are identical. A similar matching exists for the triangle sets of  $T_1$  and  $T_2$ , where matched triangles either overlap or are identical. The paper [2] further gives several polynomially-time computable *lower weight bounds* for  $MWT(S)$ , the simplest one being the weight of  $L(S)$ . Another bound can be stated as

$$\min_{g \in X(E)} \sum_{e \in E} |g(e)|$$

where  $E$  is any set of non-crossing edges, and  $X(E)$  is the set of all matchings  $g : E \rightarrow S \times S$  with the property  $g(e) = e$  or  $g(e)$  crosses  $e$ .

The concept of light edges gives rise to a partition of the greedy triangulation  $GT(S)$  into levels  $L_1, \dots, L_k$ : Let  $L_1 = L(S)$  be the set of edges that are light with respect to  $S \times S$ , let  $L_2$  be the set of edges that are light with respect to  $(S \times S) \setminus C_1$ , where  $C_1$  is the set of edges crossing  $L_1$ , and so on. Upper bounds on the ratio in weight between  $GT(S)$  and  $MWT(S)$  that depend on

the number  $k$  of levels are observed in Levcopoulos and Krznaric [50] and Aichholzer et al. [5]. In particular,  $GT(S)$  is a constant-factor approximation of  $MWT(S)$  provided  $k = O(1)$ .

### Globally Defined Subgraphs of MWT

We have seen that several subgraphs of  $MWT(S)$  can be found from local conditions, namely, via emptiness of particular inclusion regions. The subgraphs below are defined in a global way, via intersection of triangulations.

Call a triangulation  $T$  of  $S$  *locally minimal* if every 4-sided and point-empty polygon drawn by  $T$  is optimally triangulated. That is, every convex quadrilateral contains the shorter one among its two diagonals. It is easy to see that  $GT(S)$  is locally minimal and  $DT(S)$ , in general, is not. Let  $LMT(S)$  denote the intersection of all locally minimal triangulations for  $S$ . Then  $LMT(S)$  is a subgraph of  $MWT(S)$ , as this triangulation of course is locally minimal, too.

Whereas it is not known how to compute  $LMT(S)$  in polynomial time, a surprisingly large subgraph of  $LMT(S)$ , the so-called *LMT-skeleton* can be identified by a simple and efficient method, proposed in Belleville et al. [9] and in Dickerson and Montague [24]: Consider some edge set  $E \subset S \times S$ . An edge  $e \in E$  is called *redundant in  $E$*  if there is no convex quadrilateral formed by  $E$  that has  $e$  as its shorter diagonal. Edge  $e$  is called *unavoidable in  $E$*  if no other edge in  $E$  crosses  $e$ . The LMT-skeleton algorithm puts  $E = S \times S$  and proceeds in several rounds. Each round first identifies all edges redundant in  $E$  and eliminates them from the set, and then includes all edges that are unavoidable in the reduced set  $E$  into the LMT-skeleton. The algorithm stops when no more edge in  $E$  can be classified as either redundant or unavoidable. The number of rounds (but not the produced LMT-skeleton) depends on the ordering in which the edges are examined. In particular, there always exists an ordering such that one round suffices; see Hainz et al. [37].

The fact that the LMT-skeleton for  $S$ , and thus  $LMT(S)$ , tend to be connected even for large point sets comes at a surprise. From the practical point of view, the LMT-skeleton almost always nearly triangulates  $S$ . On the other hand, a 19-point counterexample to connectedness exists [9], and for uniformly dis-

tributed points, the expected number of components is  $\Theta(n)$ ; see Bose et al. [13]. The constant of proportionality is extremely small, however. It is interesting to note that the LMT-skeleton, and the graph of light edges  $L(S)$ , exhibit a similar behavior of connectedness, but do not contain each other in general. We mention further that the improved LMT-algorithm in [37], that tends to yield some additional edges of  $LMT(S)$ , indeed constructs  $LMT(S)$  provided the original LMT-skeleton for  $S$  is connected.

The LMT-skeleton clearly can be constructed in polynomial time, and several variants have been considered in order to gain efficiency [9,15,24,37]. A powerful tool is pre-exclusion of edges before starting the LMT-algorithm, using the *exclusion region* in Das and Joseph [18]: For an edge  $e$ , consider the two triangular regions with base  $e$  and base angles  $\pi/8$ . If both regions contain points in  $S$  then  $e$  cannot be part of  $MWT(S)$ . If  $S$  is drawn from a uniform distribution, reduction to an expected linear number of candidate edges for  $MWT(S)$  is achieved [22], and near-linear expected-time implementations of the LMT-algorithm exist [37,69]. The LMT-skeleton based subgraph approach enables the computation of a minimum weight triangulation for some tenthousand points in reasonable time.

### Some Related and Open Problems

Let us briefly state a few open problems related to optimal triangulations.

A fast algorithm for computing the minimum weight triangulation of a simple polygon would have many applications and thus is of practical interest. Even for convex polygons, no algorithm using less than  $\Theta(n^3)$  time and  $\Theta(n^2)$  space is known [44]. No progress has been made since 1980 on this problem.

Minimality in weight may be relaxed to *k-optimality*, meaning that all  $k$ -sided and point-empty polygons in a triangulation are optimally triangulated. This is a generalization of local minimality which constitutes the instance  $k = 4$ . Whereas it is easy to compute 4-optimal triangulations (the greedy triangulation is one), no results are known on how to compute a 5-optimal triangulation in polynomial time. An algorithm based on the edge insertion paradigm is proposed in [75].

The maximal number of triangulations of a set of  $n$  points is a quantity still not well understood. The gap between the best known upper bound,  $O(43^n)$  [68], and lower bound,  $\Omega(\sqrt{72}^n)$  [6], is large. The common belief is that the latter function is closer to the truth.

In the last ten years, a relaxation of triangulations, so-called *pseudo-triangulations*, have been become popular, especially in computational geometry. In addition to triangles, pseudo-triangles (polygons with exactly three convex internal angles) are used as faces. Unfortunately, not much is known about optimality properties of pseudo-triangulations. Some basic properties of minimum weight pseudo-triangulations are given in the paper [3], which also shows that the greedy pseudo-triangulation always has to be a triangulation.

## Introduction

Optimization techniques have found wide applications in solving various problems in ad hoc networks. Many problems in topology control, routing, maximum flow and resource allocation [23,29,33] can be formulated as optimization problems. Compared with wired networks, there are many challenges exclusive to ad hoc networks. Owing to the interdependencies across multiple layers, many factors have to be considered in a unified framework. The interdependencies complicate both problem formulation and algorithm design. For instance, interference among transmissions is a critical constraint to throughput of wireless networks; the channel is shared by all nodes in the network. Power control determines the interference range of each node. Therefore, to achieve the maximum flow in a static wireless network, power control should also be considered.

In our research, we have applied optimization-based approaches to routing, maximum flow and cross layer design problems in ad hoc networks and WSNs. The optimization problems formulated are usually nondeterministic polynomial-time (NP) hard, so the computation complexity is not affordable for resource-constrained nodes. We have devised distributed or approximation algorithms to solve the problems efficiently. In the rest of this chapter, we present some of the successful approaches that we have developed.

## Applications

### Multiconstrained Quality-of-Service

#### Multipath Routing

Although small in size, sensor nodes are built with sensing, processing and computing capabilities. They report the information collected to the sink for further processing. Depending on different applications, the packets generated show diverse attributes. Different traffic has different requirements regarding packet delivery, so quality-of-service (QoS) routing is an important issue in WSNs. We have investigated both reliability and delay constraints in QoS routing. Here, reliability is defined as the packet delivery ratio. Prone to link changes and failures, sensor networks are unreliable. The empirical result from Berkeley [28] shows that the average packet loss ratio increases 5–10% per link in sensor networks. Multiconstrained routing is faced with

time complexity and/or space complexity. For wireless networks, complete and accurate state information is not available owing to the time-varying traffic and link quality. Only soft-QoS provisioning is attainable in notoriously unpredictable wireless communications. Here soft QoS is defined as guaranteeing the QoS requirements with probability. It approximates hard QoS when the probability approaches 1. It is known that finding a path subject to two or more additive constraints is NP-complete [19]. Therefore, solving the problem in a heuristic and approximate way is the only reasonable approach for resource-limited sensor nodes. Soft QoS follows naturally from the inherent random link characteristics of ad hoc networks and WSNs. Owing to the inherent difficulty of end-to-end QoS and the limited functionality of sensor nodes, some approximate methods have to be applied to deal with the computational complexity. We first formulate the end-to-end soft-QoS problem as a stochastic program. Then we propose a distributed routing algorithm based on the linear program, which is a deterministic approximation of the original end-to-end QoS routing. Our proposed routing algorithm is hop-based, so it is scalable and convenient to implement. As another favorable feature, it circumvents the formidable computational complexity of the multiconstrained path problem.

For wired networks, many papers have proposed exact or heuristic algorithms targeted at multiconstrained path or multiconstrained optimal path problems [13,18,19,26,27,42,43]. However, WSNs differ from wired networks in the limited energy, memory and computation capabilities of nodes, and link characteristics. Multipath routing has been applied to address QoS in ad hoc networks [38], but we formulate the problem in a more rigorous way and consider multiple QoS constraints.

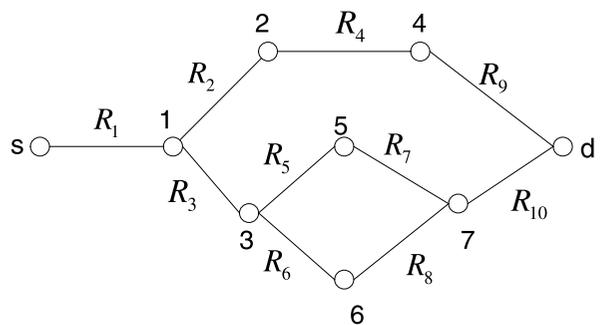

For a given path  $p$ , the end-to-end reliability can be computed as

$$\prod_{(i,j) \in p} r_{ij}, \tag{1}$$

where  $r_{ij}$  is the reliability of link  $(i,j)$  on path  $p$ . If there is no single feasible path satisfying the reliability requirement, multipath routing can be used to improve the reliability. Carefully choosing a subset of existing paths, one can transfer the packet on all those paths. Although an individual path cannot achieve the

performance goal, multiple paths may meet it aggregately as shown in Fig. 1. In Fig. 1, the source node assigns reliability  $R_1$  to its next hop node 1. Neither link  $l_{12}$  nor  $l_{13}$  could satisfy this reliability requirement alone, so node 1 distributes reliability requirement  $R_2$  to link  $l_{12}$  and  $R_3$  to link  $l_{13}$ , so that  $R_2 + R_3 \geq R_1$ . The same process is performed at each intermediate node. Finally at sink node  $d$ , the three paths,  $s \rightarrow 1 \rightarrow 2 \rightarrow 4 \rightarrow d$ ,  $s \rightarrow 1 \rightarrow 3 \rightarrow 5 \rightarrow 7 \rightarrow d$  and  $s \rightarrow 1 \rightarrow 3 \rightarrow 6 \rightarrow 7 \rightarrow d$ , can achieve the desired reliability additively. The assembly efficiency of multiple paths is a great boon to unreliable sensor networks. Obviously, there exist many feasible combinations. To save the energy cost, the set with the minimum number of paths is chosen as the forwarding set. We argue that sending a packet on more paths induces a higher energy cost, because more data packets have to be transmitted. Using more paths introduces more contention, which degrades energy efficiency. Although some paths in the set may have more hops, it is still more energy efficient to confine packets to a few paths.

First of all, the question of how to quantify the reliability achieved by a subset of paths needs to be addressed. Then how to choose the energy-efficient path set subject to the delay constraint is our main focus. Denote  $d$  as the sink, which is assumed to be stationary. Let  $P(s,d)$  denote the path set of  $P$  possible paths from a source node  $s$  to  $d$ . Each path  $p_j$  in  $P(s,d)$ ,  $j = 1, 2, \dots, P$ , is associated with delay  $d_j$  and reliability  $r_j$ . The aggregate reliability of multiple paths is approximated as the sum of the reliability of those paths. We formulate the problem as follows:  $\forall p \in P(s, d)$ , at

Optimization in Ad Hoc Networks, Figure 1  
Reliability distribution between a source–destination pair

### Optimization in Ad Hoc Networks, Table 1

#### Notation

Notation	Meaning
$(i,j)$	Link from node $i$ to node $j$
$N(i)$	Neighbor set of node $i$
$h_i$	Hop count from current node $i$ to the sink
$r_{ij}$	Reliability of link $l_{ij}$
$\alpha$	Soft-QoS probability for delay
$\beta$	Soft-QoS probability for reliability
$L_i^d$	Hop requirement for delay at node $i$
$L_i^r$	Hop requirement for reliability at node $i$
$D_i$	Actual delay of the packet arriving at node $i$
$R_i$	Reliability requirement assigned to the path through node
$i$	
$\mathbf{d}_{ij}$	Delay of link $l_{ij}$ , described as a random variable
$\mathbf{r}_{ij}$	Reliability of link $l_{ij}$ , described as a random variable
$x_j$	Decision variable of whether link $(i,j)$ is used
$d_{ij}$	Mean of $\mathbf{d}_{ij}$
$r_{ij}$	Mean of $\mathbf{r}_{ij}$
$\Delta_{ij}^d$	Standard deviation of $\mathbf{d}_{ij}$
$\Delta_{ij}^r$	Standard deviation of $\mathbf{r}_{ij}$

source node  $s$ ,

$$\begin{aligned}
 & \text{Minimize } \sum_{j=1}^P x_j \\
 & \text{subject to } x_j d_j \leq D, \\
 & \mathbf{r} = 1 - \prod_{j=1}^P 1 - x_j r_j \geq R, \\
 & x_j = 0 \text{ or } 1, \text{ for all } j = 1, 2, \dots, P,
 \end{aligned} \tag{2}$$

where  $D$  and  $R$  are denoted as the delay and reliability QoS requirements respectively, and the  $x_j$  are the decision variables for whether path  $j$  is chosen or not. This defines a 0–1 integer programming problem. For clarity, the notation used in this chapter is explained in Table 1.

The problem definition requires exact information about path quality, which is almost impossible to obtain in WSNs; hence, only soft-QoS provisioning is achievable. We can formulate the constraints of the defined

problem in a probabilistic way:

$$\begin{aligned}
 & \text{Minimize } \sum_{j=1}^P x_j \\
 & \text{subject to } P(x_j \mathbf{d}_j \leq D) \geq \alpha, \text{ for } D > 0 \\
 & P(\mathbf{r} \geq R) \geq \beta \\
 & x_j = 0 \text{ or } 1, \quad \forall j \in N(i),
 \end{aligned} \tag{3}$$

Constraint (3) can be further simplified as

$$P\left(\sum_{j=1}^P \log(1 - x_j r_j) \leq \log(1 - R)\right) \geq \beta.$$

This formulation is a nonlinear program, which could have more than one solution. Solving this nonlinear program at each node once a packet has been received is not practical. So an approximate method, which could significantly simplify the computation of the original problem, while providing comparably fine results, may be more practical.

Though the end-to-end QoS problem formulation provides the exact optimal routing solution, it is subject to many inextricable challenges. First, wireless links are susceptible to fading, interference and traffic variation; therefore, it is almost impossible to obtain the exact instantaneous link state information. So path information, which is accumulated along all links on it, is even more unpredictable. Second, keeping path metrics consistent at all nodes is an even more formidable problem. Since it takes some time for updates to propagate across the network, some nodes refresh their path information with the new updates received, while other nodes are still using obsolete information for routing decisions. A packet going through nodes with asynchronous path information may miss the QoS requirement. Third, storage of voluminous end-to-end path information is dreadfully memory demanding. Possible paths between two nodes may be numerous given densely deployed nodes, whereas a sensor node is equipped with very limited memory. Furthermore, manipulation of end-to-end information is computationally burdensome for sensor nodes. The delay-constrained path problem is known to be NP-hard. The complexity is beyond the computation and energy tolerance of sensors.

The preceding reasons shed light on link-based QoS routing. Per hop information is convenient to acquire

and maintain at a low overhead cost. The acquired neighbor information is enough to make routing decisions, which saves a large amount of computation. Thus, sensor nodes are free of intricate computation. For those superior features of per hop routing, we propose approximating path quality on the basis of link quality. In wireless networks, delay and reliability tend to fluctuate with time. To model this phenomenon, we assume that the link delay and reliability are random processes  $\mathbf{d}_{ij}(t)$  and  $\mathbf{r}_{ij}(t)$ . The time index,  $t$ , is omitted for simplicity in the following discussion. We assume that links are independent in terms of delay and reliability. Our goal is to develop a method so that both delay and reliability are ensured with high probability. We only employ the first and second moments of delay and reliability in our derivation. Now the new approximate problem to be addressed based on local information is formulated as

$$\begin{aligned} & \text{Minimize } \sum_{j \in N(i)} x_j \\ & \text{subject to } P(x_j \mathbf{d}_{ij} \leq L_i^d) \geq \alpha, \text{ for } L_i^d > 0, \\ & \quad P\left(\sum_{j \in N(i)} x_j \mathbf{r}_{ij} \geq L_i^r\right) \geq \beta, \\ & \quad x_j = 0 \text{ or } 1, \quad \forall j \in N(i), \end{aligned} \quad (4)$$

where the  $x_j$ 's are the decision variables, and  $\mathbf{d}_{ij}$  and  $\mathbf{r}_{ij}$  are the delay and reliability of link  $l_{ij}$  at the routing decision instant, respectively. This is a probabilistic integer program. In the original problem definition, the nonlinear program is to be solved only at the source based on end-to-end information. In contrast, the approximate problem is to be resolved at all intermediate nodes since the approximate problem is based on hop information. We further reduce the computation complexity of the approximation constraints [10]. The final problem formulation is

**Formulation:** At each node  $i$ ,

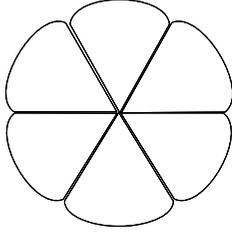

$$\begin{aligned} & \text{minimize } \sum_{j \in N(i)} x_j \\ & \text{s.t. } x_j \left( \frac{\alpha}{1-\alpha} (\Delta_{ij}^d)^2 + 2L_i^d d_{ij} - d_{ij}^2 \right) \leq L_i^{d^2}, \\ & \text{when } L_i^d - d_{ij} > 0 \\ & \quad \sum_{j \in N(i)} x_j (r_{ij} + Q^{-1}(\beta) \Delta_{ij}^r) \geq \sqrt[3]{R_i}, \\ & \quad x_j = 0 \text{ or } 1, \quad \forall j \in N(i). \end{aligned}$$

The new optimization problem is a deterministic estimate of the problem formulated in (4). The problem size is proportional to the number of neighbors, which is usually small, so it can be conveniently solved by existing algorithms.

### Maximum Flow Problem in Wireless Ad Hoc Networks with Directional Antennas

Owing to the hostile wireless channel, and interference within and among flows, how to achieve the maximum throughput in multihop wireless ad hoc networks has been of great interest over the past few decades. Especially for resource-constrained ad hoc networks, how to improve the system capacity is even more important. With switched-beam technology, the directional antenna is shown to be an appealing option for wireless ad hoc networks. By concentrating RF energy in the intended transmission direction, the spatial transmission region shrinks proportionally to the beam width of a sector. A directional antenna is able to reduce interference and energy consumption, and improve the spatial reuse ratio; thus, it can significantly boost the channel capacity. So the problem of interest is as follows: Given a network topology and existing traffic load, how can we achieve the maximum flow between a given source–destination pair through optimal path selection?

Owing to the different interference patterns induced by directional antennas in ad hoc networks, constraints for the maximum flow are novel and distinct. The maximum flow problem to be addressed here is different from the classical maximum flow problem in network flow theory [1,4,5,6,7,16,20,36,39]. In wired networks, there is no interference among transmissions. Any link can be active at any instant without interference from other links. However, the broadcasting nature of the wireless medium makes the shared wireless channel bottleneck for network flow. To avoid collision, links in a close neighborhood may not be active simultaneously. Furthermore, the interference condition of wireless networks with directional antennas is different from those with omnidirectional antennas. The asymptotic throughput bounds under certain assumptions regarding network topology and node configuration have been derived in many papers [9,14,17,30,40]. Without assumptions regarding the network topology or homo-

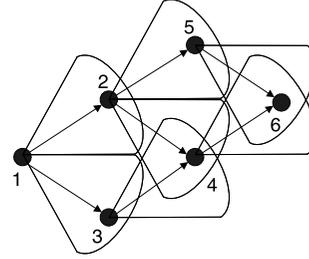

Optimization in Ad Hoc Networks, Figure 2  
The directional antenna model

generality of link capacity, we attempt to solve the problem in a generalized setting. For the first time, the interference-constrained maximum flow problem in ad hoc networks with directional antenna is formulated as an optimization problem [12]. This problem is inherently a joint multipath routing and optimal scheduling problem.

According to the beam pattern (beam radius, beam width, beam orientation), we have omnidirectional antennas, single-beam directional antennas (e.g., single-beam switched-beam antennas) and multibeam directional antennas (e.g., multibeam switched-beam antennas or sectorized beam antennas). The beam radius is the distance that a transmission reaches. The beam width is determined by the angle of a sector. For a six-beam directional antenna, the angle of a beam is  $\pi/3$ . The direction that a beam is targeting is defined as the beam orientation. For directional antennas, both directional transmission and directional reception are enabled. To be clear, for single-beam directional antennas, we assume only one directional transmitting beam or one directional receiving beam can be active at a time; for multibeam directional antennas, multiple directional transmission beams or multiple directional receiving beams can be active at a time. However, a beam can only be either transmitting or receiving at any instant. An illustration of a switched-beam antenna with six beams is shown in Fig. 2. Assume that the antenna is directed to discrete directions, with fixed beam radius and beam width. There is a link between nodes  $i$  and  $j$  if the distance from node  $j$  to node  $i$  is shorter than the beam radius.

An illustration of a node graph comprising nodes with directional antennas is shown in Fig. 3, though a realistic node graph is always more complex. Node 1

Optimization in Ad Hoc Networks, Figure 3  
Node graph  $G = (V, E)$

and node 6 are considered the source node and the destination node, respectively.

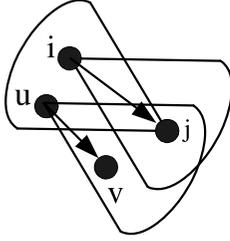

The problem to be addressed here is given network  $G(V, E)$  and existing flows, find the maximum flow supported by the network between pair  $s-d$ . Before the complete problem formulation is presented, we define the constants and variables used:

- $x_{ij}$  indicates the flow over link  $(i, j)$ .
- $f$  is the flow from source node  $s$  to source node  $d$ .
- $b_{ij}(i, l)$  indicates whether link  $(i, j)$  is in the  $l$  beam of node  $i$ .
- $B$  is the total number of beams at each node.
- $E$  is the set of edges.
- $V$  is the set of nodes.
- $\theta_i^j$  is the beam of node  $i$  that node  $j$  resides in.

Now the maximum flow problem can be formulated as the following optimization problem.

$$\begin{aligned}
 & \text{Maximize } f \\
 & \text{subject to } \sum_{\{j:(i,j) \in E\}} x_{i,j} - \sum_{\{j:(j,i) \in E\}} x_{j,i} \\
 & \quad = \begin{cases} f & i = s, \\ 0 & i = V - \{s, d\}, \\ -f & i = d; \end{cases} \quad (5) \\
 & \quad \sum_{(k,l) \in A_{i,j}} x_{k,l} \leq u_{i,j}, \quad \forall (i, j) \in E; \\
 & \quad x_{i,j} \geq 0, \quad \forall (i, j) \in E,
 \end{aligned}$$

where  $u_{ij}$  is the normalized remaining capacity or bandwidth ( $0 \leq u_{i,j} \leq 1$ ) for link  $(i, j)$ . The second constraint specifies the contention for the resource of each link. This is a traditional maximum flow problem with an added interference constraint.

**Optimization in Ad Hoc Networks, Figure 4**  
Interference caused by (u,v) to (i,j)

In wireless networks, a transmission collision occurs when a receiver is in the communication range of two transmitters, because the receiver receives both time-overlapping signals and cannot decode them correctly. We assume that an antenna both transmits and receives directionally, but that it cannot transmit and receive simultaneously. With a directional antenna, two links interfere with each other if a receiver is in the transmitting beams of both transmitters, shown in Fig. 4. To guarantee a successful reception at node  $j$ , any node in the receiving beam of node  $j$  cannot transmit towards node  $j$  before current transmission finishes.

**The protocol model:** In the protocol model, the transmission from node  $i$  to node  $j$  is successful if (1) node  $j$  is in the transmission range of node  $i$ ,  $d_{ij} \leq R$ , where  $R$  is the transmission range; (2) any node  $u$  that is in the receiving beam of node  $j$  from node  $i$  is not transmitting in the beam covering node  $j$  (when interference range equals transmission range). This means that node  $j$  must be outside the transmission beam of node  $u$ .

Since the interference region is a beam, the information about the beam to which a link belongs is essential for routing and scheduling. Assume there are  $B$  fixed beams for each antenna. Now we can recapitulate condition (2) of the protocol model in the following way:

(2') When  $(i,j)$  is active, for any node  $u$  in node  $j$ 's receiving beam towards node  $i$ , the beam  $\theta_u^j$  should keep silent. Denote  $b(i,l)$  as the  $l$ th beam of node  $i$ , where  $l = 1, \dots, B$ .

A single-beam directional antenna can only target one beam at a time. So the channel utilization is shared by all links in all beams. For a single-beam directional antenna, we can formulate the maximum flow problem as the following mixed-integer program (MIP).

*Problem formulation:*

$$\begin{aligned}
 & \text{Maximize } f \\
 & \text{subject to } \sum_{\{j: (i,j) \in E\}} x_{i,j} - \sum_{\{j: (j,i) \in E\}} x_{j,i} \\
 & = \begin{cases} f & i = s, \\ 0 & i = V - \{s, d\}, \\ -f & i = d; \end{cases} \\
 & \underbrace{\sum_{u \in b(i,l)} \sum_{(u,v) \in E} x_{u,v} b_{u,v}(u, \theta_u^i)} + \\
 & \text{interfering links in the } l\text{th beam} \\
 & \underbrace{\sum_{(k,i) \in E} x_{k,i} b_{k,i}(i, l)} \leq 1, \quad \forall l, i, \\
 & \text{incoming flows} \\
 & \sum_{l=1}^B \left( \sum_{(k,i) \in E} x_{k,i} b_{k,i}(i, l) \right. \\
 & \left. + \sum_{(i,j) \in E} x_{i,j} b_{i,j}(i, l) \right) \leq 1, \quad \forall i \in V, \\
 & b_{i,j}(i, l) = \begin{cases} 1, & \text{if } (i, j) \in b(i, l), \\ 0, & \text{otherwise} \end{cases} \\
 & x_{i,j} \geq 0, \quad \forall (i, j) \in E.
 \end{aligned} \tag{6}$$

The first constraint describes the in-flow and the out-flow at each node. The second constraint indicates the flow interference around  $i$  as specified by condition (2') in the protocol model. The first term represents the sum of flows causing interference to node  $i$  in beam  $l$ . When those flows are active, node  $i$  must restrain from receiving. The second term stands for the total incoming flows to node  $i$  in beam  $l$ . The sum of these two terms should be less than the normalized beam capacity of 1. By beam capacity, we mean the channel capacity or bandwidth, which is a constant. The third constraint describes the time-sharing constraint. The second and third constraints aggregate describe the interfering flows at a node. The contention region includes flows over all arcs in the one-hop area of a node.

Denote  $M$  as the number of links in the network,  $N$  as the number of nodes in the network. The number of variables and constraints in this MIP are  $M$  and

$O(N + M)$ , respectively, where  $O(x)$  indicates the variable on the order of  $x$ .

For a single pair of source and destination nodes in wireless networks with multibeam directional antennas, the problem formulation in (5) can be expanded more specifically as follows: *Problem formulation*:

$$\begin{aligned}
 & \text{Maximize } f \\
 & \text{subject to } \sum_{\{j: (i,j) \in E\}} x_{i,j} - \sum_{\{j: (j,i) \in E\}} x_{j,i} \\
 & = \begin{cases} f & i = s, \\ 0 & i = V - \{s, d\}, \\ -f & i = d; \end{cases} \\
 & \sum_{u \in b(i,l)} \sum_{(u,v) \in E} x_{u,v} b_{u,v}(u, \theta_u^i) \\
 & + \sum_{(k,i) \in E} x_{k,i} b_{k,i}(i, l) \leq 1, \quad \forall l, i \quad (7) \\
 & \sum_{(k,i) \in E} x_{k,i} b_{k,i}(i, l) \\
 & + \sum_{(i,j) \in E} x_{i,j} b_{i,j}(i, m) \leq 1, \\
 & \forall 1 \leq l, m \leq B, \quad \forall i \in V, \\
 & b_{i,j}(i, l) = \begin{cases} 1, & \text{if } l = \theta_i^j, \\ 0, & \text{otherwise} \end{cases} \\
 & x_{i,j} \geq 0, \quad \forall (i, j) \in E.
 \end{aligned}$$

The first two constraints are the same as those in (6). The third constraint guarantees that the flow is feasible because the in-flow and the out-flow share the capacity at the node. This constraint also implies that the in-flow from any beam should not be greater than 1. The number of variables and constraints in this MIP are  $M$  and  $O(N + M)$ , respectively.

### Joint Mobility Control and Power-Efficient Routing in Sparse Wireless Sensor Networks

Many WSNs have been deployed for environmental monitoring. Such networks are typically sparse and consist of nodes of various capabilities. In a sparse network, a target node may be far away from other nodes and data stations. It has to transmit at high power to reach another node when it reports information collected to the sink. A transmission over a long hop con-

sumes considerable energy, and thus undermines the purpose of long-term monitoring. For certain applications demanding an end-to-end path, communication over long distance is too expensive for energy-constrained sensor nodes.

Current routing protocols for intermittently connected networks are designed for collecting delay-tolerant data in the network [24,34,35,37]. They are incapable of supporting certain applications owing to the large delay and the lack of a path between the source and the destination. In order to support end-to-end data delivery in the sparse network, a novel routing algorithm is proposed to establish energy-efficient paths. Our idea is to utilize the mobility of controllable robots to realize energy-efficient on-demand routing in a sparse WSN. Adding another dimension, mobility, to our design, our work is different from traditional joint power control and routing [2,3,8,15,21,22,25,31,41]. Through optimal placement of mobile robots along with optimal power assignment and path selection, energy efficiency can be significantly improved.

We assume that all nodes have the same receiver sensitivity, or receiving power threshold,  $P_R$ . If the received power is greater than the threshold, the reception is successful. Otherwise, the node cannot decode the packet correctly. Since nodes transmit at the same data rate, the transmission time of a packet is a constant. So minimizing energy consumption is equivalent to minimizing power because the constant transmission time does not impact the result. Denote  $P_r^{ij}$  and  $P_t^{ij}$  as the receiving power and the transmission power over the directed link  $(i,j)$ , respectively. Assume the Euclidean distance between nodes  $i$  and  $j$  is  $d^{ij}$ . The propagation model [32] used in our paper is

$$P_r^{ij} = \frac{P_t^{ij} h(G_t, G_r, h_t, h_r, L, \lambda)}{d_{ij}^\gamma} = \frac{\alpha P_t^{ij}}{d_{ij}^\gamma}, \quad (8)$$

where  $G_t$  and  $G_r$  are the gain factors of the transmitter's and the receiver's antenna and  $h_t$  and  $h_r$  are the antenna heights of the transmitter and the receiver, respectively.  $L$  is the system loss factor not related to propagation.  $\lambda$  is the wavelength.  $\alpha$  is determined by  $G_t, G_r, h_t, h_r, L$  and  $\lambda$ , which is a constant in our paper.  $\gamma$  indicates the path loss exponent,  $2 \leq \gamma \leq 6$ . To correctly receive the data, the transmission power over link  $(i,j)$  must satisfy

the following condition

$$P_t^{ij} = \frac{P_r^{ij} d_{ij}^\gamma}{\alpha} \geq \frac{P_R d_{ij}^\gamma}{\alpha}. \quad (9)$$

Denote  $(x_i, y_i)$  as the coordinates of node  $i$ . Substituting  $d_{ij}$  with coordinates into (9) gives

$$P_t^{ij} \geq \frac{P_R((x_i - x_j)^2 + (y_i - y_j)^2)^{\gamma/2}}{\alpha}. \quad (10)$$

Assume the power consumed in packet reception is  $P_r$ , which is the same for all nodes. The problem of concern is how to actively place robots so that the total power consumption for data delivery is minimized. Therefore, determining the best positions of the robots, say  $(x_r, y_r)$ , is one of the objectives. Besides, choosing the path and the corresponding transmission powers of all intermediate nodes on the path also determines the total power expenditure in communications. The energy consumed in mechanical movement is not considered, because the robot is constantly roaming in its territory to collect data messages.

**Single Robot** Assume there are  $N$  sensor nodes and one robot in the field. A single path is to be established from the source node to the data station. Therefore, each node on the path just transmits to a single next-hop node. The transmission power over a link is determined by the hop distance. Wireless links are of poor quality, so the link error rate plays an important role in energy consumption. We use expected transmission count (ETX) to quantify the retransmissions caused by link error. ETX is the expected number of transmissions for a successful reception. Assume the expected transmission count over link  $(i, j)$  is  $ETX_{ij}$ , then the expected power consumption for transmitting a packet with a link retransmission mechanism is  $P_t^{ij} ETX_{ij}$ . An indicator variable  $A_{ij}$  is used to identify if link  $(i, j)$  is active. Then the transmission power of node  $i$ ,  $P_t^i$ , is

$$P_t^i = \sum_{j=1, j \neq i}^{N+1} A_{ij} ETX_{ij} P_t^{ij}.$$

When only one robot is deployed, we name it as the  $N + 1$ th node. Now the problem of finding the minimum power path from the source sensor node  $s$  to the data station  $d$  can be formulated as an optimization

problem

$$\text{Minimize } \sum_{i=1}^{N+1} \left( \sum_{j=1, j \neq i}^{N+1} A_{ij} ETX_{ij} P_t^{ij} + \sum_{k=1, k \neq i}^{N+1} A_{ki} P_r^i \right) \quad (11)$$

$$\text{subject to } A_{ij} P_t^{ij} = A_{ij} \frac{P_R((x_i - x_j)^2 + (y_i - y_j)^2)^{\gamma/2}}{\alpha}, \quad (12)$$

$$\sum_{j=1, j \neq i}^{N+1} A_{ij} \leq 1, \quad \forall i \quad (13)$$

$$\sum_{k=1, k \neq i}^{N+1} A_{ki} - \sum_{j=1, j \neq i}^{N+1} A_{ij} = \begin{cases} -1, & i = s \\ 0, & \text{otherwise} \end{cases} \quad (14)$$

$$A_{ij} = 0 \text{ or } 1. \quad (15)$$

In this optimization problem, the  $A_{ij}$  determine the path between the source and the destination. Since the locations of the sensor nodes are known and fixed by the sink, their coordinates are constant. We only need to determine the coordinates of the robot, which are  $x_{N+1}$  and  $y_{N+1}$ . Clearly, this is a three-dimensional problem. The objective in (11) is to minimize the total power consumption of all nodes on the end-to-end path. The same as for (10), to reach node  $j$  from node  $i$ , the transmission power has to satisfy (12). Since only a single path is chosen to carry the traffic, at most one incoming link can be active for every node, as shown in (13). Constraint (14) requires that only one outgoing link is selected for the node on the chosen path except the destination. As an indicator of whether a link is selected,  $A_{ij}$  is set to 1 if the corresponding link is selected, otherwise it is 0.

As the power consumption for reception is rather fixed, we could simplify  $P_r^i$  to  $P_r$ . According to (14), the objective can be rewritten as the following expression:

$$\min \sum_{i=1}^{N+1} \left( \sum_{j=1, j \neq i}^{N+1} A_{ij} (P_t^{ij} ETX_{ij} + P_r) \right).$$

As shown in [11], ETX is a constant for all links in our scenario. Then the problem of minimum energy

routing with the consideration of link retransmission is

$$\begin{aligned}
 \text{Minimize } f(A, P) &= \sum_{i=1}^{N+1} \left( \sum_{j=1, j \neq i}^{N+1} A_{ij} (P_t^{ij} \text{ETX} + P_r) \right) \\
 \text{s. t. } A_{ij} P_t^{ij} &= A_{ij} \frac{P_R ((x_i - x_j)^2 + (y_i - y_j)^2)^{\gamma/2}}{\alpha}, \\
 &\quad \forall i \\
 &\quad \sum_{j=1, j \neq i}^N A_{ij} \leq 1, \quad \forall i \\
 \sum_{k=1, k \neq i}^N A_{ki} - \sum_{j=1, j \neq i}^N A_{ij} &= \begin{cases} -1, & i = s \\ 0, & \text{otherwise} \end{cases} \\
 A_{ij} &= 0 \text{ or } 1.
 \end{aligned} \tag{16}$$

Define  $\text{EPC}_{ij} = P_t^{ij} \text{ETX} + P_r$  as the *expected power consumption* over link  $(i, j)$ . The decision variables in (16) include variables with integer and real values. The optimization problem is a nonlinear MIP, which is usually hard to solve. So we will decompose the formulated problem into subproblems, then solve them sequentially. The strategy of decomposition is as follows. First, we assume routing is fixed for any  $\tilde{A} \in \Psi$ , where  $\Psi$  denotes the solution space specified by the routing constraints (13)–(15). Given the restriction of the original problem, we could obtain the optimal solution with the coordinates of the mobile robot represented as a function of  $A$ . The physical meaning of this subproblem is that given a schedule, what is the optimal location of the robot which yields the minimum-energy path? The expected energy consumption associated with each link is the link weight. The energy consumption is the measurement of the path quality. By varying the placement of the robot over a limited number of locations in each iteration, one can discover the optimal route through the shortest-path problem. Among all the shortest paths for each specific location of the robot, the one with the optimal quality is selected. This algorithm can solve the problem in polynomial time.

In the derivation, it is interesting to observe that the optimal coordinates of the robot are the average of the coordinates of its upstream and downstream nodes; therefore, on the minimum-energy path, the robot is always situated in the middle of two sensor nodes. With

this observation, the solution space of the potential optimal position of the robot is reduced to the possible links between sensor nodes, say  $N(N+1)/2$ . This result helps us develop an algorithm to solve the minimum power routing problem efficiently. Given the possible locations of the mobile robot, the optimization problem (16) is

$$\begin{aligned}
 \text{Minimize } f(A) &= \sum_{i=1}^{N+1} \left( \sum_{j=1, j \neq i}^{N+1} A_{ij} \text{EPC}_{ij} \right) \\
 \text{subject to } \sum_{j=1, j \neq i}^N A_{ij} &\leq 1, \quad \forall i \\
 \sum_{k=1, k \neq i}^N A_{ki} - \sum_{j=1, j \neq i}^N A_{ij} &= \begin{cases} -1, & i = s \\ 0, & \text{otherwise} \end{cases} \\
 A_{ij} &= 0 \text{ or } 1.
 \end{aligned} \tag{17}$$

Taking  $\text{EPC}_{ij}$  as the weight of the associated link, the above problem is actually a shortest-path problem. It can be conveniently solved by a shortest-path algorithm, such as Dijkstra's algorithm.

**Multiple Robots** When multiple robots are deployed in the field, the problem becomes more complicated. Suppose there are  $R$  robots; we number them as the  $N+1, N+2, \dots, N+R$  nodes, respectively. Now the problem can be formulated as follows:

$$\begin{aligned}
 \text{Minimize } f(A, P) &= \sum_{i=1}^{N+R} \left( \sum_{j=1, j \neq i}^{N+R} A_{ij} (P_t^{ij} \text{ETX} + P_r) \right) \\
 \text{s. t. } A_{ij} P_t^{ij} &= A_{ij} \frac{P_R ((x_i - x_j)^2 + (y_i - y_j)^2)^{\gamma/2}}{\alpha}, \\
 &\quad \forall i \\
 &\quad \sum_{j=1, j \neq i}^{N+R} A_{ij} \leq 1, \quad \forall i \\
 \sum_{k=1, k \neq i}^{N+R} A_{ki} - \sum_{j=1, j \neq i}^{N+R} A_{ij} &= \begin{cases} -1, & i = s \\ 0, & \text{otherwise} \end{cases} \\
 A_{ij} &= 0 \text{ or } 1.
 \end{aligned}$$

In this problem, we need to determine the best positions of all robots, which may correlate with each other. In the single-robot case, the optimal location of

the robot solely depends on the locations of the sensor nodes, which are known; therefore, it is much more difficult to compute the optimal locations of multiple robots than it is to compute the optimal location of a single robot.

Following a similar technique in the single-robot case, we decompose the optimization problem into a subproblem and a master problem. The subproblem computes the best positions for the robots, while the master problem determines the optimal path. Denote  $G = (V, E, W)$  as the graph of the sensor network.  $V$  is the set of vertices with  $N + 1$  nodes (including data station  $t$ ).  $E$  contains all the edges between each pair of vertices.  $W$  specifies the weight which is EPC-associated with each edge.

**Theorem 1** Denote  $\hat{G}(\hat{V}, \hat{E}, \hat{W})$  as the resulting graph with the optimal placement of robots in the sensor network, which minimizes the energy consumption to deliver a packet from node  $s$  to node  $t$  over all possible paths. Given a path from node  $s$  to node  $t$  in graph  $\hat{G}$ , the robots must be situated on the edges in  $G(V, E, W)$ . More specifically, each robot is located at the spot that equally divides the distance along the edge in  $G$ .

Please refer to [11] for the detailed proof. Although Theorem 1 reveals the potential locations of robots given a path, it is still hard to solve the minimum-energy problem in the multiple-robots case owing to the large solution space. It remains to select the edges in  $G$  where robots reside and determine how many robots. Denote  $Q_{ij}$  as the number of robots on edge  $(i, j)$ . The problem can be formulated as follows:

Minimize

$$\sum_{i=1}^N \left( \sum_{j=1, j \neq i}^N A_{ij} \left( \frac{P_t^{ij} E T X}{(Q_{ij} + 1)^{\gamma-1}} + (Q_{ij} + 1) P_r \right) \right)$$

subject to  $A_{ij} P_t^{ij} = A_{ij} \frac{P_R d_{ij}^\alpha}{\alpha}, \quad \forall i$

$$\sum_{i=1}^N \sum_{j=1, j \neq i}^N Q_{ij} \leq R$$

$$\sum_{j=1, j \neq i}^N A_{ij} \leq 1, \quad \forall i$$

$$\sum_{k=1, k \neq i}^N A_{ki} - \sum_{j=1, j \neq i}^N A_{ij} = \begin{cases} -1, & i = s \\ 0, & \text{otherwise} \end{cases}$$

$$A_{ij} = 0 \text{ or } 1.$$

The formulation is a nonconvex integer program, which is NP-hard. In [11], an approximation algorithm is proposed to solve the problem efficiently.

## Introduction

Cancer is the second leading cause of death in the United States [2]. Treatment options are determined by the type and the stage of the cancer and include surgery, *radiation therapy*, chemotherapy, etc. Physicians often use a combination of those treatments to obtain the best results. Our application is based on radiation therapy. Thanks to the continuous development of new treatment machines and technologies, it is now possible to have much greater control over the treatment delivery than was possible in the past. Researchers in optimization community have made significant contributions in improving the quality of such treatment plans for cancer patients [5,6,12,13,24,26,27,29,36,40,42,46,47]. The common objective of radiotherapy planning is to achieve tumor control by planning a significant total dose of radiation to the cancerous region to sterilize the tumor without damaging the surrounding healthy tissues. One of the major difficulties in treatment planning is due to the presence of organs-at-risk (OARs). An OAR is a healthy organ located close to the target. The dose of radiation must be severely constrained to avoid reaching an OAR because an overdose in the OAR may lead to medical complications. OAR is also termed “sensitive structure” or “critical structure” in the literature. There are several survey articles that cover the essential elements of the radiation treatment planning problem, see [17,31,37,40].

Our aim in this chapter is to describe optimization techniques to improve the delivery of radiation for cancer patients. Two types of radiation therapy are the most common and include *teletherapy* (or external beam therapy) and *brachytherapy*. Radiation is delivered from outside the body and directed at the patient’s tumor location using special radiation delivery machines in *teletherapy*, (see Fig. 1). Different devices produce different types of radiation and they include Cobalt-60 machines (such as Gamma Knife radiosurgery), linear accelerators (such as intensity modulated radiation therapy), neutron beam machines, orthovoltage x-ray machines, and proton beam machines. In *brachytherapy*, radioactive substances are placed within the tumor region in the form of wires, seeds, or rods. Types of brachytherapy are categorized depending on how the radioactive sources are placed inside the body such as interstitial brachytherapy, in-

**Optimization Based Framework for Radiation Therapy, Figure 1**

**An external beam therapy machine**

tracavitary brachytherapy, intraluminal radiation therapy, and radioactively tagged molecules given intravenously. There are two types of radiation treatment planning: forward planning and inverse planning. In forward planning, treatment plans are typically generated by a trial and error approach. Therefore this process can be very tedious and time-consuming, and does not necessarily produce “high-quality” treatment plans. On the other hand, there has been a significant move toward inverse treatment planning. Such a move is due to significant advances in modern technologies such as imaging technologies and computer control to aid the delivery of radiation. The inverse treatment planning procedure allows modeling highly complex treatment planning problems from brachytherapy to external beam therapy. Inverse planning is also called computer based treatment planning.

In inverse treatment planning, an objective function is defined to measure the goodness (quality) of a treatment plan. Two types of objective functions are often used: dose-based models and biological (radiobiological) models. The biological model argues that optimiza-

tion should be based on the biological effects resulting from the underlying radiation dose distributions. The treatment objective is usually to maximize the tumor control probability (TCP) while keeping the normal tissue complication probability (NTCP) within acceptable levels. In the dose based model, achieving accurate radiation dose distributions on organs of interest is the main concern. The treatment objective is to minimize the deviation between the projected dose that the patient will receive and the prescribed dosage that the physician provides. This is the main approach we will describe in this chapter. The biological aspect is implicitly given in the physician's prescription.

## Applications and Methods

### The Radiation Treatment Planning Procedure

When a patient comes in for a treatment, the doctor will choose what type of radiation beam to use for the treatment. The choice of radiation will depend on the type of the cancer the patient has and how far into the body the radiation should penetrate to reach the tumor volume.

The next step is to identify the three-dimensional shapes of organs of interest in the patient's body. The location and the volume of organs are obtained by using three-dimensional imaging techniques such as computer tomography (CT) or magnetic resonance imaging (MRI). Based on three-dimensional images, a physician specifies the tumor region as gross tumor volume (GTV), clinical target volume (CTV), planning target volume (PTV), and OARs. GTV represents the volume of the known tumor. CTV represents the volume of the suspected microscopic spread. PTV is the marginal volume necessary to account for setup variations and organ and patient motion, i. e.  $PTV = GTV + \text{marginal volume}$ . Typically, PTV is used in designing treatment plans and we call PTV a *target* in this chapter. Organ geometries are the key input data for designing a treatment plan.

A radiation physicist and a dosimetrist meet to decide what kind of radiation delivery machine to use and the number of treatments for the patient. Optimization algorithms are crucial to determine how much and where to deliver radiation in the patient's body. For most types of cancer, radiation therapy is administered 5 days each week for 5 to 8 weeks. Using small radiation

doses daily rather than a few large doses helps protect normal body tissues in the treatment area. Resting over the weekend will allow some time for normal cells to recover from the radiation damage.

In optimization, the three-dimensional volume is represented by a grid of voxels. There are several inputs required in optimization approaches in radiation treatment planning. The first input describes the machine that delivers radiation. The second and troublesome input is the dose distribution of a particular treatment problem. A dose distribution consists of dose contribution to each voxel of the region of interest from a radiation source. It can be expressed as a functional form or a set of data. However, a difficulty of using such distributions are either the functional form is highly nonlinear [13] or the amount of data that specifies the dose distribution is too large [27]. This problem needs to be overcome in a desirable automated treatment planning tool. The third common input is the set of organ geometries that are of interest to the physician. Further common inputs are the desired dose levels for each organ of interest. These are typically provided by physicians. Other types of inputs can also be specified depending on the treatment planning problems. However, a desirable treatment planning system should be able to generate high quality treatment plans with minimum additional inputs and human guidance.

### Use of Optimization Techniques

Two major goals in treatment planning optimization are speed and quality. Solution quality of a treatment plan can be measured by *uniformity*, *conformity*, and *avoidance* [12,27,29]. Fast solution determination in a simple manner is another essential part of a clinically useful treatment planning procedure. Acceptable dose levels of these requirements are established by various professional and advisory groups.

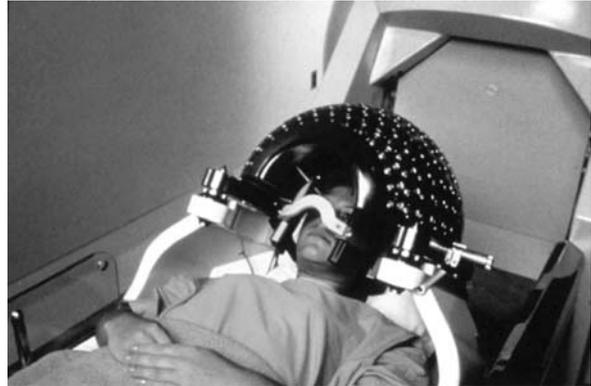

It is important for a treatment plan to have uniform dose distributions on the target so that *cold* and *hot spots* can be minimized. A *cold spot* is a portion of an organ that receives below its required radiation dose level. On the other hand, a *hot spot* is a portion of an organ that receives more than the desired dose level. The uniformity requirement ensures that radiation delivered to tumor volume will have minimum number of *hot spots* and *cold spots* on the target. This require-

ment can be enforced using lower and upper bounds on the dose, or approximated using penalization. The conformity requirement is used to achieve the target dose control while minimizing the damage to OARs or healthy normal tissue. This is generally expressed as a ratio of cumulative dose on the target over total dose prescribed for the entire treatment. This ratio can be used to control conformity in optimization models. As we mentioned earlier, a great difficulty of producing radiation treatment plans is the proximity of the target to the OARs. An avoidance requirement can be used to limit the dose delivered to OARs. Finally, simplicity requirements state that a treatment plan should be as simple as possible. Simple treatment plans typically reduce the treatment time as well as implementation error. In this chapter, we introduce a few optimization models and solution techniques that are practically useful for radiation treatment modalities: Gamma Knife radiosurgery, conventional three-dimensional conformal therapy (3DCRT) [27], intensity modulated radiation therapy (IMRT) [4,18]. Many treatment planning models are developed for proton therapy [48] and tomotherapy [11,22]. But they are beyond the scope of this chapter.

### Gamma Knife Radiosurgery

**Problem** The Gamma Knife is a highly specialized treatment unit that provides an advanced stereotactic approach to the treatment of tumor and vascular malformations within the head [14]. The Gamma Knife delivers a single, high dose of radiation emanating from 201 Cobalt-60 unit sources. All 201 beams simultaneously intersect at the same location in space to form an approximately spherical region that is typically termed a shot of radiation.

Gamma Knife Radiosurgery begins by finding the location and the size of the tumor. After administering local anesthesia, a stereotactic head frame is fixed to the patient's head using adjustable posts and fixation screws. This frame establishes a coordinate frame within which the target location is known precisely and serves to immobilize the patient's head within an attached focussing helmet during the treatment. An MRI or CT scan is used to determine the position of the treatment volume in relation to the coordinates determined by the head frame. Once the location and

Optimization Based Framework for Radiation Therapy, Figure 2

Radiation delivery: a collimator is positioned on patient's head

the volume of the tumor are identified, the neurosurgeon, the radiation oncologist, and the physicist work together in order to develop the patient's treatment plan. Multiple shots are often used in a treatment using a Gamma Knife due to the irregularity and size of tumor shapes and the fact that the focussing helmets are only available in four sizes (4, 8, 14 and 18 mm).

The plan aims to deliver a high dose of radiation to the intracranial target volume with minimum damage to the surrounding normal tissue. The treatment goals can vary from one neurosurgeon to the next. But the following requirements are typical for a treatment plan, although the level of treatment and importance of each may vary.

1. A complete 50% isodose line coverage of the target volume. This means that the complete tumor volume must receive at least 50% of the maximum dosage delivered to the target. This can be thought of as a "uniformity" requirement.
2. Minimize the nontarget volume that is covered by a shot or the series of delivered shots. This requirement is clear and can be thought of as a "conformity" requirement.
3. Limit the amount of dosage that is delivered to organs at risk that are close to the target. Such requirements can be thought of as an "avoidance" requirement.

There are standard rules established by the Radiation Therapy Oncology Group (RTOG) that recom-

mend the acceptable uniformity and conformity requirements. In addition to these requirements, it is also preferable to use a small number of shots to limit the treatment times and thus increase the number of patients that can be treated.

**Optimization Model Formulation** Most commonly known optimization models include mixed integer programming (MIP) model and mixed integer nonlinear programming (MINLP) model. MIP models guarantee the global optimality, but they are not practically useful due to the long computation time. We discuss an MINLP model that has shown to be practically useful [12]. A variant of this approach has been successfully implemented for planning treatments [39].

Suppose that the number of radiation shots for the treatment is given a priori. Adding the goal of minimizing this number is typically straightforward in the optimization model. However, solving such models can be extremely difficult.

*Decision Variables:* Consider a grid  $\mathcal{G}$  of voxels. Let  $\mathcal{T}$  denote the subset of voxels that are within the target and  $\mathcal{N}$  represents the subset of voxels that are not in the target. Let  $D_{i,j,k}$  denote the amount of radiation dose that a voxel  $(i, j, k)$  receives. In general, there are three types of decision variables.

1. *A set of discrete coordinates*  $(x_s, y_s, z_s)$ . These are the target locations for the (ellipsoidal) shots.
2. *A discrete set of collimator sizes*  $w$ : currently four different sizes of focussing helmets are available (4 mm, 8 mm, 14 mm, 18 mm).
3. *Radiation exposure time*  $t_{s,w}$ : the amount of radiation to be delivered for each shot centered at location  $(x_s, y_s, z_s)$ .

*Constraints:*

1. *Uniformity – Isodose line coverage:* A treatment plan is normally considered acceptable if a  $\theta\%$  isodose curve encompasses the tumor region. For example, 50% isodose curve is a curve that encompasses all voxels that receive at least 50% of the maximum radiation dose that is delivered to any voxels in the target volume.

$$\theta \leq D_{i,j,k} \leq 1, \quad (i, j, k) \in \mathcal{T} \quad (1)$$

2. *Choosing shot sizes:* The location of the shot center is chosen by a continuous optimization process.

Choosing the particular shot width at each shot location is a discrete optimization problem that is treated by approximating the step function

$$H(t) = \begin{cases} 1 & \text{if } t \geq 0 \\ 0 & \text{if } t = 0 \end{cases}$$

by a nonlinear function,

$$H(t) \approx H_\alpha(t) := \frac{2 \arctan(\alpha t)}{\pi}.$$

For increasing values of  $\alpha$ ,  $H_\alpha$  becomes a closer approximation to the step function  $H$ . This process is typically called smoothing.

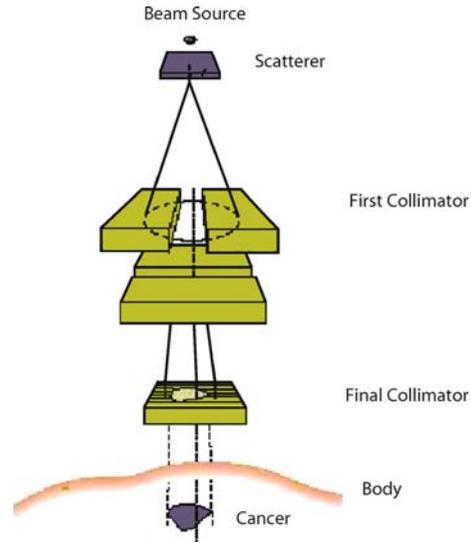

*An Optimization Model:*

$$\begin{aligned} \min \quad & \sum_{(i,j,k) \in \mathcal{N}} D_{i,j,k} \\ \text{s.t.} \quad & D_{i,j,k} = \sum_{(s,w) \in \mathcal{S} \times \mathcal{W}} t_{s,w} D_w(s,i,j,k) \\ & \theta \leq D_{i,j,k} \leq 1, \quad \forall (i, j, k) \in \mathcal{T} \\ & n = \sum_{(s,w) \in \{1, \dots, n\} \times \mathcal{W}} H_\alpha(t_{s,w}) \\ & t_{s,w} \geq 0. \end{aligned} \quad (2)$$

**Solution Techniques** The most critical problem for solving the optimization model (2) is the large number of voxels that are needed when dealing with large irregular tumors (both within and outside of the target). This makes the optimization problem computationally intractable. One approach to overcoming this problem is to remove a large number of the non-target voxels from the model. While this improves the computation time, this typically weakens the conformity of the dose to the target. Ferris et al. [12] propose a sequential solution approach to speed up the time while maintaining conformality. First, a *coarse grid* problem is solved as a nonlinear programming (NLP) model using reduced data points. Then the *finer grid* NLP problem with full data points is solved using the starting point that was obtained by the coarse grid model in the previous stage. Typically, the solution from this finer grid model is very close to a good local optimum for the MINLP. Using this solution, the full MINLP model is finally solved to determine the values of the three decision variables for this problem.

### Three-Dimensional Conformal Radiation Therapy

**Problem** We learned from Section “**Gamma Knife Radiosurgery**” that the Gamma knife is specifically designed for treating diseases in the human brain. Three-dimensional conformal radiation therapy (3DCRT) adds much greater flexibility to radiation treatments that can treat various cancer patients in the brain, breast, prostate, etc. One of the main strategies for minimizing morbidity in 3DCRT is to reduce the dose delivered to normal tissues that are spatially well separated from the tumor. This can be done by using multiple beams from different angles. A single radiation beam leads to a higher dose delivered to the tissues in front of the tumor than to the tumor itself. In consequence, if one were to give a dose sufficient to control the tumor with a reasonably high probability, the dose to the upstream tissues would likely lead to unacceptable morbidity. A single beam would only be used for very superficial tumors, where there is little upstream normal tissue to damage. For deeper tumors, one uses multiple cross-firing beams delivered within minutes of one another: All encompass the tumor, but successive beams are directed toward the patient from different directions to traverse different tissues outside the target volume. The delivery of cross-firing beams is greatly facilitated by mounting the radiation-producing equipment on a gantry: multileaf-collimator (MLC).

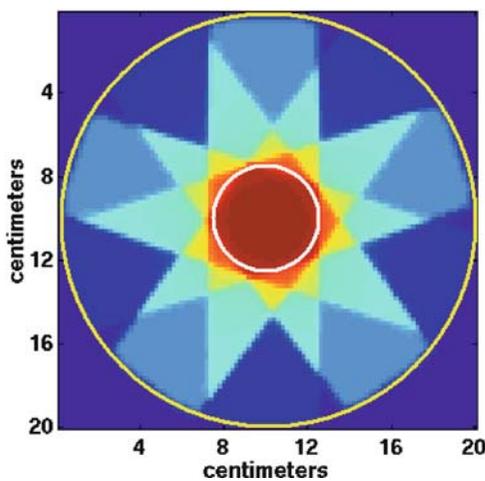

Optimization Based Framework for Radiation Therapy, Figure 4

A beam’s-eye-view is a 2D shape of a tumor viewed by the beam source at a fixed angle

Several directed beams noticeably change the distribution of dose, as is illustrated in Fig. 3. As a result, dose outside the target volume can often be quite tolerable even when dose levels within the target volume are high enough to provide a substantial probability of tumor control.

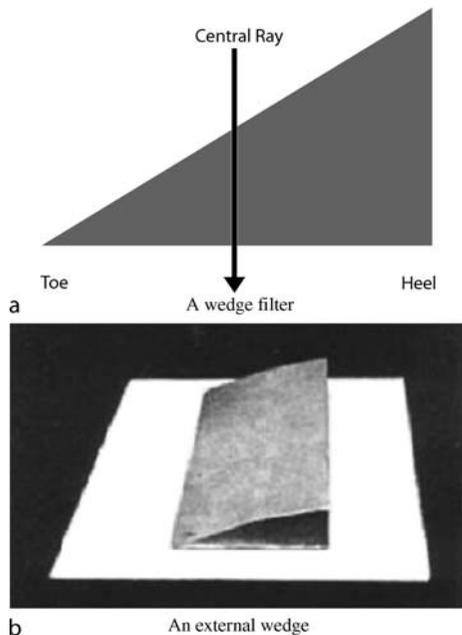

The leaves of the multileaf collimator are computer controlled and can be moved to the appropriate positions to create the desired beam shape. From each beam angle, three-dimensional anatomical information is used to shape the beam of radiation to match the shape of the tumor. Given a gantry angle, the view of the tumor that the beam source can see through the multileaf collimator is called the *beam’s-eye-view* of the target (see Fig. 4); [15]. This beam’s-eye-view (BEV) approach ensures adequate irradiation of the tumor while reducing the dose to normal tissue.

**Wedge Filters:** A wedge (also called a “wedge filter”) is a tapered metallic block with a thick side (the *heel*) and a thin edge (the *toe*); (see Fig. 5). This metallic wedge varies the intensity of the radiation in a linear fashion from one side of the radiation field to the other. When the wedge is placed in front of the aperture, less radiation is transmitted through the heel of the wedge than through the toe. Figure 5b shows an ex-

Optimization Based Framework for Radiation Therapy, Figure 3

Effect of multiple beams: a hot spot is formed in the middle by five beams

**Optimization Based Framework for Radiation Therapy, Figure 5**  
Wedges

ternal 45° wedge, so named because it produces isodose lines that are oriented at approximately 45°. The quality of the dose distribution can be improved by incorporating a wedge filter into one or more of the treatment beams. Wedge filters are particularly useful in compensating for a curved patient surface, which is common in breast cancer treatments.

Two different wedge systems are used in clinical practice. In the first system, four different wedges with angles 15°, 30°, 45°, and 60° are available, and the therapist is responsible for selecting one of these wedges and inserting it with the correct orientation. In the second system, a single 60° wedge (the *universal wedge*) is permanently located on a motorized mount located within the head of the treatment unit. This wedge can be rotated to the desired orientation or removed altogether, as required by the treatment plan.

**Optimization Model Formulation** Suppose that the data to the optimization models are given. Let  $\mathcal{D}_{(i,j,k),A}$  be the dose contribution to voxel  $(i, j, k)$  from a beam of weight 1 from angle  $A$ ,  $\mathcal{S}$  be a collection of voxels on the sensitive structure(s), and  $\mathcal{N}$  be a collec-

tion of voxels on the normal tissue. When wedges are allowed in the optimization, the data will be provided as  $\mathcal{D}_{(i,j,k),A,F}$  that represents the dose contribution to voxel  $(i, j, k)$  from a beam of weight 1 from angle  $A$ , using wedge orientation  $F$ .

*Beam Weight Optimization:* The classical optimization problem in conformal radiation therapy is to choose the weights (or intensity levels) to be delivered from a given set of angles. Suppose  $w_A$  represent the beam weight delivered from angle  $A$ ,  $D_{(i,j,k)}$  for the total dose deposited to voxel  $(i, j, k)$  and  $\lambda$  represent the relative weighting factors in the objective function. Given a set  $\Omega = \mathcal{T} \cup \mathcal{S} \cup \mathcal{N}$ , a general optimization model that determines optimal radiation intensity is

$$\begin{aligned} \min_w \quad & \lambda_t f(\mathcal{D}_{\mathcal{T}}) + \lambda_s f(\mathcal{D}_{\mathcal{S}}) + \lambda_n f(\mathcal{D}_{\mathcal{N}}) \\ \text{s.t.} \quad & D_{\Omega} = \sum_{A \in \mathcal{A}} \mathcal{D}_{\Omega,A} w_A, \\ & l \leq D_{\mathcal{T}} \leq u, \\ & 0 \leq w_A, \quad \forall A \in \mathcal{A}. \end{aligned} \quad (3)$$

Hard upper and lower bound constraints are imposed on the target dose so that, in the worst case, the resulting solution will satisfy the minimum requirement for a treatment plan. Objective function  $f(\mathcal{D})$  can be defined based on the planner's preference, but a general function can be written as

$$f(\mathcal{D}_{\cdot}) = \|\mathcal{D}(\cdot) - \theta\|_p, \quad p \in \{1, 2, \infty\}.$$

Note that  $\theta$  is the desired dose level for an organ of interest. These problems can be cast as a quadratic programming (QP) problem ( $p = 2$ ), minimizing the Euclidean distance between the dose delivered to each voxel and the prescribed dose [6,35,40,41]. Furthermore, linear programming (LP) has also been extensively used to improve conventional treatment planning techniques [3,24,32,37,40]. The strength of LP is its ability to control *hot* and *cold* spots or integral dose on the organs using constraints, and the presence of many state-of-the-art LP solvers. The LP model replaces the Euclidean norm objective function of a QP with a polyhedral one, for which standard reformulations (see [27,30]) result in linear programming problems. While these techniques still suffer from large amounts of data in  $\mathcal{D}_{(i,j,k),A}$ , they are typically solved in acceptable time frames. These models tend to find

optimal solutions more quickly than the corresponding QP formulations.

Another technique to convert the quadratic (or more generally convex) problem to a linear program is via a piecewise-linear approximation of the objective (see [36]). For a quadratic function, a uniform spacing for the breakpoints guarantees small approximation errors from the piecewise linear interpolant [23]. Since the piecewise linear interpolant is convex, standard techniques can be used to reformulate this as a linear program [16,23].

*Equivalent Uniform Dose (EUD):* Recently, some of the medical physics literature has been advocating the use of other forms of objective function in place of the ones outlined above. A popular alternative to those given above is that of generalized equivalent uniform dose (EUD). This is defined on a per structure basis as

$$EUD_a(D, \Omega) := \left( \frac{1}{\text{card}(\Omega)} \sum_{(i,j,k) \in \Omega} D_{(i,j,k)}^a \right)^{\frac{1}{a}}.$$

Note that EUD is a scaled version of the  $a$ -norm of the dose to the particular structure, and hence is known to be a convex function for any  $a \geq 1$  and concave for  $a \leq 1$  [7]. Thus the problem

$$\begin{aligned} \max_w \quad & EUD_a(D, \mathcal{T}) \\ \text{s.t.} \quad & D_\Omega = \sum_{A \in \mathcal{A}} \mathcal{D}_{\Omega,A} w_A, \quad \Omega = \mathcal{T} \cup \mathcal{S} \cup \mathcal{N}, \\ & EUD_b(D, \mathcal{S}) \leq \phi, \\ & EUD_c(D, \mathcal{N}) \leq u, \\ & 0 \leq w_A, \quad \forall A \in \mathcal{A}. \end{aligned}$$

is a convex optimization problem provided  $a \leq 1$  and  $b, c \geq 1$ . As such, nonlinear programming algorithms will find global solutions to these problems.

*Beam Angle Selection and Wedge Orientation Optimization:* Optimization also lends itself to solving the more complex problem of selecting which angles and wedge orientations to use as well as their intensities. Mixed integer programming (MIP) is a straightforward technique for these type of problems. We describe an optimization model that simultaneously optimizes beam angles, wedge orientations, and beam intensities. Wedges are placed in front of the collimator to produce a gradient over the dose distribution and can be

effective for reducing dose to organs at risk. This can be done by adding an extra dimension  $F$  to the variable  $w_A$ :

$$\begin{aligned} \min_{w, \psi} \quad & \lambda_t f(\mathcal{D}_{\mathcal{T}}) + \lambda_s f(\mathcal{D}_{\mathcal{S}}) + \lambda_n f(\mathcal{D}_{\mathcal{N}}) \\ \text{s.t.} \quad & D_\Omega = \sum_{A \in \mathcal{A}} \mathcal{D}_{\Omega,A,F} w_{A,F}, \\ & w_{A,F} \leq M \cdot \psi_A, \\ & l \leq D_{\mathcal{T}} \leq u, \\ & \sum_{a \in \mathcal{A}} \psi_a \leq K, \\ & \psi_A \in \{0, 1\}, \quad \forall A \in \mathcal{A}. \end{aligned} \quad (4)$$

The variable  $\psi_A$  is used to determine whether or not to use an angle  $A$  for delivery. The choice of  $M$  plays a critical role in the speed of the optimization; further advice on its choice is given in [27]. Note that the data for this problem is considerably larger, increasing by a factor related to the number of wedge orientations allowed.

**Solution Techniques** Simulated Annealing (SA) has been well adopted in the medical community [33,44]. But the weakness of SA in the optimization point is its inability to verify the optimality. On the other hand, it is possible to find a global optimal solution for (4). However, due to its slow convergence, using the MIP model has not been very useful for designing a treatment plan in the hospital. Recently, Lim et al. [27] proposed an iterative solution approach that solves the MIP problem fast (within 20 min in two clinical case examples). It is termed *A Three-Phase Approach*.

Three-Phase Approach is a multiphase technique that “ramps up” to the solution of the full problem via a sequence of models. Essentially, the models are solved in increasing order of difficulty, with the solution of one model providing a good starting point for the next. The models differ from each other in the selection of voxels included in the formulation, and in the number of beam angles allowed.

If the most promising beam angles can be identified in advance, the full problem can be solved with a small number of discrete variables. One simple approach for removing unpromising beam angles is to remove from consideration those that pass directly through any OAR [38]. A more elaborate approach [34] introduces a score function for each candidate angle, based on

the ability of that angle to deliver a high dose to the PTV without exceeding the prescribed dose tolerance to OAR or to normal tissue located along its path. Only beam angles with the best scores are included in the model. We now describe the *Three-Phase Approach*:

1. *Phase 1: Selection of Promising Beam Angles*: The aim in this phase is to construct a subset of beam angles  $\mathcal{A}_1$  that are likely to appear in the final solution of (4). We solve a collection of  $r$  MIPs, where each MIP is constructed from a reduced set of voxels consisting of the voxels in the PTV, a randomly sampled 10% of the OAR voxels ( $S$ ), and the voxels in  $\mathcal{R}_\rho(\mathcal{T})$ ; that is,

$$\Omega_1 = \{\mathcal{T} \cup S \cup \mathcal{R}_\rho(\mathcal{T})\}.$$

We define  $\mathcal{A}_1$  as the set of all angles  $A \in \mathcal{A}$  for which  $w_A > 0$  for at least one of these  $r$  sampled problems.

2. *Phase 2: Treatment Beam Angle Determination*: In the next phase, we select  $K$  or fewer treatment beam angles from  $\mathcal{A}_1$ . We solve (4) using  $\mathcal{A}_1$  and a reduced set of voxels defined as follows:

$$\Omega_2 = \{\mathcal{T} \cup S \cup \mathcal{R}_\rho(\mathcal{T}) \cup \mathcal{N}_1\}.$$

Note that  $|\mathcal{A}_1|$  is typically greater than or equal to  $K$ , so the binary variables play a nontrivial role in this phase.

3. *Phase 3: Final Approximation*: In the final phase, we fix the  $K$  beam angles (by fixing  $\psi_{\mathcal{A}_1} = 1$  for the angles selected in Phase 2 and  $\psi_A = 0$  otherwise) and solve the resulting simplified optimization problem over the complete set of voxels. This final approximation typically takes much less time to solve than the full-scale model, because of both the smaller amount of data (due to fewer beam angles) and the absence of binary variables.

Although there is no guarantee that this technique will produce the same solution as the original full-scale model (4), Lim et al. [27] have found that the quality of its approximate solution is close to optimal based on several numerical experiments.

## Intensity Modulated Radiation Therapy

**Introduction** A sophisticated form of treatment planning approach known as intensity modulated radiation therapy (IMRT) allows a number of differently

shaped beams with different uniform radiation intensities to be delivered from each direction, which allows a high degree of flexibility in delivering radiation dose distribution from each beam angle [4,18]. In IMRT treatment planning, two-dimensional (2D) beams are divided into several hundred or thousand pencil beams to generate very precise dose distribution on the treatment volume.

*Decision Variables*: First, one needs to decide how many beam angles need to be coordinated for the treatment (*beam angle optimization*). For each beam angle, radiation is delivered using a multi-leaf collimator (MLC). In practice, an MLC is designed so that one leaf can only move one direction with a discrete distance. Therefore, we divide an MLC as an  $M \times N$  grid of pixels.  $M$  is for the number of leaves in an MLC (note that this number can vary from one manufacturer to another), and  $N$  is for the number of discrete units that a leaf can move. Second, radiation intensity maps (fluence maps) for such beam angles need to be optimized to conform the three dimensional radiation dose requirement to control the tumor (*fluence map optimization*). For a fixed beam angle, the fluence map contains real numbers in a set of two-dimensional discrete coordinates that are associated with the MLC. Since no machine can deliver such a non-uniform real intensity map, the intensity maps are first approximated as multiples of a physically deliverable minimum discrete unit (this number can be a fraction). For example, an approximated intensity map for a  $3 \times 4$  MLC may look as follows (we assume that the minimum discrete value allowed is 0.5 in this case):

$$\begin{aligned} \mathcal{W} &= \begin{pmatrix} 0 & 0.5 & 2.0 & 1.5 \\ 0.5 & 2.5 & 3.5 & 2.0 \\ 0 & 1.0 & 2.0 & 1.5 \end{pmatrix} \\ &= 0.5 \times \begin{pmatrix} 0 & 1 & 4 & 3 \\ 1 & 5 & 7 & 4 \\ 0 & 2 & 4 & 3 \end{pmatrix}. \end{aligned} \quad (5)$$

Third, since we cannot deliver non-uniform radiation (see (5)) to the treatment volume with one open beam shape, an intensity map is decomposed into several unique shape matrices such that each matrix can contain zeros and uniform value. This is called *beam segmentation problem*.

**Optimization Model Formulations**

**Problem 1; Beam Angle and Fluence Map Optimization**

Since the optimal set of beam angles are intimately related to the optimal fluence map for each angle, these two problems must be dealt with together in the problem formulation. Let  $a$  denote an angle,  $a \in \mathcal{A}$ ,  $l$  denote the leaf index of the collimator,  $l = 1, 2, \dots, m$ , and  $p$  represent the position of the leaf,  $p = 1, 2, \dots, n$ . Then, formulating an optimization model for optimizing both beam angles and the fluence maps is a simple extension to (4) that we discussed for the conventional 3DCRT and the model is given as

$$\begin{aligned} \min_{w, \psi} \quad & \lambda_t f(\mathcal{D}_T) + \lambda_s f(\mathcal{D}_S) + \lambda_n f(\mathcal{D}_N) \\ \text{s.t.} \quad & D_\Omega = \sum_{a \in \mathcal{A}} \mathcal{D}_{\Omega, a, l, p} w_{a, l, p}, \\ & w_{a, l, p} \leq M \cdot \psi_a, \\ & l \leq D_T \leq u, \\ & \sum_{a \in \mathcal{A}} \psi_a \leq K, \\ & \psi_a \in \{0, 1\}, \forall a \in \mathcal{A}. \end{aligned} \tag{6}$$

See more details of this formulation and others in [26,28].

**Solution Methods** Solving this problem using any classical optimization techniques will take too long for any clinicians to use for their daily treatment planning. Lim et al. [28] proposes a fast MIP solution approach and an LP-based iterative method that exploits score functions. However, due to the computational difficulties with large data in solving the optimization problem, heuristic methods are often used in practice [25].

**Problem 2; Beam Segmentation Optimization** Consider a matrix

$$\mathcal{W} = \begin{pmatrix} w_{1,1} & w_{1,2} & \cdots & w_{1,n} \\ \vdots & \vdots & & \vdots \\ w_{m,1} & w_{m,2} & \cdots & w_{m,n} \end{pmatrix},$$

where  $w_{i,j} \in \mathbb{Z}$ , for  $i = 1, \dots, m$ ,  $j = 1, \dots, n$ . Our objective is to decompose the matrix  $\mathcal{W}$  into  $K$  binary matrices  $S^k$  such that

$$\mathcal{W} = \sum_{k=1}^K \mu_k \cdot S^k, \tag{7}$$

where,  $S^k = [s_{i,j}^k]$ ,  $s_{i,j}^k \in \{0, 1\}$ ,  $i \in \{1, 2, \dots, m\}$ ,  $j \in \{1, 2, \dots, n\}$ ,  $\mu_k \in \mathbb{Z}$ ,  $k \in \{1, 2, \dots, K\}$ . Solving (7) is quite easy in general. However, this problem becomes extremely difficult to solve when we impose the following two objectives and a physical constraint.

*Objectives:*

1. Minimize the value of  $K$ .
2. Minimize  $T :=$  the sum of the matrix multipliers, i. e.,  $T = \sum_{k=1}^K \mu_k$ .

*Consecutive One Constraint:* For each row of a binary matrix  $S_k$ , if there are more than one non-zero elements (1's), their sequence must be consecutive, i. e. zeros are not allowed to break the non-zero sequence. For example,

$$0 \ 1 \ 1 \ 1 \ 0$$

is a feasible sequence. But,

$$0 \ 1 \ 0 \ 1 \ 0$$

is not allowed because the sequence of ones is not continuous.

Note that there can be many more constraints to this problem depending on the machine that is used for radiation delivery. Some of the common constraints are *overlap elimination constraint*, *interleaf collision constraint*, and *tongue-and-groove constraint*. Details about these more elaborate constraints can be found in [1,19,20,43].

**Solution Methods** This is a combinatorial optimization problem that is proven to be *strongly NP-hard* [9]. Optimization formulations have been proposed including integer nonlinear program (INLP) and integer programming (IP) [28]. IP models are easier to solve than INLP models. IP models with relatively small numbers of rows and columns can be solved within a reasonable amount of time using a branch-and-bound method [45]. However, as the matrix size increases (say, larger than 10) and the maximum value of the matrix  $\mathcal{W}$  increases, finding global solutions for the IP models can take too long for treatment planners to use. Therefore, both researchers and planners use various heuristics. Engel [10] proposed a heuristic that generates optimal  $T$ , but  $K$  is still not optimal. Other approaches and extension to this problem can be found in [21]. A genetic algorithm has also been used by other researchers [8].

Multidimensional scaling

## Introduction

Very often scientific data are defined by multidimensional vectors of numerical values. To enable exploratory data analysis involving heuristic abilities of human expert's visualization of data is highly desirable: a picture is worth a thousand words. There are different approaches to visualization [8]. We consider one of the most popular approaches known as multidimensional scaling (MDS) [2,9,14,27,31,39,42]; it will be shown below that an essential part of the technique is optimization of a function possessing many optimization-adverse properties. By means of MDS a set of multidimensional vectors can be represented as a set of points in a low-dimensional space and exposed in this way to a human expert for heuristic analysis. Even more general sets of objects can be visualized: it is sufficient to know pairwise similarity/dissimilarity between the objects. Application areas of MDS vary from psychometrics [41] and market analysis [15,36] to mobile communications [22] and pharmacology [45].

## Formulation

A set of  $n$  objects is considered whose pairwise dissimilarities are given by an  $(n \times n)$  matrix  $(\delta_{ij})$ ,  $i, j = 1, \dots, n$ . It is supposed that dissimilarities are nonnegative:  $\delta_{ij} \geq 0$ , symmetric:  $\delta_{ij} = \delta_{ji}$ , and  $\delta_{ii} = 0$ . Frequently the considered objects are vectors, and dissimilarities are defined by a metric in the corresponding vector space. Sometimes (a reciprocal to dissimilarity) the proximity relation between objects is defined; this

## Optimization-Based Visualization

Institute of Mathematics and Informatics,  
Vilnius, Lithuania

case can be considered similarly to the case of dissimilarity relation.

An image of a set of objects is sought as a set of points  $\mathbf{x}_i \in \mathbf{R}^m$ ,  $i = 1, \dots, n$  in a (low-dimensional metric) *embedding* space with pairwise distances between the image points fitting the corresponding dissimilarities; normally *Minkowski distances*  $d_p(\mathbf{x}_i, \mathbf{x}_j)$  between the points  $\mathbf{x}_i$  and  $\mathbf{x}_j$  are used where

$$d_p(\mathbf{x}_i, \mathbf{x}_j) = \left( \sum_{k=1}^m |x_{ik} - x_{jk}|^p \right)^{1/p}.$$

The formula defines Euclidean distances when  $p = 2$  and city-block distances when  $p = 1$ .

The problem of constructing images of the considered objects is reduced to the minimization of an accuracy-of-fit criterion, e. g., of a least-squares *stress* function,

$$\sigma_r(\mathbf{X}) = \sum_{i < j} w_{ij} (d(\mathbf{x}_i, \mathbf{x}_j) - \delta_{ij})^2,$$

where *weights*  $w_{ij}$  are nonnegative:  $w_{ij} \geq 0$ . *Normalized stress* defined by

$$\sigma_n(\mathbf{X}) = \frac{\sum_{i < j} w_{ij} (d(\mathbf{x}_i, \mathbf{x}_j) - \delta_{ij})^2}{\sum_{i < j} w_{ij} \delta_{ij}^2}$$

shows the proportion of unexplained sum of squares and can be used for comparison of results of different problems. Stress is not everywhere differentiable. The function normally has many local minima. It is invariant with respect to translation, rotation, and mirroring. The minimization problem of stress is high dimensional: the number of variables is  $N = n \times m$ . Therefore minimization of the stress function is a difficult global optimization problem.

Many global optimization methods for minimization of stress include auxiliary local minimization algorithms. Differentiability of an objective function at a minimizer is an important factor for a proper choice of a local minimization algorithm. The well-known result on differentiability of stress with Euclidean distances at a local minimizer [12] is generalized for Minkowski distances in [21]: *positiveness of distances* holds at a local minimizer – image points in the embedding space do not coincide. In the case of Minkowski distances  $p > 1$  or  $m = 1$ , this means that stress is differentiable at a local minimizer.

The result on differentiability of stress with Minkowski distances at a local minimizer [21] does not include the case of city-block distances ( $p = 1$ ). It was shown in [44] that positiveness of distances at a local minimizer does not imply differentiability of stress with city-block distances. Examples of images at minimizers show that values of coordinates of image points in the embedding space  $m > 1$  may be equal and therefore stress may be nondifferentiable at minimizer in the case of city-block distances.

Everywhere differentiable *S-stress* is defined by

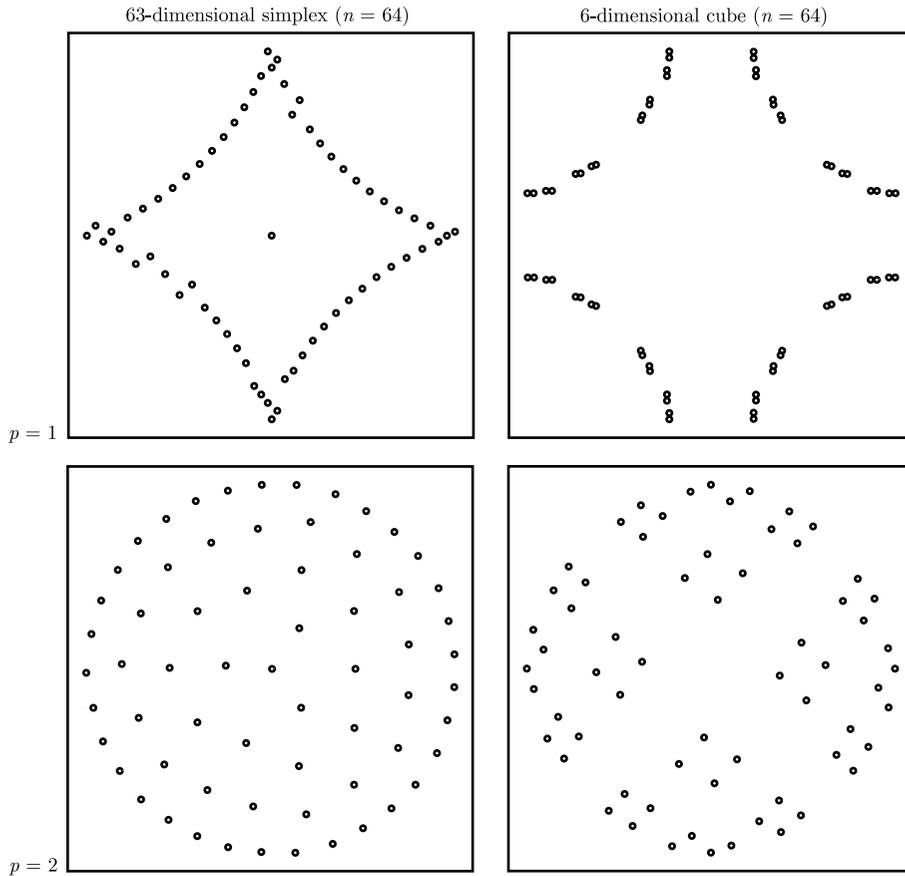

$$S_S(\mathbf{X}) = \sum_{i < j} w_{ij} \left( d^2(\mathbf{x}_i, \mathbf{x}_j) - \delta_{ij}^2 \right)^2.$$

Sometimes instead of the least-squares stress, a *least absolute deviation* ( $L_1$ -norm) function is used:

$$S_{L1}(\mathbf{X}) = \sum_{i < j} w_{ij} |d(\mathbf{x}_i, \mathbf{x}_j) - \delta_{ij}|.$$

Examples of two-dimensional images produced using minimization of stress with city-block and Euclidean distances are shown in Fig. 1. Vertices of multidimensional geometrical figures are considered as objects to be visualized. The dissimilarity between vertices is measured by the distance in the original vector space. Although it is not possible to imagine geometrical figures in the space of dimensionality larger than 3, properties of well-understood geometrical figures are known. Multidimensional simplices and cubes are special on the symmetric location of vertices, and this feature is expected in the images. Besides this common feature, the central location of the “zero” vertex is characteristic of a multidimensional simplex. The other vertices of a simplex are equally distant from the “zero” vertex. The vertices of a multidimensional cube compose clusters of  $2^k$  vertices corresponding to edges and faces. The vertices of a cube are equally distant from the center.

The images of a 63-dimensional simplex are shown in the left column of Fig. 1, and the images of a 6-dimensional cube are shown in the right column. Both geometrical figures have  $n = 64$  vertices. The images produced by city-block MDS are shown in the upper row, and the images produced by Euclidean MDS are shown in the lower row. The images of vertices are shown by circles.

**Optimization-Based Visualization, Figure 1**  
**Images of vertices of multidimensional simplices and cubes**

The image of the “zero” vertex of the simplex is located at the center of the structures. The images of the other vertices tend to form a square with a vertical diagonal when city-block distances are used and circles when Euclidean distances are used. A square with a vertical diagonal in city-block metric is equivalent to a circle in Euclidean metric – the points on such a figure are equally distant to the center. Therefore the images of the vertices are similarly distant to the “zero” vertex when city-block distances are used. The images of vertices on different circles are differently distant to the “zero” vertex when Euclidean distances are used.

The images of the vertices of the multidimensional cube tend to form a square with a vertical diagonal too when city-block distances are used; therefore they are visualized similarly distant to the center of the image. In the case of Euclidean metric, the images of the vertices of the cube tend to fill a circle; however, there is no

uniformity in the location of the images of the vertices. The images of the vertices form clusters representing lower-dimensional cubes in the cases of both metrics.

**Methods/Applications**

MDS is a generalization of unidimensional scaling (UDS) ( $m = 1$ ) [33] to the multidimensional case ( $m > 1$ ).

Minimization of the stress function with equal weights for  $m = 1$  can be changed to a combinatorial maximization problem [10]:

$$\max_{\psi \in \Psi} \sum_{i=1}^n \left( \sum_{j>i} \delta_{\psi(i)\psi(j)} - \sum_{j<i} \delta_{\psi(i)\psi(j)} \right)^2,$$

where  $\Psi$  is the set of all possible permutations of  $1, \dots, n$ . The optimal permutation  $\psi^*$  found using maximization defines the optimal sequence of objects.

Then the coordinate values of image points are found by

$$\begin{aligned}
 x_{\psi^*(1)} &= 0, \\
 x_{\psi^*(i+1)} &= x_{\psi^*(i)} + \frac{1}{n} \left( \sum_{j>i} \delta_{\psi^*(i)\psi^*(j)} \right. \\
 &\quad \left. - \sum_{j<i} \delta_{\psi^*(i)\psi^*(j)} - \sum_{j>i+1} \delta_{\psi^*(i+1)\psi^*(j)} \right. \\
 &\quad \left. + \sum_{j<i+1} \delta_{\psi^*(i+1)\psi^*(j)} \right), \\
 i &= 1, \dots, n-1.
 \end{aligned}$$

The number of local minima for the problem of UDS was estimated in [37]. There a “smoothing technique” approach was presented to locate the globally optimal solution.

A branch-and-bound method for obtaining the guaranteed globally optimal solution to the problems of UDS was presented in [7]. An interchange test and new bounding procedures were used to improve computational performance.

Guaranteed solution of larger problems is not possible; therefore heuristic approaches are used. A simulated annealing (SA) approach for the problem of UDS via maximization of the Defays criterion was presented in [5]. This algorithm includes efficient storage and computation methods to facilitate rapid evaluation of trial solutions.

Quadratic assignment methods to generate initial permutations for UDS were developed in [6]. Methods include locally optimal pairwise interchange, SA, and hybrid. It was shown that substantial improvements of UDS can be achieved using starting permutations obtained via solution to a quadratic assignment problem.

A heuristic algorithm based on SA for provision of good starting solutions for combinatorial algorithms is proposed in [3]. The heuristic starts with the partition of equally spaced discrete points. A SA algorithm is used to search the lattice defined by these points with the objective of minimizing least-squares or least absolute deviation loss function.

An algorithm implementing SA for UDS in a different way is presented in [35]. A strategy is based on a weighted alternating process: permutations and

pointwise translations are used to locate the optimal configuration.

A recursive dynamic programming strategy for some problems including UDS is discussed in [23]. Four different optimization strategies for UDS have been compared in [24]: dynamic programming, iterative quadratic assignment heuristic, smoothing technique [37], and nonlinear programming reformulation [28]. The results show that the first two strategies are better than the other two and should lead to optimal solutions if some random starts are used.

A mixed-integer programming formulation for the least absolute deviation UDS is developed in [40]. Integer linear programming models for UDS were discussed in [4]. In the case of least absolute deviation UDS, the objective function is piecewise linear.

The special geometry of squared error loss function for UDS is employed in [38]. The developed algorithm is linear in the number of parameters, as the global minimum for every coordinate is conditioned on every other coordinate being held fixed.

One of the most popular algorithms for MDS is SMACOF [11]. The algorithm is based on a majorization approach [17] that replaces iteratively the original objective function by an auxiliary majorization function, which is much simpler to optimize. The convergence properties of MDS algorithms are studied in [13]. It was proved that the majorization method is globally convergent. In almost all cases the convergence is linear, with a convergence rate close to unity. The majorization algorithm has been extended to deal with Minkowski distances with  $1 \leq p \leq 2$ , and an algorithm that is partially based on majorization for  $p$  outside this range is suggested in [21].

A tunneling method for global minimization was introduced and adjusted for MDS with general Minkowski distances in [18]. The tunneling method alternates a local search step, in which a local minimum is sought, with a tunneling step, in which a different configuration is sought with the same value of stress as the previous local minimum. In this manner successively better local minima are obtained and the last one is often the global minimum.

A method for MDS based on combining a local search algorithm with an evolutionary strategy of generating new initial points was proposed in [32]. Its efficiency is investigated by numerical experiments. The

testing results in [22,30] proved that the hybrid algorithm combining an evolutionary global search with an efficient local descent is the most reliable, though the most time-consuming method for MDS with Euclidean distances. The advantages of genetic algorithms in MDS with nonstandard stress criteria were discussed in [16].

The concept of sequential estimation in MDS was introduced in [34]. The sequential estimation method refers to continually updating estimates of a configuration as new observations are added. Locally optimal design of the experiment was constructed.

A globalized Newton method for stress and S-stress is developed in [25]. A deterministic annealing algorithm for the S-stress is presented in [26] and experimentally compared with gradient-descent methods.

General methods for MDS can be applied in the case of city-block distances if they do not rely on the differentiability of the objective function at a minimizer. However, there are some methods developed especially for city-block MDS.

A survey of city-block MDS is presented in [1]. Topics include theoretical issues, algorithmic developments and their implications for seemingly straightforward analyses, isometries with other distances, and links to graph-theoretic models.

A distance smoothing approach for city-block MDS was proposed in [19]. The technique allows avoiding of local minima in optimization. The technique was extended to any Minkowski distance, and a majorization algorithm with a monotone nonincreasing series of stress values was suggested in [20].

A heuristic algorithm based on SA for two-dimensional city-block scaling was proposed in [3]. The heuristic starts with the partitioning of each coordinate axis into equally spaced discrete points. A SA algorithm is used to search the lattice defined by these points with the objective of minimizing least-squares or least absolute deviation loss function. The object permutations for each dimension of the solution obtained by the SA algorithm are used to find a locally optimal set of coordinates by quadratic programming.

A two-stage approach for city-block MDS was proposed in [29]. The least-squares regression is used to obtain a local minimum of stress function in the first stage. SA is used in the second stage of the method.

A bilevel method for city-block MDS was proposed in [44]. The method employs a piecewise quadratic

structure of stress with city-block distances reformulating the global optimization problem as a two-level optimization problem:

$$\begin{aligned} & \min_{\mathbf{P}} S(\mathbf{P}), \\ \text{s.t. } & S(\mathbf{P}) = \min_{\mathbf{X} \in A(\mathbf{P})} S(\mathbf{X}), \end{aligned}$$

where the upper-level combinatorial problem is defined over the set of all possible permutations of  $1, \dots, n$  for each coordinate of the embedding space and the lower-level problem is a quadratic programming problem with a positively defined quadratic objective function and linear constraints setting the sequences of values of coordinates defined by  $m$  permutations in  $\mathbf{P}$ . The lower-level problems are solved using a quadratic programming algorithm. The upper-level combinatorial problem can be solved by guaranteed methods for small  $n$  and using evolutionary search for larger problems.

Interaction between optimization and visualization means not only application of optimization methods to implement visualization algorithms but also application of visualization methods to analyze properties of optimization problems. For example, optimal design of the chemical engineering process considered in [43] includes a minimization problem in nine-dimensional space where the feasible region is defined by interval constraints, and a nonexplicit (black box) indicator-type constraint. Properties of the feasible region are of interest while choosing the optimization algorithm and while making a final decision about process parameters. The properties of interest cannot be proven analytically, but heuristic analysis of the image of the set of points consisting of vertices of the nine-dimensional cube and 300 randomly generated points of the feasible region is helpful to guess the form and dimensionality of the region and its location in the hypercube.

Medical diagnosis; Inductive inference problem; Boolean classification problem; Learning algorithm; Conjunctive normal form; CNF; Disjunctive normal form; DNF; Satisfiability problem; SAT; Minimum number of clauses; One clause at a time approach; OCAT; GRASP approach; Randomized heuristics; Missing information; Unclassifiable examples

There are many situations in which it is necessary or desirable to classify objects into two or more mutually exclusive sets or classes. *Medical diagnosis*, for example, has been the focus of numerous research efforts over the past several years. Given a set of attributes, or relevant characteristics which describe a patient, the problem then is the extraction and identification of various biological and/or historical attributes in order to determine the correct diagnosis or classification.

To illustrate the magnitude of the problem, consider the case of *breast cancer diagnosis*. Based on a patient's medical history and on the results of *mammography screening* (the most effective diagnostic tool available to health care professionals), doctors attempt to classify *breast tumors* as being suspicious for malignancy or benign. Unfortunately, of all breast tumors which are suspected to be malignant, over 70% are later found to be benign through an expensive and emotionally trying surgical procedure called a biopsy [5]. In addition, almost 50% of those patients who actually have breast cancer are classified as benign by their physicians, so that many malignancies go unrecognized [27].

The decision maker, in this example the medical doctor, must infer from existing information the characteristics or combinations of characteristics which are indicative of a benign or malignant tumor in order to correctly classify new cases. In their most basic form, the characteristics used to describe each patient are represented by one or more binary attributes. That is, each object (patient) may be represented by a Boolean vector in which an attribute value is either 1 (true) or 0 (false). Often, the problem is compounded by the fact that complete information is not available. Continuing with the breast cancer example, suppose that the information related to all pertinent characteristics is not available due to the patient's inability to undergo certain tests because of excessive cost, the possibility of indeterminate test results, lack of knowledge

related to family histories, etc. Thus, in addition to the binary data indicating the presence or absence of a given characteristic, the attribute value or level of some characteristics may be unknown. The doctor is then faced with the problem of assessing a limited set of characteristics to determine whether a biopsy is warranted. He/She must decide if the available characteristics and/or combinations of characteristics provide sufficient information for an accurate classification of the tumor.

This problem, referred to as the *inductive inference problem* or *Boolean classification problem*, is illustrative of a vast number of similar situations throughout business, industry and medicine. Technological advances have created a ‘data explosion’, providing decision makers with ever increasing amounts of information. Unfortunately, this information is usually not exploited in an optimal way, and at times, not at all. Clearly, the classification problem becomes more complex as the amount of information related to the object increases. Individuals, or groups of individuals find themselves incapable of consistently and reliably handling, manipulating and analyzing the available information. As a result, the creation of computer systems capable of learning the concepts underlying the data and subsequently classifying new examples accurately and efficiently has become a practical necessity.

## Background Information

As informally presented above, solving the Boolean classification problem generally involves the development of a system that learns from feature-based examples. That is, each example is described by a set of Boolean attributes. The binary vector  $[0\ 1\ 1\ 1]$ , for instance, describes an example in which the first attribute (or characteristic) is false, and the remaining attributes are true. Each example also carries a classification: positive or negative. The goal of a *learning algorithm* is to infer from these examples a Boolean function (logical system) that is capable of accurately predicting the class of new examples. Generally, the inferred system is expressed as a Boolean function in *conjunctive normal form* (CNF) or *disjunctive normal form* (DNF).

The general form of a CNF and DNF Boolean function is defined as (1) and (2), respectively. That is:

$$\bigwedge_{j=1}^k \left( \bigvee_{i \in \rho_j} a_i \right) \quad (1)$$

and

$$\bigvee_{j=1}^k \left( \bigwedge_{i \in \rho_j} a_i \right), \quad (2)$$

where  $a_i$  is either  $A_i$  or  $\bar{A}_i$ . That is, a CNF expression is a conjunction of disjunctions, while a DNF expression is a disjunction of conjunctions. Any Boolean function can be transformed into CNF or DNF format [15].

To clarify the concepts presented thus far, suppose that the following sets of positive and negative examples are somehow known:

$$E^+ = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \end{pmatrix}$$

and

$$E^- = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 \end{pmatrix}.$$

The goal of a learning algorithm is to infer a Boolean function which correctly classifies all the examples. One such function (in CNF) is as follows:

$$(A_2 \vee A_4) \wedge (\bar{A}_2 \vee \bar{A}_3) \wedge (A_1 \vee A_3 \vee \bar{A}_4).$$

These three clauses, when are taken together, accept the previous four positive examples and reject the six negative examples.

Traditionally, there are two main methods with the goal of creating these intelligent systems: *decision trees* and *neural networks*. These tools, which have evolved over a forty-year period, represent a large portion of the literature on learning algorithms which propose to solve the Boolean classification problem. When applied

to classification problems in which the goal of the system is to learn from feature-based examples, decision trees have been one of the most popular methodologies for the extraction of knowledge. Because of the natural interpretation of knowledge, symbolic decision trees can be easily translated into a set of rules suitable for use in *rule-based systems*. The size and form of the decision tree is significantly affected by the ordering of the attributes, and often the resulting tree is nonoptimal or it may be overspecialized. A complex tree is not only more difficult to validate, but as J.R. Quinlan [16] demonstrated, a simpler tree is more likely to capture structures inherent in the data.

Neural networks comprise the other extreme in artificial intelligence approaches. These systems consist of a set of programs based on the structure of biological neural systems. Knowledge is represented in the form of a series of interconnected neurons, the structure of their interconnections, and the strength of their interconnections. To the user the process is a 'black box'. Though these systems have demonstrated the ability to provide accurate classifications in many applications, the examples are classified without explanations or justifications. In an attempt to overcome this deficiency, hybrid systems which combine neural networks and rule-based systems have been developed [4]. While these hybrid systems are efficient and effective in terms of both time and storage requirements, unfortunately, an exponential number of rules may be derived [17]. This renders attempts at justification of the process virtually useless due to the complexity of the explanation. The problem is that the logical rules are not derived within a complete logical framework.

### Optimization Approaches

Recognizing the need to minimize the resulting system, the problem of inferring a Boolean system from positive and negative examples was formulated as a satisfiability problem (SAT) and a method for inferring a minimal DNF system was proposed [8]. The SAT problem is next translated into an integer programming (IP) problem that is then solved by using an *interior point method* developed in [9]. The method makes use of a parameter, say  $k$ , which preassumes the number of disjunctions in the DNF system to be derived. The IP problem, if feasible is solved and  $k$  is successively lowered until in-

feasibility is encountered and then it is concluded that there exists no system of size  $k$  or smaller which accepts all positive examples and rejects all negative examples. Many solution methods exist for solving the SAT problem (see, for instance, [6,7,8] and [26]). Unfortunately, trying to determine a minimum size Boolean function may be computationally very difficult since it is much harder to prove that a given SAT problem is infeasible than to prove it is feasible. Thus, while the SAT approach can be used with success on small data sets and a *minimal number of DNF clauses* thus to be derived, when dealing with real world data, minimizing the size of the system may be neither feasible nor desirable due to the vast amounts of time and storage required by such algorithms.

In [25] a logical (Boolean) function approach to the classification problem has been introduced with the *one clause at a time* (OCAT) approach. Like the SAT approach, the OCAT approach formulates the *Boolean classification problem* as a series of integer programming problems. The OCAT algorithm is sequential and greedy in nature. The first iteration takes as input the  $E^+$  and  $E^-$  sets, and generates a single clause which accepts all positive examples and rejects as many negative examples as possible. This is the greedy aspect of the method. In the next iteration, it performs the same task using the original  $E^+$  set and a revised  $E^-$  set which includes only those negative examples not rejected by the preceding CNF clause. The iterations continue until a set of clauses is constructed which rejects all the negative examples and, of course, each clause accepts all the positive examples. This algorithm is as follows:

```

DO       $i = 0; C = \emptyset;$ 
        WHILE ( $E^- \neq \emptyset$ )
1        $i \leftarrow i + 1;$ 
2       Find a clause  $c_i$  which accepts all
        members of  $E^+$  while it reflects as
        many members of  $E^-$  as possible;
3       Let  $E^-(c_i)$  be the set of members of  $E^-$ 
        which are reflected by  $c_i$ ;
4       Let  $C \leftarrow C \cup c_i$ ;
5       Let  $E^- \leftarrow E^- - E^-(c_i)$ ;
REPEAT;
```

**The one clause at a time (OCAT) approach (the CNF case)**

The core of the method lies in step 2, the application of a branch and bound algorithm. Through the development of new search strategies and fathoming tests, E. Triantaphyllou [19] improved the performance of the branch and bound step. Still, like all branch and bound algorithms, it suffers from exponential time complexity. However, computational experiments indicate that the OCAT approach, when combined with the branch and bound algorithm, is a very efficient method for inferring logical clauses from sets of positive and negative examples. In fact, in over half of the test cases, this approach generated a minimum number of clauses. In addition, when compared to the SAT approach of [8], OCAT and the branch and bound was found to be considerably faster while performing at the same level of predictive accuracy [19]. Thus, while the OCAT approach may not always derive an absolute minimal system, computationally it is much less expensive than the SAT approaches and therefore more applicable to real world applications.

Continued research in this area resulted in the development of two *randomized heuristics* [2]. It should be stated here that this approach is similar, in principal, to the GRASP (greedy random adaptive search procedure) approach presented in [3]. The first heuristic (RA1) was developed to overcome the exponential time complexity of the OCAT's branch and bound algorithm. That is, RA1 derives a Boolean system from positive and negative examples in polynomial (quadratic) time. The primary difference between the branch and bound algorithm and the RA1 heuristic is that in each iteration, the branch and bound attempts to reject as many negative examples as possible; while RA1 attempts only to reject many negative examples. Again, the increased speed resulted in generally larger systems. When comparing the two algorithms, A.S. Deshpande and Triantaphyllou [2] found that the branch and bound used in the original OCAT approach produced in general, fewer conjunctions and required higher CPU times than the RA1 heuristic. Additionally, it was concluded that a conjunction of the RA1 heuristic and the branch and bound method performs much better in terms of both computational time/memory requirements of the process and the size of the derived system than either approach used alone.

Faced with real-world problems, in which there is often *incomplete information* related to both the at-

tribute values and the classifications, the goal to optimize the system becomes more desirable and necessary. Each of the methods discussed thus far have considered only positive and negative examples with complete data. That is, there is no *missing information* in the data set. Often, the complete examples represent only a portion of the available data, since in general data bases are plagued by missing information. In [1] a logical method for deriving a Boolean function from positive and negative examples was introduced in which some of the attribute values may be unknown. Since the missing information did not inhibit the classification process, these attributes are treated as 'don't care' values by the algorithm. Using a network flow algorithm, the method has been shown to efficiently derive a Boolean function with a very high predictive accuracy. The fact that the algorithm is capable of effectively handling missing information makes it more applicable to real data bases. Note, however, that the method makes no attempts at minimizing the size of the derived function.

Deshpande and Triantaphyllou [2] extended the RA1 heuristic for complete positive and negative examples, to include the use of incomplete data through the development of a second randomized heuristic, termed RA2. This method, allows not only for the inclusions of missing information in the attribute values, but it also makes use of examples which are *unclassifiable* due to the presence of missing information. That is, for some examples, the correct classification cannot be determined due to the lack of sufficient information. The objective of the second heuristic, similar to the first one, is to interactively derive a small-sized Boolean function from these three mutually exclusive sets: positive, negative, and unclassifiable examples. The algorithm consists of two phases. In each iteration of the first phase, the objective of the algorithm is to reject many negative examples while accepting all positive examples, and rejecting no unclassifiable examples. Once all negative examples have been rejected by the current set of clauses, phase II then assures that none of the unclassifiable examples are accepted by the system. When compared to the RA1 the accuracy obtained with the inclusion of unclassifiable data was always higher than the corresponding accuracy obtained without the inclusion of the unclassifiable data. This method has satisfactorily addressed the issues of efficiency and system size. Furthermore, it demonstrated that the process of extracting

knowledge from examples can be expedited by exploiting the patterns contained in missing information and unclassifiable examples.

A related issue in this area is the development of approaches for partitioning large scale problems in optimal or semi-optimal ways [24]. That was done by using a graph-theoretic approach. The same approach also allows to establish lower limits on the minimum number of clauses derivable from two given collections of input examples. Also, an approach for *guided learning* of a target Boolean function is proposed in [22]. In [10,21], and [18] the above problem was studied when the property of *monotonicity* can be established in the input data. Finally, in [12,13] and [11] some methods were presented for dealing with *fuzziness* and uncertainty.

### Concluding Remarks

Clearly, minimizing the size of the inferred system is an attractive goal. A complex system is difficult to validate, difficult to apply, and difficult to understand. On the other hand, a method which seeks to minimize the size of the system creates an inefficient process which is both computationally difficult and limits the method's applicability due to the vast time and storage requirements. In light of the success of the RA2 heuristic, the authors of this article are currently conducting research aimed at the development of an 'optimal' logical method which has the ability to handle missing information not only in the attribute values, but in the classification of the examples as well.

The new method works in conjunction with the OCAT approach. Through the application of a modified B & B algorithm, CNF clauses are interactively generated such that the set of clauses, when taken together, accepts all positive examples, rejects all negative examples and neither accepts nor rejects any unclassifiable example. We consider in this effort three optimization goals: efficiency of the process, accuracy of the derived function and the number of clauses which comprise the derived function. Thus 'optimal' in this sense implies the derivation of a small (hopefully minimum) and accurate Boolean system through the efficient exploitation of information contained in unclassifiable examples and, of course, the positive and negative examples.

In our current research efforts, optimization becomes even more vital. By allowing missing informa-

tion and unclassifiable examples, the amount of available data increases and necessitates the use of a learning algorithm which does not require excessive amounts of time and/or memory requirements. In addition, the goal of a logical approach is to derive a system capable of accurately classifying new examples and providing justification for the decision. A logical system derived from incomplete data may encounter an example which cannot be classified due to insufficient information. This system must be capable of explaining why the example is unclassifiable. That is, it has the additional responsibility of assisting the decision maker in identifying the minimal amount of additional information required for classification of the example. In a minimal system, this information is more readily accessible.

From the 1950s onwards, the search for computerized tools and mathematical models that can speed up the *classification of large collections of documents* has been the focus of many research efforts. These efforts have been centered in developing tools that can speed up the classification of documents according to some underlying context. A current example of this situation is the *Internet*. In this worldwide conglomerate of databases, one can easily see the speed at which documents on the topic, say, 'basketball' are retrieved from among the millions of documents produced daily on the Internet. Document classification is also of paramount importance in many information retrieval applications, such as news routing [7], classification/declassification of official documents [15] e-mail filtering [27], and context derivation of electronic meetings [3].

From the 1950s onwards, various fields of the human knowledge have produced several solutions for the document classification problem (see, for example, [21,23], and [2]). Some examples of these fields are mathematical optimization, computational linguistics, expert systems, neural networks, and genetic algorithms. These methodologies have been severely limited to some degree by the huge amounts of information, both textual and graphical, generated by today's information driven society. On the other hand, this 'technological' limitation has been the boost for the development of more efficient and effective classification procedures [15].

The purpose of this article is to exhibit some contributions of discrete optimization during the process of *automatic document classification*. This paper illustrates these contributions by presenting three cases (application areas) in which optimization is used in the classification process. The first case deals with a generic procedure for the selection of a set of *indexing terms* (*keywords* or *context descriptors*). The second case deals with the selection of an optimal set of indexing terms to minimize the overlapping of keywords used in different documents. The last case deals with the classification of text documents from mutually exclusive classes. These three cases are only a tiny sample of a vast collection of related instances in the field of information retrieval systems; see [1,11], and [25] for additional literature.

This article is organized as follows. The next section presents an overview of the document classification process. The subsequent section illustrates the three ap-

plication areas in which optimization has contributed in the solution of the classification problem. Finally, a summary section is given.

## Overview of Automatic Classification of Documents

The automatic classification of text documents consists of grouping documents of similar context into meaningful groups in order to facilitate their storage and retrieval [22]. *Text classification* can be viewed as a four-step process. In the first step, a representative sample of documents from various classes is presented to a computerized system, and a list of the co-occurring words with their frequencies is secured (see, for example, [22] and [4]).

In the second step the frequency of the words is analyzed, and only the most 'meaningful' words are extracted as indexing terms (keywords or context descriptors) [14]. The 'meaningful' words or keywords are the words with moderate co-occurring frequencies. H.P. Luhn [13], G. Salton [21], D. Cleveland and A.D. Cleveland [4], and Ch. Fox [6] suggest the elimination of the 'common' and 'rare' words (i. e., frequent and infrequent words, respectively) as indexing terms because they convey little lexical meaning. Some examples of common words are 'a', 'an', 'and', and 'the' [6]; 'rare' words are dependent on the document's subject [13].

In the third step the context of unclassified documents is determined by affixing them with the keywords that occur in their text. According to [4], 'the assignment of these keywords to a document is correct because authors usually repeat words that conform with the document's subject.' Finally, the documents which were indexed with similar keywords are grouped together [22].

The set of keywords attached to each document during the third step is often referred to as a *document surrogate* or just a *document* [4]. A surrogate is a convenient way to represent and to computationally process the context of real documents. For instance, the surrogate of seven words { 'document classification', 'document indexing', 'optimization', 'vector space model', 'logical analysis approach', 'OCAT algorithm', and 'machine learning' } is a condensed and convenient way to represent the context of this article which contains thousands of words, symbols, and numbers.

 \end{bmatrix}$$

**Optimization in Classifying Text Documents, Figure 1**  
A collection of  $N$  surrogates

Often, a surrogate is further simplified by defining it as a binary vector. (For nonbinary surrogates, see [22].) In this case, when a surrogate's element  $w_{ij} = 1$  (or 0), it indicates the presence (or absence) of keyword  $T_i$  ( $i = 1, \dots, t$ ) in document  $D_j$  ( $j = 1, \dots, N$ ). For example, the surrogate  $D_k = [0\ 1\ 1\ 1\ 1\ 0]$  of six binary elements indicates the presence of keywords  $T_2, T_3, T_4,$  and  $T_5$  and the absence of keywords  $T_1$  and  $T_6$  in  $D_k$ . Figure 1 shows a popular way to summarize a collection of  $N$  documents (surrogates) which are defined on  $t$  [22]:

In the last step, documents sharing similar keywords are grouped together. This classification follows from the pairwise comparison of the surrogates in Fig. 1 [22]. More on this is described in the following section.

### Examples of Optimization in Document Classification

Optimization techniques have been used in various areas of text classification with various levels of success. Their utilization has been limited mainly because the size of the document classification problem is so large that even with the current computerized technologies, it would take them very long time to produce an optimal solution. Despite these technological limitations, the contributions of optimization in this field can be seen, for example, in the selection of keywords, automatic classification of documents, automatic retrieval, etc. Some applications of these techniques are presented next.

The first example illustrates the principle of least effort [29]. This principle is used for the derivation of an indexing vocabulary based solely on the frequency of the co-occurring words in a collection of documents. The second example illustrates the application of the vector space model [23] for the derivation of an opti-

mal indexing vocabulary to minimize the overlapping of keywords used by different documents. The third example illustrates the utilization of a machine learning and operations research algorithm called the one clause at a time (OCAT) algorithm [28] for the classification of documents which belong to mutually exclusive classes.

### Optimization in the Principle of Least Effort

The *principle of least effort* (PLE) can be viewed as one of the first optimization attempts in the area of document classification. It was introduced by H.P. Zipf [29]. Although the PLE does not have a strict mathematical formulation, the problem it solves can be stated as follows. Given a collection of documents, the question is how to derive the 'best' set of indexing terms that will be used to identify the subject of documents in the collection. The set of the best indexing terms (or keywords) is often referred to as *indexing vocabulary* (see, for example, [4]). Hence, the goal of the PLE is to derive an optimal indexing vocabulary with the most *meaningful words* occurring in these documents.

Under the PLE an indexing vocabulary is derived as follows. At first all the co-occurring words and their frequencies are extracted from the collection of documents. Then, these words are ranked in descending order according to their frequencies. Finally, the words with frequencies in between some preestablished upper and lower frequency limits are selected as the indexing vocabulary. The frequency boundaries of the meaningful words are determined by a trial-and-error approach [13]. Other words with co-occurring frequencies above or below the preestablished limits are known as 'common' and 'rare' words (the frequent and infrequent words, respectively) and usually are discarded for indexing purposes because they convey little lexical meaning (see, for example, [13] and [16]).

It is interesting to notice here that although the PLE does minimize the number of keywords, its unwise utilization may jeopardize the quality of the indexing vocabulary. This can be illustrated by considering the word 'a'. The word 'a' is one of the most common words in the English language (other such words are 'an', 'and', and 'the'; see, for example, [6]). Thus, if the collection of documents is about nutrition, then 'a' may represent the name of the vitamin 'a' or 'A', and its

elimination clearly would jeopardize the quality of the indexing vocabulary.

**Optimization in the Vector Space Model**

One of the most successful models in information retrieval systems is the *vector space model* (VSM). It was introduced in the mid 1970s in [23]. The VSM solves problems of the following nature: Given are samples of documents. Then, the question here is how to derive an optimal indexing vocabulary such that keywords used in one document are minimally used in other documents. In [23], the VSM was also extended to determine a vocabulary that minimizes the overlapping of keywords used in different classes. That is, keywords used in documents belonging to one class are minimally used in other classes.

The VSM derives this *optimal vocabulary* as follows. At first, a sample of  $t$  words is taken from all the words co-occurring in a collection of  $N$  documents. This sample of words is used as a candidate indexing vocabulary. Then, all documents in the collection are indexed (their subject is defined) by using words from this candidate vocabulary. Document surrogates are formed in this step. Next, the VSM computes the *similarity of all the surrogates* in the collection according to

$$F = \sum_{i=1}^N \text{sim}(D_i, D_j) \tag{1}$$

for  $j = 2, \dots, N$  and  $i \neq j$ .

Where  $\text{sim}(D_i, D_j)$  measures the similarity between documents  $D_i$  and  $D_j$ . Usually,  $\text{sim}(D_i, D_j)$  is replaced by a function that relates any two vectors, such as the functions illustrated in Table 1. This procedure is repeated by using various candidate vocabularies. Finally, the candidate vocabulary that minimizes the expression in (1) is selected as the optimal indexing vocabulary [23]. The following example illustrates an application of the VSM with *binary surrogates*. The cosine coefficient is used to solve (1).

*Example 1* Let the words  $T_1, \dots, T_7$  be the set of all the words which were found in documents  $D_1$  and  $D_2$ . (In real practice, this set may contain hundreds or even thousands of words.) Next, let  $D_1$  and  $D_2$  be indexed with only four of these words. Hence, the question here is: what is the ‘optimal’ indexing vocabulary of four

words that make document  $D_1$  to be indexed with keywords that are minimally used by  $D_2$ ?

It is not difficult to realize that the number of candidate vocabularies of four words that can be formed out of seven words is equal to  $\binom{7}{4} = 35$ . Table 2 shows the similarities between  $D_1$  and  $D_2$  for only three vocabularies. The first column of this table shows these vocabularies. For example, words  $T_1, T_2, T_4$ , and  $T_7$  correspond to the first vocabulary. The second and third column show the binary surrogates of documents  $D_1$  and  $D_2$ . For instance, the surrogate  $D_1 = [1\ 0\ 1\ 1]$  indicates the absence of word  $T_2$  and the presence of words  $T_1, T_4$ , and  $T_7$  in  $D_1$ . Similarly, the surrogate for  $D_2 = [0\ 0\ 1\ 1]$  indicates the absence of  $T_1$  and  $T_2$  and the presence of words  $T_4$  and  $T_7$  in  $D_2$ . Finally, the fourth column shows the CC similarity values, or  $\text{sim}(D_1, D_2)$ , between  $D_1$  and  $D_2$  for the three vocabularies.

The CC similarity values in Table 2 indicate that when words  $T_3, T_4, T_5, T_6$  are used as indexing terms, the similarity of documents  $D_1$  and  $D_2$  is minimal. Furthermore, the similarity value  $\text{sim}(D_1, D_2) = 0.00$  indicates that both documents are completely different because their surrogates do not contain common words. Therefore, according to the VSM the optimal indexing vocabulary corresponds to terms  $T_3, T_4, T_5$ , and  $T_6$ . Thus, the other words  $T_1, T_2$ , and  $T_7$  can be discarded as indexing terms.

The solution presented in this table seems to be a trivial one. However, it can be easily shown that for realistic indexing problems such a solution can be quite an elaborate one. Suppose, for example, that the number of words extracted from  $D_1$  and  $D_2$  is not seven, but fifty (which still is a small number for realistic situations). Furthermore, if this time one is interested in finding candidate vocabularies of ten words, rather than combinations of four words, then the number of vocabularies that can be constructed is  $\binom{50}{10} = 10.27$  billions. That is, in addition to finding the minimization of (2), the VSM must also use an efficient search strategy to quickly eliminate many non optimal vocabularies. By the same token, it can be easily shown that if vocabularies of all sizes are considered, then the number of such vocabularies is determined by  $2^t - 1$  (where  $t$  is the number of extracted words), which even for moderate values of  $t$  this expression is a too large number.

As a result of these humongous searching spaces, researchers have been compelled to design fast heuris-

**Optimization in Classifying Text Documents, Table 1**  
Measures of vector similarity (taken from [22, Chap. 10])

similarity measure $\text{sim}(X, Y)$	Evaluation for binary term vectors	evaluation for weighted term vectors
inner product (IP)	$ X \cap Y $	$\sum_{i=1}^t x_i \cdot y_i$
dice coefficient (DC)	$2 \frac{ X \cap Y }{ X  +  Y }$	$2 \frac{\sum_{i=1}^t x_i \cdot y_i}{\sum_{i=1}^t x_i^2 + \sum_{i=1}^t y_i^2}$
cosine coefficient (CC)	$\frac{ X \cap Y }{ X ^{1/2} \cdot  Y ^{1/2}}$	$\frac{\sum_{i=1}^t x_i \cdot y_i}{\sqrt{\sum_{i=1}^t x_i^2 \cdot \sum_{i=1}^t y_i^2}}$
Jaccard coefficient (JC)	$\frac{ X \cap Y }{ X  +  Y  -  X \cap Y }$	$\frac{\sum_{i=1}^t x_i \cdot y_i}{\sum_{i=1}^t x_i^2 + \sum_{i=1}^t y_i^2 - \sum_{i=1}^t x_i \cdot y_i}$

$X = (x_1, \dots, x_i)$   
 $|X|$  = number of terms in  $X$ .  
 $|X \cap Y|$  = number of terms appearing jointly in  $X$  and  $Y$ .

Similarity  $\text{sim}(D_1, D_2)$  for three candidate vocabularies of four words

Vocabularies	Surrogates		$\text{sim}(D_1, D_2)$
	$D_1$	$D_2$	
$T_1, T_2, T_4, T_7$	[1011]	[0011]	0.50*
$T_2, T_4, T_5, T_6$	[0100]	[0110]	0.25
$T_3, T_4, T_5, T_6$	[0100]	[0011]	0.00

\* :  $\text{sim}(D_1, D_2) = 2 / (4^{1/2} \times 4^{1/2}) = 0.50$ .

tic search strategies at the expense of optimality. Furthermore, because the size of the indexing problem can be very large, suboptimal heuristic solutions have been preferred over optimal but slow ones [2].

### Optimization in the Classification of Text Documents

The process of document classification consists of grouping documents according to their underlying subject. Some examples of familiar document subjects are history, geography, music, engineering, etc. Usually, this underlying subject is determined by the set of indexing terms which was attached to each document. That is, documents about History share indexing terms whose content describes past events. Similarly, the in-

dexing terms of documents about geography share content which describes different geographic places on earth. Hence, the problem that this process of document classification attempts to solve is described as follows: Given samples of preclassified documents (i. e., their surrogates), the question is how to use the information contained in their surrogates such that new unclassified documents can be grouped into the appropriate classes.

There are many methodologies for solving this document classification problem. Some examples of such methodologies are: the vector space model for document classification [22]; fuzzy set theories [12] and [17]; semantic analysis methodologies [10] and [19]; and some others which use artificial intelligence approaches, [3], and [2]. To some extent all these methodologies use optimization in order to maximize (or minimize) some performance measure, which usually is the similarity between indexing terms. In what follows, we present only one methodology which is based on artificial intelligence and operations research approaches. This methodology is the one clause at a time (OCAT) algorithm [28] for the classification of examples (e. g., documents) in mutually exclusive classes. The OCAT algorithm uses optimization methodologies for constructing classification clauses (e. g., *word patterns*) of minimal (or near minimal) size. Figure 2 shows this algorithm.

```

Input:  E+ and E-
Output: Logical rules in CNF (or DNF) form.
        i = 1; C = ∅;
DO      WHILE (E- ≠ ∅)
1:      i ← i + 1; /* i indicates the ith iteration
        /
2:      find a clause ci which accepts all mem-
        bers of E+ while it rejects as many mem-
        bers of E- as possible;
3:      let E-(ci) be the set of members of E-
        which are rejected by ci;
4:      let C ← C + ci;
5:      let E- ← E- - E-(ci);
        END;
    
```

**Optimization in Classifying Text Documents, Figure 2**  
The one clause at a time (OCAT) algorithm

The OCAT algorithm is also a machine learning algorithm. It uses logical analysis and branch and bound approaches to extract knowledge (sets of rules) from sets of preclassified examples. It takes as input data samples of examples from (usually two) mutually exclusive classes and extracts knowledge that is represented in a compact form of key data patterns which can be used to classify new unclassified examples into these two classes.

The two mutually exclusive classes are referred to as the sets of positive and negative examples (denoted by  $E^+$  and  $E^-$ , respectively). Furthermore, the collections of examples in both classes are defined over the same set of parameters (also called atoms, characteristics, or factors) which are assumed binary valued. Figure 3 illustrates a set of four positive examples:  $e_1, e_2, e_3, e_4$  and a set of six negative examples:  $e_5, e_6, e_7, e_8, e_9, e_{10}$ . All ten examples are defined on the four atoms  $A_1, A_2, A_3$ , and  $A_4$ . For instance, example  $e_1 = [0\ 1\ 0\ 0]$  indicates the presence of atom  $A_2$  and the absence of atoms  $A_1, A_3$ , and  $A_4$  in  $e_1$ . On the other hand, example  $e_5 = [1\ 0\ 1\ 0]$  indicates that atoms  $A_1$  and  $A_3$  are present and that atoms  $A_2$  and  $A_4$  are absent.

When the OCAT algorithm is used to solve the document classification problem,  $E^+$  and  $E^-$  (i. e., the sets with the positive and negative examples, respectively) correspond to the sets of documents which belong to two mutually exclusive classes. That is, documents in the positive class are the ones that belong in only *one* of

$$\begin{aligned}
 E^+ &= \begin{matrix} e_1 \\ e_2 \\ e_3 \\ e_4 \end{matrix} \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \end{bmatrix} \\
 &\text{and} \\
 E^- &= \begin{matrix} e_5 \\ e_6 \\ e_7 \\ e_8 \\ e_9 \\ e_{10} \end{matrix} \begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 \end{bmatrix}
 \end{aligned}$$

**Optimization in Classifying Text Documents, Figure 3**  
Two illustrative sets of positive and negative examples

the two classes, while the documents in the other class are the negative examples. Hence, Fig. 3 may represent a set of ten documents (surrogates) which were indexed by using four keywords.

The OCAT algorithm is a greedy algorithm which determines a set of compact clauses either in the *conjunctive normal form* or *disjunctive normal form* (CNF or DNF, respectively, as defined below). For example, CNF clauses are determined as follows. In the first iteration it determines a clause that accepts all the examples in  $E^+$  while it rejects as many examples in  $E^-$  as possible. In the second iteration it performs the same operation using the original  $E^+$  set but this time the current  $E^-$  set contains only the negative examples that have not been rejected by any of the previous clauses. The iterations continue until the set of constructed clauses reject all the negative examples. Hence, when these CNF or DNF clauses are taken together, they accept all the positive examples while they reject all the negative examples.

The conjunctive normal form and disjunctive normal form (see, for example, [24]) are defined as in expressions (2) and (3), respectively.

$$\bigwedge_{j=1}^k \left( \bigvee_{i \in \rho_j} a_i \right), \tag{2}$$

$$\bigvee_{j=1}^k \left( \bigwedge_{i \in \rho_j} a_i \right). \tag{3}$$

Where  $a_i$  can be either  $A_i$  or  $\bar{A}_i$ . Thus, a CNF expression (also called a *logical clause*) over a vector  $v \in \{0, 1\}^t$  is a conjunction of disjunctions defined on the terms  $A_i$  ( $i = 1, \dots, t$ ). Similarly, a DNF expression is a disjunction of conjunctions on the same terms  $A_i$ .

Let  $n$  be the number of atoms and  $M_1$  the number of positive examples. It can be easily shown that the maximum number of clauses that can be formed using  $n$  atoms and  $M_1$  examples is equal to  $M_1$  [28]. To form these clauses consider the first example  $e_1 = [0\ 1\ 0\ 0]$ . It can be observed that in order to accept this positive example at least one of the four atoms  $A_1, A_2, A_3, A_4$  must be specified as follows: ( $A_1 = \text{FALSE}$ ; i. e.,  $\bar{A}_1 = \text{TRUE}$ ), ( $A_2 = \text{TRUE}$ ), ( $A_3 = \text{FALSE}$ ; i. e.,  $\bar{A}_3 = \text{TRUE}$ ), and ( $A_4 = \text{FALSE}$ ; i. e.,  $\bar{A}_4 = \text{FALSE}$ ). Hence, any valid CNF clause must include  $\bar{A}_1$ , or  $A_2$ , or  $\bar{A}_3$ , or  $\bar{A}_4$ . Similarly, the second positive example  $e_2 = [1\ 1\ 0\ 0]$  indicates that any valid CNF clause must include  $A\bar{A}_1$ , or  $A\bar{A}_2$ , or  $\bar{A}_3$ , or  $\bar{A}_4$ . In this manner, all valid CNF clauses must include at least one atom as specified from each of the following sets:  $\{\bar{A}_1, A\bar{A}_2, \bar{A}_3, \bar{A}_4\}$ ,  $\{A\bar{A}_1, A\bar{A}_2, \bar{A}_3, \bar{A}_4\}$ ,  $\{\bar{A}_1, \bar{A}_2, A_3, A\bar{A}_4\}$ , and  $\{A_1, \bar{A}_2, \bar{A}_3, A_4\}$ . Relation (4) shows a CNF system which was derived by using the OCAT algorithm on the examples in Fig. 3:

$$(A_2 \vee A_4) \wedge (\bar{A}_2 \vee \bar{A}_3) \wedge (A_1 \vee A_3 \vee \bar{A}_4). \quad (4)$$

*Example 2* An application of the OCAT algorithm can be illustrated by using a new example, say,  $e_{11} = [0\ 0\ 1\ 0]$ . When  $e_{11}$  is 'tested' by the above CNF expression, then it can be seen that  $e_{11}$  is classified as a negative example. This is as follows. The clause  $A_2 \vee A_4$  evaluates to 0 because  $e_{11}$  does not contain neither the second nor the fourth atoms. On the other hand, both clauses  $\bar{A}_1 \vee \bar{A}_3$  and  $A_1 \vee A_3 \wedge \bar{A}_4$  evaluate to 1. However, when the three clauses are taken together, expression (4) evaluates to 0, thus indicating that  $e_{11}$  is a negative example.

## Conclusions and Future Research

This article illustrated some contributions of optimization for solving the document classification problem. These contributions were illustrated by presenting three cases (application areas) in which optimization has been used. The first case dealt with the principle of least effort (PLE) which is used for the selection of an indexing vocabulary based solely in the frequency of the co-occurring words. The second case dealt with

the vector space model (VSM) for the selection of an indexing vocabulary that minimizes the overlapping of words used in various documents (or in various document classes). The third case illustrated the one clause at a time (OCAT) algorithm for the classification of documents into mutually exclusive classes.

A common characteristic of these three cases is the huge amounts of information that need to be processed before optimal solutions can be found. Therefore, the optimization techniques presented in these examples have been used extensively only on document classification problems of small size. The main reason for this limitation is that even with the current computerized technologies, these techniques would take unacceptable processing times to find optimal solutions for larger classification problems. As a consequence, scientific research efforts have focused their attention in developing effective and efficient heuristics for solving problems of more realistic size.

### Keywords

Linear programming; Mixed integer programming; Integer programming; Nonlinear programming; Multi-objective optimization; Cutting-stock problem; Load dispatching; Energy modeling; Group decision making

The engine is an essential part of a motor car but it is useless if it is not embedded in a car body with chairs, windshields, tyres, brakes, etc. Similarly, an optimization algorithm is useless if it is not embedded in an appropriate model and if it is not linked to the outside world via a system that helps the decision makers to use the data and the model.

Optimization systems may be found at all levels of decision making: at the level of operational planning with a short-term horizon (hours or days), such as the scheduling of the production of corrugated cardboard, glass, iron, and steel, the operational control of a water-management system, and the *load dispatching* in electricity generation; at the level of tactical planning with a medium-term horizon (months), such as the capacity planning of assembly-line production; and at the level of strategic planning with a long-term horizon (years), such as the choice of a strategy for the national energy

supply or the design of the infrastructure of a water-management system. In what follows we shall describe some of these systems in more detail.

In the voluminous literature on *linear programming* applications one constantly comes across references to the *cutting-stock problem* or the trimloss problem in the corrugated-cardboard industry, where long strips or rectangular plates of material are cut into smaller rectangles. The objective is to set the circular and the guillotine cutters in such a way that the cardboard production machine supplies the required number of rectangular plates for each client with a minimum of waste. Real-life conditions on the factory floor impose additional requirements, such as the reduction of the set-up costs due to the resetting of the cutters, which cannot be formulated in pure linear programming terms. They can be allowed for in a *mixed integer programming* model but this tends to become intractable for existing numerical methods because the number of zero-one variables may be large. A more successful approach is the generation of a number of promising cutting patterns followed by the selection of a small number of patterns for the actual production of corrugated cardboard. This is a pure *integer programming* formulation of the trimloss problem. An additional complication is that the format of the rectangular plates is not necessarily hard. Under certain conditions the planners may deviate from the ordered dimensions, and also from the required number of plates. This greatly alleviates their task to reduce the losses of time and material as much as possible. An interesting feature of the systems for the planning of cardboard production is that they do not only reduce the losses, but they also contribute to a smooth processing of orders, planning lists, deliveries, and invoices. Thus, these systems do not only tend to control the actual production but they also support the administrative processes in the factory.

Electricity generation is subject to the iron law that demand has to be satisfied, as and when it occurs. Under these constraints electricity companies usually pursue the economic objective of minimizing the fuel costs. The calculation of the cheapest production schedule is divided into several parts, each with its own time horizon. One of these parts is the static dispatch problem, the allocation of the electricity demand predicted for the next fifteen or sixty minutes to the available power

units. Another part is the unit-commitment problem, the daily selection of the units for actual production. In its mathematical form the *dispatch problem* can be written as the minimization of a nonlinear fuel-cost function subject to a linear demand constraint whereas upper and lower bounds are imposed on the variables. In general, the fuel-cost function can be simplified and written as a convex, separable, quadratic function of the loads assigned to the respective power units. The dispatch problem is accordingly a quadratic continuous knapsack problem which, in its primal form, can efficiently be solved via gradient methods for *nonlinear optimization*. A dramatic acceleration occurs when the dispatch problem is considered in its dual form. In each step, after the unconstrained minimization of the associated Lagrangian function, one can immediately find a number of variables which are at their optimal values so that they can be removed from the problem formulation. This rapidly reduces the size of the dispatch problem [1]. More strongly, it implies that the dispatch problem can efficiently and reliably be solved, even if there are hundreds of variables. This problem size is normal in the electricity generation for a country of 15 or 20 million inhabitants.

After the oil crisis of the early 1970s many countries stimulated the development of so-called energy models which could be used to analyze long-term strategies for the national energy supply via linear programming. Such a model has three parts at a high aggregation level: winning and/or import of primary energy carriers like crude oil, natural gas, and coal; conversion (refineries and power plants) into secondary energy carriers like petrol and electricity; and consumption in various sectors of the national economy like heavy industry, light industry, transportation, and households. Because there is a flow of materials from winning/import to consumption, the linear programming model is largely a network flow model. In the first and the second part there are certain limits to be set by the decision makers: upper limits on import and winning, and upper limits on the nuclear capacity for electricity generation, for instance. In the third part the decision makers can introduce the scenario-dependent projections of the future energy demand. In practice, since the supply of oil and natural gas is in the hands of large multi-national companies, these models are mainly concerned with strategies for the national elec-

tricity supply. For a prespecified year, using as input the projection of the electricity demand in various sectors of the economy, the projected prices of primary energy carriers, the estimates of the investment costs of new energy technologies, and the estimated supply restrictions, capacity limitations, and conversion efficiencies, the linear programming model yields an optimal mix of secondary energy carriers and technologies. An obvious extension of an *energy model* is the incorporation of multiple objective functions representing the policy objectives:

- a) to minimize the environmental damage;
- b) to maximize the
  - economic benefits;
  - safety of the energy system;
  - strategic independence of the country.

The analysis of the model usually shows that the exploitation of nuclear energy is strongly in conflict with the exploitation of fossil fuels. Nuclear energy is felt to reduce the safety of the energy system, but it also reduces the environmental damage of CO<sub>2</sub> and NO<sub>x</sub> emissions, and it enhances the strategic independence by the reduction of crude-oil imports.

In the 1980s energy modeling strongly contributed to the popularity of scenario analysis. It became fashionable to explore the future and to judge various long-term strategies for the national electricity generation within the framework of a number of scenarios. The increasing electricity demand could be covered by an increased nuclear capacity, by the construction of new and more powerful fossil-fuel plants, and/or by international cooperation and diversification. Scenarios were designed as follows. First, the factors were identified which would affect the economic, political, and social developments until a predetermined horizon and which were beyond the decision maker's control. Because these factors are mostly interconnected, the hypothetical future developments could be bundled in a small number of coherent scenarios. Strategic planners designed a trend-following business-as-usual scenario where the current developments were smoothly continued, an optimistic scenario where the developments proceeded in an upward direction, and a pessimistic scenario with a less upward or even downward direction of the future developments. Each strategy had certain desirable and/or undesirable consequences within the context of the respective scenarios.

These consequences could be evaluated via the analysis of linear programming energy models, at least to some extent. In choosing a strategy, the decision makers would have to weigh the consequences and to take into account the scenario probabilities. This complicated process was usually prepared in a network of policy committees and advisory councils who were expected to suggest a preferred strategy on the basis of a national energy outlook [2] with a horizon of ten or twenty years.

The decision support systems just described have been used for decades. The systems for operational planning support the short-term decisions of the planners who work in situations where the rules and the data are fairly well-known. Nevertheless, even in short-term planning the objectives and the constraints are not necessarily hard. The planners in a corrugated-cardboard factory, for instance, have to find a compromise between the objective to minimize the losses of material and the objective to smooth the administrative processes on the factory floor. The demand constraints may also be relaxed. The planners may deviate from the required dimensions, and they may ask the clients, either to order a larger quantity of rectangular plates now, or to postpone the delivery to the next planning period, because the order can nicely be combined with the order of another regular client.

In the systems for strategic planning, not only the rules and the data are imprecise, but also the users are difficult to identify. Strategic planning is largely a distributed decision-making process wherein many actors are involved: members of policy committees and advisory councils, managers of energy-producing companies, representatives of trade unions, members of pressure groups, the press, etc. They all have contradictory views and conflicting objectives in the energy sector, and they have widely varying power positions. In the eighties their views have been analyzed via multicriteria decision analysis and *multi-objective optimization* [3]. The study clearly identified the critical issues in the energy debate: safety and environmental protection. The proposed compromise solution to the long-term energy supply problem contained a significant contribution of nuclear energy so that it was ignored after the Chernobyl disaster.

In the late 1980s the study had to be taken up again because the choice of primary energy carriers cannot

be postponed indefinitely, certainly not when obsolete power plants have to be redesigned and replaced within the next planning period [5]. There were several options: new nuclear power plants, or larger and more sophisticated fossil-fuel plants using oil, coal, or natural gas. The objectives of the electricity companies were clear. The two small nuclear power plants in the country covered some 7% of the national demand, and the companies were convinced that the nuclear option should be increased. However, any proposal to start the design of a new nuclear plant would be rejected by the Ministry of Economic Affairs: it would politically be unfeasible. Hence, in order to avoid a negative decision that would be irreversible for a period of ten or twenty years, the electricity companies proposed to cover the peak demand in the next planning period via special contracts with foreign companies. This strategy would enable them to delay the design of nuclear power plants beyond the planning horizon of ten years. The compromise appeared to be acceptable, at least in the late eighties, and even today the consequences do not constitute an issue for the political parties and the environmental groups. The domestic nuclear capacity will be closed down within a few years, but by the electricity imports from neighboring countries the national economy will remain dependent on nuclear power, even more than in the 1980s.

We have briefly summarized the course of events in order to sketch the fortunes of a decision support system in a field full of controversies. The system cannot dictate a solution, but it can easily identify the conflicting views of the actors and the relative importance of their arguments. It makes the criteria operational because it shows the effects of the weights assigned to them.

Particular attention must be given to the interface with the decision makers. Many decisions are made in groups: in boards, councils, committees, where the members have contradictory views, opinions, aspirations, and power positions. Single-objective optimization models therefore tend to be inadequate. A realistic model has multiple objective functions, and usually these functions have different weights for the decision makers. In fact, multi-objective optimization has two subfields: the identification of the nondominated solutions, and the selection of a nondominated solution where the objective functions are felt to be in a proper

balance. The first-named subfield can be studied in the splendid isolation of mathematical research. The second subfield, however, straddles the boundary between mathematics and other disciplines because human subjectivity is an integral part of the selection process. One cannot just leave it to an optimization expert to formulate a model and to calculate an acceptable nondominated solution. At various stages the expert has to interrupt the computational process in order to fathom the preferences of the decision makers. Certain parameters (weights, targets, desired levels) are adjusted on the basis of new preference information, whereafter the computations proceed in a somewhat modified direction. It is not always clear, however, how the parameters should be adjusted in order to guarantee a rapid convergence towards an acceptable compromise. This is crucial because decision makers cannot spend much time on a particular decision problem. It is an illusion to think that many interruptions would be possible to elicit preference information. One or two sessions of the decision-making body, communication via the mail and the telephone in the time intervals between interruptions, and that's all.

In the 1980s, experts could work with questionnaires to fathom the preferential feelings in a group. The decision makers leisurely answered the questions in their office or at home, and returned the responses via the mail. In the next session of the group the calculated results were available for discussion [3]. Today, however, information technology provides sophisticated facilities for *group decision making*. Group Decision Rooms with networked PCs and a public screen for electronic brainstorming and weighted voting are commercially available. The sessions in a GDR have more impact than the questionnaires. First, the technology of the GDR eliminates the advantages of certain discussion techniques. The group members with strong verbal skills who usually dominate a meeting lose their grip on the silent majority as soon as the buttons are to be pressed. Second, the anonymous brainstorming and voting procedures promote an egalitarian attitude in the group (this may be a stumbling block in authoritarian cultures where decisions are deferred to the boss). GDR sessions create a certain commitment among the participants, possibly due to the intense communication, so that the decisions cannot easily be reverted thereafter. In summary, one may observe

a power shift in a GDR which strongly affects the choice of a strategy [4].

MPEC; Bilevel programming; Piecewise sequential quadratic programming method; Disjunctive programming; Parametric variational inequalities; Parametric complementarity problems; KKT conditions

The *piecewise sequential quadratic programming* (PSQP) method is a numerical method for solving certain mathematical programs with equilibrium constraints (MPEC), based on the classical sequential quadratic programming (SQP) method for nonlinear programming (NLP) problems [2,12]. This description draws on both [9] and [6], which extend the original proposal for PSQP [13] that was restricted to the case of MPEC with linear complementarity constraints. See [7] for a brief account of an application of PSQP to a problem in civil engineering. Its performance on randomly generated quadratic programs with affine equilibrium constraints is documented in [6] and also in [9,10].

PSQP can be applied directly to any MPEC whose lower-level problem is a mixed complementarity problem, and indirectly to any MPEC where the lower-level problem belongs to the class of variational inequalities (cf. also ► [Variational inequalities](#)) (VI) that can be written via its Karush–Kuhn–Tucker conditions (KKT conditions).

The formulation of the KKT-constrained MP is

$$\begin{cases} \min & f(x, y) \\ \text{s.t.} & G(x, y) \leq 0, \\ & F(x, y) + \sum_{i=1}^{\ell} \lambda_i \nabla_y g_i(x, y) = 0, \\ & \lambda \geq 0, g(x, y) \leq 0, \lambda^\top g(x, y) = 0, \end{cases} \quad (1)$$

where  $f: \mathbf{R}^{n+m} \rightarrow \mathbf{R}$ ,  $G: \mathbf{R}^{n+m} \rightarrow \mathbf{R}^s$  and  $F: \mathbf{R}^{n+m} \rightarrow \mathbf{R}^m$ , are twice continuously differentiable;  $g: \mathbf{R}^{n+m} \rightarrow \mathbf{R}^\ell$  is thrice continuously differentiable; and  $\nabla_y g_i(x, y)$  is the gradient with respect to  $y$  of  $g_i$  at  $(x, y)$ . This is a special case of MPEC with mixed complementarity constraints. It includes the subclass of MPEC whose equilibrium constraints are nonlinear complementarity problems by taking  $g(x, y) = -y$ . Note that to ease notation, equality constraints have been omitted in the constraints both at the upper level ( $G(x, y) \leq 0$ ) and the lower level ( $g(x, y) \leq 0$ ); these can be included without any difficulties.

A selection of MPEC applications including Stackelberg games, network design, and design of mechanical structures, is given in the monograph [9]. Also note that in many cases the equilibrium constraints arise as

the first order conditions of a (usually convex) optimization problem, in which case an MPEC problem is closely related, if not equivalent to a bilevel program (cf. also ► **Bilevel programming: Introduction, history and overview**). The volume [1] is a good source of applications of hierarchical optimization; see also the volume containing [10].

For comparison, and also later reference in the section on mathematical programs with affine equilibrium constraints, consider the general MPEC with upper-level constraints  $G(x, y) \leq 0$  and the equilibrium constraint that, given  $x, y$  solves the parametric variational inequality  $VI(F(x, \cdot), C(x))$ , i. e.

$$y \in C(x), \quad \forall y' \in C(x), \quad F(x, y)^\top (y' - y) \geq 0, \quad (2)$$

where  $C(x) = \{y: g(x, y) \leq 0\}$ . Under some conditions on the vector function  $g$ , any pair  $(x, y)$  satisfying these constraints is associated with a KKT multiplier  $\lambda$  such that  $(x, y, \lambda)$  is feasible for (1). One such condition is that  $g$  is affine, i. e. linear plus a constant; another is that each component function  $g_i$  is convex and that the Slater constraint qualification holds: There exists  $\hat{y}$  such that  $g_i(x, \hat{y}) < 0$  for all  $i$ . Conversely, under convexity of  $g$ , each feasible point  $(x, y, \lambda)$  of (1) satisfies the general MPEC constraints.

**Local Decomposition of the Feasible Set**

Let  $\mathcal{F}^{\text{KKT}}$  denote the set of feasible points  $(x, y, \lambda) \in \mathbf{R}^{n+m+\ell}$  of (1). Let  $\bar{w} = (\bar{x}, \bar{y}, \bar{\lambda}) \in \mathcal{F}^{\text{KKT}}$ . For any other feasible point  $(x, y, \lambda)$ , the conditions

$$\lambda \geq 0, \quad g(x, y) \leq 0, \quad \lambda^\top g(x, y) = 0,$$

imply *complementarity*: For each  $i$ , either  $\lambda_i = 0$  or  $g_i(x, y) = 0$ . It follows for each  $(x, y, \lambda) \in \mathcal{F}^{\text{KKT}}$  near  $((\bar{x}, \bar{y}, \bar{\lambda}))$ , that  $(x, y, \lambda)$  is also feasible for some nonlinear program of the form

$$\left\{ \begin{array}{l} \min \quad f(x, y) \\ \text{s.t.} \quad G(x, y) \leq 0, \\ \quad \quad L(x, y, \lambda) = 0, \\ \quad \quad \forall i \in \mathcal{J}_1 \quad \begin{cases} \lambda_i = 0, \\ g_i(x, y) \leq 0, \end{cases} \\ \quad \quad \forall i \in \mathcal{J}_2 \quad \begin{cases} \lambda_i \geq 0, \\ g_i(x, y) = 0, \end{cases} \end{array} \right. \quad (3)$$

where  $L(x, y, \lambda) = F(x, y) + \sum_i \lambda_i \nabla_y g_i(x, y)$  and the index sets  $\mathcal{J}_1, \mathcal{J}_2$  partition  $\{1, \dots, \ell\}$  such that  $\mathcal{J}_1 \supseteq \{i: g_i(\bar{z}) < 0\}$  and  $\mathcal{J}_2 \supseteq \{i: \lambda_i > 0\}$ .

For each such pair  $(\mathcal{J}_1, \mathcal{J}_2)$ , the feasible set of (3) is called a *branch of the feasible set*  $\mathcal{F}^{\text{KKT}}$  at  $\bar{w}$ . Decomposition is given by an easy but critical observation: The union of the branches (3) of  $\mathcal{F}^{\text{KKT}}$  at a feasible point  $\bar{w}$  is a neighborhood of  $\bar{w}$  in  $\mathcal{F}^{\text{KKT}}$ .

Each branch can be called a ‘local piece’ of  $\mathcal{F}^{\text{KKT}}$ . The PSQP method takes advantage of this piecewise, or disjunctive, or decomposition approach to  $\mathcal{F}^{\text{KKT}}$ , hence is one of the class of *disjunctive programming* methods.

A decomposition scheme at infeasible points is required, to allow for disjunctive methods that work with infeasible iterates. This decomposition is based on another easy observation that for a point  $(\bar{z}, \bar{\lambda}) \in \mathcal{F}^{\text{KKT}}$ , where  $\bar{z} = (\bar{x}, \bar{y})$ :

$$\begin{aligned} \{i: g_i(\bar{z}) < 0\} &= \{i: g_i(\bar{z}) + \bar{\lambda}_i < 0\}, \\ \{i: \bar{\lambda}_i > 0\} &= \{i: g_i(\bar{z}) + \bar{\lambda}_i > 0\}. \end{aligned}$$

Let  $w = (x, y, \lambda) \in \mathbf{R}^{n+m+\ell}$  with  $\lambda \geq 0$ , and write  $z = (x, y)$ . Let  $\mathcal{A}(w)$  denote the family of index set pairs  $(\mathcal{J}_1, \mathcal{J}_2)$  that partition  $\{1, \dots, \ell\}$  and satisfy

$$\begin{cases} \mathcal{J}_1 \supseteq \{i: g_i(z) + \lambda_i < 0\}, \\ \mathcal{J}_2 \supseteq \{i: g_i(z) + \lambda_i > 0\}. \end{cases} \quad (4)$$

**The Algorithm**

Consider multiplier vectors, called *MPEC multipliers*,  $\chi \in \mathbf{R}^s$  and  $\pi \in \mathbf{R}^m$  and  $\eta \in \mathbf{R}^\ell$  corresponding to the constraints  $G(z) \leq 0, L(z, \lambda) = 0$  and the block of constraints  $g_i(z) \leq (=) 0$ , respectively; and define the *MPEC Lagrangian* as

$$\begin{aligned} \mathcal{L}^{\text{MPEC}}(z, \lambda, \zeta, \pi, \eta) \\ = f(z) + \zeta^\top G(z) - \pi^\top L(z, \lambda) + \eta^\top g(z). \end{aligned}$$

Multipliers corresponding to the constraints  $\lambda_i \geq 0$  (or  $= 0$ ) are omitted here and in the sequel, since these turn out not to play a role in the PSQP method as a result of being linear.

PSQP can now be presented. At iteration  $k$ , given  $w^k = (z^k, \lambda^k)$  and a triple of multipliers  $v^k = (\chi^k, \pi^k, \eta^k)$ , pick an arbitrary member  $(\mathcal{J}_1, \mathcal{J}_2)$  of  $\mathcal{A}(w^k)$ . Corresponding to this pair  $(\mathcal{J}_1, \mathcal{J}_2)$ , form the quadratic program associated with the NLP (3) at  $(z^k, \lambda^k)$ ; the variables of this quadratic program are given by the vector  $dw = (dz, d\lambda)$ , with  $dz = (dx, dy)$ :

$$\left\{ \begin{array}{l} \min \quad \nabla f(z^k)^\top dz \\ \quad \quad + \frac{1}{2} dw^\top \nabla_{ww}^2 \mathcal{L}^{\text{MPEC}}(w^k, v^k) dw \\ \text{s.t.} \quad G(z^k) + \nabla G(z^k) dz \leq 0, \\ \quad \quad L(w^k) + \nabla L(w^k) dw = 0, \\ \quad \quad \forall i \in \mathcal{J}_1 \quad \begin{cases} (\lambda^k + d\lambda)_i = 0, \\ g_i(z^k) + \nabla g_i(z^k)^\top dz \leq 0, \end{cases} \\ \quad \quad \forall i \in \mathcal{J}_2 \quad \begin{cases} (\lambda^k + d\lambda)_i \geq 0, \\ g_i(z^k) + \nabla g_i(z^k)^\top dz = 0. \end{cases} \end{array} \right. \quad (5)$$

Here gradients of real-valued functions are denoted by  $\nabla$ , e.g.  $\nabla f(z^k)$ ; whereas the derivative  $\nabla G(z^k)$  is the  $s \times (n+m)$  Jacobian matrix of  $G$  at  $z^k$ ; and  $\nabla_{ww}^2 \mathcal{L}^{\text{MPEC}}(w^k, v^k)$  is the Hessian or second-derivative matrix, with respect to  $w$ , of the MPEC Lagrangian at  $(w^k, v^k)$ . A KKT tuple of this quadratic program will be used to define the next iterate.

The PSQP method for (1) is summarized below.

Recall, for use in Step 1, the definition of a stationarity: A point  $z$  is *stationary* for the general nonlinear program

$$\left\{ \begin{array}{l} \min \quad f(z) \\ \text{s.t.} \quad h(z) = 0, \\ \quad \quad g(z) \geq 0, \end{array} \right. \quad (6)$$

for smooth functions  $f, g, h$ , if there are vectors  $\lambda_h$  and  $\lambda_g$ , with dimensions matching  $h(z)$  and  $g(z)$ , respectively, such that the KKT conditions hold:  $\nabla f(z) + \nabla h(z)^\top \lambda_h + \nabla g(z)^\top \lambda_g = 0$ ,  $h(z) = 0$ ,  $g(z) \leq 0$ ,  $\lambda \geq 0$  and  $\lambda^\top g(z) = 0$ . See [6] for details on using approximate stationarity in Step 1, namely checking whether the KKT conditions approximately hold, instead of stationarity.

0. Let  $w^0 = (z^0, \lambda^0) \in \mathbf{R}^{n+m} \times \mathbf{R}_+^\ell$ ,  $v^0 = (\zeta^0, \pi^0, \eta^0) \in \mathbf{R}^{s+m+\ell}$ ,  $\mathcal{A}^0 = \mathcal{A}(w^0)$ , and  $k = 0$ .
1. (Direction finding.)  
Choose a pair  $(\mathcal{J}_1^k, \mathcal{J}_2^k) \in \mathcal{A}^k$ .  
IF the QP (5) is found to be the infeasible or unbounded below, THEN go to Step 3.  
ELSE find a stationary point  $dw$  of (5), with multipliers  $v = (\zeta, \pi, \eta)$  as above.  
IF  $dw = 0$  (hence  $w^k$  is stationary for (3)) THEN go to 3.
2. (Serious step.)  
Let  $w^{k+1} = w^k + dw$ ,  $v^{k+1} = v$ , and  $\mathcal{A}^{k+1} = \mathcal{A}(w^{k+1})$ . Let  $k = k + 1$  and go to Step 1.
3. (Null step.)  
Let  $w^{k+1} = w^k$ ,  $v^{k+1} = v^k$ ,  $\mathcal{A}^k = \mathcal{A}^k \setminus \{(\mathcal{J}_1^k, \mathcal{J}_2^k)\}$ , and  $k = k + 1$ .
4. (Stopping rule.)  
IF the stopping condition is satisfied THEN STOP ELSE go to 1.

**Algorithm PSQP**

At each iteration PSQP selects a nonlinear program, indexed by  $(\mathcal{J}_1, \mathcal{J}_2)$ , and updates  $(w^k, v^k)$  to  $(w^{k+1}, v^{k+1})$  by applying one step of the SQP method to this subproblem. The idea of selecting one of possibly several subproblems at each iteration is based on the *Kojima-Shindo method* [8] for solving piecewise smooth equations  $\Phi(x) = 0$ , where the mapping  $\Phi: \mathbf{R}^n \rightarrow \mathbf{R}^n$  is the continuous selection of a finite family of smooth functions  $\{\Phi^i\}$  each of which maps  $\mathbf{R}^n$  to itself. Given  $x^k \in \mathbf{R}^n$ , an arbitrary index  $i = i(k)$  is chosen with  $\Phi(x^k) = \Phi^i(x^k)$ , and then  $x^k$  is updated to  $x^{k+1}$  by applying a single Newton iteration to  $\Phi^i$  at  $x^k$ .

Superlinear or quadratic convergence of PSQP and of the method of [8] can be shown under appropriate conditions.

Moreover, PSQP can be viewed as a localized version of previous disjunctive approaches to finding global solutions of MPEC rather than local solution or stationary points. For instance, papers on finding global optima are given in [11], and [5]. In connection with the latter on a branch and bound approach, note that the concept of the relaxed problem, like the problem (7), can be used to generate bounds for approximating the global optimal value of an MPEC. Both [5] and [11] address problems which can be cast as MPEC with

affine equilibrium constraints; these will be discussed in a later section.

To discuss stopping conditions for Step 4, observe that if all branches of  $\mathcal{F}^{\text{KKT}}$  at the current point  $w^k$  are such that  $w^k$  is stationary for each of the associated nonlinear programs (3), then  $w^k$  is stationary for the MPEC. This follows because the union of branches of  $\mathcal{F}^{\text{KKT}}$  at  $w^k$  form a neighborhood of  $w^k$  in  $\mathcal{F}^{\text{KKT}}$ .

A) (Stopping condition A)  $\mathcal{A}^k = \emptyset$ .

Stopping condition A requires an exhaustive check of stationarity of  $w^k$  for each NLP (3) where  $(\mathcal{J}_1, \mathcal{J}_2) \in \mathcal{A}(w^k)$ . Thus, if  $w^k$  is a local minimizer, then verifying stationarity at  $w^k$  amounts to checking stationarity of the current point for  $2^\beta$  nonlinear programs where  $\beta$  is the cardinality of the set  $\mathcal{I}_0(w^k) = \{i: g_i(z^k) = 0 = \lambda_i^k\}$ .

To provide a more efficient stopping rule, introduce the *relaxed nonlinear program* at  $w^k$ , in which the complementarity condition  $\lambda_i g_i(x, y) = 0$  is relaxed for indices  $i$  in  $\mathcal{I}_0(w^k)$ . Let  $\mathcal{I}_+(w^k) = \{i: g_i(z^k) < \lambda_i^k\}$ ,  $\mathcal{I}_-(w^k) = \{i: g_i(z^k) > \lambda_i^k\}$ . The relaxed NLP is:

$$\left\{ \begin{array}{l} \min \quad f(x, y) \\ \text{s.t.} \quad G(x, y) \leq 0, \\ \quad \quad L(x, y, \lambda) = 0, \\ \quad \quad g_i(x, y) \leq 0 = \lambda_i, \quad \forall i \in \mathcal{I}_+(w^k), \\ \quad \quad g_i(x, y) \leq 0 \leq \lambda_i, \quad \forall i \in \mathcal{I}_0(w^k), \\ \quad \quad g_i(x, y) = 0 \leq \lambda_i, \quad \forall i \in \mathcal{I}_-(w^k). \end{array} \right. \quad (7)$$

Our interest in the relaxed NLP stems from the obvious fact that if  $w^k \in \mathcal{F}^{\text{KKT}}$ , then the feasible set of (7) contains every branch of  $\mathcal{F}^{\text{KKT}}$  at the current iterate  $w^k$ . Hence if the current iterate is stationary for (7), then it must also be stationary for the MPEC (1).

B) (Stopping condition B.) Either  $\mathcal{A}^k = \emptyset$  or  $w^k$  is a stationary point of (7) with corresponding multipliers  $v^k$  (corresponding to  $G, L$  and  $g$ ).

Stopping condition B, first used in [10], is an often effective heuristic to reduce the number of branches examined (null steps executed) in order to either identify a stationary point of the MPEC, or find a branch where progress can be made. It is guaranteed to verify or disprove stationarity by checking just one branch [10], provided that the active constraints at  $w^k$  of the relaxed nonlinear program (7) have linearly independent gradients. Also, see computational examples in [6,10],

where the algorithm executes considerably fewer null steps when using stopping condition B instead of the exhaustive stopping condition A, even when the relaxed NLP has linearly dependent active gradients.

### Convergence of PSQP

Superlinear local convergence of the PSQP algorithm can be shown if, as well as a second order condition, there is a uniqueness condition on the optimal multipliers associated with each nonlinear program (3) for relevant pairs of index sets  $(\mathcal{J}_1, \mathcal{J}_2)$ . The proof of convergence [9] relies on the convergence analysis of [2] and [12], which applies to stationary points of nonlinear programs such that the corresponding KKT multipliers are unique and the second order sufficient optimality condition holds. For superlinear convergence of PSQP it is also needed that the optimal multipliers be independent of the pairs  $(\mathcal{J}_1, \mathcal{J}_2)$ , so that the current value of the multipliers is (locally) a reasonable estimate for the NLP subproblem corresponding to any branch.

Recall the *second order sufficient condition* for the general nonlinear program (6); this condition will be needed below for the NLP associated with each branch of  $\mathcal{F}^{\text{KKT}}$  at a solution point of the KKT-constrained MP. Let  $\bar{z}$  be a stationary point of the NLP (6). For convenience assume (as below) that the associated KKT multipliers  $\lambda_g, \lambda_h$  are unique. Let  $H$  be the Hessian matrix, with respect to  $z$ , at  $z = \bar{z}$  of the Lagrangian mapping  $f(z) + \lambda_h^\top h(z) + \lambda_g^\top g(z)$ ; and  $\mathcal{C}$  be the *critical cone* of (6) at  $\bar{z}$ , namely the set of vectors  $d$  in  $z$ -space such that  $\langle \nabla f(\bar{z}), d \rangle = 0, \nabla h(\bar{z})d = 0$ , and  $\nabla g_i(\bar{z})d \leq 0$ , where  $\nabla g(\bar{z})_I$  is the submatrix of the Jacobian of  $g$  at  $\bar{z}$  consisting of rows  $i$  such that  $i(\bar{z}) = 0$ . The second order sufficient condition says that  $H$  is strictly copositive on  $\mathcal{C}$ , i. e.  $d^\top H d > 0$  for  $0 \neq d \in \mathcal{C}$ .

The main convergence result for PSQP is:

**Theorem 1** *In the context of the KKT-constrained MPEC (1), let the functions  $f$  and  $F$  be twice continuously differentiable, and  $g$  be thrice continuously differentiable. Let  $\bar{w} = (\bar{x}, \bar{y}, \bar{\lambda})$  be a point in  $\mathcal{F}^{\text{KKT}}$  and  $\bar{v} = (\bar{\zeta}, \bar{\pi}, \bar{\eta}) \in \mathbf{R}^{s+m+\ell}$  be such that, for each  $(\mathcal{J}_1, \mathcal{J}_2)$  in  $\mathcal{A}(\bar{w})$ ,*

- 1)  $\bar{w}$  is stationary for (3);
- 2)  $\bar{v}$  is the unique KKT multiplier for (3) associated with  $\bar{w}$ ; and

3) the second order sufficient condition for (3) holds at  $\bar{w}$ .

Then  $\bar{w}$  is a strict local minimizer of the MPEC (1). Moreover, for each  $(w^0, v^0)$  sufficiently close to  $(\bar{w}, \bar{v})$ , the PSQP algorithm is well defined and produces a sequence  $\{(w^k, v^k)\}$  that converges  $Q$ -superlinearly to  $(\bar{w}, \bar{v})$ . Finally, convergence is  $Q$ -quadratic if, in addition,  $\nabla^2 f$ ,  $\nabla^2 F$  and  $\nabla^3 g$  are Lipschitz continuous near  $(\bar{x}, \bar{y})$ .

If  $(\bar{x}, \bar{y}, \bar{\lambda}) \in \mathcal{F}^{\text{KKT}}$  is stationary for the relaxed NLP (7), it is clear that the linear independence constraint qualification for (7) at this point – linear independence of gradients of the constraints that are active at  $(\bar{x}, \bar{y}, \bar{\lambda})$  – implies the uniqueness condition on the multipliers  $\bar{v} = (\bar{\zeta}, \bar{\pi}, \bar{\eta})$  required in the above result.

The above convergence result is local in the sense that a starting point near to an eventual solution point is needed. To improve the performance of the method particularly from starting points that may be far from being optimal, it is typical in the context of nonlinear programming to use a line search or trust region strategy [3]. See [6] for a line search approach to MPEC where the objective function  $f$  is smooth and convex, the upper constraints are affine, and the lower or equilibrium constraints form an affine variational inequality. (PSQP also has special properties for this case as seen shortly.)

In this case, assuming  $w^k = (z^k, \lambda^k)$  is feasible and  $dw = (dz, d\lambda)$  is the direction computed by solving the QP (5), the update in Step 2 of the PSQP method is modified to choose a step size  $t > 0$  such that  $f(z^k + t dz) < f(z^k)$ , amongst other conditions; and then set  $w^{k+1} = w^k + t dw$ . Attempts to globalize PSQP for problems with nonlinear constraint functions, by adding penalty terms to the objective to replace these constraints, and then using line search or trust region strategies, are the subject of research. See [14,15], for example.

Quasi-Newton variants on PSQP, in which the Hessian matrix  $\nabla_{ww}^2 \mathcal{L}^{\text{MPEC}}(w^k, v^k)$  is replaced by an easily updated approximation, for example, are also the subject of research. See [3] for motivation from nonlinear programming.

### Affine Equilibrium Constraints

An important special case of the PSQP method is its application to *mathematical programs with affine equilibrium constraints* (MPAEC), that is, problems whose

equilibrium constraints are in the form of affine variational inequalities (AVI). MPEC with equilibrium constraints which can be expressed as in linear complementarity problems (cf. also ► **Linear complementarity problem**), such as [5,11,13], fall into this subclass.

Specifically, we consider the MPAEC formulated with KKT constraints, for which the upper-level constraint function  $G$ , and the functions  $F$  and  $g$  in the lower-level VI are affine (linear plus a constant):

$$\begin{cases} \min & f(x, y) \\ \text{s.t.} & Ax + By + a \leq 0, \\ & Px + Qy + q + E^T \lambda = 0, \\ & Dx + Ey + b \leq 0, \quad \lambda \geq 0, \\ & \lambda^T (Dx + Ey + b) = 0, \end{cases} \quad (8)$$

for some  $A \in \mathbf{R}^{s \times n}$ ,  $B \in \mathbf{R}^{s \times m}$ ,  $a \in \mathbf{R}^s$ ;  $P \in \mathbf{R}^{m \times n}$ ,  $Q \in \mathbf{R}^{m \times m}$ ,  $q \in \mathbf{R}^m$ ; and  $D \in \mathbf{R}^{\ell \times n}$ ,  $E \in \mathbf{R}^{\ell \times m}$ ,  $b \in \mathbf{R}^\ell$ . This is the problem (1) with

$$\begin{aligned} G(x, y) &= Ax + By + a, \\ F(x, y) &= Px + Qy + q, \\ g(x, y) &= Dx + Ey + b. \end{aligned} \quad (9)$$

Note that a point  $(x, y, \lambda)$  is feasible for (8) if and only if  $G(x, y) \leq 0$  and  $y$  solves the affine variational inequality VI( $F(x, \cdot)$ ,  $C(x)$ ) described in (2), where  $C(x) = \{y: g(x, y) \leq 0\}$  is a polyhedral convex set. Thus the KKT-constrained MP (8) is equivalent to the MPAEC problem in its standard form:

$$\begin{cases} \min & f(x, y) \\ \text{s.t.} & Ax + By + a \leq 0, \\ & y \text{ solves the AVI (2)}. \end{cases} \quad (10)$$

Some differences between the special PSQP method for MPAEC and the general method should be noted: First, in the QP subproblem (5) solved in Step 1, the objective function simplifies to

$$\nabla f(z^k)^T dz + \frac{1}{2} dz^T \nabla^2 f(z^k) dz.$$

Second, therefore, the vector  $v^k$  of MPEC multipliers is not needed except perhaps if stopping rule B is employed. Third, the specialized algorithm requires a feasible starting point and maintains feasibility of iterates. A heuristic ‘phase-1’ procedure [6] for finding a feasible

starting point is to find a local minimizer or stationary point of the indefinite quadratic program:

$$\begin{cases} \min & \lambda^\top F(x, y) \\ \text{s.t.} & G(x, y) \leq 0, \\ & F(x, y) + E^\top \lambda = 0, \\ & \lambda \geq 0, \\ & g(x, y) \leq 0. \end{cases}$$

See [4] for conditions under which all stationary points of the phase-1 problem are indeed feasible for the MPAEC.

Similar to SQP applied to nonlinear programs with linear constraints, the PSQP algorithm specialized to MPEC with affine KKT constraints exhibits locally superlinear convergence if the Hessian of the objective function  $\nabla^2 f(\bar{x}, \bar{y})$  satisfies a second order sufficient condition, regardless of whether either the KKT multiplier vector  $\lambda$  or the MPEC multiplier vectors  $\chi, \pi, \eta$  are unique. To make this precise, suppose  $\bar{z} = (\bar{x}, \bar{y})$  is feasible for the MPAEC (10), and let  $\Lambda(\bar{z})$  be the set of all KKT multipliers  $\lambda$  such that  $(\bar{z}, \lambda)$  is feasible for (8), i.e.  $(\bar{z}, \lambda) \in \mathcal{F}^{\text{KKT}}$ . Now for each  $\lambda \in \Lambda(\bar{z})$  and  $(J_1, J_2) \in \mathcal{A}(\bar{z}, \lambda)$ , let  $\mathcal{C}^{\text{KKT}}(J_1, J_2)$  be the critical cone of the linearly constrained NLP (3) at  $(\bar{z}, \lambda)$ ; and define the associated  $z$ -critical cone  $\mathcal{C}_z^{\{\text{KKT}\}}(J_1, J_2)$  as the set of vectors  $dz$  such that  $(dz, d\lambda) \in \mathcal{C}^{\text{KKT}}(J_1, J_2)$  for some  $d\lambda \in \mathbf{R}^m$ . The second order sufficient condition for  $(\bar{z}, \lambda)$  to be a local minimizer of (8) for each  $\lambda \in \Lambda(\bar{z})$  is that the Hessian matrix  $\nabla^2 f(\bar{z})$  be copositive on each of these  $z$ -critical cones.

The second order conditions act in the following way:

**Theorem 2** Consider the MPAEC problems (8) and (10) where the function  $f$  is twice continuously differentiable, and the functions  $G, F$  and  $g$  are given by (9). Let  $\bar{z}$  be a feasible point of (10) and  $\Lambda(\bar{z})$  be the (nonempty) set  $\{\lambda \in \mathbf{R}^m : (\bar{z}, \lambda) \in \mathcal{F}^{\text{KKT}}\}$ . Suppose for each  $\lambda \in \Lambda(\bar{z})$  and  $(J_1, J_2) \in \mathcal{A}(\bar{z}, \lambda)$  that  $(\bar{z}, \lambda)$  is stationary for the NLP (3); and that  $\nabla^2 f(\bar{z})$  is strictly copositive on the  $z$ -critical cone  $\mathcal{C}_z^{\{\text{KKT}\}}(J_1, J_2)$  defined above. Then  $\{\bar{z}\} \times \Lambda(\bar{z})$  consists of local minimizers of the KKT-constrained MP (8); in fact,  $\bar{z}$  is a strict local minimizer of the MPAEC (10).

The local convergence properties of PSQP applied to MPAEC are now presented.

**Theorem 3** Let  $f, G, F, g, \bar{z}$ , and  $\Lambda(\bar{z})$  be as above; and the associated first- and second order conditions hold. Then for each  $(z^0, \lambda^0)$  near  $\bar{z} \times \Lambda(\bar{z})$ , the PSQP algorithm specialized to MPAEC is well defined and produces a sequence  $\{(z^k, \lambda^k)\}$  such that  $\{z^k\}$  converges Q-superlinearly to  $\bar{z}$ . Convergence of  $\{z^k\}$  is Q-quadratic if, in addition,  $\nabla^2 f$  is Lipschitz near  $\bar{z}$ .

### Keywords

Leveled graphs; Integer programming; Crossing minimization; Planarization; Multiple sequence alignment

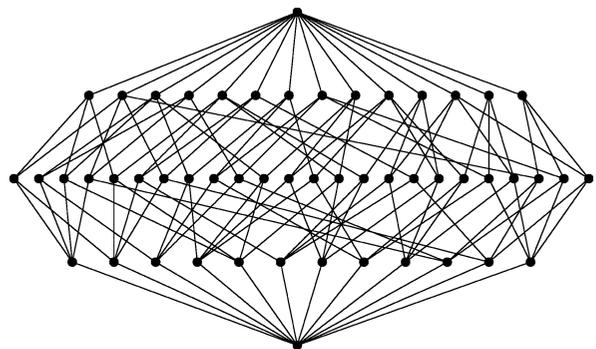

A *k*-leveled graph or a *k*-level hierarchy is defined as a graph  $G = (V, E) = (V_1, \dots, V_k, E)$  with vertex sets  $V_1, \dots, V_k$ ,  $V = V_1 \cup \dots \cup V_k$ ,  $V_i \cap V_j = \emptyset$  for  $i \neq j$ , and an edge set  $E$  connecting vertices in levels  $V_i$  and  $V_j$  with  $i \neq j$  ( $1 \leq i, j \leq k$ ).  $V_i$  is called the *i*th level. In a geometric representation of a *k*-leveled graph, the vertices in each level  $V_i$  are drawn on a horizontal line  $L_i$  with  $y$ -coordinate  $k - i$ , and the edges are drawn strictly monotone, i. e., an edge  $(v_i, v_j) \in E$ ,  $v_i \in V_i$ ,  $v_j \in V_j$ ,  $i < j$ , is drawn with decreasing  $y$ -coordinates. Essentially, a *k*-leveled graph is a *k*-partite graph that is drawn in a special way.

A *proper k-leveled graph* is a *k*-leveled graph  $G = (V_1, \dots, V_k, E)$  in which any edge in  $E$  connects vertices in two consecutive levels  $V_i$  and  $V_{i+1}$  for  $i \in \{1, \dots, k - 1\}$ . Figure 1 shows a proper leveled graph on  $k = 4$  levels. This graph represents the face lattice of the *cuboctahedron* [4].

Optimization problems in leveled graphs arise in applications in *computational biology* and in *automatic graph drawing*.

### Multiple Sequence Alignment

In computational biology the vertices in each level  $V_i$  represent letters of a sequence  $S_i$  over a finite alphabet  $\Sigma$ . The optimization problem which arises is the *multiple sequence alignment* problem. Here, the  $k$  sequences  $S_1, \dots, S_k$  should be aligned so that the cost of the align-

Optimization in Leveled Graphs, Figure 1

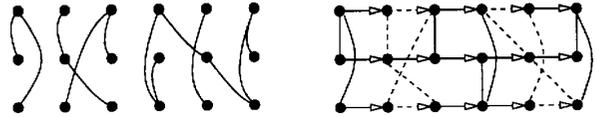

ment is maximized. An alignment can be interpreted as an array with  $k$  rows, one row for each  $S_i$ . Two letters of distinct sequences are said to be aligned if they are placed in the same column. There are many ways to measure the quality of an alignment, leading to different problem formulations. One of them is the *maximum weight trace* formulation introduced in [14]. Here, the letters of the sequences  $S_i = (s_{i1}, \dots, s_{in_i})$  are viewed as vertices in level  $i$  in a  $k$ -levelled graph  $G = (V_1, \dots, V_k, E)$ . Every edge  $e \in E$  has a nonnegative weight representing the gain of aligning the endpoints of the edge. We say that an alignment  $\hat{S}$  realizes an edge if it places the endpoints into the same column of the alignment array.

The set of edges realized by an alignment  $\hat{S}$  is called the *trace* of  $\hat{S}$ , and the weight of an alignment  $\hat{S}$  is the sum of the weights of all edges in the trace of  $\hat{S}$ . The goal is to compute an alignment  $\hat{S}$  of maximum weight.

The maximum weight trace problem is *NP-hard*, and can be solved in polynomial time for fixed  $k$ . A dynamic programming approach gives an algorithm with time complexity  $O(k^2 2^k N)$  and space complexity  $O(N)$ , where  $N = \prod_i n_i$ , which is feasible only for very small problem instances. J. Kececioğlu [15] presented a branch and bound algorithm whose implementation could optimally align six sequences of length 250 in a few minutes.

K. Reinert et al. [19] presented a first formulation as an *integer linear program*. It is based on a graph theoretical characterization of traces given in [19]. For this, the alignment graph  $G = (V_1, \dots, V_k, E)$  is extended to a mixed graph  $G' = (V_1, \dots, V_k, E, H)$  by adding a set of directed edges  $H = \{(v_{ij}, v_{ij+1}) : 1 \leq i \leq k, 1 \leq j < n_i\}$ . This graph is called the *extended alignment graph*. The weight function is extended to  $E \cup H$  by assigning weight 0 to all the edges in  $H$ . A cycle in  $G'$  is called a *mixed cycle* if it contains at least one arc of  $H$ . In [19] it has been shown that an edge set in  $T \subseteq E$  is a trace in  $G = (V, E)$  if and only if there is no mixed cycle in  $G' = (V, T, H)$ . This characterization can be strengthened to substitute ‘mixed cycle’ by ‘critical mixed cycle’ which is essentially a simple mixed cycle visiting each sequence at most once.

Figure 2 shows an alignment graph and its extended alignment graph. Two critical mixed cycles are shown by the dotted lines. A formulation in the form of an integer linear program is now straightforward. Let  $G' =$

Optimization in Levelled Graphs, Figure 2

$(V, E, H)$  be an extended alignment graph. For every edge  $e \in E$  we introduce a variable  $x_e \in \{0, 1\}$  indicating whether  $e$  is in the trace or not. Let  $w_e$  denote the alignment weight of edge  $e \in E$ . The formulation is as follows:

$$\left\{ \begin{array}{l} \max \quad \sum_{e \in E} w_e x_e \\ \text{s.t.} \quad \sum_{e \in C \cap E} x_e \leq |E \cap C| - 1, \\ \quad \forall \text{ critical mixed cycles } C \text{ in } G' \\ \quad x_e \in \{0, 1\}, \quad \forall e \in E. \end{array} \right.$$

This integer linear program can be solved via a *branch and cut* approach based on *polyhedral combinatorics*. Reinert et al. define the *trace polytope* as the convex hull of the characteristic vectors of all possible traces of  $G = (V, E)$ . Their investigation leads to some classes of tight inequalities which can be used in a branch and cut algorithm. An implementation of a branch and cut algorithm based on ABACUS [13] could optimally align 15 sequences (arising from prion proteins) of length 230 within 2.5 hours of computation time on a SparcStation Ultra 1/170.

For two sequences, Reinert et al. have given a complete description of the trace polytope. The set  $(E, \Theta) = (E, \{T : T \subseteq E \text{ is a trace in } G\})$  is an independence system, since  $\emptyset \in \Theta$  and for any  $T_1 \in \Theta$  and  $T_2 \subseteq T_1$ , also  $T_2 \in \Theta$ . The minimal dependent subsets or *circuits* of  $(E, \Theta)$  have size two. Hence, the set  $(E, \Theta)$  is a 2-regular independence system. A set  $F \subseteq E$  is a *clique* in a 2-regular system  $(E, \Theta)$  if  $\|F\| \geq 2$  and all  $\binom{\|F\|}{2}$  2-subsets of  $F$  are circuits of  $(E, \Theta)$ .

For two sequences, the trace polytope is completely described by the trivial inequalities  $0 \leq x_e \leq 1$  and by the clique inequalities  $\sum_{e \in C} x_e \leq 1$ , where  $C$  is a maximal clique in the independence system  $(E, \Theta)$ . Since the separation problem for the clique inequalities can be solved in polynomial time, this provides an algorithm to solve the maximum weight trace problem for two sequences in polynomial time.

An efficient combinatorial algorithm for solving the maximum weight trace problem for two sequences has been given in [14]. Kececioğlu has shown how to transform the problem into the heaviest increasing subsequence problem. This can be solved in time  $O(n \log n)$ , where  $n$  is the length of the sequence [9].

One can show that the maximum weight trace problem is equivalent to the 2-level planarization problem with two fixed levels arising in automatic graph drawing (see the section ‘Level Planarization’). For further information on multiple sequence alignment or on combinatorial optimization problems in computational biology, see, e. g., [23].

### Leveled Crossing Minimization

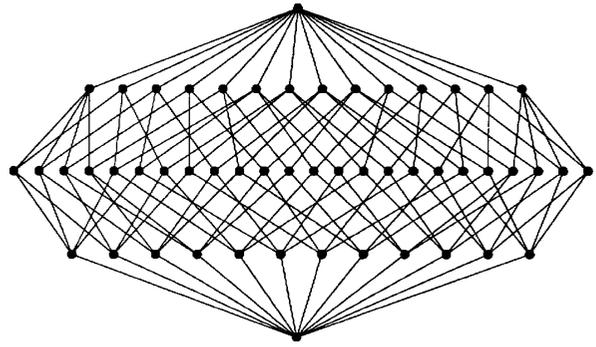

In *automatic graph drawing* the task is to compute a layout of a given graph that is easy to read and understand. Applications include flow diagrams, organization charts, entity-relationship diagrams, or PERT-diagrams.

A common method for drawing directed graphs is, as a first step, to partition the vertices into a set of  $k$  levels so that no edges have their endpoints in the same level and most of the edges point downwards. This can easily be done using a depth-first-search or a topological sorting algorithm when the graph is acyclic. The crucial step is the second one. Given a  $k$ -leveled graph, the vertices within the levels need to be permuted so that the resulting drawing is easy to read [22]. A widely used criterion for a ‘nice’ drawing is a minimum number of crossings.

The  $k$ -level crossing minimization problem arises: Given a  $k$ -leveled graph  $G = (V_1, \dots, V_k, E)$ , permute the vertices within the levels so that the resulting geometric representation of  $G$  contains a minimum number of crossings.

The  $k$ -level crossing minimization problem is NP-hard, even when the numbers of levels is two [5]. The problem can be solved in polynomial time for 2-leveled permutation graphs [21] and for 2-leveled trees [20].

An integer linear programming formulation has been given in [10]. This is the first approach attacking the  $k$ -level crossing minimization problem via polyhedral combinatorics. Recently (1999), P. Healy and A. Kuusik [8] have shown that the original formulation can be tightened using additional inequalities derived

Optimization in Leveled Graphs, Figure 3

in the so-called vertex-exchange graph. They are able to solve instances with up to 100 vertices, 100 edges, and 8 levels to provable optimality.

Figure 3 shows a  $k$ -level crossing minimum drawing of the face lattice graph shown in the first figure of this article. It turns out to be a symmetrical drawing.

F. Shahrokhi et al. [20] have suggested algorithms approximating the 2-level minimum crossing number by a factor of  $O(n \log \log n)$  and  $O(\log^2 n)$ , respectively, for a certain class  $\Gamma$  of graphs. The approximation algorithms are based on the relationship between the 2-level crossing minimization problem and the linear arrangement problem. The linear arrangement problem for a graph  $G = (V, E)$  is to find a bijection  $f: V \rightarrow \{1, \dots, \|V\|\}$  of minimum length. The length of the bijection  $f$  is given by  $L_f = \sum_{(v,w) \in E} \|f(v) - f(w)\|$ .

Shahrokhi et al. have shown that for a certain graph class  $\Gamma$  the order of magnitude for the optimal number of crossings is bounded from below, and above, respectively, by the minimum degree times the optimal arrangement value, and by the arboricity times the optimal arrangement value. The *arboricity*  $a_G$  of a graph  $G = (V_G, E_G)$  is defined as

$$\max_H \left\lceil \frac{|E_H|}{|V_H| - 1} \right\rceil,$$

where the maximum is taken over all subgraphs  $H$  of  $G$  with  $\|V_H\| \geq 2$ . Equivalent to  $a_G$  is the minimum number of edge disjoint acyclic subgraphs needed to cover  $G$ . The graph class  $\Gamma$  includes, e. g., connected 2-level graphs  $G$  of degree at most a constant  $k$  with  $\|E\| \geq (1 + \gamma) \|V\|$ , where  $\gamma > 0$  is fixed. It also includes regular graphs, degree bounded graphs, and genus bounded graphs, which are not too sparse.

In practice, the crossing minimization problem for  $k$ -leveled graphs is reduced to a series of 2-level crossing minimization problems in the following way: In a pre-processing step, we add artificial vertices to the levels  $L_i$  for all the edges traversing  $L_i (i = 2, \dots, k - 1)$ . For  $i = 1, \dots, k - 1$ , we solve the 2-level crossing minimization problem for the two adjacent levels  $L_i$  and  $L_{i+1}$  with  $L_i$  fixed, reordering the vertices on level  $L_{i+1}$ . Then we go backward, fixing level  $L_i$  and reordering the vertices on level  $L_{i-1}$  for  $i = k, k - 1, \dots, 2$ . The heuristic consists of repeating these two loops until no more improvement is obtained.

Unfortunately, the 2-level crossing minimization problem in which the permutation of the vertices in one level is fixed is also  $NP$ -hard [3]. Therefore, a lot of effort went into the design of efficient heuristics (see, e. g., [1,22]). P. Eades and N. Wormald [3] have shown that the drawings constructed using the median heuristic lead to a number of crossings that is within a factor of three times the optimal crossing number.

M. Jünger and P. Mutzel [12] transformed the 2-level crossing minimization problem with a fixed level to a *linear ordering problem*:

Any solution is obviously completely specified by the fixed permutation  $\pi_1$  of  $V_1$  and a permutation  $\pi_2$  of  $V_2$ . For  $k = 1, 2$  let  $y_{ij}^k = 1$  if  $\pi_k(i) < \pi_k(j)$  and 0 otherwise. Thus  $\pi_k (k = 1, 2)$  is uniquely characterized by the vector  $y^k \in \{0, 1\}^{\binom{n_k}{2}}$ . Let  $n_1 = \|V_1\|, n_2 = \|V_2\|, m = \|E\|$ , and let  $N(v) = \{w \in V : (v, w) \in E\}$  denote the set of neighbors of  $v \in V = V_1 \cup V_2$  in  $G$ . The number of edge crossings between the levels  $V_1$  and  $V_2$  is given by

$$C(\pi_2) = \sum_{i=1}^{n_2-1} \sum_{j=i+1}^{n_2} \sum_{k \in N(i)} \sum_{l \in N(j)} y_{kl}^1 y_{ji}^2 + y_{1k}^1 y_{ij}^2.$$

Let

$$c_{ij} = \sum_{k \in N(i)} \sum_{l \in N(j)} y_{lk}^1$$

denote the number of crossings among the edges adjacent to  $i$  and  $j$  if  $\pi_2(i) < \pi_2(j)$ . Then

$$\begin{aligned} C(\pi_2) &= \sum_{i=1}^{n_2-1} \sum_{j=i+1}^{n_2} c_{ij} y_{ij}^2 + c_{ji} (1 - y_{ij}^2) \\ &= \sum_{i=1}^{n_2-1} \sum_{j=i+1}^{n_2} (c_{ij} - c_{ji}) y_{ij}^2 + \sum_{i=1}^{n_2-1} \sum_{j=i+1}^{n_2} c_{ji}. \end{aligned}$$

For  $n = n_2, y_{ij} = y_{ij}^2$  and  $a_{ij} = c_{ij} - c_{ji}$  we solve the *linear ordering problem*

$$(LO) \begin{cases} \min & \sum_{i=1}^{n-1} \sum_{j=i+1}^n a_{ij} y_{ij} \\ & 0 \leq y_{ij} + y_{jk} - y_{ik} \leq 1, \\ & 1 \leq i < j < k \leq n, \\ & y_{ij} \in \{0, 1\}, \\ & 1 \leq i < j \leq n. \end{cases}$$

If  $z$  is the optimum value of the linear ordering problem, then

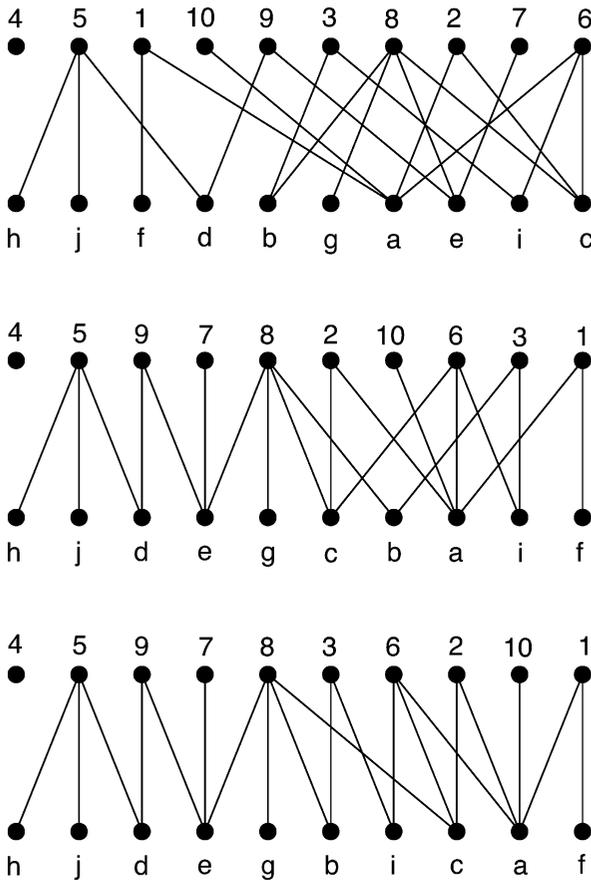

$$z + \sum_{i=1}^{n-1} \sum_{j=i+1}^n c_{ji}$$

is the minimum number of crossings in the corresponding 2-level drawing. The constraints of (LO) guarantee that the solutions indeed precisely correspond to all permutations  $\pi_2$  of  $V_2$ .

Jünger and Mutzel [12] have shown that the resulting linear ordering problem can be solved efficiently via a branch and cut algorithm for instances containing up to 250 vertices per level. Extensive computational experiments show that the running time of their exact branch and cut algorithm is comparable to that of the widely used heuristics for instances with up to 60 vertices per level.

They combined this branch and cut algorithm with a branch and bound algorithm in order to achieve a practically efficient exact algorithm for the 2-level crossing minimization problem for instances with up to 15 vertices on the smaller level. Computational experiments have shown that the results achieved via heuristic methods are far from the optimum solution (see [12]).

In Fig. 4 an example of a 2-level graph with 20 edges is shown. The first two drawings have been computed via heuristics (LR-heuristic and barycenter heuristic, respectively) and have 30 and 10 crossings, respectively. The third one is the optimum solution with only 4 crossings. This is only one example showing that it is worth searching for better algorithms for leveled graph drawing.

Optimization in Levelled Graphs, Figure 4

**Level Planarization**

Several authors have suggested minimizing the number of edges ‘producing’ crossings instead of minimizing the number of crossings in hierarchical drawings.

Figure 5 shows two drawings of the same graph. Figure 5a) has been generated after first removing the edges that ‘produce’ crossings, and then drawing the remaining graph without crossings before finally inserting the four edges again. Although the drawing shown in Fig. 5a) has 34 crossings, that is 41% more crossings than the crossing minimum drawing shown in Fig. 5b), the reader will not recognize this fact.

This example motivates careful consideration of the *k*-level planarization problem. A *k*-level graph *G* is level planar if a *k*-level representation of *G* exists in which no two edges cross except at common endpoints. Level planarity can be tested in linear time [11]. Given a *k*-

level graph  $G = (V_1, \dots, V_k, E)$  with weights  $w_e > 0$  on the edges, the *k*-level planarization problem is to extract a level planar subgraph  $G' = (V_1, \dots, V_k, F)$ ,  $F \subseteq E$ , of maximum weight, i. e., the sum  $\sum_{e \in F} w_e$  is maximum. The *k*-level planarization problem is NP-hard, even for  $k = 2$  levels.

So far (1999), no exact algorithm for the *k*-level planarization problem on  $k \geq 3$  levels is known. For  $k = 2$ , Mutzel [17] has presented a branch and cut algorithm based on polyhedral studies of the associated polytope. The integer programming formulation for the 2-level planarization problem is based on the following characterization of 2-level planar graphs (first presented in [7]).

A 2-level graph is 2-level planar if and only if it contains no cycle and no double claw.

Figure 6 shows a double claw (Fig. 6a) and a cycle (Fig. 6b). Although both graphs are planar bipartite graphs, they are not 2-level planar (see Fig. 6c) for the cycle). For double claw free graphs, the 2-level planarization problem is equivalent to the maximum forest subgraph problem that can be solved via a simple greedy algorithm. Shahrokhi et al. [20] have given a linear time algorithm for solving the 2-level planarization problem for 2-level acyclic graphs.

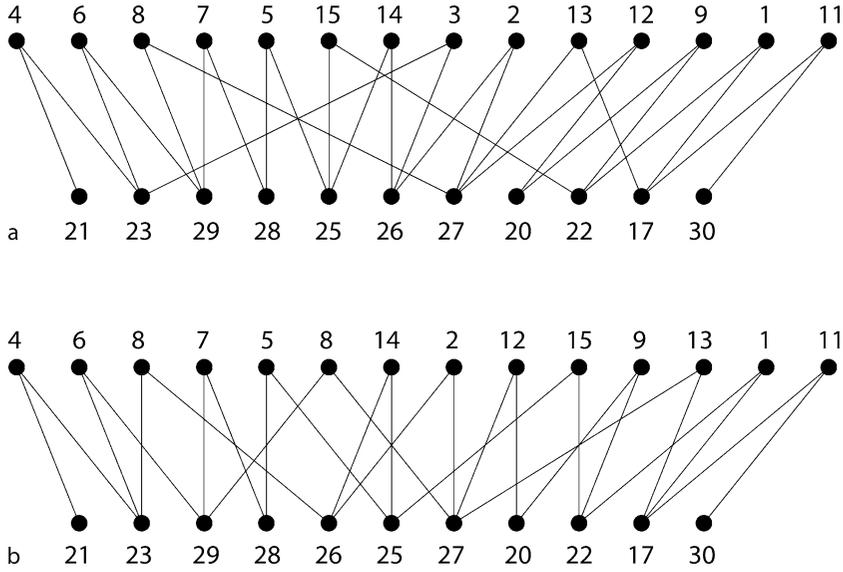

In order to get an integer linear programming formulation for the 2-level planarization problem, we introduce variables for all edges  $e \in E$  of the given 2-level graph  $G = (V_1, V_2, E)$ . For any set  $P \subseteq E$  of edges we define a characteristic vector  $\chi^P \in \mathbb{R}^{\|E\|}$  with the *i*th component  $\chi^P(e_i)$  getting value 1 if  $e_i \in P$ , and 0 otherwise. Any 0–1 vector  $x^T = (x_{e_1}, \dots, x_{e_{\|E\|}})$ , that is the characteristic vector of a 2-level planar graph satisfies the following inequalities:

$$\sum_{e \in C} x_e \leq |C| - 1, \quad \forall \text{ cycles } C \subseteq E,$$

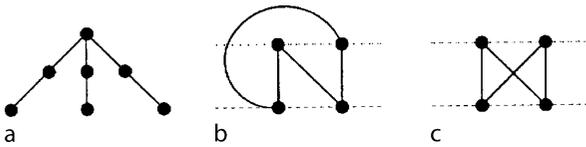

$$\sum_{e \in T} x_e \leq |T| - 1, \quad \forall \text{ double claws } T \subseteq E,$$

$$x_e \in \{0, 1\}, \quad \forall e \in E,$$

and vice versa. Hence, solving the integer linear system  $\max \sum_{e \in E} w_e x_e$  with the constraints described above will give us the solution of the maximum 2-level planar subgraph problem for a given graph  $G = (V_1, V_2, E)$  with weights  $w_e$  on the edges  $e \in E$ .

Optimization in Levelled Graphs, Figure 5

Optimization in Levelled Graphs, Figure 6

The computational experiments presented in [17] show that although most of the instances (from 20 to 100 vertices) could not be solved to optimality, solutions could be obtained which are provably within 5% of the optimum value.

As in the 2-level crossing minimization problem, the case in which the permutation in one of the two levels is fixed has also been investigated [18]. Unfortunately, this version of the problem is also NP-hard [2].

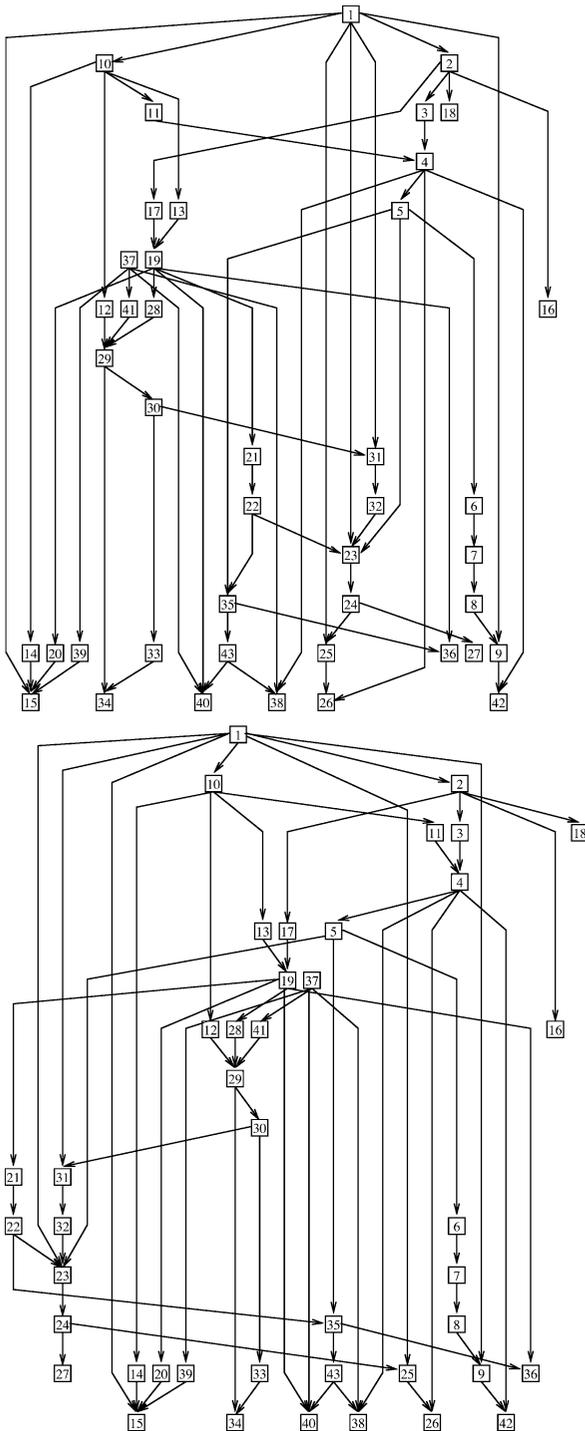

While the fixed version of the crossing minimization problem turned out to be ‘easier’ to attack in practice than the free version, unfortunately, this is not true for the one level fixed version of the 2-level planarization problem. The integer programming formulation suggested in [18] contains variables  $y_{ij} \in \{0, 1\}$  for  $i < j, i = 1, \dots, n_2 - 1, j = i + 1, \dots, n_2$  coding the permutation  $\pi_2$  of the vertices in level  $V_2$  and variables  $x_e \in \{0, 1\}$  for  $e \in E$  coding the edges contained in the subgraph. In the following integer linear programming formulation for the one level fixed 2-level planarization

problem let  $(p, i)$  and  $(q, j)$  be edges in  $E$ :

$$\left\{ \begin{array}{l} \max \sum_{e \in E} w_e x_e \\ 0 \leq y_{ij} + y_{jk} - y_{ik} \leq 1, \\ 1 \leq i < j < k \leq |V_2|, \\ y_{ij} \in \{0, 1\}, \\ 1 \leq i < j < k \leq |V_2|, \\ y_{ij} + x_{(p,i)} + x_{(q,j)} \leq 2, \\ i < j, \quad \pi_1(q) < \pi_1(p), \\ -y_{ij} + x_{(p,i)} + x_{(q,j)} \leq 1, \\ i < j, \quad \pi_1(p) < \pi_1(q), \\ x_e \in \{0, 1\}, \quad \forall e \in E. \end{array} \right.$$

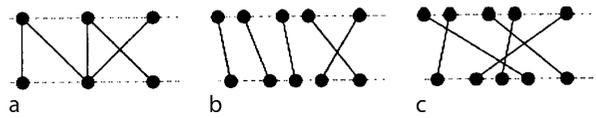

The first two constraints require the variable vector  $y$  to respect a linear ordering  $\pi_2$ . The last three constraints are responsible for introducing no crossings with respect to the ordering  $\pi_2$  coded by  $y$ .

Mutzel and R. Weiskircher have shown that all the tight inequalities of the linear ordering polytope (see, e.g., [6]) are still tight inequalities for the polytope investigated here. In particular, all the knowledge about the linear ordering polytope can be used in order to get a practically efficient algorithm. Hence, the problem considered here is tightly connected with the 2-level crossing minimization problem in which the permutation of one level is fixed.

Optimization in Levelled Graphs, Figure 7

Figure 7 shows two drawings computed via iteratively solving the one level fixed 2-level crossing minimization problem and the 2-level planarization problem

Optimization in Levelled Graphs, Figure 8

lem with one fixed level. In both drawings, the subproblems have been computed optimally.

A comparison of both drawings shows that it is worthwhile to also consider planarization and not only crossing minimization in hierarchical graph drawing. The ultimate goal is to solve these problems not levelwise but in one step. This will improve hierarchical drawings tremendously (see [12]). The authors in [18] conjecture that it will be easier to solve practical instances of the  $k$ -level planarization problem than of the  $k$ -level crossing minimization problem.

The question arises whether the 2-level planarization problem can be solved efficiently when the permutations of the vertices in both levels are fixed. This problem, however, is equivalent to the maximum weight trace problem for two sequences (see the section ‘Multiple Sequence Alignment’). The transformation in both directions is indicated in Fig. 8.

If the graph shown in Fig. 8a) is an instance of a fixed 2-level planarization problem, it is equivalent to solving the maximum weight trace problem on the instance shown in Fig. 8b). In the case that Fig. 8a) shows an instance of the maximum weight trace problem, it is equivalent to solving the fixed 2-level planarization problem in the graph shown in Fig. 8c).

It follows that the fixed 2-level planarization problem can be solved in polynomial time. Moreover, we know the complete description of the associated polytope (see also [18]). This information is very helpful for solving the 2-level planarization problem in which the permutation of one level is fixed.

Besides the application in automatic graph drawing, the 2-level planarization problem comes up in computational biology. In *DNA mapping*, small fragments of DNA have to be ordered according to the given overlapping data and some additional information. M.S. Waterman and J.R. Griggs [24] have suggested combining the information derived by a digest mapping experiment with the information on the overlap between the DNA fragments. If the overlapping data is correct, the

maps can be represented as a 2-level planar graph. But, in practice, the overlapping data may contain errors. Hence, they suggested solving the 2-level planarization problem (see also [23]). Furthermore, the 2-level planarization problem arises in global routing for row-based VLSI layout (see [16]).

Optimization; Medical imaging; Segmentation

By allowing physicians to peer into the human body, medical imaging technologies provide vital information for medical diagnosis, treatment and research. Beyond the mere visualization of anatomical structures, these imaging technologies are now being used in such roles as surgical planning, cancer diagnosis and prognosis, intra-operative navigation, radiotherapy treatment planning, and the tracking of disease progression. A key component in the effectiveness of medical imaging technologies is the development of sophisticated computer algorithms, which extract and analyze useful information. Such algorithms enable reliable and repeatable quantitative data to be extracted in order to support accurate medical diagnosis and treatment as well as clinical research. The development of such image analysis algorithms remains a rich area of research, involving numerous applications of optimization.

Medical images are generated by a variety of technologies. Among the most widely used are X-ray computed tomography (CT), emission computed tomography, magnetic resonance imaging (MRI), biomagnetic source imaging, ultrasound, and digital subtraction angiography. (See [1] for a tutorial of these medical imaging technologies). Images from these machines are typically stored as two-, three-, or four-dimensional arrays of data elements, corresponding to two or three spatial coordinates, and possibly a temporal coordinate. These data elements are generally referred to as *pixels*, but are also called *voxels* in three-dimensions and *hypervoxels* in four dimensions. The values of these elements can be scalars, such as tissue density, or vectors, such as relaxation time pairs in magnetic resonance imaging.

A central issue in extracting information from medical images is the problem of segmenting the image, either by identifying boundaries of critical structures in the image (*spatial segmentation*), or by classifying pix-

els according to some set of features, such as texture or gray levels (*feature segmentation*). In the first case, the image is segmented spatially into a number of regions which correspond to anatomical objects, such as organs. These regions typically form connected sets with well-behaved boundaries. In the second case, spatial information plays little or no role. For example, microcalcifications, which may be an early sign of breast cancer, may be scattered throughout otherwise healthy tissue. In detecting such microcalcifications, the pixels of an image would be classified either as healthy tissue or as microcalcifications. In this case, the pixel classes are not connected spatially, and can have very complex boundaries.

In either case, segmenting medical images requires the integration of low-level information about the image along with a priori high-level information about what the image represents. Extracting low-level information involves detecting features such as edges or textures. Once these features are detected, they can then be combined with high-level information either in the form of an expert system or some mathematical model of the knowledge. This integration task is made more difficult by the fact that medical images tend to suffer from sampling artifacts, spatial aliasing and noise, which can cause boundaries of structures to be indistinct and disconnected.

## Low-Level Feature Detection

Numerous algorithms have been developed for identifying low-level features of images. The most common are edge-detection methods and texture transforms. Edge detection methods work by applying a digital filter, which emphasizes edges in the image. As an example, vertical edges can be detected by convolving the image with the *Sobel edge filter*

1	0	-1
2	0	-2
1	0	-1

After applying this filter, the resulting image will have values close to zero, except at vertical edges, which will have values which are relatively large in magnitude. By changing the elements of the filter, edges with different orientations can be detected.

Another important low-level feature is texture. Generally speaking, this is a measure of image coarseness, smoothness and regularity. Numerous texture transforms have been proposed, including statistical, spectral and structural measurements. These transforms quantify various attributes of texture at every pixel in the image. Thus, after applying the texture transforms, each image pixel is represented by a vector of numbers which represent the texture.

Edge detection methods and texture transforms are described in detail in most recent image processing textbooks. (see, for example, [7]).

### Spatial Segmentation

Once low-level features of the image have been extracted, they can then be combined with high-level information to segment the image. In the case of spatial segmentation, this generally involves determining boundaries between various regions of interest. Figure 1 provides an example of a CT scan of a human abdomen which has been partially segmented spatially. In this picture, boundaries of critical organs have been highlighted in white.

More than a thousand different algorithms have been proposed for automatically segmenting images. Among the techniques used in these algorithms are thresholding, region splitting, region merging, clustering, multiscale analysis, surface fitting, rule-based expert systems, relaxation, and deformable models.

Optimization in Medical Imaging, Figure 1  
Partially segmented CT image of human abdomen. Organ boundaries are shown in white

A common theme underlying many of these techniques is the minimization of an *energy function* which in some way measures the quality of the segmentation.

### Deformable Models

A spatial segmentation technique which has attracted much recent attention, particularly in the medical field, is the use of *deformable models*. Deformable models have the capability of combining low-level information derived from the image data with high-level knowledge about the characteristics of anatomical structures. An extensive survey of deformable models in medical image processing is given in [6]. Deformable models in the form of *snakes* were first introduced by M. Kass, A. Witkin, and D. Terzopoulos [5] to segment contour objects in 2D images. Deformable models are curves or surfaces, often defined using splines, which are controlled by an *energy function*. The energy function has two major components: the *external energy*, which measures how well the spline matches image features, such as edges, and the *internal energy* which measures nonaffine deformations from some model curve. By minimizing the sum of these two energy functions, a reasonable balance is achieved between matching image features and determining boundaries which are consistent with the a priori knowledge.

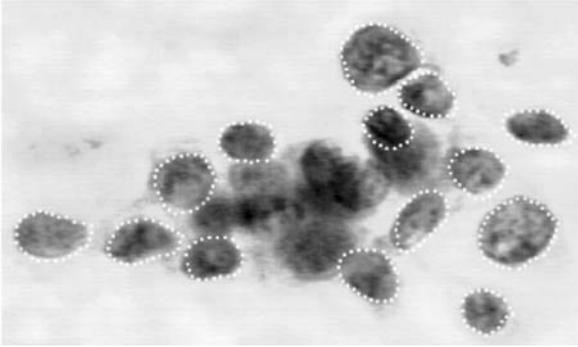

In two dimensions, the internal energy of a curve  $c(s)$  can be determined by the formula

$$E = \int_s E_{\text{elasticity}}c(s) + E_{\text{bending}}c(s) ds ,$$

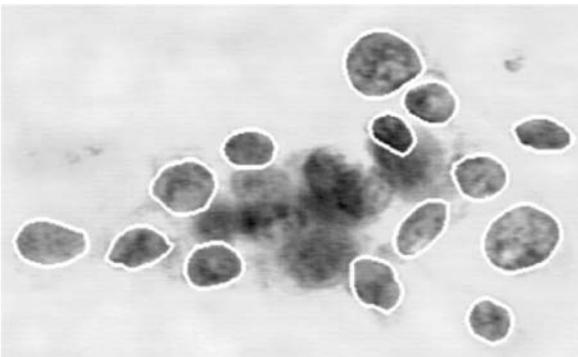

where  $s$  is the arclength of the curve,  $E_{\text{elasticity}}$  represents the energy due to the elasticity of the spline and  $E_{\text{bending}}$  represents the energy due to bending. Minimizing this internal energy results in a curve which is as close as possible to the original shape of the model curve.

The external energy of a curve is determined by how well the curve matches image features. In particular, the external energy is minimized when the curve is aligned with edges or when textures on either side of the curve are different.

Figure 2 and Fig. 3 give an example of the use of snakes to segment an image representing a breast tissue sample [9]. In Figure 2 an initial estimate of the cell boundaries is entered by a technician using a mouse

**Optimization in Medical Imaging, Figure 2**  
Initialization of snake contours for cell boundaries (Copied with permission from [9])

**Optimization in Medical Imaging, Figure 3**  
Cell contours minimizing energy (Copied with permission from [9])

to define approximate contours of cell boundaries. After these snakes are initialized, a greedy algorithm is used to achieve a local minimum of the energy function. If the energy function value at a particular snake point can be lowered by moving the point to an adjacent pixel, then the point is moved. The process is repeated for each point until all points settle into a local minimum of the energy function. The result is shown in Fig. 3.

Early implementations of deformable models possessed only generic a priori knowledge (for example, smoothness criteria) of what region boundaries should look like. More sophisticated tools, called *deformable templates* [8] have been studied which incorporate more specific a priori information with respect to expected shapes and their spatial relationships.

### Optimization Techniques for Minimizing the Energy Function

The energy function governing the deformable models or templates is, in general, a nonconvex function. Worse, in some cases, this energy function may actually be discontinuous. Consequently, local optimization techniques are usually inadequate unless the initialization of the deformable models is very accurate. This generally requires human intervention to provide an acceptable initialization.

Alternatively, global optimization techniques have been considered for minimizing the energy function. Among the more frequently used algorithms in this arena are simulated annealing (cf. ► [Simulated annealing](#)) and genetic algorithms (cf. ► [Genetic algorithms](#)).

### Feature Segmentation

In applications where regions of interest are not expected to be spatially connected, it is more natural to segment according to features. To accomplish this, a number of features are evaluated at each pixel of the image. These features might include, for example, gray levels or texture transforms. The collection of measurements for a pixel forms a vector in  $n$ -dimensional *feature space*, where  $n$  is the number of features evaluated. It is then possible to classify pixels according to where they are located in feature space.

### Clustering

One approach to classifying points in feature space is called *clustering*. Here, the  $m$  points representing the image are assigned to a predetermined number  $k$  of clusters. The problem can be stated more explicitly as that of determining  $k$  centers in  $\mathbf{R}^n$  such that the sum of the distances of each point to the nearest center is minimized. This amounts to solving the following minimization problem:

$$\min_{C_1, \dots, C_k} \sum_{i=1}^m \min_{j=1}^k \|x_i - C_j\| ,$$

where  $C_j, j = 1, \dots, k$ , represent the centers and  $x_i, i = 1, \dots, m$ , are the feature vectors for the  $m$  points. When the norm is the 2-norm, this problem is solved by the  $k$ -mean algorithm [4]. Whereas when the norm is the 1-

norm, the problem reduces to a bilinear program which is solved by the  $k$ -median algorithm [3].

Clustering algorithms are *unsupervised classification* schemes in that no a priori knowledge is used to determine the classification. However, the choice of the number of clusters  $k$  can play a significant role. If  $k$  is too large, it may be difficult to attach meaning to the clusters. Whereas, if  $k$  is too small, critical information may be missed; for example, microcalcifications may be clustered together with healthy tissue.

### Supervised Classification

Another approach to classifying pixels is to partition feature space into a number of regions according to some a priori knowledge. This knowledge can be provided by a training set of data taken from a large collection of images. Each element of the training data includes the vector of features, along with the known classification of that vector. These data elements can be partitioned into a collection of subsets, with each subset corresponding to a unique classification.

With this training data, a discriminant function can be constructed that distinguishes between the different classifications. If the conical hulls of the subsets corresponding to each classification are disjoint, then the subsets can be discriminated by a piecewise-linear function, which can be calculated by solving a single linear program (cf. also ► [Linear programming](#)) [2]. Otherwise, a decision tree can be constructed by solving a finite sequence of linear programs.

Once the discriminant function has been determined, new images can be segmented by evaluating the features of each pixel, and then applying the discriminant function to classify the pixel.

### Summary

These applications give a sense of the applicability of optimization techniques to medical image processing. Global optimization methods, such as simulated annealing and genetic algorithms, are used to minimize energy functions corresponding to deformable models; bilinear programs arise in clustering approaches to image segmentation; and linear programs arise in the training of image classification schemes.

Electric power system; Load dispatcher; Operation planning; Load curve; Thermal plant; Run-of-river plant; Storage plant; Energy purchase contract; Co-generation plant

From the 1960s onwards the computer-assisted solution of the problem to distribute the load of an *electric power system* among all generation units in operation (economic dispatch) attracted the attention of *load dispatchers* (persons, responsible for economic and secure operation of a power system) in utilities and engineering scientists [12]. Hand in hand with the development of computer hardware to high internal speed, large main storages and low costs, different optimization methods have been applied to more and more complex operation planning models of power systems to better reflect their reality [3,4,10,13]. Today, the operation planning problem is of high economic importance to the electric power industry in presence of deregulation measures, privatization, and an upcoming competitive marketing environment. This dramatic move to a market-based industry will significantly change power system operations. New pricing mechanisms (e. g., spot-market, auctions) will come in place and require a fast solution of new optimization problems to economically plan the operation of future power systems under new marketing conditions.

Therefore, this paper outlines the basic principles of how to model and optimize a power system to economically plan its operation.

## Problem Definition

The objectives of the *operation planning* problems of electric power systems are dependent on their planning period. Short-term planning problems cover a day, a weekend or a week and are designed to solve the scheduling of generation units and contracts in the most economic way possible. Long-term planning problems cover a planning period of a season or a year and more and must allocate the resources available (e. g., fuels, storage water, contracted energy amounts) to smaller time periods. Medium-term problems for more than a week or a month are often to be solved in presence of small hydro-reservoirs or amounts of fuels to be disposed in short intervals. These three planning problems with different objectives are not independent from each other. They form an hierarchical model system (long-term, medium-term, short-term) to be run continuously to plan the operation economically from a day to a year.

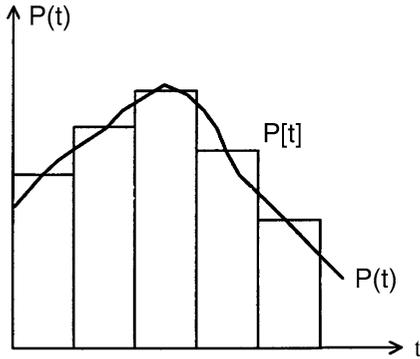

Electrical energy is not storable in large amounts. Therefore, the load dispatcher of a power system must balance its load  $P_1(t)$  and the generation  $P_g(t)$  including energy purchase contracts  $P_c(t)$  for each point in time, expressed by equation (1).

$$P_g(t) + P_c(t) = P_1(t); \quad (1)$$

$P_1(t)$  is defined by the *load curve* (total power system load over the time of day) and is given as input data representing constant load values for short time-intervals (e. g., 1 hour), called *time-steps* in modeling terms. This simplification replaces the continuous load curve by a stepwise representation. The transformation into a stepwise load curve Fig. 1, is necessary to be able to apply mathematical programming optimization methods.

The power system load  $P_1[t]$  (time-discretized representation of load curve with  $[t]$ ) is covered partially by an energy purchase contract and by generators located in different power plants.

There are two main types of power plants: *thermal plants* (including nuclear plants) and *hydro plants*, to be distinguished by their energy input (primary energy) to produce electricity (secondary energy). Thermal plants use coal, oil and gas whereas hydro plants need water of rivers or stored in reservoirs as input. Moreover, thermal generation units (a generator in a thermal

**Optimization in Operation of Electric and Energy Power Systems, Figure 1**  
Load curve representation

plant) are characterized by other operational conditions than hydro ones. These different operational conditions must be taken into account to correctly model the different types of generation units.

Thermal generation units have, in a first approach, unlimited access to their fuels (coal, oil, gas) to be paid for. The operational costs of thermal units are defined by the cost curve for fuels between a minimal and a maximal electric power output. Moreover, their start-up or shut-down procedure lasts a number of hours and also causes procedure costs. Finally, their electric power output can be changed with a small time gradient only.

There are also two types of hydro plants to be distinguished. Firstly, the *run-of-river plants* that are located on a river. They generate electricity out of the (no-cost) water transported by the river. Therefore, their electric power output is constant over longer time periods (e. g., a day) and changes only when the amount of the water freight of the river changes. There is no degree of freedom for the optimization but a run-of-river plant must be taken into account to compute correct generation schedules, accepted by load dispatchers.

Secondly, *storage plants* which can only use a small amount of their reservoir-stored water during the planning period. This condition makes the model dynamic in time and requires special attention when modeling a storage plant. Fast changes of their electric power output are possible within their generation limits. This is necessary to follow large differences of the power system load of consecutive time-steps.

Sometimes, storage plants have pumping-units too which transport water from a lower reservoir to

a higher one at times when the energy costs needed to pump the water are low (e. g. during the night). When the energy costs are high, the pumped water is released from the upper reservoir to generate electricity by running into the lower one. This pumping possibility makes the operation of a power system more flexible but also more complex. Therefore, pumping units are not considered here to not overburden the reader.

The last important power system element that contributes to cover the power system load is the *energy purchase contract* with an outside utility. Such a contract is defined by the costs for the delivered energy and is limited by a maximum power and often by a certain amount of energy allowed to be purchased during a given time period (e. g., day).

Summarizing the afore described power system elements, equation (1) can be enhanced as follows:

$$P_g[t] = P_{th}[t] + P_{rr}[t] + P_s[t] \quad (2)$$

$$P_{th}[t] + P_{rr}[t] + P_s[t] + P_c[t] = P[t], \quad (3)$$

where

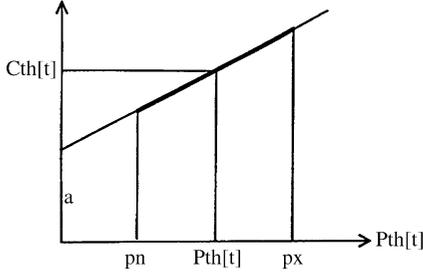

- $P_{th}[t]$ : generation of thermal plants at time-step  $t$ ;
- $P_{rr}[t]$ : generation of run-of-river plants at time-step  $t$ ;
- $P_s[t]$ : generation of storage plants at time-step  $t$ .

Equation (3) describes the power balance of a so-called hydro-thermal system in its most general form (pumping not included).

The short-term scheduling problem is chosen as a sample of the operation planning problem for the complete planning cycle (day to year). The load dispatcher must solve this operation planning problem on a regular (daily) basis in order to achieve his objective to operate the power system and its elements in the most economic way possible.

## Modeling

In the following, all power plants discussed before, the energy purchase contract, the power balance, and the objective to minimize operational costs are modeled in MIP-terms (mixed integer programming). Simple modeling approaches with linear relationships are chosen for the power system elements involved to support the understanding of the reader for the short-term

**Optimization in Operation of Electric and Energy Power Systems, Figure 2**

### Cost curve of a thermal unit

scheduling problem of the operation planning process in power systems.

Before starting with the model descriptions of the power system elements involved in covering the power system load, it is necessary to summarize the time parameters used for modeling.

The planning period is the time horizon (e. g., day, weekend, week, month, year) covered by the optimization problem. Each time horizon is split up into so-called time-steps with equal length (e. g., 1 hour, 0.5 hour) during which the power system load is approached as a constant value (see Fig. 1). This simplification makes the application of mathematical programming methods possible since the right-hand side of the matrix is transformed into a constant value.

In general, there are always more than one unit in a power plant. Here, only one generation unit is assumed. Therefore, the term unit is used synonymously with plant in the following.

### Thermal Plant

A linear relationship of the cost  $C_{th}[t]$  to electric generation  $P_{th}[t]$  is chosen for the sake of simplicity, not altering the modeling approach of the thermal unit itself.

- Fuel costs:

$$C_{th}[t] = a * Y[t] + b * P_{th}[t]. \quad (4)$$

- Limits on electric generation:

$$p_n * Y[t] \leq P_{th}[t] \leq p_x * Y[t]. \quad (5)$$

- Start-up indicator:

$$U[t] \geq Y[t] - Y[t - 1], \quad (6)$$

$$U[t] \in (0, 1), \quad Y[t] \in (0, 1). \quad (7)$$

- Start-up costs:

$$C_s[t] = c_{sth} * U[t]. \quad (8)$$

- Data (thermal unit)

- $a$ : fixed costs;
- $b$ : incremental costs;
- $p_n$ : minimum electric power output;
- $p_x$ : maximum electric power output;
- $c_{sth}$ : start-up costs.

- Variables (thermal unit)

- $C_{th}[t]$ : fuel costs at time-step  $t$ ;
- $C_s[t]$ : start-up costs at time-step  $t$ ;
- $P_{th}[t]$ : electric generation at time-step  $t$ ;
- $Y[t]$ : on/off indicator at time-step  $t$ ;
- $U[t]$ : start-up indicator at time-step  $t$ .

### Storage Plant

In a first modeling approach, the water discharge curve is assumed to be linear between zero and a maximum discharge value  $q_x$ . Moreover, a constant head  $H = H_s(t)$  is also permissible:

$$P_s(t) = k * Q_s(t) * H_s(t). \quad (9)$$

Therefore the equation (9) for the electric generation  $P_s(t)$  of a storage plant with a water discharge  $Q_s(t)$  and a water height  $H_s(t)$  can be transformed into (12) by applying equation (11):

$$P_s(t) = k * Q_s(t) * H_s(t), \quad (10)$$

$$H_s(t) = H = \text{const}, \quad (11)$$

$$P_s(t) = k_{H_s} * Q_s(t); \quad (12)$$

- Electric generation

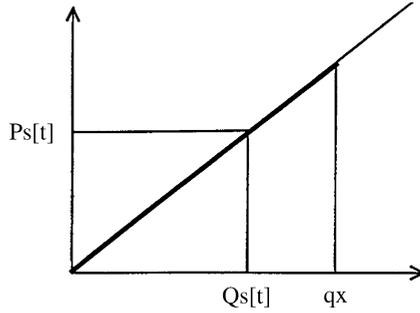

$$P_s[t] = k_{H_s} * Q_s[t]. \quad (13)$$

- Limits on water discharge

$$0 \leq Q_s[t] \leq q_x. \quad (14)$$

- Data (hydro unit; storage plant)

- $k_{H_s}$ : gradient of the linear water discharge curve;
- $q_x$ : maximum possible water discharge.

Optimization in Operation of Electric and Energy Power Systems, Figure 3

#### Water discharge curve

- Variables (hydro unit; storage plant)
  - $P_s[t]$ : electric generation at time-step  $t$ ;
  - $Q_s[t]$ : water discharge (cubicmeter per second) for electric generation at time step  $t$ .

#### Hydro-Reservoir

Each storage plant is connected to at least one hydro-reservoir. The content of the hydro-reservoir changes from time-step to time-step and can be computed from the so-called *storage equation* (15) expressing the water volume  $V[t]$  in the reservoir at the end of each time-step  $t$ :

- Water volume

$$V[t] = V[t - 1] - 3600 * Q_s[t] dt + 3600 * Q_{in}[t] * dt . \quad (15)$$

- Volume limits

$$v_n \leq V[t] \leq v_x . \quad (16)$$

- Storage condition

$$A_T = V[0] - V[T] . \quad (17)$$

The equation (15) defines the amount of water allowed for generation of the storage plant during the planning period. In short-term planning (e. g., daily optimization) it is often required that the water volume at the end of the planning horizon  $V[T]$  equals the starting volume  $V[0]$ .

- Data (hydro-reservoir)
  - $V[0]$ : volume in the reservoir at the beginning of the planning period;

- $A_T$ : water volume available for generation to the storage plant during the planning period;
- $v_n$ : minimum volume allowed in the reservoir;
- $v_x$ : maximum volume allowed in the reservoir;
- $Q_{in}[t]$ : natural inflow into the reservoir at time-step  $t$ ;
- $dt$ : time-steplength in hours.
- Variables (hydro-reservoir)
  - $P_s[t]$ : electric generation at time-step  $t$ ;
  - $Q_s[t]$ : water discharge (cubicmeter per second) for electric generation at time-step  $t$ .

#### Run-of-River Plant

The electric generation of a run-of-river plant is directly dependent from the water freight of the river. In general, the water freight of a river remains constant during a short-term planning period of a day or even a weekend. Therefore, the electric generation of a run-of-river plant remains constant during the planning period and has no degree of freedom in mathematical terms concerning its (constant) generation. Although of no mathematical importance to the optimization, run-of-river plants must be considered in the model because of practice-related reasons. A load dispatcher needs the economic dispatch problem to be solved in engineering terms, taking into account all power system elements, including run-of-river plants, contributing to cover the power system load.

- Data (hydro unit; run-of-river plant)
  - $P_{rr}[t]$ : hydro-unit (run-of-river plant) – electric generation.

#### Energy Purchase Contract

Although there is a wide variety of different contract conditions, a very simple contract is modeled here to demonstrate the basic principles.

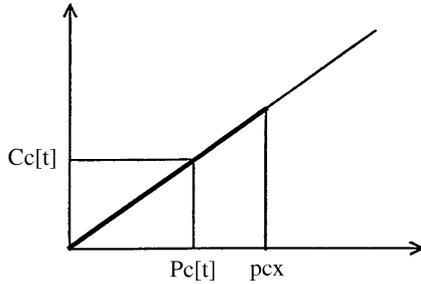

Constant incremental costs are assumed for the purchased energy between  $P_c = 0$  and  $P_c = p_{cx}$ , the maximum power allowed to be purchased from the selling utility during the planning period.

- Contract costs

$$C_c[t] = T_c * P_c[t] * dt . \quad (18)$$

- Contracted electric power limits

$$0 \leq P_c[t] \leq p_{cx} . \quad (19)$$

Optimization in Operation of Electric and Energy Power Systems, Figure 4

#### Contract cost curve

In addition to the above (basic) model of a contract, there is often a maximum amount of contracted energy allowed to be purchased from the selling utility during the planning period as follows:

$$\sum_{t=1}^T P_c[t] * dt \leq a_{cx} \quad (20)$$

- Data (energy purchase contract)
  - $T_c$ : tariff for the purchased energy;
  - $dt$ : time-steplength (already defined);
  - $p_{cx}$ : maximum power allowed to be purchased from the selling utility;
  - $a_{cx}$ : maximum energy allowed to be purchased from the selling utility during the planning period.
- Variables (energy purchase contract)
  - $C_c[t]$ : contract costs at time-step  $t$ ;
  - $P_c[t]$ : electric power of purchased energy at time-step  $t$ .

#### Power Balance

The power balance equation (3) is the most important part of an operation planning optimization model and is therefore repeated here again:

$$P_{th}[t] + P_{rr}[t] + P_s[t] + P_c[t] = P_l[t]. \quad (21)$$

Both the variables  $P_{th}[t]$ ,  $P_s[t]$  and  $P_c[t]$  and the input data  $P_{rr}[t]$  and  $P_l[t]$  were already defined when the different power system elements were modeled.

#### Objective Function

One of the main goals of utilities is to operate their power system as economic as possible. Therefore, the

operational costs during the planning period must be minimized to meet the overall target of a load dispatcher. This objective formulates as follows:

$$Z = \sum_{t=1}^T (C_{th}[t] + C_c[t]) dt + \sum_{t=1}^T C_s[t] \rightarrow \min. \quad (22)$$

The variables  $C_{th}[t]$ ,  $C_c[t]$  and  $C_s[t]$  were already defined when describing the model of the thermal plant and the model of the contract.

#### Optimization

Since the model of the power system was formulated in MIP-terms (mixed integer programming) an optimization code with integrated MIP-techniques (linear programming followed by branch and bound method) must be applied. Each professional optimization code offers MIP methods to the user in different modularity; sometimes as package with a control language (e. g., MPSX/370 and MIP/370 [6]) or as a subroutine library (e. g., OSL [9]).

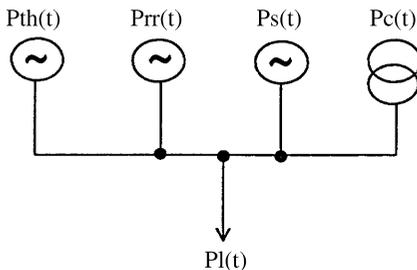

Moreover, the solution time and the accuracy of results are two main aspects that must be taken into account when planning the operation of an electric power system by applying optimization techniques. Therefore, a careful selection of the solution procedure is necessary to cope with both the accuracy of results required and a practice-related solution time that are primarily conflicting goals. But today, the solution of each operation planning problem of an electric power system as an MIP-optimization-model is possible in the solution time required and with the accuracy necessary, even for highly nonlinear and combinatorial problems (e. g., unit commitment: scheduling of a large number of thermal units taking into account time-dependent start-up costs) [2,14]. Moreover, multiprocessor hardware (e. g. RS/6000-SP) and related optimization codes (e. g., OSLp [8]) are further elements to speed up the solution time for time critical applications, sometimes arising in the operational planning environment of very large scale electric power systems. It must be emphasized in this context that three elements must be taken into account to successfully meet challenging solution-time targets. An appropriate modeling approach [14], an optimization procedure with acceleration techniques implemented and a problem dependent hardware with a professional optimization code.

### Computer Implementation: Optimization in Practice

The computer implementation is an important step when developing an optimization model for the load dispatch practice. The problem definition, the modeling approach, and the optimization techniques are relatively easy to define. However, it is much more difficult to transform the optimization model, written on a paper, into a computer executable form. This bottleneck can be overcome by modeling tools, so-called model generators (e. g., *EasyModeler/6000* [7]), allowing to formulate the optimization model in algebraic terms and at the same time offering ease-of-use support for data input and debugging. Moreover, a close program interaction between the model generation tool and an optimization code is a must for a fast and successful model development and model usage in the utility practice of planning the operation of its power system. Therefore, tools with algebraic model formulations are widely accepted by engineers.

In the sequel, the power balance equation (21) is applied as a demonstration example concerning the ease-of-use of a model generator (*EasyModeler/6000*) appropriate for application by utility engineers and load dispatchers.

#### Model Formulation

Optimization in Operation of Electric and Energy Power Systems, Figure 5  
Power balance

$$P_{th}[t] + P_{rr}[t] + P_s[t] + P_c[t] = P_l[t]. \quad (23)$$

#### Model Generator Formulation (*EasyModeler/6000*)

- DATA
  - ...
  - $P_l[t]$  (power system load);
- $P_{rr}[t]$  (generation; run-of-river plant  $\rightarrow$  constant power output);
- ...
- ENDDATA
- VARIABLE
  - ...
  - $P_{th}[t]$  (generation; thermal plant);
  - $P_s[t]$  (generation; storage plant);
  - $P_c[t]$  (energy purchase contract; power);
  - ...
- ENDVARIABLE
- CONSTRAINTS
  - ...
  - Load (FORALL  $t$ )
 
$$P_{th}[t] + P_s[t] + P_c[t] = P_l[t] - P_{rr}[t];$$
  - ...
- ENDCONSTRAINT

Comparing the power balance equation (21) with the formulation of the model generator ( $P_{rr}[t]$  as a constant value for each  $t$  appears on the right-hand side), no relevant differences occur in their algebraic representation. The same is valid for the modeling approaches of all other power system elements. Therefore, the application of a model generator to real-life problems can be learned very easily, even by self-education. Moreover, it supports a very fast development of optimization models occurring in the operational practice of utilities.

#### Numerical Example

In order to support the reader's understanding of the given problem, the numerical example is based on the (simplified) model of a power system, described before, to economically plan its operation. The result of the optimization run in Table 1 offers the schedules of the power system elements in operation and the associated costs as well as the value of the objective function.

#### Input Data

$t = 1, \dots, 7, dt = 1.$

- Thermal plant
  - $p_n$ : 100MW;
  - $p_x$ : 950MW;
  - $a$ : 0MW;

**Optimization in Operation of Electric and Energy Power Systems, Table 1**  
**Schedule for all power system elements (7 time steps)**

$t$	$P_o[t]$	$P_{th}[t]$	$P_{rr}[t]$	$P_{Io}[t]$	$P_o[t]$
1	200	110	90	—	—
2	300	210	90	—	—
3	600	410	90	—	100
4	800	615.4	90	—	94.6
5	1000	798.5	90	11.5	100
6	700	510	90	—	100
7	200	100	90	4.6	5.4

- $b$ : 26.3158MU/MW (MU denoting money unit);
- $c_{sth}$ : 1000MU.
- Run-of-river plant
  - $P_{rr}[t]$ : 200MW.
- Storage plant
  - $k_{H_s}$ : 2.304MW second/m<sup>3</sup>;
  - $q_x$ : 34.72m<sup>3</sup>/second.
- Hydro-reservoir
  - $v[o]$ : 41.23 \* 10<sup>3</sup>m<sup>3</sup>;
  - $v_n$ : 0m<sup>3</sup>;
  - $v_x$ : 150 \* 10<sup>3</sup>m<sup>3</sup>;
  - $A_T$ : 0m<sup>3</sup>;
  - $q_{in}$ : 1m<sup>3</sup>/second.
- Energy purchase contract
  - $T_c$ : 25MU/MWh;
  - $p_{cx}$ : 100MW;
  - $a_{cx}$ : 400MWh.

### Numerical Results

- Objective function: 82 470.3MU.

### Summary and Future Trends

Today, operational planning tools are state-of-the-art in utilities to support load dispatchers in meeting their objective to economically operate their power systems [15]. These planning tools are based on computer-assisted optimization models. From the 1960s onwards, these models have been closely linked to the development of computer hardware, modeling tools and optimization codes. With decreasing price/performance of computers, power system models became larger and

larger, taking into account more details of the power system elements involved and so coming closer to their technical and operational reality. It must be emphasized in this context that MIP modeling and optimization methods have turned out to be the best and most effective strategy as an overall compromise of the conflicting targets: accuracy of results and solution time. Multiprocessor hardware and an associated optimization code are also available for time critical applications with combinatorial and highly nonlinear models.

In the future, utilities (sometimes privatized) will have to operate their power systems in a widely deregulated environment of a competitive market. This expected move to a market driven industry will significantly change electric utility operations [11]. New pricing mechanisms of energy trading (e. g. spot-marketing, auctions) will require the formulation of new optimization problems [1,5]. They will have to be solved much faster than up to now in order to support effectively and efficiently the decision making process in the business environment to come for utilities in the future. This new situation of utilities is a great but fascinating challenge for future research concerning the new operation planning targets of power systems.

Although this contribution referred to electric power systems only, the same modeling and optimization principles can be applied for other line-based energy systems (e. g., gas, district heating), even for coupled ones with *co-generation plants* (plants, that produce electricity and steam for industrial or public use in district heating systems).

### Note

In memoriam Felix Schlaepfer, my friend, who contributed relevantly to the economic dispatch problem.

### Introduction

*Unit-Disk Graphs* (UDGs) are intersection graphs of equal diameter (or unit diameter w.l.o.g.) circles in the Euclidean plane. In the *geometric (or disk) representation*, each circle is specified by the coordinates of its center. Three *equivalent* graph models can be defined with vertices representing the circles [18]. In the *intersection graph model*, two vertices are adjacent if the corresponding circles intersect (tangent circles are also said to intersect). In the *containment graph model*, two vertices are adjacent when one circle contains the center of the other. In the *proximity graph model*, an edge exists between two vertices if the Euclidean distance between the centers of corresponding circles is within a specified bound. Recognizing UDGs is NP-hard [10] and hence no polynomial time algorithm is known for deriving the geometric representation from the graph model. From an algorithmic perspective this places an emphasis on whether or not the geometric representation is needed as input. UDGs are not necessarily perfect or planar [18] as several other geometric intersection graph classes are and thus motivate the need for dedicated theoretical study.

The remainder of this article is organized as follows. We introduce the necessary definitions and notations for the various optimization problems on graphs considered in this article in Sect. “[Definitions](#)”. A brief survey of applications modeled using UDGs and the role of optimization problems discussed in this chapter are presented in Sect. “[Applications](#)”. A survey of algorithms and their key ideas for cliques, independent sets, vertex covers, domination, graph coloring and clique partitioning are presented in Sect. “[Models](#)”. We conclude with a summary in Sect. “[Conclusions](#)”.

### Definitions

We consider simple, undirected graphs on  $n$  vertices and  $m$  edges denoted by  $G = (V, E)$ . For

a vertex  $v \in V$ ,  $N(v)$  is its neighborhood and  $N[v] = N(v) \cup \{v\}$  is its closed neighborhood. We denote the complementary graph by  $\bar{G} = (V, \bar{E})$  and the subgraph induced by  $S \subseteq V$  by  $G[S]$ . We denote by  $\delta(G)$  and  $\Delta(G)$  the minimum and maximum vertex degrees in  $G$  respectively. Denote by  $d(u, v)$  the shortest distance between  $u, v \in V$ , then the  $k$ -neighborhood of  $v$  is defined as  $N_k(v) = \{u \in V : d(u, v) \leq k\}$ . We also use the notation  $G - v$  and  $G - I$  to refer to the graph obtained from  $G$  by deleting vertex  $v$  (and incident edges) and by deleting a subset of vertices  $I$  (and incident edges), respectively. That is  $G - v = G[V \setminus \{v\}]$  and  $G - I = G[V \setminus I]$ .

A *clique* is a subset of pairwise adjacent vertices in  $G$ . The *maximum clique problem* is to find a largest cardinality clique in  $G$  and the *clique number*  $\omega(G)$  is the size of a maximum clique. An *independent set* (or *stable set*) is a subset of mutually non-adjacent vertices and the maximum independent set problem is to find an independent set of maximum cardinality. The *independence number* (or *stability number*) of a graph  $G$  is denoted by  $\alpha(G)$  and it is the size of a maximum independent set. A *maximal clique* (independent set) is one that is not a proper subset of another clique (independent set). Cliques and independent sets are complementary to each other in the sense that  $C \subseteq V$  is a clique in  $G$  if and only if  $C$  is an independent set in  $\bar{G}$ . For arbitrary graphs, the maximum clique and independent set problems are equivalent and possess similar complexity and approximation results. Algorithms and heuristics for one can be adapted via complement for the other. However, this equivalence is not naturally extended to geometric graphs that do not preserve upon complementing, their geometric property. For instance planar independent set is NP-complete [30] while clique is trivial. Results on UDGs will be discussed in Sect. “Cliques”, “Independent Sets”. A *vertex cover*  $S$  is a subset of vertices such that every edge in  $G$  has at least one end point in  $S$ . We denote by  $\beta(G)$ , the size of a minimum vertex cover. Clearly if  $I \subseteq V$  is independent, then  $V \setminus I$  is a vertex cover of  $G$ .

A *proper coloring* of a graph is one in which every vertex is colored (assigned a natural number) such that no two vertices of the same color are adjacent. A graph is said to be  $k$ -colorable if it admits a proper coloring with  $k$  colors. Vertices of the same color are referred to as a *color class* and they induce an independent set.

The *chromatic number* of the graph, denoted by  $\chi(G)$  is the minimum number of colors required to properly color  $G$ . Note that for any graph  $G$ ,  $\omega(G) \leq \chi(G)$ , as different colors are required to color the vertices of a clique. The famous theorem by Brooks on graph coloring [11] states that  $\chi(G) \leq \Delta(G)$  if  $G$  is neither a complete graph nor an odd cycle. A related problem is the *minimum clique partitioning* problem which is to partition the given graph  $G$  into a minimum number of cliques,  $\bar{\chi}(G)$ . Note that this is exactly the graph coloring problem on  $\bar{G}$  and  $\bar{\chi}(G) = \chi(\bar{G})$ .

A *dominating set*  $D$  is a subset of vertices such that every vertex in the graph is either in this set or has a neighbor in this set. A *minimal dominating set* contains no proper subset which is also dominating. The minimum cardinality of a dominating set is called the *domination number*, denoted by  $\gamma(G)$ . Note that every *maximal independent set* is also a *minimal dominating set*. If a dominating set  $D$  is independent, it is called an *independent dominating set*. A dominating set  $D$  is called a *connected dominating set* if  $G[D]$  is connected. The independent and connected domination numbers (obviously defined) are denoted by  $\gamma_i(G)$  and  $\gamma_c(G)$ . Naturally,  $G$  is assumed to be connected when we consider connected domination.

An approximation algorithm with approximation ratio  $\rho > 1$  for an optimization problem  $\Pi$ , outputs for every instance  $x$  of  $\Pi$  with an optimal value  $opt(x)$ , a solution of value  $sol(x)$  in time polynomial in size of  $x$ , such that  $sol(x) \leq \rho \times opt(x)$  if  $\Pi$  is a minimization problem or  $sol(x) \geq opt(x)/\rho$  if  $\Pi$  is a maximization problem.

An optimization problem  $\Pi$  admits a *fully polynomial time approximation scheme* (FPTAS) if there is an approximation algorithm with approximation ratio  $1 + \epsilon$  for any  $\epsilon > 0$  that runs in time polynomial in size of the input and  $1/\epsilon$ .  $\Pi$  is said to admit a *polynomial time approximation scheme* (PTAS) if it has a polynomial time approximation algorithm with approximation ratio  $1 + \epsilon$  for each fixed  $\epsilon > 0$ . A problem that is NP-hard in the strong sense [30], does not admit a FPTAS unless  $P = NP$ .

## Applications

A major application area for UDG models is in wireless communication. Here the underlying *connectivity*

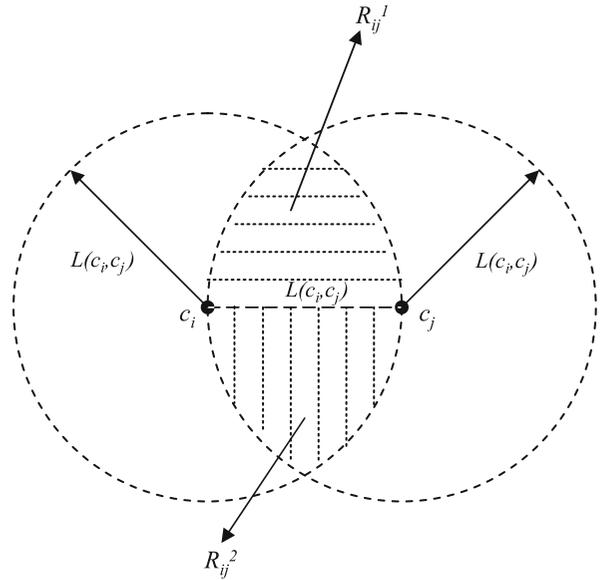

graph of the wireless nodes with equal and omnidirectional transmission-reception range can be modeled as a UDG [5,33]. Various optimization problems studied on UDGs are solved to facilitate effective operation of such networks.

For instance, a maximum independent set corresponds to a largest set of wireless nodes that can broadcast simultaneously without interference [56]. Alternately in location logistics,  $\alpha(G)$  is also the maximum number of facilities that can be located in  $n$  potential locations if proximity between any two facilities is undesirable [45,61]. Clique and clique partitioning are popular approaches for clustering wireless networks [40]. Maximal cliques are also used to model and avoid link interference in ad-hoc networks [32]. A dominating set in UDGs modeling wireless network function as a small set of nodes that can send an emergency communication to the entire graph [18]. Domination and connected domination are also used to cluster wireless networks. The vertices in a dominating set  $D$  are designated as *cluster-heads* and  $N[v]$  for each  $v \in D$  forms a cluster. Inside a cluster formed in this fashion, 2-hop communication is possible between any pair of nodes via the cluster-head. In mobile wireless networks, the nodes are weighted appropriately to find a weighted dominating that can yield cluster-heads that are less mobile [8,16]. Alternately, if a virtual backbone is desirable among the cluster-heads, a connected dominating set is used in clustering [19,20]. Clustering is an important problem in wireless networks as it helps routing and improves efficiency and throughput [57]. Graph coloring problems are used to solve channel assignment problems in wireless networks such as frequency assignment, code or time slot assignment depending on the protocols used [33]. The idea is that the chromatic number of the connectivity graph is the smallest set of frequency bands (time-slots or codes) required to communicate without interference. The UDG recognition problem also has applications in determining molecular conformations [34].

## Models

### Cliques

An  $O(n^{4.5})$  time algorithm for finding a maximum clique in a UDG  $G = (V, E)$  given the disk representation is presented in [18]. We briefly describe

**Optimization Problems in Unit-Disk Graphs, Figure 1**  
The region  $R_{ij}$  is shaded

the ideas presented in [18]. Consider the set of disks  $V = \{1, \dots, n\}$  with centers at  $c_i, \forall i \in V$ . For a pair  $i, j \in V, (i, j) \in E$  if and only if the Euclidean distance  $L(c_i, c_j) \leq 1$ . Denote by  $R_{ij}$  the region of intersection of two disks of radius  $L(c_i, c_j)$  centered at  $c_i$  and  $c_j$  (see Fig. 1). Let  $H_{ij} \subseteq V$  denote the disks with centers in the region  $R_{ij}$ . Consider a maximum clique  $C$  and let  $i, j \in C$  be the farthest pair (in terms of Euclidean distance) of vertices in  $C$ , then  $C \subseteq H_{ij}$ . If such a farthest pair  $i, j$  in some maximum clique  $C$  is known, then we only need to find a maximum clique in  $G[H_{ij}]$  to find a maximum clique in  $G$ . Since such an  $i, j$  pair is unknown, we can enumerate over all  $(i, j) \in E$  to derive a polynomial time algorithm, if we can solve the maximum clique problem in polynomial time on every  $G[H_{ij}]$ . This is facilitated by the following observation made in [18]. Consider the region  $R_{ij}$  with  $L(c_i, c_j) \leq 1$ . The line joining  $c_i$  and  $c_j$  bisects  $R_{ij}$  into  $R_{ij}^1$  and  $R_{ij}^2$ . The disk centers located in each half form a clique and hence the complement  $\overline{G[H_{ij}]}$  is a bipartite graph. Since maximum independent set problem in bipartite graphs can be solved in  $O(n^{2.5})$ , we can find the maximum clique in  $G[H_{ij}]$  in the same time which results in the claimed polynomial runtime. After the polynomial solvability was established in [18], the running time has been improved to  $O(n^{3.5} \log n)$  in [9].

A relevant notion of *robust algorithms* for restricted graph classes such as UDGs was introduced recently in [55]. A robust algorithm for solving a problem on UDGs would accept only the graph  $G$  in standard format (adjacency list or matrix) as an input and solve the problem if it is indeed a UDG, or report that  $G$  is not a UDG. A polynomial time robust algorithm is presented in [55] for finding a maximum clique in UDGs (without the geometric representation) which returns a maximum clique or reports that  $G$  is not a UDG. The existence of a *polynomial time robust* algorithm for the maximum clique problem on UDGs is a surprising result given the NP-hardness of UDG recognition. A key idea is an ordering  $L = e_1, e_2, \dots, e_m$  of edges of  $G$  (input in standard format) referred to as a *cobipartite neighborhood edge elimination ordering* (CNEEO). Denote by  $G_L(i)$  the subgraph of  $G$  with edge set  $\{e_i, e_{i+1}, \dots, e_m\}$ . Define for each edge  $e_i = (u, v)$  the set  $N_L(i)$  to be the set of vertices adjacent to both  $u$  and  $v$  in  $G_L(i)$ . The authors define an edge ordering  $L$  to be CNEEO if for each  $e_i$ ,  $N_L(i)$  induces a cobipartite (complement of bipartite) graph in  $G$ . The authors then prove that given  $G$  and a CNEEO  $L$ , a maximum clique can be found in polynomial time and describe a greedy algorithm for determining a CNEEO  $L$  if it exists or certifying that  $G$  has none in polynomial time. Finally, the authors show that every UDG admits a CNEEO there by completing the robust polynomial time algorithm for maximum clique problem on UDGs (in fact for the larger class of graphs that admit a CNEEO).

### Independent Sets

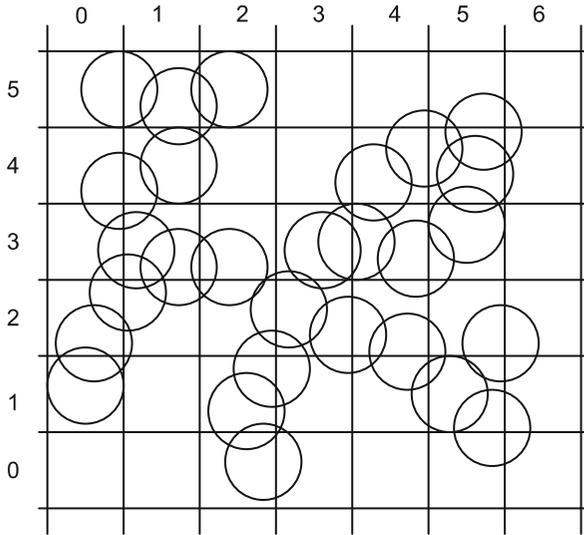

Contrary to maximum clique, the maximum independent set (MIS) problem on UDGs is known to be NP-hard, even when the disk representation is given [18]. However, simple constant factor approximation algorithms and PTASs have been developed for this problem. Note that the strong NP-hardness of the MIS problem precludes the possibility of a FPTAS unless  $P = NP$  [30].

Given a graph  $G$  that does not contain a  $(p + 1)$ -claw as an induced subgraph, an  $O(n \log n + m)$  algorithm is presented in [37] to find an independent set of size at least  $\alpha(G)/p$ . A  $p$ -claw is a graph on  $p + 1$  vertices  $V_p = \{u_0, u_1, \dots, u_p\}$  such that  $u_0$  is adjacent to all other vertices and  $V_p \setminus \{u_0\}$  is an independent

set. The algorithm proceeds by adding a vertex  $v \in V$  to  $I$  followed by the removal of  $v$  and its neighbors *i.e.*,  $N[v]$  from the graph. This step is repeated until  $V$  is empty, and the resulting independent set  $I$  is maximal. Let  $I^*$  denote a MIS in  $G$ . Suppose for the sake of argument that we sequentially removed vertices of  $N[v]$  from  $I^*$  for each  $v$  removed from  $I$ . In any step, if  $v$  removed from  $I$  is also in  $I^*$ , the number of vertices in  $I^*$  deleted in that step is exactly one. If  $v \in I \setminus I^*$ , the number of vertices removed from  $I^*$  is at most  $p$  since a MIS in  $N(v)$  has at most  $p$  vertices. Since  $I$  is maximal,  $I^*$  will be empty when  $I$  is empty and  $\alpha(G) = |I^*| \leq |I \cap I^*| + p \times |I \setminus I^*| \leq p|I|$ . By geometry, UDGs do not contain a 6-claw [45] and the above algorithm is a 5-approximation for the MIS problem on UDGs.

A simple 3-approximation algorithm is presented in [45] that, given a UDG  $G$  constructs an independent set of size at least  $\alpha(G)/3$ . This algorithm is based on the observation that every UDG has some vertex  $v$  such that  $\alpha(G[N(v)]) \leq 3$ . In particular, this is true for the vertex corresponding to the disk with minimum  $x$ -coordinate. Since every induced subgraph of a UDG is also a UDG, we can apply the same algorithm stated before from [37] and the observation will continue to hold in each step. But the vertex  $v$  added to  $I$  in each step is one with a MIS of size at most 3 in  $N(v)$  yielding the desired approximation ratio. Given the disk representation, such a vertex  $v$  can be found easily in each step and without the disk representation such a vertex can certainly be found in polynomial time ( $O(n^5)$ ).

The shifting strategy for geometric graphs introduced in [38], analogous to techniques for planar graphs introduced in [4] is the key ingredient in the PTASs developed for the MIS problem in [39,47]. The approaches are similar and we follow the presentation in [39]. Let  $G = (V, E)$  be the UDG and the center of each disk in  $V$  is specified. If we seek an independent set  $IS[G]$  such that  $|IS[G]| \geq (1 - \epsilon)\alpha(G)$ , then choose parameter  $k$  to be the smallest integer for which  $(k/(k + 1))^2 \geq 1 - \epsilon$ . Grid the region containing  $G$  with unit squares by dividing into horizontal and vertical strips of unit width. Assume that the intervals on the axes corresponding to each strip are left closed and right open. This is necessary to deal with disks with centers on the boundary of two strips. For some  $0 \leq i \leq k$ , delete all the disks with centers in ev-

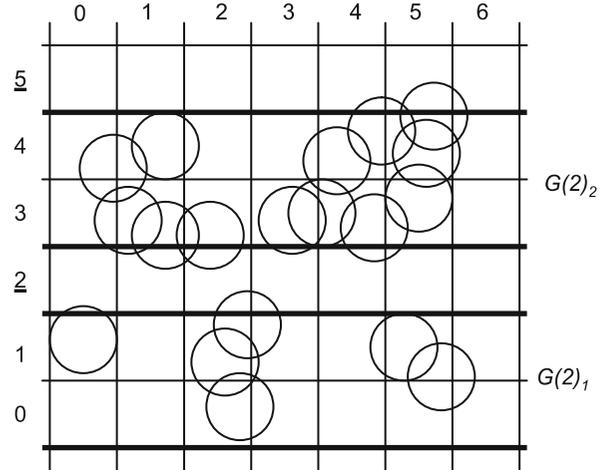

**Optimization Problems in Unit-Disk Graphs, Figure 2**  
An example UDG  $G$  with a unit grid applied

ery horizontal strip congruent to  $i \pmod{k+1}$  and denote the resulting UDG by  $G(i)$ . This leaves  $r$  disjoint horizontal “super”-strips of width  $k$  containing disjoint UDGs  $G(i)_1, G(i)_2, \dots, G(i)_r$  such that

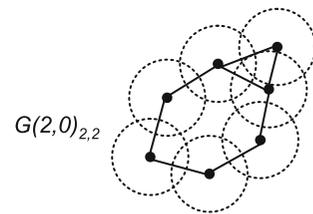

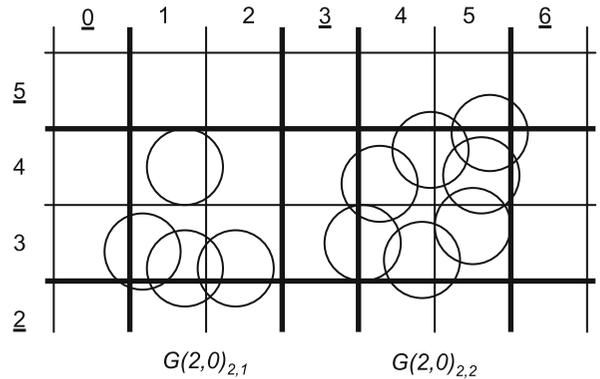

$$G(i) = \bigcup_{1 \leq j \leq r} G(i)_j .$$

See Fig. 2 and Fig. 3. Varying  $i$  varies the deleted horizontal strips and hence permits us to *shift* the horizontal super-strips vertically over the graph  $G$ .

Now for some  $1 \leq j \leq r$ , select the  $j$ th horizontal super-strip. For some  $0 \leq l \leq k$ , delete from the super-strip  $G(i)_j$ , all disks with centers in every vertical strip congruent to  $l \pmod{k+1}$  and denote the resulting UDG by  $G(i, l)_j$ . Parameter  $l$  can similarly be seen as the horizontal shift parameter for the vertical super-strips. This partitions  $G(i, l)_j$  into  $s_j$  UDGs  $G(i, l)_{j,1}, \dots, G(i, l)_{j,s_j}$  each contained in a square block of side  $k$ . See Fig. 4. Thus any MIS of  $G(i, l)_{j,t}$  with  $1 \leq j \leq r$  and  $1 \leq t \leq s_j$  is of size at most  $O(k^2)$  and can be found in time  $n^{O(k^2)}$  by enumeration. The independent set returned is the union of independent sets from disjoint UDGs, but the one corresponding to the best block partition which depends on the shift parameters  $i, l$ . This can be expressed as follows. For a fixed vertical shift  $i$  and horizontal super-strip  $j$ , and

**Optimization Problems in Unit-Disk Graphs, Figure 3**  
Graph  $G(i)$  with  $i = k = 2$ . Disks centered in the underlined horizontal strips (2,5) have been deleted leaving 2 horizontal super-strips corresponding to disjoint graphs  $G(2)_1$  and  $G(2)_2$

**Optimization Problems in Unit-Disk Graphs, Figure 4**  
Graph  $G(2, 0)_2$  with  $l = 0$  (above). Disks centered in the underlined vertical strips (0, 3, 6) have been deleted leaving two  $2 \times 2$  square blocks. Graph  $G(2, 0)_{2,2}$  inside a  $2 \times 2$  square block (below)

for some choice of  $l$ ,

$$IS[G(i, l)_j] := \bigcup_{1 \leq t \leq s_j} MIS[G(i, l)_{j,t}] .$$

The best independent set in super-strip  $j$  is then obtained by horizontally shifting the grid, *i. e.*, varying  $l$ , thus

$$\text{IS}[G(i)_j] := \max_{0 \leq l \leq r} \text{IS}[G(i, l)_j].$$

For each  $i$ , having found the best independent set in each super-strip,

$$\text{IS}[G(i)] := \bigcup_{1 \leq j \leq r} \text{IS}[G(i)_j].$$

By varying the horizontal shift parameter  $i$ , we can select the best independent set for the graph as

$$\text{IS}[G] := \max_{0 \leq i \leq k} \text{IS}[G(i)].$$

It is shown in [39] that

$$|\text{IS}[G]| \geq (k/(k + 1))^2 \alpha(G)$$

and the algorithm has a running time of  $n^{O(k^2)}$ . By the choice of  $k$ , this implies a PTAS for the MIS problem on UDGs. Suggestions for improving running time and solution quality are presented in [39,47]. After a vertical shift  $i$ , this involves solving the MIS problem optimally on each horizontal super-strip  $j$  using dynamic programming (DP) instead of approximating by horizontal shifting. This results in  $|\text{IS}[G]| \geq (k/(k + 1))\alpha(G)$  and a total running time of  $n^{O(k)}$ .

In either version, the shifting strategy helps us to divide-and-conquer by breaking down the graph into pieces on which optimal resolution is possible (by enumeration or DP) in polynomial time, but at the same time bound the error created by the division process as division is flexible. We refer to [39] for details on the performance guarantees mentioned.

Clearly, the disk representation is required for the above PTAS to work. The open problem of whether a *robust* PTAS exists for the problem in the sense described in Sect. “**Cliques**” was settled positively in [51]. Given a graph  $G = (V, E)$  (in standard format) and a desired error  $\epsilon > 0$  we seek an independent set of size at least  $\alpha(G)/\rho$  where  $\rho = 1 + \epsilon$ . The algorithm starts with some arbitrary vertex  $v$  and finds a MIS  $I_k$  in  $G[N_k(v)]$  for  $k = 0, 1, 2, \dots$  sequentially until the condition  $|I_{k+1}| > \rho|I_k|$  is violated. Let  $r$  denote the smallest  $k \geq 0$  for which  $|I_{r+1}| \leq \rho|I_r|$ . The authors show that there exists a constant (dependent on  $\rho$ )

$c(\rho)$  such that  $r \leq c(\rho)$  and each MIS  $I_k$  can be found in polynomial time. By the choice of  $r$ , we know that  $\alpha(G[N_{r+1}(v)]) \leq \rho|I_r|$ , *i. e.*,  $I_r$  is a  $\rho$ -approximate MIS for  $G[N_{r+1}(v)]$ . Suppose we have a  $\rho$ -approximate MIS  $I'$  for  $G' = G[V \setminus N_{r+1}(v)]$ , then clearly  $I = I' \cup I_r$  is independent since  $I' \subset V \setminus N_{r+1}(v)$  and  $I_r \subset N_r(v)$ . Furthermore,  $\alpha(G) \leq \alpha(G[N_{r+1}(v)]) + \alpha(G') \leq \rho|I|$ , *i. e.*,  $I$  is a  $\rho$ -approximate MIS of  $G$ . This fact combined with the fact that every vertex induced subgraph of a UDG is also a UDG, we have an inductive argument leading to the required PTAS. Robustness of the above algorithm is due to the following observations. The performance guarantee does not require  $G$  to be a UDG, and the algorithm always returns a  $(1 + \epsilon)$ -approximate solution. However, geometry of UDGs is required to establish polynomially bounded running times for finding MIS in  $k$ -neighborhoods and, the existence of a constant  $c(\rho)$ . The proof of these claims also shows that if there exists an independent set  $I_r > (2r + 1)^2$  (bound assumes unit-radius disk representation, which is equivalent to other representations discussed before) then  $G$  is not a UDG. Since this certificate can be obtained in polynomial time, this PTAS is robust.

### Vertex Cover

The minimum vertex cover problem on UDGs is also NP-hard as shown in [18]. Given a UDG  $G = (V, E)$ , a polynomial time heuristic that does not require a disk representation to find a vertex cover of size at most  $1.5\beta(G)$  is presented in [45]. This algorithm requires results from [37,50]. The first result is the well-known Nemhauser-Trotter (NT) decomposition [50] which states given an arbitrary graph  $G = (V, E)$  there exist disjoint vertex subsets  $P$  and  $Q$  such that (1) there exists a minimum vertex cover containing  $P$ ; (2) if  $D$  is a vertex cover for  $G[Q]$  then  $D \cup P$  is a vertex cover for  $G$ ; (3) any minimum vertex cover of  $G[Q]$  contains at least  $|Q|/2$  vertices. The second result from [37] states that following a NT decomposition, if  $G[Q]$  can be colored using  $k$  colors, then  $P \cup (Q \setminus S)$  is a vertex cover of size at most  $2(1 - 1/k)\beta(G)$ , where  $S$  is the largest color class in  $G[Q]$ .

The authors of [45] show that triangle-free UDGs can be colored using 4 colors. Given a UDG  $G$ , the heuristic first deletes vertices that form a triangle in

$G$  (call it  $V'$ ). With  $G := G - V'$ , NT decomposition is then applied to the resulting triangle-free UDG  $G$  to identify sets  $P$  and  $Q$ .  $G[Q]$  is then colored using 4 colors and the set  $S \subseteq Q$  corresponding to the largest color class is identified. The heuristic then returns  $V' \cup P \cup Q \setminus S$  as the approximate vertex cover. The approximation ratio follows by applying the *local-ratio principle* [6,7,45] as follows. In  $V'$  we pick 3 vertices for each triangle, and we have to pick at least 2. And for the triangle-free UDG, which is 4-colorable, the result from [37] applies. The running time of the heuristic is dominated by the time to obtain NT decomposition which can be accomplished in polynomial time.

A PTAS has been developed in [39] for minimum vertex cover that uses an approach similar to the PTAS for the MIS problem described in Sect. “Independent Sets” from the same article. For  $0 \leq i < k$ , instead of deleting a horizontal strip congruent to  $i \pmod{k+1}$ , this approach uses super-strips of width  $k+1$  overlapping at horizontal strips congruent to  $i \pmod{k}$ . Then solving the MIS problem exactly using DP on each super-strip  $G(i)_j$  also yields a minimum vertex cover. For a fixed  $i$ , the union over  $0 \leq j \leq r$  of minimum vertex covers of each  $G(i)_j$  is a valid vertex cover for  $G$  and the smallest vertex cover found over all  $i$  has size at most  $((k+1)/k)\beta(G)$ . Details are available in [39].

### Domination

Minimum dominating set (MDS) problem, minimum independent dominating set (MIDS) problem and minimum connected dominating set (MCDS) problem are known to be NP-hard for UDGs [18]. In fact, they are NP-hard even when restricted to a subclass of UDGs called *grid graphs* on which MIS is polynomial time solvable [18]. The observation that a maximal independent set is also a minimal dominating set is used frequently in approximating dominating sets. It has been proven in [45] that any maximal independent set in a UDG  $G$  is no larger than five times its domination number, *i.e.*,  $\alpha(G) \leq 5\gamma(G) \leq 5\gamma_i(G)$ . This follows from the observation that if  $D$  is a maximal independent set in a UDG  $G$ , then any vertex in a MDS (or a MIDS) can dominate at most 5 vertices in  $D$ . Any maximal independent set is hence a 5-approximate solution for

the minimum dominating set (MDS) problem and the minimum independent dominating set (MIDS) problem. A 10-approximate algorithm for MCDS problem is also presented in [45]. This bound has been improved to 8 in several papers [2,12,14,60] which present distributed implementations that are applicable in a practical setting in wireless networks. These heuristics construct a maximal independent set (which is dominating) and then connect it using a tree approach to obtain a CDS. This approach is based on the result from [2] that for a UDG  $G$ ,

$$\alpha(G) \leq 4\gamma_c(G) + 1. \quad (1)$$

The maximal independent set  $I$  that is constructed (in polynomial time [60]) also has the property that for any  $I' \subset I$ ,  $I'$  and  $I \setminus I'$  are exactly distance two away from each other *i.e.*, there exist  $u_1 \in I'$  and  $u_2 \in I \setminus I'$  with  $d(u_1, u_2) = 2$ . The maximal independent set is connected using a spanning tree approach in [2,12,60] and using a *Steiner tree* in [14]. The bound (1) was improved recently in [62] to

$$\alpha(G) \leq 3.8\gamma_c(G) + 1.2. \quad (2)$$

This tighter bound shows that the 8-approximate algorithms such as the ones from [14,60] are in fact 7.8-approximate. It is also observed in [62] that if

$$\alpha(G) \leq a\gamma_c(G) + b,$$

then  $2.5 \leq a \leq 3.8$ , which suggested that further improvement of their result was possible. Recently in [28], it has been shown that

$$\alpha(G) \leq 3.453\gamma_c(G) + 8.291 \quad (3)$$

for UDGs and a distributed algorithm is presented that finds a CDS of size at most  $6.91\gamma_c(G) + 16.58$ .

Using the bound (2), a 6.8-approximate algorithm for the MCDS problem has also been proposed recently in [48] that connects a maximal independent set using a Steiner tree approach. Given a set of vertices designated as *terminals*, a tree connecting the terminals such that every leaf is a terminal is called a *Steiner tree*. The non-terminal nodes are called *Steiner nodes*. In principle, we could find a Steiner tree with minimum number of Steiner nodes (ST-MSN) with a maximal independent set  $I$  as terminals and the Steiner nodes  $S^*_I$  union

$I$  yields a CDS for the UDG  $G$ . Instead of solving ST-MSN optimally, the authors approximate this problem. This is sufficient if we make the following observation.
